# Speciation with unsegmented continuous systems

M.D. Luque de Castro *, D.W. Bryce, A. Izquierdo

*Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain*

Received 6 December 1994; revised 10 March 1995; accepted 11 March 1995

**Abstract**

Speciation applications of the flow-injection technique are discussed in relation to the hydrodynamic manifold components that are adapted for this purpose. Alterations include double halting of the propulsion system, coupling of injection valves, modifications of the transport-reaction zone, use of switching valves, and merging and splitting points. Detector remodelling, the use of sensors and special detectors, and data processing methodologies are also reviewed in connection with the flow-injection/chromatography coupling. Finally, foreseeable trends and desirable advances are outlined.

## 1. Introduction

One of the toughest problems facing analytical chemists on the verge of the 21st century is that of specification, towards which substantial portions of R&D budgets are being alloted in developed countries.

The environment is one of the areas most seriously affected by problems arising from certain toxic physicochemical forms of elements and compounds. The vast amounts of pollutants that are being discharged into the environment, and their usually rapid interconversion, demand continuous or the least frequent monitoring of many such species. This entails developing expeditious, precise methods capable for monitoring environmentally hazardous substances in real or near-real time.

Flow-injection analysis (FIA) is one of the most attractive approaches to speciation on account of its high flexibility, throughput and automatability, as can be inferred from the abundance of literature on this topic [1–7]. As in other areas of social interest, the potential of FIA for speciation has not been fully explored; a call of the analytical community's attention to the great capabilities of FIA in this respect is, therefore, in order.

There is a current trend to refer to this technique as flow-injection (FI), on the reasoning that only in certain instances does sample treatment by this unsegmented flow approach involve true analysis.

Developments in FI/speciation coupling have so far relied on alterations of one or more of the basic elements of a hydrodynamic manifold, namely the propulsion unit, injection system, transport and/or reaction zone and detector. Speciation can also be accomplished prior to introducing the sample into an FI system [8]. In such a case, the manifold is intended to facilitate interference removal and/or derivatization, as well as (obviously) transfer the analyte to the detector. Coupling an FI manifold to a high-discrimination instrument or data processing detector can also be of assistance for speciation. Fig. 1 shows a global view of these approaches, typical examples of which are discussed below.

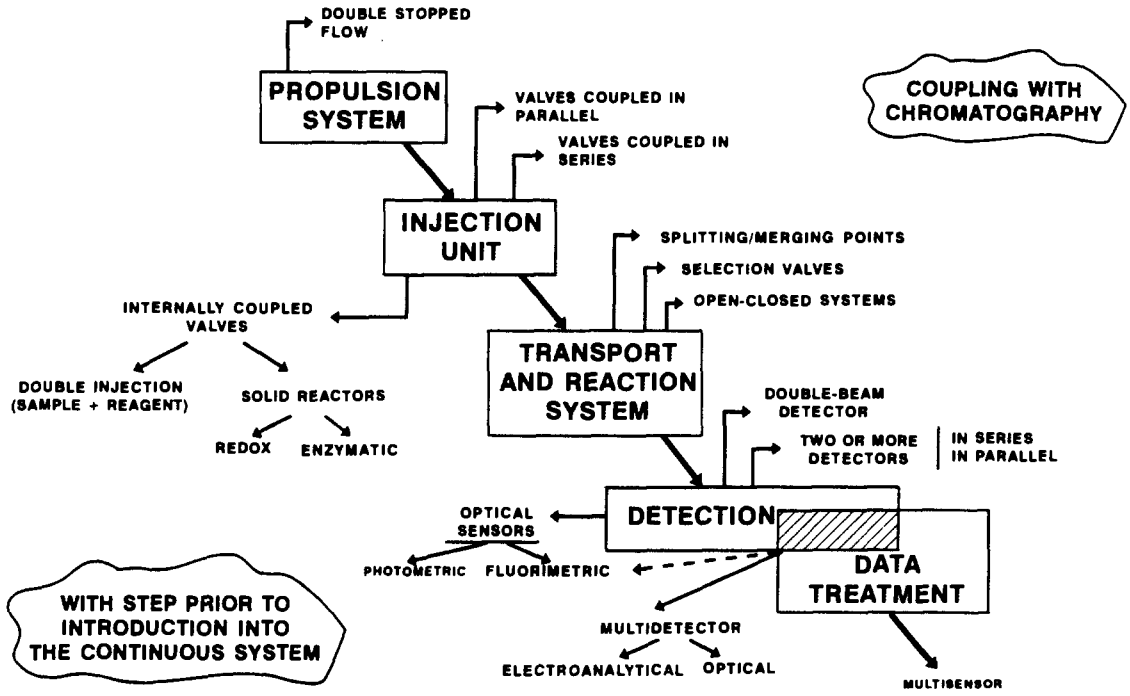

Fig. 1. Approaches to speciation in flow-injection analysis.

We should note that the conventional chemical criteria for speciation in environmental analyses (e.g. oxidation state, coordination form, electron configuration) [9] do not apply in pharmaceutical analyses, where the target problem is discrimination of chiral compounds [10–17], nor in clinical analyses, which include such well-known systems as free and esterified cholesterol [18–20] or free and combined calcium [21–25], in addition to isoenzyme discrimination, a key to diagnosing diseases of great social concern such as infarction [26–33]. This article reviews examples of speciation methods based not only on these, but also on other criteria.

## 2. Speciation prior to flow injection

Sample treatment, usually with an acid, facilitates conversion of species into forms that can be measured by the detector. Thus, alternate introduction of treated and untreated samples into the FI manifold the sequential speciation of two forms of a given compound. Such is the case of selenium speciation as Se(IV)/Se(VI) by the catalytic action of Se(IV) on the reaction

$$ClO_3^- + 5Cl^- + 6H^+ \rightleftharpoons 3Cl_2 + 3H_2O$$

The oxidation product of *o*-tolidine with $Cl_2$ is used for the quantitation at 440 nm. Selenium(VI) is reduced off-line to Se(IV) by boiling HCl [34]. The speciation of this element in sediments and planktonic material entails multistep digestion with $HNO_3$/$HClO_4$ to dissolve all the selenium, as well as dilute sodium hydroxide to relate selenite and selenate. The dissolved species are subsequently determined using a selective hydride generation/atomic absorption method [35].

Voltammetric stripping methods afford very low detection limits for selenium by virtue of preconcentration at the electrode, which is typical in stripping methods. Both the cathodic and anodic modes have been used for selenium(IV) determination with a gold working electrode (anodic stripping [36]) or a glassy carbon working electrode (cathodic stripping [37]). Alternate pretreatment of samples with hot concentrated HCl enables speciation by reduction of Se(VI). A continuous flow manifold facilities not only the removal of interferents for cationic species by use of an ion-exchange microcolumn in the sample stream prior to the injection valve, but also automatic regeneration of the Hg film of the working electrode and automatic switching of electrolyte solutions between the preconcentration and stripping step, thus dramatically increasing automatability, throughput and precision.

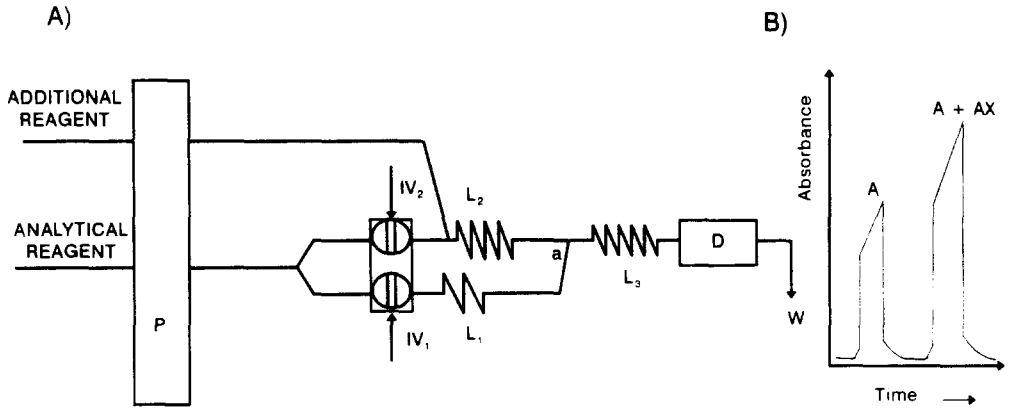

Fig. 2. Merging zones/doubly stopped-flow manifold for speciation of free and bound $SO_2$. P, IV, L, a, D, W, A and AX denote peristaltic pump, injection valve, reaction coil, confluence point, detector, waste, absorbance of free $SO_2$ and absorbance of total $SO_2$, respectively.

## 3. Speciation with a modified propulsion system

Alterations of an ordinary propulsion unit such as a peristaltic pump have opened up a wide range of FI uses such as gradient technique [38–41] (by use of programmed drum rotation speeds), reversed FI, which is particularly effective for accomplishing liquid–liquid extraction without phase separation [42–45], and reaction-rate measurements [46,47] with alternate changes in the drum rotation direction. In any case, the simplest way of manipulating a peristaltic pump is by alternately starting an stopping the flow. This approach, in combination with the merging-zones mode, enables the simultaneous determination of free and bound $SO_2$ in wine. The procedure involves simultaneous dual injection via two parallel valves and stopping the flow twice sequentially as shown in Fig. 2(A). The flow is first stopped when $plug_1$ reaches the detector, where the indicator reaction is monitored to quantify free $SO_2$. Simultaneously, $plug_2$ is stopped at $L_2$, where the bound analyte is subjected to alkaline hydrolysis. Restarting the pump flushes $plug_1$ out of the system and drives $plug_2$ to the detector, after merging at point **a** with the reacting mixture. The flow is stopped again when $plug_2$ reaches the detector. The measured absorbance changes comprise the contributions of both free and bound $SO_2$ [48].

## 4. Speciation with a customized injection unit

The injection system is one of the FI units that can be most readily altered by means available to ordinary research laboratories and not surprisingly has received by far the most attention by workers on FI/speciation [49–53]. Two or more injection valves can be arranged serially or in parallel, or be coupled internally. They can also accommodate solid reactors of different nature in their loops in order to facilitate conversion of the target analytes into their most suitable forms for subsequent derivatization-detection. By way of example, Fig. 3 shows some typical valve arrangements used for nitrogen speciation.

*Two valves connected in series or parallel* (Fig. 3(A)) have been used for nitrogen speciation as ammonia/urea [54], with fluorimetric monitoring of the $NH_3$/OPA (*o*-phthalaldehyde + mercapto-ethanol) reaction product. Simultaneous injection of two sample aliquots into the FI manifold is used to determine endogenous $NH_3$ in the plug with the shorter residence time; the other plug, delayed by passage through an enzyme reactor containing urease immobilized on controlled-pore glass (CPG), is employed to determine both nitrogen forms initially present in the sample after urea is converted into ammonia. These nitrogen species can also be determined by photometric monitoring using an asymmetric merging-zones manifold (Fig. 3(B)), where one valve is loaded with buffer and the other with Nessler's reagent. As the injection valves are simultaneously switched to their inject position, the head of the Nessler's plug reacts with the sample (carrier) to produce a signal proportional to the ammonia concentration. The buffer injected via the first valve restores the baseline before the carrier is passed through the immobilized enzyme reactor (IMER), where the urea is con-

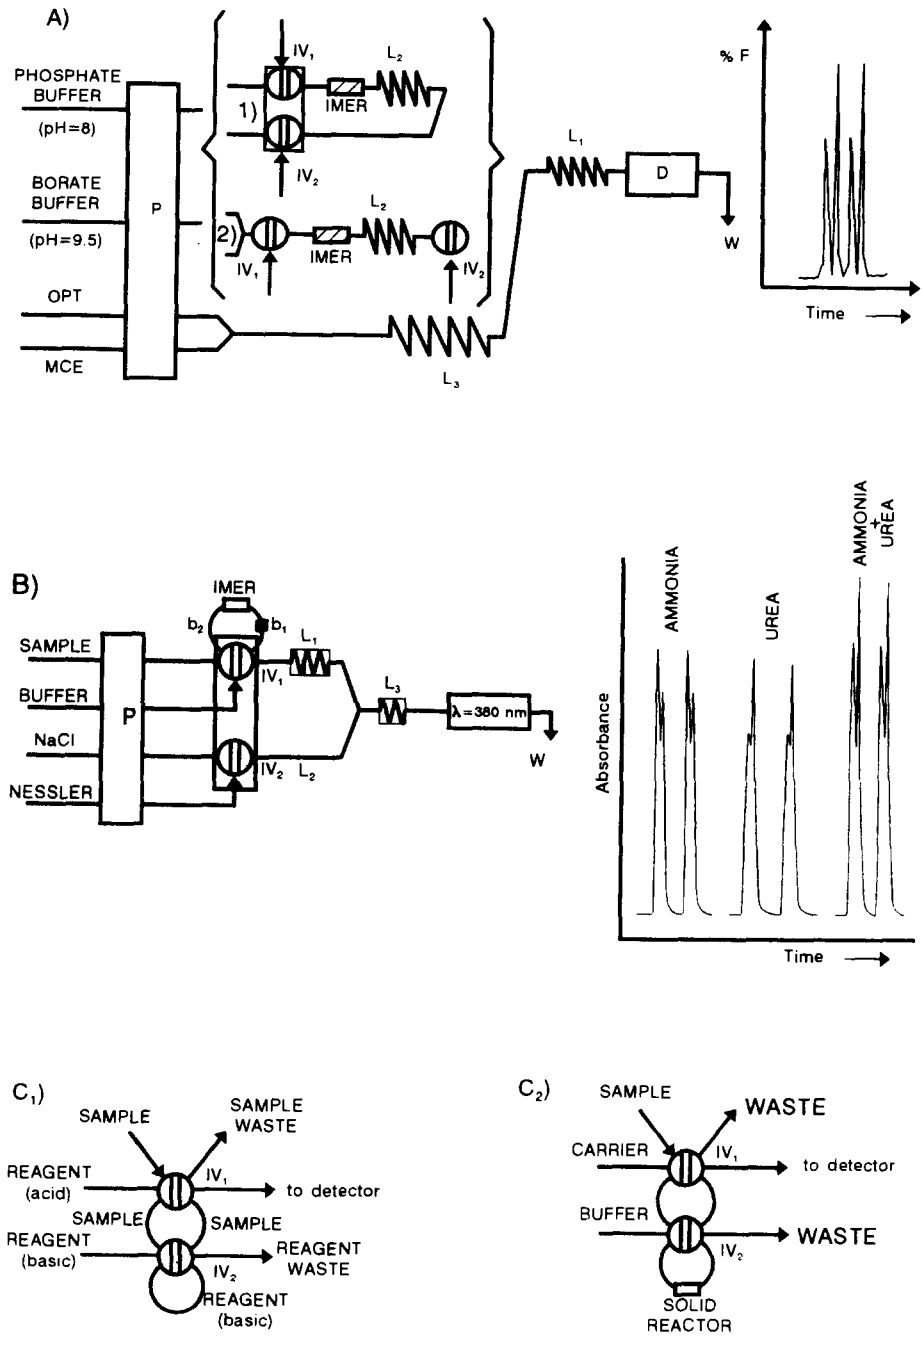

Fig. 3. Manifolds for speciating N based on an altered injection system: (A) with valves in a serial or parallel arrangement for the fluorimetric determination of $NH_3$–urea; (B) by reversed FIA using the asymmetric merging-zones mode (Nessler's reagent is used as derivatizer and the reaction product is monitored photometrically); IMER and b denotes immobilized enzyme reactor and sample sub-loops, respectively; (C) with internally coupled valves ($C_1$) and an optional solid reactor ($C_2$). OPT and MCE are *o*-phthalaldehyde and mercaptoethanol, respectively.

verted into ammonia, which subsequently merges with the tail of Nessler's plug to give a signal proportional to the concentration of ammonia plus urea. The urea concentration is then obtained by difference [55].

The *internally coupled injection valves* used to establish pH gradients [56] provide an excellent means for accomplishing speciation. One such arrangement was used in conjunction with the $NH_3/NH_2$–$NH_2$ + OPA chemical system for speciation of these nitrogen forms, based on the fact that OPA reacts with $NH_3$ in basic medium whereas hydrazine yields a fluorescent product in acid medium. OPA solutions at two different pH values are used; one acts as carrier, the other filling the loop of the secondary

injection valve (that of the main valve is filled with sample), as shown in Fig. 3($C_1$). Simultaneous injection from the two valves produces a profile including four sample/reagent interfaces, and gives rise to a pH difference between the terminal and central interfaces that is as large as required by the chemical system and which can be manipulated through the loop of both valves. The two central interfaces can give rise to a single peak providing the loop of the secondary valve is small enough. Only three peaks appear on the recording; the two outer peaks correspond to hydrazine and the central peak to ammonia [57].

One other way of using internally coupled valves is by placing a solid reactor (whether redox or enzymatic) [58] *in the loop of the secondary valve*, as shown in Fig. 3($C_2$). The assembly, including a copperized cadmium microcolumn, was used for speciation of nitrogen as nitrite/nitrate. Both sub-loops of the main valve were filled with sample, and the secondary loop with carrier. By switching both valves to their inject positions, the carrier was passed through the redox column in the opposite direction to which it was filled in order to prevent overpacking the column, which would have been a problem otherwise. The first sample sub-plug, which was not reduced, was allowed to reach the detector, where it gave a signal proportional to the nitrite concentration. The second portion passed through the redox column to reduce nitrate to nitrite, thereby effectively giving a signal proportional to nitrate plus nitrite. The nitrate concentration was then obtained by difference [58]. A similar arrangement was used for iron speciation as [Fe(II)/Fe(III)] with 1,10-phenanthroline as the derivatizing reagent. The manifold was a part of an analyzer that also enables the determination of sulphate and ammonia, and the preconcentration of the analytes on an ion-exchange microcolumn located in the loop of an auxiliary valve. A series of switching valves circulate the appropriate reagents for each determination, the reaction products being monitored with a single, conventional photometric detector [59,60].

The above system enables the simultaneous determination of the analytes according to the FI criterion, by which simultaneous determinations are those based on a single injection operation [61]. However, sequential determination of two forms of a compound can be performed with a simpler assembly, such as that reported by Sperling et al. for chromium speciation [as Cr(III)/Cr(VI)] by *on-line preconcentration with selective adsorption* on activated alumina and flame atomic absorption detection. They use a conical microcolumn designed by themselves [62] that is placed in the loop of a commutator; preconcentration and elution are done in opposite directions in order to avoid both the gradually increasing compactness of the column and passage of the sample matrix through the detector. It is worth emphasizing the low detection limits thus achieved (1.0 and 0.8 ng $ml^{-1}$ for Cr(III) and Cr(VI), respectively) [63].

## 5. Speciation with an altered reaction/transport unit

Modifications of the reaction/transport unit mainly involve using diverting/switching valves [64] and/or splitting/merging points [65]. A manifold including one such unit allows speciation in a single injection operation with fixed-time or reaction-rate measurements. Cerium speciation as [Ce(III)/Ce(IV)] was accomplished using a manifold such as that shown in Fig. 4(A), with a redox reactor in one of the *split channels*, and monitoring the native fluorescence of Ce(III). The injected plug is split into two portions, one of which is rapidly driven to the detector, where endogenous Ce(III) is monitored. The other portion is delayed by passage through the redox reactor; it does not overlap with the first portion on passage through the detector, but produces a signal that consists of the contributions from both cerium forms initially present in the sample [66].

The speciation of free- and esterified-cholesterol in serum was also accomplished using a manifold with *splitting/merging points* [67,68]. A cholesterol esterase solid reactor inserted in one of the split channels produced the enzymatic hydrolysis of esterfied cholesterol in the sub-plug circulated through the channel, while the plug in the other channel underwent no hydrolysis. A cholesterol oxidase reactor placed beyond the merging point catalyzed the oxidation of cholesterol from the two plugs, which reached the reactor and detector sequentially. An enzyme electrode (peroxidase immobilized on a gold electrode) produced a signal due to the reduction of the hydrogen peroxide formed in the previous enzymatic step.

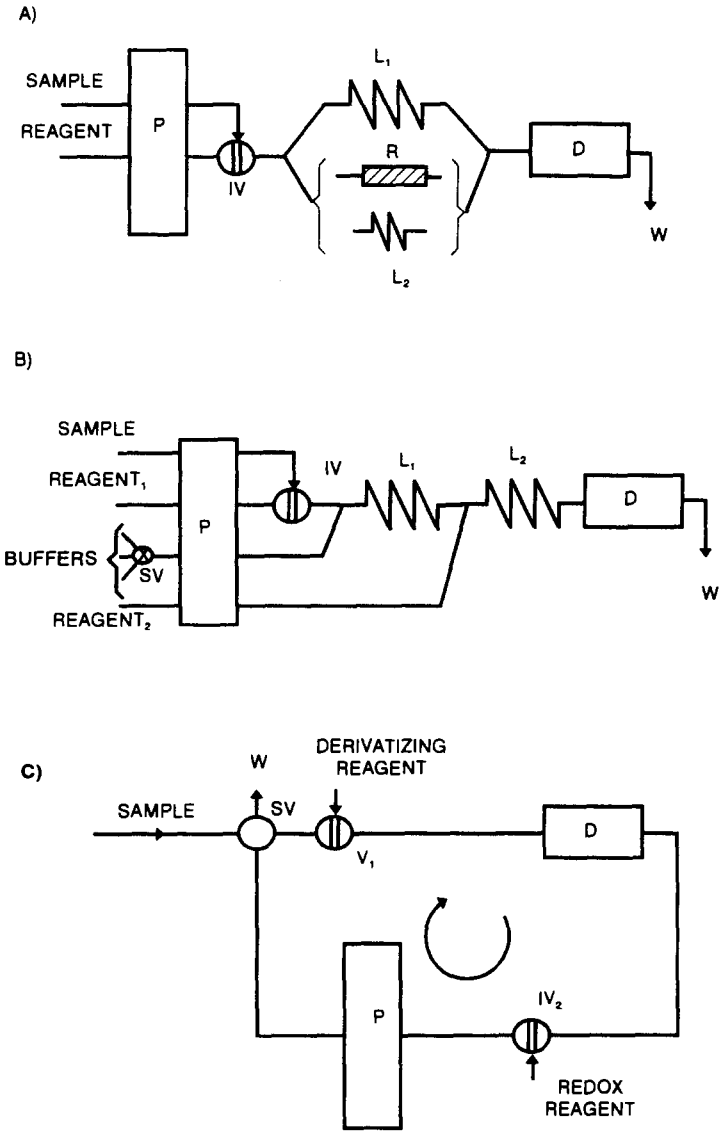

Fig. 4. Modifications of the transport/reaction zone for specification: (A) splitting and merging points, with or without a redox reactor, with fixed-time or reaction-rate monitoring, respectively; (B) selection of the reaction medium; (C) open–closed manifold for fixed-time and reaction-rate measurements for multipeak recordings. R and SV denote redox reactor and switching valve, respectively.

The different reaction-rate of cyanide with $B_6$ vitamins to yield fluorescent products also affords speciation of these compounds (as pyrodoxal-Py- and pyridoxal-5-phosphate-Py5P) in serum by means of an FI manifold with *splitting/merging points* (Fig. 4(A)). A two-peak recording is obtained per injected sample; the first peak is due to the reaction product of Py5P/cyanide, with faster kinetics; the second is due to the products of both vitamins [69]. The main drawback of this approach is the need for a compromise in the pH to be made for development of the derivatizing reactions of both analytes which detracts from the sensitivity. The sequential determination of these analytes by means of a manifold including a switching valve circumvents this shortcoming, as it allows a solution at the optimum pH for each reaction to be selected. The ensuing method is somewhat slower as it requires one sample injection per analyte; this augments sample consumption, which can be a serious drawback for clinical analyses [69].

The use of *valves for selecting* the most suitable reaction medium for each analyte has also been reported in connection with arsenic speciation (as arsenite/arsenate), and phosphate determination by measurement of the formation

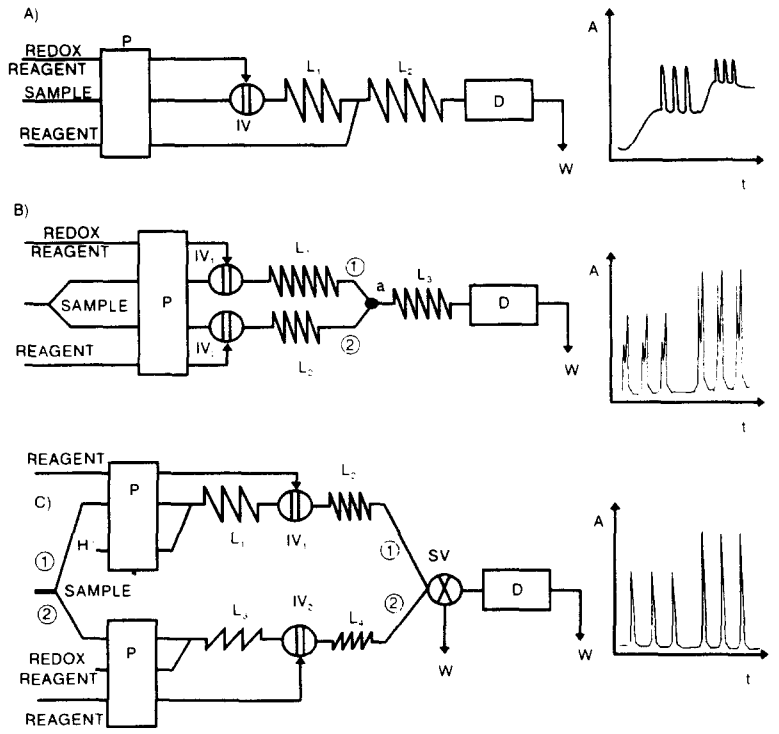

Fig. 5. Reversed FI manifolds for chromium speciation and typical recordings obtained: (A) with continous monitoring of Cr(VI) and periodic measurement of Cr(III); (B) by the asymmetric merging-zones mode (simultaneous determination); (C) by sequential determination of Cr(VI) (manifold 1) and Cr(VI) + Cr(III) (manifold 2). a is a merging point.

of a heteropolyacid with Mo(VI) and reduction to Molydenum Blue in the presence of ascorbic acid. The switching valve in Fig. 4(B) facilitates merging of the main channel with a stream of water (determination of arsenate), $KIO_3$ (determination of the arsenite/arsenate mixture) or $H_2SO_4$ (determination of $PO_4^{3-}$) [70]. Speciation of the two arsenic forms has also been accomplished using Fleitman's reaction for the selective formation of arsine, followed by efficient trapping of this volatile hydride and measurement by electrothermal atomic absorption spectrometry [71]. Rüde and Puchelt [72] recently reported a method based on flow-injection/hydride generation/atomic absorption spectrometry (FI/HG/AAS). The FI manifold provides a suitable acid medium for hydride formation for arsenic, arsenous, monomethylarsonic and dimetylarsinic acids. Switching to the specific medium by means of the valve is followed by injection of a sample aliquot for the determination of a single analyte, so only sequential determinations are feasible.

*Reversed FI* has been used to develop a wide range of speciation methods, particularly for chromium as [Cr(III)/Cr(VI)]. The derivatizing reaction involves chromic ion and diphenylcarbazide (DPC). Chromium(III) does not react with DPC, so it must have been oxidized previously, usually with Ce(IV). The most serious shortcoming of reversed FI is a high sample consumption relative to normal FI. However, this poses no problem with water samples (tap, sea, waste, etc.), which are usually abundant. The three configurations outlined in Fig. 5 were tested for speciation of chromium in water with the Cr(VI)/DPC system as indicator. Configurations A and B allow the simultaneous determination of the two oxidation states of the metal, while configuration C permits their sequential determination. Fig. 5(A) demonstrates continuous monitoring for Cr(VI) and periodical determination of Cr(III). In Fig. 5(B), asymmetric merging of a large DPC plug and a small oxidant plug gives two peaks related to the concentration of Cr(VI) and the sum of the two oxidation states, respectively. Valve SV in Fig. 5(C) is used to switch between the determination of Cr(VI) (upper manifold) and [Cr(VI)/Cr(III)] (lower manifold) [73].

A switching valve can also be employed to construct an *open–closed system* [74] for use in the reverse FI mode in order to accomplish efficient speciation with fixed-time or reaction-rate measurements. The manifold in Fig. 4(C) was used for the speciation of chromium [75]

and iron [76] by simultaneous injection of the derivatizing reagent (diphenylcarbazide and 1,10-phenanthroline, respectively) and a redox agent (Ce(IV) and hydroxylamine, respectively). The reagent injection provided several peaks for one of the analytes (Cr(VI) or Fe(II)); after the contents of the closed circuit were dispersed, the derivatizing reagent/sample mixture met the redox agent plug. Subsequent measurements consisted of the contributions from the two oxidation states.

## 6. Speciation with a modified detection unit

Discrimination between chemical forms can be accomplished using one or more detectors which can be interfaced to a computer to expedite data processing. *Two flow-cells arranged in series or parallel* in a double-beam spectrophotometer, or aligned within the optical path of a single-beam spectrophotometer, allow two peaks to be obtained per sample injection. The first peak corresponds to the species that reacts with the derivatizing reagent, and the second to both forms initially present in the sample. With serially connected cells, the point of merging of the redox agent lies between the cells, so the double peak is due to the above-described contributions. With parallel cells or cells aligned within optical path of a single-channel detector, a splitting point for the sample is used after the injection system. Each of the channels is merged with suitable reagents and leads to one of the cells. For a double peak to be obtained, the arrival of either reacting plugs at the flow-cells must be delayed in order to avoid overlap in the optical path [77].

Manifolds including *several detectors* are simpler, but also costlier, to construct. Coupled spectrophotometers have been used in combination with selective reactions for Fe(III) and Fe(II) complex formation with thiocyanate and 1,10-phenanthroline, respectively, for the determination of both oxidation states in mixed process liquors [78]. A molecular spectrometer and an atomic detector in a serial arrangement were also used for speciating Fe(II)/Fe(III) and Cr(III)/Cr(VI) (determination of one oxidation state and the total concentration) [79].

A more complex assembly consisting of *three detectors arranged in series* was used for the speciation of nitrogen (as $NH_3/NO_2^-$) and determination of pH, conductivity and residual chloride in waters [80]. The configuration is an excellent example of the versatility of FIA, in that a single-channel configuration affords five determinations under optimum conditions (pH, reagents and residence time), and switching between normal and reversed FIA as required.

*Flow-through (bio)chemical sensors* are among the most promising types of sensors on account of their ability to solve a host of real analytical problems [81]. They can play a variety of roles in speciation. Some entail no special data processing as speciation does not take place in the sensor itself, but in the hydrodynamic manifold prior to the sensor. Such is the case with the speciation of aluminium based on manipulation of the sample prior to insertion in order to discriminate reactive and total Al, and passage through an ion-exchange column to determine non-labile mono-meric Al [82–84]. Acid soluble Al and labile monomeric Al can be determined by difference. The principal use of this flow-through sensor (flow-cell packed with silica beads and $C_{18}$ as the bonded phase) is for in situ concentration in order to enhance the sensitivity [85].

## 7. Speciation based on data treatment

Most of the approaches dealt with in this section could also be included in section 6 in that they entail use of an unconventional detector, which in turn generally requires a computer for data acquistion and processing.

The simplest such devices are *fast scan voltammetric detectors*, which can be connected to $x-y$ and $x-t$ recorders (the latter are assisted by an electronic device) to obtain normal and derivative cyclic voltammograms, as in the resolution of a mixture of phenol, guaiacol and 2–4 dichlorophenol [86]. Despite the fact that the method has been applied with no computer, data treatment using one of these devices instead of direct measurement of the plateau or peaks of the recordings (normal and derivative measurements, respectively) would have ensured more accurate and reproducible results.

*Detectors with multidetection capabilities* (e.g. diode array spectrophotometers, DAS) must inevitably be interfaced to a computer in order that data may be acquired as they are produced by the detector. The reaction products of organic isomers such as 1- and 2-naphthol, or *o*-, *m*-, and *p*-cresol with 2-aminobenzothiazole/nitrite ion provide very similar absorption spectra. Binary and ternary mixtures of these

isomers have been resolved using FI-DAS for simultaneous monitoring at the 10–20 wavelengths where spectral differences between products are maximal [87]. A DAS-based multisensor was used for the speciation of aromatic amines by differences in the absorption spectra of the analytes of 10 wavelengths, using a flow-cell packed with $C_{18}$ bonded silica in a single-channel manifold with 40:60 v/v methanol/phosphate buffer as carrier-eluent. Analyte concentrations of $5 \times 10^{-7}$ M were thus resolved [88]. A similar flow-through multisensor, in a somewhat more complex FI modified effecting both hydrolysis and derivatization (Griess reaction), was applied to the speciation of carbamate pesticides. Retention of azo dyes on the solid packing of the flow-cell afforded determination limits 50 times lower than that of the conventional FI method [89].

The joint use of *FI-flow-through sensors-synchronous derivative spectrofluorimetry* [90–92] is one other approach to speciation where FI affords automated sample conditioning and derivatization. The sensor provides enhanced sensitivity, while the detector enables selectivity improvements by synchronizing the excitation/emission scan and processing data for delivering results based on a derivative signal. One such triple combination was used for speciation of $B_6$ vitamins (as pyridoxal, pyridoxal-5-phosphate and pyridoxic acid) by derivatization with cyanide to produce fluorescent compounds that were retained on $C_{18}$ bonded silica beads packed in a flow-cell. Elution/regeneration was realized with a switching valve that enabled passage of a 2 M HCl stream through the sensor. Analytes were thus determined in serum [93]. A similar assembly was used for the speciation of PAHs [94]. Halting the flow after retention was found to provide more reproducible results as regards data acquistion. A comparison of numerical vs. electronic derivation showed the best results in terms of sensitivity and reproducibility to be obtained with the former.

Multispeciation of up to seven forms of chromium (molecular, anionic and dimeric Cr(VI), and hydroxylated Cr(III)) was accomplished using a *reserved asymmetric merging-zones manifold* as described above [73], where a *glass-calomel* microelectrode was placed in the sample stream. Use of suitable *computer software* to process pH and total Cr(VI) and Cr(III) concentration data, in addition to the *acid–base equilibrium constants*, enabled calculation of the concentration of the seven forms [95].

## 8. Use of FI-chromatography for speciation

Although chromatography, particularly HPLC [96–105], provides a means for enhancing resolution in speciation analyses, its potential in this context can be further expanded by coupling with FI.

Stockwell and Corns [106] recently elaborated on commercially available continuous systems devised by them for coupling to *atomic fluorescence detectors* (AFS) for speciation of Hg, As and Se, which afford detection limits below the parts-per-trillion level. These hyphenated HPLC-FI-AFS and GC-FI-AFS systems enable optimum pretreatment/speciation of the sample components prior to atomic detection [107].

One *FI-HPLC approach* with a wide range of applications in routine analysis involved the two-fold use of the FI manifold as a screeming system and a post-column derivatizing system for analytes with similar chemical properties. The most receptive field for this type of hyphenated system is the analysis of large sample batches including only a few of interest on account of their toxicity or potential use as disease indicators. One typical example is the food analysis for aflatoxins. Screening of about 300 food samples for this type of carcinogen revealed their presence in only 6% [108]. A straightforward single-channel FI system permits measurement of up to 150 samples $h^{-1}$. A bromine solution is used as the carrier/reagent in order to enhance the fluorescence of the oxidized forms of the analytes. Only those few samples that produce signals corresponding to toxicity of suspected concentrations of the analytes are injected/separated in the chromatograph and the eluent derivatized/monitored in the FI manifold [109]. A similar assembly including an immobilized enzyme reactor for derivatization can be used for the screening/separation determination of bile acids in order to avoid overloading clinical laboratories with samples for patients with liver disorders [110].

*FI-HPLC* assemblies, such as those described above, have been used for the total and individual determination of polluting pesticides with photometric detection of the Griess product [111]. The sensitivity can be signifi-

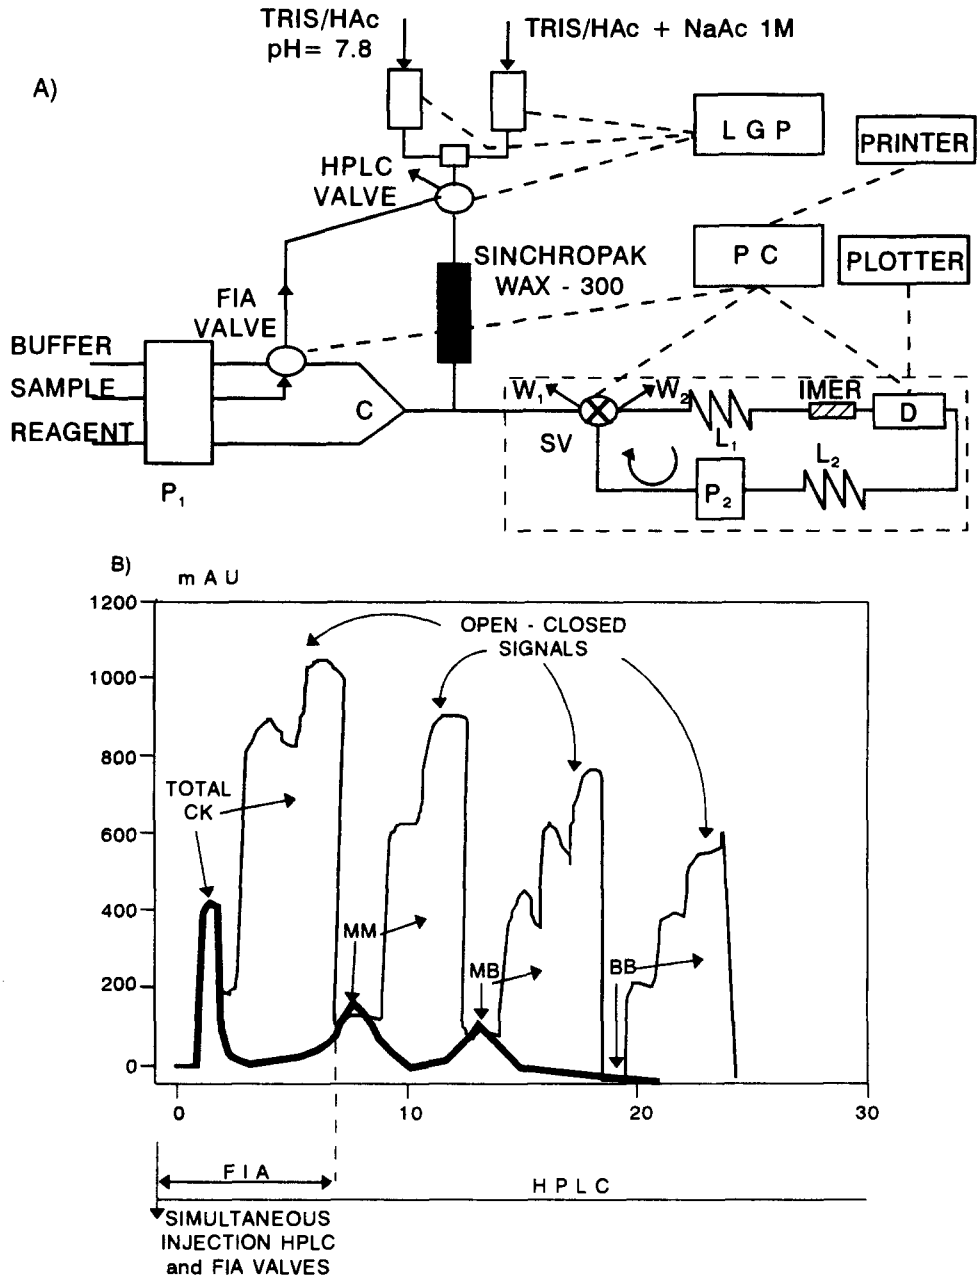

Fig. 6. (A) HPLC/FIA open–closed assembly for the total and individual determination of creatine kinase isoenzyme activities. LGP and PC denote liquid gradient programmer and personal computer, respectively. The sample stream can load both the FI and chromatographic valves or only one, depending on their positions. The lower part (FI manifold) is used for screening purposes; the upper system has a separative function, the FI manifold acting in this case as a post-column derivatization/detection system of the separated isoenzymes. (b) Recording obtained by simultaneously inserting the sample into the flow-injection system and the chromatographic column through the pertinent injection valves shown in (A). The bold line corresponds to a normal FI system (with the switching valve in the open position). The multiple-peak recording (thin line) was obtained by actuating the switching valve and trapping each zone in the closed circuit during the intervals between elution of successive isoenzymes. CK is creatine kinase, and MM, MB and BB are its isoenzymes.

cantly enhanced (50–100 times) by coupling with a flow-through sensor for preconcentration of the monitored product at the point of detection. One such set-up was used for the determination of mixtures of pesticides [112], and carbaryl and its hydrolysis product [113].

One effective way of increasing the sensitivity of an *FI-HPLC* method is by replacing the conventional manifold with an *open–closed system* [74–76] (see Fig. 6). This approach was

used for the individual and total determination of creatine kinase activities using two coupled enzymatic reactions [114]:

creatine phosphate
$$+ \text{ADP} \underset{Mg^{2+}}{\overset{CK}{\rightleftharpoons}} \text{creatine} + \text{ATP}$$
$$\text{ATP} + \text{D-glucose} \overset{HK}{\rightleftharpoons}$$
$$\text{D-glucose-6-phosphate} + \text{ADP}$$
$$\text{D-glucose-6-phosphate} + \text{NADP}^+ \overset{G6PDH}{\rightleftharpoons}$$
$$\text{D-glucose-}\delta\text{-lactone-6-phosphate} + \text{NADPH} + \text{H}^+$$

where CK, HK and G6PDH denote creatin-kinase, hexokinase and glucose-6-phosphate dehydrogenase, respectively. The two enzymes are immobilized together and the packed reactor is inserted into the open–closed circuit. Injections through an FI valve produce multipeak recordings that provide the total isoenzyme concentration. Injection through the HPLC valve, followed by sequential trapping in the circuit of each individual isoenzyme, gives rise to a multipeak recording for each isoenzyme, which enhances the sensitivity (see Fig. 6(B), which shows signals corresponding to the total determination, the conventional individual determination (with a single passage of the eluent through the detector) and the typical multipeak recording). The ensuing method was successfully applied to serum samples [114].

An *FI* system and a *gas chromatograph* are always naturally coupled in the precolumn portion. Derivatization of the analytes [115] or a two-fold derivatization/separation step by liquid–liquid [116] or ion-exchange [117] is quite common place in this context. An automatic method for the on-line preparation of fatty acid methyl esters from olive oil and other types of oil prior to their gas chromatographic determination provides excellent results [115]. Free fatty acids in dairy products can also be determined by directly coupling a continuous preconcentration ion-exchange/derivatization module to a gas chrom-atograph [117]. Pesticides of the *N*-methylcarbamate family have been quantified by use of an electron capture detector (ECD) with on-line derivatization/liquid–liquid extraction/gas chromatography. The hydrolysis products of *N*-methylcarbamates (phenols) are derivatized and extracted in a continuous fashion using pentafluoropropionic anhydride (the derivatizer) in *n*-hexane as extractant. In this way, the thermal instability of *N*-methylcarbamates is overcome by formation of fluorinated derivatives that can be identified and quantified at the ng $ml^{-1}$ level with an ECD [116].

## 9. Future of speciation analysis

As in many other areas of social interest, if the analytical process is resolved into several stages, including sampling, storage, preliminary operations, measurement-transducing, and data acquistition and processing, one can conclude that different extents of speciation development have been reached at each stage. Thus, the later stages have been the subject of more extensive research than the earlier steps. It can therefore be expected that reasearch will be focussed on such comparatively less developed stages in the future.

The main aim of sampling-storage is to preserve the integrity of the species to be determined by avoiding interconversion and losses. The principle technical choices for this purpose are as follows

(1) *Probe and flow-through sensors.* Probe and flow-through sensors enable in situ and on-line measurements, respectively, thus avoiding the need for minimizing manipulations prior to measurements. The type of sensor to be used depends on the nature of the sample matrix.

(2) *Sampling minicolumns.* These enable specific retention of each analyte form to be determined, but demand careful choice of the column.

(3) *Chemical treatment.* Chemical treatment of samples is aimed at preventing interconversion or loss of analytes. It entails thorough investigation and the use of automatic designs in order to minimize manipulation.

(4) *In situ separation techniques.* These are also intended to avoid analyte interconversions and losses; however, the target analytes are separated physically whether in different phases or as a whole.

Use of one or more of the above approaches prior to speciation-discrimination steps using a continuous separation technique, be it chromatographic or otherwise, and the most convenient hydrodynamic manifold in each case, should provide the optimal solution for each specific problem. The use of detectors with a high discrimination power (e.g. MS, FT-IR, etc.) in combination with continuous unseg-

mented techniques is also bound to play a central role in speciation analysis in the near future. All these approaches demand substantial investments in research and development if speciation is to take the place it deserves in chemical analysis.

## Acknowledgements

Dirección General de Investigación Científica y Técnica is thanked for financial support (project No. PB93/0827). One of the authors (D.W.B.) wishes to express his gratitude to the Community Bureau of Reference for award of a doctoral grant covering the expenses incurred during his stay in Spain.

# Kinetic studies of complexation reactions of water-soluble hydrazones with nickel(II) and palladium(II) ions

Tsugikatsu Odashima *, Mitsuru Yamaguchi [1], Hajime Ishii

*Institute for Chemical Reaction Science, Tohoku University, Katahira, Aoba-ku, Sendai, Miyagi 980, Japan*

Received 1 August 1994; revised 21 February 1995; accepted 23 February 1995

**Abstract**

The kinetics of complexation reactions of five water-soluble heterocyclic hydrazones with nickel(II) and palladium(II) ions have been investigated by stopped-flow spectrophotometry. Rates of complexations with nickel(II) and palladium(II) in the absence of chloride ion were found to be proportional to the first order of the ligand and metal ion concentrations and to the inverse first order of the hydrogen ion concentration except for the complexation of α-(2-benzimidazolyl)-α-(5-nitro-2-pyridyl)hydrazono-3-toluenesulfonic acid with palladium(II). Rates of complexation with palladium(II) in the presence of chloride ion were best described by a two-term expression, both terms being first order in the palladium ion and ligand concentrations and inverse first order in the hydrogen ion concentration. The first term has zero dependence of the chloride ion concentration, whereas the second is first order with respect to the chloride ion concentration. The rate constant for each complexation reaction was determined. The complexation of the hydrazones with nickel(II) was estimated to go according to an Eigen mechanism and that with palladium (II) according to the associative mechanism.

## 1. Introduction

Among the water-soluble hydrazones which consist of 5-nitro-2-pyridylhydrazine and heterocyclic ketones having one or two sulfo groups in their molecules, α-(5-nitro-2-pyridyl)hydrazono-α-(2-pyridyl)-3-toluenesulfonic acid (NPHPTS) [1], α-(5-nitro-2-pyridyl)hydrazono-α- (2-quinolyl)-3-toluenesulfonic acid (NPHQTS) [2], α-(2-benzothiazolyl) -α-(5-nitro-2-pyridyl)hydrazono-3-toluenesulfonic acid (BTNPHTS) [2], α-(2-benzimidazolyl)-α-(5-nitro-2-pyridyl)hydrazono-3-toluenesulfonic acid (BINPHTS) [2] and disulfonated (2-benzimidazolyl)(phenyl)methanone 5-nitro-2-pyridylhydrazone (DSBINPH) [3] were recently found to be very useful as highly sensitive spectrophotometric reagents for metals. Some of them were applied to the determination of trace amounts of cobalt [1,4] and nickel [3,5]. In addition, complexation equilibria between the above-mentioned five hydrazones and metal ions including cadmium(II), cobalt(II), copper(II), iron(II), palladium(II) and zinc(II) were investigated previously [6]. In this work kinetics of complexation reactions of these five hydrazones with nickel(II) and palladium(II) have been studied in detail by stopped-flow spectrophotometry in order to more fully understand these complexation reactions.

## 2. Experimental

### 2.1. Reagents

All reagents were of analytical-reagent grade

* Corresponding author.

[1] Present address: Analytical Research Center, Central Research Laboratory, Research & Development Division, Japan Energy Corporation, 3-17-35, Niizo-minami, Toda-shi, Saitama 335, Japan.

and all solutions were prepared with distilled, demineralized water, unless stated otherwise.

Hydrazone solutions, $5.0 \times 10^{-4}$ or $1.0 \times 10^{-3}$ M, were prepared by dissolving each hydrazone, synthesized as in earlier work [1–3], in water or 0.01 M sodium hydroxide solution. These solutions were further diluted with water if necessary.

Standard solutions of nickel(II) and palladium (II), about 0.5 mg $cm^{-3}$, were prepared by first dissolving their nitrates in 0.01 M perchloric acid and then standardizing by EDTA titration. Working solutions were prepared by dilution of these solutions with water.

Buffer solutions were prepared by mixing 0.2 M tris(hydroxymethyl)aminomethane (Tris) solution and 0.2 M nitric acid.

### 2.2. Apparatus

A JASCO KS-100M stopped-flow system was used, which consists of a stopped-flow module with a flow cell of optical path 10 mm, a diode-array spectrophotometer, an oscilloscope, an X–Y plotter, a microcomputer and a thermostatic bath. This system has a minimum dead-time of 2 ms and affords, on both the oscilloscope screen and the plotter, a three-dimensional (time-resolved) adsorption spectrum (corrected by subtracting the blank signal of the reaction product over the region of $\pm 170$ nm from a fixed wavelength, and its absorbance changes with time (kinetic curves) at repeated arbitrary wavelengths.

### 2.3. Procedure

Kinetic runs were performed under pseudo-first-order conditions with respect to hydrazone. Each run was repeated five times, the average signal being adopted.

Equal volumes of nickel(II) (or palladium(II)) and hydrazone solutions, both of which were buffered at a fixed pH between 7.0 and 8.5 (or adjusted to a fixed acidic pH value between 1.0 and 2.0 for the palladium(II) complex) with a constant ionic strength of 0.2 M (or 2.0 M for the palladium(II) complex), were mixed in the mixing chamber of the stopped-flow apparatus. The temperature was controlled at $25 \pm 0.1$ °C. A kinetic curve at the absorption-maximum wavelength of the complex was recorded on the oscilloscope screen and by the recorder. The absorbance values were collected regularly and processed by linear regression using programs provided with the microcomputer for the application of first-order reaction plots (Eq. (4)) and Kezdy–Swinbourne's plots (Eq. (6)) [7,8].

Kinetics measurements for the complexation of NPHQTS and BTNPHTS with nickel(II) were performed in 10% (v/v) 1,4-dioxane/$H_2O$ because of their low solubilities in water.

## 3. Results and discussion

In general, since the rate of complex formation depends on the concentrations of metal ion, ligand, and hydrogen ion, the rate of formation of the metal–hydrazone complex is assumed to be

$$-\frac{d[M]}{dt} = k^*[M]^a[R]^b[H^+]^c \quad (1)$$

where $t$ is the reaction time, $k^*$ is the rate constant, M is the metal ion, R is the hydrazone and $a$, $b$ and $c$ are the reaction orders with respect to the concentrations of metal ion, hydrazone and hydrogen ion, respectively.

Under a pseudo-first-order excess of the hydrazone and at a constant pH, the reaction rate can be expressed as

$$-\frac{d[M]}{dt} = k_{obsd}[M]^a \quad (2)$$

where $k_{obsd}$ is the observed pseudo-first-order rate constant, assuming $a = 1$. By integrating Eq. (2), taking the mass balance into consideration and then applying Beer's law, Eq. (3) can be derived, which is rewritten as Eq. (4).

$$A_\infty - A_t = (A_\infty - A_0)\exp(-K_{obsd}t) \quad (3)$$

$$-\ln(A_\infty - A_t) = -\ln(A_\infty - A_0) + k_{obsd}t \quad (4)$$

where $A_0$, $A_t$ and $A_\infty$ are the absorbance of the reaction system at $t = 0$, $t$ and $\infty$, respectively.

### 3.1. Kinetics of formation of nickel complexes

#### 3.1.1. Reaction order with respect to nickel-ion concentrations

Fig. 1 shows a kinetic curve measured in the presence of a large excess of DSBINPH and at pH 7.43 for the complex formation of DSBINPH with nickel(II), along with a $-\ln(A_\infty - A_t)$ vs. $t$ plot prepared from this

kinetic curve. The plot gives a straight line with a slope of 0.0436, which indicates that the rate of complexation is first order with respect to the nickel(II) concentration, i.e. $a = 1$ in Eq. (1), and the $k_{obsd}$ is $4.36 \times 10^{-2}\ s^{-1}$ under the experimental conditions given in Fig. 1.

In the complex formation of the other hydrazones with nickel(II), however, more than 20 h were required for attaining equilibrium. Accordingly the absorbances at infinite time ($A_\infty$) were not obtained within the experimental period (about 1 h). Therefore the kinetics analysis for these complexation reactions was performed according to Kezdy–Swinbourne's method [7,8] as follows. As is clear from Eq. (3), after the elapse of a fixed time, $\Delta t$, from $t$, Eq. (5) holds

$$A_\infty - A_{t+\Delta t} = (A_\infty - A_0)\exp[-k_{obsd}(t+\Delta t)] \quad (5)$$

From Eqs. (3) and (5), Eq. (6) is obtained

$$A_t = A_\infty[1 - \exp(k_{obsd}\Delta t)] + A_{t+\Delta t}\exp(k_{obsd}\Delta t) \quad (6)$$

Eq. (6) implies that a plot of $A_t$ versus $A_{t+\Delta t}$ gives a straight line with a slope of $\exp(k_{obsd}\Delta t)$. As the value of $\Delta t$ is known, the $k_{obsd}$ value can be calculated from this slope. Furthermore, $A_t$ is equal to $A_{t+\Delta t}$ and also equal to $A_\infty$ at $t = \infty$, so an intersecting point of this line with a straight line $A_t = A_{t+\Delta t}$ (i.e. a line with a slope of unity passing through the origin) should give the value of $A_\infty$. Fig. 2 shows a plot of $A_t$ versus $A_{t+\Delta t}$ for the BINPHTS–nickel(II) system as an example, in which the plot gives a straight line with a slope of 1.92. Similar results to that shown in Fig. 2

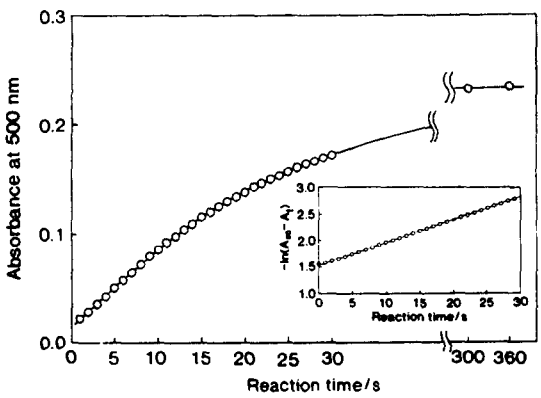

Fig. 1. Reaction curve and plot of $-\ln(A_\infty - A_t)$ vs. $t$ for the formation of DSBINPH–nickel(II) complex. (DSBINPH, $8.3 \times 10^{-5}$ M; Ni(II), $2.5 \times 10^{-6}$ M; pH 7.43; ionic strength, 0.2 M ($NaClO_4$); temperature, $25 \pm 0.1$ °C.)

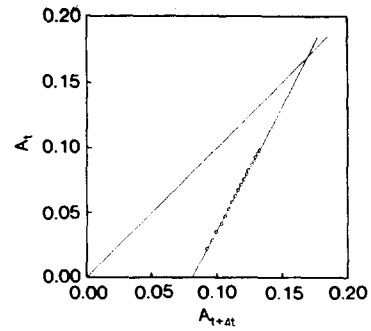

Fig. 2. Kezdy–Swinbourne plot for the BINPHTS–nickel(II) system. (BINPHTS, $7.5 \times 10^{-5}$ M; pH 7.52; Wavelength, 500 nm. Other conditions are the same as those in Fig. 1.)

were obtained for NPHPTS–, NPHQTS– and BTNPHTS–nickel(II) systems, which indicates that the rate of complexation in these systems is first order with respect to the nickel(II) concentration, i.e. $a = 1$.

### 3.1.2. Reaction order with respect to hydrazone concentration

From the above results the rate equation for the formation of the nickel complexes can be written as follows

$$-\frac{d[Ni(II)]}{dt} = k_{obsd}[Ni(II)] = k_{0(H)}[Ni(II)][R]^b \quad (7)$$

$$k_{obsd} = k_{0(H)}[R]^b \fallingdotseq k_{0(H)}C_R^b \quad (8)$$

where $k_{0(H)}$ is the conditional second-order rate constant and $C_R$ is the total concentration of the hydrazone. The effect of the hydrazone concentration on the observed rate constant was examined in order to determine the reaction order with respect to the hydrazone concentration. Fig. 3 shows the result for the DSBINPH–nickel(II) system, in which plots of $k_{obsd}$ versus $C_R$ give straight lines passing

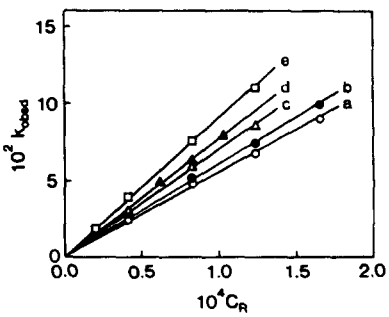

Fig. 3. Plots of $k_{obsd}$ vs. $C_R$ for DSBINPH–nickel(II) system at pH: curve a, 7.43; curve b, 8.01; curve c, 8.28; curve d, 8.37; curve e, 8.52. Other conditions are the same as those in Fig. 1.

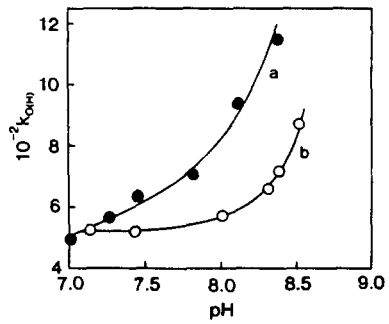

Fig. 4. Plots of $k_{0(H)}$ vs. pH for (curve a) BINPHTS–nickel(II) and (curve b) DSBINPH–nickel(II) systems. $C_R$: curve a, $9.4 \times 10^{-5}$ M; curve b, $1.0 \times 10^{-4}$ M. Other conditions are the same as those in Fig. 1.

through the origin. Similar results to that in Fig. 3 were obtained for the other hydrazone–nickel(II) systems, which indicates that the rate of complexation in these systems in first order, dependent on the hydrazone concentration, i.e. $b = 1$.

### 3.1.3. *Effect of hydrogen-ion concentration*

The effect of pH on the observed rate constant was studied, values of $k_{0(H)}$ ($\fallingdotseq k_{obsd}/C_R$) being plotted against pH for each hydrazone–nickel(II) system. According to the results, the $k_{0(H)}$ value decreased with increasing pH in the NPHQTS–nickel(II) system, but it increased with increasing pH in the other systems. This indicates that there are two controlling reactions; one is independent of, and the other is inverse first order, dependent on the hydrogen-ion concentration. Two examples of these plots are shown in Fig. 4.

### 3.1.4. *Rate-determining steps and rate constants*

Since the species of nickel in the pH range 7.0–8.5 studied in this work are $Ni(H_2O)_6^{2+}$ and $NiOH(H_2O)_5^{+}$ and those of the hydrazones are $HL^-$ for NPHPTS, NPHQTS and BTNPHTS, $H_2L^-$ for BINPHTS and $H_2L^{2-}$ for DSBINPH (where L denotes the undissociable part of the hydrazone), as is evident from the values of their acid dissociation constants [6], the equilibria and the reactions for the formation of monoligated complexes are expresseed by Eqs. (9)–(15).

For the hydrolysis of nickel(II)

$$Ni^{2+} + H_2O \overset{K_{Ni}}{\rightleftharpoons} NiOH^+ + H^+ \quad (9)$$

$$K_{Ni} = \frac{[NiOH^+][H^+]}{[Ni^{2+}]}$$

where $K_{Ni}$ is the hydrolysis constant of nickel(II).

For the formation of the NPHPTS, NPHQTS and BTNPHTS complexes, Eqs. (10) and (11) hold

$$Ni(H_2O)_6^{2+} + HL^- \xrightarrow{k_1} NiL + H^+ + 6H_2O \quad (10)$$

$$NiOH(H_2O)_5^{+} + HL^- \xrightarrow{k_2} NiL + 6H_2O \quad (11)$$

for the formation of the BINPHTS complex, Eqs. (12) and (13) hold

$$Ni(H_2O)_6^{2+} + H_2L^- \xrightarrow{k_1} Ni(HL) + H^+ + 6H_2O \quad (12)$$

$$NiOH(H_2O)_5^{+} + H_2L^- \xrightarrow{k_2} Ni(HL) + 6H_2O \quad (13)$$

and for the formation of the DSBINPH complex, Eqs. (14) and (15) hold

$$Ni(H_2O)_6^{2+} + H_2L^{2-} \xrightarrow{k_1} [Ni(HL)]^- + H^+ + 6H_2O \quad (14)$$

$$NiOH(H_2O)_5^{+} + H_2L^{2-} \xrightarrow{k_2} [Ni(HL)]^- + 6H_2O \quad (15)$$

where $k_1$ and $k_2$ represent the rate constants of respective reaction steps.

Here we consider the DSBINPH–nickel(II) system as an example. On the basis of the results described above and the assumption that the rate-determining steps are competitive reactions shown by Eqs. (14) and (15), the rate equation can be expressed as

$$-\frac{d[Ni(II)]}{dt} = k_1[Ni^{2+}][H_2L^{2-}] + k_2[NiOH^+][H_2L^{2-}] \quad (16)$$

From Eqs. (7), (8), (9) and (16), Eq. (17) can be derived.

$$k_{0(H)} = \frac{k_1 + (k_2K_{Ni}/[H^+])}{1 + (K_{Ni}/[H^+])} \quad (17)$$

Also for the complexation reactions of the other hydrazones, Eq. (17) can be derived by similar treatment. Values of $k_1$, $k_2$ and $K_{Ni}$ were calculated by the Simplex method using the data of the $k_{0(H)}$ vs. pH plot obtained already. The results are given in Table 1 and theoretical curves for the $k_{0(H)}$ vs. pH plots are shown by solid lines in Fig. 4. The $K_{Ni}$ values obtained in this work are nearly equal to that ((0.1–about 6.3) $\times 10^{-10}$ M) reported in the literature [9]. The values of $k_1$ and $k_2$ of each complexation reaction are also almost the same in the order, respectively, and the $k_2$ values are

Table 1
Rate constants of complexation reactions of hydrazones with nickel(II) and hydrolysis constant of nickel(II) at 25 ± 0.1 °C and an ionic strength of 0.2 M ($NaClO_4$)

| Hydrazone | $k_1$ ($M^{-1}s^{-1}$) | $k_2$ ($M^{-1}s^{-1}$) | $K_{Ni}$ (M) |
|---|---|---|---|
| NPHPTS | $3.6 \times 10^2$ | $3.6 \times 10^3$ | $1.1 \times 10^{-10}$ |
| NPHQTS | –[a] | –[a] | –[a] |
| BTNPHTS[b] | $5.5 \times 10$ | $1.8 \times 10^3$ | $1.0 \times 10^{-10}$ |
| BINPHTS | $2.5 \times 10^2$ | $1.8 \times 10^4$ | $1.0 \times 10^{-10}$ |
| DSBINPH | $2.4 \times 10^2$ | $5.3 \times 10^3$ | $0.99 \times 10^{-10}$ |

[a] Not determined.
[b] Determined in aqueous 10% (v/v) 1,4-dioxane.

close to the releasing rate constant ($1.5 \times 10^4\ s^{-1}$) [10] of a water molecule from the nickel aquo-ion, although the $k$ value of the BTNPHTS–nickel(II) system is somewhat small. This suggests that the complexation reactions between the hydrazones and nickel(II) proceed according to an Eigen mechanism.

### 3.2. Kinetics of formation of palladium complexes in the absence of chloride ion

#### 3.2.1. Reaction order with respect to palladium-ion concentration

All kinetics experiments were performed in strongly acidic media because the complexation reaction between the hydrazones and palladium (II) was too fast to measure in weakly acidic media. Fig. 5 shows a $-\ln(A_\infty - A_t)$ vs. $t$ plot for the formation of a BTNPHTS–palladium(II) complex measured in the presence of a large excess of DSBINPH and at an acidity of 1.16 M. The plot gives a sraight line. Similar results to those in Fig. 5 were obtained for the

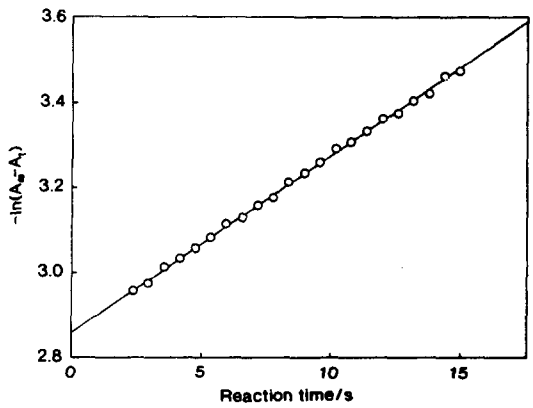

Fig. 5. Plot of $-\ln(A_\infty - A_t)$ vs. $t$ for formation of BTNPHTS–palladium(II) complex. (BTNPHTS, $7.8 \times 10^{-5}$ M; Pd(II), $2.1 \times 10^{-6}$ M; $[H^+]$, 1.16 M; ionic strength, 2.0 M ($NaNO_3$); temperature, 25 ± 0.1 °C.)

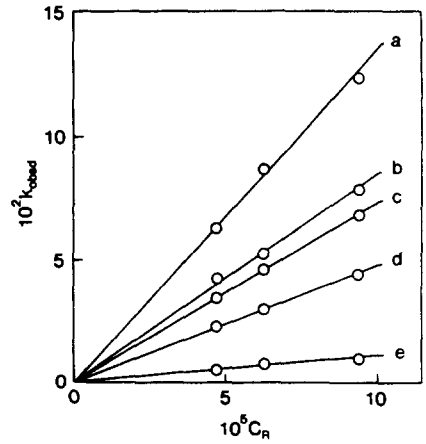

Fig. 6. Plots of $k_{obsd}$ vs. $C_R$ for BTNPHTS–palladium(II) system at pH: curve a, 0.77; curve b, 0.97; curve c, 1.16; curve d, 1.45; curve e, 1.93; wavelength, 590 nm. Other conditions are the same as those in Fig. 5.

formation of the other hydrazone–palladium (II) complexes. These results indicate that the complexation reactions between the hydrazones and palladium(II) are all first order with respect to the palladium (II) concentration, i.e. $a = 1$.

#### 3.2.2. Reaction order with respect to hydrazone concentration

Fig. 6 shows the effect of the concentration of BTNPHTS on the observed rate constant at various acidities. The plots of $k_{obsd}$ versus $C_R$ give straight lines passing through the origin. Similar results to those in Fig. 6 were obtained for the other hydrazone–palladium(II) systems, which indicates that the complexation reactions of these systems are all first order with respect to the hydrazone concentration, i.e. $b = 1$.

#### 3.2.3. Reaction order with respect to hydrogen-ion concentration

Curve a in Fig. 7 shows a $k_{0(H)}$ vs. $1/[H^+]$ plot for the formation of the DSBINPH–palladium (II) complex. The plot gives a straight line passing through the origin. Similar results to those shown by curve a in Fig. 7 were obtained for the formation of the other hydrazone complexes except for the BTNPHTS complex, for which a $k_{0(H)}$ vs. $1/[H^+]$ plot shown by curve b in Fig. 7 was obtained. These results indicate that the reaction order with respect to the hydrogen-ion concentration is inverse first order (i.e. $c = -1$) for the formation of the hydrazone complexes except for the BTNPHTS complex, and is measured as a complicated function of the hydrogen-ion concentration in

the BTNPHTS system. This discrepancy seems to be influenced by an intramolecular hydrogen bond in BTNPHTS. At the present stage, however, we cannot give a clear chemical interpretation for the intramolecular hydrogen bond.

*3.2.4. Rate-determining steps and rate constants*

The species of palladium under the conditions studied is $Pd(H_2O)_4^{2+}$ and those of the hydrazones are considered to be $H_3L^+$ and $H_2L$ for NPHPTS, NPHQTS and BTNPHTS, $H_4L^+$ and $H_3L$ for BINPHTS and $H_4L$ and $H_3L^-$ for DSBINPH. Taking into consideration the results described above, however, only Eqs. (18)–(20) are feasible as formation reactions of monoligated complexes between the hydrazones and palladium (II). For NPHPTS and NPHQTS

$$Pd(H_2O)_4^{2+} + H_3L^+ \xrightarrow{k_1} [Pd(H_2L)]^{2+} + H^+ + 4H_2O \quad (18)$$

for BINPHTS

$$Pd(H_2O)_4^{2+} + H_4L^+ \xrightarrow{k_1} [Pd(H_3L)]^{2+} + H^+ + 4H_2O \quad (19)$$

and for DSBINPH

$$Pd(H_2O)_4^{2+} + H_4L \xrightarrow{k_1} [Pd(H_3L)]^{+} + H^+ + 4H_2O \quad (20)$$

The rate equation can be expressed by Eq. (21) for every reaction system, except the BTNPHTS–palladium(II) system.

$$-\frac{d[Pd(II)]}{dt} = k_1[Pd^{2+}]\frac{C_R/[H^+]}{1+(K_{al}/[H^+])} \quad (21)$$

where $K_{al}$ is the acid dissociation constant of each hydrazone. From Eqs. (2), (8) and (21)

$$k_{0(H)}[1+(K_{al}/[H^+])] = k_1/[H^+] \quad (22)$$

is obtained. Eq. (22) means that the plot of $k_{0(H)}[1+(K_{al}/[H^+])]$ versus $1/[H^+]$ gives a straight line with a slope of $k_1$ passing through the origin. Actually this plot for each hydrazone–palladium (II) system gave a straight line. The value of $k_1$ obtained for each reaction system is given in Table 2.

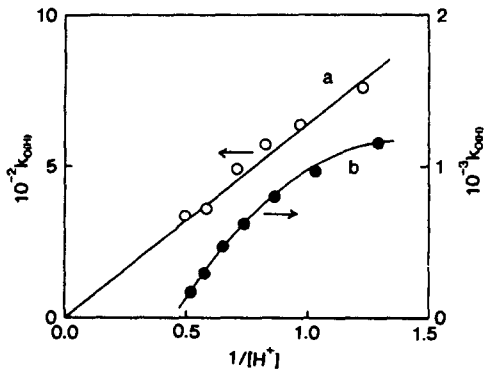

Fig. 7. Plots of $k_{0(H)}$ vs. $1/[H^+]$ for (curve a) DSBINPH–palladium(II) and (curve b) BTNPHTS–palladium(II) systems at $C_R$: curve a, $8.2 \times 10^{-5}$ M; curve b, $7.8 \times 10^{-5}$ M. Other conditions are the same as those in Fig. 5.

Table 2
Rate constants of complexation reactions of hydrazones with palladium(II) in the absence of chloride ion at $25 \pm 0.1$ °C and an ionic strength of 2.0 M ($NaClO_4$)

| Hydrazone | $k_1$ ($M^{-1}s^{-1}$) | $k_{-1}/K'_a$ ($M^{-1}s^{-1}$) |
|---|---|---|
| NPHPTS | $3.0 \times 10^3$ | – |
| NPHQTS | $2.7 \times 10^2$ | – |
| BTNPHTS | $1.5 \times 10^3$ | $7.7 \times 10^{-4}$ |
| BINPHTS | $4.3 \times 10^2$ | – |
| DSBINPH | $7.6 \times 10^2$ | – |

As for the BTNPHTS–palladium(II) system, on the other hand, the reverse reaction was taken into consideration in addition to the forward one as shown in Eq. (23) because the reaction order with respect to the hydrogen-ion concentration was not inverse first order but complex, as was already shown by curve b in Fig. 7.

$$Pd^{2+} + H_3L^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Pd(H_2L)]^{2+} + H^+ \quad (23)$$

where $k_{-1}$ is the rate constant of the reverse reaction.

The rate equation is expressed by Eq. (24)

$$-\frac{d[Pd(II)]}{dt} = k_1[Pd^{2+}][H_3L^+][H^+]^{-1} - k_{-1}[Pd(H_2L)^{2+}][H^+] \quad (24)$$

The complexation reaction of BTNPHTS with palladium(II) is represented by Eq. (25), its equilibrium constant, $K_{eq}$, being given by Eq. (26) [6]

$$Pd^{2+} + H_3L^+ \underset{}{\overset{K_{eq}}{\rightleftharpoons}} Pd(HL)^+ + 2H^+ \quad (25)$$

$$K_{eq} = \frac{[Pd(HL)^+][H^+]^2}{[Pd^{2+}][H_3L^+]} = 10^{4.9} \quad (26)$$

The proton dissociation of the complex $Pd(H_2L)^{2+}$ is represented by Eq. (27), its proton dissociation constant, $K'_a$, being given by Eq. (28).

$$Pd(H_2L)^{2+} \underset{}{\overset{K'_a}{\rightleftharpoons}} Pd(HL)^+ + H^+ \quad (27)$$

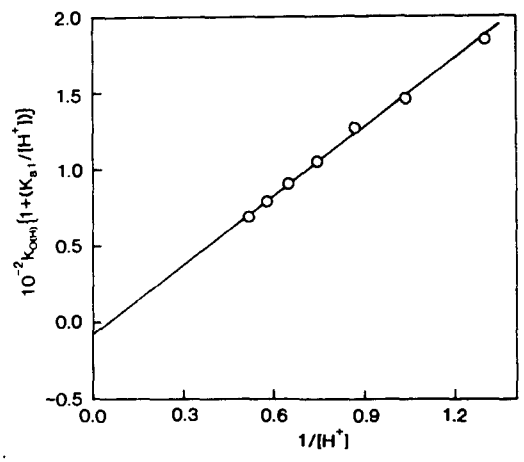

Fig. 8. Plot of $k_{0(H)}(1 + K_{a1}/[H^+])$ vs. $1/[H^+]$ for BT-NPHTS–palladium(II) system at $C_R$, $7.8 \times 10^{-5}$ M. Other conditions are the same as those in Fig. 5.

$$K'_a = \frac{[Pd(HL)^+][H^+]}{[Pd(H_2L)^{2+}]} \quad (28)$$

From Eqs. (7), (8), (24), (26) and (28), Eq. (29) can be derived, which is rewritten as Eq. (30)

$$-\frac{d[Pd(II)]}{dt} = \frac{[Pd^{2+}]C_R}{1 + (K_{a1}/[H^+])} \times (k_1/[H^+] - K_{eq}k_{-1}K'_a) = k_{0(H)}[Pd^{2+}]C_R \quad (29)$$

$$k_{0(H)}[1 + (K_{a1}/[H^+])] = k_1/[H^+] - K_{eq}k_{-1}/K'_a \quad (30)$$

Eq. (30) means that the plot of $k_{0(H)}[1 + (K_{a1}/[H^+])]$ versus $1/[H^+]$ gives a straight line, the values of $k_1$ and $k_{-1}/K'_a$ being calculated from the slope and the intercept of the line, respectively. Fig. 8 shows this plot for the BT-NPHTS–palladium(II) system, which gives a straight line. The values of $k_1$ and $k_{-1}/K'_a$ calculated are given in Table 2.

### 3.3. Kinetics of formation of palladium complexes in the presence of chloride ion

#### 3.3.1. Reaction orders with respect to concentrations of palladium ion, hydrazone and hydrogen ion

Fig. 9(A) shows an $\ln(A_\infty - A_t)$ vs. $t$ plot for the complexation of DSBINPH with palladium (II) in the presence of large excesses of DS-BINPH and chloride ion and at a constant acidity of 1.06 M. The plot gives a straight line. Figs. 9(B) and 9(C) show $k_{obsd}$ vs. $C_R$ plots at various acidities and a $k_{0(H)}$ vs. $1/[H^+]$ plot, respectively, for the DSBINPH–palladium(II) system. Every plot gives a straight line passing through the origin. Similar results to those shown in Figs. 9(A)–9(C) were obtained for the other hydrazone–palladium(II) systems. These results reveal that the reaction orders with respect to the concentrations of both palladium(II) and the hydrazone are first order.

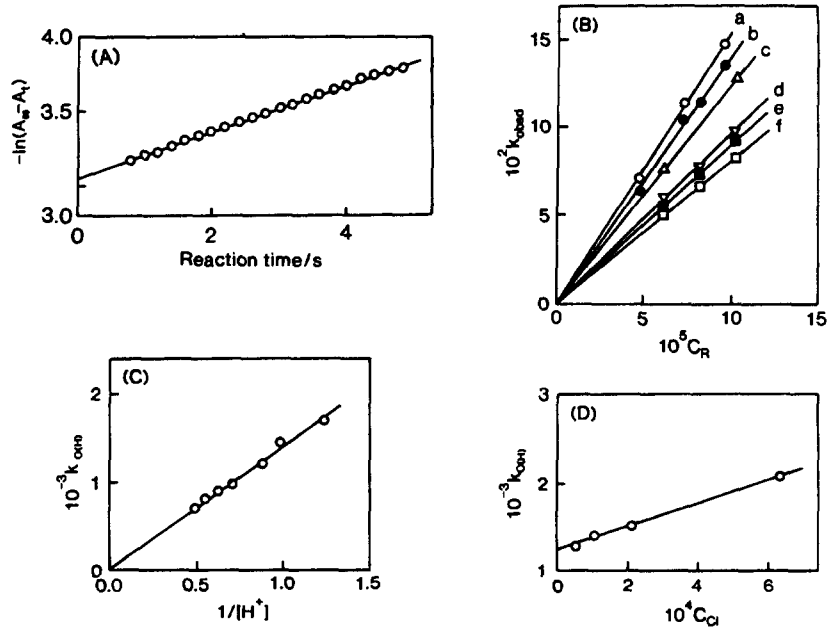

Fig. 9. Plots of (A) $-\ln(A_\infty - A_t)$ vs. $t$, (B) $k_{obsd}$ vs. $C_R$, (C) $k_{0(H)}$ vs. $1/[H^+]$ and (D) $k_{0(H)}$ vs. $C_{Cl}$ for DSBINPH–palladium(II)–chloride system. DSBINPH, $8.2 \times 10^{-5}$ M; (A), (C), (D) Pd(II), $2.1 \times 10^{-6}$ M; (B) $[H^+]$: (curve a) 0.81, (curve b) 1.01, (curve c) 1.22, (curve d) 1.42, (curve e) 1.72, (curve f) 2.03; (A), (D) $[H^+]$, 1.06; (A), (B), (C) $[Cl^-]$, $2.12 \times 10^{-4}$ M; ionic strength, 2.0 M ($NaNO_3$); wavelength, 564 nm; temperature, $25 \pm 0.1$ °C.

that with respect to the hydrogen-ion concentration being inverse first order.

### 3.3.2. Reaction order with respect to chloride-ion concentration

Fig. 9(D) shows a $k_{0(H)}$ vs. $C_{Cl}$ plot for the DSBINPH–palladium(II) system, which gives a straight line with an intercept. Similar results to those shown in Fig. 9(D) were obtained for NPHPTS– , NPHQTS– and BINPHTS–palladium (II) systems, but no such result was obtained for the BTNPHTS–palladium(II) system. These results indicate that the reaction order with respect to the chloride-ion concentration for the complex formation between palladium(II) and the hydrazones, except BTNPHTS, under the conditions studied is zero order and first order.

### 3.3.3. Rate-determining steps and rate constants

The species of palladium(II) under the conditions studied are regarded as $Pd(H_2O)_4^{2+}$, $PdCl(H_2O)_3^{+}$ and $PdCl_2(H_2O)_2$. On the basis of the above results, however, potential complexation reactions between the hydrazones and palladium(II) are restricted to Eqs. (31)–(36) and each pair of reactions is considered to proceed competitively and govern the complexation reaction in each hydrazone–palladium(II) system. For NPHPTS and NPHQTS

$$Pd(H_2O)_4^{2+} + H_3L^{+} \xrightarrow{k_1} Pd(H_2L)^{2+} + H^{+} + 4H_2O \quad (31)$$

$$PdCl(H_2O)_3^{+} + H_3L^{+} \xrightarrow{k_2} Pd(H_2L)Cl^{+} + H^{+} + 3H_2O \quad (32)$$

for BINPHTS

$$Pd(H_2O)_4^{2+} + H_4L^{+} \xrightarrow{k_1} Pd(H_3L)^{2+} + H^{+} + 4H_2O \quad (33)$$

$$PdCl(H_2O)_3^{+} + H_4L^{+} \xrightarrow{k_2} Pd(H_3L)Cl^{+} + H^{+} + 3H_2O \quad (34)$$

and for DSBINPH

$$Pd(H_2O)_4^{2+} + H_4L \xrightarrow{k_1} Pd(H_3L)^{+} + H^{+} + 4H_2O \quad (35)$$

$$PdCl(H_2O)_3^{+} + H_4L \xrightarrow{k_2} Pd(H_3L)Cl + H^{+} + 3H_2O \quad (36)$$

where $k_1$ and $k_2$ represent the rate constants. The rate equation for these complexation reactions can be expressed as

Table 3
Rate constants of complexation reactions of hydrazones with palladium(II) in the presence of chloride ion at 25 ± 0.1 °C and ionic strength of 2.0 M ($NaClO_4$)

| Hydrazone | $k_1$ ($M^{-1}s^{-1}$) | $k_2$ ($M^{-1}s^{-1}$) |
|---|---|---|
| NPHPTS | $8.0 \times 10^3$ | $1.9 \times 10^4$ |
| NPHQTS | $5.6 \times 10^2$ | $7.4 \times 10^3$ |
| BTNPHTS | –[a] | –[a] |
| BINPHTS | $3.9 \times 10^2$ | $8.1 \times 10^3$ |
| DSBINPH | $1.5 \times 10^3$ | $1.7 \times 10^4$ |

[a] Not determined.

$$-\frac{d[Pd(II)]}{dt} = k_1\frac{[Pd(II)][L]}{[H^+]} + k_2\frac{[Pd(II)][L][Cl^-]}{[H^+]} \quad (37)$$

By taking into consideration the acid dissociation of the hydrazones and the mass balance of the hydrazones and palladium(II) and using the side-reaction coefficient, $\alpha_{(Cl)}$, of palladium(II) for chloride ion and the formation constant, $\beta_1$, of the monochloro complex of palladium(II), Eq. (38) can finally be derived from Eq. (37)

$$k_{0(H)} = \frac{1}{\left(1 + \frac{k_{al}}{[H^+]}\right)[H^+]}\left[k_1 + k_2\frac{C_{Cl}\beta_1}{\alpha_{(Cl)}}\right] \quad (38)$$

where $C_{Cl}$ is the total concentration of chloride ion.

Eq. (38) means that the $k_{0(H)}$ vs. $C_{Cl}$ plot, which is equivalent to Fig. 9(D) gives a straight line; the values of $k_1$ and $k_2$ can be calculated from the intercept and the slope of this line, respectively. The results obtained are summarized in Table 3.

### 3.3.4. Mechanism of formation of palladium complexes

Palladium(II) usually forms the square planar complex [11]. As is clear from Table 3, the rate constants for the complexation of palladium(II) obtained in this work depend on the kind of hydrazone, which suggests that the complexation reaction of the hydrazones with palladium(II) goes according to the associative mechanism. The value of $k_2$ is larger than that of $k_1$ for every hydrazone–palladium(II) system, indicating that the palladium aquo-ion is activated by the formation of monochloro ion. Also, the $k_1$ values obtained here are in accordance with those obtained in the absence of chloride ions, demonstrating the reliability of this work.

# Robust regression methods to calibrate a continuous flow analyzer in the colorimetric analysis of inorganic phosphorus in seawater

M. Mecozzi

*ICRAM, Istituto Centrale per la Ricerca Scientifica e Tecnologica Applicata al Mare, via L. Respighi n.5, 00197 Roma, Italy*

Received 27 September 1994; revised 22 November 1994; accepted 17 February 1995

**Abstract**

The presence of a salinity effect in the automated analysis of phosphorus in seawater performed by a phosphomolybdate complex can cause the inaccurate estimation of the true amount, because the calibration procedure performed by least-squares regression does not take into account the different analytical response of samples and standard solutions. The error arising from this salt effect is corrected by calibrating the autoanalyzer with robust regression methods (RRMs), which allow definition of the range of salinity in which the analytical response of the autoanalyzer is only dependent on the concentration of marine nutrients. The RRMs are especially helpful in the analysis of oligotrophic samples where the salinity effect is particularly relevant.

## 1. Introduction

The study of phenomena such as eutrophication or algal blooms requires the analysis of many samples to detect the amount of principal marine nutrients such as phosphate, silicate and nitrogen compounds.

The colorimetric methods generally employed are often performed by a continuous flow autoanalyzer, which allows completion of the analysis in a short time and with good detection limits [1]. However, some interferences can be observed, either when calibration solutions and samples have different salinity (baseline drifts) or when the linearity range concentration vs. analytical response of the autoanalyzer is not well identified. In fact the analytical response of the instrument generally tends to increase with increasing salinity (Fig. 1), either a result of refractive index differences or as a stray-light effect depending on the general characteristics of the autoanalyzer. These interferences cause incorrect determinations of nutrients when the calibration is performed by a global least-squares (LS) regression.

This effect of automated techniques is called "density fluctuation", and in the analysis of phosphorus based on ion pair formation between molybdophosphate and malachite green it can be corrected by a reducing agent ($S_2O_3^{2-}$) with a modified instrument [2] and by a standard addition method (MOSA).

In this paper, new univariate calibration procedures based on different methods of robust linear regression analysis are employed in order to correct the density fluctuation in the analysis of phosphorus. The two procedures examined are the non-parametric regression according to Theil's complete method (TCM) [3] and the least median or squares (LMS) [4]. The main advantages of robust regression methods (RRMs) are no modification of the autoanalyzer is required and the operator has the potential to determine the linearity range of nutrient vs. analytical response according to the salinity characteristics of each sample.

*SSDI* 0039-9140(95)01566-3

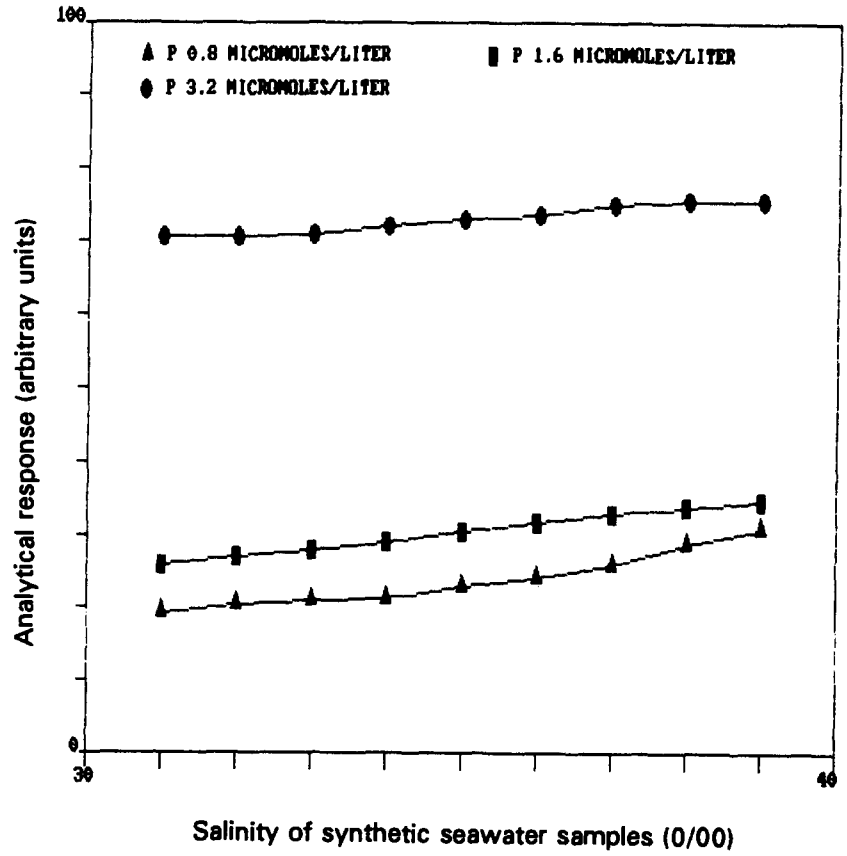

Fig. 1. Evidence of salt effect: increase in the instrumental response of identical concentrations of P with the salinity of synthetic seawater samples.

TCM and LMS regressions were applied to the analysis of phosphorus in synthetic seawater samples to verify the precision of the proposed method, and were compared with other methods of calibration such as MOSA and multilinear regression (MLR) analysis. The results were more precise than those obtained by unmodified LS regression and comparable with MOSA.

## 2. Experimental

All the measurements were performed using an Integral Alliance continuous flow autoanalyzer supported by an AST Premium 286 PC, according to the modified phosphomolybdate complex method for the analysis of inorganic P in seawater [5].

All the chemicals were of analytical reagent grade and only MilliQ deionized water was used to prepare the solutions.

Synthetic seawater samples, having a salinity of 31–39‰ and a P content of 0–3.5 μmol $cm^{-3}$, were considered in this study, and the salinity values were prepared according to the table of the major ions in seawater in relation to salinity [6].

In every test, synthetic seawater, having the lowest salinity value of the considered range, was always used as the spectroscopic blank. Such care was necessary, because the instrumental response increases with salinity (Fig. 1). Within a salinity range, baseline drifts or ghost peaks can sometimes be observed owing to the salt effect when an intermediate value of salinity is considered as the spectrophotometric blank, instead of the lowest value.

Triplicate measurements of each synthetic sample were performed to avoid outliers resulting from uncorrected concentrations of P.

LS regression, MLR, TCM and the residual regression analysis of TCM according to the studentized residual method [3] were carried out using home-made software written in GW-BASIC (ver. 3.22). LMS were performed by the PROGRESS software [7], which also includes residual regression analysis by the standardized residual method [3].

## 3. Results and discussion

The importance of applying RRMs can be illustrated by some practical examples. Let us consider the determination of phosphorus in a marine sample set having salinity between 31 and 36‰ (Table 1). This range is very common in the Adriatic Sea, where the salinity may vary from 30 to higher than 39‰ [8]. If we assume an a priori linear relationship concentration of $P$ vs. analytical response, we could inadvertently include some outliers in the automated calibration performed by LS regression. LS regression is based on the assumption of an independent and normal error distribution having a constant variance; this means that the regression residuals are presumed to have a gaussian distribution [9]. In the analysis of marine nutrients performed by an autoanalyzer, the conditions of normality could not be verified because the salinity can cause a non-gaussian distribution of residual regression.

A good procedure to correct the interference of this salt effect is the identification of sub-ranges of salinity within the sample set, where the analytical response of the autoanalyzer depends only on the concentration of P. RRMs such as TCM and LMS were considered for this purpose.

RRMs are designed to be as independent as possible of the presence of outliers [10–13]. This behaviour, defined as the breakdown point (BDP), is the percentage of outlier points on the calibration graph that can be tolerated before the regression line is significantly altered. BDP, which is equal to 0% for LS regression, ranges between 20 and 50% for RRM [3,4].

Table 1
Example of application of TCM and LMS to a data set of standard solutions of salinity between 31 and 36‰

| Salinity (‰) | P (μmol dm$^{-3}$) | Analytical response mean values of three replicates (arbitrary units) |
|---|---|---|
| 31 | 0.8 | 18.1 ± 0.18 [a] |
| 32 | 3.3 | 76.2 ± 0.20 |
| 33 | 1.3 | 36.5 ± 0.22 |
| 34 | 2.4 | 59.1 ± 0.31 |
| 35 | 0.9 | 25.9 ± 0.23 |
| 36 | 1.6 | 42.4 ± 0.32 |

| | LS 31–36‰ | LS-out$_{TCM}$ 32–36‰ | LS-out$_{LMS}$ 32–36‰ |
|---|---|---|---|
| Corr. coeff. | 0.991 | 0.998 | 0.998 |
| Res. std. Dev. [b] | 3.04 | 1.17 | 1.17 |

[a] Outlier by TCM and LMS residual analysis.
[b] Residual standard deviation, calculated according to Refs. [12] and [26].

A general property of robust methods when outliers are present is that the non-parametric regression estimators have smaller standard deviations than LS regression for all sample sizes [14], and this could suggest direct substitution of LS regression with TCM. Cruz et al. [15] instead suggested a difference procedure which allows exploitation of the power of RRMs to detect groups of aligned or unaligned experimental data by analysis of the regression residual [3,7]. This procedure is reported below.

Step 1. Application of TCM and LMS to the experimental data of calibration (having the same salinity range as the marine sample set) to obtain the robust equation $Y = A + BX$.

Step 2. Evaluation of the standardized residuals in order to detect outliers and determination of the linearity range with respect to the salinity.

Step 3. Application of LS regression —outliers excluded in order to obtain the robustly corrected equation $Y = A + BX$ according to the salinity range.

A practical application of this procedure in the analysis of P is reported in Table 1.

The results obtained showed that the linearity range lies between 32 and 36‰. The exclusion of the 31‰ solution, designated as an outlier by both TCM and LMS, improved the correlation coefficient and reduced the residual standard deviation. Hence, original salinity range was divided into two different calibration sets, the first including samples having 32–36‰ and the second one with only 31‰ samples. The linear relationships between concentration of P and analytical response were subsequently established again for each sub-set of aligned data by LS regression, as it is the most precise of all the exact estim-ations [15].

Therefore, it is possible to say that RRM can designate salinity ranges where the bias error of the determination is included in the random error of the applied analytical method.

### 3.1. Comparison between TCM and LMS

The results of Table 1 showed that TCM and LMS have similar power to detect outliers in a calibration set. However, this similarity of results is not always the case, because the BDP is

Table 2
Comparison of the power of TCM and LMS to detect outliers in a data set of synthetic seawater solutions of salinity between 35 and 39‰

| Salinity (‰) | P (μmol dm$^{-3}$) | Analytical response mean values of three replicates (arbitrary units) |
|---|---|---|
| 39 | 1.0 | 31.3 ± 0.37 [a] |
| 38 | 1.1 | 36.9 ± 0.41 |
| 35 | 1.62 | 39.9 ± 0.44 [a] |
| 36 | 2.42 | 60.3 ± 0.45 |
| 37 | 3.23 | 75.7 ± 0.39 |

$Y = 12.27_{LS} + 19.50_{LS}X$
$Y = 12.84_{TCM} + 19.46_{TCM}X$
$Y = 16.75_{LMS} + 18.17_{LMS}X$

| | LS 35–39‰ | LS–out$_{LMS}$ 36–38‰ |
|---|---|---|
| Corr. coeff. | 0.990 | 0.999 |
| Res. std. dev. | 3.00 | 0.52 |

$Y$ analytical response; $X$ = concentration of P.
[a] Outliers after LMS residual analysis by PROGRESS software

the limiting factor in the application of RRMs. In fact, the BDP value of TCM in 30% and LMS has a BDP value of up to 50% for both univariate and multivariate regressions [16,17]. This high BDP is seldom necessary in analytical chemistry, but can be usefully employed in the calibration of an autoanalyzer. The power to detect outliers tends to diminish when a small number of solutions (three or four) is included in the calibration set. The example of Table 2, referring to another range of salinity, showed the high power of LMS to detect outliers. Here the salinity range between 35 and 39‰, but only five synthetic seawater samples were included in the calibration set.

In Table 2, the equations for LS regression, TCM and LMS are reported. The LS and TCM equations are quite similar, while the LMS is different. TCM was not able to detect outliers; on the contrary, LMS detected two outliers, the samples with 35‰ and 39‰. This means that the original range of salinity must be divided into three calibration sets (the first 35‰, the second 36–38‰ and the third 39‰) to always obtain linear relationships between concentration of P and analytical response. This result also underlines a general rule of calibrating an autoanalyzer by robust methods having different BDP values: the greater the number of points in the calibration set, the greater the possibility of detecting outliers with the same power. When the number of points is small (such as the example of Table 2), the LMS with its high BDP has greater power than TCM.

### 3.2. Comparison between RRMs and MLR

A fast and simple method to correct the effect of salinity is to include the variable salinity in the calibration model using MLR analysis. In the re-examination of the data reported in Tables 1 and 2, it was always possible to obtain a good correlation according to the global equation

$$Y = a_1 S + a_2 C + \cos t$$

where $S$ is salinity, $C$ is the concentration of marine nutrient and $Y$ is the analytical response.

In fact, for the data of Table 1, the coefficient of MLR and the residual standard deviation are 0.996 and 2.25 respectively; for the data of Table 2, the coefficient of MLR and the residual standard deviation are 0.994 and 2.85 respectively. However, the multivariate calibration model has a problem in calculating the limit of detection (LOD), because it is not as unique as the univariate regression.

Lorber [18] proposed the net analytical response theory to define the LOD of multivariate regressions; Bauer et al. [19] proposed the propagation error theory to estimate the LOD of MLR; Delaney [20] and Singh and Garner [21] used the chemometrical approach based on principal component analysis to estimate the LOD in multivariate calibration. All these methods have both advantages and disadvantages [22], so the univariate RRMs are easier applications because they allow a direct and unique identification of the LOD.

### 3.3. Comparison between RRMs and MOSA

Another good procedure which avoids the salt effect is to perform the "in situ calibration" of MOSA, which works well independently of salinity and does not require knowledge of this value. This peculiarity is an advantage of MOSA in comparison with RRMs, but MOSA can also have some drawbacks compared to RRMs. In fact, in an extensive study about the properties of MOSA, Garner and Gunn [23] recommended the use of double additions up to the top of the linear range, combined with

calculation of results by a weighted linear regression in order to improve the analytical precision. This characteristic makes MOSA generally more time consuming than RRMs, because each sample needs a convenient calibration, and a short time of analysis is another critical step in the determination of marine nutrients. In fact, Koroleff [5] recommends that the analysis of P in seawater should be commenced as soon as possible, certainly within 2 h from the sampling or from the defrosting of samples.

RRMs are, in contrast, fast procedures, because their application can be performed in a single and automated step using the proper software and before starting the sample analysis. Therefore, the identification of the linear range between concentration and analytical response allows the application of MOSA to be avoided for all the samples and the time of analysis to be reduced.

Hence, the necessity of knowing the value of the salinity for each sample in the application of RRMs is only apparently a drawback because marine nutrients are often included in monitoring studies of seawater, where salinity is jointly measured with other parameters such as dissolved oxygen content, temperature, conductivity, density, and Redox potential by a multiparametric probe [24].

Finally, RRMs have a precision which can be compared with that of MOSA (Table 3).

Table 3
Oligotrophic ([P] < 2 μmol $dm^{-3}$) and eutrophic synthetic seawater samples ([P] > 2 μmol $dm^{-3}$). Comparison among results obtained by LS and LS-out and MOSA determinations. For this comparison both TCM and LMS were used for LS-out results, and MOSA results were obtained according to Ref. [23]

### 3.4. *Final consequences of applying robust regressions in the analysis of marine nutrients*

The entity of density fluctuation and the relative linearity range depend on the general characteristics of the autoanalyzer, and different measurements are necessary to establish the best conditions of analysis. The direct consequence of including one or more outliers in the calibration is the underestimation or overestimation of the pertinent analytes in a real sample. A re-examination of Fig. 1 shows that the lowest concentration of P corresponding to the highest percentage analytical error. Therefore, it is possible to say that the density fluctuation has the greatest effect at the lowest concentrations, i.e. for oligotrophic samples ([P] < 2 μmol $dm^{-3}$), while it is negligible for eutrophic samples.

The example of Table 3, in which only synthetic seawater samples have been considered, confirmed this general trend. The main reason for using synthetic seawater samples instead of real marine samples was because of the necessity of comparing the calculated values of [P] with the real ones. In fact, it is well known that in many chemical and biological investigations, seawater of a known composition of the major ions is needed [6].

For eutrophic samples, there is no evidence of density fluctuation because of the overlapping results calculated by LS and LS-out, regression. For oligotrophic samples, the LS-out values are closer to the true values than the LS ones. This result is really important in monitoring the activity of oligotrophic seawater, such as that from the Mediterranean [25].

## 4. Conclusion

RRMs such as TCM and LMS were shown to be good tools to detect outliers in the colorimetric analysis of P in seawater performed by a continuous flow autoanalyzer. The presence of outliers in the calibration step can be due to a salinity effect because analytical response vs. concentration is not linear, causing corrupted estimations of nutrients especially in oligotrophic marine samples. The advantage of applying an RRM is that no modification of the autoanalyzer is required to correct the salinity effect, while modifications of the autoanalyzer are required by other methods. A second advantage of robust methods is that they generally require a shorter time of analysis

than MOSA, although they have similar analytical precision.

This study on the determination of inorganic P was performed because a density fluctuation has only been observed for this nutrient. However, the application of RRMs can be extended to the determination of different nutrients (total P, Si and nitrogen nutrients such as $NH_3$, $NO_2^-$ when the salt effects are observed.

## Acknowledgements

# Simultaneous spectrophotometric determination of Thymol Blue, Semimethylthymol Blue and Methylthymol Blue II. Monitoring of the syntheses of Semimethylthymol Blue and Methylthymol Blue

S. Kiciak *, H. Gontarz, E. Krzyżanowska

*Institute of Chemistry and Technical Electrochemistry, Politechnika Poznańska, PL-60-965 Poznań, Poland*

Received 25 October 1994; revised 21 February 1995; acepted 22 February 1995

**Abstract**

A new version of the direct spectrophotometric method for the simultaneous determination of Thymol Blue, Semimethylthymol Blue (SMTB) and Methylthymol Blue (MTB) was developed and used for monitoring syntheses of SMTB and MTB.

## 1. Introduction

The method for the simultaneous determination of Thymol Blue (TB), Semimethylthymol Blue (SMTB) and Methylthymol Blue (MTB) given in a previous paper [1] was based on measurements of the absorbances of three solutions of these compounds in 1, 4 and 7 M sulphuric acid. Some possibilities were shown using this method for the determination of TB, SMTB and MTB in spectrophotometric reagents and in mixtures obtained during syntheses of SMTB.

In spite of the obtained results being relatively good, two aspects of the method were not satisfactory enough for the authors. The first was the necessity of preparating three solutions for each tested sample, two of them with relatively high sulphuric acid concentrations (4 and 7 M). Secondly, the drawing of figures for the given graphical version of the method was time consuming and the exact read-out of the results given in such figures was relatively difficult. The first problem was resolved when we found that good results of absorbance measurements could be obtained using solutions with a 0.5 M sulphuric acid concentration not only near 548 nm but also at 485 and 455 nm. The second problem was overcome by rearranging the newly obtained dependences of the relative absorbances on the mole fractions of SMTB and MTB ($A_{R1}=f(X_{SMTB},X_{MTB})$ and $A_{R_2}=f(X_{SMTB},X_{MTB})$ to $X_{SMTB}=f(A_{R1},A_R)$ and $X_{MTB}=f(A_{R1},A_{R2})$. This allows the calculation of mole fractions of the dyes determined without using additional figures and shows the route of the syntheses more exactly than before [1]. However, the limitation of spectrophotometrically active reagents to three main components present during the described syntheses, without taking into account the byproducts occurring in trace or low amounts [2–4] is a necessary simplification. This can be the reason for the low relative errors (mainly much below 5%).

## 2. Experimental

### 2.1. Apparatus

The absorption measurements were made with a Zeiss-Jena spectrophotometer (Specord M40) with 1-cm cells. A conventional thermostated glass apparatus with a reflux condenser was used for the syntheses.

### 2.2. Reagents

MTB (Merck) containing approximately 90% of the dye was purified by extraction in a dilute sulphuric acid–1-butanol system.

SMTB (from our own synthetic mixture containing approximately 40% of the dye) was purified by the previously reported method [5].

A commercial sample of TB was recrystallized from ethanol. All other reagents were of analytical grade. Standard solutions of the three dyes (0.001 M) were prepared in 0.01 M sulphuric acid for MTB and SMTB and in 1:1 (v/v) ethanol–aqueous 0.02 M sulphuric acid mixture for TB.

### 2.3. Syntheses and Sampling

Dissolve 235 mg of TB in approximately 50 ml of glacial acetic acid. Add the required amount of iminodiacetic acid (IDAA) and anhydrous sodium acetate, stir and heat the mixture to the required temperature — not lower than 55 °C and not higher than 65 °C. At the lower temperature the reaction rate is too slow; at the higher temperature the formation of byproducts must be taken into account. Transfer $0.25 \pm 0.05$ ml of a solution of the obtained mixture to a 50-ml standard flask (sample "zero"), Then start the synthesis by adding the required amount of formaldehyde to the stirred thermostatted mixture. The ranges of the ratios of mole concentrations used in the experiments were: $C_{IDAA}/C_{TB}$, 1.00–4.0; $C_{CH_3COONa}/C_{IDAA}$, 2.0–8.0; and $C_{HCHO}/C_{IDAA}$, 2.2–4.2. Next, remove samples after defined time intervals from the beginning of the synthesis — at first after every 1 h period, then after periods of 2 or more h. The total time of the syntheses was, 24 or 36 h.

To each of the $0.25 \pm 0.05$ ml samples (the "zero" sample and those transferred during the synthesis to 50-ml standard flasks), add 5 ml of 0.05 M sulphuric acid and dilute to the mark with water (solutions $S_0$). There is no need to remove exactly the same known amounts of reaction mixture because the relative absorbances used (in the given ranges) are practically not dependent on the concentration of solution $S_0$. Transfer 10.0-ml aliquots of solution $S_0$ to two 25-ml standard flasks for each sample. Add 10.0 ml of 1.25 M $H_2SO_4$ to each 25-ml flask containing the examined sample, and make up to the mark with water (solutions $S_{0.5}$). Solutions $S_0$ are much more stable than solutions $S_{0.5}$. The former can be used 0.1–8 h after preparation without remarkable changes occurring, but absorbance measurements on solutions $S_{0.5}$ should be performed no longer than 0.5 h after their preparation.

### 2.4. Measurements and Calculations

Measure the absorbances of the solutions $S_{0.5}$ at 455, 485 and 545 nm (1-cm path-length cells). Calculate the relative absorbances $A_{R1}$ and $A_{R2}$ and the mole fractions of the components as given below (Eqs. (6)–(10)). Use the obtained results to show the route of the synthesis on a Gibbs triangle. The molar absorptivities of pure samples of the three dyes should be determined with the equipment used, and substituted for those quoted, if there is a difference.

## 3. Results and discussion

### 3.1. Conditions for absorbance measurements

More detailed investigations than were previously carried out [1] of the dependences of the molar absorptivities of TB, SMTB and MTB on the sulphuric acid concentration show that at a much lower concentration of the acid, the absorbance measurements can be performed at 545, 485 and 455 nm in solutions with 0.5 M sulphuric acid. The molar absorptivities of the dyes, under the chosen conditions, are given in Table 1.

Table 1
Molar absorptivites of TB, SMTB and MTB (in 0.5 M sulphuric acid)

| Dye | $\varepsilon$ ($dm^3\ cm^{-1}\ mol^{-1}$) | | |
|---|---|---|---|
| | 455 nm | 485 nm | 545 nm |
| TB | 4800 | 7350 | 36400 |
| SMTB | 11100 | 11200 | 13900 |
| MTB | 18900 | 11800 | 4450 |

It is advantageous here that in 0.5 M sulphuric acid at 455 nm, the molar absorptivites of SMTB and MTB are much greater than that of TB, and at 545 nm the molar absorptivities of TB and SMTB are much greater than that of MTB.

### 3.2. Equations used for the calculations

It was stated that under the given conditions Beer's law is obeyed and the absorbances are additive over the concentration range (0.5–25) $\times 10^{-6}$ M, so according to the given molar absorptivities of the three dyes, for a path length of 1 cm, the absorbances ${}_{455}A$, ${}_{485}A$ and ${}_{545}A$ (in 0.5 M sulphuric acid) are

$${}_{455}A = (4.8C_{TB} + 11.1C_{SMTB} + 18.9C_{MTB}) \times 10^3 \quad (1)$$

$${}_{485}A = (7.35C_{TB} + 11.2C_{SMTB} + 11.8C_{MTB}) \times 10^3 \quad (2)$$

$${}_{545}A = (36.4C_{TB} + 13.9C_{SMTB} + 4.45C_{MTB}) \times 10^3 \quad (3)$$

It follows from Eqs. (1)–(3), that

$$A_{R1} = \frac{{}_{455}A}{{}_{485}A} = \frac{(4.8C_{TB} + 11.1C_{SMTB} + 18.9C_{MTB}) \times 10^3}{(7.35C_{TB} + 11.2C_{SMTB} + 11.8C_{MTB}) \times 10^3} \quad (4)$$

$$A_{R2} = \frac{{}_{545}A}{{}_{485}A} = \frac{(36.4C_{TB} + 13.9C_{SMTB} + 4.45C_{MTB})q \times 10^3}{(7.35C_{TB} + 11.2C_{SMTB} + 11.8C_{MTB}) \times 10^3} \quad (5)$$

where $A_{R1}$ and $A_{R2}$ are the chosen relative absorbances.

The mole fractions of TB, SMTB and MTB are

$$X_{TB} = \frac{C_{TB}}{\sum C_i} X_{SMTB} = \frac{C_{SMTB}}{\sum C_i} X_{MTB} = \frac{C_{MTB}}{\sum C_i}$$

where $\Sigma C_i = C_{TB} + C_{SMTB} + C_{MTB}$ and $X_{TB} + X_{SMTB} + X_{MTB} = 1$. Division of the numerators and denominators of Eqs. (4) and (5) by $\Sigma C_i$ and introduction of $X_{TB} = 1 - X_{SMTB} - X_{MTB}$ gives

$$A_{R1} = \frac{4.8 + 6.3X_{SMTB} + 14.1X_{MTB}}{7.35 - 3.85X_{SMTB} - 4.45X_{MTB}} \quad (6)$$

$$A_{R2} = \frac{36.4 - 22.5X_{SMTB} - 31.95X_{MTB}}{7.35 - 3.85X_{SMTB} - 4.45X_{MTB}} \quad (7)$$

By rearranging Eqs. (6) and (7) we obtain

$$X_{SMTB} = \frac{666.6 - 396.9A_{R2} - 82.3A_{R1}}{22.9A_{R1} + 26.25A_{R2} + 116.0} \quad (8)$$

$$X_{MTB} = \frac{305.5A_{R1} + 27.8A_{R2} - 337.3}{22.9A_{R1} + 26.25A_{R2} + 116} \quad (9)$$

and because $X_{TB} = 1\text{-}X_{SMTB}\text{-}X_{MTB}$

$$X_{TB} = \frac{114.3A_{R1} + 80.75A_{R2} - 213.3}{22.9A_{R1} + 26.25A_{R2} + 116} \quad (10)$$

### 3.3. Results of monitoring the syntheses of SMTB and MTB

The experiments carried out at the beginning of this work showed that if the molar concentration of formaldehyde was over twice to four times greater than the concentration of iminodiacetic acid, then the results of the syntheses were mainly dependent on the ratios between the molar concentrations of sodium acetate, iminodiacetic acid and Thymol Blue and on the applied temperature.

Therefore these dependences were examined in this work.

The dependence of the course of the syntheses on time, for different ratios of the initial molar concentrations of $C_{0CH_3COONa}$:$C_{0TB}$ and for a constant concentration ratio $C_{0HCHO}$:$C_{0IDAA}$:$C_{0TB}$ = 8:2:1, was investigated at constant temperatures (55, 65 or 75 °C).

The results obtained showed that at 75 °C the reaction rate and the compositions of the mixtures forming are considerably dependent on concentration changes at low concentrations of sodium acetate, but are almost independent of concentration at higher concentrations (over three times higher than the concentration of iminodiacetic acid and six times higher than the concentration of Thymol Blue).

At lower temperatures (65 and 55 °C) the influences on the reaction path of concentration changes at low concentrations of sodium acetate are much smaller than those at 75 °C.

The dependences of the course of the syntheses on time at constant temperature (65 °C) for different concentrations of iminodiacetic acid at constant concentrations of formaldehyde, sodium acetate and Thymol Blue are given in Fig. 1.

It follows from the data given in Fig. 1 that the rate of reaction considerably accelerates

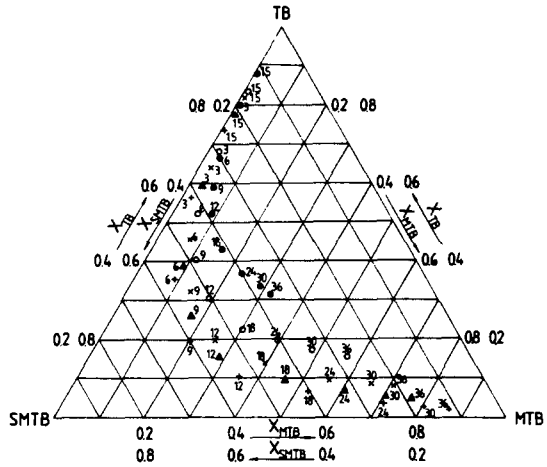

Fig. 1. The dependence of the compositions (given in mole fractions $X_i$) of TB, SMTB and MTB mixtures on the time of synthesis (h) carried out at 65 °C, for a constant ratio of the initial molar concentrations $C_{0HCHO}:C_{0CH_3COONa}:C_{0TB} = 8:8:1$ and for different ratios of $C_{0IDAA}:C_{0TB}$:(●) 1.0; (○) 1.5; (×) 2.0; (△) 3.0; (+) 4.0.

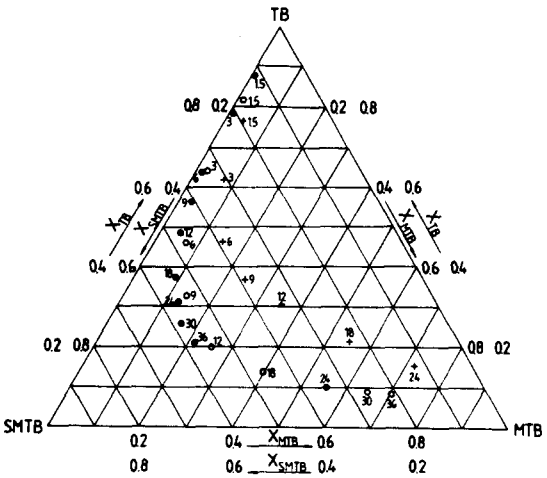

Fig. 2. The dependence of the compositions (given in mole fractions $X_i$) of TB, SMTB and MTB mixtures on the time of synthesis (h), for a constant ratio of the initial molar concentrations $C_{0IDAA}:C_{0HCHO}:C_{0CH_3COONa}:C_{0TB} = 2:8:8:1$, carried out at different temperatures: (●) 55 °C; (○) 65 °C; (+) 75 °C.

with the increase in the amount of iminodiacetic acid used. During the first period of the reaction (about 9 h) the dominant product is Semimethylthymol Blue, but in the next period the formation of Methylthymol Blue dominates.

The dependences of the course of the syntheses on time at different temperatures, at constant concentrations of sodium acetate and formaldehyde and at constant ratios of the initial molar concentrations of iminodiacetic acid and Thymol Blue, are given in Figs. 2 (for $C_{0IDAA}:C_{0TB} = 2:1$) and 3 (for $C_{0IDAA}$: $C_{0TB}$ = 4:1). The results obtained for $C_{0IDAA}$: $C_{0TB}$ = 1:1 as well as those given in Figs. 2 and 3 show that a temperature increase of the reaction mixtures accelerates the reaction rates and changes the paths of the proceeding reactions. This is clearly seen by a comparison of the values of the reaction periods necessary to obtain the maximum mole fraction for Semimethylthymol Blue ($t_{maxSMTB}$) and by a comparison of the values of these fractions ($X_{maxSMTB}$) at different temperatures and at constant ratios of initial molar concentrations of iminodiacetic acid and Thymol Blue (Table 2).

To obtain more conclusions concerning the kinetics of the investigated processes it is necessary to present dependences of mole fractions ($X_i$) on time ($t$) for each of the three dyes, as is shown in Fig. 4.

The shapes of the dependences suggest that both reactions TB → SMTB and SMTB → MTB are first order. This was confirmed by calculation of the rate constants $k_1$ and $k_2$ by using the equations

$$k_1 = -\frac{1}{t} \ln X_{TB} \tag{11}$$

$$k_2 = \frac{\Delta X_{MTB}}{X_{SMTB} \Delta t} \tag{12}$$

where $X_{TB}$ is the mole fraction of TB $t$ h from the beginning of the synthesis, $X_{SMTB} = (\Sigma X_i)_{SMTB}/n$ is the mean value of $X_{SMTB}$ for the reaction period $\Delta t = t_2 - t_1$ for $n \geq 5$ values of $X_{SMTB}$ taken every 1.5 or 3 h during the reac-

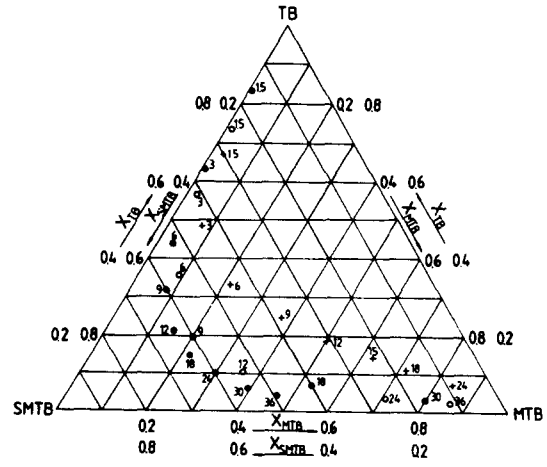

Fig. 3. The dependence of the compositions (given in mole fractions $X_i$) of TB, SMTB and MTB mixtures on the time of synthesis (h) for a constant ratio of the initial mole concentrations $C_{0IDAA}:C_{0HCHO}:C_{0CH_3COONa}:C_{0TB} = 4:8:8:1$, carried out at different temperatures: (●) 55 °C; (○) 65 °C; (+) 75 °C.

Table 2
Dependence of the maximum molar fractions of Semimethylthymol Blue ($X_{maxSMTB}$) on temperature and reaction periods ($t_{maxSMTB}$) necessary for obtaining $X_{SMTB}$ at constant ratios of the initial molar concentrations of iminodiacetic acid and Thymol Blue ($C_{0IDA}/C_{0TB}$)

| $C_{0IDAA}/C_{0TB}$ | 55 °C | | 65 °C | | 75 °C | |
|---|---|---|---|---|---|---|
| | $X_{maxSMTB}$ | $t_{maxSMTB}$ (h) | $X_{maxSMTB}$ | $t_{maxSMTB}$ (h) | $X_{maxSMTB}$ | $t_{maxSMTB}$ (h) |
| 1:1 | 0.45 | 40 | 0.41 | 18 | 0.38 | 7.0 |
| 2:1 | 0.58 | 34 | 0.54 | 10 | 0.40 | 6.0 |
| 4:1 | 0.63 | 12 | 0.60 | 8.5 | 0.46 | 4.5 |

tion period $\Delta t$, and $\Delta X_{MTB} = (X_2 - X_1)$ is the difference in $X_{MTB}$ for the reaction period $\Delta t$.

Examples of calculations of $k_1$ and $k_2$ are given in Tables 3 and 4.

The $k_1$ and $k_2$ values calculated according to Eqs. (11) and (12) for the synthesis performed at 65 °C under the given conditions (Tables 3 and 4), as well as that performed at 55 °C, are reaction rate constants of the first order.

The constants $k_1$ and $k_2$ and their standard deviations are:

for 55 °C, $_{55}k_1 = 0.132 \pm 0.008\ h^{-1}$ and $_{55}k_2 = 0.0258 \pm 0.0008\ h^{-1}$;

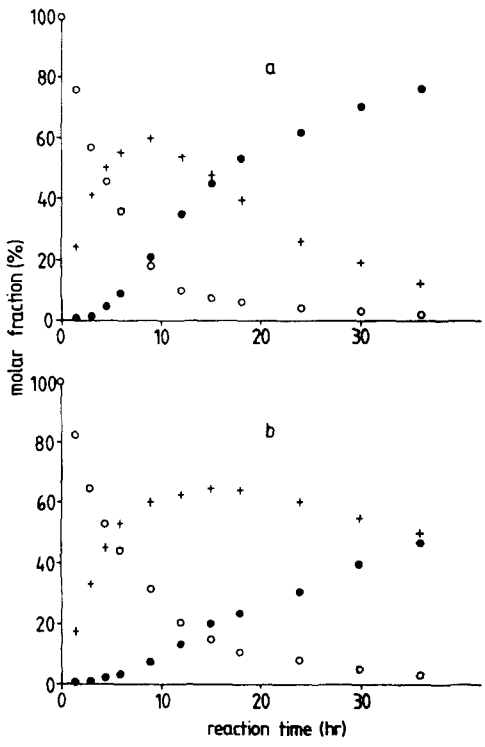

Fig. 4. Dependence of mole fractions of TB, SMTB and MTB found in the mixtures on the time of synthesis, for a constant ratio of the initial mole concentrations $C_{0IDAA}$: $C_{0HCHO}$:$C_{0CH_3COONa}$:$C_{0TB}$ = 4:8:8:1, carried out at (a) 65 °C and (b) 55 °C. (○) $X_{TB}$; (+) $X_{SMTB}$; (●) $X_{MTB}$.

for 65 °C, $_{65}k_1 = 0.179 \pm 0.009\ h^{-1}$ and $_{65}k_2 = 0.0696 \pm 0.0019\ h^{-1}$.

Comparison of these constants allows us to confirm that at 55 °C the reaction rate constant for the SMTB synthesis ($k_1$) is about five times greater than the rate constant obtained for MTB synthesis ($k_2$). However, the increase of temperature to 65 °C causes only about a 35% increase in $k_1$ ($_{65}k_1/_{55}k_1 = 1.356$) whereas the $k_2$ value then increases more than 2.5 times ($_{65}k_2/_{55}k_2 = 2.70$).

Similar calculations carried out when using the results obtained for syntheses performed at 75 °C and at lower ratios of the initial concentrations of the used reagents to the initial concentration of TB did not give stable values of $k_1$ and $k_2$.

## 4. Conclusions

The new version of the spectrophotometric method for the simultaneous determination of TB, SMTB and MTB is simpler and gives more information concerning the SMTB and MTB syntheses than the method used before [1].

The method allows us to perform relatively exact observations of the progress of the reaction during 24–36 h of the syntheses carried out below 70 °C.

The results of monitoring the syntheses of SMTB and MTB obtained by using this method can be helpful for the optimization of these syntheses. In our experiments, the highest yield for SMTB (60% or above) was reached after 12 h of reaction carried out at 55 °C and at an initial molar concentration ratio $C_{0IDAA}/C_{0TB} = 4:1$, or at 65 °C after 8.5 h, at the same ratio of $C_{0IDAA}/C_{0TB}$. However, for the MTB synthesis, the highest yield (80% or above) was obtained after 30–36 h of reaction carried out at 65 °C and at the same ratio of $C_{0IDAA}/C_{0TB} = 4:1$.

Table 3
Results of the calculation of the rate constant $k_1$ for the reaction TB → SMTB at 65 °C for a constant ratio of the initial molar concentrations of the reagents used ($C_{0TB}$:$C_{0IDAA}$:$C_{0ICHCOONa}$:$C_{0HCHO}$ = 1:4:8:8)

Table 4
Results of the calculation of the rate constant $k_2$ for the reaction SMTB → MTB at 65 °C for $C_{0TB}$:$C_{0IDAA}$:$C_{0CH_2COONa}$:$C_{0HCHO}$ = 1:4:8:8

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| $t_2$ (h) | 12.0 | 12.0 | 15.0 | 15.0 | 15.0 | 18.0 | 18.0 | 18.0 |
| $t_1$ (h) | 6.0 | 4.5 | 6.0 | 4.5 | 3.0 | 4.5 | 3.0 | 1.5 |
| $\Delta t$ (h) | 6.0 | 7.5 | 9.0 | 10.5 | 12.0 | 13.5 | 15.0 | 16.5 |
| $X_{SMTB}$ (for $n$) | 0.570 (5) | 0.558 (6) | 0.549 (7) | 0.542 (8) | 0.528 (9) | 0.518 (10) | 0.508 (11) | 0.485 (12) |
| $\Delta X_{MTB}$ | 0.245 | 0.295 | 0.355 | 0.405 | 0.435 | 0.490 | 0.520 | 0.530 |
| $k_2$ ($h^{-1}$) | 0.071 | 0.070 | 0.072 | 0.071 | 0.069 | 0.070 | 0.068 | 0.066 |

The constant values of the rate constants obtained for the SMTB and MTB syntheses, carried out at 55 and 65 °C, confirm the assumption that the sum of the mole fractions given by the equation $X_{TB} + X_{SMTB} + X_{MTB} = 1$ is correct. However, the results obtained for the syntheses carried out at 75 °C showed that at this temperature deviations from the equation may be significant.

Received 1 November 1994; revised 22 February 1995; accepted 24 February 1995

**Abstract**

The precipitation step in the developed procedure (BiAS–ITM) was optimised with the aim of achieving a lower detection limit. Losses during filtration using Triton X-100 as representative non-ionic surfactant (NS), the indirect tensammetric method (ITM) and adsorptive stripping tensammetry (AdST) for the determination of the concentration of the surfactant in the precipitate and in the filtrate were investigated. The G4 glass filter recommended up to now was found to be insufficiently effective and a source of loss. The new version of the procedure developed works within the range 2–1000 μg of NS in the sample, and thus two orders of magnitude lower than the former version of the procedure, showing satisfactory recovery and precision. The detection limit (3 × S.D.) was found to be below 1.5 μg in the sample.

Interferences of anionic surfactants (ASs) e.g. sodium dodecylbenzenesulphonate and sodium lauryl sulphate, lipids, e.g. glycerol trioleate (GTO), and chlorophyll were investigated. GTO and AS show no effect on the BiAS–ITM results although strong adsorption of ASs on the glass filter as well as a slight adsorption on the precipitate was found. Chlorophyll does not interfere with the determination up to 30 μg in the sample, whereas higher concentrations produce results that are too high.

## 1. Introduction

Control of non-ionic surfactants (NSs) in surface water requires more effective methods than those currently used. The classical BiAS procedure [1,2] though widely used in Europe, gives poor results for an NS amount lower than 100–200 μg in the sample due to an unavoidable loss of precipitate during its washing with glacial acetic acid [3]. A recently developed modification of this procedure combining the precipitation of NSs with modified Dragendorff reagent and quantification by the indirect tensammetric method (BiAS–ITM) shows several advantages in comparison with the classical BiAS procedure [4]. First of all, the BiAS–ITM does not need the washing of the precipitate with glacial acetic acid. In this way the main source of error in the classical BiAS procedure is eliminated. Additionally, the BiAS–ITM exhibits considerably fewer differences in the slopes of the calibration graphs of different NSs than the classical BiAS method and therefore shows a substantially lower "error of choice of standard" (the error when one surfactant is determined using a calibration curve for another surfactant (standard)). The BiAS–ITM can be used for the determination of NSs having 3–30 oxyethylene subunits while the classical BiAS method only applies to NSs having 5–30 subunits.

Precipitation according to the classical BiAS procedure is applied within the range 100–

SSDI 0039-9140(95)01568-X

1000 μg of NS whereas the ITM final assay requires only 2–25 μg in the sample [5]. Therefore the sample obtained after precipitation and dissolution of the precipitate should be diluted prior to the final measurement (an aliquot is used). A much better agreement of the precipitation step with the final measurement would be achieved if a lower amount of NS was precipitated. Thus the optimisation of the precipitation step was the main aim of this work. In preliminary experiments it was found that the solubility of Triton X-100 precipitate with 75 ml of Dragendorff reagent corresponds to only 0.12 μg of Triton X-100. Hence, it should be possible to precipitate several micrograms of NS. It was also observed that the temperature of precipitation within the range −5–60 °C has no marked influence on the recovery of the surfactant. A further aim of this work was the study of possible interferences from the water matrix. Anionic surfactants, lipids and chlorophyll were investigated as potential interferents. Anionic surfactants are usually present in excess compared with NSs in surface water. Lipids (one of the components of surface water) are preconcentrated during extracion or gas stripping in the boundary layer between the water and the organic phases. Numerous water samples show a fat layer on the phase boundary. Chlorophyll extracted from plants is the most serious interferent in the ITM measurements [5]. Triton X-100 was used as a representative non-ionic surfactant in all the experiments.

The ITM, which was used for the final measurement in the BiAS–ITM procedure, is a method recently developed for the determination of the total concentration of surfactants [6–8]. The lowering of the ethyl acetate tensammetric peak (the monitoring substance) is the analytical signal in the ITM. The signals of different NSs are roughly additive [8] and are sufficiently tolerant to anionic surfactants [7]. ITM can be applied both as final measurement in a separate procedure as well as in combination with the BiAS procedure [5]. Apart from the ITM, adsorptive stripping tensammetry (AdST) was used as an auxiliary technique. The analytical signals in AdST are specific and highly sensitive to the effects of mixtures. Therefore AdST can hardly be used for the final measurement. On the other hand, its high sensitivity and specificity make AdST an excellent technique for different model investigations with a single surfactant [3,9].

The experiments in this study were performed over a comparatively long period of time and the precipitation procedure was gradually improved. Thus some of the experiments were performed using much higher Triton X-100 spike concentrations and 0.5 M sodium sulphate as supporting electrolyte. Later experiments were performed under the modified conditions with lower NS spike concentrations and a supporting electrolyte containing mainly sodium chloride.

## 2. Experimental

### 2.1. Apparatus and reagents

The apparatus, cell and measuring procedure used were described in part 1 [4]. Briefly, a scan voltage of 400 mV $min^{-1}$ and an alternating voltage amplitude of 2 mV were applied. A quartz beaker instead of a glass one was used and protection of a ceramic frit on the end of a salt bridge was applied, to prevent adsorptive loss of surfactant [10].

Glass filters G1, G2, G3, G4 and G5 (Schott-Geräte) were used.

Triton X-100 (Rohm and Haas) was used without additional purification.

Chlorophyll was extracted from *Scindapsus* with acetone. Its concentration was determined by the ITM [5].

Purified sodium sulphate and sodium chloride were used for the preparation of the aqueous base electrolytes. All solutions were prepared in water triply distilled from quartz. Only freshly distilled water was used.

The modified Dragendorff reagent [1] was prepared by mixing solutions A and B before use. Solution A comprised 1.7 g of basic bismuth (III) nitrate, 65 g of potassium iodide and 220 ml of glacial acetic acid per 1000 ml. Solution B was an aqueous solution containing 290 g of barium chloride dihydrate in 1000 ml.

The solution for dissolving the precipitate (solution C) was prepared from 12.4 g of tartaric acid and 18 ml of ammonia solution (25%) made up with water to 1000 ml. For the purification of this solution of silica gel cartridge (Bakerbond spe silica gel 7086–03) was used.

### 2.2. Procedures

#### 2.2.1. Precipitation of NSs with modified Dragendorff reagent according to the BiAS procedure

*Procedure A* The surfactant sample was dissolved in a mixture of 2 ml of methanol and 16 ml of water. Solution A (8 ml) and solution B (4 ml) of the modified Dragendorff reagent were mixed and added to the sample. The reaction mixture was stirred for 20 min and left for 10 min, with the exception of the experiments related to the study of the effect of ageing of the precipitate. The orange-coloured precipitate was filtered through a glass filter (usually G5). No washing of the precipitate was used.

The precipitate was dissolved in 20 ml of hot solution C. The filter and the beaker were then washed with 3–4 ml of water; this portion of water was added to the solution containing the dissolved precipitate. After cooling, the solution volume was made up to 25 ml with water.

#### 2.2.2. ITM measurement of concentration of NSs in the precipitate

*Procedure B* An aliquot of solution obtained by dissolving the precipitate was transferred to a 25 ml volumetric flask, 12.5 ml of 1 M aqueous sodium sulphate and 1.5 ml of ethyl acetate were added, and the flask was filled to the mark with water. The mixture, containing an excess of ethyl acetate, was vigorously shaken and the emulsion transferred into the voltammetric cell. The emulsion was stirred for 10 min to achieve clarity of the solution due to evaporation of the excess ethyl acetate. This excess ethyl acetate extracts surfactants and therefore it must be removed; this is demonstrated by the disappearance of turbidity. After a quiescent period (30 s) the tensammetric curve of ethyl acetate was recorded in the cathodic direction starting from −1.20 V (vs. SCE) using a new mercury drop. The difference between the height of the ethyl acetate peak (recorded in a separate measurement) and the peak height of ethyl acetate in the presence of NS is the analytical signal. The results were quantified using a calibration curve of Triton X-100.

#### 2.2.3. ITM measurement of concentration of NSs in the precipitate

*Procedure C* An aliquot of solution obtained by dissolving the precipitate (0.5/25, 4/25 or 20/25) was transferred to a 25 ml volumetric flask, 2.5 ml of 5 M aqueous sodium chloride and 1.8 ml of ethyl acetate were added, and the flask was filled to the mark with water. The method was further continued according to procedure B.

#### 2.2.4. AdST measurement of concentration of NSs in the precipitate

*Procedure D* An aliquot of solution obtained by dissolving the precipitate was transferred to a 25 ml volumetric flask, 12.5 ml of 1 M aqueous sodium sulphate was added, and the flask was filled to the mark with water. The AdST measurement was run. The preconcentration was performed at a new mercury drop in a stirred solution at −1.20 V (vs SCE). The preconcentration time (5 min) was measured from the moment of drop formation. The tensammetric curve was recorded in the cathodic direction after a 30 s quiescent period. The analytical signal was the height of the "wide" tensammetric peak of Triton X-100 [11]. The results were quantified using a calibration graph of Triton X-100.

#### 2.2.5. AdST measurement of concentration of NSs in the filtrate

*Procedure E* Sodium chloride (10 g) was added to the filtrate in a 100 ml volumetric flask, and the flask was filled to the mark with water. NSs were extracted from the sample with 10 ml of ethyl acetate. An aliquot of the extract (50 µl) was dissolved in the 0.5 M sodium sulphate base electrolyte. The AdST measurement was performed. The preconcentration was performed at a new mercury drop in a stirred solution at −1.20 V (vs SCE). The preconcentration time (5 min) was measured from the moment of drop formation. The tensammetric curve was recorded in the cathodic direction after a 30 s quiescent period. The analytical signal was the height of the "wide" tensammetric peak of Triton X-100 [11]. The results were quantified using a calibration graph of Triton X-100 obtained in the presence of 50 µl of ethyl acetate.

*2.2.6. Determination of the concentration of anionic surfactants (ASs) in the precipitate and in the filtrate*

ASs in the precipitate were determined according to the MBAS procedure [12] after their dissolution in solution C, the AS in the filtrate being determined by AdST. The determination of AS in the filtrate by AdST was carried out in the samples after extraction of non-ionic surfactants and the bismuth (III) complex with iodide. Sodium chloride (20 g) was added to this solution which was free of NSs. ASs were extracted with 10 ml of ethyl acetate. An aliquot of the extract was evaporated and dissolved in 0.5 M sodium sulphate base electrolyte. The AdST measurement was performed using 5 min preconcentration at −1.0 V (vs SCE). The analytical signal was the height of the tensammetric peak of the corresponding surfactant. The results were quantified using calibration graphs of corresponding ASs.

## 3. Results and discussion

### *3.1. Optimisation of the procedure*

*3.1.1. Study of the influence of the porosity of the glass filter used on the loss of Triton X-100 spike*

Additional sources of the loss of surfactant become important after the elimination of the most important source of error (loss of the precipitate due to dissolution in glacial acetic acid). The loss of precipitate during filtration due to an insufficiently effective glass filter can be one of the potential reasons for the poor recovery. The use of a G4 glass filter is recommended in the classical BiAS procedure [1]. In the present study the effectiveness of filtration of the precipitate through glass filters of different porosities was examined. For this purpose, G1 (100–160 μm), G2 (40–100 μm), G3 (16–40 μm), G4 (5–16 μm) and G5 (1.6–5 μm) glass filters were used. Samples with spikes of 200 μg of Triton X-100 precipitated with modified Dragendorff reagent were filtered through these filters. The precipitates were then dissolved in hot ammonium tartrate solution (see procedure A, section 2.2.1. for details). The amount of Triton X-100 was determined by ITM (procedure B, section 2.2.2.) as well as by AdST techniques (procedure D, section 2.2.4.). The filtrate was extracted with ethyl acetate. It is necessary to stress that particles of the precipitate dispersed in the filtrate are decomposed by ethyl acetate during extraction and NSs are thus transferred into ethyl acetate. The amount of Triton X-100 in the filtrate was determined by AdST (see procedure E, section 2.2.5.). The results are shown in Fig. 1. Except for the amounts of Triton X-100 in the precipitate (as determined both by ITM and AdST) and in the filtrate, the total amount of Triton X-100 is given. The G4 filter proves to be insufficient for effective filtration as roughly 25 μg of Triton X-100 (from the initial 200 μg of the surfactant) are lost. The G5 filter is much better although loss of trace amounts is still found. The G5 filter was used in further investigations, taking into account these results.

*3.1.2. The effect of "time of precipitation"*

The precipitation of NSs with modified Dragendorff reagent depends on the period of time between the mixing of the reagents and the filtration of the precipitate, called here the "time of precipitation". The time of precipitation consists of the time of formation of the complex precipitate and the time of ageing of the precipitate in the reaction mixture prior to filtration. For the precise determination of the time of precipitation, a series of experiments involving the precipitation of 100 μg of Triton X-100 were performed. The amount of Triton X-100 was determined both in the precipitate

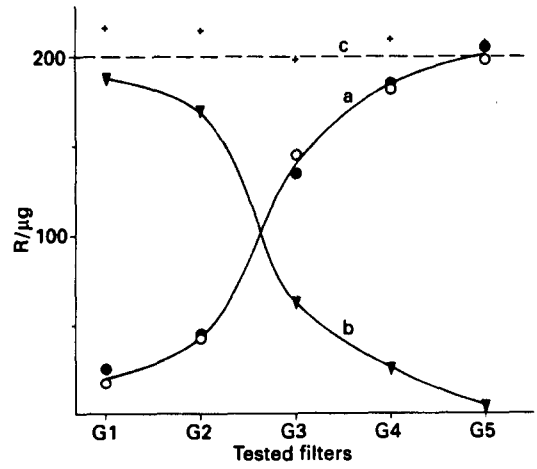

Fig. 1. Dependence of the recovery (R) of a 200 μg spike of Triton X-100 on the porosity of the glass filters used in the procedure, as determined by ITM (curve a; empty circles) and AdST (curve a; filled circles). Curve (b) shows the amount of Triton X-100 lost in the filtrate. Crosses show the sum of Triton X-100 in both fractions. The broken line (c) shows the spike of Triton X-100.

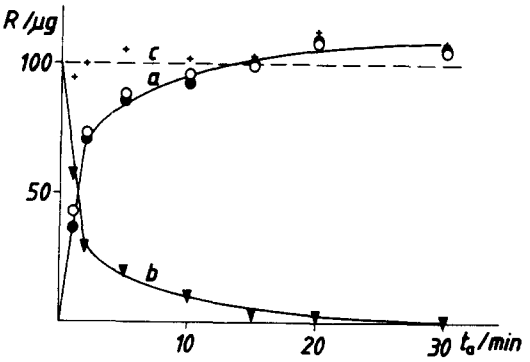

Fig. 2. Dependence of the recovery (R) of a 100 µg spike of Triton X-100 on the "time of precipitation" ($t_a$) of the precipitate, as determined by ITM (curve a; empty circles) and AdST (curve a; filled circles). Curve (b) shows the amount of Triton X-100 lost in the filtrate. Crosses show the sum of Triton X-100 in both fractions. The broken line (c) shows the spike of Triton X-100.

(by ITM, procedure B, and AdST, procedure D) and in the filtrate (by AdST, procedure E). The results are given in Fig. 2. The minimum period of time necessary to avoid serious losses of surfactant in this step of the procedure is 15 min. A further ageing time of up to 30 min seems to have some positive effect.

### *3.1.3. Preliminary attempts to precipitate sub-100 µg amounts of Triton X-100*

The elimination of several sources of error in the precipitation step of the BiAS procedure (such as removal of the washing with glacial acetic acid, a properly selected porosity of the glass filter and an optimum time of precipitation) makes the precipitation of amounts of NS below 100 µg feasible. The aim of the present study was to check whether 10–100 µg amounts of Triton X-100 are quantitatively precipitated with modified Dragendorff reagent. Spikes of Triton X-100 were precipitated with modified Dragendorff reagent [1] filtered and dissolved in hot ammonium tartrate (solution C). Triton X-100 was extracted with 10 ml of ethyl acetate. Portions (0.1–1.0 ml) of ethyl acetate solution were transferred to a 25 ml volumetric flask, 12.5 ml of 1 M aqueous sodium sulphate were added and the volumetric flask was filled to the mark with water. Triton X-100 was determined by AdST after 5 min preconcentration at −1.20 V (vs. SCE). The specific signal of Triton X-100 was used for the determination of the concentration, using a calibration curve prepared in the presence of a fixed amount of ethyl acetate. AdST was applied in this series to certify the precipitation of Triton X-100. The results are shown in Table 1. They show that spikes of Triton X-100 are correctly recovered within the investigated range, as the Triton X-100 is almost quantitatively precipitated.

### *3.1.4. Modification of the ITM measurement for the determination of small amounts of NSs*

The procedure described in the previous paper [4] is limited to the determination of NSs in amounts higher than 100 µg in the sample. Only aliquots of solution obtained after dissolution of the precipitate were used according to this procedure. However, if larger portions of the dissolved precipitate are introduced into the measuring system, the barium ions from the dissolved precipitate react with sulphate ions from the base electrolyte, forming a precipitate of barium sulphate. This concerns not only barium ions from the dissolved precipitate but also barium ions from the excess of Dragendorff reagent not removed by washing. The other factor which must be taken into account is the presence of high concentrations of tartrates, which slightly modifies the measuring conditions in the ITM procedure. Therefore the conditions for the ITM measurement were modified. Sodium chloride (0.5 M) was used instead of 0.5 M sodium sulphate as the base electrolyte (compare procedures B and C). The influence of tartrates was taken into account for the construction of the calibration graphs. A range of 2–1000 µg NS in the sample was aimed at in the modified procedure. Such a wide range could not be covered using only one calibration curve. Thus three ranges for the amount of NSs in the samples were selected: 2–20 µg, 10–100 µg and 50–1000 µg respectively. The NSs precipitated with modified Dragendorff reagent were dissolved in 20 ml of

hot ammonium tartrate solution (according to the classical BiAS procedure with additional filtration of the solution through an spe silica gel cartridge); the solution was then placed in a 25 ml volumetric flask and filled to the mark with water. For the range 50–1000 μg, a 0.5 ml aliquot is used. Further processing of the aliquot was performed according to procedures C and B. If the result obtained was below this range, the measurement was repeated with a 4 ml aliquot of sample in the range 10–100 μg. Finally, if the result was still below this range, a 20 ml aliquot of a solution (range 2–20 μg) was used. As each of these aliquots contains different amounts of tartrates, slight changes in the calibration graph result. Therefore three calibration graphs should be used, with tartrates in concentrations corresponding to the 0.5, 4 and 20 ml aliquots, respectively. The calibration graphs performed under these conditions with standard Triton X-100 are shown in Fig. 3. Curves a', b' and c' cover a wide range of concentration showing typical Γ-shape curves, while curves a, b and c cover the almost linear, most frequently used sections of the calibration graphs. Differences between the curves are best explained by the influence of tartrates or impurities introduced with the tartrates. The more tartrates, the stronger their influence on the analytical signal.

### *3.1.5. Recovery and precision according to the improved analytical procedure*

Recovery and precision were checked in model studies involving precipitation of Triton X-100 spikes, dissolution of the precipitate and the ITM measurement (following procedures A and C). The recovery was tested within the range 2–1000 μg of Triton X-100. The results are shown in Table 2. In several cases the measurements were performed using two different aliquots of the same precipitated Triton X-100 spike. The results support the possibility of precipitation and determination of NSs at concentrations below 100 μg up to 2 μg in the sample, using the BiAS–ITM procedure. The recoveries are satisfactory, although they are

usually slightly below 100%, especially for the lower concentration range. It is usual for trace analysis that at the lower concentrations the loss is more pronounced.

The precision was tested for 1000, 100 and 5 μg Triton X-100 spikes. The results are shown in Table 3. The precision is very good for the larger spikes and acceptable for the 5 μg spikes, typical for trace analysis. The detection limit of the BiAS–ITM procedure calculated on the basis of 3 × S.D. lies slightly below 1.5 μg NS in the sample.

### 3.2. *Interferences*

#### 3.2.1. *Anionic surfactants*

The ITM is tolerant to anionic surfactants [7]. However, it was necessary to check the influence of ASs on the precipitation step. To do this, 100, 200 and 1000 μg spikes of Triton X-100 were precipitated in the presence of 1000 μg of sodium dodecylbenzenesulphonate (DBS) or sodium lauryl sulphate (LS). Triton X-100 was determined according to the procedure B. Additionally, the precipitated surfactant was determined by AdST (procedure D). DBS and LS were also controlled in the precipitate using the MBAS method [12] and in the filtrate by AdST (see section 2.2.6.). The amount of surfactant in the precipitate fraction also included the surfactants adsorbed on the glass filter and surfactants washed out simultaneously with the precipitate. The results are shown in Table 4. The results obtained by the BiAS–ITM and AdST techniques are basically the same. No substantial influence of the anionic surfactants on the results for Triton X-100 is observed. Very interesting results concern the anionic surfactants. Both DBS and LS are strongly adsorbed on the glass filter, as is seen from the results of measurements in the absence of Triton X-100. No Triton X-100 spike means no precipitate formed. Therefore only the glass filter used is responsible for a roughly 20% presence of DBS and a roughly 40% presence of LS in the "precipitate" frac-

Table 5
The influence of glycerol trioleate (GTO) on the determination of Triton X-100 spikes by the BiAS–ITM procedure

| Added (μg) | | Found (μg) | |

| | | ITM | AdST |
| 100 | 1000 | 102 | 108 |
| 1000 | 1000 | 992 | 974 |

Table 6
Recovery of Triton X-100 spike in the presence of chlorophyll (calibration curve III)

| Added (μg) | | Found (μg) | Recovery (%) |
|---|---|---|---|
| Triton X-100 | Chlorophyll | | |
| 10 | 0 | 9.6 | 96 |
| 10 | 10 | 9.4 | 94 |
| 10 | 30 | 9.8 | 98 |
| 10 | 50 | 12.1 | 121 |
| 10 | 100 | 16.5 | 165 |

tion. A corresponding loss in the filtrate fraction supports this conclusion. Some DBS and LS is also adsorbed on the Triton X-100-containing precipitate, as must be derived from the fact that the amount of the anionic surfactants in the precipitate fraction increases with the increase of the spike of Triton X-100, whereas the amount of AS in the filtrate respectively decreases.

*3.2.2. Lipids*

Lipids were represented by glycerol trioleate (GTO). Spikes (100 and 1000 μg) of Triton X-100 were processed in the presence of 1000 μg of GTO. Triton X-100 in the dissolved precipitate was determined using procedure B. The results are summarised in Table 5. No substantial effect of GTO was observed.

*3.2.3. Chlorophyll*

Chlorophyll is the most serious interferent in the ITM measurements, showing much stronger signals than NSs. Therefore, water samples for the ITM measurement of NS concentration must be filtered, thereby any information concerning the amount of NSs adsorbed on particles in the surface water is lost. Loss of chlorophyll during the precipitation step is foreseeable. Experiments involving the precipitation of a 10 μg spike of Triton X-100 in the presence of increasing amounts of chlorphyll (from 10–100 μg in the sample) were carried out. The chlorophyll concentration was measured by the ITM. The Triton X-100 in the precipitate was determined according to procedure C. The results are shown in Table 6. It is apparent that 30 μg of chlorophyll are tolerated while 50 μg of chlorophyll are not. Thus, a 3:1 excess of chlorophyll is tolerated. The result is satisfactory as an excess of chlorophyll vs. NSs is not to be expected.

# Flame AAS determination of dopants and trace metal impurities in single crystals of potassium titanylphosphate

E. Ivanova *, I. Havezov

*Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, BG113 Sofia, Bulgaria*

Received 14 December 1994; revised 22 February 1995; accepted 22 February 1995

**Abstract**

A flame AAS method is used for the determination of dopants and impurities in potassium titanylphosphate (KTP) single crystals. Sample digestion using sulphuric acid and hydrofluoric acid is proposed as being the most appropriate procedure. The effect of major and minor components in the sample solution on the analytical signal is studied. The content of the dopants Cr, Mn and Ni (at a level of about 1 mg $g^{-1}$) as well as the content of the impurities Fe, Na, Mg, W and Al (from 4 μg $g^{-1}$ to 4 mg $g^{-1}$, depending on the trace metal) in the KTP single crystals is determined. The precision of the method is characterized by a relative standard deviation of 3–10%. The accuracy is checked by comparison with ICP-AES data for the trace element content in the KTP single crystals.

*Keywords:* Dopants; Flame AAS; Potassium titanylphosphate; Single crystals; Trace metal impurities

## 1. Introduction

Potassium titanylphosphate (KTP) possesses a unique combination of properties making it a superior optical crystal for second harmonic generation and electro-optic applications [1,2]. Ionic conductivity is important in the processing of waveguides in the material and in waveguide device stability [3]. The damage susceptibility of KTP has been shown to increase with increasing ionic conductivity of the crystal [3]. Doping is a way of reducing the ionic conductivity. For example, doping with chromium reduces the ionic conductivity of KTP from $10^{-6}$ to $10^{-8}\ \Omega^{-1}\ cm^{-1}$.

Along with dopants intentionally added in order to achieve specific properties, impurities can be unintentionally introduced into the crystal from the starting materials or during the crystal growth. The structural properties of typical non-linear optical oxides lead to high distribution coefficients of trace elements, and little if any purification occurs during the growth process [3]. Therefore the use of high-purity starting materials is very important for lowering the impurity level in the crystals themselves.

The correct interpretation of the specific properties of the crystals and the control of their quality requires a precise knowledge of the content of dopants and impurities incorporated.

The aim of the present work was to develop a reliable sample decomposition and flame atomic absorption procedure in order to determine the concentration of trace elements (dopants and impurities) in KTP single crystals.

## 2. Experimental

### 2.1. Reagents

Reagents of the highest available purity grade were used — 96% $H_2SO_4$ and 40% HF

* Corresponding author.

*SSDI* 0039-9140(95)01570-1

(Suprapur, Merck), 30% $H_2O_2$ (z.S., Merck), and redistilled water. Plastic or PTFE ware was used throughout.

### 2.2. Apparatus

The measurements were performed using the flame AAS spectrometer Pye Unicam SP 192, at the most sensitive analytical lines of the elements recommended in the manual. Deuterium background correction and an adjustable Pt–Ir nebulizer with an impact bead were used. A lean air–acetylene flame was used for Ni, Mn, Na, Fe, Mg, Pt and Cr; a rich $N_2O$–acetylene flame was used for Al and W. The heights of the "red feather" were 1 cm and 2.5 cm, respectively. Calibration was performed by the standard additions method.

### 2.3. Dissolution procedure

The KTP crystal was crushed into pieces and finely ground in an agate mortar. A portion (200 mg) of the sample was transferred to a PTFE beaker of 100 ml volume, and 2 ml of concentrated $H_2SO_4$ and 6 ml of 40% HF were added. The beaker was heated on a hot plate until sample dissolution occurred with subsequent removal of the excess HF. The beaker was cooled, the walls were washed with several milliliters of redistilled water and heating was repeated until $SO_3$ vapours appeared. The solution obtained was diluted with 3–4 ml of redistilled water and 0.4 ml of 30% $H_2O_2$ were added dropwise under stirring. The obtained orange-coloured solution was transferred to a 25 ml polypropylene graduated flask and was brought up to volume with redistilled water. The concentration of KTP in the solution was 0.8%, and the concentration of $H_2SO_4$ was 1.5 mol $dm^{-3}$. Where necessary, an aliquot of the sample solution was diluted with water in a polypropylene tube.

A blank sample was subjected to the whole procedure.

## 3. Results and discussion

The chemical resistance and the low solubility of KTP are among its advantages as an optical crystal. These are disadvantages, however, when considering its analysis by means of AAS, since preliminary dissolution of the sample is required.

For the dissolution of phosphates and titanates, sample digestion with sulphuric acid is proposed. The process is accelerated by the addition of ammonium sulphate [4]. The residue is dissolved in sulphuric acid with a concentration above 5% in order to avoid hydrolysis and the precipitation of titanium. A better dissolution of the residue is achieved by the addition of $H_2O_2$, tartaric or oxalic acid. Titanium oxide is readily soluble in HF [4]. In many cases, good results are obtained by fusion with potassium pyrosulphate or sodium hydroxide/sodium peroxide [4]. Titanium-containing silicate samples are digested with a mixture of $H_2SO_4$ and HF. Sulphuric acid is added in order to avoid partial losses of volatile fluorides [4].

The method of sample digestion should be in accordance with the subsequent method of analysis. From this point of view, sample digestion by fusion is not appropriate for the AAS determination of the trace element content in KTP crystals due to the high salt content of the final solution, leading to severe matrix interferences and high blank values as well as to a drift in the flame characteristics (or even burner blockage).

The method of sample digestion should also take into consideration the analyte elements in order to provide their complete dissolution without losses or contamination.

Two modes of acid digestion of the KTP crystals were tested.

(i) Digestion with a mixture of $H_2SO_4$ and $(NH_4)_2SO_4$. A 100 mg portion of the sample was heated on a hot plate with 1.2 ml of concentrated $H_2SO_4$ and 0.5 g of $(NH_4)_2SO_4$ for 1 h. After cooling, 3–4 ml of water and 0.5 ml of 30% $H_2O_2$, dropwise were added. The latter was introduced in order to maintain the titanium in solution as the complex acid $H_2[TiO_2(SO_4)_2]$ [4]. The solution became orange-coloured (the colour of the complex), a small amount of a white precipitate also being observed. Qualitative analysis of the precipitate by atomic emission spectrometry pointed to the presence of silicon, aluminium and magnesium. It may hence be assumed that the KTP crystals had been contaminated with silicon (from the furnace materials) during the synthesis and the silicic acid precipitate formed during digestion sorbed aluminium, magnesium and probably other trace elements, thus interfering with their quantitative determination in the analyte solution.

It follows then that silicic acid should be removed from the solution during digestion, as accomplished in procedure (ii).

(ii) Digestion with a mixture of $H_2SO_4$ and HF. A portion (100 mg) of the sample was heated on a hot plate (PTFE beaker) with 1.5 ml of concentrated $H_2SO_4$ and 5 ml of 40% HF. After heating for 5–10 min, a clear solution was obtained. Heating was continued in order to remove the excess HF since fluoride ions would interfere with the subsequent formation of the complex $H_2[TiO_2(SO_4)_2]$ [4]. During HF removal, a fine white precipitate appeared in the solution. After cooling, diluting with water and adding 0.5 ml of $H_2O_2$, this precipitate dissolved completely. The appearance of the precipitate upon the removal of HF and its redissolution by the addition of $H_2O_2$ gives grounds to assume that the precipitate was titanium.

The trace elements to be determined in the present study were Cr, Mn, Ni, Fe, W, Pt, Mg, Al and Na. Preliminary experiments with spiked samples showed that these elements were brought into solution quantitatively by the above digestion method. The optimized conditions of the digestion method used are given in the dissolution procedure. All the cited trace elements were determined in the solution of KTP thus obtained, some after additional 2–5-fold dilution with water.

The following KTP single crystals were analysed:

undoped KTP (four samples);
KTP doped with Mn (one sample);
KTP doped with Cr (one sample);
KTP doped with Ni (one sample).

### 3.1. Determination of dopants

The concentration of dopants in optical crystals is usually in the range of hundreds of micrograms per gram which considerably exceeds the dynamic range of flame AAS (the corresponding flame AAS limits of detection in a 0.8% solution of KTP are shown in Table 1). This allowed us to apply a 2–5-fold dilution of the sample solutions. It was important to find out whether the matrix KTP or the dissolution reagent $H_2SO_4$ affected the analytical signal. This effect was estimated by comparing the slopes of the calibration curves for various concentrations of KTP or $H_2SO_4$ with that of an aqueous calibration curve. The results of this study are shown in Tables 2 and 3. As can be seen, the matrix KTP still strongly suppresses the analytical signal of Cr, Mn and Ni at the lowest concentration examined — 0.16%, which corresponds to a five-fold dilution of the sample solution. The effect is most strongly expressed for Cr, most weakly for Ni. It may hence be assumed that at the temperature of the air–acetylene flame, the droplets produced by the nebulizer had given rise to solid particles (e.g. a Cr–Ti compound) which, because of their high vaporization temperature, are not completely converted to atomic vapour. The effect of $H_2SO_4$ is less pronounced for all three elements, i.e. viscosity and surface tension effects are negligible in the examined $H_2SO_4$ concentration range.

Reviewing the data presented in Tables 2 and 3 it may be concluded that accurate results for the content of Cr, Mn and Ni in KTP solutions can be obtained by means of flame AAS when calibration is performed by the standard additions method or if the calibration standards contain the same concentration of an undoped crystal matrix. Where possible, sample dilution is recommended.

Table 1
Flame AAS limits of detection ($3\sigma$ criterion) of the elements in a 0.8% KTP solution

| Element | Limit of detection ($\mu g\ g^{-1}$) |
|---|---|
| Cr | 17 |
| Mn | 2.8 |
| Ni | 8 |
| W | 500 |
| Al | 150 |
| Pt | 11 |
| Fe | 7 |
| Na | 1.7 |
| Mg | 0.35 |

### 3.2. Determination of impurity elements

The growth of KTP crystals takes place from a molten mixture of the composition $K_2O$–$P_2O_5$–$TiO_2$–$WO_3$, where $WO_3$ serves as a high-temperature solvent. The presence of a large amount of $WO_3$ in the growth solution leads to its incorporation in the crystal. That is why the tungsten content in the latter is of interest.

The KTP crystals may be also contaminated with platinum from the crucible used for the synthesis.

Traces of Mg, Al, Fe and Na can be incorporated in the crystal from the starting substances, from the furnace materials and from the ambient air.

The limits of detection of W, Al, Pt, Fe, Na and Mg in a 0.8% solution of KTP determined by flame AAS are presented in Table 1.

Preliminary experiments performed by means of ICP-AES revealed that the concentration of W in the KTP crystals was about 1000–4000 mg $g^{-1}$. A comparison of this concentration range with the data of Table 1 reveals that the reliable flame AAS determination of W in 0.8% solutions of KTP is hardly possible. The W content was determined only in sample 1 of the undoped KTP crystal which had the highest W content.

The content of Pt in the analysed KTP crystals was below the limits of detection shown in Table 1.

Preliminary studies of the Al content of the KTP crystals (ICP-AES) pointed to a content of about 200–700 μg $g^{-1}$. The data for Al shown in Table 1 revealed that the determination of Al in the KTP solutions is as discussed for W. Only sample 3 of the undoped KTP crystal (that with the highest Al content) was analysed for Al.

The content of Fe, Na and Mg in the KTP crystals was higher than the limits of detection shown in Table 1. Care was taken to avoid contamination from reagents and laboratory ware.

The effects of the KTP and $H_2SO_4$ contents in the solution on the analytical signals of Fe, Na and Mg are shown in Tables 2 and 3. As can be seen, the dependences are the same as for Cr, Mn and Ni: the effect of KTP is much higher than that of $H_2SO_4$. The effect of KTP is most pronounced for Mg. Fortunately the content of this element in the analysed crystals permitted its determination after five-fold dilution of the solution.

### 3.3. Analysis of KTP single crystals

The content of dopants and impurity elements in the KTP crystals was determined as described in the Section 2.2. The results are shown in Table 4. The mean value was determined from the analysis of three separate portions of each single crystal.

Table 4
Content of dopants and impurities in KTP single crystals

| Element (μg $g^{-1}$) | Undoped KTP | | | | Cr-doped | Mn-doped | Ni-doped |
|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | | | |
| Cr | – | – | – | – | 837 | – | – |
| Mn | – | – | – | – | – | 862 | – |
| Ni | – | – | – | – | – | – | 1146 |
| Fe | 108 | 94 | 76 | 59 | 48 | 51 | 47 |
| Na | 435 | 457 | 542 | 343 | 540 | 825 | 772 |
| Mg | 4.8 | 12.0 | 12.3 | 4.3 | 6.3 | 7.3 | 5.7 |
| W | 4420 [a] | – | – | – | – | – | – |
| Al | – | – | 750 | – | – | – | – |

[a] Single determination.

Table 5
Trace element determination in the Mn-doped sample by flame AAS and ICP-AES

| | ($\mu g\ g^{-1}$) | ($\mu g\ g^{-1}$) |
|---|---|---|
| Mn | $862 \pm 25$ | $835 \pm 30$ |
| Fe | $51 \pm 5.5$ | $55.6 \pm 6.0$ |
| Na | $825 \pm 39$ | $822 \pm 16$ |
| Mg | $7.3 \pm 0.50$ | $8.0 \pm 0.50$ |

The precision of the method is characterized by a relative standard deviation of 3–10%. The accuracy of the flame AAS determination of the trace element content (dopants and impurities) in KTP single crystals was checked by comparison with the results obtained by the ICP-AES analysis [5] of a sample solution obtained as described in the dissolution procedure. Results for the analysis of the Mn-doped sample are shown in Table 5. Using Student's criterion, no statistical difference between the results obtained by the two methods was found.

**Abstract**

A new fusion agent is proposed for the analysis of cement and cement raw meal using AAS. In the described method, 0.8 g of the fusion agent, consisting of equal portions of oxalic acid, lithium carbonate and lithium tetraborate, was mixed with 0.2 g of the sample, and the mixture was fused for 10 min at 925 °C in a platinum crucilbe. The fusion cake was dissolved with dilute hydrochloric acid (1 + 10) and diluted to 500 ml for the determination of Si, Al, Fe, Ti, Na and K expressed as $SiO_2$, $Al_2O_3$, $Fe_2O_3$, $TiO_2$, $Na_2O$, and $K_2O$ respectively. For the determination of Ca and Mg (expressed as CaO and MgO respectively), 10 ml of the previous sample solution were mixed with 4 ml of 6% (m/v) lanthanum nitrate solution and the solution was diluted to 100 ml. The method was found to have good accuracy and precision. The time required to determine the eight elements was around 80 min for each sample.

*Keywords:* Atomic absorption spectrophotometry; Cement; Fusion method; Limestone; Raw meal

## 1. Introduction

In the cement industry, limestone, clay and iron ore are used as raw materials and are mixed in controlled proportions and ground to form the raw meal, which is ignited at high temperature to form clinker. The clinker is ground with gypsum to give cement. Inside the cement plant, on-line control of the composition of raw meal is needed to maintain the composition of cement to within strict requirements. This is usually achieved in the cement industry by determining the content of each element of interest, expressed in terms of the respective oxide. The final composition of a typical cement is as follows: 65% CaO, 22% $SiO_2$, 3.8% $Al_2O_3$, 4.2% $Fe_2O_3$, 1.0% MgO, 0.6% $Na_2O$, 0.2% $K_2O$, 0.2% $TiO_2$.

The instrumental method commonly used for the analysis of cement and cement raw meal is X-ray fluorescence (XRF) spectrometry [1,2]; however, the instrument is expensive. Further, for the determination of trace elements in cement using XRF, tedious steps are needed to separate the analyte from the matrix [3]. Other instrumental methods applicable are UV-vis spectrophotometry [4], atomic absorption spectrophotometry (AAS) [5] and inductively coupled plasma-atomic emission spectrometry (ICP-AES) [6]. The standard methods [7,8] for cement analysis are complicated and require a long time to complete a full analysis for a single sample. Among these methods, AAS is most suitable for the analysis of cement and raw meal because it is selective, rapid and the instrument employed is cheaper and the running cost lower than those for XRF and ICP-AES, however, it requires the sample to be completely soluble.

Raw meals containing appreciable amounts of silica are difficult to dissolve and they are

either decomposed by hydrofluoric acid or by fusion. Hydrofluoric acid decomposition takes more than 1 h to complete and is not suitable for rapid analysis. In the fusion method, the agents used include sodium carbonate [9], lithium metaborate [10–13], and lithium tetraborate [14,15]. Sodium carbonate is not efficient to convert silica into a soluble form. Lithium metaborate and tetraborate are effective but are expensive and require a long time for dissolving the fusion cake. We observed that when lithium tetraborate was used, silica was precipitated during the course of dissolving the fusion cake. The lithium tetraborate–sodium carbonate system [15] does not have these drawbacks, and has been successfully applied to the analysis of cement and flyash containing up to 50% of silica; however, sodium in the samples cannot be determined.

It is the purpose of the present work to develop a new fusion agent for the rapid analysis of cement and cement raw meal using AAs, which is superior to other published fusion systems in terms of the time required for fusion and dissolution and the number of elements that can be determined.

## 2. Experimental

Analytical reagent grade chemicals and distilled water were used throughout the procedure.

### 2.1. Instrument

A Hitachi Z6100 Zeeman atomic absorption spectrophotometer was used for the absorbance measurements. The measurement conditions are shown in Table 1.

### 2.2. Reagents

To prepare the fusing agent, oxalic acid, lithium tetraborate and lithium carbonate were thoroughly mixed in equal proportions in mass and ground in a mortar with a pestle to give a homogeneous mixture.

Lanthanum nitrate solution (6%; m/V) was prepared by dissolving 30 g of the compound in 20 ml of concentrated HCl and diluting the solution to 500 ml with distilled water.

### 2.3. Procedure

A portion of the sample (0.200 g) was weighed accurately and mixed thoroughly with 0.8 g of the fusing agent in a platinum crucible, which was then covered with its lid and placed in a muffle furnace at 295 °C for 10 min. The crucible lid was then transferred to a 400 ml beaker containing 100 ml of boiling distilled water and 10 ml of concentrated hydrochloric acid. The crucible was cooled by washing its exterior wall with a stream of water, and was then placed in the same beaker, which was subsequently covered with a watch glass. The solution was heated on a water bath until the fusion cake was dissolved. The solution was then cooled and diluted to 500 ml with distilled water in a calibrated flask. This sample solution was reserved for the Si, Fe, Al, K, Na and Ti determinations. For the Ca and Mg determinations, 10 ml of the above sample solution were pipetted into a 100 ml calibrated flask and 4 ml of the 6% (m/v) lanthanum nitrate solution were added, as ionization buffer, and the resulting solution

was diluted to the mark with distilled water.

For standards preparation, 0.5000 g of a cement standard, e.g. BCS 372/1, was mixed with 2.0 g of the fusing agent and the mixture was treated similarly as for the sample, except that 20 ml of concentrated HCl instead of 10 ml were used for dissolving the fusion cake. The sample solution was diluted with distilled water to 250 ml in a calibrated flask and labelled as stock solution A. Standard solutions were prepared by pipetting 25, 35, 50, and 75 ml of the stock solution A separately into a series of 250 ml calibrated flasks and diluting to the mark with distilled water. These standard solutions were used for $SiO_2$, $Fe_2O_3$, $Na_2O$, $K_2O$, $TiO_2$ and $Al_2O_3$ determinations.

Standards for the CaO and MgO determinations were prepared by first fusing 0.2000 g of a cement standard with 0.8 g of the fusing agent for 10 min. After dissolving in hydrochloric acid (1 + 10), the solution was diluted to 500 ml in a calibrated flask and labelled as stock solution B. Standard solutions were prepared by pipetting 10, 20, 25 and 40 ml of stock solution B separately into a series of 250-ml calibrated flasks, adding 10 ml of the lanthanum nitrate solution to each flask and diluting to the mark with distilled water.

The respective reagent blanks were prepared similarly as for the sample solutions, except that no sample was used in the fusion procedure.

## 3. Results and discussion

The recently developed system sodium carbonate–lithium tetraborate [15] is efficient at converting silica into the soluble form and can save a lot of time taken up in fusion and dissolution. However, as sodium carbonate is used, it is not possible to determine sodium in the sample. To remedy the situation, sodium carbonate needs to be replaced by an appropriate compound. Lithium carbonate was chosen for the present study because it has a lower melting point so that fusion can be carried out at a lower temperature. Although lithium tetraborate is expensive, it can convert silica into the solution form, and hence should not be excluded from the system. Lithium tetraborate is preferable to lithium metaborate because it is difficult to obtain the latter in high purity. Oxalic acid is included as it was found to shorten the dissolution time when present. As the loss of alkali was reported at temperatures above 950 °C [16] the temperature used was 925 °C.

Four fusion systems were prepared to contain different proportions of lithium tetraborate, lithium carbonate and oxalic acid. The recoveries of silica in cement and flyash obtained after fusion with these systems are summarized in Table 2, where it can be seen that the proposed system gave the best recoveries for both samples. Further, the dissolution time was shortened from 30 min to less than 10 min. Also, no precipitation of silicon was observed and hence a better recovery can be obtained.

It was found that a graphite crucible was not suitable for the proposed system as the melt after fusion solidified rapidly and was difficult to transfer completely to the beaker. Further, fine particles of charcoal were also found to have been transferred, and these needed to be removed by filtration. A platinum crucible was found to be satisfactory for the proposed method.

### 3.1. Accuracy

The concentration of oxides in a number of cement, raw meal, and limestone samples were determined using the proposed and the XRF methods, and the results are shown in Tables 3 and 4, respectively. The average absolute differences between experimental and known concentrations were calculated for the cement and raw meal samples, and the ASTM-allowed differences [8] are also included for comparison. It can be seen that the average absolute differences obtained by the proposed method were all equal to or less than the respective

ASTM-allowed difference, whereas the same is not true for the XRF method. The proposed method can yield better results than the XRF method, especially for the light elements such as $Na_2O$ and MgO and for those oxides with contents of below 1%. The XRF flux yields of the light elements are very low and are easily absorbed by the environment, resulting in poor accuracy in the determination. Further, for high accuracy in XRF, the nature of the standards used must be close to the sample to be analysed. If the concentrations did not fall within the calibration range, e.g. CaO in BCS-CRM354 (Table 4), great deviations were observed.

The oxides of some of the trace elements, namely BaO, $Cr_2O_3$ and $Mn_2O_3$, have also been determined by the AAS method using the standard additions technique, yielding satisfactory results (see Table 3).

Three limestone reference standard materials were analysed using the AAS method. The accuracy is good except for those oxides with concentrations less than 0.1%.

### 3.2. Interference studies

It has been reported that $Al^{3+}$ ions interfered with the determination of silicon [17], and silicon and aluminium interfered with the determination of calcium [16] by AAS. The effects of some common interfering ions were assessed by measuring the AAS absorbances of solutions with matrices simulating the fusion conditions and containing a fixed amount of the analyte and various amounts of the interferents. The relative deviation in the signal caused by the interferent was calculated and is tablulated in Table 5. With the matrix containing lithium tetraborate, no interference was observed for most of the interferents except CaO for the determination of $Na_2O$, where CaO caused a positive error at high concentration of Ca(II), and the interference was less in the matrix with a high concentration of lithium. Further, sulphate was found to cause a negative error in the determination of calcium, possibly due to the formation of calcium sulphate which can only be broken down at high temperatures. Nevertheless, the concentration of sulphate in cement samples is much less than that of Ca(II), and so its effect need not be considered except that sulphuric acid should not be used for dissolution purposes.

### 3.3. Calibration graph, detection limit and precision

The upper limits (3% deviation from the calibration graph), detection limits (defined for three times the standard deviation of the blank) and correlation coefficients for the calibration graphs for the determination of the eight oxides are shown in Table 6. The working ranges of the method are wide for these oxides, which enable samples with great variations in compositions to be determined.

The precision for the determination of the eight oxides using the proposed and XRF methods are shown by comparing the standard deviations for replicate determinations ($n = 4$) of the oxides in a cement sample. The results are presented in Table 7, where it can be seen that the precision using the AAS method is comparable or slightly better than that using the XRF method, except for $TiO_2$ for which the precision using the XRF method is better.

### 3.4. Real sample analysis

In real sample analysis, the XRF method was taken as the countercheck method. The $t$-values calculated for cement and raw meal are less than the theoretical values, indicating

Table 5
Effect of interferents on the proposed method

| Analyte | Interferent | Interferent/analyte ratio [a] | | | |
|---|---|---|---|---|---|

that there is no significant difference between the proposed and countercheck methods (see Table 8).

In carbonate rock analysis, although the microwave oven technique [18] is time-saving, the oven used is a laboratory model (not a home appliance), which is less popular and expensive. Hence a muffle furance was used for the present investigation.

The proposed method can also be successfully applied to limestone determinations. This indicates the flexibility of the method.

For the classical gravimetric method [8], the cement and clinker samples are treated with hydrochloric acid and the amount of insoluble silica is negligible. This procedure cannot be applied to the raw meal and flyash blended cement samples without modification because they contain some acid-insoluble substances such as flyash and sand. For such samples, either fusion with sodium carbonate or clinkerization at 1400 °C must be carried out, and hence either sodium cannot be determined or a special muffle furnace (heating up to 1500 °C) is required for clinkerization. The fusion technique now proposed is shown to be effective for dissolving raw meal and flyash as well.

The standards for calibration are easily prepared from only one reference standard and can be used for calibrating all eight elements. For other published methods, different elements may require different sets of standards and chemicals [4]. Therefore, the proposed method is superior to the other method for standards preparation.

## 4. Conclusion

The proposed method is simple, rapid, accurate and has good precision. It can be applied to cement and raw meal with high silica contents of above 30%, and can also be applied to limestone samples. The standard preparation procedure is simplified, is better than other methods such as XRF, and is also applicable to determine trace elements in cement without tedious separation steps. The fusion agent is cheaper because part of the expensive lithium tetraborate is substituted with oxalic acid and lithium carbonate. The determination of eight elements for each sample can be completed within 80 min and therefore a large number of samples can be analysed within a working day.

Received 3 November 1995; revised 21 February 1995; accepted 28 February 1995

**Abstract**

A kinetic method is described for the determination of iron(III) based on its catalytic effect on the oxidation of sodium pyrogallol-5-sulphonate by hydrogen peroxide. The reaction was followed spectrophotometrically by measuring the rate of change in the absorbance of the coloured product at 436.8 nm. Nanogram amounts of iron(III) (2.0–75.0 ng $cm^{-3}$) can be determined with good accuracy and reproducibility. The influence of foreign ions on the results was investigated and the method was found to be adequately selective. It has been applied satisfactorily to the determination of iron(III) in tap water samples. The kinetic parameters of both the catalysed and uncatalysed reactions are reported.

## 1. Introduction

The catalytic kinetic method [1] is one of the most attractive procedures for achieving the ultratrace determination of iron. The advantage of the catalytic kinetic method lies in the fact that the only instrumentation required is a spectrophotometer. Many indicator reactions for the catalytic kinetic method have been reported to determine microgram per cubic centimetre or submicrogram per cubic centimetre amounts of iron(III): the oxidation of Variamine Blue B base (*N*-(*p*-methoxyphenyl)-*p*-phenylenediamine) [2], its analogue (*N* - (*p* - methoxyphenyl) - *N'*, *N'* - dimethyl - *p*-phenylene-diamine) [3], 2-hydroxybenzaldehyde thiosemicarbazone [4], and chromotropic acid [5] by hydrogen peroxide and of *p*-phenetidine [6] by periodate in the presence of 2,2'-bipyridine. However, there are few methods that have sufficient sensitivity to determine iron(III) at the nanogram per cubic centimetre level or below: the oxidation of sodium 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate by dissolved oxygen (limit of detection, 18 ng $cm^{-3}$) [7] and *N*-methyl-*p*-aminophenolate by hydrogen peroxide (limit of detection, 0.8 ng $cm^{-3}$) [8]. Recently, Nakano et al. have developed a sensitive procedure for determining 0–6 ng $cm^{-3}$ iron(III) based on the oxidative coupling of *N*-phenyl-*p*-phenylene diamine with *N*,*N*-dimethylaniline by hydrogen peroxide [9]; however, the reaction must be performed at a higher temperature (40 °C). The catalytic oxidation of 3,5-diaminobenzoic acid dihydrochloride by hydrogen peroxide was also applied for the trace determination of iron [10]. The sensitivity of these reactions is 1 ng $cm^{-3}$, but the reaction must be performed at 35 °C. Dolmanova et al. [11] determined iron(III) by its catalytic effect on the oxidation of *o*-tolidine by periodate and 2,2'-bipyridine as an activator. The method has a high sensitivity 20 pg $cm^{-3}$, but manganese(II) interferes seriously with the determination even when present, in a amount equal to

SSDI 0039-9140(95)01572-8

that of iron(III). Therefore, a still more sensitive and selective method for iron determination, the catalytic kinetic method is expected to achieve widespread application. For the development of a new indicator reaction for practical applications, attention should be paid to the following considerations: the reaction time to be analysed should be as short as possible within 20–30 min; the catalysed reaction should proceed at room temperature for convenient operation; the reaction rate can be followed spectrophotometrically by the differential tangent method; the indicator reaction preferably should be a simple mechanism, not involving a side reaction and an activator.

On the basis of the above concept, we present a new sensitive catalytic method of analysis for iron(III) based on the oxidation of sodium pyrogallol-5-sulphonate (PS) with hydrogen peroxide. The detection limit for this method was calculated to be 0.16 ng $cm^{-3}$. The method was successfully applied to the determination of trace iron in tap water without preconcentration and separation.

## 2. Experimental

### 2.1. Reagents

All chemicals were of analytical reagent grade, and were provired by Merck unless indicated otherwise. Solutions were made up in deionised water.

Hydrogen peroxide solution was prepared by appropriate dilution of the Merck pro analysi reagent and was standardised against potassium permanganate solution. PS was synthesised by dissolving 3.7833 g of pyrogallol in 100 $cm^3$ of the sulphuric acid (96%) [12]; a $8.8 \times 10^{-3}$ mol $dm^{-3}$ solution of the reagent was used. The stock iron solution, concentration 1 mg $dm^{-3}$, was prepared from iron(III) chloride and was determined by titration with EDTA using sulphosalicylic acid as indicator. Hydrolysis was prevented by adjusting the pH to about 1 with HCl [13]. A standard iron solution (100 ng $cm^{-3}$) was prepared by diluting the stock iron solution with deionised water. The perchloric acid solution (0.12 mol $dm^{-3}$) was prepared from the 70% reagent.

All the stock solutions were stored in polyethylene containers. Working solutions of iron, hydrogen peroxide and PS were prepared immediately before use.

All the polyethylene containers and glassware used were cleaned in aqueous HCl (1:1) and then thoroughly rinsed with deionised water.

### 2.2. Apparatus

A Perkin–Elmer Lamda 15 spectrophotometer, connected to a thermocirculating bath, was used for the absorbance measurements. The pH was measured by means of a Radiometer PHM 29b pH meter and a combined glass–calomel electrode, GK 2311C. The solutions were thermostatted at $25 \pm 0.1$ °C before the beginning of the reaction.

### 2.3. Procedure

Selected amounts of the reactants were transferred to a 10 $cm^3$ standard flask in the order PS, perchloric acid and catalyst. Water was added to give the predetermined volume. The flask was thermostatted for 10 min, and the solution was then made up to the mark with hydrogen peroxide and vigorously shaken. The spectrophotometer cell was rinsed well and filled with the solution. The absorbance at 436.8 nm, was measured every 30 s over a period of 5–8 min after the addition of hydrogen peroxide. The method of tangents was used and the slope of the linear section of the absorbance–time curve, $dA/dt = \tan \alpha$, was used as a measure of the reaction rate.

The measurements were made at $25 \pm 0.1$ °C.

## 3. Results and discussion

### 3.1. Catalytic oxidation of PS by $H_2O_2$

The absorption spectra were recorded of iron(III), and PS in perchloric acid solution (Fig. 1, curves 1 and 2, respectively), PS–perchloric acid–Fe(III) (curves 3 and 4) immediately after mixing (the absorption maxima is constant 1 h after mixing), PS–perchloric acid–hydrogen peroxide (curve 5) and PS–perchloric acid–hydrogen peroxide–Fe(III) (curve 6) 1 h after mixing.

The oxidation of PS with hydrogen peroxide at the higher concentrations of Fe(III) ($c_{Fe(III)} \geq 10^{-4}$ mol $dm^{-3}$) led to the formation of a yellow oxidation product at 436.8 nm, and also to the formation of a green complex at about 700 nm (curve 4). They are parallel reac-

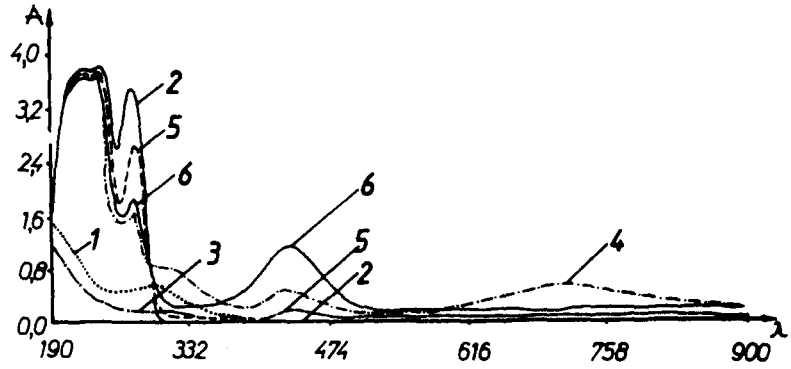

Fig. 1. Absorption spectra: spectrum 1, iron(III) aqueous solution; spectrum 2, PS in $HClO_4$; spectra 3 and 4, PS–$HClO_4$–Fe(III), immediately after the reagents were mixed; spectrum 5, PS–$HClO_4$–$H_2O_2$; spectrum 6, PS–$HClO_4$–$H_2O_2$–Fe(III) mixture 1 h after mixing.

tions, but both are under investigation. The aim of this paper is to study the catalytic effect of iron(III) on the oxidation of PS by the hydrogen peroxide reaction. For further work an iron(III) concentration of about $10^{-7}$ mol dm$^{-3}$ was selected. No characteristic absorption maxima are seen in the visible part of the spectrum of a PS–perchloric acid–Fe(III) solution mixture (curve 3) under the given optimum conditions for the iron(III).

However, the oxidation of PS by a higher concentration of hydrogen peroxide ($c_{H_2O_2}/c_{Fe(III)} \approx 10^5$) in the presence of perchloric acid is characterised by a slight maximum at 436.8 nm which significantly increases in the presence of iron(III). Therefore it can be concluded that iron(III) acts as a catalyst in the PS hydrogen peroxide oxidation reaction.

The dependence of the reaction rate on the $H_2O_2$ or PS concentration (see Figs. 3 and 4 below) indicates that the reaction proceeds through an intermediate complex of the catalyst–reductant–oxidant type [14], and, finally, the activated complex decomposes into the products and the catalyst

$$[PS\text{–}Fe(III)\text{–}H_2O_2] \rightarrow \text{Products} + Fe(II) \quad (1)$$

$$2Fe(II) + H_2O_2 \rightarrow 2Fe(III) + 2OH^- \quad (2)$$

It can be assumed that the second reaction proceeds much more quickly than the first.

The reduced iron(II) is oxidised to iron(III) by hydrogen peroxide, and then the formed iron(III) is allowed to react with PS again. Probably for this reason, a large excess of hydrogenperoxide with respect to the reagent is needed.

The oxidation product was not identified. However, PS could be oxidised by a one-electron mechanism to produce a resonance-stabilised product [15,16], a quinonoid species seems probable.

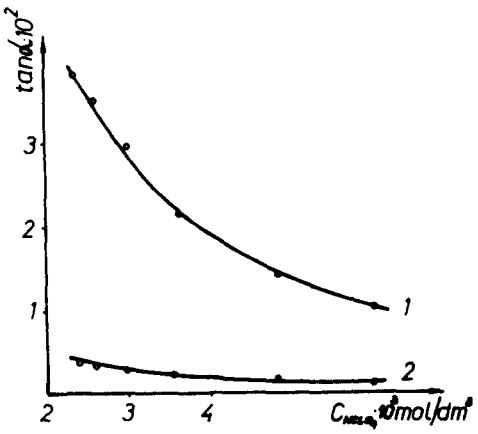

Fig. 2. Dependence of the reaction rate on $HClO_4$ concentration. Initial concentrations: PS, $8.8 \times 10^{-4}$ mol dm$^{-3}$; $H_2O_2$, 0.16 mol dm$^{-3}$; Fe(III), 0.3 μg cm$^{-3}$. Curve 1, catalytic reaction; curve 2, non-catalytic reaction.

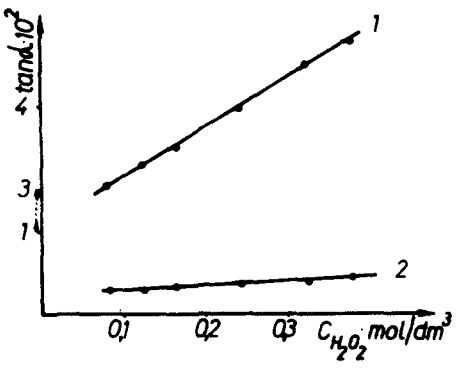

Fig. 3. Dependence of the reaction rate on $H_2O_2$ concentration. Initial concentrations: $HClO_4$, $2.6 \times 10^{-3}$ mol dm$^{-3}$; other concentrations as for Fig. 2 (except $H_2O_2$). Curve 1, catalytic reaction; curve 2, non-catalytic reaction.

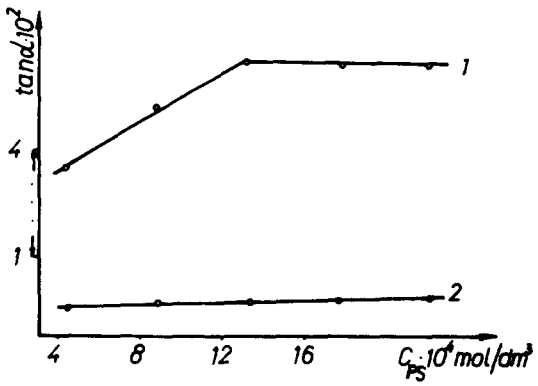

Fig. 4. Dependence of the reaction rate on PS concentration. Initial concentrations: $H_2O_2$, 0.32 mol dm$^{-3}$; $HClO_4$, $2.6 \times 10^{-3}$ mol dm$^{-3}$; Fe(III), 0.3 μg cm$^{-3}$. Curve 1, catalytic reaction; curve 2, non-catalytic reaction.

### 3.2. Effects of reaction variables

The influence of perchloric acid, temperature, and PS and hydrogen peroxide concentrations was studied for both the catalytic and non-catalytic reactions, in order to establish optimum conditions for the determination of iron(III).

Keeping all other experimental parameters constant, the perchloric acid dependence of the system was studied in the range $2.2 \times 10^{-3}$–$6 \times 10^{-3}$ mol dm$^{-3}$ (Fig. 2). It can be seen that the greatest difference between the reaction rates which occurs at $2.6 \times 10^{-3}$ mol dm$^{-3}$ maximally decreases the catalytic reaction rate. For further work a perchloric acid concentration of $2.6 \times 10^{-3}$ mol dm$^{-3}$ was selected.

The dependence of the reaction rate on $H_2O_2$ concentration is shown in Fig. 3, which shows that with increasing hydrogen peroxide concentration the difference between the rates of the catalytic and non-catalytic reactions increases. Both reactions are first order with respect to the $H_2O_2$ concentration. For further work an $H_2O_2$ concentration of 0.32 mol cm$^{-3}$ was selected.

The dependence of the reaction rates on the concentration of PS is shown in Fig. 4, which shows that the non-catalytic reaction is first order with respect to the PS concentration, whereas the catalytic reaction is first order with respect to PS concentration up to $1.32 \times 10^{-3}$ mol dm$^{-3}$ and zero order for higher concentrations. For further work, a PS concentration of $1.76 \times 10^{-3}$ mol dm$^{-3}$ was selected.

The influence of temperature on the reaction rate was studied in the range 22–34 °C (Fig. 5). The reaction rate increased as the temperature increased between 22 and 34 °C. The rate of the reaction increased by about 2 as the temperature was increased from 22 to 34 °C. However, although higher sensitivity could be obtained at the higher reaction temperature, it was troublesome to control the temperature precisely at the elevated temperature, hence a reaction temperature of 25 °C was chosen.

### 3.3. Calibration graph

A calibration graph was prepared for the optimum concentrations described above. There was a linear relationship between the reciprocal of tan α and the iron(III) concentration from $3.6 \times 10^{-8}$ to $1.3 \times 10^{-6}$ mol dm$^{-3}$ or from 2.0 to 75.0 ng cm$^{-3}$ of iron(III) in the final solution. Fig. 6 shows three calibration lines which can be used or the determination of the iron(III) concentration in the interval mentioned. The line 3 measured at 31 °C is steeper and more suitable for use than line 1, measured at 25 °C (or line 2, measured at 28 °C).

On the basis of our kinetic investigation, we formulated a kinetic equation for the oxidation of PS by hydrogen peroxide with iron as catalyst:

$$\frac{dx}{dt} = k_1 c_{HClO_4}^{-0.9} c_{H_2O_2} c_{PS} c_{Fe} \quad \text{for} \quad c_{PS} \leqslant 1.32 \times 10^{-3} \text{ mol dm}^{-3} \tag{3}$$

$$\frac{dx}{dt} = k_1 c_{HClO_4}^{-0.9} c_{H_2O_2} c_{Fe} \quad \text{for} \quad c_{PS} \geqslant 1.32 \times 10^{-3} \text{ mol dm}^{-3} \tag{4}$$

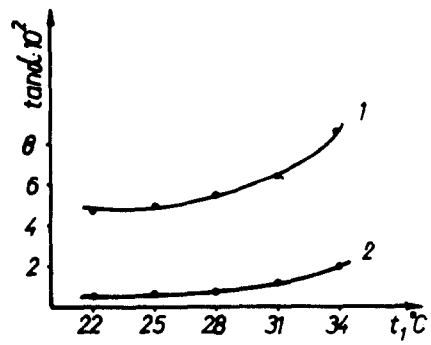

Fig. 5. Dependence of the reaction rate on temperature. Initial concentration: PS, $1.76 \times 10^{-3}$ mol dm$^{-3}$; other concentrations as for Fig. 4. Curve 1, catalytic reaction; curve 2, non-catalytic reaction.

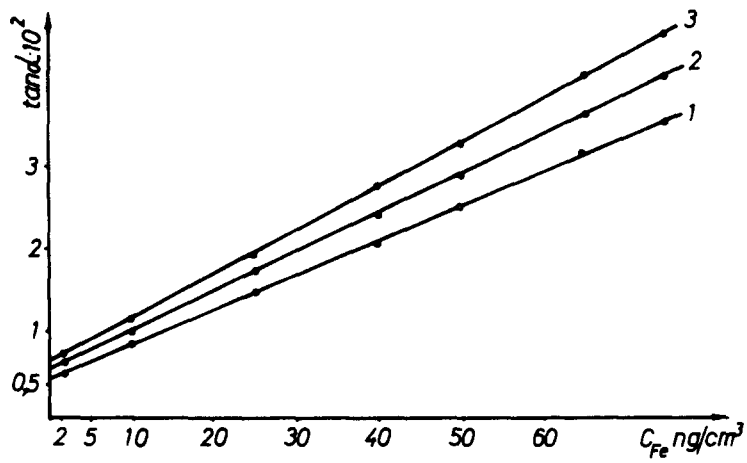

Fig. 6. Dependence of the reaction rate on Fe(III) concentration. Initial concentrations as for Fig. 5. Curve 1, 25 °C; curve 2, 28 °C; curve 3, 31 °C.

The kinetic equation for the non-catalytic reaction under the same conditions may be written as follows:

$$\frac{dx}{dt} = k_0 c_{HClO_4}^{-0.8} c_{H_2O_2} c_{PS} \quad (5)$$

where $k_1$ and $k_0$ are the relative rate constants for the catalytic and non-catalytic reactions. On the basis of these equations the rate constants for the catalytic and non-catalytic reactions were calculated.

The linear relationship between the logarithm of the relative rate constant and the reciprocal of the absolute temperature was found for the catalytic as well as the non-catalytic reaction. The activation energies were found to be 28.11 kJ mol$^{-1}$ for the catalytic reaction and 45.88 kJ mol$^{-1}$ for the non-catalytic reaction.

The minimum concentration of iron which could be determined by this method may be calculated by the method given by Yatsimirskii [17]

$$c_{min} \geqslant 0.1 \frac{k_0 c_{HClO_4}^{-0.8}}{k_1 c_{HClO_4}^{-0.9}} \quad (6)$$

By entering these values in the previous equation we find that $c_{min} \geqslant 2.9 \times 10^{-9}$ mol dm$^{-3}$ or 0.16 ng cm$^{-3}$.

The precision and accuracy of the method are also investigated. The relative error ranges from 0.5 to 7.2% in the iron(III) concentration range 75.0–2.0 ng cm$^{-3}$.

### 3.4. Interference studies

The interference effects of many cations and anions on the kinetic determination of Fe(III) ($c_{Fe(III)} = 50$ ng cm$^{-3}$) were examined and the tolerance limits for interfering ions are summarised in Table 1. It may be seen that Cu(II), Cr(VI) and I$^-$ in a 1:1 ratio with iron(III) interfere with the reaction. The other ions investigated have practically no influence on the determination of iron(III) by this method.

### 3.5. Application to tap water

The method was directly applied to the analysis of tap waters, because interfering ions (Table 2) in natural waters are tolerable. Tap water was acidified to pH 1 with hydrochloric acid (6 mol dm$^{-3}$) and then heated to remove chlorine. After this treatment, a 2 cm$^3$ portion

Table 1
Tolerance levels of interferents in the kinetic determination of 50 ng cm$^{-3}$ iron(III) using the optimum conditions as reported under the analytical procedure (Section 2.3)

| Tolerance level, $c_{ion}/c_{Fe(III)}$ | Ion added |
|---|---|
| $10^3$ | Ca(II), Sr(II), Mg(II), Ba(II) |
| $10^2$ | Zn(II), Cd(II), $AsO_4^{3-}$, $WO_4^{2-}$, $F^-$, $Br^-$, $SO_4^{2-}$, $PO_4^{3-}$ citrate, tartrate, $C_2O_4^{2-}$ |
| 10 | Pb(II), Hg(II), Ni(II), Co(II), Al(III), $SCN^-$ |
| 0.8 | Cu(II), $I^-$ |
| 0.5 | $Cr_2O_7^{2-}$ |

Table 2
Results for the determination of iron(III) in tap water using the optimum conditions reported under the application to tap water (Section 3.5)

| Sample | Sample taken ($cm^3$) | Fe(III) added ($ng\ cm^{-3}$) | Fe(III) [a] found ($ng\ cm^{-3}$) | Fe(III) in sample ($ng\ cm^{-3}$) | $G$ [b] (%) | Other method ($ng\ cm^{-3}$) |
|---|---|---|---|---|---|---|
| Tap | 2 | 0 | 9.44 | 47.20 | 3.1 | 50 [d] |
| Water [c] | 2 | 20.00 | 29.39 | 46.96 | 2.9 | |

[d] Value obtained by the AAS method.

of the sample was used for the recommended procedure. To examine the recovery of iron(III), known amounts of iron(III) were added to the samples.

The results are shown in Table 2. The recovery of added iron(III) is found to be quantitative and the reproducibility is satisfactory. Furthermore, the results obtained by the present method were compared with those obtained by the atomic absorption spectrophotometric method. The values for tap water samples are in good agreement with those obtained by the AAS method. From these results, the method seems to be applicable to the determination of soluble iron.

# Selective extraction and photometric determination of trace vanadium with cinnamohydroxamic acid in MIBK and its application to steel and rock ore analysis

A.K. Chakrabarti

*Department of Inorganic and Analytical Chemistry, Jadavpur University, Calcutta 700 032, India*

Received 18 October 1990; revised 15 February 1995; accepted 28 February 1995

**Abstract**

A sensitive and selective photometric method for the trace determination of vanadium with cinnamohydroxamic acid extracted from 1.8 M HCl in methyl isobutyl ketone is described. The wine-red chelate formed under an optimum acidity of 1.3–2.6 M HCl absorbs with a maximum at 525 nm. Beer's law is obeyed in the range 0–8 ppm of vanadium(V) and the optimum range of determination of vanadium is found to be 1–8 ppm. The molar absorptivity and Sandell's sensitivity are $6.0 \times 10^3$ l mol$^{-1}$ cm$^{-1}$ and 0.0086 μg cm$^{-2}$ of vanadium(V) at 525 nm. The photometric determination of trace amounts of vanadium in materials such as alloys, minerals and rock ores is also reported. The solvent extraction methods are simple, rapid and highly selective with fluoride used as a masking agent for Fe and Ti. The standard deviations are minimal and the mean error is only 0.015%.

## 1. Introduction

The recovery with determination and rapid assay of vanadium metal present as the vanadate in rock ores [1] are performed by wet analysis and by spectrometric methods for the prospecting of metals in geological samples and others.

Vanadium occurs at the part-per-billion level in many natural systems, alloys and geochemical minerals [2,3]. Preconcentration with selective solvent extraction has been followed by the trace analysis of vanadium in the presence of iron(III) and titanium(IV). For an assay of the metal, molecular spectrophotometry has always been rapid, simple and the preferred choice over atomic absorption spectrometry and fluorimetry. The reported use of hydroxamic acids led to the development of a unique microchemical technique and the present method for analysing specialised alloys and ores.

Cinnamo hydroxamic acid (N-CHA) reacts with vanadium(V) in both the pH and the acidity range of the media for extractions in methyl isobutyl ketone. The reagent has been studied on limited occasions [4,5]. Moreover, vanadium(V) chemistry [6] is important in extraction equilibria and has been thoroughly studied with organic acids as model compounds. Vanadyl species with a square-planar arrangement in the hydroxamate have been investigated thoroughly [7]. The mechanisms of the extractions are governed in most cases by ion pair formation, the chelate effect, synergism and mixed-ligand complex formation. The specification studies and the adverse effect of alcohol have little importance as regards the oxidation state, the nature of the solvent and extraction behaviour. The extraction method is found to be simple, rapid and sensitive, with high precision and reproducibility. Its usefulness is shown by its rapid extraction behaviour over a wide acidity range. The higher tolerance limits have indicated a major utility factor. These are some of the highlights of the method.

*SSDI* 0039-9140(95)01574-4

In this paper the synthesis of very pure cinnamohydroxamic reagent is reported following a modified procedure. The reagent (N-CHA) was synthesised and utilised in the development of a selective and sensitive photometric method for the trace analysis of vanadium. Its application to the analysis of samples demonstrated advantages over other methods reported earlier [8–10]. The analytical uses of the selective reagent, N-CHA, in binary extraction procedures for the assay of vanadium in steels, minerals and ores in the presence of rarer and other base metals are reported and are described here.

## 2. Experimental

### 2.1. Reagents

*Ammonium vanadate solution*

The metal solution was prepared by dissolving ammonium metavanadate ($NH_4VO_3$; Merck) in 3 ml of concentrated ammonia and double-distilled water and then making the volume up to 250 ml. The solution was standardised both by complexometric titration [11] and photometrically with *N*-benzoyl-*N*-phenylhydroxylamine [12]. Aliquots from a standard stock solution containing 100 μg $ml^{-1}$ were always used.

*Cinnamohydroxamic acid solutions (0.031 M)*

The pure reagent N-CHA, was prepared by a modified procedure reported in the literature [13]. The reagent was found to be pure, stable in air, and was stored in a brown bottle. The reagent readily dissolves in methyl isobutyl ketone (MIBK). A freshly prepared solution of 0.5% reagent in MIBK was used for the binary extractions.

A standard stock solution of 6 M hydrochloric acid was prepared and a 0.1 M acid solution was obtained by dilution. A standard buffer of pH 4.0 was prepared from 0.2 M acetic acid and 0.2 M sodium acetate. All other chemicals used were A.R. or G.R. grade and the solvents were purified before use.

### 2.2. Procedure

Mix an aliquot of standard vanadium solution (0–100 μg $ml^{-1}$) with 5 ml of 0.5% cinnamohydroxamic acid in a 100 ml separating funnel. To this mixture add 10 ml of pure MIBK as solvent, followed by 3 ml of 6 M hydrochloric acid, and dilute to give 10 ml of the aqueous phase. Shake the mixture for 5 min, separate the organic layer containing the wine-red complex and dry it over anhydrous sodium sulphate in a 25 ml beaker. Extract again with 5 ml of MIBK. Combine the extracts and transfer them to a 25 ml flask. Make up the volume to the mark with MIBK. Prepare a reagent blank similarly. However, a solvent blank alone was found to be satisfactory. Measure the absorbance at 525 nm against the solvent blank.

### 2.3. Procedure for steel analysis

Dissolve 0.5 g of steel in 20 ml of sulphuric acid (1:1) in a beaker on a hotplate. Add 5 ml of concentrated nitric acid and evaporate to strong fumes of sulphur trioxide. Cool, add 50 ml of water, boil, filter with a Whatman no. 42 paper and wash the residue several times with hot dilute sulphuric acid and finally with hot water. Cool the filtrate and washings, transfer to a 250 ml standard flask, make up to the mark and mix well.

To 5 ml of this solution add 0.1% potassium permanganate solution until a pink colour persists. Add this mixture to hot 15% sodium hydroxide solution in excess and boil. Filter off the precipitate and redissolve it in dilute hydrochloric acid. Reprecipitate the hydroxides as above and filter. Combine the filtrates and evaporate to a low bulk. Cool, add 15 mg of sodium fluoride, and determine the vanadium content by the described procedure (acidity, 1.8 M). Measure the absorbance at 525 nm as appropriate.

### 2.4. Procedure for rock (mineral) analysis

Fuse 0.5 g of the sample for 2 h with 3 g of sodium carbonate and 1 g of sodium hydroxide in a nickel crucible. Cool the melt, leach with hot water and allow to stand overnight. Filter the solution through Whatman no. 42 filter paper, transfer to a 100 ml volumetric flask and make up the volume with double-distilled water. Take an appropriate amount of the solution and determine the vanadium content by the above procedure using 15 mg of fluoride as masking agent.

### 2.5. Procedure for ore analysis

Fuse 0.5 g of the sample for 2 h with 3 g of sodium carbonate and 1 g of sodium hydroxide in a nickel crucible. Cool the melt, leach with hot water and allow to stand overnight. The aqueous extract contains vanadium along with iron and titanium. Filter the solution through a Whatman no. 42 filter paper, transfer to a 100 ml volummetric flask and make up the volume with double-distilled water. Take an appropriate amount of the solution and determine the vanadium content by the above procedure using 15 mg of fluoride as masking agent.

## 3. Results and discussion

### 3.1. Absorbance spectra

The reagent mainly extracts V(V) quantitatively from 1.8 M HCl. The wine-red complex absorption maximum is at 525 nm with the solvent as reference.

### 3.2. Effects of acidity, reagent, time and stability

The optimum acidity range for the binary extraction is 1.3–2.6 M HCl (i.e. 2.2–4.4 ml of 6 M HCl). The acidity of 1.8 M was always adjusted by adding 3 ml of 6 ml HCl. The absorbances of the wine-red complexes remained constant with the optimum reagent required being 2–8 ml of a 0.5% solution in MIBK. A 5 ml amount of 0.5% CHA was always added. The per cent extraction was maximum with a water:MIBK ratio of 10:10 (v/v). The extraction time for complete reaction was 4–7 min. The complex was found to be stable for 24 h at room temperature.

### 3.3. Beer's law, optimum range, absorptivity, and sensitivity

The complex obeyed Beer's law in the range 0–8 ppm and the optimum range [15] of determination is 1–8 ppm of V(V) at 525 nm. The molar absorptivity (TMA) determined by the method of Chakrabarti and Bag based on the free ligand [16] concentration is $7.6 \times 10^3$ l mol$^{-1}$ cm$^{-1}$. The molar absorptivity and Sandell's sensitivity values are $6.0 \times 10^3$ l mol$^{-1}$ cm$^{-1}$ and 0.0086 μg cm$^{-2}$ of V(V) respectively.

### 3.4. Tolerance limits for diverse ions

Interference studies were carried out with 4 ppm of vanadium in a 1.8 M acid system, the tolerance limit being the amount causing a deviation of more than 0.005 absorbance units.

A large number of diverse ions have been studied, A 60-fold excess of acetate, oxalate, Cu(II), Cr(III), Zr(IV); a 12-fold excess of Ti(IV) and W(VI); a 30-fold excess of Mo(VI) and Pd(II), and a 150-fold excess of Ca(II), Mn(II), Co(II), Al(III) and fluoride were tolerated. A very large excess of citrate, tartrate, EDTA, nitrate, sulphate, phosphate, Ni(II), Zn(II), Cd(II), Hg(II), Th(IV) and Pb(II) was tolerated, the tolerance ratio being 500-fold excess for metal ions and 1000-fold amounts for anions. Only Fe(III) interferes, but with fluoride as masking agent the tolerance limit increased to a 25-fold excess. The method is thus rendered highly selective. The tolerance limits are given in Table 1.

### 3.5. Binary extraction with N-CHA in MIBK over the acid pH range

A yellow-brown or yellow-orange complex formed at pH 3.8–4.4, adjusted with 0.1 M HCl and a pH 4.0 acetate buffer. Its absorption

Table 1
Tolerance limits for the determination of vanadium (4 ppm) with N-CHA in the presence of interfering ions

| Ions | Tolerance limit (ppm) | Ion | Tolerance limit (ppm) |
|---|---|---|---|
| Acetate | 250 | Pd(II) | 125 |
| Oxalate | 250 | Cr(III) | 240 |
| Tartrate | 1000 | Mn(II) | 600 |
| Citrate | 1500 | Th(IV) | 1000 |
| EDTA | 1500 | Co(II) | 600 |
| Phosphate | 8000 | Ni(II) | 1000 |
| Fluoride | 600 | Al(III) | 600 |
| Phosphate | 8000 | Ni(II) | 1000 |
| Fluoride | 600 | Al(III) | 600 |
| Sulphate | 8000 | Hg(II) | 2000 |
| Nitrate | 8000 | Cd(II) | 2000 |
| Fe(III) | N.I.[a] (100[b]) | Zn(II) | 1000 |
| Ti(IV) | N.I.[a] (50[b]) | Pb(II) | 1000 |

| W(VI) | 50 | Nb(V) | 40[b] |
| $UO_2$(II) | 400 | Ta(V) | 40[b] |
| Zr(IV) | 250 | Ba(II) | 600 |
| Ca(II) | 600 | Sr(II) | 600 |

[a] No interference; interferences were removed by double precipitation as the hydroxides using 15% NaOH.
[b] Fluoride used as masking agent.

maximum was at 430–460 nm. The chloro or acetate complexes were found to be unstable in the MIBK phase. Binary extractions of the wine-red chelate formed with 1.8 M HCl have been thoroughly investigated.

### 3.6. Stability of the reagent

With regard to the purity and stability of the reagent (N-CHA) in air it has been observed that its method of isolation as reported in the literature was found to result in an impure reagent with low yield. Moreover, it is unstable in the presence of light. Both these shortcomings were solved by making sure that the reagent was free from traces of ester. This additional step was considered and carefully controlled. thus, the yellow sodium salt of N-CHA was thoroughly washed with a petroleum ether three or four times to free it completely from ethyl cinnamate ester and other impurities. The reagent is generated in the pure form by acidification. The isolated solid (m.p. 100–111 °C) was stored in a brown bottle and was found to be stable for an indefinite period. Thus it is not available commercially and the reason is obvious.

### 3.7. Selectivity

The review in the monograph showed limited selectivity in the methods due to interferences normally by iron and titanium. A close association of V with Fe and Ti is very common for its matrices and analyte solutions. The tolerance ratio of V:Fe lies in between 1:10 and 1:50, and mostly this ratio is found to be 1:10 with or without the masking agents studied with such acid reagents. The adopted methods vary among those available to chemists, and the error is viewed differently [18,20]. The selectivity and tolerance limits with Fe and Ti are low and masking with fluoride greatly improved these effectively for a moderate excess of Fe and Ti. The major interferences of iron and titanium ores in a 25-fold excess have been removed by a double precipitation technique using 15% sodium hydroxide. The results were found to be accurate and reproducible, as reported for two of the ilmenite minerals and a bauxite ore.

### 3.8. Analysis of steel and rock ores

The ilmenite ores were processed before being used as the sample analytes and were passed through sieves for the bulk analyses. Their specifications were obtained. The method is highly reliable for all commercial low grade ores. Interfering ions were removed during the digestion with the reagents and the acids, and the filtration. The chief advantage is that the separations by extraction with recovery of vanadium from its ores are comparable for accurate and reproducible routine analyses. The method is simple and rapid. The results obtained after several runs were verified and compared with standard spectroscopic results or certified values. The results of the comparison give and reflect the method that is most rapid and has the highest accuracy. In conclusion, the aim of the work was to develop and devise an analytical technique that was obviously simple and rapid, for application as a routine assay in geochemical mining and prospecting of rocks [19].

Application of the technique to samples was tested using BAS 64b steel and two ilmenite samples collected from Putka Pahar, Madhya Pradesh (M.P.), India, and Tamil Nadu (Hornbendite rock), India, through the Geological Survey of India and IOL, Calcutta. The samples were finely ground (200 mesh) before direct analysis after separation. The methods were found to be excellent because of their high selectivity. The photometric procedures were found to be accurate, simple and highly reproducible when fluoride was used for masking more than a 25-fold ratio of Fe and Ti present in excess. The samples were analysed by a spectroscopic method [20] and the results agreed well. The results are shown in Table 2.

### 3.9. Nature of the complex

The primary aim was to investigate the choice of a solvent that would readily dissolve the N-CHA reagent and quantitatively distribute the metal as a red chelate in the organic phase in a single extraction. The solvent MIBK was found to be satisfactory for application over a wide acidity range of 1.3–2.6 M HCl for the extraction. A 1:2 complex, i.e. $VO(OH)(CHA)_2$ chelate, is formed in MIBK when extracted with 0.5% reagent. The composition of the complex was determined by Job's method and verified by the mole ratio method.

Table 2
Spectrometric determination of trace vanadium in steel, minerals and ores with cinnamohydroxamic acid reagent

| Sample | Vanadium in sample (%) | | Error (%) | Standard deviation |
|---|---|---|---|---|
| | Found | Certified | | |
| BAS Steel 64b | 1.977<br>1.975<br>1.976 | 1.99 | 0.014 | ±0.001 |
| Ilmenite I<br>Hornbendite rock | 0.089<br>0.085<br>0.091 | 0.1 | 0.012 | ±0.003 |
| Ilmenite II | 0.142<br>0.144<br>0.141 | 0.15 | 0.008 | ±0.002 |
| Bauxite (ore) | 0.223<br>0.225<br>0.221 | 0.2 | 0.023 | ±0.004 |

Stable V=O, V–O(H) and V–O(LH) bonds are formed with the highly stable closed five-membered ring ether structure. This has been established by elemental analysis and spectroscopic studies of such complexes. The configuration is similar to that of the vanadium complexes with other hydroxamic acid compounds reported previously [4,17]. The ligands do not simply coordinate but a molecule with tautomeric forms –C(O)–NH(OH) ⇌ –C(OH)=N(OH) enhances the phase transfer processes with enhancement of polarisation and rapid recovery via membrane transport. This has led to a selective extraction even in the presence of large amounts of other metal ions. Al:1(aqueous:organic) volume ratio leads to maximum sensitivity and high selectivity. Traces of alcohol are to be avoided because they cause a detrimental effect.

Complex formula: $VO(OH)(CHA)_2$
Tautomeric forms:
–C(O)–NH(OH) ⇌ –C(OH)=N(OH)

# FIA-AAS determination of salicylic acid by a solid-phase reactor of copper carbonate incorporated in polyester resin beads

G.A. Rivas [1], J. Martínez Calatayud *

*Department de Química Analitica, Universitat de València., Moliner 50, Burjasot València, Spain*

Received 19 September 1994; revised 4 January 1995; accepted 28 February 1995

**Abstract**

The determination of salicylic acid was carried out by reaction of the drug with copper carbonate entrapped in a polymeric material in a solid-phase reactor; the released cupric ions were monitored by flame atomic absorption at 324.8 nm. The calibration graph is linear over the range 4.0–75 μg $ml^{-1}$ of salicylic acid, with a relative standard deviation of less than 1.5% and a sample throughput of 257 $h^{-1}$. The influence of foreign compounds was studied and the method was applied to the determination of salicylic acid content in two different pharmaceutical formulations.

*Keywords:* Flow injection analysis; Pharmaceutical analysis; Solid-phase reactor

## 1. Introduction

Salicylic acid is 2-hydroxybenzoic acid, and occurs as white or colourless aciculate crystals or a white crystalline powder. It is slightly soluble in water, freely soluble in ethanol and in ether, and sparingly soluble in chloroform. Salicylic acid has keratolytic properties and is applied topically in the treatment of hyperkeratotic and scaling skin conditions; it is often used in conjunction with many other agents. Salicylic acid also possesses fungicidal properties and is used in the treatment of skin fungal infections [1].

The analysis of the drug (official procedures) is established by titration in an ethanol–aqueous medium with sodium hydroxide, using phenol red as an indicator [2]. Different spectrophotometric procedures have been published for the determination of salicylic acid on the basis of the complex formed with Fe(III) [3] or Cu(II) [4]. The yellowish-green species with copper is stable in the pH range 5.5–6, and presents its maximum absorbance at 730 nm with a molar absorptivity of 20 l $mol^{-1}$ $cm^{-1}$. An FIA-electrochemical procedure [5] came to the notice of the authors when the work reported here had already been concluded; the method makes use of the enzyme salicylate hydroxylase immobilized on a solid-phase reactor, which should be sorted in buffer at 4 °C. The enzyme catalyses the conversion of salicylic acid to catechol, which can then be detected amperometrically.

The use of solid-phase reactors in continuous-flow manifolds is an advantageous alternative to reagents in solution. The interest is ascribed to different advantages offered over homogeneous systems, which have been discussed earlier [6]. The present paper deals with a solid-phase reactor placed in a flow manifold;

the immobilization is based on the physical entrapment of the reagent, copper carbonate [7], by means of the polymerization reaction of linear unsaturated polyester chains. The analytical procedure is based on the reaction of the injected sample with the immobilized copper carbonate and monitoring of the release of copper (complexed by salicylic acid) by an atomic absorption spectrometer.

## 2. Experimental

### 2.1. Reagents

Aqueous solutions of salicylic acid (Guinama, a.r.) were in distilled water. Urea, thymol, boric acid, benzocaine, resorcinol, procaine hydrochloride, lactic acid, glucose, sucrose and fructose (Guinama, a.r.) were used. All other reagents were of analytical grade unless stated otherwise.

### 2.2. FIA manifold

Fig. 1 shows the continuous-flow manifolds used. The sample injector was from Rheodyne, model 5041, and a Gilson Minipuls 2 pump was used. The determination of copper was carried out by means of an AA spectrometer from Varian, Model SpectrAA-10, at a wavelength of 324.8 nm. The PTFE tubing was of 1.2 mm internal diameter for the solid-phase bed reactor and 0.8 mm for the rest of the manifold.

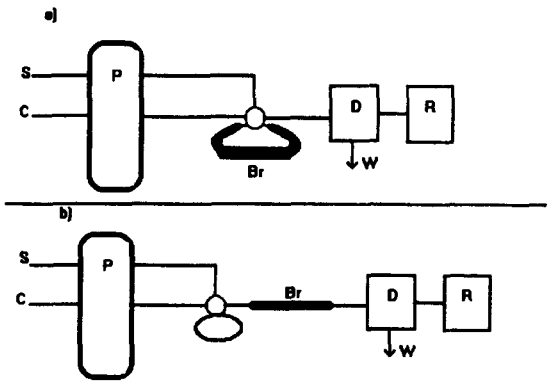

Fig. 1. Flow manifolds tested in preliminary experiments for the determination of salicylic acid. (Manifold (b) was selected for the optimization studies): P, pump; D, atomic absorption detector; R, recorder; Br, bed-reactor; S, sample solution; C, carrier stream; W, waste.

### 2.3. Procedures

*Preparation of the solid-phase reactor*

The bed-reactor was prepared as described previously [8]. A 45 g mass of $Cu(CO_3)$ $Cu(OH)_2 \cdot 10H_2O$ (Panreac) was added to 15 g of the resin solution AL-100 A (from Reposa); after homogenization by manual stirring, 1 ml of the catalyst (ethyl methyl ketone, from Azko) was added and stirred before it became solid. The obtained solid was reduced to small particles, washed with distilled water and dried at 80 °C. The particles selected by size, 90–200 μm, were washed and introduced into the PTFE tubing (1.2 mm internal diameter and 5.0 cm length) by suction. Specific conditions for storage were not required.

*Pharmaceutical formulations*

The proposed procedure was applied to two formulations: Callicida Gras and Pyralvex. The solution of Pyralvex (0.80 ml) was directly diluted in pure distilled water, filtered and levelled to 500 ml with distilled water; aliquots of the resulting solution were then injected into the carrier stream. The solution of Callicida Grass was weighed (about 2 g), dissolved in ethanol by ultrasonic stirring and levelled to 100 ml with ethanol. 1 ml of the resulting solution was diluted to 500 ml with pure distilled water and then injected as usual into the FIA manifold.

## 3. Results and discussion

### 3.1. Preliminary studies

Preliminary studies were designed to examine the reaction between the immobilized copper carbonate and the salicylic acid in a continuous-flow manifold. These experiments were carried out by means of a flow assembly in which the solution of salicylic acid in distilled water merged with different acidic or basic aqueous solutions; the resulting mixture was then passed through the solid-phase reactor and, after reaction, the released copper was measured by atomic absorption. The obtained transient signals (absorbance units) were contained as the mean value of 10 replicates at wavelength 324.8 nm and 0.5 nm slit window; the results obtained for different media and pH values (potentiometrically measured) are depicted in Table 1.

An increase in base-line noise was clearly observed when the sample solution merged

Table 1

| Medium | pH | Absorbance |
|---|---|---|
| $Na_2CO_3/NaHCO_3$ | 9.80 | 0.967 |
| $Na_2CO_3/NaHCO_3$ | 9.12 | 0.983 |
| $NaHCO_3$ | 8.33 | 0.853 |
| NaOH/HCl | 7.04 | 0.984 |
| Deionized water | | 1.081 |
| $CH_3$-COOH/NaOOC-$CH_3$ | 6.30 | 1.041 |
| $CH_3$-COOH/NaOOC-$CH_3$ | 6.10 | 0.856 |
| $CH_3$-COOH/NaOOC-$CH_3$ | 6.00 | 0.128 |
| HCl | 5.40 | 0.883 |
| HCl | 4.40 | 0.816 |

with acidic solutions (mainly with hydrochloric or acetic acid concentrated solutions), owing to the copper released by the acidic solvent. The presence of organic solvents like ethanol did not result in increased outputs. The highest peak-height was observed for acetic/acetate buffered solutions, which was slightly higher than that obtained with distilled water, i.e. 1.041 vs. 1.081 (absorbance units). As the difference is small, distilled water was the selected carrier for further work.

Further tests were devoted to the study of the suitable flow-injection assembly; the two assemblies depicted in Figs. 1(a) and 1(b) were pre-selected after some experiments. Different sets of injections (varying the flow-rates of carrier and sample solutions) were carried out to compare the behaviour of both manifolds. Transient outputs from the assembly in which the solid-phase reactor was nesting in the sample loop (Fig. 1(a)) were about 5% higher (peak-height) than those corresponding to the assembly with the reactor between the injector and detector (Fig. 1(b)). However, bearing in mind the life-span of the reactor (the former is continuously exposed to an acidic stream, pH of the sample solution 3.0) the assembly depicted in Fig. 1(b) was selected for further work.

Having selected the FIA manifold, the experimental parameters, temperature, "concentration" of the reagent (copper carbonate) in the polymeric matrix, reactor length, particle size, internal diameter of the reactor, sample volume and carrier flow-rate, were successively optimized by means of the univariate method. The injected sample solutions (salicylic acid in distilled water) contained 10, 40 or 100 μg $ml^{-1}$ of salicylic acid, respectively.

The tested range for each studied parameter and the optimum selected values are depicted in Table 2. A study on the influence of the temperature was carried out by introducing into a water bath: (a) the solution containers; (b) the solid-phase reactor; and (c) the whole assembly. The tested range was room temperature to 80 °C. The obtained results in series (b) revealed an increase of peak-height with temperature; the maximum increase, about 20% in the peak-height (compared with the peak-height at room temperature), was obtained at 60 °C. Higher values of the temperature then resulted in lower outputs. In contrast, the highest temperatures tested induced the release of cupric ions from the solid-phase reactor by passing the carrier, which meant a shorter life-span of the reactor. From these observations, it was decided that the slight gain in peak-height was not valuable, and room temperature was selected for further work.

The "concentration" of the reagent (mass of copper carbonate vs. mass of resin) in the solid-phase reactor showed a critical influence; the ratio (g/g) copper carbonate/resin solution was studied over the range 1/1–3/1; higher ratios were not tested as they resulted in solid particles without mechanical resistance. The ratio 3/1 was selected as giving the best output.

The influence of the reactor parameters, such as length, internal diameter and particle size, on the transient outputs was very important. The length was tested by injecting series of salicylic acid solutions of different concentrations, from 10 to 500 μg $ml^{-1}$. Fig. 2 depicts the calculated sensitivity (linear slope) of each tested reactor-length. A length of 5 cm was selected as resulting in the best output. This strategy of testing a series of salicylic acid concentrations was also used for studying the influence of the particle size and internal diameter of the reactor. The influence of the particle size was tested by preparing calibration

Table 2
Optimization of experimental parameters (for details set text)

| Parameter | Tested range | Selected value |
|---|---|---|
| Temperature (°C) | room–80 | room |
| Ratio copper carb./resin (g/g) | 1/1–3/1 | 3/1 |
| Reactor length (cm) | 5.0–30.0 | 5.0 |
| Particle size (μm) | 90–300 | 90–200 |
| Internal diameter reactor (mm) | 0.8–1.5 | 1.2 |
| Sample volume (μl) | 100.0–500.0 | 195.2 |
| Carrier flow-rate (ml $min^{-1}$) | 2.0–6.0 | 5.2 |

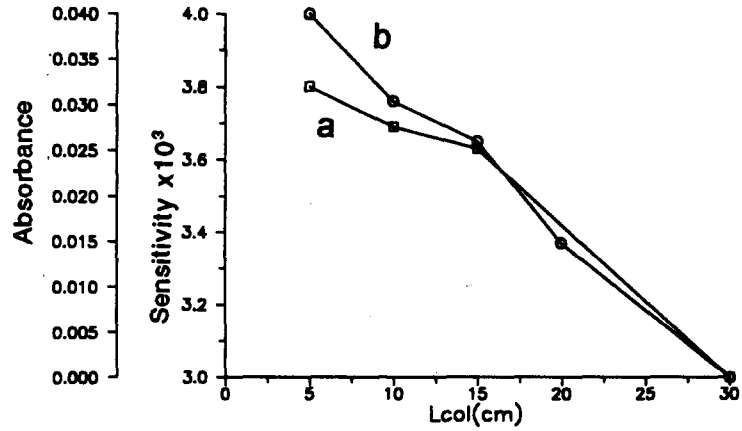

Fig. 2. Influence of the reactor-length on the peak-height. Right axis depicts the absorbance of injected solutions containing 10 μg ml$^{-1}$ of salicylic acid. Left axis depicts the sensitivity (slope of the linear graph) of the series of salicylic concentrations for each tested column length. Curve a, FIA outputs in absorbance units, obtained with salicylic concentration of 10.0 μg ml$^{-1}$. Curve b, slope of linear graphs.

graphs with each tested size; the obtained results showed that the best outputs for two different sizes, 200–300 μm and 90–200 μm, calculated from linear slopes (absorbance vs. concentration of salicylic acid in μg ml$^{-1}$) were 2.99 and 2.90 ($\times 10^{-3}$), respectively. The study of the internal diameter (tested in the range 0.8–1.5 mm internal diameter) revealed slightly better results with the thinner tube, but owing to the ease of the column preparation the 1.2 mm tube was selected.

The sample volume is also a critical parameter influencing peak-height and base-width. Fig. 3 depicts the absorbance of the peak vs. the sample volume; bearing in mind the best compromise of sensitivity/sample throughput, the selected value was 195 μl. The influence of the carrier flow-rate, tested for three different concentrations of acid salicylic, is depicted in Fig. 4, 5.2 ml min$^{-1}$ being the value selected as the optimum that could be obtained. The results of the optimization are depicted in Table 3.

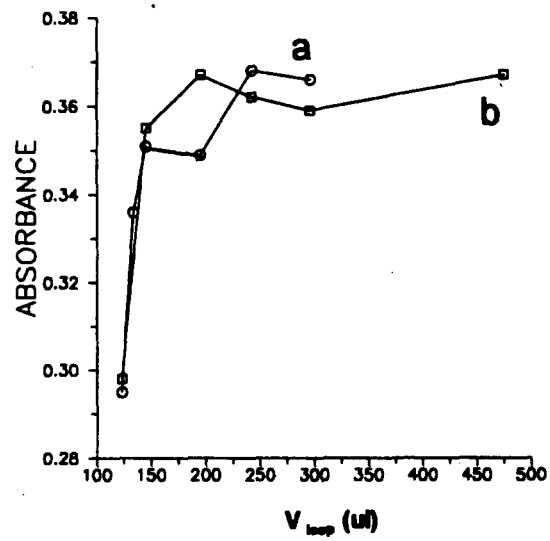

Fig. 3. Influence on the peak-height of the sample volume for two different solid-phase reactors. Reactor length: a, 10 cm; b, 5 cm.

## 4. Analytical application

The calibration graph shows linear behaviour over the range 4.0–75 μg ml$^{-1}$ of salicylic acid, with the equation Abs. $= 2.1 \times 10^{-3} + 3.8 \times 10^{-3}C$ ($C$ is the concentration of salicylic acid in μg ml$^{-1}$) and correlation coefficient 0.9991. The repeatabilities calculated as RSD (%) (salicylic acid concentration in μ ml$^{-1}$, number of replicates, mean absorbance, and RSD) were: 50.0, 16, 0.191, 1.5; 40, 6, 0.155; 0.0; 10, 13, 0.042, 0.0. The sample throughput, according to different studied concentrations of the sample, varied from 220 (40 μg ml$^{-1}$ of salicylic acid) to 257 (5 μg ml$^{-1}$) h$^{-1}$.

The day-to-day reproducibility was studied by preparing calibration graphs with independent solutions and using three different columns on different days (up to 21). The obtained results (column, day, linear slope of the calibration graph $\times 10^{-3}$ and correlation coefficient) are depicted in Table 3.

The influence of foreign compounds that are commonly found in pharmaceutical formulations containing salicylic acid was also investigated. The results in terms of concentration

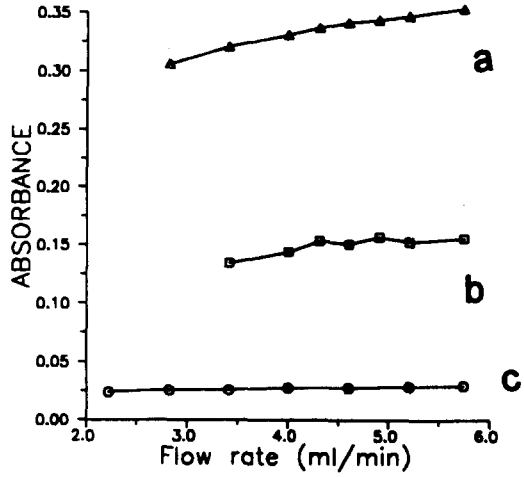

Fig. 4. Influence on the peak height of the carrier flow-rate for three different concentrations of salicylic acid ($\mu g\ ml^{-1}$): a, 100.0; b, 40.0; c, 10.0.

Table 3
Day-to-day reproducibility of the analysis using the solid-phase reactor

| Column | Day | Slope | Corr. coeff. |
|---|---|---|---|
| 1 | 1 | 3.80 | 0.9991 |
| 1 | 2 | 3.73 | 0.9990 |
| 1 | 8 | 3.82 | 0.9981 |
| 1 | 9 | 3.68 | 0.9941 |
| 2 | 1 | 3.89 | 0.9981 |
| 2 | 2 | 3.56 | 0.9978 |

| 3 | 13 | 3.17 | 0.9972 |

($\mu g\ l^{-1}$) and relative error (%) are depicted in Table 4. Procaine chlorhydrate, pilocarpine, methyl nicotinate, and the acetic, benzoic and lactic acids resulted in very serious interferences.

Salicylic acid was determined in two different pharmaceutical formulations: (a) Pyralvex (from Instituto Berna de España S.A.); declarated contents of anthraquinonic glucosides, 0.05 g $ml^{-1}$, and salicylic acid, 0.01 g $ml^{-1}$; (b) Callicida Grass (from Quimifar S.A.); declarated contents of salicylic acid, 250 mg $g^{-1}$, and ethanol, 365 mg $g^{-1}$. The relative errors (%) in the obtained results, according to the label claim, were: Pyralvex, 0.8%; Callicida Gras, 3.6%.

Table 4
Influence of foreign compounds on salicylic determination

| Compound | Conc. ($\mu g\ ml^{-1}$) | Rel. error (%) |
|---|---|---|
| Sorbitol | 1742 | 0.6 |
| Fructose | 2500 | 1.7 |
| Sucrose | 2500 | 0.9 |
| Glucose | 2500 | 5.0 |
| Nicotinamide | 412 | 4.4 |

| Thymol | 526 | 0.0 |
| Urea | 584 | 1.7 |

Salicylic acid concentration, 50 $\mu g\ ml^{-1}$; except for compounds marked with *, when it was 25 $\mu g\ ml^{-1}$.

## 5. Conclusions

An FIA-AAS procedure is proposed for the determination of salicylic acid by means of a solid-phase reactor of copper carbonate incorporated in polyester resin beads. The reactor is prepared from an easily available reagent by a quick and easy procedure, and the analytical properties of the resulting solid remain unchanged for more than two years. No special conditions are required.

The resulting manifold is suitable for the determination of salicylic acid in pharmaceutical formulations with competitive precision and high sample throughput.

# Extraction and spectrophotometric determination of lead(II) with pyridine-2-acetaldehyde salicyloylhydrazone

Muralidhar N. Bale, D.P. Dave, A.D. Sawant *

*Inorganic Chemistry Division, Institute of Science, 15, Madam Cama Road, Bombay 400032, India*

Received 15 July 1994; revised 24 February 1995; accepted 3 March 1995

**Abstract**

Lead(II) reacts with pyridine-2-acetaldehyde salicyloylhydrazone (PASH) in the pH range 8.6–9.3 to form a yellow-green, 1:2 chelate which can be extracted into chloroform. Beer's law is obeyed in the concentration range 1.5–6.2 $\mu g\,ml^{-1}$ of lead(II). The molar absorptivity of the extracted species is $1.93 \times 10^4$ $l\,mol^{-1}\,cm^{-1}$ at 380 nm. The proposed method is sensitive, simple, rapid, accurate and has been satisfactorily applied for the determination of lead in synthetic mixtures, alloys, water and soil samples.

## 1. Introduction

Lead is a transition metal and has significance in many industrial applications [1]. In spite of its various applications, lead is a very toxic and harmful element [2]. Hence it is very important to estimate lead at the trace level in different samples. Various reagents for the extractive spectrophotometric determination of lead, such as 8-hydroxy-7-[α-(2-methoxycarbonylanilino)-benzyl]quinoline [3], thio-2-thenoyltrifluoroacetone [4], *N*-(4-chlorophenyl)benzohydroxamic acid [5], 2-(salicylideneamino)benzenethiol [6], morphine-4-carbodithioate [7], *N,N'*-bis(2-hydroxy-5-nitrobenzyl)cryptand-22 [8], cyclohexane-1,3-dione-bis-(4-methylthiosemicarbazone) [9], monothiothenoyltrifluoroacetone [10], sodium *N,N*-diethyl-dithiocarbamate [11] and dithizone [12] have been reported. However these methods suffer from some limitations such as strict temperature control [6], long extraction times [4,6,8–10] and interference from some ions [3,4,6–10,12], etc. A method, superior in sensitivity to those reported in the literature [3,5,7,11], is developed for the extraction and spectrophotometric determination of lead(II) with pyridine-2-acetaldehyde salicyloylhydrazone (PASH). The method is rapid, simple and accurate. Earlier PASH was employed for the extractive spectrophotometric determination of vanadium(V) [13], iron(III) [14], nickel(II) [15], palladium(III) [16], copper(II) and ruthenium (III) [17]. PASH reacts with lead(II) to give a yellow-green coloured complex extractable in chloroform. The method is free from many limitations.

## 2. Experimental

### 2.1. Apparatus

A Bausch and Lomb Spectronic-20 spectrophotometer with glass cells, a ditigal ELICO pH meter (model LI-120) with a combined glass electrode and a Carl Zeiss Jena (DDR) atomic absorption spectrometer were used.

* Corresponding author.

*SSDI* 0039-9140(95)01578-7

### 2.2. Reagents

All chemicals used were of analytical grade unless otherwise stated. Double-distilled water was used.

*PASH*

The ligand was synthesised by the reaction of pyridine-2-acetaldehyde (Fluka) and salicyloylhydrazide (Aldrich) as reported in the literature [13]. A stock solution (10 mg $ml^{-1}$) of PASH was prepared by dissolving it in DMF. The appropriate volume was diluted to 100 ml with chloroform to give a 0.05% reagent solution of PASH.

*Lead(II) solution*

Lead nitrate (3.99 g) was dissolved in 3 ml of concentrated nitric acid, and the solution was diluted to 250 ml with double-distilled water and standardised by a known method [18].

*Lithium chloride (4M)*

Lithium chloride (17 g) was dissolved in 100 ml of distilled water.

*Buffer solution (pH 9.0)*

The pH of the aqueous (1:1) $NH_3$ solution was adjusted to the required pH with 4 N HCl using a pH meter.

### 2.3. Recommended procedure

To an aliquot of solution containing 15–62 μg of lead (II) in a separating funnel add 2 ml of 4 M lithium chloride solution and 2 ml of pH 9.0 buffer. Dilute the mixture to 10 ml with distilled water and equilibrate with 10 ml of a 0.05% reagent solution of PASH in chloroform for 1 min. Separate the two layers and measure the absorbance of the organic phase containing the complex at 380 nm against a reagent blank.

## 3. Results and discussion

### 3.1. Absorption spectra

The absorption spectra of PASH and the lead(II)–PASH complex are shown in Fig. 1. The absorption maximum of the ligand is at 345 nm and that of the complex is at 380 nm.

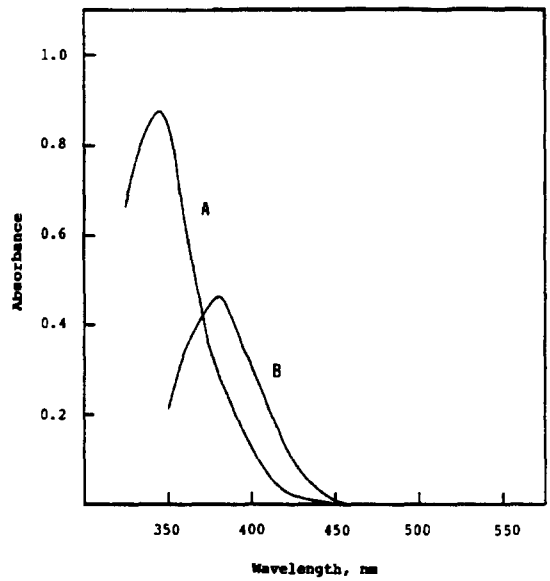

Fig. 1. Absorption spectra of PASH and its lead(II) complex extracted into chloroform. ([PB(II)] = 5 μg $ml^{-1}$; pH 9.0; [LiCl] = 0.8 M; [PASH] = 0.05%.) Spectrum A, PASH vs. chloroform; spectrum B, Pb(II)PASH complex vs. reagent blank.

### 3.2. Extraction conditions

Lead(II) was extracted over the pH range 2–11 from lithium chloride solution in the range 0.1–1.4 M with varying (0.005–0.060%) concentrations of PASH. The extraction coefficients were determined by atomic absorption spectrometry. At pH 8.6–9.3 the extraction reached a maximum, and lead(II)

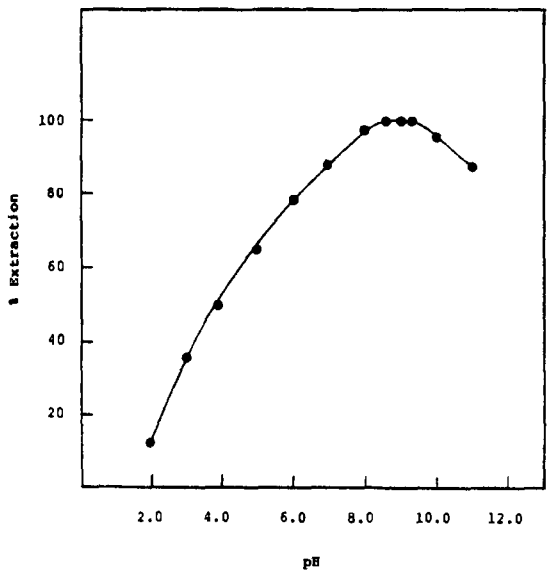

Fig. 2. The effect of pH on the extraction of lead(II) with PASH.

was quantitatively extracted as shown in Fig. 2. Therefore all extractions were performed at pH 9.0. The optimal concentrations of lithium chloride and PASH were found to be 0.8 M and 0.05%, respectively, for the extraction of lead(II). The equilibration time for the extraction of lead(II) was varied from 10–180 s, the minimum time required for the extraction of lead(II) was 60 s. A longer extraction time has no adverse effect. The lead(II) complex was stable for 40 h.

### 3.3. Effect of solvents

The effect of various solvents such as chloroform, benzene, xylene, toluene, carbon tetrachloride, methyl isobutyl ketone, amyl acetate and ethyl acetate on the extraction of lead(II) with PASH was studied and it was found that the extraction of lead(II) was quantitative with chloroform. The reagent solution of PASH (0.05%) in other solvents gave only 35–93% extraction of lead(II).

### 3.4. Beer's law and sensitivity

The absorbance is a linear function of lead(II) concentration in the range 1.5–6.2 μg $ml^{-1}$ of solution. The molar absorptivity is $1.93 \times 10^4$ 1 $mol^{-1}$ $cm^{-1}$ and the Sandell sensitivity is 0.0107 μg $cm^{-2}$.

### 3.5. Composition of the extracted species

The composition of the complex was determined by plotting of log $D$ against log $[PASH]_{org}$ at fixed pH, where $D$ denotes the distribution ratio of lead(II) between the two phases and $[PASH]_{org}$ is the equilibration concentration of PASH in the organic phase. As shown in Fig. 3, a straight line with a slope equal to about 2 shows that the metal-to-ligand ratio is 1:2.

### 3.6. Effect of foreign ions

The effect of various foreign ions on the extraction and determination of lead(II) was studied, and tolerance limits are shown in Table 1. The tolerance limit of the foreign ion was taken as the amount required to cause an error of not more than ±2% in the lead(II) recovery.

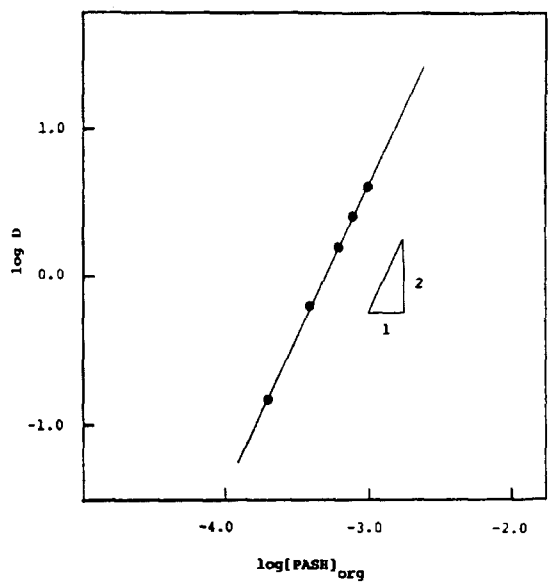

Fig. 3. Logarithmic plot of the distribution of lead(II) vs. concentration of PASH. ([Pb(II)] = 5 μg $ml^{-1}$; pH. 9.0; [LiCl] = 0.8 M; absorbance measurement at 380 nm.)

### 3.7. Application to the determination of lead in synthetic mixtures

The present method was applied to the determination of lead (30 μg) in various synthetic mixtures containing copper, nickel, zinc, iron, bismuth, tin, arsenic, antimony and manganese. The results are shown in Table 2.

### *3.7. Application to determination of lead in water samples*

Water samples were collected from a water tank at Kotwali and samples of industrial waste water from Nocil were also used. The samples were filtered and acidified with nitric acid. To 1–2 ml of the samples in a separating funnel were added 2 ml each of 4 M lithium chloride and pH 9.0 buffer. This mixture was diluted to 10 ml and extracted with 10 ml of a 0.05% reagent solution of PASH. After the separation of the two layers, the absorbance of the organic phase was measured at 380 nm against a reagent blank. The concentration of lead was determined from the standard curve. The results shown in Table 3 are in good agreement with each other and with those obtained by atomic absorption spectrometry.

### *3.8. Application to the analysis of soils*

The soil samples were collected from the area of a lead smelter.

*Sample dissolution*

To a 1 g soil sample in a beaker, 15 ml of aqua regia and 2 ml of perchloric acid were added and heated nearly to dryness. The process was repeated until a white residue was formed. The residue was dissolved in 30 ml of 5 N HCl and filtered through a Whatman no. 42 filter paper. The undissolved material was washed with 30 ml of distilled water and the volume of the filtrate was made up to 100 ml with distilled water. An aliquot of this solution was used for the determination of lead.

Table 4
Analysis of alloys

[b] 60 μg amount of Pb was taken.

*Determination of lead*

To 1 ml of the above solution in a separating funnel, 2 ml each of 4 M lithium chloride and pH 9.0 buffer were added. Iron(III) was masked with 3 ml of 2 M sodium citrate. The volume of the mixture was made up to 10 ml and extracted with 10 ml of a 0.05% reagent solution of PASH for 1 min. After the separation of two layers, the absorbance of the organic phase was measured at 380 nm against a reagent blank. The concentration of lead was determined from the standard curve. The results shown in Table 3 are in good agreement with each other and with those obtained by atomic absorption spectrometer.

### 3.9. Application to analysis of alloys

The proposed method was applied to the determination of lead in solder, brass, leaded gun metal and tin base white metal.

*Dissolution of solder, brass and leaded gun metal*

Alloy (0.01–0.1 g) was dissolved [19] in 5 ml of concentrated nitric acid. The solution was evaporated to dryness to remove excess of acid. The residue was dissolved in 5 M nitric acid, any metastannic acid was filtered off, and the filtrate was washed with hot dilute nitric acid and finally with 10 ml of hot water. The filtrate was diluted to 100 ml with distilled water.

*Dissolution of tin base white metal*

Alloy (0.1 g) was dissolved in 5 ml of 47% hydrobromic acid [19]. The solution was evaporated to dryness, cooled and 3 ml of 25% (v/v) sulphuric acid was added. Again, the mixture was evaporated nearly to dryness. Finally the white mass was dissolved in 4 ml of concentrated hydrochloric acid and diluted to 100 ml with distilled water.

*Determination of lead*

A 1 ml portion of the above prepared solution was taken in a separating funnel, and 2 ml each of 4 M lithium chloride and pH 9.0 buffer were added. To this mixture, 2 ml of a saturated solution of ammonium thiocyanate and sodium tartrate were added to mask the interfering ions. This mixture was diluted to 10 ml and extracted with 10 ml of a 0.05% reagent solution of PASH for 1 min. The two layers were separated and the absorbance of the organic phase was measured at 380 nm against a reagent blank. The concentration of lead was determined from the standard curve. The results are shown in Table 4.

**Abstract**

Two enzyme reactors prepared by the co-immobilization of two different glucose-6-phosphate dehydrogenases (G6PDH; from *Leuconostoc mescenteroides* (LM) and yeast (Y) and diaphorase are employed to enhance the sensitivity of NAD(P) coenzymes as on-line amplifiers based on substrate recycling in a chemiluminometric flow-injection system. The NAD(P) coenzymes are recycled enzymatically during passage through the reactor in the presence of sufficient glucose-6-phosphate and oxygen in the carrier solution to produce a large amount of hydrogen peroxide, which is detected chemiluminometrically in the subsequent flow line. The G6PDH(LM)/diaphorase co-immobilized reactor is not specific between the NAD and NADP coenzymes, but shows a six fold selectivity towards NADP coenzymes compared to NAD coenzymes; the amplification factors for NAD and NADP coenzymes are 60 and 380, respectively, at a flow rate of 0.3 ml $min^{-1}$. In contrast, the G6PDH(Y)/diaphorase co-immobilized reactor is specific for NADP coenzymes with an amplification factor of about 600 (at a flow rate of 0.3 ml $min^{-1}$). The detection limit is 6 fmol for both $NADP^+$ and NADPH.

*Keywords:* Chemiluminometric flow-injection; Co-immobilization; NADP coenzymes; Substrate recycling

## 1. Introduction

Enzymatic amplification based on substrate recycling is an interesting approach for enhancing sensitivity. The analyte is recycled by choosing a combination of coupled enzymes such that the product of the first enzyme is the substrate of the second. Such an amplification has been accomplished by incorporating a small reactor packed with co-immobilized coupled enzymes into an appropriate flow-injection analysis (FIA) system [1,2]. Considerable amplification has been achieved even with a short residence time of the sample zone in the enzyme reactor. The sensitivities of an on-line detection of L-lactate/pyruvate [3–6], L-glutamate [7], phosphate [8], purine nucleotides [9], adenosine-5′-triphosphate [10] and NAD coenzymes [11–13] have been increased by using the enzyme reactor and substrate recycling.

We are particularly interested in the on-line amplification of nicotinamide coenzymes which are physiologically important coenzymes. Previously [11], we proposed the usefulness of an amperometric FIA system with a glucose-6-phosphate dehydrogenase/lactate dehydro-

genase/lactate oxidase co-immobilized reactor for the selective amplification of NAD coenzymes ($NAD^+$: oxi-dized form; NADH: reduced form) compared to NADP coenzymes ($NADP^+$: oxidized form; NADPH: reduced form). Kronkvist et al. [13] described the use of a glycerol dehydrogenase/diaphorase co-immobilized reactor for a similar purpose. However, an enzyme-amplified reactor that functions specifically for NADP coenzymes has not been developed as yet.

This paper describes a chemiluminometric FIA system with a glucose-6-phosphate dehydrogenase (G6PDH)/diaphorase co-immobilized reactor which permitted the selective detection with signal amplification of NADP coenzymes, due to differences in the substrate specifically between two varieties of the enzyme reactor prepared from different commercially available G6PDHs and diaphorase from *Clostridium kluyveri*. Diaphorase from *Clostridium kluyveri* catalyses the oxidation of NADPH to $NADP^+$ to produce hydrogen peroxide, consuming oxygen without a mediator such as hexacyanoferrate(III) [13].

## 2. Experimental

### 2.1. Materials

Distilled water purified with use of a Millipore Milli-Q system (Nippon Millipore Ltd., Tokyo) was used throughout. G6PDH (EC.1.1.1.49; 689 U $mg^{-1}$ from *Leuconostoc mescenteroides* and 468 U $mg^{-1}$ from yeast), diaphorase (EC.1.6.99; 399 U $mg^{-1}$, from *Clostridium kluyveri*), glucose-6-phosphate (G6P), $NAD^+$, NADH, $NADP^+$ and NADPH were purchased from Oriental Yeast (Tokyo) and flavin adenine dinucleotide, disodium salt (FAD), luminol (biochemical grade), potassium hexacyanoferrate(III) and glutaraldehyde were from Wako (Osaka). All other chemicals were of analytical reagent grade and were used as received. Controlled-pore glass (aminopropyl CPG; mean pore size, 527 Å; particle size, 120–200 mesh) was obtained from CPG Inc. (Fairfield, NJ) and was used as a support material for enzyme immobilization. For the determination of chemiluminescence (CL), 7 mM luminol and 200 mM potassium hexacyanoferrate(III) stock solutions were prepared according to a procedure described in the literature [14]. The carbonate buffers were prepared from sodium hydrogen carbonate.

### 2.2. Preparation of immobilized enzyme reactors

Aminopropyl CPG was packed into three glass columns (18 mm × 3 mm i.d.) furnished with small nylon nets (300 mesh) at each end. They were activated by circulating glutaraldehyde solution into the glass beads as previously described [15]. After washing with 0.1 M sodium carbonate buffer (pH 8.0), diaphorase (260 U) was loaded onto the column by circulating enzyme/sodium carbonate buffer solution (0.1 M; pH 8.0) through the column at 1.0 ml $min^{-1}$ for 2 h at room temperature. G6PDH from *Leuconostoc mescenteroides* (G6PDH(LM); 620 U) and diaphorase (260 U) were also co-loaded onto another column, and G6PDH from yeast (G6PDH(Y); 420 U) and diaphorase (260 U) were loaded onto the other column according to the same procedure. The weight ratio of coupled enzymes in the enzyme solution used for the preparation of the latter two reactors was 3:2 (G6PDH:diaphorase). This ratio was suitable for the substrate recycling experiments. When not in use, all the enzyme reactors were stored in 0.1 M sodium carbonate buffer (pH 7.5) in a refrigerator at 4 °C to minimize microbiological degeneration.

### 2.3. Apparatus and procedures

The FIA manifold used is outlined in Fig. 1. The reciprocating pump used was a multichannel Sanuki Kogyo (Tokyo) 4P3U model. A microsyringe was used to introduce the sample solution (20 µl) into an injector (Rheodyne model 7125) with a 100 µl loop, in the carrier stream (0.1 M sodium carbonate buffer, pH 8.0, containing 20 µM FAD and 1 mM G6P) pumped at a flow rate of 0.3 ml $min^{-1}$. The

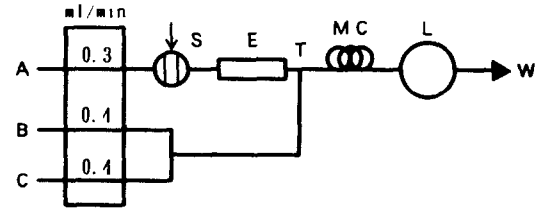

Fig. 1. Otimized chemiluminometric FIA manifold for the determination of NAD(P) coenzymes: A, carrier solution (0.1 M sodium carbonate buffer, pH 8.0); B, luminol solution (0.05 mM); C, potassium hexacyanoferrate(III) solution (50 mM); S, injector (20 µl); E, enzyme reactor; T, T-connector; MC, mixing coil (PTFE, 20 cm × 0.5 mm i.d.); L, luminometer; W, waste.

injected sample passed through the enzyme reactor inserted in the line as shown, where the substrate was oxidized by dissolved oxygen to form the product and hydrogen peroxide. After mixing at a confluence T with a mixed confluent of 0.05 mM luminol and 50 mM hexacyanoferrate(III) solutions pumped at 0.4 ml $min^{-1}$, respectively, the enzymatically generated hydrogen peroxide was detected as the intensity of light emitted in a luminol chemiluminescent reaction. The light intensity was measured with a luminometer (Yanagimoto, Kyoto) equipped with a 100 µl flow-through cell, which was directly attached to the photomultiplier tube operated at −700 V.

## 3. Results and discussion

### 3.1. System without amplification

Diaphorase is an enzyme that is most frequently employed for NADH (or NADPH) oxidation, but the presence of an acceptor, such as hexacyanoferrate(III), is required, as is shown in Eq. (1):

$$\text{NAD(P)H} + \text{acceptor} \xrightarrow{\text{diaphorase}} \text{NAD(P)}^+ + \text{reduced acceptor} \quad (1)$$

In the preliminary experiments, however, the enzyme reactor prepared by immobilizing diaphorase from *Clostridium kluyveri* was found to catalyse the subsequent reaction (Eq. (2)) incorporating an oxygen molecule as the acceptor:

$$\text{NAD(P)H} + \text{O}_2 \xrightarrow{\text{diaphorase}} \text{NAD(P)}^+ + \text{H}_2\text{O}_2 \quad (2)$$

However, repeated injections of NADH solution ($10^{-4}$ M; 20 µl) led to a gradual decrease in the response. This decrease was restored by passing 20 µM FAD solution through the enzyme reactor. This probably indicates that the activity of immobilized diaphorase decreases by releasing FAD from an active centre of the enzyme during the course of the reaction (Eq. (2)). Phosphate buffers (0.1 M) containing 20 µM FAD at various pH values were tested as the carrier solution. The resulting enzyme activity–pH plots showed a maximum plateau in the pH range 6.0–8.4. At pH values below 5.8 and above 8.6, the response decreased sharply. The conversion efficiency of NADH (or NADPH) to $NAD^+$ (or $NADP^+$) (and hydrogen proxide) was calculated from a comparison of the (CL) signals for NADH (or NADPH) and $H_2O_2$, and was found to be independent of the carrier flow rate and about 100% at every flow rate (0.3–1.5 ml $min^{-1}$) at room temperature.

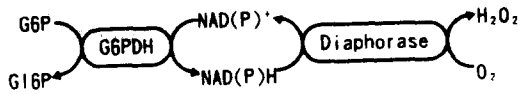

Fig. 2. Enzymatic recycling model of $NAD(P)^+$ and NAD(P)H in the co-immobilized glucose-6-phosphate dehydrogenase (G6PDH)/diaphorase reactor: G6P, glucose-6-phosphate; Gl6P, gluconolactone-6-phosphate.

In this system, NADH and NADPH gave nearly equal CL signals, because the diaphorase-immobilized reactor was not selective between the two coenzymes (NADH or NADPH). When 0.1 M phosphate buffer (pH 7.0) containing 20 µM FAD was pumped at a flow rate of 0.3 ml $min^{-1}$ as a carrier solution, the calibration graph for the CL signal was linear over the range $(1 \times 10^{-6})$–$(5 \times 10^{-4})$ M NADH. The calibration graph obtained for NADPH was essentially the same over the entire concentration range. The linear correlation coefficient was 0.998 ($n = 7$) for both graphs. The detection limit was $5 \times 10^{-7}$ M for both coenzymes (corresponding to 10 pmol).

### 3.2. System with amplification

Diaphorase is not specific between NADH and NADPH, while G6PDHs from two sources, *Leuconostoc mescenteroides* (LM) and yeast (Y), exhibited a difference in the reaction specificity for the coenzymes; the G6PDH(LM) is not specific between the coenzymes ($NAD^+$ and $NADP^+$) and G6PDH(Y) is specific for $NADP^+$. Two enzyme reactors prepared by co-immobilizing G6PDHs from different sources and diaphorase were tested for the amplification of NAD(P) coenzyme detection. The operating principle of the enzyme reactors used for the substrate recycling is shown schematically in Fig. 2. On passage through the enzyme reactor, the coupled enzymes (G6PDH and diaphorase) permit the recycling of NAD(P) coenzymes in the presence of G6P and oxygen in the carrier solution. Thus, the coenzymes are shuttled between the reduced and oxidized forms producing one molecule of hydrogen peroxide and gluconolactone-6-phosphate in each cycle. As a result, for every coenzyme molecule, a number of oxygen molecules are converted to form a large

amount of hydrogen peroxide, which can be detected chemiluminometrically (Fig. 1).

Experiments were conducted to establish the optimum experimental conditions for the amplification and to evaluate the differences in the reaction specificity between the two enzyme reactors. Table 1 shows the range over which each variable was studied and the determined optimal values.

Four types of buffer (0.1 M; pH 8.0; phosphate, carbonate, Tris–HCl, and borate) containing 2 mM G6P and 20 μM FAD, were tested as the carrier solution, and were pumped at a constant flow rate of 0.5 ml $min^{-1}$ through the co-immobilized G6PDH(LM)/diaphorase reactor. A sodium carbonate buffer was used as the carrier solution as it provides the greatest signal for the amplification of NADH. The borate buffer greatly inhibited the G6PDH-catalysed reaction, while Tris–HCl buffer inhibited the chemiluminometric reaction of hydrogen peroxide (the sensitivity to hydrogen peroxide was approximately half of that in the carbonate buffer).

When 0.1 M carbonate buffer containing 2 mM G6P and 20 μM FAD was used as the carrier solution, the G6PDH(LM)/diaphorase reactor gave an amplified peak-shaped signal for NADH and $NAD^+$, but the G6PDH(Y)/diaphorase reactor produced no response for the same NAD coenzymes. Furthermore, both enzyme reactors gave a small broad signal for the NADP coenzymes (Fig. 3). However, the shape of the signal varied from a rounded to a sharp peak after the addition of NaCl to the carrier solution (Fig. 3). This is probably due to the ionic interactions between the NADP coenzyme and the CPG particles. As the NaCl concentration in the carrier was increased from 0 to 0.5 M, the sensitivity to NADP coenzymes was increased, but the increase was only slight at the higher concentration.

Without G6P in the carrier solution, only a negligibly small signal for NADPH was observed, with no signal for $NADP^+$ upon the

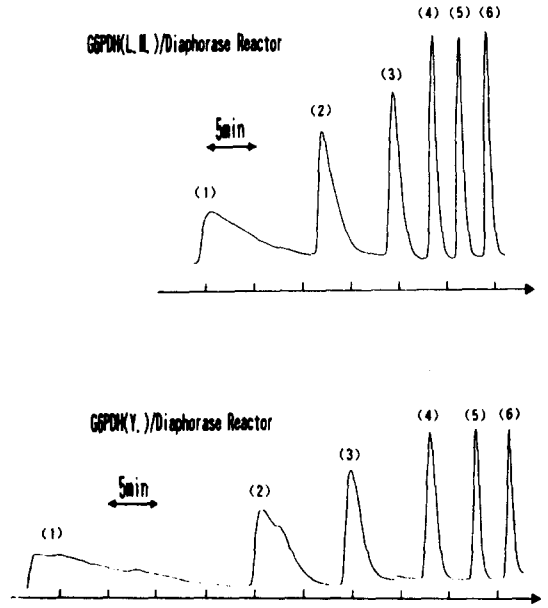

Fig. 3. Effect of NaCl addition to the carrier solution on the chemiluminescent signal for $NADP^+$. NaCl concentration: peak(1), 0; peak (2), 0.1 M; peak (3), 0.2 M; peak (4), 0.3 M; peak (5), 0.4 M; peak (6), 0.5 M. A 20 μl aliquot of $10^{-6}$ M $NADP^+$ solution was injected into the carrier stream (0.1 M carbonate buffer, pH 8.0, containing 2 mM G6P, 20 μM FAD and a variety of NaCl concentrations) pumped at 0.3 ml $min^{-1}$.

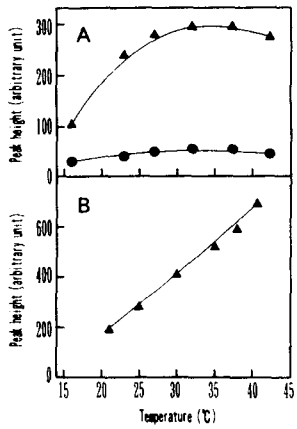

Fig. 4. Effect of reactor temperature on substrate amplification in the FIA system with (A) the G6PDH(LM)/diaphorase reactor and (B) the G6PDH(Y)/diaphorase reactor: amplified response for a 20 µl injection of $5 \times 10^{-7}$ M $NAD^+$ (●) and $5 \times 10^{-7}$ M $NADP^+$ (▲).

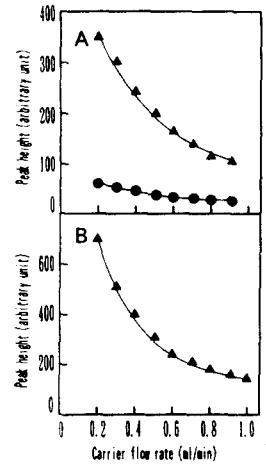

Fig. 5. Effect of carrier flow rate on substrate amplification in the FIA system with the G6PDH(LM)/diaphorase reactor (A) and the G6PDH(Y)/diaphorase reactor (B): amplified response for a 20 µl injection of $5 \times 10^{-7}$ M $NAD^+$ (●) and $5 \times 10^{-7}$ M $NADP^+$ (▲).

use of both enzyme reactors. When the G6P concentration in the carrier was increased from 0 to 2 mM, the sensitivity to NADPH was increased 380 times and 600 times, respectively, for the G6PDH(LM)/diaphorase and G6PDH(Y)/diaphorase reactors. This indicates that the recycling of $NADP^+$ and NADPH occurs effectively between the coupled enzymes in the presence of G6P because oxygen is dissolved in the carrier solution. However, the increase was only slight at higher concentrations of G6P, probably because of limited oxygen in the solution.

A 20 µM concentration of FAD in the carrier solution was selected as it provided reproducible signals for $NADP^+$ and NADPH after repeated injections.

The effect of the pH of the carrier solution (0.1 M sodium carbonate buffer containing 2 mM G6P, 20 µM FAD and 0.5 M NaCl) was investigated next. Maximum response for $NADP^+$ and NADPH was obtained at pH 8.0–8.5 for both enzyme reactors. At pH values below 7.5 and above 9.0, the response decreased sharply, probably because of the decrease in activity of immobilized G6PDHs. Therefore, 0.1 M sodium carbonate buffer (pH 8.0) containing 2 mM G6P, 20 µM FAD and 0.5 M NaCl was selected as the optimum carrier solution for both enzyme reactors.

The temperature of the enzyme reactors was increased by immersing them in a thermostatted water bath. Fig. 4A shows the effect of reactor temperature on the amplified response to $NAD^+$ and $NADP^+$ in the system with a G6PDH(LM)/diaphorase reactor; the maximum response was obtained at 32–37 °C and at higher temperature the response decreased gradually, probably because of a decrease in the activity of the G6PDH(LM). However, in the system with the G6PDH(Y)/diaphorase reactor (Fig. 4B), the amplified response to $NADP^+$ increased with an increase of the temperature up to 42 °C. This difference may be attributed to the thermostability of immobilized G6PDH(Y) compared with immobilized G6PDH(LM).

The carrier flow rate is related to the residence time of the sample zone in the reactor (i.e. the turnover numbers of recycling) and, therefore, the signal intensity increased with

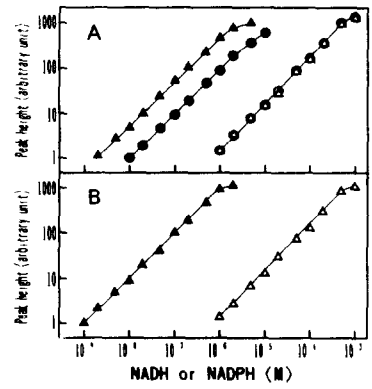

Fig. 6. Calibration graphs for NAD(P)H coenzymes obtained by FIA with the G6PDH(LM)/diaphorase reactor (A) and the G6PDH(Y)/diaphorase reactor (B): ○ and △, no amplified response for NADH and NADPH, respectively; ● and ▲, amplified response for NADH and NADPH, respectively. (Injection volume, 20 µl.)

decreasing flow rate (Fig. 5). Fig. 6 shows the calibration graphs for coenzymes with and without G6P in the carrier solution at a flow rate of 0.3 ml $min^{-1}$. When the G6PDH(LM)/diaphorase reactor was used (Fig. 6A) without G6P in the carrier solution, the response depended linearly on the NADH concentration up to $5 \times 10^{-4}$ M, and the detection limit was $5 \times 10^{-7}$ M; the linear correlation coefficient was 0.999 ($n = 7$). In contrast, the presence of 2 mM G6P in the same carrier solution resulted in a greatly increased signal. The calibration graphs for the amplified response were linear over the range $10^{-8}$–$5 \times 10^{-6}$ M NADH and $2 \times 10^{-9}$–$10^{-6}$ M NADPH; the correlation coefficients were 0.998 for NADH and 0.999 for NADPH, respectively. The detection limit was $8 \times 10^{-9}$ M for NADPH (corresponding to 160 fmol and 12 fmol, respectively). The cycle could also be initiated with $NAD^+$ and $NADP^+$, and so the calibration graphs obtained for them were essentially the same over the entire concentration range as those for NADH and NADPH, respectively. Similarly, in the system with the G6PDH(Y)/diaphorase reactor, the calibraiton graphs were amplified greatly for $NADP^+$ and NADPH over the range $10^{-9}$–$10^{-6}$ M; the calibration graphs for two NADP coenzymes were essentially the same, and were linear with a correlation coefficient of 0.999 ($n = 9$). The detection limit was $3 \times 10^{-10}$ M for both coenzymes (corresponding to 6 fmol). In this system NADH and $NAD^+$ gave no signal, because the G6PDH(Y) used was specific for $NADP^+$. Therefore, this system is useful for the highly sensitive detection of the $NADP^+$ and NADPH pair.

The reproducibility of the measurements was tested by repeated injections ($n = 10$) of $10^{-7}$ M $NADP^+$ and NADPH. The relative standard deviations were 1.5–2.3% for the systems with the two different reactors.

The immobilized enzyme reactors were used repeatedly to confirm the instability with time; even after repetitive use (about 10 samples per day) for 2 months, the enzyme reactors retained over 95% of their original activities.

## 4. Conclusions

A FIA approach with an immobilized enzyme reactor involving amplification by substrate recycling is very attractive with respect to the enhancement of the sensitivity for the selective detection of substrate in the nanomolar to micromolar range. The amplification of nico-tinamide coenzymes is particularly important, because they furnish the redox driving force for many dehydrogenase-catalysed reactions and are frequently used as substrates in enzyme immunoassays. This work demonstrated the usefulness of two enzyme reactors prepared by co-immobilizing two different commercially available G6PDHs and diaphorase for *Clostridium kluyveri* in order to increase greatly the sensitivity of NAD(P) coenzymes by substrate recycling. In particular, the G6PDH(Y)/diaphorase coimmobilized reactor was specific for NADP coenzymes with an amplification factor of about 600 (at a flow rate of 0.3 ml $min^{-1}$) in the determination of $NADP^+$ and NADPH. The difference in the specificity obtained by the combination of the coupled enzymes is very attractive for the specific detection of NAD(P) coenzymes. However, the proposed FIA system was not specific between the oxidized and reduced forms of NAD(P) coenzymes, because the cycle was initiated with each of them. This disadvantage can be overcome by using this amplified FIA system as a postcolumn detector for liquid chromatography. Also, the FIA system with the G6PDH(Y)/diaphorase coimmobilized reactor should prove useful as a highly sensitive detection system for enzyme immunoassays when using alkaline phosphatase as a label and $NADP^+$ (or NADPH) as the substrate.

# A multivariate chemometric approach to fluorescence spectroscopy

Lars Nørgaard

*Royal Veterinary and Agricultural University, Department of Dairy and Food Science, Food Technology, Thorvaldsensvej 40, DK-1871 Frederiksberg, Denmark*

Received 29 December 1994; revised 7 March 1995; accepted 10 March 1995

**Abstract**

A multivariate approach to the solution of problems often encountered in the spectrofluorometry of natural samples, utilising information from whole spectra is presented. (a) Piecewise direct standardisation is implemented and employed to transfer emission spectra measured with two different xenon lamps of different ages as if the spectra were measured with the same lamp. (b) It has been shown using a multivariate analysis approach that it is possible to use the raw data points instead of the smoothed data based on an algorithm included in the instrument software by the manufacturer. (c) It is documented that Raman scattering does not hamper the performance of multivariate calibration; on the contrary, in an experiment with sugar samples the concentration prediction errors become about five times lower by including the whole emission spectrum in the analysis instead of using a univariate calibration based on an emission wavelength that only reflects the analyte of interest. (d) An algorithm for variable selection is implemented and employed in the selection of optimal excitation wavelengths. Among 13 emission spectra recorded for a sugar sample at different excitation wavelengths, four of these are chosen that describe 98.51% of the total variance in the original data. (e) Finally the combination of fluorescence spectroscopy and multivariate calibration with conventional chemical data according to the near-infrared black box model is presented. The refined sugar quality parameter, the ash content and the fluorescence emission spectra are correlated by a partial least-squares regression model. Five experiments employing different monochromator slit widths and sugar concentrations are performed, and the best correlation obtained by full cross-validation of the 15 sugar samples is $R = 0.98$.

## 1. Introduction

Fluorescence spectroscopy has been used for decades as a powerful analytical tool in all sorts of chemical, biochemical, food and environmental laboratories due to its two principal properties: excellent sensitivity and specificity. The use of fluorescence excitation and emission spectra has so far mostly been qualitative, with the purpose of finding a pair of excitation–emission wavelengths where the analyte of interest is the only chemical component giving rise to the recorded signals [1,2].

On searching the literature, very few papers are encountered dealing with the application of multivariate chemometric methods in fluorescence spectroscopy. This seems especially striking bearing in mind the enormous number of publications using chemometrics in combination with traditional spectroscopic techniques like near-infrared (NIR) spectroscopy [3–6]. In the majority of the papers dealing with fluorescence spectroscopy and chemometrics, only synthetic samples or natural samples containing very few chemical species are analysed with the aim of resolving a measured excitation–emission matrix (EEM) into pure excitation and emission spectra of the chemical components in the samples, and with the aim of

*SSDI* 0039-9140(95)01586-8

predicting analyte concentrations by rank annihilation methods [7–12]. When the number of signal-producing chemical components in a sample becomes larger than 5–6 it is very difficult to perform this resolution within acceptable limits of accuracy and precision [9].

In studies by Lindberg et al. [13] and Sjöström et al. [14] concentrations of two- and three-component synthetic mixtures are successfully predicted from fluorescence emission spectra by the method of partial least-squares regression. In Refs. [15–18] fluorescence spectroscopy in combination with partial least-squares regression is used for predicting botanical tissue components of complex wheat flour samples. The latter example is analogous to the widespread use of multivariate calibration in NIR spectroscopy [3–6], and illustrates how the chemical information for "dirty" natural samples can be enhanced by fluorescence spectroscopy in combination with multivariate statistical methods.

In this paper, the focus is on the analysis of spectra from refined sugar samples in order to investigate different intrinsic instrumental parameters as well as the combination of fluorescence spectroscopy of given samples and multivariate calibration. The study both serves as a general investigation of how to enhance the potential of fluorescence spectroscopy by chemometrics as well as a special investigation of how fluorescence spectroscopy of sugar samples can be approached in a multivariate sense. Sugar samples are real samples and all topics treated reflect the problems of measuring fluorescence spectra on real samples.

Refined sugar is a very pure foodstuff containing only small concentrations of impurities (below 1%). These impurities, such as phenolic compounds, amino acids, melanoidins, and melanins [19], stem from the sugar beet delivered to the sugar factory superimposed the chemical compounds produced at the individual unit operations of the factory. It is the long-term purpose of the project, of which this publication is a part, to use fluorescence spectroscopy for the on-line prediction of (a) refined sugar quality [20] and (b) optimal adjustment of process parameters. The fluorescence measured is autofluorescence (or primary fluorescence), i.e. the native fluorescence of the impurities in the dissolved sugar sample. The beauty of this approach rests in the fact that nature and processing combined respond with a multivariate fluorescent fingerprint [21].

Using several examples, the potential of multivariate analysis in fluorescence spectroscopy will be demonstrated. The topics addressed are as follows.

(i) Transferring spectra between different instrumental set-ups. Spectrofluorimeters are all different due to differences in lamps, monochromators and photomultipliers [2]. When analysing large sample sets, which is the case in on-line/at-line process applications, it is essential in the case of instrument break-down to be able to compare samples measured with different set-ups or even on different instruments. It is outlined how this problem can be solved by the piecewise direct standardisation algorithm originally developed for the standardisation of NIR instruments [22–24].

(ii) Smoothing of spectral data. The spectrofluorimeter employed for analysis automatically smooths the measured emission spectra. Raw data will be compared to data smoothed with binomial and Savitzky-Golay smoothing algorithms.

(iii) Raman scattering. This often overlaps the analyte emission spectra. The classical way of circumventing the problem of Raman scattering is to employ suitable filters [25] (if available), to subtract a blank emission spectrum from all the samples [25], or to change the excitation wavelength [25]. An example will be given of how multivariate methods are capable of overcoming the problem of the Raman scattering peaks by including whole emission spectra in the mathematical analysis.

(iv) Selection of wavelengths. The measurement of fluorescence emission spectra at a large number of excitation wavelengths is a time-consuming operation. It will be demonstrated how the principal variable algorithm [26] chooses a small but optimal number of excitation wavelengths describing the main variations in the excitation–emission data matrix. The wavelength selection is especially important in the multivariate calibration of large sample sets as well as for fast on-line prediction of analyte concentrations in future samples.

(v) Multivariate calibration. Multivariate calibration [27] of the sugar quality parameter ash content in refined sugar samples is performed. Experiments with different excitation monochromator and emission monchromator slit widths and sugar concentrations are performed in order to investigate their influence on the multivariate calibration models. The influence of pH and the use of corrected/not

corrected emission spectra in connection with multivariate modelling will be touched on.

## 2. Materials and methods

### 2.1. Instrumentation

All experiments are performed on a Perkin–Elmer LS 50B spectrometer. The computer controlling the instrument through an RS232C interface is an IBM-compatible 486/50 MHz PC. Uncorrected fluorescence spectra samples with 0.5 nm intervals are recorded in all experiments.

### 2.2. Programs

Calculations are performed with Matlab for Windows version 4.2c.1 (MathWorks, Inc.) and Unscrambler version 5.5 (CAMO A/S). A chemometric toolbox made by B.M. Wise [28] is used for piecewise direct standardisation. The Perkin-Elmer LS50 FLDM Instrument program (version 4.00) is used for controlling the instrument. Spectral data are converted to ascii files by a program made in the OBEY language furnished by Perkin-Elmer (OBEY, version 3.50). An OBEY program made by S. Huckins, Perkin-Elmer, is applied to obtain the raw fluorescence emission spectra from the instrument.

### 2.3. Measurement conditions

In experiments including several excitation wavelengths, the measurement always starts with the largest excitation wavelength and ends with the lowest excitation wavelength in order to minimise photodecomposition of the sample. This problem needs no further concern as long as each sample in a given experiment is subject to exactly the same measurement cycle. In all experiments the sample holder is thermostatted to 24 °C ± 0.1, which is the average room temperature during a normal working day.

### 2.4. Samples

Double ion exchanged water was used for all sugar solutions and dilutions. There was a high degree of repeatability of the sample measurements (see Figs. 12 and 15). The buffer capacity of refined sugar is extremely low and it is impossible to obtain reliable pH measurements of such samples. In the pH experiment, phosphate buffers with $C = 0.1$ M were prepared from sodium dihydrogen phosphate. The glassware and cuvettes were kept extremely free from contamination by washing with methanol and a 2% Extran solution (Merck). The sample sets analysed are arranged as follows (including relevant instrumental parameters).

(i) Sample set A (Piecewise Direct Standardisation) comprises solid standard blocks nos. 1 (anthracene and naphthalene mixture), 2(ovalene), 3(*p*-terphenyl), 4(tetraphenylbutadiene), and 5(compound 610) from the Perkin-Elmer C 520-7440 standard set, and a refined sugar sample (15.00 g of refined sugar added to 15.00 ml of water); six samples in total. Instrumental parameters were excitation wavelength, 300 nm; emission range recorded, 320–540 nm; excitation monochromator slit width, 5.0 nm; emission monochromator slit width, 5.0 nm; and emission scan velocity, 500 nm $min^{-1}$. The spectra are binomial smoothed (filter factor 9) by the FLDM software.

(ii) Sample set B (smoothing of spectra) comprises standard block 2 (ovalene) from the Perkin-Elmer set. Instrumental parameters were excitation wavelength, 342 nm; emission range recorded, 440–600 nm; excitation monochromator slit width, 3.0 nm; emission monochromator slit width, 5.0 nm; and emission scan velocity, 500 nm $min^{-1}$.

(iii) For sample set C (Raman scattering), a stock solution consisting of 25.00 g of refined sugar added to 50.0 ml of water was prepared. From this stock solution, 10 samples were prepared containing from 0.5 ml to 5.0 ml (with 0.5 ml intervals). All solutions were diluted to 10.0 ml with water, i.e. the concentrations are given as 5.0, 10.0, . . . , 50.0% v/v of the stock solution. A blank solution (water) was prepared. Instrumental parameters were excitation wavelength, 300 nm; emission range recorded, 315–540 nm; excitation monochromator slit width, 8.0 nm; emission monochromator slit width, 5.0 nm; and emission scan velocity, 1000 nm $min^{-1}$. The emission spectra are not smoothed.

(iv) Sample set D (multivariate calibration of fluorescence spectra) was as follows. (I) Fifteen different refined sugar samples consisting of 15.00 g of sugar added to 15.00 ml of $H_2O$ (approximately 50% (w/w)). (II) Each sample in sample set 1 was diluted 1:1 (10.00 ml of sugar solution added to 10.00 ml of $H_2O$). (III) The same original 15 sugar samples but with

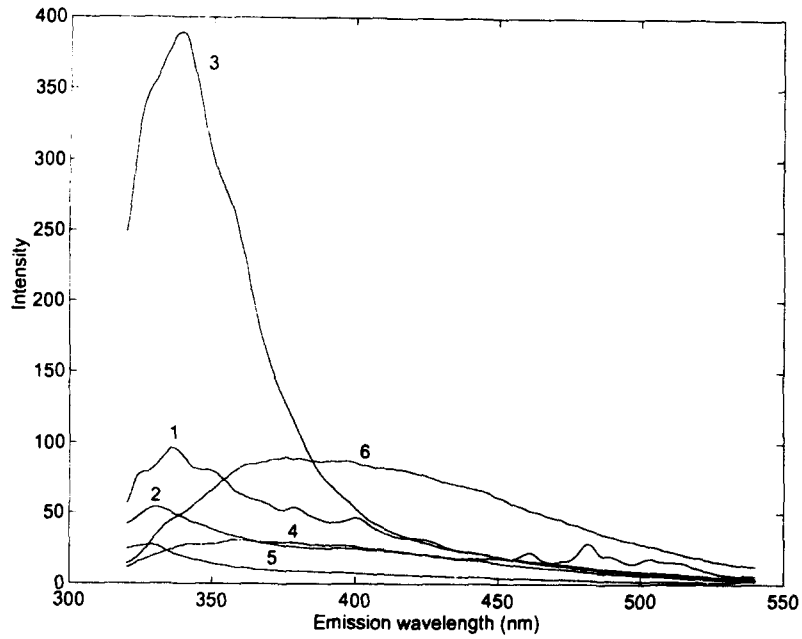

Fig. 1. Emission spectra of the 6 samples used in piecewise direct standardisation measured with lamp 1 mounted. The numbers correspond to sample set A.

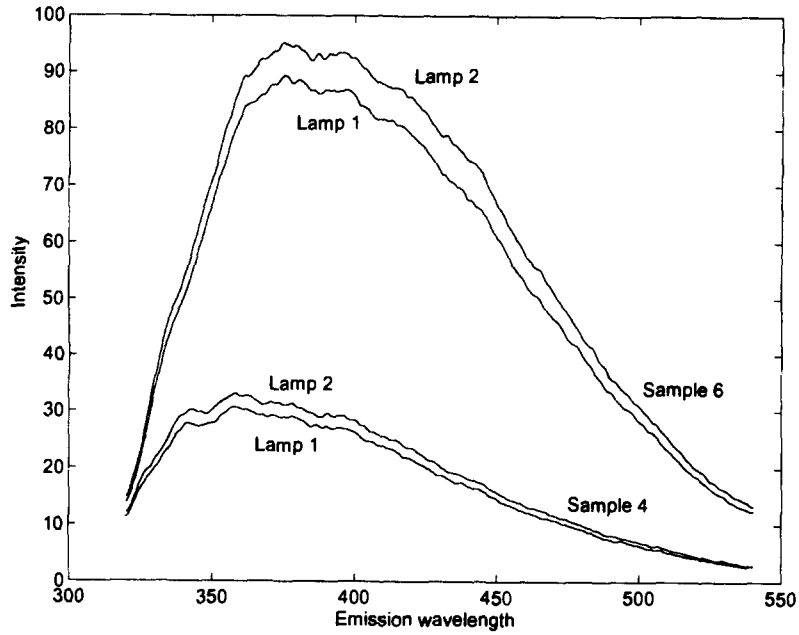

Fig. 2. Emission spectra of samples 4 and 6 measured with two different lamps mounted. Lamp 1 is older than lamp 2.

1.50 g of sugar added to 15.00 ml of $H_2O$ (approximately 10% (w/w)). Instrumental parameters were excitation wavelengths, 230 nm (emission, 245–435 nm), 240 nm (emission, 255–455 nm), 290 nm (emission, 305–555 nm), and 330 nm (emission, 345–635 nm), (1864 data points in total); and emission scan velocity, 1000 nm $min^{-1}$. The emission spectra are not smoothed.

### 2.5. Chemometric methods

The chemometric methods employed are described in detail in the literature, so only a brief description including the relevant literature references will be given here. Nomenclature: capital, italic bold face letters symbolise matrices, small, italic bold letters symbolise vectors and small italic characters are scalars. The number

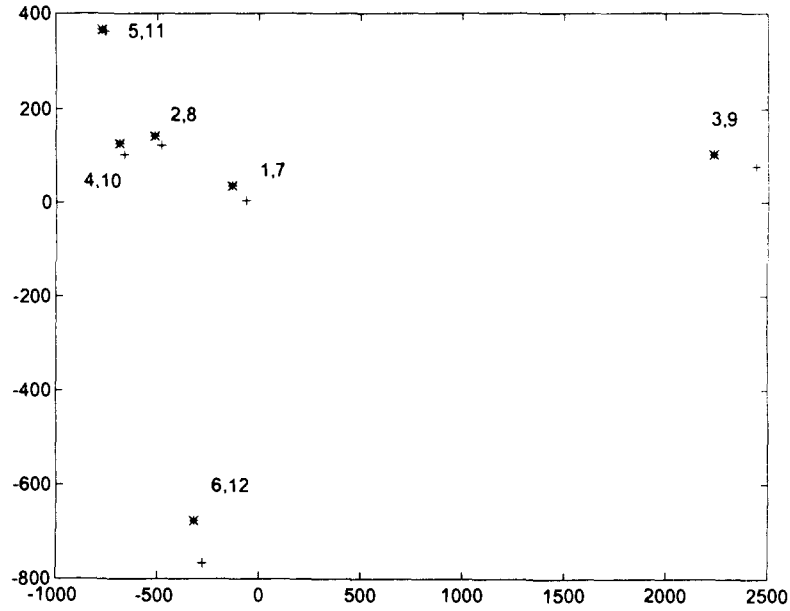

Fig. 3. Score plot (first two PCs) of 12 emission spectra before standardisation. Samples marked * (1–6) are measured with lamp 1 and samples marked + (7–12) are measured with lamp 2. Corresponding pairs of samples are 1, 7; 2, 8; . . . ; 6, 12.

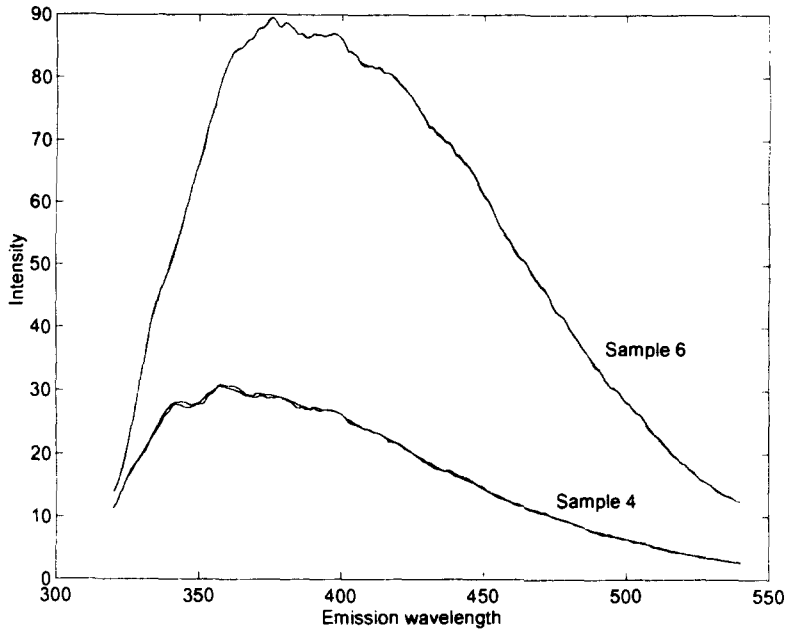

Fig. 4. Emission spectra of samples 4 and 6 measured with lamp 1 and the transformed spectra of the same samples originally measured with lamp 2. The spectral differences after transformation are very small.

of samples, the wavelength, and factors are denoted by $s$, $w$ and $f$, respectively.

*Principal component analysis (PCA)*

Principal component analysis finds the main variation in a multidimensional data set by creating new linear combinations of the raw data [27,29]. In matrix form we have

$$\boldsymbol{X} = \boldsymbol{TP}'$$

where $\boldsymbol{X}$ is the analysed data matrix with dimensions $s \times w$, $\boldsymbol{T}$ is the score matrix with dimensions $s \times min(s, w)$, and $\boldsymbol{P}'$ is the loading matrix with dimensions $w \times min(s, w)$. Only the significant number of principal components (PCs), $f$, equal to the chemical rank of the $\boldsymbol{X}$

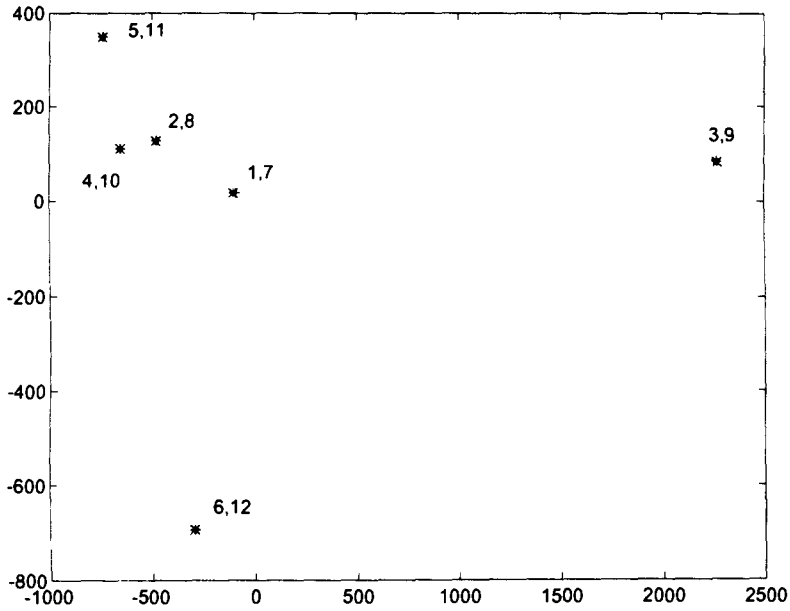

Fig. 5. Score plot (first two PCs) of 12 emission spectra after standardisation. Samples marked * (1–6) are measured with lamp 1 and samples marked + (7–12) originally measured with lamp 2 are transformed as if they were measured with lamp 1. Corresponding pairs of samples are 1, 7; 2, 8; . . . ; 6, 12. Samples 2, 3, and 6 are used as transformation standards.

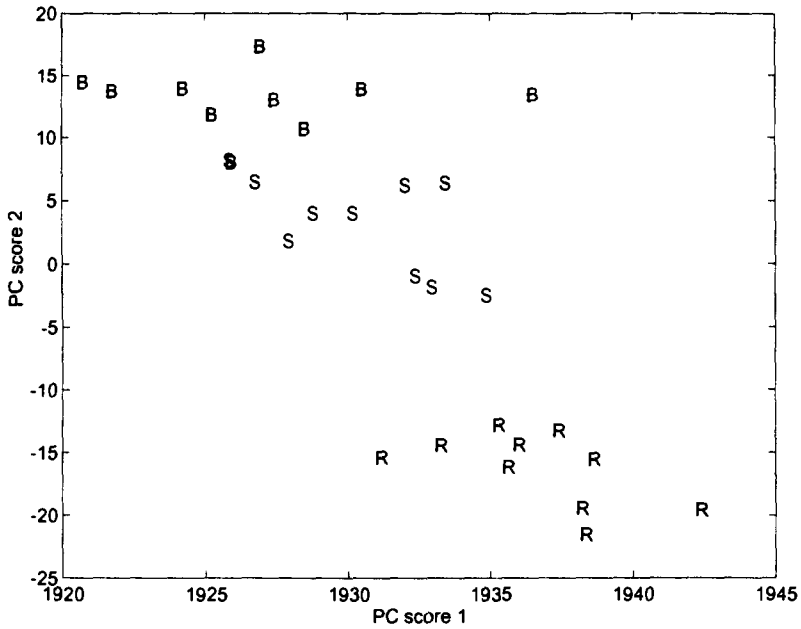

Fig. 6. Score plot (PC1 versus PC2) of 30 emission spectra of standard block 2. Three clusters are observed: binomial (B) smoothed, Savitzky-Golay (S) smoothed and raw (R) data. Two S and B samples are overlapping.

matrix is relevant in describing the information in $X$. This leads to the following decomposition of $X$

$$X = T_f P_f' + E$$

where $T_f$ is the score matrix with dimensions $s \times f$, $P_f$ is the loading matrix with dimensions $w \times f$, and $E$ is a residual matrix with the same dimensions as $X$.

*Partial least-squares regression (PLS)*

The purpose of regression is to build a model between $X$ and $y$, where $X$ (see above) contains the fluorescence spectra and $y$ ($s \times 1$) is a vector containing the property of interest (if several properties have to be modelled, we have a matrix $Y$ with dimensions $s$ multiplied by the number of properties). In principal component regression [27,30] (PCR) a multiple linear re-

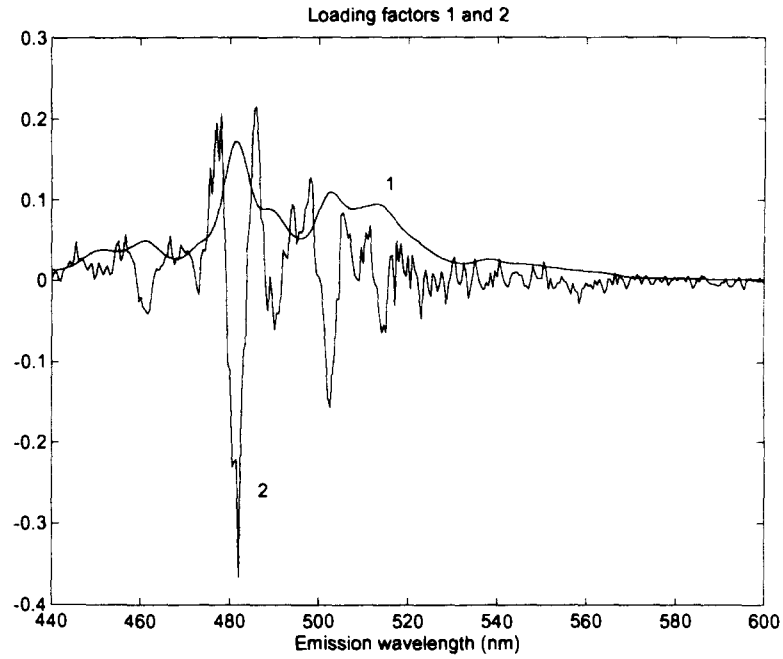

Fig. 7. Loadings from the PCA on 30 emission spectra (smoothed and raw). Loading vector 1 is smooth, while loading vector 2 indicates the spectral differences between the three data types.

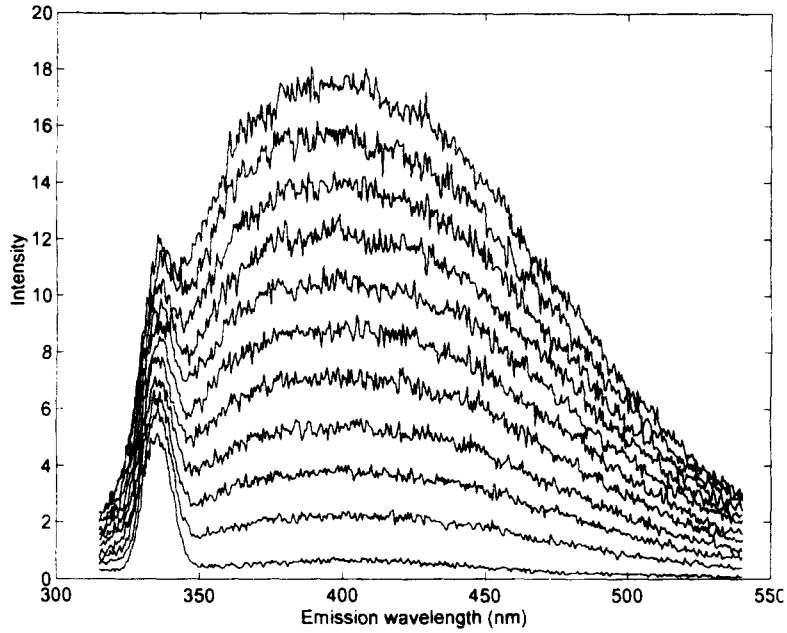

Fig. 8. Emission spectra of 11 samples with different concentrations of the same refined sugar sample (including a blank sample). The Raman scattering overlaps the analyte spectrum in the region around 334 nm.

gression model is built between the significant PCA scores ($T_f$) and $y$. PCR maximises the variance in $X$ followed by a regression to $y$. In partial least squares the significant score values $T_f$ are found in a slightly different way, taking into account the variation in $y$ during the decomposition of $X$, i.e. in PLS the covariance between $X$ and $y$ is maximised [27, 30–33].

The number of factors (principal components or partial least-squares components) to include when applying the above mentioned methods is found by test set validation [27]. In the case of small data sets, cross-validation [27,34] is an alternative way of validating the model performance.

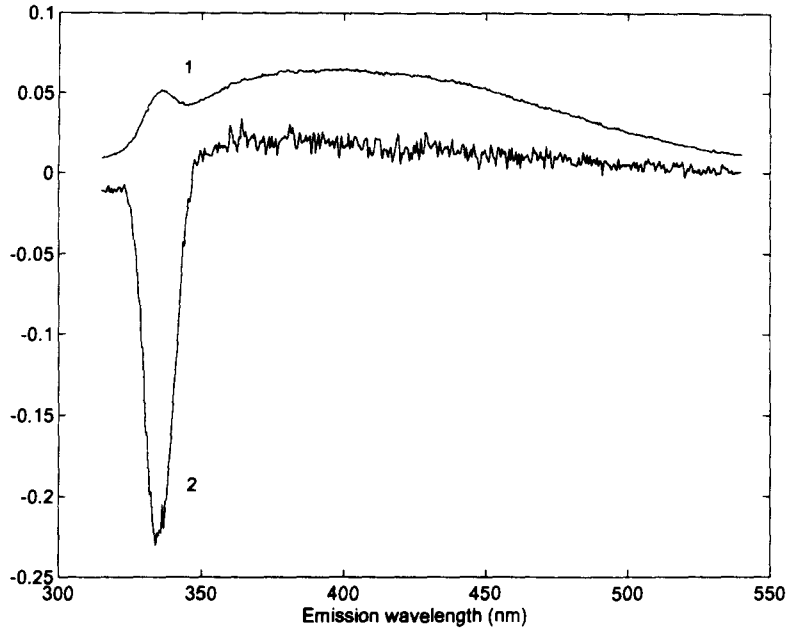

Fig. 9. Loading weights 1 and 2 for the PLS prediction of sugar concentration. The Raman scattering contributes to both loading vectors.

Table 1
Prediction of sugar concentrations
(A) Results of PLS calibration (with and without mean centring) and univariate calibration based on raw data

| | With mean centring RMSEP [a] | $R$ [b] | Without mean centring RMSEP [a] | $R$ [b] |
|---|---|---|---|---|
| One PLS component | 0.017 | 0.9999 | 0.134 | 1.000 |

| Two PLS components | – | – | 0.029 | 0.9998 |

[a] RMSEP $= \sqrt{\Sigma_{i=1}^{N} (C_i^{\text{predicted}} - C_i^{\text{reference}})^2/N}$, where $C_i^{\text{predicted}}$ is the model estimated concentration, $C_i^{\text{reference}}$ is the reference value and $N$ is the number of samples.
[b] Correlation coefficient.

*Piecewise direct standardisation (PDS)*

Piecewise direct standardisation [22–24] works on two data matrices $\boldsymbol{A}$ and $\boldsymbol{B}$. These matrices contain spectra of the same standards measured under two different instrumental conditions $\boldsymbol{A}$ and $\boldsymbol{B}$ (dimensions are number of standards multiplied by $w$). No data preprocessing is performed prior to the standardisation. A multiple of local multivariate regression models between each spectral point (wavelength) in $\boldsymbol{A}$ and a window of spectral points (including the wavelength chosen in $\boldsymbol{A}$) in $\boldsymbol{B}$ are then built. This yields a banded transfer matrix $\boldsymbol{M}$ ($w \times w$) with a window of non-zero regression elements along the matrix diagonal and zeros elsewhere [22]. In matrix notation, we have

$$\boldsymbol{A} = \boldsymbol{BM}$$

Future measurement of a sample under instrumental condition $B$ can now be transformed as if it were measured under instrumental condition $A$ by

$$\boldsymbol{a}'_{\text{rec}} = \boldsymbol{b}'_{\text{new}}\boldsymbol{M}$$

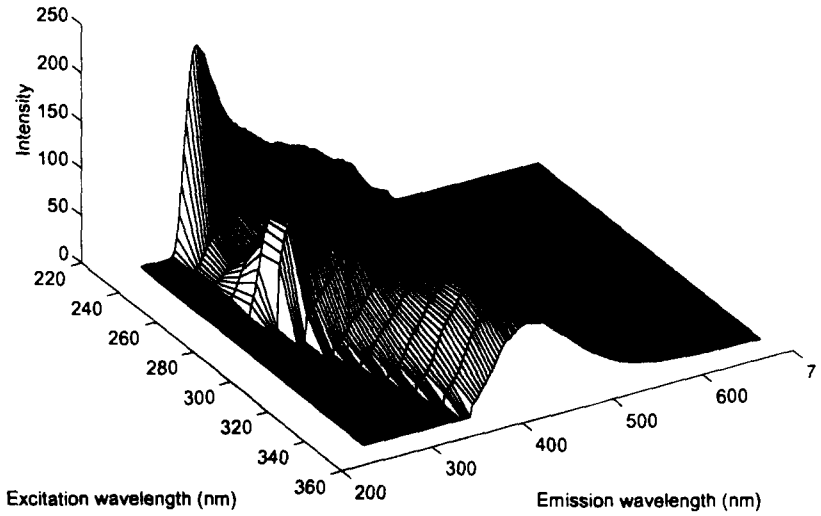

Fig. 10. A three-dimensional plot of an excitation–emission matrix (EEM) measured on a refined sugar sample. (Every 2.5 nm of the emission spectra are used in the plot).

where $b_{new}$ is a column vector containing the measured spectrum and $a_{rec}$ is the reconstructed spectrum. The selection of appropriate standards is important [22].

*Principal variables (PV)*

Assume that we have a matrix $X$ ($s \times w$). The method of principal variables [26] aims at finding few variables (in this case columns corresponding to wavelengths) that describe as much of the total variance in the data matrix as possible. The method is based on finding the largest diagonal value of

$$X'XX'X \quad (1)$$

with the dimension $w \times w$. The wavelength variable indexed by this value is the first principal variable, designated $w$ ($s \times 1$). In the next step $X$ is orthogonalised with respect to the chosen variable

$$k = (X'w)/(w'w) \quad (2)$$

$$X_{new} = X - wk' \quad (3)$$

where $w$ ($s \times 1$) and $k$ ($w \times 1$) are column vectors. The next PVs are found by repeating the procedure from step 1 to 3 with $X_{new}$ found in step 3. The number of PVs to choose depends on the actual problem to be solved. By analysing the matrix $X'yy'X$ instead of $X'XX'X$, the method of principal variables is extendible to deal with the selection of wavelength variables to obtain optimal correlations with properties of interest ($y$ values).

Table 2
Experiments performed to investigate the multivariate calibration of sugar samples with respect to ash content

[a] Description of the sample sets is given in the text.
[b] Emission ranges are 260–420 nm (ex. 230 nm), 270–440 nm (ex. 240 nm), 320–540 nm (ex. 290 nm), 360–620 nm (ex. 330 nm) (1624 data points in total).

## 3. Results and discussion

### 3.1. Piecewise direct standardisation

When using multivariate methods including many calibration samples, it is very important to be able to transfer spectra between different instrumental set-ups (lamps, slit widths, scan velocities) of the same spectrofluorimeter and, if necessary, between different instruments. Furthermore, the xenon lamp in the spectrofluorimeter also needs continuous standardisation due to a change of spectral characteristics during ageing. If, by accident, for example, the lamp breaks down after the measurement of 100 calibration samples, it is of the utmost importance to be able to use the calibration models based on these samples for the concentration prediction of samples measured with a new lamp with other spectral characteristics.

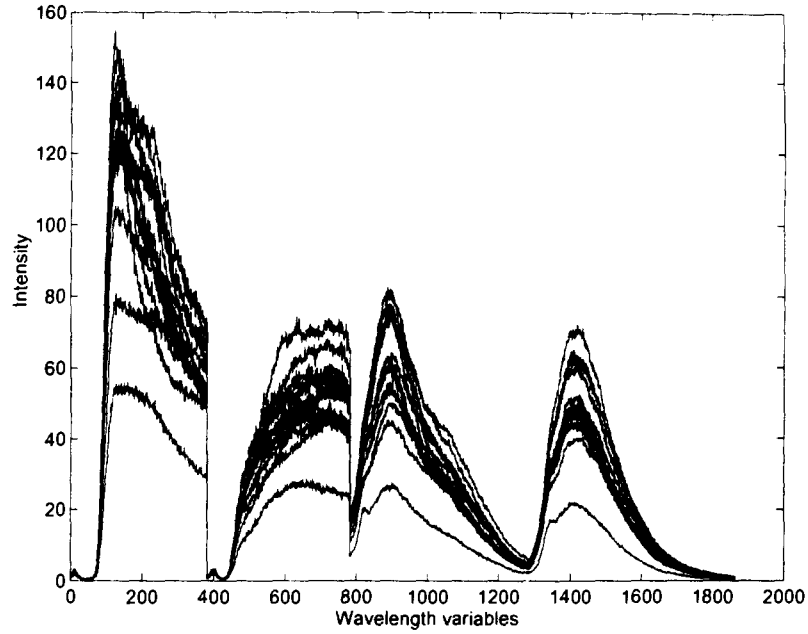

Fig. 11. Concatenated emission spectra of 15 different sugar samples (experiment 3, sample set DII) measured at four excitation wavelengths (230, 240, 290 and 330 nm). Emission variables 1–381 correspond to 245–435 nm; variables 382–782 correspond to 255–455 nm, variables 783–1283 correspond to 305–555 nm, variables 1284–1864 correspond to 345–635 nm.

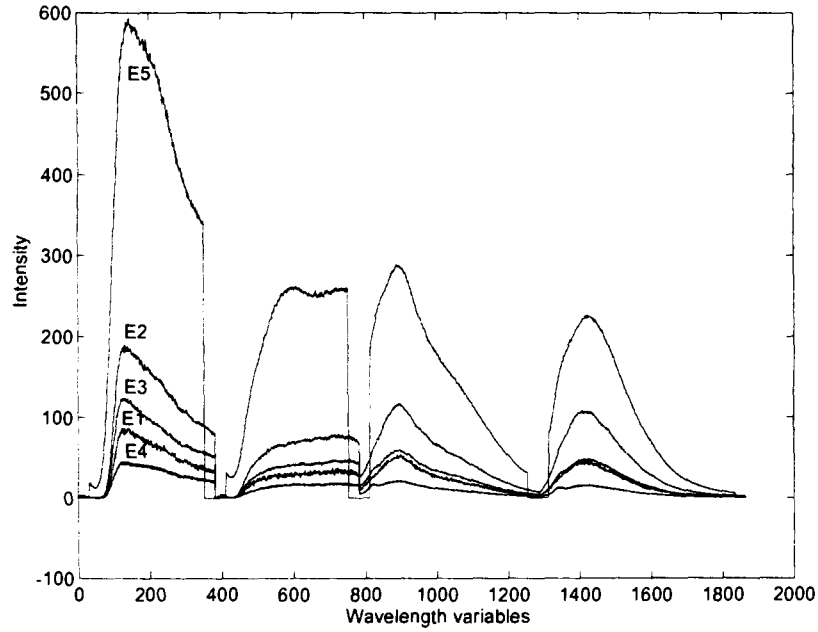

Fig. 12. Concatenated emission spectra of sugar sample 4 from experiments 1–5 (E1–E5). A replicate made in experiment 4 is included to illustrate the small replicate and measurement variation.

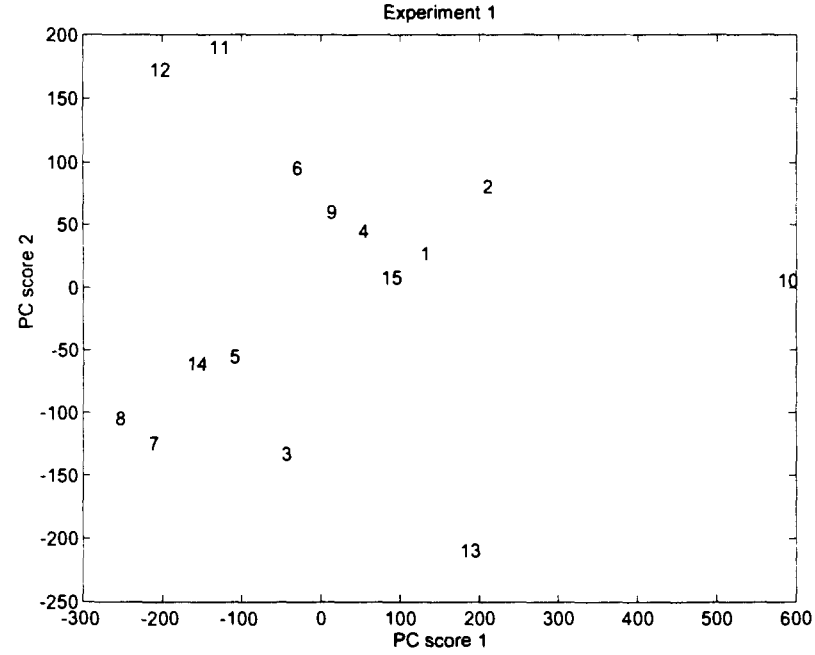
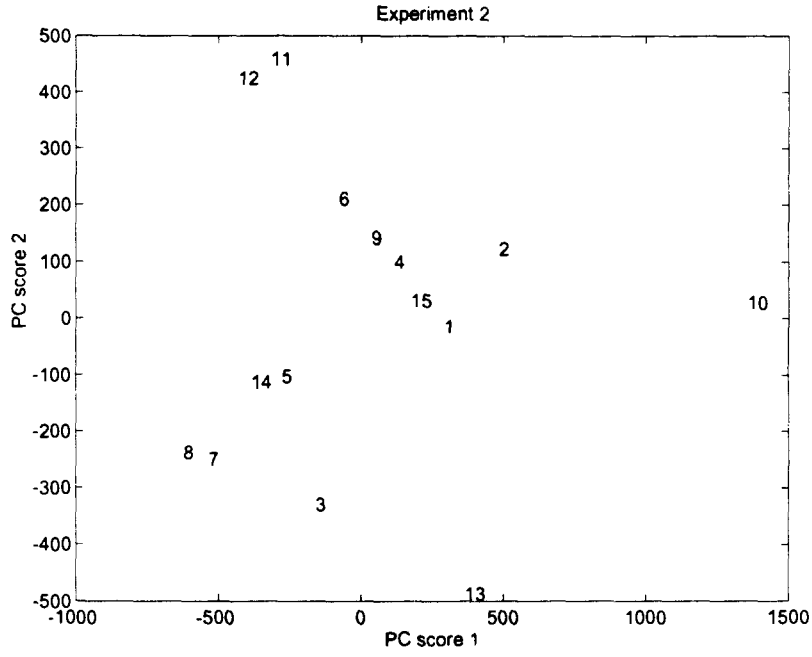
In order to make a preliminary investigation of the potential of using piecewise direct standardisation (PDS) on the fluorescence spectra, two experiments were performed with the same fluorescence spectrometer. In the first experiment, six samples (sample set A) are measured with xenon lamp 1 (old) mounted on the apparatus, while in the second experiment the samples are measured with xenon lamp 2 (new) fitted. The raw fluorescence emission spectra of all six samples measured with excitation at 300 nm and with xenon lamp 1 are shown in Fig. 1. In Fig. 2 the emission spectra of samples 4 and 6 measured with both lamps are shown. A distinct difference between the spectra is observed and principal component analy-



(a)



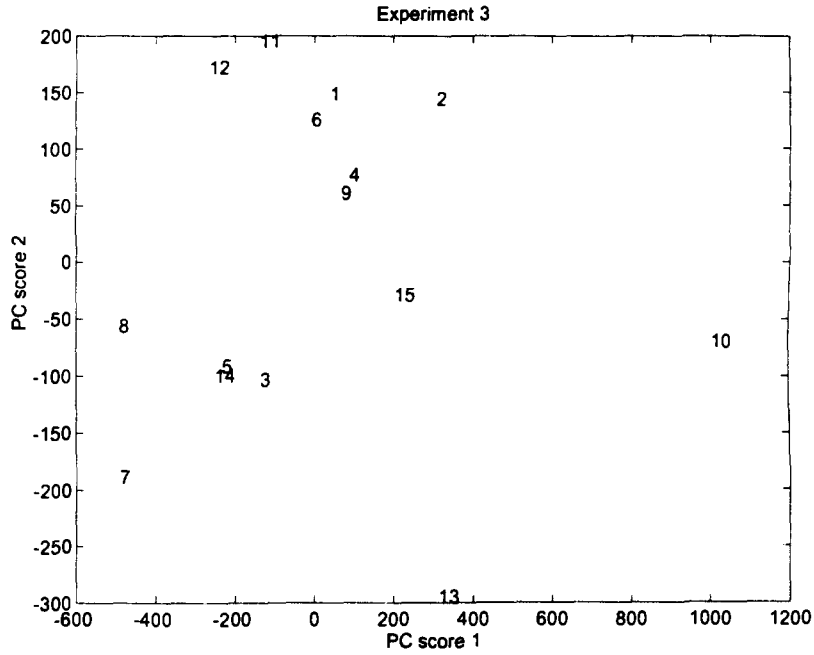
(b)

Fig. 13 (a) and (b).

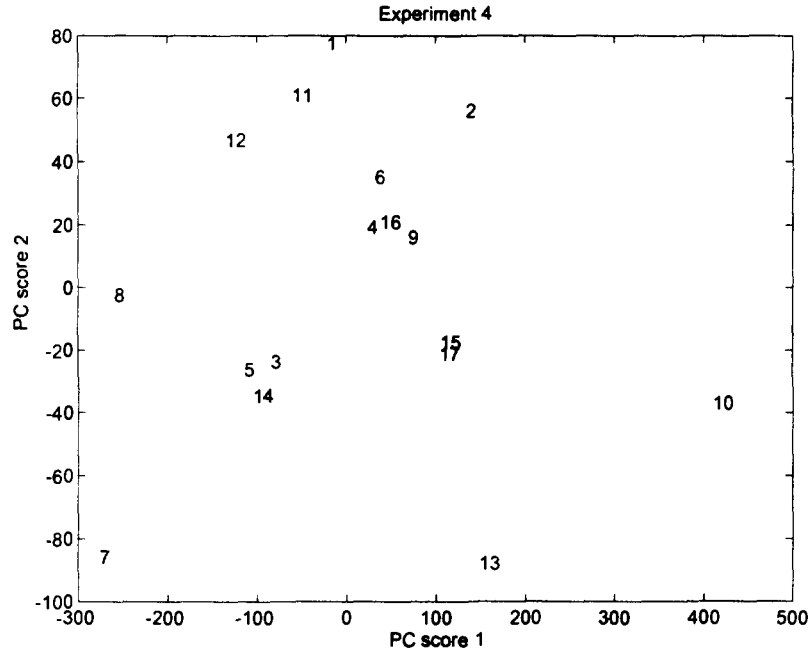
sis of all 12 emission spectra shows the displacement of identical samples as seen in the score plot in Fig. 3. Samples 2, 3 and 6 are chosen as transfer standards in the PDS algorithm (how to select appropriate standards is described in Ref. [22]). The PDS algorithm calculates a matrix capable of transforming the spectra measured with lamp 2 as if they were measured with lamp 1.

$$\boldsymbol{A}_{\text{rec}} = \boldsymbol{B}\boldsymbol{M}_{\text{transfer}}$$

where $\boldsymbol{A}_{\text{rec}}$ is a matrix with 6 objects and 441 variables containing the reconstructed spectra, $\boldsymbol{B}$ is a $6 \times 441$ matrix containing the spectra measured with lamp B and $\boldsymbol{M}_{\text{transfer}}$ is a $441 \times 441$ transfer matrix. In this case the optimal window size was found to be 7, i.e. 7 spectral points in $\boldsymbol{B}$ (this corresponds to an emission range of 3 nm) are used to model the chosen wavelength in $\boldsymbol{A}$.



(c)

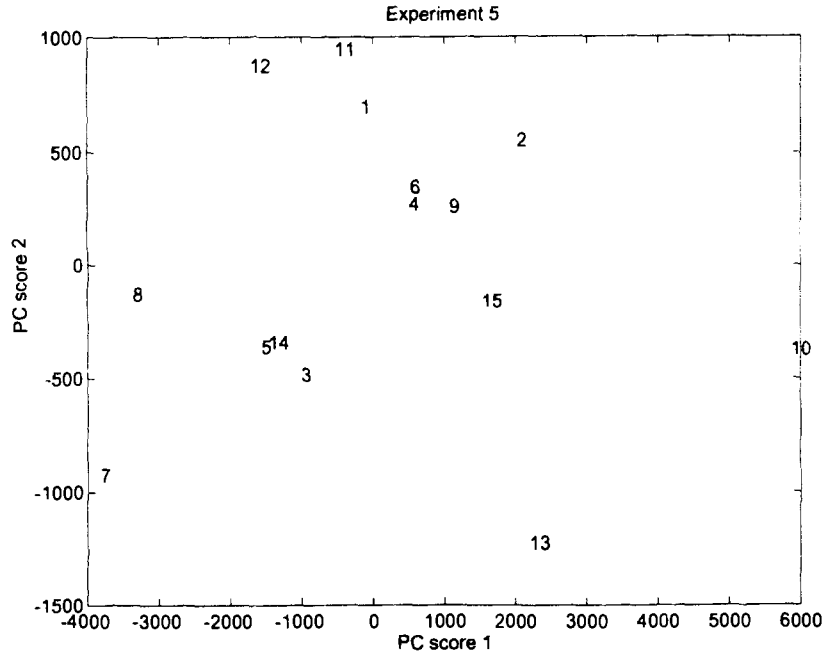


(d)

Fig. 13 (c) and (d).

In order to estimate the efficiency of PDS transformation, the true spectra measured with lamp 1 are compared with the transformed (reconstructed) spectra (Fig. 4). A PCA score plot of the 6 original lamp 1 spectra and the 6 transformed spectra is given in Fig. 5. As expected, the spectra of the three standards used in calculating the transfer matrix compare very well, but the three samples not included in the transfer calculation also compare satisfactorily.

This example indicates that the PDS is a valuable tool in transferring fluorescence spectra between different instrumental set-ups for the same fluorescence instrument and between different instruments. An extensive investigation of the performance of the PDS algorithm in combination with multivariate calibration methods of fluorescence spectra (including a larger sample set) is presented in Ref. [35].



(e)

Fig. 13. Score plots (PC1 against PC2) for (a) experiment 1; (b) experiment 2; (c) experiment 3; (d) experiment 4; and (e) experiment 5. In experiment 4 replicates of samples 4 and 15 are included (nos. 16 and 17, respectively).

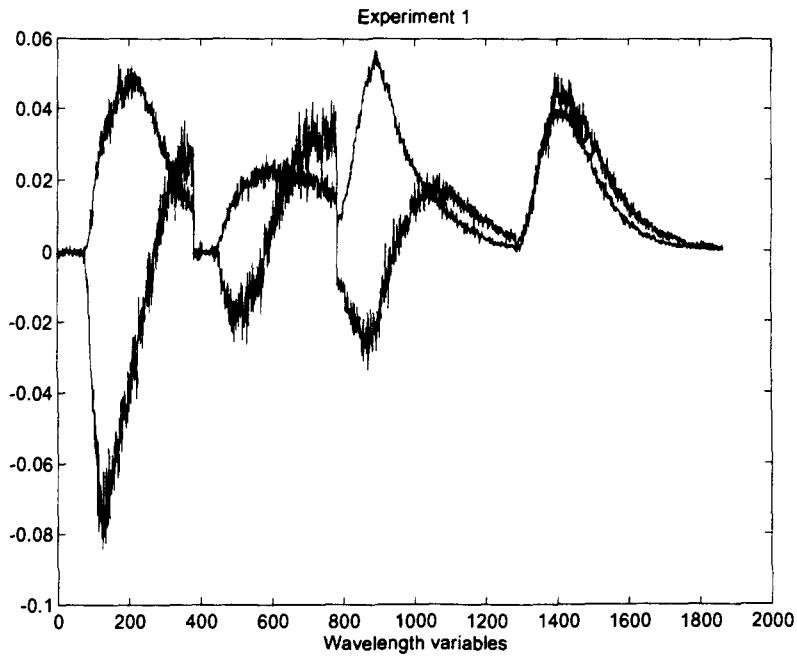
### 3.2. Smoothing of spectra

The Perkin-Elmer LS 50B instrument is sold with two types of software smoothing filters, i.e. the chemist must choose either binomial or Savitzky-Golay smoothing of the raw data. To investigate the smoothing effect on spectral shape an OBEY program was written to obtain the raw unsmoothed data as output from the instrument (see Section 2). Ten emission spectra were recorded on standard block 2 (sample set B) for each smoothing type. A PCA of the 30 spectra shows three clusters each for one of the data types (Fig. 6). The data were not preprocessed in any way in order to illustrate the sizes of the two significant principal components (the first PC explains 99.988% of the total variance and the second PC explains 0.004% of the total variance). In Fig. 7 the corresponding loadings are plotted. The first loading vector primarily describes the intensity level, while the second loading substantiates that the differences indeed are very small but still significant. Furthermore, the second derivative shape of the second loading vector at peak locations might indicate peak broadening. This agrees with the broadening effect of the smoothing algorithms.

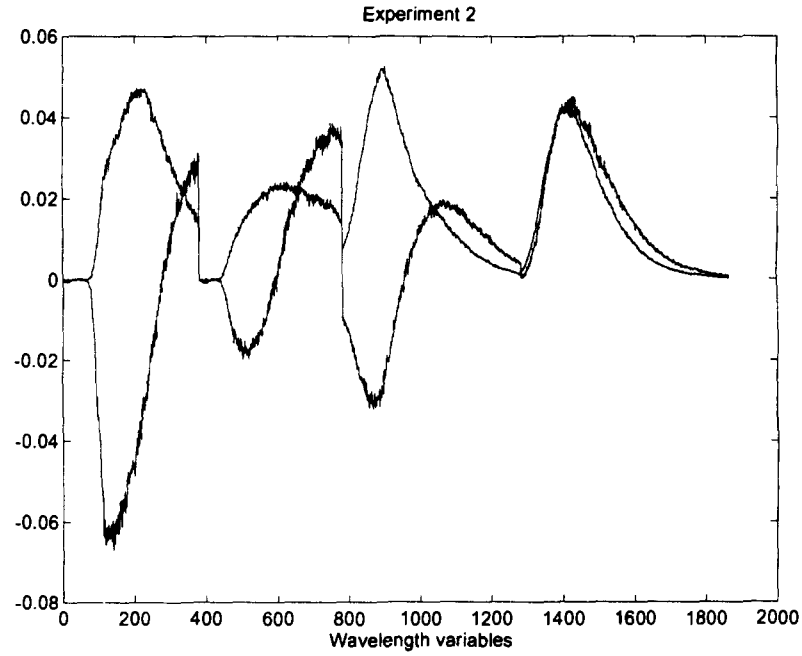
In the section below (3.3) it is shown that instrumental Savitzky-Golay smoothing of data during recording of the spectra produces slightly larger prediction errors than when raw data are used as spectral input into a multivariate calibration model of the sugar concentration. It is concluded that no special smoothing algorithms are needed when the multivariate data approach is used.

### 3.3. Raman scattering

Raman scattering appears as a solvent-dependent emission occurring at longer wavelengths than the excitation wavelength [25]. Furthermore, the Raman frequency shifts are independent of the excitation frequency [25]. This can be a problem in classical univariate calibration if the spectral region of the analyte of interest is overlapped by the Raman scattering caused by the actual solvent (in this case water). A way of circumventing the influence of the Raman scattering is [25] (a) to subtract the blank spectrum from each of the sample spectra, assuming that the Raman scattering is independent of the analyte concentration and that the blank measurement is possible; (b) to employ appropriate filters (if it is possible in the actual case); or (c) to use another excitation wavelength with the risk of loosing relevant analyte information.



(a)



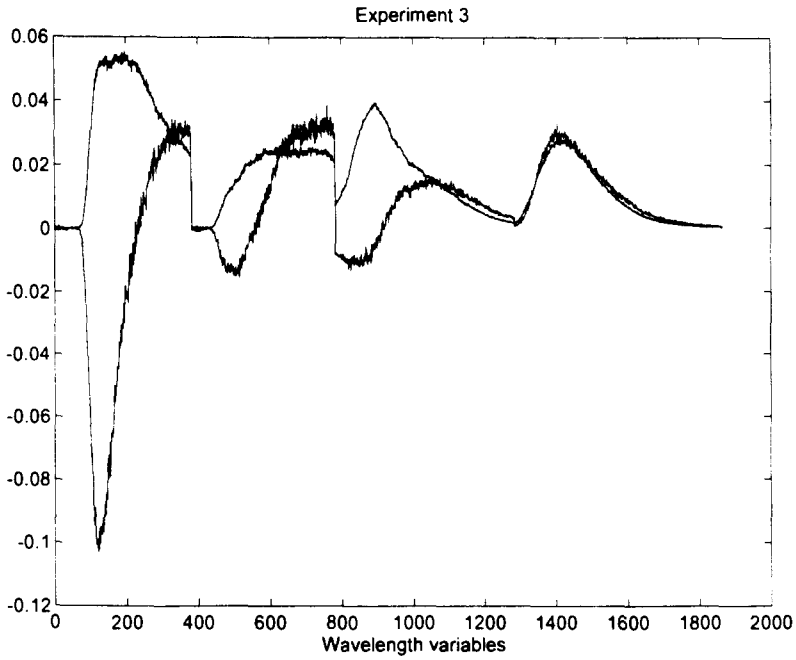
(b)

Fig. 14 (a) and (b).

A multivariate approach to the problems of Raman scattering is to analyse the whole emission spectrum including the Raman scatter. In multivariate calibration the Raman signals are treated as interferent(s) and cause no problems for the multivariate modelling of the analyte emisison spectra. This is illustrated by the following examples.

The emission spectra of 11 solutions of a given refined sugar sample having different concentrations are measured at an excitation wavelength of 300 nm (sample set C). At this excitation wavelength, Raman scattering will occur at around 334 nm, overlapping the emission spectrum of the sample. The fluorescence emission spectra are depicted in Fig. 8. A full cross-validated PLS model with the fluores-

(c)



(d)

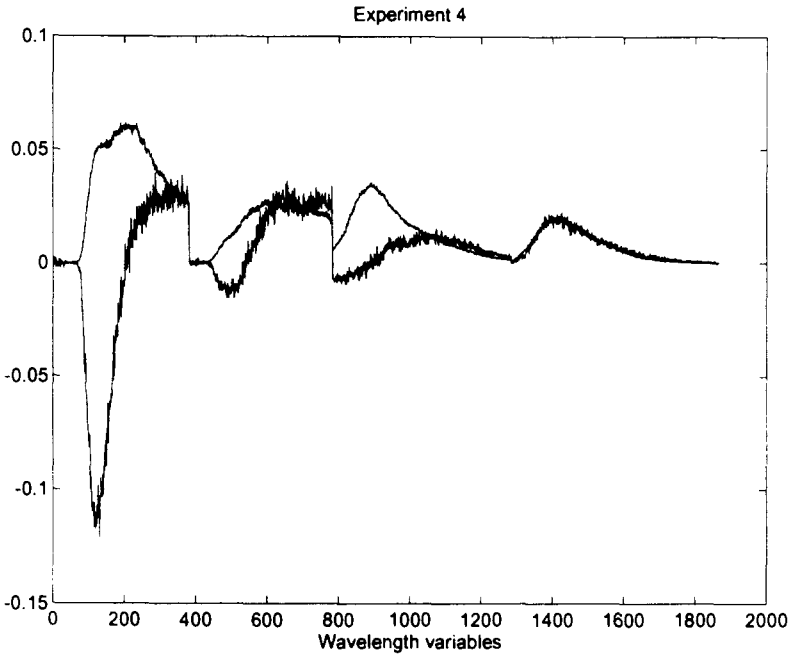


Fig. 14 (c) and (d).

cence emission spectra in $X$ (11 × 451) and the concentrations in $y$ (11 × 1) shows two significant components; the loading weights of the PLS analysis are given in Fig. 9. The Raman effect is seen in both loading vectors, i.e. both components are necessary in a full description of the data set (see Table 1). The PLS model was built without any preprocessing of the data to illustrate how PLS takes into account the Raman scattering. If the data are mean centred, a one-factor solution is achieved due to the fact that the Raman scattering has the same intensity in all the samples. The results are compared with full cross-validated univariate calibration (at emission wavelength, 395 nm) in Table 1(A). The prediction errors obtained when using multivariate models are approximately five times smaller than the error

obtained in univariate calibration, i.e. even in the case of single analyte calibration multivariate modelling should be used. The prediction errors obtained with and without mean centring are of comparable size. In the case of no centring two factors are included in the model to handle the interfering Raman scattering.

The effect of the instrumental Savitzky-Golay smoothing of the raw data during recording of the spectra as input to the PLS model is shown in Table 1(B). The prediction errors obtained by this data preprocessing are slightly larger than when using raw data in the PLS model (see smoothing of spectra, section 3.2.).

In this one-analyte example (the same sugar solution diluted several times) PLS is capable of predicting the sugar concentrations of the samples without removal of the Raman signal in advance; in the case of several analytes being present and possible interaction between the Raman signals and the analyte signals, it is a necessity to use multivariate methods.

### 3.4. Selection of excitation wavelengths

The selection of a subset of excitation wavelengths is essential in order to minimise the time necessary to analyse a chemical sample. It takes approximately 40 s automatically to record one emission spectrum by the OBEY software at a given excitation wavelength (including the adjustment of the excitation monochomator), i.e. to be able to measure at least 20 samples per hour for on-line/at-line purposes, four to five excitation wavelengths have to be chosen. One way of selecting the excitation wavelengths from a large excitation–emission matrix (EEM) is the principal variable [26] (PV) algorithm, which is illustrated by the analysis of a refined sugar sample (sample 1 from sample set DI). An EEM is recorded at the excitation wavelengths 230–350 nm with 10 nm intervals, i.e. 13 emission spectra are obtained in the emission range 245–685 nm (excitation and emission monochromator slit widths were 8.0 nm and 5.0 nm, respectively). Rayleigh scattering peaks are removed from the emission spectra by filling with zeroes. In Fig. 10 a three-dimensional plot of the EEM is depicted. The PV algorithm applied to this EEM determines the optimal subset of excitation wavelengths to be 230 nm, 330 nm, 290 nm and 240 nm. The variances computed explain 60.28%, 33.91%, 3.57% and 0.75%, respectively, of the total variance. In total 98.51% of the original variance is explained. "Optimal" signifies a compromise between variance explained and the precision (see Ref. [26]).

### 3.5. Multivariate calibration of fluorescence spectra

The multivariate calibration of the ash content in sugar samples is important in developing fast on-line/at-line methods for detecting the end-product quality, which among others, is described by the ash content. Clear solutions of 15 refined sugar samples with measured levels of ash content determined at the laboratory of The Danish Sugar Factories (International Commision for Unified Methods of Sugar Analysis, ICUMSA) are analysed by spectrofluorimetry without pH correction.

Table 3
Prediction of ash content. Performance of PLS modelling in the five experiments performed

| | | $10^3$ RMSEP [a] | $10^3$ Bias [b] | $R$ [c] |
|---|---|---|---|---|
| Expt. 1 | (a) | 1.06 | −0.067 | 0.903 |
| | (b) | 1.11 | −0.071 | 0.763 |
| Expt. 2 | (a) | 1.06 | −0.200 | 0.916 |
| | (b) | 1.07 | 0.000 | 0.788 |
| Expt. 3 | (a) | 0.775 | 0.067 | 0.951 |
| | (b) | 1.04 | 0.071 | 0.826 |
| Expt. 4 | (a) | 0.516 | 0.000 | 0.979 |
| | (b) | 0.463 | −0.071 | 0.966 |
| Expt. 5 | (a) | 0.683 | −0.20 | 0.967 |
| | (b) | 0.707 | −0.21 | 0.933 |

Key: (a), All 15 samples; (b), sample 10 left out.
[a] RMSEP = $\sqrt{\Sigma_{i=1}^{N}(C_i^{\text{predicted}} - C_i^{\text{reference}})^2/N}$, where $C_i^{\text{predicted}}$ is the PLS estimated concentration, $C_i^{\text{reference}}$ is the reference value and $N$ is the number of samples.
[b] Bias = $\Sigma_{i=1}^{N}(C_i^{\text{predicted}} - C_i^{\text{reference}})/N$.
[c] Correlation.

Table 4
Ash content reference value and predicted ash content, from PLS modelling of fluorescence spectra measured on sugar samples in experiment 3

| Sample | Reference | Predicted |
|---|---|---|
| 1 | 0.012 | 0.011 |
| 2 | 0.009 | 0.010 |
| 3 | 0.012 | 0.012 |
| 4 | 0.010 | 0.010 |
| 5 | 0.011 | 0.011 |
| 6 | 0.010 | 0.011 |
| 7 | 0.010 | 0.011 |
| 8 | 0.014 | 0.014 |
| 9 | 0.009 | 0.010 |
| 10 | 0.003 | 0.003 |
| 11 | 0.012 | 0.011 |
| 12 | 0.012 | 0.011 |
| 13 | 0.008 | 0.007 |
| 14 | 0.010 | 0.011 |
| 15 | 0.008 | 0.008 |

Based on the results in the previous paragraph, the chosen excitation wavelengths are 230 nm, 240 nm, 290 nm and 330 nm, with the respective emission wavelength ranges 245–435 nm, 255–455 nm, 305–555 nm and 345–635 nm. The four emission spectra are concatenated, i.e. one sample is associated with 1864 spectral data points.

Five experiments were performed to investigate the influence of excitation monochromator and emission monochromator slit widths as well as the sugar concentration on the modelling of the ash content (Table 2). Rayleigh scattering becomes very broad when the slit widths are fully open, so the region of each recorded emission spectrum in experiment 5 is reduced by 30 nm (see Table 2).

Raw emission spectra from the 15 measurements in experiment 3 are illustrated in Fig. 11, and raw emission spectra of sample 4 from all five experiments, including a replicate from experiment 4, are given in Fig. 12. For qualitative comparison of the spectral shapes produced under different experimental conditions, a PCA was performed on each of the data sets. In Figs. 13a–13e, score plots (score 1 against score 2) including two replicates in experiment 4, are shown. The orders of samples are much alike in experiments 1 and 2 and in experiments 4 and 5, and it is seen that experiment 3 fits into the shift of the samples between experiments 2 and 4. The amount of variance explained by the first two significant factors are 81.6%, 86.4%, 89.9%, 91.3% and 93.7%, respectively. Figs. 14a–14e shows the first two loading vectors of each experiment. The shapes of the loading vectors are much alike, indicating that the experimental conditions give rise to the same kind of measured emission spectra. Moreover, it is observed that the noise level increases with decreasing slit widths and that it increases with decreasing sugar concentration.

A quantitative measure is obtained by looking at PLS models of the ash content. For each experiment, a full cross-validated [27,34] PLS model of the ash content is performed. RMSEP, Bias and the correlation coefficient $R$ for all experiments with and without sample number 10 are given in Table 3. Reference values and predictions obtained in experiment 3 are given in Table 4. Sample 10 has a low level of ash content but it is still very well predicted by the PLS models. It should be stressed that the prediction of sample 10 is based on models excluding this sample, i.e. sample 10 is a

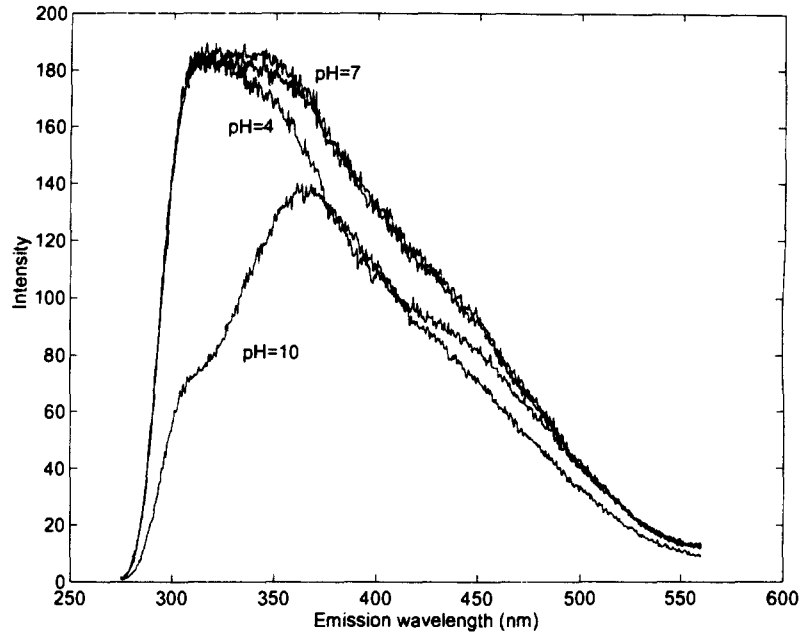

Fig. 15. Emission spectra of a refined sugar sample dissolved in buffer solutions at pH 4, 7, 10. The excitation wavelength is 230 nm. A replicate is made of the sample buffered to pH 7.

"good" outlying sample stabilising the models, as seen when comparing RMSEP and $R$.

From the prediction results it is seen that the selective wavelength information lost by using fully open slit widths is recovered in the signal-to-noise ratio by the employment of multivariate modelling. Furthermore, low concentrations of sugar yield lower prediction errors, indicating some kind of quenching or perhaps a viscosity effect. The conclusion is that the sugar concentration should be within the range 10–20% and the slit widths should be in the middle region of their respective extremes (excitation slit, 2.5–15 nm; emission slit, 2.5-20 nm). However, it is a very small difference in correlation ($R$) from the middle region slits to the fully open slits.

It is demonstrated how the multivariate method PLS is capable of utilising the information in fluorescence spectra despite very different conditions of measurement with respect to slit widths and sugar concentrations. These promising results are confirmed on a larger scale when about 90 refined sugar samples with and without pH correction are analysed [20]. Similar correlations to the ash content ($R = 0.93$) are documented as well as high correlations to quality parameters like amino-nitrogen and colour.

### 3.6. The pH and corrected spectra

*pH*

It is well known that the spectral shapes of fluorescing components are pH-dependent. This is confirmed in Fig. 15 where the difference in spectral shape obtained at pH 4.0, 7.0 and 10.0 for a given refined sugar sample is illustrated. The measurement at pH 7.0 has been repeated to show the uncertainty of a sample replicate. In ref. [20] comparisons of prediction errors from a large sample set of refined sugar sampes (about 90) dissolved in pure water and in buffer solution at pH 7.0 are presented. The value of $R$ with respect to the ash content is shown to be 0.92 with pH correction and 0.93 without correction. Even though the difference in prediction error is insignificant, the spectral shapes are systematically different in the two experiments, indicating that the information content is changed when going from water solutions to buffered solutions. It may be that some sample and process information is lost on pH correction of the solutions.

*Corrected emission spectra*

Throughout this presentation, uncorrected spectra are recorded in all experiments. When the fluorescence spectra are corrected [36] all spectra are wavelength multiplied by the same correction spectrum which stems from a stan-

dard measurement of, for example, a quinine sulphate solution, which introduces a reproducible small bias because of the inherent limitations in the choice of the standard. In multivariate calibration methods like PCR and PLS, however, a more general optimal weighting of wavelengths is found by the algorithms, so the present choice is not to correct the fluorescence spectra before they are introduced to the multivariate calibration model. In the area of transferring spectra between instruments, the method of piecewise direct standardisation using several transfer standards is much more preferable than using corrected spectra based on only one standard sample.

It should be noted that if resolution methods like rank annihilation factor analysis [9] (RAFA) and the generalised rank annihilation method [37] (GRAM) are employed and a library search of the resolved fluorescence spectra is performed, the measured spectra have to be corrected to compare with library spectra.

## 4. Conclusions

The outlined multivariate problems with regard to the evaluation of different data, all due to complex natural samples, individual spectrofluorimeters, Raman scattering, smoothing algorithms, and selection of excitation/emission wavelengths, may in part explain why fluorescence spectroscopy is a tool infrequently chosen by the analytical chemist as opposed to other spectroscopic methods. It has been demonstrated that by the use of multivariate chemometric methods, these problems are circumvented and fluorescence spectroscopy can be an important tool for the analytical chemist.

The NIR analogy of predicting reference values from spectra has been transferred to spectrofluorimetry, by determining the ash content in refined sugar samples from concatenated emission spectra. The potential of autofluorescence in this context is enormous for the analysis of all kinds of chemical, biological and environmental samples including on-line/at-line process analyses [21]. A further enhancement of spectrofluorimetry can be obtained by utilising the instrumental methods of polarisation and synchronous fluorimetry in combination with multivariate statistics and by the development and implementation of N-way algorithms [37–40] capable of dealing with the higher-order data structures produced by a full excitation–emission scan.

# On-line flow injection analysis of volatile organic compounds in seawater by membrane introduction mass spectrometry

N. Kasthurikrishnan, R.G. Cooks *

*Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393, USA*

Received 27 December 1994; revised 14 March 1995; accepted 14 March 1995

**Abstract**

The combination of flow injection analysis with membrane introduction mass spectrometry for analysis of volatile organic compounds (VOCs) in seawater is examined and is compared to measurements made in water. Membrane introduction mass spectrometry is performed using a benchtop ion trap mass spectrometer, and characterization of various aspects of the flow injection and ion trap combination for the analysis of volatile organic compounds (including anthropogenic halocarbons) in seawater is carried out. The analyte responses are shown to be linear over several orders of magnitude (e.g. for methylene chloride), independent of seawater pH (e.g. for chlorobenzene) and independent of matrix effects for the VOCs studied. A comparison of the performance of a microporous (Teflon) membrane with that of an amorphous silicone membrane is made, and the former is shown to provide lower detection limits which are in the parts-per-trillion range (300 ppt for chlorobenzene, 190 ppt for *trans*-1,2-dichloroethene). The microporous membrane provides faster response times by a factor of four to five for relatively more polar compounds, such as chlorobenzene. An analysis of a seven-component mixture demonstrates the ability of this on-line combination to allow multicomponent analysis of mixtures of some complexity.

## 1. Introduction

Seawater is a complex mixture consisting of many salts, suspended silts, various dissolved gases, living matter and decaying organic material. The analysis of various organic species in marine water is of great importance for monitoring water quality [1]. Among the volatile organic compounds (VOCs), anthropogenic and biogenic halocarbons are significant indicators of pollution in environmental samples. These halocarbons are usually present at low (ppb) levels in seawater samples, and may thus require a preconcentration step before identification and quantification by conventional techniques, such as gas chromatography/mass spectrometry. Common methods of preconcentration include the dynamic headspace technique which uses cold trapping [2] and liquid–liquid extraction with organic solvents [3]. Although preconcentration can extend absolute and relative detection limits, and may be essential for determinations of some compounds, it requires increased analysis times and carries the risk of contamination, and the possibility of loss of trace analytes. In addition, volatile halocarbons produced by marine organisms may interfere with the analysis [4]. Membrane introduction mass spectrometry (MIMS) is a specific yet sensitive method of analysis of volatile compounds in water, which often does not require a preconcentration step and which nevertheless displays good molecular specificity. As such, it may prove useful for the analysis of a whole range of VOCs in seawater.

*SSDI* 0039-9140(95)01588-4

MIMS has been applied to environmental [5–7] and bioreactor monitoring [5,7,8], and the technique has been reviewed [5,9,10]. MIMS is a relatively simple method which is flexible in terms of choice of membranes (amorphous silicone or microporous Teflon among many others, sheet or capillary configuration), is easily automated, has fast response times, and exhibits a response that is linear over a few orders of magnitude. It can be adapted to various sample introduction systems, especially flow injection analysis (FIA), and to different mass analyzers (triple quadrupole, ion trap and sector instruments inter alia). If a number of VOCs are present in the sample, the response is the sum of those for the separate analytes. When MIMS is used with a triple quadrupole mass spectrometer capable of tandem mass spectrometry, the spectra of individual compounds can be recorded [23]. A major drawback of the MIMS technique is the difficulty of analyzing compounds with molecular weight >300 dalton and polar compounds.

A number of improvements in the analysis of organic compounds by MIMS have been reported. For example, MIMS experiments have been shown to provide detection limits in the ppt (ng $l^{-1}$) range, i.e. at levels below the limits of quantification set by the US EPA [10] for a number of VOCs in aqueous solutions examined without preconcentration. On-line monitoring of chloroethylenes generated in bioreactors at low ppt levels has also been reported [11]. Detection of some organic compounds in air at ppt levels has been achieved using a membrane/jet separator interface and ion trap mass spectrometer [12]. On-site analysis of environmental pollutants in complex matrices has been demonstrated using a membrane inlet mass spectrometric method in a mobile analytical laboratory [13]. For example, a toluene concentration of 58 ppm and a trichloroethylene concentration of 30 ppb were measured in a contaminated ground water sample. Recently, stored waveform inverse Fourier transform (SWIFT) methods of selective ionization in the ion trap have been combined with MIMS to further improve detection limits. Measurements have been made in the ppq range in the ideal cases of toluene and dichloroethylene in pure aqueous solutions [14]. All of the above establish that MIMS can be used to analyze at least some VOCs at very low levels. Thus, MIMS is an attractive choice for analyzing VOCs in seawater, and indeed Bauer and Solyom have already presented data on these samples [15]. A direct insertion capillary probe fitted with a silicone capillary membrane, a 1 ml flow injection sample volume and an ion trap mass spectrometer were used to study 59 VOCs at the ppt level. Analysis of VOCs in seawater samples (Atlantic Ocean at Dayton Beach, FL) produced good quality mass spectra and showed no matrix effects.

There are a number of MIMS configurations in existence [16–18], among which the more recently introduced versions have yielded the lowest detection limits. In one of the earlier interfaces, the membrane was located at some distance from the mass spectrometer and the analyte solution was in contact with the membrane [16]. Although this configuration was employed for various successful applications, the vapor phase transport of the permeate led to the drawbacks of poor response times, memory effects, and analyte dilution problems. This led to modified versions of MIMS interfaces in which the membrane was located within a probe which could be inserted into the ion source of the mass spectrometer [17]. The probe could be fitted with either a sheet membrane or a capillary membrane. Slivon et al. were the first to pneumatically assist the transport of the analyte from a remote membrane into the mass spectrometer [19]. This concept was incorporated in a later membrane/jet separator combination which used a jet separator to provide enrichment of the analyte [18]. One of the advantages of this configuration is that the membrane is easily accessible. Studies on membrane inlet geometries by LaPack et al. have shown improved rates of permeation for a configuration where the sample flows on the inside and the permeate gas flows on the outside of a capillary membrane, as opposed to the reversed configuration [20]. A recent membrane/jet separator combiantion which uses this configuration requires lower sample flow rates for optimum analyte response [21]. Thus, the newer versions of membrane interfaces promise equal or lower detection limits with reduced analysis time, and these systems may be well suited for the analysis of VOCs in seawater samples. The highly sensitive ion trap mass spectrometer is an appropriate choice of analyzer for this type of experiment.

One concern in analyzing VOCs in seawater samples using a membrane and an ion trap mass analyzer is the corrosive nature of seawater and the possibility of membrane clogging.

Hence, special care was taken to minimize sample volumes using FIA to provide sample to the membrane for short periods of time as a narrow plug. As many as 12–15 samples per hour can be determined with FIA using an alternating standard/sample cycle (with a custom-built FIA unit [22]), as opposed to a rate of a few samples per hour in continuous aspiration experiments in which equilibrium response is measured. Although some loss is suffered in terms of signal magnitude, it is more than compensated for by the increased speed of analysis, high reproducibility, absence of clogging, and automation capability offered by FIA. The choice of FIA in combination with MIMS for analyzing VOCs in seawater was therefore made.

In this work we characterize various aspects of the analysis of VOCs (including anthropogenic halocarbons) on-line in a seawater matrix. Of particular interest is the effect of the seawater matrix on signal response, response times, and detection limits of VOCs. The effects of pH, flow rate, and sample volume on signal response are also studied. A few volatile organic compounds in seawater are quantified with two types of capillary membranes (microporous and silicone) and a comparison between the membranes is made. To facilitate this comparison, a seven-component mixture in seawater is analyzed.

## 2. Experimental

### 2.1. Instrumentation

A Finnigan (San Jose, CA, USA) ITS 40 quadrupole ion trap mass spectrometer was used for all experiments. This instrument has been modified to accommodate a two-stage analyte enrichment system (membrane/jet separator) described elsewhere [21]. The operating conditions of the ion trap were 50 °C manifold temperature, 80 μA filament current, electron impact ionization, and 25 ms ionization time. Data were acquired by scanning at 2 s per scan over the $m/z$ range of 40–160 using the ITS 40 data acquisition system.

### 2.2. Membrane interface

The membrane (4 cm in length) is encased in a 3/16″ stainless steel tube in a coaxial arrangement. All experiments were performed by flowing the analyte solution through the membrane while passing helium gas over its surface in the opposite direction [21]. The capillary membranes used were of two types: silastic and microporous. The dimensions of the membranes were 0.635 mm i.d. ± 1.19 mm o.d. for silicone (Dow Corning, Midland, MI) and 1 mm i.d. × 1.8 mm o.d. for the microporous PTFE (2 μm pore size, Anspec, Ann Arbor, MI). The ends of the silicone membranes were soaked in *n*-hexane prior to assembly for a tight fit onto the fluid transport lines.

### 2.3. Jet separator assembly

The coaxial membrane assembly is connected to a glass jet separator (Finnigan, San Jose, CA, USA, Part No. 10008-40010) which is connected to a mechanical vacuum pump (Alcatel, Kurt Lesker, Clairton, PA, USA, Model M2008A). This helps to enrich the permeate stream in the analyte by removing helium and water. The flow of helium is controlled by a variable gas flow controller of the Finnigan ITS 40 system. Higher pressures of helium gas led to the formation of bubbles due to helium gas permeation to the solution side of the membrane, and lower pressures led to reduced signal intensity. Thus, an optimum helium pressure (nominal 5 psi) was maintained throughout the experiments. A 51 cm stainless tube (1.588 mm o.d. × 0.762 mm i.d.) connected the jet separator interface to the ion trap via the GC transfer line and a Teflon front ferrule was used for sealing. The introduction of samples was carried out with the help of a custom-built FIA unit [22].

### 2.4. Heating assembly

The jet separator and the membrane assembly were heated individually by programmable heater controllers (Omega Engineering Inc., Stamford, CT, Model CN(*) 20). The jet separator and the membrane assembly were heated using 1/4″ adhesive heating tape (Clayborn, Roseville, CA, Model K16) and an 8″ × 8″ Kapton insulated heater (Omega Engineering Inc., Stamford, CT), respectively. Optimum temperatures for the jet separator and the membrane assembly were 150 °C and 80 °C, respectively [21].

### 2.5. FIA system

A schematic diagram of the FIA system is given elsewhere [22]. Plugs of solutions of desired volume were injected into a stream of carrier solution (water) by a Waters (Milford, MA) Filter Acquisition Module (FAM, Model 000024). The volume of the sample loop was 250 μl for some studies and 1 ml in the case of others. The FAM contains a TTL controllable sample/standard switching valve and a Rheodyne six port HPLC sampling valve (Biochem Valve Corporation, East Hanover, NJ). All the valves are controlled manually by a custom-built FIA control unit. In this unit, sample or standard could be loaded and injected by depressing a switch; no syringes were needed for loading purposes. The water, sample, and standard streams were maintained at a flow rate of 1–1.2 ml $min^{-1}$ for most of the experiments, except when the effect of flow rate was of interest. An Ismatec multichannel peristaltic pump (Cole-Parmer, Niles, IL) was used for maintaining flow rates between 1 and 1.2 ml $min^{-1}$, and a Masterflex pump (Cole-Parmer, Niles, IL) was used for the flow rate effect study.

### 2.6. Sample preparation

Commecially available reagents were purchased from Mallinckrodt (St. Louis, MO) or Fisher (Pittsburgh, PA) and were of analytical reagent grade. In all cases, aqueous solutions of VOCs were prepared by dissolving 1 ml of the commercially available reagent in 100 ml of methanol (stock solution), followed by serial dilution in water and seawater. VOCs dissolved in water (deionized water) were used as standards, and solutions in seawater constituted the sample. The seawater used a synthetic material prepared according to ASTM standard specifications for ocean water substituents (D1141-52).

## 3. Results and discussion

Optimization of the FIA-MIMS experiment was sought for the effects of flow rate, sample volume, membrane length and temperature. Previous studies using FIA with direct insertion probes have shown the flow rate to be at an optimum around 1 ml $min^{-1}$ [23]. In contrast, continuous monitoring experiments are often performed at higher flow rates to minimize boundary layer effects at the membrane surface. The present membrane/jet separator assembly showed no significant flow rate effect from 1 to 6 ml $min^{-1}$. The flow rate independence of FIA-MIMS offers flexibility of sample, carrier, standard and reagent volume. In order to simplify sample handling, the flow rate was maintained at 1.0–1.2 ml $min^{-1}$ for all experiments.

The volume of the sample loop plays an important role in experiments with short sample plugs introduced by FIA. In an FIA-MIMS system, the analyte signal increases with the sample volume, until equilibrium is achieved. Based on such studies, a range of sample volumes of 250 μl–1 ml was determined to be the optimum for analyzing VOCs in seawater. The optimum membrane temperature, jet separator temperature and membrane length were determined to be 80 °C, 150 °C and 4 cm, respectively [21].

Since the pH of seawater may vary, an attempt was made to study the effect of pH. The seawater pH was adjusted by adding sodium hydroxide and the range of pH 7–12 was examined. Fig. 1 shows results obtained using a silicone membrane and 100 ppb chlorobenzene solution. The analyte signal intensity is found to be almost independent of seawater pH. Studies on seawater by Bauer and Solyom also indicated no pH effect, except when organic acids and bases are present in the sample [15]. Microporous membranes show a similar lack of pH effect, and based on these results no pH adjustment is deemed necessary in the case of real samples.

Seawater matrix contains dissolved electrolytes of very high ionic strengths, and an important step in developing methodology for analyzing VOCs in seawater samples by FIA-MIMS is to determine matrix effects. In the membrane/jet separator combination, matrix effects may occur owing to the difference in concentration gradient or pressure gradient (seawater vs. helium, water vs. helium). In an FIA-MIMS system, the salts and ionic compounds do not pass through the membrane; nevertheless, in spite of small volumes of sample input, fouling of the membrane might be expected after prolonged operation. This is especially true with microporous membranes, as they are more prone to membrane fouling compared to amorphous membranes such as silicone. In these studies we used microporous

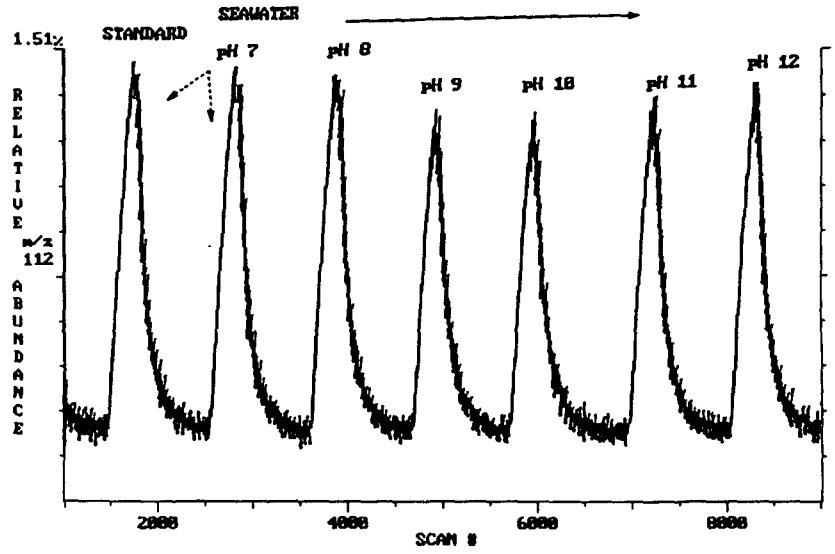

Fig. 1. Response of chlorobenzene ($m/z$ 122) in seawater at different pH (7–12) compared to water solutions. The standard (first peak) constitutes the response for chlorobenzene in water and all other peaks represent the response in seawater. The study was performed using the FIA-MIMS system, 250 µl sample volume, the silicone membrane, 100 ppb chlorobenzene ($m/z$ 112), and sodium hydroxide 0.1 M to adjust the pH.

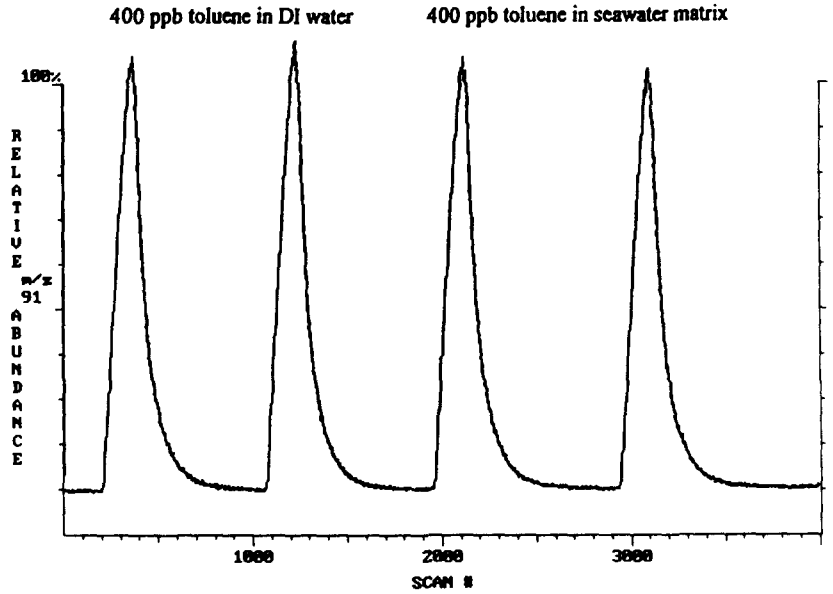

Fig. 2. Response due to toluene in water and seawater. This study was performed using the silicone membrane, 250 µl sample volume and 400 ppb of toluene monitored as $m/z$ 91.

membranes for 2–3 h of continuous operation without encountering clogging problems.

Fig. 2 shows the effect of the seawater matrix on the response of toluene using a silicone membrane. Two 250 µl injections, both of 400 ppb toluene, in water and seawater were made. This preliminary experiment failed to show any matrix effect. The experiment was repeated with randomly chosen concentrations of toluene (within the linear dynamic range of the ion trap) and no matrix effect was observed. This absence of a matrix effect is noteworthy. Since water and seawater have different solubilities for organic compounds, it would not be surprising for the nature of the mobile phase to have an effect.

In order to explore matrix effects further, an experiment was performed with three analytes (toluene, chlorobenzene, nitrobenzene) of different polarities (nitrobenzene > chlorobenzene > toluene). Each analyte, dissolved in water and then in seawater, was passed across the

membrane until equilibrium was reached. A typical result is shown in Fig. 3. Note that the widths of the peaks in this experiment have no particular significance; equilibrium was established making the peak heights the significant parameter. In each of these cases the analyte showed modest effects due to differences which may be associated with analyte polarity. These could be analogous to some of the salt effects observed in a reverse-phase LC system [24]. The change in the polarity of the mobile phase upon addition of salts may cause the analyte signal to increase or decrease depending on the ionic strength of the solution. In these experiments, salt concentrations were such as to decrease the analyte signal for the less polar compounds. Nitrobenzene, the most polar analyte, was least affected by seawater, whereas

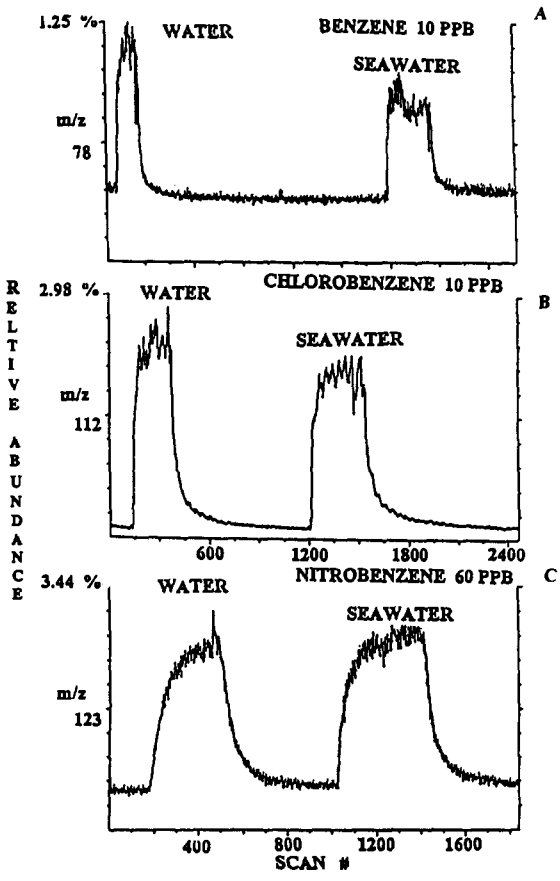

Fig. 3. (A) Response obtained for benzene (10 ppb, $m/z$ 78) in water and seawater with continuous aspiration and a microporous membrane. (B) Response obtained for chlorobenzene (10 ppb, $m/z$ 112) in water and seawater with continuous aspiration and a microporous membrane. (C) Response obtained for nitrobenzene (60 ppb, $m/z$ 123) in water and seawater with continuous aspiration and a microporous membrane. The widths of the peaks carry no significance.

benzene, the least polar, showed the largest reduction in signal. The study was repeated using FIA methods to provide small injection volumes for both silicone and microporous membranes, as shown in Fig. 4. This experiment failed to show any significant change in analyte signal with changes in the analyte and in mobile phase polarity. The lack of matrix effects in the FIA experiment cannot be fully explained because of operating away from equilibrium in the MIMS system, and we are still investigating this effect. Thus, it appears from preliminary studies that no compromise in detection limits or in the speed of the analysis need to be made when analyzing VOCs in seawater with FIA.

Figs. 5 and 6 depict the background subtracted mass spectrum of 100 ppb toluene in water and seawater obtained using an amorphous silicone membrane. The mass spectrum recorded in seawater is similar to and shows slightly better signal to noise characteristics than the spectrum of the same compound in water. One possible reason that the relative abundances of the $(M + H)^+$ ions are not the same is the difference in partial pressure of the analyte in water and seawater.

A typical log–log plot of signal intensity vs. concentration in water and seawater for methylene chloride solutions examined with a microporous membrane by FIA-MIMS is shown in Fig. 7. The data show a highly linear response over several orders of magnitude of analyte concentrations. The lack of difference between the water and seawater calibration of methylene chloride is a further indication of the absence of significant matrix effects. Similar results showing the lack of matrix effects and linear analyte responses over several orders of magnitude were obtained for the other VOCs, and are listed in Table 1.

An attempt was made to characterize and compare the performance of microporous and silicone membranes for a number of analytes. The applicability of FIA-MIMS to a variety of VOCs is evident from Table 1, which lists a few compounds studied, together with rise times and detection limits both in water and seawater using silicone and microporous membranes. It is observed that highly polar compounds give longer response times compared to less polar compounds with silicone membranes. Silicone membranes are hydrophobic and are best suited to the analysis of non-polar compounds, whereas mi-

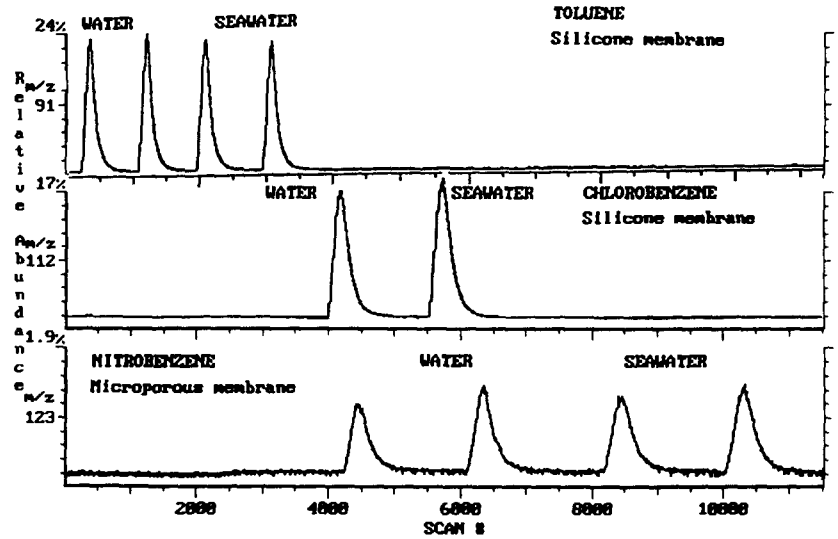

Fig. 4. Responses due to three diffrent analytes (toluene, chlorobenzene, nitrobenzene) in experiments using two types of membrane (silicone and microporous). Plugs of 250 μl injections were made for toluene (500 ppb, $m/z$ 91), chlorobenzene (500 ppb, $m/z$ 112) and nitrobenzene (3 ppm, $m/z$ 123) respectively. The first two peaks for toluene (silicone membrane) and nitrobenzene (microporous membrane) represent the signal for the analyte in water, and the last two represent that in seawater respectively. Only two injections were made for chlorobenzene, one representing the analyte in water and the other in seawater (silicone membrane).

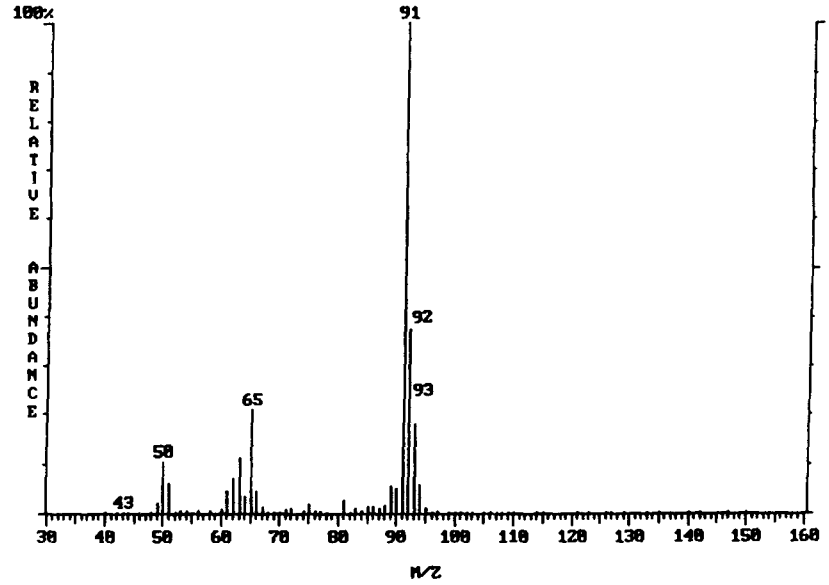

Fig. 5. Background subtracted mass spectrum of 300 ppb toluene ($m/z$ 91) in water using a silicone membrane.

croporous membranes are non-selective and are better suited to the analysis of more polar compounds. As is evident from the detection limit data (based on three times the standard deviation of the blank), non-polar compounds give similar or slightly lower detection limits (1–1.5 times) when using microporous membranes compared to silicone, whereas with polar compounds the microporous membrane yields far lower detection limits (4–5 times) than silicone. The improved detection limits achieved using microporous membranes for polar compounds is a result of poor transmission by silicone membranes, rather than any selectivity for polar compounds by microporous membranes. A universal aspect of microporous membranes is their speed of analyte transfer. Another important aspect of microporous membranes is their ability to pass sufficient amounts of water to facilitate the use of water as the CI gas [23].

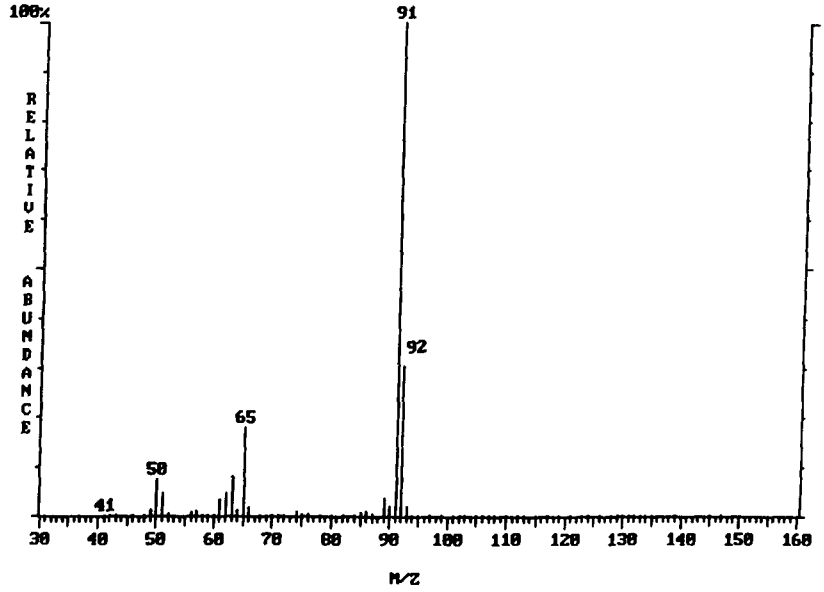

Fig. 6. Background subtracted mass spectrum of 300 ppb toluene ($m/z$ 91) in seawater using a silicone membrane.

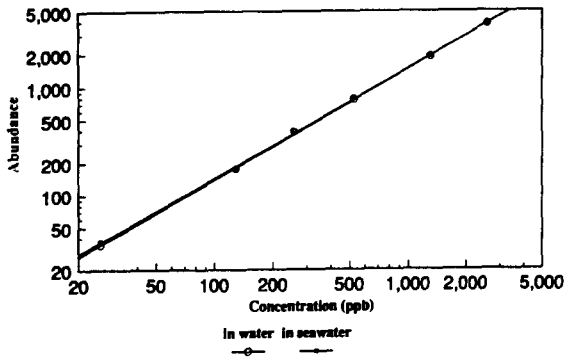

Fig. 7. Log–log plot of ion abundance ($m/z$ 49) vs. concentration for methylene chloride in water (○) and in seawater (■) using a microporous membrane.

Ion chromatograms obtained with a carefully chosen mixture containing seven volatile organic compounds are illustrated for silicone (Fig. 8) and microporous (Fig. 9) membranes. Since the detection limits of methylene chloride, *trans*-1,2-dichloroethylene, benzene, toluene, chloro-benzene, carbon tetrachloride, and 1,1,2-tri-chloroethene are all around 1 ppb, a mixture with concentrations close to the limit of quantification (10 ppb) was prepared in water and seawater. The mixture was chosen so as to contain both polar and non-polar compounds, and experiments with silicone and microporous membranes were carried out under identical conditions on the same day. To further facilitate the comparison, the acquisition scan rate and the mass scan range were held constant. Since the custom-built FIA unit has an RSD of 5–8% and the temperature of the membrane assembly varies by at least $\pm 3$ °C, any small variations in analyte signal intensities can be neglected. The different analyte responses are due to their varying membrane

Table 1
Comparison of detection limits and rise times for amorphous silicone and microporous membranes. Rise times are calculated based on 10–90% of the peak height

| Compound | Silicone membrane | | | | Microporous membrane | | | |
|---|---|---|---|---|---|---|---|---|
| | Detection limit | | Rise time | | Detection limit | | Rise time | |
| | Water | Seawater | Water | Seawater | Water | Seawater | Water | Seawater |
| | (ppb) | | (s) | | (ppb) | | (s) | |
| Toluene | 0.9 | 0.9 | 64 | 65 | 0.6 | 0.6 | 40 | 39 |
| Benzene | 0.5 | 0.5 | 31 | 29 | 0.3 | 0.3 | 18 | 19 |
| *trans*-1,2 Dichloroethene | 0.4 | 0.4 | 26 | 24 | 0.2 | 0.2 | 16 | 17 |
| Carbon tetrachloride | 1.2 | 1.0 | 38 | 38 | 0.7 | 0.7 | 16 | 16 |
| Chlorobenzene | 1.0 | 1.1 | 105 | 102 | 0.3 | 0.3 | 15 | 17 |

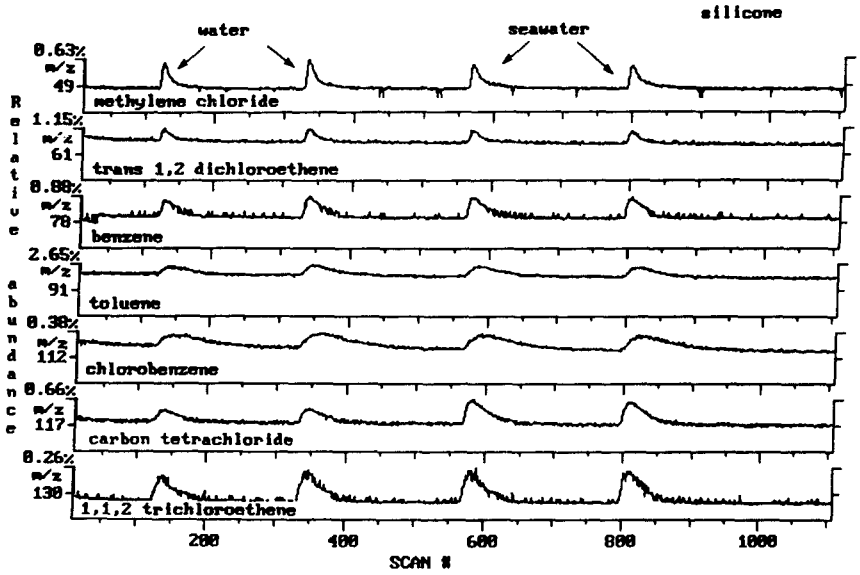

Fig. 8. Ion chromatograms recorded for a seven-component mixture (methylene chloride, *trans*-1,2-dichloroethylene, benzene, toluene, chlorobenzene, carbon tetrachloride and 1,1,2-trichloroethene) at 10 ppb, each using a silicone membrane and 1 ml sample volume. The arrows mark the introductions of the water and seawater samples.

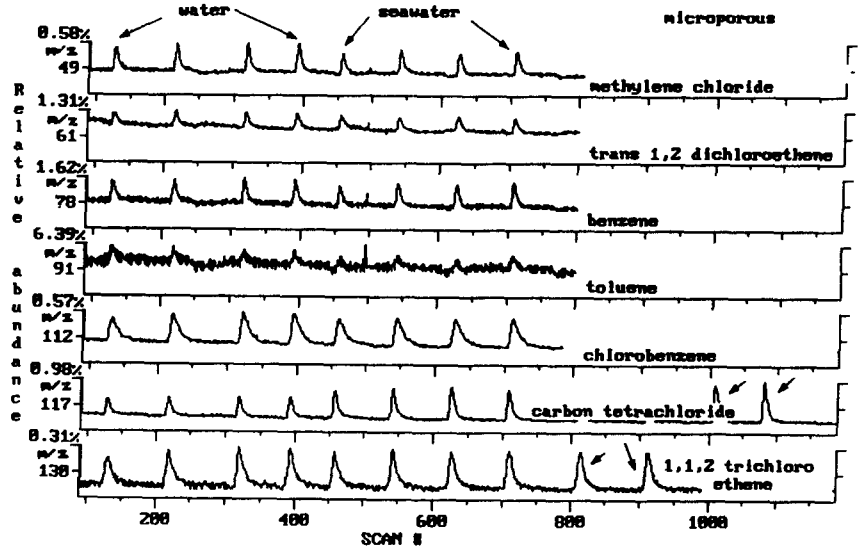

Fig. 9. Ion chromatograms recorded for a seven-component mixture (methylene chloride, *trans*-1,2-dichloroethylene, benzene, toluene, chlorobenzene, carbon tetrachloride and 1,1,2-trichloroethene) at 10 ppb, each using a microporous membrane and 1 ml sample volume. The arrows indicate the injections of water and seawater samples. The last four arrows, two for 1,1,2-trichloroethene and two for carbon tetrachloride, represent each analyte prepared in water in the absence of the other six components.

permeabilities and not due to differences in ionization cross sections. The non-polar compounds methylene chloride, *trans*-1,2-dichloroethene, benzene, toluene, and carbon tetrachloride respond much faster than the relatively polar compounds chlorobenzene and 1,1,2-trichloro-ethene when using the silicone membrane. Thus, the more polar the compound, the slower the response for the silicone membrane. The ion chromatogram for the same mixture recorded using a microporous membrane shows a reduced analysis time and this allowed 12 sample injections in the time requested for four injections with the silicone membrane.

Another possible matrix effect studied was that of one organic analyte on the signal of another. Previously, such analyte matrix effects were observed in the study of binary and ternary solutions performed with a direct inser-

tion probe using a TSQ 4500 mass spectrometer [23]. Under EI conditions, hardly any matrix effect occurred, but using CI a small matrix effect was observed, especially if the proton affinities of the analytes varied significantly. To confirm the lack of mutual matrix effects among the analytes, standards of carbon tetrachloride and 1,1,2-trichloroethylene were prepared in deionized water. Carbon tetrachloride and 1,1,2-trichloroethylene were chosen to represent a non-polar compound and a relatively polar compound respectively. Two injections of each standard were made, as shown in Fig. 9 (the last two peaks of carbon tetrachloride and 1,1,2-trichloroethylene). The signal intensities obtained are identical to that of the mixture, indicating no mutual matrix effects among the analytes for these compounds.

## 4. Conclusion

For the range of analytes and concentrations examined, no preconcentration or sample work up is required for seawater analysis by MIMS. The present results are consistent with and extend the seawater studies of Bauer and Solyom [15]. An attractive feature of the present FIA-MIMS is the simplicity of the experimental set up. The membrane accessibility, availability of various types of membranes, extended operation without membrane clogging, and detection limits in the ppb–ppt range pave the way for the in situ analysis of VOCs in seawater samples. Microporous membranes offer lower detection limits and give faster response times than silicone membranes. By increasing the sample volume, using microporous membranes, and optimizing membrane length, temperature and flow rate, one can achieve detection of specific analytes in the lower ppt range. If FIA-MIMS is combined with SWIFT in addition to the extremely low LODs ($pg\,l^{-1}$), one should be able to perform MS/MS to confirm the identity of minor components in seawater. In addition, the methods used here may prove useful for monitoring of VOCs in real environmental samples and industrial effluents of high ionic strengths.

**Abstract**

Chrome azurol S immobilised on XAD-2 has been used in this study as a reagent phase for the development of an optical fibre Al(III) sensor. Using a kinetic approach, this sensor was able to give a linear response in the Al(III) concentration range of $1.3 \times 10^{-5}$–$2.0 \times 10^{-4}$ M with a limit of detection of $1.0 \times 10^{-4}$ M. The optimum responses were obtained at pH 6.0 and when the solution was stirred. The sensor response was found to have a repeatability and reproducibility of 1.6% and 5.8%, respectively. The results obtained for Al(III) determination in aqueous sample were in good agreement with those obtained using graphite furnace-atomic absorption spectrometry.

## 1. Introduction

In the past, immobilised reagents have been widely used as preconcentrating agents in analytical detection schemes where the analytes were generally eluted prior to the quantitation step [1]. With a growing interest in the area of chemical sensing using optical fibre, immobilised reagents are now used as a reagent phase in the development of such sensors. The reagents are normally adsorbed onto, chemically bonded to, physically entrapped in or electrostatically attracted to the support. The immobilised reagent is then coupled to the distal end of the fibre.

The performance of the immobilised eriochrome cyanine R on XAD-2 when used as a reagent phase in the development of a flow-cell type optosensor [2] and a probe type sensor [3] has been previously described. In this paper, we report the potential of immobilised chrome azurol S (CAS) as a reagent phase in the development of a probe type sensor.

## 2. Experimental

### 2.1. Reagent

An ammonia acetic buffer of pH 6.0 was prepared as follows. About 50 ml of glacial acetic acid (AR) was mixed with approximately 500 ml of distilled deionised water. Sufficient ammonia solution (s.g. 0.88, AR) was then added to adjust the pH to 6.0 (approximately about 50 ml required), and the mixture was diluted to 1 l with distilled deionised water.

An aluminium standard solution of $4.0 \times 10^{-4}$ M was prepared by dissolving the required amount of aluminium potassium sulphate, $Al_2(SO_4)_3K_2SO_4 \cdot 24H_2O$ in deionised water and then diluting the solution with deionised water to 250 ml. 0.019 g of cetylpyridinium chloride (CP) was dissolved in deionised water and the solution made up to 250 ml volume with deionised water to give a

CP standard solution of $2.0 \times 10^{-4}$ M. A solution of CAS (Fluka) was prepared daily in the buffer.

### 2.2. Instrumentation

An aluminium probe incorporated in an optical fibre reflectance measurement rig was used in this study to measure the reflectance of the probe before and after reaction with aluminium. The design of the probe used in this study was the same as described previously [3].

Graphite furnace-atomic absorption spectrometry (GF-AAS) was performed on a Perkin-Elmer 3100 model for atomic absorption measurement of the aluminium samples. The wavelength was set at 309.3 nm. Pyrolytic graphite coated graphite tubes were employed and a hollow aluminium cathode lamp was used as a light source.

### 2.3. Procedure

Adsorption was used in this study to immobilise the reagents onto a solid support. This technique is the most convenient method of immobilisation, since it is exceedingly easy to perform, merely requiring stirring of the reagent and the support. Weak forces such as van der Waals forces and hydrogen bonding may act to immobilise the dye onto a substrate.

The absorbent materials used in this work include the Amberlite XAD series of porous polymers (XAD-2, XAD-4, XAD-7 and XAD-8) and anion exchange resins (Dowex 1-X8 (Cl), IRA-400(Cl), IR-45(OH)). All the solid supports used were supplied by BDH.

Prior to use, the XAD resins had to undergo a pretreatment process, since they were supplied impregnated with ammonium chloride to prevent the formation of mould during storage. The XAD resins were washed thoroughly with distilled water, soaked in acetone and finally thoroughly washed in distilled water again. The ion exchange resins were first washed using acetone and then thoroughly washed with distilled water. All the solid supports were used as supplied without further grinding.

The adsorption of the reagents onto the solid supports was investigated qualitatively using an aqueous CAS solution of $2.0 \times 10^{-4}$ M. The reagent was immobilised alone in the presence of CP and as its aluminium ternary complexes. In the former, 10 ml of distilled water, 30 ml of CP and 30 ml of CAS solution were added to approximatley 1 g of solid support and stirred for about 5 h at room temperature. In the latter, the same procedure was repeated, but instead of distilled water, 10 ml of $2.0 \times 10^{-4}$ M aluminium solution was added. A sample of the solid support with immobilised reagent was then removed from the supernatant liquid, washed with deionised water and left to dry in a desiccator. The solid support, which bound the reagent firmly and at the same time retained the properties of the reagent as in its solution form, was considered the best.

The reflectance measurement was carried out by the use of a kinetic approach where the signal was measured 3 min after placement of the probe in the aluminium solution. The measurements were expressed as a reflectance difference, which is defined as the difference between the reflectance of the aluminium complex and that of the immobilised reagent alone (in the presence of CP), both recorded at the same measurement wavelength (635 nm).

The use of repeatability and reproducibility terms to express variations in probe response has been suggested by Alabbas et al. [4]. The sensor repeatability refers to the successive runs made using a single sensor to evaluate discrepancies in its response. The sensor reproducibility refers to the discrepancies in response between individual members of a batch of similarly constructed sensors. The repeatability and reproducibility of optical fibre sensors are two of its important characteristic features and were studied in this work at an aluminium concentration of $2.0 \times 10^{-4}$ M.

The response of the probe was optimised by studying the effects of pH, stirring of the solution and reagent concentration. The influence of stirring was studied by comparing the response of the probe towards the same concentration of aluminium when the solution was stirred and unstirred. The effect of reagent loading on the probe response was studied using immobilised reagents prepared from different reagent concentrations. The time of immobilisation (5 h) and stirring speed were maintained constant.

The effect of foreign ions was studied by introducing different amounts (moles) of interfering ions to the sensing probe. The degree of interference of these ions was evaluated with reflectance measurements, recorded in the presence and absence of the interfering ion in the determination of a given concentration ($2.0 \times 10^{-4}$ M) of aluminium.

For determination with GF-AAS, three different samples of known concentration (Table 2) were prepared in the laboratory. These samples were diluted 100 times, and 20 μl of the diluted sample was injected into the graphite furnace. The reading (peak height) was recorded at a wavelength of 309.3 nm. The calibration graph was prepared in a similar way using a standard aluminium solution ranging from $1.3 \times 10^{-5}$ to $8.0 \times 10^{-4}$ M.

## 3. Results and discussion

The Amberlite XAD series of porous polymers gave better results than ion exchange resins, since they could make available the reagent functional groups to form a complex with aluminium ion. The colour change of the immobilised reagents after reaction with aluminium was noted to be similar to that in solution (from red to blue). The reagent could also be successfully immobilised on the anionic exchange resin, but the changes in the reflectance signals in presence of aluminium were noticed to be very small. Among the XAD series, the highest reflectance change between the immobilised reagents and its complexes was observed for XAD-2. Therefore, XAD-2 was chosen for further study as a solid support for the immobilisation of CAS.

XAD-2 is an aromatic hydrophobic absorbent which has a styrene–divinylbenzene cross-linked structure [5]. In an adsorption process, XAD-2 will selectively adsorb water soluble organic substances. The hydrophobic portion of the organic substance is preferentially adsorbed while the hydrophilic portion of the molecule will remain oriented in the aqueous phase. The interaction between XAD-2 and CAS may involve the interaction depicted in Fig. 1, since colour changes were observed to be similar to that in solution. Further, as shown in Fig. 2, the optimum pH

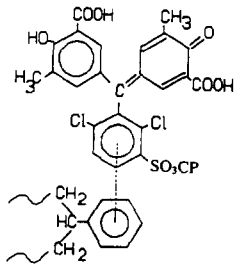

Fig. 1. The possible interaction of XAD-2 with CAS.

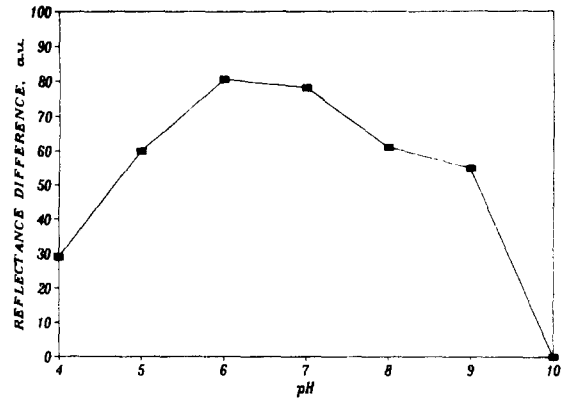

Fig. 2. The effect of pH on the ternary complex formation of aluminium with immobilised CAS in the presence of cationic surfactant.

value for complex formation was found to be identical to that in the solution. Quinolin-8-*o*-sulphonate was found to behave in the same manner when electrostatically immobilised on Amberlite CG-400 resin [6]. From this observation, it can be stated that the interaction between the immobilised reagent and XAD-2 had no effect on the functional groups of the reagent which was used in the formation of complexes with aluminium. Because of competition between hydrogen and aluminium ions for the organic ligands at low pH values and competition between hydroxyl and organic ligand ions for aluminium ions at high pH values, Driscoll and Schecher [7] reported that aluminium–organic complexation is generally at a maximum in the acidic to neutral pH range.

Fig. 3 shows the reflectance spectra of the reagents immobilised alone in the presence of CP and as their aluminium ternary complexes. The decrease in reflectance at all wavelengths in the range 520–720 nm is due to the forma-

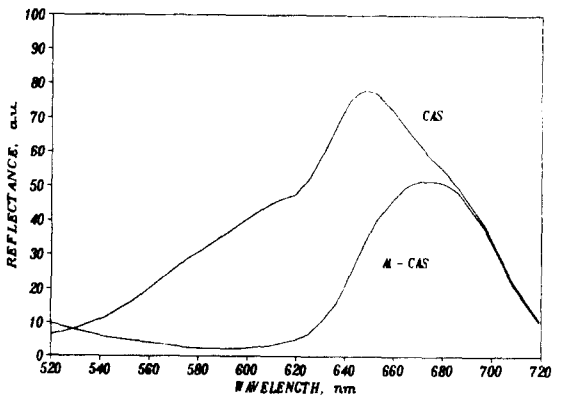

Fig. 3. Reflectance spectra of the reagent CAS immobilised alone in the presence of CP and as its ternary complex with aluminium.

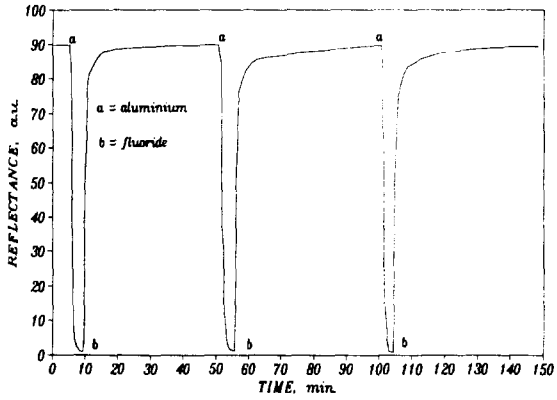

Fig. 4. The alternate reaction of immobilised CAS with aluminium and fluoride solution (regenerating solution).

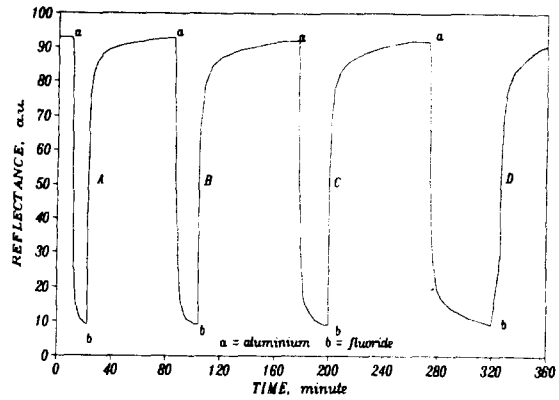

Fig. 5. The response of immobilised CAS to four different concentrations of aluminium, i.e. $6.4 \times 10^{-3}$ M (A), $3.2 \times 10^{-3}$ M (B), $1.6 \times 10^{-4}$ M (C) and $7.8 \times 10^{-4}$ M(D).

tion of a coloured aluminium complex which strongly absorbs the incident light and thus attenuates the intensity of the reflected light. Reflectance measurements were made at a chosen wavelength at which a large change in reflectance signal with aluminium concentration was observed. Therefore, a wavelength of 635 nm was used for measuring reflectance signal from the immobilised CAS.

Fig. 4 shows the reflectance response (measured at a single wavelength of 635 nm) of the immobilised CAS after reaction with aluminium solution and generation with fluoride solution. As can be discerned, regeneration of the reagent was time-consuming. The long regeneration time for CAS can be explained by the fact that it has a bulk chemical structure, since it contains two chlorine atoms. As fluoride has the same ionic charge as chlorine, repulsive forces due to chlorine will be experienced by the fluoride ions approaching the complex to react with aluminium. This repulsion will slow down the regeneration process of the reagent and a longer time is required for regeneration. Eriochrome cyanine R, which has exactly the same structure as CAS except for the two chlorine atoms, was found to be easily regenerated in a shorter time when the same regenerating solution was used [2].

The response of immobilised CAS towards different aluminium concentrations is shown in Fig. 5. As for immobilised eriochrome cyanine R [2], the response was independent of the aluminium concentration used since different concentrations of aluminium were found to give the same final response. The time taken to reach the steady state response, however, depended on the concentration of aluminium. A kinetic approach, whereby the reflectance difference of the system is measured at a fixed time, was therefore used in further studies to characterise this reagent. Fig. 6 shows the responses of immobilised CAS towards different concentrations of aluminium at different reaction times. Reaction times greater than 3–4 min would limit the determination to within a very narrow range.

Stirring the aluminium solution has a significant effect on the response of the probe. As shown in Fig. 7, the rate of increase of the reflectance difference is much higher when the aluminium solution is stirred compared to that without stirring. Stirring the aluminium solution could facilitate the diffusion of aluminium ions across the nylon mesh to the reagent, and therefore speed up the reaction between the reagent and the aluminium. Without stirring, however, the diffusion depended solely on the concentration gradient across the membrane.

The effect of the reagent concentration on the probe response was studied using different concentrations of the reagent during its immobilisation. These immobilised reagents were

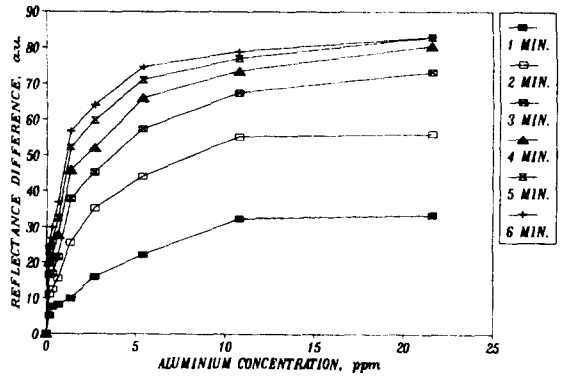

Fig. 6. The response of immobilised CAS to different aluminium concentrations at different reaction times.

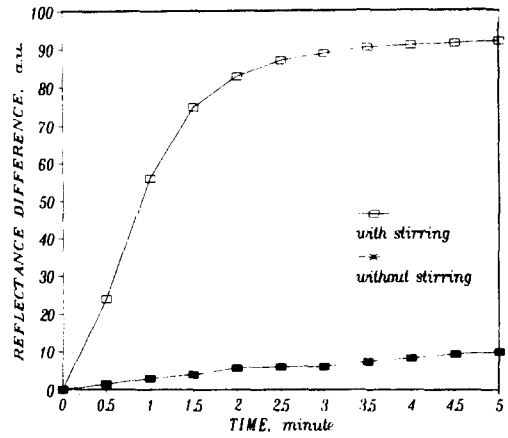

Fig. 7. The effect of stirring on the probe response based on immobilised CAS.

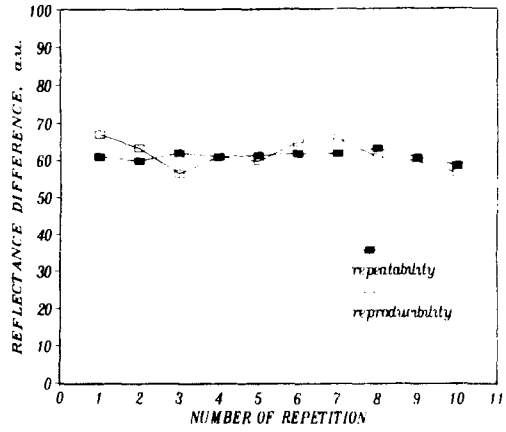

Fig. 9. Reproducibility and repeatability of the aluminium probes based on immobilised CAS.

used for reaction with aluminium of $6.4 \times 10^{-3}$ and $2.0 \times 10^{-4}$ M concentrations. The results, shown in Fig. 8, indicate that the higher the reagent concentration used for immobilisation, the higher the reflectance signal obtained for the same concentration of aluminium. A similar observation was made for blood pH sensor based on compound 5-91 immobilised on cellophane [8]. As indicated in Fig. 8, the amount of reagent in the matrix can be controlled by choosing the appropriate concentration of reagent during immobilisation. No reagent concentration higher than 0.01 M was studied, since at room temperature a saturated solution is produced. Higher solution of concentrations of reagent allowed more of it to be immobilised, resulting in the reaction of more aluminium ions to produce a higher reflectance signal. Although it seems desirable to immobilise as much indicator as possible in order to obtain an intense signal, it is advisable to immobilise just enough indicator to obtain a reasonable signal. For a pH sensor, for example, too heavy a loading of the matrix with the reagent was found to result in lower $pK_a$ values, worse reproducibility of the response and a strong background whose intensity did not vary with pH [9].

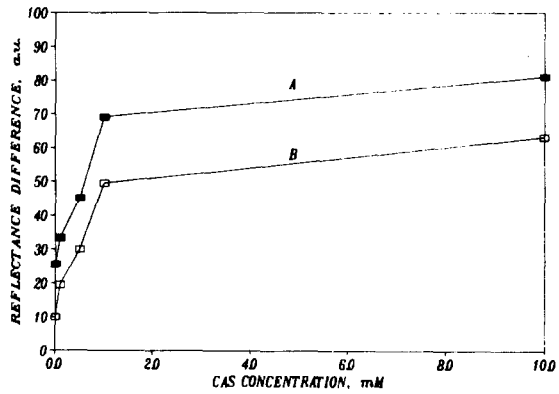

Fig. 8. The effect of concentration of the reagent used for immobilisation on the probe response based on immobilised CAS, at two different aluminium concentrations, i.e. $6.4 \times 10^{-3}$ M (A) and $2.0 \times 10^{-4}$ M (B).

Fig. 9 shows that the repeatability of the probe was always better than its reproducibility. The repeatability of the probe was found to be 1.6% whereas the reproducibility was found to be 5.8%. In the literautre, there is hardly any comment on the effect of variation in construction parameters of the sensor, e.g. the indicator concentration for immobilisation, the amount of polymeric support matrix and the particle size of the matrix. According to Alabbas et al. [4], the variation in the response of an optical fibre sensor has been noted to arise from two main sources, i.e. construction variation and operational variation. The former includes the variation caused by the quantity of matrix, concentration of reagent, particle size and shape of the probe, while the latter is due to variations in analyte concentration. They concluded that the major source of non-uniformity of response lay in the sensor construction (6.5–9.5%) rather than sensor operation (2.6%).

Table 1 shows the results obtained for anion and cation interference studies during aluminium determination. Generally, negative interference was observed for anions whereas cations showed positive interference. Negative interference can result from the reaction of the interferent with the analyte being determined, leading to an incomplete reaction [10]. The most common type of such an interference is the complexing of the analyte by the interfer-

ent. Since most of the anions used in this study have a tendency to react with aluminium ions to form a colourless complex, a negative type of interference is expected. Positive interferents normally react directly with the reagent along with the analyte and produce coloured species, so that high absorbance is obtained.

Interference from anions such as fluoride, oxalate, EDTA and tartrate is expected, since they form a stable complex with aluminium [11]. As the stability constant (in logarithms) for EDTA, citrate and oxalate complexes with aluminium was reported to be 16.5, 8.1 and 6.1, respectively [12], the degree of anion interferent is expected to vary in the order EDTA > citrate > oxalate. No interferent from hydroxide ions was observed even if its concentration was 100 times higher than of aluminium. This indicates that, at least at the pH used in this study, the tendency of the aluminium to hydrolyse is very small in the presence of the ligands. As well as anions, interference from iron and beryllium ions is also expected, since the ionic radius of the former is similar to that of the aluminium ion [13]. The use of eriochrome cyanine R (which has a similar structure as CAS) solution for the determination of beryllium has been reported in the literature [14].

EDTA showed the highest interference effect, clearly because it has six potential sites for binding with the aluminium ion (the four carboxyl groups and the two amino groups, each of the amino nitrogens with four unshared electrons). The complex formed between EDTA and aluminium is sufficiently stable, which undoubtedly results from the multiple complexing sites within the molecule by which an aluminium ion is effectively surrounded and isolated from the solvent molecules [15].

It should be noted that although a reasonable number of ions in this study were found to interfere with the aluminium determination, not all of these are expected to be present in real water samples. Of these, fluoride and iron ions are normally present in water samples with aluminium. Fluoride ions originate from the salt used to treat the water, whereas iron is present in the sample because of its natural occurrence. One should remember, however, that aluminium is the third most common constituent of the Earth's crust after silicon and oxygen. Thus, the possibility of having a very high concentration of these interfering ions compared to that of aluminium in the water samples is less. At a 1:1 ratio of these interfering ions to aluminium, the interference was shown to be slight and can be overcome by the use of conventional methods, such as applica-

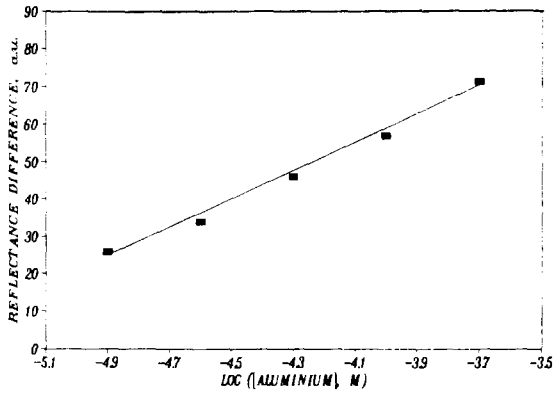

Fig. 10. The dynamic range of aluminium concentration determined by a probe based on immobilised CAS. The reflectance difference was measured 3 min after placement of the probe in the aluminium solution.

tion of a masking agent, or more practical methods, such as synchronous derivative spectrometry. Capitan and co-workers [16,17] have demonstrated the use of the latter type of methods as providing a means for the simultaneous determination of many metal ions.

Fig. 10 shows that the aluminium probe based on immobilised CAS produced a linear relationship between the reflectance difference and the logarithm of aluminium concentration in the range of $1.3 \times 10^{-5} - 2.0 \times 10^{-4}$ M.

An attempt was also made to study the reliability of the results obtained using these probes by comparison with well-established methods such as GF-AAS. The results obtained are shown in Table 2. Although the standard deviation of the reflectance method is found to be slightly greater than that of GF-AAS, the results obtained show very good agreement with the aluminium concentration determined in the sample using the optical sensor.

The limit of detection, defined as the concentration of sample that yields a detector response equal to three times the detector noise, was found to be $1.0 \times 10^{-5}$ M.

Table 2
Determination of aluminium in aqueous sample using both GF-AAS and optical fibre aluminium sensors based on immobilised CAS. With the latter, the reflectance difference was measured 3 min after placement of the probe in aluminium solution

| Concentration | $[Al^{3+}]$ determined by GF-AAS (M) | $[Al^{3+}]$ determined using the CAS probe (M) |

| $3.0 \times 10^{-4}$ | $3.0(\pm 0.2) \times 10^{-4}$ | $3.3(\pm 0.3) \times 10^{-4}$ |
| $8.0 \times 10^{-5}$ | $8.0(\pm 0.2) \times 10^{-5}$ | $7.8(\pm 0.4) \times 10^{-5}$ |
| $2.0 \times 10^{-5}$ | $2.0(\pm 0.1) \times 10^{-5}$ | $2.2(\pm 0.4) \times 10^{-5}$ |

## 4. Conclusion

Immobilised CAS on XAD 2 provides good reagent phases for the development of an optical aluminium sensor. The sensor based on this reagent showed optimum response at pH 6.0. The amount of reagent loaded into the matrix was also found to have a significant effect on the response of the probe. The probe appears to be ideal for measurement of the aluminium content in a dynamic system, since it produced a very high reflectance signal when the solution was stirred.

The same steady state response was produced by the probe irrespective of the aluminium concentration used. The time taken to achieve this response is, however, dependent on the aluminium concentration, leading to the use of the kinetic method for quantification of the measurements. This study has also shown that on reaction with aluminium, the reagent produced a reproducible signal especially when the same probe was used in the measurement. Major interferences were observed from fluoride, EDTA, oxalate, citrate, tartrate, $Be^{2+}$, $Cu^{2+}$ and $Fe^{3+}$.

A linear relationship was obtained between the log of the aluminium concentration and the reflectance signal at aluminium concentrations in the range of $1.3 \times 10^{-5}$–$2.0 \times 10^{-4}$ M, with a limit of detection of $1.0 \times 10^{-5}$ M. The results obtained for aluminium determination in unknown samples using the reflectance method were in good agreement with those obtained using the GF-AAS technique.

# Extraction spectrophotometric determination of mercury(II) using thiacrown ethers and Bromocresol Green

Bahruddin Saad [1], Salah M. Sultan *

*Department of Chemistry, KFUPM Box 2026, King Fahd University of Petroleum and Minerals, Dhahran 31261, Saudi Arabia*

Received 19 September 1994; revised 27 December 1994; accepted 5 January 1995

**Abstract**

A reasonably sensitive and highly selective spectrophotometric method for the determination of mercury(II) is proposed. The method is based on the extraction of the ion-associate formed by a mercury(II) thiacrown ether cationic complex with Bromocresol Green as the anionic counter-ion using chloroform as the extracting solvent. The effect of thiacrown ethers of different cavity sizes, namely 1,4,7,10,13-pentathiacyclopentadecane (PTP) and 1,4,7,10,13,16-hexathiacyclooctadecane (HTO), the thiacrown ether concentration, the extracting solvent, the bromocresol green concentration and the aqueous phase pH on the extraction were investigated. Measurement of the absorbance at the $\lambda_{max}$ (420 nm) of the extracted ion-associate reveals that Beer's law is obeyed over 0.5–12.0 ppm mercury(II) for both ligands. Slight interference from copper(II) and cadmium(II) is exhibited by the PTP ligand, while HTO is negligibly affected by these metal ions. Strong interference from silver(I) is evident for both ligands while alkali, alkaline earth and other transition metals tested posed negligible interference. Analysis of mercury in synthetic complex mixtures was satisfactory

## 1. Introduction

The toxicity of mercury compounds have caused widespread public concern as a result of several widely publicized disasters, beginning with the Minamata, Japan incident in 1950 where 111 people were poisoned after eating seafood containing high levels of methyl mercury (27–102 ppm dry wt) [1–3]. This incident and others [2,3] took place in limited areas where there had been heavy localized pollution with mercurial compounds.

Several analytical methods have been developed for the determination of mercury. Currently the most frequently used method for ultra-trace mercury analysis in environmental samples is flameless atomic absorption spectrophotometry [2,4,5]. Other analytical methods reported include spectrophotometry [2,5–8], fluorimetry [2,9] titrimetry [10], neutron activation analysis [11], optical [12] and electrochemical [2,13] methods. These methods, with the exception of neutron activation analysis, are generally suitable for the determination of trace levels of mercury. The spectrophotometric methods reported are mainly based on ion-associates of mercury(II) complexes, using reagents such as Bindschedler's Green [7], tetraphenylpyridine [6], Crystal Violet [5] and triazenes [8]. Although these methods are generally sensitive, they lack selectivity, making them only suitable for the analysis of simple samples.

Our strategy to minimize the interference problem is to exploit the complexing- and ion-

discriminating ability of thiacrown ethers, which is a class of crown ethers where the donor oxygen atoms on the macrocycle ring have been replaced either partially or totally with sulfur atoms. Since sulfur atoms are soft Lewis bases, thiacrowns are expected to have strong affinity for soft Lewis acids such as mercury(II) [14–18]. Furthermore, thiacrown ethers can form stable cationic complexes with class b metal ions as classified by Ahrland et al. [14], which in turn can be reacted with an appropriate anion to form an ion-associate. Upon extraction with suitable solvents, a spectrophotometric procedure for mercury(II) may be viable. Although some mercury(II) complexes of thia ethers have been isolated and characterized [15,16], there are only a few studies concerning their analytical applications. In this paper we report the investigation of using a five- (**I**) and six- (**II**) membered ring sulfur macrocycle for the extractive spectrophotometric determination of mercury(II), using Bromocresol Green as the counter-ion.

(II) n = 2, HTO

## 2. Experimental

### 2.1. Apparatus

Absorbance measurements were made with a Perkin-Elmer Lambda 5 UV/VIS spectrophotometer in conjunction with a quartz cuvette of 10 mm path length. pH measurements of the aqueous phase were performed with a Corning combination glass electrode (Catalog no. 476530) connected to a Corning pH meter Model 21. Unless otherwise stated, all data are the average of two determinations mainly carried out on different days.

### 2.2. Reagents and chemicals

All inorganic chemicals used were of analytical reagent grade. Sulfates of chromium(III), copper(II), manganese(II), iron(II), zinc(II), cadmium(II), nitrates of nickel(II), lead(II), silver(I) and chloride of cobalt(II) were used. Chloroform stabilized with ethanol of purity at least 99.9% was supplied by Fluka, while Bromocresol Green, sodium salt was purchased from Allied Chemical. The thiacrown ethers **I** and **II** were obtained from Aldrich. Deionized, distilled water was used throughout.

### 2.3. Stock solutions

Mercury(II) standard solution (0.01 M) was prepared by dissolving 0.340 g mercury(II) nitrate (BDH) in 2.0 ml of 2 M nitric acid and diluting to 100 ml with water. The solution was standardized as suggested by Vogel [19].

Bromocresol Green stock solution (0.010 M) was prepared by dissolving 0.360 g of the sodium salt in water and dilution to 50 ml with water.

Thiacrown ether stock solution (0.010 M) were prepared by dissolving 0.1503 and 0.1804 g PTP (**I**) and HTO (**II**), respectively, in chloroform and diluting to 50 ml. Ligand solutions were diluted from the stock solution daily. Macrocyclic sulfur ligands are highly toxic and should be handled with care.

Buffer solution pH (3.5) was prepared by dissolving 100.0 g ammonium acetate in water and adjusting the pH to 3.5 with 7 M hydrochloric acid followed by dilution to 200 ml with water.

### 2.4. Recommended procedure

Aliquots of mercury(II) standard solutions (0.10 or 1.0 mM) were transferred into a series of 125-ml separatory funnels, and 1.00 ml buffer solution (pH 3.5) and 1.00 ml Bromocresol Green solution (1.0 mM). The total volume of the aqueous phase was adjusted to 5.00 ml by addition of distilled water. Finally, 5.00 ml of 0.10 mM thiacrown ether in chloroform was added to each separatory funnel and the contents were shaken for 60 s. The organic phase was allowed to separate from the aqueous phase for at least 120 s and the absorbance of the separated chloroform layer was measured at 420 nm against a reagent blank. Blank solutions were treated in the same manner, except that no mercury(II) was added.

## 3. Results and discussion

### 3.1. Absorption spectra

The absorption spectra of the extracted ion-associates are shown in Fig. 1. Maximum absorption occurred at 420 nm for both ligands and all measurements were made at this wavelength.

### 3.2. Effect of pH

The influence of pH on the extraction was evaluated by measuring the absorbance of 40 ppm of mercury over the pH range 2–6, while keeping the Bromocresol Green and thiacrown ethers solutions constant at 1.0 mM. The pH was adjusted by addition of 1.0 M hydrochloric acid and/or 1 M ammonium hydroxide. Maximum absorbance was obtained for extraction at about pH 3–4.5 for both ligands (Fig. 2). Throughout the studies, an acetate buffer of pH 3.5 was used.

### 3.3. Thiacrown ether concentration

The influence of the ligand concentration on the absorbance signal of the extracted ion-associate was studied with a fixed amount of mercury(II) (2 ppm) and variation of the ligand concentration from 0.050 to 2.0 mM. The results show that the absorbance becomes constant at ligand concentrations of 0.10 mM and above (Fig. 3). To conserve the ligands, studies were conducted with 0.10 mM concentrations for both ligands.

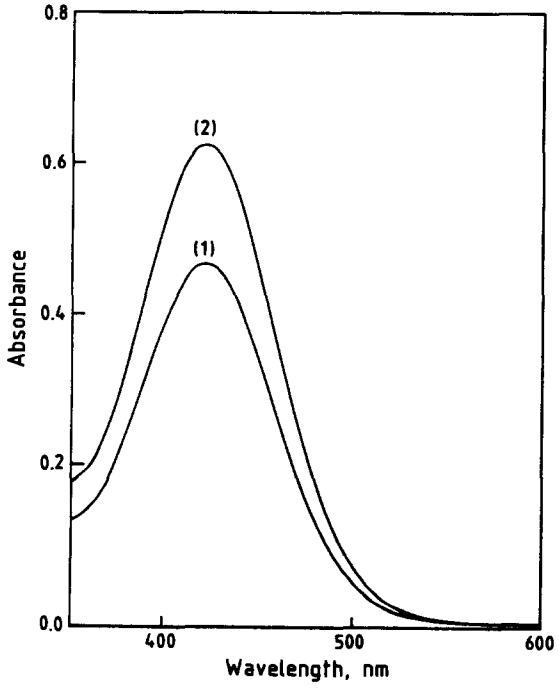

Fig. 1. Absorption spectra of chloroform extracts of thiacrown ether mercury(II)-Bromocresol Green complex. (1) PTP, [mercury(II) = 2.5 ppm]; (2) HTO, [mercury(II) = 4.0 ppm]. Reference: respective blanks.

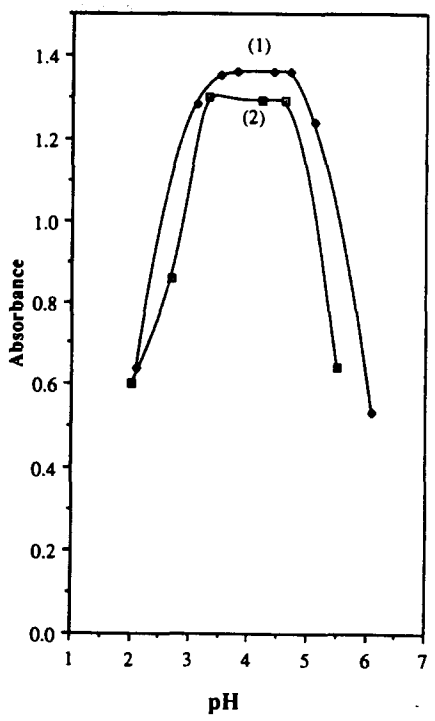

Fig. 2. Effect of pH on the chloroform extracts of thiacrown ether mercury(II)–Bromocresol Green complex, (1) PTP; (2) HTO. Conditions: mercury(II), 40.0 ppm; Bromocresol Green, 1.0 mM; ligand concentration, 1.0 mM.

### 3.4. Bromocresol Green concentration

The superiority of Bromocresol green as a counter-ion for ion-association extraction systems has been demonstrated previously [20,21]. Therefore, the use of other counter-ions was not investigated in this study. The influence of the Bromocresol Green concentration on the absorbance is shown in Fig. 4. For both ligands, the absorbance was constant for counter-ion concentrations of 1.0 mM and above.

### 3.5. Effect of shaking time

Mercury(II) was extracted with shaking times ranging from 30 to 300 s. The absorbance was found to be constant over this time period. A shaking time of 60 s was adopted.

### 3.6. Choice of extracting solvent

Mercury(II) was extracted at pH 3.5 with 1.0 mM Bromocresol Green and 1.0 mM ligand in chloroform, dichloromethane or toluene. The use of a low dielectric constant solvent such as toluene ($\varepsilon = 2.30$) [22], not only resulted in extraction with poor efficiency but also has poor phase separation. The use of chloroform ($\varepsilon = 4.8$) and dichloromethane ($\varepsilon = 9.08$) was satisfactory, probably owing to their higher dielectric constant, which favours extensive ion-pair formation [22]. Chloroform was selected because of its lower volatility.

### 3.7. Precision

The procedure was applied to the repetitive determination of 2.0 ppm of mercury(II) over a period of several days. The relative standard deviation for four determinations was found to be 1.04 and 1.08 for chloroform extractions based on HTO and PTP, respectively.

### 3.8. Calibration graph

The most suitable extraction conditions finally adopted is as follows: ligand concentration (0.10 mM), buffer pH 3.5, Bromocresol Green concentration (1.0 mM), shaking time (60 s), and chloroform as extracting solvent. The results for the extractions based on PTP and HTO are summarized in Table 1. The detection limit, calculated as described earlier [20,23] was found to be similar to that of flame atomic absorption spectrometry (0.14 ppm) [4]. Generally, the analytical characteristics of extractions based on the two ligands are similar.

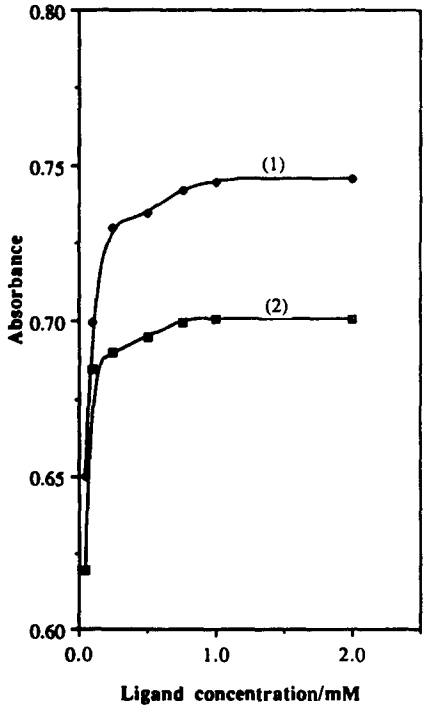

Fig. 3. Effect of ligand concentration on the chloroform extracts of thiacrown ether mercury(II)-Bromocresol Green complex. (1) PTP; (2) HTO. Conditions: mercury(II), 4.0 ppm; pH 3.5; Bromocresol Green, 1.0 mM.

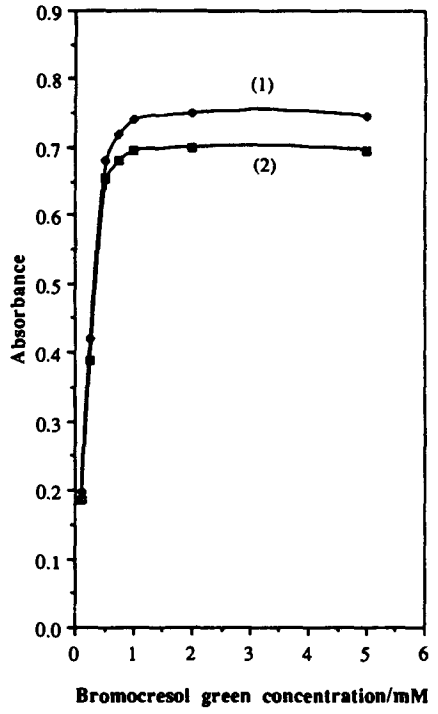

Fig. 4. Effect of Bromocresol Green concentration on the chloroform extracts of thiacrown ether mercury(II)–bromocresol green complex (1) PTP; (2) HTO. Conditions: mercury(II), 4.0 ppm; ligand concentration, 1.0 mM; pH 3.5.

[b] Contains 500 molar each of $Zn^{2+}$, $Pb^{2+}$, $Ni^{2+}$, $Cu^{2+}$ and $Cd^{2+}$.

### 3.9. *Effect of foreign metal ions*

Thiacrown ethers generally exhibit high extractability for mercury(II) and silver ions [13–18,22]. The effect of some alkali, alkaline earth and transition metals on the determination of 2.0 ppm of mercury(II) was examined. Initially, solutions were prepared containing 1000 molar excess of the foreign ions relative to mercury(II). For metal ions that were found to cause interference, a lower concentration of the foreign ion was then prepared. The results are shown in Table 2. The data indicate that neither ligand exhibits interference by alkali and alkaline earth metal ions even though they are present in 1000 molar excess to that of mercury(II). Of the transition metal ions tested, only slight interference from copper(II) and cadmium(II) was observed for 1000 molar excesses of the foreign ions for both ligands. Interference with 500 molar excesses of these two metal ions continue to persist for the PTP ligand, while for HTO, the interference is negligible at this level. Based on the cavity size-ionic diameter considerations alone, copper(II) (ionic diameter 1.44 Å) [22] and Cd(II) (ionic diameter 1.94 Å) [22] would be expected to form stronger complexes with the smaller cavity size ligand PTP than HTO. This is probably reflected in the stronger interference of these metal ions by PTP. However, it must be pointed out that selectivity depends not only on the stability of the metal–ligand complex, but also on the nature of the extracting system [17,18].

Silver ion has a disastrous effect on all mercury(II) determinations. Probably the affinity of the thiacrown ether for silver(I) is as great, if not greater, than that for mercury(II). The cavity of the HTO macrocycle seems to be large enough to accommodate mercury(II) (ionic diameter 2.20 Å) and silver (ionic diameter 2.52 Å) ions [15]. The greater affinity of silver ions towards thiacrowns is well known and several analytical applications making use of this phenomenon have been reported. [13,17,18,24,25]. Thallium ion is also known to have high affinity to sulfur-containing ligands and, therefore, expected to exhibit high interference by using thiacrown in the present spectrophotometric method. Nevertheless, the proposed method is generally superior in terms of selectivity to the other spectrophotometric [5–8] and fluorimetric [9] methods reported earlier. However, the proposed method is considered more sensitive than the cold vapor atomic absorption method with lower detection limits. Moreover, the atomic absorption method suffers interferences from all metallic ions reduced together with the mercury especially if they amalgamate or form stable compounds with mercury, thus rendering our present method more selective. A quantitative comparison of the selectivity is difficult to make due to differences in the methods used for their assessment. Strong interference from cadmium(II), silver(I), iron(II) and copper(II) is evident for the use of crystal violet [5] while the use of tetraphenylpyridine [6] as a spectrophotometric reagent exhibits strong interference from cadmium(II) and silver(I). The use of a triazene reagent for mercury(II) determination, while exhibiting good sensitivity, suffer from interference by from these metal ions and others [8]. Interference from silver(I), lead(II) and manganese(II) is exhibited by the fluorimetric procedure [9].

The good recoveries obtained with the HTO ligand in the determination of mercury(II) in complex mixtures containing 100 (Mixture A) and 500 (Mixture B) molar excess each of

zinc(II), lead(II), nickel(II), copper(II) and cadmium(II) are further testimonials of the good selectivity characteristics of the proposed method (Table 2).

It has been reported that silver(I) picrate forms various complexes with HTO such as Ag(HTO)Pic and $Ag_2$(HTO)$Pic_2$ (Pic = picrate ion) [15]. In contrast, it has been established that mercury only forms a 1:1 mercury–thiacrown complex of the type Hg(HTO) $Pic_2$ [15]. Based on this consideration, the nature of the extracted species in this study is believed to be Hg(PTP)$(BCG)_2$ and Hg(HTO)$(BCG)_2$ (BCG = Bromocresol Green anion).

## 4. Conclusion

A sensitive and highly selective spectrophotometric procedure for the determination of mercury(II) which utilizes thiacrown ethers is demonstrated. The use of PTP and HTO thiacrown ethers yields system with identical sensitivity, but HTO is better in terms of overall selectivity. The proposed method has detection limits comparable to that of flame atomic absorption sepectrometry [4] and selectivity characteristics superior to the reported spectrophotometric [5–8] and spectrofluorimetric [9] procedures for mercury(II) determination. Under the conditions examined, the procedure exhibits serious interference only by silverI) and this method could be applied to mercury(II) determinations in complex silver-free samples, such as industrial effluents.

# A microwave digestion-based determination of low molecular weight organic acids in Bayer process liquor

A.R. Baker, A.M. Greenaway *, C.W. Ingram [1]

*Chemistry Department, University of the West Indies, Mona, Kingston 7, Jamaica*

Received 2 May 1994; revised 28 December 1994; accepted 5 January 1995

**Abstract**

A new technique for the determination of low molecular weight organic acids in Bayer process liquors is reported. The acids are partitioned from acidified liquor into butanol, followed by butylation using microwave heating. This method is both rapid (sample preparation time < 15 min) and capable of detecting acids larger than previously reported in the low molecular weight fraction (up to RMM 176). A standard solution containing 15 acids was used to calibrate the technique and 13 of these acids were detected and quantified in a Bayer liquor sample.

## 1. Introduction

Bauxites which are used in the production of alumina through the Bayer process commonly contain between 0.1 and 0.3% organic carbon [1,2]. Much of this carbon is in the form of structurally complex humic materials. Humic concentrations in the Bayer liquor are considerably higher than those of bauxite owing to the cyclical nature of the process [3]. The continual input of organic matter with the bauxite is counterbalanced by degradation of the humics as a result of the harsh process conditions (140–240 °C, 15 atm, 3.5 M NaOH). Eventually both the humics and their degradation products (polycarboxylic benzoic and phenolic acids, aliphatic acids, oxalate and carbonate) reach equilibrium levels in the liquor.

Detrimental effects on plant efficiency and alumina product quality have been attributed to organic matter in general [4–6] and to some low molecular weight acids in particular [1,2,4,7]. These considerations have lead to attempts to characterize the organic components of Bayer liquor [1,2,7], and to efforts to remove organic matter from the process [4,8,9].

Two methods for the determination of low molecular weight acids in Bayer liquors have been reported. Lever [1] used a complicated procedure for the removal of inorganic components from the liquor, prior to butylation of the acids at 110 °C in a sealed vial for 40 min. A much simpler determination was reported by Guthrie and co-workers, [2], in which acidified liquor was heated with butanol (70 °C, 1 h) in a sealed vial to accomplish butylation.

The butyl esters of acids from formic acid up to succinic acid (RMM 118) were detected by these two methods [1,2], and concentrations were calculated using an internal standard (nonanoic acid) by reference to a standard solution [1]. Good recoveries ( ~ 85%) have been reported for the method of Lever [7], despite the analysis involving evaporation of the liquor to dryness several times and the potential loss of the more volatile acids on each occasion. However, in this later work a more vigorous butylation procedure was used (110 °C, 4 h, pressure bomb) and higher molecular weight acids ($M \leqslant 166$) were detected [7].

In this paper we report an improved procedure for the determination of low molecular weight ($M_r \leqslant 176$) organic acids, based on microwave heating of the butylation mixture, which offers advantages in both reduced analysis time and a greater range of organic acids detected over previous methods.

## 2. Experimental

### 2.1. Apparatus

Microwave digestions were carried out in an unmodified Panasonic domestic microwave oven (Model no. NN-7500), containing a sealed 500 ml vessel filled with water to prevent damage to the magnetron. Reactants were contained in Teflon digestion vessels (Savillex Corp., Minnesota). Butylated fractions were analysed by splitless injection on a Varian 3700 gas chromatograph, fitted with a flame ionization detector. The stationary phase was SPB-1 supported on a 30 m capillary column (i.d. 0.75 mm, film thickness 1 μm), with nitrogen (30 ml/min) as a carrier gas. The injector and detector temperatures were 250 and 270 °C, respectively, while the column was initially held at 50 °C for 4 min and then programmed to 250 °C at 10 °C/min and maintained at 250 °C for a further 7 min. Peak areas were determined by a Hewlett Packard HP3396A computing integrator.

### 2.2. Reagents

Extractions were carried out using very high purity butanol (99.4%). Analar grade HCl and Na $HCO_3$ were used for acidification of the process liquors and neutralisation of the butylated products. Low molecular weight acids used in the calibration of the procedure were of the highest grade available (AnalaR or Reagent). Nonanoic acid internal standard was of 90.0% minimum purity (Sigma Chemical Co).

### 2.3. Procedure

A 5 ml aliquot of an acidic (pH 1) solution containing low molecular weight acids (standard mixtures or acidified Bayer liquor) was shaken with 2 ml of an internal standard solution (1 g/l nonanic acid in butanol) for 5 min. After settling, the butanol phase was transferred to a 120 ml. Teflon microwave digestion vessel with 3 drops of 6 M HCl. The vessel was sealed and butylation of the acids was accomplished by heating the sample in a microwave oven (high setting, power output 1.2 kW). After cooling in an ice bath, the butanol layer was removed and neutralized with $NaHCO_3$. The concentrations of organic acids present were then determined by injection of 1 μl of the butanol fraction into the GC and determination of peak areas.

Apparent extraction efficiencies ($E$) for each component (x) of the standard solution were calculated according to eq. (1).

$$E = \frac{A_x V_{Bu} C_{NA}}{A_{NA} V_{aq} C_x} \quad (1)$$

where $A$ is the peak area of the component or the nonanoic acid, $V$ is the volume of the aqueous or butanol phases and $C$ is the concentration of the component or nonanoic acid. The values of $E$ obtained cannot be considered absolute since the flame ionization detector does not respond equally to each of the components of the mixture. However, this difference in flame response is implicitly corrected for in the calibration procedure enabling component concentrations to be determined quantitatively.

## 3. Results and discussion

### 3.1. Solubility of butanol and nonanoic acid

The loss of the internal standard (nonanoic acid) into the aqueous phase during extraction was examined by butylation of the internal standard solution before and after equilibrium with acidified deionized water. While the slight solubility of butanol in water leads to an increase in absolute peak intensity after equilibration, the integrated peak area per original unit volume of internal standard solution was found to be constant (area/ml before equilibration 5.28%, area/ml after equilibration 5.24%).

The concentration effect on component peak areas resulting from dissolution of butanol has been accounted for explicitly in this work. In all cases the relative properties of butanol and water have been kept constant and it is assumed that the fraction of butanol dissolving is also constant.

### 3.2. Calibration

Solutions containing two or three of the low molecular weight organic acids previously reported to be present in Bayer liquors (Table 1) were used to identify GC retention times for each component and to optimize microwave extraction conditions.

Digestion sequences based on numerous short pulses of microwave energy (10 × or 20 × 20 second bursts at 1 min intervals) and on one prolonged irradiation (3–8 min) were examined. Extraction efficiencies for the test solution components were found to be very similar for the short and long pulse regimes. The shorter extraction time and greater simplicity of the long pulse digestion was, therefore, preferred. Increasing digestion time was found to decrease the apparent extraction efficiencies of the lowest molecular acids (particularly formic and acetic acids) while increasing the yields for the larger acids (pentanoic, glutaric and phthalic) (see Fig. 1). A digestion time of 5 min was found to give the highest average extraction efficiencies over all the components.

Once optimum extraction conditions had been identified, a standard solution containing a number of acids of interest was prepared. The major Bayer liquor acids (formic, acetic and succinic) were initially present at concentrations of ca. 1.2 g/l, while the concentrations of the remaining components were ca. 0.6 g/l. The solution was sequentially diluted to one tenth of its original concentration, with three aliquots being removed for butylation at each dilution.

Table 1
Concentrations of low molecular weight organic acids reported in Bayer process liquors

| Acid | Concentration (g/l) | | |
|---|---|---|---|
| | Ref. [1] | Ref. [2] | Ref. [7] |
| Formic | 2.3 | 3.4, 5.9 | 3.0 |
| Acetic | 4.4 | 6.1, 11.0 | 4.6 |
| Propanoic | | – [a] | 0.1 |
| Butanoic | | – [a] | 0.2 |
| Pentanoic | | | 0.6 |
| Lactic | 0.2 | – [a] | 0.1 |
| Oxalic | 2.5 | – [a] | |
| Malonic | | – [a] | |
| Succinic | 1.4 | – [a] | 9.8 |
| Methylsuccinic | | – [a] | 0.4 |
| Hydroxysuccinic | | – [a] | |
| Glutaric | | – [a] | 0.9 |
| Tricarballylic | | – [a] | |

[a] Reported but not quantified.

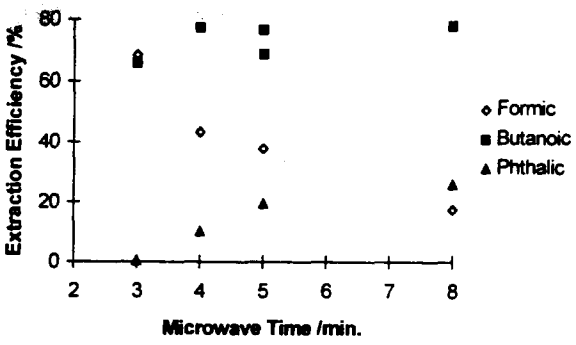

Fig. 1. Variation in extraction efficiency with microwave heating time for formic, butanoic and phthalic acids.

It was noted from preliminary experiments that under some conditions malonic acid underwent decarboxylation during butylation, producing acetic acid. Malonic acid was therefore not included in the standard solution, but was added to an aliquot of it (@0.6 g/l). Dilution of this solution allowed the effect of malonic acid decarboxylation on the apparent acetic acid concentration to be quantified.

The change in component peak area with concentration was quantified by linear regression of the ratio of the component area to that of the internal standard ($R_x$, dependent variable) against concentration ($C_x$, independent variable) (eq. (2)). The results of this regression analysis and the mean and standard deviation extraction efficiencies for each component are shown in Table 2.

$$R_x = m_x \cdot C_x + a_x \quad (2)$$

### 3.3. Calibration results

The extraction efficiencies listed in Table 2 vary between 6.5 and 92.8%, with four compounds having extraction efficiencies below 20%. Of these, the low $E$ value for formic acid is a result of the butylation conditions used (see section 3.2.). It is interesting to note that there is a roughly linear increase in $E$ with carbon number for the $n$-monocarboxylic acids. There is a similar trend for the dicarboxylic acids (malonic, succinic, glutaric), so that the low $E$ value of malonic acid is also probably a consequence of the microwave conditions used. The hydroxycarboxylic acids (lactic and hydroxysuccinic) have the lowest $E$ values (11.8 and 6.5%), as well as high relative standard devia-

Table 2
Results of linear regression analysis on standard solution dilution experiments and component extraction efficiencies.

| Acid | Slope ($m_x$) | Intercept ($a_x$) | $R^2$ | $n$ | Efficiency [$E$ (%)] |
|---|---|---|---|---|---|
| Formic | 0.472 ± 0.016 | −0.023 ± 0.011 | 0.979 | 20 | 16.3 ± 2.3 |

| Tricarballylic | 0.447 ± 0.031 | 0.023 ± 0.011 | 0.921 | 19 | 22.7 ± 4.1 |
| Phathalic | 0.426 ± 0.051 | 0.025 ± 0.018 | 0.796 | 20 | 22.5 ± 6.5 |

$n$ is the number of data points used for regression.
[a] Dilution series carried out in the presence of malonic acid.

tions (16 and 20%, respectively), and it is apparent that these species are not well butylated under the conditions used here.

There is no difference, within experimental error, between the extraction efficiency values determined for acetic acid in the absence and presence of malonic acid (30.0 ± 1.2% absent, 30.1 ± 0.9% present).

Relative standard deviations of the extraction efficiencies are below 5% for most of the components. They are higher for formic acid, lactic and hydroxysuccinic acids and benzoic, pathalic and tricarballylic (1,2,3-propanetricarboxylic) acids. Formic acid elutes on the shoulder of the solvent peak (Fig. 2) and this may account for the variability in its data. Benzoic acid is not completely butylated under the microwave conditions used, and two peaks (one being the unbutylated acid) are seen in the chromatogram (Fig. 2). By using the sum of these two peaks in the calibration the standard deviation is considerably reduced ($E = 95.3 \pm 5.9\%$). However, at low concentrations the smaller, unbutylated acid peak is very difficult to detect and the butylated species only has been used for regression analysis. Incomplete butylation may also be the source of the variability in the phthalic and tricarballylic acid data, although only one peak each was detected for these compounds.

Linear regressions ($R_x$ on $C_x$) of the dilution series data for each acid generally gave $R$-squared values of better than 0.99, with lower values being found for the acids identified above as having high standard deviation extraction efficiencies.

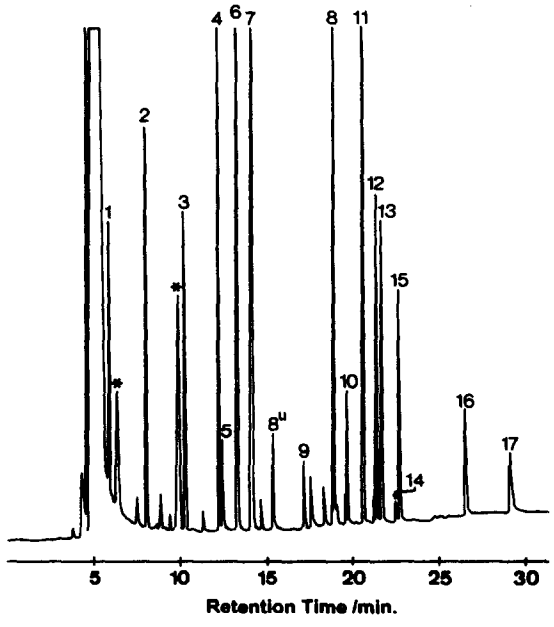

Fig. 2. Chromatogram obtained for the most concentrated standard solution. Peak identities are as follows: 1, formic; 2, acetic; 3, propanoic; 4, butanoic; 5, lactic; 6,3-methylbutanoic; 7, pentanoic; 8, benzoic, 9, 1,1 dibutoxybutane; 10, malonic; 11, nonanoic (internal standard); 12, succinic; 13, methylsuccinic; 14, hydroxysuccinic; 15, glutaric; 16, phthalic; 17, tricarballylic. Peaks marked with an asterisk are solvent impurities, the superscript u indicates that the peak is an unbutylated acid, rather than a butyl ester.

Triplicate analysis.
[a] Calculated using the results of the dilution series carried out in the presence of malonic acid

### 3.4. Analysis of Bayer liquors

A small aliquot (2.5 ml) of Bayer liquor was transferred to a 25 ml beaker and carefully acidified to pH 1 with 6 M HCl. Equilibration and butylation of the sample was then carried out as for the standard solutions and a portion of the butanol fraction was injected into the GC column.

The concentration of each component in the butanol fraction was calculated from the regression data and its concentration in the Bayer liquor was then determined by correcting for the dilution of the liquor upon acidification (eq. (3)). The uncertainty in the concentration measurement was estimated from the standard errors of the regression.

$$C_x^{BL} = \frac{V_2(R_x - a_x)}{V_1 m_x} \quad (3)$$

where $V_1$ is the original volume of Bayer liquor used, $V_2$ is the total volume of acidified Bayer liquor.

The results of the analysis (in triplicate) of a spent Bayer liquor sample are shown in Table 3. In general, the agreement between the measured concentrations of each of the acids in the three samples is very good. The results for tricarballylic acid are an exception to this, with the first sample giving a much higher concentration than the other (1180, 270 and 420 mg/l). The reason for this discrepancy is unclear, although tricarballylic acid did show a relatively high level of variability in the calibration experiment.

The concentrations of formic and acetic acids determined for this sample (mean values 2.70 and 2.96 (3.05*) g/l, respectively) are comparable to those reported for other Bayer liquors (Table 1). The two concentrations calculated for acetic are the same within experimental error, indicating that the malonic acid present in the Bayer liquor has not undergone a significant amount of decarboxylation. The succinic acid concentration of this sample (mean value 1.14 g/l) is very much lower than that reported by Brown, but is similar to that of another liquor (Table 1). These values probably reflect the natural variability of organic acid concentrations in Bayer liquor, which are affected by the quantity and nature of the incoming organic matter as well as plant operating conditions.

Propanoic, butanoic, 3-methylbutanoic, pentanoic and benzoic acids are all present in the sample studied at concentrations lower than 100 mg/l. The latter four acids are all close to their detection limits, with pentanoic acid detected in only one of the three replicates. Estimated detection limits ($C_d$, eq. (4)) for these acids are 58, 46, 64, 28 and 250 mg/l respectively, these values being greater than the measured concentrations for all but propanoic acid. ($a_x$ approximates the blank reading for each acid and $s_{y/x}$ is an estimate of the error in the blank reading and is obtained from the linear regression.)

$$C_d = a_x + 3s_{y/x} \quad (4)$$

Glutaric acid co-elutes with an unknown Bayer liquor component, so that the concentrations listed in Table 3 are maximum values only. Hydroxysuccinic and phthalic acids were not detected in this sample.

## 4. Conclusions

The procedure set out above offers several advantages over previously reported methods for determining concentrations of low molecular weight organic acids in Bayer liquors. The use of a microwave oven for heating the butylation mixture both significantly reduces the analysis time and increases the number of liquor components which can be quantified. Selection of microwave conditions which are more sensitive to the larger (and less abundant) acids than the more abundant formic and acetic acids can also increase the range of compounds analysed. More vigorous conventional heating techniques may be used to extend the range of components analysed [7], but there is a corresponding increase in analysis time.

## Acknowledgements

We would like to express our thanks to Alcan (Jamaica) Ltd. for supplying a sample of Bayer liquor for analysis and to Mr Gregory Simpson of Chemistry Department, UWI, for assistance with GC instrumentation.

Received 10 October 1994; accepted 28 December 1994

**Abstract**

The application of evolving projection analysis (EPA) to second-order bilinear data sets consisting of more than two components is described. EPA is a method for rank analysis of ordered data matrices where the components appear sequentially as a function of time or some other ordinal variable. It was found that extension of the method to mixtures of more than two components was best accomplished using principal components analysis to preprocess the data. The algorithm is demonstrated using simulated four-component chromatographic data, and experimental data from liquid chromatography (three- and four-component mixtures) and a spectrophotometric titration (four components), both employing UV-visible diode array detection.

## 1. Introduction

The determination of the number, identity and concentration of chemical components in a mixture is a difficult and pervasive problem in analytical chemistry. Quite often a physical separation of the components in a mixture can be accomplished through chromatography or other means, but this is not always possible. In some cases, mixture components may be incompletely resolved by the chromatography. In other cases, such as the study of solution equilibria or chemical kinetics, it may not be possible to remove a representative sample for physical separation. In these cases, a mathematical separation of the components may be possible even if the identities or characteristics of the components are unknown. For this to be accomplished, three criteria have to be met. First, measurements must be made with a first-order detector, that is, one with multiple sensor elements, such as a spectrometer. Second, a series of mixtures must be available in which the component concentrations vary independently. It is not necessary to know the precise nature of how the concentrations change, and many situations exist in chemistry where such variations occur naturally. These include partially overlapped peaks in chromatography, reacting mixtures, and equilibria perturbed by some external factor (e.g. temperature, pH). The third requirement is that each of the components present exhibits a unique response pattern (e.g. spectrum) at the detector. The response is also required to change linearly with concentration for most methods.

When the above conditions are met, an $m \times n$, data matrix, **D**, is produced, where $m$ is the number of mixtures and $n$ is the number of sensor elements in the detector. A mathematical rank analysis of **D** can yield information about the number of observable components present in the mixture. In chemistry, the most common approach to this problem has been principal components analysis (PCA) [1]. This method, and others like it, take advantage of the fact that components with different response and concentration profiles (i.e. observable components) will increase the rank of **D** so that it is equal to the number of observable components. In practice, the determination of the number of components (chemical rank) is

* Corresponding author. Fax: (902)494-1310.

*SSDI* 0039-9140(95)01522-1

complicated by the fact that the mathematical rank is not usually equal to the chemical rank. There are three main reasons for this. First, experimental noise tends to inflate the mathematical rank to its maximum possible value (i.e. the smaller of the number of rows or number of columns in **D**). Various methods have been devised to account for the problem of residual measurement errors, with varying degrees of success. A second complication is the problem of observability. Taking chromatography as an example, if two components have concentration or spectral profiles with identical shapes, it is impossible to distinguish them on a purely mathematical basis. Obviously, the degree of similarity in each of these domains relative to the level of measurement noise is an important factor in the rank estimation process. Finally, the validity of the model is an important consideration. PCA and related methods assume a linear model of the form:

$$\mathbf{D} = \mathbf{CK} + \mathbf{E}$$

where **C** is the $m \times p$ matrix of component concentrations ($p$ components), **K** is the $p \times n$ matrix of detector response factors, and **E** is the $m \times n$ matrix of residual errors. Deviations from this model, particularly in the form of nonlinear response characteristics, can artificially inflate the rank.

PCA has been successfully used for rank analysis in a wide variety of chemical applications for many years. More recently, a number of PCA-based methods designed to examine local rank have become popular [2–12]. These methods seek to determine the number of components in substructures of the full matrix, **D**, and exploit the fact that data sets such as those already mentioned are ordered; that is, the rank changes systematically with some ordinal variable such as time. One advantage of these methods is that they provide a relative measure of changes in rank, making it easier to distinguish the appearance of additional components in the mixture from measurement noise. A second advantage is that these techniques indicate regions in the data set where a smaller number of components may be represented, making the mathematical extraction of concentrations and spectral profiles easier.

One method which has been quite successful for the analysis of ordered data sets is called evolving projection analysis (EPA) [13–15]. Formerly referred to as evolving principal components innovation analysis (EPCIA), this technique is normally implemented through the use of parallel Kalman filter networks, although this is not essential. EPA has several advantages over similar techniques and can be adapted to deal with such practical problems as nonlinear responses and non-uniform measurement noise [15]. So far, applications of this method have focused mainly on peak purity determination in chromatography and have been limited to two-component mixtures. In this paper, the extension of the EPA algorithm to mixtures of more than two components is investigated. Experimental and simulated data sets are used, and examples are drawn from chromatography and spectrophotometric titrations.

## 2. Background

The theoretical basis of EPA has been covered in detail elsewhere, so only a brief summary of the method is given here to accentuate the modifications to the algorithm necessary for multicomponent mixtures. If **D** is an $m \times n$ matrix of $n$ responses for $m$ mixtures, each of the $m$ mixtures can be plotted in an $n$-dimensional response space. In the case of liquid chromatography with diode array detection (LC-DAD), one of the most common examples, each of the $m$ mixtures corresponds to a different elution time for the fused peak. The coordinates of the point for each of these mixtures in the $n$-dimensional absorbance space ($A^n$ space) would correspond to the absorbance values at the wavelength used, i.e. the spectrum of each mixture. Assuming a bilinear matrix in the absence of random and systematic errors, and assuming that the components in the mixture are not completely overlapped and exhibit adequate spectral differences, these points will define a space whose dimensionality is equal to the chemical rank of the mixture under study; i.e. the number of independently observable components. Therefore, if there is a single component present, all the points will lie on a straight line. If there are two components present, the points should define a two-dimensional plane in $A^n$ space; three components will define a three-dimensional hyperplane; and so on. Therefore, if one could determine the dimensionality of this subspace, the chemical rank of the mixture could be found. PCA has long been used for this purpose, although experimental errors often make it difficult

to clearly confirm the presence of minor components.

The principle behind EPA is to first project the $m$ points in the $n$-dimensional space onto $n-1$ two-dimensional subspaces. If there is only one component present, then all of the points should project onto straight lines. Therefore, linear models in all of the subspaces, obtained by regression, should adequately model the data within experimental error. If any of these models fails to represent the corresponding projection, a rank greater than one is indicated. Likewise, the points can be projected into $n-2$ three-dimensional subspaces and modeled with planar equations, or $n-3$ four-dimensional subspaces and modeled with three-dimensional hyperplanar equations, and so on. This process is continued until the dimensionality of the model is sufficient to describe the data within experimental error. This is taken as the chemical rank of the data set. Models of higher order will also adequately model the data (e.g. data that fall on a line will also lie on a plane), but overestimate the rank.

The 'evolving' part of this projection analysis comes in the analysis of ordered data sets, such as spectrochromatograms. In these instances, response vectors (e.g. spectra) are added to the data matrix in a sequence determined by the ordinal variable (e.g. time). The data matrix is analyzed by the projection procedure described above after each new addition. To evaluate the validity of each model, the residual for the *newest* point is calculated. Unlike the usual regression analysis (where errors are assumed to be only on one axis) the residual is not calculated in the vertical direction but rather in a direction orthogonal to the model. This avoids excessively large residuals if the projection happens to be aligned close to the vertical axis. This orthogonal residual will be referred to as the *fit error*, FE. The original implementation of EPA employed a prediction error instead [13], but it has since been found that the fit error is somewhat more well behaved in certain circumstances [15].

The fit error is calculated for each projection with each iteration of the cycle; that is, as each new response vector (e.g. spectrum) is added to the data matrix. As long as the model being used is valid, the sequence of fit errors should exhibit the characteristics of the measurement noise. When model errors occur owing to an increase in rank beyond the dimensionality of the current model, the sequence of fit errors will exhibit a systematic variation. This is illustrated in Fig. 1 with a typical projection into a two-dimensional response space. Initially, the projections fall on a straight line and the fit errors follow the expected distribution. As the rank of the matrix increases, however, the model no longer holds and the fit error sequence begins to show systematic deviations. It is this deviation that signals the presence of a new component.

Of course, not all projections for a given dimensionality may show systematic deviations in the fit errors. Depending on the system under study, the variations could be confined largely to one projection or distributed evenly over all projections. For this reason, the root mean square of the fit error (RMS(FE)) is calculated for all projections of a given dimensionality. In the absence of systematic deviations, this quantity should reflect the magnitude of experimental noise. When systematic deviations appear, there should be an increase in RMS(FE).

The EPA algorithm is normally implemented through the use of Kalman filter networks which have been described elsewhere [13]. The recursive nature of the Kalman filter makes it ideal for this purpose. The details of this implementation will not be discussed here.

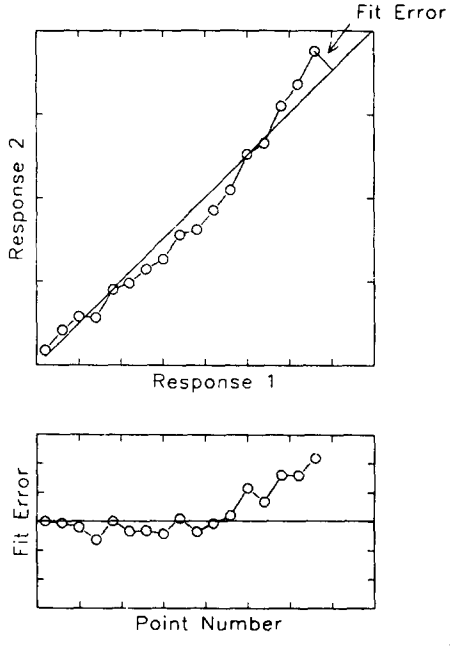

Fig. 1. Typical projection of ordered data into a two-dimensional response space and the evolution of fit errors for a one-component model. Systematic deviations of the fit error (orthogonal residual for the most recent point) indicate the appearance of a second component.

The usual procedure with EPA is to apply several models of increasing dimensionality to an ordered data set. Failure of a model with a given dimensionality signals an increase in rank beyond that value and the appearance of a new component. For example, in the analysis of a spectrochromatogram containing three overlapping components, one would expect to see failure of the one-component model when the second component appears, and failure of the two-component model when the third component appears. The fit error traces for the three-component model (and models of higher dimensionality) should remain flat throughout the chromatogram since it has sufficient dimensionality to model the entire data set.

One aspect of EPA that needs to be addressed when moving to higher dimensions is the selection of wavelengths to be used for the projections. Consider, for example, the equation for one projection of UV-visible absorbance values onto a four-dimensional space:

$$A_i = \alpha_i A_p + \beta_i A_q + \gamma_i A_r \quad (i \neq p, q, r) \tag{1}$$

The indices of the wavelengths corresponding to the independent axes in the model have been designated as $p$, $q$, and $r$. These will be the same for all $n-3$ models. The index $i$ corresponds to the wavelength being modeled for this particular projection and will vary for the $n-3$ models, as will the coefficients of the regression, $\alpha$, $\beta$, and $\gamma$. The selection of $p$, $q$, and $r$ is important. For numerical stability, absorbances at these wavelengths should exceed baseline values and should not exhibit a high degree of collinearity. Also, they should be selected to optimally distinguish among the components. In peak purity applications, the selection of the wavelength to act as an independent variable is not critical since the problem of collinearity does not arise for a one-component model. For multicomponent analysis, however, the selection is important for determining the success of the algorithm.

Several approaches to the problem of wavelength selection were tried. In one approach, a wavelength for the one-component model was first selected and that model was applied to the data set. When the one-component model failed, the wavelength showing the greatest deviation was then selected as the second independent axis, and the two-component model was applied. This procedure was repeated until the dimensionality of the model satisfied the data set. Unfortunately, the success of this approach was found to be very dependent on the nature of the data set. For example, the second wavelength selected, while effective for distinguishing between the first two components, may not be as effective for components two and three.

A successful alternative approach was found to be pretreatment of the data with PCA. The first $k$ principal components were then used to represent the data; i.e. the scores on the first $k$ eigenvectors were used instead of the absorbances at $n$ wavelengths. Typically $k$ was chosen to be large enough to ensure that it exceeded the rank of the data set, yet small enough so some of the noise was excluded. A value of $k = 10$ was found to be satisfactory for this work. Since the eigenvectors are ordered according to the proportion of variance they encompass, and since they are by definition orthogonal, the independent axes were simply selected as the first $j$ eigenvectors, where $j$ is the dimensionality of the model. Therefore, the three-component model is defined in a manner analogous to Eq. (1):

$$T_i = \alpha_i T_1 + \beta_i T_2 + \gamma_i T_3 \quad (i \neq 1, 2, 3) \tag{2}$$

where $T_i$ represents the score on principal component $i$. Using this data pretreatment step had several advantages. First, it provided a reliable method of variable selection that resulted in consistent performance of the algorithm. Second, it increased sensitivity to model deviations by reducing the contribution of wavelengths containing little or no information. Finally, because the algorithm only needed to deal with $k$ variables rather than $n$ wavelengths, computation time was reduced. For all of the results presented here, preprocessing via PCA was used and the first 10 principal components were retained.

## 3. Experimental

### 3.1. Chromatography

Chromatographic data obtained from simulations and from real three- and four-component mixtures were used to evaluate the EPA algorithm. The three-component mixture consisted of toluene (11.48 mM), naphthalene (0.42 mM) and *m*-xylene (8.12 mM) in a 7:1 (v:v) methanol: water solvent (analytes are given in the order of elution). The effective

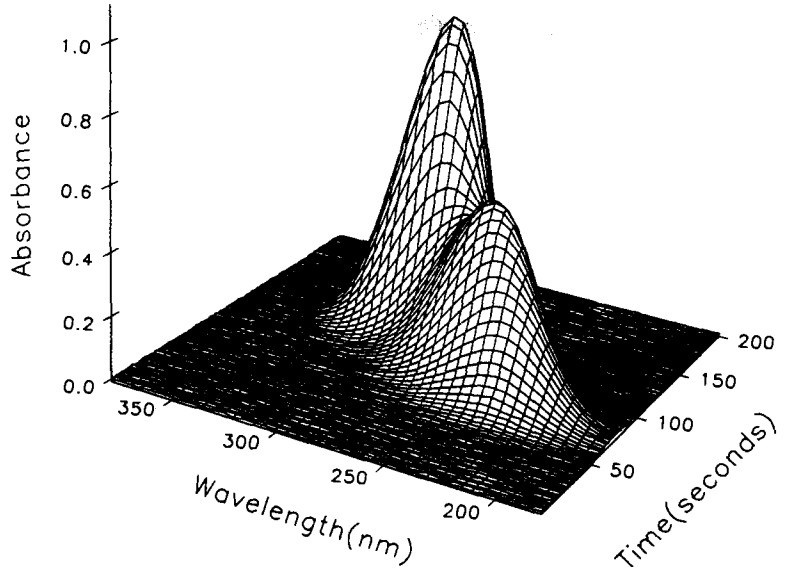

Fig. 2. Typical spectrochromatogram for a simulated four-component mixture.

concentration ratio of the analytes (i.e. compensating for the maximum molar absorptivity of each compound) is ca. 1.3:1:1.1. The four-component mixture consisted of toluene (11.54 mM), napththalene (0.42 mM), *m*-xylene (7.97 mM) and biphenyl (0.22 mM), with an effective concentration ratio of 1.3:1:1.1:2. These mixtures were analyzed on a chromatographic system consisting of a Shimadzu LC-6A pump (Shimadzu, Columbia, MD), a 50 µl injection valve (Rheodyne model 5020, Cotati, CA), a Partisphere $C_8$ column (12.5 cm × 4.6 mm with 5 µm packing) (Whatman, Hillsboro, OR), and an HP 8452A diode array spectrometer (Hewlett-Packard, Palo Alto, CA) with 30 µl flow cell (Hellma Cells, Jamaica, NY). Isocratic elution was used with 7:1 methanol:water as the mobile phase. These conditions ensured sufficiently poor resolution to test the algorithm. Spectra were obtained at 0.5 s intervals with an integration time of 0.4 s. Data were acquired between 61 and 169 s after injection for the three-component mixture, and up to 183.5 s for the four-component mixture.

### 3.2. Spectrophotometric titration

The spectrophotometric titration of pyrocatechol violet (Aldrich, Milwaukee, WI) was carried out by first placing 100 ml of a 0.01 M solution in a beaker and adding dilute hydrochloric acid to adjust the pH to 3.00. Spectra were obtained on an HP 8452A diode array spectrometer between pH 3.00 and 12.00 at intervals of 0.25 pH units by adding small amounts of dilute sodium hydroxide. Spectra were obtained between 266 and 818 nm at 4 nm intervals with an integration time of 1 s.

### 3.3. Computational aspects

All calculations were carried out on a 33-MHz 80486-based computer using Matlab 4.0 (Mathworks, Natick, MA) for Windows (Microsoft, Redmond, WA).

## 4. Results and discussion

### 4.1. Chromatography

Initial investigations into the application of EPA to multicomponent chromatographic systems were carried out using simulations. This permitted an examination of the algorithm in the absence of certain experimental artifacts that can complicate real chromatograms, such as scan time effects, baseline variations, detector nonlinearity and heteroscendastic noise. It also allowed a direct comparison to be made between the times at which components begin to elute and the fit error traces for EPA. A typical simulated spectrochromatogram for a four-component mixture are shown in Fig. 2. In this case, Gaussian profiles were used in both the spectral and chromatographic domains. The spectrum and elution profile of each component was shifted by one standard deviation from the preceding one. The effective concentration ratio (components 1–4) was

1:2:1:4. The maximum absorbance was set to unity and Gaussian noise was added at a level of 0.1% of the maximum.

The noise free chromatographic elution profiles for the four components in the mixture are shown in Fig. 3a, and the fit error traces after processing the data with the EPA algorithm in the forward and reverse directions, respectively, are shown in Fig. 3b and c. Focusing first on Fig. 3b, it can be seen that the fit error trace for the one-component model shows deviations from the baseline shortly after the appearance of the second component. Likewise, the two- and three-component models fail with the elution of the third and fourth components. As expected, the RMS(FE) for the four-component model remains flat throughout the chromatogram. Figure 3c, which is obtained by presenting the chromatographic data to the algorithm in the reverse order, provides complementary information to that in Fig. 3b. The results confirm the presence of four components and indicate where the elution of each component is complete. A knowledge of the regions where each component elutes can be useful in curve resolution for the individual components.

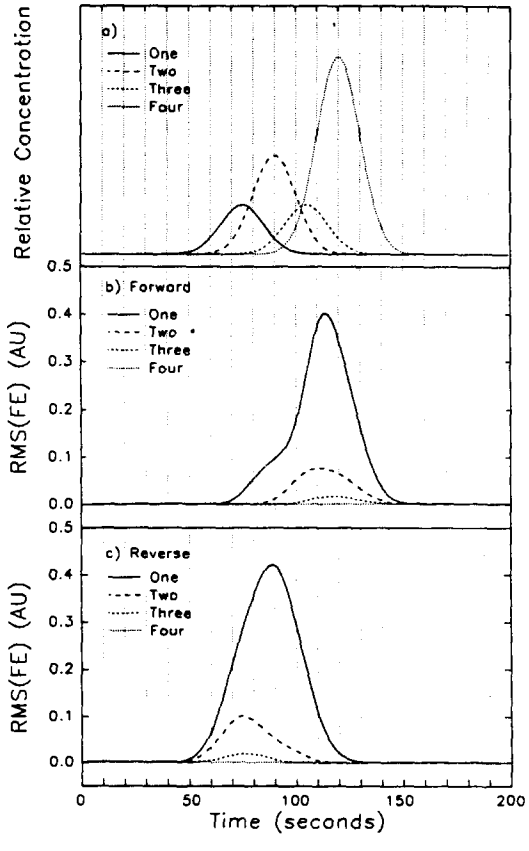

Fig. 3. Evolving projection analysis of the data in Fig. 2: (a) chromatographic elution profiles for the individual components; (b) fit error traces obtained from processing the data with the EPA algorithm in the forward direction (increasing time); and (c) fit error traces obtained by processing the data in the reverse direction (decreasing time).

In earlier work with two-component mixtures, it was demonstrated that the error traces for the one-component model closely matched the chromatographic elution profile of the second component [14]. With more than two components, the shape of the fit error trace to the elution profiles is more complex, arising from a combination of elution profiles for multiple components. The precise shape of the trace, including the position of the maximum, will depend on a number of factors, including the order of the model, the number of components present, spectral and chromatographic resolution, and relative concentration ratios. However, it appears that the trace for the final component (i.e. the $(n-1)$th order model for an $n$-component mixture) matches the elution profile for that component well. Therefore, it is possible to obtain an indication of the elution profiles for the first and last components with this approach.

Another feature of the RMS(FE) traces is that they tend to decrease in maximum amplitude as the order of the model increases. This is expected, since deviations from high-order models will be smaller than for the low-order models, which are less capable of describing the multicomponent mixture. Again, absolute magnitudes will depend on chromatographic resolution and spectral correlation of the overlapped components, as well as their concentrations and elution order. These factors, along with the level of measurement noise, will ultimately determine the sensitivity of this method to minor components in the mixture. While the sensitivity of this method has been studied for two-component mixtures [14], the case of multicomponent mixtures is more difficult because of the large number of factors influencing performance. Nevertheless, a simple study to test the limitations of the method was undertaken. In this study, a four-component mixture with Gaussian spectral and chromatographic profiles was simulated, with equal peak separation in the chromatographic and spectral domains. The first three components had a maximum absorbance of 0.25, while the fourth component was varied from 0 to 0.025. The maximum amplitude of RMS(FE) was then

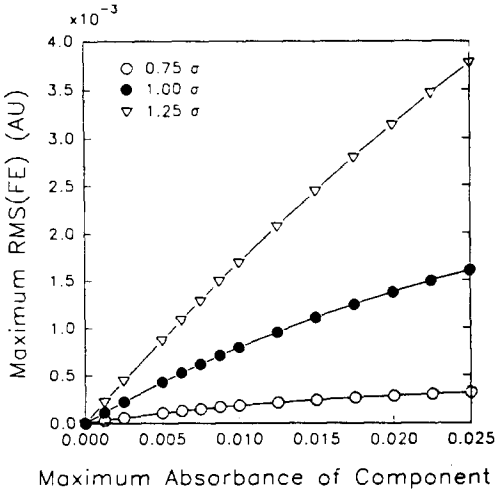

Fig. 4. Maximum fit error obtained for the three-component model applied to a simulated four-component mixture as a function the maximum absorbance of the fourth component. Three cases of chromatographic/spectral resolution are shown. The maximum absorbance of each of the other three components was set to 0.25.

measured for the three-component model running in the forward direction. This should represent a 'worst-case' scenario, since the last component will produce the smallest trace. Results from this study are plotted in Fig. 4 for peak separations of 0.75, 1, and 1.25 standard deviations. As expected, larger model deviations are observed as the relative concentration and resolution (spectral and chromatographic) of the fourth component increase. As was found to be the case for peak purity detection [14], the detectability of the fourth component will depend on the level of experimental noise. For example, if noise at a level of $1 \pm 10^{-3}$ A.U. were added to the simulated data sets, the fourth component will not be detectable when its effective concentration falls below 0.3 and 0.7% of the total for chromatographic/spectral separations of 1.25 and $1\sigma$, respectively.

The analysis of real chromatographic mixtures is more problematic. A number of non-idealities, such as baseline drift, refractive index effects, detector scan time effects, heteroscedastic noise, and detector nonlinearity, are well known to cause problems in the rank analysis of real chromatographic data [14–18]. The spectrochromatograms for the three- and four-component mixtures used in this study are shown in Fig. 5. Spectra for the four components used are shown in Fig. 6 and are presented in the order of elution. The forward and reverse rms fit error sequences for the three-component study are shown in Fig. 7. As expected, the traces in the forward direction indicate the presence of the second and third components with the successive failure of the one- and two-component models, but the traces are somewhat different from the simulation results in several ways. First, the shape is different, but this is expected since the non-ideal chromatographic conditions promote non-Gaussian peaks. Second, it is clear that the fit error traces for the three- and four-component models do not remain completely flat, making it difficult to detect the presence of additional minor components. It is expected that this is due to baseline variations and/or non-ideal detector behavior. Finally, small perturbations in the fit error traces are often observed coincident with the appearance of new components in the mixture. These perturbations, appearing as small 'bumps', precede the true failure of the model when it occurs. This behavior is routinely observed for real chromatographic data and arises from the fact that the baseline noise has some non-random structure. In the case of the one-component model, for example, this structure will be fit to the model. When the first component does appear, a couple of iterations are necessary for the model to lock onto the true structure of the data, and it is during this transition that increased errors are observed. Similar effects are observed for the higher order models. Nevertheless, the forward fit error traces clearly indicate the presence of at least three components.

The reverse traces (Fig. 7b) complement the information in the forward traces. Again, the presence of three components is indicated by the failure of the one- and two-component models, and again the traces are not completely flat for the three- and four-component models. The error traces have a somewhat different shape in this case, since the chromatographic profiles are not symmetric under these conditions. Also, there is a shift towards earlier times for the peaks in the reverse trace as the order of the components being modeled has changed. By combining the two traces, information such as the region occupied by component 2 can be extracted.

The forward and reverse fit error traces for the four-component mixture are shown in Fig. 8. The comments made for the three-component case are also valid here, except for the additional component. The deviations for the

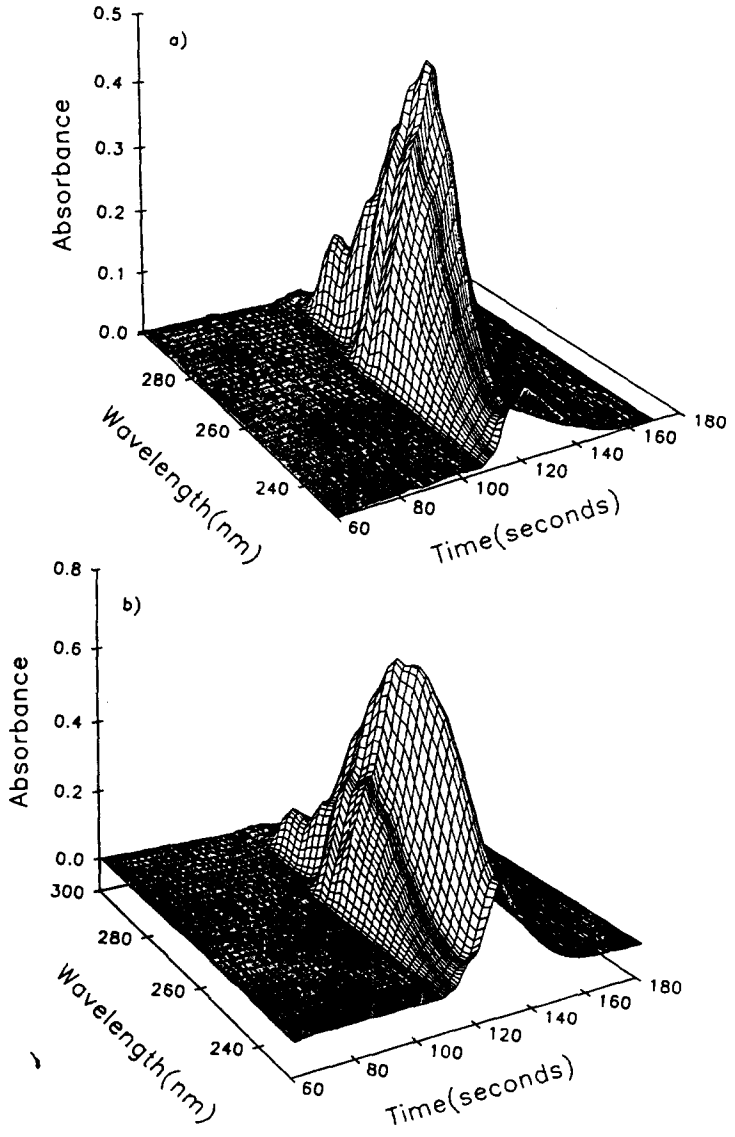

Fig. 5. Experimental spectrochromatograms for (a) three-component and (b) four-component mixtures.

three-component model are smaller than for models of lower order, as expected from the simulation studies, and begin to approach levels that make them difficult to discern from the artifacts already noted. The presence of a fourth component is still clearly indicated in this case, however.

### 4.2. *Spectrophotometric titration*

The spectrophotometric titration of pyrocatechol violet was employed as an alternative example of an ordered data set. Although this is not an exceptionally challenging case for rank analysis since the spectral profiles of the four species are reasonably well separated, it serves to illustrate the principles of the method. The data from the spectrophotometric titration are shown in Fig. 9 and the expected distributions of species calculated using reported equilibrium constants in Fig. 10 [19]. The fit error traces in the forward and reverse directions are shown in Fig. 10b and c, respectively. The traces are not as smooth as for the chromatography example, since the points are sampled less frequently, but clearly indicate the presence of four components. The successive failure of the models in the forward direction approximately matches the expected distribution, although deviations for the two- and three-component models seem to lag the appearance of the third and fourth components slightly. There is also an unexpected perturbation of the four-component model at the very

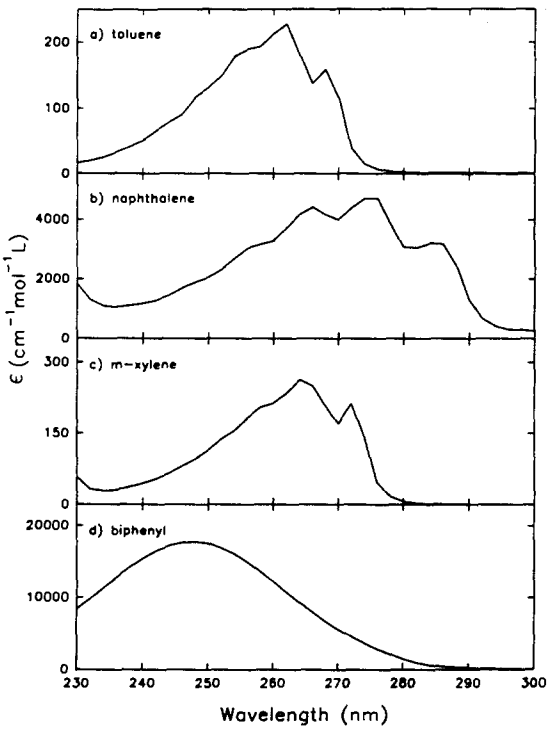

Fig. 6. Spectra for the four components employed in the chromatography experiments.

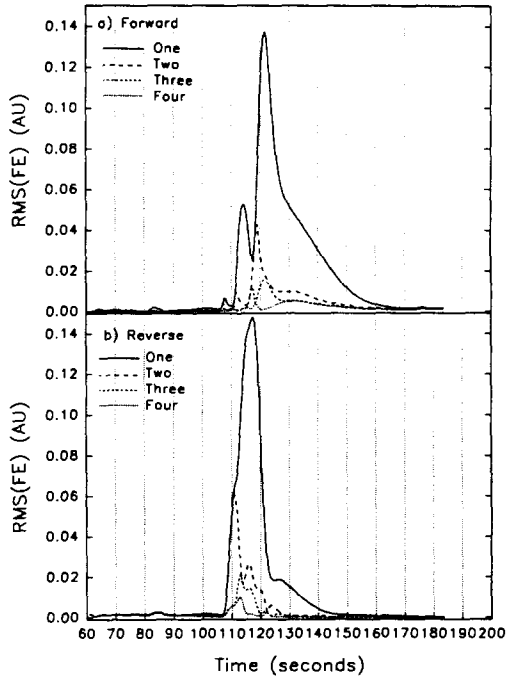

Fig. 8. Results of evolving projection analysis of the four-component data in Fig. 5b in (a) the forward and (b) the reverse directions.

end, but the number of points is insufficient to support the presence of a fifth species. The fit error trace in the reverse direction (Fig. 10c) is less well-behaved because there is no initial one-component region for the models to stabilize. Nevertheless, the trace for the four-component model remains flat while the others show obvious deviations, clearly signaling the presence of three components. In this case, the initial point of model failure for the two- and three-component models seems to be displaced to higher pH. This, coupled with the observations for the forward traces, suggests that perhaps there are some deviations from the reported values for the equilibrium constants.

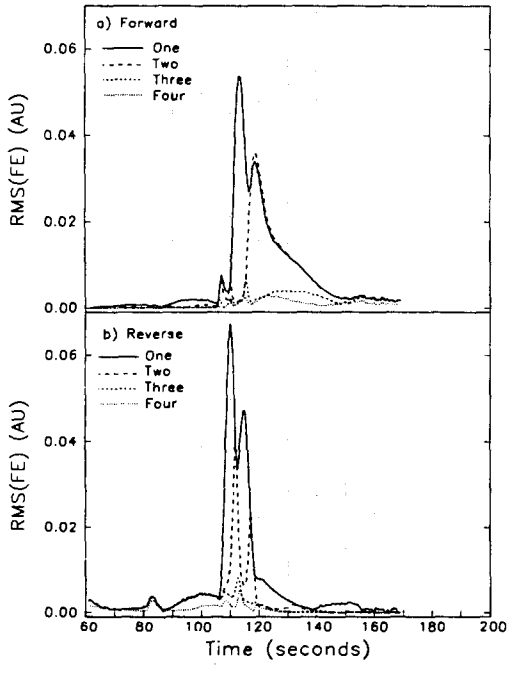

Fig. 7. Results of evolving projection analysis of the three-component data in Fig. 5a in (a) the forward and (b) the reverse directions.

## 5. Conclusions

The results presented here demonstrate the EPA is a useful technique for the rank analysis of ordered data sets consisting of more than two components. Best results were obtained when the original data were preprocessed with PCA and the scores were used in place of the original data. EPA has the advantage of providing relative measures of changes in rank and indicates where new components appear in the data set. No prior information needs to be presented to the algorithm. In the case of chromatographic data, simulations have shown that, in the ideal situation, minor components

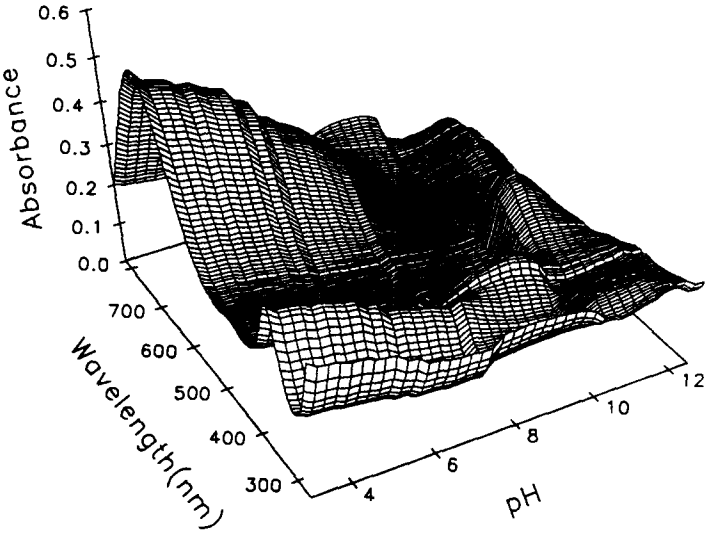

Fig. 9. Data from the spectrophotometric titration of pyrocatechol violet.

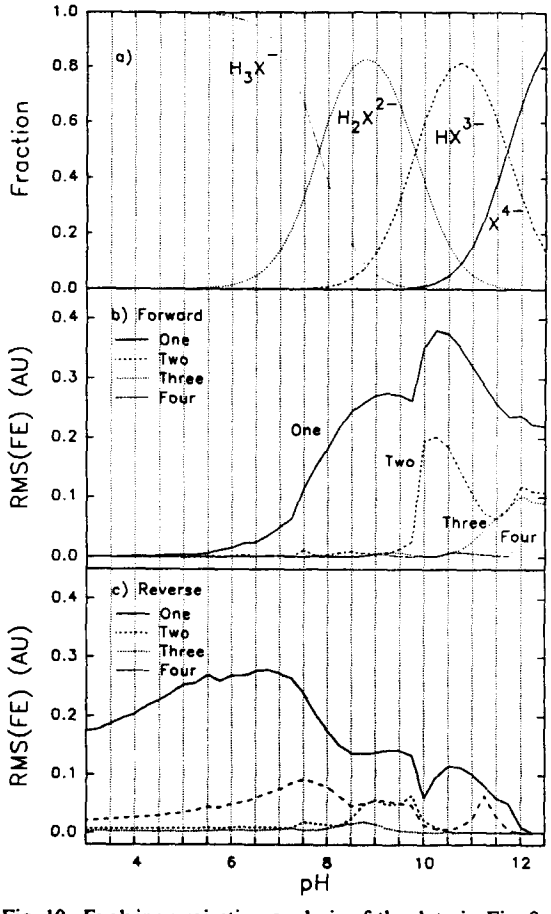

Fig. 10. Evolving projection analysis of the data in Fig. 9: (a) distribution of four forms of pyrocatechol violet as calculated from equilibrium constants; (b) results of EPA in the forward direction (increasing pH); and (c) results of EPA in the reverse direction (decreasing pH).

can be detected at relatively low concentrations. In practice, artifacts such as baseline drift and non-ideal detector characteristics are likely to limit the method before baseline noise. This is expected to be a problem for all evolving rank analysis methods, however, and clearly is a problem which deserves more attention.

# A modified program for computation of formation constants of synergetic extraction complexes with two-phase titrations by using the Marquardt–Fletcher algorithm

Cai Qingyan, Peng Yan, Nie Lihua, Yao Shouzho *

*Chemistry and Chemical Engineering Department, Hunan University, Changsha, Hunan 410082, People's Republic of China*

Received 19 August 1994; revised 6 December 1994; accepted 27 December 1994

**Abstract**

A modified computer program SCTPT for the computation of formation constants of extraction complexes with two-phase pH titration data by using the Marquardt–Fletcher algorithm is described. It can be used to deal with extraction systems which consist of a metal, an acidic extractant and a neutral synergistic reagent with no need of new subroutine. It has been applied successfully to the Pb–PMBP(1-phenyl-3-methyl-4-benzoyl-pyrazolone-5)–TBP (tributyl phosphate) system. The results obtained are in agreement with those published in the literature.

## 1. Introduction

PH titrations have been widely used in the study of stability of metal complexes with acidic ligands [1]. There are, however, few reports for this method being used in the study of the extraction equilibrium [2–5]. The main difficulty is the treatment of the experimental data. Compared with partition methods by which both pH and metal concentration in aqueous phase or organic phase are to be determined, the two-phase titration method is a simple and time-saving experimental method since only the determination of pH in the aqueous phase is required. All the quantitative information needed from the system studied can be obtained if the experiment is designed step by step. By this method, the chelate and synergistic extraction mechanism of metal ions can be studied with a pH electrode only. The method was first proposed by Dyrssen [6] to determine dissociation constants of weak acid (HA) in water and the partition constants between two phase solutions, and was then used by Jensen [2] to determine formation constants of extraction complexes. In recent years, the method has been applied to chelate and synergistic extraction systems [3–5]. However, graphical methods were used in the treatment of the data and complicated mathematical calculations and a number of mathematical approximations were involved in their procedure [2–4,6], which made it impossible to apply the method to complicated systems (e.g. more than three unknown species present). In order to obtain reliable results and simplify the complicated calculation, it is necessary to design a powerful program for data treatment.

Many computer programs for the computation of formation constants of metal complexes in aqueous solution equilibrium have been described [7] but programs for the evaluation of two-phase pH titrations have not been seen so far except one that we reported previously [5]. The most used programs are SCOGS [8] and MINIQUAD [9] which are both based on the Newton–Gauss algorithm. In these programs, good estimates of the initial parameters are usually important. However, Marquardt's

* Corresponding author.

*SSDI* 0039-9140(95)01523-X

method [10], which combines the steepest descent and Newton–Gauss algorithm in a powerful way, has no strict demands of the initial estimates and has been introduced in some programs [11,12]. The Marquardt–Fletcher algorithm, i.e. Marquardt's method modified by Fletcher [13], is more effective on the convergence efficiency. We have compared the Marquardt–Fletcher algorithm [13] with MINIQUAD, the result shows that there is no difference between them for general nonlinear refinement problems such as $y = f(x,t)$ (where $y$ and $x$ are the observation points, and $t$, the parameters to be refined); but for two-phase systems in which the parameters to be resolved are formation constants and free concentrations effected by formation constants, the Marquardt–Fletcher algorithm is more stable. However, as it is easy for the unknown parameters to be near to linear correlation in a two-phase system, the Marquardt–Fletcher algorithm should be used cautiously. When the initial estimates are far from the truth, it often gives an erroneous descent direction in the first iterations. If it is limited so that the sum of the squares of the residuals should be reduced in each iteration according to the Marquardt-Fletcher algorithm, the refinement will diverge or pace up and down on a saddle point, so the control of the shifts is important, especially in the first iterations. Sometimes when an iteration cannot give a smaller sum of squares and the Marquardt's parameter is very large, it is allowable that the iteration ends without decrease of the sum of squares in order to skip over the saddle point.

We have previously reported a FORTRAN program SCTPT [5] (Stability Constants for Two-Phase Titrations) for the computation of pH titrations in an extraction system with an acidic extractant. In this paper, a new version of the SCTPT is described. It can be used to deal with extraction system with an acidic extractant and a neutral synergetic reagent. Owing to the use of analytical derivatives combined with the Marquardt–Fletcher technique, the program SCTPT can converge to a stable minimum with no need of a good estimate of the initial parameters. The work of the program will be illustrated by using data for the lead – 1 - phenyl - 3 - methyl - 4 - benzoyl - pyrazolone-5–tributyl phosphate (Pb–PMBP-TBP) extraction system.

## 2. Mathematical background

For a system which consists of a metal M, an acidic extractant $H_nA$ and a neutral synergistic reagent B, the equations related to the equilibrium and formation constants $\beta$ are:

$$lM + mA + nB_o + hH = M_lA_mB_nH_{ho} \quad (1)$$

$$\beta_{lmnh} = [M_lA_mB_nH_h]_o/[M]^l[A]^m[B]^n_o[H]^h \quad (2)$$

$$lM + mA + hH = M_lA_mH_h \quad (3)$$

$$\beta_{lmh} = [M_lA_mH_h]/[M]^l[A]^m[H]^h \quad (4)$$

The total concentration of metal ion M can be expressed as follows:

$$V_{aq} \cdot T_M = V_{aq} \cdot [M] + V_{aq} \sum l[M_lA_mH_h] + V_0 \sum l[M_lA_mB_nH_h]_o \quad (5)$$

$$T_M = [M] + \sum l[M_lA_mH_h] + V_0/V_{aq} \sum l[M_lA_mB_nH_h]_o \quad (6)$$

where $V_{aq}$ is the total aqueous volume and $V_0$ the total organic volume. Let $R = V_0/V_{aq}$ and $R = 1$ for aqueous species and omit the subscript 0, Eqs. (7) and (8) can be obtained.

$$T_M = [M] + R \cdot \sum l[M_lA_mB_nH_h] \quad (7)$$

$$E = T_M^{calc} - T_M^{exp} = [M] + R \cdot \sum l[M_lA_mB_nH_h] - C_M V_M/V_{aq} \quad (8)$$

For A, B and H, their residual function can be obtained in the same way:

$$F = T_A^{calc} - T_A^{exp} = [A] + R \cdot \sum m[M_lA_mB_nH_h] - C_{H_nA} \cdot V_{H_nA}/V_{aq} \quad (9)$$

$$G = T_B^{calc} - T_B^{exp} = R \cdot [B]_o + R \cdot \sum n[M_lA_mB_nH_h] - C_B \cdot V_B/V_{aq} \quad (10)$$

$$H = T_H^{calc} - T_H^{exp} = [H] - [OH] + R \cdot \sum h[M_lA_mB_nH_h] - (C_H \cdot V_H + N \cdot C_{H_nA} \cdot V_{H_nA} - C_{OH} \cdot V_{OH})/V_{aq}, \quad (11)$$

where $C_M$, $C_{H_nA}$, $C_B$, $C_H$ and $C_{OH}$ represent, respectively, the initial concentration of M, $H_nA$, B, inorganic strong acid and base; $V_M$, $V_{H_nA}$, $V_B$, and $V_H$ are their added volume correspondingly, and $V_{OH}$ is the titrated volume. From the above equations we can see that the form of the mass balance equations for the two-phase system is the same as that for aqueous solution except that the species in the organic phase are multiplied by the phase ratio $V_0/V_{aq}$. From Eqs. (8)–(10) the three unknown concentrations [M], [A] and [B] represented by $M$, $A$ and $B$ can be calculated by the Newton–Raphson [8] method in which the functions $E$, $F$, and $G$ are expanded as a Taylor series truncated at the first-order term (Eqs. (12)–(14)):

$$0 = E = E^\circ + \partial E/\partial M \cdot \Delta M + \partial E/\partial A \cdot \Delta A + \partial E/\partial B \cdot \Delta B \quad (12)$$

$$0 = F = F^\circ + \partial F/\partial M \cdot \Delta M + \partial F/\partial A \cdot \Delta A + \partial F/\partial B \cdot \Delta B \quad (13)$$

$$0 = G = G^\circ + \partial G/\partial M \cdot \Delta M + \partial G/\partial A \cdot \Delta A + \partial G/\partial B \cdot \Delta B \quad (14)$$

With the shift $\Delta M$, $\Delta A$ and $\Delta B$, the solutions are obtained by iteration at a set of given parameters. At this point the concentrations of all species $M_lA_mB_nH_h$ are also known and hence the function $H$ to be fitted (Eq. (11)) and the residuals square sum (Eq. (15)) can be obtained.

$$U = \sum_{\text{points}} (T_H^{\text{calc}} - T_H^{\text{exp}})^2 = \sum_{\text{points}} H^2 \quad (15)$$

To obtain the best parameters the minimum of $U$ must be found and according to the standard least-squares expression (Eq. (16)) the parameters $\beta_{lmnh}$ represented by $\beta_l$ can be obtained by iteration (Eq. (17)).

$$(J^TJ + P \cdot I)S = J^TH \quad (16)$$

$$\beta_j^{k+1} = \beta_j^k + \beta_j^k \cdot S, \quad (17)$$

where $P$ is the Marquardt parameter, $I$ the unit matrix, and J the Jacobian matrix given by $J_{ij} = \partial H_i/\partial \log \beta_j$ ($i$, the experimental points). As discussed by Nagypal et al. [14], $J_{ij}$ is determined in Eq. (18):

$$\partial H_i/\partial \log \beta_j = R \cdot h \cdot [M_lA_mB_nH_h]_j + \frac{\partial H_i}{\partial M}\frac{\partial M}{\partial \log \beta_j} + \frac{\partial H_i}{\partial A}\frac{\partial A}{\partial \log \beta_j} + \frac{\partial H_i}{\partial B}\frac{\partial B}{\partial \log \beta_j} \quad (18)$$

$\partial H/\partial M$, $\partial H/\partial A$ and $\partial H/\partial B$ can be calculated from Eq. (11), whereas $\partial M/\partial \log\beta_j$, $\partial A/\partial \log \beta_j$ and $\partial B/\partial \log \beta_j$ are determined from the three linear equations shown below:

$$0 = \partial E/\partial \log \beta_j = R \cdot l \cdot [M_lA_mB_nH_h]_j + \frac{\partial E}{\partial M}\frac{\partial M}{\partial \log \beta_j} + \frac{\partial E}{\partial A}\frac{\partial A}{\partial \log \beta_j} + \frac{\partial E}{\partial B}\frac{\partial B}{\partial \log \beta_j} \quad (19)$$

$$0 = \partial F/\partial \log \beta_j = R \cdot m \cdot [M_lA_mB_nH_h]_j + \frac{\partial F}{\partial M}\frac{\partial M}{\partial \log \beta_j} + \frac{\partial F}{\partial A}\frac{\partial A}{\partial \log \beta_j} + \frac{\partial F}{\partial B}\frac{\partial B}{\partial \log \beta_j} \quad (20)$$

$$0 = \partial G/\partial \log \beta_j = R \cdot n \cdot [M_lA_mB_nH_h]_j + \frac{\partial G}{\partial M}\frac{\partial M}{\partial \log \beta_j} + \frac{\partial G}{\partial A}\frac{\partial A}{\partial \log \beta_j} + \frac{\partial G}{\partial B}\frac{\partial B}{\partial \log \beta_j} \quad (21)$$

where $\partial E/\partial M$, $\partial E/\partial A$, $\partial E/\partial B$, $\partial F/\partial M$, $\partial F/\partial A$, $\partial F/\partial B$, $\partial G/\partial M$, $\partial G/\partial A$ and $\partial G/\partial B$ are already known from the Newton–Raphson solution for the concentrations.

In order to ensure that $\beta$ is positive in each iteration, $s'$, the smallest shift of $S$, should be greater than $-0.99$, otherwise, let $S = S \cdot (-0.99/s')$. On this occasion, it is unreasonable to adjust the Marquardt's paramater $P$ according to the Marquardt–Fletcher algorithm. So the following is done: in the case of convergence, set $P$ constant; in the case of divergence, $P$ is increased by multiplying it by 5 until convergence. When $P$ is much greater (greater than a predetermined value $P_m$) and no smaller $U$ can be obtained, this iteration is ended too and $P$ is set to a smaller value $P_c$, which is calculated according to Marquardt–Fletcher algorithm or is assigned by experience. The refinement may be terminated when both the relative shifts and the relative variation of the residual square sum are less than a predetermined tolerance (e.g. $10^{-4}$, or $10^{-5}$).

## 3. Program

The program SCTPT is written in FORTRAN77 and has been compiled and run on a

desk-top computer, PC/XT 386. It contains a main program which reads the experimetal data, the parameters describing the model and the initial estimates of the formation constants either through the keyboard or through a data file by using the DOS pipe command. The $\beta$ values may be held to be constant (KEY = 0) or varied (KEY = 1) at will. After subroutine MINI is called to refine parameter $\beta$, it then prints out the results and calls subroutine PLOT to plot the concentration distribution diagram and the fitting titration curves at will (LPT = 0 or 1). The dimension statement in the program is such that a total number of 300 titration points (points per curve times number of curves) and up to 10 complex species can be used. For a single curve, up to 60 points can be used. This program can perform different tasks by changing the value of the parameters ML and MLB:

ML = −1 Only water solution system, no B presents

0 Two-phase system containing no metal

1 Two phases system containing metal

The synergetic reagent B is present or not if MLB = 1 or 0 for a two-phase system. If strong acid is added as titrant, its concentration should be given a negative sign and the pre-added strong base, if present, should be given a negative sign also.

CAFUN: to calculate the free concentrations, the squares sum $U$ and to set up matrix $J^TJ$ or not by setting NXC = 1 or 0 point by point.

CHOL: a general purpose symmetric linear equations solver based on Choleski factorization.

PLOT: a plot sub. It can also be designed as a program so that it can be run on another computer with strong plot function. To run this program, the β values are input.

MINI: a main minimization sub. Its flow diagram is following:

(1) Call CAFUN to calculate $U^k$, matrix $J^TJ$ and vector $J^TH$

(2) Call CHOL to solve equations $(J^TJ + P \cdot I) \cdot S = -J^TH$

(3) If $s'$, the smallest shift of $S$, is greater than $-0.99$, goto (7), otherwise goto (4)

(4) Set $S = S \cdot (-0.99/s')$, Call CAFUN to calculate $U^{k+1}$

(5) If $U^{k+1} < U^k$ goto (8); otherwise goto (6)

(6) $P = P \times 5$, if $P < P_m$ ($P_m$ is set by experience) goto (2), otherwise set $P = P_c$, goto (8)

(7) Adjust $P$ according to Marquardt–Fletcher method

(8) Set $\beta^{k+1} = \beta^k + \beta^k \cdot S$, $k = k + 1$

(9) If the termination tolerance is achieved or the number of iterations is greater than the predetermined number, go out, otherwise goto (1).

## 4. Experimental

The Pb–PMBP(1-phenyl-3-methyl-4-benzoyl-pyrazolone-5)-TBP(tributyl phosphate) system was chosen for use as a model system to test the program.

### 4.1. Chemicals and solutions

All chemicals were analytical-grade. Solvent benzene was pre-saturated with 0.1 M $KNO_3$ and the solvent water was pre-saturated with benzene also. TBP and PMBP were purified according to the literature [3]. Their solutions were prepared with benzene in different concentrations. Other chemicals were used without further purification. All solutions were prepared with doubly distilled water. The ionic strength was kept at 0.1 M with $KNO_3$ and the temperature was kept constant at 25.0 ± 0.2 °C.

### 4.2. Operation

A 10 ml $Pb^{2+}$ solution, 10 ml PMBP–benzene solution, 2 ml TBP–benzene solution and a certain quantity of strong acid ($HNO_3$) were taken into a double walled cell. Under the protection of $N_2$, a certain quantity of potassium hydroxide was added and the solution was stirred until the equilibrium was achieved. Then the pH value in the aqueous phase was determined.

The experiment was divided into several parts. Firstly, the two-phase solution involving PMBP and TBP was titrated. The result shows that no synergistic compounds (such as $H_nA \cdot nB$) were present. Then the solution containing PMBP and $Pb^{2+}$ was titrated at two different concentrations of PMBP. Finally the titrations with $Pb^{2+}$, PMBP and TBP were run at three different concentrations of TBP. In this way, the number of unknown parameters de-

Table 1

|---|---|---|
| 0, 1, 0, $1_o$ | 7.53 [a] | 7.55 |
| 0, 1, 0, $1_{aq}$ | 4.1 [a] | 4.1 |
| 1, 2, 0, $0_o$ | 11.93 (0.029) | 12.08 |
| 1, 2, 1, $0_o$ | 12.90 (0.018) | 13.00 |

[a] Value is taken from the literature [5].

creases gradually and linear correlation between the parameters is prevented. For each curve, at least 30 points were titrated.

## 5. Results

The computed values of formation constants, together with those published in the literature [3] are given in Table 1. The effect of initial estimates on formation constants is given in Table 2. The concentration distribution and the fitting curves are given in Figs 1 and 2. The values found are in agreement with those already published in the literature [3]. The main complexes are $Pb(PMBP)_2$ and $Pb(PMBP)_2 \cdot TBP$ in the Pb–PMBP–TBP system. We also postulated the presence of $PbA_2 \cdot HA$ (HA represents PMBP). The $\beta_{1310}$ varied with its initial estimate and the sum of squares was unchanged, indicating that the species must be rejected.

## 6. Discussion

The program SCTPT possesses the following advantages over other programs for formation-constant calculation. (i) The refinement was

Table 2
Effect of initial estimates on formation constants

| Species $l, m, n, h$ | Log $\beta_{lmnh}$ (initial estimates) | Log $\beta_{lmnh}$ (computed value) | Number of iterations |
|---|---|---|---|
| 1, 2, 0, $0_o$ | 2.0 | 11.93 | 13 |
| | 18.0 | 11.93 | 7 |
| | 24.0 | 11.93 | 10 |
| 1, 2, 1, $0_o$ | 6.0 | 12.90 | 6 |
| | 13.0 | 12.90 | 4 |
| | 23.0 | 12.90 | 9 |

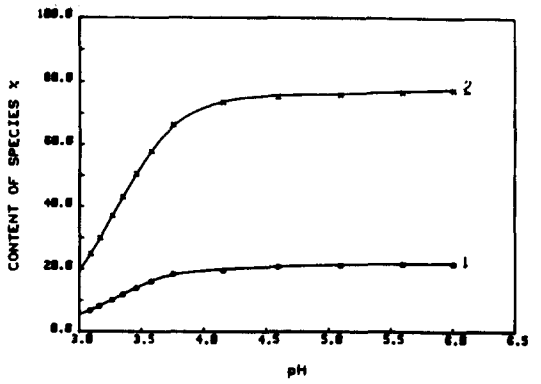

Fig. 1. The concentration distribution of the complex species. (1) $Pb(PMBP)_{2o}$; (2) $Pb(PMBP)_2(TBP)_o$.

done with the Marquardt–Fletcher algorithm [13] in which the Marquardt parameter $P$ was adjusted according to the ratio of the practical decrease of the sum of squares $U$ to the expected decrease in the sum of the squares. Thus, it possesses a more effective convergence than the Marquardt method. (ii) The use of the analytical derivatives eliminates the errors inevitably introduced during numerical differentiation. Consequently the initial estimates of the parameters need not be accurate and can be varied in a large range (about $\pm 10^5$). (iii) The formation constants are stored in mantissa and exponent form $(a, b)$, i.e. $\beta = a \cdot 10^b$ and the refinement is made to refer to the mantissa of the formation constants only, the exponent remaining unchanged. So that the partial products are not fortuitously larger or smaller than can be held in the computer's store. (iv) When a synergetic extraction system is too complicated and weak species are present (e.g. more than three species unknown present), the following method may be taken: at first compute

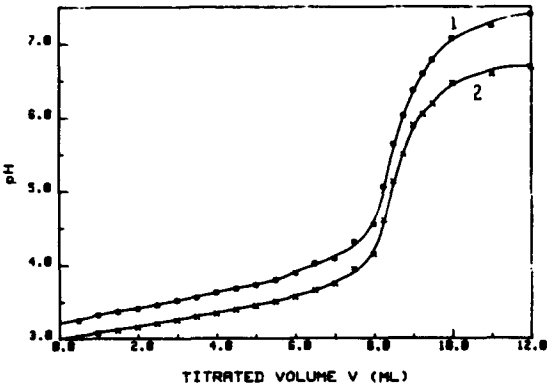

Fig. 2. The fitting titration curve. ○ and × are the experimental points. (1) $C_{PMBP} = 0.0212$ M, $C_{TBP} = 0.0220$ M; (2) $C_{PMBP} = 0.0212$ M, $C_{TBP} = 0.0110$ M.

$\beta$ of the main species and neglect the weak species, since their presence has little effect on $\beta$ of the main species; then compute $\beta$ of the weak species by setting $\beta$ of the main species constant (KEY = 0); finally all the parameters $\beta$ are computed with above calculated value as initial estimates which should be close to the true value.

The running time of the Program SCTPT on the model is less than 2 min on a PC/XT 386 computer.

# Sample illumination configurations for spatially resolved Raman spectrometry using a charge-coupled device detector

L.M. Cabalín, J.J. Laserna *

*Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, E-29071 Málaga, Spain*

Received 19 October 1994; revised 16 January 1995; accepted 16 January 1995

**Abstract**

In this paper two simple configurations for sample illumination using a charge-coupled device (CCD) detector have been shown. The choice of an appropriate sample illumination can be crucial to obtain spatial and spectral information of complex samples. It is demonstrated that simultaneous Raman spectra of a heterogeneous sample of three compounds can be obtained using a vertical sample illumination. Spatially resolved resonant Raman and surface-enhanced resonant Raman spectra of a complex (Ni-PAPH) have been observed with a low integration time. Dividing the CCD in two regions and with horizontal multiline sample illumination (argon–ion laser at 488 nm and He–Ne laser at 632.8 nm) spatially resolved fluorescence spectra of a homogeneous mixture of dyes have been obtained. The total image was acquired in only 1 s.

## 1. Introduction

Owing to the modern analytical technique requirement for detectors with high sensitivity and low noise, charge-coupled device (CCD) detectors have recently been introduced in analytical spectroscopy as an alternative to photomultiplier tubes (PMT) and photodiode arrays (PD). A description of the devices, their characteristics and spectroscopic applications was first reported by Denton and co-workers [1–7].

The characteristics of CCDs of high quantum efficiency, high sensitivity from the soft *X*-ray to the near-IR regions, minimum dark current, large dynamic range, low read noise and the ability to integrate for long periods of time make them ideal tools for a wide variety of analytical applications [8–16]. However, CCDs are usually preferred for low-light-levels spectroscopies such as Raman [17] and luminescence. As CCDs have few restrictions on the choice of laser wavelength for Raman excitation, researchers have addressed their investigation in all spectral regions. Pemberton et al. have reported the combination of a CCD detector and He–Ne laser for Raman spectroscopy [16]. Wang and McCreery [18] have demonstrated that NIR-Raman spectroscopy with a CCD detector may offer superior sensitivity to Nd:YAG excited FT-Raman, while avoiding fluorescence excitation in most molecules. The coupling of CCD/diode laser system to fiber optic was also reported [19]. Other researchers have exploited a variety of novel readout techniques directed at improving the capabilities of the CCD, including binning [20,21] fast spectral framing and time-delayed-and-integration (TDI) mode imaging.

The main characteristics of CCDs derive from their bidimensional configuration, which permits the spatial information imaged on the spectrograph entrance slit to be readily investigated [22–25]. Imaging spectrographs com-

bined with CCD detectors have been applied to simultaneous acquisition of multiple spectral inputs from several optical fibers [26]. In a recent work, we reported the spatially resolved SER spectrometry on silver-coated filter paper substrate of 9-aminoacridine using simple excitation–collection optics [27]. In this work the performance of a CCD detector for spatially resolved Raman and fluorescence techniques is demonstrated. Two different sample illumination modes have been employed whose configurations are simple and inexpensive compared with the other CCD methods reported in the literature and do not require the use of the optical fiber or cylindrical lens.

## 2. Experimental

### 2.1. Instrumentation

A schematic diagram of two illumination configurations employed is shown in Fig. 1. In the first configuration (Fig. 1A), the sample was excited by the 488-nm line of an argon-ion laser (Coherent, model Innova 70-5) and was vertically illuminated. In the second configuration (Fig. 1B) the sample along the vertical axis was excited by two different wavelengths, an argon–ion laser turned at 488 and 632.8 nm line of a He–Ne laser (Siemens, model LGK 7626S) were used. Two laser beams were horizontally focused on the glass cuvette. The separation between two laser beams was 0.7 cm.

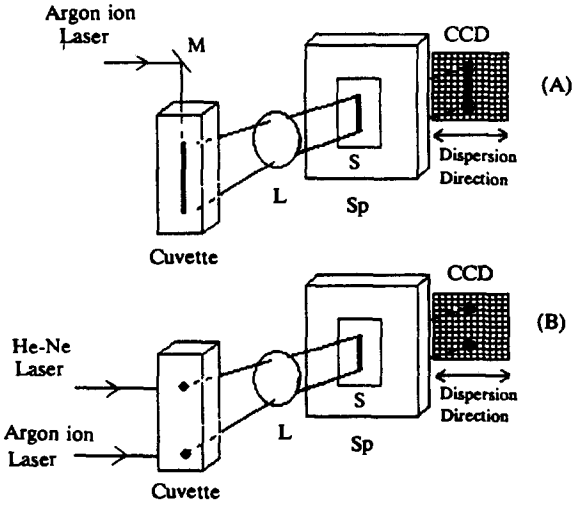

Fig. 1. Configurations for vertical (A) and horizontal (B) sample illumination of the CCD detector. L = Lens; M = mirror; S = spectrograph entrance slit; Sp = spectrograph.

In both systems, the laser beams were focused into the cuvette with a plano convex glass lens with a focal length of 25 cm and f-number of 4. Collection was performed with a glass biconvex lens with focal length of 25.4 mm and f-number of 1. The cuvette was placed approximately 11.5 cm from the collection lens, with the distance from the entrance slit to the lens being 5 cm. Thus the optical magnification was ca. 0.5. The scattered light was collected onto the entrance slit of a triple indexable granting spectrograph (Acton Research Corporation, SpectraPro 275, Czeny-turner; with F number of 3.8; fitted with three gratings of 300, 600 and 1800 grooves/mm). The spectral coverage and resolution varied gradually with spectral region and grating employed. The reciprocal linear dispersion of the spectrometer are 12 and 1.5 nm/mm with the 300 and 1800 grooves/mm gratings, respectively.

A solid-state two-dimensional charge coupled device (CCD) (EG&G Princeton Applied Research, Thomson CSF, THX-31159A) was used as detector. The CCD consists of $512 \times 512$ elements each being $19 \times 19$ μm. The active area $9.7 \times 9.7$ mm overall. This system has a quantum efficiency of 32% at 550 nm. The CCD was cooled to $-70$ °C by a Peltier system. When cooled to $-70$ °C, this detector exhibits a dark current of 10 photoelectrons pixel$^{-1}$ s$^{-1}$ and a readout noise of 4–5 electrons per scan. The calibration of the detector system was conducted with a mercury pen lamp. Operation of the detector was controlled by a personal computer (486 computer at 66 MHz, equipped with 8 Mbytes of extended memory and math coprocessor) with OMA Spec 4000 software. The spectrometer was connected to the controlling PC by a conventional IEEE-488 general-purpose interface bus (GPIB).

### 2.2. Chemicals and procedure

Analytical-reagent grade chemicals and distilled, deionized water were used throughout. Cresyl Violet 670, rhodamine 6G and 2-pyridinecarboxyaldehyde 2-pyridylhydrazone (PAPH) were purchased from Merck and used as methanolic solutions. Silver colloids were prepared at room temperature by adding 1 ml of $1 \times 10^{-3}$ M silver nitrate to 3 ml of $2 \times 10^{-3}$ M sodium tetrahydroborate. After mixing, 0.1 ml of 100 μg/ml analyte solution was added. Ni–PAPH complexes were prepared at room temperature by adding the

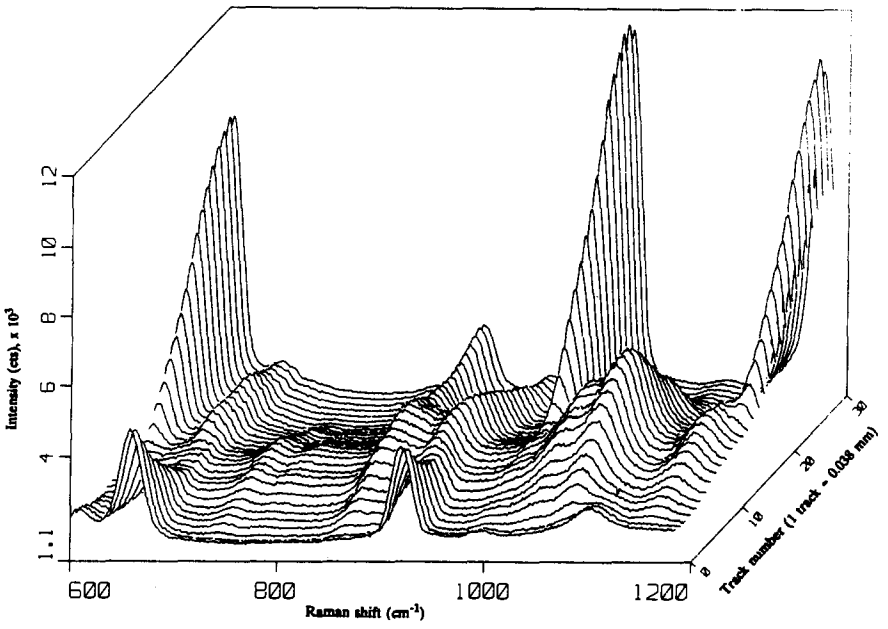

Fig. 2. Space-resolved Raman spectra of nitromethane (bottom), triethanolamine (middle) and benzene (top). Binning was 10-fold in the slit dimension. Acquisition time was 120 s and laser power 40 mW (Argon ion laser was tuned at 488 nm).

volume ratio (1:1 v/v) of 100 μg/ml PAPH (in aqueous or chloroform solutions) to 25 μg/ml of nickel(II) nitrate prepared in water.

## 3. Results and discussion

One of the main goals of the introduction of charge-coupled devices (CCD) as detectors in analytical chemistry was to exploit their two-dimensional nature. This feature permits to obtain simultaneous spectral and spatial information of the analyzed sample. The acquisition of high-quality space-resolved spectra requires an appropriate sample illumination and collection of scattered light by the spectrograph/detector system. In this work, two sample illumination configurations have been evaluated for improving device performance and operation of Raman analysis of liquid samples (Fig. 1). Figure 1A shows a configuration involving vertical illumination of sample. Since the dispersion direction of the spectrograph used was horizontal, the vertical direction in the CCD is available for spatially resolved spectrometry. To create a spatially heterogeneous sample, three immiscible solvents: nitromethane, triethanolamine and benzene were located in a glass cuvette. The separation of the compounds of the sample was determined by the different densities of the solvents (1.14, 1.12 and 0.88 g/ml for nitromethane, triethanolamine and benzene, respectively). The spatially resolved Raman spectra of this immiscible sample are shown in Fig. 2. The height dimension in the figure represents the tracks number (each track was made up of 10 rows of pixel) in the CCD detector. Since the pixel height is 19 μm and the optical magnification of the collection optics is about 0.5, each track represents 0.038 mm in the cuvette height. This means that only 1.5 cm of cuvette height is observed by the small area of the CCD detector. In this case the image was binned 10-fold in the slit dimension and the resulting 31 spectra were acquired. The power at the laser head was 300 mW of which 40 mW reached the sample. The Raman bands corresponding to nitromethane (up to 10 track), triethanolamine (from 10 to 20 track) and benzene (from 20 to 30 track) are well resolved (Fig. 2). It should be noted that the acquisition time of this image was only 120 s. The less intense zones in the figure result from the interphases nitromethane–triethanolamine and triethanolamine–benzene.

The simultaneous acqusition of the resonant Raman (RR) spectrum and the surface-enhanced resonant Raman (SERR) spectrum of the complex of nickel with 2-pyridinecarboxyaldehyde 2-pyridylhydrazone (PAPH) is shown in Fig. 3, using the vertical approach described in the Experimental section (Fig. 1A). The sample was placed into a glass cuvette, with the Ni–PAPH complex dissolved in

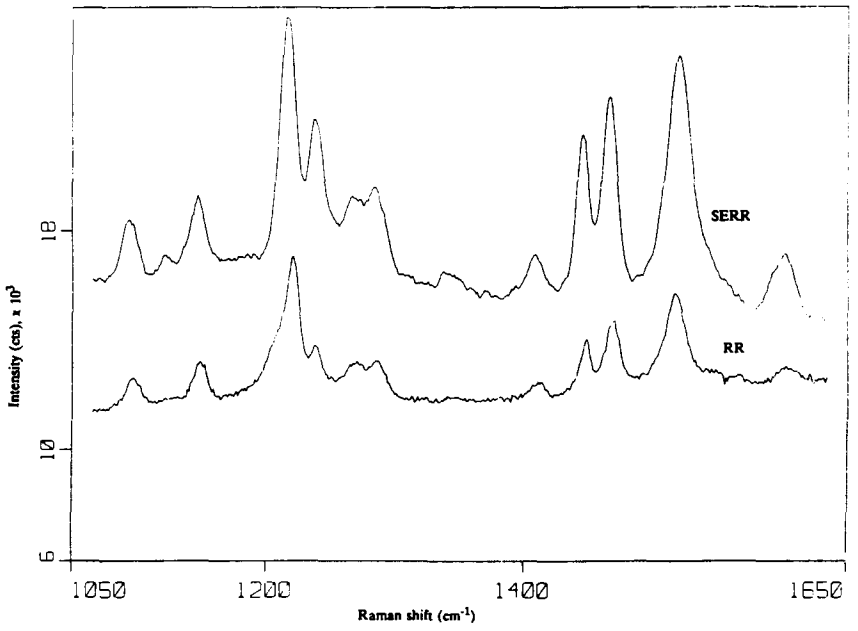

Fig. 3. Simultaneous acquisition of resonant Raman (bottom) and SERR (top) spectra of Ni–PAPH complex. Binning were 200-fold and 20-fold in the slit dimension for RR and SERR spectra, respectively. Acquisition time was 180 s. The 488-nm line of the argon ion laser (25 mW) was used.

chloroform at the bottom and the aqueous Ni–PAPH complex adsorbed on silver hydrosol at the top, so RR and SERR spectra were obtained, respectively. As shown, the line positions and relative intensities in the RR and SERR spectra correlate quite well. What is of interest for the present is that, as expected, the SERR bands are more intense than the corresponding RR bands. The flexibility of the CCD system permits comparable intensities in both spectra to be obtained by using different binning in the two spatial regions. Binning was 200-fold in the slit dimension for the RR spectrum and 20-fold for the SERR spectrum. This difference in the binning was also due to the attenuation of the laser power by the aggregated colloidal silver, thus more binning was needed for RR spectrum. The image was acquired in 180 s with a laser power of 25 mW.

The sensitivity and imaging performance of the instrument for analytical purposes was also tested with a homogeneous mixture of Cresyl Violet 670 and rhodamine 6G. The spatially resolved fluorescence spectra of the mixture are shown in Fig. 4. An argon ion laser tuned at 488 nm (2 mW) and a He–Ne laser at 632.8 nm (12 mW) were aligned horizontally so that two regions of the sample along the vertical axis were excited by the two beams (see Fig. 1B). The emitted light from the sample was then imaged onto the entrance slit of the spectrograph, dispersed and detected by the CCD detector. As each vertical region was excited by a wavelength (488 or 632.8 nm as excitation source) different fluorescence spectra are observed. In this figure, the first region (bottom) was excited by the 488 nm line and only the spatially resolved fluorescence spectrum of rhodamine 6G was observed. In the second region (top) the excitation wavelength was 632.8 nm and only Cresyl Violet was detected. The fluorescence maxima of rhodamine 6G and Cresyl Violet are at 550 and 621 nm, respectively. The large peak observed at 632.8 nm corresponds to the He–Ne laser line. The CCD was binned 10-fold in the spatial dimension, and the resulting 32 spectra are stored. The total image was acquired in only 1 s.

To conclude, the combination of imaging spectrographs and CCD detectors have revolutionized the field of spectroscopic investigation and have helped to interpret the results. Space resolved spectra of complex samples can be acquired simultaneously in a fraction of the time previously required by conventional detectors. To fully exploit CCD performance, an adequate and simple configuration is needed to illuminate the sample and to collect the scattered light in the small area of CCD detectors.

Depending on the illumination mode, components in heterogeneous or homogeneous samples can be studied in situ with satisfactory

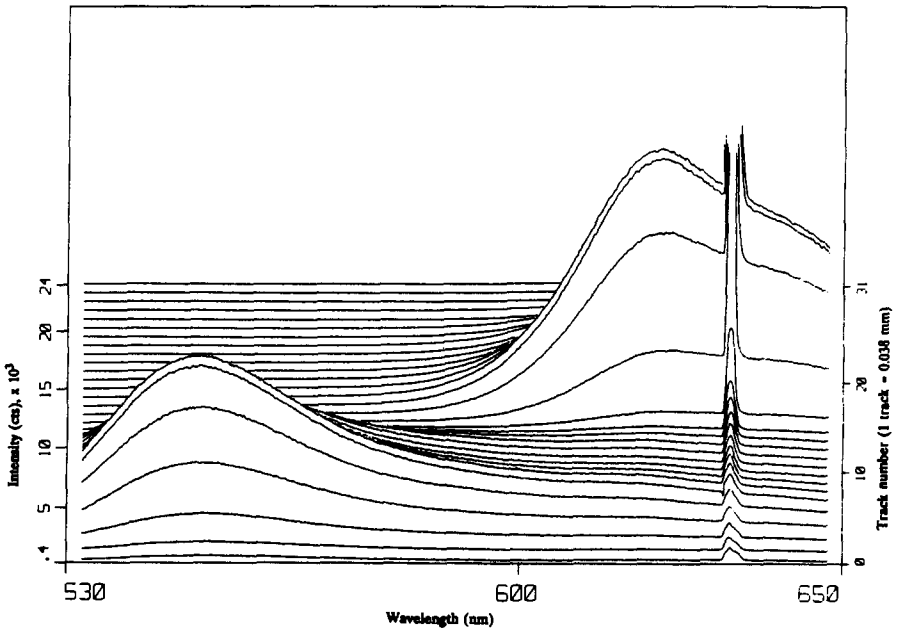

Fig. 4. Space-resolved fluorescence spectra of a mixture of rhodamine 6G ($10^{-6}$ M) and Cresyl Violet ($10^{-5}$ M) excited by the 488 nm line of the argon ion laser (2 mW) and the 632.8 nm line of the He–Ne laser (12 mW). Binning was 10-fold in the slit dimension. Acquisition time 1 s.

spatial and spectral resolution and low integration time.

# Application of the Folin–Ciocalteau reagent to the determination of salbutamol in pharmaceutical preparations

Novelette P. Sadler *, Helen Jacobs

*Department of Chemistry, University of the West Indies, Mona, Kingston 7, Jamaica*

Received 27 July 1994; revised 23 January 1995; accepted 24 January 1995

**Abstract**

A method for the determination of salbutamol in both tablets and syrups is described. It utilizes the reduction of the Folin–Ciocalteau reagent by the phenolic group, monitoring the absorbance of the resulting complex at 760 nm. Results obtained are linear over the range 0–6 μg $ml^{-1}$ salbutamol. Coloring material was removed by anionexchange chromatography prior to analysis and there was no interference from sucrose, neutral flavorings or the common preservative sodium benzoate. This method appears suitable as a general assay for salbutamol.

## 1. Introduction

Salbutamol, 1, α-[(*tert*-butylamino)methyl]-4-hydroxy-*m*-xylene-α,α′-diol, the structure of which is shown in Fig. 1, is a sympathomimetic amine containing a phenolic group. Salbutamol sulfate in various forms — aerosol spray, tablets, syrups, injection — is extensively used in the treatment of asthma.

The recent expiration of the proprietary rights of the original patent holders has led to the widespread utilization of the generic substance in formulations for oral dosage, many of which are flavored and colored to appeal to specific local tastes.

The most recent official B.P. [1] and U.S.P. [2] assays for salbutamol (as the sulfate) in formulation are based on HPLC and non-aqueous titration, and are described specifically for tablets, injection solutions and aerosol sprays. Although the non-aqueous titration method is straightforward, it is inapplicable to syrups and solutions, while the other methods are unsuitable for the technologically less well-developed settings in which it is often necessary to quantify salbutamol in formulations. An earlier B.P. method [3] is based on anion-exchange chromatography and the UV absorption at 276 nm of the salbutamol cation in acid. Although suitable to relatively low-technology environments and, in principle, applicable to a number of formulations, this method is described specifically for tablets only; it is subject to interference from neutral and cationic excipients, and additives, several of which absorb in the same mid-UV region as salbutamol.

Recently published salbutamol assays include a microtitrimetric method [4], described in application for tablets only, and a number of others which entail the formation of highly unstable derivatives with various chromogenic agents [5–16].

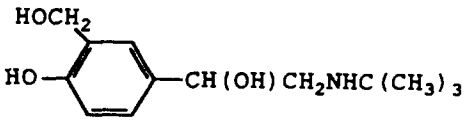

Fig. 1. Structure of salbutamol.

The phenolic group in salbutamol makes it a reductant for the Folin–Ciocalteu reagent, a chromogenic agent which has been widely applied to the determination of a number of compounds with reducing properties [17], and has been successfully used to quantify phenol morphine in the presence of its methyl ether codeine [18].

## 2. Experimental

### 2.1. Apparatus

A Phillips single beam P48670 visible/near-IR spectrophotometer was used for the absorbance measurements at 760 nm. For the B.P. method [3] and the measurement of spectra of neutral solutions obtained by ion-exchange chromatography of syrups, UV absorbances were determined on a Hewlett-Packard 8452 diode array spectrophotometer. A 1 cm quartz cell was used in both cases. An Orion model EA 920 pH meter was used for pH measurements.

### 2.2. Materials

Pure drug samples were obtained from P.A. Benjamin Manufacturing Co. Ltd., Kingston, Jamaica. Dosage forms were acquired from local and overseas sources, and the following formulations were used.

(A) Ventasol syrup, salbutamol sulfate equivalent to 2 mg salbutamol per 5 ml syrup, no color or flavor. (P.A. Benjamin Manufacturing Co. Ltd., Kingston, Jamaica).

(B) Fedbutamol syrup, salbutamol sulfate equivalent to 2 mg salbutamol per 5 ml syrup, colored and flavored. (Federated Pharmaceutical Co. Ltd., Kingston, Jamaica).

(C) Ventolin tablets, salbutamol sulfate equivalent to 2 mg salbutamol per tablet, colored. (Glaxo Operations UK Ltd., Greenford, UK).

(D) Ventolin syrup, salbutamol sulfate equivalent to 2 mg salbutamol per 5 ml syrup, no color or flavor. (Glaxo Operations UK Ltd., Greenford, UK).

(E) Albuterol syrup, salbutamol sulfate equivalent to 2 mg salbutamol per 5 ml syrup, colored and flavored. (Allen & Manbury's (Division of Glaxo), Research Triangle, NC 27709, USA).

### 2.3. Reagents

Distilled deionized water was used throughout. Folin–Cioicalteu reagent was prepared according to a published procedure [18]. The reagent was used as soon as possible after preparation, although colorimetric solutions prepared from reagent that was 54 h old gave results indistinguishable from those obtained with freshly prepared reagent.

Ion-exchange chromatography utilized the commercially available chloride form of a strongly basic ion-exchange resin (usually Dowex 1-X2, 50–100 mesh) which, prior to use, was stirred briefly with 0.1 M NaCl or 0.1 M HCl and washed free of chloride ions.

Saturated $Na_2CO_3$ solutions were cooled and filtered before use.

### 2.4. Standard drug solutions

A solution of salbutamol sulfate in water of concentration equivalent to 50 $\mu g\,ml^{-1}$ salbutamol was made up, and appropriate aliquots taken for preparation of colorimetric solutions used to generate the standard curve.

### 2.5. Analytical samples from pharmaceutical preparations

Anion-exchange chromatography was carried out to remove coloring materials where present, as most common food dyes are anionic and non-phenolic. This procedure also removed benzoate.

*Tablets*

Ten tablets were weighed and powdered, and a quantity of powder containing the equivalent of 5 mg salbutamol suspended in 30 ml water. The suspension was filtered, the filtrate passed through 10–15 ml of the chloride ion-exchange resin contained in a 50 ml burette, and the resin washed with water until the volume of eluant was 100 ml.

*Syrups*

For syrups with and without color, a volume of syrup containing the equivalent of 5 mg salbutamol was diluted with an equal volume of water, the solution passed through 10–15 ml of the chloride resin, and 100 ml eluant collected. Solutions of syrups without color were also prepared by dilution to 100 ml of a volume of syrup containing the equivalent of 5 mg salbutamol.

Table 1
Limits, optical characteristics, accuracy

| | |
|---|---|
| Beer's law limits ($\mu g\ ml^{-1}$) | 0–6 |
| Molar absorptivity ($l\ mol^{-1}\ cm^{-1}$) | 15240 |
| Regression equation [a] | |
| Slope ($m$) | $15240 \pm 99$ |
| Intercept ($n$) | $0.005 \pm 0.001$ |
| Correlation coefficient ($r$) | 0.998 |
| $R$-squared [b] | 99.7% |

[a] $y = n + mc$, where $c$ is the concentration in $\mu g\ ml^{-1}$.
[b] Six replicate samples of each concentration.

### 2.6. Preparation of colorimetric solutions

Aliquots of standard or sample solutions containing the equivalent of 5, 10, 20, 30, 40, 50, 100, 200, 400, 600 and 800 μg salbutamol were placed in 100 ml volumetric flasks. To each flask was added 2 ml of Folin–Ciocalteu reagent and 3 ml of saturated $Na_2CO_3$ solution, and the volume made up to the mark with water. Five hours were allowed for development of the maximum blue color, after which the absorbance could be measured within 18 h.

## 3. Results and discussion

### 3.1. Effect of concentration

Plots of optical density versus concentration were made over the range 0–8 $\mu g\ ml^{-1}$ using salbutamol standards. Excellent linear correlation was obtained up to 6 $\mu g\ ml^{-1}$, and the slope of the plot over this range was used to calculate the molar absorptivity at 760 nm by Beer's law. The results of linear regressional analysis of the data are shown in Table 1. The salbutamol concentration in each pharmaceutical preparation was again determined using Beer's equation, making substitutions for the above-determined molar absorptivity and for the measured absorbance. Several concentrations of each preparation were used and the average calculated, along with its standard deviation. Table 2 summarizes the results obtained.

### 3.2. Effect of flavoring and benzoate

The flavorings and benzoate present in the syrups did not interfere with the determination of salbutamol using the colorimetric method. The results obtained using syrup solutions prepared via ion-exchange chromatography were identical to those for solutions made up by simple dilution of syrups. UV analysis (monitoring 278 nm) of neutral solutions obtained from the ion-exchange chromatography of colorless syrups in some cases revealed severe interference by cationic or neutral species present as flavoring.

In all the cases studied, the salbutamol concentrations obtained by this method were in agreement with those stated by the manufacturers of the formulations, which were given to one significant figure.

The reaction between salbutamol and the Folin–Ciocalteau reagent results in the formation of an intensely blue complex ($\lambda_{max} = 760$ nm), which is probably a reduced heteropolyanion of molybdenum and tungsten [19]. Isopoly- and heteropolyanions of molybdenum and tungsten have been extensively studied, and their structures are fairly well understood. They can be reversibly reduced by the addition of one to six electrons per anion to give the "heteropoly blues", a generic name derived from their intense coloration. These "blues" can be classified as mixed-valence complexes containing Mo(V) and Mo(VI), or W(V) and W(VI). It is likely that the phenolic group of salbutamol reduces the Mo(VI) and W(VI) centers to produce these relatively stable mixed-valence complexes. The intense, fairly broad band observed at 760 nm in the visible/near IR is typical of these complexes, and has been attributed to intervalence charge-transfer bands between Mo(V) and Mo(VI) via an oxo bridge, or to d–d bands for Mo(V) [20]. The large value of $\varepsilon$ obtained in this study is consistent with those usually observed for d–d transitions [19,20].

Table 2
Salbutamol determination in formulations

| Formulation | Nominal amount (mg per tablet or mg per 5 ml syrup) | Found [a] | Official method [3] |
|---|---|---|---|
| *Tablets* | | | |
| Ventolin | 2 | $2.05 \pm 0.13$ | $1.96 \pm 0.06$ |
| *Syrups* | | | |
| Ventolin | 2 | $2.10 \pm 0.11$ | |
| Fedbutamol | 2 | $2.02 \pm 0.17$ | |
| Albuterol | 2 | $2.16 \pm 0.05$ | |
| Ventasol | 2 | $1.93 \pm 0.02$ | |

[a] Average $\pm 2 \times$ standard deviation of six determinations.

## Acknowledgment

The authors thank P.A. Benjamin Co. Ltd., Kingston, Jamaica, for providing samples of Ventasol and some funding for this research.

# Indirect measurement of brucine by adsorptive stripping voltammetry at mercury electrode

Meixian Li, Naifei Hu*, Shuchang Lin

*Department of Chemistry, Beijing Normal University, Beijing 100875, People's Republic of China*

Received 26 October 1994; revised 3 February 1995; accepted 17 February 1995

**Abstract**

After reaction with nitric acid, brucine can be transformed into cacotheline, and then measured indirectly by adsorptive stripping voltammetry. This method is based on the adsorptive accumulation of cacotheline at a hanging mercury drop electrode, followed by cathodic linear sweep voltammetry. The cathodic peak potential is about −0.35 V (vs. saturated Ag/AgCl). The detection limit of $2.0 \times 10^{-9}$ M is obtained under optimized conditions. The electrochemical behaviour of cacotheline and the mechanism of the electrode reactions are discussed.

## 1. Introduction

Brucine is an alkaloid, and exists mainly in the seeds of *Strychnos nux-vomica*. Its structure is shown in Fig. 1a. The seeds of *Strychnos nux-vomica* have been used in traditional Chinese medicine with a long history. Its main efficacy includes pain relief, reduction of swelling and promotion of circulation [1,2]. Several well-known traditional Chinese medicines have the seeds as one of their main ingredients. As a drug, brucine itself is known as a central nervous system stimulant. It can be adsorbed by the human body and enters into the bloodstream. Generally, the concentration of brucine in urine and blood is low after metabolization. Thus, the establishment of highly sensitive methods for the determination of brucine is of pharmacological importance. Brucine is also known as a drug with great toxicity. The determination of trace amounts of brucine is thus not only of toxicological, but also of forensic significance. Various chromatographic and other procedures have been employed for this purpose [3–6]. For example, Dadisch [7] established a chromatographic method for the detection of brucie in urine. Korany and Seif El-Din [8] developed a spectrophotometric method to determine brucine in *nux vomica* liquid extract. The limit of detection was about $8 \times 10^{-6}$ M. Nyasulu [9] studied the electrochemical oxidation of brucine at a carbon paste electrode. However, brucine has no electroactivity of reduction at a mercury electrode [10].

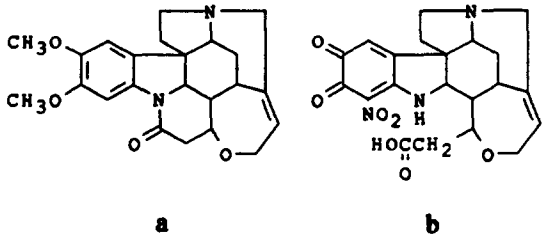

Fig. 1. Structure of (a) brucine and (b) cacotheline.

Cacotheline (CAC), as a nitration product of brucine, is an analytical reagent used in the detection and determination of various metal

* Corresponding author.

*SSDI* 0039-9140(95)01563-9

ions and organic compounds [11–13]. Its structure is shown in Fig. 1b. Vijayalakshmi and Saraswathi [14] studied the polarographic and cyclic voltammetric behaviour of cacotheline at a mercury electrode. They found there were two cathodic polarographic waves between pH 2.0 and 12.0. The first wave involved two electrons for the reversible reduction of the *o*-quinone group to hydroquinone, while the second underwent a four-electron irreversible reduction of the nitro group to hydroxylamine. However, they did not mention the adsorptive properties of cacotheline at a mercury electrode, and the detection limit of determination of cacotheline was only about $1 \times 10^{-4}$ M.

This paper studied the electrochemical properties of cacotheline, especially its adsorptive characteristics at a mercury electrode. On the basis of this, a new electroanalytical method for the indirect measurement of brucine was established. After reaction with nitric acid, brucine was transformed into cacotheline, which was then determined by adsorptive stripping voltammetry at a mercury electrode. Adsorptive stripping voltammetry (AdSV) has been used for trace measurements of numerous compounds of pharmaceutical significance [15]. As illustrated in this paper, by this method a detection limit of $2 \times 10^{-9}$ M was achieved for the determination of cacotheline or brucine.

## 2. Experimental

### 2.1. Apparatus

A model 370 electrochemical system (EG&G Princeton Applied Research, U.S.A.) was used for cyclic voltammetry, adsorptive stripping voltammetry and phase-selective a.c. voltammetry. The working electrode was a model 303 static dropping mercury electrode (SDME). A medium-sized drop (surface area, 0.0171 $cm^2$) was employed. The counter electrode was a platinum wire and the reference electrode was a saturated Ag/AgCl electrode.

### 2.2. Chemicals

Brucine was obtained from Heidelberg (U.S.A.). A stock standard solution of brucine ($1.00 \times 10^{-3}$ M) in 5% ethanol–95% water (v/v) was prepared and stored in the dark; working standard solutions ($1.00 \times 10^{-4}$, $1.00 \times 10^{-5}$ and $1.00 \times 10^{-6}$ M) were prepared by dilution with water. Cacotheline was obtained from Drs. Fraenkel and Landau (Germany). A stock standard solution of cacotheline ($1.00 \times 10^{-3}$ M) in water was prepared and stored in the dark; working standard solutions ($1.00 \times 10^{-4}$ M and less) were prepared by dilution with water. All other chemicals were of analytical reagent grade. Triply distilled water was used throughout.

### 2.3. Procedure

*Measurement of cacotheline by AdSV*

A 10-ml volume of 0.02 M acetic acid–sodium acetate (HOAc–NaOAc) buffer solution (pH 4.0) containing a specific amount of cacotheline sample solution was added to the cell, which was purged with purified nitrogen for at least 4 min to remove oxygen. The SDME was set to the hanging mercury electrode mode. The preconcentration potential (−0.1 V) was then applied to a new mercury drop for a selected time while the solution was stirred at 400 rev $min^{-1}$. The stirring was then stopped, and after 15 s the voltamperogram was recorded by applying a linear sweep scan. The scan was terminated at −0.5 V.

*Nitration of brucine*

A certain amount of brucine (about 0.05 g) was placed in a flask and 1 ml of 3.5 M nitric acid was added. The flask was then heated on a water bath and kept at 60–70 °C while stirring the solution inside. After 2 h of reaction, brucine was believed to be completely transformed into cacotheline. All the products and the solution were thoroughly transferred into a beaker. With water added, the beaker was heated until all the solid product was dissolved. After cooling down, the solution was transferred to a 100 ml volumetric flask and diluted with water to the mark. This solution or its diluted version could be used as sample solutions. After measuring cacotheline in this solution by adsorptive stripping voltammetry, the amount of brucine could be determined indirectly.

## 3. Results and discussion

### 3.1. Nitration of brucine

Brucine is electroinactive at a mercury electrode. For example, in buffer solution of

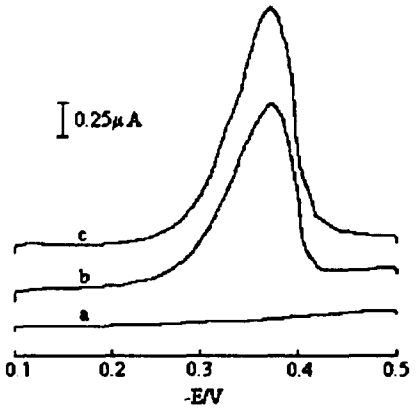

Fig. 2. Cathodic sweep voltamperograms for (curve a) $3 \times 10^{-5}$ M brucine, (curve b) $3 \times 10^{-5}$ M cacotheline and (curve c) nitration product of $3.45 \times 10^{-5}$ M brucine. (Electrolyte, 0.02 M HOAc–NaOAc, pH 4.0; scan rate, 100 mV s; initial potential, −0.10 V.).

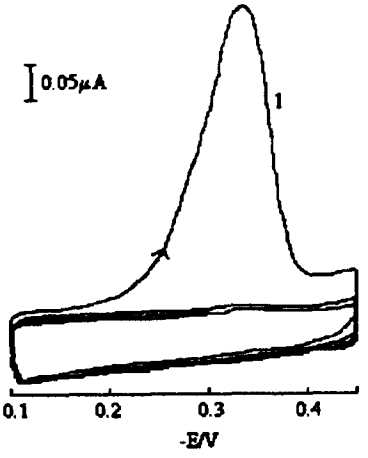

Fig. 3. Repetitive cyclic voltamperograms for $1 \times 10^{-6}$ M cacotheline after 30 s accumulation at −0.1 V. Four cycles; other conditions as for Fig. 2.

HOAc–NaOAc (pH 4.0), brucine does not show any reduction peak over the potential range −0.10– −0.50 V (Fig. 2, curve a). Thus, there is no way of determining brucine by voltammetry at the mercury electrode. However, in the same electrolyte, cacotheline shows a well-defined reduction peak at about −0.37 V (Fig. 2, curve b). This prompted us to use a nitration method to transform brucine into cacotheline first, and then determine cacotheline by voltammetry. Brucine can thus be measured indirectly. The procedure of nitration of brucine was described in detail in the experimental section. The voltamperogram of the nitration product is shown in Fig. 2, curve c. Compared with Fig. 2, curve b, this product has the same cathodic peak potential as cacotheline, which indicates that the nitration product of brucine obtained by this procedure is indeed cacotheline.

### 3.2. Adsorptive properties of cacotheline

Fig. 3 is a repetitive cyclic voltamperogram for $1 \times 10^{-6}$ M cacotheline, recorded after preconcentration at −0.1 V for 30 s. A large and well-defined cathodic peak is observed at the first scan (designated as 1) at −0.32 V. Subsequent scans exhibit a dramatic decrease of the peak to a stable value representing the response of the solution species. This is an obvious indication that cacotheline has adsorptive characteristics at a mercury electrode. No peaks are observed in the anodic branch, illustrating that the reduction of cacotheline at a mercury electrode is irreversible.

Fig. 4 shows plots of cathodic peak current ($i_{pc}$) of linear sweep voltammetry vs. preconcentration time ($t$) for different concentrations of cacotheline. At first, $i_{pc}$ increased linearly with $t$ at all four levels, indicating that before adsorptive equilibrium is reached, the longer the preconcentration time, the more cacotheline was adsorbed and the larger the peak current. However, after a specific period of accumulation time, the peak current at different concentration levels invariably tended to level off, showing that the adsorptive equilibrium of cacotheline on the mercury electrode surface was achieved.

The adsorption of cacotheline can be used as an effective preconcentration step before the voltammetric measurements. In this way, highly sensitive adsorptive stripping voltammetric measurements of cacotheline can be achieved.

### 3.3. Selection of experimental conditions

Various supporting electrolytes, such as HCl, HOAc–NaOAc, $NH_3$–$NH_4Cl$, $KH_2PO_4$–$K_2HPO_4$, NaOH, KCl, $Na_2B_4O_7 \cdot 10H_2O$ and Britton-Robinson buffer solution, were tested by AdSV and HOAc–NaOAc was found to be the best because of the well-defined voltamperogram and reasonably high sensitivity. The experiments revealed that the conditions of a total concentration of HOAc–NaOAc between 0.002 and 0.18 M, and pH value between 3.7 and 5.0 offered the best responses. Thus 0.02 M HOAc–NaOAc and pH 4.0 was chosen in all experiments. The experiments of the effect of preconcentration

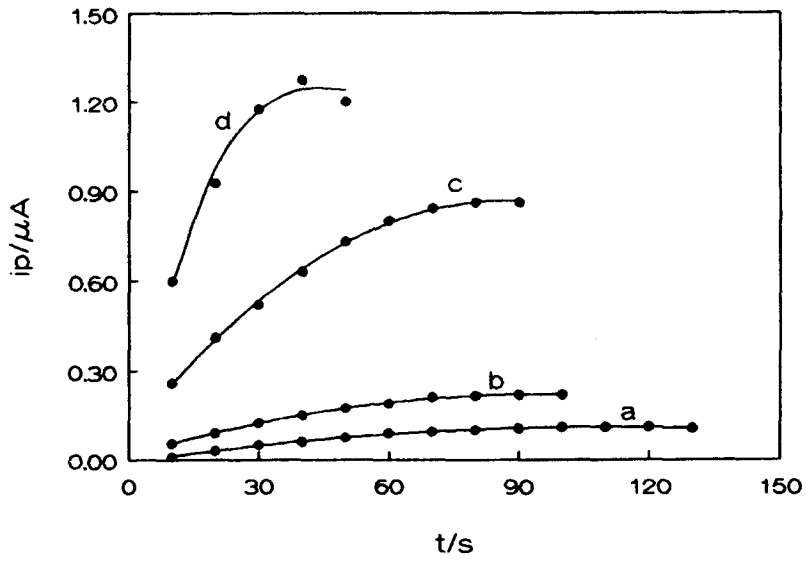

Fig. 4. Effect of preconcentration time on the cathodic voltammetric peak current for (curve a) $5 \times 10^{-8}$ M, (curve b) $1 \times 10^{-7}$ M, (curve c) $5 \times 10^{-7}$ M and (curve d) $1 \times 10^{-6}$ M cacotheline. Other conditions as for Fig. 2.

potential showed that over the range 0– $-0.15$ V, $i_{pc}$ remained almost constant at a high level, but beyond this range it decreased. Thus $-0.10$ V was chosen as the best preconcentration potential.

The adsorptive stripping voltammetric response of cacotheline was further characterized concerning concentration ($c_{CAC}$) dependence, detection limit and reproducibility. Under the optimized conditions with a 100 mV $s^{-1}$ scan rate, the peak current had a linear relationship with $c_{CAC}$ over the range from $2.0 \times 10^{-8}$ to $1.0 \times 10^{-6}$ M when the accumulation time was 30 s (correlation coefficient, 0.9991). The detection limit achieved was $2.0 \times 10^{-9}$ M when the preconcentration time was set to 3 min ($S/N = 3$). The precision was estimated by nine successive measurements of $5 \times 10^{-7}$ M cacotheline under the same conditions as above with a 30 s accumulation. The average peak current was 0.46 μA, range 0.43–0.52 μA, and relative standard deviation 2.7%.

Table 1
Results of indirect measurement of brucine

| No. | Amount of brucine added (g) | Amount of brucine measured[a] (g) | Recovery rate (%) | Standard deviation (%) |
|---|---|---|---|---|
| 1 | 0.0559 | 0.0538 | 96.2 | 2.4 |
| 2 | 0.0473 | 0.0453 | 95.8 | 1.3 |

[a] $n = 5$.

As described above, brucine can be transformed into cacotheline by nitration and then determined by AdSV. Under the optimized conditions mentioned above, brucine was measured indirectly by the standard additions method. Certain results are listed in Table 1. The transformation rate of above 95% indicated that brucine was almost completely transformed into cacotheline. This result illustrated again that the method of first nitrating and then determining by AdSV was feasible for the indirect measurement of brucine.

### 3.4. System weakly adsorbed reactant

The effect of the square root of the scan rate ($v^{1/2}$) on $i_{pc}$ of cacotheline at different preconcentration times was examined. When $t = 0$, $i_{pc}$ had a linear relationship with $v^{1/2}$, illustrating that the reduction of cacotheline was diffusion-controlled. When $t = 10$ s, the $i_{pc}$ vs. $v^{1/2}$ curve showed upward bending, indicating that the system began to show some adsorptive characteristics. When $t = 60$ s, as more cacotheline was adsorbed, upward turning of the $i_{pc}$–$v^{1/2}$ curve became more pronounced.

The effect of the concentration of cacotheline on $i_{pc}$ is shown in Fig. 5. When $t = 0$, the relative peak current expressed as the ratio of $i_{pc}/c_{CAC}$ was small and remained nearly constant on increasing the concentration of cacotheline (curve a). This indicated that the reduction of cacotheline at the mercury electrode was almost totally diffusion-controlled.

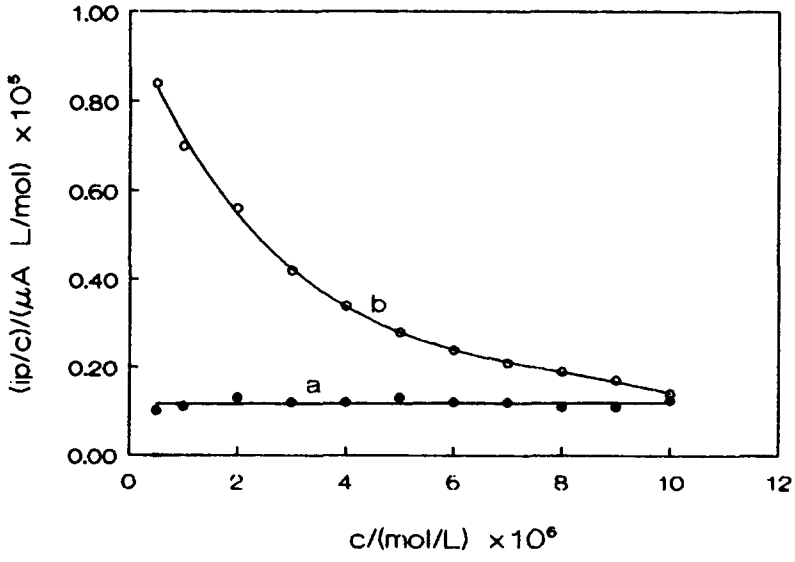

Fig. 5. Effect of concentration of cacotheline on the relative peak current as the ratio of the cathodic peak current to the cacotheline concentration. Preconcentration period: (curve a) 0 s; (curve b) 30 s. Other conditions as for Fig. 2.

However, when $t = 30$ s, because more cacotheline was adsorbed on the mercury surface, the values of $i_{pc}/c_{CAC}$ were much larger than those of curve a at lower $c_{CAC}$. At higher $c_{CAC}$, however, the adsorption of cacotheline reached saturation and its contribution to the peak current did not increase any more. The ratio then declined very rapidly with increasing concentration of cacotheline, and eventually tended toward the constant value of curve a (curve b). All of these suggest a gradual transformation of the system from adsorption-controlled to diffusion-controlled when the concentration of cacotheline increases. This is also a characteristic of the system involving a reactant that is weakly adsorbed [16].

### 3.5. Mechanism of reduction of cacotheline at mercury electrode

Over the potential range from 0.20 to −0.50 V, cacotheline has a pair of reversible peaks at about 0.03 V and an irreversible peak at −0.40 V. Electrolysis experiments with a

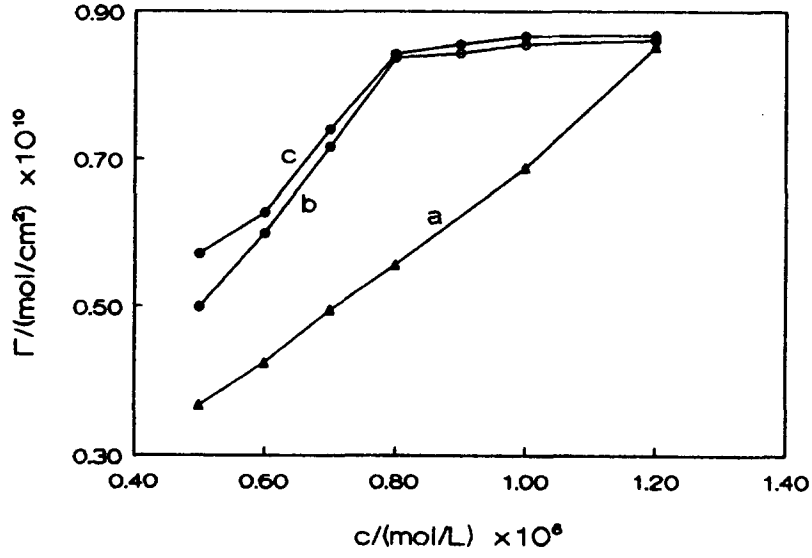

Fig. 6. Influence of cacotheline concentration on the amount of cacotheline adsorbed on the mercury electrode surface. Preconcentration time: (curve a) 30 s; (curve b) 60 s; (curve c) 90 s. Other conditions as for Fig. 2.

large area of the mercury cathode at the potential of −0.2 V showed that the number of electrons transferred for the first cathodic peak ($n_1$) was 2. Electrolysis at −0.50 V revealed that the number of electrons transferred for both cathodic peaks was 6. Thus, the number of electrons for the second irreversible reduction peak ($n_2$) should be equal to 4. This result is in good agreement with that of Vijayalakshmi and Saraswathi [14]. The mechanism of electrode reduction of cacotheline at the mercury electrode involves two processes. The first cathodic peak is most probably due to the reversible reduction of the *o*-quinone group to hydroquinone involving two-electron transfer. The second is possibly the irreversible reduction of the nitro group to hydroxylamine with four-electron transfer. It is the second peak, showing adsorptive characteristics, that we are interested in.

### *3.6. Measurement of the amount of cacotheline adsorbed*

As mentioned above, under the conditions of low $c_{CAC}$, long $t$ and fast $v$, the reduction of cacotheline can be considered to be totally controlled by the adsorption of cacotheline. In this case, the cathodic peak current almost decays to its baseline with little diffusion tail (see Fig. 3). Integration of this peak gives a charge $Q_a$, which represents the reduced charge of the surface species of cacotheline adsorbed at the mercury electrode. According to the equation

$$\Gamma = Q_a/(nFA)$$

the surface coverage $\Gamma$ (mol cm$^{-2}$) can then be calculated, where $A$ is the area of electrode (0.0171 cm$^2$), $n$ is the number of electrons transferred (4) and $F$ is the Faraday constant.

Fig. 6 illustrates the relationship between $\Gamma$ and $c_{CAC}$ at three different accumulation times. When the concentration of cacotheline was small, the surface coverage increased linearly with $c_{CAC}$. However, at higher concentrations of cacotheline, the curves tended to level off. The surface coverage $\Gamma$ at three different levels tended to reach the same constant value, which represented a full surface coverage of $8.60 \times 10^{-11}$ mol cm$^{-2}$. Each cacotheline molecule adsorbed thus occupied an area of 1.93 nm$^2$, if the adsorption of cacotheline was as a monolayer.

# Evaluation of metal fractions in river sediments and waters: application of chelation chromatography-differential pulse anodic stripping voltammetry

S. Sundd, B.B. Prasad *

*Analytical Division, Chemistry Department, Faculty of Science, Banaras Hindu University, Varanasi-221 005, India*

Received 1 August 1994; revised 6 December 1994; accepted 28 February 1995

**Abstract**

The ability of chelation chromatography in combination with differential pulse anodic stripping voltammetry (DPASV) to provide a simple, fast and reliable way of dealing with interionic interferences, competitive complexations, re-adsorption of released metal ions and sorption of spiking metal ions by organic/inorganic materials in the complex matrixes of real natural samples has been critically examined. The technique is based on the selective complexation of target metal fractions on some novel sorbents which are polymeric chelating resins doped on stationary supports (Whatman No. 1 paper and silica gel). The usual complications of leaching of the resin and/or the chelating ligand and colloid retention on the sorption bed at any stage of separation were largely obviated with these sorbents under the operational conditions of metal sorption. A detailed study on the application of such sorbents to the differentiation of ionic (free), labile (ionic plus weakly complexed) and bound (strongly complexed) metal fractions present in local river-sediment and water samples was carried out. Chelating resin-impregnated paper (CRIP) and chelating resin-immobilized silica gel column (CRISC) methods of chromatographic separation of analyte trace metals in combination with the follow-up 'standard addition' procedure of the DPASV technique were employed. A modest attempt has been made to formulate a speciation (fractionation) scheme for metal contents present in river-sediments and waters on the basis of selective retention of ionic and labile fractions on complexing resins.

## 1. Introduction

Selective separation of trace metals from aquatic complex matrixes and their fractionations in different forms is considered an arduous task, owing to the severe interferences caused by the high levels of cations, anions, organic colloids and particulates present in the natural sample [1–6]. Of several chromatographic techniques widely used to isolate trace metals, the applications of chelating resins are found to be potentially more selective than those of ordinary cation-exchange resins. However, it may be recalled that the retention of total metal species by a chelating resin (Chelex-100) column was found to be quantitative using synthetic solutions, but later was found prone to error using natural waters and seawater. The reason is that the heavy metals in natural samples may not exist entirely in the free (ionic) form, but may be present partly as the colloidal and/or complexed form, which will not equilibrate with the added ionic spike during the time of the separation experiments [7,8]. Also, the natural samples may contain a large fraction of the trace metals in a form which is not retained by the resin, and the anodic stripping voltammetry (ASV) method used to determine labile metal content may not respond to this inactive fraction [7]. In another technique where ion-exchangers were used to collect only labile forms, anodic ASV was

aided by cation-exchanger [9,10] retention. This was found useful to some extent in combating the general problems of trace metal analysis, such as ASV peak distortion [3–6], peak resolution owing to competing complexations (metal-supporting electrolyte complexation [11], chlorocomplexation [12], metal-humate complexation [6]), re-adsorption of labile metals onto particulates [9], adsorption of suspended matter onto an electrode [5,6,13], and sorption of metal ions used in peak spiking by colloidal hydrous oxides or humic acid components of sediments [14]. Nevertheless, all these procedures have limitations in overcoming other major complications, i.e. interionic interferences due to diverse metal ions, intermetallic formation [15,16] and the dissociation of sparingly soluble salts along with surface-held ions [9]. Moreover, the retention of metal-rich colloidal particles in the larger pores of resins may cause spurious results on acid digestion/elution.

In the quest for a fool-proof solution to various problems as stated above and to procure chelating functionalities immobilized on polymeric substrates which are effective for the quantitative retention of trace metal ions with desired selectivity, some novel chelating polyelectrolytes (Fig. 1) doped on stationary supports (Whatman No. 1 paper strip and silica gel), in accordance with Grahame's modification of Stern–Gouy–Chapmans' electrical double layer theory [17], appeared quite promising. The application of these sorbents in the chelating resin-impregnated paper (CRIP) and chelating resin-immobilized silica gel column (CRISC) method of chromatographic separation has already been established with synthetic water samples [18–21]. In the present investigation, a total speciation (fractionation) scheme of metals was formulated employing these methods for river-sediments, on the basis of selective chemical extraction followed by selective retention of the metal fraction of de-

sired 'lability' on complexing sorbents. An attempt has also been made to employ the CRIP method for metal fractionations in river water samples.

## 2. Experimental

### 2.1. Sediment samples

Sediment sampling from a local river (Ganges) was carried out separately for two types of samples. The first type is the natural sediments which were collected from the middle current of Nagwa Ghat (NG), Shivala Ghat (SG) and Raj Ghat (RG). Samples of the other type were drawn from the section of the river in the vicinity of the outfalls of sewage and waste-water drains through Nagwa nullah (NN) and City nullah (CN). The sampling was conducted by a USBM-54 bed material sampler which scoops bed samples from about 6–9 inches depth in the river bed. The samples were dried in air under atmospheric conditions, packed in polyethylene bags, properly labelled and brought to the laboratory for analysis. The water samples tested were drawn from two local ghats (Harishchandra Ghat (HCG) and Rajendra Prasad Ghat (RPG)) with the help of a dissolved oxygen water sampler. The collection points at these centres were adjoining nullah, mixing point of nullah and river (each at a depth of 1 m from the top), and the middle current of the river (0.6 m of the total depth from the top of the river).

### 2.2. Chemical extractant solutions

A small amount of sediment (400 mg) was placed in a vial with 30 ml of extracting solution and then sealed. This was equilibrated overnight by mixing with the help of an end-over-end mixing unit and allowed to settle for several hours; only supernated suspension was taken as test aliquot. The extractants used were: 0.02 M $HNO_3$ (pH 1.8–2.3), 4 M $CH_3COOH$/0.4 M $NH_2OH$–HCl, 0.13 M $CH_3COOH$/0.4 M $CH_3COONa_3$ (pH 5) and 0.05 M $CaCl_2$. These four base solutions cover the entire range of labile metal contents, e.g. 0.02 M nitric acid, low-pH labile; hydroxylamine hydrochloride in acetic acid, metals in reducing conditions; acetic acid/acetate buffer, weakly sorbed and carbonate bound; 0.05 M calcium chloride, exchangeable fraction at neutral system pH.

### 2.3. Selective retention of labile metal species by chelation chromatography

The use of two different modes (CRIP and CRISC) of chromatographic separation lead to the detection of primarily two different categories of biologically available metal ions, namely (a) ionic form by CRIP and (b) ionic plus weakly bound metal ions by CRISC (if the CRIP and CRISC methods give identical results, this indicates the presence of the ionic form only in the sample). The following chelating resins, which were originally reported [18–21] from our laboratory, were used in the chromatographic separations (structures are shown in Fig. 1):

(i) poly[*N*-*p*-xylylene piperazinium-di-iodohydroxyquinoline sulfonate] (PXPi(IHQS)$_2$) (MW 36 310);
(ii) poly[*N*-*p*-xylene piperazinium-di-sulfosalicylate] (PXPi(SSA)$_2$) (MW 25 680);
(iii) poly[*N* - chloranil - *N*,*N*,*N*′,*N*′ - tetramethyle -thylenediammonium-di-sulfosalicylate] (PCED(SSA)$_2$) (MW 2979);
(iv) poly[*N*-*p*-xylylene-*N*,*N*′-dicyclohexylethyl-enediammonium-di-iodo-hydroxyquinoline sulfonate] ($C_2$EX-[IHQS)$_2$) (MW 21 364).

The CRIP chromatographic method was executed on Whatman No. 1 paper strips (25 × 1.5 cm$^2$) which were impregnated with finely powdered chelating resins, PXPi(IHQS)$_2$ and PXPi(SSA)$_2$, in the manner described elsewhere [18,19]. Sediment extract was placed as a single spot (0.2 ml) on the bottom of the paper with the help of a microsyringe pipette for ascending chromatographic separations based on differential migration of heavy metals in suitable solvents (water; PXPi(IHQS)$_2$ strip and acetone–water (97:3, v/v); PXPi(SSA)$_2$ strip) based on the differences in their solubility product equilibria [22]. The lower portion of the paper fixes the target metal at the starting point through complexation, whereas in the upper portion, all the mobile ions were found together as stable complexes in an 'elliptical zone' with PXPi(IHQS)$_2$-impregnated strip [18] and in a 'narrow band' with PXPi(SSA)$_2$-impregnated strip [19]. The preferential order of selectivity for cations is $Fe^{3+} > Cu^{2+} > Cd^{2+}$, $Pb^{2+}$, $Zn^{2+}$. The chelation of $Cu^{2+}$ at the starting point was only feasible in the absence of $Fe^{3+}$; other diverse metal ions $Cd^{2+}$, $Pb^{2+}$ and $Zn^{2+}$ moved with the solvent and had an affinity for the functional groups of the sorbent

in the upper zone. The fine particles of metal-rich colloids/clays introduced at the starting point by microsyringe, although negligible, were dispersed around the middle of the paper by ascending carrier solvent; the upward moving metal ions with the solvent front have apparently higher $R_f$ values required for separation from strongly bound metals, if any, on colloids/clays. Both upper and lower parts were perfectly digested in 2 ml of concentrated $HNO_3$ (Suprapur ExcelaR), diluted to 25 ml and finally subjected to DPASV measurements.

CRISC chromatography was performed with two sorbents, silica gel–PCED(SSA)$_2$ and silica gel–$C_2$EX(IHQS)$_2$, and their column performance with a synthetic water sample containing different heavy metals has been reported elsewhere [20,21]. Column operations were employed in the usual manner with 1.5 g chelating sorbent (≈20–60 mesh) loosely packed (1 cm height) in a glass column (13 × 1.4 cm) under optimized conditions: pH 3.0 ($Fe^{3+}$), 4.0 ($Pb^{2+}$), 5.0 ($Cu^{2+}$) with flow rate 5 ml min$^{-1}$ for silica gel–$C_2$EX(IHQS)$_2$ sorbent; pH 5.0 ($Fe^{3+}$), 3.2 ($Cd^{2+}$), 4.5 ($Cu^{2+}$) with flow rate 5 ml min$^{-1}$ for silica gel–PCED(SSA)$_2$ sorbent. In all cases, 1 ml of the extract was diluted to 50 ml at the optimized pH and then passed through the column at a specified flow rate of analyte metal ions. This was followed by double or triple washings of bed materials with water to remove impurities due to fine particles or metal-rich colloids, if any, introduced during the loading step of the test aliquot. It may be pointed out that both sorbents have fast sorption kinetics suitable for column operation [23] with a $t_{1/2}$ (time required to reach half of the maximum sorption) value of 2 min and a $P_{2\,min}$ (the percentage attainment of equilibrium in 2 min) value of 50% metal sorption [20,21]. Moreover, with the thin bed of chelating resin and the flow rate of 5 ml min$^{-1}$, the contact time (10 min) of soluble complexes with the resin phase is apparently sufficient for the dissociation of labile metal fractions from weakly complexed metal-humate and fulvate or colloid species. Metal ions sorbed onto the column were finally eluted by 10 ml of Suprapur ExcelaR grade 0.1 M HCl (silica gel–$C_2$EX(IHQS)$_2$ column) and 1 M $HNO_3$ (silica gel–PCED(SSA)$_2$ column), diluted to 50 ml and finally subjected to DPASV (standard addition) monitoring.

### 2.4. Differential pulse anodic stripping voltammetry (DPASV) operating conditions

Differential pulse anodic stripping voltamperograms were obtained at ≈25 °C in the conventional manner with an EG and G Princeton Applied Research model 264A polarographic analyzer in conjunction with a model 303A static mercury drop electrode (SMDE) stand and an Omnigraphic $X$–$Y$ recorder. The mercury drop was renewed after de-aeration of the cell contents for each run. The DPASV peaks were spiked by the corresponding standard metal ion solution to evaluate the metal contents of the various solutions following the 'standard addition method' of quantitative analysis. The spiked standard peaks were relatively sharper than test ASV peaks, giving a better comparison of their respective peak heights.

In each run, 1 ml of digested/eluted test aliquot was added to 10 ml of buffer containing background electrolytes[1], sodium tartrate buffer ($\mu = 0.001$ M, pH = 11) for $Fe^{3+}$ and ammonium citrate buffer ($\mu = 0.2$ M, pH = 3) for $Cu^{2+}$, $Cd^{2+}$, $Zn^{2+}$, $Pb^{2+}$. The representative curves obtained under optimized conditions (see Figure captions) of voltammetric operation after CRIP and CRISC separation methods are shown in Figs. 2 and 3.

Direct and simultaneous analyses of the sediment extracts [13] were also undertaken by introducing 10 ml of extract directly into the voltammetric cell. Typical runs are depicted in Fig. 4. Suitable voltammetric operational parameters, such as deposition potential, scan rate and pulse height, were examined for all the sample extracts, as exhibited in Fig. 5. The optimum DPASV parameters — deposition time, 240 s; deposition potential vs. Ag/AgCl, −1.2 V; pulse height, 25 mV; scan rate, 5 mV s$^{-1}$ — were exercised for all sediment extracts. Prior to each deposition step, the test sample was purged with nitrogen for 4 min. In the reproducible repeat analysis, the cell contents had to be mechanically mixed between each deposition step. For both standard solution and suspension, the relative standard deviation of repeated scans was ±8% or better, and the replicate precision was of the same order. The peak potentials for different metal ions in sediments in direct and simultaneous

[1] Purified buffers were obtained following the CRISC method, as reported in Ref. [21].

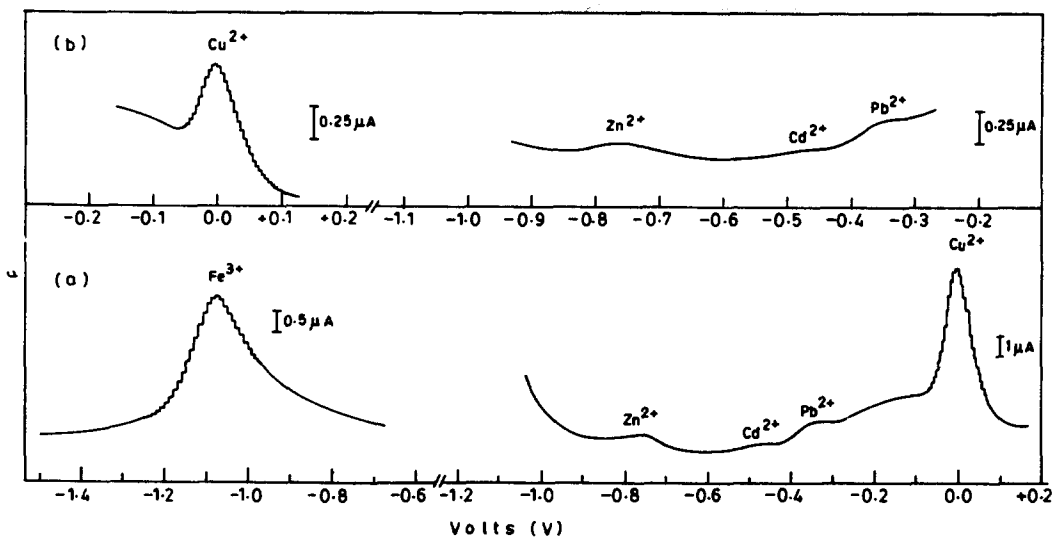

Fig. 2. Differential pulse stripping voltammograms of metals in Nagwa nullah sediment preconcentrated by the CRIP method. (a) $PXPi(IHQS)_2$ impregnated strip (0.02 M $NHO_3$ sediment extract), ($Fe^{3+}$, 0.001 M sodium tartrate buffer, pH 11; $Zn^{2+}$, $Pb^{2+}$, $Cu^{2+}$, 0.2 M ammonium citrate buffer pH 3). (b) $PXPi(SSA)_2$ impregnated strip (sodium acetate sediment extract) ($Cu^{2+}$, 0.2 M ammonium citrate buffer, pH 3; $Zn^{2+}$, $Cd^{2+}$, $Pb^{2+}$, 0.2 M ammonium citrate buffer, pH 3). (DPASV operational conditions: deposition time = 60 s, scan rate = 10 mV $s^{-1}$, pulse height = 25 mV, deposition potential (vs. Ag/AgCl) = −1.5 V ($Fe^{3+}$), −1.2 V ($Zn^{2+}$, $Cd^{2+}$, $Pb^{2+}$), −0.6 V ($Cu^{2+}$).)

DPASV analysis when varied with base electrolyte solution are portrayed in Table 1.

The residual metal impurities introduced during various stages of separation, digestion or elution in the present work were always subjected to the necessary corrections. The blank runs in DPASV determination of residual metal ions were made with 1 ml of digested (25 ml)/eluted (50 ml) solution (without any sediment extract or water samples) in 10 ml of an appropriate buffer of known pH, and corresponding amounts were calculated for subtraction from the final results. In direct and simultaneous analysis, the metal impurities present in extractants were determined by separate DPASV runs, prior to extract analysis for blank corrections.

### 2.5. Total metal contents

The total metal contents were determined by DPASV after sample digestion using a $KNO_3$–

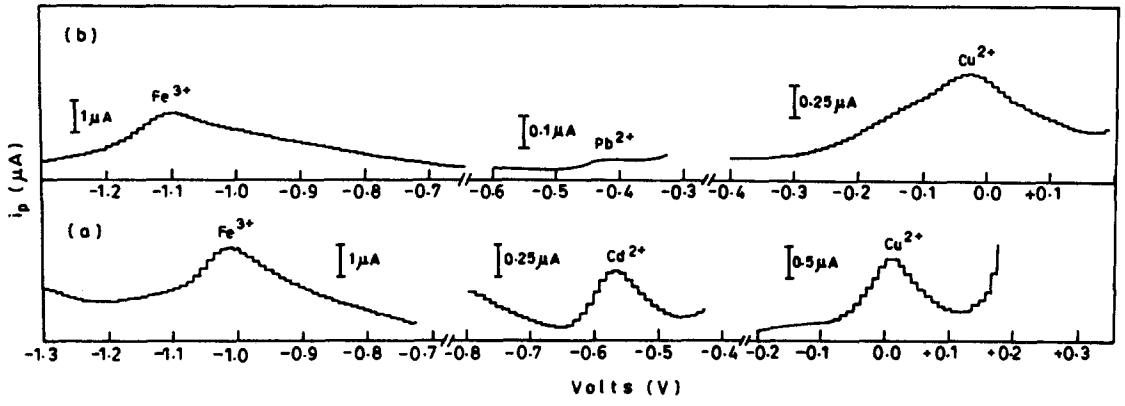

Fig. 3. Differential pulse stripping voltammograms of metals in Nagwa Ghat sediment preconcentrated by the CRISC method. (a) Silica gel–$PCED(SSA)_2$ column (0.02 M $HNO_3$ sediment extract) ($Fe^{3+}$, 0.001 M sodium tartrate buffer, pH 11; $Cd^{2+}$, $Cu^{2+}$, 0.2 M ammonium citrate buffer, pH 3). (b) Silica gel–$C_2EX(IHQS)_2$ column (0.02 M $HNO_3$ sediment extract) ($Fe^{3+}$, 0.001 M sodium tartrate buffer, pH 11; $Cu^{2+}$, $Pb^{2+}$, 0.2 M ammonium citrate buffer, pH 3). (DSPASV operational conditions: deposition time = 60 s, scan rate = 10 mV $s^{+1}$, pulse height = 25 mV, deposition potential (vs. Ag/AgCl) = 1.5 V ($Fe^{3+}$), −1.2 V ($Zn^{2+}$, $Cd^{2+}$, $Pb^{2+}$), −0.6 V ($Cu^{2+}$).)

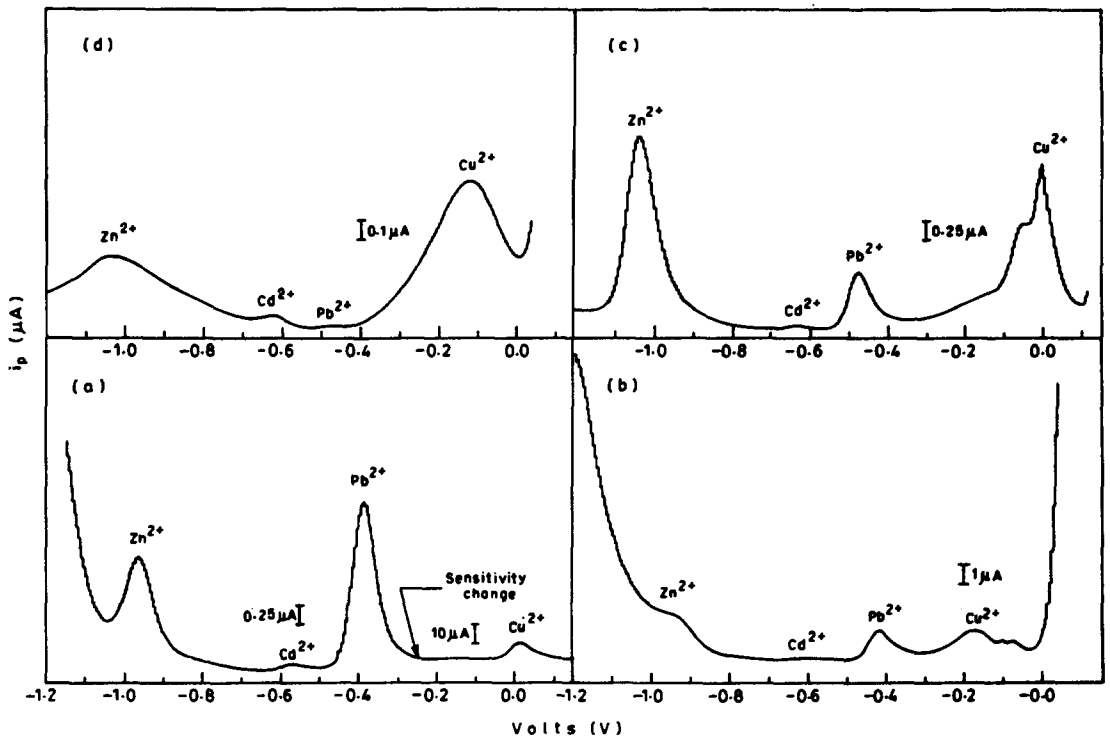

Fig. 4. Typical voltammograms of direct and simultaneous analysis of metals in Raj Ghat sediment in different extracts: (a) 0.02 M $HNO_3$, (b) 0.4 M $NM_2OH \cdot HCl$/4 M $CH_3COOH$, (c) 0.13 M $CH_3COOH$/0.4 M $CH_3COONa$ (pH 5) and (d) 0.05 M $CaCl_2$ extract.

$NaNO_3$ fusion technique [24] in which 2.0 g sediment sample was predigested in 5 ml concentrated $HNO_3$ at low heat. This was subsequently treated with $KNO_3$–$NaNO_3$ melts at 400 °C. The follow-up involved adding 10.0 ml aqueous acid, $NH_4OH$ neutralization and ammonium citrate buffer maintaining pH 3.0. Comparison was also made here between the direct simultaneous analysis of extracts and the amounts obtained after chromatographic separations (Table 2).

## 3. Results and discussions

The four major extractants (acidic, reducing, metal complex and neutral salt) used for the extraction of metal ions from sediments have distinctive characteristics in metal speciation [13]. The trace analyses with the CRIP and CRISC techniques are found to be equally efficacious for real as well as synthetic samples, insofar as evaluation of free and labile fractions is concerned. The ligand anions exposed outwardly as gegenions of polyelectrolyte coated on the stationary support are found to be readily available for strong chelation of even trace levels of labile metal species with a higher degree of selectivity and sensitivity. Hence, no spiking of sediment extracts is required, e.g. with chelex-100 resin [7], in the present study. Despite the fact that the CRIP and CRISC techniques are likely to give an estimation of only ionic (free) and labile (ionic plus weakly-complexed) metal fractions, respectively, strongly bound metals (and unreactive labile fractions if any) are not extracted at all. The instability problem of chelating resins caused by their bleeding, preswelling and cracking under the influences of medium effects and elution processes is found to be completely obviated in the present instance. Further, the sorbents studied here only take less than 4 min for 100% metal sorption [18–21]. A very small amount of colloids or fine particles in test aliquots of sediment extracts would not vitiate the sorption kinetics and also could not be retained with polymer coated resins of negligible pore size, during the extract loading.

The retention of heavy metals from local river (Ganges) sediments and waters on CRIP and/or CRISC supports was studied by analysing the original natural sample and the paper or column effluent, using DPASV moni-

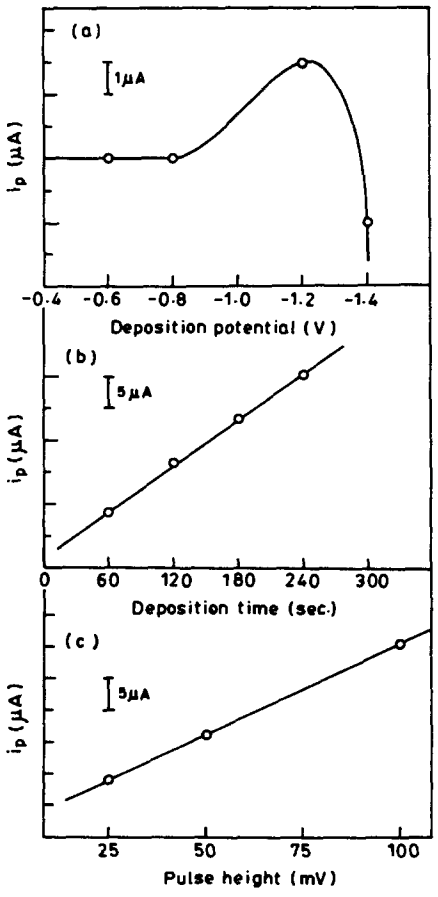

Fig. 5. Effect of operational parameters on copper peak current. (a) Deposition potential, −0.4 V to 1.4 V vs. Ag/AgCl; deposition time 60 s; pulse height, 25 mV. (b) Deposition potential, −1.2 V vs. Ag/AgCl; deposition time, 60–240 s; pulse height, 25 mV. (c) Deposition potential, −1.2 V vs. Ag/AgCl; deposition time, 60 s; pulse height, 25–100 mV.

toring. Retention of the total metal, naturally present, was not quantitative since only ionic and labile fractions were retained by chelating sorbents in the present study. The direct DPASV analysis of the original sample suffers the serious set-back of readsorption effect(s) in contrast with the earlier works [7,13]. As a matter of fact, the substantial shift in $E_p$ values (Table 1) of metal ions in sediment extracts studied can be considered as an indication of difficult oxidation due to the heavy sorption of diverse materials during both the deposition and stripping steps. However, the combination of chelation chromatography with DPASV appears to be an advantageous approach to the alleviation of serious problems of ASV peak resolution, owing to the competitive role of calcium ions [10] released through particle dissolution of sediment component, interionic interferences [14], intermetallic formation [15,16] and also to the readsorption effect in cells by diverse metal ions, surfactants and organic colloids present in the complex matrixes of real natural samples.

### 3.1. Low-pH labile contents

Dilute nitric acid (0.02 M) treatment of sediments releases metal ions associated with acid soluble matrix components (e.g. carbonates and amorphous hydroxides) and also displaces metals from organic acid colloids and surface sites [13]. The direct and simultaneous DPASV of $Cu^{2+}$, $Cd^{2+}$, and $Pb^{2+}$ gave flat baselines, where as a sloping baseline was obtained for $Zn^{2+}$ (Fig. 4(a)).

The increase in peak height was accompanied by an increase in pulse height and deposition time (Fig. 5). However, in all cases, a pulse height of 25 mV was used for DPASV runs, which provided a current well within the range of the recorder. In fact, a deposition time of a few seconds should have been adequate to avoid colloid effects for sediment extracts containing high levels of metal ions. However, the weakly-complexed colloid surface-held trace metal ions (ASV labile fraction) might not be easily retrieved and migrate to the mercury drop cathode under the influence of the applied potential, in such short time of deposition. As a matter of fact, a relatively large peak current was observed in the present study, when a higher negative potential of −1.2 V vs. Ag/AgCl and sufficient time of 240 s were employed (Fig. 5(b)) for ASV deposition for extracts containing large amounts of insoluble colloids/clay particles in direct DPASV analysis. The effects of variation of pulse height, deposition time and deposition potential are almost similar in all extracts for each metal studied.

It has been observed that direct DPASV through the standard addition method for $Fe^{3+}$ in nitric acid extract has never been possible, as the current for a sample consisting of free or weakly- bound iron metal is drastically reduced on spiking (Fig. 6). This reflects a favoured complexation equilibrium upon addition of spiking metal solution and consequent electrode adsorption perturbation. The problem is successfully solved by the application of CRIP/CRISC methods of isolation of iron from the extract. This step is also advantageous in combating the iron interferences [14] in the

DPASV measurement of multi-element samples. Both PXPi(IHQS)$_2$ and PXPi(SSA)$_2$ resins were found to be equally suitable for $Fe^{3+}$ retention by the CRIP method (Table 3) within the limit of errors incurred during the separation and monitoring steps. In contrast, sorbent silica gel–PCED(SSA)$_2$ is selective for $Cu^{2+}$, $Cd^{2+}$, $Fe^{3+}$, whereas silica gel–$C_2$EX(IHQS)$_2$ is selective for $Cu^{2+}$, $Pb^{2+}$ and $Fe^{3+}$ under the specified conditions of pH and flow rate. The selective retention of $Zn^{2+}$ was not possible by the CRISC method. A very low or almost negligible value for $Cu^{2+}$, $Cd^{2+}$, $Zn^{2+}$ and $Pb^{2+}$ in real samples is obtained by direct DPASV as compared to those obtained after chromatographic separations by both techniques. This indicates the drastic reduction of metal ion concentrations in direct DPASV analysis of sediment extract, presumably due to the re-adsorption of ionic and ASV labile loosely bound ions by colloidal particles along with the massive $Fe^{3+}$ interferences; this questions the validity of the data and tenuous nature of the direct method of sample monitoring with sediment samples.

Table 3 shows 'low-pH labile' metal content data, after chromatographic separation, in various sediments by the CRIP method to estimate only the ionic form, and the CRISC method to estimate ionic plus weakly-complexed (or loosely sorbed ions on particles in the extract) fractions as total biologically available 'low-pH labile' metals. The larger values of labile metal contents obtained by the CRISC method can be rationalized from the fact that the solution is passed slowly in this method, allowing enough equilibration time to extract metal easily from weakly complexed materials in addition to the free metal ions (stability constants [25] (log $K$) of complexes $Cu^{2+}$–SSA (9.5) and $Cu^{2+}$–I HQS (11.8) are larger than those for $Cu^{2+}$–humic acid (6, 8)/$Cu^{2+}$–fulvic acid (7.8, 8.5) complexes [26]). On the basis of a comparative study of 'low-pH labile' metal contents where the CRISC method gave higher results than the CRIP method, it may be concluded that there were weakly-bound metal fractions of $Cu^{2+}$ in Nagwa nullah, City nullah, Shivala Ghat, and $Pb^{2+}$ in all four samples barring City nullah. The metals $Cd^{2+}$ and $Fe^{3+}$ were always present as free ionic fraction ($Zn^{2+}$ could be only estimated as the free form by the CRIP method, as the CRISC method was not feasible).

### 3.2. Low-pH labile reducing conditions

The major fraction of total metal contents in soils and sediments is associated with hydrous oxides of iron, manganese and aluminium, and can be extracted with the help of reducing agents e.g. hydroxyl amine hydrochloride in 25% acetic acid [13].

A typical direct DPASV voltammogram in $NH_2OH \cdot HCl$/25% acetic acid medium is shown in Fig. 4(b). A system peak appears at $-0.75$ V at lower pulse height ($<100$ mV) as a consequence of the absorption of colloidal matter on the baseline slope of $Cu^{2+}$ [13]. As usual, the drastic iron interferences as well as the presence of organic particulates and $Cl^-$ ions impart a negligibly small amount of metal ions ($Cu^{2+}$, $Cd^{2+}$, $Zn^{2+}$, $Pb^{2+}$) by direct and simultaneous DPASV measurements. It is interesting to note that direct iron analysis in $NH_2OH \cdot HCl$/acetic acid did not pose any

Table 1
Peak positions of different metals in sediment sample extractants in direct DPASV measurements

| Extractant solution | Peak position (V) vs. Ag/AgCl [a] | | | |

NN = Nagwa nullah, CN = City nullah, NG = Nagwa Ghat, SG = Shivala Ghat, RG = Raj Ghat; Error $\leq \pm 8\%$.

problem in spiking, unlike in the nitric acid extract. It is noted that the results by direct analysis of iron are practically consistent with those obtained (excluding Nagwa Ghat sample) after chromatographic separations within the error limit ($\pm 8\%$). The reason may be that $NH_2OH \cdot HCl$ extract leaves very few active sites for reabsorption of iron by completely dissolving the organic colloidal particles. The exception with the Nagwa Ghat sample may be attributed to the presence of favoured adsorption by inorganic particulates in direct analysis. In the case of other metals, direct analysis data (Table 4) are always spurious owing to severe adsorption by undissolved residues other than hydrous oxides.

Chromatographic separations (Table 4) reveal that the zinc and copper contents are higher in Nagwa Ghat but lower in Raj Ghat. A small amount of $Cd^{2+}$ ions are found in Raj Ghat, and a higher amount in Nagwa nullah. The tributary Nagwa nullah has a lower $Pb^{2+}$ content, although Nagwa Ghat showed a relatively high $Pb^{2+}$ deposit in the river bed. The $Fe^{3+}$ contents were found to be relatively lower in Shivala Ghat as compared to Nagwa nullah.

The comparison of the CRIP and CRISC methods in $NH_2OH \cdot HCl$/acetic acid extract revealed that $Cu^{2+}$, $Cd^{2+}$ and $Fe^{3+}$ were present only in the free (ionic) form in all ghats, as the CRIP and CRISC values are in agreement with each other without showing a significant contribution from weakly labile complexed metal. Both weakly bound and free $Pb^{2+}$ were found in Nagwa nullah, City nullah, Nagwa Ghat, Raj Ghat and Shivala Ghat, as the CRISC method resulted in larger values than the CRIP method.

### 3.3. Weak acid (pH 5) labile

The sodium acetate buffer releases metal bound to ion-exchange sites or carbonate minerals through acetato complexation, rendering minimized pH effects on peak size [13]. Table 5 revealed that $Cu^{2+}$ is present in negligible amounts in all the sediments studied. The reason may be that the acetato complex is inefficient in destroying the weak bonding of metal ions and, further, hydrous oxides associated with large amounts of other metal ions are readily dissolved. In the direct analysis of the acetate buffer extract of Raj Ghat and Shivala Ghat, $Cu^{2+}$ peak splitting (Fig. 4(c)) was observed, probably owing to metal-humate complex formation. However, the emergence of a second copper wave can also be assigned to the formation of copper(I) hydroxy species or adsorption of Cu(II) hydroxy species in moderately acidic medium (pH > 5) [27].

The chromatographic separation results (Table 5) show that all samples are relatively

[a] Upper part of strip (except $Fe^{3+}$, which was preconcentrated in the lower part).

free from copper. Raj Ghat contains virtually no $Zn^{2+}$, $Pb^{2+}$ and $Cd^{2+}$. On moving from Raj Ghat to Nagwa Ghat, it is observed that the $Zn^{2+}$ contents in the free ionic form are increasingly higher compared to other metal ions. Although the $Cd^{2+}$ ion content is negligible in Nagwa nullah, it is substantial in Nagwa Ghat sediment.

On comparison of the CRIP and CRISC methods, Table 5 showes that $Cu^{2+}$ and $Cd^{2+}$ are present in trace amounts only in the free (uncomplexed) form in all samples studied. Some of the bound $Pb^{2+}$ contents are also present in Nagwa nullah, City nullah and Shivale Ghat, along with the free species.

### 3.4. Sediment pH (6–8) labile

Insofar as the extractions of metal ions held by electrostatic forces (i.e. occupying ion-exchange sites) are concerned, neutral salt solutions have been recommended [13]. For instance, 0.05 M $CaCl_2$ has been considered as a suitable medium for the selective extraction of copper in direct analysis.

A typical direct DPASV voltammogram in $CACl_2$ medium is shown in Fig. 4(d), where the broadening of the $Cu^{2+}$ peak is attributed to the presence of $Cl^-$ ions [9]. The low values of $Cu^{2+}$ (Table 6) found by both the CRIP and CRISC techniques reveal that abundances of electrosticted $Cu^{2+}$ are apparently less in all sediments, although the total $Cu^{2+}$ content is estimated to be considerably large (Table 2). The much smaller $Cu^{2+}$ ion content in the sediments from the middle of river current is probably due to the severe deterioration of the ion-exchange structure of sediments by the changing kinetics of water flow in adjacent layers. Nevertheless, the chromatographic sepa-

Table 4

rations (CRIP and CRISC) gave enhanced $Cu^{2+}$, particularly in City nullah and Nagwa nullah sediments as compared with direct techniques, whereas in the middle river-sediments $Cu^{2+}$ remained unaltered irrespective of the techniques employed (Table 6). The negligible value of $Cu^{2+}$ obtained from direct analysis may be taken as suggestive of exclusive adsorption onto the complexed matrices in $CaCl_2$ extract or drastic deterioration of the sediment network as suggested above, for any of the samples studied. The almost equal value of $Cu^{2+}$ from CRIP and CRISC strongly supports that all river sediments studied have an exclusively free form of copper in trace levels in their respective $CaCl_2$ extracts.

### *3.5. A general survey of the metal contents in sediment samples*

The chemical speciation procedure in the present instance is limited to only fractionation of metal contents of sediments. In spite of the ambiguous links between extraction category and 'biological availability', the selective chemical extraction by four major extractants covers almost all metal fractions present in sediment samples. If $M_1$ is taken as the total sum of all free (ionic) metals determined by the CRIP method and $M_2$ is the total sum of labile (ionic + weakly complexed) metals determined by the CRISC method available in all four extracts, the weakly complexed fraction could be obtained as $(M_2 - M_1)$. The

strongly complexed (bound) fraction is also estimated by subtraction of $M_2$ from the total metal contents obtained by the CRIP method from Table 2 (total metal contents obtained by the direct method are not acceptable owing to readsorption and matrix complications). $Zn^{2+}$ was obtained only in the ionic form by the CRIP method; other fractions could not be estimated. The results obtained on the basis of the above-formulated speciation (fractionation) scheme for metal contents of different sediments are portrayed in Table 7.

A decreasing trend of 'biologically available' metal contents ($Cu^{2+}$, $Ca^{2+}$, $Pb^{2+}$) ($M_2$) is observed on moving from Nagwa Ghat (upstream) to Raj Ghat (downstream) in sediments. This can only happen if the waste-water from the city chemically interacts with river-water to release the metal contents of sediments from solute phase to solution phase. In other words, city-waste disposal into the river through nullah introduces sufficient chelator/ligands for retrieval of metals from the sediment-bed, and subsequently pushes away these metals with the flowing water layers causing a drastic reduction in the metal contents of the sediments.

An entirely opposite trend of $Fe^{3+}$ contents, i.e. an increasing trend proceeding from Nagwa Ghat downwards, to Raj Ghat, can be attributed to the following possibilities: large contents of $Fe^{3+}$ being introduced into the river via Nagwa nullah which slowly settle on the river bed as ferrous hydroxides during the course of its flow downstream (Raj Ghat). Further substantial addition of City nullah enhances $Fe^{3+}$ as a free and weakly complexed form to a greater extent. Also, the $Fe^{3+}$ ions released by chelator/ligand tend to resettle on the river bed as ferrous hydroxide layers during the course of the downstream flow of the river.

### 3.6. Evaluation of copper in water samples

A modest attempt is made to analyse Ganges water samples in Varanasi, which were collected from two different stations, i.e. Rajendra Prasad Ghat (RPG) and Harischandra Ghat (HCG). The complexing ability of $Cu^{2+}$ has been determined for different samples by the

method of ASV titrations [26]. A combination of chromatography and direct DPASV analysis led to the fractionation of copper; the other metals present as labile fractions could not be detected. In addition, the laboratory tap-water was also analysed. The problem of re-adsorption was immaterial in water samples, in contrast to the sediment analysis; therefore, the direct and simultaneous analysis yielded ASV labile metal fractions (ionic plus weakly complexed) of copper. To obtain the total $Cu^{2+}$, 10 ml water sample was digested in the voltammetric cell with 2 ml of concentrated nitric acid without boiling, and eventually evaporated to dryness. The direct and simultaneous analysis of the residue was then carried out in 0.2 M ammonium citrate buffer (pH 3) by DPASV.

As is evident from Table 8, both the CRIP and direct DPASV methods gave similar results for Rajendra Prasad nullah. Hence, it is obvious that this sample does not particularly contain weakly complexed species except the ionic form of free $Cu^{2+}$ ion. On the contrary, the mixing points of nullah and river at Rajendra Prasad and Harish Ghandra Ghat containing the purely weakly complexed form of $Cu^{2+}$ ion, obtainable in the direct method of simultaneous analysis as the CRIP method, fails to detect any free metal ions. The non-detectable ionic fraction of $Cu^{2+}$ ions in the CRIP method at the mixing points of nullah and river at these stations strongly reveals the presence of chelating matters like humic and fulvic acids or any other organic substances which complex $Cu^{2+}$ ions very effectively. The middle streams of Rajendra Prasad Ghat and Harishchandra nullah were devoid of both ionic and weakly complexed forms of copper. Here, it could be surmised that the higher complexing ability of these samples may be the governing factor restricting 'ASV labile' fraction in direct and/or CRIP analysis. The tap-water sample had only the ionic form of $Cu^{2+}$ available for CRIP analysis, while the weakly labile form could not be detected through direct analysis.

The very low values of total $Cu^{2+}$ contents are surprisingly unrealistic, and this could be only rationalized if one assumes that there is a strong possibility of the formation of intermetallic compounds on the surface of SMDE, which might result in illusive and frivolous values.

## 4. Conclusion

A major objective in this investigation was to evaluate the feasibility of a chelation-chromatographic approach to the differentiation of ionic and labile metal fractions in river/water samples. It has been concluded that the direct and simultaneous analysis of metals in sediment undoubtedly has drastic re-adsorption/competitive effects from a complex matrix of sediment extract. The introduction of a filtering step before analysis is not advisable, as some fractions loosely bound with the suspension are likely to be lost. However, the application of the CRIP and CRISC methods to the selective retention of heavy metals has proven to be an advantageous step to remove the possible complications of re-adsorption, intermetallic formation, separation of exchanger from sediment, competitive effect of multi-elemental matrix, and electrode perturbation, etc. The CRIP method measures only ionic (free) met-

als, whereas the CRISC method gives an estimation of the labile (ionic plus weakly complexed) fraction of the metals. Further, the validity of the standard addition method, which has been reported to be unsuccessful in direct analysis, could be restored by chelation-chromatographic analysis. The pH effect of the base extractants on peak height is also eliminated, since analyte metal ions are essentially isolated prior to analysis and monitored by DPASV in the suitable buffers at optimized pH. Further, the proposed CRIP-DPASV technique is found to be very simple and an efficient alternative to avoid peak distortion and iron interferences in the direct analysis of heavy metals at trace levels in water.

Although we cannot fully account for the wide spectrum of results at different intervals of time (or season) in different sections of the river, the present work, within a limited framework, merits special significance to establish an analytical scheme for the classification of various types of metal fractions present in real natural samples.

# The separation of platinum, palladium and gold from silicate rocks by the anion exchange separation of chloro complexes after a sodium peroxide fusion: an investigation of low recoveries

Jacinta Enzweiler [1], Philip J. Potts *

*Department of Earch Sciences, The Open University, Walton Hall, Milton Keynes, MK7 6AA, UK*

Received 8 December 1994; revised 1 March 1995; accepted 2 March 1995

**Abstract**

A series of experiments was undertaken to measure the recovery efficiency of platinum, palladium and gold from silicate rocks using a sodium peroxide fusion followed by anion exchange separation of the analytes as chloro complexes. Results obtained by graphite furnace atomic absorption spectrometric analysis of standard solutions prepared in dilute HCl or HCl-acidified sodium peroxide solution showed that recoveries were near quantitative. However, when standard solutions were added to an alkaline sodium peroxide solution, which was then acidified, low results were obtained for platinum and gold (46% and 76% respectively). Low and variable results were also obtained when standard solutions were added to a peridotite sample that had been dissolved by the state procedure, and in the analysis of the South African Bureau of Standards certified reference material, SARM 7. Various experiments were undertaken to investigate these low recoveries, but the reason proposed here is the formation of hydroxychloro compounds in alkaline solution which are not, on acidification with HCl, converted quantitatively to the chloro complex necessary for quantitative anion exchange separation. It is concluded that a sodium peroxide fusion followed by an anion-exchange separation does not appear to form the basis of a successful technique for the determination of platinum, palladium and gold in silicate rocks.

## 1. Introduction

In the absence of "definitive methods" for the determination of the platinum group elements (Pt, Pd, Rh, Ru, Os, Ir) in geological samples, there is continuing interest in the development of new and more effective analytical procedures. These elements present a significant analytical challenge since the concentration in many geological samples is in the nanograms per gram or even the sub-nanograms per gram range. Even when using the most sensitive analytical techniques, it is necessary to separate the platinum group elements (PGEs) from matrix elements and concentrate them before analysis.

One of the most widely used separation techniques is based on fire assay using nickel sulphide [1,2], or for a more limited selection of elements, lead-based fluxes [3,4]. These preconcentration procedures are considered by the geological community to be some of the most reliable and offer the advantage of accepting

relatively large sample masses (normally up to 10–50 g). However, the fire assay procedure is not without some difficulties, notably the requirement to adjust flux composition according to sample matrix composition and the relatively large quantities of reagents required with the potential consequential increase in blank levels. Furthermore, some reports have suggested that the nickel sulphide fire assay procedure does not always yield quantitative recoveries of Au and the PGEs [5] and that without care, losses can also occur in the subsequent dissolution of the nickel sulphide button prior to analysis [6].

For these reasons, there is considerable contemporary interest in developing alternative analytical procedures which offer advantages over established techniques. Of the alternative procedures, ion exchange separations offer considerable potential. In particular, Alimarin et al. [6a] have shown that high performance liquid chromatography is capable of separating the PGEs as 8-hydroxyquinolinates, and they recommended their procedure for the analysis of "technological solutions, concentrates, alloys and catalysts". For the analysis of geological samples, our particular interest was in a review of published distribution coefficients [7], which indicated that conventional anion exchange resins have, in theory, several advantages. Not only are the PGEs and Au chloro complexes strongly adsorbed by anion exchange resins from dilute hydrochloric acid solutions, but few other elements that are found at significant concentrations in silicate rocks form anionic species under these conditions (Table 1). More specifically, according to Korkisch [7], only the following restricted range of elements is also adsorbed by anion exchange resins from 0.5 M HCl solutions: Ag, Cu(I), Re(VII), Tc(VII), Zn, Cd, Hg, Tl(III), Sn, Pb, Sb(III), Bi, Te(IV). Chromium, which may be present at substantial concentrations in silicate rocks, is also strongly adsorbed as Cr(VI), but if it is reduced to Cr(III), no adsorption occurs. Consequently, solutions resulting from anion exchange separation are likely to be free of high dissolved salt contents as well as species that could cause interferences in high sensitivity techniques such as graphite furnace atomic absorption spectrophotometry (GF-AAS) or inductively coupled plasma-mass spectrometry (ICP-MS).

An anion exchange separation was used by Branch and Hutchinson [8] to preconcentrate Pt and Pd after an aqua regia attack of the sample, with determinations made by GF-AAS. Their results were near quantitative, but alternative work [9] has shown that aqua regia is not capable of dissolving the more refractory PGE minerals, so this procedure is not appropriate for all silicate rock samples. An alternative, and potentially more effective dissolution procedure is one based on a sodium peroxide fusion (or sinter) [10]. Such procedures have been used extensively and successfully in radiochemical separations [11–14], particularly for the determination of the rare earth elements, but not so commonly with other analytical procedures. However, sodium peroxide fusion offers the advantage that sulphide and refractory minerals are effectively attacked and the released PGEs are uniformly converted to a high oxidation state. An anion exchange separation procedure has then the potential to separate selectively the PGEs and Au from the large concentrations of flux and matrix elements. To accommodate the relatively large volume of solution which results from dissolution of the peroxide cake, the anion exchange can be carried out in batch rather than column mode, a procedure that has been shown to offer quantitative recoveries for species with high distribution coefficients such as the PGE and Au chloro complexes [8,15]. However, despite these favourable characteristics, a review of the scientific literature did not reveal any methods in which anion exchange chromatography had been used following a sodium peroxide fusion of geological samples for the determination of the PGEs and Au at the nanograms per gram level — hence the justification for the present work.

In this paper, the results of a preliminary investigation are presented into the development of a method for the determination of platinum, palladium and gold in silicate rock samples based on sodium peroxide sample fusion, followed by anion exchange separation in the column or batch mode. Unexpected difficulties attributable to low recoveries of these analytes are described and discussed.

## 2. Experimental

### 2.1. Reagents

Stock standard solutions of platinum and palladium were prepared by dissolving $(NH_4)_2PdCl_4$ and $(NH_4)_2PtCl_6$ (Johnson Matthey Chemicals Ltd.) in 1 M HCl. For gold, an atomic absorption solution (100 μg $ml^{-1}$) (Aldrich) was used. Quartz-distilled HCl, subboiling distilled nitric acid and deionised water were used in the analytical procedures. All other chemicals were analytical reagent grade. PTFE apparatus and glassware were cleaned by soaking in aqua regia overnight and then by repeatedly soaking and rinsing with deionised water. Between fusions, the zirconium crucible was cleaned by soaking in hot concentrated HCl and then rinsing with deionised water.

### 2.2. Sample dissolution

Samples were digested by either sintering or fusing with sodium peroxide in zirconium crucibles, using the following procedure. About 2 g of sodium peroxide were weighed into the crucible and 0.5 g of sample (which had been dried at 105 °C) was added. After thorough mixing, more sodium peroxide was added (0.5 g for sinter or 1 g for fusion) and mixed with the contents of the crucible. The crucible was then covered with a lid and placed in a cold furnace.

For the sintering procedure, the temperature was raised to about 200 °C and maintained for 15 min. The temperature was then raised to 480 °C and held for about 90 min. The crucible was removed from the furnace and allowed to cool for 2 min before transferring to a 600 ml beaker, adding 60 ml of warm water and covering with a watch glass. After the reaction had subsided, the crucible was rinsed with water, 6 M HCl (2 ml) and then water again and these rinses were added to the sample solution. The precipitate was dissolved by adding 25 ml of 6 M HCl, stirring the solution whilst the acid was added.

For the fusion procedure, the temperature of the furnace was raised to 550 °C and maintained for about 20 min. The crucible was swirled to ensure mixing and then placed back in the furnace, and the temperature was raised to 575 °C and maintained for a further 20 min. The crucible was swirled again and the temperature was raised to 600 °C for 20 more min. The crucible was removed from the furnace and allowed to cool for some minutes before being transferred to a beaker, to which 20 ml of cold water were added. The beaker was covered with a watch glass to allow the cake to dissolve. After completion of the reaction, the same procedure as described above was followed. Both the crucible and the lid were rinsed with small amounts of 6 M HCl, which were added to the main solution.

In each case, the volume of solution was adjusted to approximately 150 ml. Hydrogen peroxide (1 ml) was then added and the solution was boiled for some minutes to reduce chromium(VI), which otherwise would be strongly retained by the anion exchange resin. The solution was cooled to room temperature and the pH was adjusted to 0.3.

### 2.3. Anion exchange

A strongly basic anion exchange resin (Bio-Rad AG1-8X; 100–200 mesh) was used in this work. In the majority of the experiments a batch procedure was employed, but the cleaning and conditioning of the resin was always undertaken in PTFE columns 0.5 cm in diameter with a 30 ml bulb and a polypropylene frit to retain the resin. Resin (1 g) was transferred to the column in the form of a slurry. The resin was cleaned and conditioned following the procedure of Colodner et al. [16], using hot 12 M nitric acid (10 ml), followed by 8 M nitric acid (10 ml), water (20 ml), 6 M HCl (10 ml) and finally 0.5 M HCl (20 ml).

For a batch separation, the resin was added to the sample solution and stirred for 1 h using a magnetic stirrer. Experiments on the kinetics of absorption confirmed that this time was sufficient for the quantitative recovery of the elements of interest. After this time the resin slurry was quantitatively transferred to the column and washed with 0.5 M HCl (20 ml) and water (20 ml). The column was eluted with hot (approximately 90 °C) 12 M $HNO_3$ (30 ml), added 1 ml at a time. The eluate was collected in a 40 ml PTFE beaker. The solution was evaporated down to a volume of approximately 0.5 ml under an infrared lamp. It was then transferred to a 5 ml volumetric flask and the volume made up with 0.5 M HCl. The elements Pt, Pd and Au were determined using a Perkin–Elmer Zeeman 3030 graphite furnace atomic absorption spectrophotometer, employing the conditions listed in Table 2.

In some experiments, the separation was undertaken by passing the solution through the column instead of using a batch separation procedure. As well as separations involving dissolved silicate rock samples, experiments were also performed with standard elemental solutions, to evaluate the behaviour and recovery of the PGE chloro complexes.

## 3. Results and discussion

Preliminary results on applying the proposed scheme to the analysis of the certified reference material SARM-7 gave low and sometimes variable recoveries of the elements of interest when analysed values were compared with certified values. To evaluate the effectiveness of the anion exchange procedure, therefore, a series of experiments was carried out using standard solutions of Pt, Pd and Au. The concentrations of Pt, Pd and Au, and where appropriate, sodium peroxide and hydrochloric acid, were selected to match those found in sample solutions prepared from SARM-7 by the procedure summarised above. The results of these experiments showing the percentage recoveries of the elements of interest are listed in Table 3. The interesting and unexpected differences may be summarised as follows.

### 3.1. Standard solution experiments

When Pt, Pd and Au were added to a simple solution of 0.5 M HCl (experiment (a) in Table 3) or to an acidified solution of sodium peroxide (experiment (b)), the recoveries of Pt, Pd and Au after anion exchange were near quantitative (within experimental error), having mean values in the range 92–98%. These results indicate that the anion exchange procedure summarised above is effective, as expected from the favourable distribution coefficients for chloro complexes of PGEs. The large excess of sodium ions in acidified solutions does not appear to interfere significantly with the batch separation.

However, when the standard solutions were added to an alkaline solution of sodium peroxide, which was then acidified with HCl, as would be required in the full procedure for silicate rocks summarised above, recoveries were more variable, ranging from 46% (Pt) to 76% (Au) to 96% (Pd) (experiment (c) in Table 3). Thus, the palladium recovery was still near quantitative, but less than 50% of the platinum was detected after anion exchange separation, and the gold recovery was also low and variable.

These data suggested that on acidifying the alkaline solution, complete conversion of the Pt and probably the Au species to anionic chloro

Table 3
Results obtained for Pt, Pd and Au recoveries using an anion exchange resin

| Experiment [a] | Recovery (%) [b] | | |
|---|---|---|---|
| | Pt | Pd | Au |
| (a) Std. soln. in 0.5 M HCl ($n = 6$) | 97 ± 6 | 98 ± 5 | 92 ± 6 |

| (l) SARM-7, fusion, Te coprecipitation | 99 | 91 | 107 |

[a] When not stated, $n = 1$.
[b] ±, One standard deviation.

complexes was not occurring. A further experiment was, therefore, carried out in which chlorine gas was bubbled through the acidified sodium peroxide solution to promote the formation of anionic chloro complexes (experiment (d) in Table 3). In these circumstances, the recovery of platinum was increased to 83% with the palladium recoveries remaining near quantitative, but the recovery of Au was reduced to 55%, for reasons which are not clear.

Two further experiments were undertaken in which standard solutions were added to a peridotite sample which had been dissolved following the procedure listed above. In the first case, the standard solution was added to the peridotite sample before fusion with peroxide, dissolution to form an alkaline solution, acidification and anion exchange separation (experiment (e) in Table 3). Following the trend observed in experiment (c), low recoveries were observed for all elements as follows: Pt (15%), Pd (74%) and Au (65%). In the second experiment ((f) in Table 3), the standard solution was added after acidification of the solution derived by fusion of the peridotite sample (i.e. just before anion exchange). Although near-quantitative recoveries might be expected by analogy with experiment (b), in fact recoveries were 12–23% lower, as follows: Pt (84%), Pd (75%), Au (80%). This result indicated that the presence of the peridotite sample or some aspect of the fusion procedure had interfered with the anion separation procedure.

### 3.2. Experiments using certified reference material, SARM 7

A series of experiments was then carried out using the certified reference material SARM-7 (platinum ore) distributed by the South African Bureau of Standards. This silicate sample has relatively high abundances of Pt, Pd and Au (3.74 $\mu g\,g^{-1}$, 1.53 $\mu g\,g^{-1}$ and 0.31 $\mu g\,g^{-1}$, respectively) compared with "typical" silicate rocks. However, it offers the advantage in testing the procedure that determinations made by GF-AAS are well above the detection limit of the technique and so results would not be affected seriously by poor analytical precision.

In the first series of experiments, the sample was attacked using the sintering procedure. These data were compared with results using the full fusion procedure. No significant difference was detected between the respective ranges of measurements, and the average of all 10 determinations are listed as experiment (g) in Table 3. The measured recoveries were Pt (34%), Pd (78%) and Au (84%).

To evaluate further these discrepancies, additional experiments were undertaken as follows: fusion of SARM-7 followed by chlorination of the acidified solution before anion exchange (experiment (h)); substitution of nickel for zirconium crucibles in the standard procedure in case the presence of small amounts of Zr dissolved from the crucible interfered with the separation procedure (experiment (i)); and treatment of SARM-7 with HF prior to fusion to remove Si in case the presence of silica

interfered with the separation (experiment (j)). Low recoveries were observed in all these experiments, with values ranging as follows: Pt (30–38%), Pd (64–79%) and Au (68%–125%).

The final two experiments with SARM-7 (experiments (k) and (l) in Table 3) employed an alternative sample dissolution or preconcentration procedure as follows. In experiment (k), SARM 7 was dissolved by an HF-aqua regia attack using a pressure bomb. The sample (1.0 g), HF (11 ml) and aqua regia (4 ml) were mixed in a PTFE bomb and sealed with a PTFE gasket in a stainless steel jacket, which was left in an oven at 180 °C overnight. After evaporation of the resultant solution and conversion of the residue to chlorides, the solution was filtered, the pH of the filtrate adjusted to 0.3 and the solution was passed through an anion-exchange column. Pt and Au recoveries were near quantitative (99% and 98% respectively, Pd being lower at 80%. In experiment (l), SARM-7 was attacked using the peroxide fusion procedure but a Te coprecipitation was carried out on the resultant solution using established procedures [14]. The Te precipitate was filtered using a Millipore type HA 0.45 mm filter disk which was then removed from the PTFE holder and the precipitate quantitatively washed into a PTFE beaker using concentrated nitric acid. The same was done with any precipitate adhering to the holder. The solution was evaporated, and the residue dissolved in 0.5 ml of aqua regia, and was transferred to a 5 ml vessel, which was made up to volume with 0.5 M HCl and the analytes determined by GF-AAS. Recoveries for Pt were again near-quantitative (99%) with high recoveries for Pd (91%) and Au (107%).

### 3.3. PGE chemistry

All these results show that the separation of the PGEs by anion-exchange as the chloro complexes is not as simple as might be expected from the favourable distribution coefficient data. However, some conclusions can be made from these experiments in relation to potential difficulties previously reported in the literature.

#### 3.3.1. Formation of hydroxy complexes

The first problem concerns the formation of PGE and Au hydroxy and hydroxychloro species in the alkaline solution during dissolution of the sodium peroxide cake, species which may not easily be converted to chloro complexes on acidification with HCl. In a paper dealing with the speciation of gold(III) chloride complexes in aqueous systems, Peck et al. [17] showed that with increasing pH, measurements by UV-vis and Raman spectroscopy were consistent with the successive replacement of chloride by hydroxide ligands with $[AuCl(OH)_3]^-$ and $[Au(OH)_4]^-$ being formed at high pH. The results of Peck et al. also showed that these hydroxychloro complexes were more stable than predicted on the basis of theoretically estimated stability constants. Hartley [18] reported that hydroxy complexes of Pt(IV) are obtained when a chloroplatinum(IV) complex is treated with sodium hydroxide. If this effect influenced the procedure used in the present work, it would be expected that by bubbling chlorine for several minutes through the acidified solution obtained after dissolving the peroxide cake, the recovery of Pt would be increased. An increase in recovery was in fact observed when a standard solution was used (experiment (d)) but not with SARM-7 (experiment (h)), and no improvement was observed when the peroxide cake was dissolved directly in 6 M HCl instead of first leaching in water (the resultant silica precipitate had to be separated by filtration before anion exchange).

Davidson and Jameson [19] measured the equilibrium constant of the reaction

$$[PtCl_6]^{2-} + H_2O = [PtCl_5(H_2O)]^- + Cl^-$$

as $3.25 \times 10^{-2}$ at 50 °C. From these data, it would then be expected that more than 90% of the platinum present in 0.5 M HCl solutions should be in the form of the hexachloro complex. This statement agrees with the results obtained from standard solutions added to HCl solutions or to already acidified solutions of sodium peroxide (experiments (a) and (b)). However, when Pt was added to the basic solution and then acidified (experiment (c)), the results are not satisfactory. Chugaev and Klopin [20] obtained ammonium dihydroxyplatinate from the reaction between diammonium tetrachloroplatinate and hydrogen peroxide in acidic medium. The same workers reported that in alkaline medium, the reactions are complex and that all chlorine atoms are substituted by $OH^-$ ligands. This substitution reaction cannot be reversed except by heating with HCl at 150 °C. These conditions could not be applied in the current scheme of analysis as $SiO_2$ would dehydrate and precipitate. Colod-

ner et al. [16], using the anion-exchange procedure to preconcentrate Pt from seawater and sediments, reported recoveries above 80%, but obtained systematically lower results when their work was compared with other published data. They attributed this discrepancy to the fairly unreactive nature of Pt in sea water and the slow kinetics of Pt–ligand exchange reactions (as previously reported by Elding [21]), both of which could affect the spike equilibration of their isotope dilution technique.

Although this effect (the presence of PGE/Au hydroxychloro complexes) appears to us to be the most likely cause of the discrepancies described here, other sources were evaluated.

*3.3.2. Interference from Zr*

Zirconium from the crucible oxidises to zirconium dioxide during heating and it has been shown [22] that hydrated zirconium dioxide can be used to concentrate trace amounts of chlorocomplexes of the Pt group elements, an effect that could lead to low recoveries. However, substitution of a nickel crucible did not significantly improve recoveries (experiment (i)).

*3.3.3. Coprecipitation with silica*

The presence of any silica in solution could interfere either by coprecipitating the noble metals and/or affecting the anion exchange procedure. However, when one sample was treated with HF, which was then removed together with silica by evaporation with $HNO_3$ and HCl (experiment (j)) and the residue fused (minus silica) with peroxide, the Pt recovery was only 38%.

From all these results, it is inferred that in alkaline solution, platinum forms hydroxychlorocomplexes and that the substitution of chloro ligands for hydroxy ligands is not quantitative when the solution is then acidified with HCl. Any alternative explanation involving the precipitation of significant amounts of Pt as an insoluble residue during dissolution of the sodium peroxide cake is not supported by results presented here. The selectivity of the anion exchange resin is much higher towards the choro rather than the hydroxy complexes [23]. For this reason, if hydroxychloro complexes are present in solution, then the recovery efficiency is likely to be much lower and it is this that is inferred as the limiting factor from the Pt data reported in Table 3. Although direct measurements have not been carried out to confirm this hypothesis, it is possible that future experiments involving the application of high-performance liquid chromatography (e.g. Alimarin et al. [6a]) might permit identification of the hydroxychloro Pt species present.

Palladium and Au showed a more consistent behaviour in experiments using both standard solutions and the reference sample SARM-7. However, the results obtained for Pd for sample SARM-7 are systematically low for all the procedures used (experiments (g)–(k)). This observation was not the case in the experiments using standard solutions where results were quantitative. One possibility, which could explain incomplete recoveries of Pd, is that after dissolution of the sodium peroxide cake, Pd may be present as $Pd(OH)_2$, a proportion of which may be reduced to metallic Pd by hydrogen peroxide [18] in alkaline medium. However, this explanation does not fit in with the low results obtained when an acid attack was used (experiment (k)) or with the quantitative results obtained in experiment (c). Nevertheless, this possibility cannot be rejected completely and it must be considered for Pt and Au as well, since the hydroxy species of these metals can also be reduced by hydrogen peroxide in alkaline medium.

Attempts were not made to determine the other Pt group elements for the following reasons: Os forms the volatile tetroxide in acidic medium and so would be lost from sample solutions. Ruthenium(IV) is strongly absorbed from 1 M HCl solutions, but in more dilute HCl medium [24], it forms species like $Ru(OH)_2Cl_2$ which is not retained by the resin. Rhodium(III) forms $RhCl_2^+$ in 0.1–0.5 M HCl solutions and is not absorbed by anion exchange resins, while Rh(IV) is very strongly absorbed, but oxidation of rhodium in solution to form the tetravalent state is not possible with common oxidising agents. Iridium is strongly adsorbed by the resin when oxidised and complexed as $IrCl_6^{2-}$, but this species is easily reduced to the trivalent complex, which is not retained by the resin.

## 4. Conclusions

The results obtained in this work show that the solution chemistry of Pt, Pd and Au is more complicated than expected when investigating a method for determining these elements in silicate rocks by peroxide fusion, followed

by an anion ion exchange separation. Although both Pt and Pd chloro complexes have favourable distribution coefficients towards anion exchange separation, and the separation procedure is potentially highly selective towards these elements (the dichromate ions of Cr being the only other species likely to interfere), the advantage of these favourable characteristics cannot readily be taken in the analysis of silicate rocks. It is suggested that hydroxy- and/or hydroxychloro- Pt complexes formed in alkaline sodium peroxide solutions do not react quantitatively to form the equivalent chloro complexes when these solutions are acidified with HCl, even when a chlorination procedure is used. Equivalent reactions may affect Pd and Au, although apparently to a lesser extent. Alternative procedures must be investigated in order to develop a successful analytical technique, examples of which are given by Van Loon and Barefoot [26].

# Direct determination of boron in a cobalt-based alloy by graphite furnace-atomic absorption spectrometry

Benling Gong *, Yongming Liu, Yuli Xu, Zhuanhe Li, Tiezheng Lin

*Dalian Institute of Chemistry Physics, Academia Sinica, 161 Zhongshan Road, Dalian, People's Republic of China*

Received 10 November 1994; revised 28 February 1995; accepted 10 March 1995

**Abstract**

A matrix modifier composed of nickel and zirconium, and a graphite tube treated with zirconium solution were proposed for the determination of boron in cobalt-based alloys by graphite furnace-atomic absorption spectrometry. The effects of this matrix modifier and the treated graphite tube were studied, and the combination of 60 μg of nickel and 20 μg of zirconium as matrix modifier, and a graphite tube soaked with 10 g $l^{-1}$ of zirconium solution were found to give the highest analytical sensitivity. The interference effects of major components (cobalt) and eight minor components (chromium, nickel, tungsten, iron, tantalum, molybdenum, titanium, aluminium and manganese) were studied. Boron in four cobalt-based alloys was determined by graphite furnace-atomic absorption spectrometry employing the proposed matrix modifier and the treated graphite tube, without the preseparation of matrix. The relative standard deviation was 3.3% for 0.048% of boron. A characteristic mass was 500 pg.

## 1. Introduction

The addition of appropriate amounts of some elements improves the performance of steels and alloys appreciably. A microamount of boron increases the degree of quenching and the strength and toughness of steels and alloys. However, excess amounts of boron may cause their performance to deteriorate. Therefore the exact determination of boron in steels and alloys is required for metallurgical applications.

Cobalt-based alloys contain many components (chromium, nickel, tungsten, aluminium, tantalum, iron, manganese, silicon, carbon, etc.), as well as its main component (cobalt) and boron. Such a complex composition causes severe spectral and chemical interferences in the determination of boron by atomic spectroscopy. Although separation of the matrix from the sample solution before the measurements are performed and overcome these interferences, this requires a tedious treatment, easily resulting in either contamination or loss. Therefore it is preferable to determine boron in such alloys by direct measurements without the preseparation of the matrix from the sample solution.

Inductively coupled plasma-atomic emission spectrometry has been widely used for the determination of microamounts of boron [1–11], but this method is unsuitable for direct determinations because it necessitates preseparating the matrix from the sample solution in order to remove spectral interferences.

Graphite furnace-atomic absorption spectrometry, another sensitive method, also suffers severely from matrix interferences. Moreover, boron combines very easily with the carbon of the graphite tube, resulting in low analytical results and severe memory effects. Nevertheless, the selective application of a suitable matrix modifier and the pretreatment of the graphite tube could resolve the above problems. To date, some matrix modifiers such as

calcium [12,13], strontium [14], magnesium [13,14], nickel [15] and some pretreatment methods for the graphite tube have already been proposed.

In this work, a mixture of nickel and zirconium as a matrix modifier, and the coating of the graphite tube with zirconium solution are proposed, because zirconium was often used for coating the graphite tube to protect against the formation of carbide during the analyses of elements that easily form carbides, and nickel was one of the commonly used matrix modifiers. It was found that this combination of a mixed matrix modifier and a zirconium-coated graphite tube resulted in excellent performance, increasing the analytical sensitivity and suppressing the memory effect for the determination of boron. With the application of this mixed matrix modifier and a zirconium-coated graphite tube, satisfactory results for the determination of boron in cobalt-based alloys by graphite furnace-atomic absorption spectrometry without the preseparation of the matrix were obtained.

## 2. Experimental

### 2.1. Apparatus

A Perkin-Elmer model 5000 atomic absorption spectrometer equipped with a model HGA 500 graphite furnace, a Data Station 10 and a PR 100 printer was used. An Eppendorf micropipette was used for injecting the sample solution into the graphite furnace.

A pyrolytic graphite tube was soaked in a 10 g $l^{-1}$ solution of zirconium for 2 days, then dried at 120 °C for 2 h and stored in a desiccator. Such a tube can be used for 200–300 firings. Alternatively, the pyrolytic graphite tube was placed in the graphite furnace, 20 μl of 10 g $l^{-1}$ zirconium solution were injected and one heat cycle of the heating programme was performed. This operation was repeated five times. The life of the tube treated using the latter method was shorter than that of the tube treated using the soaking method.

Instrumental parameters and operating conditions were optimized by means of experiments, and are shown in Table 1.

### 2.2. Reagents

All chemicals used were of analytical grade, and distilled, deionized water was used throughout.

A stock standard solution of boron (1000 mg $l^{-1}$) was prepared by dissolving boric acid in water, and was stored in a polyethylene bottle. The working standard solution (10 mg $l^{-1}$) was prepared by dilution of the stock standard solution with 0.2% nitric acid solution.

A 20 g $l^{-1}$ solution of nickel was prepared by dissolving 9.90 g of $Ni(NO_3)_2 \cdot 2H_2O$ in 100 ml of water.

A 20 g $l^{-1}$ solution of zirconium was prepared by dissolving 7.06 g of $ZrOCl_2 \cdot 8H_2O$ in 100 ml of water.

A 20 g $l^{-1}$ solution of iron was prepared by dissolving 9.68 g of $FeCl_3 \cdot 6H_2O$ and diluting to 100 ml with 0.2% nitric acid.

A 10 g $l^{-1}$ solution of chromium was prepared by dissolving 1.00 g of metallic chromium in a minimum volume of concentrated hydrochioric acid and diluting to 100 ml with water.

A 10 g $l^{-1}$ solution of cobalt was prepared by dissolving 4.94 g of $Co(NO_3)_2 \cdot 6H_2O$ and diluting to 100 ml with 0.2% nitric acid.

A 10 g $l^{-1}$ solution of tungsten was prepared by dissolving 17.95 g of $Na_2WO_4 \cdot 2H_2O$ in about 200 ml of water, 100 ml of 10% NaOH solution were added, and the solution was diluted to 1 l with water and stored in a polyethylene bottle.

A 5 g $l^{-1}$ solution of aluminium was prepared by dissolving 0.50 g of aluminium foil in 10 ml of hydrochloric acid, adding several drops of nitric acid, and diluting to 100 ml with water.

A 5 g $l^{-1}$ solution of titanium was prepared by dissolving 1.61 g of $TiCl_3$ in 20 ml of hydrochloric acid and diluting to 100 ml with water.

A 2 g $l^{-1}$ solution of manganese was prepared by dissolving 2.00 g of manganese metal in a minimum volume of (1:1) $HNO_3$ and diluting to 1 l with 0.2% $HNO_3$.

A 2 g $l^{-1}$ solution of tantalum was prepared by dissolving 3.96 g of $TaCl_5$ in 1 l of water.

A 1 g $l^{-1}$ solution of molybdenum was prepared by dissolving 1.00 g of metallic molybdenum in 25 ml of nitric acid and diluting to 1 l with water.

To construct the calibration graphs, 0, 0.5, 1, 1.5 and 2 ml of a 5 mg $l^{-1}$ working solution of boron were placed in 10 ml volumetric flasks, 1.5 ml of a 20 g $l^{-1}$ solution of nickel were added to each flask, and the solutions were diluted to the mark with water. The pH values of the final solutions were 5–7.

### 2.3. Procedure

About 30 mg of finely granulated sample was weighed exactly in a quartz beaker, 2.5–3.0 ml of aqua regia were added, and the solution was allowed to stand for at least 1 h at room temperature. The beaker was then heated in a water bath at about 70 °C to decompose the sample completely until some carbon particles only remained in the sample solution. After cooling, the sample solution was transferred to a 20 ml graduated test tube with the minimum volume of 0.2% nitric acid solution. A yellow precipitate of tungstic acid may stick on the beaker bottom, but this did not affect the analytical results. The sample solution was neutralized to pH 5–7 carefully with concentrated ammonia solution, and was diluted to the mark with water. After shaking, a 5 ml aliquot of this solution was pipetted into a 10 ml graduated test tube containing 1.5 ml of a 20 g $l^{-1}$ nickel solution, and the solution was diluted to the mark with water. After shaking well, a 20 µl aliquot of this final sample solution and 10 µl of a 2000 mg $l^{-1}$ solution of zirconium were injected into the graphite furnace, and the peak height was measured.

## 3. Results and discussion

### 3.1. Neutralization of the sample solution to be measured

After the decomposition, the sample solution must be carefully neutralized with ammonia solution to pH 5–7 to match the pH of the standard solution used for preparing the calibration graph. At this time, a pink precipitate of cobalt hydroxide may appear. The acidity of the injected sample solution affects the analytical sensitivity considerably, i.e. the sensitivity decreases with increase of acidity.

### 3.2. Effect of coating the graphite tube

The effect of coating the pyrolytic graphite tube was studied for the determination of 500 µg $l^{-1}$ of boron with 60 µg of nickel and 20 µg of zirconium as matrix modifier, using a zirconium-coated and an uncoated pyrolytic graphite tube. The results, shown in Table 2, indicated that coating with zirconium enhanced the sensitivity approximately two fold.

Table 2
Effect of coating the graphite tube on the sensitivity [a]

| Type of tube | Absorbance, $A$ |
|---|---|
| Coated | 0.090 |
| Uncoated | 0.048 |

[a] For 500 µg $l^{-1}$ boron, 60 µg of nickel/20 µg of zirconium modifier.

| 40 | 0.000 |

[a] For 500 μg $l^{-1}$ of boron.

### 3.3. Effect of matrix modifier

The bond strength of Zr–C ($134 \pm 6$ kcal $mol^{-1}$) is larger than that of B–C ($107 \pm 7$ kcal $mol^{-1}$) [16], so when boron and zirconium are atomized simultaneously, zirconium may combine predominantly with carbon in the graphite tube. This results in the retarding of the combination of boron with carbon. Hence it makes the sensitivity increase, and at the same time causes the memory effect to be suppressed. Nickel was known to be useful as a matrix modifier for many elements, and was found by us to be able to increase the ashing temperature for the analysis of steels and alloys up to 1200 °C. This is undoubtedly useful for decreasing the matrix effect.

The effect was studied of a matrix modifier composed of nickel and zirconium on the determination of 500 μg $l^{-1}$ of boron with a zirconium-coated pyrolytic graphite tube. The results obtained are shown in Tables 3, 4 and 5.

In Table 3 it is worth noticing that although both nickel and zirconium have some enhancing effects on the analytical sensitivity, the combination of these two elements shows a multiple enhancing effect, i.e. a matrix modifier composed of nickel and zirconium increases the analytical sensitivity six times, which is higher than the sum (4 times) of the enhancing factor of nickel (2.4 times) and that of zirconium (1.6 times).

In Tables 4 and 5 it is seen that nickel and zirconium both have an optimal quantity for achieving the best sensitivity, i.e. a larger or smaller quantity than the optimal one causes the sensitivity to decrease. Combination of these elements leads to the same situation, i.e. the combination of 60 μg of nickel and 20 μg of zirconium gives the highest analytical sensibility. Moreover, the above experiments also show that the memory effect decreases rapidly with increasing amount of zirconium.

Table 4
Effect of different amounts of nickel with a constant amount (20 μg) of zirconium on the sensitivity [a]

| Amount of Ni (μg) | Absorbance, A |
|---|---|
| 20 | 0.075 |
| 60 | 0.090 |
| 100 | 0.042 |
| 200 | 0.043 |

[a] For 500 μg $l^{-1}$ of boron.

### 3.4. Interferences of coexisting elements

The investigated cobalt-based alloys contain 53–57% of cobalt, 25% of chromium, 10–14% of nickel, 7–7.5% of tungsten, 0.8% of aluminium, 0.15–0.35% of zirconium, 0.25% of tantalum, 0.16% of iron, 0.15% of titanium, 0.07% of silicon, 0.03% of manganese and 0.48–0.8% of carbon, as well as 0.027–0.05% of boron.

The interference effects from the above elements except nickel, zirconium, silicon and carbon were studied with use of a matrix modifier composed of 60 μg of nickel and 20 μg of zirconium, and a zirconium-coated tube. The results are shown in Table 6. It is seen that among these coexisting elements, chromium shows the most severe interference effects relatively, but the use of a matrix modifier composed of nickel and zirconium and a zirconium-coated graphite tube could avoid the interferences from all coexisting elements including chromium, provided the amount of sample does not exceed 35 mg.

Table 6
Permissible amounts of coexisting elements [a]

| Element | Maximum content in sample (%) | Maximum amount [b] calculated ($mg\,l^{-1}$) | Permissible amount obtained ($mg\,l^{-1}$) |
|---|---|---|---|
| Co | 57 | 427 | 1375 |

[c] Mean of ten determinations.

### *3.5. Determination of boron in cobalt-based alloys*

The proposed method was applied to the determination of boron in four cobalt-based alloys. The results are shown in Table 7. It is seen that the differences between the values obtained and the certified values are all smaller than the permissible differences.

The relative standard deviation was 3.3% for 0.0480% boron ($n = 10$; the values were 0.0475, 0.0472, 0.0463, 0.0493, 0.0507, 0.0487, 0.0508, 0.0465, 0.0480 and 0.0489; with a mean of 0.0480).

A characteristic mass was 500 pg.

# Colorimetric determination of macrolide antibiotics using ferric ion

Patricia A. Gallagher, Neil D. Danielson *

*Department of Chemistry, Miami University, Oxford, OH 45056, USA*

Received 8 December 1994; revised 13 March 1995; accepted 14 March 1995

**Abstract**

Macrolide antibiotics such as erythromycin, oleandomycin, spiromycin, and tylosin are found to react with $Fe^{3+}$ in the presence of an acetic acid–sulfuric acid mixture to form a colored product having a useful absorption band at 592 nm. Troleandomycin forms only a weakly colored product upon reaction. The molar absorptivity is about 2900 l mol$^{-1}$ cm$^{-1}$ for erythromycin and the detection limit is 5 μg ml$^{-1}$. This colorimetric method permits the analysis of fermentation broths containing either erythromycin or tylosin without a separation step.

## 1. Introduction

Macrolide antibiotics, all composed of either a 14-membered or a 16-membered oxygenated ring with several sugars attached, have proved to be effective antibacterial agents for many years. The structures of five common macrolide antibiotics are shown in Fig. 1. Erythromycin is certainly the most well-known compound of this class; however troleandomycin is also available as a pharmaceutical product and tylosin is used widely by veterinarians [1].

At least six colorimetric methods have previously been developed for several of these macrolide antibiotics. Hydrolysis of the sugar groups of erythromycin [2] or oleandomycin [3] in concentrated sulfuric acid produced a yellow product measurable at 470 nm. This reaction has recently been extended to the other three macrolide antibiotics shown in Fig. 1 with a comparison of linearity and detection limits [1]. Tetrazolium blue can react generally with reducing agents such as erythromycin to form a dark blue solution [4]. Complex formation with Bromcresol Purple has been applied to the colorimetric determination of erythromycin [5]. A variety of other dyes which undergo ion pair formation with erythromycin in chlorinated solvents can be utilized [6]. Erythromycin and tylosin have been determined at 842 nm using tetracyanoquinodimethane [7]. A colorimetric method at 532 nm for oleandomycin using diazotized sulphanilic acid is known [8]. However, all of these methods are nonspecific or require a nonaqueous solvent and would be difficult to use for the determination of macrolide antibiotics in aqueous complicated matrices such as fermentation broths without a prior separation step. The reaction of *cis*-aconitic anhydride with a tertiary amine such as a macrolide antibiotic permits the formation of a colored product detectable at 525 nm. Although this reaction has been applied to the determination of tylosin in fermentation broths, extraction of the broth with sufficient isopropyl acetate to give a residue that could be reconstituted to attain a 1 mM concentration level is required [9].

We report here a colorimetric method for macrolide antibiotics which involves the

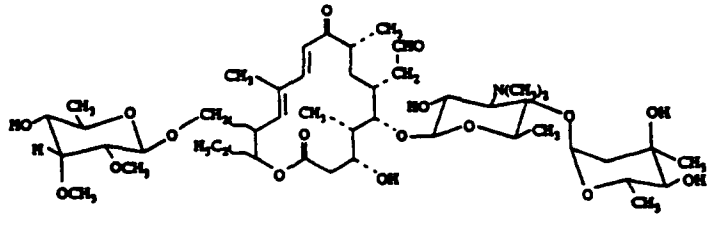
SPIRAMYCIN



TYLOSIN

Fig. 1. Structures of macrolide antibiotics.

macrolide ring and not the sugar or tertiary nitrogen moiety. After dehydration of the macrolide antibiotic in concentrated acetic acid, the addition of $Fe^{3+}$ will generate a coloured product measurable at 592 nm. The determination of erythromycin or tylosin in fermentation broths is possible without sample pretreatment.

## 2. Experimental

### 2.1. Chemicals

The macrolide antibiotics (Fig. 1) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). The erythromycin ethylsuccinate and sulfisoxazole acetyl oral suspension was

obtained from Abbott Laboratories (North Chicago, IL, USA). There were two different fermentation broths used for this research. One was a dehydrated Antibiotic Medium 3 purchased from Difco Laboratories (Detroit, MI, USA) and the second, donated by Eli Lilly (Indianapolis, IN, USA) was a dehydrated fermentation broth used for tylosin production. The Difco product was composed of beef extract, yeast extract, peptone, dextrose, sodium chloride, dipotassium phosphate, and monopotassium phosphate. The Eli Lilly sample was made up of yellow corn meal, fish meal, corn gluten meal, sodium chloride, ammonium phosphate, calcium carbonate, crude soybean oil, and cane molasses. The ferric chloride was purchased from MCB Manufacturing Chemists, Inc. (Cincinnati, OH, USA). The sulfuric acid and acetic acid were both purchased from Fisher Scientific (Cincinnati, OH, USA) and the triply distilled water obtained from a Barnstead Nanopure distillation unit (Sybron/Barnstead, Dubuque, IA, USA).

### 2.2. Equipment

The spectrophotometry was conducted either on a Varian (Humboldt, CA, USA) DMS 90 UV-ViS spectrophotometer or a Hewlett-Packard (Palo Alto, CA, USA) model 8452A diode-array instrument. The sample compartment was heated to 50°C using a Fisher Scientific (Cincinnati, OH, USA) model 900 isotemp refrigerated circulator water bath.

### 2.3. Procedure

A 500 $\mu g\ ml^{-1}$ erythromycin stock solution prepared in glacial acetic acid was allowed to react at 45°C for at least 30 min (often 2 h) before use. A ferric ion stock solution was prepared by weighing 0.080 g of ferric chloride, pipeting 2 ml concentrated sulfuric acid and 2 ml of triply distilled water into the 100 ml volumetric flask, and diluting to the mark with concentrated glacial acetic acid. Erythromycin–ferric ion standards generally ranging from 10–250 $ug\ ml^{-1}$ were prepared by pipeting 5 ml of ferric ion stock solution and the appropriate amount of erythromycin stock solution before dilution to a 10 ml volume with glacial acetic acid. The fermentation broths were prepared by adding either 17.5 g of dehydrated Antibiotic Medium 3 or the entire Eli Lilly sample to a 1000 ml volumetric flask and filling to the mark with triply distilled water. A 5 ml aliquot of the spiked fermentation broth sample was placed in a 50 ml volumetric flask and filled to the mark with concentrated glacial acetic acid. The blank was prepared in exactly the same way as the sample except that the fermentation broth was not spiked with the macrolide antibiotic. All fermentation samples and blanks were heated in the 45°C water bath. The standards for this part were prepared exactly the same as for the sample except triply distilled water was used instead of the fermentation broth. The pharmaceutical sample was prepared by measuring out in a volumetric test tube 1 ml of the erythromycin ethylsuccinate–sulfisoxazole acetyl oral suspension and quantitatively transfering it to a 100 ml volumetric flask before filling to the mark with concentrated glacial acetic acid. This was heated in the 45°C water bath. The above procedure for preparing the erythromycin–ferric ion standards was carried out for all the samples. All standards, samples and blanks, after mixing with ferric ion, were allowed to react in the heated (50°C) curvette holder for 15 min before the absorbance measurement was taken.

## 3. Results and discussion

### 3.1. Proposed reaction mechanism

Previously, it had been proposed [10] that the reaction of cholesterol in an acetic acid–sulfuric acid mixture with $Fe^{3+}$ will lead to the formation of trienylic and tetraenylic cations detectable at about 480 nm and 560 nm, respectively (Fig. 2). The wavelength maxima are dependent on the sulfuric acid concentration in the $Fe^{3+}$ stock solution. It is also known [11] that erythromycin in the presence of concentrated acetic acid can undergo dehydration, forming the 8,9-anhydroerythromycin-6,9-hemiketal (Fig. 3). The hydroxy group beta to the double bond in this hemiketal product is a remarkably similar key functional group to that in cholesterol. Using LC–MS, we confirmed the formation of this hemiketal product as evidenced by the disappearance of the $M^+$,$MH^+$ ion peak pair at $M/z = 734$, 735 and the formation of the ion peak at $M/z = 716$. No peak for the diene carbonium ion was evident. A peak at $M/z = 558$ present in both the erythromycin and hemiketal spectra represents the fragment ion of erythromycin minus a

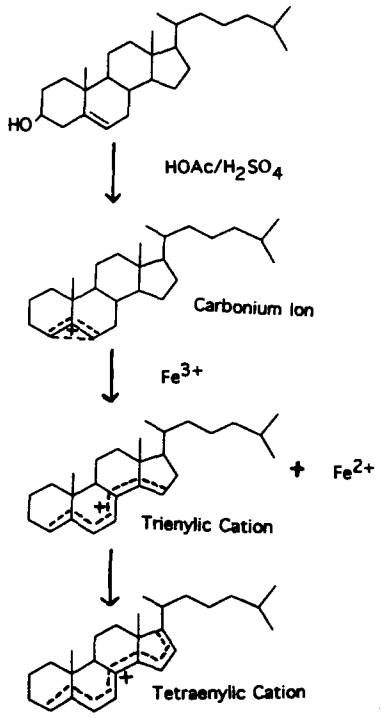


Fig. 2. Proposed mechanism of the cholesterol–$Fe^{3+}$ reaction (from Ref. [10]).

sugar group. An absorption spectrum of the hemiketal product after reaction with $Fe^{3+}$ using the optimum conditions shows two strong peaks at 484 and 592 nm (Fig. 4). A spectrum of the cholesterol reaction run using an 80% acetic acid–20% sulfuric acid $Fe^{3+}$ solution showed three peaks with wavelength maxima at 620, 453, and 412 nm. A spectrum of the hemiketal product run using the same 80% acetic acid–20% sulfuric acid $Fe^{3+}$ solution also showed three peaks with wavelength maxima of 596, 486, and 412 nm. A glucose stock solution gave no reaction with $Fe^{3+}$, providing furthur evidence that the likely source of the colored product was from the macrolide ring and not the sugar groups attached to the macrolide ring. Although LC–MS could not provide a clear mass spectrum for the formation of trienylic or tetraenylic cations for the $Fe^{3+}$–erthyromycin reaction, we feel this is the likely type of colored product.

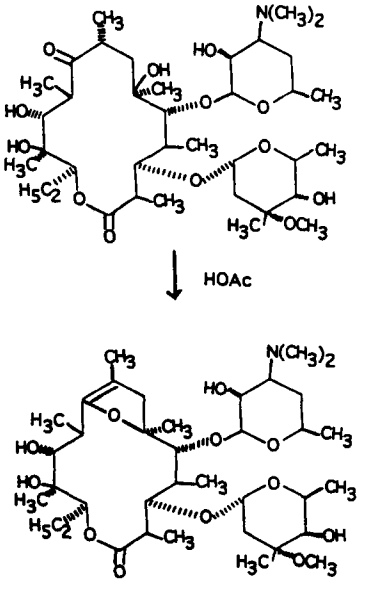

Fig. 3. Acetic acid degradation of erythromycin A to form the hemiketal product.

### 3.2. Optimization of colorimetric response

A time study of the dehydration reaction in concentrated acetic acid at 45°C for all five compounds shown in Fig. 1 was carried out (Fig. 5). All the macrolide antibiotics except troleandomycin seemed to undergo significant dehydration to form a product that would react with $Fe^{3+}$ ion. Because troleandomycin has an ester group instead of the hydroxyl group as in oleandomycin, this difference in reactivity is not surprising. Both spiramycin and tylosin already have some conjugation in their structures which is apparently expanded after reaction with $Fe^{3+}$. The spectra of the $Fe^{3+}$–antibiotic products for oleandomycin, spiromycin, and tylosin were similar to that of erythromycin. The following optimum heating times for the macrolide antibiotic stock solutions were 120 min for erythromycin, 90 min for oleanomycin, 60 min for spiromycin and 0 min for tylosin. Although the optimum heating times were quite varied, in general a reaction time of only 30 min would be sufficient for good dehydration to the $Fe^{3+}$ reactive product.

The effect of water in the erythromycin stock solution on the colorimetric reaction was studied (Fig. 6). It appears that 20% water can lower the absorbance to zero; only 5% water in the acetic acid solution caused a 50% decrease in the absorbance of the $Fe^{3+}$–hemiketal product. Therefore, it was decided that for best detectability the macrolide antibiotic stock solution in acetic acid should be a prepared if possible from a solid instead of an aqueous sample.

The proper amount of sulfuric acid needed to be added to the ferric chloride stock solution prepared in glacial acetic acid to give maxi-

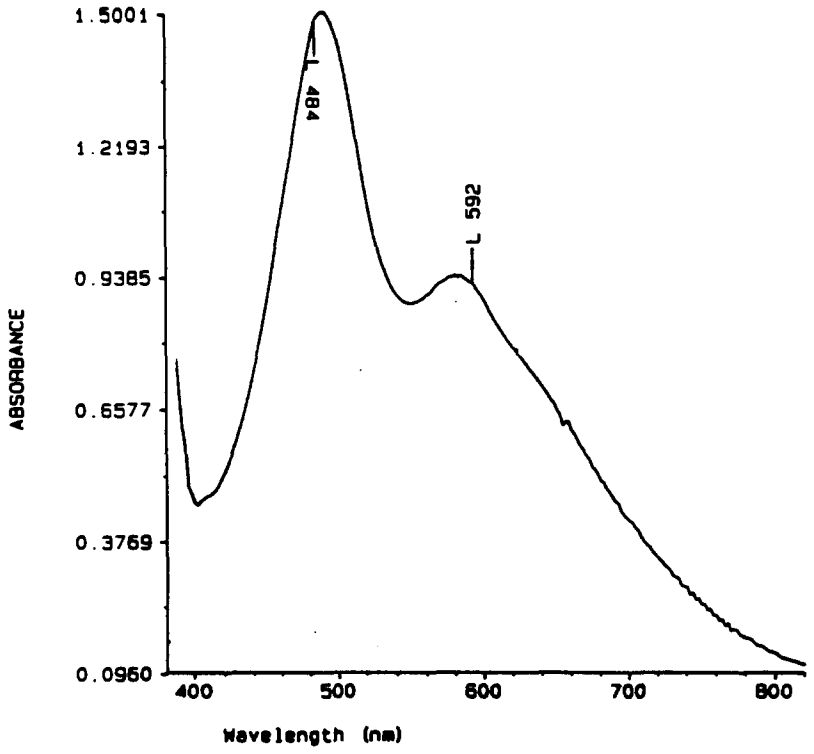

Fig. 4. Absorbance spectrum of the $Fe^{3+}$–hemiketal reaction product of erythromycin (250 μg $ml^{-1}$).

mum absorbance was determined. Ferric chloride solutions containing 1, 2 and 4 ml of sulfuric acid were prepared and time studies were completed (Fig. 7). In comparison, the cholesterol–$Fe^{3+}$ reaction would not work using such low concentrations of sulfuric acid. The absorbance profiles for the 2 and 4 ml solutions were almost exactly the same. There were some reproducibility problems; the inconsistency in the results were believed to be caused by the sulfuric acid absorbing water. To alleviate this problem, small amounts of water were added to the ferric chloride stock solution (Table 1). Therefore, it was determined that 2 ml of water as well as 2 ml of sulfuric acid should be added to 100 ml of ferric chloride solution to obtain the optimum absorbance and reproducibility.

At room temperature, the $Fe^{3+}$–anhydrohemiketal macrolide reaction rate is very slow; therefore, the solution was heated at 40, 50 and 60°C (Fig. 8). At 50°C, the data obtained produced a reproducible plateau from approximately 10 to 30 min. Some loss in signal was observed after 10 min using a 60°C reaction temperature. Therefore reaction con-

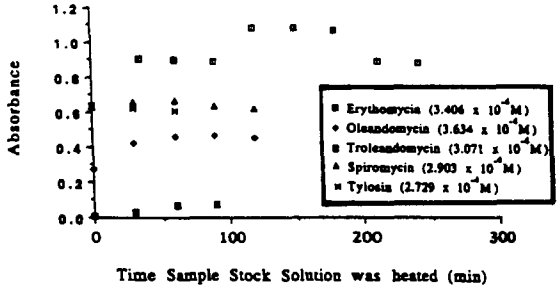

Fig. 5. Reaction of macrolide antibiotics with acetic acid at 45°C as a function of time. The reaction was followed at 592 nm using $Fe^{3+}$.

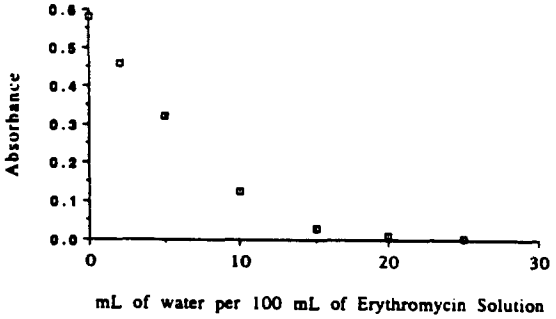

Fig. 6. Effect of water in the erythromycin stock solution on the absorbance. The reaction was followed at 592 nm using $Fe^{3+}$.

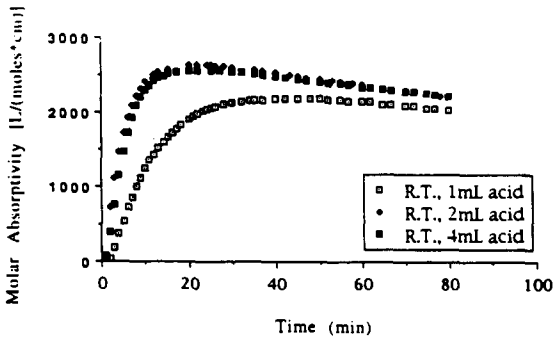

Fig. 7. Optimization of the molar absorptivity as a function of sulfuric acid volume in the $Fe^{3+}$–acetic acid solution. The reaction was followed at room temperature (RT) at 592 nm using $Fe^{3+}$.

ditions of 15 min at 50°C were used for all analytical work.

A detailed linearity and reproducibility study of this colorimetric reaction was completed (Table 2). It was determined that the detection limit was 5 ppm erythromycin at the 592 nm wavelength. At 10 ppm the average absorbance was 0.025 with a relative standard deviation (RSD) of 16%; at 100 ppm the average absorbance was 0.369 with a RSD of 1.7%; at 250 ppm the average absorbance was 0.938 with a RSD of 1%. The RSD of the slope at 592 nm was 1%. The detection limit was determined to be 2.5 ppm of erythromycin at a wavelength of 484 nm; however, the linearity at 484 nm was not as good as at the 592 nm. The RSD of the slope at 484 nm was 2.5%.

### 3.3. Real sample analysis

Because of the better selectivity at 592 nm, all real samples were analyzed at this wavelength despite the sacrifice in sensitivity. The real life samples chosen to be tested were spiked fermentation broths and an erythromycin oral suspension (Table 3). The determination of erythromycin in the oral suspension, a white sample matrix containing suspended solids, gave mixed results. It is believed that the error fluctuation was due to the difficulty in measuring the 1 ml aliquot of the oral suspension or the inhomogeneity of the sample. More work is necessary to decide if pharmaceutical samples can be assayed in this way. The fermentation broths represented a more challenging matrix due to their dark brown color as well as suspended solids. The assay of fermentation broths is commercially important in order to determine which microorganisms are effective in producing antibiotics in high yield. The expected range for macrolide antibiotics in fermentation broths is from about 1 to 10 ppt (mg $ml^{-1}$). Therefore,

Table 1
Effect of water in the ferric ion solution on the absorbance of the $Fe^{3+}$–erythromycin product at 592 nm

| Amount of water added to 100ml of ferric chloride solution (ml) | Average absorbance ($n = 3$) | Standard deviation | Relative standard deviation |
|---|---|---|---|
| 5 | 0.317 | 0.00289 | 0.00912 |
| 2 | 1.141 | 0.00785 | 0.00688 |
| 1 | 0.741 | 0.0197 | 0.0265 |
| 0.5 | 0.750 | 0.0497 | 0.0663 |

Spectrophotometric linearity of the erythromycin–ferric ion complex

| Wavelength (nm) | Data points | Linear range (mg $l^{-1}$) | Least squares [a] | Correlation coefficient |
|---|---|---|---|---|
| 592 | 29 | 5–250 | $m = 3.9 \times 10^{-3} \pm 3.9 \times 10^{-5}$<br>$b = -9.2 \times 10^{-3} \pm 5.1 \times 10^{-3}$ | 0.9997 |
| 484 | 16 | 2.5–250 | $m = 5.92 \times 10^{-3} \pm 1.5 \times 10^{-4}$<br>$b = 2.90 \times 10^{-2} \pm 1.8 \pm 10^{-2}$ | 0.9979 |

[a] Equations $Y = mx + b$.

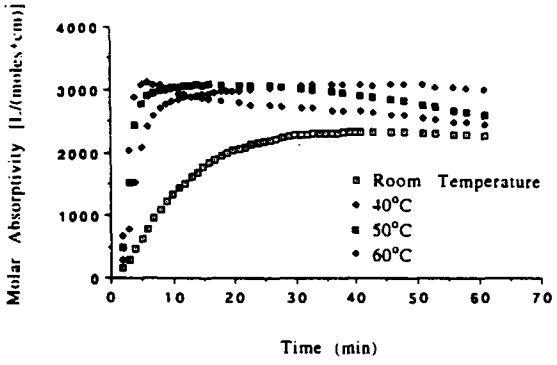

Fig. 8. Optimization of the molar absorptivity as a function of temperature for the $Fe^{3+}$–hemiketal reaction.

three samples of Difco broth were spiked with erythromycin from 0.8–5 ppt. The recoveries at 2 and 5 ppt averaged 103% while that at 0.8 ppt was 94%. The lower recovery at 0.8 ppt may be because the actual erythromycin determined was at the low end of the linear range, 25 μg $ml^{-1}$. The recovery of tylosin at 10 ppt from the Eli Lilly broth was good. The results from these spiked samples imply that this technique could easily and accurately determine the macrolide antibiotic concentration in actual incubating fermentation broths.

## 4. Conclusion

It was determined that erythromycin will react with ferric ion in the presence of an acetic acid–sulfuric acid mixture to form a colored product likely due to a tetraenylic cation in the macrolide ring. The erythromycin molar absorptivities are about 2900 l $mol^{-1}$ $cm^{-1}$ at 592 nm and 4400 l $mol^{-1}$ $cm^{-1}$ at 484 nm. This colorimetric reaction is general for similar macrolide antibiotics except troleandomycin. Because this method requires two 15–30 min heated reaction steps, automation by flow injection would likely be difficult. Although dilution of aqueous samples in concentrated acetic acid is required, this simple inexpensive colorimetric method can be used on fermentation broth samples with an average recovery of 99%.

## Acknowledgments

Summer support was provided by an NSF Undergraduate Research grant. We thank A. Tietz of Eli Lily for on of the fermentation broths and T. Pekol for assistance with the LC–MS study.

# Potentiometric characterization of weak acids by multiple sample addition
# II. The effect of chemical interferences and the practical performance of linearization methods

Carlo Maccà *, Arben Merkoci [1], G. Giorgio Bombi

*Department of Inorganic and Analytical Chemistry, University of Padua, Via Marzolo 1, I-35131 Padova, Italy*

Received 28 October 1994; revised 1 March 1995; accepted 1 March 1995

**Abstract**

Potentiometric multiple addition of a sample containing a pure weak acid to a solution of supporting electrolyte has been previously shown [C. Maccà and A. Merkoci, Talanta, 41 (1994) 2033] to be formally suitable for the determination of the dissociation constant and concentration of the sample acid. Linear equations have been developed for the treatment of experimental data to yield, simultaneously or separately, the chemical parameters of the acid solution. These equations are now tested on real samples together with analogous equations for titrations, and the results are compared with those obtained with rigorous statistical methods. For the determination of the acidity constant with samples of known concentration, multiple samples addition is comparable with titration. When the sample concentration is unknown and must be determined simultaneously to the acidity constant, the results obtained by linearized multiple sample addition can be seriously affected by impurities present, even at low level, either in the sample or in the supporting solution. Linear equations accounting for the effects of basic or acidic impurities in the sample or in the supporting solution are developed.

Sample addition is confirmed to be a useful complement to pH-metric titration for the determination of acidity constants of moderately weak acids by non-linear regression; linearization of data is a convenient technique for screening purposes and a powerful means of detecting and correcting some common pitfalls, interferences and contaminations, whose effects are enhanced in linearized sample addition.

## 1. Introduction

It has been shown [1] that the multiple sample addition technique is suitable for characterization of weak acid in pure solution. The basic equation relating the experimental variables (added sample volume and hydronium ion concentration) to the analytical parameters of the sample solution, i.e. the acidity constant and the sample concentration, has been rearranged in different forms for the convenience of applications. For this purpose, pairs of auxiliary variables have been defined, by which the experimental data are transformed to fit linear equations. Thereby, both the analytical parameters of the sample (Table 1 of Ref. [1], Eqs. (8)–(13)), or one of them if the other is known (Eqs. (6) and (2) of Ref. [1]) can be calculated from the parameters of a linear equation or of the corresponding plot. The effect of systematic and random errors of measurement has been discussed, in order to evaluate the intrinsic performance of the method in its different applications, with particular concern for the determination of the acidity constant [1].

*SSDI* 0039-9140(95)01592-2

In this paper, the results of some of the experimental tests to which the method has been subjected for validation are reported and interpreted by considering the different causes of error that can occur in practice, particularly those of chemical origin.

Solutes with acidic or basic properties other than the sample acid cause the hydronium ion concentration in the measured solution to be different from that of the pure sample acid at the given concentration. As a consequence, the plots of the auxiliary variables of the equations for pure acid (Eqs. (2), (6), (8)–(13) of Ref. [1]) are expected to deviate from the theoretical behaviour to some extent, causing errors in the analytical parameters thereby calculated. Interfering substances are here assumed to be present only at the level of impurities. Equations suitable for forecasting the deviations due to impurities and, at least in principle, for evaluating the amount of impurities and to correct for their presence are developed in the Theory section. The theoretical deviations from linear behaviour caused by impurities are examined in the Discussion section.

The experimental results of linearized sample addition are compared with those of titration and are also checked by a least-squares treatment of the original variables.

## 2. Experimental

### 2.1. Apparatus

The measured solution, contained in a jacketed cell, was flushed with purified nitrogen and stirred with a PTFE-coated magnetic bar and a magnetic stirrer. Motor-driven microburettes (MicroBUR 2030 Crison, Barcelona) equipped with 1, 2.5 or 10 ml Hamilton syringes (0.4, 1 and 4 µl resolution, respectively; standard deviation better than resolution) were used for the additions of standard, sample and titrant solutions. The additions were managed with a potentiometric titrator MicroTT 2050 Crison. The e.m.f. of a combination glass electrode with encapsulated Ag/AgCl reference electrode in 3 M KCl and sleeve junction (Ingold type 405.60.88.E) was measured with 0.1 mV resolution (instrumental standard deviation better than resoluton) during the additions. For each part of an experiment, a data file was created by the titrator on a PC.

### 2.2. Reagents

Analytical or higher grade reagents (e.g. recrystallized NaCl or Merck Suprapur KCl, as the supporting electrolyte) were dissolved in freshly prepared ultrapure water (MilliQ-Plus grade). HCl solutions for electrode calibration were prepared from primary standard acid obtained by azeotropic distillation of an analytical reagent grade product.

### 2.3. Procedure

A typical experiment began with electrode calibration by multiple addition ($5 \times 8.0$ µl + $24 \times 40.0$ µl) of 0.1 M primary standard hydrochloric acid to 25 ml of 0.1 M supporting electrolyte (sodium of potassium chloride or nitrate). The smaller initial additions allowed the presence of basic impurities in the supporting solution to be detected (see Calculations section). Calibration was completed by titration through multiple constant addition ($20 \times 100.0$ µl) of 0.1 M sodium hydroxide. After careful washing, the cell was again filled with supporting electrolyte and multiple addition (typically, 20 additions of 50 or 125 µl) of the sample acid at suitable concentration (1–0.003 M) was performed; thereafter, the acid was titrated by multiple constant addition of sodium hydroxide. After three to five complete experiments of sample addition and titration, a second calibration by strong acid addition and titration with sodium hydroxide was performed.

### 2.2. Calculations

Calibration by multiple (hydrochloric) acid addition at practically constant ionic strength allowed the hydronium ion concentration $[H^+]$ to be measured in the pH range of interest. The data of hydrochloric acid multiple addition were beforehand linearized by least-squares fitting with the Gran function [2] using the theoretical electrode slope (Nernst factor); a statistically significant, although small, positive value of volume at the intercept was taken as an indication of the presence of basic impurity in the supporting electrolyte solution. The same data, after correction for impurity, were used for calculation of the electrode calibration parameters.

The sample addition data were linearized using the linear functions introduced in Ref. [1]

and in the following Theory section. The data of the subsequent titration were used to obtain reference values of the sample analytical parameters, as described in the Results section. All the experimental data were also treated with the generalized (non-linear) least-squares program based on a modification of the pit-mapping method [3].

## 3. Theory

Impurities can be present either in the original sample or in the supporting solution (water + supporting electrolyte) to which the sample is added. In the first case, the concentration ratio (interfering substance)/(analyte) in the measured solution is constant throughout each experiment; in the second case, this ratio decreases with the progress of addition. Impurities whose presence is hardly avoidable are volatile substances easily dissolved or absorbed by chemicals from the laboratory atmosphere, such as the acid carbon dioxide or the base ammonia. Reasonably, under the conditions of measurement, all the bases present at the impurity level behave as strong bases. Indeed, a weak base originally present in the sample as a very small fraction of the acid reacts completely with it, notwithstanding the dilution undergone by both reactants in the measured solution. When present in the supporting solution, weak bases can be assumed to react completely if their concentration ratio to the acid added with the sample is small after the first addition. The interference by weak acids present at the level of impurities is moderate, particularly for acids weaker than the analyte. Therefore, only strongly basic impurities and, to a lesser detail, strongly acid contaminants will be considered in the following.

### 3.1. Basic impurities in the sample

A sample containing a weak acid contaminated by a strong base can be treated as being composed either of the acid with a strong base or of the acid with its salt. The second assumption yields slightly simpler equations which, moreover, are more suitable for comparison between the experimental results of multiple addition and of titration. Therefore, it is assumed here that the sample contains the weak acid HA at concentration $C$ and the conjugated weak base, i.e. the salt NaA, at concentration $C_i$. The presence of the base modifies the mass balances from which the basic equation relating the measured variable (the hydronium ion concentration $[H^+]$) with the controlled variable (the added volume $V$) is obtained (see Eq. (2) of Ref. [1]). The relevant mass balances express the total amount of the solute system (acid + salt) after each sample addition:

$$(C + C_i)V = (V^\circ + V)([HA] + [A^-]) \quad (1)$$

the amount of counter-ion of the salt:

$$C_i V = (V^\circ + V)[Na^+] \quad (2)$$

and the electroneutrality condition:

$$[H^+] + [Na^+] = [OH^-] + [A^-] \quad (3)$$

Substitution for the equilibrium concentrations in Eq. (1) using Eqs. (2) and (3) together with the expression of the acid dissociation constant, $K_a = [H^+][A^-]/[HA]$, and the expression for $K_w$ yields

$$\begin{aligned} CV &= (V^\circ + V)([H^+] - K_w/[H^+])(1 + [H^+]/K_a) \\ &\quad + C_i V[H^+]/K_a \\ &= H(1 + [H^+]/K_a) + C_i V[H^+]/K_a \end{aligned} \quad (4)$$

where [1]

$$H = (V^\circ + V)([H^+] - K_w/[H^+]) \quad (5)$$

(in acidic solution, $H \approx (V^\circ + V)[H^+]$).

Eq. (4) must be compared with the 'rigorous Gran function' $F$ for the determination of $C$ by addition of pure weak acid sample (see Eqs. (2) and (4) of Ref. [1]):

$$F = H(1 + [H^+]/K_a) = CV \quad (6)$$

The function $F$ can be calculated from the experimental data when the acidity constant is known; the concentration of acid in the sample, $C$, is obtained as the slope of the linear plot $F$ against $V$ [1]. However, when $C_i$ has a non-zero value, the value of $F$ calculated as above corresponds to

$$F = CV - C_i V[H^+]/K_a \quad (7)$$

instead of $CV$; therefore, deviation of the plot of $F$ against $V$ from linearity and of its (mean) slope from $C$ must be expected.

Eq. (4) can be rearranged to give the equation

$$H(1 + [H^+]/K_a)/V = C - C_i[H^+]/K_a \quad (8)$$

which is transformed into a linear equation, $Y = a + bX$, by introducing the auxiliary variables $X = [H^+]/K_a$ and $Y = F/V = H(1 + [H^+]/$

Table 1
Linear equations for the determination of the acidity constant $K_a$ and of the content of basic impurities $C_i$ of a weak monoprotic acid by multiple sample addition ($H$, Eq. 5)

| $X$ | $Y$ | $C_i$ | $K_a$ | Equation $Y = a + bX$ | |
|---|---|---|---|---|---|
| $\frac{CV-H}{V[H^+]}$ | $\frac{H}{V}$ | $-a$ | $b$ | $\frac{H}{V} = -C_i + K_a\frac{CV-H}{V[H^+]}$ | (9) |
| $\frac{V}{H}$ | $\frac{CV-H}{H[H^+]}$ | $\frac{b}{a}$ | $\frac{1}{a}$ | $\frac{CV-H}{H[H^+]} = \frac{1}{K_a} + \frac{C_i}{K_a}\frac{V}{H}$ | (10) |
| $\frac{V[H^+]}{CV-H}$ | $\frac{H[H^+]}{CV-H}$ | $-b$ | $a$ | $\frac{H[H^+]}{CV-H} = K_a - C_i\frac{V[H^+]}{CV-H}$ | (11) |

$K_a)/V$, which can be calculated from the experimental data, and the values of the known parameters $V°$, $K_a$ and $K_w$. Accordingly, $C$ can be obtained together with $C_i$ from the parameters of the transformed Eq. (8) from the intercept $Y(X=0)$ and from the slope, respectively, by least-squares or graphical interpolation. However, it must be expected that the results are strongly affected by the imprecision of $[H^+]$ and by the inaccuracy of $K_a$ [1].

The determination of $K_a$ using a sample with known $C$ is a more suitable application of the sample addition method [1]. For this purpose, Eq. (4) is rearranged to give Eqs. (9)–(11) of Table 1; $K_a$ is obtained together with $C_i$ by calculating the parameters of a linear equation using any pair of auxiliary variables $X$ and $Y$ defined in the Table.

Other possible cases can be solved, at least in principle, with different linear transformations of Eq. (4). When both $C$ and $C_i$ are known, according to

$$[H^+](H + C_iV) = K_a(CV - H) \quad (12)$$

the acidity constant can be obtained from the slope of a straight line with the auxiliary variables $X = CV - H$ and $Y = [H^+](H + C_iV)$. When only $C_i$ is known, equations of forms corresponding to those of the Eqs. (8)–(13) of Ref. [1] are obtained. For brevity, only the Hofstee-type [1,4,5] equation (Eq. 13), giving $C$ as the intercept and $K_a$ as the negative reciprocal of the slope, is reported here:

$$H/V = C - [H^+](H + C_iV)/VK_a \quad (13)$$

Eqs. (12) and (13) (and the other analogous equations) are of little interest for the present purpose; however, they could be useful for the determination of the acidity constant by multiple addition of a buffer with known composition or with known content of base, respectively.

When both $C$ and $K_a$ are unknown and evidence is found of a finite but unknown concentration of basic impurity in the sample, for the determination of all the three parameters $C$, $C_i$ and $K_a$ it is necessary to resort to a numerical optimization method, employing either Eq. (4) or directly the system of simultaneous equations used for its derivation.

In practice, impurities of the sample undergo a large dilution in the measured solution and, therefore, are possibly of lesser concern than impurities present in the supporting solution, at least when their original concentration level is similar.

### 3.2. Basic impurities in the supporting solution

Basic impurities present in the supporting solution before the beginning of additions are most probably weak bases, such as ammonia dissolved in the water from the atmosphere or carbonate originating from the supporting electrolyte. It is reasonably assumed that the initial concentration, $C_j$, of any basic impurity in the measured solution is small enough for it to behave like a strong base and react quantitatively with the sample weak acid, this being present in excess after the first addition. By substituting the equilibrium concentration in the relevant mass balance of the sample acid:

$$CV = (V° + V)([HA] + [A^-]) \quad (14)$$

and using the mass balance of the contaminant, for instance ammonia,

$$C_jV° = (V° + V)([NH_3] + [NH_4^+]) \approx (V° + V)[NH_4^+] \quad (15)$$

the electroneutrality condition,

$$[H^+] + [NH_4^+] = [OH^-] + [A^-] \quad (16)$$

Table 2
Linear equations for the determination of the acidity constant $K_a$ and of the concentration $C$ of weak monoprotic acid by multiple addition to a solution of strong base at known concentration $C_j$ ($H$, Eq. 5)

| Named after [1] | $X$ | $Y$ | $C$ | $K_a$ | Equation $Y = a + bX$ | |
|---|---|---|---|---|---|---|
| Hofstee | $\frac{(H + C_jV^\circ)[H^+]}{V}$ | $\frac{H + C_jV^\circ}{V}$ | $a$ | $-\frac{1}{b}$ | $\frac{H + C_jV^\circ}{V} = C - \frac{(H + C_jV^\circ)[H^+]}{K_aV}$ | (21) |
| Lineweaver and Burk | $[H^+]$ | $\frac{V}{H + C_jV^\circ}$ | $\frac{1}{a}$ | $\frac{a}{b}$ | $\frac{V}{H + C_jV^\circ} = \frac{1}{C} + \frac{1}{CK_a}[H^+]$ | (22) |
| Scott | $\frac{1}{[H^+]}$ | $\frac{V}{(H + C_jV^\circ)[H^+]}$ | $\frac{1}{b}$ | $\frac{b}{a}$ | $\frac{V}{(H + C_jV^\circ)[H^+]} = \frac{1}{CK_a} + \frac{1}{C[H^+]}$ | (23) |

and the expressions for $K_a$ and $K_w$, Eq. (17) is obtained:

$$CV = (V^\circ + V)([H^+] - K_w/[H^+])(1 + [H^+]/K_a) + C_jV^\circ(1 + [H^+]/K_a) = (H + C_jV^\circ)(1 + [H^+]/K_a) \quad (17)$$

The Gran function $F$ for weak acid addition, Eq. (6), calculated from the experimental data is thereafter affected by the presence of a base with a non-zero value of $C_j$, corresponding in this instance to

$$F = CV - C_jV^\circ(1 + [H^+]/K_a) \quad (18)$$

instead of $CV$. However, according to

$$H(1 + [H^+]/K_a)/V = C - C_jV^\circ(1 + [H^+]/K_a)/V \quad (19)$$

obtained by rearrangement of Eq. (17), both $C$ and $C_j$ can be obtained, when $K_a$ is known, by linearizing the experimental data with the use of the auxiliary variables $X = F/V = H(1 + [H^+]/K_a)/V$ and $Y = (1 + [H^+]/K_a)/V$. The least-squares intercept $Y(X = 0)$ of the transformed linear equation $Y = a + bX$ yields the sample concentration $C$, while the slope factor, on division by $V^\circ$ (the initial volume of supporting solution), yields the original concentration of basic contaminant. It must be expected, however, that the results are very sensitive to the inaccuracy of $K_a$ [1].

Unfortunately, it is impossible to linearize Eq. (19) in the more interesting case when $C$ is known and $K_a$ and $C_j$ are unknown, i.e. for the determination of the acidity constant by addition of sample at known concentration in the presence of unknown background basic impurities. A solution of this problem (as in the case when $C$ is also unknown) can only be sought by treatment of the experimental data of sample addition with a numerical optimization method.

If both $C$ and $C_j$ are known, the acidity constant can be obtained from the slope of the plot of $Y = (C_jV^\circ + H)[H^+]$ against $X = (CV - C''V^\circ + H)$, according to

$$(C''V^\circ + H)[H^+] = K_a(CV - C_jV^\circ - H) \quad (20)$$

If only $C_j$ is known, it is possible to determine $C$ together with $K_a$ by means of the linear Eqs. (21)–(23) in Table 2. The relationships between the quantities $C$ and $K_a$ and the parameters $a$ and $b$ of Eqs. (21), (22) and (23) are the same as for Eqs. (8), (10) and (12), of Ref. [1], respectively (the correspondence is made clear by putting $C_j = 0$); equations related to Eqs. (9), (11) and (13) of Ref. [1] can be obtained by interchanging the auxiliary variables (for convenience, each one of these new equations could be termed according to the name [4–7] assigned to the corresponding equation of Ref. [1]).

It is interesting to note that, as a consequence of the approximation made by assuming a quantitative reaction of the weak base (see Eq. 15), Eqs. (17)–(23) are the same as the titration of a strong base at concentration $C_j$ with weak acid at concentration $C$. However, the use of Eqs. (17)–(23) with titration data is out of the scope of the present work.

### 3.3. Strongly acidic impurities

For completeness, the effect of the presence of strong acids either in the sample or in the supporting solution is also shortly considered.

A strong acid contamination in the sample solution can arise, for instance, from the synthesis or purification of the substance investigated. By combining the mass balance of the contaminant, for instance hydrochloric acid, present in the added sample solution at concentration $C_h$:

$$C_h V = (V^\circ + V)[Cl^-] \quad (24)$$

with the mass balance (Eq. 14), the electroneutrality condition:

$$[H^+] = [OH^-] + [A^-] + [Cl^-] \quad (25)$$

and the expressions of the equilibrium constants, the following equations are obtained:

$$CV = (H - C_h V)(1 + [H^+]/K_a) \quad (26)$$

as the Gran-type equation for the determination of $C$ at known $K_a$ and $C_h$;

$$H(1 + [H^+]K_a)/V = C + C_h(1 + [H^+]/K_a) \quad (27)$$

for the determination of $C$ and $C_h$ at known $K_a$; and

$$(H - C_h V)/V = C - [H^+](H - C_h V)/VK_a \quad (28)$$

as the Hofstee-type equation for the simultaneous determination of $K_a$ and $C$ at known $C_h$ (even in this instance, five more equations can be formulated for the same purpose). Linearization is not possible when only $C$ is known.

The salts of analytical purity employed as the supporting electrolyte are more frequently contaminated by traces of strong acids than commonly believed (however, a prolonged heating of sodium or potassium chloride at 120°C has been found to be effective for a practically complete elimination of hydrochloric acid traces). By combining the mass balance of the contaminant, for instance hydrochloric acid, at concentration $C_k$ in the initial solution:

$$C_k V^\circ = (V^\circ + V)[Cl^-] \quad (29)$$

with the mass balance (Eq. 14), the electroneutrality condition (Eq. 25) and the expressions of the equilibrium constants, the following equations are obtained:

$$CV = (H - C_k V^\circ)(1 + [H^+]/K_a) \quad (30)$$

as the Gran-type equation for the determination of $C$ at known $K_a$ and $C_k$;

$$H(1 + [H^+]/K_a)/V = C + C_k V^\circ(1 + [H^+]/K_a)/V \quad (31)$$

for the determination of $C$ and $C_k$ at known $K_a$; and

$$(H - C_k V^\circ)/V = C - [H^+](H - C_k V^\circ)/VK_a \quad (32)$$

as the Hofstee-type equation for the simultaneous determination of $K_a$ and $C$ at known $C_k$ (as before, five other equations can be formulated for the same purpose). Linearization is not possible when only $C$ is known.

The above equations, particularly those including the contaminant concentration as one of the parameters to be determined, are reasonably suspected to be strongly affected by the uncertainty in the measured variable. In the present work, they have been used only to evaluate the reliability of the results obtainable with the equations [1] valid for pure solutions, and to investigate qualitatively the causes of the experimental deviations from the anticipated linear behaviour.

## 4. Discussion

Linear methods of data treatment are specially suited for obtaining preliminary data of acidity constants and for general use in laboratories that are not particularly equipped to deal with sophisticated experimental apparatus and computer programming. Therefore, the present experimental work was more aimed at testing the robustness of the proposed method when subjected to the disturbances most commonly encountered in practice, than confirming with ideally behaving model systems the theoretical expectations of the equations proposed.

Preliminarily, the way in which the different causes of deviation affect the results of the linear equations has been investigated by determining the extent of their theoretical effect. For brevity, discussion is restricted here to those deviations of chemical origin that, by comparison with experimental results, seemed the most important ones in practice. The attention is focused on the linear equation for determination of the acidity constant by addition of pure acid at known concentration:

$$H[H^+] = K_a(CV - H) \quad (33)$$

(Eq. (6) of Ref. [1]), on the linear equations for the simultaneous determination of $K_a$ and $C$ (Eqs. (8)–(13) of Ref. [1]), taking as an example the Hofstee-type function:

$$\frac{H}{V} = C - \frac{H[H^+]}{K_a V} \quad (34)$$

and on some of the equations that take into account the presence of an impurity in the supporting solution.

### 4.1. The effect of basic impurities in the supporting solution

For the evaluation of the effect of basic contaminants present in the supporting solution on the results obained using the linear equations for pure solutions, the auxiliary variables of the various linear equations have been calculated using theoretical values [8] of hydronium ion concentration, $[H^+]$, for series of additions at different values of the parameters $K_a$, $C$ and $C_j$. These synthetic data were interpolated by linear least-squares fitting to recalculate the desired parameters of the sample acid.

According to the results thus obtained, the determination of $K_a$ using Eq. (33) is only moderately impaired by the presence of basic impurities in the supporting solution, if the ratio of the concentration of acid made up in the measured solution:

$$C_{HA} = CV/(V^\circ + V) \quad (35)$$

to the concentration of contaminant base, $C_j$, is large enough. As a rough indication, the ratio $C_{HA}/C_j$ must be larger than 10 after the first sample addition; however, the weaker the sample acid, the more adverse the effect of a given concentration of contaminant and the larger the ratio $C_{HA}/C_j$. Therefore, basic impurities can limit the application of Eq. (33) towards small acidity constants. It must be remembered that, in contrast, the condition $C_{HA}/K_a > 1$ required [1] for minimizing the effect of systematic and random e.m.f. measurement errors on the results of Eq. (33) is more easily satisfed with weaker acids. Both these contrasting requirements must be considered in planning the experimental use of Eq. (33) for determination of $K_a$.

Plots of Eq. (33) are shown in Fig. 1 for three synthetic experiments, differing only by the impurity level. These plots show that the presence of basic impurities in the supporting solution may cause barely appreciable deviations from linearity, even when it causes errors in $K_a$ (indeed, simulated experiments give apparently curved plots only at $C_{HA}/C_j < 10$). Therefore, apparent linearity does not give safe evidence of the acceptability of experimental $K_a$ values. A significant negative value of the intercept $Y(X = 0)$ (see Fig. 1) has been found to be a more suitable indicator of unacceptably large (negative) errors in $K_a$ due to basic contaminants in the supporting solution. (However, a negative volume error of the first addition, due, for instance, to an air bubble in the tip of the dispensing capillary, which can be significant if the added volume aliquots are very small, can have a similar effect [1] on the intercept, without altering the slope with respect to the theoretical value.)

The same synthetic data as above have been used to calculate the auxiliary variables $Y = H/V$ and $X = H[H^+]/V$ of the Hofstee-type function, Eq. (34). Data from a few simulated experiments are plotted in Figs. 2 and 3; for easier comparison, auxiliary variables have been normalized to the form $Y' = 1 + X'$ by putting $Y' = Y/C$ and $X' = XCK_a$. It is seen that simultaneous determination of $K_a$ and $C$ is very badly affected by basic impurities in the supporting solution, even at a low contamination level. The error in $K_a$ is positive (in contrast with the negative error caused by basic contaminants when Eq. (33) is used); the error in $C$ is negative, and relatively smaller. Acceptable errors are obtained only with stronger acids at higher $C_{HA}/C_j$ ratios. Even with these equations, the deviations due to basic impurities in the supporting solution are in the same direction as those due to constant negative error in the added volume (see Fig. 8 of Ref. [1]).

It has been shown [1] that the effect of random errors of $[H^+]$ measurement on the

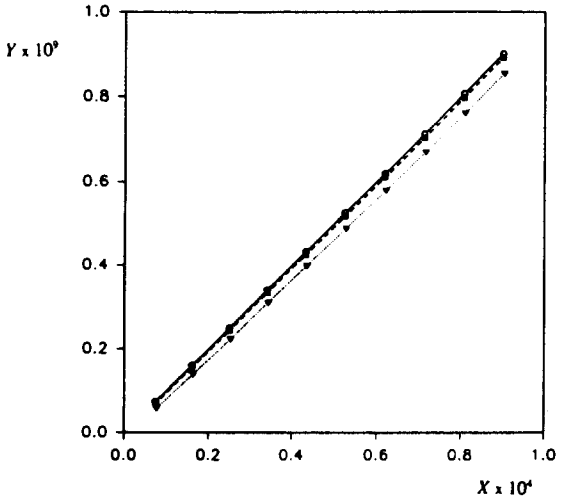

Fig. 1. Plot of Eq. (33) with synthetic data including the effect of basic impurities in the supporting electrolyte solution. Auxiliary variables $X = CV - H$, $Y = H[H^+]$ ($H$, see Eq. 5) calculated for 10 additions of weak acid sample with $pK_a = 5$, $C = 0.01$ M, $V^\circ = 100$ ml, $V = i$ ml, $i = 1$–10. ○ ——, concentration of basic impurities $C_j = 0$; □ – – –, $C_j = 1.0 \times 10^{-6}$ M; ▽ · · ·, $C_j = 5.0 \times 10^{-6}$ M.

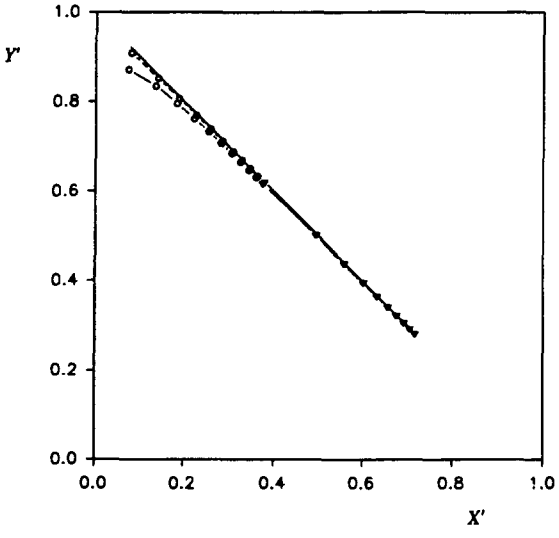

Fig. 2. Plot of Hofstee-type function, Eq. (34), with normalized auxiliary variables $X' = X/CK_a$ and $Y' = Y/C$ calculated from synthetic values of $[H^+]$ for multiple addition of an acid with $pK_a = 3$ over different $C_{HA}/K_a$ ranges in the presence of basic contaminant in the supporting solution at initial concentration $C_j$. $V^\circ = 100$ ml, $V = i$ ml, $i = 1-10$. ○, $C = 0.001$ M, $C_{HA}/K_a \approx 0.1-1$; ▽, $C = 0.01$ M, $C_{HA}/K_a \approx 1-10$. ——, $C_j = 0$; – – –, $C_j = 1.0 \times 10^{-6}$; · · ·, $C_j = 5.0 \times 10^{-6}$. $X'$ increases and $Y'$ decreases with the progress of sample addition.

precision of values of $K_a$ and $C$ obtained with Eq. (34) and the other equations of Ref. [1] (Table 1) depends strongly on the ratio $C_{HA}/K_a$ of the actual weak acid concentration in the measured solution, $C_{HA} = CV/(V^\circ + V)$, to the acidity constant. For optimal precision, each experiment should cover at least a decade of $C_{HA}/K_a$ ratios, for instance 0.1–1, 1–10, or, less preferably, $10-10^2$; the effect of measurement errors is amplified both at smaller and larger ratios. When $K_a$ is small, attainment of this optimal concentration range requires a small acid concentration; as a consequence, the concentration of impurities in the supporting solution becomes important. This makes Eq. (34) and similar equations practically unsuitable for the simultaneous determination of acidity constant and sample concentration of acids with a $pK_a$ larger than 4 or 5, unless special precautions are taken against the uptake of base by the measured solution.

A better insight can be gained by inspection of Table 3, in which representative results obtained with Eqs. (33) and (34) (including Figs. 1–3) are summarized. For each simulated experiment, the parameters (column 1–6) were arranged so as to operate over one decade of values of the $C_{HA}/K_a$ ratio (column 4) within or near to the optimal range [1]. The values in columns 7–10 are calculated by linear least-squares fitting; the standard deviations due to variations from linearity are seen to be, in many instances, sufficiently small to be concealed in practice by random measurement errors. The normalization of the intercept $Y(X = 0)$ of Eq. (33) as the ratio to $Y_{max}$ calculated for the last addition (column 7) allows direct comparison between different experiments.

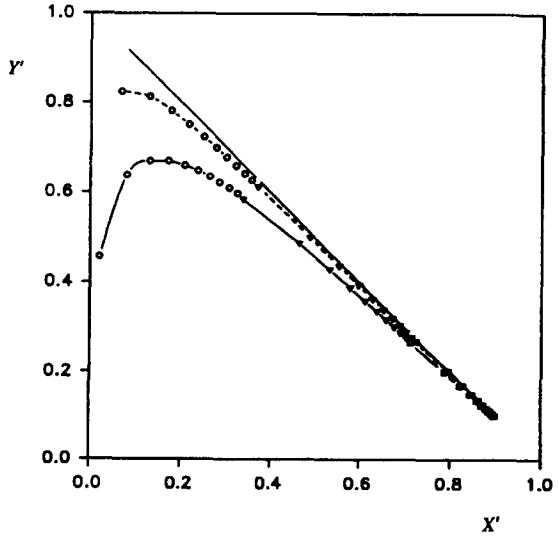

Fig. 3. Plot of Eq. (34) for an acid with $pK_a = 4$. □, $C = 0.1$ M; $C_{HA}/K_a \approx 10-10^2$; other symbols and parameters as in Fig. 2.

### 4.2. Other types of impurities

Basic impurities in the sample cause the plots to deviate towards the same side as do basic impurities in the supporting solution. However, the deviation increases with addition by effect of the increase in contaminant concentration in the measured solution, proportional to the increasing acid concentration, so affecting the calculated parameters with errors in the opposite direction to those for bases in the supporting electrolyte. This effect is shown in Fig. 4 (to be compared with Fig. 3) for the Hofstee-type function, Eq. (34), where the deviation causes a negative error in $K_a$ and a positive error in $C$.

Strong acid impurities, either in the sample or in the supporting solution, cause deviations qualitatively symmetrical with those due to strong basic contaminants, as shown in Fig. 4 (where, in order to make deviations clearly detectable, the assumed level of contaminants in the sample is much higher than reasonably

Table 3
Effect of basic impurities at concentration $C_j$ in the supporting solution on the values of $K_a$ and $C$ determined in simulated experiments (concentrations in mol $l^{-1}$)

| Parameters | | | | | | Results | | | |

expected in practice). In the case of strong acid impurities in the sample, it is easy to understand why deviations caused by contaminants in the sample increase with the progress of addition; indeed, the dissociation degree of the sample weak acid decreases with increasing concentration and, therefore, the ratio between strong and weak acid being constant, the relative contribution of the contaminant to the measured $[H^+]$ becomes more and more important. The opposite decrease in the deviations caused by contaminants in the supporting solution, whose concentration remains practically constant with the progress of addition, is quite trivial.

## 5. Results

Many series of experiments were performed with sample acids of different strength and concentration. Only a limited selection, most suitable for emphasizing the performance differences and the advantages or pitfalls of the various applications of the linearized sample addition method, is reported here.

Most experiments of sample addition were followed by titration of the final solution with strong base. Thereby, the mean values of sample concentration determined by titration were taken as the reference values. Titration data were also used to calculate the acidity constant. The sample concentration was first determined from the equivalence volume of the titration, obtained by linearization of the part of the titration preceding the equivalence point with the appropriate Gran function [2,4]:

$$G = V_t \times 10^{E/S} \tag{36}$$

where $V_t$ is the added titrant volume, $E$ is the measured electromotive force, and $S$ is the electrode slope factor (the theoretical Nernst value was taken, being generally within the uncertainty of the experimental slope). Only titration points lying in the theoretical linearity range of the approximate Gran function [9,10] were considered. Using this value of $C$, the value of the acidity constant was calculated as the least-squares slope of the auxiliary variable $Y = W[H^+]$ against $X = (CV_s - W_s)$, according to the equation

$$W[H^+] = K_a(CV_s - W) \tag{37}$$

where $W$ is given by

$$W = C_b V + (V^\circ + V_s + V_t)([H^+] - K_w/[H^+]) \quad (38)$$

$V_s$ is the total sample volume added stepwise before titration, $C_b$ is the concentration of the titrant base, and the other symbols have the customary meanings (see Theory section; Eq. (37) is easily obtained by rearrangement of the basic equation [4] for the titration of a weak acid with a strong base).

The values of the chemical parameters $C$ and $K_a$ determined by titration were also used when the equation employed for treatment of experimental multiple samples addition data required one of them to be known.

It was deemed interesting to compare the performance of linearized titration [4] and of linearized multiple sample addition for the simultaneous determination of the weak acid concentration and of its acidity constant. For this purpose, the titration data were treated using the three types of relevant linear equations (Hofstee, Lineweaver–Burk and Scott) [4] corresponding to those used for multiple addition.

The auxiliary variables of practically all of the linearized equations are not independent of each other, as they contain both the experiment variables. As a consequence, the linearized equations do not fulfil important requirements for treatment by simple least-squares fitting. However, this treatment was chosen to preserve a moderate level of sophistication (indeed, if a rigorous statistical evaluation of results is required, we presume that a treatment of direct experimental variables with one of the existing generalized least-squares computer programs is to be chosen, rather than treatment of transformed variables with any of the modified linear least-squares programs proposed for similar purposes). When the uncertainty of the measured variable $[H^+]$ was found to affect the auxiliary variable defined as the $X$ of a transformed equation to a greater extent than the corresponding $Y$ [1], the auxiliary variables were inverted [1,4] in the least-squares treatment of data.

Generally, when $K_a$ was calculated with Eqs. (33) and (37), respectively, at a given sample concentration, the results of multiple sample addition were found to be in very good agreement with the results of titration, and both were in satisfactory agreement with literature data.

For the simultaneous determination of $K_a$ and $C$, linearized titrations generally yielded good results. On the contrary, the results obtained from sample addition data with Eq. (34) and the other equations of Table 1, Ref. [1], were generally poorer. The deviations found in each series of experiments had a systematic component definitely depending on the batch of supporting electrolyte used. Most frequently, the direction of deviations was in agreement with the presence of a base in the supporting solution. When this kind of deviation occurred, the presence of a base in the supporting electrolyte was also suggested by the trend of data of the electrode calibration, performed by multiple strong acid addition to an identical portion of supporting electrolyte solution (see Experimental section); indeed, Gran linearization [2] yielded a positive intercept with abscissa (that is, a positive equivalence volume, corresponding to the titration of a base), although most freqently at the limits of statistical significance. When the supporting electrolyte was directly dissolved (at 0.1 mol $l^{-1}$) in the measuring vessel, the concentration level of contaminant base was never much higher than $10^{-6}$ M, corresponding to a reasonable contamination level of $10^{-5}$ mol of base per 1 mol of electrolyte salt; larger amounts, indicating a stronger contamination by absorption of volatile bases from the atmosphere, were found when a batch of supporting solution prepared a long time beforehand was repeatedly used. In some instances, however, deviations occurred in the opposite direction, leading to a suspected contamination of the supporting electrolyte by traces of (strong) acid.

Moreover, the deviations found showed a dependence on both the strength and the concentration of the sample acid, i.e. on the ratio $C_{HA}/K_a$, in qualitative agreement with the theoretical expectations [1].

The results of a series of experiments representative of the adverse effects of impurities on measurements of two acids of different strength, formic acid and acetic acid, are summarized in Table 4. 2.5 ml of approximately 0.3 M formic acid (literature value $pK_a = 3.55 \pm 0.01$ at 25°C and 0.1 M ionic strength) [11] were added stepwise (in 20 aliquots) to 0.1 M potassium chloride, and were subsequently titrated with standard sodium hydroxide (0.1 M, in order to produce negligible variation of ionic strength). Using the value of

GLS = generalized least squares.
[a] One adjustable parameter.
[b] Two adjustable parameters.

the sample concentration obtained from Gran titration, $pK_a = 3.520 \pm 0.002$ was obtained from the titration data with Eq. (37) and $pK_a = 3.521 \pm 0.003$ from the sample addition data with Eq. (33), with excellent agreement between the two sets.

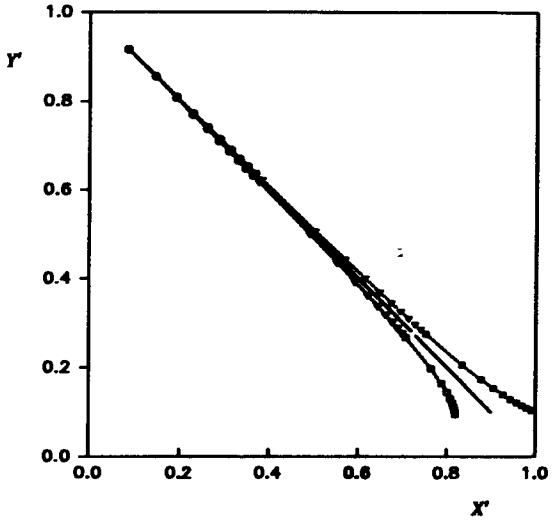

Fig. 4. Plot of Hofstee-type function, Eq. (34), with normalized auxiliary variables $X' = X/CK_a$ and $Y' = Y/C$ calculated from synthetic values of $[H^+]$ for multiple addition of an acid with $pK_a = 4$ over different $C_{HA}/K_a$ ranges in the presence of contaminant in the samples. $V^\circ = 100$ ml, $V = i$ ml, $i = 1-10$. ——, $C_j = 0$. Basic impurity (conjugated base) at 1% concentration ratio: ○, $C = 0.001$ M, $C_{HA}/K_a \approx 0.1-1$; ▽, $C = 0.01$ M, $C_{HA}/K_a \approx 1-10$; □, $C = 0.1$ M, $C_{HA}/K_a \approx 10-10^2$. Strong acid impurity at 1% concentration ratio represented by full symbols; other parameters as above.

The results of the simultaneous determination of $K_a$ and $C$ from the linearized titration data are also good, although they show some dependence upon the linear equation used. In contrast, the corresponding experimental plots of the sample addition data (see Eq. (34) and Table 1 of Ref. [1]) deviate from the theoretical plots calculated with the above values of the chemical parameters in the direction corresponding to the presence of a base in the supporting electrolyte, in qualitative accordance with Figs. 2 and 3. As a consequence, the calculated value of the acidity constant is affected by a positive error and that of the sample concentraton by a negative error. In spite of the appreciable shifting, any deviation from linearity, being small in the experimental concentration range (see Discussion section), is practically masked by the dispersion of the points (although small).

As expected (see Discussion section, Figs. 2 and 3), larger shifts in the experimental plots and, therefore, larger errors in the simultaneous determination of $K_a$ and $C$, were found with the weaker acetic acid in the same concentration range ($pK_a = 4.50 \pm 0.03$ at 25°C) [11] with supporting electrolyte taken from the same batch. Larger deviations also occurred with more dilute solutions of the same acids. In contrast, the determination of the acidity constant with Eq. (33) using an independently determined value of sample concentration yielded good results over a much larger range of experimental conditions.

The results of linearized titration and sample addition were also evaluated by comparison with generalized least-squares treatment of the original experimental variables. The results obtained with the data from the same experiments are shown in Table 4. Data treatment with the acidity constant as the only adjustable parameter shows very good agreement with linearization for both titration and sample addition. When both acidity constant and sample concentration are adjusted, generalized least-squares results of titration and of sample addition agree very well each other, and with those obtained from titration by linear equations. When the concentration of impurities in the supporting solution is also taken as an adjustable parameter, the value of sample concentration does not change and that of the acidity constant only changes a little; however, for several experiments, an unreasonably high concentration of basic impurities was calculated, apparently due to high correlation between this quantity and the acidity constant.

## 6. Conclusions

The theoretical investigation of the effect of basic and acid impurities and the experimental results have confirmed that multiple sample addition of weak acid is very suitable for the determination of the acidity constant by multiple sample addition, particularly when a standard solution is used, i.e. when the sample concentration is accurately known. The accuracy and precision of $K_a$ are comparable with those attained by titration. Multiple sample addition is then a convenient substitute for titration, removing the problems inherent in the use of a strong base as the titrant (for instance, the massive absorption of carbon dioxide by the titrant solution). More generally, multiple sample addition can offer a valid complement to titration, particularly when a very limited amount of the substance to be investigated is available; indeed, potentiometric measurements during the stepwise addition of the sample to be subsequently titrated, in accordance with the procedure herein followed, make it possible to double the number of experimental data using the same amount of sample (the effect is much more significant than that of intensifying the titration points). For simultaneous determination of acidity constant and sample concentration by multiple sample addition, a more scrupulous control of contaminants is necessary, with additional limitations on the strength and concentration of the acid.

Rigorous mathematical solution requires application of non-linear regression. Linearized multiple addition, besides not being a statistically sound method of data treatment, is more affected than non-linear regression (to a greater extent than linearized titrations) by pitfalls, interferences and contaminations common in pH-metric measurements. However, by addition of standard solution, good or acceptable values of the acidity constant are easily obtained. In contrast, the adverse effects are particularly enhanced when the acidity constant and sample concentration are simultaneously determined. In this instance, data linearization is only suitable for a rough preliminary evaluation of the desired quantities.

Notwithstanding the above limitations, linearized multiple sample addition has a place in analytical research. According to our experience, a great benefit can be gained from the preliminary use of this method just because of such amplified deviations from the linear models. A comparison of the shape of deviations of the linearly transformed data with the behaviour anticipated by the theoretical treatment (which, for this reason, is rather detailed in this and in the previous paper [1]) is frequently highly diagnostic of the nature of the contaminants and, in general, of the pitfalls of the analytical environment; it also helps to detect and to eliminate, correct or counteract some important sources of error, perhaps to greater effect than the distribution of residuals in non-linear regression.

**Abstract**

A novel glassy carbon electrode design, permitting medium exchange in batch mode without loss of electrode potential control, has been used for the study of copper(I) and copper(II) species formed during constant current stripping oxidation of copper in chloride media. It was found that copper(II) species dominated at chloride concentrations below about 1 mM and that soluble copper(I) species dominated at chloride concentrations above about 100 mM. In the concentration range 1–100 mM, soluble copper(I) and copper(II) species are formed as well as solid copper(I) chloride, the latter giving rise to a split peak as it is further oxidised to copper(II). The experimental results agreed satisfactorily with computer calculated equilibria data using the HALTAFALL program. The medium exchange procedure has, furthermore, been used for the determination of copper(II) in seawater reference samples, 7.5 M ammonium acetate/2.5 M acetic acid being used as stripping medium. The detection limit, after 15 min of electrolysis, was found to be 6 ng $l^{-1}$ (0.10 nM) and the relative precision 6–10%.

## 1. Introduction

Although copper is one of the elements most frequently studied electroanalytically, the stripping analysis for copper(II) is far from straightforward in practical work. Batley [1] has summarised five main problems in the study of copper(II) in natural waters using stripping analysis as (i) the ability of copper(II) to bind strongly to organic and inorganic ligands, (ii) its existence in two oxidation states, (iii) the occurrence of the copper stripping peak at potentials at which many organic species are adsorbed onto mercury electrodes, (iv) the low solubility of copper in mercury and (v) the irreversibility of the copper reduction. Nelson [2,3] and Nelson and Mantoura [4–6] have extensively studied the reduction of copper in natural waters containing, in addition to chloride, other complexing agents, e.g. glycine, as well as surfactants such as gelatine. Recently, Boussemart et al. [7], in a study involving chromatographic fractions of commercial humic substances, explained the split peaks, frequently observed during oxidative stripping of copper, by the oxidation of organic copper(I) species adsorbed onto the mercury electrode surface.

In all the studies referred to above, the electrochemical reduction (electrolysis) of

* Corresponding author.

*SSDI* 0039-9140(95)01593-0

copper(II) and the subsequent electrochemical oxidation (stripping) was performed in the same solution. This means that effects from various complexing agents and surfactants on the reduction process could not be distinguished from the effects of these substances on the oxidation process. For this reason, the interpretation of the results is complicated and sometimes speculative. The introduction of a novel "three-in-one" electrode design, permitting medium exchange under a controlled electrode potential in batch mode [8], considerably simplifies the separate study of the reduction and the oxidation reactions. In addition, the electrode design makes it possible to perform stripping in a medium of optimum composition, with respect to e.g. selectivity, linear range and sensitivity, irrespective of sample composition.

In this article, the novel electrode design has been used to study the effect of the chloride concentration on the reduction of copper(II) and the subsequent rapid oxidation of copper. Stripping potentiometry has been chosen for the experiments, since this is the electroanalytical stripping technique best suited to the study of rapid electrode reactions. The experimental results have been interpreted using computer calculations based on known thermodynamical data. Further, a method for the determination of copper(II) in the $ng\,l^{-1}$ range, involving medium exchange, is presented as well as results from the analysis of reference seawater samples.

## 2. Experimental

### 2.1. Instrumentation, software and electrodes

All experiments were performed using a stripping potentiometry analyser (Tracelab™, PSU 22) in combination with a sample changer (SAC 80), both controlled by the TAP2 Trace Talk Method Builder and Commander through a personal computer. The software and all equipment, except the computer, were produced by Radiometer Analytical S.A., Lyon, France.

Two different commercial three-in-one electrodes (gCC 540, Radiometer Analytical S.A., Lyon), based on the principles described by Jagner et al. [8], were used for the measurements. The Ag/AgCl reference and counter electrodes inside the electrodes were immersed in 3 M hydrochloric acid, which also provided the electrical connection to the outside 3 mm diameter glassy carbon disk working electrode through a ceramic plug. When lifted out of a solution, a droplet always remained under the electrode, i.e. under the glassy carbon disk and the ceramic plug surrounding it. In this way the electrical conductance between the three electrodes, and thus the working electrode potential, could be preserved when the sample changer moved the electrode from one solution to the next. Unless otherwise stated, all potentials given below are vs. Ag/AgCl (3 M HCl).

### 2.2. Transformation of experimental potential values to the standard hydrogen electrode potential scale

In order to be able to compare the experimentally determined electrode potentials, $E_{exp}$, obtained from the Ag/AgCl (3 M HCl) reference electrode with the standard hydrogen electrode potential, $E_{SHE}$, used in the thermodynamic calculations, the experimental values must be transformed to the latter potential scale. This was achieved by measuring the potential difference between the Ag/AgCl (3 M HCl) electrode and a saturated calomel electrode, SCE, in 0.001, 0.01, 0.1, and 1 M hydrochloric acid, i.e. in the media used in the computer calculations. Measurement was also made in 3 M hydrochloric acid in which the liquid junction potential in the Ag/AgCl (3 M HCl) is equal to zero. A potential value of 0.248 V was used for SCE vs. SHE and the liquid junction potentials of the calomel electrode, at different acid concentrations, were taken from Linnet [9]. The electrical resistance in the ceramic plug separating the Ag/AgCl (3 M HCl) electrode from the sample solution was found to be approximately 0.7 kΩ, i.e. the iR potential drop due to the stripping current of 10 μA was equal to 7 mV and this value was corrected for in the transformation between the two potential scales.

### 2.3. Chemical and cleaning of sample vessels

All chemicals were of analytical grade except the hydrochloric acid which was freshly distilled. Millipore water was used for the preparation of all solutions which were handled in a laminar flow cabinet except during analysis. Prior to use, the 45 ml volume polyethylene sample vessels were soaked in 4 M hydrochlo-

ric acid for at least one week and then carefully rinsed with Millipore water.

### 2.4. Solutions and seawater reference samples

The mercury plating solution was prepared by adding concentrated hydrochloric acid and a stock solution of 20 g $l^{-1}$ of mercury(II), prepared by dissolving high purity liquid mercury in concentrated nitric acid and subsequent dilution with 1 M hydrochloric acid, to Millipore water to yield total concentrations equal to 0.10 M and 200 mg $l^{-1}$, respectively. The blank solution referred to below contained 0.025 M hydrochloric acid, 5 μg $l^{-1}$ of lead(II) and 10 mg $l^{-1}$ of mercury(II). The calibration sample used for the determination of copper(II) in seawater was prepared by adding 1 μg $l^{-1}$ of copper(II) to the blank solution. The stripping solution used for the determination of copper(II) in seawater was prepared by mixing acetic acid and ammonia to give an ammonium acetate concentration equal to 7.5 M and an acetic acid concentration equal to 2.5 M (pH = 5, $\eta$ = 0.01 Pa s at 25°C).

The reference seawater samples were obtained from the National Research Council of Canada, apart from the preliminary European Commission Reference Sample BCR 505. The samples had been acidified to pH = 1.6 with nitric acid on sampling, and 10 mg $l^{-1}$ of mercury(II) and 5 μg $l^{-1}$ of lead(II) (internal standard) were added to the samples prior to analysis. All certified lead(II) values were below 50 ng $l^{-1}$, i.e. negligible in comparison with the lead(II) concentration added as internal standard.

### 2.5. Electrode pretreatment

Prior to first use, the electrodes were polished with diamond paste with a diameter of 1 μm and then carefully rinsed ultrasonically in 50% v/v ethanol–water containing 0.10 M hydrochloric acid. Once polished, the electrodes were never repolished. The inner electrode solution of 3 M hydrochloric acid was changed monthly. On storage in 0.1 M hydrochloric acid, the glassy carbon electrode surface of one of the two electrodes used slowly deteriorated, and this gave rise to ghost stripping peaks close to that of copper. This interference, which was of minor concern when the copper(II) concentration exceeded 1 μg $l^{-1}$, was eliminated by a daily electrochemical cleaning procedure involving electrolysis in the plating solution for 4 min at a potential of −2.00 V. The second electrode never gave rise to any ghost peaks.

### 2.6. Electroanalytical procedure

All electroanalytical measurements were composed of three steps: deposition of a fresh mercury film in the mercury plating solution, electrolysis in the samples and, finally, oxidation of the element(s) in the stripping solutions. The electrode was automatically moved from one solution to the next by the sample changer. Prior to each experiment, the electrode was rinsed with Millipore water and ethanol and finally cleaned with a tissue whereby the used mercury film was removed. All solution volumes were 20 ml.

In all experiments, a fresh mercury film was obtained by electrolysis for 30 s at a potential of −1.00 V in the mercury plating solution, the rotation rate of the propeller stirrer being 1500 rpm. The potential was then increased to −0.05 V for 1 s in order to oxidise copper emanating from possible trace impurities of copper(II) in the plating solution. After that, the potential was decreased to −0.15 V, the stirrer stopped, and the electrode transferred to the sample solution. Deposition of copper was performed for 5–15 min, depending on the copper(II) concentration in the sample, at a potential of −0.80 V and a stirring rate of 1500 rpm. During deposition, the electrolysis potential was decreased to −2.00 V for 0.2 s at intervals of 30 s in order to remove trace organic impurities which might have adsorbed onto the electrode surface [10]. Subsequent to copper deposition, the stirrer was stopped and the electrode was transferred to the stripping solution at a controlled potential of −0.80 V. After 30 s at this potential, with a stirring rate of 1500 rpm, the stirrer was stopped and 5 s later the electrode was lifted out of the stripping solution. Another 10 s later stripping was initiated, under quiescent conditions in the stripping solution drop hanging under the electrode employing oxidative currents in the range 1–12 μA. Finally, the electrode was again immersed in the stripping solution and stirring at 1500 rpm was started in order to remove copper(II) ions close to the electrode surface. After this, the measurement cycle in the stripping medium described above was repeated, the first stripping curve registered being denoted as the analytical stripping curve, and the second as the background stripping curve.

## 3. Computational

### 3.1. Software and equilibrium constants

All calculations were performed with the HALTAFALL program [11] using a Turbo Pascal version modified for use by personal computers and running under Microsoft DOS [12]. The stability, solubility and redox constants used in the calculations are specified in Table 1 according to the nomenclature used in Ref. [13]. In spite of the fact that the ionic strength varied greatly between the different media investigated, the same constants were used for all calculations, i.e. no activity factor corrections were made. Owing to the considerable controversy [14,15,17–20] among different authors on the stability and solubility constants in the copper(I) chloride system in aqueous solution, corrections of the constants in Table 1, due to different ionic strengths, were not considered meaningful.

### 3.2. Electron activity and total concentrations

The aim of the computer calculations was to simulate the chemical reactions taking place at the interface between an electrode surface and solutions containing different chloride concentrations, as the electrode potential was made increasingly oxidative and copper consequently oxidised to different copper(I) and copper(II) species. In the calculations, four different chloride concentrations, 0.001, 0.01, 0.10 and 1.0 M, were investigated, and the electrode potential was varied between −0.200 and 0.500 V vs. SHE in steps of 0.020 V. The electron activity, $\{e^-\}$ values used in the computer calculations [12,13] were obtained from the $E$ vs. SHE values as

$$\{e^-\} = \exp(-EF/RT) \quad (1)$$

where $R$, $T$ and $F$ have their usual meanings. All computer calculations were carried out with a relative accuracy equal to $10^{-6}$% of the total concentrations [12,13].

The total concentration of oxidised copper species at the electrode surface, $C_{x=0}$, during constant current oxidation of copper was approximated according to Buffle [21] as

$$C_{x=0} = C_{x=\infty} + (\delta/D) i_{ox}/nFA \quad (2)$$

where $i_{ox}$ denotes the stripping current, $\delta$ is the diffusion layer thickness during stripping, $C_{x=\infty}$ is the stripping medium concentration of analyte, $D$ is the diffusion coefficient of the oxidised copper species, $n$ is the number of electrons involved in the oxidation, and $A$ is the electrode surface area. In the experiments described below, the applied oxidative current was equal to 10 μA and the chemical contribution (see below) to the oxidation equal to approximately 3 μA. By comparing the diffusion current obtained during stirring with that obtained under quiescent conditions in the hanging stripping medium drop and by assuming a $\delta$ value equal to 30 μm under stirring conditions, the diffusion layer thickness in the hanging drop was estimated to be 460 μm. Using a $D$ value of $10^{-5}$ cm$^2$ s$^{-1}$ and an $n$ value equal to unity, the surface concentration of copper was estimated to be 8.8 mM at the 3 mm diameter disk electrode, $C_{x=\infty}$ being, of course, equal to zero after medium exchange. This concentration was used in all computer simulations below.

## 4. Results

### 4.1. Effect of chloride concentration on the reduction rate of copper(II)

The effect of chloride ion concentration on

the reduction of copper(II) was investigated by electrolysis for 5 min in samples containing 5 μg $l^{-1}$ of copper(II) and lead(II), and hydrochloric acid at concentrations varying between 0.001 and 1.00 M. Stripping was performed in 7.5 M ammonium acetate–2.5 M acetic acid with an oxidative current of 1 μA. The dependence of the copper and lead signals on the chloride concentration is shown in Fig. 1. From this, it is obvious that the rate of copper(II) reduction is independent of the chloride concentration, which is also found, as expected, for lead(II). In addition, it can be seen that the reproducibility of the copper signal (RSD = 4.8%; $n = 13$) is lower than that for lead (RSD = 3.6%; $n = 13$). The relative standard deviation of the ratio between the two signals, 4.9%, indicates a modest co-variation between the two signals (Fig. 1).

### 4.2. *Effect of chloride concentration on the oxidation of copper*

On electrochemical oxidation of copper, either copper(I) or copper(II) species are formed initially. In order to elucidate the effect of the chloride concentration on the oxidation state, electrolysis was performed for 5 min in samples containing 50 μg $l^{-1}$ of copper(II) and lead(II) prior to stripping in solutions containing 0.0005, 0.001, 0.002, 0.005, 0.01, 0.10, 1.00 and 3.00 M hydrochloric acid. Perchloric acid, at a total concentration of 0.025 M, was used as an inert electrolyte. Six different stripping currents, 2, 4, 6, 8, 10 and 12 μA, were used at each chloride concentration. The experiment was also performed using 7.5 M ammonium acetate–2.5 M acetic acid as stripping medium. During constant current oxidation of elements, electrons are removed by two sources [22]: one is the applied oxidative current, $i_{ox}$, and the other is the flow of oxidants, present in the stripping solution, to the electrode surface. In non-deaerated solutions, dissolved oxygen is normally the main oxidant to be considered. The chemical contribution to the oxidation of an element can be expressed as a chemical current, $i_{chem}$. By plotting the inverse of the stripping signal, $t_s^{-1}$, vs. the applied oxidative currents, a linear relationship is obtained from which the chemical current, at each chloride concentration and for each element studied, can be obtained as the negative intercept on the current axis when $t_s^{-1}$ is extrapolated to zero [22].

The total charge, $Q_M$, used for the oxidation of an element, M, can thus be calculated as

$$Q_M = t_s(i_{chem} + i_{ox}) \quad (3)$$

Assuming that lead is oxidised to lead(II), irrespective of chloride concentration, and, by plotting $R = Q_{Cu}/Q_{Pb}$ vs. the chloride concentration in the stripping medium normalised with the value for this ratio, obtained at a chloride concentration equal to 0.5 mM, it was found that copper(II) species dominated at chloride concentrations below approximately 0.002 M (Fig. 2). Copper(I) species were found to dominate at chloride concentrations above approximately 0.05 M, the normalised value for $R$ being equal to 0.50 within experimental errors. At intermediate chloride concentrations, both copper(II) and copper(I) species were formed (Fig. 2). It was also found that only copper(I) species were formed in 7.5 M ammonium acetate–2.5 M acetic acid medium. Owing to the high viscosity of this medium, the copper(I) species formed diffused very slowly away from the electrode surface and, as the electrode potential was made increasingly oxidative, a second stripping peak, due to the oxidation of copper(I) to copper(II), was sometimes observed, particularly at copper(II) concentrations above 5 μg $l^{-1}$.

Species formed during oxidation of copper were further investigated by comparison with computer calculations as shown in Figs. 3(a)–

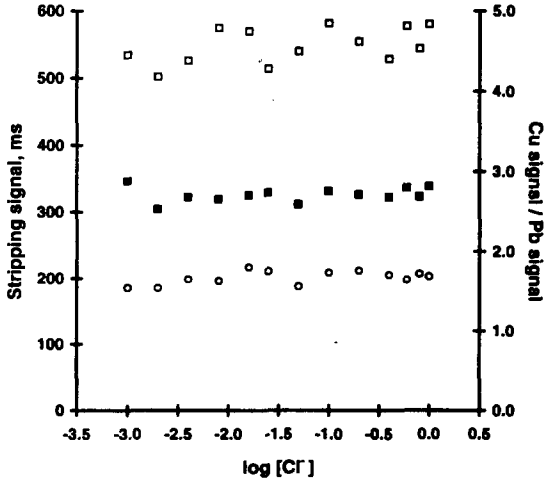

Fig. 1. Dependence of copper and lead stripping signals on sample chloride concentration. Electrolysis for 5 min in samples containing 5 μg $l^{-1}$ of copper(II) and lead(II), and chloride concentrations varying between 0.001 and 1.00 M. ■ = Pb, □ = Cu, ○ = Cu/Pb (right-hand scale).

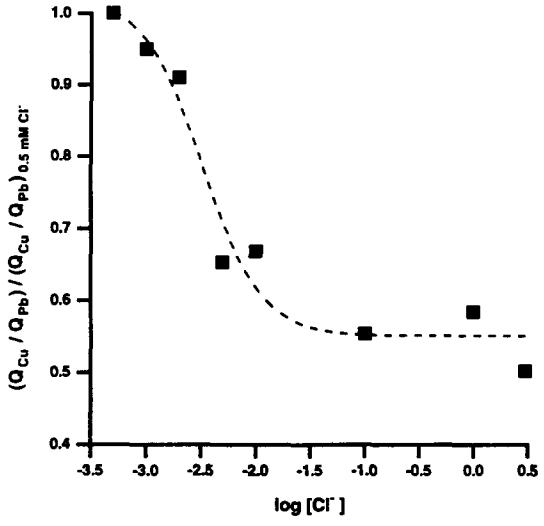

Fig. 2. Dependence of copper oxidation state on stripping medium chloride concentration. Electrolysis for 5 min in samples containing 50 μg $l^{-1}$ of copper(II) and lead(II), and subsequent oxidation in 0.0005, 0.001, 0.002, 0.005, 0.01, 0.10, 1.00 and 3.00 M hydrochloric acid. The total charge needed for the oxidation of copper, $Q_{Cu}$, was divided by the total charge needed for the oxidation of lead, $Q_{Pb}$, and normalised with the value for this ratio at a hydrochloric acid concentration of 0.0005 M.

3(d). In these, calculated molar fractions, $X$, have been plotted against electrode potentials, on the SHE potential scale, for four different hydrochloric acid concentrations, 0.001, 0.01, 0.1 and 1 M (Figs. 3(a)–3(d), respectively). Experimental stripping curves, obtained after electrolysis for 5 min in a solution containing 0.025 M hydrochloric acid, 50 μg $l^{-1}$ copper(II) and 10 mg $l^{-1}$ mercury(II) prior to stripping in 0.001, 0.01, 0.10 and 1.0 M hydrochloric acid containing 0.025 M perchloric acid with an oxidative current equal to 10 μA, are also shown, on the SHE potential scale, in Figs. 3(a)–3(d). Experimental curves (3) show the background strips, curves (2) the analytical strips and curves (1) the background corrected strips.

The calculated molar fraction diagrams in Fig. 3(a) indicate that only copper(II) species are formed during copper oxidation in 0.001 M hydrochloric acid. This is also shown by the experimental stripping curves, the experimental stripping peak potential being close to the calculated potential. At a chloride concentration equal to 0.01 M, the computer calculations (Fig. 3(b)) indicate that copper(II) is formed simultaneously with solid copper(I) chloride. On increasing oxidative potentials, the latter compound is oxidised to copper(II) giving rise to the split stripping peak in the experimental stripping curves in Fig. 3(b). On increasing the chloride concentration to 0.10 M, only copper(I) species are formed according to the calculated molar fraction diagrams in Fig. 3(c). This is also indicated by the disappearance of the split peak in the experimental curves. The computer calculations show that both soluble and insoluble copper(I) species are formed in 0.10 M chloride. They also show that not all the solid copper(I) chloride had been oxidised to copper(II) at the oxidation potential at which the experimental oxidation was stopped in order to avoid mercury oxidation (0.30 V vs. SHE). The remaining solid copper(I) chloride, adhering to the electrode surface, is reduced to copper as the electrode potential is made negative, prior to the registration of the background strip, and gives rise to a stripping peak in the background strip as seen in Fig. 3(c). Finally, the molar fraction diagram in Fig. 3(d) indicates that at a chloride concentration equal to

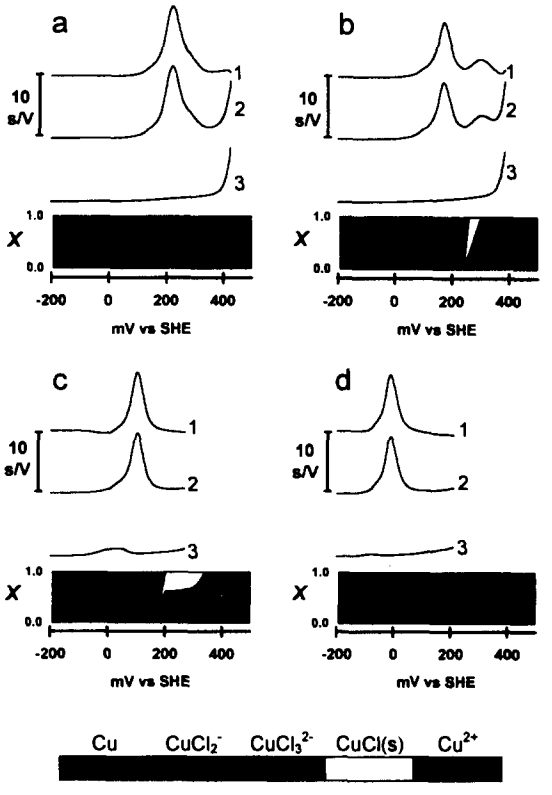

Fig. 3. Computer calculated molar fraction diagrams for the electrochemical oxidation of copper in (a) 0.001 (b) 0.01 (c) 0.10 and (d) 1.00 M hydrochloric acid. Comparison with experimental results obtained after electrolysis for 5 min in samples containing 50 μg $l^{-1}$ of copper(II) and subsequent stripping in (a) 0.001 (b) 0.01 (c) 0.10 and (d) 1.00 M hydrochloric acid. (1) Background corrected stripping curves, (2) analytical curves and (3) background curves.

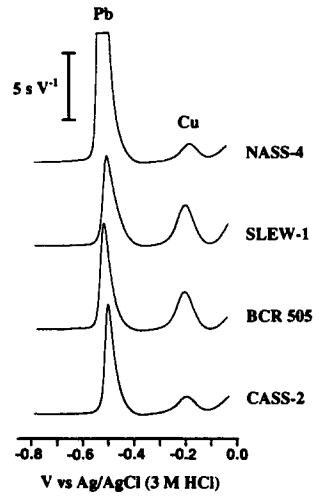

Fig. 4. Stripping potentiometry curves obtained in the determination of copper(II) in four different reference seawater samples to which 5 μg $l^{-1}$ of lead(II) had been added as internal standard. Electrolysis for 5 min (NASS-4, 15 min) was carried out prior to stripping in 7.5 M ammonium acetate–2.5 M acetic acid (see Table 2).

1.00 M, only soluble copper(I) species are formed, $CuCl_2^-$ being the predominant one.

### 4.3. Determination of copper(II) in seawater reference samples

The three-in-one electrode design used in this investigation makes it possible to choose the stripping medium composition independent of the sample composition. A stripping medium to be used for the determination of copper(II) in the ng $l^{-1}$ range must, of course, be extremely pure with respect to copper(II). Further, the stripping medium should, preferably, be a concentrated electrolyte so that the dissolved oxygen concentration is low and the viscosity high, both properties decreasing the chemical oxidation rate [23]. The ammonium acetate–acetic acid medium used in this investigation fulfils these requirements.

Fig. 4 shows the background corrected stripping curves, obtained after electrolysis for 5 min (15 min for NASS-4) in four different seawater reference samples, with a certified copper(II) concentration ranging between 0.23 and 1.7 μg $l^{-1}$, and subsequent stripping in ammonium acetate–acetic acid solution with a constant current equal to 1 μA. Prior to analysis, 5 μg $l^{-1}$ of lead(II) had been added to the samples as internal standard. The copper(II) concentrations in the reference samples were evaluated subsequent to calibration in a sample containing 1 μg $l^{-1}$ of copper(II) and 5 μg $l^{-1}$ lead(II) in 0.025 M hydrochloric acid. The results, evaluated with and without internal standard, are shown in Table 2. The reference value given for BCR 505 in Table 2 was obtained employing the solvent extraction/graphite furnace method described by Danielsson et al. [24].

As can be seen from Table 2, the results obtained by the proposed method agree satisfactorily with the certified values for the seawater reference samples. The value obtained for the deep ocean sample NASS-4 is, for unknown reasons, significantly below the certified range. As is also seen from Table 2, the relative standard deviation of the proposed method is in the range 6–10%, both with and without internal standard.

### 4.4. Detection limit, sensitivity and linear range

The detection limit of the proposed method was studied by adding known copper(II) concentrations to the blank solution. Fig. 5 shows the background corrected stripping curves obtained after the addition of 0, 10, 20, 40, 60, 80 and 100 ng $l^{-1}$ of copper(II) and electrolysis for 15 min prior to stripping in the ammonium acetate–acetic acid medium with a constant current of 1 μA. Also shown in Fig. 5 is the calibration plot, the correlation coefficient being equal to 0.9958, the intercept on the concentration axis equal to −0.90 ng $l^{-1}$ and the slope 0.35 ms l $ng^{-1}$.

The minimum detectable signal when using a 90 kHz potentiometric stripping analyser is normally 0.2–0.3 ms, corresponding to approximately 20–30 real time measurements. Since, however, the copper stripping peak is close to the commencement of mercury oxidation, the background is higher than it is for e.g. lead and cadmium [25], which makes the background correction difficult. A detection limit of 2 ms, corresponding to a copper(II) concentration of approximately 6 ng $l^{-1}$ (0.10 nM) after 15 min of electrolysis, is thus a more realistic value for the detection limit (see Fig. 5).

The linear range was investigated by analysing blank solutions to which 0, 1, 2, 3, 4 and 5 μg $l^{-1}$ of copper(II) had been added, the time for electrolysis being 15 min and the stripping current 1 μA. The correlation coefficient of the calibration plot was 0.9999 ($n = 6$), the intercept on the concentration axis −0.025 μg $l^{-1}$ and the sensitivity 0.28 ms l $ng^{-1}$. The last number indicates that the sensitivity decreases

Table 2
Copper(II) determination in seawater reference samples. The reference value for BCR 505 was obtained according to the method of Danielsson et al. [24]

| Reference sample | Electrolysis time (min) | Certified range ($\mu g\,l^{-1}$) | $[Cu]_{found} \pm \sigma$ ($\mu g\,l^{-1}$)($n = 6$) | |
|---|---|---|---|---|
| | | | With internal standard | Without internal standard |
| SLEW-1 | 5 | 1.67–1.85 | $1.66 \pm 0.10$ | $1.55 \pm 0.09$ |
| BCR 505 | 5 | (1.65) | $1.63 \pm 0.07$ | $1.59 \pm 0.06$ |
| CASS-2 | 5 | 0.636–0.714 | $0.682 \pm 0.062$ | $0.652 \pm 0.062$ |
| NASS-4 | 15 | 0.217–0.239 | $0.186 \pm 0.009$ | $0.176 \pm 0.010$ |

slightly as the sample concentration of the analyte is increased, as is frequently the case in electroanalytical stripping techniques.

## 5. Discussion and conclusions

The experimental results and the computer calculations clearly show that the reactions taking place on the electrochemical stripping oxidation of copper are highly dependent on the chloride concentration in the oxidation medium. Copper(II) species only dominate at chloride concentrations below about 1 mM, i.e. at concentrations considerably lower than in most real samples. In the concentration range 1–100 mM, both copper(I) and copper(II) species are formed. The interpretation of the stripping data in this concentration range is further complicated by the fact that copper(I) species initially formed, and remaining in the vicinity of the electrode surface, can be further oxidised giving rise to an overlapping peak. Since, furthermore, the fraction of copper(I) species oxidised to copper(II) is highly dependent on the hydrodynamic conditions at the electrode surface, the second stripping peak is frequently very irreproducible. A further complication is that solid copper(I) chloride can be formed. This adheres to the electrode surface and is only partly oxidised to soluble copper(II) species. It is, however, easily reduced on an electrode surface. Consequently, if the same mercury film is used for consecutive analysis, as is frequently the case, copper(I) chloride will be carried from one sample to the next yielding an overly high copper stripping signal in this sample. Medium exchange, as used here, is obviously one way of circumventing the problem arising from varying chloride concentrations in real samples. If this possibility is not available, an alternative way of solving the problem would be the addition of excess chloride, e.g. 1 M hydrochloric acid, to each sample prior to analysis. In this way, formation of solid copper(I) chloride is prevented and, moreover, hydrochloric acid is normally free from copper(II) impurities.

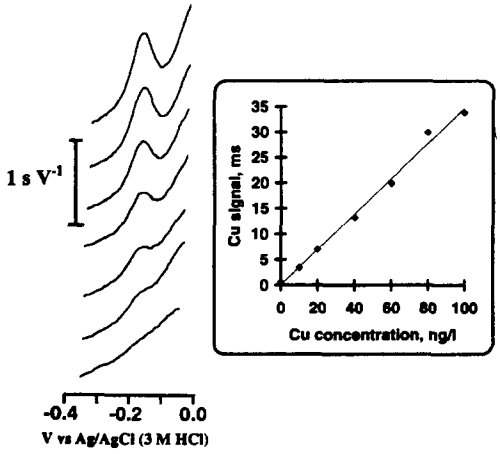

Fig. 5. Stripping potentiometry curves (left) and calibration plot (right) obtained after 15 min of electrolysis in samples containing (from the bottom) 0, 10, 20, 40, 60, 80 and 100 $ng\,l^{-1}$ of copper(II) and subsequent stripping in 7.5 M ammonium acetate–2.5 M acetic acid.

A medium exchange procedure, similar to that described in this article, has previously been applied to the determination of cadmium(II) and lead(II) in seawater [25]. In this investigation a detection limit equal to 0.2 $ng\,l^{-1}$ was obtained for cadmium(II) by exploiting a multiple stripping procedure. On a molar scale, this is approximately 50 times lower than that obtained for copper(II) in this investigation. The main reason for this is that multiple stripping cannot be used for the determination of copper owing to the high background close to the commencement of mercury oxidation, which makes the re-reduction efficiency very low [25]. Another reason for the difference in detection limit is, of course, that oxidation of copper in the stripping medium involves only one electron while lead and cad-

mium are always oxidised to their divalent oxidation states.

Although not demonstrated here, the proposed medium exchange procedure would, undoubtedly, be suitable for the study of copper(II) speciation and copper(II) complexing capacity [26–30] in natural waters. Specific advantages would be that mercury(II) ions do not have to be used, the addition of which to the natural water might alter the equilibria. Further, oxidation of copper would always take place under uniform conditions making the interpretation of the results considerably simpler. From a practical point of view, the investigations could, moreover, be made fully automatic taking advantage of the sample changer and flexible software of the stripping analyser.

Received 6 January 1995; revised 22 March 1995; accepted 23 March 1995

**Abstract**

Carbaryl and its hydrolysis product, 1-naphthol, are determined simultaneously, and in a mixture of other pesticides, by reversed-phase high-performance liquid chromatography (HPLC). Fluorometric detection affords a higher degree of selectivity than absorbance detection, while providing detection limits of 1.0 ng $ml^{-1}$ and 1.4 mg $ml^{-1}$ for 1-naphthol and carbaryl, respectively. The described method requires no enrichment of samples and includes a simple hydrolysis step. Additionally, enhancement of fluorescence detection signal intensity is explored through HPLC solvent composition effects as well as through formation of cyclodextrin inclusion complexes. The method described in this report is a selective and fast alternative to the currently accepted U.S. Environmental Protection Agency (EPA) method of detection carbaryl in ground water.

## 1. Introduction

Carbaryl ($C_{12}H_{11}NO_2$), a member of the carbamate class of nitrogen-containing organic pesticides, is a broad spectrum pesticide, and is extensively used owing to its effectiveness and relatively low acute mammalian toxicology (560 mg $kg^{-1}$) [1]. Carbaryl is an inhibitor of acetylcholinesterase and is degraded very rapidly compared to other classes of pesticides, such as the organophosphorus esters [2]. Unfortunately, the primary metabolite of carbaryl, 1-naphthol, is as toxic to many marine invertebrates as the parent pesticide. Owing to the widespread use of carbaryl, as well as the toxicity of its hydrolysis product, a rapid, selective, economical and sensitive method is needed to monitor both compounds in enviromental water samples.

The carbamate class of pesticides is characterized by susceptibility to thermal degradation, which complicates determination by gas chromatography or any other method involving temperatures significantly above ambient [3]. Therefore, methods used to determine carbaryl content implement primarily high-performance liquid chromatography (HPLC) with either UV/vis absorbance or fluorescence detection, owing to the non-thermal properties of this method [4–6]. Derivatization, followed by fluorometric measurement, is another useful means of detection [7]. Carbaryl can also be hydrolyzed and reacted with diazotized sulfanillic acid, and the carbaryl content subsequently determined with a spectrophotometer [8]. Enviromental Protection Agency (EPA) Method 531.1 prescribes hydrolysis of carbaryl and then derivatization, followed by fluorometric detection. The retention time of carbaryl for the EPA method is approximately 20.29 min and the estimated detection limit is 2.0 ng $ml^{-1}$.

Although both carbaryl and 1-naphthol (as the 1-naphtholate ion) fluoresce, 1-naphtholate is more sensitive to fluorescence detection over the experimental range of $1.0-10^3$ ng ml$^{-1}$. Given the greater relative fluroescence intensity of 1-naphtholate than that observed for carbaryl, a reversed-phase HPLC method was devised to detect 1-naphthol as the hydrolysis product of carbaryl. Detection of carbaryl by this coupled assay provides a lower detection limit for the pesticide, because 1-naphthol can be determined in lower quantities than can carbaryl by direct analysis.

Cyclodextrin inclusion complexes and variations in HPLC solvent composition were also studied with regards to their effect upon the fluorescence spectra of carbaryl and 1-naphthol. The modifications in the mobile-phase matrix could be implemented to improve the detection limits of carbaryl or 1-naphthol in solution where fluorometric detection is employed.

Carbaryl, as well as its hydrolysis product 1-naphthol, forms inclusion complexes with certain cyclodextrins (CDs). CDs are cyclic oligosaccharides composed of six or more glucopyranose units bonded via 1–4 ether linkages [9]. The inclusion complex is characterized by a guest molecule physically moving into the hydrophobic inner cavity of the CD. The pesticide/CD complex is dependent upon the spatial qualities of the pesticide relative to those of the internal cavity of the CD ring, as well as the polarity of the pesticide. Three native varieties of CDs are available: alpha ($\alpha$), beta ($\beta$) and gamma ($\gamma$), with internal cavity diameters of 0.57, 0.78 and 0.98 nm respectively. Complexation alters physical and chemical properties of the guest molecule, such as availability of substituents for reactions and interaction with the stationary phase in HPLC.

Cyclodextrin complexation has been shown to increase luminescence efficiency with certain compounds versus that observed in a bulk solution of water. The factors responsible for this increase in luminescence efficiency are: (1) shielding of the analyte molecule from quenching due to water molecules or water-borne quenchers, (2) decrease in oxygen quenching, and (3) the analyte experiencing a less polar and more rigid local microenviroment [10]. Far fewer compounds fluoresce than absorb strongly, so fluorescence is a more selective method of detection than absorbance. If the fluorophor exhibits increased emission intensity due to CD complexation, it can be determined at a lower detection limit.

The described HPLC procedure to detect 1-naphthol as the hydrolysis product of carbaryl is fast, highly selective, sensitive, accurate, economical and little sample preparation is required. Other benefits are few possible interferents and the lack of necessity for a complex derivatization procedure. This procedure is effective for the simultaneous determination of carbaryl and 1-naphthol, and could prove environmentally useful in the monitoring of agricultural drainage as well as water supplies. Economy is another asset over EPA Method 531.1, as no post-column reaction equipment is required. Also, CD inclusion studies provide information which may be used to improve the fluorometric analysis of carbaryl or its hydrolysis product.

## 2. Experimental

### 2.1. Reagents

All reagents were used without further purification, with the exception of 1-naphthol. Water, methanol and acetonitrile were HPLC grade and purchased from Mallinkrodt. The NaOH was 99% pure from Fisher and the HCl was obtained from EM Science. A borax/NaOH buffer was prepared with pH $\approx$ 10 from 99% pure reagents from Fisher.

The carbaryl was 99+% pure from Reagents, Inc. and the 1-naphthol was Sigma Grade 3 obtained from Aldrich. Recrystallization of 1-naphthol was performed in chloroform. Stock solutions were prepared for carbaryl and 1-naphthol by dissolving an appropriate quantity of the compound in HPLC-grade methanol to give a final concentration of 0.2 ng ml$^{-1}$. The carbaryl and 1-naphthol were stored with refrigeration and prepared every two weeks. Serial dilutions were made from these stock solutions in order to obtain experimental concentrations. Methanolic NaOH (5%) was prepared with HPLC-grade water, HPLC-grade methanol and 99% pure Fisher NaOH pellets.

CDs and CD derivatives were provided by Amaizo and also purchased from Aldrich. All CDs were used without further purification; however, a method of purification has recently been developed should impurities in the CD present a problem [11].

### 2.2. Apparatus

Steady-state fluorescence measurements were taken using a Spex Industries Model 1680 Fluorometer with accompanying fluroescence management software, also by Spex.

A Bronson 3200 Sonic Bath was used for preparation of experimental solutions to expedite dissolution.

HPLC experiments were performed on a Bio Rad series 800 HRLC system. The solvent delivery system was Bio Rad model 2700 and the fluroescence detector was Fluor LC model 304 by Linear. An automated sampling system was employed. The HPLC reversed-phase column was a Zorbax $C_8$.

### 2.3. Procedure

All fluorometric determinations were performed at ambient temperature. Excitation wavelengths used were 282 nm and 330 nm for carbaryl and 1-naphthol, respectively. Maximum emission occurs around 333 nm for carbaryl and 472 nm for 1-naphthol, which is actually the 1-naphtholate ion and not the molecular form in this method. Incident radiation and emission bandwidths were both 5 nm for steady-state fluorometric determinations, and 5 nm for the HPLC detector. The integration time constant was 0.5 s with a wavelength resolution of 1 nm. Each experiment was performed three times to ensure reproducibility. All solutions were sonicated for 30 min and allowed to cool to room temperature before fluorometric determination of HPLC analysis of the sample. A water bath was not employed, as no experimental variation was noted with minor fluctuations in column temperature.

All experimental solutions were prepared by dilution of the stock methanol solution containing the 1-naphthol or carbaryl in an appropriate volume of the aqueous experimental solution for steady-state fluorometric analysis, or methanol for HPLC analysis of the sample. A borax/NaOH buffer with a pH of $\approx 10$ was prepared with HPLC-grade water and used as the aqueous portion for each experimental solution requiring water, unless otherwise specified.

Preliminary experiments involved the determination of relative fluorescence intensities for carbaryl versus 1-naphthol. Relative sensitivities were then calculated for both compounds over a range of $1.0–2.0 \times 10^3$ ng ml$^{-1}$.

Solvent composition was varied in order to optimize the mobile-phase composition, providing maximum fluorescence enhancement. The mobile phase was a standard aqueous/organic composition. Methanol and acetonitrile were compared as organic components of the mobile phase.

Once fluorescence enhancement data had been acquired, the method for hydrolyzing carbaryl to 1-naphthol was developed. The rate of hydrolysis of carbaryl is a function of pH and solvent used [12]. The method of hydrolysis used in this report is similar to one defined in previous literature regarding the kinetic determination of carbaryl and its hydrolysis product, 1-naphthol [1]. An appropriate quantity of the stock methanolic solution of carbaryl, to provide the desired final concentration, was spiked into a 10 ml volumetric flask. One ml of 5% methanolic 2 M sodium hydroxide was then added, and the mixture allowed to stand in the dark for 15 min to allow complete hydrolysis. One ml of 2 M hydrochloric acid was then added to neutralize the base and terminate the hydrolysis reaction. The final step was dilution to the mark with methanol for HPLC experiments, or the appropriate buffer or solution for steady-state fluorescence measurements.

The optimized experimental conditions for the described procedure are as follows. A mobile-phase matrix of 45:55 acetonitrile/water was utilized. The fluorescence detector was adjusted to $\lambda_{ex} = 330$ nm and $\lambda_{em} = 472$ nm, which are the relative maxima of the 1-naphtholate anion. A buffer of pH 10 was used as the aqueous portion of the mobile phase, as fluorescence of 1-naphtholate is considerably greater than that of the molecular form and significantly larger than cation fluorescence. It should be noted that the described procedure actually only detects the 1-naphtholate ion. Although the molecular form does fluoresce, the observed emission wavelength is around 345 nm. To avoid confusion over which ionic/molecular form of this compound is being assayed, the molecular form is not measured and any appearance of 1-naphthol in the discussion should be considered to refer to the anionic form.

Although the final procedure does not include a CD-modified mobile phase, additional observations regarding this topic are included owing to possible application in future methods. Adequate details involving CD-modified

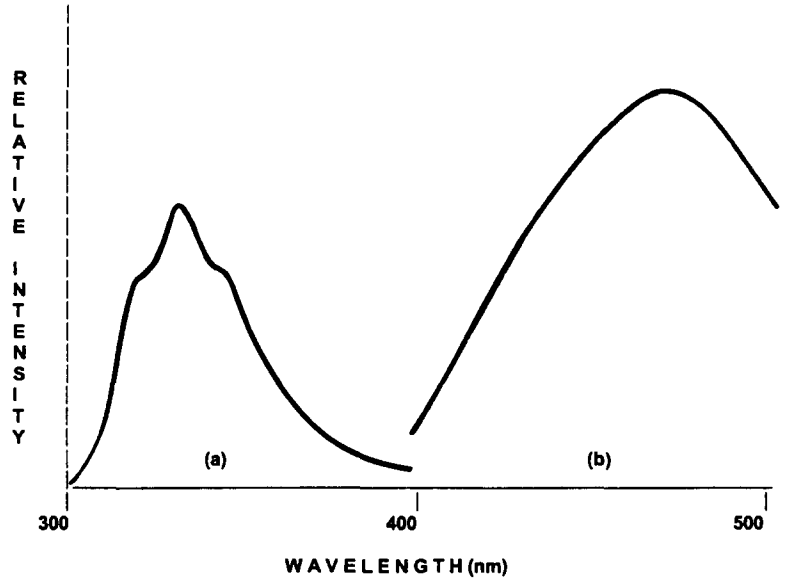

Fig. 1. Relative fluorescence intensity of 1-naphtholate (b), which is greater than that of an equimolar quantity of carbaryl (a) in aqueous solution.

mobile-phase compositions are provided to incorporate such improvements into this or similar procedures, where fluorescence enhancement and/or retention time decreases would be beneficial.

The final experiments prove the selectivity of this method for determining the concentration of carbaryl via its hydrolysis product in a mixture of four other commonly used pesticides and herbicides which could act as possible interferents. Additionally, carbaryl and 1-naphthol were simultaneously assayed in a mixture of the two, without other pesticides present. For the simultaneous determination of carbaryl and 1-naphthol, each analyte was present at similar concentrations.

The four pesticides combined with carbaryl were: azinphos-methyl, methomyl, chlorimuron ethyl and aldicarb. These pesticides (possible interferents) were spiked into the sample in identical (ng $ml^{-1}$) concentrations to that of the carbaryl. These experiments indicate the value of this method for the determination of carbaryl in a mixture of other pesticides, or in a solution with 1-naphtho initially present before hydrolysis.

## 3. Results and discussion

Results of the relative fluorescence emission intensity studies indicate that 1-naphtholate displays greater relative intensity than an equimolar concentration of carbaryl (see Fig. 1). The relative fluorescence intensity of $4.97 \pm 10^{-6}$ molar 1-naphthol (as the 1-naphtholate ion) was a factor of 1.33 greater than $4.97 \pm 10^{-6}$ molar carbaryl.

Likewise, carbaryl had a lower relative sensitivity than 1-naphthol, where relative sensitivity is a measure of signal change versus change in concentration. Given that 1-naphthol is more sensitive to fluorescence detection and is also characterized by greater relative fluorescence intensity, it is beneficial to perform trace-analysis of carbaryl via the determination of its hydrolysis product.

Fluorescence emission of 1-naphthol is also a function of the pH of the solution. The HPLC mobile phase was buffered at a pH of approximately 10.0, which was observed to be the pH of greatest luminescent efficiency for 1-naphthol. The hydrolysis of carbaryl takes place instantaneously in 2 M NaOH, which allowed for quick sample preparation. EPA Method 531.1 uses a post-column hydrolysis chamber as well as a derivitization reaction chamber. This requires additional reagent preparation and apparatus set-up, which is absent in the method presented here.

Control of pH was an important factor owing to the fact that high hydronium ion concentrations are known to quench fluorescence for 1-naphthol [13]. 1-Naphthol can experience efficient excited state ionization in solution. Since the anionic form is the one actually de-

termined by this method, the buffered mobile phase keeps the pH at an optimum level for ionization to occur, producing the highly fluorescent anion. It is possible to have both the molecular and anionic forms present in some binary aqueous–organic solvents. At low pH values, molecular 1-naphthol and ionic 1-naphtholate are converted to the 1-naphtholonium ion, which does not fluoresce. The use of a buffer should compensate for any pH changes due to volumetric errors that may occur when hydrolyzing carbaryl with sodium hydroxide and then adding an equimolar concentration of hydrochloric acid. A small pH variance in the experimental solutions used for HPLC determinations is not important, since the mobile phase is buffered and an isocratic solvent composition is used in this method.

The experimental yield of hydrolysis for the method described in the procedure section was confirmed to be 100% as follows. A solution of carbaryl was hydrolyzed as described above and the intensity of the fluorescence spectrum was compared to that of a known equimolar solution of 1-naphthol. Within experimental error, the results were identical in terms of fluorescence intensities for both the hydrolyzed sample and the prepared sample.

Once fluorescence data had been acquired in aqueous solution, different solvent compositions were studied fluorometrically in conjunction with carbaryl and 1-naphthol, in an attempt to develop an optimum mobile-phase composition which would provide maximum fluorescence enhancement. Methanol/water and acetonitrile/water solutions were investigated in order to maximize their effect on the fluorescence emission of 1-naphthol and carbaryl.

Solvent effects were an important factor in optimizing emission intensity. Methanol is not a suitable organic solvent for 1-naphthol owing to fluorescence quenching. A trend was noted in which increasingly concentrated methanol solutions quenched the observed fluorescence in proportion to the percentage of methanol by volume.

Acetonitrile was determined to be the most desirable organic solvent for use in the HPLC mobile phase. A concentration of 55% water and 45% acetonitrile, without CD, enhanced the relative fluorescence of 1-naphthol by a factor of 1.86 above that observed in an aqueous solution (see Table 1). The retention time for the hydrolyzed carbaryl on the $C_8$ column with a mobile phase of 55% water, 45% acetonitrile and pH 10 was approximately 3.3 min, which allows for rapid analysis. The $R_t$ for carbaryl was 5.2 min.

A calibration graph for 1-naphthol, and an estimate of the detection limit and the relative sensitivity over the range of $1.0–10^3$ ng ml$^{-1}$ was obtained experimentally by the use of HPLC. A line or fit to the calibration data with a correlation coefficient ($R$ value) of 0.997 was obtained. The calibration curve was linear over the experimental range of $1.0–10^3$ ng ml$^{-1}$ for 1-naphthol, allowing reasonably accurate extrapolation of data to determine experimental 1-naphthol concentrations.

Having verified the accuracy of 1-naphthol detection at low concentrations, a method was developed for the simultaneous determination of carbaryl and 1-naphthol by HPLC. Carbaryl and 1-naphthol can be assayed simultaneously be determining the 1-naphthol present before and after the sample has been hydrolyzed. The difference in 1-naphthol concentrations can be correlated with the molar quantity of carbaryl initially present. A series of experiments were designed to explore this possibility.

The selectivity available by this method should be noted. EPA Method 531.1 tests for approximately 10 of the *N*-methylcarbamoyloximes and *N*-methycarbamates. The presented method only tests for carbaryl and its primary metabolite, 1-naphthol. However, possibilities of peak overlap and interference are eliminated, as no compounds aside from the two analytes are detected in this procedure. This quality could prove an asset in a situation where only carbaryl and/or 1-naphthol are assayed.

Compared to EPA Method 531.1, with a carbaryl $R_t$ of over 20 min, the given procedure is much more conducive for rapid analysis as the actual analysis time is greatly reduced. Multiple sample assays should be less time-consuming as a result. Additionally, gradient elu-

tion techniques are not utilized, which translates to fewer equipment requirements. A single eluent suffices here, because essentially one compound is being assayed and separations are rendered unnecessary owing to the selective nature of this scheme.

Table 1 provides results for the simultaneous determination of carbaryl and 1-naphthol in the same solution, which were the only compounds present. This experiment involved the determination of 1-naphthol initially present followed by a hydrolysis step. After hydrolysis, the 1-naphthol was determined again and the difference in 1-naphthol concentrations represented the molar quantity of carbaryl initially present. Standard deviations were within accepted ranges given the concentrations of the analytes.

Table 2 represents data from a series of experiments designed to determine carbaryl at varying concentrations in the presence of other pesticides and herbicides, which could possibly be found along with carbaryl in environmental samples. For each solution, the four additional compounds were present at approximately the same concentration as carbaryl. None of the additional pesticides were detected in this scheme and there was no interferents in the detection of the hydrolysis product of carbaryl. Sample solutions were prepared in methanol with carbaryl and a combination of four other pesticides and herbicides (see Table 2). Each experiment was repeated three times and the standard deviations (S) estimated. The experiments involving hydrolysis of a mixture of pesticides, including carbaryl, gave highly reproducible results.

Experiments were also performed with varying mobile-phase media to possibly improve upon the coupled assay described in this report. When a suitable organic mobile-phase component had been identified, the effects of native CDs as well as β-CD derivatives were investigated fluorometrically to determine if the fluorescence intensity of 1-naphthol could be further increased. The derivatized CDs examined were: hydroxypropyl-β-CD, hydroxyethyl-β-CD, heptakis (tri-o-methyl)-β-CD and heptakis(2,6-di-o-methyl)-β-CD. Previous literature suggests the possible advantages of these derivatives over the native CDs [9]. The solubilities of the CD derivatives are usually much greater in water-based solutions than those of the native CDs.

Table 3 summarizes a series of experiments designed to determine the effects of various solvent compositions and CD inclusions on the fluorescence emission intensities of 1-naphthol and carbaryl.

The greatest fluorescence enhancement for carbaryl occurred in a 50/50 aqueous/methanol solution with β-CD. Steady-state fluorescence enhancement was increased by a factor of 1.77 above that observed for native carbaryl in a bulk aqueous solution. The CD derivative, hydroxypropyl-β-CD, had the greatest fluorescence enhancement factor for 1-naphthol in a pure aqueous solution.

Native β-CD had a greater enhancement factor for 1-naphthol than heptakis(2,6-di-o-methyl)-β-CD, heptakis(tri-o-CD and hydroxyethyl-β-CD. Urea-solubilized β-CD solutions were also tried with limited success. Although native β-CD is only soluble to approximately 14 mM in water, it performed significantly bet-

ter than the two other commonly used native CDs, i.e. alpha ($\alpha$) and gamma ($\gamma$). Both $\alpha$-CD and $\gamma$-CD enhanced the fluorescence of 1-naphthol by factors of 1.05, while $\beta$-CD gave an enhancement factor of 1.60 for 1-naphthol in aqueous solution.

CD complexes coupled with mobile-phase solvent conditions provided greater emission intensity than the solvent effect alone, for both carbaryl and 1-naphthol. CDs should be considered as a component of the mobile phase for future fluorometric analysis of carbaryl and 1-naphthol.

The CD-modified acetonitrile/water mobile phase did not enhance the fluorescence intensity of 1-naphthol over that of the same mobile phase without the presence of the CD. The relative emission intensity was independent of the presence of CD. The relative emission intensity was independent of the presence of CD. However, when the CD was present, a 10% decrease in retention time for 1-naphthol was observed. The pesticide/CD complex might not be expected to occur in a acetonitrile mobile phase owing to competition from the acetontrile to occupy the hydrophobic cavity of the CD. Although 1-naphthol fluorescence intensity is unaltered in the CD/acetonitrile/water matrix, the shortened retention time would indicate increased interaction with the mobile phase when CD is present. Whether a complex is actually forming or some other mechanism exists to decrease the retention time will be explored in the future.

This HPLC method exhibited sensitivity, speed and high selectivity with good precision. The greatest potential for an interferent would be another compound which hydrolyzes to 1-naphthol, which is unlikely. The limits of detection were 1.0 ng $ml^{-1}$ and 1.4 ng $ml^{-1}$ for 1-naphthol and carbaryl, respectively. These detection limits are comparable to those of other methods [14–16]. The detection limit obtained here for carbaryl is certainly comparable to that of the EPA method, which is 2 ng $ml^{-1}$. No complex derivatizations were necessary as in other commonly used procedures [17,18], which makes this method an attractive alternative to determine carbaryl or its metabolite in a variety of water sources.

Received 18 August 1994; accepted in final form 21 March 1995

**Abstract**

Flow-injection analysis for the determination of hydrazine derivatives based on their nucleophilic substitution reaction with 4-chloro-5,7-dinitrobenzofurazan in aqueous medium, and spectrophotometric detection has been described. The calibration graphs were linear in the range from 0.15 to 4.0 μg $ml^{-1}$ of hydrazine derivatives, with sampling rates of up to 28–32 samples $h^{-1}$. Interferences from amino compounds, benzoic acids, aliphatic amines and ammonia have been evaluated. The procedure has been applied to the determination of hydrazine derivatives in serum, urine, apressin drugs and artificial mixtures.

## 1. Introduction

Hydrazine derivatives (hydrazides and N-substituted hydrazines) are very important groups of organic compounds, having various applications in analytical chemistry [1]. Many of these substances are physiologically active and are used as a remedy against tuberculosis, leprosy, mental disorder and hypotension. Various analytical techniques have been applied for their determination in biological fluids, drugs and other substances. Among the assay procedures listed in official compendia [2], titrimetric methods for the determination of pure drugs are most widely used. Other methods described in the literature are based on high-performance liquid chromatography [3–5], gas chromatography [6], fluorimetry [7], colorimetry and specrophotometry [8–10]. In these cases, the preliminary derivatization of the compounds under determination by various reagents (4-dimethylaminobenzaldehyde, 2,4-pentadione, 3-salicyclic aldehyde, 4-trinitrobenzenesulfonic acid and others) is needed. However, these reactions are rather slow and often demand high temperatures [11]. That is why their applications in a flow-injection analysis (FIA) system for the determination of hydrazine derivatives is undesirable. Besides, the spectral characteristics of the reaction products formed from the substituted hydrazines and other amino compounds (alkylamines, amino acids, etc.) are similar. Therefore, the utilization of these reactions in the FIA of compounds of complicated composition with spectrophotometric detection is restricted. At the same time, there is a necessary to use FIA for the determination of substituted hydrazines in various substances.

The application of 4-chloro-5,7-dinitrobenzofurazan (DNBF) in selective spectrophotometric determinations of hydrazine, hydrazides acids and arylamines in complicated mixtures containing alkylamines, phenols, amino acids and other organic and inorganic substances has been described in previous papers [12–15]. It was stated that DNBF exhibited high reactivity in modification reactions with amino compounds. The colored products have high molar

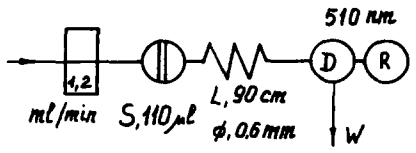

Fig. 1. Manifold used for the determination of hydrazine derivatives.

absorptivity. The application of DNBF in FIA determinations of the substituted hydrazines in pure forms of drugs, tablets and biological matrix is of great interest.

## 2. Experimental

### 2.1. Apparatus

The Carl Zeiss Jena M-40 (Germany) and LOMO SF-26 (Russia) spectrophotometers with 10 mm pathlength glass cells were applied for spectral recording and absorbance measurements, and a Pracitronic MV-87S pH-meter was used for pH measurements. The home-made flow-injection system (see Fig. 1) consisted of a Zalimp 304 peristaltic pump (Poland), Mikrotechna six-way injection valve and SPECOL-210 (Carl Zeiss Jena) spectrophotometer, with a 5 mm pathlength glass microcell as a detector. The connecting tubes were 0.6 mm bore PTFE, and end fittings and connectors (Microtechna) were applied. The output of the detector was monitored by a Carl Zeiss Iena K-100 chart recorder.

Sendimentation of proteins from biological liquids was performed using a centrifuge K-23 (Janetzki).

### 2.2. Reagents

All inorganic chemicals were of analytical-reagent grade and were used without further purification. Doubly-distilled water was used throughout.

DNBF was prepared as previously described [14]. A 0.02 M solution of DNBF was prepared by dissolution in pure acetonitrile.

$10^{-3}$ M stock solutions of isonicotinic (isoniazide, INH), diphenylphosphinylacetic (phosphabenzide, DPPAH), salicylic (SH) and benzoic (BH) hydrazides, and 1-hydrazinophthalazine hydrochloride (apressin, hydralazine, HPH) were made from commercial compounds by dissolution in water. Since the DNBF derivative of INH is only slightly soluble in water, a $10^{-3}$ M stock solution of isoniazide was prepared by dissolution in a mixture of water and dimethylsulfoxide (70:30, v/v). Working solutions were prepared from this stock solution by dilution with water or water–dimethylsulfoxide (70:30, v/v). Freshly prepared solutions were used.

An acetate buffer solution (analytical grade, pH 5.5) was used for determination of hydrazine derivatives in biological samples.

Liophilized human albumin and standard amino acid solutions were of analytical grade.

The solution of trichloracetic acid (analytical grade) was prepared by dissolving 30 g of this chemical in 100 ml of water.

### 2.3 Procedure

Fig. 1 shows the manifolds used for the determination of hydrazine derivatives by FIA and the experimental conditions. The 0.02 M reagent solution of DNBF was injected directly into a carrier solution of the hydrazine derivatives (concentration range 0.15–4.0 μg $ml^{-1}$) and the peak height at 510 nm was measured. For the determination of HPH in apressin drug, 20 tablets were weighed and powdered. An accurately weighed amount of powder equivalent to 10 mg of the drug was transferred into a 100 ml standard flask and diluted to the mark with distilled water. The mixture was shaken vigorously and filtered through dry paper, discarding the first portion of filtrate. A 5 ml portion was then diluted with the distilled water to obtain a final solution containing 1 μg of the drug per ml.

For the determination of chemicals in a complex biological matrix (plasma, urine and albumin) the proteins were eliminated by addition of 1 ml of solution of trichloroacetic acid to 4 ml of a sample followed by centrifugation at 6000 r.p.m.

The supernatant was neutralized by addition of 0.5 ml of pH 5.5 buffer solution. When analyzing plasma and urine, blank samples were prepared by precipitation and centrifugation as above, and the supernatant was destroyed by addition of 0.1 ml of 30% hydrogen peroxide solution. The amount of DPPAH in blood and urine was calculated by extrapolaction.

## 3. Results and discussion

Hydrazine derivatives react rapidly in organic and mixed solutions with DNBF, form-

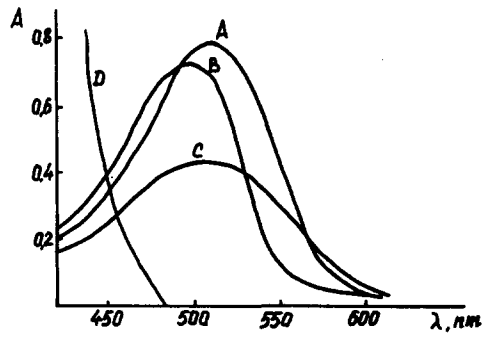

Fig. 2. Absorption spectra of DNBF derivatives ($2 \times 10^{-5}$ mol $l^{-1}$) of: (A) INH; (B) DPPAH; (C) HPH in dimethylsulfoxide. (D) Reagent blank.

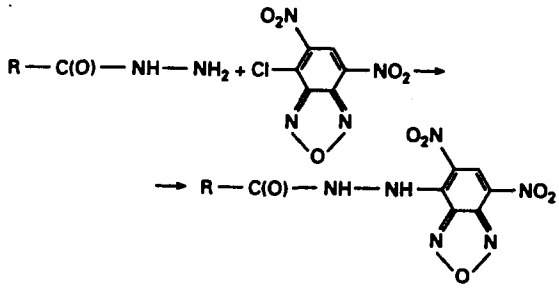
ing intensively colored red products of nucleophilic substitution:



These products were isolated [15], and found to have a maximum absorption at 500–515 nm (see Fig. 2). The molar absorptivity of these compounds is $2.2 \times 10^4$–$3.9 \times 10^4$ l mol$^{-1}$ cm$^{-1}$ in water–dimethylsulfoxide (90:10, v/v). Absorbance measurements were performed in the 500–520 nm range where the reagent blank had negligible absorbance against the pure solvent. Quantitative determination showed the reaction to be completed immediately after the reagent was mixed with the compounds at temperatures of 15–30 °C, owing to high DNBF reactivity. The reaction products were stable for several days. In accordance with the high reactivity of DNBF in water and aqueous organic mixtures, it is hydrolyzed forming on inactive hydroxy derivative (4-hydroxy-5,7-dinitrobenzofurazan). The reaction is rapidly completed even in the presence of a small amount of water in non-aqueous solvents (such as alcohols, dimethylsulfoxide and dimethylformamide). However, solutions of DNBF are stable in acetonitrile even in the presence of high amounts of water (up to 5%, v/v). For this reason, acetonitrile was used as a solvent for preparing DNBF solutions. At the same time, completion of the raction between DNBF and the substituted hydrazines in aqueous–organic mixtures is not influenced by the water content, because of differences in nucleophilic properties of analytes and solvent. Therefore, an acetonitrile solution of the reagent is preferable in the converted variant of FIA for which the reagent is injected into the analyte stream. Our approach is guided by the restricted solubility of the determined substraces and the products of their reactions with DNBF in acetonitrile. Moreover, this restricted solubility can lead to a change in the baseline with time in the FIA system.

The optimum pH was found by use of universal buffer solutions in the pH range 2–8. Absorbance measurements of the products and the reagent blank showed that the color system was not influenced by pH in the range 4–7.

The Beer's law plots were linear over the whole concentration range of $2 \times 10^{-6}$–$10^{-4}$ mol $l^{-1}$ for all hydrazine derivatives under the conditions described for acetonitrile, dimethylsulfoxide, methanol, ethanol and their water mixtures. Since the absorbance for the blank at 510 nm was negligible and the reaction was fast, the formation of derivatives with DNBF was suitable for the routine determination of substituted hydrazines.

The flow-rate of the carrier was varied between 0.8 and 2.5 ml min$^{-1}$. A value of 1.2 ml min$^{-1}$ was chosen as a good compromise between residence time and sampling frequency.

A reactor length ($L$) of less than 90 cm had no influence on peak height, and $L = 90$ cm and an inner diameter of 0.6 mm were chosen as a compromise between maximum peak height and sampling frequency. The optimum volume of injected DNBF solutions was found to be 110 μl.

The influence of DNBF concentrations on the peak heights was studied in the range $5 \times 10^{-3}$–$4 \times 10^{-2}$ M. The highest peaks were obtained with $1 \times 10^{-2}$ M DNBF, and the peak height was unaffected by higher concentrations.

Analytical characteristics of FIA are summarized in Table 1. With the manifold described, peak height without correction for the blank vs. concentration of hydrazine derivatives in the sample was linear in the range 0.15–4.0 μg ml, a small intercept being on the ordinate. During the determination of hydrazine derivatives in serum and urine, the peak

Analytical characteristics of FIA methods for hydrazine derivatives

| Chemical [a] | Calibration equation ($\mu g\ ml^{-1}$) | Linear range ($\mu g\ ml^{-1}$) | Correlation coefficient | Sampling frequency ($h^{-1}$) |
|---|---|---|---|---|
| INH | $H$ (mm) = 73.7 [INH] − 0.7 | 0.15–2.5 | 0.9986 | 32 |
| DPPAH | $H$ (mm) = 28.5 [DPPAH] − 0.7 | 0.25–3.5 | 0.9993 | 28 |
| SH | $H$ (mm) = 35.6 [SH] − 0.8 | 0.35–4.0 | 0.9992 | 28 |
| BH | $H$ (mm) = 41.2 [BH] + 0.5 | 0.2–2.5 | 0.9987 | 30 |
| HPH | $H$ (mm) = 58.2 [HPH] − 0.8 | 0.15–2.5 | 0.9991 | 30 |

[a] INH = isonicotinic hydrazide; DPPAH = diphenylphosphinylacetic hydrazide; SH = salicylic hydrazide; BH = benzoic hydrazide; HPH = 1-hydrazinophthalazine hydrochloride.

heights were corrected with respect to the pretreatment of biological solutions (see Section 2.3). If blank samples are not used, the biological matrix components cause an error of 6% in DPPAH determination at a concentration of 1 $\mu g\ ml^{-1}$ in urine and plasma.

A systematic study of potential interferences in the proposed method was carried out. Amino acids, ammonia, and methyl- and dimethylamine also react with 4-chloro-5,7-dinitrobenzofurazan, yielding yellow DNBF derivatives [16]. The absorption spectra of the products obtained under these conditions and used for hydrazine derivative determination have bands with maximum absorption between 430 and 450 nm. The low absorbance of these products at 510 nm leads to an increase in hydrazine derivative signal and to positive errors in the determination when their concentration exceeds the concentration of hydrazine 25 times (see Table 2). The high content of benzoic and salicylic acids, and inorganic salts does not influence the peak height. To investigate the application of FIA, the hydrazine derivative content in apressin drug, serum, urine and in model samples was determined using recovery tests. The results are summarized in Table 3. The accuracy of HPH determination in drugs was estimated by comparison with data obtained by an official compendia method, based on iodine titration [2].

## 4. Conclusion

Hydrazine derivatives can be determined as pharmaceuticals in a biological matrix in the presence of various biogenic amines using spectral characteristics of their derivatives with DNBF. Since the entire analytical cycle can be accomplished within 2 min, the FIA approach seems to be of interest and relevance. We also believe that our technique has significant potential for the assay of pharmaceutical hydrazine derivatives in serum samples.

**Abstract**

This paper reports the concentration of some dissolved organic phosphorus insecticides in water by open-cell polyurethane foam. The results of preliminary screening tests on the retention of the tested insecticides (Diazinon, Malathion and Chloropyrifos) by polyester foams indicated that a very high percent removal of the insecticides was obtained. The retention rate was fast and reaches equilibrium in a few minutes. The various parameters affecting the preconcentration of the tested insecticides by unloaded foam, e.g. pH, extraction media, shaking time, salt effect, flow rate, temperature and sample volumes have been optimized via the static mode of separation. The unloaded foams were employed in columns for the retention and recovery of the tested species. The sorption efficiency and the recovery of the tested compounds by the unloaded foam column were found to be up to 95.5%. The equivalent to a theoretical plate by the unloaded foam was found in the range $1.12-1.32 \pm 0.2$ mm. The sorption mechanism of the tested species by the foam is discussed. The separation of some of the tested species in a mixture was achieved. The foam membrane offers unique advantages over conventional bulk-type granular sorbents and solvent extraction in offering high flow rates, rapid, versatile, effective separation and preconcentration of different species from aqueous samples. The foam provides the advantages of being, insoluble, easily separable and non-polluting, as well as inexpensive.

## 1. Introduction

The classes of compounds responsible for the pollution of potable water resources include polyaromatic hydrocarbons, detergents, phenols, polychlorinated biphenyls and pesticides [1]. The pesticides are not toxic agents and are widely and regularly applied over large areas accessible to the public [2]. The compounds can enter water systems from various sources, e.g. run-off from agricultural land, direct entry from crop spraying, industrials and sewage effluent, cattle spraying, dust and rainfall [3,4]. These species are deliberately directed against living organisms and applications almost occur without control [5].

The removal or reduction of these water pollutants to an acceptable concentration by extraction with cellulose triacetate membrane filters, steam distillation, oxidation reactions, reversed liquid–liquid partition filter chromatography and adsorption on active carbon has been reported [6–9]. Such preconcentration methods are often slow or cumbersome and are too expensive for routine analysis where large volume samples are concentrated on-site prior to quantitative analysis [8,9].

The use of unloaded polyurethane foams (PuF) in separation and preconcentration pro-

cesses led to the revealing of the potential of their spherical geometric form: a spherical membrane-shaped geometry and the proposal of their general use in column operations as a substitute for the traditional granular supports in extraction chromatography [10]. Thus, in recent years considerable progress has been made in the use of polyurethane foam as an inexpensive solid extractor and effective sorbent for the removal of water pollutants [11–23]. The membrane-like structure of the foams together with efficient sorption and mass-transfer properties offer a higher concentrating ability and flow rate compared with other solid supports. The solid foam concentrates various species in solution by a phase distribution mechanism rather than adsorption.

The object of the work described herein was to evaluate the applicability of polyurethane foam for the extraction and separation of some insecticides from large volume samples of aqueous media. Conclusions concerning the most probable sorption mechanism by the foam have also been drawn.

## 2. Experimental

### 2.1. Reagents and materials

All reagents and chemicals used were of analytical reagent grade. Universal Britton-Robinson (B-R) buffer solutions containing a mixture of equal amounts (0.04 mol $l^{-1}$) of phosphoric acid, boric acid and acetic acid with sodium hydroxide (0.01 mol $l^{-1}$ were used to provide different pH ranges. Polyurethane foam, an open-cell polyester-type (bulk density, 30 kg $m^{-1}$) was supplied by Greiner K.G. Schaum (Stoffwerk, Kremsmunster, Austria). Foam cubes of volume approximately 1 $cm^3$ were cut from polyurethane foam sheet. These foam cubes were soaked in 1 M hydrochloric acid for 10 h with occasional squeezing to remove any possible inorganic species, and were washed with water until they were acid-free. They were then washed with acetone in a Soxhlet extractor for 24 h to remove organic contaminants and finally dried as previously reported [18].

The insecticides tested were Chloropyrifos, *o,o*-diethyl-*o*-(3,5,6-trichloro-2-pyridyl)phosphorothioate; Malathion; diethyl [(dimethoxyphosphinothioyl)thio]butanedioate and Diazinon, *o,o*-diethyl-*o*-(3-isopropyl-6-methyl-pyrimidine)phosphorothioate. Stock solutions (200 μg $cm^{-3}$) of each compound were prepared in 10 $cm^3$ ethanol and were diluted with distilled water. A series of standard solutions of these compounds was prepared by diluting their stock solutions with distilled water. The solutions were stored in polyethylene bottles.

### 2.2. Apparatus

A Pye–Unicam double-beam UV-Visible spectrophotometer model Sp 8-400 with 10 mm quartz cells was used for all the absorbance measurements. An Orion pH meter, a mechanical shaker type G10 Gyrotary (New Brunswick, Scientific Co.) and glass columns (15 cm × 1.5 cm i.d.) were also employed.

### 2.3. General procedures

*Batch experiments*

To investigate the effect of shaking time on the sorption of the tested insecticides on polyurethane foam, the foam cubes (0.2 g) were equilibrated with 100 $cm^3$ of each compound (100 μg $cm^{-3}$) in separate polyethylene bottles, and were shaken for time intervals up to 2 h. The foam cubes were then separated by decantation. The amount of compound remaining in the solution was measured spectrophotometrically at the wavelength of maximum absorption. The sorption behaviour of the compounds as evaluated from the degree of sorption ($E$) and the distribution ratio ($D$)

$$E = \frac{[C]_i - [C]_f}{[C]_i} 100 \quad (1)$$

$$D = \frac{[C]_i - [C]_f}{[C]_f} \frac{V}{W} \quad (2)$$

where $[C]_i$, and $[C]_f$ are the initial and final insecticide concentrations, respectively, in the solution, $V$ is the volume of the solution ($cm^3$) and W is the weight of dry foam (g). Following these procedures, the effects of solution pH employing Britton-Robinson buffer, acidity, temperature, compound concentration, extraction medium and increasing salt concentration ($\leqslant$0.1 M) of different alkali metal ($Li^+$, $Na^+$, $K^+$, $NH_4^+$) chlorides on the sorption efficiency of the tested species by the polyester-based polyurethane foam were critically examined.

[a] Extraction from aqueous solution (100 $cm^3$) at the pH of maximum extractibility of each insecticide (80 $\mu g\ cm^{-3}$). Average of five measurements ± standard deviation (S.D.) at room temperature.

*Flow experiments*

In the column experiments, 3 g of dry foam were homogeneously packed into the column using the vacuum method of foam column packing [12]. Tap or distilled water (0.1–5 $dm^3$) samples containing 0.1 mg of the insecticide tested were passed through the foam column at 10–15 $cm^3\ min^{-1}$. After squeezing water from the foam, the compound was then recovered quantitatively from the foam with 200 $cm^3$ of acetone in a Soxhlet extractor for 8 h. The analyte was determined by measuring the absorbance of the solution against a reagent blank after being concentrated to a volume of 25 $cm^3$ with a rotary evaporator. The effect of sample volume, flow rate and column foam bed on the extraction efficiency of the compounds by the foam were also determined. The chromatographic separation of Malathion and Chloropyrifos were carried out employing the foam packed column procedures.

## 3. Results and discussion

Preliminary experiments using unloaded polyester-type-based polyurethane foam have shown that the extraction of the investigated compounds (I, II, III in Fig. 1) is rapid and equilibrium is reached in less than 50 min, followed by a plateau. The results obtained are summarized in Fig. 2. (Each point in the figure represents an average of five measurements ($n = 5$) with relative standard deviations in the range 1.8–2.1%.) Rapid preconcentration and good extraction efficiency of the tested compounds from aqueous media were obtained. The average values of the half-life ($t_{1/2}$) of equilibrium sorption calculated from Fig. 2 are in the range 2–3 min.

### 3.1. Extraction isotherm

The uptake of the tested compounds from aqueous solution by the unloaded foam was dependent on the initial concentration. There-

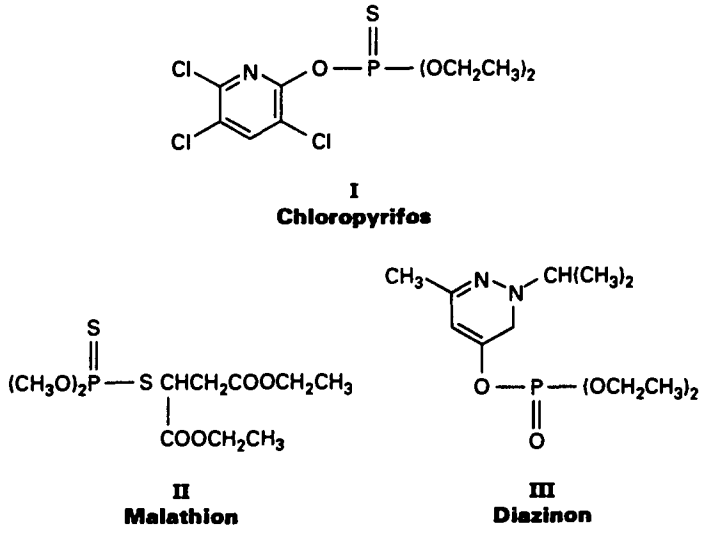

Fig. 1. Structure of the tested insecticides.

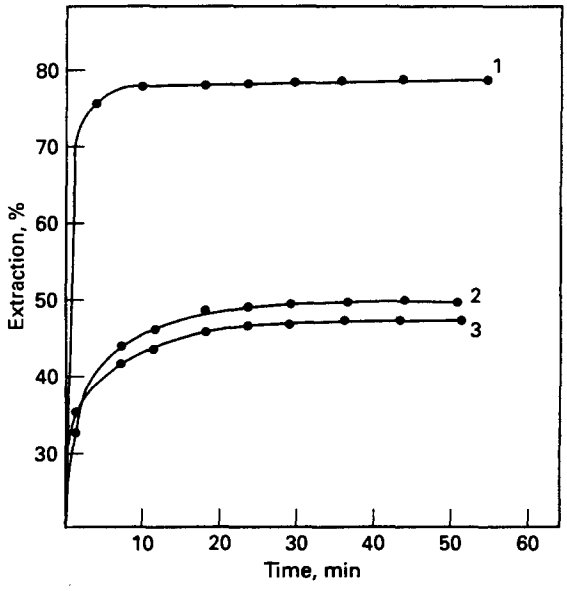

Fig. 2. Effect of shaking time on the sorption profiles of (curve 1) Chloropyrifos, (curve 2) Malathion, and (curve 3) Diazinon at 100 μg cm$^{-3}$ in aqueous solution (100 cm$^3$) at pH 5–6 and 20 ± 0.1°C by unloaded foams (0.3 g).

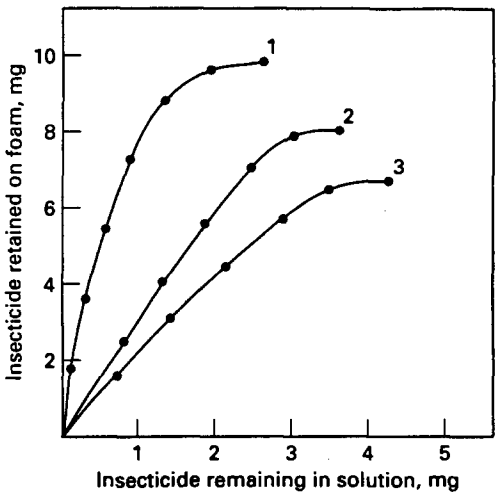

Fig. 3. Extraction isotherms of (curve 1) Chloropyrifos, (curve 2) Malathion and, (curve 3) Diazinon at concentrations 10–200 μg cm$^{-3}$ by unloaded foams from a 100 cm$^3$ aqueous solution sample at pH 5–6 and 20.0 ± 0.1°C and 1 h extraction time.

fore, the sorption isotherms were determined over a wide range of equilibrium concentrations (10–200 μg cm$^{-3}$) for each insecticide at 20°C. The pH values of the aqueous media in these experiments were adjusted with Britton-Robinson buffer to pH 5–6, so that the compounds were predominantly in the undissociated form. At low concentration of the compounds, the sorption isotherms exhibited first-order behaviour and tended to plateau at higher bulk solution concentration as shown in Fig. 3. The sorption of the different species by the unloaded foam increases in the order

Chloropyrifos > Malathion > Diazinon

Similar trends for the sorption of the tested compounds were obtained with diethyl ether and for other similar species retained on polyurethane foams [14,15]. Therefore solvent extraction is the most probable mechanism for the sorption of the tested species by the polyester foam from aqueous media at the tested pH [15]. However, it is worth noting that the molecular weight ($Mw$) of Chloropyrifos ($Mw = 345.5$), Diazinon ($Mw = 268$) and Malathion ($Mw = 330.5$) are also participating factors in the extraction step by the polyester foam. These data are consistent with the general understanding that the higher the molecular weight of the sorbate, the larger the amount of the tested insecticides retained on the foam when the substances concerned are similar in nature [24,25].

The influence of the pH of the aqueous solution on the sorption profile of the compounds at concentration 100 μg cm$^{-3}$ by the unloaded foams was determined over a pH range of 1–12 employing 0.1 mol l$^{-1}$ hydrochloric acid solution and Britton-Robinson buffer. The sorption profiles of the compounds by the unloaded foams are summarized in Fig.

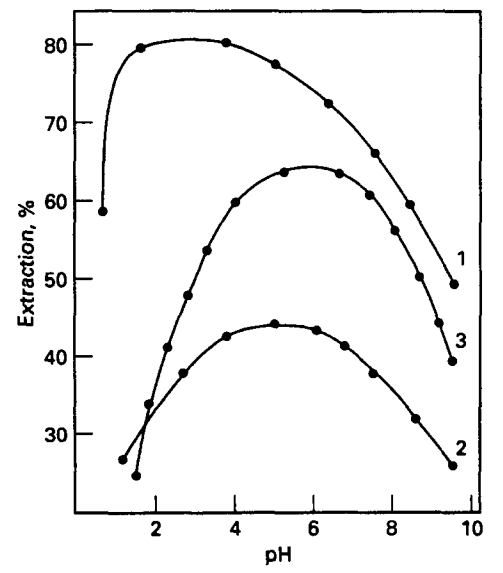

Fig. 4. Effect of pH on the extraction percentage of (curve 1) Chloropyrifos, (curve 2) Malathion and, (curve 3) Diazinon by unloaded foam (0.3 g) from a 100 cm$^3$ aqueous sample (80 μg cm$^{-3}$). Other conditions in Fig. 2.

4. The extraction percentage of Chloropyrifos reached a maximum in the pH range 2–4 and decreased at moderate and higher pH. Diazinon and Malathion display maximum retention at pH 6–8, at which the compounds exist in the neutral form. Thus the sorption mechanism involves neutral species and this is consistent with a solvent-extraction mechanism as previously reported [14,20].

The effect of different concentrations of alkali metal chlorides, e.g. LiCl, NaCl, KCl and $NH_4Cl$, at concentrations $\leq 0.1$ M on the sorption profiles of the tested compounds (80 μg $cm^{-3}$) was investigated. The results obtained are summarized in Table 1. A significant increase in the sorption profiles of Diazinon and Malathion by the polyester foam was observed in the presence of the salts LiCl, NaCl, KCl and $NH_4Cl$ at concentrations $\leq 0.1$ M and the order of sorption $Li^+ > Na^+ > K^+ > NH_4^+$ was observed for Diazinon and Malathion (Table 1). The distribution ratio of Malathion increased with the amount of salt added from $\log D = 2.9$ and 1.7 to $\log D = 3.6$ and 1.9 (Table 1) while for Diazinon it changed from $\log D = 2.3$ and 1.9 to $\log D = 2.8$ and 0.4 for $Li^+$ and $Na^+$ ions at 0.01 M and 0.1 M, respectively. The added salts ($Li+$, $Na^+$) increased the sorption profiles of the Diazinon and Malathion into the foams by reducing the number of water molecules available to solvate the sorbed species which would therefore be forced out of the solvent phase into the foam, since some amount of "free" water molecules are preferentially used to solvate the ions added [17,18]. Hence the influence of these salts can be explained by the salting out effect and "solvent extraction" is the most probable mechanism [21,26].

The sorption profiles of Chloropyrifos by the foam increased in the presence of the alkali salts in the following order of cations: $K^+ > NH_4^+ > Na^+ > Li^+$ (Table 1). Therefore, the ion–dipole interactions of $NH_4^+$ ions with oxygen atom sites of the polyurethane foam are possibly highly predominating in the sorption of Chloropyrifos. According to the "cation-chelation mechanism", the presence of $K^+$ ions should facilitate the extraction of the Chloropyrifos by the foam more than the other alkali metal ions ($NH_4^+$, $Na^+$ or $Li^+$) because of the better fit of this ion into the central cavity of the oxygen-rich helix in the polyurethane foam. Therefore, the obtainable results of the sorption profiles of Chloropyrifos are in good agreement with the data recently reported by Palagyi et al. [26,27]. Therefore the "cation-chelation mechanism" is the most probable mechanism for the sorption of Chloropyrifos. In accordance with this mechanism, the polyalkenoxy chains of the PuF sorbent form a helical structure [28]. This helical structure of the polyurethane foam sorbent forms a clathrate with suitable simple cations.

To confirm the salting out of the salts added on the sorption profiles of Diazinon and Malathion by the foams, an extraction of 200 $cm^3$ of the former compound at 80 μg $cm^{-3}$ was investigated at pH 4 and 9 after shaking for 30 min. The added $Li^+$ ions (0.01 M) to the sorption media enhanced the distribution ratio of Diazinon more in a solution of pH 4 ($\log D = 3.6$) than at pH 9 ($\log D = 2.4$). This behaviour is possibly attributed to the increased amount of neutral species at pH 4 as compared to pH 9 and the compound is highly extractable in the neutral form. Thus a "solvent-extraction mechanism" with the salts acting as salting out agents is the most probable mechanism for the preconcentration of Diazinon and Malathion by the polyurethane foam [14].

The influence of temperatures of 35, 45 and 55°C on the sorption profiles of the tested species by the foam were determined at the pH of maximum extraction of each insecticide. Similar trends to that obtained at 20°C were found and the percentage retention increases slightly with increasing temperature. Assuming no precipitation or chelation and that the extracted compounds exist as neutral species, then the equilibrium constant $K$ for the equation

$$\text{Compound}_{aq} \rightleftharpoons \text{Compound}_{org} \quad (3)$$

is equivalent to the partition ratio, $D$. Employing the equation

$$\ln K = -\Delta H^\circ/RT + \Delta S^\circ/R \quad (4)$$

the values of the standard entropy change, $\Delta S^\circ$ for the sorption of the Diazinon and Malathion by the unloaded foams were found to be in the range $-32 - -36 \pm 2$ J $mol^{-1}$ $deg^{-1}$. The value of $\Delta S^\circ$ for the sorption of Chloropyrifos by the foam was found to be $-19 \pm 2$ J $mol^{-1}$ $deg^{-1}$. The low values of the entropy change for Diazinon and Malathion are possibly attributed to the decrease in the freedom of movement of the organic compound in the polyurethane foam as previously

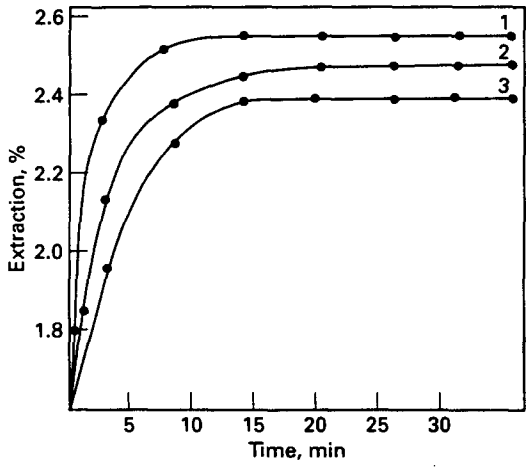

Fig. 5. Effect of extraction media on the sorption profile of Malathion by unloaded foam at pH 6–7 and a 1 h extraction time. Ethanol additions: curve 1, 0%; curve 2, 10%; curve 3, 15%. Other conditions as in Fig. 2.

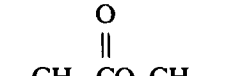
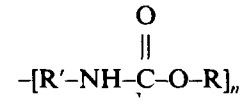
reported [14]. These results are consistent with the solvent-extraction mechanism. The values of the standard enthalpy change, $\Delta H°$ were found to be in the range $26 \pm 4$ kJ mol$^{-1}$. Raising the temperature may facilitate the partition of the tested species through the polyurethane foam via the urethane linkage and/or ester oxygen atoms.



or



The influence of the extraction media on the sorption percentage of the tested species by the polyurethane foam was examined by the addition of ethanol (0–15%). The sorption profiles of Diazinon and malathion by the unloaded foams decreased on the addition of ethanol to the aqueous media up to 15%. Representative results are summarized in Fig. 5. This behaviour is possibly due to the formation of a lipophilic association in the aqueous solution [29]. Water is a solvent with a high dielectric constant; therefore, ions in the aqueous solution are well solvated and so it is difficult for these species to form ion pairs in the aqueous solution. These data are consistent with the fact that with a compound of low dielectric constant and another which has a high dielectric constant, the retention percentage should increase with increase in the solvent polarity of the polar phase. These results are also consistent with the solvent-extraction mechanism in the sorption of these species by the unloaded foam. The nature of the media has therefore a marked effect on the sorption characteristics of the compounds.

### 3.2. Flow experiments

The sorption behaviour of the tested compounds from aqueous solution with the unloaded polyurethane foam suggests a possible application of the foam in the column extraction mode for the quantitative collection and recovery of the tested compounds from aqueous media at the pH of maximum extractability for each compound. Distilled or tap water samples (0.1–5 dm$^3$) containing 0.1 mg of each compound were percolated separately through the foam columns at a flow rate of 10–15 cm$^3$ min$^{-1}$. Complete retention of the tested compounds was achieved by the foam column. After squeezing water from the foam the compounds were then recovered from the foam with acetone in a Soxhlet extractor. Satisfactory recovery percentages (91.5–95.5%) of the tested compounds from the aqueous media by the proposed foam column method are obtained (Table 2). The effects of flow rate and sample volume on the retention of the compounds by the unloaded foams were also examined by percolating aqueous sample volumes (0.1–5 dm$^3$) of Diazinon (0.1 mg) through the column at various flow rates between 5 and 25 cm$^3$ min$^{-1}$. Complete retention of the compound was obtained from 5 dm$^3$ of aqueous

Table 2
Extraction and recovery of the tested insecticides (0.1 mg) from 3 dm$^3$ of aqueous solution at a 10 cm$^3$ min$^{-1}$ flow rate by the proposed unloaded foam column [a]

| Compound | Recovery % | | Wavelength [b] (nm) | p*Ka* |
|---|---|---|---|---|
| | (a) | (b) | | |
| Chloropyrifos | 93 ± 2 | 95 ± 2 | 206 (4.4) | 4.55 |
| Malathion | 92 ± 1 | 93 ± 3 | 280 (3.13) | 5.21 |
| Diazinon | 95 ± 2 | 96 ± 2 | 290 (2.94) | 4.97 |

[a] Conditions: Extraction from aqueous solution (200 cm$^3$) at the pH of maximum sorption of each insecticide. Average of five measurements from (a) distilled water and (b) tap water ± SD at room temperature.
[b] The logarithm of the extinction coefficient ($\epsilon$, 1 mol$^{-1}$ cm$^{-1}$) of the tested insecticides is given in parentheses.

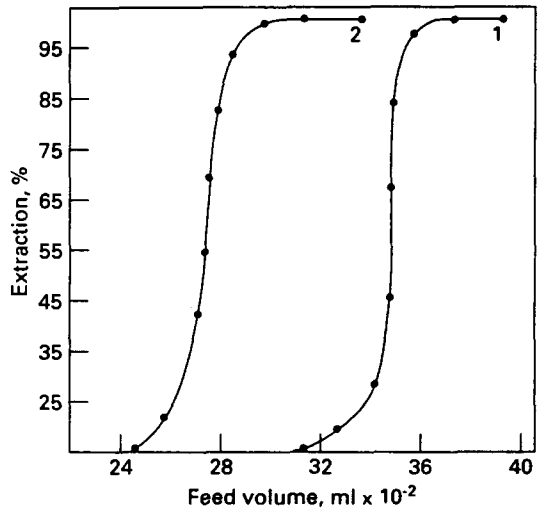


Fig. 6. Break through capacity curves of the sorption profiles of Diazinon by unloaded foam at flow rates of (curve 1) 15 $cm^3 min^{-1}$ and (curve 2) 25 $cm^3 min^{-1}$ by unloaded foam column.

solution and the extraction efficiency decreased significantly to 76% at 25 $cm^3 min^{-1}$ from a 5 $dm^3$ aqueous volume. To determine the performance of the foam column by the chromatogram method, quantitative retention of Diazinon (0.01 mg) followed by elution with 200 $cm^3$ of acetone–HCl (3:1 (v/v)) through the foam column at a 5 $cm^3 min^{-1}$ flow rate was carried out. The height equivalent to a theoretical plate (*HETP*) was obtained from the elution curves using the equation [11]

$$N = \frac{8V_{max}^2}{W_e} = \frac{L}{HETP}$$

where $N$ is the number of theoretical plates, $V_{max}$ is the volume of eluate at the peak maximum, $W$ is the width of the peak at 1/e the maximum solute concentration and $L$ is the length of the column foam bed. The *HETP* values were found to be equal to 1.1 ± 0.2 mm and 1.3 ± 0.2 mm at flow rates of 15 $cm^3 min^{-1}$ and 20 $cm^3 min^{-1}$, respectively.

The *HETP* value for the unloaded foam column was also calculated from the breakthrough capacity curve (Fig. 6) of Diazinon at 15 $cm^3 min^{-1}$ and 25 $cm^3 min^{-1}$ employing the equation [11]

$$N = \frac{V\bar{V}}{(V\bar{V})^2} = \frac{L}{HETP}$$

where $V$ is the volume of effluent at the center of the S-shaped section of the breakthrough capacity curve where the concentration is one-half of the initial concentration, and $\bar{V}$ is the volume at which the effluent has a concentration of 0.1578 of the initial concentration. The value of the *HETP* obtained by this method was 1.2 ± 0.2 mm, confirming the values obtained from the elution curves.

The separation of Malathion (0.1 mg) from Chloropyrifos (0.05 mg) in aqueous solution at pH 2 and in the presence of sodium chloride (0.1 M) for Chloropyrifos has been successfully carried out on the polyurethane foam. The solution mixture was percolated through the foam column at 15 $cm^3 min^{-1}$. The sorption of Chloropyrifos took place while Malathion was not retained on the foam column and collected quantitatively in the effluent. Chloropyrifos was then recovered from the foam with 100 $cm^3$ of acetone at 2–3 $cm^3 min^{-1}$ and was determined spectrophotometrically at 206 nm.

## 4. Conclusion

Unloaded foams in the batch and the column modes can be applied to trap trace amounts of insecticides from water, and the retained species can be recovered with an appropriate eluent. The separation of the tested species can be achieved provided that there is a sufficiently large difference in the optimum condition of extraction of each compound. A study of the rested compounds shows that the insecticides are extracted in their neutral form by a simple solvent-extraction mechanism. This conclusion is supported by the short time required for extraction equilibrium and the slating out phenomenon. The nature of the sorption media has a marked effect on the extraction performance of the tested species by the foam. Moreover, the foam offers a wider range of modifications than normal granular solids. The good hydrodynamic properties of the foam sorbent give the unique advantage of rapid, and versatile preconcentration of the tested compounds.

## Acknowledgment

The authors wish to thank Professor Salah Elnahwy, Dean of the Faculty of Science for his excellent support and help during this work.

# Spectrophotometric methods for the determination of tamoxifen citrate

Chilukuri S.P. Sastry *, J.S.V.M. Lingeswara Rao, Kolli Rama Rao

*Foods and Drugs Laboratories, School of Chemistry, Andhra University, Visakhapatnam 530 003, India*

Received 4 November 1994; revised 29 February 1995; accepted 28 March 1995

**Abstract**

Three simple and sensitive spectrophotometric methods for the determination of tamoxifen citrate have been developed. They are based on the formation of an ion-association complex between the drug and a dye, Erioglaucine A, which is extractable into chloroform and has an absorption maximum at 625 nm (method A), oxidation with excess potassium permanganate and the determination of unconsumed permanganate using Fast Green FCF (method B), or by the formation of a coloured cobalt thiocyante coordination complex which is extracted into benzene and measured at 635 nm (method C). Beer's law limits for methods A, B, and C are 0.5–3.0 μg $ml^{-1}$, 1.0–6.0 μg $ml^{-1}$ and 100–500 μg $ml^{-1}$, respectively. No interference was observed from tableting additives and the applicability of the methods was examined by analysing tablets containing tamoxifen. The quantities determined were 99.0–100.03% of the exptected values.

## 1. Introduction

Tamoxifen (molecular formula $C_{26}H_{29}NO$; molecular weight, 371.48 g) is chemically known as [Z]-2-[4-(1,2-diphenyl-l-butenyl)-phenoxy]-*N*,*N*-dimethylethanamine. It is an antineoplastic agent used as its citrate in the treatment of breast cancer. The drug is official in the British Pharmacopoeia [1] and the United States Pharmacopoeia [2]. A survey of the literature revealed that only a single ultraviolet and two visisble spectrophotometric methods have been reported [3]. The latter two methods are based on the formation of an ion-association complex between tamoxifen and Methyl Orange and the reaction of tamoxifen citrate with a citric acid–acetic anhydride reagent [3]. Other methods include polarography [4], thin layer chromatography [5], gas chromatography [6–10], and high-performance liquid chromatography [11–13]. The reported spectrophotometric methods possess deficienceis such as a low $\lambda_{max}$ value or lower sensitivity. It is, therefore, of interest to develop simple and sensitive procedures with higher $\lambda_{max}$ values for the determination of tamoxifen citrate in pharmaceutical formulations. This paper describes three visible spectrophotometric methods for the determination of tamoxifen citrate, exploiting its basic nature, unsaturation, and the presence of an aliphatic tertiary amine group.

Acidic dyes have been utilised for the determination of compounds exhibiting basic properties [14]. In method A, the acidic dye, Erioglaucine A (EG-A) (C.I. no. 42 090), was choosen for the direct determination of tamoxifen citrate. Gordon reported few indirect colorimetric procedures for the determination of some organic compounds possessing double bonds by oxidimetry [15]. Cobalt thiocyanate (CTC) has been used as a reagent for the determination of compounds containing a tertiary amino group [16,17]. We have applied these reagents to the determination of tamoxifen citrate in bluk form and in pharmaceutical formulations. Method A describes the spectrophotometric determination of an ion-associ-

ation complex formed between the drug and EG-A which is extracted into chloroform. In method B, the drug was treated with standard $KMnO_4$ in excess. The consumed $KMnO_4$ corresponding to tamoxifen citrate was obtained by determining unconsumed $KMnO_4$ spectrophotometrically with Fast Green (FG)-FCF based on a report that the decolorisation of FG-FCF by $KMnO_4$ is quantitative [15]. Method C involves the formation of a coloured CTC coordination complex of the drug, which is benzene extractable.

## 2. Experimental

### 2.1. Apparatus

A Systronics model 106 spectrophotometer with 1 cm matched glass cells and a Milton Roy spectronic 1201 spectrophotometer with 1 cm matched quartz cells were used for absorbance measurements in the visible and ultraviolet regions respectively. An Elico-digital model LI-120 pH meter was used for the pH measurements.

### 2.2. Materials and reagents

All reagents were analytical grade, and all solutions were prepared with double-distilled water. Freshly prepared solutions were always used.

Aqueous solutions of sodium sulphate (BDH; 1.0 M), potassium permanganate (BDH; $2.0 \times 10^{-3}$ M) in 2.0 M $H_2SO_4$, and FG-FCF (Chroma; $1.23 \times 10^{-5}$ M) in 1.0 M $H_2SO_4$ were prepared with double-distilled water.

EG-A (Chroma; $2.53 \times 10^{-5}$ M) was prepared in aqueous medium and washed with chloroform prior to use. A buffer solution (pH 1.2) was obtained by mixing 146 ml of 0.1 M glycine solution (0.1 M, 7.507 g of glycine + 5.85 g of NaCl dissolved in 1 l of distilled water) to 854 ml of 0.1 M HCl and adjusting the pH of the solution to 1.2.

CTC ($2.5 \times 10^{-1}$ M) was prepared by dissolving 7.25 g of cobaltous nitrate and 3.8 g of ammonium thiocyanate in 100 ml of distilled water. A buffer solution (pH 2.0) was prepared by mixing 306 ml of trisodium citrate (0.1 M), 694 ml of HCl (0.1 M), and adjusting the pH of the solution to 2.0.

### 2.3. Preparation of standard drug solutions

#### 2.3.1. Preparation of tamoxifen standard for method A

An accurately massed amount of tamoxifen citrate equivalent to 100 mg of tamoxifen was transferred to a 125 ml separatory funnel containing 10 ml of aqueous 1.0 M sodium hydroxide and the free base was extracted with chloroform (4 × 15 ml). The combined chloroform extracts were diluted to 100 ml to obtain a stock solution of 1 mg $ml^{-1}$. Diluted standard solutions were prepared by dilution of the stock solution with chloroform.

#### 2.3.2. Preparation of tamoxifen citrate for methods B and C

A 1 mg $ml^{-1}$ standard solution of tamoxifen citrate prepared in a DMF: $H_2O$ (1:5) mixture by warming was used as such for method C. The solution was further diluted with distilled water to obtain a concentration of 50 μg $ml^{-1}$ for method B.

### 2.4. Optimisation experiments for the methods

The optimum conditions for the development of methods A–C were established by varying the parameters one at a time, keeping the others fixed, and observing the effect produced on the absorbance of these solutions.

In order to establish the optimum pH range for method A, the drug was allowed to react with EG-A in aqueous solution bufferred to pH 1.0–3.0, and the complex formed was extracted with chloroform for measurement. Constant absorbances were obtained over the pH range 1.1–1.4. Hence a pH of 1.2 was chosen. A 10 ml portion of EG-A solution was found to be optimal. Shaking times of 1–3 min produced a constant absorbance; hence a shaking time of 2 min was selected. A ratio of 2:1 aqueous to non-aqueous phases was required for the efficient extraction of the coloured species. A series of experiments with other organic solvents such as $CCl_4$, $CH_2Cl_2$, and *n*-butanol showed that chloroform was the best choice. The absorption spectrum of the coloured species is shown in Fig. 1.

In order to establish the experimental conditions for method B, the strength and the volume of $KMnO_4$ was studied. The use of 0.5 ml of $KMnO_4$ in 2.0 M $H_2SO_4$ was found to give constant and reproducible absorbance values. The strength of the acid in the preparation of

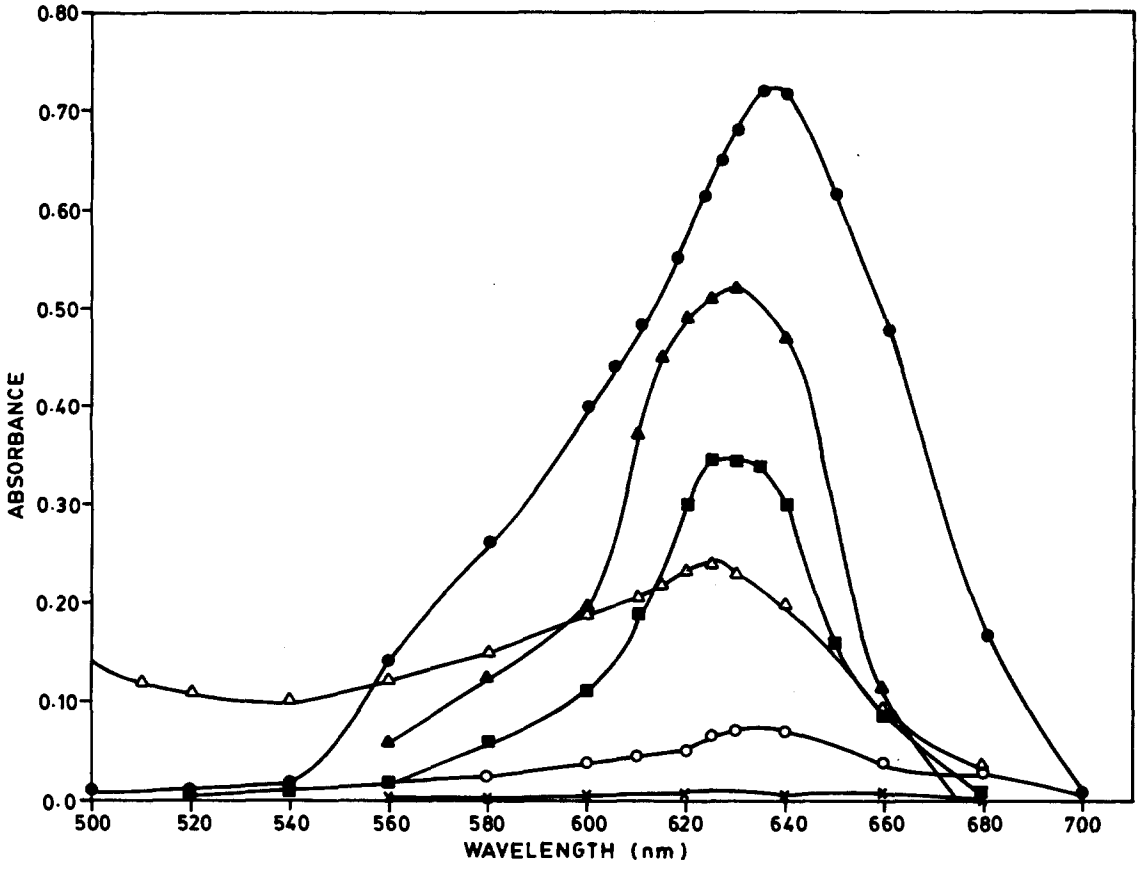

Fig. 1. Absorption spectra of the tamoxifen–EG-A system (tamoxifen concentration $1.07 \times 10^{-5}$ M; EG-A concentration $2.53 \times 10^{-3}$ M) the tamoxifen citrate–FG-FCF/$KMnO_4$ system (tamoxifen citrate concentration $7.09 \times 10^{-6}$ M; FG-FCF concentration $4.94 \times 10^{-5}$ M; $KMnO_4$ concentration $4.0 \times 10^{-5}$ M) and the tamoxifen citrate–CTC system (tamoxifen citrate concentration $8.87 \times 10^{-4}$ M; CTC concentration $1.25 \times 10^{-1}$ M). The three spectra are blank-corrected. ●, CTC; ▲, $KMnO_4$–FG-FCF; ■, EG-A; ○, EG-A BLK; ×, CTC BLK; △, $KMnO_4$–FG-FCF BLK.

$KMnO_4$ was found to have a significant effect on the absorbance. The oxidation time was established by increasing it in increments of 5 min. The absorbance values (after colour development) were found to increase to a maximum up to an oxidation time of 15 min and remained constant for 15 min. Hence, an oxidation time of 15 min at room temperature ($28 \pm 5$°C) was chosen. Increasing the temperature produced no additional increase in absorbance. The addition of 0.4 ml of FG-FCF and 4.0 ml of sodium sulphate were found to be optimal. The spectrum obtained for these solutions produced by the suggested procedure is shown to have maximum absorbance at 630 nm, as shown in Fig. 1.

To establish the experimental conditions for method C, the drug was allowed to react with CTC in aqueous solution buffered from pH 1.1 to 3.0 and the complex was extracted with benzene. Constant absorbances were obtained over the pH range 1.8–2.4; hence a pH of 2.0 was used. It has been found that 2.0 ml of buffer are necessary to maintain the pH of the aqueous phase. From 4 to 7.0 ml of CTC were found to give a constant absorbance value; hence a 5.0 ml portion of CTC was used. Benzene was used for the selective extraction of the coordination complex formed between the drug and CTC. A ratio of 1.2:1.0 aqueous to organic phases was required for efficient extraction of the coloured species. Constant absorbance was obtained for shaking periods between 1 and 4 min; hence a shaking time of 2.0 min was chosen for use.

### *2.5. Procedures*

#### *2.5.1. Method A*

Aliquots of the tamoxifen standard solution (1.0–6.0 ml; 5 μg $ml^{-1}$) were placed in a series of 125 ml separatory funnels, and 10.0 ml of buffer (pH 1.2) and 10.0 ml of EG-A solution were added to each. The total volume of the

chloroform layer in each separating funnel was adjusted to 10.0 ml. The contents were shaken for 2 min and absorbance of the separated chloroform layer was measured at 625 nm against a reagent blank within 30 min. The amount of drug was computed from a Beer–Lambert plot.

*2.5.2. Method B*

To a series of 25 ml calibrated tubes containing aliquots (0.5–6.0 ml) of tamoxifen citrate ($50\ \mu g\ ml^{-1}$), 0.5 ml of $KMnO_4$ solution was added to each and the total volumes were adjusted to 10.0 ml with distilled water. After allowing to stand for 15 min at room temperature, 0.4 ml of FG-FCF solution and 4.0 ml of sodium sulphate solution were added successively. After 10 min, the volume was increased to 25 ml with distilled water. The absorbances were measured against a reagent blank at 630 nm within 3 h. The amount of drug were computed from a Beer–Lambert plot.

*2.5.3. Method C*

Aliquots of drug standard solution (1.0–5.0 ml, $1\ mg\ ml^{-1}$) were transferred to a series of 125 ml separatory funnels, and 2.0 ml of buffer (pH 2.0) and 5.0 ml of CTC solution were added to each. The total volume of the aqueous phase in each separatory funnel was adjusted to 12.0 ml with distilled water. After the addition of 10 ml of benzene the contents were shaken for 2 min. The two phases were allowed to separate and the absorbances of the benzene layers were measured at 635 nm against a reagent blank. The amount of drug was computed from the Beer–Lambert plot.

*2.5.4. Pharmaceutical formulations*

Twenty tablets were massed and powdered. The powder equivalent to 100 mg of tamoxifen was treated with chloroform in the presence of alkali (for method A) or a DMF:$H_2O$ (1:5) mixture (for methods B and C) as under the standard drug solution preparation (Section 2.3). The insoluble residue was filtered to obtain the solution of concentration $1\ mg\ ml^{-1}$. Stock solutions were further diluted to the requisite concentration and analysed using the procedure for the bulk drug.

*2.5.5. British Pharmacopoeia reference method [1]*

Twenty tablets were massed and powdered. To a quantity of the powder containing the equivalent of 25 mg of tamoxifen, 100 ml of methanol were added. The mixture was shaken for 15 min, and the volume was adjusted 250 ml with methanol. After filtration, 10 ml of the filtrate were diluted to 100 ml with methanol, and the absorbance of the resulting solution was measured against a methanol blank at 275 nm. The content of the drug was computed from its Beer–Lambert plot.

*2.6. Analytical data*

The Beer's law limits, molar absorptivity, Sandell's sensitivity, detection limits [20], regression equation, and correlation coefficient obtained by a least-squares treatment of the results are given in Tables 1 and 2. The precision of each method was tested by analysing six replicate samples containing $2.0\ \mu g\ ml^{-1}$, $4.0\ \mu g\ ml^{-1}$ or $350\ \mu g\ ml^{-1}$ of the bulk drug for methods A, B or C, respectively. The per cent standard deviation and the per cent range

[a] With respect to $Y = mC + b$ where $C$ is the concentration ($\mu g\ ml^{-1}$) and $Y$ is absorbance units.

of error at a 95% confidence level of the method are given in Table 1.

Values obtained by these methods and the British Pharmacopoeia reference method for pharmaceutical formulations are incorporated into Table 3. They are in good agreement. As an additional demonstration of accuracy, recovery experiments were performed by adding a fixed amount of the drug to the preanalysed formulations. These results are summarised in Table 3.

### 2.7. Chemistry of the coloured species

Tamoxifen, being basic in nature, forms an ion-association complex with the acidic dye EG-A in method A which is extractable into chloroform from the aqueous phase. The stoichiometric ratio of the drug to the dye was determined with use of the slope-ratio method [18,19], and was found to be 3:1 (scheme 1).

Method B involves two steps. In the first step, tamoxifen citrate was treated with excess $KMnO_4$ of known concentration; 7 mol of potassium permanganate are required to oxidise 1 mol of tamoxifen citrate. The oxidation of citric acid under similar conditions shows that each mole of citric acid consumes 4 mol of potassium permanganate. From this study it is clear that each mole of tamoxifen (free base) consumes 3 mol of potassium permangante. Attempts to estimate tamoxifen directly with permangante have failed due the insoluble nature of the free base in a water: DMF mixture. In the second step, unreacted $KMnO_4$ was determined by using the dye FG-FCF. Approximately 1.8 $KMnO_4$ molecules are reduced to Mn(II) by 1 dye molecule (a $9e^-$ reaction). The consumed $KMnO_4$ corresponds to the concentration of the drug.

The coloured species formed in method C can be regarded as a coordinate complex of the drug (electron donor) and the central metal atom of cobalt thiocyanate (electron acceptor) based on an analogy in previous work [16,17]. The composition of the coloured complex in benzene was studied by re-extraction into the aqueous phase with 3 x 20 ml portions of distilled water, and cobalt was determined with 0.01 M EDTA solution using Xylenol Orange as the indicator. The thiocyanate concentration was determined by Volhard's method. It was observed that the drug, cobalt, and thiocyanate were in the ratio of 2:1:4 in complex, as indicated in Scheme 2.

## 3. Conclusion

The order of $\lambda_{max}$ values among the proposed methods and a reference method (R) in the determination of tamoxifen is $C > B > A > R$. The higher $\lambda_{max}$ of the proposed methods is a decisive advantage since the interference from the associated ingredient should be far less at higher wavelengths than at lower wavelengths. The senstivity order of the methods is $R > B > A > C$.

Method A has the advantage that it can be applied to the determination of individual components in a multicomponent mixture. This aspect of spectrophotometric analysis is of major interest in pharmaceutical analysis, since it offers distinct possibilities in the assay of a particular component in a complex dosage formulation. Although method B is an indirect one, it is more sensitive. Method C is selective for the estimation of compounds containing an aliphatic tertiary amino group.

Table 3
Analysis of pharmaceutical preparations by proposed and reference methods

| Pharmaceutical preparation (tablets) | Nominal amount (mg) | Found [a] (mg) | | | Reference [b] method | Recovery (%) [c] | | |
|---|---|---|---|---|---|---|---|---|

# Simultaneous determination of Ru(III) and Rh(III) using octadecyldithiocarbamate by first-derivative spectrophotometry

K. Malathi, M. Subbaiyan *

*Department of Analytical Chemistry, University of Madras, Guindy Campus, Madras-600 025, India*

Received 10 November 1994; revised 22 March 1995; accepted 28 March 1995

**Abstract**

A first-derivative spectrophotometric method is described for the simultaneous determination of Ru(III) and Rh(III) using octadecyl dithiocarbamate. The complexes are insoluble in water, but easily extractable into chloroform. Quantitative determination of Ru(III) and Rh(III) is possible in the ranges 0.5–6.0 μg $ml^{-1}$ and 1.0–10.0 μg $ml^{-1}$ respectively, with a standard deviation of ±0.10. A statistical evaluation of the experimental results is reported.

## 1. Introduction

Derivative spectrophotometry has been used to increase the selectivity and sensitivity of the determination of various substances whose absorption spectra overlap. The selectivity of the determination can be improved using the zero-crossing method, as described by many workers [1,2]. In this method, the derivative amplitude is measured at the wavelength at which the interfering derivative band crosses the zero line, thus yielding a suitable measurement for the analyte of interest.

Interest in the analytical applications of derivative spectrometry has been on the increase for the past few decades, owing to the introduction of commercial spectrometers capable of operating in the derivative mode. Notable reports are the determination of beryllium and magnesium with 1-hydroxy-2-carboxyanthraquinone [2], ruthenium and palladium with 2-thiobarbituric acid [3], iron and copper with 2-thiobarbituric acid [4] and uranium and thorium with arsenazo III [5].

Dithiocarbamates of lower series have been used in inorganic analysis, in the colorimetric estimation of many metal ions [6]. Dithiocarbamates derived from higher homologues of hydrocarbon series offer scavenging capacity for metal ions and easy extractability over the lower series. The present work describes the application of first-derivative spectrophotometry to the simultaneous determination of ruthenium and rhodium using octadecyldithiocarbamate.

## 2. Experimental

### 2.1. Apparatus

A DMS varian-80 double beam spectrophotometer was used for recording the normal and first-derivative spectra of the complexes.

An AR3410 ICP-atomic emission spectrometer was used for the estimation of the metal ions.

* Corresponding author.

*SSDI* 0039-9140(95)01599-X

### 2.2. Reagents

Analytical reagent-grade chemicals and doubly-distilled water were used throughout the estimations.

The ammonium salt of octadecyldithiocarbamate (ODDTC) was prepared from octadecylamine (Fluka) according to the method of Srinivasan [7]. Ethanolic ODDTC solutions (0.2% (m/v)) were employed.

Rhodium(III) and ruthenium(III) stock solutions (1 mg ml$^{-1}$) were prepared from $RhCl_3$ and $RuCl_3$ (CDH) respectively. The exact metal content was determined by ICP-AES.

### 2.3. Procedure

The absorption spectra (normal and first-derivative) of the following solutions were recorded against the reagent blank in order to determine the characteristics of absorption of the metal–reagent complexes and their mixture.

(1) An aliquot of the sample (1 ml) containing 2–20 μg of ruthenium was placed in a 25 ml separating funnel. To this were added 2 ml of acetate buffer solution (pH 5), 2 ml of 0.2% (m/v) ODDTC in ethanol and 5 ml of water. The above solution was extracted with 5 ml of chloroform.

(2) An aliquot (1 ml) of the sample containing 2–20 μg of rhodium was placed in a separating funnel and processed as in (1).

(3) An aliquot of the sample (1 ml) containing 2–20 μg of ruthenium and 2–20 μg of rhodium was placed in a separating funnel. To this were added 2 ml of acetate buffer (pH 5), 4 ml of 0.2% (m/v) ODDTC in ethanol and 3 ml of water. Extraction was carried out with 5 ml of chloroform.

## 3. Results and discussion

Octadecyldithiocarbamate forms green and greenish-yellow coloured complexes with ruthenium and rhodium respectively in slightly acidic media (pH 5–6), which are easily extractable into chloroform. Maximum absorbances of both the complexes were observed when 2 ml of 0.2% (m/v) ODDTC in ethanol was used. The composition of both the complexes was found to be 1:3 (M:L) by Job's continuous variation method. The complex formation was found to be instantaneous and the absorbance was found to remain stable for more than 24 h. Quantitative extraction was observed for single equilibration. Alcohol, used to form a solution of ODDTC, remained in the aqueous phase and was not extracted into $CHCl_3$ under the experimental conditions.

### 3.1. Spectral characteristics

The absorption spectra of the solution of Ru complex, Rh complex and a mixture of Ru and Rh complexes in chloroform exhibited $\lambda_{max}$ values at 420 nm, 430 nm and 430 nm respectively (Fig. 1). The reagent did not show any significant absorbance in this region. Among the various solvents tried, chloroform, benzene and dichloromethane were found to be more potent in extracting the complexes. Of the three solvents, the complexes evinced maximum molar absorptivity and higher solubility in chloroform. Hence, $CHCl_3$ was chosen as the suitable solvent.

Since there is a large overlap between the spectra of the individual elements in the normal mode, spectrophotometric determination of these ions when present in the same sample becomes difficult. To overcome this, derivative spectrophotometry, which involves the differentiation of a normal spectra with respect of wavelength, was used.

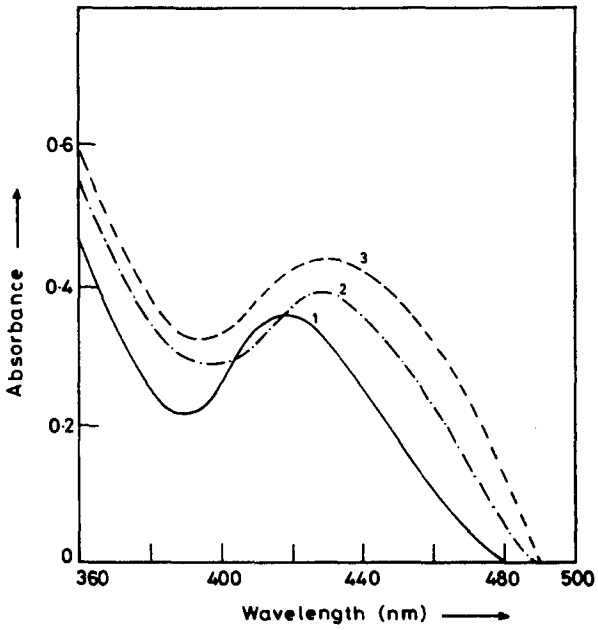

Fig. 1. Absorption spectra of (1) Ru–ODDTC complex, (2) Rh–ODDTC complex and (3) mixture of Ru–ODDTC and Rh–ODDTC complexes. Ru(III) = 2.00 μg ml$^{-1}$; Rh(III) = 3.38 μg ml$^{-1}$.

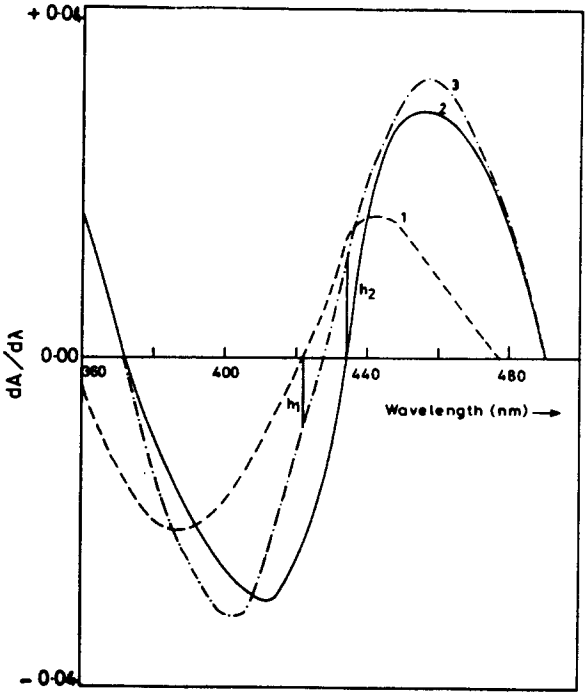

Fig. 2. First-derivative spectra of (1) Ru–ODDTC complex, (2) Rh–ODDTC complex and (3) mixture of Ru–ODDTC and Rh–ODDTC complexes.

Fig. 2 shows the first-derivative spectra of Ru complex, Rh complex and a mixture of Ru and Rh complexes in chloroform. The two most commonly used techniques in derivative spectrophotometry [8] are the "graphical method", which involves graphical constructions on a chart recording of the spectrum, and the "zero-crossing method", which involves measurement of the absolute values of the total derivative spectrum at a wavelength corresponding to the zero-crossing point of the derivative spectrum of the interfering component. In this case, the graphical method cannot be used, because of the closeness of the overlapping spectra which results in poor resolution of the spectrum of the mixture. Hence, the zero-crossing method was used in this work. The heights $h_1$ and $h_2$ in the first-derivative spectrum of the mixture corresponding to the values taken at 423 nm and 435 nm are proportional to the Rh(III) and Ru(III) concentrations respectively.

A sensitivity of 0.007–0.010 unit is lost for both the elements on going from absorbance to first-derivative spectra. In the normal mode, since they have closer $\lambda_{max}$ values, they interfere with each other in their estimations if present in the same sample. Therefore, it is necessary to mask one element, which can be avoided when first-order spectra (zero-crossing method) are recorded.

Fe, Cu, Ni, Bi, Pd and Pt interfere strongly in the determination (tolerance limit ≈ 1 ppm), and they should be removed prior to the estimation of the metal ions. Anions like $Cl^-$, $Br^-$, $OAc^-$, $SO_4^{2-}$ and $PO_4^{3-}$ can be tolerated up to 10 000 ppm. The tolerance limit for EDTA is 0.05 M. The ODDTC complexes of the base metals like Fe, Cu, Ni etc., are soluble in $CCl_4$ while those of Ru and Rh are insoluble in the pH range 3–5. Hence, such interferences can be avoided by carrying out a preliminary extraction with $CCl_4$ or chloroform extraction in the presence of 0.01 M EDTA.

The instrumental parameters such as wavelength scan rate and slit width which affect the shape of the derivative spectra are to be optimised to give good selectivity and sensitivity in the determination. An optimised scan rate of 100 nm $min^{-1}$ and a slit width of 1 nm were used throughout the investigation.

### *3.2. Statistical analysis of the determination of ruthenium and rhodium in mixtures*

The following experiments were performed to test the non-interference of the analytical signals of Ru(III) and Rh(III).

Two calibration graphs were constructed from first-derivative signals for standards containing between 0.5 and 10 μg $ml^{-1}$ of ruthenium in the presence of 2.0 and 4.0 μg $ml^{-1}$ of rhodium. Similarly, two calibration graphs were prepared for standards containing between 0.5 and 10 μg $ml^{-1}$ of rhodium in the presence of 2.1 and 4.0 μg $ml^{-1}$ of ruthenium.

A critical evaluation of the proposed method was performed by assessing the results of the statistical analysis of the experimental data [9]. The slope, intercept, correlation coefficient and standard deviation are shown in Table 1. The linearity of the calibration graphs and adherence of the systems to Beer's law are validated by the high value for the correlation coefficient of the regression equation and by the intercept value on the $y$-axis, which is close to zero. Ten calibration points were generated to obtain the above correlation.

From Table 1 it can be seen that the slope of the calibration graphs for ruthenium is independent of the rhodium concentration. Similarly, the slope of the calibration graph for rhodium is independent of ruthenium concentration. Therefore, it can be inferred that the amplitude of the derivative signal of the mixture, measured at the zero-crossing point of the

Table 1
Statistical analysis of the determination of ruthenium and rhodium in mixtures by first-derivative spectrophotometry

| Element detd. | Other element | | Slope | Intercept | Correlation coefficient | Standard deviation ($\mu g\ ml^{-1}$) |
|---|---|---|---|---|---|---|
| | Element | Conc. ($\mu g\ ml^{-1}$) | | | | |
| Ru(III) | Rh(III) | 4.0 | 1.977 | $5.37 \times 10^{-2}$ | 0.999 | 0.110 |
| | | 2.0 | 1.968 | $5.26 \times 10^{-2}$ | 0.999 | 0.059 |
| Rh(III) | Ru(III) | 4.0 | 0.9924 | $7.60 \times 10^{-3}$ | 0.999 | 0.079 |
| | | 2.1 | 0.9965 | $2.30 \times 10^{-3}$ | 0.999 | 0.048 |

derivative spectrum of one of the two components, is a function of the concentration of the component under consideration in accordance with theoretical predictions.

Statistical analysis of the experimental results permits the calculation of the error $S_c$ in the determination of a given concentration, $c$, of a component, and is calculated using the equation

$$S_c = \frac{S_0}{b}\left[1 + \frac{1}{n} + \frac{(D-\bar{D})^2}{b^2(\Sigma\, c^2 - n\bar{c}^2)}\right]^{1/2}$$

where $S_0 = [\Sigma\,(D-D')^2/n-2]$; $D$ = experimental value of the first derivative; $D'$ = first-derivative value calculated from the regression equation; $b$ = angular coefficient of the regression line; $\bar{c}$ and $\bar{D}$ are the average concentration and first-derivative value, respectively, for '$n$' standard specimens. Graphs of $S_c$ versus rhodium and ruthenium concentration are shown in Figs. 3 and 4, respectively, as histograms.

The quantity $S_c$ allows the calculation of confidence limits at the selected level of significance for the determination of unknown concentrations. The results are shown in Fig. 5 in the form of percentage uncertainty in the concentration ($t_p S_c/c$) for all the calibration graphs, where $t_p$ is the value of the Student's quantity at a 0.05 level of significance (95% probability) for $n-2$ degrees of freedom.

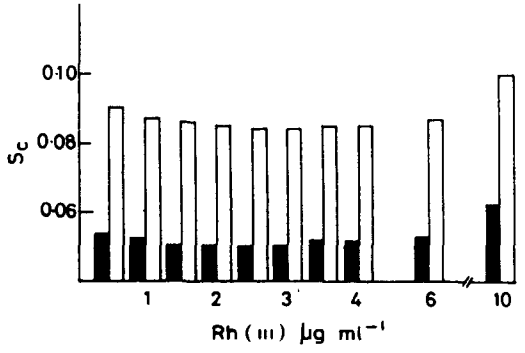

Fig. 3. Histograms of the error in the determination of Rh(III) concentration. Shaded area, in the presence of 2.1 $\mu g\ ml^{-1}$ of Ru(III); unshaded area, in the presence of 4.0 $\mu g\ ml^{-1}$ of Ru(III).

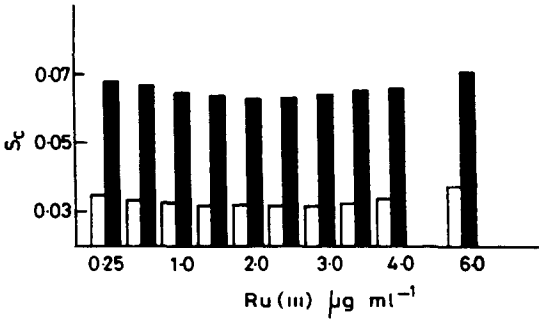

Fig. 4. Histograms of the error in the determination of Ru(III) concentration. Shaded area, in the presence of 4.0 $\mu g\ ml^{-1}$ of Rh(III); unshaded area, in the presence of 2.0 $\mu g\ ml^{-1}$ of Rh(III).

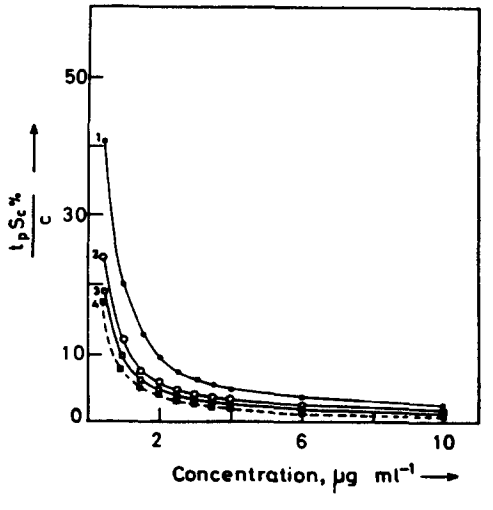

Fig. 5. Variation of the confidence limit at a level of significance of $p = 0.05$ (95% probability) in the form of percentage uncertainty in the concentration of Ru(III) and Rh(III). (1) Ru(III) = 4.0 $\mu g\ ml^{-1}$; (2) Ru(III) = 2.1 $\mu g\ ml^{-1}$; (3) Rh(III) = 4.0 $\mu g\ ml^{-1}$; (4) Rh(III) = 2.0 $\mu g\ ml^{-1}$.

Table 2
Results of the quantitative determination of ruthenium and rhodium by first-derivative spectrophotometry

| Amount taken ($\mu g\ ml^{-1}$) | | Amount found ($\mu g\ ml^{-1}$) | | Relative error (%) | |
|---|---|---|---|---|---|
| Ru | Rh | Ru | Rh | Ru | Rh |
| 1.20 | 1.20 | 1.25 | 1.20 | 4.16 | 0.00 |
| 2.00 | 1.20 | 2.00 | 1.20 | 0.00 | 0.00 |
| 4.00 | 6.00 | 4.00 | 6.10 | 0.00 | 1.66 |
| 6.00 | 4.80 | 5.90 | 4.65 | −1.66 | −3.12 |

The method was applied to the determination of Rh(III) and Ru(III) in binary mixtures, and the results are presented in Table 2. The method can successfully be applied to determination of the title metal ions when present above 0.1 $\mu g\ ml^{-1}$ in ores and minerals.

## 4. Conclusions

A general procedure for the determination of ruthenium and rhodium in mixtures by first-derivative spectrophotometry using ODDTC as a reagent is proposed, and the usefulness of derivative spectrophotometry is discussed. The proposed method permits the simultaneous determination of ruthenium and rhodium in mixtures in the range 0.5–6.0 $\mu g\ ml^{-1}$ for Ru(III) and 1.0–10.0 $\mu g\ ml^{-1}$ for Rh(III), without a prior separation procedure. The method based on "zero-crossing measurement" gives satisfactory levels of precision and accuracy, and can be used for the simultaneous determination of Ru and Rh in ore samples.

# Solvent extraction separation of cobalt(II) with hexaacetatocalix(6)arene

Anita Gupta, S.M. Khopkar *

*Department of Chemical Technology, University of Bombay, Matunga, Bombay 400 019, India*

Received 3 November 1994; revised 7 March 1995; accepted 28 March 1995

**Abstract**

A new method is proposed for the solvent extraction separation of cobalt(II) with hexaacetatocalix(6)arene in toluene. Cobalt(II) was extracted at pH 7.4 with $10 \times 10^{-4}$ M hexaacetocalix(6)arene, stripped with 2 M nitric acid, and determined spectrophotometrically at 500 nm as its complex with nitroso-*R*-salt. Cobalt was separated from any associated elements. The method was extended to the analysis of cobalt(II) in real samples such as vitamin B-12.

## 1. Introduction

The calixarenes constitute a new class of supramolecular compounds with a variety of cavity sizes [1,2]. The annular space in calixarene compounds provide a unique basket-like structure which is useful for trapping metal ions in their three-dimensional network [3]. Many oxygenated solvent and chelating extractants have been found to be ineffective for extraction of cobalt [4]. When crown ethers were used from perchlorate media, 18-crown-6 was found to be most effective [5]. Crown ethers with 4 acylpyrazol-5-ols could be used to extract [6] cobalt at pH 3.5. Tetraazacrown ether has also been used for the extraction of cobalt at pH 1.0–7.0 with metanil yellow, facilitating separation of cobalt from manganese, bismuth, aluminium and iron [7]. The extraction chromatographic separation of cobalt [8] with DB18-crown-6 as the stationary phase is also effective. The complexation behaviour of calixarene [9] was recently discovered. Calix(4)-arene and calix(6)arene proved to be versatile extractants [10] for transition metals, while derivatives of *p-tert*-butylcalixarenes in carboxylic acid [11] were useful for the extraction of inner transition metals.

This paper describes the synthesis and application of hexaacetatocalix(6)arenes for extraction of cobalt(II). The proposed method was tested for the analysis of cobalt in vitamin B-12. Although atomic absorption or emission spectoscopic methods are good for the determination involving no separation, the proposed method is useful when it is necessary to separate cobalt from interfering ions before subsequent analysis by a suitable method other than AAS.

## 2. Experimental

### 2.1. Apparatus and reagents

A UV visible spectrophotometer (Model Lamda 3B) with 10 mm matched quartz cells was used.

A stock solution of cobalt(II) was prepared by dissolving 0.403 g of cobalt chloride hexahydrate (BDH, Anal R) in 1 l of distilled water containing 5 ml of concentrated hydrochloric acid. The solution was standardized complexometrically [12] and was found to contain

* Corresponding author, Professor Emeritus, Indian Institute of Technology, Bombay -400 076, India.

*SSDI* 0039-9140(95)01600-7

100 μg ml$^{-1}$ of cobalt(II). A diluted solution containing 10 μg ml$^{-1}$ of cobalt(II) was prepared by tenfold dilution of the stock solution.

Hexaacetatocalix(6)arene was synthesized [3] by the following procedure.

5, 11, 17, 23, 29, 35-Hexatertbutyl-37, 38, 39, 40, 41, 42-hexahydroxycalix(6)arene was prepared by dissolving about 10 g (0.666 mol) of *p-tert*-butyphenol in 6 ml of 5 M potassium hydroxide and 9.70 g of 37% formaldehyde solution. The mixture was heated at 110–120°C for 2 h to give a light yellow taffy-like precursor. This precursor was mixed with 10 ml of xylene and heated to 210–220°C for 3 h in an atmosphere of nitrogen with a Dean and Stark collector. The cooled reaction mixture was filtered and then suspended in 300 ml of chloroform, and was shaken with 100 ml of 1 M hydrochloric acid. The organic layer was separated, washed with water, dried over anhydrous sodium sulphate and concentrated to 100 ml. The addition of methanol caused precipitation of a solid which was removed by filtration to give the colourless product. Recrystallization was carried out from chloroform and methanol. The product had a melting point of 380–388°C and a yield of 80%. The spectral characteristics were as follows. IR (KBr): 3400, 3150 cm$^{-1}$ (OH stretching). $^1$H NMR ($CDCl_3$): $\delta$ 10.2 (s, 1, ArOH), $\delta$ 7.10 (s, 2, ArH), $\delta$ 3.88 (s, 2, $CH_2$), $\delta$ 1.25 (s, 9, $C(CH)_3)_3$. $^{13}$C NMR ($CDCl_3$): $\delta$ 147.2 (15% Ar), $\delta$ 144.2 (15% Ar), $\delta$ 126.1 (65% Ar), $\delta$ 34.0 (17% $ArCH_2Ar$), $\delta$ 33.1 (25% $C(CH_3)_3$).

Synthesis of hexaacetatocalix(6)arene derivative was carried out as follows. About 2.0 g of *tert*-butylcalix(6)arene was treated with 50 ml of acetic anhydride as well as two drops of concentrated sulphuric acid. The mixture was heated and refluxed for 2 h. The crude product on recrystallization from chloroform/methanol gave white platelets with an m.p. of 360–362°C and a yield of 84%. The spectral characteristics of the derivative were as follows. IR (KBr): 1760 cm$^{-1}$ (>C=O stretching). $^1$H NMR ($CDCl_3$): $\delta$ 6.9 (s, ArH), $\delta$ 3.6 (br, CH), $\delta$ 1.9 (s, $OCOCH_3$), 1.2 (s, $C(CH_3)_3$).

### 2.2. Procedure

An aliquot of a solution containing cobalt(II) was taken. Its pH was adjusted to 7.4 with hydrochloric acid or tetramethyl ammonium hydroxide. The solution was then transferred to a separating funnel. The total volume was made up of 10 ml. 10 ml of a $10.0 \times 10^{-4}$ M solution of hexaacetatocalix(6)arene in toluene was added. The solution was shaken for 5 min. The two phases were allowed to settle and separate. Colbalt from the organic phase was stripped with 10 ml of 2 M nitric acid, and was determined spectrophotometrically as its complex with nitroso-*R*-salt [13] at 500 nm against the reagent blank. It is possible to carry out extractions with a large volume of the aqueous phase. For the purpose of simplicity, in calculations the volumes of the aqueous and organic phases were maintained the same at 10 ml.

## 3. Results and discussion

### 3.1. Extraction as a function of pH

When cobalt(II) was extracted in the pH range of 1.0–10.0 with $10.0 \times 10^{-4}$ M hexaacetatocalix(6)arene in toluene, the extraction was quantitative between pH 7.0 and 7.6 (Table 1). Therefore, all extractions were carried out at pH 7.4. The results represent figures for triplicate determinations, and are reproducible and precise.

### 3.2. Extraction as a function of extractant concentration

Cobalt(II) was extracted with varying amounts of hexaacetatocalix(6)arene. The concentration was varied from $0.1 \times 10^{-4}$ to $25.0 \times 10^{-4}$ M (Table 2). The extraction was quantitative with $10.0 \times 10^{-4}$ M of hexaaceta-

Table 1
Extraction of cobalt(II) as a function of pH

| pH | $E^a$ (%) |
|---|---|
| 1.0 | 55.2 |
| 2.0 | 56.8 |
| 3.0 | 58.4 |
| 4.0 | 60.8 |
| 5.0 | 64.8 |
| 6.0 | 72.0 |
| 7.0 | 99.2 |
| 7.2 | 99.9 |
| 7.4 | 99.9 |
| 7.6 | 99.9 |
| 7.8 | 97.6 |
| 8.0 | 80.8 |
| 9.0 | 60.0 |
| 10.0 | 51.2 |

[a] *E*, percentage extraction.

Table 2
Effect of calixarene concentration on extraction of cobalt-(II)

| Calixarene concentration ($1 \times 10^{-4}$ M) | $E$ (%) |
|---|---|
| 0.10 | 2.0 |
| 0.25 | 18.0 |

| 10.0–25.0 | 99.9 |

tocalix(6)arene; hence, this concentration was utilized for routine work. The extractant itself was stable for a number of days in the solvent.

### 3.3. Extraction with various diluents

Cobalt(II) was extracted with $10.0 \times 10^{-4}$ M of hexaacetatocalix(6)arene in different diluents. The percentage extraction was as shown in brackets: carbon tetrachloride (73%), cyclohexane (62%), benzene (48.2%), toluene (99.9%), xylene (60%), chloroform (62.9%), dichloromethane (89%), 1,2-dichloroethane (84%), chlorobenzene (56%) and nitrobenzene (54.6%). Thus, the extraction was quantitative only with toluene as diluent, while with other solvents the extraction was incomplete. Hence, toluene was perferred as the diluent.

### 3.4. Effect of various stripping agents

After extraction, cobalt(II) was stripped with various stripping agents (Table 3). It was noted that cobalt was backwashed completely with 1.5–4 M nitric acid, while with other acids stripping was incomplete. Therefore, 2 M nitric acid was generally used as the stripping agent.

Table 3
Effect of various stripping agents

| Stripping acid | Extraction (%) | | | | |
|---|---|---|---|---|---|
| | 0.5 M | 1 M | 1.5 M | 2 M | 4 M |

### 3.5. Period of equilibriation

The extraction of cobalt(II) was carried out with varying periods of shaking. The optimum period of shaking was 5 min. A 5 min equilibration period was therefore employed throughout the investigation.

### 3.6. Nature of extracted species

Calix($n$)arene is a three-dimensional network with annular space with a basket-like structure where the metal is trapped. There is no true covalent bond formation in these supramolecular compounds, but a kind of ionic attraction; hence, the chloride ion is not involved in complexation. Further, no kind of aggregate formation is usually encountered. The trapping of cobalt is favoured in alkaline media promoting higher extraction due to increasing electrostatic attraction.

Plots of log $D$ versus log[hexaacetatocalix(6)-arene] at a fixed pH of 7.4 had a slope of 2.91. Therefore the probable composition of the extracted species is 1:3 (Co:hexaacetato-calix(6)-arene). Of course, these findings need additional support with X-ray diffraction studies [14].

### 3.7. Effect of diverse ions

Cobalt(II) was extracted in the presence of a large number of diverse ions (Table 4). It was possible to carry out actual separations. The tolerance limit was set as the amount of foreign ion causing an error of ±2.0% in the recovery of cobalt(II). The s-block metals and p-block metals, such as arsenic, tin and bismuth, were tolerated in ratios of 1:100. Aluminium, in-

Table 5
Analysis of cobalt(II) from real sample

| No. | Co Concentration | | Recovery (%) | Error |
|---|---|---|---|---|
| | Taken (μg) | Found (μg) | | |
| 1 | 5.22 | 5.30 | 101.53 | +1.53 |
| 2 | 7.83 | 7.60 | 97.06 | −2.94 |
| 3 | 10.44 | 10.30 | 98.66 | −1.34 |

dium, selenium and tellurium were tolerated in ratios of 1:50. Yttrium, zinc, cadmium and cerium were tolerated in ratios of 1:25. Molybdenum, vanadium, tungsten, mercury, lead and thorium were tolerated in ratios of 1:5. Chromium, iron and uranium were tolerated in the lower ratio of 1:1. Nickel, copper, silver and palladium showed strong interference. Most of the anions were tolerated in ratios exceeding 1:1. It is thus observed that, amongst various derivatives of calix(6)arene, the acetate derivative gives the best results [15].

### *3.8. Application to analysis of cobalt in vitamin B-12*

Vitamin B-12 (IP, 1000 mcq, Anglo French Company) from an ampoule of 1 ml was used for the preparation of stock solution. It was diluted to 25 ml with deionized water. An aliquot containing vitamin B-12 was taken and its pH was adjusted to 7.4 as usual. It was then extracted by the procedure described earlier. The experimental results showed good agreement with certified values (Table 5).

# The application of trimesic acid to the determination of terbium by spectrofluorimetry☆

Jinzhang Gao *, Guohu Zhao, Jingwan Kang

*Institute of Chemistry, Northwest Normal University, Lanzhou 730070, People's Republic of China*

Received 19 December 1994; revised 30 March 1995; accepted 3 April 1995

**Abstract**

A sensitive, direct spectrofluorimetric method for the trace determination of terbium with use of trimesic acid (TMA) has been developed. The reaction conditions for the fluorescence system of terbium with TMA were studied. The terbium ion can form a stable binary chelate with TMA, having a ratio of 1:1 in the pH range 3.5–6.5. The maximum excitation and emission wavelengths are 260 nm and 545 nm for the terbium chelate, respectively. The reaction is instantaneous and the fluorescence intensity of the terbium chelate remains stable from 0.25 to 4 h. Under the optimal experimental conditions the fluorescence intensity is a linear function of concentration in the range 0.0248–6.35 $\mu g\,ml^{-1}$ of terbium. The relative standard deviation is still within $\pm 4\%$ in the presence of one-thousandfold amounts of the other lanthanide ions, and common foreign ions hardly interfere in the determination. The method can be employed for the determination of trace amounts of terbium in rare earth ores or oxides because of its high sensitivity and selectivity with good reproducibility and accuracy.

## 1. Introduction

The fluorescence method for the determination of rare earth element has long been recognized [1], especially for the analytical determination of samarium, europium and terbium. The derivative spectrofluorimetric method has received much attention and has been an important subject of our studies in recent years [2–7]. The analytical method involving derivative fluorescence spectra shows a higher sensitivity and selectivity than the method utilizing normal fluorescence spectra. When it is employed for the simultaneous determination of trace amounts of samarium, europium and terbium, this method shows good reproducibility and accuracy. As part of this study, we have recently made a systematic investigation of the new fluorescence system of terbium with trimesic acid (benzene-1,3,5-tricarboxylic acid (TMA)). TMA has already been used extensively as a catalytic agent for chemical reactions and as an additive etc. [8,9], as well as compounds similar to TMA; benzene-1,2-dicarboxylic acid, benzene-1,2,4,5-tetracarboxylic acid, pyridine-2-carboxylic acid, pyridine-3-carboxylic acid and pyridine-2,6-dicarboxylic acid etc. have been employed as complexing agents or chelating agents for studying the fluorescent properties of a solid chelate with terbium [10], the crystal structure of complexes with Eu and Er [11,12] and the intermolecular interaction energy between lanthanide complexes in solution [13]. However, up to now it has not been applied as a fluorescence reagent. In this work we report a new fluorescence reagent and the development of a fluorimetric method for the determination of terbium.

## 2. Experimental

### 2.1. Apparatus

Fluorescence measurements were made with a Shimadzu RF-540 spectrofluorimeter (Japan) equipped with a xenon light source, and the excitation and emission slits used were both 5 nm. The pH measurements were obtained with use of an SPM-10 pH meter (Shanghai, China).

### 2.2. Reagents

All the chemicals used in this paper were of analytical reagent grade or the highest purity available, and distilled, deionized water was employed throughout the study.

A stock solution of lanthanide ions (0.0200 mol $l^{-1}$) was prepared by dissolving requisite amounts of the corresponding oxides (purity, 99.99%): $La_2O_3$, $Pr_6O_{11}$, $Nd_2O_3$, $Sm_2O_3$, $Eu_2O_3$, $Gd_2O_3$, $Tb_4O_7$, $Dy_2O_3$, $Ho_2O_3$, $Er_2O_3$, $Tm_2O_3$, $Yb_2O_3$, $Lu_2O_3$ and $Y_2O_3$, in concentrated HCl and evaporating the solution to a syrup and diluting with distilled deionized water to the desired volume. A stock solution of cerium (0.0200 mol $l^{-1}$) was obtained by dissolving cerium oxide (purity, 99.99%; $CeO_2$) in a mixture of sulphuric acid and ammonium sulphite followed by the addition of $H_2O_2$ to the solution, converting $Ce^{4+}$ to $Ce^{3+}$. All the stock solutions were standarized with EDTA, using Xylenol Orange as indicator. Working solutions of lanthanide ions (0.0010 mol $l^{-1}$) were obtained by diluting corresponding stock solutions of lanthanide ions with distilled, deionized water. An HAc–NaAc buffer solution (pH 5.5) was obtained by adjusting the pH of a saturated sodium acetate solution to 5.5 with concentrated acetic acid. A solution of the chelating agent, TMA, (0.0100 mol $l^{-1}$) was prepared by dissolving 0.5250 g of TMA in 200 ml of distilled, deionized water with heating, and then diluting the solution to 250 ml with distilled, deionized water. Solutions of a large number of inorganic ions were prepared from their water-soluble salts (or oxides and carbonates in hydrochloric acid).

### 2.3. Procedure

A standard solution of terbium or the sample solution was placed in a calibrated tube with 3 ml of TMA solution (0.0100 mol $l^{-1}$) and 5 ml of acetic acid–sodium acetate buffer solution, pH 5.5. The final volume was made up to 25 ml with distilled, deionized water. The relative fluorescence intensity of the chelate was measured within 0.25–4 h at an emission wavelength of 545 nm in a 1 cm quartz cell, keeping the excitation wavelength maximum at 260 nm.

## 3. Results and discussion

### 3.1. Fluorescence spectra

The excitation and emission spectra of the system Tb + TMA at pH 5.5 were recorded with use of the spectrofluorimeter. The maximum wavelengths of excitation and emission were found to occur at 260 nm and 545 nm, respectively. The excitation spectrum is shown in Fig. 1a. In aqueous media at room temperature, a $4 \times 10^{-5}$ mol $l^{-1}$ solution of $Tb^{3+}$ only gives a very weakly measurable emission and a $8 \times 10^{-4}$ mol $l^{-1}$ solution of TMA does not give measurable emission upon excitation at 260 nm. The addition of a more than twentyfold excess of TMA to the $Tb^{3+}$ solution does not induce any emission changes, but results in greatly enhanced $Tb^{3+}$ emission. For $Tb^{3+}$ four distinct emission bands are

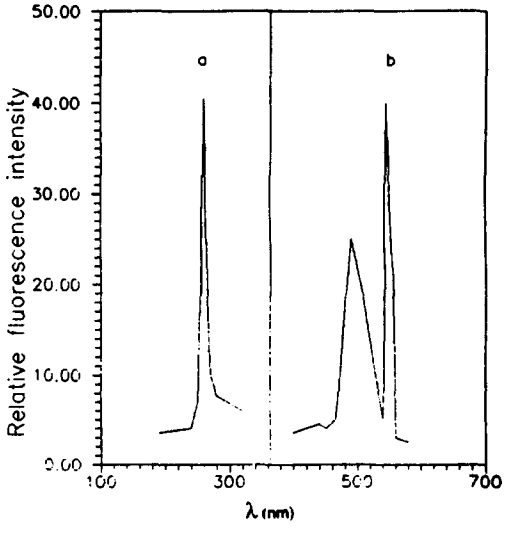

Fig. 1. (a) Excitation spectrum of the chelate of terbium with TMA. (b) Emission spectrum of the chelate of terbium with TMA. (Conditions: Tb, 1.589 μg $ml^{-1}$; TMA, $1.2 \times 10^{-3}$ mol $l^{-1}$; pH 5.5; excitation slit, 5 nm; emission slit, 5 nm.)

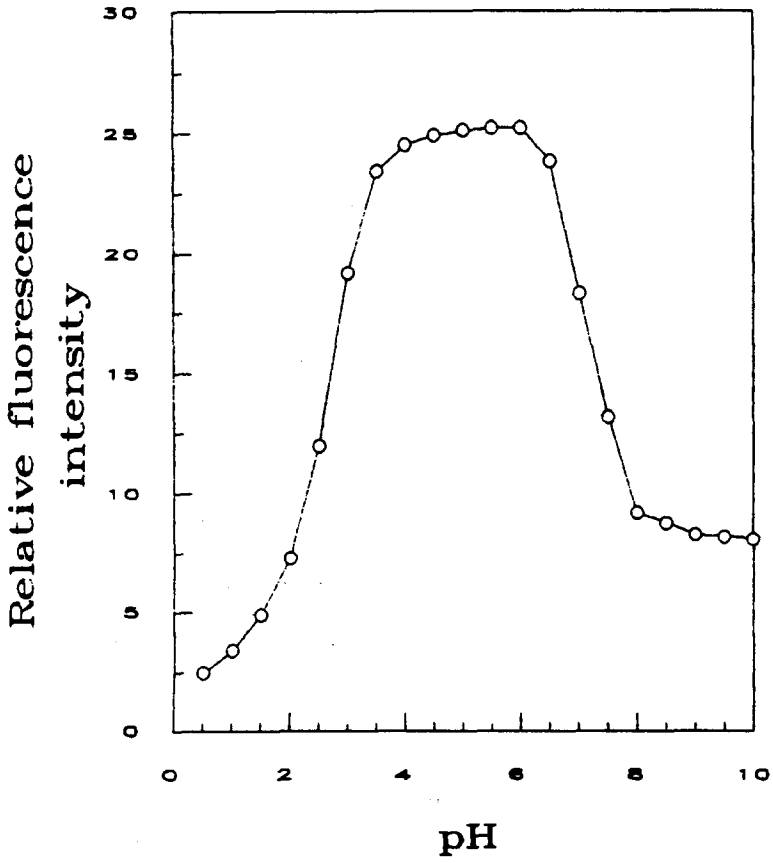

Fig. 2. Effect of pH on the fluorescence intensity of the terbium chelate. The pH values of the solution systems were adjusted with standard 0.1000 mol $l^{-1}$ KOH or HCl solutions. (Terbium, 1.589 μg $ml^{-1}$; TMA, $1.2 \times 10^{-3}$ mol $l^{-1}$.)

observed and these are found at 491 nm, 545 nm, 585 nm and 621 nm, respectively, corresponding to the $^5D_4 \rightarrow {}^7F_6$, $^5D_4 \rightarrow {}^7F_5$, $^5D_4 \rightarrow {}^7F_4$ and $^5D_4 \rightarrow {}^7F_3$ transitions [14,15]. Only the $^5D_4 \rightarrow {}^7F_6$ and $^5D_4 \rightarrow {}^7F_5$ transitions have appreciable intensity, with the transition to the $^7F_5$ level being the most intense. All the above are represented in Fig. 1b. Thus we can speculate that the mechanism for obtaining the luminescence spectra is an A–LMET–E process [16,17], i.e. the triplet level of the chelating agent, TMA, lies just above that of the terbium ion, so TMA absorbs ultraviolet light and transfers energy to the central terbium ion (namely the Antenna effect) [18–21], and then the terbium ion produces the characteristic sensitive metal-centred (MC) fluorescence spectrum.

### 3.2. *Effect of the acidity of the solution*

The variation in the fluorescence intensity at 545 nm for the terbium chelate was investigated as a function of pH. Maximum constant fluorescence intensity was obtained when the pH of the fluorescent chelate solution was maintained between 3.5 and 6.5 by the addition of dilute HCl or KOH. When the pH was adjusted using a buffer solution containing sodium acetate and acetic acid (pH 5.5) instead of HCl and KOH, it caused no change in the emission wavelength and only a slight change in the emission intensity. In this paper, a buffer solution containing sodium acetate and acetic acid (pH 5.5) was selected to maintain the solution acidity.

Fig. 2 shows that the fluorescence intensity of the terbium chelate becomes weaker at pH < 2.5 and pH > 8. The reason for this is that the protonation of three carboxyl groups of the chelating agent at pH < 2.5 and the intensive hydrolysis of the trivalent terbium ion at pH > 8 both result in a decrease in the concentration of the chelate of terbium with TMA, causing a decrease in the fluorescence intensity of the terbium chelate with TMA.

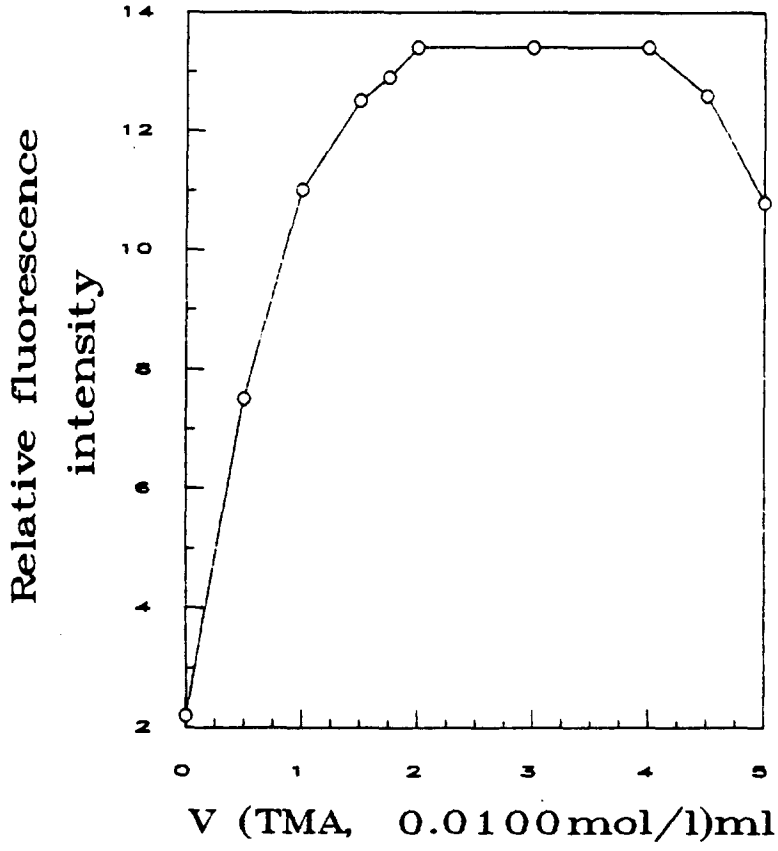

Fig. 3. Effect of the volume of 0.0100 mol $l^{-1}$ TMA on the fluorescence intensity of the terbium chelate with TMA. (Terbium, 1.589 μg $ml^{-1}$; pH 5.5.)

### 3.3. *Effect of the concentration of the chelating agent TMA*

Fig. 3 shows the variation in fluorescence intensity with the variation in volume of 0.0100 mol $l^{-1}$ TMA. The variation in fluorescence intensity was examined as a function of the volume of 0.0100 mol $l^{-1}$ TMA.

A set of solutions, each of volume 25 ml, was prepared by mixing a fixed amount of terbium ($4 \times 10^{-5}$ mol $l^{-1}$), different amounts of the reagent and a fixed volume of the sodium acetate–acetic acid buffer solution (5.00 ml). It was found that the fluorescence intensity of the chelate was most intense and constant over the volume range 2–4 ml for a 0.0100 mol $l^{-1}$ TMA solution.

### 3.4. *Effect of time*

The fluorescence intensity remained at its maximum from 15 min to 4 h, and then started to alter, with the relative standard deviation going beyond ±4%.

### 3.5. *Composition of the terbium chelate*

The Job's method of continuous variation was applied to determine the stoichiometric composition of the binary fluorescent chelate of terbium with TMA. Fig. 4 shows the curve of the relative fluorescence intensity as a function of the mole fraction of terbium. The branch point of two tangent lines indicates a composition ratio of 1:1 of terbium to TMA in water. TMA is a neutral electron donor and its chelate with terbium exists in the form of a positively charged ion. Therefore, the general formula of the chelate is $[Tb(TMA)]Cl_3$ in water.

### 3.6. *Calibration curve*

Fig. 5 shows the calibration curve for the determination of terbium. Using the experi-

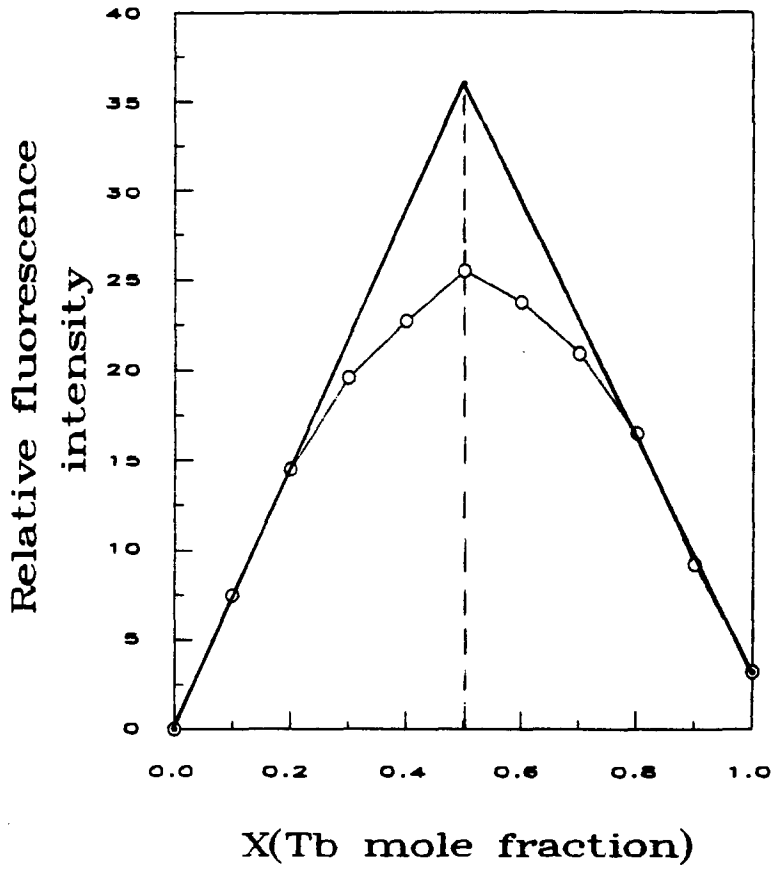

Fig. 4. Plot of the fluorescence intensity versus mole fraction of terbium. (pH 5.5.)

mental method described above, the relative fluorescence intensity is a linear function of concentration in the range 0.0248–6.356 μg ml$^{-1}$ of terbium. The linear equation is $F = 1.155 + 11.036C$ (where $F$ is the relative fluorescence intensity and $C$ is the concentration of terbium), and the linear correlation coefficient $R = 0.9996$.

### 3.7. Determination of the recovery

A standard sample of biyttrium trioxide (99.988%) as the matrix was obtained from the Rare Earth Company of Gansu, Gansu, P.R. China. It is actually a mixture of oxides and its composition is as follows: $La_2O_3$ (0.0040%), $Ce_2O_3$ (0.0002%), $Pr_6O_{11}$ (0.0005%), $Nd_2O_3$ (0.0005%), $Sm_2O_3$ (0.0005%), $Eu_2O_3$ (0.00015%), $Gd_2O_3$ (0.0004%), $Tb_4O_7$ (0.0005%), $Dy_2O_3$ (0.0005%), $Ho_2O_3$ (0.0004%), $Er_2O_3$ (0.0004%), $Tm_2O_3$ (0.0004%), $Yb_2O_3$ (0.0004%), $Lu_2O_3$ (0.0002%), $Y_2O_3$ (99.988%), and trace amounts of $Fe^{3+}$, $SiO_3^{2-}$, etc. Obviously, if a good recovery is obtained with a matrix of this type of $Y_2O_3$, the results will show that the determination of terbium using the Tb–TMA fluorescence system has good repeatability.

The synthesized samples 1 and 2 have molar ratios of 100:1 and 25:1 for Y:Tb, respectively.

The requisite amount of sample was dissolved in hot, concentrated HCl, and the solution was evaporated to a syrup then diluted with distilled, deionized water to the desired volume. The determination was performed according to the experimental method given above.

The analytical results are listed in Table 1.

### 3.8. Interferences of foreign ions

In the fluorescence determination of rare earth ions, interference occurs between these ions themselves, which is especially serious for $Sm^{3+}$, $Eu^{3+}$, $Tb^{3+}$ and $Dy^{3+}$ (with ethanol or DMF as solvents, the interference is even more serious). We were surprised to find that $Eu^{3+}$, $Sm^{3+}$ and $Dy^{3+}$ ions give rise to few interfer-

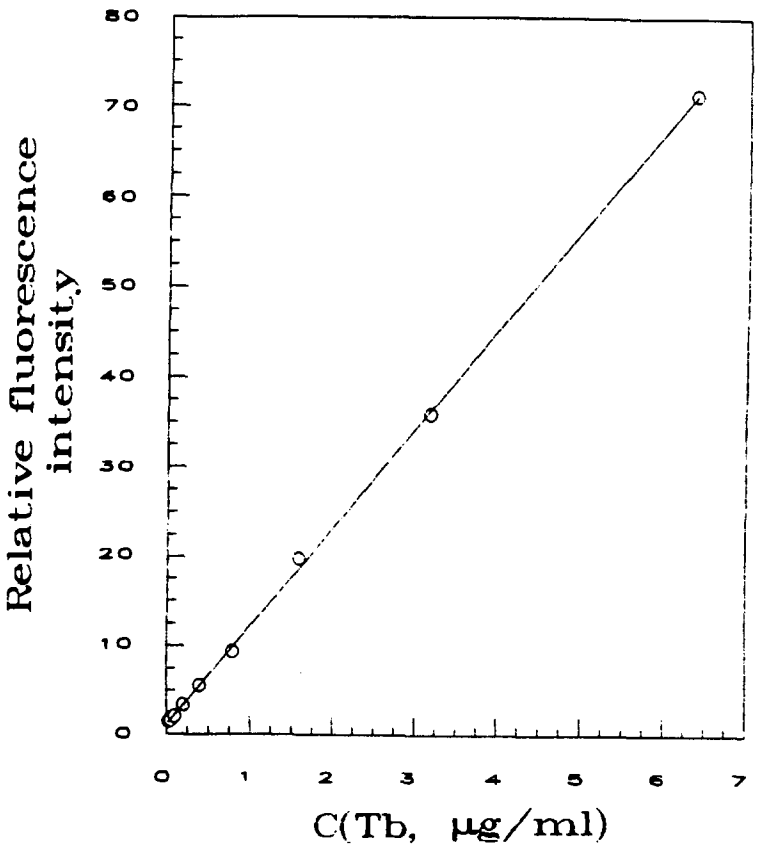

Fig. 5. Calibration curve. ($C_{Tb}$ = 0.0246–6.35 μg ml$^{-1}$; TMA, 1.2 × 10$^{-3}$ mol l$^{-1}$; pH 5.5.)

ences in the determination of terbium with the TMA–Tb system; perhaps $H_2O$ can extinguish the fluorescences of $Eu^{3+}$, $Sm^{3+}$ and $Dy^{3+}$.

When the concentration of terbium was maintained at 1.589 μg ml$^{-1}$, the interferences of 39 ions were examined by measuring the fluorescence intensity under the same experimental conditions. In this work, as the relative standard deviation was kept within ±4%, it was confirmed that 800 μg ml$^{-1}$ of $NH_4^+$, $K^+$, $Na^+$, $Ca^{2+}$, $Mg^{2+}$, $F^-$, $Cl^-$, $Br^-$, $Ac^-$, $SO_4^{2-}$, $NO_3^-$, $PO_4^{3-}$ and $SiO_3^{2-}$ ions; 220 μg ml$^{-1}$ of $Ba^{2+}$ ions; 40 μg ml$^{-1}$ of $Nd^{3+}$ ions; 16 μg ml$^{-1}$ of $Ti^{4+}$ and $Ag^+$ ions; 12 μg ml$^{-1}$ of $Co^{2+}$ ions; 10 μg ml$^{-1}$ of $Cr^{3+}$ ions; 6 μg ml$^{-1}$ of $Ta^{4+}$, $Th^{2+}$ and $Mn^{2+}$ ions; 4 μg ml$^{-1}$ of $Fe^{2+}$ ions; 2 μg ml$^{-1}$ of $Fe^{3+}$ and $Cu^{2+}$ ions; 158.9 μg ml$^{-1}$ of $Ce^{3+}$, $Pr^{3+}$, $Nb^{3+}$ ions; 320 μg ml$^{-1}$ of $Sm^{3+}$, $Eu^{3+}$, $Gd^{3+}$, $Dy^{3+}$, $Ho^{3+}$, $Er^{3+}$, $Tm^{3+}$, $Tm^{3+}$, $Yb^{3+}$, $Lu^{3+}$ and $Y^{3+}$ ions; and 3.2 μg ml$^{-1}$ of $La^{3+}$ ions did not interfere with the determination.

### *3.9. Analyses of artificially mixed ore samples and a standard ore sample*

Following Ref. [22] and taking into account the interferences listed above, two kinds of ore samples, Cainosite ($Y_2Ca_2[Si_4O_{12}]CO_3 \cdot H_2O$) and Fergusonite ($YNbO_4$), were synthesized artificially. Solutions of artificially mixed ore samples and a standard ore sample were obtained according to the method for producing working solutions of lanthanide ions. Under the experimental conditions given in section 2, the relative fluorescence intensity was determined and the results are shown in Table 2.

From the above, it can be concluded that the method can be used to determine trace amounts of terbium with the new fluorescence agent TMA because of the predominant advantages of high sensitivity, high selectivity, high accuracy and high reproducibility.

# Solid-surface room-temperature phosphorescence detection of serotonin, tryptamine, and gramine enhanced by inorganic salts and sodium dodecyl sulfate

José de Ribamar F. Júnior, A.D. Campiglia *

*Departamento de Química, Universidade de Brasília, Brasília, DF, CEP 70910-900, Brazil*

Received 5 October 1994; revised 27 March 1995; accepted 3 April 1995

**Abstract**

Room-temperature phosphorescence characteristics of serotonin (5-hydroxytryptamine), typtamine, and gramine ([3-(dimethylaminomethyl)indole]) were studied on low-background paper substrates. Several experimental parameters were optimized for maximum signal intensity. Sodium iodide, thallium(I) nitrate, silver(I) nitrate, and lead(II) nitrate were tested as phosphorescence enhancers. The effect of sodium dodecyl sulfate on the enhancement efficiency of these inorganic salts was also studied. The pH values of the solutions were adjusted to optimize the interaction between analyte molecules and solid substrates. Under the experimental conditions for maximum phosphorescence intensity, working curves ranging from two (gramine) to four (typtamine) orders of magnitude were obtained. Limits of detection at the nanogram level were estimated for the three compounds, showing the potential of solid-surface room-temperature phosphorimetry as a detection technique for biogenic amines.

## 1. Introduction

The role played by indole alkylamines in the central nervous system (CNS) has been a subject of interest in the area of clinical chemistry [1–3]. Serotonin (5-hydroxytryptamine) and tryptamine, which are naturally present in the CNS as a result of tryptophan biotransformation [4,5], are two important indole alkylamines acting as neurotransmitters. Incorrect concentrations of these compounds in physiological fluids and body tissues have been related to several pathological conditions [6–8]. Their determination has been performed by analytical methods involving HPLC [5,9–11], fluorimetry [12,13], radioimmunological assays [14,15], and enzymatic techniques [16].

In this article, we will report on a sensitive method of detection of serotonin and tryptamine based on solid-surface room-temperature phosphorimetry (SSRTP) [17,18]. Our studies have also been extended to gramine ([3-(dimethylaminomethyl)indole]), which is another biogenic amine present in the CNS, resulting from tryptophan biotransformation [19].

Although tryptophan phosphorescence emission has been extensively studied at 77 K [20,21] and at room temperature [22–24], this is the first time—to the best of our knowledge—that the room-temperature phosphorescence (RTP) characteristics of these indole alkylamines are reported.

Several experimental parameters that usually affect phosphorescence emission were optimized for maximum signal intensity. Chromatography paper previously treated for paper background reduction [25] was employed as the solid substrate. KI, $AgNO_3$, $TlNO_3$, and $Pb(NO_3)_2$ were tested as phosphorescence enhancers [26,27].

*SSDI* 0039-9140(95)01602-3

The effect of sodium dodecyl sulfate, which is a surfactant commonly employed to increase heavy atom enhancement efficiency [28–30], was also studied. Finally, the interactions responsible for RTP emission between analyte molecules and a solid substrate were optimized by adjusting the pH of the solutions [31–33].

Under experimental conditions for a maximum RTP signal, calibration curves with linear dynamic ranges varying from two to four orders of magnitude, and limits of detection in the nanogram range were estimated. The analytical figures of merit, associated with the practical advantages of SSRTP [17,18], show the potential of the technique for the detection of biogenic amines.

## 2. Experimental

### 2.1. Instrumentation

The treatment for paper background reduction was performed in a Rayonet photochemical reactor using five lamps with maximum wavelengths ($\lambda_{max}$) of emission at 250 nm, and seven with $\lambda_{max}$ at 300 nm.

The absorption spectra of the studied compounds were monitored with use of a single-beam spectrophotometer (model DU-650, Beckman Instruments, Fullerton, CA) equipped with deuterium and tungsten lamps, a concave holographic grating, and a silicon photodiode detector.

All RTP spectra and intensity measurements were collected with an Aminco–Bowman spectrofluorimeter (SLM Instruments, Urbana, II) equipped with a 150 W xenon arc lamp (Conrad-Hanovia, Newark, NJ) as an excitation source. The optical transducer was a potted IP21 photomultiplier (Hamamatsu Corp.) with an S4 spectral response. The signal from the detector was amplified by means of an SLM–Aminco microphotometer and fed to a Hewlett-Packard $X-Y$ recorder (model 7010 B). Short-lived scattering and possible fluorescence signals were minimized with an Aminco–Keirs rotating-can phosphoroscope attachment. A laboratory-constructed sample holder [34] was employed to introduce solid substrates into the spectrofluorimeter.

### 2.2. Reagents

All the chemicals were analytical-reagent grade and were used without further purification. Whatman no. 1 chromatography paper (USA) and tridistilled (in glass) water were used throughout.

Gramine (Gra), typtamine (Try), and serotonin (50HTry) were acquired from Sigma (USA). Ethanol, hydrochloric acid, sodium hydroxide, and silver(I) ntirate were purchased from Merck (Brazil). Sodium dodecyl sulfate (specically purified for biomedical work), lead(II) nitrate, and potassium iodide were from BDH Chemicals Ltd, UK. Thallium(I) nitrate was obtained from Fluka (Switzerland).

### 2.3. Procedures

*Paper treatment*

The treatment for paper background reduction has been described in detail elsewhere [25]. It basically consisted of a combination of water extraction and ultraviolet irradiation. The strips of chromatography paper were water-extracted in a Soxhlet apparatus for 8 h, dried under a stream of hot air, and exposed to ultraviolet irradiation for the same period of time. To fit in the sample holder [34], the paper strips were cut in appropriate sizes ($20 \times 10\ mm^2$). The solid supports were then stored in a dessicator to be used during the analysis.

*Solution preparation*

Stock solutions of gramine, tryptamine and serotonin (each $10^{-2}$ M) were prepared in ethanol/water (50:50 (v/v)). Working solutions were obtained by appropriate dilution of the stock solutions with an ethanol/water (50:50 (v/v)) solution.

The 1 M KI, 0.5 M $AgNO_3$, 0.5 M $Pb(NO_3)_2$, and 0.1 M $TlNO_3$ solutions were made up in water. The KI and $TlNO_3$ solutions employed in the optimization of heavy atom concentrations were prepared, respectively, by serial dilution of a 5 M and a 0.25 M solution. Serial dilution was also used to prepare the sodium dodecyl sulfate solutions. A 0.5 M stock solution (in water) was prepared. Lower surfactant concentrations were obtained by appropriate dilution of the stock solution.

The analyte solutions for the pH studies were made up by adding concentrated HCl or NaOH to volumetric flasks with the compounds dissolved in ethanol/water (50:50 (v/v))

The standard solutions for the calibration curves were prepared in ethanol/water (50:50 (v/v)) (5-OHTry) and at basic pH (Gra and

[a] Heavy atom (HA) salt solutions were prepared in water.
[b] A 2% solution in water was employed.
[c] Analyte solutions ($10^{-4}$ M) prepared in ethanol/water (50:50 (v/v)) were employed.
[d] Net RTP signals were obtained by subtracting the blank signals from the analyte + blank signals. In each case, six determinations were employed in order to calculate the average values. The precision of the measurements was within 10–15%.
[e] The $\lambda_{exc}/\lambda_{em}$ ratios are given in parentheses, where $\lambda_{exc}$ and $\lambda_{em}$ are the excitation and emission wavelength maxima in nanometers. The variation in wavelength for instrumental response was $\pm 2$ nm.

Try). Basic solutions were made up using appropriate volumes of concentrated NaOH. Tryptamine and gramine standard solutions were, respectively, 1 M and 0.1 M in NaOH.

*General Procedure*

Analyte solutions were spotted on solid substrates with a microliter pipette. The heavy atom and surfactant solutions were added with a microliter syringe. In all cases, a volume of 5 μl was employed. The spotted substrates were vacuum-dried at room temperature for 1 h and were then placed in a desiccator with silica until the measurements were carried out. The desiccator was covered with aluminium foil to avoid possible light effects. Prior to the measurements, a flow of dry nitrogen was directed towards the surface of the paper substrate for 5 min. All RTP measurements were performed under this gas to avoid possible quenching effects from oxygen and moisture [17,18]. A silica gel bed was used to remove water vapour traces from the drying flow.

## 3. Results and discussion

### 3.1. RTP characteristics of Gra, Try, and 5-OHTry on low background paper

*Heavy atom and sodium dodecyl sulfate effect*

The deposition of $10^{-4}$ M solutions of Gra, Try, and 5-OHTry on chromatography paper substrates were an inefficient attempt to observe their phosphorescence emission. The analyte-to-background signals ratios were close to unity, showing a lower capacity of the indole alkylamines for emitting RTP. Since the broad, featureless bands of the excitation and background emission of cellulose substrates usually overlap the analyte spectra [25,35–37], we applied a background reduction treatment to the paper substrate [25].

Table 1 presents the RTP characteristics of the three compounds on low-background paper substrates. Try was the only one to show phosphorescence emission in the absence of RTP enhancers. Surprisingly, the hydroxyl group of 5-OHTry, which is capable of increasing the analyte rigidity by establishing hydrogen bonding with the solid substrate, did not favor phosphorescence emission from the compound. Usually, substituent groups with a hydrogen bonding capacity enhance the RTP signal of the indole moiety [30].

The external heavy atom (HA) effect was tested by taking five inorganic salts with general phosphorescence enhancers [26,27]. Before analyte deposition, 1 M KI, 0.1 M $TlNO_3$, 0.5 M $AgNO_3$, 0.5 M $Pb(NO_3)_2$, and 0.25 M $HgCl_2$ were deposited on low-background paper substrates. In the presence of Tl(I), Ag(I), Pb(II), and Hg(II) ions, none of the studied compounds showed RTP enhancement. On the other hand, 1 M KI increased the phosphorescence emission of the three compounds. The

| 5-OHTry | 100 (294/454) | 93.2 (293/454) | 33.5 (290/456) | – | 83.1 (298/461) | 62.4 (300/459) | – |

[a] Analyte solutions of concentration $10^{-3}$ M were employed. Acid and basic soltuions were prepared in ethanol/water (50:50 (v/v)).

[b] Net RTP signals were obtained by subtracting the blank signals from the analyte + blank signals. In each case, six determinations were employed to calculate the average values. All RTP signals were normalized to the net analyte signals in neutral media.

[c] The $\lambda_{exc}/\lambda_{em}$ ratios are given in parentheses. When necessary, the maximum excitation peak is underlined.

net analyte signals in the presence of 1 M are presented in Table 1.

The addition of sodium dodecyl sulfate (NaDS) to the solid substrate usually increases the HA efficiency and enhances the phosphorescence emission [28–30]. Apparently, the long hydrocarbon chains of the surfactant promote the necessary interaction between analyte molecules and HA ions, thus improving RTP enhancement [28]. We tested, therefore, the effect of NaDS on the RTP signals of Gra, Try, and 5-OHTry.

The presence of the surfactant increased the $TlNO_3$ efficiency for the three indole alkylamines. The net RTP signals in the presence of Tl(I) and Ag(I) are presented in Table 1. The $Pb(NO_3)_2$ and $HgCl_2$ efficiencies, on the other hand, were not increased by NaDS. Probably, these two HA salts do not favor the singlet–triplet intersystem crossing rates of the studied indoles [17,18]. Finally, the surfactant improved iodiode efficiency for Gra and Try. The 5-OHTry signal, however, was higher in the absence of NaDS (see Table 1). This signal reduction could have been caused by the use of an incorrect concentration of sufactant. In previous studies [38,39], Aucélio and Campiglia have shown that, depending on the compound and HA ion, there is an optimum concentration of NaDS for improvements in HA efficiency to be observed.

*pH effect*

The RTP characteristics of Gra, Try, and 5-OHTry were studied at several pH values (see Table 2) employing $10^{-3}$ M analyte solutions which guaranteed (in a neutral medium) analyte-to-background signal ratios higher than 4.

All solutions were monitored by absorption spectrometry in the ultraviolet and visible regions. A pH variation did not cause significant modifications in the absorption spectra of Gra and Try. However, the 5-OHTry spectrum was drastically altered in alkaline medium. Neutral solutions of 5-OHTry (ethanol/water (v/v)) gave three peaks with absorption maxima at 219, 262, and 279 nm. In 0.01 M NaOH solution the 5-OHTry spectrum showed four peaks (241, 269, 279, and 309 nm), and in 1 M NaOH solutions, showed six peaks (228, 252, 269, 281, 317, and 324 nm). In addition, after 2 h of solution preparation, a change in color was observed. The neutral solutions were colorless, while the 0.01 M NaOH and 1 M NaOH solutions were pink and purple, respectively. These observations strongly suggest that 5-OHTry decomposed in basic medium.

The pH variation caused minor shifts in the maximum RTP excitation and emission wavelengths of the studied compounds. Gra showed an additional excitation peak in basic medium, of which the maximum wavelength depended upon the NaOH concentration (see Table 2).

The intensities of the RTP signals, on the other hand, were drastically affected by the pH values of the solutions. The phosphorescence signals were quenched in acidic medium. The degree of quenching increased with acid concentration, obviously along with the degree of protonation of indole alkylamines [19]. The

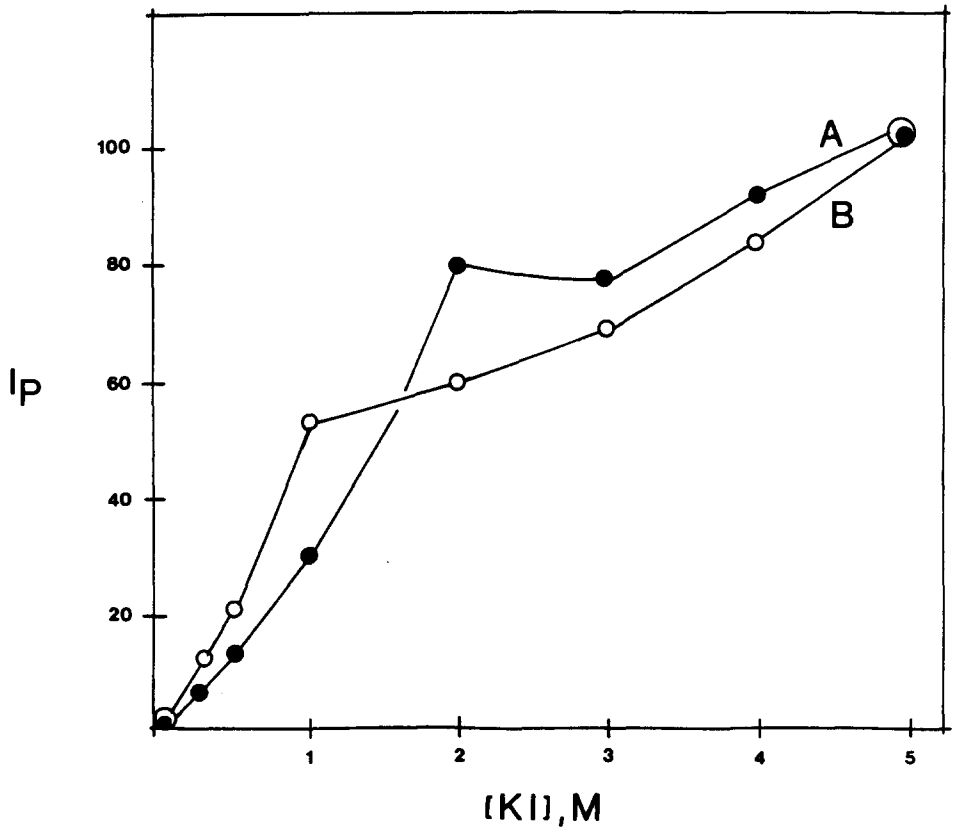

Fig. 1. Net phosphorescence intensity ($I_p$) of (curve A) 5-OHTry and (curve B) Try as a function of molar concentration of potassium iodide. Analyte solutions of concentration $10^{-4}$ M were employed. The 5-OHTry was dissolved in ethanol/water (50:50 (v/v)), and Try was dissolved in 1 M NaOH (ethanol/water (50:50 (v/v)). Net analyte signals were normalized to the maximum intensity observed.

acid quenching could result from a lower capacity of the protonated species for forming hydrogen bonds with the solid substrate. In addition, the excess of $H_3O^+$ ions in acid solutions, which increases competition for the OH groups of the solid substrate and inhibits hydrogen bonding with the analyte molecules, could also contribute to reduce the RTP signals.

These assumptions are also supported by the fact that Gra and Try showed their highest signals in basic media. In NaOH solutions, the dissociation equilibrium of these indoles is inhibited, the $H_3O^+$ ion concentration is at a minimum, the unprotonated species are predominant. On the other hand, 5-OHTry showed the highest RTP signal in neutral medium. As previously mentioned, however, this compound might have undergone degradation in basic medium. Its degradation product obviously does not have characteristics needed for RTP emission.

*Analytical figures of merit*

The analytical figures of merit (AFOM) were obtained under the experimental conditions for maximum RTP emission. The HA salt and NaDS concentrations were optimized for each compound. Based on the results shown in Table 1, $TlNO_3$ was used to enhance the Gra RTP signal, and KI was employed to obtain the AFOM for Try and 5-OHTry. The pH values of the solutions were chosen in agreement with the data presented in Table 2. Gra solutions were prepared in 0.1 M NaOH, Try solutions in 1 M NaOH, and 5-OHTry solutions in ethanol/water (50/50 (v/v)).

Fig. 1 shows the phosphorescence intensity of Try and 5-OHTry as a function of KI molar concentration. In both cases, the maximum phosphorescence intensity was obtained with a 5 M KI solution. Higher concentrations were not tested due to KI solubility limitations. Fig. 2 shows the RTP signal of Gra as a function of $TlNO_3$ molar concentration. The highest emission was observed with a 0.025 M $TlNO_3$ solution. More concentrated solutions than 0.025 M reduced the analyte signal. Probably, the excess of $TlNO_3$ caused a matrix prefilter

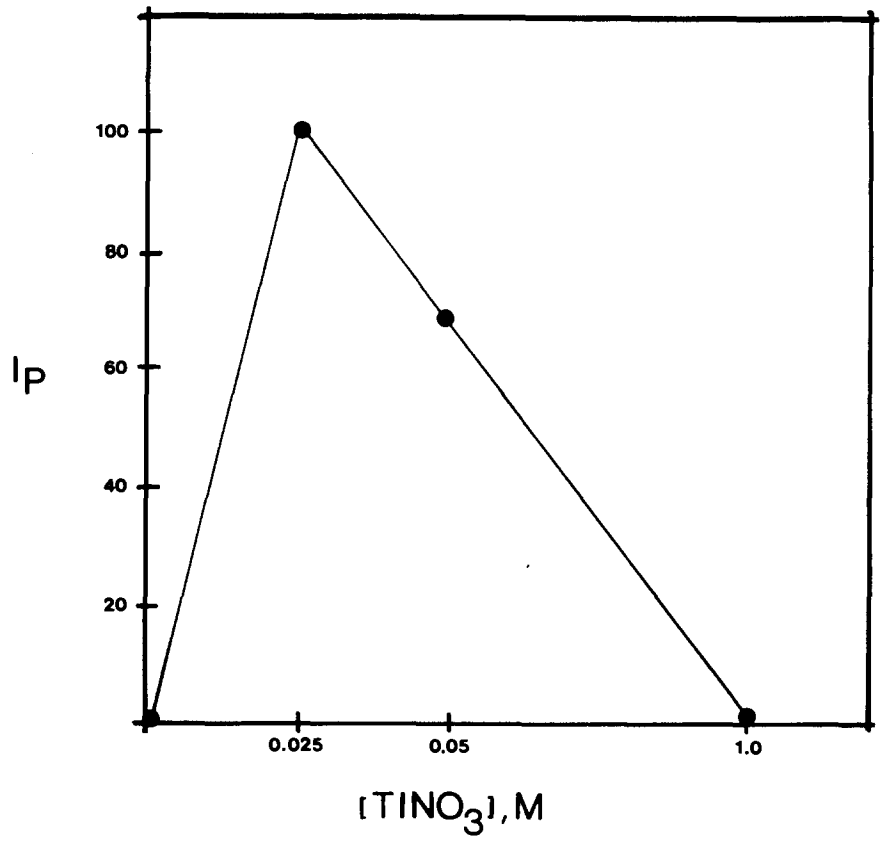

Fig. 2. Net phosphorescence intensity ($I_p$) of Gra as a function of molar concentration of thallium(I) nitrate. A $10^{-4}$ M Gra solution prepared in 0.1 M NaOH (ethanol/water (50:50 (v/v)) was used. Net Gra signals were normalized to the maximum intensity observed.

effect and reduced the excitation energy reaching the analyte molecules [25].

The NaDS concentration was optimized in the presence of the HA salts. A 5 M KI solution was employed for Try and 5-OHTry, and 0.025 M $TlNO_3$ was used for Gra. In all cases, the surfactant concentration varied from 0.01 to 0.5 M. The optimum value depended on the compound. Gra and 5-OHTry showed the highest RTP signals with a 0.2 M NaDS solution, while Try showed its maximum signal with a 0.1 M surfactant solution.

Table 3 summarizes the AFOM at optimum pH, and HA and NaDS concentrations. Try showed a calibration curve with the linear dynamic range (LDR) extended over four orders of magnitude ($4.8 \times 10^{-7}$–$5 \times 10^{-3}$ M) while the 5-OHTry and Gra LDRs extended, respectively, over three ($3.2 \times 10^{-7}$–$2 \times 10^{-4}$ M) and two ($6.4 \times 10^{-6}$–$5 \times 10^{-4}$ M) orders of magnitude. The slopes of the log–log plots showed a linear relationship between phosphorescence intensity and analyte concentration. For Try and 5-OHTry, the correlation coefficients of the calibration curves were close to unity, showing a good precision of the measurements. The relative standard deviations (within the LDR) varied form 10 to 15%. For Gra, however, a poorer precision was obtained (20%). Apparently, the presence of $TlNO_3$ in the solid substrate caused the observed variation. The standard deviation for 16 blank repetitions with this salt was considerably higher than that obtained with KI. The limits of detection (LOD) were estimated from the equation $C_L = Ks_b/m$, where the standard deviation ($s_b$) from 16 blank determinations, the slope of the calibration curve ($m$), and $K = 3$ were employed [40]. The absolute LOD, for a sample volume of 5 μl, were in the nanogram level.

## 4. Conclusions

In this article, we have reported the RTP characteristics of Gra, Try, and 5-OHTry on low-background paper substrates. Several experimental parameters that usually affect the

intensity of phosphorescence emission were studied. KI, $TlNO_3$, $Pb(NO_3)_2$, $HgCl_2$, and $AgNO_3$ were tested as RTP enhancers. With the exception of KI, none of the HA salts increased the phosphorescence signals of the studied compounds. With 1 M KI, the intensities of the net analyte signals varied from 248.6 (Gra) to 621.1 (Try). The addition of NaDS to the paper substrates, however, improved the enhancements efficiency of $TlNO_3$ and $AgNO_3$. With 0.1 M $TlNO_3$, and employing a 2% surfactant solution, the Gra net RTP intensity was 379.5, which was higher than that observed with 1 M KI. In addition, NaDS increased the iodide efficiency, causing the highest enhancements for Try and 5-OHTry net RTP signals, 688.47 and 219.4, respectively.

The effect of the pH was also studied. Gra and Try showed the highest RTP signals in basic medium (in 0.1 M and 1 M NaOH solutions, respectively), while 5-OHTry, which apparently degrades in alkaline solution, emitted the highest signal in neutral solution (ethanol/water (50:50 v/v)).

To obtain the AFOM under the experimental conditions for maximum RTP emission, optimizations of HA and NaDS concentrations were performed. The strongest emissions of Try and 5-OHTry were observed with 5 M KI. The NaDS optimum concentrations were, respectively, 0.1 M and 0.2 M. $TlNO_3$ enhance the Gra signal to its highest intensity at a concentration of 0.025 M, and so did NaDS at a concentration of 0.2 M. Employing these HA and NaDS concentrations, and preparing the analyte solutions at optimum pH, the LDRs of the calibration curves varied from two (Gra) to four (Try) orders of magnitude. The ALOD, for a sample volume of 5 µl, were in the nanogram range.

The sensitivity of SSRTP, therefore, has shown to be adequate for determining biogenic amines at the concentration levels usually required [1–3]. The proximity of the $\lambda_{exc}$ and $\lambda_{em}$ obtained, however, shows a lack of selectivity. The detection of one of these compounds in binary mixtures, for example, will require previous separation steps. HPLC–SSRTP analysis [41,42] will certainly overcome this limitation. The experimental parameters optimized in this study, therefore, could be employed in order to obtain maximum sensitivity.

Received 30 December 1994; revised 27 March 1995; accepted 3 April 1995

**Abstract**

A method for the preconcentration of trace amounts of tungsten as its thiocyanate complex, using a column filled with Amberlite XAD-1180 resin, is proposed. After elution with a small volume of acetone, the analyte was determined spectrophotometrically with potassium thiocyanate and stannous chloride. The influence of several ions, as interferents, is discussed. The proposed method was applied to the determination of tungsten in geological samples with good analytical results, such as recoveries of 95% or above, relative standard deviations of 6% or below ($n = 10$) and a detection limit of 12 $\mu g\, l^{-1}$.

## 1. Introduction

The direct determination of tungsten in various matrices such as geological samples, steels, natural waters, etc. has presented some problems, due to the low tungsten content and large concentration of accompanying elements. Many preconcentration and separation methods have been used for the determination of tungsten at low concentrations, such as liquid–liquid extraction [1,2], adsorption [3] and ion exchange [4,5].

Up to now, a tin(III) chloride–thiocyanate method has been combined with a preconcentration and separation procedure for the determination of tungsten [6–10]. Columns filled with Amberlite XAD resin have been used for the preconcentration and separation of trace amounts of several metal ions from various matrices [11–13]. However, little work in this field has been done using Amberlite XAD-1180 resin [14,15].

This paper describes a sorbent extraction system for the preconcentration of tungsten based on its solvent extraction as a thiocyanate complex. In this system, the sorption of the W(V)–thiocyanate complex is carried out by using Amberlite XAD-1180 resin. After elution, tungsten is determined spectrophotometrically. The procedure has been applied satisfactorily to the determination of tungsten in geological samples.

## 2. Experimental

### 2.1. Apparatus

A Hitachi 150-20 double-beam spectrophotometer equipped with a pair of 1 cm path length quartz cuvettes was used for the absorbance measurements. The determination of tungsten was performed at 400.0 nm.

* Corresponding author.

*SSDI* 0039-9140(95)01604-X

### 2.2. Reagents and solutions

All the chemicals used were of analytical grade, and aqueous reagents were prepared in doubly distilled, deionized water.

A 1000 μg $ml^{-1}$ stock solution of tungsten was prepared by dissolving an appropriate amount of sodium tungstate dihydrate in water and diluting it to 1000 ml. The stock solution was standardized gravimetrically by the tannic acid–phenazone method [16]. Appropriate standards and solutions of tungsten were prepared daily by dilution with water. $SnCl_2$ solution (20% (w/v)) was prepared in concentrated HCl. KSCN solution (25% (w/v)) was prepared in water.

Amberlite XAD-1180 resin (particle size, 0.1–0.2 mm; Rohm and Haas Co.) was prepared using the reagents and the washing steps as reported previously [17].

### 2.3. Column preparation

An Amberlite XAD-1180 column, 10 cm long and 1 cm in diameter, containing about 400 mg of resin (about a 20 mm bed) was used for the experiments. The column was prepared by aspirating a water slurry of Amberlite XAD-1180 (400 mg) into the glass column. It was equilibrated with 10–15 ml of 3 M HCl solution containing 1.0 ml of 25% KSCN and 1.0 ml of 20% $SnCl_2$, after which the column was used in the preconcentration study.

### 2.4. Column preconcentration

The column method was optimized using 25–100 ml of model solution containing 40 μg of tungsten. Solutions containing 0.2–5 ml of 25% KSCN and 0.2–5 ml of 20% $SnCl_2$ were prepared in 0.5–10 M HCl solution. The resulting solutions were drawn through the column at a flow rate of about 3–5 ml $min^{-1}$ by vacuum. The column was then washed with the blank solution and the retained tungsten was eluted into a 25 ml beaker with 2–10 ml of acetone at a rate of 1–2 ml $min^{-1}$. The eluate was evaporated to 0.5–1 ml on a hot plate, then cooled. The concentrated residue was transferred to a calibrated volumetric flask containing 1.5 ml of 25% KSCN and 1.5 ml of 20% $SnCl_2$, and the solution was made up to 5–10 ml with 3 H HCl solution. The tungsten concentration was determined spectrophotometrically as the thiocyanate complex at 400.0 nm [8].

### 2.5. Determination of tungsten concentration in geological samples

The geological samples were collected from Sorgun Yeni Çeltek Mine Quarry (Yozgat, Turkey). The decomposition procedure described by Welsch [18] was applied to the determination of the tungsten concentration in geological samples. The samples were ground and sieved to 80–100 mesh, 0.1–0.5 g amounts were weighed and transferred to 100 ml Teflon beakers, and 5 ml of concentrated nitric acid and 20 ml of concentrated HF were added to each beaker. The sample mixtures were evaporated to dryness, heated overnight at 125°C in a sand bath, and 2 ml of warm water and 8 ml of concentrated HCl were added to each residue and mixed. The mixtures were filtered through Whatman no. 42 filter paper, and 20 ml of water were added to each filtrate. The resultant solutions were drawn through the column as in the described procedure above.

## 3. Results and discussion

### 3.1. Effects of the reagents and hydrochloric acid concentration on the recovery of tungsten

The effects of the KSCN and $SnCl_2$ amounts on the recovery of tungsten on Amberlite XAD-1180 resin were examined. The recoveries were quantitative (above 95%) in the range 0.5–5 ml of 25% KSCN and in the range 0.2–0.5 ml of 20% $SnCl_2$ (Fig. 1).

The influence of the hydrochloric acid concentration on the retention of tungsten on Amberlite XAD-1180 resin is shown in Fig. 2. The highest sensitivity for tungsten was obtained in the HCl concentration range 2–9 M.

In all subsequent studies, 1.0 ml of 25% KSCN and 1.0 ml of 20% $SnCl_2$, as optimum amounts, were used. The concentration of the medium was made up to 3 M HCl with concentrated HCl.

### 3.2. Influences of eluent type and volume

The effects of the various eluents on the retention of tungsten on XAD-1180 resin was investigated. As can be seen in Table 1, elution with chloroform and diethyl ether was not quantitative. The recoveries of tungsten were quantitative when acetone, methanol, ethanol, *n*-butanol and *n*-propanol were used as eluent.

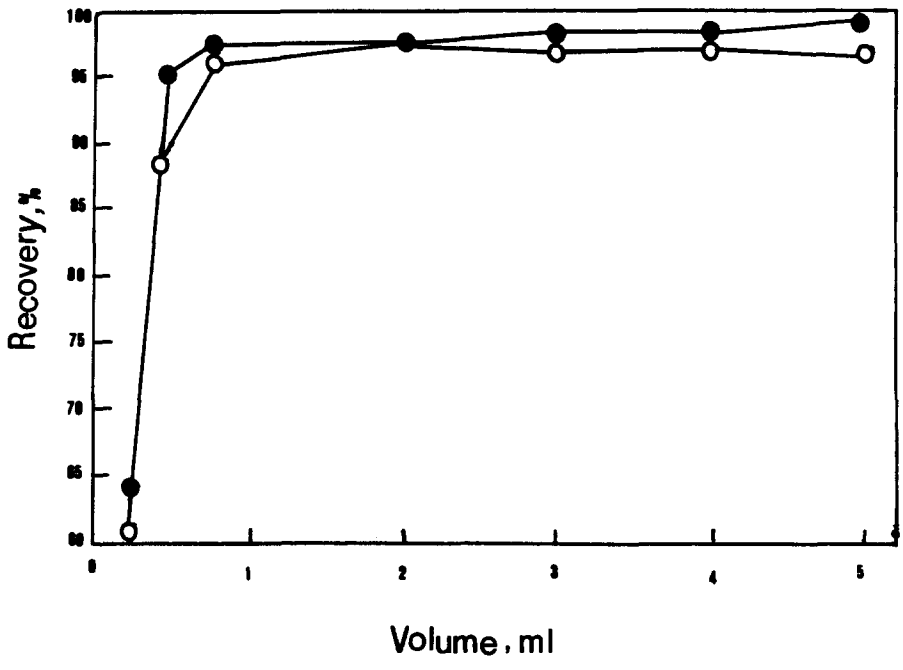

Fig. 1. Effect of the $SnCl_2$ and KSCN amounts on the recovery of tungsten on Amberlite XAD-1180 resin ((●) ml of 20% $SnCl_2$ and (○) ml of 25% KSCN).

However, the evaporation of *n*-propanol and *n*-butanol is slower than that of acetone. The period of elution with methanol and ethanol is longer than that for the other eluents. As a result, acetone was selected as eluent in subsequent work.

The influence of the eluent volume on the recovery of tungsten was studied by using various volumes of acetone varying from 2 to 30 ml. The recoveries were quantitative in the range 2–20 ml. In the subsequent studies, 10 ml of eluent were used.

### 3.3. *Effects of resin amounts and sample volume*

The effect of XAD-1180 resin amounts on the recovery of tungsten was studied by varying the amounts of resin from 200 to 800 mg. Quantitative recoveries were obtained in the range 300–600 mg of the resin; as the optimum, 400 mg of Amberlite XAD-1180 resin were used. The same resin sample was used repeatedly for 300 sample analyses at least without loss of activity.

The effect of sample volume was examined with solutions containing 40 μg of tungsten. Recoveries of the analyte concentrated into 2–10 ml of eluent from 50 to 500 ml sample volumes were found to be 97–100%. In this case, the highest preconcentration factor was found to be 250.

### 3.4. *Calibration graph and detection limit*

The calibration graph for a 100 ml sample was linear up to 200 μg of tungsten. The detection limit, based on three times the standard deviation of the blank, was 12 μg $l^{-1}$ ($n = 21$) and the relative standard deviation was 2% ($n = 10$) at the 40 μg of tungsten per 100 ml level.

### 3.5. *Effects of foreign ions*

The effects of foreign ions on the determination of tungsten were investigated. For these studies, different amounts of the ionic species were added to 40 μg of tungsten determined by the standard procedure. The results are summarized in Table 2. The tolerance limits of the foreign ions were obtained with a relative error not greater than 5%.

The results in Table 3 show that the recoveries were unaffected when the solution contained chloride, sulfate, iodide, fluoride, sodium, magnesium and calcium ions. However, $Cu^{2+}$, $Mo^{6+}$ and $Fe^{3+}$ ions interfere. The interference of copper was prevented by the addition of appropriate amounts of a 10% potassium ferricyanide solution [18]. $Fe^{3+}$ ions in the samples were completely reduced with 3 ml of 20% $SnCl_2$. Therefore, the interference effect of the $Fe^{3+}$ ions was prevented. The concentrations

[a] Sample volume, 250 ml; $n = 4$.

of $Co^{2+}$, $Zn^{2+}$, $Bi^{3+}$, $Cd^{2+}$ and $Mo^{6+}$ ions in the geological samples were found to be within their tolerance limits.

### 3.6. Tungsten content of geological samples

The method was applied to the determination of tungsten in geological samples collected from the Mine Quarry (Yozgat, Turkey). The results are given in Table 3. The determination of the tungsten content in the samples was also performed using a well-known and accepted extraction method [9]. There are no significant differences between the concentration values obtained by both methods at the 95% confidence level. However, better precision is obtained with the column method.

## 4. Conclusion

The Amberlite XAD-1180 column method was applied to the determination of the tungsten concentration in geological samples, and accurate results were obtained. The results obtained using this column method and the extraction method are in agreement. The

Table 3
Concentration of tungsten in geological samples collected from the Sorgun Yeni Çeltek Mine Quarry (Yozgat, Turkey)

| Depth (m) | Concentration of tungsten ($\mu g\ g^{-1}$)[a] | | | |

# The polarographic and voltammetric behaviour of the copper(II) mitoxantrone complex and its analytical application

Hongfei Wang, Erbing Hua, Pin Yang *

*State Key Laboratory of Coordination Chemistry, Nanjing University, Nanjing, People's Republic of China*

Received 13 December 1994; revised 28 March 1995; accepted 3 April 1995

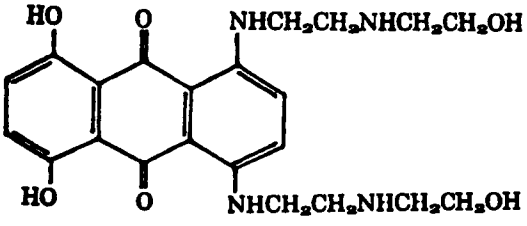
**Abstract**

The polarographic and voltammetric behaviour of the copper(II)–mitoxantrone complex have been studied. A well-defined linear sweep voltammetric peak was obtained at −0.275 V (vs. Ag/AgCl) or −0.325 V (vs. SCE) in ammonia–ammonium chloride (20 mmol $l^{-1}$, pH 9.0). The characteristics of the peak have been examined in detail. The experimental results show that the reduction of the copper(II) mitoxantrone complex is irreversible and the peak displays adsorption characteristics at the dropping mercury electrode. A mechanism is proposed for the reduction of the complex, comprising one-electron reduction of the copper(II) of the complex, is reduced directly in the complex form. A single-sweep oscillopolarographic method was developed for the determination of copper(II). The peak current is proportional to the concentration over the range $5 \times 10^{-8}$–$2 \times 10^{-5}$ mol $l^{-1}$. The method reported here has the advantage that the interference of many common metal ions is small.

## 1. Introduction

Polarography and voltammetry are very sensitive methods for the determination of many trace metal ions; for example, stripping voltammery is based on concentration by electrolysis. However, the formation of intermetallic compounds with coexisting metal ions at the electrode can cause serious errors [1]. Adsorptive accumulation is useful for concentrating an analyte selectively for voltammetric analysis or for concentrating the metal ions when they are converted into adsorbable complexes by reaction with an organic ligand [2,3]. The voltammetric determination of copper(II) based on the adsorptive accumulation of the Cu(II)-5-Br-PADAP complex on a hanging mercury drop electrode has been reported [4], but the interference of many common metal ions is still obvious.

In this paper, the polarographic and voltammetric behaviour of the Cu(II) complex with mitoxantrone (1,4-dihydroxy-5,8-bis(2-((2-hydroxyethyl)amino)ethylamino)-9,10-anthracenedione; MX) was studied by various electrochemical methods. The structure of mitoxantrone is shown in Scheme 1. The characteristics of the reduction peak and the reduction mechanism have been examined in detail. Furthermore, the conditions of complexation including the coordination group and the



Scheme 1. Structure of mitoxantrone.

* Corresponding author. Present address: Institute of Molecular Science, Shanxi University, Taiyuan 030006, People's Republic of China.

*SSDI* 0039-9140(95)01605-8

coordination configuration were analyzed. The stability constants of the complex were also calculated by pH titration. MX is a ligand more fitted for the voltammetric determination of copper(II); the method described here has the advantage of little interference from many coexisting metal ions. On the basis of the above results, the cause of the small amount of interference of many common metal ions was discussed.

## 2. Experimental

### 2.1. Apparatus

A BAS-100A electrochemical analytical instrument (Bioanalytical System, Inc., USA), with a PAR 303 electrode system (SMDE, DME, HMDE) as the working electrode, a saturated Ag/AgCl reference electrode, and a platinum wire as auxiliary electrode, was used. All figures were drawn on a DMP-40 digital plotter (USA). A JP-2 single-sweep oscillopolarograph (Chengdu Instrument Factory, China) with a saturated calomel electrode (SCE) as the reference electrode was used for the quantitative analysis of the samples. The absorption and fluorescence spectra were measured on a UV-365 spectrophotometer (Shimadzu) and an RF-850 fluorescence spectrophotometer (Hitachi), respectively. The pH was recorded by means of a pHS-2 acidic meter (Shanghai Leici Factory, China).

### 2.2. Reagents

Mitoxantrone (chromatographically pure) was provided by the Zhenan Pharmaceutical Corporation, China. A $2 \times 10^{-4}$ mol $l^{-1}$ stock solution of mitoxantrone was prepared by dissolving an appropriate amount of MX in ammonia–ammonium chloride (20 mmol $l^{-1}$; pH 9.0). A $1 \times 10^{-2}$ mol $l^{-1}$ stock solution of copper(II) was prepared by dissolving copper metal (99.999%) in 5% nitric acid. The stock solutions were transferred and diluted with ammonia–ammonium chloride (20 mmol $l^{-1}$; pH 9.0) to give the working solutions before the measurements. Other chemicals were of analytical reagent grade, and deionized, distilled water was used.

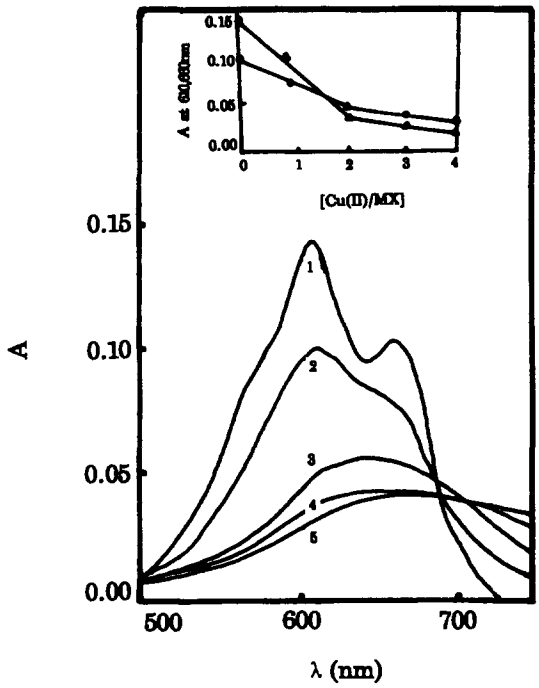


Fig. 1. Absorption spectra for different molar ratios of copper(II)/MX. 1, $1.0 \times 10^{-5}$ mol $l^{-1}$ MX; 2, 1:1; 3, 2:1; 4, 3:1; 5, 4:1.

### 2.3. Procedure

Appropriate amounts of mitoxantrone and the copper(II) solutions were transferred to a 10 ml volumetric flask, then ammonia–ammonium chloride (20 mmol $l^{-1}$; pH 9.0) was added, and the solution was diluted to give the final volume. The solution was deaerated by the passage of pure nitrogen for 5 min. The potentials were scanned in a negative direction over the range $-100$– $-500$ mV; all measurements were carried out at room temperature.

## 3. Results and discussion

### 3.1. Complexation properties

On adding copper(II) to $1 \times 10^{-5}$ mol $l^{-1}$ MX solution, obvious changes in the absorption spectra and fluorescent spectra were observed, as shown in Figs. 1 and 2. When the molar ratio of [Cu(II)]/[MX] was increased to 2:1, the absorption spectra did not obviously change, and the fluorescence emission peak was quenched complemently. On adding copper(II) to the $1 \times 10^{-5}$ mol $l^{-1}$ MX solution, a new reduction peak appeared at $-0.275$ V (vs. Ag/AgCl), as shown in Fig. 3. The peak at

$-0.817$ V (vs. Ag/AgCl) corresponds to the reduction potentials of the 9,10-quinone of MX [5]. Adding MX to $1 \times 10^{-5}$ mol $l^{-1}$ copper(II) solution determined the height of the peak current at $-0.275$ V; when the [MX]/[Cu(II)] ratio was 1:2, the height did not change and then levelled off. This indicated that one molecule of drug can bind with two Cu(II) ions. The height of the peak current at $-0.275$ V increased with added amounts of copper(II) and then levelled off; however the peak potential and peak current at $-0.817$ V changed very little. This showed that the Cu(II) ion complexes with nitrogen atoms of the side-chain of MX, but not with the oxygen atoms of the hydroxyl groups at the 1,4 position and the oxygen atoms of the carbonyl function at C9 and C10. The Pd(II)–MX complex has been studied by analyzing the absorption spectra of MX and ametantron (a drug without the 1,4-hydroxyl group of MX) [6]; the results showed that the Pd(II) ion is only bound to the nitrogen atoms of the side-chain. This study is similar to ours, and supports our points also. The nitrogen atoms of the drug molecules are candidates for the binding to copper(II), taking into account steric hindrance and that Cu(II)–amine complexes are usually tetracoordinated.

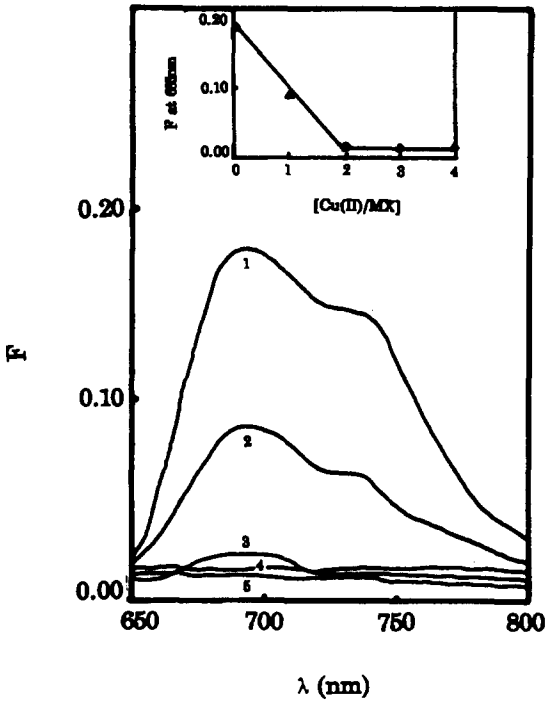

Fig. 2. Fluorescence spectra for different molar ratios of copper(II)/MX. 1, $1.0 \times 10^{-5}$ mol $l^{-1}$ MX; 2, 1:1; 3, 2:1; 4, 3:1; 5, 4:1.

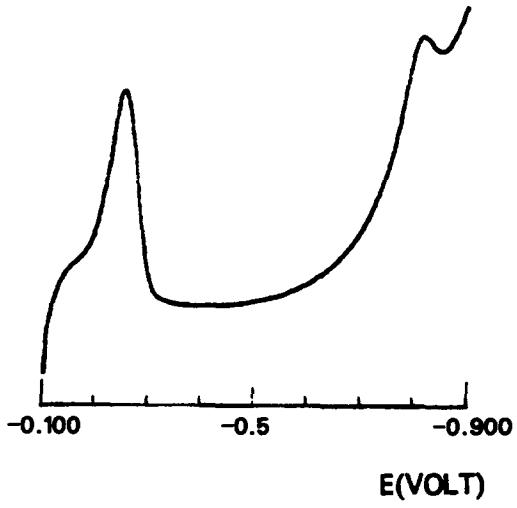

Fig. 3. Linear sweep voltammogram of the copper(II)–MX complex ($1.0 \times 10^{-6}$ mol $l^{-1}$ Cu(II); $1.0 \times 10^{-5}$ mol $l^{-1}$ MX) in ammonia–ammonium chloride (20 mmol $l^{-1}$, pH 9.0) solution. (Scan rate, 250 mV $s^{-1}$; rest time, 10 s.)

We suggest that one Cu(II) ion is bound to the two nitrogen atoms of the side-chain at C5 of the drug molecule, and the second Cu(II) ion to the two nitrogen atoms of the side-chain at C8 of the drug molecule; the other two coordination positions of copper(II) are $NH_3$ or $H_2O$. A tetrahedral coordination geometry is preferable.

The pH titration curves are shown in Fig. 4. These show that the complex formed above

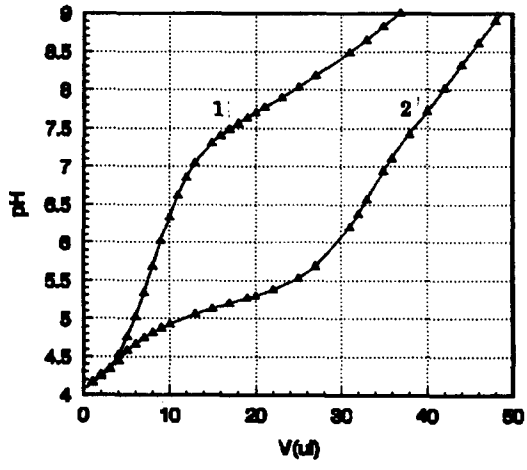

Fig. 4. pH titration curves. 1, MX ($1 \times 10^{-4}$ mol $l^{-1}$). 2, MX + Cu(II) (1:1; $1 \times 10^{-4}$ mol $l^{-1}$) ($I = 0.1$ N $KNO_3$; $T = 25$°C; $N_2$ flow).

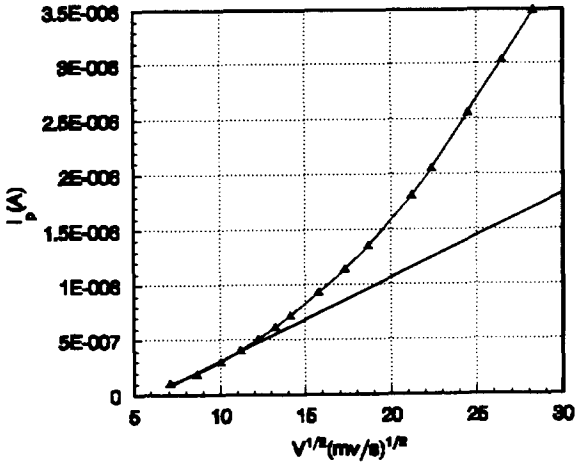

Fig. 5. Variation of $i_p$ with $v^{1/2}$.

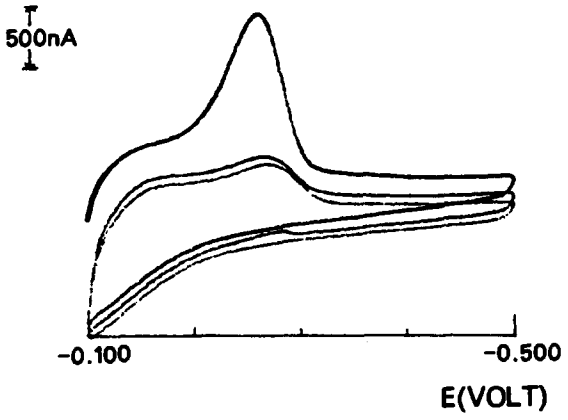

Fig. 6. Repetitive cyclic voltammogram of copper(II)–MX complex ($1.0 \times 10^{-6}$ mol $l^{-1}$ Cu(II); $1.0 \times 10^{-5}$ mol $l^{-1}$ MX) in ammonia–ammonium chloride (20 mmol $l^{-1}$, pH 9.0) solution. (Scan rate, 250 mV $s^{-1}$; rest time, 10 s.)

pH 4.5. From the equation of material equilibrium and the non-linear least-squares method [7], the stability constants of the complex were calculated

$$\log \beta_{CuHL} = 9.9, \log \beta_{CuH_2L} = 6.5$$

where subscript L denotes the ligand.

### 3.2. Adsorption properties

The effects of rest time, starting scan potential and scan rate ($v$) on the peak current were investigated. The results indicated that the peak current increased as the rest time increased, and decreased as the starting potential became more negative. If the rest time and starting scan potential are fixed, plotting $i_p$ against $v^{1/2}$ gave an ascending curve, shown in Fig. 5, according to the Randles–Sevcik equation, in a linear diffusion-controlled process, $i_p \propto v^{1/2}$. This resulted in an upward inclined curve, which indicated the adsorptive nature of the reduction current and that the reductant is adsorbed on the SMDE [8].

The electrocapillary curve showed that the surface tension of the mercury drop decreased in the presence of $1.0 \times 10^{-6}$ mol $l^{-1}$ Cu(II)–MX complex. The peaks decreased with the addition of surfactant (0.01 mol $l^{-1}$ sodium dodecyl sulfonate, 0.002% Triton X-100). The temperature coefficients are 1.97% per °C (5.5–18.0°C), 1.77% per °C (18.0–30.5°C) and 0.61% per °C (30.5–44°C), respectively. These are all the characteristic feature of adsorptive wave.

In order to elucidate further the electrode reaction of the complex, a repetitive cyclic voltammogram (Fig. 6) at the SMDE was recorded. In the cyclic voltammogram, the reduction peak is observed on the cathodic branch; no oxidation peak is observed on the anodic branch. The cathodic peak current decreased in the second and following cycles. This indicated that the electrode reaction is irreversible and that the peak current is influenced by the adsorption of reactant.

The above experimental results indicate that the reduction peak of the complex is an irreversible polarographic wave having adsorption characteristics.

### 3.3. Mechanism of the reduction

The effect of scan rate ($v$) on the peak potential ($E_p$) was determined by linar sweep voltammetry (LSV); the results are shown in Table 1. These indicated that $E_p$ shifts to a more negative direction with increasing scan rate. From the equation [9]

Table 1
The effect of scan rate ($v$) on peak potential ($E_p$)

| $v$ (mV $s^{-1}$) | $E_p$ (mV) | $v$ (mV $s^{-1}$) | $E_p$ (mV) |
|---|---|---|---|
| 50 | −231 | 300 | −275 |
| 75 | −240 | 350 | −281 |
| 100 | −247 | 400 | −284 |
| 125 | −253 | 450 | −288 |
| 150 | −258 | 500 | −290 |
| 175 | −260 | 600 | −292 |
| 200 | −264 | 700 | −297 |
| 250 | −271 | 800 | −301 |

$$E_p = E^\circ + RT/\alpha nF[\ln(k_s/D^{1/2}) - 0.5\ln(\alpha nFv/RT) - 0.78]$$

where $\alpha$ is the transfer coefficient, and $n$ is the number of electrons, a value of $\alpha n$ of 0.499 was calculated from the slope of the line (correlation coefficient, $r = 0.9989$) and $\alpha = 0.5$, so $n = 0.998$, namely, the number of electrons transfered in the reaction was equal to 1. The peak potential of the complex between MX, $\Delta E_p$, is independent of pH and the concentration of Cu(II). Therefore the reduction mechanism of the Cu–MX complex is such that it does not dissociate but is directly reduced in the complex form [9]. According to the above results, the following reduction mechanism can be proposed

$$Cu(II) + 1/2MX \rightleftharpoons [Cu(II)-MX_{1/2}]ads$$

$$[Cu(II)-MX_{1/2}]ads + e \rightleftharpoons Cu(I)-MX_{1/2}$$

### 3.4. Analytical application

The dependence of the derivative peak heights on concentration was investigated by single-sweep oscillopolarography (SSOP). The calibration curve demonstrates good linearity over the range $5 \times 10^{-8}$–$2 \times 10^{-5}$ mol $l^{-1}$, with a correlation coefficient of 0.9985. The limit of detection is $1 \times 10^{-8}$ mol $l^{-1}$. The peak current is stable over the range of continuous measurements for 2 h. The precision of the SSOP determination of copper(II) is excellent; at a concentration of $5 \times 10^{-7}$ mol $l^{-1}$, the relative standard deviation is 2.9% ($n = 5$).

The influence of metal ions was investigated by adding them to a solution containing $1 \times 10^{-6}$ mol $l^{-1}$ Cu(II) and $1 \times 10^{-5}$ mol $l^{-1}$ MX. One-thousandfold amounts of K(I), Na(I), Ca(II), Mg(II) and Mn(II), and ten-to-fiftyfold amounts of Fe(III), Cr(III), Co(II), Cd(II), Ni(II) and Zn(II) did not interfere. The results are very encouraging.

We think that the interference of the co-existing metal ions arises in two ways. First, both the interfering metal ions and the ions to be determined can complex with the same group on the organic ligand; this binding contest has an effect on the normal complexation and reduction of the determined metal ions. Second, the reduction potentials of the interfering and determined metal ions in the same matrix are close to each other; this may have an effect on the normal shape of the reduction peak of the determined ions. In the system described here, for example, Fe(III) can complex with MX, but it complexes with the oxygen atoms of 9,10-quinone, not with the nitrogen atoms of the side-chain, which is the coordination group of the Cu(II) ion. Therefore, it does not influence the complexation of Cu(II) with MX and the reduction of Cu(II). Although Zn(II), Ni(II) and Co(II) in the matrix of the system produce stronger reduction peaks, the reduction potentials are more negative than $-0.6$ V, far from the reduction potential of the Cu(II)–MX complex, so they do not influence the determination of Cu(II) due to a change in the shape of the reduction peak. According to the Irving-Williams rule, complexes of the Cu(II) ion with dozens of ligands have the highest stability among the divalent metal ions of first-row transition elements. The stability constants of the Cu(II) ion with ligands such as $NH_2$–$CH_2$–$CH_2$–$NH_2$, $OH^-$, and $NH_3$, are thousands of times higher than those of Zn(II), Ni(II), Co(II), etc. [11]. Therefore, although Zn(II), Co(II) and Ni(II) may complex with MX, under the condition of sufficient ligand, the effect of the binding contest can be eliminated. From the above study and analysis, we think that selecting the appropriate ligand and increasing the amount of organic ligand are important for improving the analytical selectivity and sensitivity.

The SSOP method described here is sensitive, rapid, reliable, and simple to perform, and the interference of many common metal ions in this system is small; thus it is very suitable for analytical application in practical systems.

## Acknowledgments

We are very grateful for the help of Professor Jinhao Pan, Gerong Zhou and Huizhi Fan. Part of the work was completed in their laboratory.

Received 27 November 1994; revised 31 March 1995; accepted 4 April 1995

**Abstract**

A method is described for the determination by solid phase spectrophotometry (SPS) of trace amounts of vanadium in natural water and crude petroleum samples. The procedure is based on fixation on a dextran-type anion exchanger of the complex V(IV)–Eriochrome Cyanine R. The absorbance of the gel, at 563 and 750 nm, packed in a 1 mm cell, is measured directly. Vanadium can be determined in the 0.6–25.0 $\mu g\, l^{-1}$ range with a relative standard deviation of 2.2%. The comparison of the SPS method and the gallic acid persulphate method shows that the linearity, analytical sensitivity and precision were better for the SPS method, and that the latter method has lower detection and quantification limits than the gallic acid persulphate method.

## 1. Introduction

The toxicity of vanadium and its compounds and the fact that its industrial use produces occupational health problems are well known [1,2]. In addition, crude petroleum and its derivatives produce an environmental problem, due to the presence of vanadium in the form of porphyrin complexes in these products [2]. However, it has been established that there is a relationship between the presence of vanadium at the microgram per litre level in tap water and the prevention of the cardiopathies [3]. Therefore the determination of vanadium in biological and environmental samples is necessary [4,5], requiring sensitive techniques [6,7].

Triphenylmethane reagents have been widely used for the spectrophotometric determination of vanadium(IV), producing a coloured compound [8]. One of these, Eriochrome Cyanine R (ECR), is a good chromogenic reagent for the determination of V(IV), and its ternary complexes with cationic surfactants have been described and used for spectrophotometric analysis in solution [9]. Ascorbic acid can be used as a reducing agent; V(V) is reduced to V(IV) and a complex between ECR and V(IV) is formed [8,10].

Solid phase spectrophotometry (SPS) is a methodology that is based on the production of a chromogenic compound between the analyte and an appropriate reagent, the preconcentration of this compound on a solid matrix, usually an ion exchanger, and the direct measurement of the absorbance in the solid phase. This provides an increase in selectivity and sensitivity for SPS methods with respect to solution methods [11,12].

The fixation of the V(IV)–ECR complex on a dextran-type exchanger is discussed here. The application of SPS methodology has produced a higher sensitivity and a lower detection limit than is given by the solution methods for the determination of vanadium at microgram per litre levels.

*SSDI* 0039-9140(95)01608-2

A comparison was made of the proposed SPS method and the gallic acid persulphate method [13,14]. It was concluded that the linearity, analytical sensitivity and precision were better with the SPS method than with the gallic acid persulphate method, and that the detection and quantification limits were lower for the SPS method.

The proposed method was applied to the determination of vanadium in natural water and crude petroleum samples, and the results were compared with those obtained by the gallic acid persulphate method and the ASTM method [15], respectively. No significant differences were observed.

## 2. Experimental

### 2.1. Reagents

All chemicals used were of analytical grade unless stated otherwise. The water used for the dilution of the reagents and samples was reverse-osmosis quality water. All experiments were carried out at room temperature.

Eriochrome Cyanine R (ECR; Carlo Erba) solutions of various concentrations were prepared by dissolving the necessary amount of dye in reverse-osmosis water and adjusting the final acid concentration to $5 \times 10^{-3}$ M with HCl. The solutions were stored under refrigeration. Under these conditions the solutions are stable for 1 day.

Vanadium(V) stock solution ($1\ g\ l^{-1}$) was prepared by dissolving 0.2297 g of ammonium metavanadate (Merck) in 1 ml of concentrated nitric acid and 75 ml of reverse-osmosis water, and dilution to volume with reverse osmosis water in a 100 ml standard flask. The working standard solution was freshly prepared every day by dilution with reverse-osmosis water.

Ascorbic acid (PanReac) was used in the solid state, due to the instability of ascorbic acid solutions.

As a solid ion exchanger, Sephadex DEAE A-25 anion exchanger (Sigma) was used in the chloride form as received from the supplier and without pretreatment in order to avoid contamination.

Buffer solutions of the required pH were prepared from 2 M sodium acetate solution (Merck) and 2 M acetic acid (Merck).

### 2.2. Apparatus

The apparatus used included a Perkin–Elmer Lambda 2 UV/Vis spectrophotometer equipped with 1 mm cells and connected to a IE 486 computer, an Agitaser model 2000 rotating-bottle agitator, and a Crison Digit-501 pH meter with a combined glass–Calomel electrode.

### 2.3. Absorbance measurements

The absorbance of the reaction product fixed on the exchanger was measured in a 1 mm cell at 563 and 750 nm (the latter is within the range where the exchanger only causes attenuation of light) against a 1 mm cell well-packed with exchanger equilibrated with water. The absorbance of the blank (a 1 mm cell packed with resin equilibrated with blank solution) was measured at the same wavelengths. The blank absorbance results from the Eriochrome Cyanine R fixed on the exchanger.

The net absorbance, $A_{NC}$, for the complex was obtained from [12] $A_{NC} = A_{complex} - A_{blank}$, where $A_{complex} = A_{563} - A_{750}$ (for the sample) and $A_{blank} = A_{563} - A_{750}$ (for the blank).

### 2.4. Standard procedure

The following, in this order, were introduced into a 2000 ml polyethylene bottle: a 1000 ml sample containing 0.6–25.0 $\mu g\ l^{-1}$ of V(V), 5 ml of 2 M buffer solution (pH 5.0), 0.2 g of ascorbic acid, 3 ml of $7.46 \times 10^{-3}$ M ECR solution and 0.080 g of the Sephadex DEAE A-25 anion exchanger. The mixture was shaken mechanically for 45 min. The coloured exchanger beads were then collected by filtration under suction and, with the aid of a pipette, were packed into a 1 mm cell together with a small portion of the filtrate. The cell was centrifuged for 1 min at 25 *g*. A blank solution containing all the reagents was prepared in the same way as described for the sample. The absorbances at 563 and 750 nm for the sample and the blank were measured against a 1 mm reference cell, similarly packed with exchanger equilibrated with water, and the net absorbance, $A_{NC}$, was obtained as described in section 2.3.

For a 250 ml sample system, solutions containing 3.0–130.0 $\mu g\ l^{-1}$ of V(V), 5 ml of 2 M buffer solution (pH 5.0), 0.3 g of ascorbic acid, 1 ml of $7.46 \times 10^{-3}$ M ECR solution and

0.080 g of the Sphadex DEAE A-25 anion exchanger were added. The mixture was shaken mechanically for 15 min. The absorbance of the coloured beads was measured as above.

### 2.5. Treatment of the sample

*Natural water samples*

The water samples were preserved by the addition of nitric acid (2 ml of concentrated nitric acid per litre), and were collected in a polyethylene container that had been carefully cleaned with nitric acid. Prior to the measurements, the water sample was filtered through 0.45 μm pore-size membrane filters (Millipore, type HA).

*Crude petroleum samples*

A suitable quantity of the three different crude petroleum samples (between 7 and 25 g in order to permit also the application of the ASTM method) was treated with concentrated sulphuric acid (1 ml per gram of sample) with continuous agitation to avoid foam formation, followed by combustion of the carbonaceous ash at 525 ± 25°C. The inorganic residues were treated for 10–15 min with 20 ml of hydrochloric acid (1:1). After complete dissolution of the ash and concentration to 3–4 ml of solution 0.2 ml of concentrated nitric acid was added and the solutions were heated gently. The solutions were finally diluted to 50 ml with reverse-osmosis water. The pH of the samples, prior to the determination, was adjusted with 2 M NaOH (0.5–1 ml).

## 3. Results and discussion

### 3.1. Absorption spectra

In solution, ECR reacts with vanadium(IV) at pH 4.9 to form a red complex having a maximum absorbance at 550 nm [9]. In addition, ternary complexes are formed at pH 4.5–5.2 in the presence of cationic surfactants, producing a hyperchromic effect and a bathochromic shift of the absorption maximum (580–620 nm), whereas vanadium(V) does not form ternary complexes with these cationic surfactants [9,10].

Vanadium(V) does not react with ECR in the presence of anion exchanger while the complex obtained from the reaction between vanadium(IV) and ECR at pH 5.0 is fixed on the Sephadex anion exchanger (Fig. 1). The wavelength and the absorbance of the compound formed and fixed on the exchanger vary when the [ECR]/[V] molar ratio is modified. A red colour is obtained with an absorption maximum between 560 and 593 nm and a small increase in the absorbance using the Sephadex DEAE A-25 anion exchanger (Fig. 1, spectra a and b). Furthermore, a significant hyperchromic effect is also observed in relation to the binary complex of vanadium(IV) with ECR in solution at pH 5.0 (Fig. 1 spectrum c). This change is similar to that observed, in solution, between the binary complex (V(IV)–ECR) and the ternary system (V(IV)–ECR–cationic surfactants).

The complex of vanadium(IV) with ECR is anionic in nature due to the fact that it is not fixed on cation exchangers.

### 3.2. Optimization of conditions

*pH dependence*

The optimum pH for the formation and fixation of the complex falls in the range 4.7–5.0 (Fig. 2). At pH values below 4.0 the complex was not fixed on the exchanger and at pH values above 5.1 the net absorbance, at 563 nm, decreased due to two opposing effects: the increase in the absorbance of the blank and

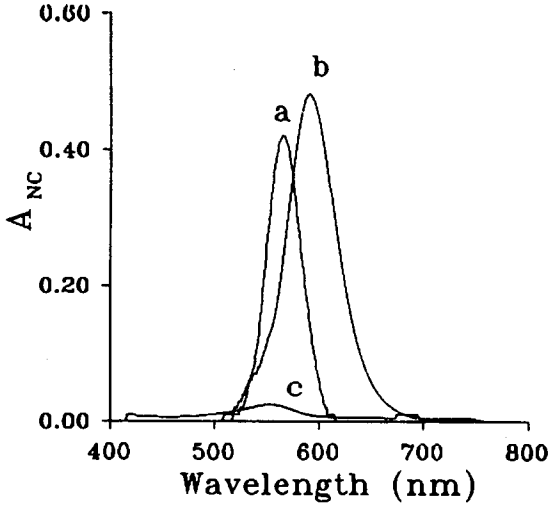

Fig. 1. Net absorption spectra of the Vanadium(IV)–ECR complex at pH 5.0. Spectra a and b, with the ion exchanger: spectrum a, $[ECR] = 2.24 \times 10^{-5}$ M, 0.2 g of ascorbic acid; spectrum b, $[ECR] = 3.73 \times 10^{-5}$ M, 0.2 g of ascorbic acid ($[V] = 1.96 \times 10^{-7}$ M; 80 mg of Sephadex DEAE A-25; sample volume, 1000 ml; stirring time, 45 min; optical path length, 1 mm). Spectrum c, in aqueous solution ($[V] = 1.57 \times 10^{-6}$ M, $[ECR] = 2.24 \times 10^{-5}$ M; 0.2 g of ascorbic acid; optical path length, 10 mm).

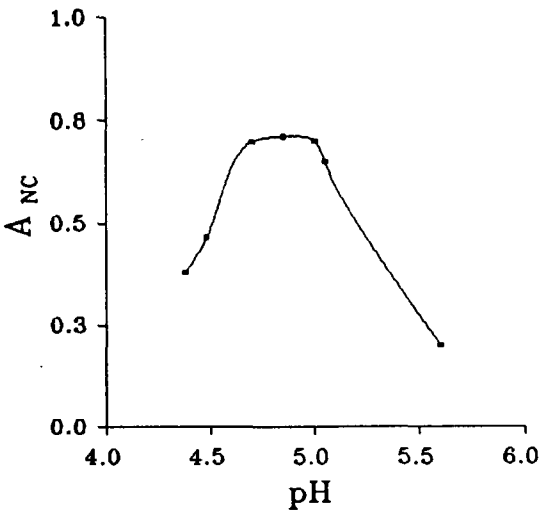

Fig. 2. Influence of pH on the colour development (conditions: 50 μg · l$^{-1}$ of vanadium; 1.87 × 10$^{-5}$ M ECR; 0.3 g of ascorbic acid; 80 mg of Sephadex DEAE A-25; stirring time, 20 min; sample volume, 1000 ml.)

the decrease in the absorbance of the V(IV)–ECR complex. We chose pH 5.0 as the best pH value for the standard procedures. The best of the buffer systems examined was acetic acid–sodium acetate.

*Influence of buffer concentration*

The effect of buffer concentration on the absorbance of the blank and the absorbance of the V(IV)–ECR complex was tested for concentrations in the range 0.01–0.12 M. Within this range, an increased absorbance of the blank and the complex as observed. Between buffer concentrations of 0.01 and 0.04 M the net absorbance was practically constant, due to a similar increase in absorbance both in the blank and in the sample. Meanwhile, in the range 0.04–0.12 M the absorbance of the blank increased to a greater degree than the sample absorbance, and the decrease in the net absorbance in this interval was very nearly 55%. Therefore the use of 5 ml of 2 M acetic acid–sodium acetate buffer was chosen for both the 1000 ml and the 250 ml sample systems, with the aim of maintaining the pH value at 5.0 despite the addition of ascorbic acid.

*Influence of ascorbic acid and ECR concentrations*

A certain amount of ascorbic acid is necessary due to the fact that this is the reducing agent. The absorbance of the complex is constant between molar ratios of 3000 and 9200 (ascorbic acid to vanadium). Molar ratios greater than 9200 produce a larger increase in the absorbance of the blank than the absorbance of the complex. Hence, to propose two methods for different ranges of vanadium concentrations, 0.2 g of ascorbic acid (a molar ratio of about 6000) was selected for the 1000 ml sample system and 0.3 g (a molar ratio of about 8600) for the 250 ml sample system. Furthermore, an optimum range of molar ratios (ascorbic acid to ECR) of between 25 and 250 was obtained for both methods, in which the net absorbance of the complex was practically invariable. Thus, as a consequence of the quantity of ascorbic acid employed in each sample system, a concentration of 2.98 × 10$^{-5}$ M was required for the 250 ml sample system, and for the 1000 ml sample system the necessary reagent concentration was 2.24 × 10$^{-5}$ M.

*Other experimental conditions*

The optimum stirring time was 15 min for the 250 ml sample system and 45 min for the 1000 ml sample system. The fixed compound was stable for at least 50 min after equilibration.

The reproducibility of the method is improved if the cells packed with the solid phase are centrifuged before spectrophotometric measurements are taken [16]. The time of centrifugation used here was 1 min at 2500 rev min$^{-1}$ (25*g*).

The quantity of exchanger must be chosen as being a compromise between obtaining the highest absorbance (minimum quantity of exchanger) and working under adequate operational conditions (between 0.025 and 0.100 g of exchanger). An quantity of 0.08 g of exchanger was chosen as the most suitable for our purpose in this occasion. However, the use of lower quantities, within the preceding range, is possible, and this will permit us to develop methods with different sensitivities.

The order of addition used here was vanadium + buffer + ascorbic acid + ECR + exchanger.

*3.3. Nature of the fixed complex*

The probable nature of the species fixed on Spehadex was established at the working pH of 5.0 using the Yoe–Jones method and a log–log plot. The plot of the logarithm of the distribution ratio versus the logarithm of the ECR

Table 1
Analytical parameters

| Parameter | Sample volume (ml) | |
|---|---|---|
| | 250 | 1000 |
| Intercept | $-6.8 \times 10^{-3}$ | $-9.9 \times 10^{-3}$ |
| Slope (1 $\mu g^{-1}$) | 0.010 | 0.044 |
| Linear dynamic range ($\mu g\,l^{-1}$) | 3.0–130 | 0.6–25 |
| Correlation coefficient | 0.995 | 0.999 |
| RSD (%) | 2.2 | 2.2 |
| Detection limit ($\mu g\,l^{-1}$) | 3.0 | 0.6 |
| Quantification limit ($\mu g\,l^{-1}$) | 10.0 | 2.0 |

concentration gave a slope of 1.1, and using a fixed ECR concentration, the plot of the logarithm of the distribution ratio versus the logarithm of the V(IV) concentration gave a slope of 1.1. Moreover, the Yoe–Jones method showed a ratio [ECR]/[V(IV)] = 1.1. The results show that the stoichiometry of the V(IV)–ECR complex fixed on the anionic exchanger is 1:1.

### 3.4. Analytical data

The calibration graphs are reasonably linear over the concentration ranges 3.0–130.0 $\mu g\,l^{-1}$ of vanadium for the 250 ml sample system and 0.6–25.0 $\mu g\,l^{-1}$ for the 1000 ml sample system using 0.080 g of exchanger. The analytical parameters are shown in Table 1.

The reproducibility was established for a series of nine independent determinations at 52 $\mu g\,l^{-1}$ of vanadium for the 250 ml samples and 10 $\mu g\,l^{-1}$ for 1000 ml samples (Table 1).

The fluctuations in the background absorbance measured for the blank, calculated as the average of ten determinations and expressed as SD units, for the 250 ml and 1000 ml sample systems were 0.010 A and 0.008 A, respectively. The IUPAC detection limit ($K = 3$) [17] and the quantification limit ($K = 10$) [18] were calculated for both sample systems (Table 1). From the data shown in Table 1, it can be seen that the 1000 ml sample system has a lower detection limit (0.6 $\mu g\,l^{-1}$) than obtained by the gallic acid persulphate method (1.92 $\mu g\,l^{-1}$) [3] and an even lower one than than those for some sensitive techniques such as flame atomic absorption spectrometry or atomic emission spectrometry [6].

The sensitivities of the proposed methods, expressed as Sandell's index $S$ (concentration ($\mu g\,ml^{-1}$) of vanadium required to obtain an absorbance of 0.001 in a 1 cm cell), are compared in Table 2 with those of spectrophotometric procedures in published methods. The higher sensitivity of our methods is apparent.

### 3.5. Effects of foreign ions

The effect of foreign ions on the determination of vanadium at the 40 $\mu g\,l^{-1}$ level was studied, following the above procedure, for a 250 ml sample system. Tolerance is defined as the amount of foreign ions which produces an error of $\pm 5\%$ in the determination of the analyte. The results are summarized in Table 3.

In order to apply the method to the determination of vanadium in water and crude petroleum samples, the interferences of those species commonly found in these types of samples was studied. The interference was negative for Pb(II), Cu(II), Mn(II), Zn(II) and $PO_4^{3-}$, and positive for the other ions.

The interference level, however, can be reduced by diluting the samples, taking into account the sensitivity on the sample volume. Furthermore, this is possible without reducing the accuracy and at the same time maintaining the simplicity and the short duration of the analysis (Table 1).

For the purpose of studying the recovery in the 1000 ml sample system, a synthetic water sample was prepared having 10 ppb of V(V) and different concentrations of various metallic ions: Fe(III), 40 ppb; Mn(II), 50 ppb; Cu(II), 15 ppb; Zn(II), 40 ppb; U(VI), 10 ppb; Co(II), 20 ppb; Mo(VI), 40 ppb; Ni(II), 50 ppb; Be(II), 5 ppb and Al(III), 30 ppb. A recovery of 98.4% was obtained as the average of six determinations and with an RSD of 2.3%.

Table 2
Comparison of the sensitivities of some vanadium determination methods

| Method | $10^6 S$ ($\mu g\ ml^{-1}$) | Reference |

### 3.6. Comparison of SPS and gallic acid persulphate method

As it is difficult to obtain analytical data from the literature in order to compare methods, we developed a comparative study of the SPS method and the standard method for the determination of vanadium at the microgram per litre concentration in water samples [3], i.e. the gallic acid persulphate method. We choose for the study an application of a statistical model for single linear regression on the calibration graphs [19]. This allows a comparative study under similar experimental conditions using a relatively small number of experiments. In addition, this model has the advantage that the errors inherent in the calibration graphs are included.

We performed an analysis in triplicate of five samples with the vanadium concentration ranging from 0.0 to 20.0 $\mu g\ l^{-1}$ by both the SPS method (1000 ml sample system) and the gallic acid persulphate method (final volume, 12 ml). Table 4 shows the quality parameters calculated from the results obtained in the analysis. Examination of these data shows that the SPS method displays better linearity and lower RSD values of the concentration, RSD ($C$)%, than does the gallic acid persulphate method. The lower analytical sensitivity of the SPS method compared to the other method shows that it is possible to discern smaller differences in concentration than in the gallic acid persulphate method. In addition, the quantification limits for the solution method and the SPS method are about 6.6 $\mu g\ l^{-1}$ and 3.6 $\mu g\ l^{-1}$, respectively.

Table 3
Effect of foreign ions on the determination of 40 $\mu g\ l^{-1}$ of vanadium

| Foreign ion | Tolerance level ($\mu g\ l^{-1}$) |
|---|---|
| $NO_3^-$ | 30000 |
| Ca(II) | 28000 |

| | 1.8 [e] | 3.3 [e] |

[a] The statistical model proposed in ref. [19] was used.
[b,c,d,e] At vanadium concentrations of 5.0 $\mu g\ l^{-1}$, 10.0 $\mu g\ l^{-1}$, 15.0 $\mu g\ l^{-1}$ and 20.0 $\mu g\ l^{-1}$, respectively.

Table 5
Analytical applications in water samples

| Method | Sample Volume (ml) | Vanadium concentration ($\mu g\ l^{-1}$) Mean, $n = 3$ | Standard deviation |
|---|---|---|---|
| Gallic acid | 10.0 | 12.7 | 0.46 |
| SPS | 500.0 | 13.2 [a] (1.82) | 0.35 (1.67) |
| | 750.0 | 13.9 (2.92,s) | 0.56 (1.50) |

The experimental $t$ and $F$ values are given in parentheses; $t_{5,0.05} = 2.57$; $t_{4,0.05} = 2.78$; $F_{2,3,0.05} = 19.2$; $F_{2,2,0.05} = 19$; s, significant.
[a] $n = 4$.

Table 6
Analytical applications in petroleum samples

| Sample | Method | Vanadium concentration (mg per 100 g of sample) Mean, $n = 3$ | Standard deviation |
|---|---|---|---|
| Leona | ASTM | 10.49 | 0.08 |
| | SPS | 10.29 (2.56) | 0.02 (10.63) |
| Light Iran | ASTM | 2.75 | 0.08 |
| | SPS | 2.60 (2.42) | 0.07 (1.16) |
| Kirkuk | ASTM | 10.40 | 0.06 |
| | SPS | 10.75 (2.70) | 0.12 (3.56) |

The experimental $t$ and $F$ values are given in parentheses; $t_{4,0.05} = 2.78$; $F_{2,2,0.05} = 19$.

### 3.7. Analytical applications

The SPS methodology allows the creation of made-to-measure methods by selecting the sample volume. In this way it is possible to analyse different samples with great differences in vanadium concentration. Thus the SPS sample systems proposed have been applied to the determination of the vanadium content of natural water and crude petroleum samples.

*Determination, of vanadium in water samples*

The method was applied to the determination of vanadium in natural water samples by the standard additions method. The 1000 ml sample system was used. The constant error was corrected by using the Youden blank [20]. The results obtained by the proposed method were compared with those obtained by the gallic acid persulphate method. Table 5 summarizes the results. According to a $t$-test for the means and $F$-test for the standard deviations, the results show that there is only a significant difference between the mean derived from the SPS method (750 ml) and the mean from the gallic acid persulphate method, while the precision of both methods is the same.

*Determination of vanadium in crude petroleum samples*

The 250 ml sample system was used to analyse crude petroleum samples due to a larger concentration of vanadium in the samples. As a reference method, the ASTM method was used. The ASTM and the proposed method were applied to an aliquot of the solution obtained from three crude petroleum samples of difference composition and density, after the treatment previously described. The results are presented in Table 6. A statistical comparison by the $F$-test and the $t$-test showed no significant difference between the results of both methods. However, it is necessary to point out that due to the higher sensitivity of the SPS methods over the ASTM method (Table 2) it is possible to treat a smaller amount of the crude petroleum sample (between 1.5 and 3 g in our samples, depending on the vandium concentration) with a shorter duration of the analysis and equivalent precision and accuracy.

# Determination of $^{34}S$:$^{32}S$ ratios by FTIR spectroscopy

Antonio F. Fuentes[1], Iain L. Marr *

*Chemistry Department, University of Aberdeen, Aberdeen, AB9 2UE, UK*

Received 22 December 1994; revised 24 March 1995; accepted 24 March 1995

**Abstract**

A new method for determining $^{34}S$:$^{32}S$ ratios using Fourier transform infrared spectroscopy has been developed. The four sulphur-containing gases SCO, $H_2S$, $SF_6$ and $SO_2$ are assessed as possible compounds for the spectroscopic measurements, from which, after a consideration of available lines showing a clear isotopic shift and also of possible synthetic routes to the gas starting from a range of natural sample types, $SO_2$ was selected for further development of the instrumental method for the isotopic ratio determination. Sulphur in the samples present as the element, as metal sulphides or as organosulphur compounds, is converted by heating with $V_2O_5$ into gaseous $SO_2$, and a part of the 518 $cm^{-1}$ band is recorded in the absorbance mode. The optimisation of instrumental parameters and of the chemical reaction conditions is described, and the results from the application of the method to the measurement of the level of enrichment of $^{34}S$ in a soil fungus are presented. The agreement between results at the natural abundances of 4.2% was better than 0.04% absolute for a sample size of 1.5 mg of sulphur.

## 1. Introduction

The determination of $^{34}S$:$^{32}S$ ratios, largely used in geochemical studies, has only recently become relevant in other fields such as soil–plant systems [1,2]. The element is an essential nutrient for plants; it is used in the synthesis of amino acids present in proteins and is needed in the synthesis of chlorophyll, even though it does not appear in the final molecule. Attention is now focusing on the availability of soil sulphur, making the use of stable isotopes the obvious choice for understanding chemical reactions and in tracing the path that sulphur follows in different living organisms.

The high natural abundance of the isotope of mass 34 (4.21% on average) should make it rather easy to quantify in a natural sample, but on the other hand it presents the problem that relatively large amounts of the isotope would have to be added (as a tracer) for experiments involving spiking. Isotopic ratio determinations are routinely made by mass spectrometry. Sulphur compounds present in nature must therefore normally be first transformed into suitable sulphides such as those of cadmium, lead or silver which in turn are burned in the inlet system of the mass spectrometer, yielding sulphur dioxide which is allowed to leak into the analyser.

Isotopic sulphur determinations by mass spectrometry do, however, present some difficulties derived from the "stickiness" of sulphur dioxide which makes it slow to leak into the inlet system as well as creating problematic memory effects, and also from the existence in nature of the various oxygen isotopes. The first factor has been found to be dependent on both the length of the inlet system and its temperature, and necessitates the use of correction factors which will be different for different systems [3]. The surface adsorption effects render difficult any comparison of results between laboratories while the existence in nature of

*SSDI* 0039-9140(95)01609-0

different stable oxygen isotopes makes it necessary to carry out complex theoretical corrections on the experimental data, since both species used in these determinations, $SO^+$ and $SO_2^+$, involve atoms of oxygen. It is generally accepted that this problem can be overcome if the samples and standards are obtained in the same way and by using the same oxygen source.

Sulphur hexafluoride has also been proposed as a vehicle for sulphur isotopic determinations by mass spectrometry [4]. When using $SF_6$, it is not necessary to make any theoretical correction of the experimental data regarding the presence of different isotopes since fluorine has only one stable isotope, $^{19}F$. However, difficulties in the preparation of $SF_6$ have limited its use.

All these problems, and the success obtained in this Department in determining isotopic ratios for nitrogen [5] and for carbon [6] by FTIR spectroscopy of small molecules in the gas phase, led us to the idea of applying the same technique to sulphur isotopic ratio determinations. The initial problem lay in the choice of a suitable sulphur compound, and the second in optimising the experimental conditions for quantitative measurement.

Since the frequencies of both the vibrational and rotational modes of a molecule depend upon the masses of their constituent atoms, substitution of one isotope for another in a small molecule will produce an infrared spectrum different from that of the normal molecule. The isotopic shift in an infrared band will depend upon the extent to which the atoms exchanged participate in the specific vibration which produces the band, and in particular on the change in the moment of inertia due to the substitution. The magnitude of this change is given by the ratio between the reduced mass ($\mu$) of the normal species and that of the isotopically substituted species:

$$\frac{\nu_i}{\nu} = \sqrt{\frac{\mu}{\mu_i}} = \alpha < 1$$

Thus the heavier isotope will be associated with the lower vibrational frequency.

The aim of this work was to test the applicability of Fourier transform infrared spectrometry (FTIR) as an alternative to mass spectrometry for sulphur isotopic determinations: its characteristics of high resolution, and high spectrometric and photometric accuracy make FTIR a very powerful analytical tool. In addition, as has been shown for the analysis of the nitrogen and carbon isotopes [5,6], adequate resolution for these applications can sometimes be obtained with smaller bench-top instruments. This makes the proposed technique more widely applicable than if it were to demand the use of a high performance research instrument.

The ideal compound for such a determination would have to meet several criteria.

(i) It should be volatile at room temperature, since only in the gas phase is it possible to see the fine rotational structure, necessary if isotopic lines are to be measured.

(ii) It should contain only one atom of sulphur so as to avoid problems derived from the presence in the same molecule of different isotopes of sulphur at the same time.

(iii) The IR spectrum should exhibit at least one intense band which should not be too complicated if the isotopic shifts are to be identified, and which should be in an area of the spectrum free from overlap with bands of common atmospheric molecules such as water and carbon dioxide.

(iv) The isotopic shift in the band should be such that the fingerprint of the different isotopes can be easily identified.

(v) The selected compound should be easy to synthesise from a variety of different chemical forms of the element.

The compounds considered for investigation were carbonyl sulphide, SCO, hydrogen sulphide, $H_2S$, sulphur hexafluoride, $SF_6$, and sulphur dioxide, $SO_2$.

## 2. Experimental

### 2.1. Instrumentation

All the IR spectra were collected on a Nicolet model 7199 FTIR spectrometer, fitted with a liquid-nitrogen-cooled MCT detector. As it is a single-beam device, a background spectrum must be collected before, and preferably also after, each set of sample spectra. The spectra must be displayed in the absorbance mode.

### 2.2. Materials

Isotopes were purchased as elemental sulphur. Pure $^{32}S$ was obtained through Delta Isotopes from the Soviet–Great Britain Joint Venture "ISOFLEX" with a purity of 99.97%. The $^{34}S$ was purchased from MSD Isotopes and came with purity of 91.6 at.% $^{34}S$.

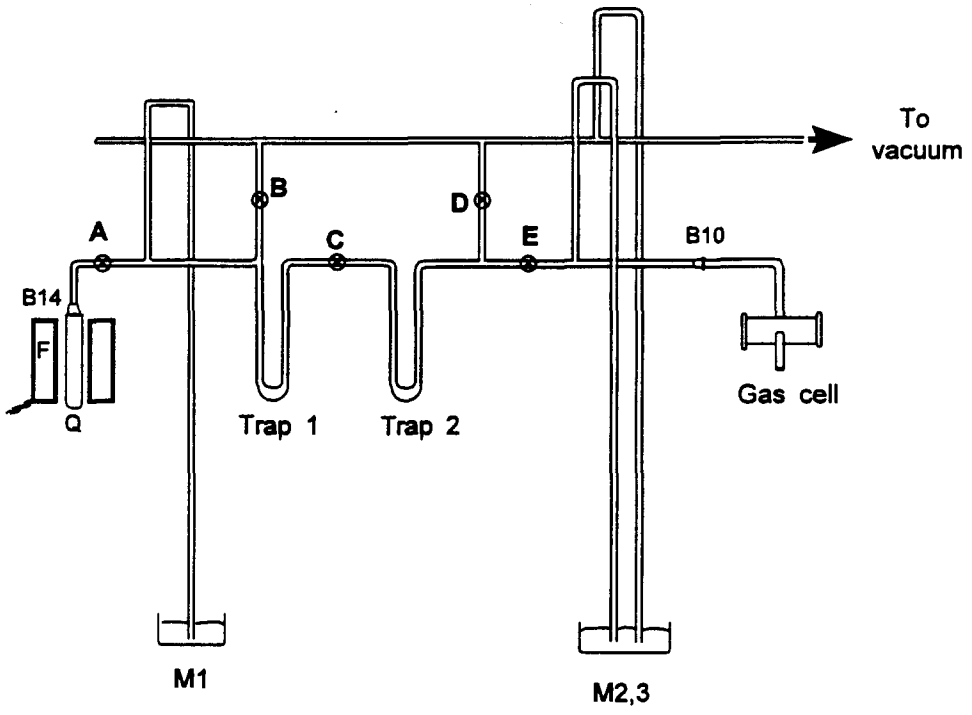

Fig. 1. Schematic diagram of the vacuum line: A, B, C. D and E are Teflon keyed vacuum stopcocks; M 1, M 2 and M 3 are mercury manometers; F is a small furnace, (750 W) surrounding the quartz reaction tube Q.

### 2.3. *Handling $SO_2$ on the vacuum line*

The synthesis was carried out on a vacuum line (shown diagramatically in Fig. 1) which was evacuated by a rotary pump down to 0.1 Torr. Trap 1 was cooled with a liquid nitrogen/carbon tetrachloride mush bath (−23 °C) to remove water, and trap 2 in liquid nitrogen (−196 °C), to collect the sulphur dioxide (m.p., −72.7 °C). Gaseous $SO_2$ could be transferred from the cold trap 2 to an evacuated gas cell for measurement of the spectrum, or to a 30 ml glass storage tube fitted with a Teflon keyed tap.

### 2.4. *Preparation of $SO_2$ from elemental sulphur or from cadmium sulphide*

Weigh out around 10 mg of elemental sulphur (or 30 mg of cadmium sulphide) of natural abundance, or consisting of two separately weighed portions of the isotopically pure $^{34}S$ and $^{32}S$ isotopes, and transfer the sample to a quartz reaction tube 10 mm in external diameter 100 mm long, and fitted with a B-14 cone by which it can be attached to the vacuum line. Add to this about 30 mg of oven-dried vanadium pentoxide and mix well by shaking. Push a wad of glass wool down the tube to a few centimetres above the reaction mixture (a part of the tube which will not reach the maximum temperature of the furnace) and cover the glass wool with a 5 mm layer consisting of pieces of partly oxidised copper wire (as used for the Dumas nitrogen determination). This is to reduce any $SO_3$ which might be formed.

Fit the reaction tube to the vacuum line and evacuate it. Raise the small tube furnace (closed at the lower end) to envelop the reaction tube, start heating, and continue pumping until the furnace temperature reaches 200 °C. At this point, close tap B, leaving the quartz reaction tube connected only to the traps, and place the mush baths in position. Increase the temperature further to 800 °C and collect the evolved $SO_2$ in trap 2 over a period of 20 min. Now close tap C to isolate the product, and remove the liquid nitrogen bath round trap 2. Transfer the gas to either a gas cell or a storage tube, as required, by evacuating the cell or the tube, cooling the cold finger of the gas cell, or the lower part of the storage tube in liquid nitrogen, and opening the connecting tap E. The reaction can be followed by noting the changing height of the mercury manometer M1. Likewise, the pressure in the cell can be measured, in mmHg (Torr), on manometer M2.

### 2.5. Synthesis of $SO_2$ from barium sulphate

Weigh out about 50 mg of barium sulphate, mix well with 300 mg of a 1:1 (m/m) mixture of vanadium pentoxide and ground silica, and take the furnace temperature up to 1000 °C. Follow the remainder of the procedure given above for starting with elemental sulphur.

### 2.6. Preparation of fungus samples for isotopic ratio measurements

Suspensions containing the fungus *Aspergillus flavus* were filtered using Whatman ashless filter paper number 42, and were washed using a solution with the same composition as that of the growing medium, then sucked free of solution. After freeze drying for 24 h, the samples were ground by shaking in a plastic container together with four steel balls. At this stage, they were ready for sulphur analysis.

### 2.7. Recommended FTIR parameters

Fill a Pyrex gas cell, 150 mm long, 15 mm in diameter and fitted with KBr windows (ground to a 1° wedge to avoid interference fringes), with $SO_2$ to a pressure of $30 \pm 3$ Torr. Record the IR spectrum at a resolution of 0.25 $cm^{-1}$ with 100 scans, from 600 to 400 $cm^{-1}$ using the Happ–Genzel apodisation function. Integrate the lines with baseline correction (see below) and calculate the area ratios of the line pairs 548 $cm^{-1}$ (line a) for $^{34}S$ and 588 $cm^{-1}$ (line 6) or 592 $cm^{-1}$ (line 7) for $^{32}S$. Compare the ratios with the two calibration lines to estimate the isotopic composition of the sample.

## 3. Results and discussion

### 3.1. Selection of a gas for the determination of sulphur stable isotope ratios

*Carbonyl sulphide, SCO*

Carbonyl sulphide is an asymmetric linear molecule with the atom of carbon in the centre, and therefore belongs to the symmetry group $C_{\infty v}$. It presents three fundamental vibrations of which, using the notation given by Herzberg [7], $\nu_3$ and $\nu_1$ are the two stretching modes of higher and lower frequency respectively and $\nu_2$ is the bending mode (see Table 1).

Callomon et al. [9] and Allen et al. [10] pointed out the difficulties in assigning the spectrum due to overlapping and coupling between bands. Interactions between pairs of bands are very strong, producing variations in the frequencies of the bands from those predicted theoretically. Additionally, the whole spectrum is complicated by the superposition of bands due to "hot" transitions upon the main absorption bands.

The isotopic analysis of the IR spectrum of carbonyl sulphide is further complicated by the fact that the number of possible combinations of different isotopes within the molecule is large. Oxygen has three stable isotopes, $^{16}O$ (99.76%), $^{17}O$ (0.04%) and $^{18}O$ (0.2%), and carbon another two, $^{12}C$ (98.89%) and $^{13}C$ (1.11%), which, added to the four isotopes of sulphur, $^{32}S$ (95.0%), $^{33}S$ (0.76%), $^{34}S$ (4.2%) and $^{36}S$ (0.014%), makes for 24 possible isotopic combinations. Overlap between the bands of $^{32}S^{12}C^{16}O$ and those of the isotopically substituted species, and the numerous "hot" bands is frequent, making necessary the use of very high resolution if a detailed study of the rotational structure is desired.

The lack of a suitable band in its IR spectrum on which to base our study, together with the difficulty in synthesising it from elemental sulphur, drove us to the conclusion that SCO was not a suitable compound for carrying out sulphur isotopic determinations.

*Hydrogen sulphide, $H_2S$*

The hydrogen sulphide molecule belongs to the symmetry group $C_{2v}$ and presents three fundamental vibrations. Table 2 shows the designation and position of the main bands.

Table 1
Bands seen in a low resolution IR spectrum of carbonyl sulphide, SCO [8]

| Band | Frequency ($cm^{-1}$) |
|---|---|
| $\nu_2$ | 520 |
| $\nu_1$ | 858 |
| $2\nu_2$ | 1047 |
| $2\nu_1$ | 1711 |
| $\nu_1 + 2\nu_2$ | 1892 |
| $\nu_3$ | 2062 |
| $4\nu_2$ | 2104 |
| $\nu_1 + \nu_3$ | 2918 |
| $2\nu_2 + \nu_3$ | 3095 |

Table 2
Bands seen in a low resolution IR spectrum of hydrogen sulphide, $H_2S$ [11,12]

| Band | Frequency ($cm^{-1}$) |
|---|---|
| $\nu_2$ | 1182 |
| $2\nu_2$ | 2353 |
| $\nu_1$ | 2614 |
| $\nu_3$ | 2628 |

This molecule presents a large absorption area between 2200 and 2800 $cm^{-1}$ which can be divided into three parts corresponding to strong, weak and medium absorptions, but any interpretation of this area is complicated by the strong interactions between the three bands. Another inconvenience is the existence in this area of the main absorption band of carbon dioxide which has its centre at 2396 $cm^{-1}$.

The other fundamental vibration $\nu_2$ has the centre of its band at 1182.7 $cm^{-1}$, in a part of the spectrum where water vapour absorbs. Gillis and Edwards [12], using a grating spectrometer with 0.05 $cm^{-1}$ resolution, made a detailed study of the $\nu_2$ band, and were able to assign some lines to the $^{33}S$ and $^{34}S$ isotopes, but the number of lines and quality of the spectrum did not allow them to carry out a complete isotopic analysis.

Though the gas can be prepared readily from metal sulphides, and they in turn can be prepared from elemental sulphur, the complexity of the spectrum, together with the extreme weakness of the absorption bands, forced us to the conclusion that this was not a suitable candidate for the isotopic analysis of sulphur either. However, as the synthesis is straightforward, it could serve as a useful intermediate for the extraction of sulphur from natural samples, before conversion to another, spectroscopically more suitable, compound.

*Sulphur hexafluoride, $SF_6$*

Sulphur hexafluoride has a highly symmetrical structure with the sulphur atom at the centre of a regular octahedron whose corners are occupied by the six fluorine atoms. Thus the molecule belongs to point group $O_h$ and shows six fundamental vibrations of which only two, $\nu_3$ at 947.98 $cm^{-1}$ and $\nu_4$ at 615.02 $cm^{-1}$, are IR active [13,14]. As fluorine is monoisotopic, this molecule does meet one of the important criteria for an FTIR determination of the sulphur isotopic ratio.

However, a large number of combination bands is present in its IR spectrum: 29 bands have been described by McDowell et al. [15], using an FTIR spectrometer at a resolution of 0.05 $cm^{-1}$. The $SF_6$ spectrum is further complicated by the fact that at room temperature, only some 34% of the molecules are present in the vibrational ground state [16], which results in a high probability (and hence intensity) of "hot" bands in the spectrum, and in a considerable susceptibility of the normal band intensities to changes in temperature.

The spectrum shows eight bands — two of them are the fundamental vibrations and the other six are combination bands. The designations of these combination bands as well as their positions in reciprocal centimeters are given in Table 3.

Four of the combination bands have their frequencies in the region 1900–1250 $cm^{-1}$ where the $\nu_2$ band of the water molecule lies. Therefore, in a high resolution spectrum, it is possible to see numerous water absorption lines superimposed on those of sulphur hexafluoride. The isotopic shifts for the combination bands $(\nu_1 + \nu_3)$ and $(\nu_1 + \nu_4)$ have been given by Klimov and Lobikov [17] as 16 $cm^{-1}$ and 2 $cm^{-1}$ respectively. The centre of the combination band $(\nu_2 + \nu_3)$ for the species $^{34}SF_6$ was given by the same authors as 1569 $cm^{-1}$, which gives an isotopic shift of approximately 17 $cm^{-1}$. However, these isotopic shifts are not useful for our purposes since no lines are observed as clean "fingerprints" of the different isotopes.

The other two combination bands, $(\nu_5 + \nu_6)$ and $(\nu_2 + \nu_6)$, do not exhibit any sulphur shifts since the sulphur atom is not involved in the fundamental vibrations which contribute to these combination bands.

The rotational structure of the strongest band in the spectrum, $\nu_3$, is not resolved even

Table 3
Combination bands seen in a low resolution IR spectrum of $SF_6$ [16]

| Band | Frequency ($cm^{-1}$) |
|---|---|
| $(\nu_5 + \nu_6)$ | 870 |
| $(\nu_2 + \nu_6)$ | 991 |
| $(\nu_2 + \nu_4)$ | 1257 |
| $(\nu_1 + \nu_4)$ | 1388 |
| $(\nu_2 + \nu_3)$ | 1587 |
| $(\nu_1 + \nu_3)$ | 1719 |

when using 0.25 $cm^{-1}$ resolution. A maximum spacing of 0.04 $cm^{-1}$ between two successive lines has been calculated by Brunet and Perez [18] — much smaller than the resolution of the spectrometer. The isotopic shift for the $\nu_3$ $^{34}SF_6$ band has been given as 17.4 $cm^{-1}$, based on the assumption that the small peak in the natural $SF_6$ spectrum at 930.50 $cm^{-1}$ is due to the $^{34}S$ isotope [18]. However, because quantitative work for our purposes would require integration of the whole of the $^{32}SF_6$ band at 948 $cm^{-1}$, which is broad and unresolved at 0.25 $cm^{-1}$ resolution, and very susceptible to changes in shape with change in pressure, this compound was ruled out. Synthesis in the laboratory, using elemental fluorine, is in any case difficult and unattractive for routine use.

*Sulphur dioxide, $SO_2$*

The molecule of sulphur dioxide, like that of hydrogen sulphide, belongs to the symmetry group $C_{2v}$ and therefore shows three fundamental vibrations. Two of them ($\nu_1$ and $\nu_2$) are B-type bands and the other one ($\nu_3$) is A-type. In A-type bands the oscillating dipole moment lies along the axis of the least moment of inertia and they are characterised by a strong central Q branch and J subbranches. The rotational structure in this group of bands presents strong irregularities and it is not possible to see individual lines without using a very high resolution.

In B-type bands the oscillating dipole moment lies along the axis of the intermediate moment of inertia and they are represented by Q branches, in this case spaced approximately 3.4 $cm^{-1}$ apart. While in A-type bands a considerable number of Q lines fall near the band centre, for B-type bands no Q line occurs near the centre but instead they overlap the P and R branches. Each Q branch has associated with it a P and an R branch giving rise to numerous weak lines which form the background absorption between Q branches.

The low-resolution IR spectrum of sulphur dioxide is shown in Fig. 2. It was collected using 1 $cm^{-1}$ resolution and 20 Torr of gas in a 10 $cm^{-1}$ gas cell. Along with the fundamental vibrations there is also a combination band ($\nu_1 + \nu_3$) at 2500 $cm^{-1}$ which is strong enough to be seen in a low pressure spectrum. The positions of these bands are listed in Table 4.

The IR spectrum of isotopically substituted sulphur dioxide has been studied by different workers [19–22]. A summary of their findings,

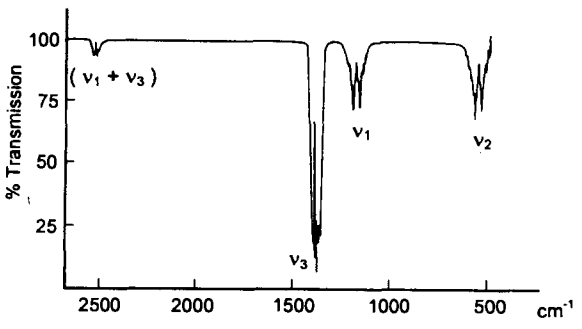

Fig. 2. Low-resolution infrared spectrum of sulphur dioxide, $SO_2$.

in the form of frequencies of the origins of the four main bands for the species $^{32}SO_2$ and $^{34}SO_2$, is shown in Table 4.

Values in Table 4 show a significant isotopic shift for each band ranging from approximately 7 $cm^{-1}$ for $\nu_1$ to 22 $cm^{-1}$ for ($\nu_1 + \nu_3$), which is the largest shift presented by any of the sulphur compounds assessed. However, it is not possible to identify individual peaks corresponding to different isotopes in the A-type bands, ($\nu_1$ and $\nu_2$) which makes than unattractive for isotopic analysis.

It follows then, that only the $\nu_1$ and $\nu_2$ bands can be used if individual lines are going to be integrated. A closer look at $\nu_1$ (Fig. 3) reveals a very complex band without well-defined rotational lines. It was decided not to use this band since a changeable shape was going to make for poor integration reproducibility. Besides, it was not possible to identify any single line in this band as a fingerprint of the $^{34}S$ isotope in sulphur of natural abundance.

The only band left was $\nu_2$ at 512 $cm^{-1}$, which is not exempt from problems either. The fact that it lies close to the end of the working range of both the Hg–Cd–Te detector and the KBr windows (400 $cm^{-1}$) makes its baseline noisier than it should be. It is also affected by the presence in this area of a "hot" band

Table 4
Bands seen in a low resolution IR spectrum of $SO_2$ [20,22,23]

| Band | Frequency ($cm^{-1}$) | |
|---|---|---|
| | $^{32}SO_2$ | $^{34}SO_2$ |
| $\nu_2$ | 517.87 | 512.30 |
| $\nu_1$ | 1155.71 | 1144.48 |
| $\nu_3$ | 1362.06 | 1345.09 |
| ($\nu_1 + \nu_3$) | 2499.87 | 2475.83 |

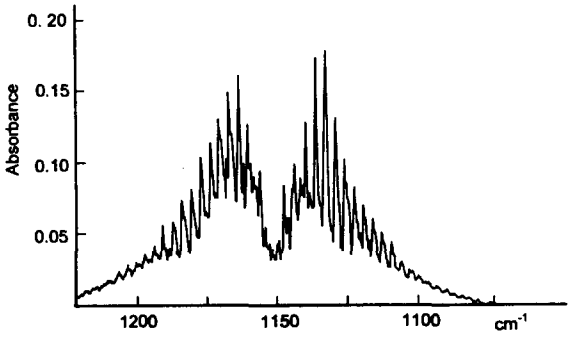

Fig. 3. Fundamental vibration band, $\nu_1$ for $SO_2$ at 1156 $cm^{-1}$.

$(2\nu_2 - \nu_2)$ centred at 517.25 $cm^{-1}$ which gives rise to additional peaks complicating the background absorption [23].

Nevertheless, the high frequency part of the band, around 550–600 $cm^{-1}$, is relatively well defined, and it was decided to investigate this further. Fig. 4 shows the relevant section of the spectra of the natural abundance $SO_2$ and of the isotopically substituted molecules $^{34}SO_2$, from which it can be seen that the isotopic shift is significant, and that there are three lines in the natural abundance spectrum, at 560.39, 552.27 and 548.29 $cm^{-1}$, which are clearly due to the $^{34}S$ isotopically substituted molecule. The final choice for the determination of sulphur isotopic ratios was therefore $SO_2$ as the gas, and the high frequency end of its $\nu_2$ band around 550 $cm^{-1}$ as the region of the spectrum.

### 3.2. Optimisation of experimental parameters

*Synthesis of $SO_2$*

The synthesis of $SO_2$ from elemental sulphur by combustion in oxygen is apparently the simplest route. However, this was tried and discarded since most of the sulphur taken crept up the walls of the silica tube where the reaction was taking place and condensed as a liquid in those parts of the tube close to the upper end of the electric furnace, remaining unavailable for chemical conversion.

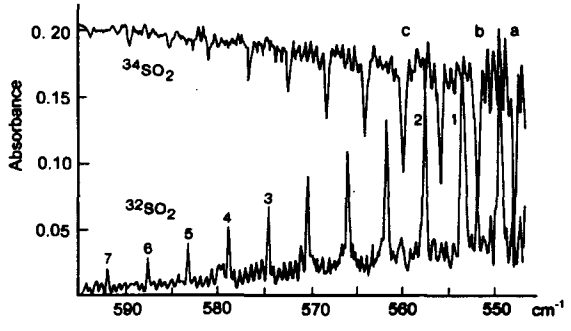

Fig. 4. A section of the 518 $cm^{-1}$ fundamental vibration band $\nu_2$ of $SO_2$ with the natural abundance spectrum recorded in the absorbance mode (bottom) and the $^{34}SO_2$ spectrum in the transmission mode (top).

Solid oxygen donors offer an alternative route to the synthesis. Copper (I) oxide has been suggested as a solid oxygen donor for sulphides [24] but it needs to be prepared shortly before use, to prevent oxidation to the copper (II) oxide and the absorption of other gases. Vanadium pentoxide, which is commercially available and which can be used without needing major purification, has been proposed by Gavelin for producing $SO_2$ from precipitated cadmium sulphide [25]. Yanagisawa and Saka [26] published a variation of this procedure using barium sulphate as the source of the sulphur, in which ground silica was added to the reaction mixtures to moderate the evolution of $SO_2$. It also increased the viscosity of the reaction mixture so that it did not creep up the wall of the reaction tube. Vanadium pentoxide serves in this case as both an acid flux and an oxygen buffer, rather than just as an oxygen donor, and lowers the decomposition temperature of the sulphate to roughtly 1000 °C, which is the reaction temperature employed in the proposed procedure. Ueda and Krouse applied this modified approach to transform sulphide and sulphate minerals into gaseous $SO_2$ for isotopic analysis by mass spectrometry [27]. This approach has been adopted in the present investigation, and has been shown to work well also with elemental sulphur.

*FTIR parameters*

Isotopic analysis by FTIR is affected by the choice of instrumental parameters such as resolution, number of scans, apodisation function and choice of spectral lines, as well as by variables such as the size of the sample (working pressure), the method of peak measurement (area or height) and the reference background. All these variables need to be optimised.

*Choice of spectral lines*

There are three lines in the $\nu_2$ region of the spectrum from natural abundance sulphur dioxide which are due mainly to the $^{34}S$ isotope: these situated at 548.29 $cm^{-1}$, 552.27 $cm^{-1}$ and 560.39 $cm^{-1}$, labelled a, b,

and c respectively in Fig. 4. The band shows an irregular baseline which could not be improved by collecting the spectrum with a higher number of scans, indicating that there is an important contribution from the presence of numerous P and R branches in between the Q branches, and of a "hot" band centred at 517.25 $cm^{-1}$ as suggested by Coudert et al. [23]. It was even possible to see these lines in the spectrum of pure $^{32}SO_2$, proving that they are not entirely due to the presence of $^{34}S$ in the molecule. However, the lack of any other peaks which could be used made these lines the only possible choice. For $^{32}SO_2$, those lines with the best baseline were chosen (line 6 or 7 in Fig. 3) even though they were not the most intense of the band. These circumstances make for a noisier background absorption which is due not to instrumental noise but to the molecular structure itself. In general, lines selected for the $^{34}S$ isotope, which is present at lower concentrations, are more affected than those chosen as "fingerprints" of the major isotope, $^{32}S$.

The intention was to construct a calibration graph for the isotopic composition by plotting the ratio of a pair of lines (one line for each isotope) versus concentration of $^{34}S$. The first point to consider was the choice of spectral resolution.

*Resolution*

In FTIR spectroscopy, resolution is determined by the distance traversed by the moving mirror in the interferometer. The optimum instrumental resolution is that which is equivalent to the natural resolution of the sample spectrum itself. If too low a resolution is used, separated bands will not be resolved and information will be lost, while if the resolution is too high, the spectrum will be noisier and no additional information will be obtained. Additionally, collecting a spectrum at higher resolution is more time consuming. To collect and transform 100 scans at 1 $cm^{-1}$ will take about 4 min, while at 0.25 $cm^{-1}$ it will require over 12 min. It is important to find a compromise between the volume of information required and the time needed for the analysis.

Three resolutions, 0.25, 0.5 and 1 $cm^{-1}$, were investigated. With 1 $cm^{-1}$ resolution it was not possible to pick up any $^{34}S$ isotope line. A resolution of 0.5 $cm^{-1}$ partially resolved the $^{34}S$ lines, but with 0.25 $cm^{-1}$ resolution the lines were well resolved although the baseline became noisier with a large number of extra lines appearing (see Fig. 5). Nevertheless, this was the resolution chosen since it gave the best peak profiles.

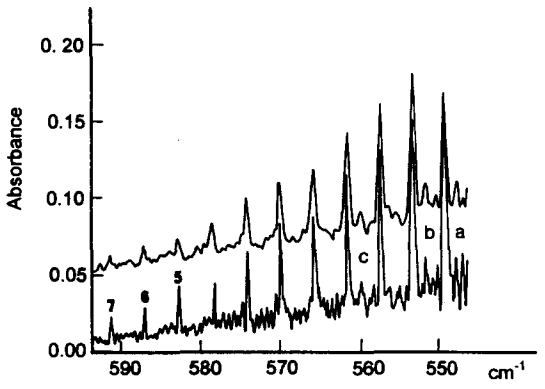

Fig. 5. A section of the $\nu_2$ band of natural abundance $SO_2$ showing the lines selected for measurement of the isotopic ratio, recorded at 0.25 $cm^{-1}$ (lower) and 0.5 $cm^{-1}$ (upper) resolution.

*Peak measurement*

Individual lines can be measured in terms of peak absorbance or integrated area. Both possibilities have been investigated.

*Peak area (A)*

The NICOLET has a routine which allows one to integrate a band/peak between two given limits, with or without baseline correction (Fig. 6). If baseline correction is chosen (AwBLC) the computer draws an imaginary line between the two limits specified by the operator and integrates the area of the peak

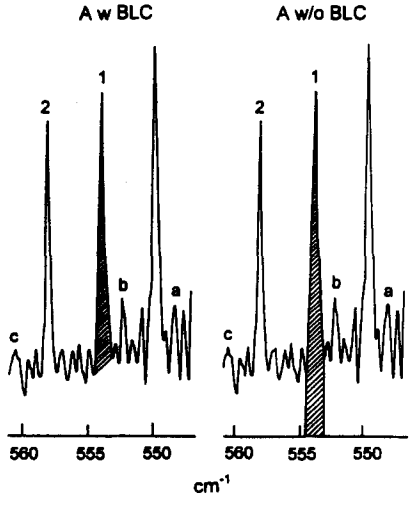

Fig. 6. Measurement of peak areas by integration: (a) AwBLC; (b) Aw/oBLC.

Table 5
Precision of line ratio measurements for selected line pairs

| Line pair | Relative standard deviation of ratio (%) | | |
|---|---|---|---|
| | AwBLC | Aw/oBLC | ABS |
| b/1 | 1.35 | 0.78 | 1.14 |
| b/2 | 1.13 | 0.75 | 0.75 |
| a/1 | 1.65 | 0.51 | 1.13 |
| a/2 | 1.57 | 0.58 | 0.75 |
| c/2 | 1.53 | 0.95 | 1.24 |
| c/3 | 1.62 | 0.45 | 1.04 |

enclosed between this line and the peak contour. This possibility is preferred since it is free from the influence of possible instrumental drift. Integration without baseline correction (Aw/oBLC) measures the area under the peak, but above the line $A = 0$, and may include a large background component.

*Peak absorbance*

The true absorbance of a peak (ABS) can be measured if the spectrum is first drawn using the $X-Y$ plotter, but this is rather time-consuming. Alternatively, it is possible to work directly on-screen using the cursor. The "baseline" absorbance was read at two points, in the valleys on either side of the peak, averaged and the mean subtracted from that at the peak maximum. Such results (*ABS*) were considered to be the "real" absorbances of the lines and were also used for calculating the ratios.

A comparison of these three possible methods of quantitation, given as the precision of five measurements, is shown in Table 5. The resolution used was 0.25 $cm^{-1}$, the number of scans was 100 and the working pressure was 30 Torr in a 15 cm long gas cell.

Table 5 shows that the best precision was obtained when working with areas without baseline correction but this apparently better performance is probably attributable to the rather large, but very constant, area below the base of the peak and above the line of zero absorbance. The precision referred to the area of the peak itself, without the large instrumental artefact, which is here called area with baseline correction (AwBLC), is poorer, but more realistic. Moreover, for the same reason, AwBLC is more sensitive to change in the isotopic ratio so it is more appropriate for this determination.

*Choice of spectral lines*

Several line combinations (e.g. a for $^{34}SO_2$ and 3 for $^{32}SO_2$) were measured and the area ratios were compared. The sensitivity would be poorer if there were a significant peak in the $^{32}SO_2$ spectrum, arising, for example, from a hot band or an overtone, coinciding with the selected line in the $^{34}SO_2$ spectrum. However, as the line pair ratios change by much the same for all combinations (see Table 6), there is no one line which seems to suffer significantly more or less than the others from this problem. The results are summarised in Table 6.

*Running the background*

A background spectrum was run at the beginning of the session and then again immediately after four replications for the sample. This method gave good precision and is also time-saving since the gas cell is filled only once with each sample. Additionally, possible errors derived from adjusting the position of the gas cell in the cell holder or from reading the pressure when filling the cell a few times are avoided. Instrumental drift is also minimised since all the operations are carried out in the smallest interval of time possible.

*Number of scans*

The signal-to-noise ratio depends on the square root of the number of scans. The relative standard deviations of the line ratios were compared for 50, 100 and 200 scans with 30 Torr of $SO_2$. This comparison showed, as predicted, that the performance was best for the highest number of scans, with RSD of 1.25%, 1.03% and 0.63% respectively for the a/3 line-pair combination.

However, it was decided to use only 100 scans as a good compromise between precision and time needed for the analysis. The working

Table 6
Area ratios (AwBLC) for natural abundance $SO_2$ and $^{32}SO_2$

| Ratio | $SO_2$, nat [a] | $^{32}SO_2$ [a] | Difference relative (%) |
|---|---|---|---|
| a/3 | 1.214 (0.70%) | 1.065 (1.03%) | 14 |
| a/5 | 2.003 (1.49%) | 1.734 (0.92%) | 15.5 |
| c/5 | 1.140 (1.12%) | 0.985 (1.31%) | 15.8 |
| b/3 | 0.777 (1.66%) | 0.680 (1.51%) | 14.3 |

The resolution was 0.25 $cm^{-1}$ for a sample pressure of 30 Torr in a 15 cm cell. The number of scans was set at 100.
[a] The RSD is given in parentheses.

Table 7
Effect of sample size on the precision of the line area ratio

| Line pair | Precision RSD (%) [a] | | |
|---|---|---|---|
| | 20 Torr | 30 Torr | 50 Torr |
| a/2 | 1.61 | 1.50 | 1.00 |
| b/1 | 2.51 | 1.35 | 1.29 |
| b/2 | 2.05 | 1.13 | 1.04 |

[a] $n = 5$.

time would be approximately doubled if 200 scans were collected, which means, for five replications plus two background scans, nearly 1 h longer for only a small improvement in the precision of the measurement.

*Sample size*

Increasing the pressure of a gas sample may result in band broadening, which could affect the measured line absorbance ratios. Data obtained for one sample run at 20, 30 and 50 Torr working with AwBLC are shown in Table 7. The improvement in precision on going to 50 Torr was significant but not large, and in the interest of minimising sample size it was decided to use 30 Torr as working pressure (which means about 1.5 mg of $SO_2$ in the cell, and about double this to allow for filling the manometer on the line).

The effect of sample pressure on the ratio itself was then investigated, covering a smaller working range, from 25 to 37.5 Torr. ANOVA showed that the variance of the line ratios between sample pressure was not significantly different from the variance at any one pressure, form which one may conclude that changes in pressure within this range do not have a noticeable influence on the ratios within reasonable margins.

### 3.3. Calibration graphs

Sulphur isotopic standards were prepared form elemental sulphur (using 99.9% $^{32}S$ and 92% $^{34}S$) by combustion on a vacuum line with vanadium pentoxide as solid oxygen donor. These standards covered the range form 3.5 to 10 at.% $^{34}S$. All the spectra were collected on the same day and in the shortest possible interval of time. Lines were integrated between the limits chosen previously (valleys on either side of the line), ratios calculated and the regression lines of the calibrations plotted.

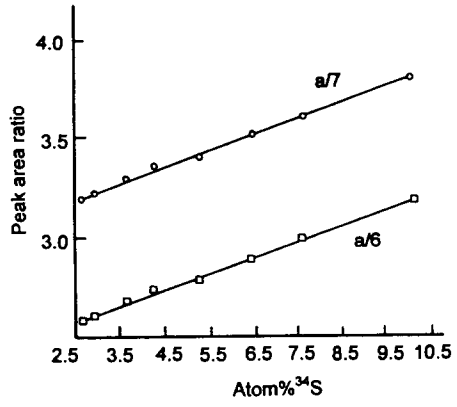

Fig. 7. Calibrations for sulphur isotopic ratio determinations using line pairs a/6 and a/7.

Several possible linear calibrations were obtained using AwBLC. The $^{34}S_2$ line at 560 $cm^{-1}$ (designated as c in Fig. 4) did not give good results in most cases, possibly due to the fact that it is strongly affected by the background absorption of the band. The line designated as b (552 $cm^{-1}$) gave good results in a number of cases, while it was with the one designated as a, located at 548 $cm^{-1}$, that the best calibration lines were obtained. This is the most intense of those $^{34}S_2$ lines which appear reasonably free from intererence, and it is also the most sensitive to changes in the isotopic composition as can be seen from the fact that it gives, in general, the graphs with the largest slopes. Two such calibration lines are shown in Fig. 7.

Parameters of some calibration lines are shown in Table 8. The slopes are small but sufficient for the quantification of modest enrichments of $^{34}S$. Relative standard deviations for the points which make up the calibration graphs were in most cases between 1% and 2%. Taken over the natural abundance of the $^{34}S$ isotope, this precision implies an uncertainty of 0.16% (absolute) when determining isotopic ratios by this method.

The intercepts of these calibration graphs were found to vary with time. Although slopes

Table 8
Parameters of calibrations for sulphur isotopic abundance measurements

| Line pair | Correlation coefficient | Intercept | Slope $(\%\ ^{34}S)^{-1}$ |
|---|---|---|---|
| a/6 | 0.996 | 2.261 | 0.0906 |
| a/7 | $0.997_5$ | 2.874 | 0.0909 |
| a/5 | 0.997 | 1.718 | 0.0719 |

Table 9
Results for the analysis of labelled *Aspergillus flavus*

| Sample | $^{34}S$ in samples (% (m/m)) | | |
|---|---|---|---|
| | Mass spectrometry | FTIR | Difference (% absolute) |
| Natural abundance | 4.224 | 4.190 | 0.034 |
| Enriched in $^{34}S$ | 4.468 | 4.429 | 0.039 |

were constant, the lines moved up and down with respect to each other. A similar situation was noticed by other workers when performing quantitative determinations by FTIR [5,28]. A possible explanation for this change is to be found in the long-term instabilities of the interferometer. This phenomenon was studied by Van Karsten [29] and was thought to be due to slow thermal or material elasticity of the interferometer or non-uniformity in temperature or composition of the purge gas.

### 3.4. Sulphur isotope ratio measurements on a $^{34}S$-labelled soil fungus

To evaluate the proposed method on some real samples, a sulphur isotopic analysis of a labelled fungus was carried out. The species chosen for this project was *Aspergillus flavus* which has a large sulphur requirement. It was provided by Prof. K. Kilham from the Plant and Soil Science Department, University of Aberdeen (UK). Two sets of samples were grown: one in a Czapek–Dox nutrient medium containing natural abundances of each sulphur isotope and the other one in a medium enriched in $^{34}S$. The latter was prepared by combusting some pure $^{34}S$ and absorbing the $SO_2$ in aqueous potassium hydroxide.

Portions of this (neutralised) solution were then used in the preparation of the nutrient medium. Fungal spores were incubated in the nutrient medium for 1 week, on an orbital shaker, then the suspensions were analysed using the procedure given under Section 2. Samples were also analysed by isotopic ratio mass spectrometry with the aim of comparing the results given by both techniques. These results can be seen in Table 9.

It should be pointed out that the results given in Table 9 were obtained using a compromise set of conditions, and that by accumulating 200 scans instead of 100, and by filling the cell to 50 Torr instead of 30, a modest improvement in precision could be attained. This would reduce the estimated uncertainty of 0.16% (absolute) to around 0.1% (absolute) in the measurement of 4% (absolute) $^{34}S$. In the light of these estimates, the agreement between the FTIR values and the IR–MS ratios seen from Table 9 — differences of 0.03–0.04% absolute — is very satisfactory. However, the RSD (%) obtained by the FTIR method is larger than that obtained by mass spectrometry. This fact does confirm that although FTIR cannot compete with IR–MS when determining sulphur isotopic ratios at natural levels, it could be used with a degree of confidence to carry out this kind of analysis when working with isotopically enriched samples.

## Acknowledgements

The authors would like to express their gratitude to the Spanish Ministry of Education and Science for the grant given to Dr. Fuentes which made possible this project. Thanks are also due to the UK SERC for funding for the Nicolet spectrometer. And finally, the authors wish to express their gratitude to Professor D.C. McKean for his continued interest in their work on isotope ratio measurements, and to Prof. Ken Kilham for his assistance with growing the soil fungi.

# Flow/sequential injection determination of gaseous ammonia with a glass diffusion denuder

Yongyi Luo, Rashed Al-Othman, Gary D. Christian *, Jaromir Ruzicka

*Center for Process Analytical Chemistry, Department of Chemistry, BG-10, University of Washington, Seattle, WA 98195, USA*

Received 17 January 1995; revised 28 March 1995; accepted 28 March 1995

**Abstract**

A new combination of a flow/sequential injection method for the analysis of ammonia has been developed. Gaseous ammonia is selectively absorbed in a phosphoric acid coated glass tube and determined with Berthelot reagents by flow injection. The combination of the gas diffusion denuder sampler with flow injection makes this method very sensitive and selective. The limit of detection of 0.15 μg $NH_3$.

## 1. Introduction

Ambient air continuously receives ammonia through the decomposition of organic material, and human activity. Because ammonia is an important indicator of environmental pollution and a predominant gas-phase atmospheric base, it plays a paramount role in atmospheric chemistry [1]. Traditional colorimetric methods [2], as well as ion-selective electrode [1,3], photothermal beam deflection [4] and fluorometric methods [5] have been used for the determination of ammonia in aqueous solution.

To determine ammonia in air with the methods described above, gaseous ammonia must first be collected by a suitable solid or liquid phase. Among all the sampling methods, the diffusion-based samplers, such as the diffusion denuder tube, have the following advantages: low back pressure, high collection efficiency and enrichment factor, and no interference of particle-borne ammonium [6].

A diffusion denuder is a glass tube whose inner wall has been coated with a suitable sorbent for gaseous analytes. Stevens et al. [7] were the first to describe the use of a phosphorous acid coated tube for the collection of atmospheric ammonia. Oxalic acid [1] and citric acid [8] coated tubes were used for the same purpose. Glass tubes coated with different chemicals have been used to collect other gases, e.g. $HNO_2$ [9], $HNO_3$ [9–12], HCl [13], $SO_2$ [13], and the simultaneous collection of several gases [9,12,13]. Although the diffusion denuders have the above mentioned characteristics, the coating, drying and washing are laborious procedures. Automating this technique will also improve the precision and reduce the risk of contamination. Bos [8] reported an automatic system in which three pumps were used and the washing solution was delivered to the measuring cuvette by gravity.

More recently, much research has been devoted to the theoretical [14] and practical [15] aspects of membrane-based gas diffusion in flow injection analysis (FIA). The theory is based on two flowing streams (donor and acceptor) which are physically separated by a hydrophobic membrane that allows only gases to cross. Thus, reactive gases can be determined by monitoring the gas that crosses the membrane and accumulates on the acceptor side via reaction with the acceptor reagent. A gas-permeable membrane in combination with

* Corresponding author.

*SSDI* 0039-9140(95)01610-4

a pH indicator has been used for determination of ammonia in air [16], water [17,18] and fermentation medium [19]. The actual limit of detection for gaseous ammonia is 200 ppb [16], but acidic gases in sample air, such as $CO_2$, $NO_2$ and $SO_2$, interfere with the determination of low ammonia concentrations. A more complex membrane-based diffusion denuder, called a diffusion scrubber or permeation denuder [20], was introduced by Dasgupta [21] for the continuous collection and analysis of water-soluble gases, such as $NH_3$, $SO_2$, $H_2O_2$ and HCHO. With a fluorescence detection system, the detection limit for gaseous ammonia is estimated to be 0.01 ppbv [22]. Unfortunately, the collection of gases in a diffusion scrubber is not 100% effective, and usually in the range 5–30% [20]. The collection efficiency (fluorescence response) depends on the length of the membrane, atmospheric pressure, temperature and relative humidity [22].

Our research has been focused on the development of a simple injection system which is capable of measuring gases at low concentrations (ppbv) without the influences of varying enviromental parameters and interferences from other gases. Ammonia is taken as a model for its important role in the atmosphere as mentioned above. The present paper is studying the feasibility of coupling a gas diffusion denuder with a flow/sequential injection system for the measurement of ammonia.

## 2. Experimental

### 2.1. Apparatus

Fig. 1 provides a schematic diagram of the injection system used in this study. The flows were driven by an Alitea XV peristalic pump (Alitea USA, Medina, WA) with Masterflex # 13 pump tube (Cole-Parmer Instrument Company, Chicago, IL) and solutions were selected by an eight-port rotary selection valve $V_1$ (Valco Instruments Co. Inc., Houston, TX). Unused ports were plugged with Upchurch fittings (Upchurch, Oak Harbor, WA). Valves $V_2$ and $V_3$ were three-port glass valves with inner diameter (i.d.) of 1.0 mm (Machine Shop of the Chemistry Department, University of Washington), both of which were switched manually. The diffusion denuder sampling tube (ST) was a 20 cm long Pyrex glass tube of 1.0 mm i.d. The holding coil (HC) was 300 cm

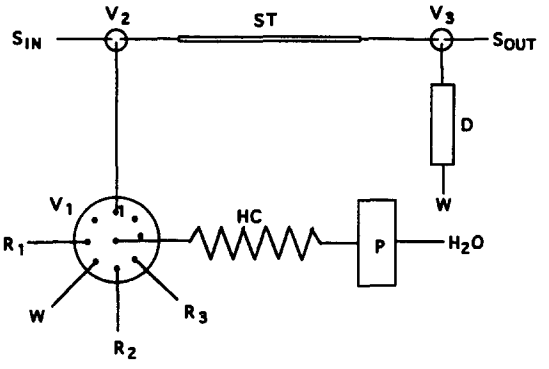

Fig. 1. Schematic diagram of the injection manifold: P, pump; HC, holding coil; $V_1$, $V_2$, $V_3$, valve; $R_1$, coating solution; $R_2$, hypochlorite solution; $R_3$, phenate solution; ST, sampling tube; $S_{IN}$ and $S_{OUT}$, inlet and outlet of gas sample; D, flow through detector; W, waste.

of 0.8 mm i.d. Teflon tubing (Upchurch, Oak Harbor, WA) and was connected to the common port of the selection valve. Teflon tubing (0.8 mm i.d.) and Teflon nuts and ferrules (Upchurch, Oak Harbor, WA) connected valves and the detection cell. The connections of the glass tube and valves were made with Masterflex # 13 pump tube (Cole-Parmer Instrument Company, Chicago, Il) and the section was made as short as possible to reduce the contact of flows with the pump tubing. The detection cell was a sandwich cell made of two pieces of rigid PVC (30 mm × 30 mm × 12 mm) with a 1.0 mm Teflon spacer [23]. A Brinkmann colorimeter (PC-701, Brinkmann Analytical, Wesburg, NY) served as both the light source and the detector. The reflected light was passed through a 610 nm filter and was measured as the absorbance. The pump and valve $V_1$ and the data collection were controlled with Atlantis (Lakeshore Technologies Inc, Chicago, IL) and subsequent data processing was performed with Matlab (The Math Works Inc. Natick, MA).

### 2.2. Chemicals

All chemicals (except household bleach solution) were reagent grade. All solutions were prepared in purified water (NANOpure II, Syborn Barnstead, Dubuque, IA). Calibrated gaseous ammonia standards were obtained from gas permeation tubes, part numbers 111-200-0140 (5730 ng $min^{-1}$ at 30 °C) and 112-010-0140 (288 ng $min^{-1}$ at 30 °C) from VICI Metronics, Inc., Santa Clara, WA.

The coating solution was made by diluting 5.0 ml of phosphoric acid and 5 ml of glycerol with water to 100 ml. An alkaline phenate solu-

tion was made by dissolving 5.0 g of phenol, 12.0 g of sodium hydroxide and 33 ml of ethanol in water and diluting to 100 ml. Alkaline hypochlorite solution was prepared by dissolving 2 g of sodium hydroxide and 2 g of sodium tetraborate decahydrate in 61 ml of household bleach solution (containing 5.25% active chlorine) and diluting to 100 ml.

### 2.3. Procedure

The standard gaseous ammonia used was from a calibrated gas permeation tube. The permeation tube bleeds a certain amount of ammonia per unit time at a specified temperature, given by the calibration equation provided by the manufacturer. Ammonia from a permeation tube was diluted with zero air (house air purified with phosphoric acid impregnated silica gel) in the permeation tube holder (VICI Metronics Inc. Santa Clara, CA) using a gas calibrator (GC Industries, Chatsworth, CA) at a flow rate of 300 ml $min^{-1}$ (unless otherwise specified). Since the amount of ammonia in the gaseous flow is time dependent, accurate amounts of ammonia are acquired by exact timing.

The flow cycle typically followed the following scheme. With valves $V_1$, $V_2$ and $V_3$ open from the pump/holding coil to the detector (position 1), water was driven through valves $V_1$ and $V_2$, the sampling tube, valve $V_3$ and the detection cell to wash all the system for 15 s at a flow rate of 0.6 ml $min^{-1}$. Valve $V_3$ was then changed to position 2, and the pump was reversed to remove water from the sampling tube while leaving water in the detector. When all the wash water was back to the holding coil, valve $V_1$ was switched to port $R_1$, and the coating solution was aspirated into the holding coil for 20 s. Next, the pump was changed back to forward and at the same time valve $V_1$ was switched back to position 1. The coating solution was driven through valves $V_1$ and $V_2$ to the sampling tube, and when the coating solution arrived at valve $V_3$, the pump was reversed to drive the coating solution back to the holding coil. Following that, valve $V_2$ was changed to the sampling position ($S_{in}$) to start the sampling, and the gas sample flowed through the sampling tube and exited at $V_3$ (a real sample can be aspirated through the sampling tube by the connection of an air pump at the outlet of $V_3$). Valve $V_1$ was switched to port W and the pump was changed back to forward to push all the coating solution and wash water in the holding coil to the waste bottle. After a certain sampling time, valve $V_2$ was turned back to position 1 to end the sampling, Valve $V_1$ was switched first to port $R_2$ and then $R_3$ to sequentially aspirate hypochlorite solution and phenate solution for 4 s each, with the pump reversed, then valve $V_1$ was switched back to position 1 and the pump back to forward. The phenate solution and hypochlorite solution were driven through the sampling tube. When the solution arrived at valve $V_3$ (just to the far end of the hole in the valve), the pump was stopped for 45 s, and valve $V_3$ was turned back to position 1. Finally, the pump was started to drive the colored liquid (including the sorbent) through the detection cell, the signals were collected at 2 Hz and the data were saved in Atlantis for further processing, and a response curve (as shown in Fig. 2) was obtained.

## 3. Results and discussion

### 3.1. Colorimetric determination

When the air sample passes through the coated glass diffusion tube, gaseous ammonia diffuses to the wall of the tube and is converted to ammonium phosphate ($NH_4H_2PO_4$). Nessler's reagent and the Berthelot reaction are the most frequently used colorimetric methods for the determination of ammonium and/or ammonia. Both have been utilized in flow injection systems [24–28]. We first attempted to use Nessler's reagent because only one reagent solution is needed. Unfortunately, it forms a precipitate with ammonia and some of the precipitate is adsorbed on the wall of the tube. Neither linear response nor reproducible results were obtained. With the Berthelot reagent, ammonia is oxidized by hypochlorite to form chloramine which then reacts with phenol to generate a blue indophenol dye. In the range 0.15–4.0 μg ammonia, the absorbance of the indiphenol dye at 610 nm is quite linear with the amount of ammonia. In addition, the sensitivity and reproducibility of the Berthelot reaction are much better than with Nessler's reagent. Thus, the Berthelot reaction is chosen for the colorimetric determination of ammonia collected in the tube wall.

The effects of the sequence of the addition of hypochlorite and phenate solutions on the formation and intensity of the color was checked

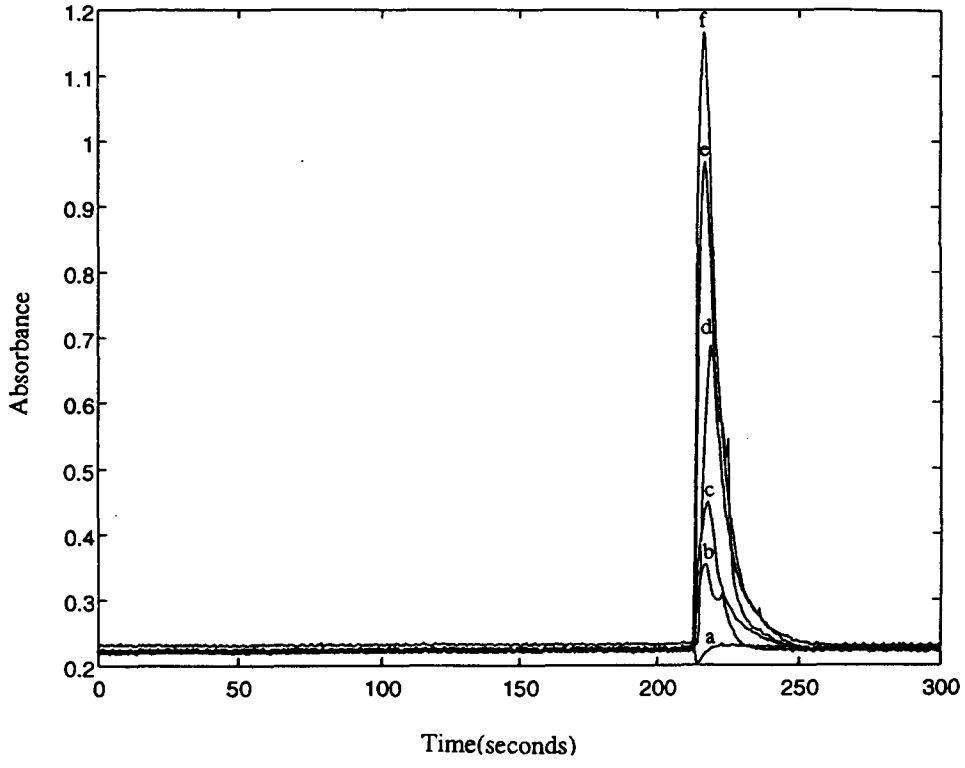

Fig. 2. Response curves for gaseous ammonia standards from a permeation tube: curve a, blank; curve b, 0.5 μg $NH_3$; curve c, 1.0 μg $NH_3$; curve d, 2.0 μg $NH_3$; curve e, 3.0 μg $NH_3$; curve f, 4.0 μg $NH_3$. Conditions: tube length, 20 mm; coating solution, 5% $H_3PO_4$ + 5% glycerol; gas flow rate, 300 ml $min^{-1}$; liquid flow rate, 0.6 ml $min^{-1}$.

by changing the orders in which the reagents were aspirated into the holding coil. The volume and ratio of the reagents, the flow rate of liquid flows and the time for color development were optimized, with the following results.

(i) Reproducible results can be obtained only with the sequence described in the analytical procedure, i.e. the alkaline phenate zone should be the first solution passing through the glass diffusion tube.

(ii) The peak height decreased slowly with increased reagent volumes in the range 20–100 μl. When the volumes of hypochlorite and phenate solution are less than 20 μl, the reproducibility decreases dramatically.

(iii) A ratio 1:1 of the volume of hypochlorite and phenate solutions gave the highest absorbance.

(iv) With fixed volume and ratio of the reagents, the peak height did not change significantly with flow rate of liquid flows in the range 0.4–1.0 ml $min^{-1}$, even though the peak width decreased with the increased flow.

(v) The color intensity of the indophenol dye increased with the time for color development very quickly in the first 20 s, then slowly, and after 40 s, the color development essentially finished and the increase of absorbance was not significant. Instead of a reaction coil between the glass diffusion sampling tube and detection cell, the pump was stopped for 45 s for color development. Thus the dispersion of the colored indophenol dye was reduced.

### 3.2. Sampling tube

The diffusion sampling tube is a glass tube, the inner wall of which has been coated with sorbent. Tubes with 3–5 mm i.d. [1,8] were used for off-line batch analysis, but these tubes are not suitable for flow injection analysis because of their large inner diameter. Glass tubes with 1 mm i.d. were chosen in this study. When an air sample passes through the coated tube, gaseous ammonia diffuses to the tube wall and is absorbed by reaction with the coated sorbent. The following equations have been used to describe the absorption of ammonia in a coated tube [1]:

$$C/C_0 = 0.819\exp(-14.6272\Delta) + 0.0976\exp(-89.22\Delta) + 0.01896\exp(-212\Delta) \quad (1)$$

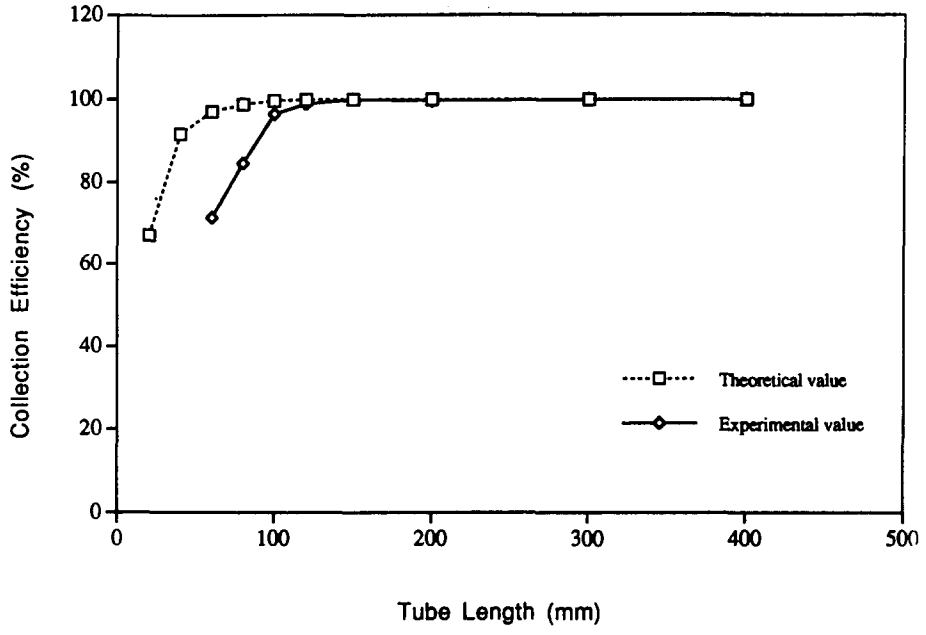

Fig. 3. Effect of tube length on the collection efficiency. Conditions are the same as for Fig. 2 except the tube length.

with a laminar gas flow (Re < 2000).

$$\Delta = \pi DL/4F \quad (2)$$

where $C$ is the mean ammonia concentration in the gas leaving the tube, $C_0$ is the concentration in the incoming gas, $D$ is the diffusion coefficient, $L$ is the length of tube, $F$ is the gas flow rate, and Re is Reynolds number.

It is readily apparent in these equations that the absorption efficiency of a coated tube is a function of the gas flow rate and the tube length. The determination of the collection efficiency of tubes with different lengths was carried out in the following manner. Two glass tubes (1 mm i.d.) were connected in series. The length of the second tube was always 20 cm, but the first one was changed as needed. Both of the tubes were coated with the coating solution, and 4 μg of ammonia from the permeation tube were aspirated through the tubes at a flow rate of 300 ml $min^{-1}$. The ammonia collected in the two tubes was separately determined by the proposed method. Braman et al. [29] pointed out that there is a minimum tube length value after which Eq. (1) is valid. The equation was derived on the assumption that there was an infinite number of chemisorption sites, i.e. the tube is very long. Fig. 3 shows that theoretical calculation and the experimental collection efficiencies of our system. The threshould tube length is about 10 cm, and a 20 cm glass tube was used in the proposed system.

### 3.3. Coating solutions

Two substances have formerly been used as sorbents for ammonia: oxalic acid, $H_2C_2O_4$ [1] and phosphorous acid, $H_3PO_3$ [7]. Although very effective, both of them are reductants and will probably interfere with the color formation and density for the reaction of ammonia with Berthlot reagents [25]. Phosphoric acid was used in the proposed method as absorbent for gaseous ammonia and it was demonstrated to be very effective. The collection capacity of the coated tube (20 cm × 1.0 mm i.d.) increases almost linearly with phosphoric acid concentration in the coating solution (shown in Fig. 4). For constant color development, a corresponding increase in sodium hydroxide concentration is needed as the acid concentration increased. Glycerol was added to the coating solution to increase the viscosity, thus aiding in the coating of the tube wall.

### 3.4. Gas flow rate

Eq. (1) and (2) indicate that the collection efficiency of a coated tube is a function of gas flow rate. The effect of the gas flow rate on the collection efficiency was checked by aspirating

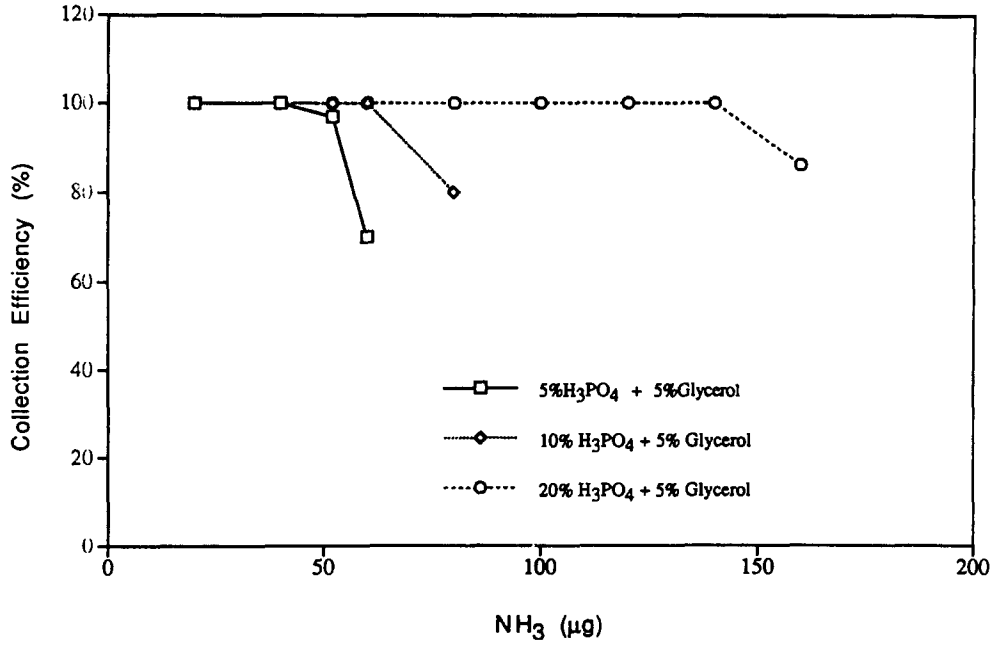

Fig. 4. Effect of coating solutions on the collection efficiency. Conditions are the same as for Fig. 2 except the coating solution.

an accurate amount (4 μg) of ammonia through the coated sampling tube at different flow rates and then determining the ammonia absorbed in the tube. No significant decrease in collection efficiency was observed with the gas flow rate in the range 200–1000 ml $min^{-1}$ (data not shown). Flow rates higher than 1000 ml $min^{-1}$ have not been studied because they are not available with our gas calibrator. It is evident that the collection efficiency will decrease when the gas flow rate exceeds a certain limiting value, because the flow conditions in the sampling tube will not be laminar if the flow rates are larger than 1.45 l $min^{-1}$ [1,8].

### 3.5. Calibration curve and statistics

Fig. 2 shows typical response profiles of ammonia from the permeation tube. The peak height is proportional to the ammonia amount in the range 0.15–4.0 μg. The calibration curve from the data presented in Fig. 2 was

$$Y = (0.243\ \text{AU}\ \mu g^{-1})X - 4.80 \times 10^{-3}\ \text{AU} \qquad (R^2 = 0.997)$$

The negative response of the blank is due to the presence of ethyl alcohol in the phenate solution and its value depends on the mixing process of the reagent with water. We have noted that less than 0.15 μg of ammonia can produce a positive signal, but these levels cannot be discriminated from each other. The actual LOD is 0.15 μg ammonia. The LOD for an air sample depends on the gas flow rate and sampling time. If air sample was collected at 800 ml $min^{-1}$ for 5 min at 25 °C, the LOD for air was 50 ppb. Lower LODs can be achieved by increasing sampling time and/or flow rate. The total time of a single analysis also depends on the sampling resolution. The time of a typical analysis shown in Fig. 2 is 5.0 min. The relative standard deviations for the determination of 1.2 μg ammonia ($n = 7$) and 2.7 μg ammonia ($n = 8$) were 4.4% and 3.25% respectively.

## 4. Conclusion

The combination of a gas diffusion denuder sampler and flow/sequential injection results in a selective and sensitive measurement of gaseous ammonia. The selective absorption of ammonia in the glass sampler eliminates the interference of coexisting acidic gases, such as $SO_2$, $NO_2$ and $CO_2$, which interfere with membrane and pH indicator systems. The high collection efficiency and enrichment factor of the sampler concentrates low levels of ammonia in a large air sample into a very small amount of sorbent. In combination with SIA, only small amounts of reagents are needed, and the developed color is limited to a small zone of the

flow, making this method very sensitive. As an ongoing study, we will investigate the deposition of the particles at the inlet of the sampling tube which will probably happen when real samples are analyzed. Further, the system will be modified so that higher flow rates can be used and the effect of long-term sampling on the reproducibility of the measurements will be studied. This system can be used for both online and offline analysis of ammonia and exploited for the determination of other gaseous analytes, such as $SO_2$, $NO_2$ and $H_2S$.

## Acknowledgments

The authors would like to thank Mr. Oleg Egorov for valuable help in running Atlantis and Dr. David Holman and Ms. Kristina Peterson for their helpful discussion in the preparation of this manuscript. The financial support of the U.S. Environmental Protection Agency is acknowledged.

Short communication

# TLC separation and derivative spectrophotometry of some amino acids

Irena Baranowska *, Małgorzata Kozłowska

*Department of Analytical and General Chemistry, Silesian Technical University, 44-101 Gliwice, Poland*

Received 22 November 1994; revised 23 February 1995; accepted 24 February 1995

**Abstract**

Chromatographic systems for the separation of amino acid mixtures on RP-18 as a stationary phase have been elaborated. The best results were obtained using methanol–water (1:1, v/v; 1:3, v/v; 1:5, v/v) as a mobile phase.

The following amino acids have been examined: asparagine, arginine monohydrochloride, cystine, cysteine chloride, glycine, histidine monohydrochloride, hydroxyproline, isoleucine, leucine, lysine monochloride, methionine, ornithine monohydrochloride, phenylalanine, proline, threonine, tryptophan, tyrosine, serine, valine. Histidine (as monohydrochloride) and methionine were determined by first-, second- and third-derivative spectrophotometry in a mixture of several amino acids.

*Keywords:* Amino acids; Spectrophotometry; TLC

## 1. Introduction

The analysis of amino acids as well as their chromatographic separation is still a current problem, especially in medical analysis. In the literature, several chromatographic systems, based on adsorption TLC, are described for chosen groups of amino acids. Separation has been carried out on silica gel [1–5] and cellulose [6,7]. Bidirectional adsorption chromatography has also been used [8]. Several works are concerned with the method of detection of chromatograms [2–4]; ninhydrin is most often used. In the present work, reversed-phase partition TLC (RP-18) was applied to separation of a chosen group of amino acids. Up to the present time, such separation has not been described.

In addition to these investigations, derivative spectrophotometry was used. Spectrophotometry is also frequently applied to the analysis of amino acids which form coloured compounds with various substances. Cystine and cysteine have been determined spectrophotometrically with Cu(II)–neocuproin reagent [9,10], and also with $OsO_4$ in urine [11]. Amino acids have been analysed as compounds with carbon disulphide [12] and cystein as a compound with OPA [13]. *p*-Benzoquinoline has also been used for the determination of amino acids [14]. The obtained results were not always satisfactory.

The reason for applying derivative spectrophotometry [15] is that it can be more sensitive and selective than zero-order spectrophotometry. A derivative spectrum is a graphical dependence of a value of the differential of absorbance with respect to wavelength on the wavelength. It can be described by the formula

$$\frac{d^n A}{d\lambda^n} = {}^nD_{x,\lambda} = f(\lambda)$$

where $n$ is the derivative order, and ${}^{n}D_{x,\lambda}$ is the value of the $n$th-order derivative of the absorption spectra of a substance x at a certain wavelength $\alpha$.

Derivative spectrophotometry is especially useful in improving selectivity. Tryptophan and tyrosine in synthetic peptides [16], and aromatic amino acids — tryptophan, tyrosine and phenylalanine — in proteins [17], were analysed by the use of second-order derivative spectrophotometry.

In the present paper, the determination of histidine and methionine in the mixtures containing several amino acids was elaborated.

## 2. Experimental

### 2.1. Equipment

TLC separation was done on $10 \times 20\ cm^2$ glass plates covered with a 0.25 mm layer of

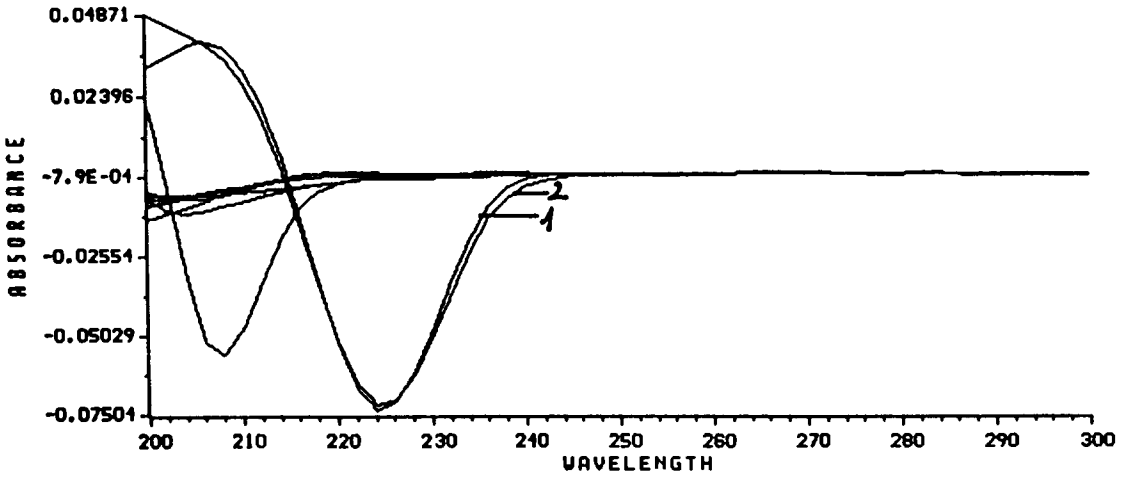

Fig. 2. First-derivative spectra of histidine (1), arginine, ornithine, asparagine, proline, hydroxyproline, isoleucine, serine, valine and mixtures (2).

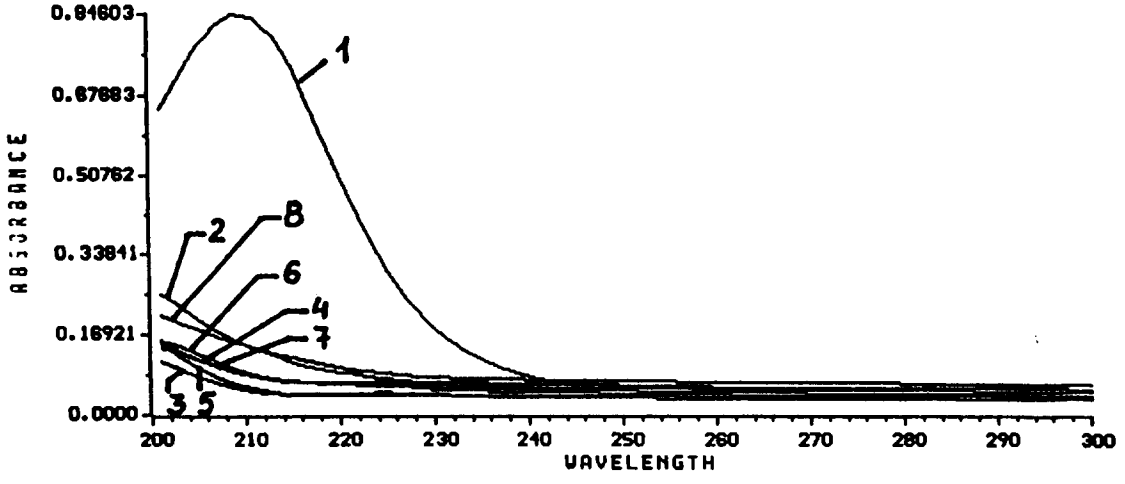

Fig. 3. "Zero-order" spectra of methionine (1), asparagine (2), hydroxyproline (3), isoleucine (4), ornithine (5), proline (6), serine (7) and valine (8).

RP-18 (E. Merck, Darmstadt) in Shandon's containers. The absorption spectra were recorded on a Hewlett Packard HP-8452A UV/vis spectrophotometer with 1 cm cells.

### 2.2. Reagents

All amino acids were produced by E. Merck, Darmstadt. 1 mg $ml^{-1}$ aqueous solutions of amino acids were used, except in the case of cystine (0.1 mg $ml^{-1}$) and tyrosine (0.45 mg $ml^{-1}$), for TLC. Solutions containing 0.1 mg $ml^{-1}$ of amino acids, except for histidine (0.05 mg $ml^{-1}$), were used in derivative spectrophotometry.

### 2.3. Procedure

All chromatograms were developed over a distance of 15 cm in Shandon's containers. The following developing mixtures were applied: methanol–water (3:1, v/v; 1:1, v/v; 1:3, v/v; 1:5, v/v), propanol–water (3:1, v/v; 1:1, v/v; 1:3, v/v) and acetonitrile–water (1:1, v/v). Chromatograms were detected by a 0.25% solution of ninhydrin in acetone. Derivative spectra were calculated by the use of a standard software procedure.

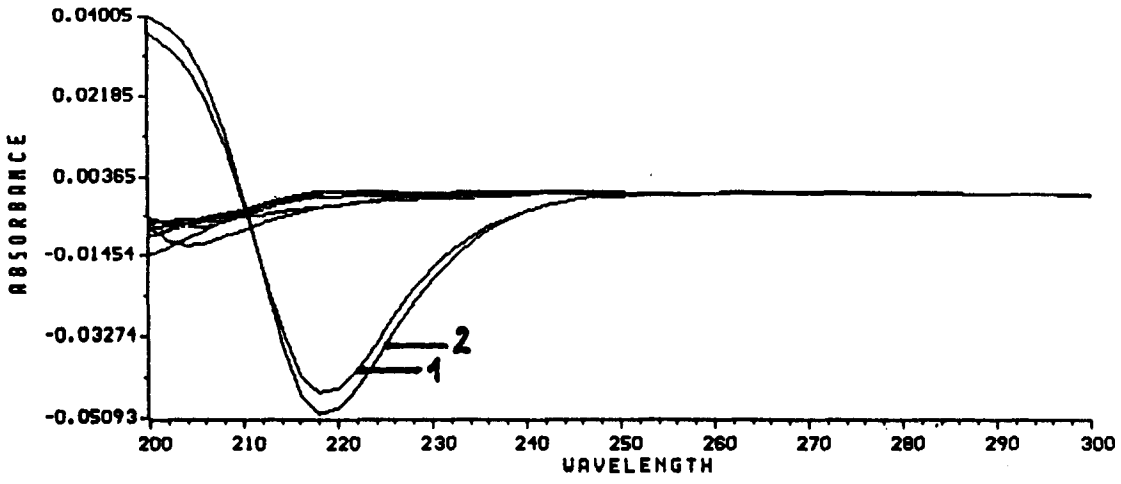

Fig. 4. First-derivative spectra of methionine (1), ornithine, asparagine, proline, isoleucine, hydroxyproline, serine, valine and mixtures (2).

Table 2
Parameters of the straight line dependence and correlation coefficient of histidine and methionine for first-derivative (D), second-derviative ($^2$D) and third-derivative ($^3$D) spectrophotometry

| | Histidine | | | | Methionine | | | |
|---|---|---|---|---|---|---|---|---|
| | $\lambda$ (nm) | $a$ | $b$ | $r$ | $\lambda$ (nm) | $a$ | $b$ | $r$ |
| D | 224.6 | $-1.97 \times 10^{-3}$ | −1.49 | 0.998 | 218.9 | −2.76 | −0.49 | 0.997 |

## 3. Results and conclusions

### 3.1. Thin-layer chromatography

Some systems suitable for the separation of amino acids have been found (Table 1). The greatest differences between $R_f$ values of investigated compounds were obtained for the systems containing methanol and water. The six amino acids cysteine chloride, isoleucine, phenylalanine, methionine, serine, tryptophan were separated in the mixture methanol–water (1:1, v/v); phenylalanine, methionine, threonine, tryptophan, tyrosine, valine were separated in the mixture methanol–water (1:5, v/v).

The best results were obtained for the mixture methanol–water (1:3, v/v). Under these conditions, seven amino acids can be separated: asparagine acid, hydroxyproline, phenylalanine, leucine, methionine, proline, and tryptophan.

In spite of the fact that the results obtained in the systems propanol–water are not so good, monohydrochlorides and monochlorides of chosen amino acids can be separated in these circumstances. To the best of our knowledge, such separations are not reported in the literature.

Spots of all amino acids were of good visibility, with sharp edges against the white background of the plates.

### 3.2. Derivative spectrophotometry

Spectrophotometric determination of histidine was carried out by the use of derivative spectrophotometry to complete chromatographic separation and analysis of this amino acid in the mixture. The following amino acids were used in this determination: histidine, arginine, ornithine, asparagine, proline, hydroxyproline, isoleucine, serine, valine (Figs. 1 and 2).

Zero-order spectrophotometry cannot be applied in this case, while first-, second- and third-order derivative spectrophotometry allows histidine to be determined with a good accuracy at a concentration of 8 $\mu g\ ml^{-1}$.

Methionine in a mixture with ornithine, asparagine acid, proline, hydroxyproline, iso-

leucine, serine, valine was analysed in the same way (Figs. 3 and 4). In this case it was also possible to determine a methionine concentration of 10 μg ml$^{-1}$. Straight line dependence was evaluated for amino acids by the use of derivative spectrophotometry. Parameters of the equation

$$''D = ac + b$$

where $''D$ is the value of derivative, $c$ is the concentration, $a$ is the intercept and $b$ is the slope, for a particular order of derivatives and suitable correlation coefficients for histidine and methionine, are gathered in Table 2.

# Studies on urea biosensors based on immobilized corynebacterium glutamicum and their kinetic response processes

Cheng-Hong Lei [a], Ya-Fang Bao [a], Jia-Qi Deng [a,*], Cheng-Xiang Lei [b]

[a] *Department of chemistry, Fudan University, Shanghai 200433, People's Republic of China*
[b] *Institute of Genetics, Fudan University, Shanghai 200433, People's Republic of China*

Received 5 January 1995; accepted 20 March 1995

**Abstract**

Two novel biosensors for urea based on immobilized corynebacterium glutamicum 617 and corynebacterium glutamicum ATCC13032 in calcium alginate gel coupled with an ammonia gas-sensing electrode, were designed and constructed. Calibration plots of measured potential difference (mV) vs. log of urea concentration were linear in the range of $5.6 \times 10^{-5}$–$1.4 \times 10^{-2}$ and $5.6 \times 10^{-5}$–$1.1 \times 10^{-2}$ mol $l^{-1}$, with slopes of 59.2 and 61.3 mV per decade respectively, in pH 8.0, 0.1 mol $l^{-1}$ phosphate buffer solution at 30°C. The relationship between the initial response velocity and the substrate concentration was also discussed. The results indicate that the kinetic response process of the reaction catalyzed by bacteria is similar to that by isolated enzyme. Using an Eadie–Hofstee plot, the apparent Michaelis constant $K_m$ and the maximum initial response velocity $V_m$ for urease in the immobilized bacterial membrane were determined. The two urea biosensors were successfully applied for the actual measurement of urea in urine and were relatively stable for 20 and 40 days respectively.

## 1. Introduction

As the development of enzyme electrodes is limited by the need to purify the required enzyme and the demanding conditions for preserving it, and as the pure enzyme without any cofactors is not efficient enough to catalyze the expected biochemical reactions, a current trend in the development of biosensors is the utilization of novel biological materials as biocatalytic layers. Among these are living microorganisms, animal and plant tissues [1]. The use of living microorganisms such as bacteria, because of their good catalytic behavior, abundant source and lack of seasonal limitations, as possible alternatives to highly expensive isolated enzymes is a rapidly developing method. Divies designed the first amperometric bacterial biosensor [2], and the first potentiometric-based one was later reported by Rechnitz et al. [3]. Bacterial sensors sensitive to L-glutamine [4], L-cysteine [5], glucose [6], methane [7], L-aspartate [8,9], glutamic acid [10], sulfate [11], DL-phenylalanine [12], etc., have successively been reported by many workers.

The determination of urea by means of biosensors is of importance in clinical and other areas. Several urea biosensors based on immobilized isolated urease were constructed by various groups [13–15] in the 1970s. A jack bean meal biosensor for urea was reported by Arnold and Scott [16] in 1984 to be a good alternative to the urease-based ones, but a demand of fresh jack bean must be satisfied. With this in mind, living microorganisms containing abundant urease would be considered. Proteus mirabilis was applied as a paste to the dialysis membrane and coupled with a gas-permeable

*SSDI* 0039-9140(95)01594-9

electrode to constitute the biosensors for urea by Ihn and co-workers [17,18]. In this paper, we found two kinds of corynebacterium glutamicum (617 and ATCC13032) containing abundant urease that can specifically catalyze the decomposition of urea into carbon dioxide and ammonia. These two immobilized bacterial membranes in calcium alginate gel were held on an ammonia electrode to constitute the biosensor for urea. Both resulting biosensors showed a longer lifetime and linear detection range from a lower substrate concentration than that based on Proteus mirabilis. The relationship between the initial response velocity and the substrate concentration was also studied. The results indicate that the kinetic response process of the reaction catalyzed by bacteria is similar to that catalyzed by isolated enzyme [19–21]. The authors think this is just the theoretical basis on which bacteria can be used instead of isolated enzyme. Corynebacterium glutamicum, which can be cultured rapidly and used safely, is usually utilized in the fermentation industry. To our knowledge, the utilization of corynebacterium glutamicum as a biocatalytic material for biosensors has not been previously described.

## 2. Experimental

### 2.1. Apparatus and reagents

A Hitachi 20PR-52D type high speed refrigerator centrifuge was used to treat the cultured bacterium suspension liquid. All potentiometric measurements were made with a model PXS-215 ionic activity recorder (No. 2 Shanghai analytical instrument factory) in conjunction with a YEW type 3086 strip chart recorder. A model 501 ammonia electrode (Jiangsu Electroanalytical Instrument Factory, Taixian, China) was employed and modified as described below. Measurements were carried out in a thermostated stirrer.

Analytical grade reagents were used to prepare all buffers and standard solutions. All solutions were prepared in freshly deionized water. The amino acids were obtained from Shanghai biochemical reagents store. Corynebacterium glutamicum 617 was obtained from the Genetics Institute of Fudan University, and ATCC13032 from American Type Culture Collection.

### 2.2. Procedure

The medium for culturing bacteria was composed of 1.0% peptone, 0.5% yeast powder, 1.0% sodium chloride and 0.004% nalidixic acid. This medium was autoclaved at 121°C, 1.1 kg $cm^{-2}$ for 20 min. The solution was allowed to cool and the corynebacterium glutamicum was aspetically inoculated on this liquid medium. The inoculated medium was kept in a temperature controlled vibratile culture case at 30°C for 20 h. The cells were harvested by centrifuge at 7000$g$ for 6 min at 4°C, washed twice with 0.1 mol $l^{-1}$ phosphate buffer solution and centrifuged. The cells were kept in a refrigerator at 4°C when not in use. 90 mg of the collected cells and 150 mg of 4% sodium alginate were completely mixed and spread on a glass plate to make a $6 \times 1.5$ $cm^2$ membrane. This was immersed in a 4% calcium chloride solution for 1 h to immobilize the cells. A piece (weight 20 mg, thickness 0.2 mm, diameter 10 mm) of such an immobilized bacterial membrane was cut off and washed with water, and then sandwiched between two piece of cellulose acetate dialysis membranes and held on the gas-permeable membrane of an ammonia gas-sensing electrode to construct the biosensor for urea (see Fig. 1). An internal reference solution of 0.1 mol $l^{-1}$ $NH_4Cl$ was used. This prepared biosensor was stored in the 0.1 mol $l^{-1}$ phosphate buffer in a refrigerator when not in use.

Potentiometric measurements of the steady-state response were carried out in the usual manner. An aliquot of the 0.1 mol $l^{-1}$ urea stock solution was pipetted into a 25 ml beaker

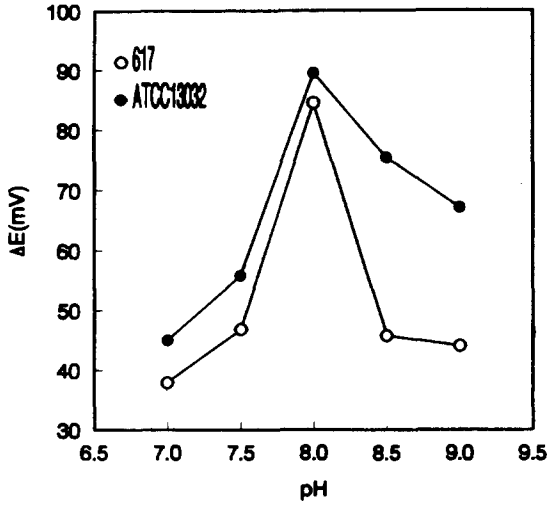

Fig. 2. pH profile for two urea biosensors in 0.1 mol $l^{-1}$ $Na_2HPO_4$–$KH_2PO_4$ buffer solution at 30°C; [urea] = $10^{-3}$ mol $l^{-1}$.

containing 10 ml of 0.1 mol $l^{-1}$ phosphate buffer. The solution was magnetically stirred and the steady-state potential was recorded. After a measurement, the biosensor was washed free of residual urea and ammonia with water until a stable blank potential was obtained.

## 3. Results and discussions

### 3.1. Working conditions

The principal reactions of corynebacterium glutamicum to urea are

$$NH_2CONH_2 + H_2O \xrightarrow{\text{urease}} CO_2 + NH_3$$

$$NH_3 + H_2O \rightarrow NH_4^+ + OH^-$$

The optimal pH value of the urease catalyzed reaction is from 6 to 7. However, the strong pH dependence of the enzymatic activity and the gas-sensing electrode make the solution pH a critical parameter. The effect of pH on the bacterial sensor response was studied at different pH values in 0.1 mol $l^{-1}$ $Na_2HPO_4$–$KH_2PO_4$ buffer. Fig. 2 shows the pH profile for the two biosensors. It can be seen that optimal biosensor responses are obtained at pH 8.0. Borax–potassium dihydrogen phosphate buffer solution was also tried as a working buffer system, but showed very poor response. This result indicates that the buffer system not only controls the pH value of the working solution, but also inhibits or activates the enzymatic activity of bacteria. Hence, the buffer solution of pH 8.0, 0.1 mol $l^{-1}$ $Na_2HPO_4$–$KH_2PO_4$ was used throughout this paper.

The variation in signal was only 5% as the temperature increased from 20 to 40°C. However, at temperatures lower than 20°C, the activity of the enzyme in the cells was rather lower and the response time was relatively longer. At temperatures higher than 35°C, the lifetime of the sensors was shortened. Taking both the lifetime and response time into consideration, 30°C was the selected temperature for this work.

### 3.2. Biosensor response characteristics and lifetime

Typical calibration curves were obtained from two biosensors (Fig. 3). A comparison of the response characteristics of the two urea biosensors is shown in Table 1.

It can be seen that the biosensors based on both corynebacterium glutamicum 617 and ATCC13032 show good Nernstian behavior. The latter can provide a satisfactory reproducible potential even at lower concentrations. Thus, the nonlinear portion of its calibration curve could be used without significant error. Comparing these two sensors, that based on corynebacterium glutamicum ATCC13032 had a narrower linear range, but a lower detection limit, faster response and longer lifetime than the other.

It took 1–5 and 3–7 min to obtain a 98% response for the biosensors based on corynebacteria glutamicum ATCC13032 and 617 within the linear range of the sensors' response. It took

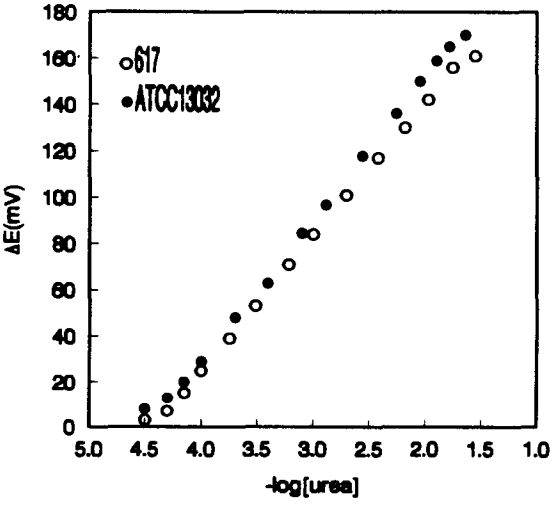

Fig. 3. Typical calibration curve for two urea biosensors.

Table 1
Comparison of the response characteristics of two urea biosensors

| | Bacteria | |
|---|---|---|
| | 617 | ATCC13032 |
| Linear range (mol $l^{-1}$) | $5.6 \times 10^{-5}$–$1.4 \times 10^{-2}$ | $5.6 \times 10^{-5}$–$1.1 \times 10^{-2}$ |
| Slope (mV per decade) | 59.2 | 61.3 |
| Detection limit (mol $l^{-1}$) | $2.0 \times 10^{-5}$ | $1.5 \times 10^{-5}$ |
| Response time (min) | 8–14 | 5–9 |
| Lifetime (days) | at least 20 | at least 40 |

a longer time to obtain the steady-state response (see Table 1).

After 28 days, the ATTCC13032 sensor slope reached a constant value of 58 mV per decade, and showed little change in the response and linear range. It continued to respond in a useful fashion after 40 days. In contrast, the 617 sensor reached a remained constant value of 45 mV per decade, and showed little change in the response and linear range after 12 days; it continued to be usable for up to 20 days (see Table 2).

The biosensors based on both corynebacterium glutamicum 617 and ATTCC13032 showed linear ranges from a lower substrate concentration and a longer lifetime than that based on Proteus mirabilis [17,18].

An isolated enzyme biosensor and a jack bean biosensor that display excellent response characteristics for urea have been reported by Mascini and Guilbault [15] and Arnold and Glazier [16]. However, isolated urease is considerably more expensive and it is not easy to obtain fresh jack bean. Corynebacterium glutamicum that can be cultured at any time at room temperature, which is usually used for producing glutamic acid by employing urea as a nitrogen source, is an effective replacement for pure urease.

### 3.3. Selectivity and recovery

Although urease is highly selective for urea, it is known that microorganisms sometimes contain certain kinds of deaminases for amino acids. Hence, the interference that might be caused by them was investigated (see Table 3). The results indicated only six out of all the usual amino acids were involved in interference for urea. Glucose, saccharose and some inorganic salts also gave rise to a bit of interference. DL-Alanine, L-lysine, L-leucine, DL-threonine, L-proline, glycine, DL-methionine, L-histidine, L-tyrosine, DL-tryptophan, DL-phenylalanine, L-ornithine, L-cystine, L-glutamate, adenine monohydrochloride, $ZnSO_4$, $NaSO_4$, $MgSO_4$, $Cd(NO_3)_2$ and NaAc gave no response. The bacterial urea biosensors based on immobilized corynebacterium glutamicum gave similar results to those from Proteus mirabilis [17,18].

Interference, created in particular by amino acids, is a problem which is hard to avoid owing to living bacteria usually containing more than one kind of enzyme. However, this does not obstruct the successful measurement of some real world samples containing a much higher concentration of urea than its interference substances or no main interference (see Table 4). Further studies are being carried out, employing enzyme inhibitors or HPLC, on the selectivity of bacterial urea biosensors based on immobilized corynebacterium glutamicum at this laboratory.

The recoveries of six urea samples with concentrations of $1.0 \times 10^{-4}$–$1.0 \times 10^{-2}$ mol $l^{-1}$ were determined by a calibration curve method. The average recoveries of the two sensors were in the range 94.0–103%.

### 3.4. Determination of urea in urine

A standard addition method was used for the determination of urea in urine by employing the two urea biosensors (617 and ATCC13032, see Table 4). The procedure was the same as described above. The raw urine samples were measured without any pretreatment by mixing 0.2 ml of urine with 10 ml of 0.1 mol $l^{-1}$ phosphate buffer in the thermostated cell. The potential was recorded under stirring, until a steady-state reading was established. 0.2 ml of 0.1 mol $l^{-1}$ urea standard solution was then added and the new steady-state potential recorded. The urea concentration was determined from the calibration curve. Corresponding experiments were carried out on an

ASTRA-8 automated stat/routine analyzer (the Auto-Analyzer) by a local hospital, for which the same samples had to be urease-treated and diluted 100-fold throughout.

As shown in Table 4, the analytical results using the bacterial urea biosensors correspond to those using this kind of Auto-Analyzer. However, the method using the urea biosensors described here does not require such sophisticated equipment, or the elimination of proteins and coloration for the conventional spectrophotometric method and any other pretreatment. Therefore, it is an easy, quick and precise means of determining urea.

### 3.5. Kinetic response process

Fig. 4 shows the relationship between the initial response velocities ($V$, $dE/dt$) and the substrate concentration ([S]) for two urea biosensors. It can be seen that when [S] < $6.0 \times 10^{-4}$ mol $l^{-1}$, $V$ increased rapidly and linearly with [S]. However, when [S] was higher than this concentration, $V$ rose more and more slowly towards a maximum, indicating that the urease in the bacterial cells was gradually saturated by the substrate urea. Such a kinetic response process is similar to that of the reaction catalyzed by isolated enzyme [19–21]. This is just

Table 4

[urea]*: mol $l^{-1}$.

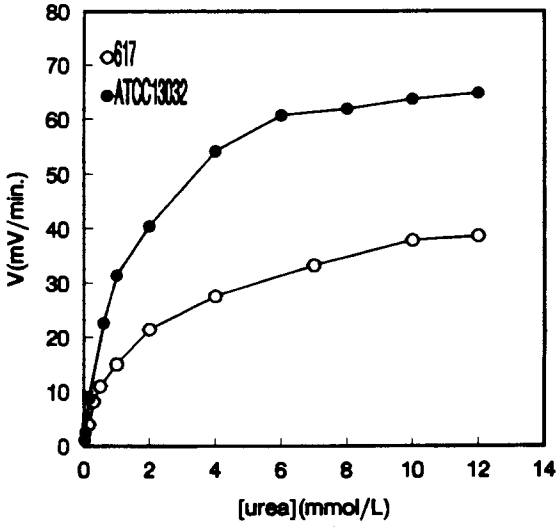

Fig. 4. Relationship between [S] and V for two urea biosensors.

Table 5
The kinetic data for two biosensors

| Bacteria | $K_m$ mol $l^{-1}$ | $V_m$ (mV $min^{-1}$) |
|---|---|---|
| 617 | $2.8 \times 10^{-3}$ | 49.1 |
| ATCC13032 | $1.4 \times 10^{-3}$ | 73.2 |

the theoretical basis on which bacteria can take the place of isolated enzyme as a biocatalyst. This phenomenon shows that the enzyme in the whole bacterial cell could directly catalyze the substrate. It combined with the substrate to give a kind of transient state [19,20]:

First step: $B(E) + S \rightleftharpoons B(E) \cdot S$

Second step: $B(E) \cdot S \rightleftharpoons B(E) + P$

where B(E) represents the enzyme in the whole bacterial cell.

From the Michaelis–Menten equation, $V = (V_m[S])/(K_m + [S])$, using an Eadie–Hofstee plot [19,20], $V = V_m - K_m(V/[S])$, the maximum response velocity $V_m$ ($dE/dt$, mV $min^{-1}$) and the apparent Michaelis constant $K_m$ for urease in the bacterial membrane of sodium alginate were determined. For the same substrate, the higher the rate at which the enzyme catalyzes a given biochemical reaction, the greater the activity of the enzyme. A comparison of the kinetic data of the two urea biosensors is shown in Table 5. The results indicate that the biosensor ATCC13032 had a lower $K_m$ and higher response velocity, i.e. the urease activity within corynebacterium glutamicum ATCC13032 was higher than that within corynebacterium glutamicum 617. Similarly, the biosensor ATCC13032 had a longer lifetime. Under identical experimental conditions, the activity of identical enzymes in different bacteria should be relative to the nature of the bacteria themselves in which the enzyme exists.

Received 14 October 1994; revised 27 March 1995; accepted 27 March 1995

**Abstract**

A fractal analysis is presented for the binding of pyrene in solution to β-cyclodextrin attached to a fiber-optic chemical sensor. The specific ($k_1$) and non-specific binding rate coefficients and the fractal dimension ($D_f$) (specific binding case only) both tend to increase as the pyrene concentration in solution increases from 12.4 to 124 ng ml$^{-1}$. Predictive relations for the binding rate coefficient (specific as well as non-specific binding) and for $D_f$ (specific binding case only) as a function of pyrene concentration are provided. These relations fit the calculated $k_1$ and $D_f$ values in the pyrene concentration range reasonably well. Fractal analysis data seem to indicate that an increase in the pyrene concentration in solution increases the "ruggedness" or inhomogeneity on the fiber-optic biosensor surface. The fractal analysis provides novel physical insights into the reactions occuring on the fiber-optic chemical surface and should assist in the design of fiber-optic chemical sensors.

*Keywords:* Binding rate coefficient; Chemical sensor; Fractal dimension

## 1. Introduction

There is an increasing demand for sensitive detection systems which are required to detect analytes in often very dilute and diverse circumstances. Fiber-optic biosensors have recently gained a lot of interest, and different 'schemes" have been proposed and applied to detect a wide variety of analytes [1–16]. Biosensors are finding increasing application nowadays. The antibody–antigen or enzyme–analyte recognition or reaction provides the basis for the sensitivity and/or selectivity of the reaction. The transduction of the biochemical signal to an electrical signal is often a critical step wherein a large fraction of the "signal loss", for example, fluorescence (by quenching) may occur. This leads to deleterious effects on the sensitivity and selectivity of the biosensor, besides decreasing the quality of the reproducibility of the biosensor.

The above "sensing principles" proposed initially for biosensors have recently been extended to a "chemical sensor" [17]. Here the analyte molecule that has to be detected is "sequestered" in β-cyclodextrin molecules immobilized on the distal end of the fiber-optic chemical sensor. Cyclodextrins are sugar molecules that possess the structure of a truncated cone with a hydrophobic cavity (see Fig. 1). It is in this hydrophobic cavity that the analyte is complexed and placed in a hydrophobic environment. This leads to fluorescence quenching protection (for example, from water) that can lead to a fluorescence enhancement effect [18].

The complexation of the analyte by β-cyclodextrin (β-CD) is influenced by the van der Waals interaction, hydrogen bonding, displace-

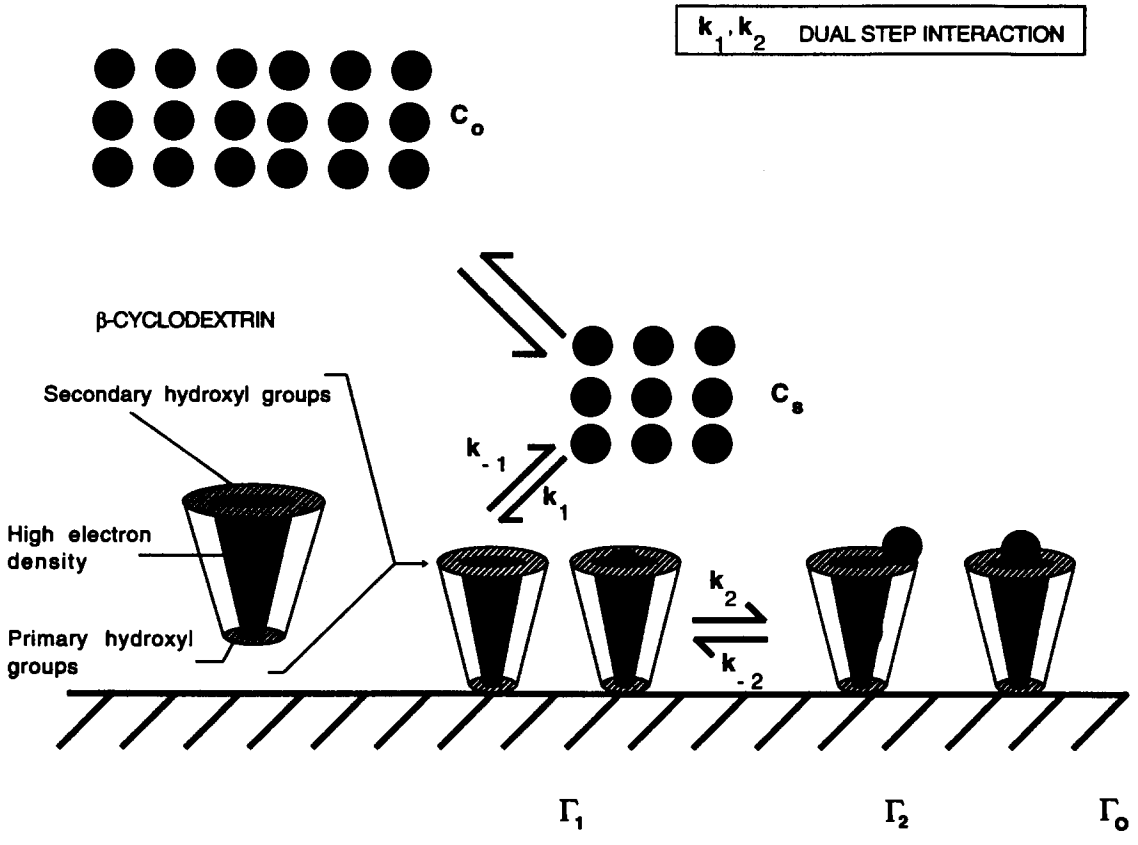

Fig. 1. Elementary steps involved in the binding of the pyrene (analyte) in solution to the $\beta$-cyclodextrin ($\beta$-CD) immobilized to the chemical sensor surface (dual-step binding).

ment of high energy molecules from the cavity, and release of the strain energy of the $\beta$-CD on inclusion of the guest molecule [19,20]. Furthermore, the hydrophobicity of the guest molecule plays a critical role in the stability of the complex. Considering the different factors that are involved in the formation of the complex, it is reasonable to assume that, in the real situation, one obtains a distribution (Gaussian or otherwise) or inhomogeneity of the "sequestered" analyte states in the $\beta$-cyclodextrin cavity. Furthermore, the sequesteration of an analyte molecule may very reasonably influence the complexation of the analyte by nearby $\beta$-cyclodextrin molecules (the "nearest neighbor" effect). Also, it has been emphasized that the extent of complexation, which is directly connected to the sensitivity is strongly dependent on analyte geometry as well as on functional group orientation [16]. It has been indicated [21] that these types of surface irregularities or inhomogeneities may be characterized using Mandelbrot's non-Euclidean fractal geometry [22].

Fractal analysis has provided novel physical insights into the diffusion-limited reactions occurring at the antibody–antigen interface [23,24]. It is worthwhile extending the fractal analysis concept for antibody–antigen systems for biosensor applications to $\beta$-cyclodextrin–analyte systems for chemical sensor applications. More generally, one may extend the analysis to "receptor–analyte" systems. It has been emphasized that when too many parameters are involved in a reaction, the fractal dimension for reactivity may be useful as an "integrated" or "lumped" parameter [25]. There is no reason to believe that the fractal analysis should be restricted only to antibody–antigen reaction systems. The capture of different molecules by $\beta$-cyclodextrins immobilized on a chemical sensor surface may also, as indicated above, in the general sense, be analyzed by the treatment presented below.

Fractals are disordered systems which can be described in terms of non-integral dimensions [26]. The fractal dimension is a global property, and is insensitive to structural or morphologi-

cal details [27]. As long as surface irregularities show scale invariance (that is, dilatation symmetry) they can be characterized by a single number, the fractal dimension, $D_f$ [27].

Antibodies are heterogeneous and their immobilization on a fiber-optic surface, for example, would exhibit a certain degree of heterogeneity. Similarly, the immobilization of $\beta$-cyclodextrins on a silica optical fiber by Armstrong's method [28] would also exhibit some degree of heterogeneity. In this method a silanized silica gel is obtained with thermal epoxy, alkene, or haloalkyl groups by reacting by anhydrous organic solvent containing $C_{2-20}$ silanes with a high purity particulate silica gel. These are good examples of a "disordered" system, and a fractal analysis is appropriate for such systems. In this type of diffusion–reaction system, the diffusion is conventional in the sense that it follows the classical diffusion equation. It is the boundary condition on the fractal surface (chemical sensor surface in our case) that is complicated. The cyclodextrin–analyte reactions on the surface are good examples of a low dimension reaction system in which the distribution tends to be "less random" [29].

In this paper the fractal dimension values for the kinetics of the binding of pyrene molecules (analyte) to immobilized $\beta$-cyclodextrin in a chemical sensor system is presented and analyzed. The influence of a variable (pyrene concentration) on the fractal dimension value is also presented and analyzed.

## 2. Theory

The binding of the antigen in solution to the antibody on the surface has been described previously [30,31]. It is briefly presented here as a model example since no formal presentation of $\beta$-cyclodextrin–analyte binding kinetics presumably is available in the literature. It is anticipated that the general form of the "capture kinetics" of molecules in solution by "receptors" immobilized on a chemical sensor surface would also exhibit similar characteristics (kinetics).

### *2.1. Analyte in solution/receptor on the surface [32]*

*Dual-step binding*

The modeling of binding of an analyte in solution to a "receptor" immobilized on the surface is done in a two-step process. The elementary steps involved in the reaction scheme are shown in Fig. 1. Here $\Gamma_0$ is the total concentration of the receptor sites on the surface, $\Gamma_1$ is the surface concentration of receptors that are bound to a single analyte at any time $t$, $c_S$ is the concentration of the analyte close to the surface, $k_1$ and $k_2$ are the forward reaction rate constants, $k_{-1}$ and $k_{-2}$ are the reverse reaction rate constants, and $\Gamma_2$ is the surface concentration of the receptor which binds two analyte molecules. For initial binding kinetics, it has been shown that the rate of binding can be described by Eq. (1) [31]:

$$d\Gamma_1/dt = k_f c_s^2 \Gamma_0 \tag{1}$$

## 3. Variable rate coefficient

Kopeman [29] has recently indicated that classical reaction kinetics are sometimes unsatisfactory when the reactants are spatially constrained on the microscopic level by either walls, phase boundaries, or force fields. Such heterogeneous reactions, for example bioenzymatic reactions, that occur at interfaces of different phases, exhibit fractal orders for elementary reactions and rate coefficients with temporal memories. In such reactions, the rate coefficient exhibits a form given by

$$k_1 = k' t^{-h} \qquad 0 \leqslant h \leqslant 1 \qquad (t \geqslant 1) \tag{2}$$

In general, $k_1$ depends on time, whereas $k' = k_1(t = 1)$ does not. Kopelman [29] further indicates that in three dimensions (homogeneous space), $h$ equals zero. This is in agreement with the results obtained in classical kinetics. Also, with vigorous stirring, the system is made homogeneous and $h$ again equals zero. However, for diffusion-limited reactions occurring in fractal spaces, $h > 0$; this yields a time-dependent coefficient.

Havlin [33] has briefly reviewed the role of the diffusion of reactants towards fractal surfaces and indicates that the diffusion of a particule (for example, analyte) from the homogeneous solution to a solid surface (the chemical sensor surface) where it reacts to form a product (analyte–"receptor" complex) is given by [34–36]

$$(\text{Analyte–receptor}) \propto \begin{cases} t^{(3-D_f)/2} = t^{h} & t < t_c \\ t^{1/2} & t > t_c \end{cases} \tag{3}$$

Table 1
Experimental and predicted values of the fractal dimension $D_f$ and the integrated binding rate coefficient $k_1$ for a $\beta$-cyclodextrin fiber-optic chemical sensor

| Pyrene concentration (ng ml$^{-1}$) | $k_1$ | | $p$ | $D_f$ | |

[a] Not predicted.

where $D_f$ is the fractal dimension of the surface and $p$ is a coefficient. Havlin indicates that the cross-over value $t_c$ (where the fractal nature is lost) may be determined by $t_c \approx r_c^2$. Above the characteristic length $r_c$, the self-similarity of the surface is lost and may be considered homogeneous. Note that the product (analyte–receptor) in the reaction, analyte + receptor → (analyte–receptor), on a solid fractal surface scales with $p = (3 - D_f)/2$ at short time scales, and $p = 1/2$ at intermediate time scales. The equation is associated with the short-term properties of a random walk on a fractal surface. Also, note that in perfectly stirred kinetics on a regular surface, $k_1$ is a constant, and is independent of time. The appearance of the exponent $p = -b$ different from $p = 0$ is the consequence of two different phenomena: the heterogeneity (fractality of the surface), and the imperfect mixing (diffusion-limit) condition.

## 4. Experimental

### 4.1. Optical configuration

The optical system configuration has been described previously [17]. Briefly, the 325 nm line of an He–Cd laser was passed through a beam splitter consisting of a mirror with a 2 mm pinhole through its center. The laser beam was then focused into the distal end of the optical fiber. The fluorescence emitted was transmitted back through the fiber, reflected by the mirror and focused into the photomultiplier detector with a 400 ± 10 nm bandpass filter selecting the fluorescence wavelength. The current from the photomultiplier tube was measured with a picoammeter and recorded on a strip chart recorder.

The fibers were derviatized with $\beta$-CD as previously described [17]. In this case, the fibers were pulled to a 25 nm tip using a Sutter Instruments model P-2000 fiber puller prior to derivatization with $\beta$-CD.

### 4.2. Measurements

All measurements were performed as follows. The fiber was placed in distilled $H_2O$ to determine the baseline and background signal. The fiber was then placed in the pyrene solution and the fluorescence signal was monitored periodically over the 10 min incubation period. All curve-fittings procedures were performed using SigmaPlot (Jandal Scientific, San Rafael, CA).

## 5. Results

Alarie and Vo-Dinh [17] have developed a CD-based fiber-optic chemical sensor with $\beta$-CD immobilized at the distal face of an optical fiber. Their process combines the selectivity of the CD along with enhancement of the fluorescence of the complexed molecule, pyrene. Detailed studies of the capture of pyrene present in different initial concentrations in solution by $\beta$-CD immobilized on an optical fiber were performed (Table 1(a)). In this study the influence of non-specific binding (no $\beta$-CD immobilized on the optical fiber) was also analyzed (Table 1(b)).

In the pyrene concentration range studied (12.4–124 ng ml$^{-1}$) an increase in the pyrene concentration in solution increases $D_f$ or the inhomogeneity (disorder) on the surface. Table 1(a) shows the values (along with the error bars) of the fractal dimension $D_f$ and the binding rate coefficient $k_1(t = 1)$. An increase in the pyrene concentration by a factor of 10 from 12.4 to 124 ng ml$^{-1}$ increases the fractal dimension by 7.6% from 2.4468 to 2.6332. The high values of $D_f$ obtained indicate a significant amount of spatial inhomogeneity at the analyte–receptor interface. The fractal dimension $D_f$ may provide a useful integrated parameter for evaluating sensor performance and a predictive equation for $D_f$ was generated in an attempt to understand (a) the nature of $D_f$ and (b) how $D_f$ changes with pyrene concentration. In the pyrene concentration range studied, $D_f$ may be represented by

$$D_f = (2.243 \pm 0.04438)[\text{pyrene}]^{0.03391 \pm 0.0048} \quad (4)$$

Different functional forms were attempted such as the linear form, etc. Eq. (4) accurately predicts within 1% the $D_f$ values obtained in the pyrene concentration range studied. Note the functional form of the slight dependence (of "empirical" power 0.034) of $D_f$ on the pyrene concentration. This non-integer dependence indicates mechanistic complexities at the reaction interface, and also points towards or lends support to the fractal nature of the surface. Further studies are required to delineate the significance of this power dependence, presumably by unraveling the elementary steps involved in the reaction mechanism, and/or by making more quantitative the extent of disorder or inhomogeneity that exists on the surface. It is also of interest to note that an increase in pyrene concentration in solution leads to increases in both the $D_f$ and $k_1$ values. In other words, higher degrees of inhomogeneity on the surface also yield higher binding rate coefficients, in this case. Previous work on antibody–antigen systems also shows this type of behaviour [37]. Further experiment along the theoretical modeling is required to "tie-in" the changes in the fractal dimension with biosensor performance parameters such as sensitivity, stability, response time, and reproducibility.

Fig. 2 shows the fit of Eq. (3) for the amount of pyrene in solution bound to the $\beta$-CD. Once again, the model is able to fit the experimental data with a high degree of accuracy. A model involving a constant binding rate coefficient $k_1$ cannot fit the data (especially the curve nature at later times); thus this is a simple way of justifying (pictorially) why a time-dependent (temporal) coefficient works better than a constant $k_1$. Besides, the fractal and changing nature of the surface warrants the utilization of a temporal binding coefficient vis-a-vis a constant binding coefficient. One notes that an increase in the pyrene concentration in solution increases the $k_1$ value. An increase in the pyrene concentration by a factor of 10 from 12.4 to 124 ng ml$^{-1}$ increases $k_1$ by a factor of 10.38 from 207.1 to 2152. In the pyrene concentration range studied, $k_1$ may be represented by Eq. (5):

$$k_1 = (17.98 \pm 0.4436)[\text{pyrene}] \quad (5)$$

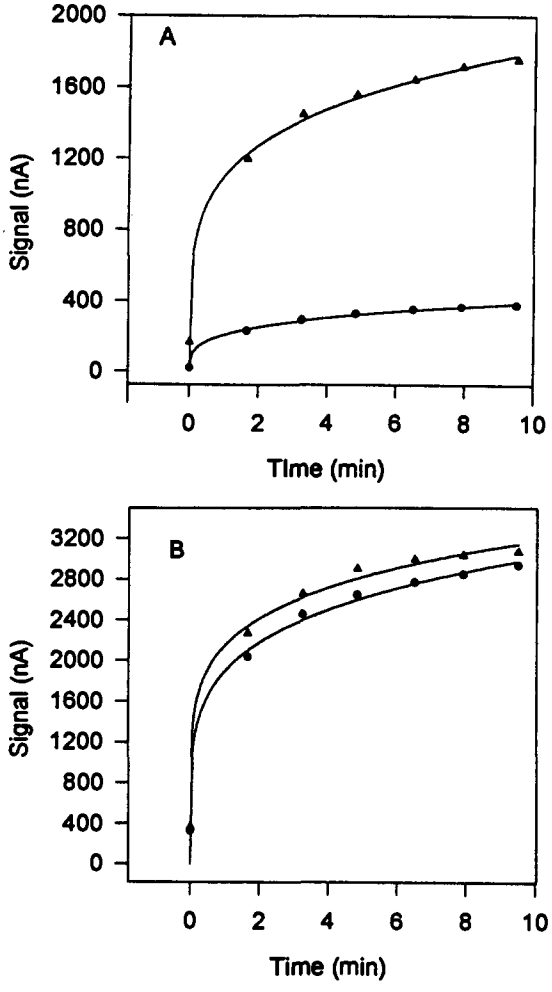

Fig. 2. Fit of the model (Eq. (3)) to the binding of different initial pyrene concentrations in solution to the $\beta$-CD immobilized to the chemical sensor surface: (A) ●, 12.4 ng ml$^{-1}$; ▲, 62 ng ml$^{-1}$. (B) ●, 99.8 ng ml$^{-1}$; ▲, 124 ng ml$^{-1}$.

where [pyrene] is the concentration (ng ml$^{-1}$). The predicted values of $k_1$ (Table 1) obtained from Eq. (5) are within 8% of the experimental $k_1$ values obtained by the curve-fitting procedure. Predictive equations for the binding coefficient would be of considerable assistance in the design of biosensors, besides helping to understand better the reactions and kinetics at the interface.

Non-specific binding can play a significant role in the development of effective fiber-optic biochemical and chemical sensors since it affects the sensitivity, stability, response time, and reproducibility of these sensors. Often, only estimates of the amount of non-specific binding relative to the amount of specific binding are available in the literature.

Table 1(b) shows the values (along with error bars) of the fractal dimension $D_f$ and the binding rate coefficient for non-specific binding, $k_{ns}$. As seen in Table 1, the error bars for $D_f$ are four to six times the change in the $D_f$ values obtained. This makes it impossible to develop accurately a functional form for $D_f$. For all practical purposes, considering the error bars, there is hardly any change in $D_f$ as the pyrene concentration in solution changes by a order of magnitude from 12.4 to 124 ng ml$^{-1}$. Strictly speaking, there is no "chemical" driving force to the chemical sensor surface, i.e. there is no complexation. Apparently, in this case the extent of inhomogeneity or disorder on the surface is "dominated" by the characteristics of the non-specific binding, with "minor" contributions coming in due to increased pyrene concentrations in solution. Note that in this case the pyrene is not "permanently" adsorbed. The removal of the chemical sensor from the pyrene solution and placing it in water yields a very small residual signal. In the $\beta$-CD case, a strong signal remains from the complexed pyrene–$\beta$-CD.

Fig. 3 shows the fit of Eq. (3) for the amount of pyrene in solution "reversibly" adsorbed to the fiber-optic chemical sensor with no $\beta$-CD immobilized to the fiber-optic surface. Once again, Eq. (3) is able to fit the experimental data reasonably well. An increase in the pyrene concentration increases $k_{ns}$ (as also observed for the specific binding rate coefficient $k_1$). An increase in the pyrene concentration by a factor of 10 from 12.4 to 124 ng ml$^{-1}$ increases $k_{ns}$ by a factor of 8.5 from 62.86 to 534. Note the relatively high values of the error bars for $k_{ns}$ values for all of the pyrene concentrations

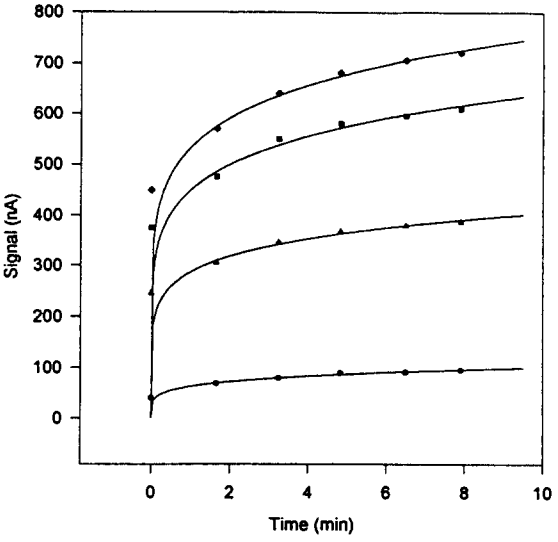

Fig. 3. Fit of the model (Eq. (3)) to the binding of different initial pyrene concentrations in solution directly to the chemical surface (with no $\beta$-CD attached — non-specific binding): ●, 12.4 ng ml$^{-1}$; ▲, 62 ng ml$^{-1}$; ■, 99.8 ng ml$^{-1}$; ◆, 124 ng ml$^{-1}$.

studied. Presumably, this reflects a characteristic (at present, undetermined) of the non-specific binding of the polycyclic aromatic hydrocarbon in solution directly to the fiber-optic surface. In the pyrene concentration range studied, $k_{ns}$ may be represented by Eq. (6):

$$k_{ns} = (4.433 \pm 0.08034)[\text{pyrene}] \quad (6)$$

Eq. (6) fits the $k_{ns}$ values in the pyrene concentration range studied within 13%.

## 6. Conclusion

The fractal analysis of the $\beta$-cyclodextrin–pyrene reaction occurring on the chemical sensor surface provides a semi-quantitative indication of the state of disorder and inhomogeneity of the system at the "receptor–analyte" surface.

The data presented in Table 1(a) and Table 1(b) provide valuable physical insights by providing a "semi-quantitative" measure of the degree of disorder or inhomogeneity that exists on the chemical sensor surface. The influence of the pyrene concentration in solution on the specific $k_1$ and non-specific $k_{ns}$ binding rate coefficients and on the fractal dimension $D_f$ could be correlated. When $\beta$-CD is immobilized on the fiber-optic surface, one notes that an increase in the pyrene concentration in solu-

tion increases both the $k_1$ and $D_f$ values. It is of interest to note that an increase of the spatial inhomogeneity or disorder on the surface (increasing $D_f$ values) with higher pyrene concentrations in solution leads to higher $k_1$ values. "Predictive type" relations suggested for $D_f$ and $k_1$ are of considerable value in helping to design biosensors and in understanding the kinetics. These equations do seem to fit the calculated values of $k_1$ and $D_f$ respectively well.

When no $\beta$-CD is attached to the fiber-optic surface (non-specific binding studies), one notes that an increase in the pyrene concentration in solution increases the non-specific binding rate coefficient $k_{ns}$ values. The high error bars obtained for $k_{ns}$ values indicates presumably a characteristic of non-specific binding, at least for this case. More data of this type and for other chemical sensor systems are required to help further validate and/or modify the above for chemical sensor applications. Further studies on the complexation of pyrene and of other analytes of interest by $\beta$-CD will be undertaken in this laboratory in the near future to delineate further the reaction complexities and the degree of inhomogeneity that exists at the chemical sensor surface.

The fractal analysis of the $\beta$-CD–pyrene chemical sensor application helps provide novel physical insights into the conformational states of the $\beta$-CD–pyrene binding complex on the chemical sensor surface. The analysis of different chemical sensors taken together would help form a framework, wherein the data on different chemical sensors may be compared. The build-up of the database on conformational states should also assist in helping to improve the sensitivity, stability, reproductibility, and reaction time of fiber-optic chemical sensors. Predictive relations for $k_1$, $D_f$ and for other important parameters are particularly appealing, and should be of considerable assistance in the design of chemical sensors. It may be recommended that further similar studies (both theoretical as well as experimental) be carried out to delineate further the conformational states of the "receptor–analyte" on chemical sensor surfaces.

Received 19 January 1995; accepted 3 April 1995

**Abstract**

A fluorimetric procedure for the determination of hydrogen peroxide, based on the oxidation of acetaminophen with hydrogen peroxide in acidic medium, is described. The calibration graph was linear in the range $5.0 \times 10^{-8}$–$2.4 \times 10^{-5}$ M hydrogen peroxide at an emission wavelength of 333 nm with excitation at 298 nm. The method has been applied to the determination of hydrogen peroxide in rain water, and the recoveries in milk samples were good.

## 1. Introduction

Hydrogen peroxide is produced by photochemical reactions in the atmosphere. Acid rain may possibly form when hydrogen peroxide reacts with $SO_2$ [1]. Therefore the chemistry of hydrogen peroxide is very important in the field of environmental science. In addition, its carcinogenicity has raised interest in recent years. A rapid, simple method for its microlevel determination is needed. Fluorimetric methods for the determination of hydrogen peroxide have been reported [2–4]. Some of the methods require very expensive reagents.

The use of acetaminophen as a fluorescent reagent for the determination of Ce(IV) has been developed [5]. In this paper, a new fluorimetric method, based on the oxidation of non-fluorescent acetaminophen to a fluorescent compound by hydrogen peroxide in 0.12 M $H_2SO_4$, is described. The method possesses distinct advantages over other fluorimetric methods with respect to simplicity, expense, and determination range.

* Corresponding author.

## 2. Experimental

### 2.1. Apparatus

An RF-540 spectrofluorimeter (Shimadzu, Kyoto, Japan) was used.

### 2.2. Reagents

Analytical-grade reagents and distilled water were used throughout.

A solution of hydrogen peroxide was prepared by dilution of a 30% solution and was checked by permanganimetry.

Acetaminophen stock solution (0.01 M) was prepared by dissolving 0.3780 g of acetaminophen in warm water, stirring for 10 min and diluting to 250 ml in a calibrated flask after cooling.

Sulphuric acid solution of concentration 2 M was used.

### 2.3. Procedure

To a 25 ml volumetric flask were added 2.5 ml of acetaminophen solution ($1.0 \times 10^{-2}$ M), 1.5 ml of sulphuric acid solution (2 M) and

*SSDI* 0039-9140(95)01603-1

a suitable working solution of hydrogen peroxide. The flask was placed in a boiling-water bath for 40 min, then it was cooled under tap water and diluted to the mark with water. The fluorescence intensity resulting from an excitation wavelength of 298 nm and an emission wavelength of 333 nm was measured against a reagent blank.

## 3. Results and discussion

### 3.1. Fluorescence spectra

The excitation and emission spectra of the system investigated are shown in Fig. 1. The fluorescent species has excitation and emission maxima at 298 nm and 333 nm, respectively.

### 3.2. Effect of acetaminophen concentration

The effect of acetaminophen concentration on the fluorescence intensity of the system was studied. It was found that a maximum and constant fluorescence intensity was obtained for acetaminophen concentrations in the range $8.0 \times 10^{-4}$–$1.1 \times 10^{-3}$ M. An acetaminophen concentration of $1.0 \times 10^{-3}$ M was selected (Fig. 2).

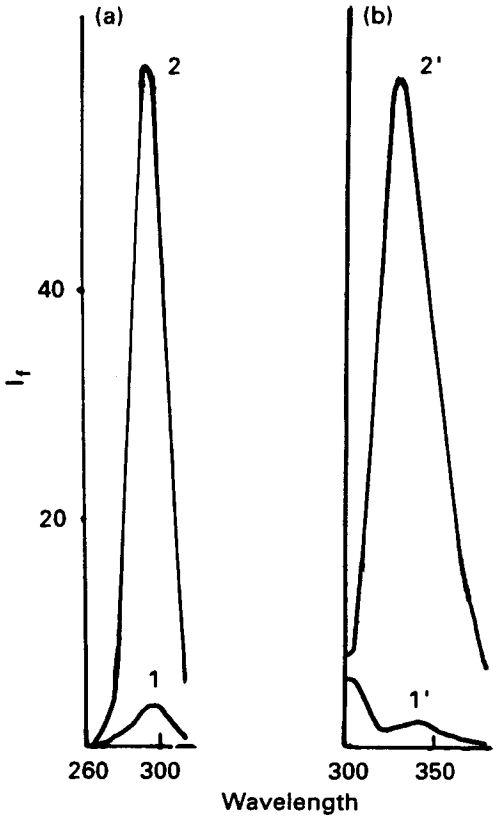

Fig. 1. Fluorescence spectra: (a) excitation, 298 nm; (b) emission, 333 nm. Curves 1 and 1', acetaminophen–$H_2SO_4$ system (reagent blank): curves 2 and 2', acetaminophen–$H_2O_2$–$H_2SO_4$ system. Conditions: $[H_2O_2]$, $4.0 \times 10^{-6}$ M; [acetaminophen], $1.0 \times 10^{-3}$ M; $[H_2SO_4]$, 0.12 M.

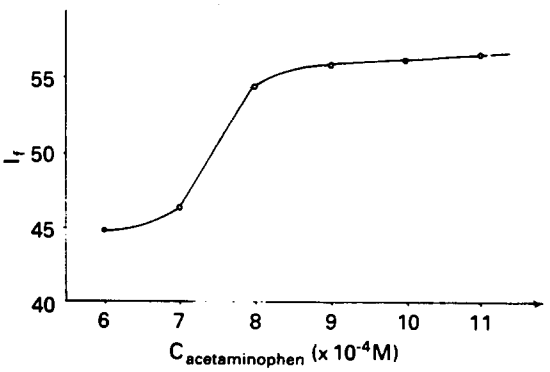

Fig. 2. Effect of acetaminophen concentration. Conditions as in Fig. 1.

### 3.3. Effect of sulphuric acid concentration

The experimental results indicated that when the concentration of sulphuric acid was between 0.08 and 0.16 M, the fluorescence inten-

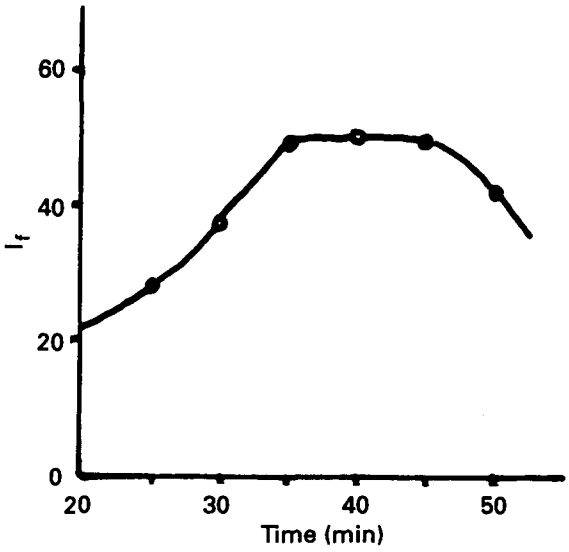

Fig. 4. Effect of heating time. Conditions as in Fig. 1.

sity reached a maximum. A sulphuric acid concentration of 0.12 M was chosen (Fig. 3).

### 3.4. Effect of temperature and time

Optimal reaction conditions of temperature and time were investigated for the assay of hydrogen peroxide, and a standard procedure was established, involving standing for 40 min at 100°C (Fig. 4).

### 3.5. Calibration graph

A linear calibration graph of fluorescence intensity of the system vs. hydrogen peroxide concentration was obtained, covering the ranges $5.0 \times 10^{-8}$–$2.8 \times 10^{-6}$ M and $2.0 \times 10^{-6}$–$2.4 \times 10^{-5}$ M. The detection limit is $1.5 \times 10^{-8}$ M, the blank plus three times the standard deviation of the blank [6].

### 3.6. Effect of diverse ions

The influence of diverse ions on the determination of 1 μg per 25 ml of hydrogen peroxide was examined, and the tolerance limits were taken as the amounts that caused about a ± 5% error in the fluorescence intensity. Table 1 shows that only Fe(III), Hg(II), and Cr(VI) caused severe interference, because of their oxidizing nature. These ions can be masked by adding EDTA.

### 3.7. Application

The proposed method was used to assay hydrogen peroxide in rain water. The samples were collected and filtered before analysis. A suitable volume of rain water was transfered to a 25 ml volumetric flask. The determination was carried out by the procedure described above. The results obtained are presented in Table 2. The recovery of hydrogen peroxide in rain water was 96–102%.

In addition, the recovery of hydrogen peroxide in milk was tested. To 1 ml of pasteurized milk were added 0.1 ml of glacial acid and 2.5 μg, 5.0 μg, or 12.0 μg of hydrogen peroxide. The solution was mixed and centrifuged, and the supernatant was assayed. The recovery was good (95%, 98%, and 102%, respectively).

### 3.8. Luminescence mechanism

Sultan et al. [7] reported that acetaminophen is oxidized by Ce(IV) to form *p*-benzoquinone, which has been used for the spectrophotometric determination of acetaminophen (paracetamol). In this system, acetaminophen might be oxidized to p-benzoquinone. In order to investigate the nature of the reaction product of the system, the ultraviolet and fluorescence spectra of the acetaminophen–$H_2SO_4$–$H_2O_2$ and *p*-benzoquinone–$H_2SO_4$ systems were studied. Fig. 5 shows that *p*-benzoquinone in 0.12 M sulphuric acid solution has excitation and emission maxima at 298 nm and 333 nm, respectively. This is similar to those of the acetaminophen–$H_2SO_4$–$H_2O_2$ system. The ultraviolet spectra show that the absorption bands of the two systems are also very similar (Fig. 6). These results indicate that a product might be *p*-benzoquinone. The reaction between acetaminophen and hydrogen peroxide is as follows:

Table 2
Determination of $H_2O_2$ in rain water

| Sample | $H_2O_2$ found (μg ml$^{-1}$) | |
|---|---|---|
| | Proposed method | Other method [a] |

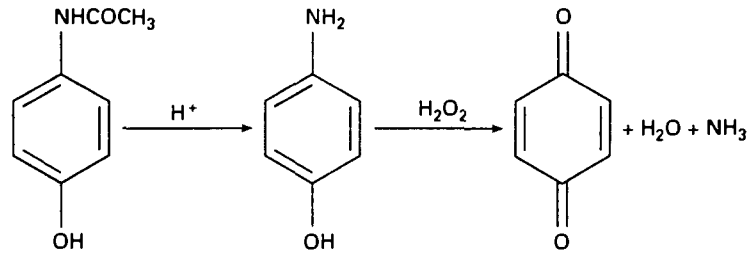
| 2 | 0.56 | 0.61 |

[a] Using HPMQ (*N*–(4'-hydroxyphenyl)-*N*-(4-methylquinolinyl)-amine) as the fluorescent reagent (Ref. [4]).



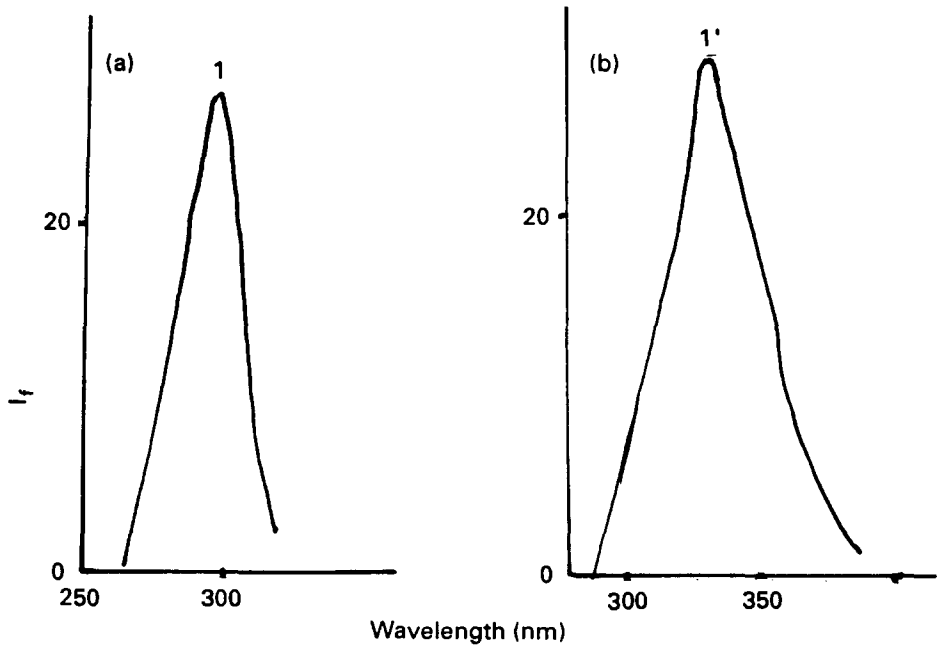


Fig. 5. Fluorescence spectra: (a) excitation, 298 nm; (b) emission, 333 nm. Curves 1 and 1', $p$-benzoquinone–$H_2SO_4$ system. ([$H_2SO_4$], 0.12 M.)

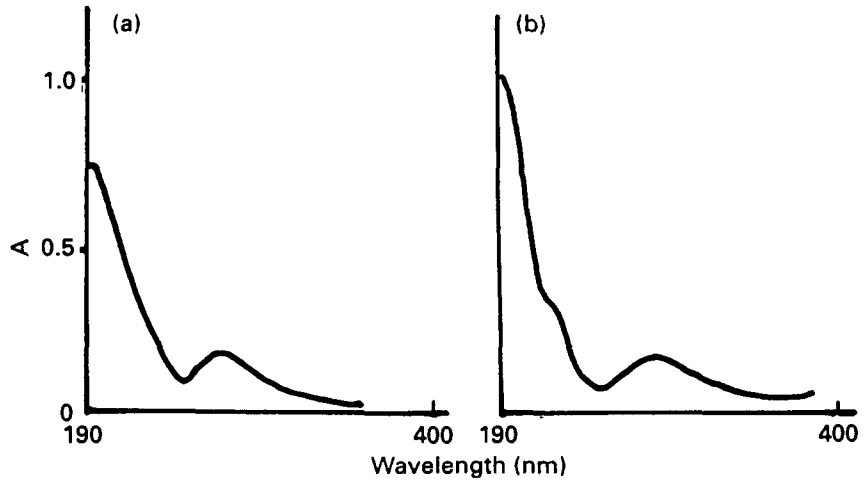

Fig. 6. Ultraviolet spectra: (a) $H_2O_2$ (excess)–acetaminophen–$H_2SO_4$ system; (b) $p$-benzoquinone–$H_2SO_4$ system. ([$H_2SO_4$], 0.12 M).

## 4. Conclusions

In summary, this report presents a new fluorimetric method useful for the determination of hydrogen peroxide in rain water. The method is rapid, simple and inexpensive.

**Abstract**

The preparation, composition and structure of copper hexacyanoferrates have been investigated. Three methods were used: precipitation, local growth in an aqueous solution, and growth in a gel. Four compounds were obtained, either in powdered form or as single crystals: $Cu^{II}_2Fe^{II}(CN)_6 \cdot xH_2O$, $Cu^{II}_3[Fe^{III}(CN)_6]_2 \cdot xH_2O$, $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10H_2O$ and $K_2Cu^{II}Fe^{II}(CN)_6$. Powders of $Cu^{II}_2Fe^{II}(CN)_6 \cdot xH_2O$ and $Cu^{II}_3[Fe^{III}(CN)_6]_2 \cdot xH_2O$ are easily prepared by precipitation and can also be obtained by local growth. They crystallise generally with cubic symmetry, in space group $Fm\bar{3}m$, and are structurally disordered. The mixed copper hexacyanoferrates of general formulae $M^I_2Cu^{II}Fe^{II}(CN)_6$ or $M^ICu^{II}Fe^{III}(CN)_6$ (here $M^I$ is Na, K) were not obtained by precipitation. The appropriate method was local growth for the preparation of powders of $K_2Cu^{II}Fe^{II}(CN)_6$. Single crystals of $Na_2Cu^{II}Fe^{II}(CN)_6$ were obtained by growth in a gel, and their study using single crystal X-ray diffraction revealed a new monoclinic structure.

## 1. Introduction

Transition metal hexacyanoferrates are well known for their high affinity towards caesium in a wide range of pH [1,2]. They have numerous applications in analytical chemistry for the concentration of radioactive caesium and the measurement of radioactive fall-out in the environment [3–5]. They are primary candidates for caesium removal from radioactive liquid wastes. They are also efficient for the recovery of silver and palladium from dilute solutions [6–8]. The concentration of these elements could be useful for analytical purposes or for recovery from liquid wastes. Hexacyanoferrates(II) and (III) with several different transition metals were studied for the removal of caesium [9–12]. The question concerning the best compound is still pendant. One of the reasons for this uncertainty is that these compounds exhibit a great variety of compositions and structures. Several kinds of compound may be observed with the same transition metal, depending on the preparation method. It is therefore difficult to establish a relationship with the sorption properties. In an effort to clarify this situation, we performed a systematic study of the preparation methods, compositions and structures of zinc and nickel hexacyanoferrates(II) [13,14]. More recently we started with copper hexacyanoferrates(II) and (III). These compounds not only exhibit a strong affinity for caesium [15–17], but they are also of potential interest for the fixation of palladium and other precious metals [7,18]. The applications of such products in analytical chemistry and for industrial separations are strongly connected with obtaining reproducibly

defined compounds. Their use would be greatly facilitated if they could be produced under the form of hard granular solids mechanically stable in ion exchange columns.

Before undertaking a systematic study of the exchange properties of these compounds, it was essential to define a few preparative methods which lead to reproducible chemical compositions and structures. Certain general features may be deduced from a review of the literature [19]. Copper hexacyanoferrates(II) exhibit several compositions and structures. They belong to at least two families, having formulae $Cu_2^{II}Fe^{II}(CN)_6$ and $K_2Cu^{II}Fe^{II}(CN)_6$. Methods leading to these compounds have been described [20,21]. Other definite mixed hexacyanoferrates(II) such as $K_2Cu_3^{II}[Fe^{II}(CN)_6]_2$ [22,23], have often been reported but their existence is questionable. Copper hexacyanoferrates(III) have been less studied, and the formula generally presented is $Cu_3[Fe^{III}(CN)_6]_2$ [24–28]. In a few cases, potassium has been found in this compound [25,28,29].

Since the first publication by Keggin and Miles [30], hexacyanoferrates of divalent metals such as Cu, Ni and Co [31–33] have frequently been described as cubic, space group $Fm\bar{3}m$, with $a_0 \approx 10$ Å. This $a_0$ value is equal to twice the length of the Fe–C–N–$M^{II}$ group. These compounds seem to remain isostructural when alkali metal ions are incorporated into them [26,34,35]. One potassium copper hexacyanoferrate(II) departs from this cubic structure [21]. In previous studies, we ascribed several different structures to compounds belonging to the zinc hexacyanoferrate group. $Zn_2Fe^{II}(CN)_6 \cdot 2H_2O$ was found to have a trigonal structure $P\bar{3}m1$, $M_2^{I}Zn_3[Fe^{II}(CN)_6]_2 \cdot xH_2O$ (here $M^{I}$ is Na, K, Cs) has a rhombohedral arrangement $R\bar{3}c$ [36–39] and $Zn_3[Fe^{III}(CN)_6]_2 \cdot xH_2O$ is either cubic $Fm\bar{3}m$ or rhombohedral $R\bar{3}c$ ($x = 2$) [40,41].

However, several questions still remain. Apart from the compounds of end compositions $Cu_2^{II}Fe^{II}(CN)_6$ and $K_2Cu^{II}Fe^{II}(CN)_6$, what are the regions of alkali metal ion content in mixed copper hexacyanoferrates? Do solid solutions really exist? If not, what are the formulae of the other mixed alkali-metal copper compounds of defined composition?

We have tested various methods of preparation and have characterised the products obtained in each case. We report here results concerning the composition, granulometry, yield of various particle sizes, and the structure of four compounds: $Cu_2^{II}Fe^{II}(CN)_6$, $Cu_3^{II}[Fe^{III}(CN)_6]_2$, $K_2Cu^{II}Fe^{II}(CN)_6$ and $Na_2Cu^{II}Fe^{II}(CN)_6$. Single crystals of $Na_2Cu^{II}Fe^{II}(CN)_6$ (main dimension larger than 100 $\mu$m) were prepared for the X-ray diffraction studies.

Practical interest in copper hexacyanoferrates includes the production of sorbents with good mechanical properties for use in columns. One of the aims of this study was to find a preparation process which controls the grain size and produces granular materials suitable for this purpose. We have tested a new process that leads to the formation of beads [42,43].

## 2. Experimental

### 2.1. Reagents

The alkaline hexacyanoferrates $Na_4Fe^{II}(CN)_6 \cdot 10\,H_2O$, $K_4Fe^{II}(CN)_6 \cdot 3\,H_2O$, $K_3Fe^{III}(CN)_6$, mineral acids and copper sulphate were of reagent grade and were supplied by Prolabo (France). Cupric nitrate and granular cuprous chloride ($Cu^{I}Cl$) were obtained from Carlo Erba Farmitalia (Italy), Dowex 50 W-X8 resin and tetramethoxysilane from Fluka (Switzerland), and sodium metasilicate from Baker (Netherlands).

### 2.2. Synthesis

New synthetic procedures were developed and compared with published methods. The three principal preparation modes can be classified as: precipitation, local growth and gel growth.

#### 2.2.1. Precipitation methods

The preparation conditions are described in Tables 1 and 2. For compounds that have been described previously, we quote the main reference for the experimental procedure. $H_4Fe^{II}(CN)_6$ solution was prepared by the ion exchange of $Na_4Fe^{II}(CN)_6$(0.125 M) on Dowex 50 W-X8 resin in the $H^+$ ion form. The solution was used immediately. The solution turns blue on standing.

A solution of $Li_4Fe^{II}(CN)_6$ was prepared from $Na_4Fe^{II}(CN)_6$(0.6 M) using a Dowex 50 W-X8 resin in the $Li^+$ form ($H^+$ form treated with $LiNO_3$(1 M) until no $H^+$ ions were detected in the eluted solution). The concentration of the hexacyanoferrate ions in the solutions prepared was measured by iodometric titration [44], and was then adjusted by dilution.

[a] See experimental section.

Three procedures were used: (i) and (ii) are classical laboratory processes, which differed mainly in the washing methods and the reagent addition rates; and (iii) was used for the preparation of larger quantities (up to a few kilograms).

(i) Solutions of the appropriate reagents were mixed in a 6 l round-bottomed flask by slow simultaneous addition at speeds between $0.5 \times 10^{-3}$ and $2.25 \times 10^{-3}$ mol $h^{-1}$, with gentle mechanical stirring. The temperature was maintained constant with a water bath. The slurries were washed with deionised water by decantation at least eight times using a total washing volume of at least 1.7 l. The precipitate was allowed to dry in air and was weighed (giving the total yield) after which 200, 100 and 25 $\mu$m sieves were used to separate the fractions having particles sizes above and below 25 $\mu$m. The fractions were dried in air between 20 and 40°C and were weighed (giving the above 25 $\mu$m yield).

(ii) The rate of addition was varied from $0.15 \times 10^{-3}$ to $2.25 \times 10^{-3}$ mol $h^{-1}$. If not otherwise stated, the slurries were then allowed to stand for 48 h at 70°C, filtered (0.2 $\mu$m) and dried at 40°C in air. The powders were then washed with water, decanted, dried in air at temperatures below 50°C and weighed (giving the global yield).

(iii) One solution was rapidly added to the other with stirring. Small particles ($\phi \leq 100$ $\mu$m) recovered from sieving a previous preparation were added to this solution, which was allowed to stand for 20 h. The slurries were then filtered under pressure for 2 h. They were washed on the filters with 0.006 M nitric acid and filtered before drying on a warm surface (80°C) for 48 h. The product was ground. The particles with dimensions less than 100 $\mu$m were separated and those with dimensions above 500 $\mu$m were ground again.

*2.2.2. Local growth method*

This method was developed with the aim of preparing beads having particles of controlled size [45]. This procedure was used when the above precipitation methods led to colloidal solutions.

The preparation conditions are given in Table 3. Crystals of the corresponding alkali metal hexacyanoferrate were placed in a concentrated solution of copper nitrate or, alternatively, crystals of copper sulphate were placed in a concentrated solution of alkali metal hexacyanoferrate. Under defined conditions of concentration and temperature, a film of insoluble hexacyanoferrate appears around the crystal, the thickness of which increases until the starting solid is completely consumed. This procedure is described more in detail in Ref. [42], while the growth mechanisms are discussed in Ref. [43].

*2.2.3. Growth of single crystals in gels*

The preparation of single crystals is required for a complete structural determination by X-ray diffraction. Single crystals of zinc hexacyanoferrates have previously been obtained by slow diffusion of the reagents [46]. The details of the syntheses are given in Table 4. In order to slow down the speed of diffusion of copper ions, copper tartrate crystals were used, prepared by diffusion of a copper nitrate solution through a tetramethoxysilane gel containing tartaric acid. The copper tartrate crystals were placed at the bottom of a test tube and covered by a metasilicate solution neutralised to various pH values with a 1 M acetic acid solution. After formation of a metasilicate gel, an alkaline hexacyanoferrate solution was introduced and allowed to diffuse slowly (for at least 1 month) [47].

The crystals were individually separated from the gel using a binocular magnifier and glass capillaries and were washed several times in a drop of water.

*2.3. Chemical analysis*

Non-destructive neutron activation analyses were performed for the determination of the concentration of the elements Na, K, Cl, Cu and Fe using the facilities of the Pierre Süe Laboratory. Analyses were performed in duplicate when the discrepancy between the two results was less than 5%, otherwise one more analysis was made. The compositions represent the mean values of the results. The water content was deduced by difference, and considering that one Fe atom is bound to six cyanide groups. For a complete determination of the anions, some products were analysed at the Service Central d'Analyses of the CNRS, Vernaison, France.

Due to the small quantities available, single crystal compositions were determined during observation with a scanning electron microscope by analysis of the secondary X-ray beam. We used a Quantum detector, a Kevex analysis

system and the XPP software [48] to calculate the relative atomic percentages. The determination of the compositions is semiquantitative because of the uncertainty of the geometry between the surface sample and the detector. To confirm these results, a few milligrams of single crystals were also analysed by neutron activation analysis; some other crystals were analysed by the secondary X-ray beam method. No discrepancies greater than 5% in the Cu/Fe and Na/Fe ratios were found (see S1 in Table 4).

### 2.4. Morphology

Optical microscopy and scanning electron microscopy were used to characterise the morphology.

### 2.5. Yield

The product yield was calculated as the ratio of the quantity of iron or copper in the product obtained to that introduced with the minor reagent. The global yield refers to the quantity of dry product obtained after decantation (precipitation by method (i)) or filtration (precipitation by methods (ii) and (iii)). The yield of the fraction composed of particles whose sizes are above 25 μm is also given when possible.

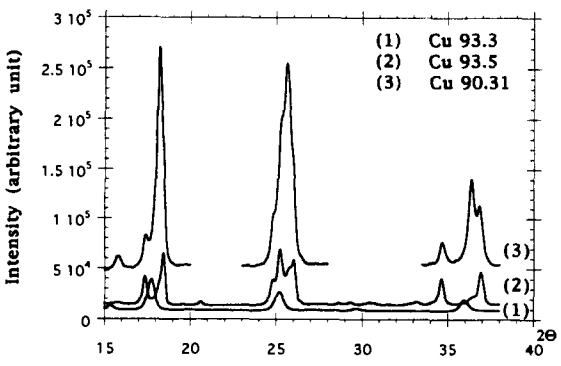

Fig. 1. Superposition of the X-ray powder diffraction patterns of Cu93-3 ($Cu_2Fe(CN)_6$), Cu93-5 ($K_2CuFe(CN)_6$) and Cu90.31, a mixture of the former phases.

### 2.6. X-ray crystallographic analyses

A Siemens diffractometer D500 and an Enraf Nonius CAD4 diffractometer were used for studies on the powders and single crystals, respectively.

The identification of the phases present was made by reference to the ICDD database (release 1993). X-ray powder diffraction was simulated using Cerius$^2$ (release 1.5) software from Molecular Simulations Incorporated.

## 3. Results and discussion

### 3.1. Composition and yield of preparation

We indicate in Tables 1–4 the main experimental conditions, the compositions, as they result from the chemical analyses, the overall yield of each product and the yield for particles of sizes greater than 25 μm. We also give the solid phases detected by X-ray diffraction by reference to the ICDD database.

The water content was deduced from the elemental analysis by difference. An excess of cations with respect to the hexacyanoferrate complex anion was frequently observed; this was particularly noticeable when high concentrations of the starting salts were used and with the local growth method. The presence of other anions resulting from the adsorption of the starting compound (nitrate, sulphate or chlo-

ride), as occurs in nickel and zinc hexacyanoferrates [14], was confirmed by chemical analysis. In a few cases, we observed a deficit of cations. $Cu^{II}$ solutions are acidic (pH about 3), and the introduction of protons into the solid compounds could account for this apparent reduction in the copper content.

*3.1.1. Precipitation*

The results obtained by using the precipitation method (i), (ii) and (iii) are given in Table 1. The compounds resulting from the use of lithium, hydrogen, sodium and potassium hexacyanoferrates(II) are presented successively.

A very general feature of our results is that, for lithium and sodium hexacyanoferrate(II) solutions, low concentrations of alkaline metals are incorporated into the precipitate. The only exception to this rule is sample 90–15. However, in this last case, we observe an excess of cations, which may be explained by sorption of sodium salts on a precipitate with very small particles: the washing process used during filtration (ii) seems to be less effective than in the multiple decantation method (i). When potassium hexacyanoferrate(II) solutions are used, a more alkaline element is incorporated into the precipitate (Cu93-6, FeCuAR, FeCul). In the case of $H_4Fe(CN)_6$, it seems that some protons are incorporated into the precipitate (Cu93-13), as a deficit of cations has been measured (Na and Cu).

A general rule is that, in all our experiments, the only crystalline phase detected by X-ray diffraction is the cubic $Cu_2^{II}Fe^{II}(CN)_6$ (ICDD 1.0244), with, however, some discrepancies concerning the positions of the diffraction lines and their intensities.

The highest yield was obtained starting from lithium hexacyanoferrate(II) (Cu93-10). The use of ferrocyanhydric acid leads to an overall yield of 55% (Cu93-13). This precipitate is not stable and turns rapidly to a navy-blue colour.

In the case of sodium hexacyanoferrate(II), the main parameter influencing the yield seems to be the copper-to-iron ratio. For ratios of 1 or less, very small particles are obtained although the yield is close to zero (Cu93-25 and 90-15). The yield can be increased by adding a salt such as $NaNO_3$ to the solution (Cu93-2). For Cu/Fe above 2, a rather good yield is obtained (Cu93-3 to 90-21).

Using potassium hexacyanoferrate(II), a high K/Cu ratio also leads to very small particles and to a low yield (90-25). Higher yields are obtained by using lower K/Cu ratios (FeCu 1) or by adding $KNO_3$ (Cu93-6). By comparison to other alkali metals, a significant

quantity of potassium is incorporated into the solid. The phase detected by X-ray diffraction is $Cu^{II}_2Fe^{II}(CN)_6$ (Cu93-6 to FeCu 1). The presence of another phase containing potassium is not excluded, but this phase is not detected by X-ray diffraction, because of too-small crystallites or amorphous particles.

The poor yield of some preparations may probably be explained by the formation of a copper hexacyanoferrate(II) including alkali metal ions in a colloidal form or in very small particles. The higher the alkaline-metal-to-copper ratio, the higher the proportion of this small particulate hexacyanoferrate(II), and the lower the yield. For potassium, it seems that a non-negligable part of this alkali metal containing hexacyanoferrate(II) is mixed with the separated solid phase (Cu93-6 to FeCu 1), but, nevertheless, in no case is any alkali metal containing hexacyanoferrate(II) detected by X-ray diffraction.

These results may be compared with those of Shabandeh and Streat [49] who reported a $Na_{0.47}Cu_{1.77}Fe(CN)_6$ composition but an X-ray diffraction pattern similar to that of $Cu^{II}{}_2Fe^{II}(CN)_6$. To the best of our knowledge, Gellings [21] described the only case in the literature where a potassium copper hexacyanoferrate(II) phase was detected by X-rays. We could not reproduce this result, probably because our experimental conditions were different. The behaviour of lithium is different from that of the other alkali metals. This element does not seem to incorporate into hexacyanoferrates [50], thus leading to the precipitation of $Cu^{II}_2Fe^{II}(CN)_6$ with a 100% yield.

The solids obtained starting from soluble hexacyanoferrates(III) are given in Table 2. Potassium hexacyanoferrate(III) was the only available salt. Ferricyanhydric acid was prepared from this by ion exchange. In all the solids studied, only cubic $Cu^{II}_3[Fe^{III}(CN)_6]_2$ could be detected (ICDD 13.0214), despite the presence in the solid of varying amounts of potassium. The Cu/Fe ratio is close to 1.5, although generally slightly lower. As for copper hexacyanoferrates(II), it is probable that a phase containing the alkali element is removed with the liquid phase. A small part of this solid phase may also be mixed with $Cu^{II}_3[Fe^{III}(CN)_6]_2$.

### 3.1.2. *Local growth from a solid compound*

In this method of preparation, the choice of reagents, of their state (solid or in aqueous solution) and of the concentration in solution is limited to a narrow range suitable for adequate osmotic pressures and favourable growth conditions [43]. The compositions of the solids obtained are strongly dependent on the experimental conditions (Table 3). Interpretable X-ray diffraction patterns were not always obtained, owing to the small sizes of the crystals, the possible mixture of phases and the lack of reference spectra.

When $Na_4Fe(CN)_6$ is used as the solid reagent, chemical analysis and X-ray diffraction show the presence of $Cu^{II}_2Fe^{II}(CN)_6$ (Cu90.6). If $CuSO_4$ is used as the solid reagent in a solution of $K_4Fe(CN)_6$, much more alkali element is incorporated into the solid (Cu89.9 to Cu90.31). A pure $K_2Cu^{II}Fe^{II}(CN)_6$ phase is detected (ICDD 20.0875) with a chemical composition close to this formula (Cu89.9 to Cu93-24). Such a phase could not be obtained alone by precipitation. In some cases, we also obtained mixtures of $Cu^{II}_2Fe^{II}(CN)_6$ and $K_2Cu^{II}Fe^{II}(CN)_6$, as revealed by X-ray diffraction (Cu93-26 and Cu90.31) (Fig. 1).

Local growth from solid cuprous chloride was also attempted. Copper seems to be partly oxidised in the product obtained, but the composition is close to $K_2Cu^{I}_2Fe^{II}(CN)_6$ (Cu93-19 and Cu93-20).

Using solid potassium hexacyanoferrate(III), a $Cu^{II}_3[Fe^{III}(CN)_6]_2$ phase was detected (Cu90.3 and Cu89.13). Using solid $CuSO_4$ in a solution of $K_3Fe^{III}(CN)_6$, a composition close to $Cu^{II}_3[Fe^{III}(CN)_6]_2$ was obtained, but the yield was low (Cu93-30, Cu93-31, Cu90.34). The use of cuprous chloride led to irreproducible results, probably on account of oxidation (Cu90.38, Cu90.42).

### 3.1.3. *Preparation of single crystals by the gel method*

The results are presented in Table 4. The largest crystals were obtained in a sodium silicate gel containing copper tartrate in contact with a $Na_4Fe(CN)_6$ solution (S1). This produced a compound of composition $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10H_2O$ with a novel structure. The yield could be estimated as 20%. A sodium or lithium silicate gel containing copper tartrate in contact with a $K_4Fe(CN)_6$ solution leads to $K_2Cu^{II}Fe^{II}(CN)_6 \cdot x\,H_2O$ (S3, S4). The X-ray powder diffraction patterns of S3 and Cu89.9 to Cu93-24 are similar and do not reveal a tetragonal structure, contrary to Gellings [21]. $Cu^{II}_3[Fe^{III}(CN)_6]_2 \cdot xH_2O$ was ob-

tained in a gel containing sodium silicate and potassium hexacyanoferrate(III) in contact with a cupric nitrate solution (A90-25, A90-26). $Cu_2^{II}Fe^{II}(CN)_6$ was not obtained using this method.

*3.1.4. Reproducibility of the preparations*

In the cases when $Cu_2^{II}Fe^{II}(CN)_6$ or $Cu_3^{II}[Fe^{III}(CN)_6]_2$ were obtained with a good yield, it was easy to repeat the experiments. For example, starting from $Li_4Fe^{II}(CN)_6$, we always obtained $Cu_2^{II}Fe^{II}(CN)_6$ (see Cu93.10); starting from $K_3Fe^{III}(CN)_6$, a composition next to $Cu_3^{II}[Fe^{III}(CN)_6]_2$ was reached (see Cu93.28; Cu90.20; Cu93.29).

Using the local growth method, it was more difficult to prepare a single-phased $K_2Cu^{II}Fe^{II}(CN)_6$ product. In many cases, we could detect a small percentage of the $Cu_2^{II}Fe^{II}(CN)_6$ phase. The factors affecting the results are numerous, such as the quantities of the reactants, the size of the crystals of the starting solid and the volume of water used for washing the precipitates.

*3.2. Morphology*

*3.2.1. Precipitation*

On the laboratory scale (total amount below 100 g), the particles formed have dimensions ranging between 10 μm and 1 mm. For preparations concerning larger quantities (about 20 kg), drying was performed up to 80°C, which causes the particles to agglomerate, and the fraction of particles larger than 1 mm is high. The mechanical strength of these aggregates when they are shaken in solution is questionable. Observations by electron microscopy did not permit the observation of the crystallites in the products obtained by the precipitation. The crystallite sizes have been determined by X-ray diffraction and the Cerius software, the dimensions are between 100 and 200 Å.

*3.2.2. Local growth method*

Particles prepared by growth on solid copper salts or alkaline hexacyanoferrate crystals differ from those obtained for nickel or zinc hexacyanoferrates [42]. The large particles (100 μm or above) are irregular in shape with a rough surface. In the cases of the zinc and nickel salts, spheres of diameters related to the starting crystals sizes were obtained. In Cu90.31, a mixture of $Cu^{II}{}_2Fe^{II}(CN)_6$ and $K_2Cu^{II}Fe^{II}(CN)_6$, the crystallite sizes are 100 Å and 300 Å, respectively.

*3.2.3. Single crystals obtained by the gel method*

The dimensions and main morphological characteristics are indicated in Table 4. Single crystals of $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10\,H_2O$ up to 500 μm in size were obtained. An example of the dimensions is $272 \times 273 \times 16\ \mu m^3$. These single crystals are destroyed by dehydration, leading to a stack of thinner plates.

*3.3. Crystal structure determination*

Compounds of composition closest to stoichiometric $Cu_2^{II}Fe^{II}(CN)_6$, $Na_2Cu^{II}Fe^{II}(CN)_6$ and $Cu_3^{II}[Fe^{III}(CN)_6]_2$ were selected for the structure determination. Crystal models were built with the Cerius[2] software and compared to the experimental diffraction patterns.

The powder pattern of $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10\,H_2O$ is not reported in the ICDD database, and a complete determination on a single crystal showed the presence of a new structural arrangement [47]. $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10\,H_2O$ crystallises in the monoclinic system, with space group P2/m (Table 5, part a). The $Fe(CN)_6$ and $Cu(CN)_4$ units are linked into layers, which lie parallel to the *ab* plane, through bridging cyano groups. Chains of hydrated Na ions $-(H_2O)_2-Na-(H_2O)_2-Na-$ run parallel to the hexacyanoferrate/tetracyanocuprate sheets, and water molecules above and below the plane of these chains serve to complete the coordination spheres both of sodium and copper, and to link the cyanometallate layers together. $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10\,H_2O$ dehydrates spontaneously in air with a concomitant loss of single crystal character.

$Cu_3^{II}[Fe^{III}(CN)_6]_2 \cdot x\,H_2O$ is cubic $Fm\bar{3}m$ and with $z = 1 + 1/3$, leading to a disordered structure. $FeC_6$ octahedra and planar $CuN_4$ units are linked by cyanide bridging, leading to the usual parameter of about 10 Å (Table 5, part b).

$Cu_2^{II}Fe^{II}(CN)_6 \cdot x\,H_2O$ is cubic $Fm\bar{3}m$ ($z = 2 + 2/3$) and is also a disordered structure. The distribution of copper in the cell is quite different from that of $Cu_3^{II}[Fe^{III}(CN)_6]_2$ (Table 5, part c).

Determinations of the structure (from a Rietveld refinement of powder X-ray diffraction data) of $Cu_2^{II}Fe^{II}(CN)_6$ and $Cu_3^{II}[Fe^{III}(CN)_6]_2$ are to be published [47]. Powder diffraction patterns correspond to ICDD 1.0244 and ICDD 23.0214 respectively, but with some discrepancies.

In the case of $K_2Cu^{II}Fe^{II}(CN)_6$, the diffraction patterns have only a few lines and hence are difficult to index. Intensities and reflections are somewhat different from those published by Gellings (ICDD 20.0875) and do not correspond to the quadratic structure mentioned [21].

## 4. Conclusion

Three methods were evaluated for the preparation of copper hexacyanoferrates(II) and (III): precipitation, local growth and growth in a gel. The aim of the two former methods was to obtain powders, while the latter was used to produce single crystals for structure determination. A systematic and accurate study by X-ray diffraction has been performed. Four compounds, identified by their chemical analysis and X-ray diffraction patterns were obtained, either in powdered form, or as single crystals: $Cu^{II}_2$-$Fe^{II}(CN)_6$, $Cu^{II}_3[Fe^{III}(CN)_6]_2$, $Na_2Cu^{II}Fe^{II}(CN)_6$ and $K_2Cu^{II}Fe^{II}(CN)_6$. The structure of the last compound remains undetermined as yet because of the lack of single crystals. However, its X-ray powder diffraction pattern does not correspond to the reported cubic [31] or tetragonal structures [21].

$Cu^{II}_2Fe^{II}(CN)_6$ and $Cu^{II}_3[Fe^{III}(CN)_6]_2$ powders are easily prepared by precipitation and by local growth. They are cubic $Fm\bar{3}m$ and present disordered structures. These two compounds differ from each other in the positions of the copper atoms. The distribution of copper could be an important parameter for the fixation of caesium: the sorption of caesium on $Cu^{II}_3[Fe^{III}(CN)_6]_2$ is very low compared to that on $Cu^{II}_2Fe^{II}(CN)_6$.

Although cited in the literature, the mixed copper hexacyanoferrates of general formulae $M^I_2Cu^{II}Fe^{II}(CN)_6$ or $M^ICu^{II}Fe^{III}(CN)_6$ (where $M^I$ is Na, K) could not be synthesised by precipitation as pure phases, in a form easily separated from the solution and detected by X-ray diffraction. However, the presence of such compounds in the form of colloids or very small particles is not excluded, except in the case of lithium. The most appropriate method for the preparation of $K_2Cu^{II}Fe^{II}(CN)_6$ powders was local growth. Single crystals of $Na_2Cu^{II}Fe^{II}(CN)_6 \cdot 10\,H_2O$ were obtained by growth in a gel. The complete X-ray crystallographic characterisation of this compound has shown a new structural arrangement whereby the $Cu(CN)_4$ and $Fe(CN)_6$ groups are linked into layers.

In all cases, X-ray diffraction revealed a limited number of compounds of defined composition. Mixed non-stoichiometric compounds such as $M^I_{2x}Cu^{II}_{2-x}Fe^{II}(CN)_6$ were not observed, and their very existence is questionable.

The aim of our work is the selection of the product presenting the highest affinity for caesium and at the same time stable enough for long term storage. Disordered and layered structures could be involved in quantitative sorption of caesium. The basic data presented here are fundamental for our studies concerning the mechanisms of the fixation of caesium on these compounds and their further analytical and industrial applications.

# Direct ICP-MS determination of trace and ultratrace elements in geological materials after decomposition in a microwave oven
# I. Quantitation of Y, Th, U and the lanthanides☆

J.G. Sen Gupta *, N.B. Bertrand

*Geological Survey of Canada, Ottawa, Ont. K1A OE8, Canada*

Received 7 October 1994; revised 10 February 1995; accepted 10 April 1995

**Abstract**

A microwave digestion technique using a mixture of $HF + HNO_3 + HCl + H_3BO_3$ was found to be effective for the rapid dissolution of various silicate rock and sediment reference samples. From the solutions thus prepared, it was possible to determine quantitatively trace and ultratrace amounts of yttrium, thorium, uranium and the lanthanides by inductively coupled plasma-mass spectrometry (ICP-MS) without any separation of matrix elements or preconcentration. In the ICP-MS determinations, oxide and non-spectral interferences on individual masses of the rare earth element ions were corrected by the method of algebraic approach of elimination and dilution, respectively, and measurement drift was controlled by ruthenium and rhenium internal standards. The method yielded excellent results comparable with "recommended", "consensus" and "working" values of the literature for the specified elements on various well-known international reference materials such as andesite (AGV-1), basalts (BCR-1, BHVO-1, BIR-1 and BE-N), granites (G-2 and NIM-G), syenite (SY-2), gabbro (MRG-1), diabase (W-2 and DNC-1), marine mud (MAG-1), river sediment (NBS 1645), lake sediments (LKSD-1–LKSD-4) and stream sediment (GSD-1, GSD-5, GSD-6 and STSD-1–STSD-4)). New values for Er, Gd, Ho, Pr and Tm in LKSD-1–LKSD-4 and STSD-1–STSD-4, and Er, Ho, Lu, Nd, Pr, Tb, Tm and Yb in NBS 1645 are first reported in this work.

## 1. Introduction

The rare-earth elements (REEs) play an important role in geochemistry for modelling earth's crustal and mantle evolutionary processes and for dating ages of rocks. Their applications in industry varies from uses in electronics to the manufacture of superconductors, supermagnets and cathode ray tubes. A knowledge of their behaviour and abundances in aqueous environment helps to devise effective ways of disposal of nuclear wastes since they are produced in nuclear generators during the fission of uranium and polonium.

Since Y and the REEs are a group of closely related elements having similar physical and chemical properties, their terrestrial and extraterrestrial abundances being very low, special preconcentration procedures such as solvent extraction [1], co-precipitation [2–5] or ion exchange separation [2,4–11] are needed before their determination by instrumental methods. Some early examples of the utilization of these preconcentrations techniques are found in their determinations by flame and electrothermal atomic absorption spectrometry [2–4], X-ray fluorescence spectrometry [5,6],

neutron activation [7], spark source mass spectrometry [9], isotope dilution mass spectrometry [8–12], inductively coupled plasma-atomic emission spectrometry (ICP-AES) [12,13], direct current plasma-atomic emission spectrometry [14], and inductively coupled plasma-mass spectrometry (ICP-MS) [1,15,16].

Since the use of a preconcentration procedure before determination by an instrumental method is laborious and time-consuming, some workers have used silicate rock sample solutions prepared by acid digestions in open vessels with or without fusion of any insoluble residue for the direct determination of the REEs by ICP-MS [15,17,18], Bailey et al. [19] determined Th and U in basalts by ICP-MS after digestion in an open vessel with acids. Pin et al. [20] used the isotope dilution ICP-MS method to determine Th and U in silicate rocks after decompositions with acids and ion-exchange separation of the matrix elements.

The sample dissolution procedure used in most ICP-MS laboratories involving open vessel digestions with acids, repeated evaporations to expell HF and/or $HClO_4$, dissolution, filtration and subsequent fusion of any insoluble residue is very tedious and slow for the routine analyses of a large number of geological materials in a day, There is, therefore, a need for an alternative technique which is less labour-intensive and faster with respect to the sample dissolution procedure to improve productivity.

A microwave digestion procedure which involved heating the sample with HF + aqua regia + $H_3BO_3$ + EDTA in a Teflon pressure vessel was used by Sen Gupta and Bouvier [21] for the direct determination of some trace and ultratrace elements in geological materials by multielement Zeeman-effect graphite furnace-atomic absorption spectrometry (GF-AAS). The same decomposition procedure found relatively fast and environmentally friendly compared to the conventional open vessel digestion procedures [22] was used in this work for preparation of solutions of some geochemical reference materials. Since the sensitivities of Y, Th, U and most REEs were not sufficient for their direct determination from rock solutions by multielement GFAAS, it was decided to determine these elements by a much more sensitive ICP-MS method. This paper describes the results of such a study.

The accuracy and precision of the proposed microwave digestion and direct ICP-MS determination procedure for the specified elements were evaluated by four to five replicate analyses of United States Geological Survey (USGS) reference rock BCR-1 (basalt) and Canadian Certified Reference Materials Project (CCRMP) reference rocks SY-2 (syenite) and MRG-1 (gabbro). The analytes were also determined from 21 other international geochemical reference materials, mostly in duplicate. The results were then compared with "consensus" [23,24], "working" [25], or "recommended" [26] literature values. In most cases, excellent agreement was found with the "working" values of Govindaraju [25]. In some cases the results of this work were within the statistical range of "consensus" or "recommended" values of Gladney et al. [23,24,26].

## 2. Experimental

### 2.1. Apparatus

A Perkin-Elmer/Sciex model 5000 ICP-mass spectrometer equipped with an AS-91 autosampler and an IBM PS/2 (model 70) computer was used for multielement mass spectral analysis. The mass spectrometer operating conditions and the data acquisition parameters are given in Table 1.

A Milestone microwave oven (model MLS-1200 MEGA) equipped with six 100 ml Milestone pressure decomposition Teflon vessels, a micrwave digestion rotor (model HPR 100016) and a remote control panel was used for the decomposition of the samples.

Table 1
Instrumental operating conditions and data acquisition parameters

| Condition/parameter | Result |
|---|---|
| ICP mass spectrometer | |
| R.f. power (kW) | 1.0 |
| Plasma argon gas flow rate (l $min^{-1}$) | 15 |
| Auxiliary argon gas flow rate (l $min^{-1}$) | 0.9 |
| Nebulizer argon gas flow rate (l $min^{-1}$) | 0.9 |
| Sampler skimmer | Nickel |
| Data acquisition | |
| Dwell time (ms) | 100 |
| Scan mode | Peak hopping |
| Points across peak | 1 |
| Sweeps reading$^{-1}$ | 10 |
| Number of replicates | 2 |

A Hamilton digital diluter was used for diluting all sample solutions.

### 2.2. Reagents and standard solutions

All reagents used were of A.C.S. grade, and ultrapure water (ASTM type 1) prepared by reverse osmosis with a Millipore apparatus was used throughout the procedure.

Synthetic standard solutions were prepared by diluting 10 μg $ml^{-1}$ mixed high purity ICP-MS standard solutions (Delta Scientific Laboratory Products Ltd., Mississauga, Ont.) with 3% (v/v) nitric acid to obtain solutions of elemental concentration range 20–100 ng $ml^{-1}$. Ruthenium and rhenium were added (as internal standards to control drift) to each standard solutions to give a final concentration of 50 ng $ml^{-1}$ of each. Also, 2 drops of concentrated hydrofluoric acid were added to each standard solution before making up the final volume in order to approximately match the concentration of hydrofluoric acid in the microwave-digested sample solution.

To prepare a mixed solution of boric acid (2.2%) and ethylenediaminetetraacetic acid (EDTA; 0.165%); in a 1 l borosilicate beaker, 1.65 g of EDTA were treated with concentrated ammonia solution dropwise with stirring until the solution became clear. To this solution 22 g boric acid were added, the mixture was diluted with water to 500 ml and the beaker was heated on a hot plate with stirring until the solid dissolved. The solution was then diluted with water to 1 l.

All solutions were stored in Nalgene bottles fitted with screw caps.

### 2.3. Procedure

Details of the sample decomposition procedure are given in a previous paper [21]. Briefly, the method involved heating 0.5 g of the finely powdered sample in a Teflon pressure vessel with a mixture of 2.5 ml of 27 M HF, 3 ml of 16 M $HNO_3$ and 3 ml of 12 M HCl in a Milestone microwave oven for 16 min using Program 1 of Table 2. After cooling, 30 ml of the boric acid and EDTA mixture were added, and then the vessel was further heated for 8 min using Program 2 of Table 2. After bringing to room temperature by cooling in a cold water bath, the contents of the vessel were quantitatively transferred to a 50 ml graduated polypropylene tube by rinsing with 2% (v/v) nitric acid and the volume was made up to 50 ml. A clear solution was obtained at this stage for most silicate rocks and sediments. An aliquot of this solution was diluted 10 times in the digital diluter with 3% (v/v) nitric acid containing ruthenium and rhenium internal standards, and the solution was transferred to a 15 ml polypropylene tube equipped with a stopper. The concentration of Ru and Re in the final diluted solution was 50 ng $ml^{-1}$ of each. A reagent blank was run throughout the procedure.

Table 2
Milestone microwave oven operating programmes

| Power (W) | Time (min) | Vent (min) |
|---|---|---|
| Program 1 | | |

### 2.4. Multielement ICP-MS determination

The calibration curves were prepared with a blank and three synthetic mixed standard solutions with concentrations as follows.

Standard 1, 20 ng $ml^{-1}$ of each element.
Standard 2, 50 ng $ml^{-1}$ of each element.
Standard 3, 100 ng $ml^{-1}$ of each element.

In constructing these calibration curves, instrumental operating parameters given in Table 1 and isotopic masses listed in Table 3 were used, and corrections for isobaric oxides (Table 4) were made using the method of algebraic approach of elimination [27].

The unknown sample solutions (ten fold diluted solutions of concentration 1 ng $ml^{-1}$ each and containing 50 ng $ml^{-1}$ each of Ru and Re internal standards) were run in a group of six through the automatic sampler. Each group of these six samples was preceded by and followed by the reading of the concentration of a 20 ng $ml^{-1}$ synthetic standard to check the recovery. The accuracy of the re-

Table 3

[b] Used as an internal standard to correct for instrumental drift and matrix effects on Group 2 elements.

sults was also checked at intervals of six samples and the said synthetic standard by analyzing three USGS geochemical reference rocks (AGV-1, BCR-1 and BHVO-1), solutions of which were prepared identically to the unknown sample solutions. The use of ruthenium and rhenium internal standards automatically corrected for instrumental drift and matrix effects.

The instrument software automatically performed blank subtraction, calibration, oxide correction, drift control, and calculation of elemental concentrations of the synthetic standard, unknown samples and the reference materials. From the print-out of these concentration data, the recovery of the 20 ng ml$^{-1}$ synthetic standard was checked, and, if required, a correction factor was applied to the results for the unknown samples and the reference materials. If the final data of the reference materials thus obtained fell within the range of "consensus values" [23,28], then the data for the unknown samples were considered acceptable for reporting. In actual practice, this procedure worked well since the data for the specified reference materials obtained in this way were always within the range of acceptable literature values.

## 3. Results and discussion

The ICP-MS determination limits of this work were Y, Pr, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm and Lu 0.02 μg g$^{-1}$; La, Ce and Nd, 0.10 μg g$^{-1}$; Yb, 0.05 μg g$^{-1}$.

Interferences in the determination of the REEs by ICP-MS have been discussed by other workers [15,17,27,29]. In the analysis by ICP-MS the analyte ion $M^+$ may also be distributed among several other species such as $MO^+$, $MOH^+$ or $M^{2+}$. This will cause spectral interferences due to mass overlaps or isobaric interferences. For the REEs the spectral interferences are principally due to oxide-forming elements which cause isotopic mass overlaps as shown in Table 4. However, in choosing the isotopic masses of the REEs in this analysis, only those isotopes were selected for which isotopic mass overlaps due to oxide-forming elements were at a minimum. The method for isobaric oxide correction used in this work was mentioned earlier in Section 2.4. The contribution of $MOH^+$ in the REE analysis by ICP-MS, representing about 1/10th of the oxide correction, was negligible. Also, no correction for a doubly charged ion ($M^{2+}$) was required in the lanthanide determination.

Tables 5–7 show the results obtained by the proposed method for some geochemical reference materials of the USGS (AGV-1, BCR-1, BHVO-1, BIR-1, W-2, DNC-1, G-2 and MAG-1), the CCRMP (MRG-1, SY-2, LKSD-1–LKSD-4 and STSD-1–STSD-4), the National Institute of Metallurgy, South Africa (NIM-G), the International Working Group, France (BE-N), the Institute of Geophysical and Geochemical Exploration, China (GSD-1, GSD-5 and GSD-6) and the National Bureau of Standards (NBS 1645). The mean and standard deviations of four replicate determinations of BCR-1 and of five replicate determinations of MRG-1 and SY-2 are given in Tables 5 and 6, respectively. For most other samples the results for two independent

determinations are given (See Tables 5–7). These results are then compared with the "consensus" [23,24,28], "recommended" [26,30], "working" [25] or "provisional" [31] literature values. It should be pointed out here that these "consensus", "recommended", "working" or "provisional" literature values were derived by the respective workers from a compilation of data from many laboratories and then subjecting them to rigorous selections in which very low or high values, called outliers, were rejected and a cluster of values at the median, where the majority of data converged, were accepted for the statistical calculation. Therefore, for any method development work a comparison of the recovery or "accuracy of elemental concentrations" for natural geochemical reference materials cannot be made with "absolute" values. It should be sufficient if the results of the proposed method fall within a "median" statistical range of values. Bearing this in mind, an attempt will be made to discuss the results of this work and a correlation with the literature values.

The data of Tables 5-7 (mean values) are plotted in Figs. 1 and 2 for a quick assessment of the nature of the correlation between the results of this work and the literature values. It is found that excepting two Ce values higher than 150 $\mu g\, g^{-1}$, there is a fairly good correlation between the two sets of values for each element since the 45° line passes through the majority of the points.

The microwave digestion ICP-MS (MDICPMS) data from this work (mean values), normalized to the C1 chondritic abundance data of Sun and McDonough [32] are plotted in Figs 3 and 4. Yttrium was plotted between Dy and Ho because of its similar chemical properties to those of the REEs, its ionic radius (0.0893 nm) being close to those of Dy (0.0908 nm) and Ho (0.0894 nm). Excepting negative anomalies for europium in SY-2, G-2, BCR-1, NIM-G and sediment samples ($Eu^{+2}$) and a few minor anomalies for Ce in some samples, these figures show very smooth patterns for Y and most REEs, fitting the curves, thereby providing support to the accuracy of the MDICPMS data.

A more detailed discussion of the data for individual sample would be pertinent at this point. In Table 5 excellent agreement between the MDICPMS results and the literature range of values is noted for all elements in BCR-1. Satisfactory agreement between the results of this work with the range of other values is also noted for other samples in Table 5. For MRG-1 and SY-2 (see Table 6), although initially the results for some REEs from various laboratories were few and scattered, as found in the compilation of data by Abbey et al. [33], more representative data became available much later through the compilation of Gladney and Roelandts [26]. The MDICPMS replicate data for MRG-1 (see Table 6) agree very well with the "recommended" values [26]. For SY-2, except for somewhat lower mean values for Ce and La, there is very good agreement with the "recommended" values for the other REEs. However, the chondrite-normalized plot for SY-2 in Fig. 3 shows no scatter for Ce and La, thereby supporting the validity of the results.

For lake and stream sediment samples (see Table 6), the MDICPMS data could be compared with the "provisional" values of Lynch [31] only for Ce, Dy, Eu, La, Lu, Nd, Sm, Tb, Th, U, Y and Yb. It is found that the MDICPMS results for these elements are within the range of the literature values. New data for Er, Gd, Ho, Pr and Tm obtained by MDICPMS in this work are given in Table 6. These data fit well in the chondrite-normalized plots (see Fig. 4).

Since for NIM-G, BE-N, GSD-1, GSD-5, GSD-6 and NBS 1645 (Table 7) recommended values are not available in the literature, a comparison of the MDICPMS values is made with the "range of other values" [34] (NIM-G) and/or Govindaraju's "working" [25] values. Except for Ce in BE-N, the MDICPMS data for these samples either fall within the range of other values or agree well with Govindaraju's working values in most cases. However, in the chondrite-normalized plot of BE-N (Fig. 3), MDICPMS data for Ce seem to fit well between La and Pr, supporting its acceptability.

For NBS 1645, new values for Er, Ho, Lu, Nd, Pr, Tb, Tm and Yb are first reported in this paper. The data for these elements give a smooth pattern in the chondrite-normalized plot (see Fig. 4).

From the data of Tables 5–7 it would appear that the "recommended" or "working" values for certain elements (e.g. Pr in AGV-1, W-2 and NIM-G; Gd in NIM-G and BE-N; Er in SY-2, NIM-G and BE-N) may require revision since they are either low or there are significant standard deviations from the mean

Table 5
Determination of Y, Th, U and the lanthanides in some USGS reference rocks and a sediment by ICP-MS after dissolution by microwave digestion ($\mu g\ g^{-1}$)

values. From the above discussion and the data presented, it may be concluded that direct ICP-MS determination of Th, U, Y and the lanthanides in common rocks and sediments is possible with acceptable accuracy and precision after the decomposition of the samples by microwave digestion with acids and the complexation of excess HF and fluorides with boric acid and EDTA. The method is reasonably fast, less strenuous compared to open vessel digestion and fusion methods, and environmentally friendly since no evaporation of acids is required.

**Acknowledgements**

The authors are indebted to J.L. Bouvier for the decomposition of some of the samples reported in this work, and to K.N. De Silva for critical reading of the manuscript.

# On the spectrophotometric flow injection determination of chromium(VI) in natural waters after on-line preconcentration on activated alumina

Mauricio C. Pannain, Ricardo E. Santelli *

*Geochemistry Department of Federal Fluminense University, Niterói-RJ, 24020-007, Brazil*

Received 9 May 1994; revised 3 April 1995; accepted 7 April 1995

**Abstract**

The feasibility of chromium(VI) preconcentration on to activated alumina in a continuous flow system with spectrophotometric detection was investigated. Chemical and flow variables, and the influence of concomitant species were studied both with and without preconcentration systems. The best results were obtained by using a 2.5 cm long, 1.6 mm i.d. alumina minicolumn, and selecting $1 \times 10^{-4}$ M nitric acid as the preconcentrating medium and 0.1 M ammonium hydroxide as the eluent. The eluted chromium(VI) was mixed with diphenylcarbazide in acidic medium and the absorbance of the colored complex was measured at 540 nm. Linear calibrations for 5, 25 and 50 ml sample volumes were established over the concentration ranges 10–50 $\mu g\,l^{-1}$, 2–10 $\mu g\,l^{-1}$ and 1–5 $\mu g\,l^{-1}$ with sensitivity enhancements of 44, 196 and 392 and detection limits ($3\sigma$) of 3.0 $\mu g\,l^{-1}$, 0.3 $\mu g\,l^{-1}$ and 0.2 $\mu g\,l^{-1}$, respectively. The method is relatively fast and cheap. Natural waters were analyzed with use of the developed procedure.

*Keywords:* Activated alumina; Chromium(VI) determination; Chromium(VI) preconcentration; Flow analysis; Spectrophotometry

## 1. Introduction

Chromium(III) is considered an essential micronutrient for humans [1], whereas chromium(VI) is a potential carcinogenic agent [2]. This leads to a great interest in the speciation and determination of chromium in biological and environmental samples, especially chromium(VI), due to its potential toxicity.

Vast quantities of chromite ore are used for the production of stainless steel, chrome-plated metals, pigments and chemicals [3]. The main chromium emissions into surface waters are from metal-finishing processes such as electroplating, pickling and bright dipping. Uncontrolled emissions are potential contaminating sources in fresh waters, especially with regard to the toxic chromium(VI). Other discharges of chromium(VI) are related to additives in circulating cooling waters, laundry chemicals and animal glue manufacture [3].

Several techniques have been utilized for chromium determination, such as inductively coupled plasma-atomic emission spectrometry (ICP-AES), flame atomic absorption spectrometry (FAAS), electrothermal atomic absorption spectrometry (ETAAS), and spectrophotometry, the latter being favored for rapid analysis in view of its ease of automation and simple and low-cost instrumentation. The 1,5-diphenylcarbazide (DPC) method is used worldwide, and is highly sensitive and selective.

Flow injection analysis (FIA) is a very fast, multipurpose analytical technique which reduces the use of volumetric glassware and manual sample manipulation [4,5]. Also, the

implementation of separation/preconcentration procedures in a continuous flow mode has gradually superseded their manual batch counterparts [6]. Several solid/liquid interfaces using ion exchange [7], chelating resins [8,9], precipitation/dissolution [10–12], C-18 bonded silica [13], functionalized cellulose [14] and activated carbon [15] have been exploited for the preconcentration of metal species. FIA systems with spectrophotometric detection proposed for chromium determination and/or speciation are summarized in Table 1 [16–24]. Some of them take advantage of the fact that chromium(III), being kinetically inert, is easily oxidized to chromium(VI) in order to determine chromium(VI) and total chromium. The concentration of chromium(III) is then obtained by difference. These procedures have seldom been applied to real samples and the sensitivity is not sufficient for trace concentration determination. For the latter separation/preconcentration steps are needed.

Activated alumina has often been used for chromatographic purposes. The possible mechanisms of the retention of inorganic salts on activated alumina were discussed in early 1949 by Sacconi [25]. Schmitt and Pietrzyk [26] in 1985 pointed to ion exchange as being the major factor contributing to the retention of inorganic ions from aqueous solutions. Activated alumina can then behave as a cation exchanger in basic medium and as an anion exchanger in acidic medium. More recently, Cox et al. established FIA procedures for chromium determination with desirable on-line separation/preconcentration on activated alumina. In the first method [27], 0.01 M nitric acid was used as the carrier and chromium(III) (neutral or cationic) was not retained; chromium (VI) (anionic) was preconcentrated and both ions were detected by ICP-AES. In the second method [28], chromium(III) was preconcentrated on an activated alumina minicolumn in the basic form and detected by ICP-AES. This procedure was successfully applied to human urine. Sperling et al. [29] exploited alumina's amphoteric characteristics to preconcentrate and determine both chromium species with a flow injection system with FAAS detection. Using a 50 µl microcolumn, recoveries of 90–106% (20, 50 and 100 µg of chromium (III) and chromium(VI)) were achieved for spiked natural water samples.

Also, modern automated techniques such as adsorptive cathodic stripping voltammetry (ACSV) [30], high-performance flow atomic spectrometry (HPF-AS) [13], anodic stripping voltammetry (ASV), a flow system interfaced

with inductively coupled plasma-mass spectrometry (ICP-MS) [31] and high-performance liquid chromatography (HPLC) coupled to direct current plasma-atomic emission spectrometry (DCP-AES) [32] have been used for chromium(VI) determinations.

The aim of this work was to study activated alumina as a preconcentrator of the toxic anionic chromium(VI) in natural water analysis in continuous flow. The effect of concomitant species typically found in waters was also studied in depth in order to establish an inexpensive, fast, reproducible and accurate flow system for the determination of toxic chromium(VI), including a minicolumn for on-line preconcentration and spectrophotometric detection.

## 2. Experimental

### 2.1. Reagents and solutions

All solutions were prepared using distilled water and analytical reagent grade chemicals.

Chromium(VI) stock solution, 1000 μg $ml^{-1}$, was prepared by dissolving 2.8287 g of $K_2Cr_2O_7$ in water and diluting to a final volume of 1 l. Working solutions were prepared daily by dilutions of the stock in $1 \times 10^{-4}$ M nitric acid.

The reagent solution, 0.05% (w/v) 1,5-diphenylcarbazide, was prepared by dissolving 0.125 g of 1,5-diphenylcarbazide in 12.5 ml of acetone and diluting to 250 ml with water. This solution was prepared daily.

The eluent solution was 0.1 M ammonium hydroxide, the acidifier solution was 0.7 M nitric acid, and the carrier solution was $1 \times 10^{-4}$ M nitric acid.

Activated alumina, acid form, Brockman grade 1, particle size range 63–100 μm (Merck, Germany), was used as received.

### 2.2. Apparatus

A Desaga PLG peristaltic pump furnished with Tygon and silicone rubber tubes, and a Micronal B 380 spectrophotometer equipped with a Hellma 178.011 flow cell (80 μl inner volume, 10 mm optical path) and connected to a Phillips PM 8251 single pen recorder were used. The manifolds were constructed with 0.8 mm i.d. polypropylene and PTFE tubing and both Tygon and silicone rubber connectors. To commutation, a proportional injector [33], manufactured by Perspex, was used. A minicolumn made of silicone rubber (length, 2.5 cm, 1.6 mm i.d.) was packed with 50 μl of activated alumina.

## 3. Results and discussions

### 3.1. Flow system without preconcentration

With the intention of studying the spectrophotometric 1,5-diphenylcarbazide method, a flow system was built, as can be seen in Fig. 1A. In this system, the sample (S; 90 μl) is introduced into the carrier stream (C, 5.10 ml $min^{-1}$) and merges immediately with the reagent (R; 0.36 ml $min^{-1}$). The color is developed in the 100 cm reaction coil (RC), and the passage of the colored zone through the flow cell results in a transient signal measured at 540 nm. The peak height was used for all calculations.

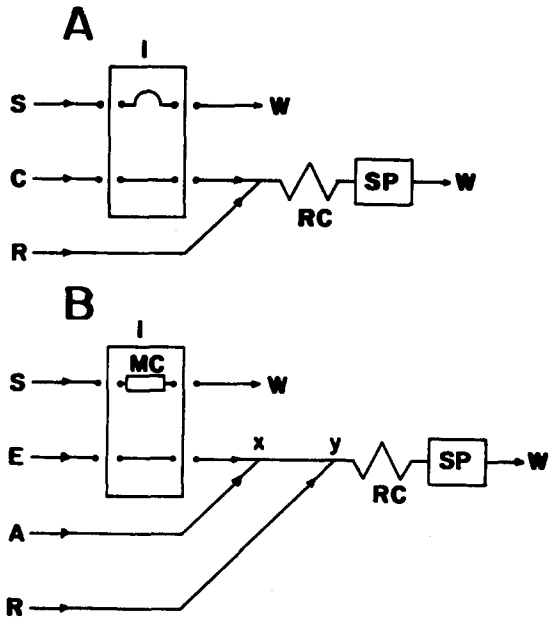

Fig. 1. Flow diagrams. (A) Flow system without preconcentration: S, sample (90 μl); C, carrier solution (0.1 M nitric acid, 5.10 ml $min^{-1}$; R, reagent (0.05% DPC, 0.36 ml $min^{-1}$); RC, reaction coil (100 cm); SP, spectrophotometer; I, proportional injector; W, waste. (B) Flow system with preconcentration: S, sample, (5.10 ml $min^{-1}$); E, eluent solution (ammonium hydroxide, 2.73 ml $min^{-1}$); A, acidifier solution (0.7 M nitric acid, 0.92 ml $min^{-1}$); R, reagent (0.05% DPC, 0.76 ml $min^{-1}$); MC, activated alumina minicolumn; RC, reaction coil (100 cm); SP, spectrophotometer; I, proportional injector; W, waste.

Table 2
Relative signals obtained for chromium(VI) in the presence of interferents using the flow system without preconcentration (Fig. 1A)

| Interferent species | Interferent concentration ($\mu g\ ml^{-1}$) | | | | | |
|---|---|---|---|---|---|---|
| | 100 | 50 | 10 | 5 | 1 | 0,1 |
| $Cl^-$ | 1.02 | – | – | – | – | – |
| $BO_3^{3-}$ | 1.00 | – | – | – | – | – |
| $SiO_4^{4-}$ | 1.02 | – | – | – | – | – |
| $PO_4^{3-}$ | 1.00 | – | – | – | – | – |
| $SO_4^{2-}$ | 1.13 | 1.10 | 1.00 | 1.00 | 1.03 | 1.02 |

Chemical and flow variables were studied in order to obtain the best sensitivity. This study was carried out by the univariate method, a 0.5 $\mu g\ ml^{-1}$ Cr(VI) solution always being introduced into the system in triplicate.

The influence of the pH was studied within the 0–4 range. The best results were obtained at pH 1, which is in agreement with Sandell's [34] description of the batch process but not with the results of other FIA workers [16,17]. Next 0.1 M nitric acid was chosen as the reaction medium and as the carrier stream. The DPC concentration was studied in the range 0.01–0.2% (w/v), and the best sensitivity was obtained with a concentration of 0.05% (w/v), in agreement with literature data [18–23]. The proportion of acetone in the reagent was investigated in the range 5–20% (v/v), and no changes in the analytical signals were observed. A 5% (v/v) concentration was then chosen in order to use less organic solvent in the solution. The influence of the ionic strength was studied by using analytical solutions containing 0.1–3.0 M potassium nitrate, all in 0.1 M nitric acid. No effect due to variations of this parameter was found, so the ionic strength did not need to be regulated.

The reactor coil (RC; Fig. 1A) was place in a thermostated bath at temperatures from 26 to 67°C. The signal increased constantly with the increase in temperature. At 67°C the signals were 30% higher than at 26 °C. However, ambient temperature was used in all measurements in order to simplify the system design.

The reagent flow rate was varied from 0.18 to 1.76 ml $min^{-1}$ keeping the carrier flow rate at 1.76 ml $min^{-1}$. No changes in the absorbance signals were observed and therefore a flow rate of 0.36 ml $min^{-1}$ was chosen, yielding enough reagent for the reaction. The carrier flow rate was studied between 0.76 and 5.85 ml $min^{-1}$. From 0.76 to 5.10 ml $min^{-1}$, the absorbance signals remained constant, but a slight decrease at higher flow rates was observed (at 5.85 ml $min^{-1}$ the decrease in signal was only 10%). Therefore a flow rate of 5.10 ml $min^{-1}$ was chosen because it allowed good sample throughput.

In order to verify the effect of concomitant species, some anions were tested as potential interferents. Solutions containing each interferent alone at a concentration of 100 $\mu g\ ml^{-1}$ were prepared and introduced into the flow system. Also, solutions containing 0.5 $\mu g\ ml^{-1}$ of chromium(VI) and 100 $\mu g\ ml^{-1}$ of each interferent individually, were measured. As a control, chromium(VI) analytical solutions containing 0.5 $\mu g\ ml^{-1}$ were measured also. In this way, the maximum ratio of analyte: interferent tested was 1:200. Phosphate, chloride, silicate, borate and sulphate were investigated. The results are shown in Table 2. Only sulphate displays some interference at concentrations higher than 50 $\mu g\ ml^{-1}$.

This flow system without preconcentration (Fig. 1A) shows such typical calibration equations as $A = -0.002 + 0.1052$ [Cr(VI)] where [Cr(VI)] is in micrograms per milliliter with $r = 0.999$. The relative standard deviation (RSD) when introducing 0.5 $\mu g\ ml^{-1}$ Cr(VI) solutions, was below 1% for triplicate measurements. The flow system dispersion coefficient measured with the aid of a dye was 2.

### 3.2. Flow system with preconcentration

In Fig. 1B a schematic diagram of the manifold with a preconcentration column can be seen. The sample (S, 5.10 ml $min^{-1}$) flows through an activated alumina minicolumn (MC) during the time of preconcentration. By switching the proportional injector (I), the minicolumn with adsorbed chromium is inserted into the eluting stream (E) and chromi-

um(VI) is then displaced by ammonium hydroxide. At the point x this solution coalesces with the acidifier solution (A) for suitable pH adjustment. The sample zone merges with the reagent stream (R), at point y, the color is developed in the reaction coil (RC) and the transient signal is measured at 540 nm.

Both the chemical and flow variables were studied in this flow system in order to improve the preconcentration step. This study was also carried out by using the univariate method employing 50 $\mu g\,l^{-1}$ Cr(VI) solution.

The influence of the sample pH was tested in the range 1–5. The best analytical signals were observed with $1 \times 10^{-4}$ M nitric acid (pH 4). At pH values below and above 4 reductions in the signal were observed, and all subsequent studies were carried out at pH 4. The possibility to using a buffer to keep a constant pH of 4 was investigated using sodium acetate/acetic acid from 0.05 to 0.2 M for both species (pH adjusted to 4 with nitric acid). When this buffer system was used, a considerable drop in sensitivity was noted (at a 0.05 M buffer concentration, a drop in signal of 30% was observed and at 0.2 M this reduction was 50%). This effect probably occurs due to anionic competition between acetate and chromium(VI) ions. Therefore, buffer was not used further. The eluent concentration was investigated by using 0.01–2.0 M ammonium hydroxide streams. Between 0.01 and 0.1 M $NH_4OH$, the signals improved significantly but in the range 0.1–1 M they remained constant. The concentrations higher than 1 M showed a significant decrease in signal; therefore, 0.1 M was chosen as the eluent concentration. Also, higher eluent concentrations should be avoided in order to avoid Schlieren noise. Sodium hydroxide was also tested as eluent at the same concentrations, but the signals were lower and not reproducible, probably due to a modification of the alumina surface by strong alkali. This effect was also observed by Cox et al. [27] when using potassium hydroxide. As the colorimetric reaction takes place in acidic medium and elution requires basic media, the use of an acidifier solution (A, Fig. 1B) became necessary. For this task, nitric acid was tested in the range 0.1–2.0 M. As between 0.6 and 2.0 M the signal variations were insignificant (about 3%), 0.7 M nitric acid was chosen.

The eluent flow rate was studied between 1.76 and 5.10 ml $min^{-1}$. Lower flow rates, below 2.26 ml $min^{-1}$, were not enough to perform effective elution thereby causing smaller signals. From 2.73 to 5.10 ml $min^{-1}$ the peak heights were the same and total elution was obtained, without a memory effect. For that reason, 2.73 ml $min^{-1}$ was chosen as the eluent flow rate. The flow rate of the acidifier solution was changed from 0.28 to 1.76 ml $min^{-1}$. Smaller signals at reduced flow rates (25% at 0.28 ml $min^{-1}$) due to an insufficient acid amount were observed. At flow rates of 0.55 ml $min^{-1}$ upwards, the signals were highest and constant. Thus, a 0.92 ml $min^{-1}$ flow rate was chosen. Analytical solutions in $1 \times 10^{-4}$ M nitric acid at flow rates ranging from 3.8 to 6.0 ml $min^{-1}$ were introduced into the system. No analytical signal variations were observed, and a flow rate of 5.1 ml $min^{-1}$ was then selected. The reagent flow rate was examined within the 0.55–3.80 ml $min^{-1}$ range. The signals were constant up to a flow rate of 1.54 ml $min^{-1}$. At 3.80 ml $min^{-1}$ a decrease in the signal occurred probably due to the increase in dispersion. A 0.76 ml $min^{-1}$ reagent flow rate was chosen. The volume of the reactor coil, needed for the completion of the spectrophotometric reaction, was investigated from 125 to 1350 µl. With volumes from 125 to 400 µl, the signals did not change but with volumes above 400 µl they decreased (a 20% reduction in the signal with an 800 µl reactor coil was observed). A 200 µl reactor was chosen (100 cm, 0.5 mm i.d.). The length of a coil placed immediately after the point of introduction of the acidifier solution (point x, Fig. 1B) was also investigated. The best results were obtained without this coil, although the reactor coil (RC, Fig. 1B) is suitable for all reagent mixtures and reactions.

The length of the activated alumina column was investigated between 2.5 and 10 cm (50–200 µl). In the analytical range of this work, an increase in the activated alumina amount did not improve the preconcentration and recovery of chromium(VI). Both the retention and elution were the same and because of this a minicolumn 2.5 cm long was selected.

### 3.3. Interference studies

When considering the utilization of activated alumina as preconcentrator for chromium(VI) in water analysis, the following potential interferents were examined: chloride, borate, silicate, phosphate, sulphate, fluoride, bicarbonate and iron(III). Solutions containing the interfer-

[a] Not tested.

ents individually at several concentrations, and binary solutions of analyte interferent were prepared and introduced into the flow system, always with volumes of 5 ml. Table 3 shows the results. Chloride, borate, silicate, bicarbonate and fluoride did not exhibit any interference at the 50 $\mu g\ ml^{-1}$ level. Sulphate, phosphate and iron(III) showed interferences at the 50 $\mu g\ ml^{-1}$ level. Sulphate concentrations up to 10 $\mu g\ ml^{-1}$ (200 times the analyte concentration) revealed no influence on the signal. Phosphate interference was more severe and a level of 1 $\mu g\ ml^{-1}$ (20 times the analyte concentration) only allowed in the solution. The results of McLeod et al. [35] corroborated this observation that activated alumina has a great affinity for phosphate ions. Sperling et al. [29] also observed hard phosphate interference although they used phosphate buffer for the pH experiments, concluding that the signal disappeared in this medium. These concomitant ion effects could only be explained in terms of ion-exchange competition between the chromium(VI) species ($CrO_4^{2-}$ or other chromium(VI) anionic species) and the concomitants. The most severe interference is due to iron(III). Its presence reduces drastically the absorbance signals. Only concentrations below 0.1 $\mu g\ ml^{-1}$ (twice the analyte concentration) can be present. This fact cannot easily be explained unless by the presence of any anionic species containing iron(III) or as being due to the formation of an anionic complex containing both species. Interferents present individually, even at the highest concentrations, did not give rise to analytical signals. As activated alumina has a distinct affinity for anionic species in acidic medium, the species compete with the anionic chromium(VI), impairing its retention. Analytical solutions with 50 $\mu g\ l^{-1}$ of chromium(VI) and all the interferents with the exception of iron(III) and fluoride present at levels up to 10 $\mu g\ ml^{-1}$ did not show any interference (ratio of analyte:interferent of 1:200). However, from a level of 25 $\mu g\ ml^{-1}$ upwards, a sharp signal reduction, proportional to the interferent concentrations, was observed. Also, an analytical solution containing all these interferents at a level of 50 $\mu g\ ml^{-1}$ without chromium(VI) did not show any analytical signal (Table 3).

It was verified that daily use of the preconcentration system with the activated alumina minicolumn (Fig. 1B) for 6 months, with analytical chromium(VI) solutions as samples, does not change its efficiency. However, when working with more complex matrices than water (geological or biological matrices which contain higher concentrations of iron(III) and anionic interferents), its efficiency gradually diminished, and replacement of the activated alumina was needed. Several analytical curves were constructed for different preconcentration volumes. These analytical characteristics as well as the enrichment factors can be seen in Table 4. Also, in a test involving the introduction of a solution containing 2 $\mu g\ l^{-1}$ Cr(VI) in $1 \times 10^{-4}$ M nitric acid, from 10 to 200 ml sample volumes the analytical curve was linear (Abs = 0.002 + 0.000980 [volume]) where the volume is in milliliters, showing preconcentration is possible even when larger sample volumes are used.

Table 4
Analytical features of the flow system with preconcentration

| Injected volume (ml) | Concentration range ($\mu g\,l^{-1}$) | Equation [a] | RSD (%) | Detection limits ($\mu g\,l^{-1}$) | Enrichment factors [b] | Sampling rate ($h^{-1}$) |
|---|---|---|---|---|---|---|
| 5 | 10–50 | Abs = 0.002 + 0.00338 [Cr(VI)] | 0.6 | 3 | 44 | 40 |
| 25 | 2–10 | Abs = −0.002 + 0.0207 [Cr(VI)] | 2.5 | 0.3 | 196 | 10 |
| 50 | 1–5 | Abs = −0.001 + 0.0412 [Cr(VI)] | 4.7 | 0.2 | 392 | 5 |

[a] Chromium(VI) concentration given in micrograms per liter.
[b] Enrichment factors were calculated by slope relationship compared to the flow system without preconcentration.

### 3.4. Sample pH and preservation

The sample pH and sample preservation are very important in the trace chromium determination. Sperling et al. [36] found an optimum sample pH of 9 for the preconcentration of chromium(VI) on C-18 bonded silica reverse-phase sorbent with ETAAS. According to these workers, the reduction of chromium(VI) to chromium(III) can occur due to the presence of various substances in river water, and it can be eliminated by using pH 9 and also by the addition of 1 drop of 5% (w/v) potassium permanganate to the river water before spiking. These workers also recommend avoiding conventional sample preservation with nitric acid for the speciation of chromium. The same pH 9, but using carbonate buffer and ethylenediaminetetraacetic (EDTA), was found to be optimum for the preservation of chromium(VI) by Pavel et al. [37]. Also, pH 4 was considered safe by Sperling et al. in their work [29], which included preconcentration on alumina. In the present work the water samples were preserved with nitric acid at pH 4 at the time of sampling.

### 3.5. Application to real samples

Water samples were introduced into the flow system with the minicolumn (Fig. 1B) according to the procedure described elsewhere. Analytical solutions, blanks and samples were similarly run. Recovery tests showed that even for samples with relatively simple matrices, the presence of interferents reduced or eliminated the chromium(VI) signals, due to the competition between the anionic species. In order to circumvent this drawback, it was decided to carry out all determinations by using the standard additions method. The results are shown in Table 5. This determination could only be carried out successfully for some water samples, due to low chromium concentrations or interferences. These limitations have been often reported by other workers [29,36,38].

## 4. Conclusions

The flow system with preconcentration studied here is suitable for preconcentrating chromium(VI) from diluted solutions. Depending on the volumes introduced, concentrations as low as 1 $\mu g\,l^{-1}$ can easily be determined, and precise results are obtained (RSD < 4.7% for three measurements). Sample throughput is relatively high and depending on the sample volume, a preconcentration of 5 ml of water takes only 1.5 min until the signal measurement (40 $h^{-1}$). The spectrophotometric method is inexpensive and therefore can be used by any analytical laboratory. The detection limits found with the developed methodology (3–0.2 $\mu g\,l^{-1}$) are very good owing to enhanced sensitivity when using the preconcentration system, and were of the same order of magnitude as those in the literature [14,27,29].

However, an interference study emphasized serious interference effects which reduces the chromium(VI) retention. In this work, the presence of more than 10 $\mu g\,ml^{-1}$ of sulphate or 1 $\mu g\,ml^{-1}$ of phosphate has an effect on the analytical signals. These results agree with the affinity order of sorption of anions on acid alumina [39]. Other "ion exchangers", such as functionalized cellulose, show the same interference effects; the presence of 10 $\mu g\,ml^{-1}$ of sulphate causes a significant decrease of chromium(VI) sorption [14].

In the study of Sperling et al. [29] the tolerance level was 500 $\mu g\,ml^{-1}$ for sulphate and 10 $\mu g\,ml^{-1}$ for phosphate. The effect of phosphate was very drastic when phosphate buffer was used to control the pH. Aspects of this work and the work of Sperling et al. [29] which

Table 5
Results obtained in the determination of chromium(VI) in water

| Sample | Introduced volume (ml) | Cr(VI) found ($\mu g\,l^{-1}$) | Additions curve slopes |
|---|---|---|---|
| Mineral water 1 | 5 | <3 | 0.00501 |
| Mineral water 1 | 25 | 1 | 0.00170 |
| Mineral water 1 | 50 | 1 | 0.0108 |
| Mineral water 2 | 25 | <0.3 | 0.0194 |
| Mineral water 3 | 25 | <0.3 | 0.00297 |
| Mineral water 4 | 25 | 3.4 | 0.00173 |
| Drinking water | 25 | <0.3 | 0.00193 |

differ are probably the sample compositions and the analytical range. In the work of Sperling [29] the analytical range varied from 20 to 100 $\mu g\,l^{-1}$, while in this study the analytical range varied from 2 to 10 $\mu g\,l^{-1}$, i.e. ten times lower. Also, the samples were always spiked with 20 $\mu g\,l^{-1}$ of chromium(VI) before analysis in the work of Sperling et al. [29]. Cox et al. [27] established a similar FIA ICP-AES methodology for preconcentrating and determining chromium(VI), which performed well but was not applied to real sample analysis. Recent work [40] described an interlaboratory comparison for chromium determinations in water samples. The two laboratories that employed alumina as preconcentrator did not obtain good results for the analysis of water samples spiked with 9.3 $\mu g\,l^{-1}$ of chromium(VI) (analytical range similar to that used in this work).

In the flow system studied for chromium(VI) preconcentration and determination, the most relevant problem was iron(III) interference. Its effect on the decreasing chromium(VI) signals could not be easily explained. Atomic absorption tests with the preconcentration system revealed that even at a level of 1000 $\mu g\,ml^{-1}$, iron(III) is not retained on the activated alumina. All the iron(III) passes through the minicolumn in the preconcentration step, because the elution step does not give rise to any signals. Otherwise, AAS recovery tests show that the presence of iron(III) impaired the quantitative recovery of chromium(VI). Any chemical interaction between chromium(VI) and iron(III) could take place in the solution environment, promoting poorer recovery in the flow system.

In the majority of papers, found in the literature concerning activated alumina or other sorption methods, the workers were not able to detect chromium(VI) in natural water samples, either due to the lower concentration or to the interference effects of concomitants [13,14,29,36].

In conclusion, continuous flow methodology using activated alumina could be used in real sample analysis with appropriate care. Also, to minimize interferences, the standard additions method should be utilized. To succeed well with methodologies involving chromium(VI) preconcentration on activated alumina appear to be more difficult, especially when more complex matrices and lower chromium(VI) concentrations are involved. Apparently, this means that better results will be achieved by eliminating or reducing the effects of the main interferents.

Received 25 January 1995; revised 10 April 1995; accepted 11 April 1995

**Abstract**

A novel chemiluminescent system, fluorescein–$NH_2OH$–$OH^-$, was developed for the determination of copper(II) in serum. A weak light emission arises from hydroxylamine in the presence of the organic reagent fluorescein in basic aqueous solution. Under the conditions of $1.2 \times 10^{-3}$ mol $l^{-1}$ $NH_2OH$ and $5 \times 10^{-3}$ mol $l^{-3}$ fluorescein, the light intensity is linearly dependent upon the concentration of copper(II) within the range 1–20 ppb. The relative standard deviation of the determination of copper(II) is 4.2% ($n = 13$) and the detection limit is 0.5 ppb. The system is highly selective for copper except in the presence of iron(II,III) and cobalt(II). In conjunction with potassium fluoride as masking agent, the method was successfully applied to the determination of microamounts of copper(II) in serum. A mechanistic study of the chemiluminescence reaction is also discussed.

## 1. Introduction

The determination of copper in body fluids such as serum is of increasing clinical importance. A number of investigations regarding the use of chemiluminescence have been proposed [1–3]. Most analytical methods for copper using liquid-phase chemiluminescence are based on the reaction of chemiluminescent reagents (such as luminol, lecigenin, lophine, and oxalate esters) with $H_2O_2$ catalysed by copper, which results in poor selectivity. In our laboratory, we have developed two new systems for copper determination without chemiluminescent reagents [4,5], both of which were used for tap water [4] or sea water [6]. The application of fluorescein as a chemiluminescent reagent has been reported previously [7], and recently it was also used for the determination of ultratrace amounts of copper(II) [8], unfortunately, which were also concerned with luminol or horseradish peroxidase, respectively. In the course of our studies on the application of the chemiluminescence method to the determination of copper, we found that in alkaline aqueous solution, a trace amount of copper can lead to hydroxylamine luminescence, which can be enhanced by adding an appropriate amount of fluorescein solution. Among 20 coexisting ions tested, only iron(II,III) and cobalt(II) showed interferences when their concentrations exceeded by two fold that of copper(II). Based on this finding, we have proposed a highly selective chemiluminescent system for the determination of copper(II). Experimental variations such as pH values, reactant concentrations and the effects of coexisting ions have been studied. The application of this method to the determination of copper in serum gave a good result. A possible mechanism for the chemiluminescence of the $Cu^{2+}$–

$NH_2OH$–fluorescein system has been discussed. It was thought that the emission was from the excited molecular oxygen species and the light arose either from the deactivation of the excimer oxygen species or was emitted from the excited organic molecules generated by energy transfer.

## 2. Experimental

### 2.1. Apparatus and reagents

A home-made biochemiluminescence detector was used. Details of the construction and principles of the apparatus have been described elsewhere [9]. A Shimadzu C-E3A Chromatopac instrument (Kyoto, Japan) was used for the measurement of the chemiluminescence signals.

A copper(II) standard solution was prepared by dissolving 0.25 g of analytical-reagent-grade copper chloride in 100 ml of 0.05 mol $l^{-1}$ HCl solution to give a concentration of about 1 mg $ml^{-1}$ of copper. The concentration of copper in the solution was determined by EDTA titration. A working solution was prepared by dilution of the stock solution with water just before use. Fluorescein (FL) was purchased from Merck; a stock solution was prepared by dissolving 0.3323 g of FL in 5 ml of 0.2 mol $l^{-1}$ KOH–50% ethyl alcohol solution, then adding water to 100 ml. Diluted solutions were prepared from the stock solution. Hydroxylamine hydrochloride was prepared by dissolving an appropriate amount of $NH_2OH \cdot HCl$ in water to obtain the requisite concentration before use.

All chemicals were analytical-reagent-grade and were used as received. Redistilled water was used throughout the experiment.

### 2.2. Procedure

To the luminescence cell, 100 µl of 0.01 mol $l^{-1}$ fluorescein solution, 500 µl of 0.10 mol $l^{-1}$ borate buffer solution (pH 12.00) and 170 µl of $1.25 \times 10^{-3}$ mol $l^{-1}$ $NH_2OH$ solution were added by means of micropipettes. The cell compartment was then transferred into the dark room of the chemiluminescence meter and the light gate was opened for passage of light through the cell. Finally, 100 µl of standard copper(II) solution or sample solution are injected into the luminescence cell from the sample injection system. The chemiluminescence signals were then recorded.

## 3. Results and discussion

### 3.1. Primary experiment for chemiluminescence reaction

By using the home-made biochemiluminescence meter, we studied the chemiluminescence behaviour of the reducing agent hydroxylamine hydrochoride, and discovered that in basic aqueous solution, some metal ions such as copper(II), iron(II,III), cobalt(II) and nickel(II) can react with $NH_2OH$, giving a faint light without any oxidation reagent being present. The addition of fluorescein solution to copper(II) can affect the luminescence sensitivity significantly, especially at high pH values, and the peak heights of the chemiluminescence signals show a linear relationship with the concentration of copper(II).

### 3.2. Effect of pH

Although various buffer solutions such as Tris–HCl, carbonate and phosphate were examined for the chemiluminescence reaction, the most promising was $H_3BO_3$–KOH buffer solution. The effect of pH on the chemiluminescence (peak height) is shown in Fig. 1. The peak height increased with the increase in pH to pH 11.7. The most favourable value of the pH was 12.0.

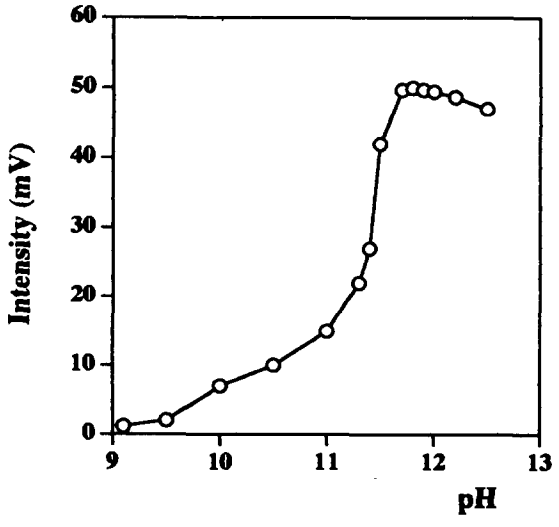

Fig. 1. Effect of pH on the luminescence intensity.

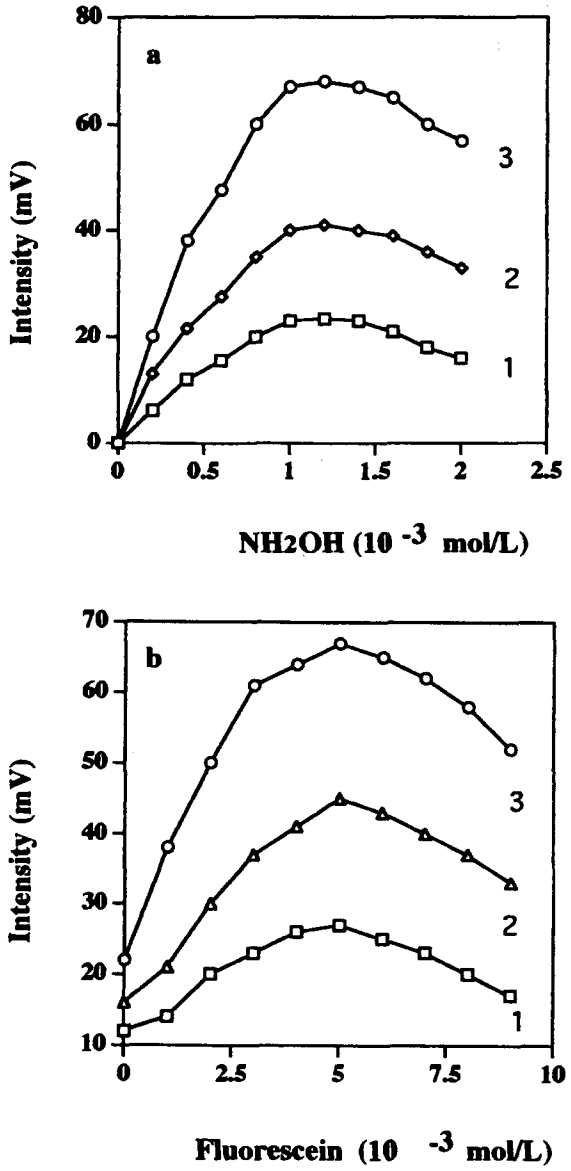

Fig. 2. Effect of concentrations of hydroxylamine and fluorescein on the chemiluminescence intensity. (a) $NH_2OH$; (b) Fluorescein. Curve 1, 5 ppb Cu(II); curve 2, 10 ppb Cu(II); curve 3, 15 ppb Cu(II).

### 3.3. *Effects of the concentrations of hydroxylamine and fluorescein*

The effect of the concentrations of hydroxylamine and fluorescein on light emission are shown in Figs. 2a and 2b, respectively. Almost constant chemiluminescence was observed for hydroxylamine in the range $(1.0–1.5) \times 10^{-3}$ mol $l^{-1}$, and the most suitable concentration was $1.2 \times 10^{-3}$ mol $l^{-1}$. The chemiluminescence intensity increased as the concentration of fluorescein was increased from 0 to $5 \times 10^{-3}$ mol $l^{-1}$. A $5 \times 10^{-3}$ mol $l^{-1}$ fluorescein concentration was chosen for subsequent experiments.

### 3.3. *Calibration graph and detection limit*

Using the optimum conditions described above, a calibration graph was obtained for the determination of copper. The analytical characteristics of the graph are summarised in Table 1. The relative standard deviation for thireen replicate analyses of 1 ppb of copper(II) was 4.2%, which means that this method is satisfactory for the determination of copper.

### 3.4. *Interferences of coexisting ions*

The effects of various inorganic ions on the determination of 5 ppb of copper(II) were examined using the proposed method. The tolerance limit was taken as the amount which caused an error of $\pm 5\%$ in each peak height. The results are summarised in Table 2. Most ions have almost no effect on the copper(II) determination at high concentrations. Only iron(II,III) and cobalt(II) interfered seriously when their concentrations were over two fold higher than that of copper(II). Therefore a 0.01 mol $l^{-1}$ potassium fluoride solution was chosen for masking the iron ions because a low concentration of KF has no effect on the luminescence intensity. The influence of cobalt(II) was not investigated further because the samples to be tested contained very little cobalt.

### 3.5. *Application*

There are many analytical methods available for the determination of copper. One of those most frequently employed for copper determination is atomic absorption spectrometry (AAS) although there are some reproducibility and interference problems [10]. The present method was applied satisfactorily to the determination of copper(II) in serum and was found to be simple, highly sensitivity and displayed excellent selectivity. The samples were pretreated with a mixture of concentrated nitric acid and 30% hydrogen peroxide in a small beaker, carefully heated under a cover on a hot plate until the liquid had almost evaporated, and then treated with concentrated hydrochloric acid and evaporated by dryness. The residue was dissolved in 10 ml of 0.01 mol $l^{-1}$ KF solution. An aliquot of the resulting solution was

Table 1
Analytical characteristics of copper obtained by the present method

| Characteristic | Result | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Copper (ppb) | 0 | 0.5 | 1 | 4 | 8 | 12 | 16 | 20 |
| Intensity (mV) | 2.5 | 5 | 8 | 19 | 38 | 57 | 73 | 82 |
| Linear range (ppb) | 1 – 20 | | | | | | | |
| Limit of detection [a] (ppb) | 0.5 | | | | | | | |

[a] Signal-to-noise ratio, 2.

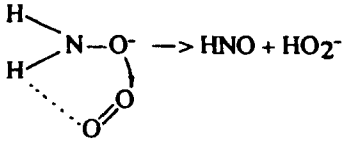
determined by using the standard curve. The results agreed well with those obtained by AAS. The recoveries were good enough for practical use and all the results are listed in Table 3.

### 3.6. Possible mechanism of the present chemiluminescence (CL) reaction

It is well known that light emission is frequently accompanied by an oxidation reaction involving large free energy changes. Most chemiluminescence of organic molecules occurs in the presence of $H_2O_2$ or other oxidising agents. In contrast, the present CL system does not have such reagents added deliberately. This enables us to discuss the possible CL reaction scheme of the hydroxylamine–fluorescein system.

*Chemiluminescence and fluorescence spectra*

The chemiluminescence spectrum of the $NH_2OH$ reaction with copper was detected by means of a series of filters. The results indicated that there were two luminescence peaks at 480 nm and 580 nm, respectively. The CL spectrum of hydroxylamine–fluorescein was similar to the fluorescence spectrum ($\lambda_{max} = 560$ nm) before and after reaction with copper(II). When nitrogen or oxygen was bubbled through the solution the copper(II) peak height decreased with nitrogen and increased with oxygen. The results indicated that the reaction involved dissolved oxygen. Brown [11] and Khan and Kasha [12] reported that the single exited molecular oxygen species ($^1O_2^*$) and the formation of the $(^1O_2^*)_2$ species arose from the emission due to the deactivation of excimer oxygen species; we thought that the luminescence emitted from the $NH_2OH$–Cu(II) system was due to the generation of $O_2(^1\Sigma_g^+)$ and thus a molecular pair, $O_2(^1\Delta_g)O_2(^1\Sigma_g^+)$. In this work, however, no detectable emission was observed during the reaction. Khan and Kasha [12] proposed that in a system generating excited molecular oxygen, luminescence arising from any energetically favourable species can be produced, and observed as the CL reaction direct energy transfer from the excited oxygen molecular pairs. Therefore, there was significant evidence that dissolved oxygen has an important role in the CL reaction. The oxidation mechanism of hydroxylamine has been investigated [13]. Hughes and Nicklin [14] proposed a possible mechanism for hydroxylamine oxidation in basic aqueous solution. They thought that in the presence of alkaline solution, $NH_2OH$ existed in the form of $NH_2O^-$, which can be attacked by the dissolved oxygen



(1)

Table 2
Tolerance limits of foreign ions on the determination of 5 ppb of copper(II)

| Tolerance limit (ppb) | Foreign ion |
|---|---|
| $5 \times 10^3$ | $Cl^-$, $SO_4^{2-}$, $PO_4^{3-}$, $HCO_3^-$, $NO_3^-$, $F^-$, $Na^+$ $K^+$, $Ca^{2+}$, $Mg^{2+}$ |
| $1 \times 10^3$ | $Zn^{2+}$, Al(III), $Cd^{2+}$, Se(IV), Au(III), Bi(III) |
| $1 \times 10^2$ | Ga(III), $Ag^+$, $As^{3+}$, $Au^{3+}$ |
| 50 | Cr(III), $Pb^{2+}$, $Ni^{2+}$, Fe(III) |
| 10 | Fe(II), Co(II) |

The oxidation scheme of metal-ion-catelysed hydroxylamines has been studied by Anderson [15]. It was described as the following

$$2Cu^{2+} + NH_2OH \rightarrow 2Cu^+ + NOH + 2H^+ \quad (2)$$

$$2NOH \rightarrow N_2O + H_2O \quad (3)$$

$$H^+ + 2Cu^+ + O_2 \rightarrow 2Cu^{2+} + HO_2^- \quad (4)$$

Table 3
Determination of copper in serum samples

| Serum | Cu content [a] (ppm) | | Cu added (ppm) | Cu found (ppm) | Recovery (%) |
|---|---|---|---|---|---|
| | This method | AAS method | | | |
| 1 | 1.08 | 0.98 | 1.00 | 0.94 | 94 |
| 2 | 1.04 | 1.00 | 1.00 | 0.97 | 97 |

| 4 | 0.84 | 0.85 | 1.00 | 0.94 | 94 |
| 5 | 0.89 | 0.91 | 1.00 | 0.96 | 96 |
| 6 | 0.92 | 0.90 | 1.00 | 0.96 | 96 |

[a] $n = 3$.

Stauff [16] reported that $HO_2^-$ free radicals can attack each other, giving a molecular pair $(O_2^*)_2$

$$O_2H^- + O_2H^- \rightarrow (O_2O_2)^* \quad (5)$$

In the present work, the reaction scheme of hydroxylamine may be represented by the following two equilibria

$$O_2H^{-*} + O_2H^{-*} \rightarrow (O_2O_2)^* \quad (6)$$

$$(O_2O_2)^* \rightarrow 2O_2 + h\gamma(\lambda_{max} = 478, 580\ nm) \quad (7)$$

The chemiluminescence of fluorescein used in analytical chemistry has been reported [8,17], and was based on the reaction of fluorescein with $H_2O_2$ and horseradish peroxidase (HRP).

$$FL + H_2O_2 \xrightarrow{HRP} FL^* \rightarrow FL + h\gamma \quad (8)$$

From the above discussion, a possible reaction scheme is proposed for the chemiluminescence of fluorescein–$NH_2OH$ with copper(II). First, an autoxidation reaction to give hydroxylimine took place in the basic aqueous solution with copper(II) ions as catalyst. The emission was thought to be from the excited molecular oxygen species (excimers) which were produced from hydroxylamines reacting with dissolved oxygen, catalysed by copper(II). The excited molecular oxygen species $(^1O_2^*)_2$ then transferred energy to the fluorescein molecule, forming excited organic molecules, and the emission was generated.

$$(^1O_2^*)_2 + FL \rightarrow 2^3O_2 + FL^*$$

$$FL^* \rightarrow FL + h\gamma(light)$$

## 4. Conclusion

A simple and selective chemiluminescence method for the determination of copper in serum has been proposed. The method utilises the autoxidation of hydroxylamine in alkaline solution catalysed by copper(II). The chemiluminescence intensity was enhanced by the addition of fluorescein. The mechanism has also been discussed.

**Abstract**

The adsorption isotherms of $MCl_2$ (M = Mn, Ni, Cu, Zn and Cd) and $FeCl_3$ by silica gel chemically modified with benzimidazole molecules ($\equiv Si(CH_2)_3-NC_7H_5N$) were studied in ethanol solution at 298 K. A column made of modified silica was used to adsorb and preconcentrate the above metal ions from ethanol solution. Elution was done with 0.1 M hydrochloric acid in an ethanol/water mixture having a mole fraction of water of 0.8. The material was applied in the preconcentration of metal ions from commercial ethanol normally used as engine fuel.

*Keywords:* Benzimidazole; Preconcentration of heavy metals; Adsorption isotherms; Silica gel functionalized

## 1. Introduction

Surfaces of inorganic solids have been modified with chelating groups in order to adsorb and preconcentrate metal ions from solutions [1–7].

The preparation of a silica chemically modified with benzimidazole molecules ($\equiv Si(CH_2)_3-NC_7H_5N$) and a study of the adsorption of $CuX_2$ (X = Cl, Br, $ClO_4$) from non-aqueous solvents were recently investigated [8–10]. This material, abbreviated here as SiL, can react with copper(II) ions in ethanol solution forming very stable complexes. Considering the potential usefulness in chemical analysis, the SiL can be applied to the preconcentration of metal ions from commercial ethanol (a mixture of ethanol and water).

The development of methods to determine traces of metals has been one aspect of interest in the research on ethanol as a fuel. The presence of some metal ions in ethanol fuel can induce corrosion in the vehicle components in contact with the liquid [11–14].

Since benzimidazole can coordinate with several metals, and considering the growing interest in the modification of surfaces, we report in this work the results of our sorption and preconcentration study of Mn(II), Fe(III), Ni(II), Cu(II), Zn(II) and Cd(II) by SiL in ethanol solution. The coordination complexes that are formed upon adsorption were characterized by infrared spectroscopy. The application of this material to the preconcentration and removal of the above metal ions from commercial ethanol is also described.

## 2. Experimental

### 2.1. Preparations

Silica gel 60 (Merck, Darmstadt, Germany) having a particle size between 0.2 and 0.05 mm was chemically modified with a benzimidazole molecule according to the procedure described earlier [8]. Silica gel (≈50 g) previously activated at 420 K under vacuum ($10^{-3}$ torr, ≈0.133 Pa), was suspended in dry xylene (200 ml), 3-chloropropyltrimethoxysilane (15 ml) was added and the mixture was stirred for 24 h at 380 K in a nitrogen atmosphere. The resulting modified silica, $\equiv Si(CH_2)_3Cl$, was immersed in pure dimethylformamide (150 ml) and benzimidazole (17.5 g, 0.15 mol) was added. The mixture was stirred for 24 h at 380 K under a nitrogen atmosphere. The resulting modified silica was filtered off and washed with dimethylformamide and ethanol. The product was heated for 8 h at 353 K under vacuum ($10^{-3}$ torr).

The amount of benzimidazole attached to the silica surface was determined by nitrogen analysis using the Kjeldahl method. The specific surface area was determined by the Brunauer–Emmett–Teller (BET) method using a Micromeritics Flow Sorb 2300 apparatus of Micromeritics Instrument Corporation (Norcross, USA).

### 2.2. Adsorption isotherms

The adsorption isotherms of metal ions on benzimidazole-modified silica, hereafter denoted as SiL, were determined for $MCl_2$ (M = Mn, Ni, Cu, Zn and Cd) and $FeCl_3$ in dry ethanol solutions. Solutions of the metal ions (concentration between $1 \times 10^{-4}$ and $5 \times 10^{-3}$ M) were shaken with SiL (0.1 g) at $298.0 \pm 0.2$ K for 40 min. The supernatants were decanted and the amount of metal ions was determined by flame atomic absorption spectroscopy (flame AAS).

### 2.3. Preconcentration experiments

For these experiments, a glass column of 20 cm height and 0.8 cm internal diameter was packed with about 2 g of the sorbent to give a bed height of about 10 cm. The material was activated for each run by washing with 5 ml of aqueous solution of 0.1 M hydrochloric acid, treating with 5 ml of 0.5% (w/v) potassium hydroxide in ethanol, and finally washing with 20 ml of ethanol to remove all hydroxide.

Solutions of Mn(II), Fe(III), Ni(II), Cu(II), Zn(II) and Cd(II) ions with concentrations of $5 \times 10^{-3}$ M were prepared in dry ethanol. In each run, 5 ml ($25 \times 10^{-6}$ mol) of metal ion solution was passed through the column with a flow rate between 0.5 and 1.0 ml $min^{-1}$. The adsorbed metal ions were eluted by passing 10 ml of an aqueous ethanolic 0.1 M hydrochloric acid solution in which the ethanol/water ratio was varied. Lower acid concentrations such as 0.075 or 0.05 M were less effective in desorbing the metal. The metals were quantified by flame AAS.

### 2.4. Adsorption and recovery of a mixture of ions

In these studies, solutions of Mn(II), Fe(III), Ni(II), Cu(II), Zn(II) and Cd(II) ions ($0.1 \times 10^{-3}$ M each) were used. Higher concentrations ($5.0 \times 10^{-3}$ or $0.5 \times 10^{-3}$ M) were also tested. For adsorption, 10 ml of solution was percolated through the column. The adsorbed metal ions were eluted by passing 10 ml of 0.1 M HCl in 0.8 mole fraction ethanol/water through the column and collected for analysis by flame AAS.

## 3. Results and discussion

### 3.1. Characteristics of the material

The chemical analysis of SiL showed $0.48 \times 10^{-3}$ mol $g^{-1}$ attached molecules and a specific surface area of 477 $m^2$ $g^{-1}$. The maximum retention capacity for individual ions from ethanol solution was evaluated by adsorption isotherms (see Table 1). This retention

Table 1
Adsorption of $MX_2$ and $FeCl_3$ by SiL from ethanol solution at 298 K

| | $10^{-3}$ $b$ (l $mol^{-1}$) | $10^3$ $N_f^S$ (mol $g^{-1}$) | $r$ |
|---|---|---|---|
| $CuCl_2$ | 3.4 | 0.26 | 0.998 |
| $NiCl_2$ | 1.4 | 0.19 | 0.998 |
| $ZnCl_2$ | 6.4 | 0.28 | 0.999 |
| $CdCl_2$ | 12.3 | 0.30 | 0.999 |
| $FeCl_3$ | 10.5 | 0.43 | 0.999 |
| $MnCl_2$ | 0.8 | 0.14 | 0.995 |

$b$ is a constant given by the ration $b = Keq/a$; $N_f^S$ is a constant representing the maximum sorption capacity.

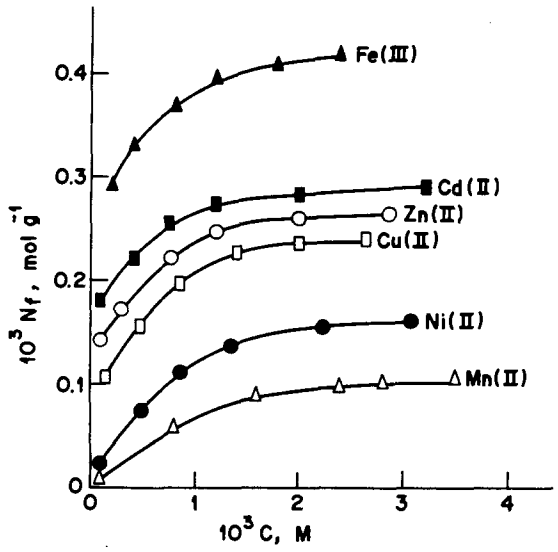

Fig. 1. Adsorption isotherms of metal ions from solution by SiL at 298 K. $N_f$ is the amount of metal ions adsorbed per gram of the solid phase, and $C$ is the residual concentration of metal ions in equilibrium with the solid phase.

capacity was not affected after several retention/elution cycles during 6 months of continuous use. The adsorbent material was resistant to the attack of concentrated acids, but not to the attack of concentrated aqueous alkali solution.

### 3.2. Adsorption isotherms

The results of the adsorption measurements of metal ions, as plots of $N_f$ against $C$, are shown in Fig. 1. Isotherms with similar shapes but different adsorption capacities were observed, Fe(III) being the most adsorbed and Mn(II) the least adsorbed.

The metal ions are adsorbed from solutions by the immobilized benzimidazole molecule, in a process of competition between solute and solvent. The isotherm obtained by these systems can be represented by the Langmuir adsorption model [8]:

$$\frac{C}{N_f} = \frac{1}{bN_f^S} + \frac{C}{N_f^S}$$

In this expression, $C$ is the residual concentration (M) of the metal ion in equilibrium with the solid phase, $N_f$ is the number of moles of the solute adsorbed per gram of solid, $N_f^S$ is a constant which represents the maximum sorption capacity (mol of solute per gram of adsorbent), and $b$ is a constant given by the ration $b = Keq/a$, where $a$ represents the activity of the solvent in solution. The value of $b$ and $N_f^S$ were obtained from the angular and linear coefficients by plotting $C/N_f$ against $C$, and the values are listed in Table 1. The correlation coefficients $r$ of the straight lines were always $>0.99$.

The maximum retention capacity of metal ions on the solid SiL showed the sequence Fe(III) > Cd(II) > Zn(II) > Cu(II) > Ni(II) > Mn(II).

The calculated values of the constant $b$ are very high in every case, suggesting that the sorption of the metal from solution by the solid phase occurs with the metal directly coordinating with the unsubstituted benzimidazole nitrogen.

### 3.3. Infrared spectra

Recently, we reported [8–10] that coordination of copper(II) ion benzimidazole nitrogen shifted the band at 1500 cm$^{-1}$ of SiL infrared spectrum to a higher frequency. This particular band is assigned to the skeleton vibrational mode of the ring which involves coupled vibration ($\nu$CN + $\nu$CC). This is an evidence that the copper(II) ion is coordinated to the benzimidazole free nitrogen and is not only physically sorbed onto the surface. The remaining spectra of the other metals adsorbed onto the modified surface, are very similar to that of SiL $CuX_2$, as shown in Table 2.

### 3.4. Preconcentration and elution of individual metal ions

In every run, the effluent was collected and a quantity of metal ions analyzed. The metals were eluted by passing 10 ml of 0.1 M HCl in ethanol/water through the column. The results are shown in Fig. 2.

It can be observed that, under the experimental conditions used, for Mn(II) and Ni(II) the extents of elution are independent of the ethanol/water ratio. Cu(II), Zn(II) and Cd(II) ions showed nearly similar behaviour and were completely eluted from the column with a mole fraction of water ($\chi_B$) of approximately 0.8, 0.85 and 0.9, respectively. However, the beginning of the elution was different for the three cases: elution of Cu(II) began at $\chi_B \approx 0.2$, Zn at $\chi_B \approx 0.35$ and Cd(II) at $\chi_B \approx 0.65$.

In contrast, Fe(III) was completely eluted at $\chi_B \approx 0.4$, but the elution decreased with an increase in the mole fraction of water in the

[a] Starred metal halides indicate adsorbed metal on the modified silica; v = very; m = medium; w = weak; br = broad.

mixture. Previously, it was reported that in a binary mixture of methanol and water the hydrolysis constant of Fe(III), expressed by $K = [Fe(OH)_2^+][H^+]/[Fe^{3+}]$, increases with the mole fraction of methanol in the mixture [15,16]. If such behaviour can be extended to Fe(III) in a mixture of ethanol and water, it seems likely that the less charged complex ion $Fe(OH)^{2+}$, which is present at higher concentrations for lower $\chi_B$, will be more easily eluted than the $Fe^{3+}$ ion itself. Ni(II) and Mn(II) were eluted from the column in a similar way, whether the silica was modified or not; also, they were not completely retained (Table 1). Presumably, nickel and manganese complexes with benzimidazole groups are very weak.

### 3.5. Adsorption and recovery of a mixture of ions

Adsorption and elution studies of a mixture of metal ions were carried out. In these studies, a series of solutions was prepared in which the metal ion concentrations were fixed at $0.1 \times 10^{-3}$ M, except for one of them which was fixed at $5.0 \times 10^{-3}$ or $0.5 \times 10^{-3}$ M. The results are presented in Table 3.

It can be observed that the recoveries of Mn(II) and Ni(II) were practically complete in the presence of other metal ions at concentrations 5 or 50 times higher. In view of this, the percentage of elution of Mn(II) and Ni(II) was higher than that found for the individual ion experiment. This fact is reasonable, taking into account that there was no loss of Mn(II) and Ni(II) when the mixture was passed through the column, since the concentrations of the metals were 25 times lower than that used for the individual ion experiments.

The recovery of Fe(III) was about the same as in the individual ion experiment, whereas for Cu(II), Zn(II) and Cd(II) the recoveries were lower. Generally, it can be considered that the presence of one of the ions in excess did not significantly affect the recoveries of the others.

### 3.6. Determination of metals in ethanol fuel

Quantitative sorption–desorption of the heavy metals studied serves as a basic for a rapid method for the preconcentration and subsequent determination by flame AAS of these metals in commercial ethanol from five different plants.

In general, Cd(II) does not occur in commercial ethanol, or its content is lower than the contents of the other metals by a factor of 10–100. The content of Fe(III) depends on the degree of corrosion of the distillation equipment [14]. The concentration of Ni(II) normally found in the commercial ethanol is below $50\ \mu g\ l^{-1}$ and Zn(II) is not detected when the conventional preconcentration method is used, in which the first step has been to evaporate the ethanol solution to dryness [14].

Therefore, the contents of the metals studied were determined in commercial ethanol from five different plants using the recommended method by passing, depending on the origin, between 0.2 and $6.5\ l^{-1}$ of the sample through the column. Complete elution of the metals adsorbed was carried out using about 40 ml of an ethanol/water mixture with a mole fraction of water of 0.80. All the experiments were done in triplicate.

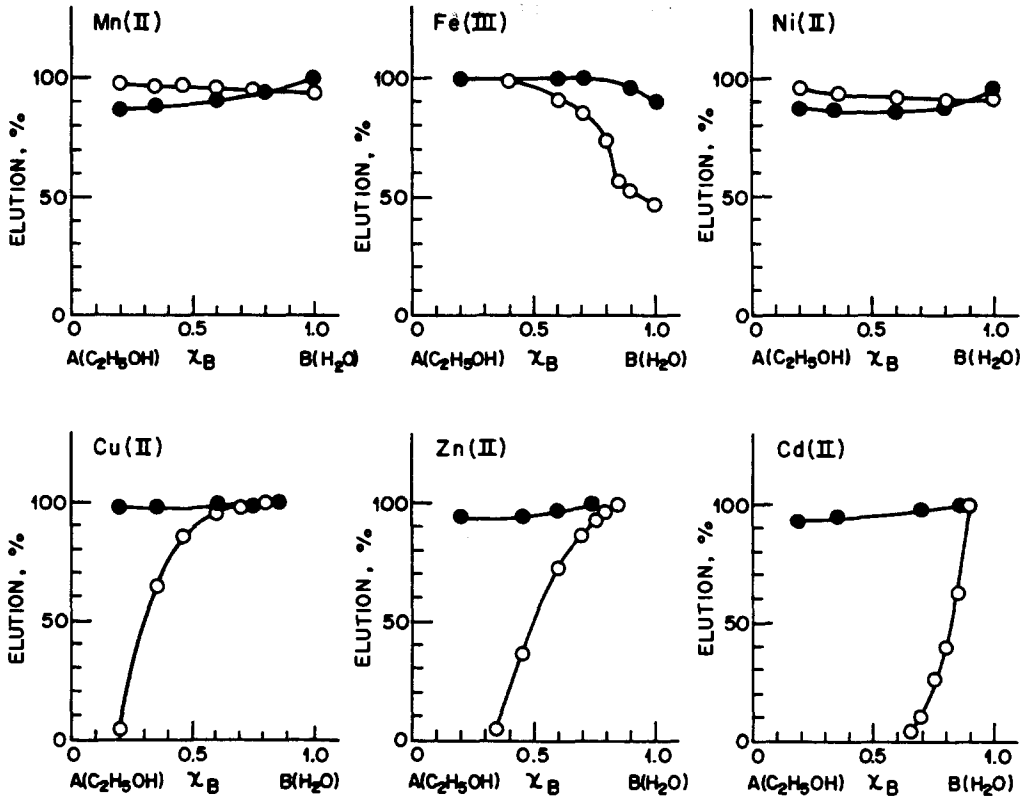

Fig. 2. Elution of the metal ions from different column packings: (○) modified silica; (●) untreated silica.

Table 3
Recovery of metal ions from a mixture

| Ion | Concentration ($10^{-3}$ M) | Recovery (%) [a] | | | | | |
|---|---|---|---|---|---|---|---|
| | | Mn(II) | Fe(III) | Ni(II) | Cu(II) | Zn(II) | Cd(II) |
| Mn(II) | 5.0 | – | 76 | 100 | 79 | 30 | 22 |
| | 0.5 | – | 77 | 100 | 86 | 26 | 26 |
| Fe(III) | 5.0 | 97 | – | 97 | 78 | 32 | 24 |
| | 0.5 | 98 | – | 100 | 71 | 25 | 33 |
| Ni(II) | 5.0 | 100 | 77 | – | 85 | 28 | 19 |
| | 0.5 | 100 | 78 | – | 77 | 25 | 23 |
| Cu(II) | 5.0 | 100 | 76 | 100 | – | 29 | 13 |
| | 0.5 | 100 | 76 | 100 | – | 23 | 19 |
| Zn(II) | 5.0 | 100 | 81 | 100 | 76 | – | 26 |
| | 0.5 | 100 | 84 | 100 | 84 | – | 25 |
| Cd(II) | 5.0 | 98 | 75 | 97 | 86 | 28 | – |
| | 0.5 | 100 | 76 | 98 | 78 | 27 | – |

[a] Concentration of each ion was $0.1 \times 10^{-3}$ M.

The results are shown in Table 4. Cd(II) was not detected in any sample. The accuracy of this method was tested and the results obtained using the recommended method are in good agreement with those obtained by direct determination, without any preconcentration.

# Third order derivative spectrophotometric determination of ascorbic acid in fruits and vegetables

Mahmure Üstün Özgür *, Sıdıka Sungur

*Yıldız Technical University, Department of Chemistry, Şişli, 80270, Istanbul, Turkey*

Received 2 November 1993; revised 21 September 1994; accepted 11 April 1995

**Abstract**

Ascorbic acid (AA) has been determined in kiwi, parsley and grapefruit by third order derivative spectrophotometry without using any separation or background correction techniques and reagents. The method is based on the measurement of the distances between two extremum values (peak-to-peak amplitudes) in the third order derivative spectra of the extracts. A metaphosphoric acid (3% w/v)–acetic acid (8% v/v) mixture was found to be the most suitable extraction solution. In the third order derivative spectrum, the extrema of 259.4 nm and 276.2 nm were used for the quantitative determination of AA in kiwi, and the extrema of 227 nm and 237 nm were used for the quantitative determination of AA in parsley and grapefruit. Calibration curves were constructed for the 2.0–10.0 μg $ml^{-1}$ concentration range. Relative standard deviations were calculated from the assay results of 14 samples. They were found to be in the ranges of 0.53–2.45% and 0.50–1.41% for the proposed method and the Association of Official Analytical Chemists (AOAC) method, respectively.

The obtained results were statistically compared with those of the official method of AOAC using the *F* test. There was no significant difference between the precisions at a 95% confidence level.

*Keywords:* Ascorbic acid; Fruits; Derivative spectrophotometry

## 1. Introduction

Ascorbic acid (AA) is widely distributed in plant materials, with fruits and vegetables being the major source in most human diets.

The concentration of AA in vegetables and fruits is a maturity index, and the determination of this constituent in such samples is of special interest in quality control.

The need for a fast and selective method is obvious, especially when routine determinations are required. Many analytical methods have been developed for the determination of AA and the quality control of products containing AA. These include titrimetric [1–3], spectrophotometric [4–7], fluorimetric [8], chromatographic [9–11], polarographic [12–14], amperometric [15,16], coulometric [17,18] and enzymatic methods [19–21], as well as combinations of various other techniques [22,23].

The titrimetric AOAC method [24] with 2,6-dichlorophenolidophenol as the titrant is used in many of the determinations. Although this method is rapid, the reagent itself is unstable and must be standardized before use. Moreover, the technique is unsuitable for coloured samples which interfere with the detection of the end point. Titrimetric methods suffer the disadvantage of using a large amount of sample and undergoing interference from many redox reagents with the determination. The fluorimetric method is too time consuming. For the chromatographic methods, the use of expensive equipment and the demand for more operator attention prevent their application in

small industrial laboratories where only a few analyses are performed each day. The polarographic method requires long analysis time and suffers interferences from electrochemical impurities present in the food sample, whereas the enzymatic technique is generally considered to be too specialized for ordinary chemical laboratory use.

Spectrophotometry is a fast and simple method for AA determination, but it cannot be used in samples with complex matrices because of background absorption in the UV region. Various background correction techniques have been proposed such as thermal decomposition, direct ultraviolet irradiation, alkaline treatment and an enzymatic method [25,26]. Some visible spectrophotometric methods often require tedious pre-separation techniques to remove possible interferences from coloured materials.

Derivative spectrophotometry is a useful technique for extracting qualitative and quantitative information from spectra composed of unresolved bands [27], and for eliminating the effect of baseline shifts and baseline tilts [28]. Derivative spectrophotometry is now a reasonably priced standard feature of modern microcomputerized UV/vis spectrophotometry.

The purpose of this work is to develop a direct and simple UV-spectrophotometric method for the determination of AA in fruits and vegetables without pre-seperation or background correction procedures.

Among fruits and vegetables, kiwi, parsley and grapefruit were chosen owing to their high AA content. Several kiwi, parsley and grapefruit samples were analyzed for their AA content and the results were compared with those obtained by AOAC [24].

## 2. Experimental

### 2.1. Apparatus

A Philips PU 8700 UV/vis spectrophotometer was used with a cell having a path length of 1 cm and a volume of 3 ml. For the spectrophotometric measurements, suitable settings were chosen: 2 nm slit width, 250 nm $min^{-1}$ scan speed for kiwi samples; 2 nm slit width, 125 nm $min^{-1}$ scan speed for parsley and grapefruit samples; very high smoothing for derivative spectra.

### 2.2. Reagents

All reagents used were of analytical reagent grade. Bidistilled water was used throughout the work.

The extraction solution was 3% (w/v) metaphosphoric acid–8% (v/v) acetic acid. This reagent can be kept for three days in a refrigerator.

The ascorbic acid stock solution (100 μg $ml^{-1}$) was prepared by dissolving 10 mg of AA in 100 ml extraction solution. This solution was freshly prepared and was diluted to obtain standard solutions for the preparation of calibration curves.

### 2.3. Analytical procedures

*Preparation of sample solutions*

Samples were purchased from the local markets for analysis. The edible portions of each sample were analyzed using two methods on the same day of purchase.

In the case of grapefruit, the juice was easily obtained from the fruit with a glass press. A 25 ml aliquot of the juice was homogenized with 75 ml of extraction solution using a mechanical stirrer for about 5 min.

The parsley and kiwi samples (5–10 g) were chopped and then homogenized with 100 ml extraction solution using a mechanical stirrer (with a glass rood) for about 45 min.

After homogenization of the samples, the extracts were clarified by centrifuging at 2000 rpm for 5 min and then filtering through a filter paper (Whatman 541) using a vacuum pump.

The filtrates were then diluted to provide the necessary working concentration (2.0–10.0 μg $ml^{-1}$).

### 2.4. Determination

*Calibration graph*

The third order derivative absorption spectra of AA standard solutions (2.0–10.0 μg $ml^{-1}$) were recorded against extraction solution between 190–300 nm.

In these spectra, the peak-to-peak amplitudes of 227 nm and 237 nm were used for the establishment of the calibration graphs for parsley and grapefruit samples.

For kiwi samples, 259.4 nm and 276.2 nm extrema were used for the same purpose. A regression equation of the calibration graph was calculated by the method of least squares.

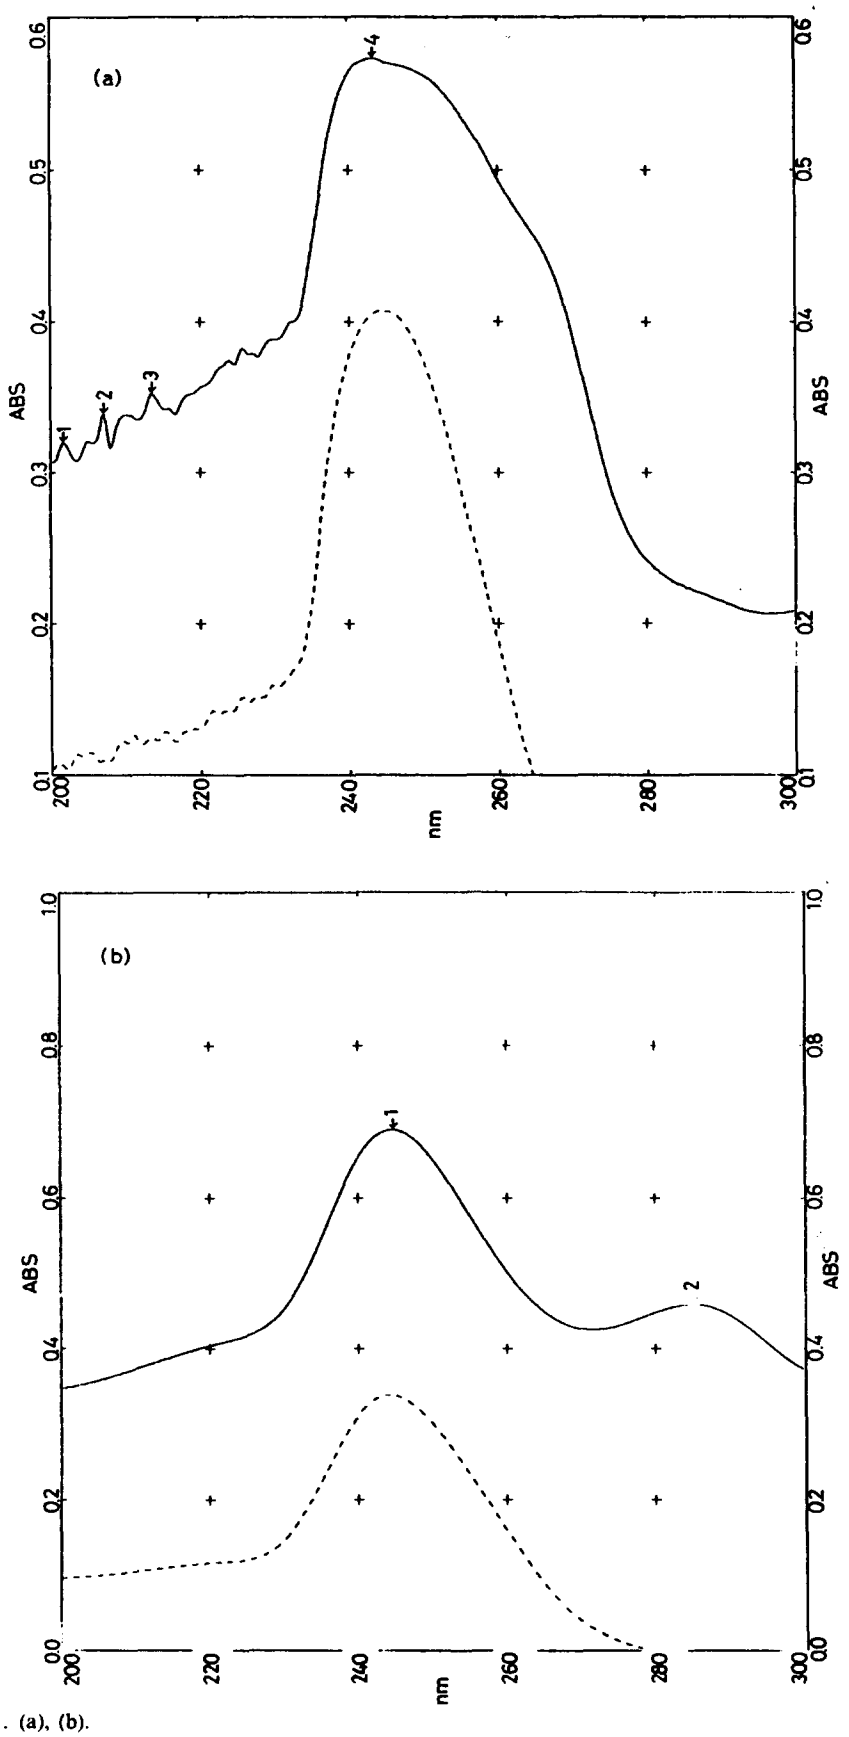

Fig. 1. (a), (b).

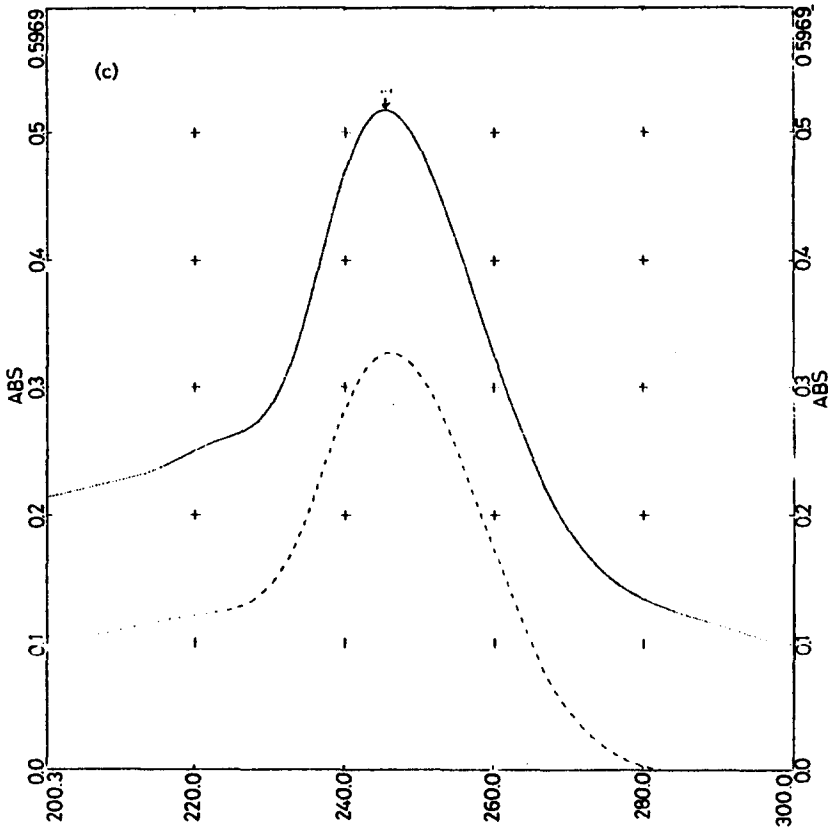

Fig. 1. Absorption spectra of (a) parsley (——); (b) grapefruit (——); (c) kiwi (——); and ascorbic acid (– – –) solutions. Concentration: 6 μg ml$^{-1}$ in extraction solution. Reference: extraction solution.

*Sample analysis*

Third order derivative spectra of sample solutions were recorded against the extraction solution. Peak-to-peak amplitudes of 227–237 nm (for parsley and grapefruit samples) or 259.4–276.4 nm (for kiwi samples) were obtained from these spectra.

The concentration of AA in the sample solutions was deduced by means of the regression equation of the related calibration graph.

## 3. Results and discussion

A UV-spectrophotometric method cannot be used directly for the determination of ascorbic acid in fruits and vegetables owing to the matrix effect of UV-absorbing substances in the sample matrix. This effect is clearly seen in Fig. 1, which shows the absorption spectra of kiwi, parsley and grapefruit extracts, together with the spectra of standard ascorbic acid solutions prepared in the same solvent medium having the same concentration as the sample extract. To overcome this difficulty, some tedious background correction techniques have been used [25,26]. In contrast, the derivatization of the absorption spectrum and measurement of the distance between two neighbouring extremum values allow the elimination of matrix effects, because the variable background absorptions overlapping the analyte peaks are smoother in derivative spectra. Figs. 2, 3 and 4 show first, second and third order derivatives, respectively, of the absorption spectra given in Fig. 1. As seen, the third order spectra of sample and standard solutions completely overlap each other in the regions of 259.4–276.2 nm for kiwi, and 227–237 nm for parsley and grapefruit. This means that matrix effects are eliminated by derivatization of the absorption spectra. The extraction solution of these samples is the mixture metaphosphoric acid (3%)–acetic acid (8%). It was found to be the most suitable extraction medium among the various mixtures tested for the extraction such as oxalic acid (5%), trichloroacetic acid (5%), metaphosphoric acid (6%), acetic acid (8%), citric acid (5%) and metaphosphoric acid–acetic acid (3%–8% and 1.5%–4%).

Fig. 2. (a), (b).

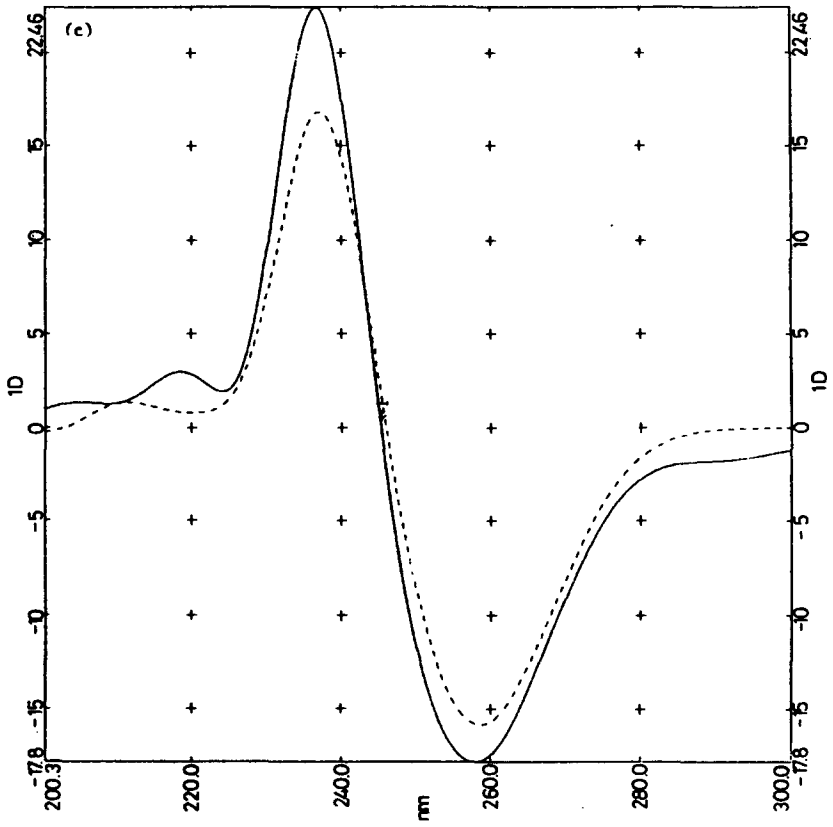

Fig. 2. First order derivative spectra of (a) parsley (——); (b) grapefruit (——); (c) kiwi (——); and ascorbic acid (– – –) solutions. Concentration: 6 μg ml$^{-1}$ in extraction solution. Reference: extraction solution.

Linear relationships were obtained between the AA concentration (2.0–10.0 μg ml$^{-1}$) and peak-to-peak amplitudes ($^3D$) of third order spectra at the wavelengths stated above. The regression equations were as follows:

$$^3D_{259.4-276.2} = 0.0367C + 0.0046$$

(kiwi) ($r = 0.9998$)

$$^2D_{227-237} = 0.1871C - 0.0132$$

(parsley and grapefruit) ($r = 0.9994$)

The contents of AA in five parsleys, five kiwis and four grapefruits were determined by the proposed method. With the purpose of comparison of the results obtained by derivative spectrophotometry, the same extracts were analyzed for AA by the official method recommended in AOAC. The results obtained by the two methods were statistically compared. This statistical comparison is depicted in Table 1. The results obtained by the developed method and by the official method were compared at the 95% confidence level with the aid of an $F$ test for precision.

As can be seen from Table 1, the calculated $F$ values were less than the corresponding ones obtained from the standard table for the selected confidence level and population number.

As a conclusion, the derivative spectrophotometric method is relatively easy, fast and cheap for determination of the ascorbic acid content of kiwi, parsley and grapefruit. Because it does not require expensive solvents and reagents, it may be recommended for the rapid precise and sensitive quantification of ascorbic acid in these products. The major instrument required is a modern, microcomputerized UV/vis spectrophotometer, which can be purchased at a reasonable price. This method also takes less time than the others, and the absorption values of the solutions used are stable for at least 2 h. The method can be extended to ascorbic acid determination in various fruits and vegetables provided that the proper wavelengths for peak-to-peak measurements are accurately selected.

Received 13 May 1994; revised 13 March 1995; accepted 19 April 1995

**Abstract**

Two simple, inexpensive and rapid iodometric and spectrophotometric procedures were developed for trace amount determination of ruthenium. The proposed methods were based on the oxidation of ruthenium(II or III) with sodium periodate at pH 2.4–3.6, masking the excess periodate with sodium molybdate. The released iodate was then allowed to react with KI at pH 3, with subsequent determination of the released iodine spectrophotometry as triiodide at 350 nm or iodometry with 0.005 M sodium thiosulphate. This procedure offers an 18- and 15-fold amplification per Ru(II) or Ru(III) ion, respectively. Alternatively, the produced iodine was extracted with $CHCl_3$, shaken with an aqueous solution of sodium sulphite and the produced iodide ion was then allowed to react with bromine (or sodium periodate). The released iodate was subsequently determined by iodometry or spectrophotometry after addition of KI. The bromine and sodium periodate oxidation procedures offered 90- and 360-fold amplification per ruthenium(III) ion, and 108- and 432-fold amplification per ruthenium(II) ion. Ruthenium(IV) content was determined by these procedures after prior reduction to Ru(III) with sulphurous acid. The binary mixtures Ru(II)–Ru(III); Ru(III)–Ru(IV) and Ru(II)–Ru(IV) in aqueous solution at concentration 0.05 $\mu g\ ml^{-1}$ were successfully analyzed by the developed procedures. The utility of the proposed methods for the analysis of ruthenium in its complexes was demonstrated. Natural seawater and seawater spiked with ruthenium were analyzed satisfactorily.

*Keywords:* Ruthenium; Iodometry; Spectrophotometry; Trace analysis; Natural water

## 1. Introduction

Compared to most other elements, ruthenium has a limited influence on the biosphere because only small quantities ever reach living organisms [1]. The amount of ruthenium readily introduced into rivers, lakes and oceans through industrial wastes is minute [1]. Thus, sensitive, reliable and practicable methods are required for the quantitation of ruthenium at trace levels. The most common reported spectrophotometric procedures for ruthenium determination require laborious enrichment steps [2–6], e.g. flotation, precipitation and solvent extraction. However, most of these methods suffer from lack of selectivity and sensitivity [3–5].

Recently, several polarographic and voltammetric methods have been developed for the determination of ruthenium [7–10]. These methods were based on adsorptive collection of ruthenium(III) chelates on HMDE, but neither their sensitivity nor selectivity are very satisfactory and they are not practicable in routine analysis of ruthenium.

Recently, the application of the so-called Leipert amplification reaction [11] was reported, in which potassium periodate solution in aqueous acidic media was used for the oxidation of various metal ions [12–15] and the produced iodate was subsequently determined by iodometry. The present paper describes two simple and accurate amplification procedures for the measurement of trace levels of ruthenium in aqueous solution.

## 2. Experimental

### 2.1. Reagents and materials

Unless otherwise specified, all reagents were of analytical reagent grade. All solutions were prepared from doubly-distilled water. Stock solutions (1 mg $ml^{-1}$) of ruthenium(III) (atomic absorption standard, BDH) and 100 mg $ml^{-1}$ of Ru(V) were prepared from ruthenium dioxide [16] and diluted with water for standard addition whenever required. Ruthenium(II) solution (100 μg $ml^{-1}$) was prepared by the reduction of a measured solution of $RuCl_3 \cdot 6H_2O$ (Johnson Mathey, London) in HCl–$H_2O$ (1:20, v/v) as previously reported [17]. Buffer solutions of pH 2.4–4.6 were prepared by mixing about 200 ml of glacial acetic acid with approximately 200 ml of water and the pH adjusted with a saturated solution of sodium acetate. Sodium thiosulphate (0.005–0.01 M) was prepared and standardized against $KIO_3$ (0.01 M) of the same normality. Sodium periodate (0.35% w/v), sodium molybdate (10% w/v) and sodium sulphite (5% w/v) solutions were prepared in doubly-distilled water.

### 2.2. Apparatus

A Pye-Unicam double beam UV/visible spectrometer model Sp-8-400 with 10 mm quartz cells was used for the absorbance measurements. A Philips digital pH-meter (model 9418) with glass and saturated calomel electrodes, and a 250 ml oxygen-flask with fused silica sample holder were used.

### 2.3. Recommended procedure

*I. Determination of ruthenium(II) or (III)*

To a 100 ml conical flask (or 100 ml separating funnel) was transferred 1–5 ml of sample solution containing 5–200 mg of Ru(II) or Ru(III) solution and 10 ml of water. The pH (2.4–3.6) of the solution was adjusted with 10 ml acetate buffer, 5 ml of sodium periodate added and the reaction mixture left for 5 min. $Na_2MoO_4$ (5 ml) was added to mask the unreacted periodate and the solution shaken twice with 10 ml (2 × 5) of $CCl_4$. The aqueous layer was separated and then treated by one of the following procedures.

*(a) 18- or 15-fold amplification.* To the aqueous solution of the produced iodate was added a few crystals of KI at pH ≈ 3, and the released iodine was determined by spectrophotometry as triiodide at 350 nm or by iodometry with 0.005 M $Na_2S_2O_3$. These procedures offer 18- and 15-fold amplification of Ru(II) and Ru(III), respectively. A blank was run for correction.

*(b) 108- or 90-fold amplification.* The aqueous solution of the released iodate was allowed to react with KI (50–70 mg) at pH 3 and the released iodine twice extracted with 10 ml (2 × 5) of $CHCl_3$ in a separating funnel. The chloroform solution was shaken with 25 ml of water containing 2 ml of sodium sulphite to reduce the iodine to iodide. The aqueous (upper) layer was transferred to a 100 ml Erlenmeyer flask, 5 ml of bromine added, and the solution left for 3–5 min. The excess bromine was removed by boiling off the solution or by drop-wise addition of formic acid. Five millilitres of 2N $H_2SO_4$, and three to four crystals of KI were added and the released iodine determined by spectrophotometry or iodometry, as described earlier. A blank was run to correct the reagent error. This procedure offers 108- and 90-fold amplification of Ru(II) and Ru(III), respectively.

*(c) 432- or 360-fold amplification.* To the aqueous solution of the produced iodide was added 5 ml of $NaIO_4$, the flask stoppered, and the reaction mixture allowed to stand for 5 min at room temperature. The flask was placed in a boiling water bath for about 15 min, allowed to cool and then 10 ml of acetate buffer, 5 ml of $Na_2MoO_4$, three to four crystals of KI (≈0.1 g) were added and the released iodine determined by spectrophotometry or by iodometry; a blank was run for correction.

*II. Determination of ruthenium(IV)*

Aliquot portions (1–100 μg) of the ruthenium(IV) element were transferred to a 100 ml conical flask. Five millilitres of $Na_2SO_3$ and 5 ml of HCl (20% w/v) were added and the reaction mixture left to stand for 5 min.

The solution was evaporated gently on a hot plate until the excess $SO_2$ was completely removed, and then 20 ml of $H_2O$ and 0.5 g of $Na_2CO_3$ were added to neutralize the unreacted acid; the produced ruthenium(III) was determined using the recommended procedure I. A blank was run for correction. Quantitative reduction of Ru(IV) to Ru(III) was confirmed by determining the content of the ruthenium(III) produced colorimetrically [18].

*III. Analysis of the binary mixtures ruthenium(II) and (III)*

Aliquots of the mixture were transferred into a 100 ml flask and the recommended procedure I-a followed. Another aliquot of sample mixture was reduced to the divalent ruthenium as previously reported [17] and procedure I-a followed. On the basis of the proposed procedure, if the volume of the sodium thiosulphate consumed in the first solution is $V_1$ ml and for the second solution is $V_2$ ml, the concentration of Ru(II) and Ru(III) can be obtained.

*IV. Analysis of binary mixture ruthenium(III) and (IV)*

Aliquots containing various amounts of ruthenium(III) and (IV) were transferred into a 100 ml conical flask and the described procedure I-a followed. Another aliquot sample was then reduced to the trivalent ruthenium as described in procedure II and the solution determined according to procedure I-a. According to the proposed procedure, if the volume of thiosulphate solution consumed for the first aliquot mixture is $V_1$ ml and that used for titration of the second aliquot mixture is $V_2$ ml, the concentration of Ru(III) and Ru(IV) can be obtained.

*V. Analysis of ruthenium(II) or (III) in their complexes*

The ruthenium complexes used in this work were prepared by the previously reported [19,20] procedures. Exactly 2–3 mg of the organoruthenium complexes was weighted and wrapped as usual by the Schoniger technique [21] in a 250 ml oxygen-flask filled with a fused silica spiral. Ten millilitres of aquaregia was placed in a 250 ml oxygen-flask, the flask filled with oxygen and the sample combusted. When the combustion was complete, the flask was shaken for 2–3 min, opened and the stopper and the sample holder rinsed down with 5 ml of $HNO_3$ (5% v/v). The solution was heated to dryness and 10 ml of $H_2O$, 2 ml of conc. HCl and 10 ml of $Na_2SO_3$ added. The solution was left for 2 min at room temperature. It was then boiled to remove $SO_2$, and reduced with hydroxylamine as previously reported [17], finally the recommended procedure I-a was followed for ruthenium(II) determination. A blank was run for corrections.

## 3. Results and discussion

Amplification reactions proved to be very efficient for the determination of analytes at low levels [12–15]. Thus iodometric amplification procedures with their simplicity and sensitivity are still of special attraction. This motivated us to search for new procedures for the determination and speciation of microamounts of various ruthenium species with the use of iodine–starch end point or spectrophotometry of the released iodine as triiodide at 350 nm.

Amplification procedures based on oxidation with sodium periodate are extendable to any species possessing two oxidation states with sufficiently low standard redox potential. Thus, the proposed procedures for ruthenium(II), (III) or (IV) determination were principally based on oxidation of these ions in acid media to octavalent ruthenium with sodium periodate according to the following equations:

$$Ru^{2+} + 3IO_4^- + 6H^+ \rightarrow Ru^{8+} + 3IO_3^- + 3H_2O \quad (1)$$

$$Ru^{3+} + \tfrac{5}{2}IO_4^- + 5H^+ \rightarrow Ru^{8+} + \tfrac{5}{2}IO_3^- + \tfrac{5}{2}H_2O \quad (2)$$

$$Ru^{4+} + 2IO_4^- + 4H^+ \rightarrow Ru^{8+} + 2IO_3^- + 2H_2O \quad (3)$$

The released iodate and ruthenium(VIII) can oxidize potassium iodide according to the equations

$$IO_3^- + 5H^- + 6H^+ \rightarrow 3I_2 + 3H_2O \quad (4)$$

$$RuO_4 + 5I^- + 8H^+ \rightarrow Ru^{3+} + \tfrac{5}{2}I_2 + 4H_2O \quad (5)$$

[b] Error % = [(metal taken-metal found) × 100]/(metal taken).

Reactions (1)–(4) proceeded rapidly and quantitatively in acidic media (pH < 4) as can be predicted from the redox potential concerned [15]. Moreover, reaction (5) took place and proceeded forwards in acidic medium, i.e. ruthenium(VIII) liberated iodine from KI. This statement is criticized in this work, where preliminary experiments showed that the Ru(VIII)–I reaction was a function of the solution pH and the reaction was quite negligible in the solution of pH > 2.4, while in 2N $H_2SO_4$ it took place faster and proceeded quantitatively.

Further preliminary experiments showed that the oxidation of ruthenium(II), (III) or (IV) with sodium periodate was pH and reaction time dependent. Therefore, the effects of these factors were studied for a fixed concentration (60 mg) of each of these ions in the pH range 2.4–6. The solutions were then allowed to react with $NaIO_4$ for different time intervals (2–30 min). The pH of the solutions was adjusted to pH ≈ 3 using acetate buffer and the excess unreacted $NaIO_4$ was masked with sodium molybdate at the same pH. The released iodate and ruthenium(VIII) were then allowed to react with KI and the liberated iodine was determined by iodometry (with 0.005 M $Na_2S_2O_3$) and by spectrophotometry of the triiodide species formed at 350 nm against a reagent blank. The results indicated that the optimum pH of the complete oxidation of the ruthenium species was in the range 2.5–4 after 5 min. Under these conditions, each original ruthenium(II), (III) and (IV) released 18, 15 and 12 equivalent iodines, i.e. the proposed method afforded 18-, 15 and 12-fold amplification per ruthenium(II), (III) and (IV) ion, respectively. At pH < 2, reactions from (5)–(9) proceeded rapidly with 23-, 20- and 17-fold amplification of Ru(II), (III) and (IV) respectively, but under these conditions sodium molybdate did not mask the unreacted periodate quantitatively since the molybdate–periodate complex was partially decomposed [22] and also aerial oxidation of iodide could occur. Thus, the percentage recovery of the tested ruthenium ion and blank values were erroneously high owing to reaction of the released periodate with iodide. At pH > 5, reactions (5)–(7) proceeded slowly to form perruthenate ($RuO_4^-$) ions [2] of lower amplification, and the iodide–iodate reaction was slow under these conditions. Fortunately, the pH values suitable for the quantitative oxidation of ruthenium(II), (III) or (IV) ions were quite appropriate for masking the excess unreacted periodate with molybdate. The developed method was employed for the determination of various amounts (5–200 mg) of ruthenium(II) or (III) by iodometry and spectrophotometry. The results are summarized in Table 1. Satisfactory results with standard deviations ($n = 5$) in the range 0.2–0.5 and 0.2–0.3 were obtained employing the iodometry and spectrophotometry procedures for Ru(II) or (III) respectively. It is worth mentioning that before addition of KI it was advisable to shake the solution with 10 ml $CCl_4$ (2 × 5) to remove the produced $RuO_4$ and to prevent any possibility of reaction between $RuO_4$ and KI at the optimum pH.

Moreover, the sensitivity of the proposed method for ruthenium(IV) determination can be increased by prior reduction to Ru(III) using sodium sulphite, hydroxylamine or zinc/HCl followed by determination according to procedure I. Sodium sulphite in acidic media

[a] Average ± standard deviation ($n = 5$).

was found to be the most suitable reagent, where the unreacted sulphite ion could be easily removed by boiling off the formed sulphur dioxide. The determination of various amounts (10–100 μg) of ruthenium(IV) in aqueous media by the proposed method is given in Table 2. Satisfactory results were obtained by iodometry and spectrophotometry with relative standard deviations in the range 0.5–2.9 and 0.2–1.9%, respectively.

The proposed method was also employed for the anlysis of the binary mixture Ru(II) and (III) in aqueous media. An aliquot mixture was first allowed to react with sodium periodate employing procedure I-a. Another aliquot mixture was then reduced to ruthenium(II) as previously reported [16], followed by determination of the total Ru(II) by the proposed procedure I-a. On this basis, if $V_1$ and $V_2$ ml were the volumes of the sodium thiosulphate equivalent to the aliquot mixture in the first and second steps, respectively, then we obtain

$$C_1(\mu g) = (6V_1 - 5V_2)M(\text{A.W.})10^3/18 \quad (6)$$

$$C_2(\mu g) = (V_2 - V_1)M(\text{A.W.})10^3/3 \quad (7)$$

where $C_1$ and $C_2$ are the concentrations of Ru(II) and Ru(III), in μg, respectively, A.W. is the atomic weight of ruthenium and $M$ is the molarity of sodium thiosulphate. Satisfactory results were obtained (Table 3) employing iodometric procedures with 18- and 15-fold amplifications. The absolute standard deviation was found in the range 0.3–0.4.

Moreover, the analysis of the binary mixture Ru(II) and (IV) was also employed by the proposed 15- and 12-fold amplification procedure. An aliquot mixture was first reacted with sodium periodate employing procedure I-a. Another aliquot mixture was then reduced with sulphite ions in acidic media to reduce ruthenium(IV) to Ru(III) as described in procedure II, followed by determination of the total Ru(III) by the described procedure I-a. According to these procedures, if $V_1$ and $V_2$ ml were the volumes of the sodium thiosulphate consumed for the first and second aliquot, then we obtain

$$C_1(\mu g) = (5V_1 - 4V_2)M(\text{A.W.})10^3/15 \quad (8)$$

$$C_2(\mu g) = (V_2 - V_1)M(\text{A.W.})10^3/3 \quad (9)$$

where $C_1$ and $C_2$ are the concentration of Ru(II) and Ru(IV), in μg, respectively. The results obtained are summarized in Table 4, with a relative absolute error in the range 0.5–3.4%. In separate experiments, aliquot samples containing various amounts of Ru(III) and (IV) in a concentration range of 0.05–1 μg ml$^{-1}$ ($n = 5$) were analyzed by the developed spectrophotometric procedure. Satisfactory results were obtained with 99 ± 2% recovery and absolute standard deviations in the range 0.12–0.28.

The proposed iodometric procedure for the analysis of various amounts of the binary mixture Ru(II) and Ru(IV) was also carried out. An aliquot mixture was first allowed to react with $NaIO_4$ employing procedure I-a. Another aliquot mixture was reduced with sulphite ions in acidic media from Ru(IV) to Ru(III) and the reaction mixture was then allowed to react with sodium periodate as described in procedure II. On this basis, if $V_1$ and $V_2$ ml were the volumes of the sodium thiosulphate consumed in the first and second aliquot mixture, then we obtain

$$C_1(\mu g) = \frac{(5V_1 - 4V_2)M(\text{A.W.})10^3}{18} \quad (10)$$

$$C_2(\mu g) = \frac{(V_2 - V_1)M(\text{A.W.})10^3}{3} \quad (11)$$

where $C_1$ and $C_2$ are the concentrations of Ru(II) and Ru(IV), in μg, respectively in the binary mixture. Satisfactory results were obtained with good accuracy and reproducibility in the concentration range 5–100 μg of Ru(II) or Ru(IV) ions.

Moreover, the proposed 18-, 15- and 12-fold amplification procedures of Ru(II), Ru(III) and Ru(IV), respectively could be increased by employing further oxidation by bromine water and sodium periodate [23]. The released iodine from Eqs. (1)–(3) after addition of potassium iodide was quantitatively extracted twice with 10 ml portions (2 × 5) of $CHCl_3$ or $CCl_4$ and shaken with sodium sulphite solution to reduce the iodine to iodide. The released iodide in the aqueous (upper) layer was then allowed to react with bromine as well as with sodium periodate to produce iodate ions. The produced iodate was quantitatively determined iodometrically or spectrophotometrically after adjusting the pH and addition of KI as described earlier. The overall fold amplifications of ruthenium(II) determination were 108- and 432-fold employing oxidation of the produced iodide by bromine and sodium periodate, respectively. Similarly, the overall amplifications of ruthenium(III) determination involving oxidation of the produced 15 $I^-$ by bromine and sodium periodate were 90- and 360-fold, respectively. The two proposed amplification procedures, 90- and 360-fold have been employed iodometrically for the analysis of various amounts (2–50 μg) of ruthenium(III). The results obtained are summarized in Table 5 with an average absolute error of 0.2–2.5%. The blank values taken through the whole procedure using freshly prepared periodate, doubly-distilled water and molybdate solutions ranged between 0.10 and 0.15 ml of 0.005 M $Na_2S_2O_3$. The sensitivity of the proposed procedures could be improved by the addition of traces of ascorbic acid after addition of iodide to prevent the oxidation of iodide by atmospheric oxygen [24].

In addition, the spectrophotometric procedure employing 90-fold amplification of ruthenium(III) determination was carried out. The absorbance–concentration relationship was found to be linear in the concentration range from 0.1 to 5 mg $l^{-1}$ of ruthenium(III). A linear calibration curve was also obtained in the concentration range 0.05–5 mg $l^{-1}$ at 360-fold amplification and $\lambda = 350$ nm for ruthenium(III) determination. Moreover, the sensitivity of these amplification procedures could be extended to lower concentrations (<0.1 mg $l^{-1}$) of ruthenium(III), by extraction of the released iodine in $CHCl_3$–$C_2H_5OH$–KI and measuring the absorbance of the triiodide at 360 nm [24]. The standard deviation ($n = 3$) for a solution of 5 mg $l^{-1}$ Ru(III) was 0.4 and 0.22 at 90- and 360-fold amplification, respectively. The detection limit (3× noise) was 0.03 mg $l^{-1}$. It is worth mentioning that, for a reasonably large amount of ruthenium(II) or (III) (>50 mg) present, it is advisable to dilute the solution of the released iodate from oxidation of iodide ions by bromine or sodium periodate and follow the previously recommended procedure.

### 3.1. Interference studies

The interference of various cations, e.g. $Cd^{2+}$, $Ni^{2+}$, $Sn^{2+}$, $Pd^{2+}$, Ir(III), Os(III), $Au^+$, $Ca^{2+}$, $Mg^{2+}$, $Al^{3+}$, $UO_2^{2+}$, $Pt^{2+}$, $Pt^{4+}$, $Zn^{2+}$, and $Li^+$, at 0.5 mg and pH 3 on the selectivity of the proposed method were examined by the determination of a fixed concentration (30 mg) of ruthenium(II) or (III) in aqueous solution. The percentage recovery of ruthenium(II) or (III) was found to be 100 ± 2.4%. The toler-

Table 4
Simultaneous determination of various amounts of ruthenium(III) and (IV) in their binary mixtures by iodometry employing the 15- and 12-fold amplification procedure [a]

| Metal ion taken (μg) | | Metal ion found (μg) | |
|---|---|---|---|
| $Ru^{3+}$ | $Ru^{4+}$ | $Ru^{3+}$ | $Ru^{4+}$ |
| 20 | 50 | 20.1 ± 0.3 | 51.1 ± 0.2 |
| 40 | 50 | 40.3 ± 0.4 | 51.2 ± 0.3 |
| 100 | 50 | 101.3 ± 0.2 | 51.2 ± 0.2 |
| 150 | 100 | 153.3 ± 0.5 | 101.6 ± 0.5 |
| 200 | 100 | 202 ± 0.3 | 103.4 ± 0.3 |

[a] Average ± standard deviation ($n = 4$).

ance limits of various anions at 30 μg ruthenium(II) or (III) in the presence of a relatively high excess (1 mg) of the anions $AsO_2^-$, $AsO_3^-$, $SbO_2^-$, $SbO_3^-$, $SeO_3^{2-}$, $SeO_4^{2-}$, $TeO_4^{2-}$, $NO_3^-$, $SO_4^{2-}$, $PO_4^{3-}$, $HPO_4^{2-}$, $Cl^-$, $Br^-$, $SCN^-$, formate, $WO_4^{2-}$ and $SiO_3^{2-}$ have been critically investigated. The percentage recovery of ruthenium(III) was 100 ± 2.6% and the standard deviation was found in the range 0.2–0.7. In the presence of some other ions which are commonly found associated with ruthenium, e.g. $V^{5+}$ and $Pb^{2+}$ at 100-fold excess of ruthenium(III) at 30 μg concentration, simple modifications involving addition of 10 ml of NaF (1 M) to the aqueous solution were introduced. The percentage recovery of ruthenium(III) was 100 ± 3%. Interference of cobalt(II), iron(III) and bismuth(III) at 100-fold excess of ruthenium(III) was eliminated by adding 5 ml of EDTA (0.01 M). Bismuth(III) was also eliminated by shaking the aqueous solution at pH 9–10 with 10 ml xylene in the presence of sodium diethyldithiocarbamate (2% v/v). Copper(II) interfered seriously with the proposed procedure.

Under the optimum conditions of the proposed procedures ($2.5 < pH < 3.6$), chromium(VI) did not interfere owing to the reaction

$$Cr_2O_7^{2-} + 6I^- + 14H^+ \rightarrow 2Cr^{3+} + 3I_2 + 7H_2O \quad (12)$$

This reaction was pH dependent and did not occur at $pH > 2.3$. These results are in good agreement with the published work by El-Wakil et al. [13] on chromium(VI) determination.

Chromium(III) interfered seriously with the proposed method, since the reaction

$$2Cr^{3+} + 3IO_4^- + 4H_2O \rightarrow Cr_2O_7^{2-} + 3IO_3^- + 8H^+ \quad (13)$$

proceeded at $pH < 4$. However, this interference from chromium(III) could be removed easily by oxidizing the aliquot solution of chromium(III) with $H_2O_2$ in 2N $H_2SO_4$, and the produced blue perchromic acid extracted quantitatively with diethylether as previously reported [25] according to

$$CrO_4^{2-} + H_2O_2 \rightarrow \underset{\text{deep blue colour}}{CrO_5} + H_2O \quad (14)$$

$$CrO_5 + C_2H_5OC_2H_5 \rightarrow \underset{\text{adduct}}{CrO_5C_2H_5OC_2H_5} \quad (15)$$

Thus, chromium(III) interference could be removed completely. The excess hydrogen period was eliminated by adding tin(II), and the ruthenium species was then determined by the proposed procedure II.

Table 5
Determination of various amounts of ruthenium(III) by iodometry using 90-fold and 360-fold amplification procedures [a]

state was reduced to ruthenium(II) [17], and determined by iodometry and spectrophotometry with the help of the concurrently proposed standard curve under the same experimental conditions as the described procedure I-a. The results are summarized in Table 6 with an average absolute error of 0.2–0.3. The blank values taken throughout the whole procedure using freshly prepared reagents ranged between 0.2 and 0.25 ml of 0.005 M $Na_2S_2O_3$. Evidently, for ruthenium complexes containing a large percentage of ruthenium, it was advisable to dilute the solution of the produced iodate in the first procedure I-a to 25 ml with distilled water and treat 5 ml of this solution as described earlier.

### *3.2.2. Determination of ruthenium in natural waters*

The applicability of the proposed method for the determination of low concentrations of spiked ruthenium(III) ions to tap-, mineral and seawater (0.1–1 l) is possible by the standard addition procedure. In separate experiments, aliquot samples were allowed to react with 5 ml of bromine water for 10 min, and the excess bromine was removed by boiling off the solution. The samples were then spiked with various amounts (5–40 μg) of Ru(III). Filtration of the sample solution through a 0.45 μm membrane was carried out, followed by addition of 10 ml of EDTA (0.001 M) and 10 ml of NaF (1 M); the sample was then analyzed employing procedure II. The concentration of the tested ruthenium species in such water was under the detection limit and recovery of the spiked Ru(III) was achieved. The results of the analysis of various amounts of ruthenium(III) spiked tapwater and seawater are summarized in Table 7. Good reproducibility with relative standard deviations in the range 1–2.9% ($n = 5$) was obtained. The analysis of very low concentrations (less than nanomolar levels) of Ru(III) in water is also possible using the proposed procedure by prior preconcentration of the element from a large sample volume on polyurethane foam column, followed by elution of the extracted Ru(III) species from the foam as reported earlier [26] and subsequent determination of the ruthenium(III) in the effluent according to the described procedure I-a with the help of a concurrently prepared standard curve at the same instrumental setting.

## 4. Conclusion

The present work presents accurate, precise, inexpensive, reliable methods in routine analysis for the trace determination of ruthenium ions in their matrix. Therefore, the method provides an attractive alternative approach to determination of the atomic absorption of ruthenium. The advantages of the method are that it is not only applicable to Ru(II), (III) and (IV) speciation in their solutions, but it can also be used for the analysis of ruthenium in its complexes and natural water samples. The sensitivity and selectivity of the developed methods can be improved by prior preconcentration of the trace amounts of ruthenium species from large sample volumes on polyurethane foam column. Elution of ruthenium from the column is possible with selective eluting agent followed by determination with the proposed procedure. The 15-fold amplification procedure for Ru(III) determination was faster, but the 90- and 360-fold amplification procedures were more sensitive and applicable at very low concentrations of the tested element. The determi-

**Abstract**

Insoluble species were identified in the systems $Ca^{2+}$–hemimellitate, $Ca^{2+}$–1,2,3,4-butanetetracarboxylate and $Ca^{2+}$–citrate, and their solubilities were determined in aqueous solution at $T = 25°C$. Values of $pK_{s0}$ were obtained for the species CaLH (L = benzene-1,2,3-tricarboxylate or hemimellitate), $Ca_2L$ (L = 1,2,3,4-butanetetracarboxylate), CaLH and $Ca_3L_2$ (L = citrate), together with their dependence on ionic strength. Solid compounds were also characterized by thermogravimetry. The complex formation in solution for the system $Na^+$– and $Ca^{2+}$–hemimellitate was studied too.

*Keywords:* Calcium–carboxylic ligands; Solubility

## 1. Introduction

In recent years, there has been a upsurge in the study of solution equilibria because of: (a) the interest of these studies in the speciation of natural and biological fluids, such as sea, river, lake, and underground water, urine, blood, etc.; (b) the need to use equilibrium data in modeling multicomponent solutions, i.e. solutions containing a large amount of metal ions and ligands; (c) the availability of excellent calculation programs, and powerful and fast computers.

Compilations in this field report a very large number of papers dealing with thermodynamic formation data, related to ligand protonation, simple and mixed metal–ligand complexation, cation hydrolysis, etc. [1–5].

Notwithstanding this, there remains a series of substantial gaps. (1) Studies on weak interactions between alkali and alkaline-earth cations with low molecular weight ligands are still to be examined closely and to be completed. (2) The dependence of thermodynamic formation parameters on ionic strength has still not been thoroughly investigated. (3) Studies of solution equilibria are generally carried out neglecting both the possibility of the formation of solid and/or gaseous phases, and interaction with other phases. If we consider the last three points together, it is evident that they are very closely linked.

Therefore, we decided to make a systematic further study of a research topic already begun [6] on the stability and solubility of some Ca–polycarboxylate complexes. In this paper, we report the results obtained for the following systems: Ca–(hmt), Ca–(btc) and Ca–(cit) (hmt = benzene-1,2,3-tricarboxylate, or hemimellitate; btc = 1,2,3,4-butanetetracarboxylate; cit = citrate). Moreover, since we use formation constants of the species present in solution for the determination of the solubilities of the salts,

potentiometric measurements for the systems $Na^+$– and $Ca^{2+}$–hemimellitate (whose thermodynamic data are not reported in the literature) were performed.

## 2. Experimental

### 2.1. Materials

The solution of NaCl was prepared from C. Erba A.C.S. reagent, previously dried at 110°C. $CaCl_2$ solution was prepared from analytical reagent Fluka and standardized with EDTA [7]. NaOH and HCl solutions were prepared by diluting concentrated ampoules (C. Erba), and standardized against potassium biphthalate or sodium carbonate, respectively. Tetramethylammonium chloride ($(Me_4N)Cl$) and tetraethylammonium iodide ($(Et_4N)I$) (Fluka or C. Erba) were recrystallized from acetone/methanol [8] before use. $Ca_3(cit)_2 \cdot 4H_2O$ (Fluka), was used as purchased. Hemimellitic, 1,2,3,4-butanetetracarboxylic and citric acids were used without further purification, because their purity, checked alkalimetrically, was always >99.6%. All solutions were kept free from $CO_2$ using soda lime traps.

### 2.2. Apparatus

Hydrogen-ion concentration was measured with a Metrohm mod. 654 potentiometer, coupled with a combination pH glass electrode Orion mod. 81-02 (Ross type). The titrant, standard NaOH, was delivered by a motorized burette Metrohm Dosimat mod. 665. Both potentiometer and dispenser were controlled by a personal computer and suitable software was used in order to run automatic titrations and data reading. The glass electrode was standardized by titrating HCl (20–30 mM) with standard NaOH under the same ionic strength conditions as the solutions being investigated, and therefore $E^0$ and the junction potential, $E_j = j_a[H^+]$, were calculated; following this procedure we obtained $pH \equiv \log[H^+]$, i.e. pH in terms of molar concentration. The accuracy of the system was $\pm 0.15$ mV in e.m.f. measurements and $\pm 0.002$ ml in the delivered titrant volume. The measurement cell was thermostatted at $25.0 \pm 0.1$°C and magnetic stirring was employed. All the titrations were carried out by bubbling pre-saturated and purified nitrogen through the solution, in order to exclude $CO_2$ and $O_2$.

The solids were characterized by thermogravimetric analysis using a Perkin Elmer thermobalance TBS-2 equipped with data station, working at a heating rate of 10°C $min^{-1}$, in air.

### 2.3. Potentiometric measurements

Alkalimetric titrations were performed under the following analytical conditions (L = hemimellitic acid): for protonation constants, $C_L$ = 5–7 mM, $C_{(Et_4NI)} = 0.1–0.75$ M (25 titrations); for $Na^+$ complex formation constants, $C_L$ = 5–7 mM, $C_{NaCl} = 0.1–0.75$ M (25 titrations); for $Ca^{2+}$ complex formation constants, $C_L$ = 2–5 mM, $C_{CaCl_2} = 3–20$ mM, $C_{NaCl} = 0–0.7$ M; or $C_{CaCl_2} = 3$ mM, $C_{(Et_4NI)} = 0.2–0.4$ M (31 titrations). For each titration, 40–60 data points were obtained. In several cases, an excess of HCl (20–30 mM) was added to the solutions in order to calculate internal $E^0$, $E^0_{int}$ (i.e. the standard potential obtained from the same solution being investigated); when $|E^0_{int} - E^0| > 1$ mV, the titration was rejected and repeated.

### 2.4. Preparation and analysis of insoluble compounds[1]

Insoluble compounds were prepared in plugged ampoules by mixing suitable quantities of reactants in 100 ml of total volume, as reported in Table 1. The proton concentration was varied by adding NaOH and/or $Ca(OH)_2$, and the ionic strength was adjusted with NaCl and/or $(Me_4N)Cl$. The ampoules were mechan-

ically shaken in a box thermostated at 25.0 ± 0.1°C, for 24 h; shaking times of up to 72 h gave equal results. The solution was recovered first, by filtration (Schleicher Schnell 589/3) into a 100 ml volumetric flask, in which 10 ml of distilled water had previously been placed, in order to prevent precipitation. Then, the solid was filtered using a Gooch crucible (porosity 10–15 μm), washed with a small quantity of water and vacuum-dried. The solutions were analyzed in order to determine their analytical concentrations in proton and calcium ions, by using standard NaOH and EDTA, respectively. Each titration was repeated at least twice. The ligand concentration was estimated on the basis of mass balance, i.e. solution electroneutrality.

### 2.5. Calculations

The purities of the reagents and the $E^0$ values were calculated by the computer program ESAB2M [9]. Protonation and formation constant values of $H^+$–, $Na^+$–, $Ca^{2+}$–hemimellitate complexes were determined by the non-linear least-squares computer programs STACO [10] and/or BSTAC [10]; both programs can deal with potentiometric data at different ionic strengths, and compute parameters $C$ and $D$ of the dependence of formation constants on ionic strength (see text).

For the calculation of solubilities, free concentrations of proton, calcium and ligands were computed (ES4ECI [10] computer program) from the correspondent analytical concentrations, and from the protonation and formation constants determined here or reported previously [1–5,11–13]. All the calculations were performed by also considering the interactions of the background salt with all the components of the solutions, such as reported in previous investigations [11,13,17].

## 3. Results and discussion

### 3.1. Formation constants of hemimellitate

Table 2 reports the protonation constants of hemimellitate and formation constants with $Na^+$ and $Ca^{2+}$, at infinite dilution and $T$ = 25°C. Values obtained in $(Et_4N)I$ can be considered as "effective" protonation constants, since the interaction of $(Et_4N)^+$ with carboxylic ligands is negligible. The protonation

[c] Eq. (2).

constants are in agreement (Table 3) with those reported in both Refs. [14] and [15], whilst there is disagreement with $\log K_1$ and $\log K_2$ of Ref. [16]. As regards the Na–L–H system, we found, under our experimental conditions, three mononuclear ($NaLH_2^0$, $NaLH^-$, $NaL^{2-}$) and two binuclear ($Na_2LH^0$, ($Na_2L^-$) species. Comparison with literature findings is not possible, since these are the first available data; nevertheless, we can attempt a comparison (see Table 3) with the Na-complexes of other similar ligands having the same residual charge, i.e. −3: citrate [11], 1,2,3-propanetricarboxylate [17], hydrogen-1,2,3,4-butanetetracarboxylate [13]. As we can see, the values of the constants for the same reaction are fairly similar. Calcualtions (L = 1 mM, NaCl = 0.25 M) of the distribution of the species vs. pH show high formation percentages of $NaL^{2-}$ and $Na_2L^-$ (at pH 7, ≈75% of the ligand). Analysis of the potentiometric data of the Ca–hemimellitate–H system, allowed us to identify four complex species, and the formation constant values are reported in Table 2. Since other literature data are not available at present, we can only compare the thermodynamic values of Ca-complexes of hemimellitate with those of 1,2,3-propanetricarboxylate [17], citrate [12] and hy-

$$M^{z+} + (M_{p-1}LH_q)^{[z(p-1)+q-3]} = (M_pLH_q)^{(zp+q-3)}$$

drogen-1,2,3,4-butane-tetracarboxylate [13] (see Table 3). Fig. 1 shows the distribution of the species vs. pH, evidencing the preferential formation of $CaLH_2^+$ and $Ca_2L^+$ complexes.

The dependence of thermodynamic parameters on ionic strength was taken into account using a Debye–Hückel type equation [11,14,18, 19] ($I$ = ionic strength, M):

$$\log X = \log {}^TX - z^*\sqrt{I}/(2 + 3\sqrt{I}) + CI + DI^{3/2} \quad (1)$$

with

$X = \beta$ or $K$ or $K_{s0}$; ${}^TX = \beta$ or $K$ or $K_{s0}$ values at $I = 0$;

$C = c_0p^* + c_1z^*$ and $D = dz^*$,

where

$c_0 = 0.1$, $c_1 = 0.23$, $d = -0.1$;

$p^* = \sum (\text{moles})_{\text{reactants}} - \sum (\text{moles})_{\text{products}}$;

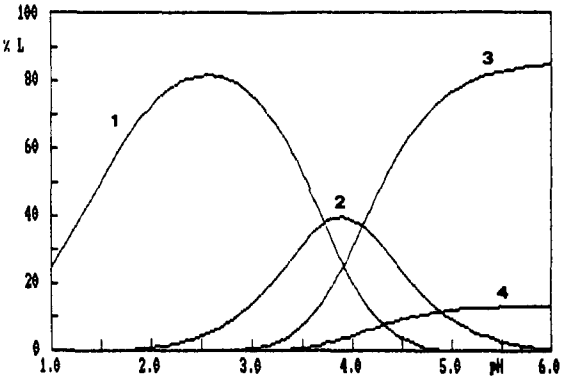

Fig. 1. Distribution diagram of complex species in the Ca–hemimellitate–H system (protonation omitted) versus pH, at $T = 25°C$ and $I = 0.25$ M.
Species: (1) $CaLH_2^+$, (2) $CaLH^0$, (3) $Ca_2L^+$, (4) $CaL^-$.
Concentrations: L = 0.001 M; $CaCl_2$ = 0.09 M.

$z^* = \sum (\text{charges})^2_{\text{reactants}} - \sum (\text{charges})^2_{\text{products}}$.

A simplified equation, used in this work, is

$$\log X = \log {}^TX - z^*g(I) + CI \quad (2)$$

with

$$g(I) = \sqrt{I}/(2 + 3\sqrt{I}) + 0.1I^{3/2}$$

In Table 2, experimental values of $C$ are reported.

### 3.2. Insoluble compounds

*Ca–hemimellitate–H system*

From the differences between the concentrations of $H^+$ and $Ca^{2+}$ reactants and those found by titration of solutions after precipitation, it is possible to compute the quantities of $H^+$ and $Ca^{2+}$ in the solid phase: the ratio (mmol $Ca^{2+}$)/(mol $H^+$) is always close to 1.0 (average of 12 runs = 0.98 ± 0.03) and, therefore, in the precipitate the ratio $Ca^{2+}$:$H^+$:$L^{3-}$ is 1:1:1, i.e. minimum formula CaLH. The thermodynamic value of $pK_{s0} \pm 3s$ together with its dependence on ionic strength ($0.06 \leqslant I \leqslant 0.03$ M), is 12.98 ± 0.05 (Eq. (1), $C = 2.4$, $D = 0$) or (see Eq. (2)) $pK_{s0} = 12.95 \pm 0.05 - 14g(I) + 3.28I$.

*Ca–1,2,3,4-butanetetracarboxylate–H system*

Quantitative analysis of 20 different solutions has shown that the number of mmol of $Ca^{2+}$ recovered was lower than at the start, whereas that of $H^+$ was always the same. This experimental evidence allows us to assert that the insoluble compound formed must contain only $Ca^{2+}$ and $L^{4-}$, with the formula $Ca_2L$.

For the calculation of $Ca_2L$ solubility, the total concentration of $Ca^{2+}$ was directly determined, and that of $L^{4-}$ was estimated as the initial value minus half the amount of $Ca^{2+}$ lost in the precipitation. The thermodynamic value of $pK_{s0}$ ($0.03 \leqslant I \leqslant 0.62$ M) is $14.60 \pm 0.05$ (Eq. (1), $C = 2.8$, $D = 0$) or, using Eq. (2), $pK_{s0} = 14.53 \pm 0.05 - 24g(I) + 4.63I$.

*Ca–citrate–H system*

The saturated solutions were analyzed for their $H^+$ and $Ca^{2+}$ content, whereas the concentration of the ligand was computed on the basis of the electroneutrality of the solutions. The found quantities of $Ca^{2+}$, $H^+$ and $L^{3-}$ are not consistent with the formation of a single compound, except for the trials for which the precipitate, in the absence of protons, kept the formula $Ca_3L_2$. To establish the composition of the species present into the mixed precipitates, we took the following into account: (a) a study on the crystal lattice of $CaLH \cdot 3H_2O$ is reported in the literature [20]; (b) the crystal lattice of $Mg_3L_2 \cdot 10H_2O$ [21] shows an aquate magnesium ion which is like a bridge between two $MgL^-$ units; owing to the strong likeness between $Mg^{2+}$ and $Ca^{2+}$, it is possible to assume similar behavior for the $Ca^{2+}$; (c) in any trial in which acids were present, their initial quantity was always greater than that found after precipitation, i.e. among the precipitates, some are protonated; (d) the charge on $CaL^-$ can be saturated with a proton, to give the neutral species CaLH (see (a)). Therefore, starting from the diminished concentration in solution of the proton, due to the formation of CaLH, we calculate the quantities of two species. We experienced a certain difficulty in obtaining the formation of CaLH, which is always $<50\%$ owing to the many equilibria involving the protonated species of $L^{3-}$ in the interval of pH taken into consideration ($3.76 \leqslant pH \leqslant 5.03$). The precipitation of protonated species is a maximum in the solutions having $pH \approx 4.8$, since at these pH values there is maximum formation $HL^{2-}$ [14], i.e. the optimum acidity conditions required to obtain CaLH. Attempts to obtain quantitative formation of CaLH (trials with increased proton concentration) failed owing to the formation of more protonated citrate soluble species. In the interval $0.2 \leqslant I \leqslant 0.54$ M we calculate, for CaLH and $Ca_3L_2$, $pK_{s0} = 11.39 \pm 0.09$ (Eq. (1), $C = 4.9$, $D = 0$) and $pK_{s0} = 17.03 \pm 0.08$ (Eq. (1), $C = 6.3$, $D = 0$), respectively; using Eq. (2), we obtain $pK_{s0} = 11.35 \pm 0.09 - 14g(I) + 5.95I$ and $pK_{s0} = 16.95 \pm 0.08 - 30g(I) + 8.52I$, respectively.

### 3.3. Thermal analysis[2]

The results concerning the thermoanalytical curves of the insoluble compounds are as follows.

CaLH (L = hemimellitate) is monohydrate, and the water is lost gradually starting from $T = 80$°C up to $T = 200$°C. At $T = 365$°C, the decomposition of the anhydrous compound into $CaCO_3$ begins, and the reaction is complete at $T = 600$°C. At $T = 780$°C the familiar pyrolysis of the carbonate steps in and, under our experimental conditions, the reaction is complete at about $T = 815$°C. We also note an inflexion of the thermogram at $T = 530$°C due to superimposed decomposition of CaLH into benzoic acid and $CaCO_3$. $Ca_2L$ (L = 1,2,3,4-butanetetracarboxylate) is hexahydrate, and the water is lost in two steps: the first dehydration begins at room temperature and continues up to $T = 145$°C, when the second dehydration is superimposed, which proceeds very gradually. At about $T = 400$°C the decomposition of the anhydrous compound starts, to give $CaCO_3$ and then, at $T = 770$°C, the usual formation of CaO takes place. The thermogram of $Ca_3L_2$ (L = citrate) shows a two-stage dehydration reaction: at first one molecule and then, at $T = 135$°C, three molecules. The anhydrous citrate decomposes in three clear transformations: their decomposition ($T = 350$°C) to give $CaCO_3$ and then CaO, and the superimposition of a thermal decomposition at about $T = 480$°C, due to the loss of a molecule of water from a H– and an OH– of the citrate. Thermograms of mixtures of $Ca_3(cit)_2 + Ca(cit)H$ have not supplied clear evidence of the stages of decomposition, but only on the degradation of the solid in $CaCO_3$ and then in CaO.

### 3.4. Solubility and ionic strength

The solubility of the above reported species is fairly low in pure water or in tetraalkylammonium salt solution, whilst it increases appreciably in sodium salt solutions. This is due to the formation of Na–carboxylate and Ca–Cl soluble complexes [22,23]. For example, the

[2] Supplementary material is reported in Appendix B.

solubility of $Ca_2(btc)$ at $I = 0.5$ M in tetraalkylammonium salt solution is $s = 6.6 \times 10^{-5}$ M, whilst in a NaCl solution, at the same ionic strength, it is $s = 1.4 \times 10^{-3}$ M. As regards the dependence on ionic strength, the $C_{exp}$ values (Eq. (2)) obtained for both $pK_{s0}$ and $\beta_{pq}$ are in fairly good agreement with previous findings [11,14,18,19] (see Appendix C).

## 4. Conclusions

A simple laboratory technique allowed us to characterize the formation of insoluble calcium–carboxylic ligand complexes. Quantitative results on solubility, together with the complete speciation of solution, are of great help in modeling the interaction of calcium with natural compounds containing several carboxylic groups. Results relative to the dependence on ionic strength of $pK_{s0}$ are quite useful, since they allow calculation of the solubilities for different natural fluids under different ionic strength conditions. We underline that in the calculation of $pK_{s0}$ values, all the interactions occurring in the solutions are taken into consideration.

## Appendix A — Solubility

*Example of calculation*

Here we report analytical details and calculations referring to the systems Ca–hmt–H (Tables A1–A3), Ca–btc–H (Tables A4–A6) and Ca–cit–H (Tables A7–A9). In particular, we consider here, as an example, the run no. 4 of the Ca–cit–H system.

In 100 ml of total volume we mixed $Ca_3L_2$, NaOH and NaCl in order to obtain the following initial concentrations (mM) before precipitation: $Ca^{2+} = 53.68$, $L^{3-}$ 35.79, $H^+ = 10.86$, NaCl = 102.7 (see Table A7, columns 2,3,4 and 5). After 24 h, we separated the precipitate from the solution, which was analyzed for $Ca^{2+}$ and $H^+$ concentrations (14.04 and 7.19 mM, respectively (see Table A7, columns 7 and 9). The analytical concentration of $L^{3-}$ after precipitation was estimated as the differ-

[a] ES4ECI calculations, from analytical concentrations of the species, after precipitation (Table A7) and from formation constants of citrate with $H^+$, $Na^+$, $Ca^{2+}$. The formation of $NaCl^0$ and $CaCl^+$ was also taken into consideration.

erations in the text), mmol CaLH = mmol $H^+$ (0.367) and mmol $Ca_3L_2$ is 1/3 of the difference between the total mmol $Ca^{2+}$ in the precipitate minus mmol CaLH (1.199), as reported in Table A8 columns 5 and 6).

Starting from analytical concentrations of $Ca^{2+}$, $L^{3-}$, $Na^+$, $Cl^-$ and $H^+$ in solution, we have calculated the relative free concentrations. We underline that in the input data files to run ES4ECI, the mass balance equations of all the equilibria that taken place into the solution are taken into considerations, i.e. protonation of $L^{3-}$, complex formation between $L^{3-}$, $Na^+$ and $Ca^{2+}$, and formation of $NaCl^0$ and $CaCl^+$. For the considered run, we have obtained the following results: pCa = 2.023, pL = 4.284. pH = 4.342 (see Table A9, columns 2,3 and 4). Taking into consideration the definition of

Table B1
Analytical data and results of the thermogravimetric analysis

| Stage | Theoretical % weight loss | Reactions involved | Ratios of % weight loss | |

# Cyclic voltammetric analysis of pH-dependent complex formation equilibria in anion coordination chemistry

Antonio Doménech *, Enrique García-España, Jose Antonio Ramírez

*Department of Inorganic Chemistry, University of Valencia, c/Dr. Moliner 50, 46100 Burjassot, Valencia, Spain*

Received 5 January 1995; revised 29 March 1995; accepted 18 April 1995

**Abstract**

A procedure to analyze pH-dependent complex formation equilibria from cyclic voltammetry is described. Application to adduct formation equilibria between $[Fe(CN)_6]^{4-}$ and $[Fe(CN)_6]^{3-}$ with different polyammonium receptors is discussed. Extension to the interaction of substrates such as ATP, $NAD^+$, $NADP^+$, and carboxylate ions with these receptors by means of competitive interaction with hexacyanoferrate(II) ion is presented.

*Keywords:* Anion coordination chemistry; Cyclic voltammetry

## 1. Introduction

Anion coordination chemistry has been extensively studied over the last two decades [1–7]. A representative part of the research in this field is focused on the coordination of $[Fe(CN)_6]^{4-}$, $[Co(CN)_6]^{3-}$, carboxylates, ATP, ADP, and polyphosphates by polyammonium macrocycles and linear polyamines [8,9]. These compounds behave as anionic receptors because of their ability to form charged species in aqueous solution even at neutral pH and because of their capability to form multisite hydrogen-bond networks. These reagents are useful for analytical purposes; for instance, double armed crown ethers and armed macrocycles can be used as metal-selective reagents [10] and polyammonium macrocycles are useful for selective recognition of carboxylate ions [11].

The formation equilibria of anion-receptor adduct species can be represented as (charges omitted for brevity)

$$rX + sL + wH \rightleftharpoons X_r L_s H_w \quad (1)$$

In this kind of system, different receptor-substrate species differing only in their number of protons, $r$, are formed in a stepwise manner. Formation equilibria take place simultaneously with the protonation equilibria of the ligand, L, and, eventually, of the anionic substrate, X:

$$X + tH \rightleftharpoons XH_t \quad (2)$$

$$L + jH \rightleftharpoons LH_j \quad (3)$$

Since multiple protonation and complex formation equilibria are involved, computer-assisted analysis of potentiometric data has been extensively used to determine the stoichiometry and stability constants of the complex species [12].

Although potentiometry has surely been revealed as the most accurate technique to analyze multiple anion coordination equilibria [1–9], it is advisable to develop complementary techniques allowing for an independent quantitative study.

In some favourable cases there is a reduced number of complex species predominating in solution over a well-defined pH range. It is then possible to determine their stoichiometry

and conditional formation constant by applying the classical stoichiometric methods to other techniques, such as spectrophotometry or polarimetry. In particular, the generalized Molar-Ratio method [13] can be applied to cyclic voltammetric and chronoamperometric techniques, yielding satisfactory results including, as already reported [14], the analysis of non-electroactive species from competitive complexation equilibria by electroactive agents.

In the present article, a method involving cyclic voltammetry is described as a generalization of the classical Viossat method [15–17]. The current method provides direct estimates of the degree of condensation, stoichiometry and number of protons in the complex species. This is based on estimations of the molar fraction of complexed substrate at different pH values by cyclic voltammetric and, eventually, chronoamperometric measurements. In spite of the fact that a variety of electrochemical techniques can be used, the simplicity of the treatment presented here together with the simplicity and versatility of cyclic voltammetric and chronoamperometric techniques makes this procedure a potentially interesting way of rapidly analyzing the data. The main points are: (i) the method can be applied to a variety of systems for which spectrophotometric techniques are unavailable; (ii) complex formation in two different oxidation states can be simultaneously investigated; (iii) the method can be applied to non-electroactive species by introducing any competing electroactive agent.

## 2. Cyclic voltammetric analysis of complex formation equilibria

Polarographic methods have long been found useful for studying complex formation equilibria. From the seminal work of DeFord and Hume [18], different methods have been developed for analyzing single and multiple complex formation equilibria, including, among others [19], multiple ligand systems [20] and investigation of non-electroactive species by means of the competitive complexation forming electroactive species [21,22].

The extension to cyclic voltammetry of classical polarographic techniques to study single and multiple metal–ligand equilibria has recently been described [23,24]. In addition, general simulation procedures for linear scan or cyclic voltammetric curves have been described for the characterization of complexes at small and large excess of ligand, and in pH-dependent complex equilibria [25–28]. Despite their usefulness, the extension of simulation procedures to complicated systems requires an accurate fit of a number of parameters, namely the diffusion coefficients of all the electroactive species and their electron transfer coefficients in the case of completely irreversible electrode processes. Further, deviations from reversibility in almost reversible systems or uncompensated ohmic losses in the cell can significantly distort the voltammetric curves [29], therefore increasing the difficulty of simulating the $i-E$ curves. The present method is based on the analysis of the currents for diffusion-controlled processes, as used in polarography for single [30–32] and competitive systems [21,22]. The application of competitive electrochemical studies in anion coordination chemistry was suggested in 1981 [33]. We consider here the general case in which both the uncomplexed anionic substrates and their complex ions are reversibly reduced (or oxidized) from a higher to a lower valency state, as occurs for the coordination of the $[Fe(CN)_6]^{4-}$ ion by polyammonium receptors.

Aqueous solutions of $[Fe(CN)_6]^{4-}$ exhibit a well-known reversible or quasi-reversible one-electron cyclic voltammetric couple which can be represented as

$$[Fe^{II}(CN)_6]^{4-} \rightleftharpoons [Fe^{III}(CN)_6]^{3-} + e^- \quad (4)$$

As shown in Fig. 1, upon addition of increasing amounts of a macrocyclic receptor at constant pH, an anodic shift of the peak potentials accompanied by a significant decrease of the peak current is observed. For receptor/$[Fe(CN)_6]^{4-}$ molar ratios $>1$, the cyclic voltammetric pattern remains unchanged [34,35]. The dependence of potentials and peak currents on the receptor/$[Fe(CN)_6]^{4-}$ molar ratio ($c_L/c_M$), plotted in Fig. 2 (curves A), clearly suggests that 1:1 electroactive complex species are formed.

In an excess of receptor, the observed dependence of the peak current and the peak potentials with the sweep rate corresponds to that expected for a one-electron process without kinetic or chemical complications [36]. Thus, one can conclude that electroactive $[Fe(CN)_6]^{4-}$-receptor species are oxidized reversibly:

$$[Fe^{II}(CN)_6LH_q]^{(4-q)-} \rightleftharpoons [Fe^{III}(CN)_6LH_q]^{(3-q)-} + e^- \quad (5)$$

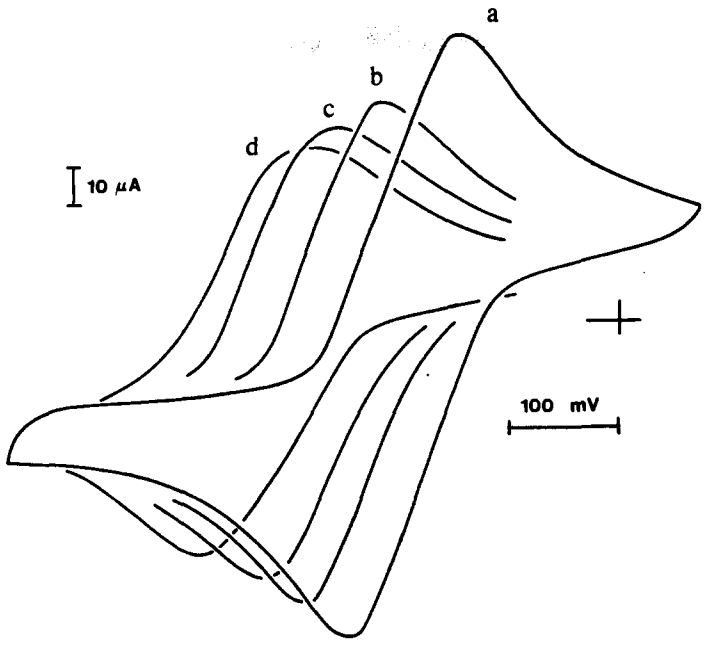

Fig. 1. pH-dependence of the cyclic voltammogram of a solution containing $[Fe(CN)_6]^{4-}$ (2.0 mM) and [21]aneN$_7$ (2.5 mM). Platinum electrode, $v = 0.10$ V s$^{-1}$. pH values: (a) 10.0; (b) 9.0; (c) 8.0; (d) 7.0.

As shown in Fig. 3, the formal potential of this couple becomes more positive when the pH decreases. In fact, at acidic pH values and for receptor/$[Fe(CN)_6]^{4-}$ molar ratios between 0 and 1, the difference in the formal potentials of free and coordinated $[Fe(CN)_6]^{4-}$ is sufficiently large to produce cyclic voltammetric curves which appear to be the superposition of two waves.

The observed cyclic voltammetric pattern must be described in terms of oxidation of two electroactive species in chemical equilibrium. This problem, subject to recent studies [37,38], is complicated by the fact that the electroactive species exhibit different diffusion coefficients and formal potentials.

For receptor/$[Fe(CN)_6]^{4-}$ molar ratios less than unity, no single correlations between the $i-E$ curves and the solution composition are available in the pre-peak region of potentials. Therefore, peak potentials and peak currents are not strictly suitable for measuring the composition of the solution.

The simplified treatment adopted here is based on the assumption that for potentials sufficiently past the electrode potential of all the electroactive species, the total current is governed by the diffusion of uncomplexed $[Fe(CN)_6]^{4-}$ and its adduct species. Thus, for potentials less than the voltammetric peaks, the current is controlled by Nernstian behaviour, while for potentials sufficiently past both the anodic and cathodic peaks, the current becomes purely diffusion-controlled in such a way that it can be described in terms of the $i-E$ form of the Cottrell equation [39–41]:

$$i = \frac{nFAcD^{1/2}v^{1/2}}{\pi^{1/2}(E - E^*)} \tag{6}$$

where $E^*$ represents the convergence potential at which the linear sweep voltammetric current becomes equal to the chronoamperometric current, and the other symbols have their usual significance. Since $E^*$ is, a priori, not known, it is convenient to rearrange this equation to give

$$\frac{1}{i^2} = \frac{\pi}{n^2F^2A^2c^2Dv}E - \frac{\pi E^*}{n^2F^2A^2c^2Dv} \tag{7}$$

For pure diffusion control, a plot of $1/i^2$ versus $E$ should give a straight line whose slope allows a direct estimate to be made of the diffusion coefficient $D$ for a defined composition of the solution. For a system in which both the metal and its complexes are electroactive, Eq. (7) can be applied inserting a mean diffusion coefficient, $D$, which can be defined as in polarography [19] verifying

$$D = \frac{\sum D_q\beta_q[L][H]^q}{\sum \beta_q[L][H]^q} \tag{8}$$

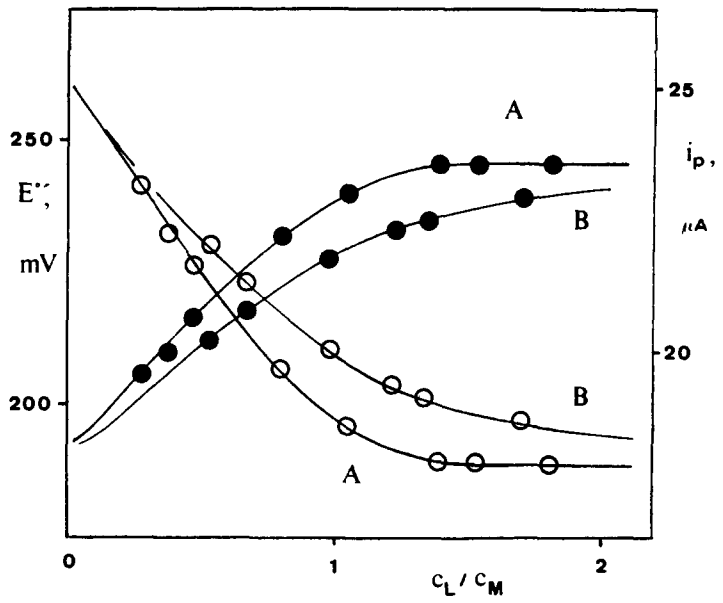

Fig. 2. Plots of the peak potential (●) and the peak current (○) as a function of the $c_L/c_M$ ratio for the $[Fe(CN)_6]^{4-}$–[18]aneN$_6$ (a) and $[Fe(CN)_6]^{4-}$–[18]aneN$_6$–ATP (B) systems at pH 7.50. All concentrations were 1.50 mM. CV at the GCE, scan rate 0.13 V s$^{-1}$.

Therefore, the molar fraction of complexed metal, defined as $\alpha_M = \Sigma [ML_nH_q]/c_M$, can be calculated at a given pH by

$$\alpha_M = (D - D_M)/(D_{ML} - D_M)$$
$$= (D/D_M - 1)/(D_{ML}/D_M - 1) \quad (9)$$

where $D_M$ denotes the diffusion coefficient of the $[Fe(CN)_6]^{4-}$ ion. $D_{ML}$ is the value for the diffusion coefficient of the complex species, which can be obtained as the limiting $D$ value in solutions containing a sufficiently large excess of receptor. As depicted in Fig. 4, the mean diffusion coefficient changes drastically with pH in the presence of receptor species, and the $D_{ML}$ values can be assigned to the plateau values in the $D = f(\text{pH})$ curve.

A direct estimate of these coefficients can be obtained from chronoamperograms at a potential sufficiently large to ensure diffusion-limited current for all species [39–41]. Alternatively, the diffusion coefficients can be directly calculated from the chronoamperometric analysis of the diffusive portion of the cyclic voltammograms. Independent $\alpha_M$ values for the Fe(II) and Fe(III) systems can then be calculated by studying separately the anodic and cathodic portions of the cyclic voltammograms. Providing a sufficiently large switching potential is attained, it is convenient to use a strip-chart recorder for satisfactorily defining the base line for current measurements [42].

If the total concentration of ligand reaches a sufficient excess, the plateaus in the $E^{\circ\prime} = f(\text{pH})$ curve can be associated with a sequence of different complex species quantitatively formed. The cyclic voltammograms thus obtained allow direct estimates of the formal potential and the diffusion coefficient of such complex species. The formal potential determined at the selected pH values as the half-sum of the peak potentials is given by

$$E^{\circ\prime}(M^{III}L/M^{II}L) = E^{\circ\prime}(M^{III}/M^{II}) + \frac{59}{n} \log \frac{\beta_{II}}{\beta_{III}} \quad (10)$$

Where $\beta_{II}$ and $\beta_{III}$ are, respectively, the stability constants of the $Fe^{II}$ and $Fe^{III}$ complexes. This equation can be applied to calculate the $\beta_{III}$ constants provided the $\beta_{II}$ constants are known.

For intermediate pH values, the apparent formal potential of the $Fe^{III}/Fe^{II}$ couple may be approached as [19]

$$E^{\circ\prime} = E^{\circ\prime}(M^{III}/M^{II}) + \frac{59}{n} \log \frac{\sum \beta_{II}[L][H]^p}{\sum \beta_{III}[L][H]^q} \quad (11)$$

On the assumptions that (a) all species exhibit nernstian behaviour, (b) total equilibrium is rapidly reached near the electrode surface, and (c) the pH of the solution does not change during the potential scan, not even near the electrode surface, Eq. (11) becomes

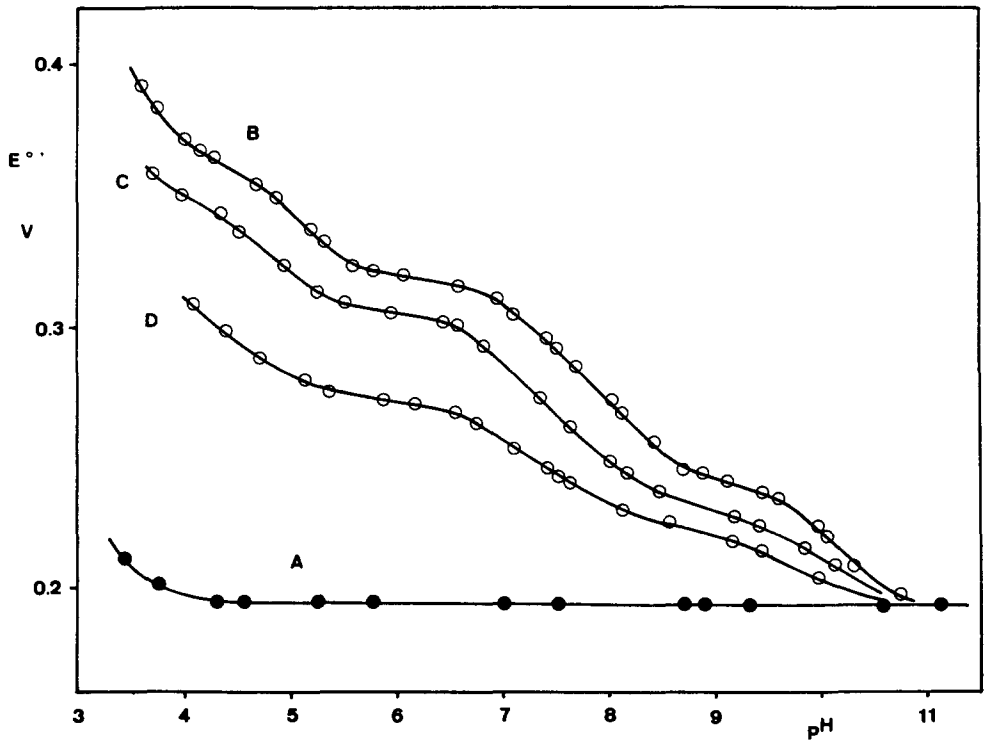

Fig. 3. Dependence of the formal potential on the pH for solutions containing: (A) $[Fe(CN)_6]^{4-}$; (B) $[Fe(CN)_6]^{4-}$ and [21]aneN$_7$; (C) as B in the presence of $NAD^+$; (D) as B in the presence of $NADP^+$. In all cases, from CV at the Pt electrode at $v = 0.10\ V\ s^{-1}$. All concentrations were 2.0 mM.

$$E^{\circ\prime} = E^{\circ\prime}(M^{III}/M^{II}) + \frac{59}{n} \log \frac{\sum \beta^{II}(c_L - n\alpha^{II}_M c_M)[H]^p}{\sum \beta^{III}(c_L - \alpha^{III}_M c_M)[H]^q} \quad (12)$$

where $c_L$, $c_M$ represent, respectively, the total concentrations of ligand and metal. The case $p = q$ must correspond to the plateau regions in the $E^{\circ\prime} = f(pH)$ curve.

Once the stability constants and the molar fractions have been calculated, the experimental values of $E^{\circ\prime}$ can be compared with those determined inserting into Eq. (12) different sequences of protonation numbers.

The above procedure can be extended to study the complexation of non-electroactive anions using the $[Fe(CN)_6]^{4-}$ ion as a competing substrate. Thus, upon addition of increasing amounts of ATP, $NAD^+$, $NADP^+$ and carboxylate anions to a equimolar solution of $[Fe(CN)_6]^{4-}$ and a macrocyclic ligand, the cyclic voltammogram exhibits intermediate parameters between that of free $[Fe(CN)_6]^{4-}$ and the limiting voltammogram in the presence of receptor as can be seen in curves B in Fig. 2.

In the used potential window (from +0.6 to −0.2 V versus SCE) no electrode processes affecting competitive $NAD^+$, $NADP^+$ substrates were detected, in agreement with data in the literature [43]. No adsorption complications were detected in ternary systems, and cyclic voltammograms exhibited identical parameters to those of the $[Fe(CN)_6]^{4-}$–receptor systems. Under these conditions, the evaluations of the molar fraction of complexed $[Fe(CN)_6]^{4-}$ allows for a direct estimate of the competitive effect of the non-electroactive anion.

## 3. Determination of the metal:ligand:proton stoichiometry

### 3.1. Single systems

To confirm the stoichiometry of the adduct species as well as the number of protons involved in the first formation step, a modified version of the Viossat method may be applied [15]. This requires that each one of the complex species predominates in a well-defined pH range. Thus, if the formation equilibrium of an $m$-nuclear complex is represented as,

$$mM + nL + qH = M_m L_n H_q \quad (13)$$

for given $c_L$, $c_M$, and pH values, $[M_m L_n H_q] =$

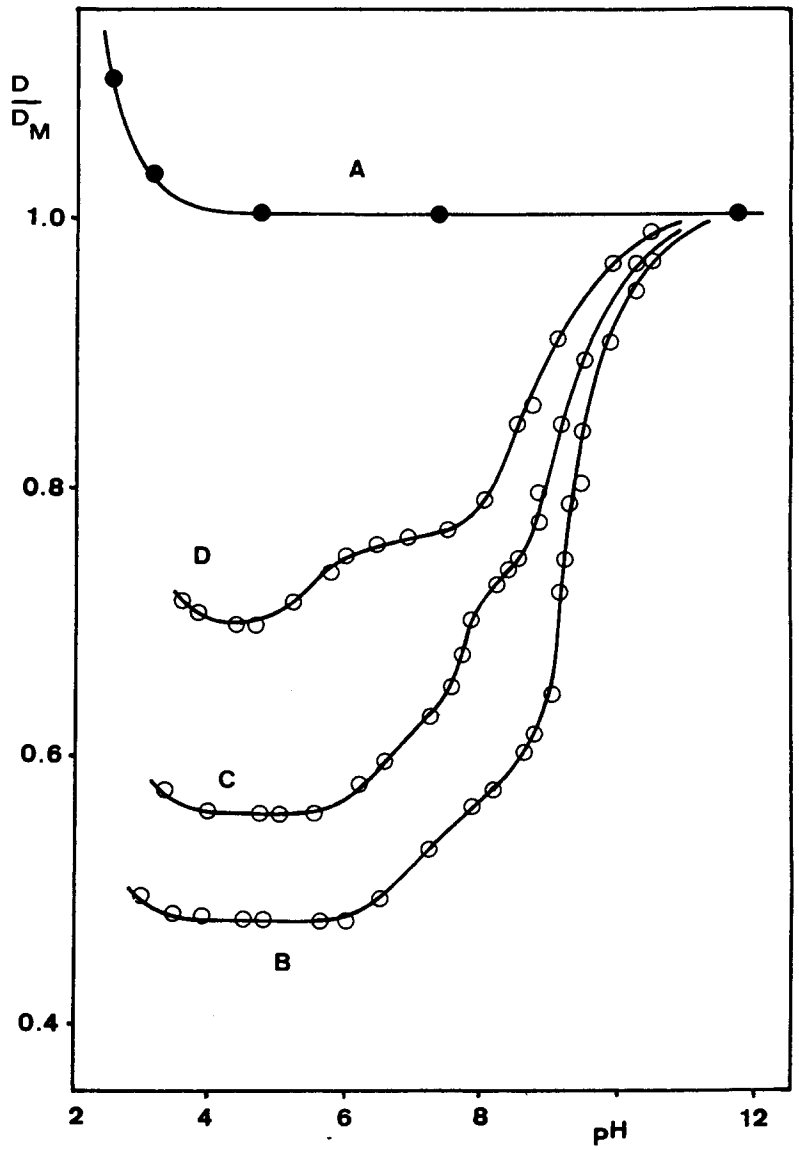

Fig. 4. Plots of $D/D_M$ versus pH for 2.0 mM solutions of potassium hexacyanoferrate(II); (A) alone; (B) with 2.0 mM [24]aneN$_8$; (C) as B with 2.0 mM $NAD^+$; (D) as B with 2.0 mM $NADP^+$.

$\alpha_M c_M/m$, $[M] = (1-\alpha_M)c_M$, and $[L] = (c_L - n\alpha_M c_M/m)/(1+\Sigma\beta_j[H]^j)$, $\beta_j$ being the protonation constant of the ligand. The equation for the equilibrium constant then reduces to

$$\beta_q = \frac{\alpha_M c_M^{1-m}(1+\Sigma\beta_j[H]^j)^n}{m(1-\alpha_M)^m(c_L - n\alpha_M c_M/m)^n[H]^q} \quad (14)$$

This equation can be rewritten as

$$f(\alpha, H) = \log \frac{\alpha_M^{1/n}(1+\Sigma\beta_j[H]^j)}{m^{1/n}(1-\alpha_M)^{m/n}(c_L - n\alpha_M c_M/m)^n}$$
$$= (1/n)\log\beta_q + [(m-1)/n]\log c_M + (q/n)\text{pH} \quad (15)$$

Providing the cumulative protonation constants of the ligand are known, this equation predicts a linear variation of $f(\alpha_M, H)$ with pH only for adequate values of the stoichiometric coefficients, $m$ and $n$. The number of protons, $q$, involved in the first complexation step is directly given by the slope of the $f(\alpha_M, H) = f(\text{pH})$ representation. The method can be easily extended to determine the number of protons involved in each intermediate complex formation step and must apply to both the $M^{II}$ and $M^{III}$ oxidation states.

### 3.2. Competitive systems

If the stoichiometry and stability constants of the adducts $M_m L_n H_q$ are known, the de-

scribed method can be extended to elucidate the number of protons of the complexes formed by the ligand with a non-electroactive substrate X (Eq. 1).

For a solution containing the electroactive species M, the substrate X, and the receptor, L, and assuming that only one M–L and one X–L complex species exist in the investigated pH range, the total concentration of ligand is

$$c_L = [L](1 + \Sigma \beta_j[H]^j) + n[M_m L_n H_q] + s[X_r L_s H_w] \quad (16)$$

If one calculates the concentration of uncomplexed ligand from the molar fraction of coordinated M (estimated from cyclic voltammetric data)

$$[L] = \frac{\alpha_M}{(1-\alpha_M)\beta_q[H]^q} \quad (17)$$

The molar fraction of complexed substrate, $\alpha_X$, can be calculated as

$$\alpha_X = \frac{c_L - (n/m)\alpha_M c_M - [L](1 + \Sigma \beta_j[H]^j)}{(s/r)c_X} \quad (18)$$

where $c_X$ is the total concentration of X. The $\alpha_M$ and $\alpha_X$ values must verify

$$g(\alpha_M, \alpha_X) = \log\left[\frac{m^{1/n}\alpha_X^{1/s}(1-\alpha_M)^{m/n}}{r^{1/s}\alpha_M^{1/n}(1-\alpha_X)^{r/s}}\right] = \log\frac{\beta_w^{1/s}}{\beta_q^{1/n}} + \log\frac{c_X^{(1-r)/s}}{c_M^{(1-m)/n}} + \left(\frac{w}{s} - \frac{q}{n}\right)\text{pH} \quad (19)$$

enabling us to evaluate the stoichiometry and number of protons involved in the complexation of the substrate X.

## 4. Experimental

A series of samples containing a constant amount of potassium hexacyanoferrate(II), ligand, and, eventually, competitive product, with a constant excess of ligand were prepared at different pH values in the range from pH 2.0 to 10.0. The supporting electrolyte was 0.15 M $NaClO_4$, the pH being adjusted to the required value by adding the appropriate amounts of $HClO_4$ and/or NaOH.

Cyclic voltammograms were obtained using a conventional device with a potentiostat (AR 100), a signal generator (Newtronic 200P), an $x$–$y$ recorder (Riken-Denshi F35) and a $y$–$t$ recorder (JJ CR550). A standard three-electrode cell was used with platinum ($A = 0.11$ cm$^2$), gold ($A = 0.018$ cm$^2$) and glassy carbon ($A = 0.071$ cm$^2$) working electrodes, a saturated calomel reference electrode (SCE) and a platinum-wire auxiliary electrode. No adsorption processes were detected and all working electrodes provided comparable results. To compensate for eventual differences in the effective area of the electrodes, $[Fe(CN)_6]^{4-}$ solutions were used as standard for each one of the series of experiments. The ratio $D/D_M$ was then tabulated for calculations.

All experiments were carried out under an argon atmosphere in a cell thermostatted at 298.15 K. Prior to a series of runs the working electrodes were cleaned, polished and activated [42].

The diffusion coefficients were also determined from the experimental $i$–$t$ chronoamperometric curves by applying the Cottrell equation, ($i = nFAcD^{1/2}/(\pi t)^{1/2}$) from the slope of the $i$ versus $t^{-1/2}$ plot. Since a recent report has stated that chronoamperometric data obtained at short times (< 1 s) are often unreliable and seems to imply that such data cannot be used to accurately determine diffusion coefficients [44], conventional long-time experiments were used. In all experiments, linear relationships between the observed anodic current and $t^{-1/2}$ were observed for times up to 3 s after the potential step.

For the cyclic voltammetric data, linear relationships between $1/i^2$ and $E$ were found in all cases for the +0.40 to 0.60 V potential range, corresponding to the diffusive region of the anodic cyclic voltammetric curve. The $D$ values calculated from the slope of these representations agreed with those calculated from chronoamperometric data.

Potentiometric measurements were carried out in aqueous solution at 298.1 K in the same medium by using equipment already described [8,9]. The program SUPERQUAD [45] was used to calculate the stability and protonation constants. The titration curves for each system were treated as a single set or separately without significant variations in the values of the constants.

## 5. Results and discussion

Different polyazaalkane–$[Fe(CN)_6]^{4-}$ systems have been examined to compare theoreti-

cal and experimental data. Prior potentiometric studies were carried out for each one of these systems. Several complexes with 1:1 receptor:$[Fe(CN)_6]^{4-}$ stoichiometry and different numbers of protons are formed in a stepwise manner. The stability constants of the hexacyanoferrate(II)–receptor species and protonation constants of ligand and, eventually, competitive agent were obtained.

CV-pH titrations confirm the stepwise pH-dependent formation of different complex species. Fig. 3 shows the pH-dependence of the formal potential for the system $[Fe(CN)_6]^{4-}$–[21]aneN$_7$ ([21]aneN$_7$ = 1,4,7,10,13,16,19-heptaazacyclohenicosane). Curve A corresponds to hexacyanoferrate(II) solutions and curve B corresponds to samples with a $[Fe(CN)_6]^{4-}$/ligand ratio of 1.50. The pH-dependence of the formal potential exhibits in all cases a close agreement with the distribution diagram calculated from potentiometric data.

Direct estimates of the percentages of complexed $[Fe(CN)_6]^{4-}$ calculated from the cyclic voltammetric diffusion coefficients (Eq. 7) are in close accordance with those independently obtained from the potentiometric data. Insertion of the $\beta_{II}$ and $\beta_{III}$ values calculated from anodic and cathodic currents into Eq. (12) provides $E^{\circ\prime}$ values close to that determined as the half-sum of the determined peak potential in all the studied cases.

The anion coordination equilibria between polyammonium receptors and non-electroactive monohydrogen carboxylate and dihydrogencarboxylate anions [8,9], ATP [46], and other anions has been studied by cyclic voltammetry and chronoamperometry on the basis of the competitive effect with the $[Fe(CN)_6]^{4-}$ ions. The addition of competitive anions to a solution containing $[Fe(CN)_6]^{4-}$ and a receptor causes a displacement of the cyclic voltammetric parameters towards those corresponding to the uncomplexed hexacyanoferrate(II). This can be seen in curves B of Fig. 2, and curves C and D of Fig. 3. As expected, increasing the amounts of substrate X leads to curves which increasingly differ from the limiting curves in the absence of competitive agent and approach those of uncomplexed hexacyanoferrate(II) solutions. Fig. 4 presents the pH dependence of the $D/D_M$ ratio for solutions of$[Fe(CN)_6]^{4-}$, [24]aneN$_8$ ([24]aneN$_8$ = 1,4,7,10,13,16,19,22-octaazacyclotetracosane) and $NAD^+$ or $NADP^+$ as a competitive agent. The diffusion coefficient of uncomplexed $[Fe(CN)_6]^{4-}$ at pH > 4 was taken as a reference ($D_M$). Below pH 4, this diffusion coefficient increases as the pH decreases; this fact is attributable to the protonation of the hexacyanoferrate(II) ion [47,48]. From these data, direct estimates of the molar fraction complexed $[Fe(CN)_6]^{4-}$ can be made quantifying

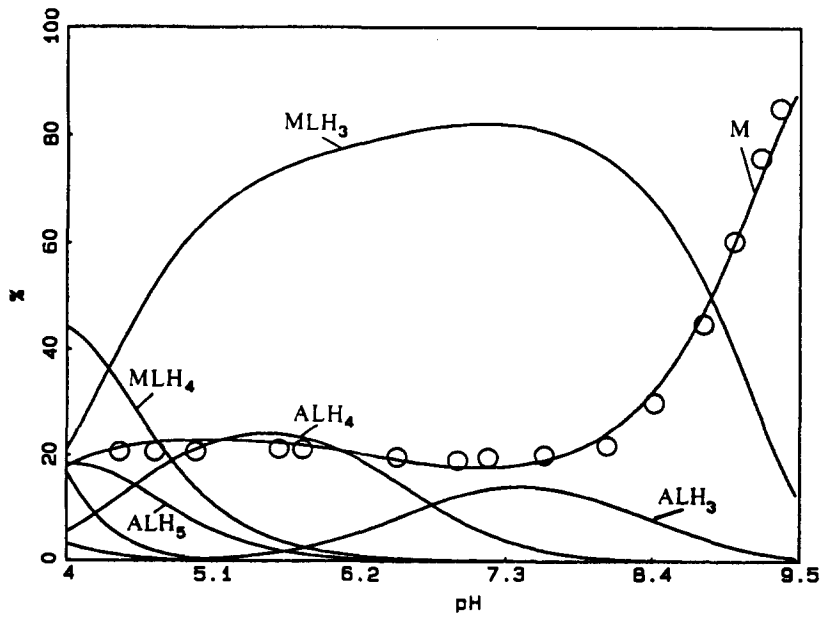

Fig. 5. Distribution diagram for a solution of $[Fe(CN)_6]^{4-}$ (1.36 mM), Me$_4$[18]aneN$_6$ (1.44 mM) and ATP (1.25 mM) calculated from potentiometric data. Circles represent the values of the molar fraction of uncomplexed $[Fe(CN)_6]^{4-}$ calculated from CV data.

the ability of $NAD^+$ and $NADP^+$ to link with the anionic receptor.

The $\alpha_M$ values calculated from CV and CA measurements can be compared with those estimated from the numerical analysis of potentiometric data. Fig. 5 plots the distribution diagram for the mixed system $[Fe(CN)_6]^{4-}$–$Me_4[18]aneN_6$–ATP($Me_4[18]aneN_6$ = 1,4,7,10,13,16-hexaazacyclooctadecane) in which the values of the molar fraction of uncomplexed $[Fe(CN)_6]^{4-}$ calculated from CV data have been represented as individual data points. This procedure allows a way of evaluating the selectivity in the different anion–receptor systems by measuring the differences in the molar fraction of complexed competitive agent [34].

However, the stoichiometry of the complex and the number of protons involved in the first complexation stage were calculated from the $D = f(pH)$ curves. As depicted in Fig. 6, corresponding to the $[Fe(CN)_6]^{4-}$–bmaph (bmaph = 1,17-bis(methylamino)-3,6,9,12,15-pentaazaheptadecane) system, a linear relationship between $f(\alpha_M, H)$ and pH is obtained only for the correct stoichiometric coefficients, $m = 1$ and $n = 1$. The slope of such a representation was $q = 4$, in accordance with potentiometric data. From Eq. (15) one obtains $\log \beta_q = 39.8(4)$ in excellent agreement with the potentiometric value, $\log \beta_q = 40.40(1)$.

Competitive experiments also provide satisfactory results. For instance, Table 1 shows the $g(\alpha_M, \alpha_X)$ values in the pH range from 8.4 to 9.6 for the competing complexation of [21]$aneN_7$ with hexacyanoferrate(II) and 1,3-BDC. A complex species with 1:1 sustrate:receptor stoichiometry was found, the first protonation step involving three protons: $q = w = 3$. For these cases, Eq. (20) reduces to $g(\alpha_M, \alpha_X) = \log(\beta_w/\beta_q)$, predicting the pH-independence of the $g(\alpha_M, \alpha_X)$ values. As can be seen in Table 1, for other $r$, $s$ values, the $g(\alpha_M, \alpha_X)$ function monotonically increases or decreases. Finally, the value of $\log(\beta_w/\beta_q)$ ($-0.31(5)$) is in good agreement with those calculated from potentiometric data ($\log \beta_q = 31.03(4)$, $\log \beta_w = 30.66(4)$). Table 2 summarizes the results for the competitive

complexation of [21]aneN$_7$ by $[Fe(CN)_6]^{4-}$ and $NAD^+$, $NADP^+$ and different carboxylates.

To summarize, cyclic voltammetric data can be used in suitable cases to quantitatively study complex formation equilibria allowing direct estimates of the stoichiometry and the number of protons involved. A reasonable combination of potentiometric and voltammetric techniques is potentially interesting for analyzing complex formation in unstable oxidation states. Finally, cyclic voltammetric monitoring of competitive complexation can be used to establish the selective character of complexing agents.

# Palladium complexes in concentrated nitrate and acid solutions

E. Camacho Frias [1], H. Pitsch K. *[,2], J. Ly [2], C. Poitrenaud

*CEA-SACLAY, INSTN/SECh, 91191 Gif sur Yvette, France*

Received 25 January; revised 10 April 1995; accepted 11 April 1995

**Abstract**

A spectrophotometric study of palladium complexation in concentrated nitrate and acid solutions is presented. The water activity of the solutions was fixed to control activity coefficients. The existence of the species $PdNO_3^+$, $Pd(NO_3)_2$ and $PdOHNO_3$ has been evidenced and their stability was evaluated. An activity diagram for the predominance of soluble palladium species is presented and the precipitation limit is drawn.

*Keywords:* Palladium complexes; Concentrated solutions; Spectrophotometry

## 1. Introduction

Palladium is one of the most abundant transition metals among the fission products in nuclear spent fuel. Highly hydrolysable, it induces disturbances in the reprocessing operations: it interferes in the acidity monitoring of aqueous layers and complicates the separation of the phases in the liquid–liquid extraction operations by the formation of insoluble compounds. Within the programs devoted to control this type of problem in order to improve the Purex process, the purpose of the present work is to provide an accurate description of the chemical behaviour of palladium in acid solutions containing high concentrations of nitrate.

In aqueous solutions, the prevailing oxidation state of palladium is II, except for very strong complexes of Pd(IV) [1]. Shmidt et al. [2] confirmed this statement for nitric media when they reprecipitated $Pd(NO_3)_2$ from solutions obtained by dissolution of metallic palladium in 12 M nitric acid. Neither paratoluenesulphonate nor perchlorate forms complexes with palladium [3]. Jørgensen et al. [4] demonstrated that in concentrated perchloric acid, $Pd^{2+}$ is the unique species up to 0.01 M total metal; its absorption spectrum shows a large band with a maximum at 380 nm and a second one at 170 nm.

Hydrolysis of $Pd^{2+}$ is easily performed: in very dilute solutions, the formation of the complexes $PdOH^+$ and $Pd(OH)_2$ starts at pH $\approx$ 1 and insoluble $Pd(OH)_2$ precipitates from fairly acid solutions. Above pH 2, when the total concentration of palladium is higher than $10^{-5}$ M, polynuclear forms have been identified and their evolution into red-brownish polycondensated products has also been described [5–7]. Complexation with chloride ions has been studied spectrophotometrically [8,9], and it is known that palladium forms stable complexes or insoluble species with numerous organic molecules [3]. As far as nitrate is concerned, the complexes are certainly much less stable than those with chloride, but evolution of the absorption spectrum with the concentration of

nitrate shows evidence of complexation: the stability constant $\beta_1 = 1.2 \pm 0.4$ has been evaluated in nearly 2 M mixtures of $HNO_3$, $HClO_4$ and $NaClO_4$ at pH $\approx 0$ [4]. Mixed complexes with nitrate ions and organic ligands have also been reported [10]. Considering the strong hydrolysability of palladium, mixed species such as $PdOHNO_3$ are to be expected.

From the reviewed literature, several conclusions may be drawn. In the first place, perchloric acid is a good non-complexing reference medium for the purpose of this work. Secondly, spectrophotometry is an adequate method for characterising soluble nitric species of palladium. Considering the known stability data, large variations in the concentration of nitrate are necessary for an accurate determination of the thermodynamic constants; this implies that a strict control of medium effects is necessary. Finally, special care has to be taken at each step to avoid rapid or even slow precipitation of hydroxide.

## 2. Model for the non-ideality

The determination of low stability constants requires discrimination between chemical and medium effects, i.e. to strictly control the activity coefficients when the concentration of the ligand is varied over a large interval. This problem has been discussed elsewhere [11–13] and only the conclusions will be recalled here. For *simple systems*, i.e. solutions that obey Zdanovskii's law of water activity conservation through mixing [14], the activity coefficient of any species in the solution depends only on $a_w$, the water activity of the solution, and $\sigma$, the total concentration of dissolved species [15]:

$$y_k = f_k(a_w)/\sigma$$

where $f_k$ is a characteristic function of species k.

The activity of species k may be written as

$$a_k = (k) = [k] \cdot y_k = f_k(a_w) \cdot [k]/\sigma$$

where [k] is the concentration of k.

Hence, it appears that, at constant water activity, the activity of k is proportional to the ratio of its concentration to the total concentration of dissolved species. Consequently, we will from now on refer to this ratio as *the relative activity of k at the considered water activity*.

A further consequence is that any equilibrium may be described by a characteristic function of the water activity, say $G(a_w)$; for example, if $\beta_i^\circ$ is the thermodynamic constant of the following equilibrium:

$$M + iL \rightleftharpoons ML_i$$

$$\beta_i^\circ = [ML_i]/([L]^i[M])$$

$$= [[ML_i]/([L]^i[M])][f_{ML_i}/(f_L^i f_M)]\sigma^i$$

$$G_i(a_w) = \beta_i^\circ[(f_L^i f_M)/f_{ML_i}]$$

$G_i(a_w)$ depends only on the temperature and the water activity. When its value has been experimentally determined, the previous equations show that the concentration constant in any specific medium of known $a_w$ and $\sigma$ can be calculated in a simple way:

$$\beta_i = [ML_i]/([L]^i[M]) = G_i(a_w)/\sigma^i \quad (1)$$

The expression of the classical complexation coefficient [16,17] is

$$\alpha_{M(L)} = \sum [G_i(a_w)([L]/\sigma)^i]$$

Its value depends only on the temperature, on the activity of water and on the relative activity of the ligand at this value of $a_w$.

An important consequence is that a strict control of medium effects is obtained if the water activity in the system is fixed. Practically, this may be obtained in a relatively simple way using solutions with the same water activity. According to Zdanovskii's law, all their mixtures will have the same water activity. As far as data processing is concerned, the significant variable will be the above-mentioned ratio [k]/$\sigma$.

## 3. Experimental

### 3.1. General conditions

The fixed value of the activity of water ($0.750 \pm 0.002$) was chosen according to the conditions of the Purex process ($0.7 < a_w < 0.85$), the necessity to obtain the highest possible concentration of nitrates and the restrictions due to the limited solubility of the pure background salts that had to be used. Mixtures of nitrates, alkaline perchlorates and their corresponding acids follow Zdanovskii's rule over a large range of concentrations [18]. This oriented the choice of the electrolytes, as the

Table 1
Mother solutions

| Electrolyte | Concentration (mol $l^{-1}$) | Density (25°C) |
|---|---|---|
| $HNO_3$ | $5.180_1$ | 1.1632 |
| $HClO_4$ | $3.788_2$ | 1.2118 |
| $NaNO_3$ | $7.562_2$ | 1.3784 |
| $NaClO_4$ | $5.402_1$ | 1.4010 |

former model of non-ideality effects applies to these systems.

A highly acid medium was necessary to avoid precipitation risks and to limit hydrolysis in order to characterise pure nitrate complexes. Therefore, perchloric and nitric acid, diluted in order to reach $a_w = 0.75$, were used as the non-complexing and the most complexing medium, respectively, at the highest acidity level. To be able to explore the domain of hydroxylated or mixed complexes, sodium perchlorate and nitrate were chosen because of their high solubility, good hygroscopy and available purity; owing to the high concentration of the electrolytes (see Table 1), it is of course very important to use very pure products in order not to introduce any strong complexing agent which may interfere. All the media described in this paper were obtained by mixing these "pure poles"; Fig. 1 shows the corresponding points on the relative activity diagram. To avoid precipitation of palladium hydroxide, mother solutions of palladium could only be prepared in the pure acids. Therefore, the experimentally accessible activity domain is limited in the less acidic region. The lower limit in nitrate activity is due to the nitrates from the palladium salt which was dissolved to obtain the perchloric mother solution. The limits of the experimental domain are not straight lines because of the variation of $\sigma$ throughout the diagram and because of the formation of molecular nitric acid at high concentrations of nitrate [19].

### 3.2. Preparation of solutions

Vials, flasks, funnels and other glassware were rinsed with deionised water (MilliQ sys-

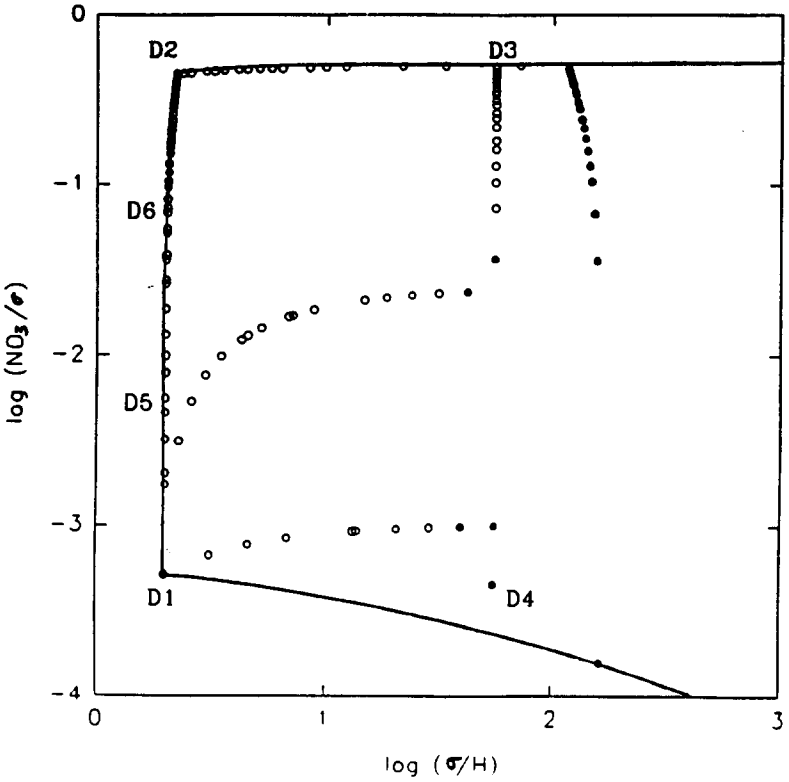

Fig. 1. Relative activity domain accessible at $a_w = 0.75$. Upper limits are imposed by the background electrolytes. The lower limit in the nitrate activity is set by the nitrates of the dissolved palladium salt. The experimental points used for the interpretation of solution equilibria are indicated by circles. Filled symbols denote solutions where slow precipitation was observed. Daughter solutions: D1, $HClO_4$; D2, $HNO_3$; D3, $HNO_3 + NaNO_3$; D4, $HClO_4 + NaClO_4$; D5 and D6, $HClO_4 + HNO_3$.

tem from Millipore), cleaned with 0.1 M perchloric acid and rinsed with water again. All reagents were of analytical grade (Merck, Prolabo and Strem Chemicals).

All primary solutions were prepared by weighing on a AE 260 Delta range balance from Mettler. They were filtered on Millipore HA (nitrates) or PTHK (perchlorates) filters; the porosity was 0.45 μm for "pure poles" and 0.22 μm for palladium solutions. Concentrations of background electrolytes were checked by densitometry at 25°C with a PAAR DMA 55 densitometer and adjusted to the exact value. Absence of precipitation was assumed if no diffusion of the light beam of a helium–neon laser was observed. Mixtures of solutions were also prepared by weighing, equilibrated at 25°C and checked for the absence of precipitation. Their density was measured and used to calculate the exact molar concentrations of the components. The error in the concentrations is estimated to be less than 0.1%.

Palladium nitrate was used to prepare the mother solutions in spite of its hygroscopy. Indeed, Pd is only soluble in concentrated nitric acid and its dissolution is difficult to control in terms of by-products, PdO is insoluble even in hot acids and $PdCl_2$ could not be used because of the complexing effect of the chloride. Two mother solutions were prepared by carefully adding the concentrated acid at $a_w = 0.75$ to the weighed salt and shaking on a Certomat HK thermoregulated bench for several hours. After filtering at 0.22 μm, the concentration was checked by the classical gravimetric method with dimethylglyoxime [20]; both solutions contained $(4.82 \pm 0.05) \times 10^{-2}$ mol $l^{-1}$ of palladium, in $HClO_4$ (solution M1) or $HNO_3$ (solution M2).

### 3.3. Spectrophotometry

Except when otherwise mentioned, absorptiometry in the region 350–800 nm was carried out on solutions containing a total palladium concentration of $2.41 \times 10^{-3}$ mol $l^{-1}$; this was chosen to be high enough to give a signal measurable with good accuracy and precision ($\pm 0.002$ uA) and sufficiently low to avoid precipitation. Neither the salt nor the acids used here absorb in this region, the only absorbing species being palladium components. The strong bands of the nitrate (maximum at 303 nm and 250 nm) do not allow work at shorter wavelengths. A model 634 UV/vis double-beam spectrophotometer from Varian and a Servotrace registrator were used for spectra scanning and absorption measurements. All experiments were carried out on solutions equilibrated at 25°C. In order to compensate for slight fluctuations in the temperature or instabilities of the instrument during the measurements, the actual analysed signal was the difference between the absorption at the desired wavelength and the absorption at 800 nm, where no significant signal is observed.

Table 2
Molar absorptivity coefficients (l $mol^{-1}$ $cm^{-1}$) of $Pd^{2+}$ in 3.788 M $HClO_4$

| Wavelength (nm) | This work | Literature | Ref. |
|---|---|---|---|
| 380 | $88.9 \pm 0.7$ | 86 | [4] |
| 392 | $91.1 \pm 0.7$ | | |
| 400 | $84.6 \pm 0.6$ | $85.0 \pm 0.5$ | [21] |
| 415 | $72.3 \pm 0.5$ | | |

## 4. Results and discussion

### 4.1. Absorbance of palladium solutions

In agreement with previous observations [3,4,21], it was assumed that, in the absence of chemical effects, the absorption spectrum of a given species in the visible region does not depend on the medium. This is likely to be true in our experimental conditions, inasmuch as the activity of water is maintained constant. Consequently, the changes in the spectrum of palladium solutions have been interpreted as the effect of complexing reactions.

The first question was then to define the reference point, i.e. to check that the free cation is the actual species in perchloric acid. This was done by measuring the variation in the absorbance at different wavelengths with the concentration of palladium nitrate dissolved in 3.788 M $HClO_4$. A straight line is obtained, showing that $Pd^{2+}$ is the unique species; the formation of a complex would have induced a non-linear dependency. At 415 nm, the regression equation on ten experimental points is $A = (72.3 \pm 0.5)C - (0.0006 \pm 0.0010)$, with $r^2 = 0.9999$. Similar results were obtained at other wavelengths, and the absorptivity coefficients of $Pd^{2+}$ are in good agreement with previous results (Table 2).

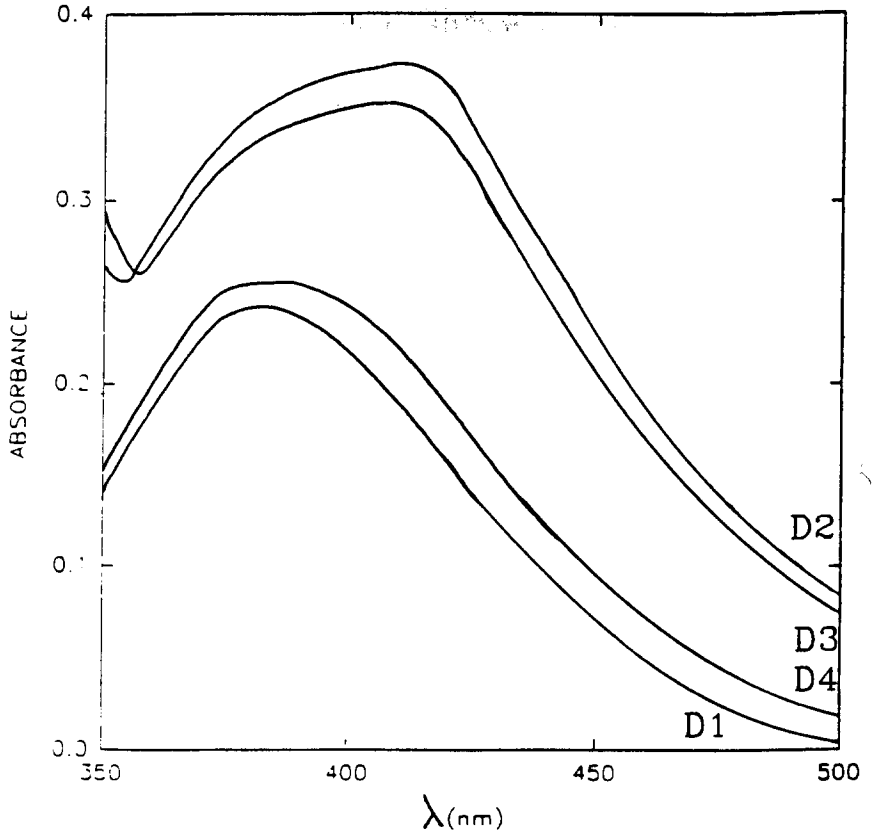

Fig. 2. Spectra of solutions of $2.41 \times 10^{-3}$ M palladium at the extremities of the explored domain. D1, $HClO_4$; D2, $HNO_3$; D3, $HNO_3 + NaNO_3$; D4, $HClO_4 + NaClO_4$.

Four daughter solutions containing $2.41 \times 10^{-3}$ M of total palladium were prepared by dilution of M1 with $HClO_4$ (solution D1) or $NaClO_4$ (D4), and of M2 with $HNO_3$ (D2) or $NaNO_3$ (D3), respectively. The absorption spectra of these solutions, which represent the extreme points of the accessible domain (Fig. 1) are shown in Fig. 2. It can be observed that, with respect to the perchloric acid solution (D1), the presence of nitrate greatly increases the absorbance (D2) whereas a decrease in the acidity has a much lesser, but not negligible, influence in a nitric (D3) as well as in a perchloric medium (D4). It can be concluded that complexation occurs with both nitrate and hydroxyl, and that a mixed complex cannot be discarded in the region of concentrated nitrate and low acidity (D3).

Complementary experiments have shown that in more concentrated nitric acid, up to 11.7 M, the large absorption band spreads onto two bands, indicating the presence of at least two nitric complexes. However, $2.41 \times 10^{-3}$ M palladium precipitates at pH 1 from dilute media without forming intermediate soluble complexes with $OH^-$ [6]. At $a_w = 0.75$, we observed that solutions of low acidity, denoted by filled symbols in Fig. 1, showed a relative instability; a colloidal precipitate formed after several weeks, while the other solutions remained stable for four months at least. It is possible that hydroxylated species like $Pd(OH)_x$ or $Pd_x(OH)_y$ could form as intermediates in a slow precipitation process and account for the differences between the spectra of D1 and D4. As this does not correspond to a thermodynamical equilibrium situation, the corresponding points were discarded from the selected set for the quantitative interpretation. As a reasonable hypothesis for the remaining domain, the following species were presumed: $Pd^{2+}$, $PdNO_3^+$, $Pd(NO_3)_2$ and $PdOHNO_3$.

### 4.2. Basic equations

For the considered species, according to the model chosen for non-ideality, the basic complexation equations and their characteristic water activity functions are

$$Pd^{2+} + iNO_3^- \rightleftharpoons Pd(NO_3)_i^{2-i}$$

$$G_{i0} = \frac{[Pd(NO_3)_i^{2-i}]}{[Pd^{2+}]([NO_3^-]/\sigma)^i}$$

$$Pd^{2+} + NO_3^- + H_2O \rightleftharpoons PdOHNO_3 + H^+$$

$$G_{11} = \frac{[PdOHNO_3]}{[Pd^{2+}]([NO_3^-]/\sigma)(\sigma/[H^+])}$$

The total concentration of palladium in any solution containing nitrates is

$$C_T = [Pd^{2+}] + [PdNO_3^+] + [Pd(NO_3)_2] + [PdOHNO_3]$$

and its complexation coefficient can be written as

$$\alpha_{Pd(NO_3,OH)} = C_T/[Pd^{2+}] = 1 + G_{10}[NO_3^-]/\sigma + G_{20}([NO_3^-]/\sigma)^2 + G_{11}([NO_3^-]/\sigma)(\sigma/[H^+])$$

The absorbance of this solution is

$$A = \varepsilon_{00}[Pd^{2+}] + \varepsilon_{10}[PdNO_3^+] + \varepsilon_{20}[Pd(NO_3)_2] + \varepsilon_{11}[PdOHNO_3]$$

where $\varepsilon_{ij}$ is the molar absorptivity coefficient of the species $Pd(NO_3)_i(OH)_j$.

Dividing $A$ by $C_T$ and rearranging the equation by introducing the formation functions, yields the following expression:

$$A = C_T \frac{\varepsilon_{00} + \varepsilon_{10}G_{10}[NO_3^-]/\sigma + \varepsilon_{20}G_{20}([NO_3^-]/\sigma)^2 + \varepsilon_{11}G_{11}([NO_3^-]/\sigma)(\sigma/[H^+])}{1 + G_{10}[NO_3^-]/\sigma + G_{20}([NO_3^-]/\sigma)^2 + G_{11}([NO_3^-]/\sigma)(\sigma/[H^+])} \quad (2)$$

It is then possible to calculate the complexation functions $G_{ij}$ and the absorptivity coefficients $\varepsilon_{ij}$ by fitting this function of the two variables $\sigma/[H^+]$ and $[NO_3^-]/\sigma$ to the measured values of the absorbance. $C_T$ is known, and $\varepsilon_{00}$ has been determined separately, as has been stated above. To calculate the values of the variables from the total acid and salt concentrations introduced in each solution, the formation equilibrium of nitric acid, which is the only weak background electrolyte, had to be taken into account:

$$H^+ + NO_3^- \rightleftharpoons HNO_3 \qquad G_H = \frac{[HNO_3]\sigma}{[NO_3^-][H^+]}$$

The value of $G_H$ can be calculated from published data of the dissociation coefficient of pure nitric acid in water [22]; at $a_w = 0.75$ it is 2.0212.

### 4.3. Determination of the complexation functions and the absorptivity coefficients

Different series of 10–25 solutions have each been prepared by mixing different proportions of two of the daughter solutions D1, D2, D3, D4 and two additional ones: D6 (M1 diluted with $HNO_3$) and D5 (M2 diluted with $HClO_4$). All these solutions contained the same concentration of palladium ($2.41 \times 10^{-3}$ M) and, according to Zdanovskii's law, had the same water activity (0.75). Their absorption at 415, 392 and 380 nm was measured after equilibration at 25°C. As the major absorbance difference in the spectra is observed at 415 nm, this wavelength has been chosen for the determination of the complexation functions. The results were interpreted for four series independently, after discarding those solutions where diffusion of the light beam of a laser showed initiating precipitation:

- — high acidity, large variation of $[NO_3/\sigma]$; mixture of D1 with D6 and D2 with D5;
- — low acidity, large variation of $[NO_3/\sigma]$; mixture of D3 with D4;
- — concentrated nitrates, variation of the acidity; mixture of D2 with D3.

Fig. 1 shows the representative points of all the examined solutions in the relative activity diagram.

As an example, the results for the first series are represented in Fig. 3: in these very acidic media, only $PdNO_3^+$ and $Pd(NO_3)_2$ are present and the expression of the absorbance reduces to

$$A = C_T \frac{\varepsilon_{00} + \varepsilon_{10}G_{10}[NO_3^-]/\sigma + \varepsilon_{20}G_{20}([NO_3^-]/\sigma)^2}{1 + G_{10}[NO_3^-]/\sigma + G_{20}([NO_3^-]/\sigma)^2}$$

The results for the four series provided compatible values of the absorptivity coefficients and the complexation functions which were used as initial values for a refined fitting over the whole set of data, numbering 97 altogether, using a Marquardt–Levenberg algorithm (Sigmaplot software, Jandel). The residuals of the fitting appear in Fig. 4; the mean relative absolute difference between measured and calculated values is 1.2%, and the relative standard deviation is 1.6%. The complexation functions are reported in Table 3, as well as the stability constants that can be deduced for a pure nitric acid medium at $a_w = 0.75$, using Eq. (1). The value obtained for $\beta_1$ is not significantly different from the estimate given by Jørgensen et al. [4], who did not strictly control

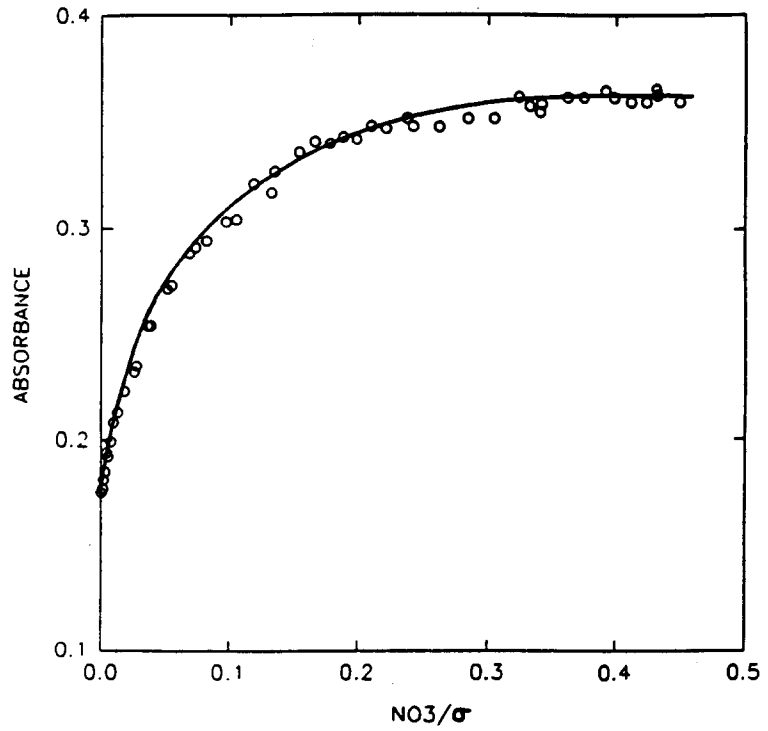

Fig. 3. Experimental absorbance values at $\lambda = 415$ nm in the very acidic region and fitted curve, considering only complexation with nitrate ions.

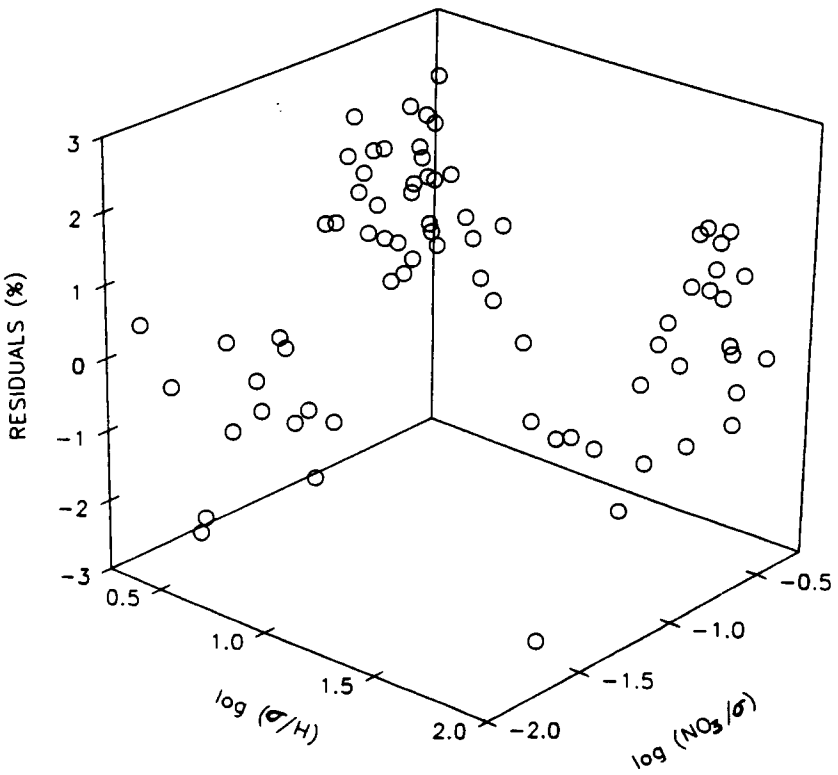

Fig. 4. Residuals of the final fitting to absorbance data at 415 nm.

Table 3
Complexation functions at $a_w = 0.75$ and deduced stability constants in 5.18 M nitric acid

| Species | $G_{ij}$ | $\beta_{ij}$ |
|---|---|---|
| $PdNO_3^+$ | 15.5 ± 0.8 | 1.47 ± 0.08 |
| $Pd(NO_3)_2$ | 19.2 ± 1.7 | 0.173 ± 0.015 |
| $PdOHNO_3$ | 0.224 ± 0.018 | 0.224 ± 0.018 |

Table 4
Molar absorptivity coefficients ($l\,mol^{-1}\,cm^{-1}$) of palladium complexes at different wavelengths

| Species | 415 nm | 392 nm | 380 nm |
|---|---|---|---|
| $PdNO_3^+$ | 163 ± 3 | 123 ± 5 | 116 ± 6 |
| $Pd(NO_3)_2$ | 147 ± 8 | 118 ± 16 | 112 ± 13 |
| $PdOHNO_3$ | 133 ± 5 | 104 ± 9 | 102 ± 6 |

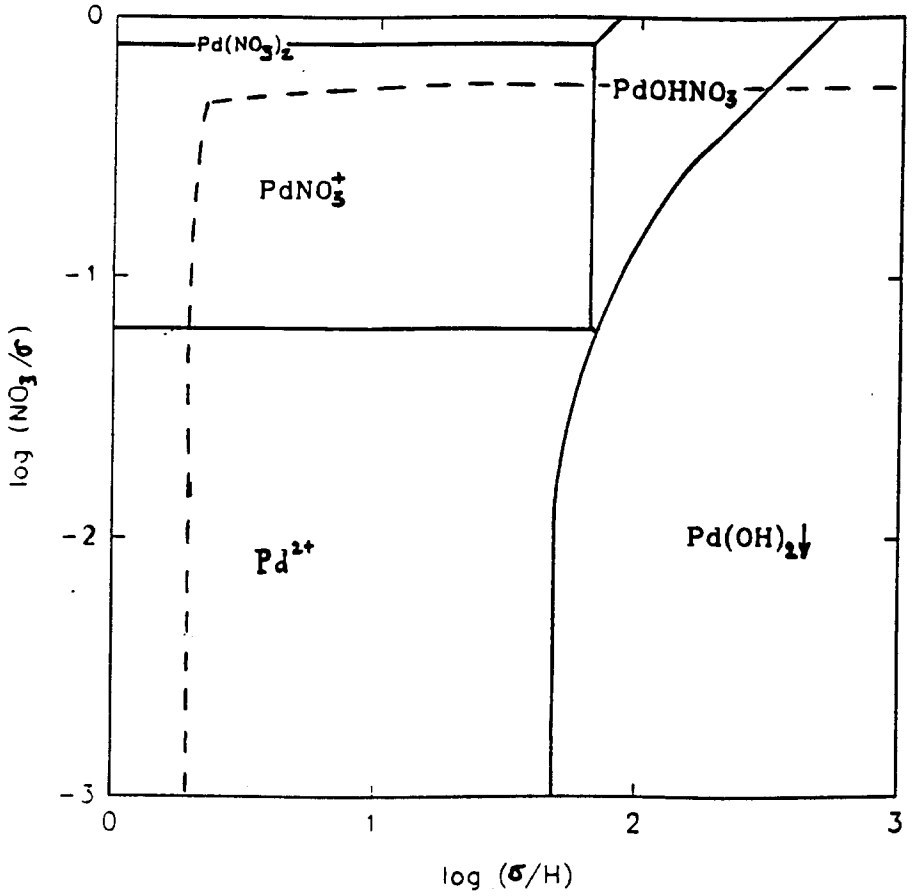

Fig. 5. Predominance zones for palladium species at $a_w = 0.75$, as a function of the relative activities of nitrate and proton. The limit of precipitation is indicated for a relative activity of palladium of $10^{-4}$.

the medium effects: in their experiments, $\sigma$ was 2.05 ± 0.05 M and $a_w$ varied between 0.91 and 0.93. This shows a weak influence of the medium effects on stability, at least for this first complex.

The molar absorptivity coefficients of the complex species at the other wavelengths were then calculated, by fitting function (2) to the absorbances at 380 and 392 nm respectively keeping the complexation functions constant. The final results appear in Table 4 and show sufficient regularity to affirm robustness of the model.

Finally, the complexation functions were used to calculate the borders of the predominance zones in the relative activity diagram presented in Fig. 5. It appears that the most important complexes at $a_w = 0.75$ are $PdNO_3^+$ and $PdOHNO_3$. The zone where $Pd(NO_3)_2$ predominates is clearly out of the accessible domain: at the most, this species can represent 40% of the total dissolved palladium.

### 4.4. Precipitation limit

As was stated before, precipitation occurred in the solutions denoted in Fig. 1 by a filled symbol. This provides an experimental limit for

the solubility in each series. As at each of these points the complexation coefficient of the palladium is easily obtained using the previously determined complexation functions, it is possible to estimate the value of the precipitation function corresponding to the equilibrium

$$Pd^{2+} + 2H_2O \rightleftharpoons Pd(OH)_2 \downarrow + 2H^+$$

$$G_s = \frac{[H^+]^2}{[Pd^{2+}]\sigma} = \frac{\sigma\alpha_{Pd(NO_3,OH)}}{C_T(\sigma/[H^+])^2}$$

$$G_s \approx 4$$

From this value, the precipitation limit can be calculated over all the activity diagram for any activity of palladium. This was done for a relative activity of palladium of $10^{-4}$, which corresponds approximately to a concentration of $10^{-3}$ M. The precipitation line is indicated in the predominance diagram of Fig. 5.

## 5. Conclusion

The model for non-ideality used here allowed us to draw the speciation diagram in terms of relative activities of the ligands; hence, the medium effects are included in the predictive capacity of the representation. For any solution of water activity equal to 0.75, whatever its composition may be, the concentrations of palladium complexes with $NO_3^-$ and $OH^-$ can be calculated from the presented characteristic functions, provided these are the only ligands or the stability of other complexes is also known.

Further developments should include the variation of the water activity to extend the domain of applicability. Taking into account the experimental difficulties in obtaining palladium solutions of precisely known composition, a serious improvement would be to perform whole spectrum analysis and hence to process simultaneously a much larger set of data, with the help of appropriate software. This would suppose, of course, numerical acquisition of the spectra, which was unfortunately not available for the present work.

Received 16 December 1994; revised 24 April 1995; accepted 24 April 1995

**Abstract**

When a silver/silver chloride (Ag/AgCl) reference electrode was used continuously in a low conductivity solution or reductive solution, it was often observed that stability of the liquid junction potential was lost. This phenomenon was remarkable with a Ag/AgCl reference electrode compared to a calomel reference electrode. We found that 340 mg $l^{-1}$ of silver was dissolved in 3 M potassium chloride (KCl) internal solution as silver complex ions ($AgCl_x^{-(x-1)}$) for $x = 2$ or 3. However, only 1.93 mg $l^{-1}$ of silver chloride (AgCl) can theoretically be dissolved in water. The complex ion that effused into the sample solution through the liquid junction clogged the liquid junction (e.g. porous ceramic) as AgCl, or as metallic silver (Ag) in reducing solution. Therefore, the constant effusion of KCl internal solution was inhibited, and the liquid junction potential became unstable or fluctuating. A new reference electrode was developed, which can eliminate $AgCl_x^{-(x-1)}$ in 3 M KCl internal solution by the use of chelating resins. A combination of this reference electrode with a pH electrode made long-term stable pH measurements possible.

*Keywords:* pH measurement; silver/silver chloride reference electrode

## 1. Introduction

The stability of a reference electrode in potentiometry is very important for the reliability and accuracy of the obtained data because a potential error of 1 mV causes about 0.02 pH error in pH measurement and also an approximate 4 or 8% concentration error, respectively, for mono- and divalent ion measurements using ion-selective electrodes.

The calomel electrode introduced by Ostwald in 1890 has been used as a reference electrode for glass pH electrode measurements, since their inception [1]. These days, because of the toxicity and environmental concern of mercury, the Ag/AgCl reference electrode has been used instead of the calomel reference electrode. An agar–agar salt bridge is generally not used as a laboratory or industrial reference electrode because of its high maintenance and stability, but alternative ion transfer vehicles such as exudation of KCl have been used [2]. In reference electrodes with ion transfer such as KCl exudation, continuous exudation of KCl is one of the most important parameters for reliable performance [3]. Sometimes, the KCl internal solution is pressurized by compressed air to stabilize the rate of KCl exudation. Thus, 0.1 to several ml per day of KCl internal solution exudes constantly through the liquid junction of the reference electrode. If the exudation of

*Corresponding author. Present address: Research Center, DKK Corp., 4-13-14, Kichijoji Kitamachi, Musashino, Tokyo 180, Japan. Fax: (81)422-52-2042.

*SSDI* 0039-9140(95)01628-7

KCl internal solution from the inside of the breference electrode to the outside (into sample solution) is stopped, the KCl solution on the surface of the liquid junction becomes dilute. The reference electrode loses its normal efficiency and gives a different liquid junction potential, and the liquid junction potential becomes unstable or fluctuating. However, this restriction of exudation of KCl solution is considered to be caused by particles of dirt and soil in the sample solution. Even when no dirt or soil was present in the sample solution, we occasionally found that plugging of the liquid junction occurred. In an Ag/AgCl reference electrode, clogging of its liquid junction is thought to be the essential problem. To maintain the initial stable condition in the reference electrode, it is important that the mechanism of plugging be made clear. Nevell and Walsh [2] noticed that silver effused through the liquid junction from a Ag/AgCl reference electrode, and mercury effused from a calomel reference electrode. They stated only that the toxicity of Ag or Hg might adversely influence some substances in the sample solution. Brezinski pointed out that AgCl clogged the liquid junction in a Ag/AgCl reference electrode [4]. We found that chelating resins could eliminate Ag ions existing in the KCl inner solution, and developed a long-term stable reference electrode with a liquid junction that could be kept clean using chelating resins.

## 2. Experimental

### 2.1. Reagents

All chemicals used were of analytical reagent grade. Potassium chloride (KCl) and silver chloride (AgCl) were obtained from Wako Chemicals (Osaka, Japan). Pure water was used throughout the work. Cation chelating resin Model CR-10 was purchased from Mitsubisi kasei (Tokyo, Japan). Chelating resin Model MX-8, Z-7 and S-1 were purchased from Miyosi Oil & Fat (Tokyo, Japan). The functional groups of each chelating resin of Model CR-10, Model MX-8, Model Z-7 and Model S-1 are $-N(CH_2COOH)_2$, $>N-CH_2-CH_2-COOH$, $>N-CS_2H-SH$ and $-SH$, respectively.

### 2.2. Apparatus

A Hitachi Model 208 atomic absorption spectroscopy (air–acetylene flame) was used for the determination of silver in 3 M KCl solution. A DKK Model COM-20 potentiometer, a DKK Model EL7100 silver ion electrode, a DKK Model EL7020 chloride ion electrode and a DKK Model EL4083 reference electrode were used for silver ion measurements. A DKK Model EL6156 glass electrode was used for pH adjustment throughout this work.

### 2.3. Measurement of silver in 3 M KCl solution

In water, the solubility of AgCl is 0.7 mg $l^{-1}$ at 0°C, 1.93 mg $l^{-1}$ at 25°C, 5.4 mg $l^{-1}$ at 50°C and 21 mg $l^{-1}$ at 100°C [5]. However, in high concentrations of KCl solution such as 3 M KCl, the solubility of Ag is not found in the literature. Therefore, we measured the total silver concentration for saturated AgCl in 3 M KCl solution at 25°C and at 80°C.

To keep silver ions in the complex state, sample solutions were prepared in 3 M KCl solution. Two 3 M KCl solutions containing 1% (supersaturated) AgCl were prepared. These were allowed to stand overnight in a water bath at 25°C and 80°C, respectively. Sample solutions were prepared by accurately diluting ten-fold each supernatant solution containing 3 M KCl solution. The sample solution was analyzed at 25°C.

Table 1 shows the result of measurements by atomic absorption spectroscopy. At 25°C, the solubility of AgCl in 3 M KCl solution is 340 mg $l^{-1}$, although it is 1.93 mg $l^{-1}$ in water. At 80°C, it is 700 mg $l^{-1}$ in 3 M KCl solution, and is approximately 13 mg $l^{-1}$ in water. With an increase in the concentration of KCl, the colour of the flame changed to purple owing to the potassium and the flame was not stable. Although the values of measurements by atomic absorption spectroscopy were not pre-

Table 1
Concentrated of total silver in 3 M KCl solution

| Condition | | Concentration of silver |
|---|---|---|
| Temperature (°C) | Chelate resin [a] | |
| 25 | None | 340 mg $l^{-1}$ |
| 80 | None | 700 mg $l^{-1}$ |
| 25 | Added | ND (less than 0.2 mg $l^{-1}$) |
| 80 | Added | ND (less than 0.2 mg $l^{-1}$) |

[a] Model S-1 and Model Z-7 were used effectively.

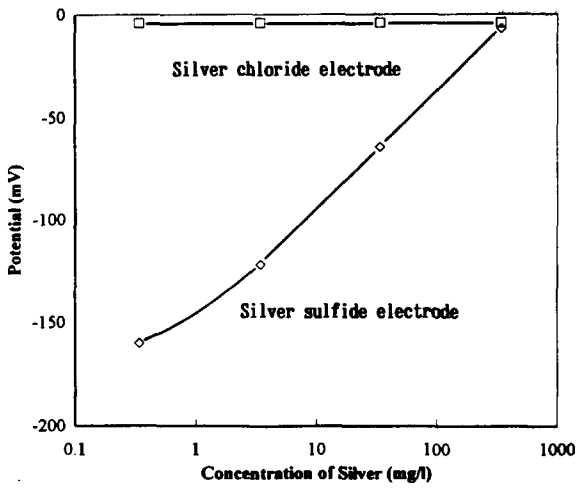

Fig. 1. Relationship between electrode potential and silver ion concentration.

cise, we could estimate the concentration of silver in 3 M KCl solution. The data obtained were sufficiently accurate for the purpose of this experiment.

### 2.4. Elimination of silver in 3 M KCl solution

Silver in 3 M KCl solution exists as $AgCl_x^{-(x-1)}$ complex ions. We tried to use cation ion exchange resin for the adsorption of $Ag^+$ ions, in equilibrium with the chloro-complex. A preliminary simple experiment was tried using several types of ion exchange resin. According to a study on adsorption properties towards heavy metal ions [6], we found that chelating resins were effective at eliminating $Ag^+$ ions in the presence of high concentrations of $K^+$ ions.

### 2.5. Potentiometric measurements of silver in the presence of chelating resin

Silver standard solutions were prepared as follows. Saturated AgCl in 3 M KCl solution at 25°C was used as 340 mg $l^{-1}$ silver standard solution. By ten-fold dilution of this 340 mg $l^{-1}$ silver standard solution with 3 M KCl solution, 34 mg $l^{-1}$ silver standard solution was prepared. In a similar manner, 3.4 mg $l^{-1}$ and 0.34 mg $l^{-1}$ silver standard solutions were prepared. The relationship between potential and silver concentration is shown in Fig. 1. Chloride ion electrodes with AgCl membrane (□) do not respond to silver ion concentration. Silver ion electrodes with $Ag_2S$ membrane (◇) show good Nernstian response. Silver ions in 3 M KCl solution could be measured with a silver ion electrode, but not with a chloride ion electrode.

Chelating resin (10 g was a sufficient amount for eliminating Ag) was added to 100 ml of 3 M KCl solution, the pH of which was adjusted to about 7 with hydrochloric acid or potassium hydroxide. The silver ion electrode potential was initially measured in 100 ml of saturated AgCl in 3 M KCl solution at 25°C. After adding 10 g chelating resin to this solution, the potential was measured periodically every 10 min for 12 h.

### 2.6. Improvement of the structure of the reference electrode

We developed a double junction reference electrode as shown in Fig. 2. The inner chamber is a conventional Ag/AgCl reference electrode, in 3 M KCl solution. The outer chamber is filled with some chelating resin and 3 M KCl solution. The inner chamber is closed, but the outer chamber and the inner chamber are connected through an inner chamber ceramic junction. The 3 M KCl solution in the outer chamber serves to keep the junction more stable. There is a hole in the outer chamber for pressure balance, and to supply 3 M KCl solution. The small amount of silver ions in the 3 M KCl solution that diffuses through the inner chamber ceramic junction is adsorbed by chelating resin. The 3 M KCl solution effusing through the outer chamber ceramic junction does not contain any appreciable amount of dissolved silver.

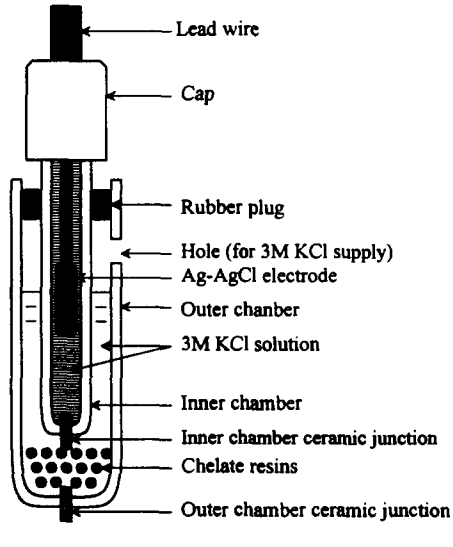

Fig. 2. Structure of long-term stable double junction reference electrode.

## 3. Results and discussion

Two kinds of double junction reference electrodes were prepared. One was placed in a water bath at 25°C, and the other in a water bath at 80°C. As the inner solution of the outer chamber was gradually reduced, 3 M KCl solution was supplied to the initial level periodically. Water in the water bath was often exchanged to maintain low conductivity. Once a month, the silver concentration of the inner solution in the outer chamber was measured by atomic absorption spectroscopy. The measurement was continued for 6 months.

### *3.1. Change in silver concentration of the outer chamber solution*

Depending upon the chelating resin, different results were obtained. In Model CR-10, the silver concentration in the outer chamber solution gradually rose to 10 mg $l^{-1}$ at 25°C and to 50 mg $l^{-1}$ at 80°C over 6 months. In Model MX-8, it was below the detection limits (less than 0.2 mg $l^{-1}$) at 25°C, but gradually rose to 10 mg $l0^{-1}$ at 80°C. In Model Z-7 and Model S-1, it was not detected (less than 0.2 mg $l^{-1}$) at 25°C or 80°C. After 6 months, the rate of effusion of the outer inner solution was measured. In the test reference electrode, in which was observed the existence of dissolved silver in the outer chamber, i.e. in Model CR-10 at 25°C and 80°C and in Model MX-8 at 80°C, the rate of effusion was reduced to one-half or one-quarter of its initial value, and the appearance of the outer chamber ceramic junction changed to brown owing to AgCl. Table 1 shows the concentration of silver in 3 M KCl solution after 6 months measured by atomic absorption spectroscopy. In the case of addition of Model S-1 chelate resin or Model Z-7 chelate resin, silver was not detected. The addition of these chelate resins was very useful for the elimination of silver in the KCl solution.

### *3.2. Eliminating ability with chelating resins*

Fig. 3 shows the eliminating ability of the chelating resins. The silver ion electrode potential decreased gradually with addition of chelating resins, and became constant after 12 h. Final potentials showed 187, 30, 2.4, 0.3 mg $l^{-1}$ $Ag^+$ concentration, respectively, against each chelating resin of Model CR-10, Model MX-8, Model S-1 and Model Z-7. The adsorption ability of chelating resins for $Ag^+$ changed in the order Model Z-7 > Model S-1 > Model MX-8 > Model CR-10. Model Z-7 had the best adsorption power among them.

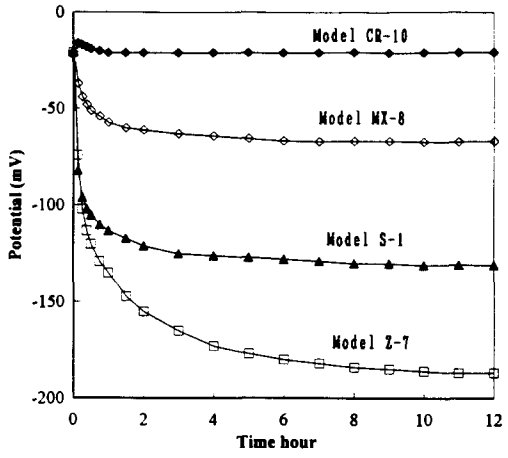

Fig. 3. Eliminating ability of chelate resins.

### *3.3. Application to pH combination electrode*

In Fig. 4, a conventional-type electrode is shown which is the most popular model of a combination pH electrode. It consists of a glass electrode, reference electrode and temperature sensor. To compensate for temperature effects, the glass electrode and reference electrode have similar structures. In addition, an inner junction tube of porous polypropylene resin for improved-type electrodes was added to the inner chamber of the pH and reference electrodes for prevention of diffusion of $Ag^+$ or $AgCl_x^{-(x-1)}$ ions.

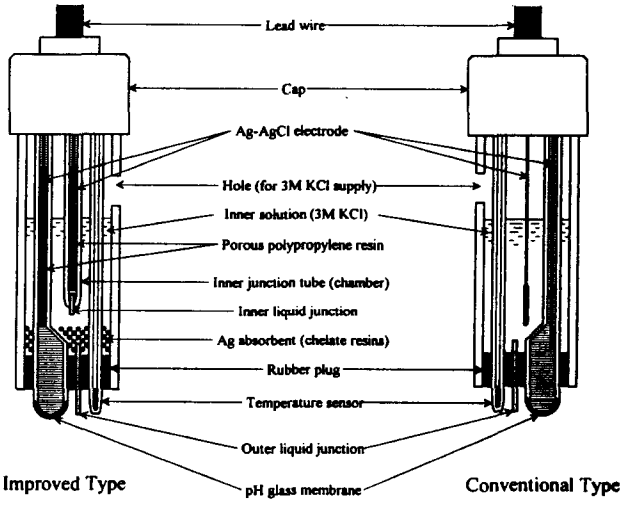

Fig. 4. Comparison of pH electrode structure in improved-type and conventional-type combination electrodes.

Based on the results mentioned above, we improved our conventional-type combination pH electrode as shown in Fig. 4. A double junction-type reference electrode was fabricated. The Ag/AgCl electrode was enclosed in the plastic junction tube, i.e. the inner chamber. The Ag/AgCl electrode was made shorter than in the conventional-type electrode, and was put in the upper part of the improved-type electrode. The distance between the Ag/AgCl electrode and the inner ceramic junction was longer than in the conventional-type electrode. Further, porous polypropylene resin was packed between them. Using this idea, the rate of diffusion of Ag complex ions became slow. As a result, the activation rate of the junction based on Ag was minimized. The silver absorbent, i.e. the chelating resin, was placed in the outer chamber of the reference electrode. Owing to the presence of this chelating resin, silver complex ions were no longer exuded from the outer ceramic junction to the sample solution, and the junction potential became very stable for long periods of time.

### 3.4. Effect of improved pH combination electrode in field test

When a pH electrode is used in a low conductivity solution (less than 0.1 mS $cm^{-2}$), abnormal phenomena in pH measurements, such as errors and fluctuation of pH values, sometimes occur. These phenomena are accelerated when the sample temperature becomes high. Fig. 5 shows an example of measurements in low conductivity solution. There is a remarkable difference between the improved-type pH electrode and the conventional-type pH electrode. The data of continuous pH measurement using the improved-type pH electrode were in fairly good agreement with the pH from the batch sampling method, within $\pm 0.05$ pH units.

When the pH electrode was used in boiler water containing a reductant such as hydrazine in a power plant, some abnormal phenomena in pH measurements occurred, which are shown in Fig. 6. The data of continuous pH measurement using the improved-type pH electrode were again in fairly good agreement with the pH from the batch sampling method, within $\pm 0.02$ pH units. In the case of the conventional-type pH electrode, the observed pH values are generally lower than normal. This error often reaches pH $-0.3$ to $-0.7$.

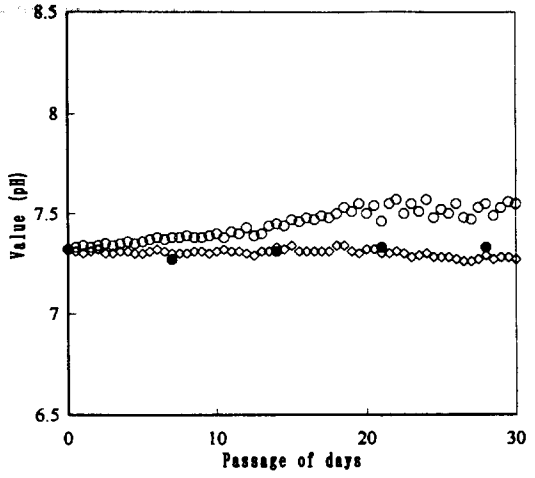

Fig. 5. Example of measurements in a low conductivity solution. The sample is an industrial supply of water (underground water), the electric conductivity of which is about 0.05 mS $cm^{-2}$. Data from the conventional-type pH electrode (○) and improved-type pH electrode (◇) are shown, as well as data from a laboratory pH electrode by the batch sampling method (●). ○ and ◇ are from continuous measurement data, and ● are manual analysis data taken once a week.

### 3.5. Mechanism of deterioration in the Ag/AgCl reference electrode

Although silver chloride is only slightly soluble in water, AgCl is more soluble in concentrated KCl solution than in water. We measured the concentration of silver in 3 M

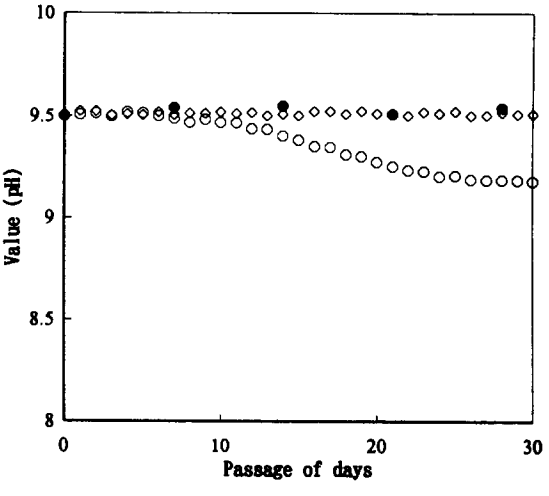

Fig. 6. Example of measurements in boiler water containing several mg $l^{-1}$ hydrazine. The electric conductivity is about 0.01 mS $cm^{-2}$. Data from the conventional-type pH electrode (○) and improved-type pH electrode (◇) are given, as well as data from a laboratory pH electrode by the batch sampling method (●). ○ and ◇ are from continuous measurement data, and ● are manual analysis data taken once a week.

KCl solution, and showed that the solubility was larger by about two orders of magnitude than in water. In 3 M KCl solution, Ag seems to exist as $AgCl_x^{-(x-1)}$ for $x=2$ or 3. The inner solution containing $AgCl_x^{-(x-1)}$ in the reference electrode effuses to the sample solution through the liquid junction. At the surface of the liquid junction, the effused solution is then diluted by the sample solution, and the concentration of KCl becomes lower. Therefore, $AgCl_x^{-(x-1)}$ ions that were soluble in the inner solution revert to AgCl, and AgCl is deposited on the surface of the liquid junction. Silver chloride adheres gradually on the material comprising the liquid junction such as porous ceramic or a glass sleeve. Further, when reductant was present in the sample solution, AgCl was reduced and changed to metallic Ag. The form of silver under some conditions is shown as follows:

$$\underset{\text{(in concentrated KCl solution)}}{AgCl_x^{-(x-1)}} \longrightarrow \underset{\text{(in water)}}{AgCl} \longrightarrow \underset{\text{(after reduction)}}{Ag}$$

The potential of a liquid junction covered with AgCl will be influenced by the $Cl^-$ ion concentration or activity; further, one covered with Ag will be influenced by the redox potential, because the functioning of the reference electrode deteriorates on adhesion of AgCl or Ag at the liquid junction. Some examples of this are as shown in Figs. 5 and 6.

We believe there are various mechanisms by which the inner solution containing $AgCl_x^{-(x-1)}$ is prevented from effusing through the liquid junction. One is that gelation of the inner solution prevents its diffusion or convection, and slows down the movement of $AgCl_x^{-(x-1)}$ from the Ag/AgCl electrode to the sample solution; another is that diffusion is slowed down by a sufficiently long distance between the Ag/AgCl electrode and the liquid junction. Although Brezinski reported a method for eliminating AgCl by mechanical barriers such as cation-selective membrane [4], it is not desirable to create membrane potentials between the Ag/AgCl electrode and the liquid junction in a reference electrode. The use of mechanical barriers seems to provide incomplete elimination of AgCl, resulting in an unnecessary potential or high electrical resistance. We conclude that this method with chelating resins is one of the most practical, because the operational characteristics of the reference electrode are kept stable for long periods of time.

**Abstract**

The kinetic synergistic effect of 1,10-phenanthroline (phen) on the extraction rate of Ni(II) with dithizone (HDz) into chloroform was studied by means of a high-speed stirring method combined with photodiode-array spectrophotometry. The initial extraction rate of the adduct complex $NiDz_2phen$ depended upon the concentrations of both HDz and phen, suggesting the formation of $NiDzphen^+$ as the rate-controlling step. When [HDz] < [phen], the initial extraction of $NiDz_2phen$ competed with the formation of an intermediate complex, which was adsorbed at the interface and assigned most probably to $NiDzphen_2^+$. The intermediate complex was gradually converted to $NiDz_2phen$ at a later stage of the extraction. The rate constants for the formation and consumption of the intermediate were determined, and the kinetic mechanism in the synergistic extraction was discussed.

## 1. Introduction

The kinetics of the solvent extraction of metal complexes has been extensively studied, but further efforts are still required to clarify the dynamics of chemical and physical processes taking place at an interface as well as in bulk phases. Our previous studies employing the high-speed stirring method demonstrated the important role of the liquid–liquid interface in the kinetic mechanisms of chelate extraction and ion-pair extraction [1]. The high-speed stirring method made the best use of stirring a two-phase system by achieving a larger specific interfacial area, as high as 400 $cm^{-1}$, and by promoting mass transfer between the two phases. It was shown in the chelate extraction of Ni(II) and Cu(II) with hydrophobic 2-hydroxyoximes that the interfacial adsorption of the extractants and the formation of a 1:1 complex at the interface were the principal factors determining the kinetic extraction mechanism [2,3]. In the ion-association extraction of Fe(II) with 1,10-phenanthrolines, the interfacial adsorptivity of the Fe(II)–1,10-phenanthroline complexes as well as that of the extractants affected the extraction rates [4].

Our current interest is in the role of the interface in synergistic extraction systems which could be thought of as combinations of the chelate and ion-association extraction systems. Freiser and Freiser reported the synergistic effect of 1,10-phenanthroline (phen) on both the equilibrium and kinetics of the extraction of nickel(II) with dithizone (HDz) [5]. They determined the extraction constants as $\log K_{ex} = -0.7$ and $\log K'_{ex} = 5.3$ for the following extraction reactions respectively:

$$Ni^{2+} + 2HDz_o = NiDz_{2,o} + 2H^+ \quad K_{ex} \qquad (1)$$

$$Ni^{2+} + 2HDz_o + phen = NiDz_2phen_o + 2H^+ \quad K'_{ex} \qquad (2)$$

This synergistic system is advantageous for the photometric determination of Ni(II), because the absorption spectrum of the adduct complex in the organic phase (a maximum at 520 nm) can readily be distinguished from that of HDz (a maximum at 605 nm). Akaiwa et al. reported the accelerating effect of phen on the rate of extraction of Ni(II) with thenoyltrifluoroacetone [6]. However, nothing has been reported on the role of the interface in these synergistic systems.

In the present study, we will assess the role of the interface in the kinetics of extraction of Ni(II) with HDz and phen by means of the high-speed stirring method, which made it possible to monitor the spectral change in the organic phase with the aid of photodiode-array spectrophotometry.

## 2. Experimental

### 2.1. Chemicals

Dithizone, Wako G.R., was purified by a back extraction from its chloroform solution into aqueous ammonia and by subsequent neutralization with sulfuric acid of the aqueous phase. 1,10-Phenanthroline, Wako G.R., was used as purchased. The stock solution of $1.0 \times 10^{-3}$ M nickel(II) was prepared by dissolving nickel(II) sulfate hexahydrate in distilled and deionized water. The pH of the aqueous phase used in the kinetic studies was controlled by 0.006 M acetate buffer and the ionic strength was maintained at 0.1 by sodium sulfate. Chloroform, Wako G.R., was triply washed with an equal volume of water prior to use.

### 2.2. High-speed stirring measurements

The extraction rate of Ni(II) with HDz in the presence or absence of phen was measured by means of the high-speed stirring apparatus. Absorption spectra of the organic phase during the extraction were measured at an acquisition rate of 0.64 or 1.28 s per spectrum in the range of 380–670 nm using a photodiode-array UV/vis detector Shimazu SPD-M6A interfaced with a NEC PC9801 microcomputer.

A typical procedure for the extraction rate measurement was as follows: 45 ml of aqueous buffer solution, and 50 ml of HDz and phen in chloroform were agitated at a stirring rate of 4700 rpm in the glass stir cell. The stirring rate was controllable over the range 200–4700 rpm. The organic phase was continuously separated from the agitated mixture by means of a Teflon phase separator and circulated through a flow cell at a flow rate of 13–16 ml $min^{-1}$ by the Flumax Junior pump. 5 ml of Ni(II) stock solution was injected into the mixture and the extraction of Ni(II) was initiated.

For the measurement of the extraction rate of the pre-formed Ni(II)–phen complex in aqueous phase with HDz, the aqueous phase (50 ml) containing $Ni^{2+}$ and phen was left for 1 h to equilibrate in the stir cell. Chloroform (45 ml) was added and the two phases were stirred for 1 min, and then 5 ml of HDz in chloroform was injected into the mixture to start the extraction.

The rate of reaction between Ni(II) and phen in the aqueous phase was also measured by the high-speed stirring apparatus, making use of the unextractability of the Ni(II)–phen complex ion. A chloroform solution of phen (50 ml) and an aqueous buffer (45 ml) were stirred, and 5 ml of Ni(II) solution was then injected. The decrease in the absorbance of phen in the chloroform phase was recorded as a function of time at the absorption maximum (280 nm).

### 2.3. Stopped-flow measurement

The rate of adduct formation, i.e. the reaction between $NiDz_2$ and phen in chloroform, was measured by the use of the stopped flow spectrophotometer RA-401 (Photal, Japan). The $NiDz_2$ solution, prepared by the extraction of Ni(II) with HDz in chloroform in the presence of excess nickel ion, and the chloroform solution of phen was mixed within 5 ms in a mixing cell. The formation rate of the adduct was measured at 520 nm as a function of time. By the use of Guggenheim analysis, the apparent first-order rate constants for the adduct formation were calculated.

All the kinetic measurements were carried out at $25.0 \pm 0.1$°C.

## 3. Results

### 3.1. Photodiode-array measurements of extraction rates

The extraction rate of Ni(II) with dithizone alone was rather slow, even under the neutral

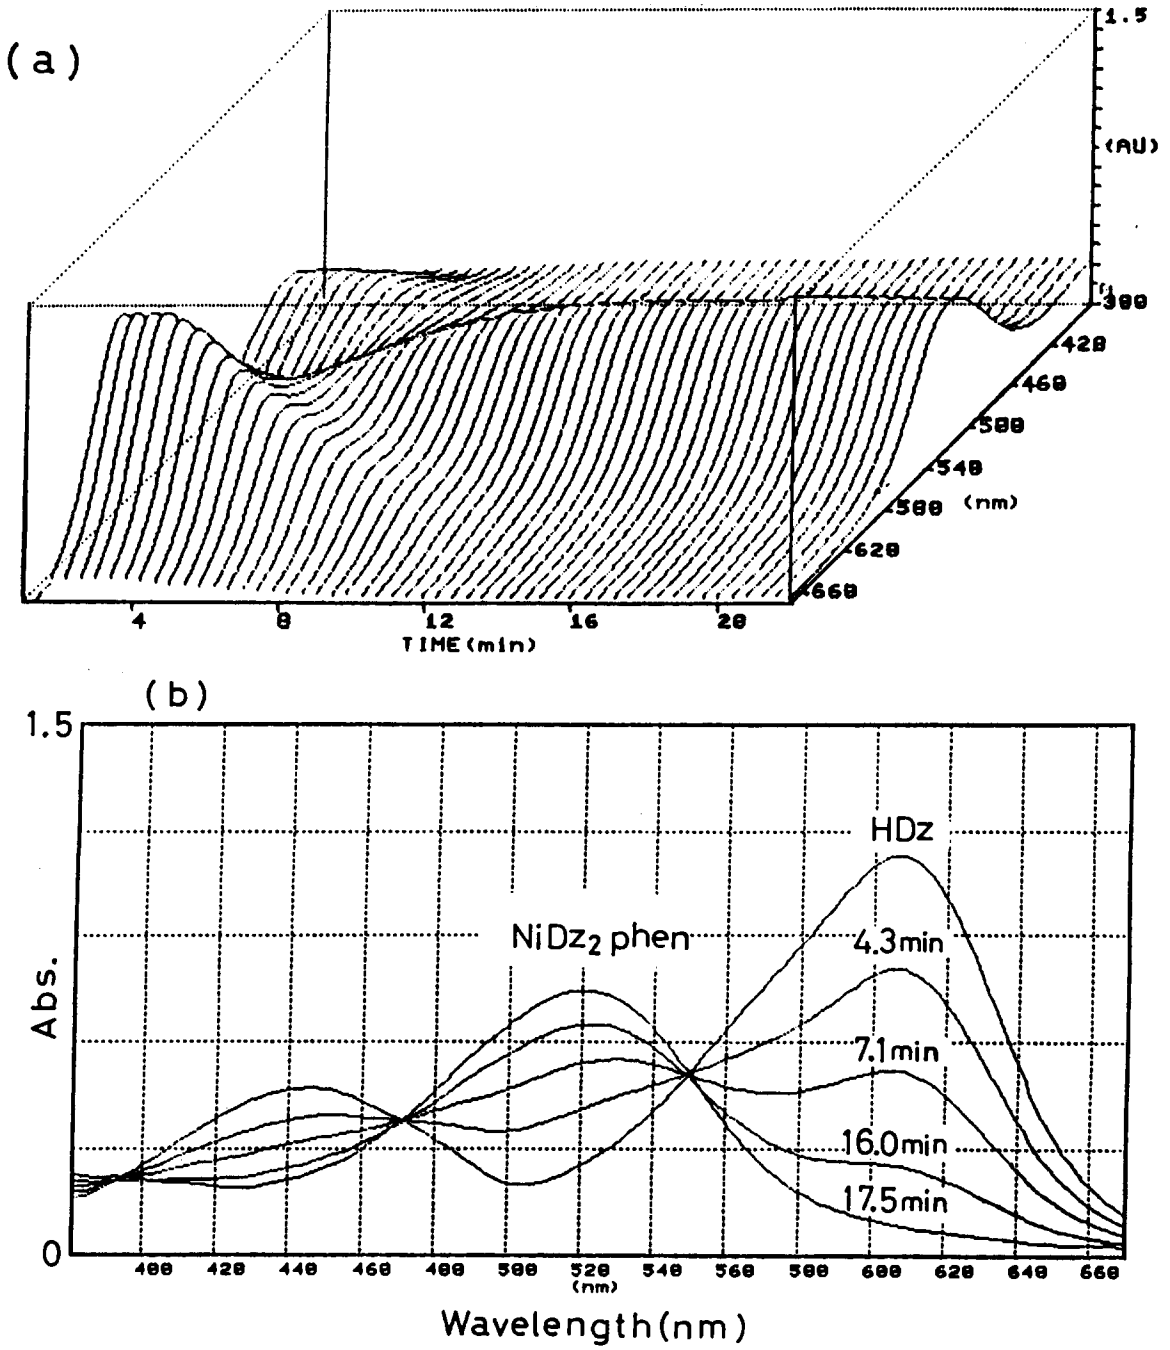

Fig. 1. (a) Three-dimensional representation of the absorbance change in the chloroform phase on the course of the Ni(II) extraction and (b) the spectral change showing isosbestic points; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, [HDz] = $2.99 \times 10^{-5}$ M and [phen] = $4.0 \times 10^{-5}$ M.

conditions (pH = 6–7) and high nickel concentration ($10^{-3}$ M), because of the large distribution constant of HDz, $K_D = 10^{6.4}$ [7], which resulted in an extremely low aqueous HDz concentration. In the presence of phen, the extraction rate of Ni(II) was significantly accelerated, yielding the adduct complex $NiDz_2phen$ in the organic phase. Fig. 1(a) represents the three-dimensional spectral change in the organic phase during the extraction. Soon after the injection of Ni(II) solution, the absorbance of HDz at 605 nm decreases and simultaneously that of the adduct complex at 520 nm increases. When the concentration of phen was

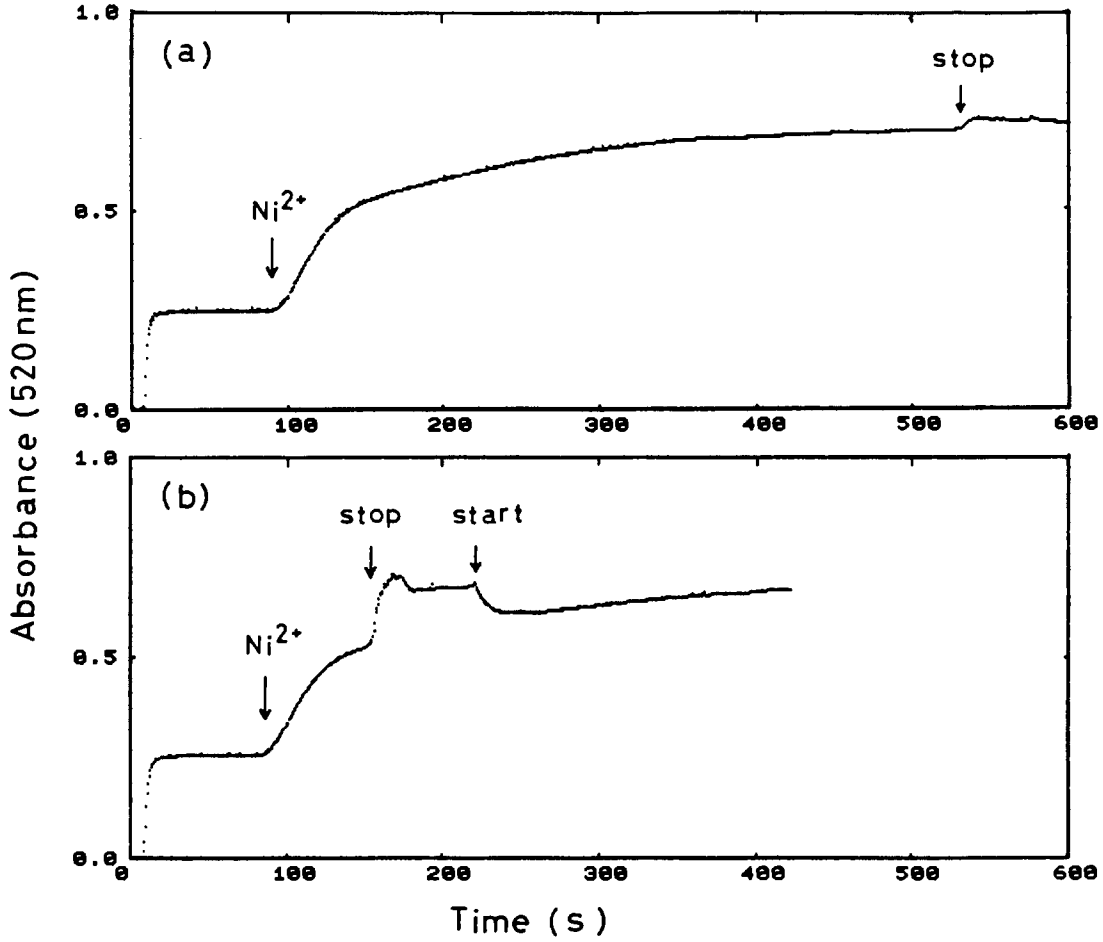

Fig. 2. Profile of the synergistic extraction of Ni(II), in which the stirring (4700 rpm) was stopped (a) at the final stage of the extraction and (b) at the initial stage where an abrupt increase in the absorbance was noticed; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, $[HDz] = 2.99 \times 10^{-5}$ M and $[phen] = 1.0 \times 10^{-3}$ M.

lower than that of HDz, the time-resolved spectra exhibited distinct isosbestic points as shown in Fig. 1(b). The absorbance at 520 nm was monotonously increased, and the rate of increase of the adduct was exactly one-half of rate of decrease of HDz, corresponding to the stoichiometry shown in Eq. (2). In contrast, at a higher concentration of phen than that of HDz, the extraction profile apparently showed two steps, the faster step in the earlier stage and the slower step in the later stage, as seen in Fig. 2(a). In this case, there were no distinct isosbestic points in the time-resolved spectra. Stopping the stirring during the extraction caused an abrupt increase in the organic phase absorbance, and restarting the stirring lowered the abosrbance, as shown in Fig. 2(b). These stirring effects suggested the existence of some Ni(II) complex adsorbing at the liquid–liquid interface.

### 3.2. Initial extraction rates

The extraction rate of Ni(II) with HDz alone was observed at 490 nm, an absorption maximum wavelength of $NiDz_2$ in the chloroform phase. The absorbance of the organic phase at a given wavelength $\lambda$ can be written as

$$A(\lambda) = \varepsilon_\lambda [HDz]_o + \varepsilon'_\lambda [NiDz_2]_o \quad (3)$$

where $\varepsilon_\lambda$ and $\varepsilon'_\lambda$ are the molar absorptivities of HDz and $NiDz_2$ in chloroform respectively, and the subscript "o" refers to the concentration in the organic phase. Hence, the rate of change of absorbance can be written as

$$dA(\lambda)/dt = \varepsilon_\lambda d[HDz]_o/dt + \varepsilon'_\lambda d[NiDz_2]_o/dt \quad (4)$$

Thus, the initial extraction rate of $NiDz_2$ defined by $(d[NiDz_2]_o/dt)_{t=0}$ was obtained by the next equation, taking into account the spectral overlap of $NiDz_2$ and HDz:

$$\begin{vmatrix}(dA(490)/dt)_{t=0}\\(dA(605)/dt)_{t=0}\end{vmatrix} = \begin{vmatrix}\varepsilon_{490} & \varepsilon'_{490}\\ \varepsilon_{605} & \varepsilon'_{605}\end{vmatrix} \times \begin{vmatrix}(d[NiDz_2]_o/dt)_{t=0}\\(d[HDz]_o/dt)_{t=0}\end{vmatrix} \quad (5)$$

where $(dA(490)/d)_{t=0}$ and $(dA(605)/dt)_{t=0}$ are the initial rates in the absorbance changes at 490 nm and 605 nm respectively, and the molar absorptivities in chloroform are $\varepsilon_{490} = 2.8 \times 10^4$ and $\varepsilon_{605} = 7.8 \times 10^3$ for $NiDz_2$, and $\varepsilon'_{490} = 1.8 \times 10^4$ and $\varepsilon'_{605} = 3.6 \times 10^4$ for HDz. The rate-determining step in the extraction of $NiDz_2$ has been reported as the formation of $NiDz^+$ in the aqueous phase [7,8]:

$$Ni^{2+} + Dz^- \rightarrow NiDz^+ \qquad k_0 \quad (6)$$

In the aqueous reaction regime, the initial extraction rate can be represented by

$$(d[NiDz_2]_o/dt)_{t=0} = k_0 K_a [Ni^{2+}][HDz]_o / K_D[H^+] \quad (7)$$

where $k_0$ and $K_a$ refer to the formation rate constant of $NiDz^+$ in the aqueous phase and the dissociation constant of HDz respectively. Hence, the value $(d[NiDz_2]_o/dt)_{t=0} = 6.00 \times 10^{-8}\ M^{-1}\ s^{-1}$ obtained in the present study, under the conditions $[HDz] = 3.6 \times 10^{-5}$ M, $[Ni^{2+}] = 1.0 \times 10^{-3}$ M and pH 7.1–7.6, gave the value of $k_0 = 5.97 \times 10^3\ M^{-1}\ s^{-1}$ using $K_a/K_D = 10^{-10.21}$ [7].

The initial extraction rate of $NiDz_2phen$ can also be represented by an equation analogous to Eq. (5):

$$\begin{vmatrix}(dA(520)/dt)_{t=0}\\(dA(605)/dt)_{t=0}\end{vmatrix} = \begin{vmatrix}\varepsilon_{520} & \varepsilon''_{520}\\ \varepsilon_{605} & \varepsilon''_{605}\end{vmatrix} \begin{vmatrix}(d[NiDz_2phen]_o/dt)_{t=0}\\(d[HDz]_o/dt)_{t=0}\end{vmatrix} \quad (8)$$

where $\varepsilon''$ denotes the molar absorptivity of $NiDz_2phen_o$ in the chloroform phase. From Eq. (8), the initial extraction rate $r^0$ was derived as

$$r^0 = (d[NiDz_2phen]_o/dt)_{t=0} = 2.06 \times 10^{-5}\{[dA(520)/dt]_{t=0} - 0.224[dA(605)/dt]_{t=0}\} \quad (9)$$

where the numerical coefficients were calculated from the molar absorptivities at 520 nm and 605 nm for each of HDz and $NiDz_2phen$. The values of $r^0$ thus obtained depended on the concentrations of HDz, phen and pH, as shown in Figs. 3–5 respectively. The stirring speed was also one of the factors governing the initial extraction rate. For example, the observed initial rate, $r^0_{obs}(520) = (dA(520)/dt)_{t=0}$, increased with the stirring speed in the region 1000–3000 rpm, and reached a constant value in the region 4000–5000 rpm; thus, 4700 rpm was adopted for the kinetic measurements.

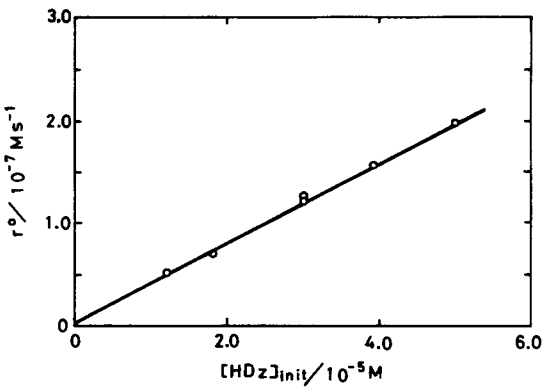

Fig. 3. Dependence of the initial extraction rate on HDz concentration; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, [phen] = $1.0 \times 10^{-4}$ M, pH = 6.7.

When the aqueous phase containing both Ni(II) and phen was mixed with the chloroform solution of HDz, the initial extraction rate of the adduct complex was remarkably increased even at a phen concentration lower than $10^{-4}$ M, as shown in Fig. 6. At a phen concentration higher than $2 \times 10^{-4}$ M, it was reduced to a constant value independent of the phen concentration.

### 3.3. Formation rate of the Ni(II)–phen complex

The rate of consumption of phen in the chloroform phase with Ni(II) in the aqueous phase was measured at 280 nm by means of the

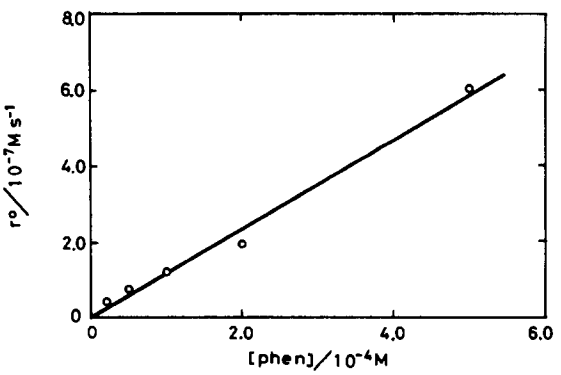

Fig. 4. Dependence of the initial extraction rate on phen concentration; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, [HDz] = $5.88 \times 10^{-5}$ M, pH 6.4.

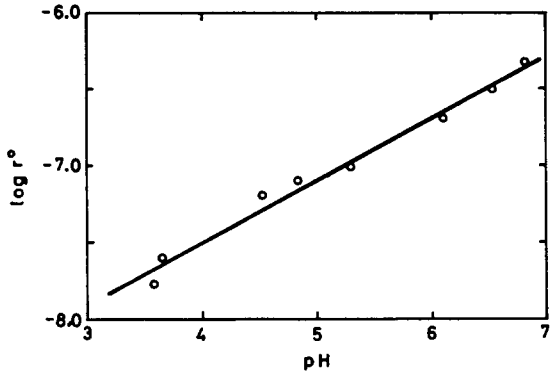

Fig. 5. pH dependence of the initial extraction rate; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, $[HDz] = 3.00 \times 10^{-5}$ M and $[phen] = 1.0 \times 10^{-3}$ M.

high-speed stirring method, in order to obtain the rate constant between Ni(II) and phen in the aqueous phase. The observed initial consumption rate of phen, $r^0_{obs}$, was linearly proportional to the total phen concentration $[phen]_T$, as shown by

$$r^0_{obs} = 4.21[phen]_T + 3.06 \times 10^{-5}$$
$$\text{(correlation coefficient} = 0.998) \qquad (10)$$

### 3.4. Adduct formation rate in chloroform

The observed formation rate constants of the adduct in chloroform were linearly proportional to each concentration of $NiDz_2$ and phen, as expected from the equation

$$NiDz_{2,o} + phen_o \rightarrow NiDz_2phen_o \qquad (11)$$

From the observed first-order rate constants at 520 nm, the rate constant for reaction (11) was determined as $(1.74 \pm 0.05) \times 10^5$ $M^{-1}$ $s^{-1}$, as given in Table 1.

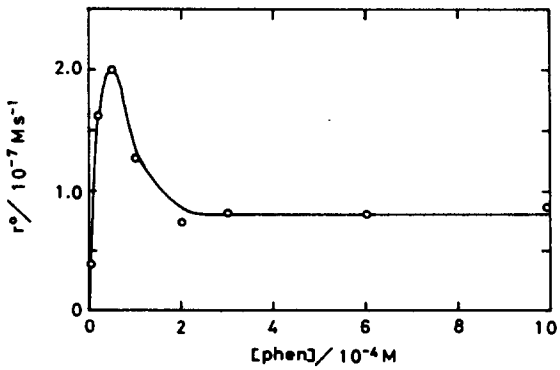

Fig. 6. Initial extraction rates of Ni(II) from the aqueous phase including pre-equilibrated $Ni^{2+}$–phen complexes; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, $[HDz] = 3.00 \times 10^{-5}$ M, pH 6.50 and 4700 rpm.

## 4. Discussion

### 4.1. Reaction between Ni(II) and phen in the aqueous phase

The linear relationship of Eq. (10) can be interpreted by the following reactions:

$$phen \rightleftharpoons phen_o \qquad K_{DL} \qquad (12)$$

$$Ni^{2+} + phen \rightarrow Niphen^{2+} \qquad k_1 \qquad (13)$$

The observed initial rate can then be represented by

$$r^0_{obs} = \frac{\varepsilon_L l k_1}{1 + K_{DL}} [Ni^{2+}]_{init}[phen]_T \qquad (14)$$

where $\varepsilon_L$, $l$, $k_1$ and $K_{DL}$ refer to the molar absorbtivity of phen in the organic phase, the optical length of the flow cell, the formation rate constant of $Niphen^{2+}$ and the distribution constant of phen respectively, and $[Ni^{2+}]_{init}$ is the initial concentration of free $Ni^{2+}$ in the aqueous phase. Therefore, the coefficient 4.21 in Eq. (10) corresponds to $\varepsilon_L k_1 [Ni^{2+}]_{init}/(1 + K_{DL})$. The values of $\varepsilon_L$ and $K_{DL}$ were previously determined as $3.49 \times 10^3$ and 723 [9], and the value of $[Ni^{2+}]_{init}$ was calculated as $1.29 \times 10^{-4}$ M from the total $Ni^{2+}$ concentration of $1.0 \times 10^{-3}$ M and the total $SO_4^{2-}$ concentration of 0.033 M, taking into account the formation constant of 209 [10] for the following reaction:

$$Ni^{2+} + SO_4^{2-} \rightleftharpoons NiSO_4 \qquad (15)$$

Finally, the value of $k_1$ was calculated as $6.79 \times 10^3$ $M^{-1}$ $s^{-1}$, which is fairly comparable with the values available in the literature, $1.4 \times 10^4$ $M^{-1}$ $s^{-1}$ [11] and $3.9 \times 10^3$ $M^{-1}$ $s^{-1}$ [12].

### 4.2. Formation of an intermediate complex at the interface

Under the condition $[HDz] < [phen]$, the decreasing rate of $[HDz]_o$ became larger than twice the increasing rate of $[NiDz_2phen]_o$. This implies that the total concentration of HDz in the organic phase, $[HDz]_o + 2[NiDz_2phen]_o$, is less than the initial concentration of HDz in the organic phase before contact with the aqueous phase. When the stirring was stopped during the extraction, an abrupt increase in the organic phase concentration of the adduct complex was observed. These facts suggest the existence of some interfacially adsorbed Ni(II) species which includes at least one molecule of

Table 1
The reaction rate constant between $NiDz_2$ and phen in chloroform at 25°C [a]

| No. | Concentration | | $k_{obs}$ ($s^{-1}$) | $k$($M^{-1}$ $s^{-1}$) |
|---|---|---|---|---|
| | $NiDz_2$ (M) | phen (M) | | |
| 1 | $6.58 \times 10^{-6}$ | $5.0 \times 10^{-5}$ | 8.15 | $1.63 \times 10^5$ |
| 2 | $6.58 \times 10^{-6}$ | $5.0 \times 10^{-4}$ | 85.4 | $1.71 \times 10^5$ |
| 3 | $3.32 \times 10^{-6}$ | $2.5 \times 10^{-4}$ | 41.9 | $1.68 \times 10^5$ |
| 4 | $3.32 \times 10^{-6}$ | $5.0 \times 10^{-5}$ | 9.33 | $1.87 \times 10^5$ |
| 5 | $1.33 \times 10^{-6}$ | $5.0 \times 10^{-6}$ | 0.909 | $1.82 \times 10^5$ |
| Average | | | | $(1.74 \pm 0.05) \times 10^5$ |

[a] Measured by the stopped-flow method.

dithizone. According to this assumption, the total concentration of HDz in the two-phase system can be represented by

$$[HDz]_T = [HDz]_o + 2[NiDz_2phen]_o + [INT]A_i/V_o \quad (16)$$

where [INT], $A_i$ and $V_o$ stand for the interfacial concentration of the adsorbed complex (mol $cm^{-2}$), the total interfacial area ($cm^2$) and the volume of the organic phase (l) respectively. The absorbance changes at 605 nm and 520 nm allowed calculation of the concentration of each species on the right hand side of Eq. (16) as a function of time. Fig. 7 shows typical examples of the calculated concentration changes of the three species at lower and higher concentrations of phen than that of HDz. At a higher concentration of phen, the formation of the interfacial complex and its slow conversion to the adduct complex $NiDz_2phen$ are clearly demonstrated.

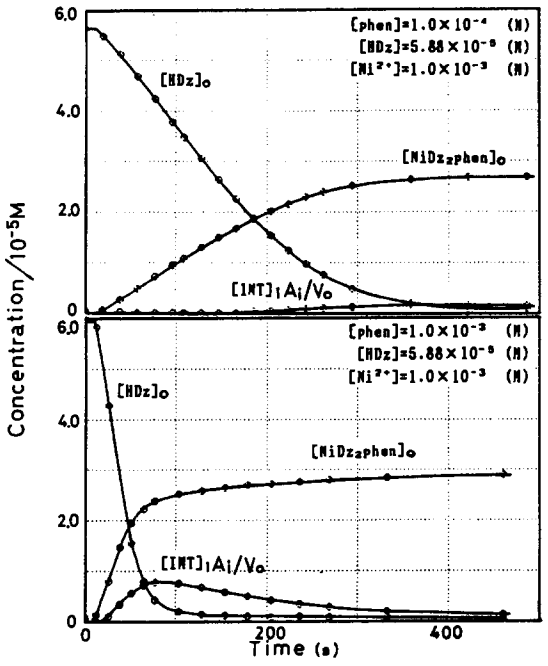

Fig. 7. Calculated changes in $[HDz]_o$, $[NiDz_2phen]_o$ and $[INT]_iA_i/V_o$ during the course of the extraction.

The change in the interfacial complex concentration calculated by Eq. (16) has been analyzed by a non-linear least-squares procedure based on the Marquardt method [13]:

$$[INT]A_i/V_o = c_1k_1'(k_2' - k_1')^{-1} \times \{\exp[-k_1'(t + c_2)] - \exp[-k_2'(t + c_2)]\} \quad (17)$$

where $c_1$ and $c_2$ are constants, and $k_1'$ and $k_2'$ refer to the apparent rate constants for the increase and decrease of the interfacial complex respectively. The four parameters, $c_1$, $c_2$, $k_1'$ and $k_2'$, were optimized until the sum of the squared difference between the calculated and observed values for $[INT]A_i/V_o$ could be minimized.

Fig. 8 shows a typical fitting curve for the concentration change of the interfacial complex. The differentiation of Eq. (17) with respect to $t$ at $t = -c_2$ gave an expression for the initial formation rate of the interfacial complex, $r^{0'}$:

$$r^{0'} = \left(\frac{d[INT]A_i/V_o}{dt}\right)_{t=0} = c_1k_1' \quad (18)$$

The values of $r^{0'}$ depended linearly on the HDz concentration, while those of $k_2'$ were independent of HDz concentration, as shown in Fig. 9. An average value of $k_2'$ of $3.1 \times 10^{-3}$ $s^{-1}$ was obtained. These results suggest that $r^{0'}$ most probably reflects the interfacial complexation:

$$Niphen_2^{2+} + Dz^- \rightarrow NiDzphen_2^+ \quad (19)$$

because the predominant species in the aqueous phase is $Niphen_2^{2+}$, as described be-

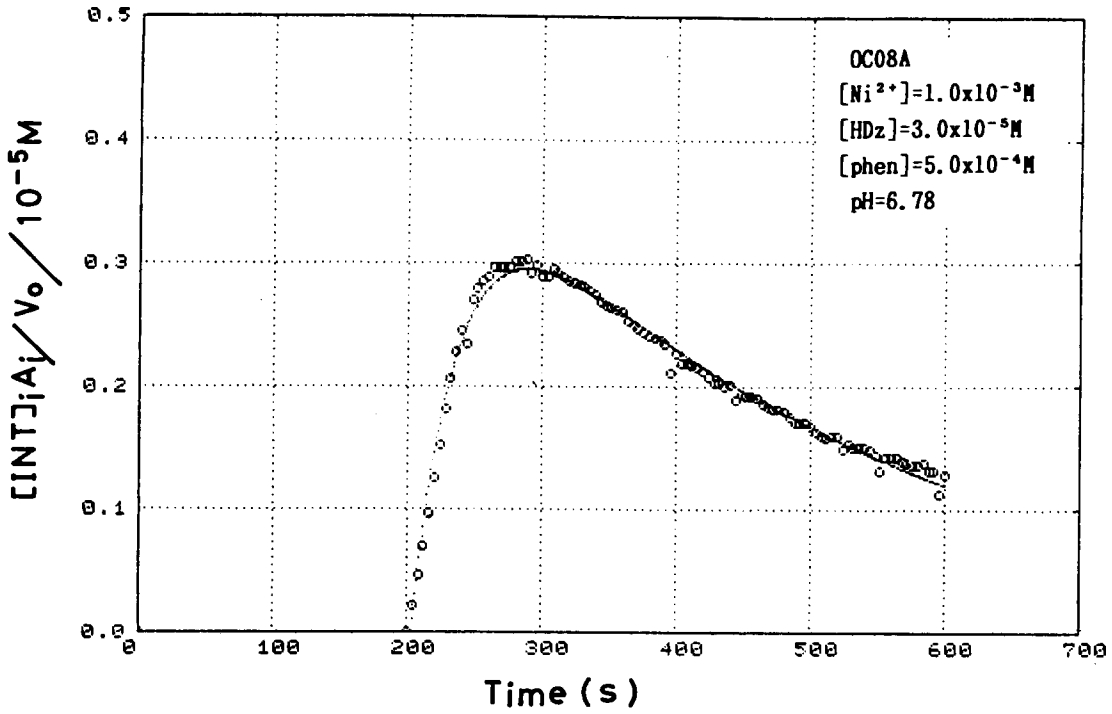

Fig. 8. Non-linear regression analysis of the concentration change of the interfacial complex; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, $[HDz] = 3.00 \times 10^{-5}$ M, [phen] = $5.0 \times 10^{-4}$ M, pH 6.78.

low. $k'_2$ is ascribable to the first-order dissociation reaction of the interfacial complex:

$$NiDzphen_2^+ \rightarrow NiDzphen^+ + phen \quad (20)$$

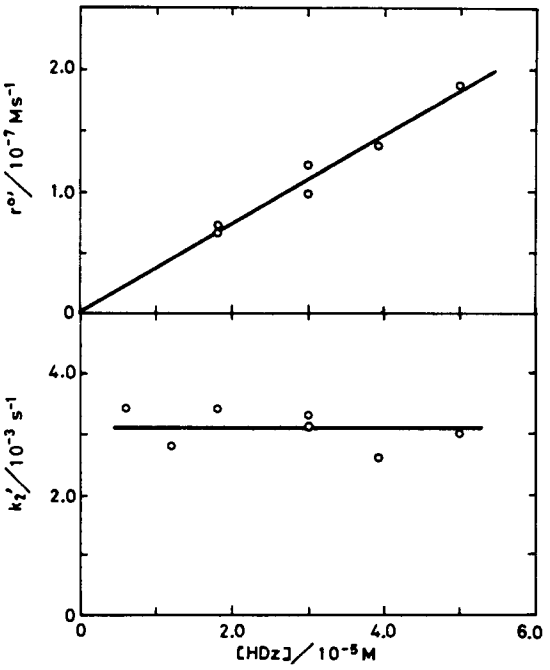

Fig. 9. Dependences of $r^0$ and $k'_2$ on HDz concentration; $[Ni^{2+}] = 1.0 \times 10^{-3}$ M, [phen] = $5.0 \times 10^{-4}$ M, pH 6.52–6.78.

which leads to the formation of $NiDz_2phen$. The overall conversion of $NiDzphen_2^+$ to $NiDz_2phen$ is represented by a disproportionation reaction:

$$2\ NiDzphen_2^{2+} \rightarrow NiDz_2phen + Niphen_3^{2+} \quad (21)$$

The extraction rate of $NiDz_2phen$ from the aqueous solution containing Ni(II)–phen complexes with the chloroform solution of HDz gave further insight into the composition of the interfacial species. As noticed in Fig. 6, there was no phen concentration dependence on the initial extraction rate in the higher concentration range of [phen] > $2 \times 10^{-4}$ M, showing the constant value of $r^0 = 7.7 \times 10^{-8}\ M^{-1}\ s^{-1}$. The calculation of each concentration of $Niphen^{2+}$, $Niphen_2^{2+}$ and $Niphen_3^{2+}$ in the aqueous phase using the corresponding formation constants [14] revealed that the concentrations of $Niphen^{2+}$ and $Niphen_2^{2+}$ are comparable when [phen] > $2 \times 10^{-4}$ M, while at phen concentrations below $2 \times 10^{-4}$ M, $Niphen^{2+}$ is the predominant species. Thus, it can be reasonably expected that when [phen] = $2 \times 10^{-4}$–$1 \times 10^{-3}$ M, the adsorbed complex $NiDzphen_2^+$ is rapidly formed through Eq. (19) and converts slowly to $NiDz_2phen_o$. The constant value of the initial extraction rate shown in Fig. 6 can therefore be related to $k'_2$ by the equation $r^0 = k'_2[INT]A_i/V_0$. Thus, $k'_2 = 3.5 \times 10^{-3}\ s^{-1}$

was determined from the values of $r^0 = 7.7 \times 10^{-8}\ M^{-1}\ s^{-1}$ and $[INT]A_i/V_0 = 2.2 \times 10^{-5}$ M calculated from Eq. (16). The value $3.5 \times 10^{-3}\ s^{-1}$ is in good agreement with $3.1 \times 10^{-3}\ s^{-1}$ obtained from the decreasing rate of $[INT]A_i/V_0$. These results strongly support the mechanism proposed herein.

### 4.3. Kinetic scheme of the synergic extraction

The first step of the extraction should be the reaction of $Ni^{2+}$ with $Dz^-$ and/or phen in the aqueous phase, i.e. Eqs. (6) and (13). The rate constants for the two processes in the aqueous phase are comparable: $k_0 = 5.97 \times 10^3\ M^{-1}\ s^{-1}$ for Eq. (6) and $k_1 = 6.79 \times 10^3\ M^{-1}\ s^{-1}$ for Eq. (13). Therefore, the relative significance of the two processes will be determined by the initial aqueous phase concentrations of $Dz^-$ and phen. The calculated concentrations using the values of $K_{DL}$ and $K_a/K_D$ are $[Dz] = 2.0 \times 10^{-8}$ M and $[phen] = 1.4 \times 10^{-7}$ M, provided that the initial concentrations for $[HDz]_o$ and $[phen]_o$ are $1.0 \times 10^{-4}$ M at pH 6.5. In this situation, reaction (13) will proceed in preference to reaction (6) by a factor of 70.

$Niphen^{2+}$ will further react with $Dz^-$ and phen according to the following competitive reactions:

$$Niphen^{2+} + Dz^- \rightarrow NiDzphen^+ \quad k_2 \qquad (22)$$

$$Niphen^{2+} + phen \rightarrow Niphen_2^{2+} \quad k_3 \qquad (23)$$

Reaction (22) may be responsible for the formation of the adduct complex to be extracted, while reaction (23) can become significant when [HDz] < [phen], leading to the formation of the interfacial complexes, $NiDzphen_2^+$ and $Niphen_3^{2+}$ [9]:

$$Niphen_2^{2+} + Dz^- \rightarrow NiDzphen_2^+ \quad k_4 \qquad (24)$$

$$Niphen_2^{2+} + phen \rightarrow Niphen_3^{2+} \qquad (25)$$

According to Eqs. (6), (13) and (22)–(24), the initial extraction rate of $NiDz_2phen$ and the initial formation rate of the interfacial complex are respectively represented by

$$r^0 = \left(\frac{d[NiDz_2phen]_o}{dt}\right)_{t=0} = \frac{k_1 k_2 [Ni^{2+}][phen][Dz^-]}{k_{-1} + k_2[Dz^-] + k_3[phen] - \alpha} \qquad (26)$$

and

$$r^{0'} = \left(\frac{d[INT]A_i/V_o}{dt}\right)_{t=0} = \frac{k_1 k_3 k_4 [Ni^{2+}][phen][Dz^-]}{(k_{-1} + k_2[Dz^-] + k_3[phen] - \alpha)(k_{-3} + k_4[Dz^-])} \qquad (27)$$

where $k_{-1}$ and $k_{-3}$ are the rate constants for the reverse reactions of Eqs. (13) and (23) respectively, $\alpha = k_3 k_{-3}[phen]/(k_{-3} + k_4[Dz^-])$, $[Dz^-] = K_a[HDz]_T/K_D[H^+]$ and $[phen] = [phen]_T/723$. The plots of Fig. 3 confirmed the linear correlation between $r^0$ and $[Dz^-]$, which was predicted from Eq. (26) under the condition $k_{-1} + k_2[Dz^-] - \alpha \ll k_3[phen]$ and gave the value $k_2 = 1.1 \times 10^5\ M^{-1}\ s^{-1}$ by introducing $k_1 = 6.79 \times 10^3\ M^{-1}\ s^{-1}$ and $k_3 = 7.4 \times 10^3\ M^{-1}\ s^{-1}$ [11]. When $k_{-1} + k_3[phen] - \alpha \ll k_2[Dz^-]$, Eq. (26) can be approximated by $r^0 = k_1[Ni^{2+}][phen]$. Fig. 4 confirmed the linear relation between $r^0$ and [phen], and gave a value of $k_1 = 6.57 \times 10^3\ M^{-1}\ s^{-1}$, which was fairly close to $k_1 = 6.79 \times 10^3\ M^{-1}\ s^{-1}$ determined by the separate experiment. The pH dependence of $r^0$, giving a slope of 0.40 as shown in Fig. 5, was different from the inverse first-order behavior expected from Eq. (26). This may be ascribable to the difference between the pH near the interface and the bulk pH [15]. Eq. (27) predicts that the initial formation rate of the interfacial complex is proportional to [phen], provided $k_2[Dz^-] \ll k_3[phen]$. Experimental results indeed supported the linear relationship, suggesting $k_1$ to be in the order of $10^3\ M^{-1}\ s^{-1}$.

In conclusion, the existence of the intermediate complex formed at the liquid–liquid interface was proved in the present study and the kinetic features of the interfacial complex were revealed. It was also shown by this study that even thermodynamically unfavorable complexes in homogeneous solutions could be formed in appreciable amounts at the liquid–liquid interface. The formation of charged complexes such as $NiDzphen_2^+$ at the interface may be of relevance to the response mechanism in the liquid–membrane ion-selective electrodes [16]. Further studies on the kinetics and equilibria in the interfacial complex formation with other extractants are in progress.

Received 25 October 1994; revised 13 February 1995, accepted 5 May 1995

**Abstract**

During investigation of the formation of $Cu^{2+}$ ion complexes with *N,N,N′,N′*-tetrakis-(2-hydroxypropyl)-ethylenediamine (Quadrol-Q) by means of constant current polarography (20°C, ionic strength $J = 3$ mol $l^{-1}$), the possibility of the formation of two complex compounds; $CuQ^{2+}$ and $CuQ_2^{2+}$, was shown within the pH range from 6 to 8. The logarithms of the stability constants for these compounds are $10.6 \pm 0.3$ and $14.6 \pm 0.4$ respectively. Cu(II) complexation increases sharply when the pH increases from 8 to 10. It was shown that the data at a pH of greater than 10 are in accordance with the existence of the hydroxy complexes $CuQ(OH)_2$ and $CuQ_2(OH)_2$, the logarithms of the stability constants being $26.9 \pm 0.5$ and $29.1 \pm 0.3$.

*Keywords:* Copper; Complexation; Polarography

## 1. Introduction

*N,N,N′,N′*-tetrakis-(2-hydroxypropyl)-ethylenediamine, which is also known as Quadrol, is widely used as a ligand in solutions of electroless copper plating [1,2]. There is little information about Cu(II) complexes with Quadrol in the literature. The authors of Ref. [3] have investigated the formation of the above complex by means of spectrophotometric, conductometric and pH-metric titration methods. They have determined that Quadrol forms complexes with Cu(II) ions in the ratio 1:1 and the stability constant logarithm is approximately 9. The authors of Ref. [4] identified the same complex with a stability constant logarithm of 8.45 (25°C, $J = 0.1$) when the pH-metric titration method was used. Only the authors of Ref. [5] detected the presence of $CuQ_2^{2+}$ complex ($\log \beta = 13.6$, 25°C, $J = 0.5$) besides the $CuQ^{2+}$ complex ($\log \beta = 9.80$). As can be seen from the literature, it is not quite clear whether the diligand complex $CuQ_2^{2+}$ really exists. Further, based on the data of the stability of the known complexes, it is not at all clear how the alkaline solutions of electroless copper plating can exist when Quadrol is used as a ligand for Cu(II) ions. The calculations show that $Cu(OH)_2$ should precipitate in solutions with a pH value exceeding 8–9. Apparently, Quadrol forms more stable complexes with Cu(II) in alkaline solutions.

Therefore, this work describes the investigation of Cu(II) complex formation with Quadrol by means of the DC-polarographic method which has not been used for this system before.

## 2. Experimental

$NaNO_3$ and NaOH were used to keep the ionic strength of the solutions constant, and the pH of the solutions was controlled using aqueous

* Corresponding author.

*SSDI* 0039-9140(95)01635-X

NaOH and $HNO_3$. Analytical grade chemicals were used, and Quadrol was of a practical grade (over 98%) from Fluka.

The polarographic curves were recorded by a PU-1 polarograph (Belorusia) using a dropping mercury electrode in a thermostatted three-electrode cell at $20 \pm 0.1$°C. The potential scanning rate was 100 mV $min^{-1}$, and the capillary characteristics were $m = 2.95$ mg $s^{-1}$, $t = 3.73$ s. The reference electrode was a silver–silver chloride electrode with saturated KCl solution. The total concentration of Cu(II) ions was $5 \times 10^{-4}$ mol $l^{-1}$.

The slope of the dependence $\log(\bar{i}/\bar{i}_{lim} - \bar{i}) - E$ for Cu(II) polarographic waves is equal to 35–38 mV, i.e. the waves are quasireversible. The values of the reversible half-wave potential $E^r_{1/2}$ were determined within $\pm 1$ mV from the plots of $\log(\bar{i}/\bar{i}_{lim} - \bar{i}) - E$ using the method of quasireversible polarographic waves of Matsuda and Ayabe [6].

The values of the reversible half-wave potential were used for calculations of parameters of copper complexes by equations from Ref. [7]. On the grounds of experimental dependencies of $E^r_{1/2}$ on pH and total Quadrol concentration, we assumed that the complexes $CuQ_n(OH)_m^{2-m}$, where $n = 1,2$ and $m = 0–4$, could be formed in the solution under investigation. The possibility of complex formation with protonated Quadrol $HQ^+$ — $Cu(HQ)^{3+}$, $CuQ(HQ)^{3+}$, $Cu(QH)_2^{4+}$ — was also considered. The stability constants of copper complexes were obtained during iterative approximation by minimizing the least squares functional, obtained from equations published in Ref. [7]. To estimate the accuracy of the stability constants we made an assumption that the determination of the reversible half-wave potential was within $\pm 2$ mV. If in the next iteration the accuracy of any stability constant diverges to infinity, then deletion of such a complex from the functional has no influence on the least-squares sum. In this case we assume that such a complex does not exist under these conditions.

## 3. Results and discussion

### 3.1. Quadrol protonation

Usually, unprotonated Quadrol molecules form complexes with $Cu^{2+}$ [3–5]. Since we found no information about Quadrol protonation constants under the conditions of our work at 20°C when $J = 3$ mol $l^{-1}$, we carried out a series of pH-metric titrations of Quadrol solutions at different ionic strengths. The first and the second protonation constants were calculated according to Ref. [8] (Fig. 1). The values $\log K_1 = 9.5 \pm 0.1$ and $\log K_2 = 5.0 \pm 0.1$ were used for further treatment of the polarographic data obtained at $J = 3$.

### 3.2. Solutions at pH < 8

We carried out several series of experiments with different concentrations of Quadrol and at different pH values in solutions of pH = 5–8, which had been investigated earlier by other authors. As can be seen from the results obtained (Fig. 2(a)), with an increase in the pH of the solutions and an increase in the total Quadrol concentration, $E^r_{1/2}$ is shifted to more negative potential values. $\Delta E_{1/2}$ changes by 30–45 mV on a 10-fold increase of the total Quadrol concentration at constant pH. This shows that one or two Quadrol molecules can participate in the complex formation when a one-step two-electron discharge of copper ions occurs. When the total Quadrol concentration is constant, an increase in the pH of the solution by one unit shifts $\Delta E^r_{1/2}$ to more negative values by 45–50 mV. This also confirms that one or two Quadrol molecules take part in the complex formation, since the equilibrium concentration of unprotonated Quadrol increases 10-fold with one pH unit in this region.

When minimising the least-squares functional, it was shown that the data are in accor-

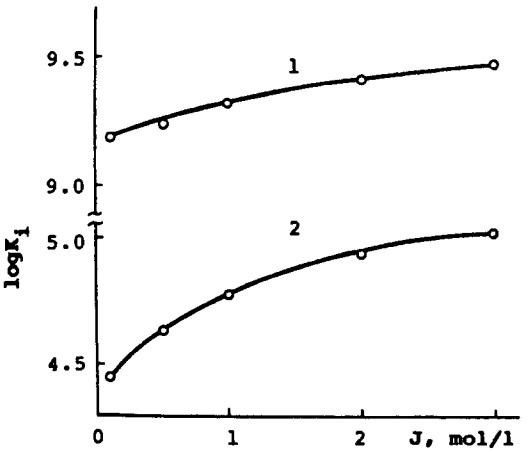

Fig. 1. Dependence of the first (curve 1) and second (curve 2) Quadrol protonation constants on the solution ionic strength.

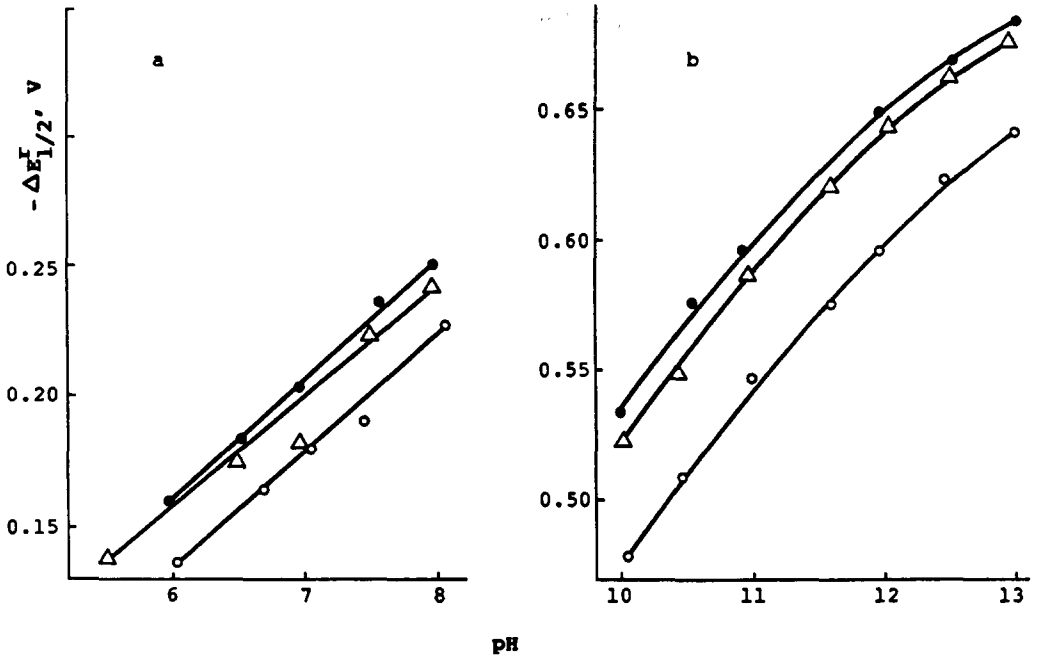

Fig. 2. Dependence of the reversible half-wave potential shift ($\Delta E^r_{1/2}$) on pH. The total Cu(II) concentration is $5 \times 10^{-4}$ mol $l^{-1}$, and the total Quadrol concentrations are $5 \times 10^{-3}$ (○), $2.5 \times 10^{-2}$ (△) and $5 \times 10^{-2}$ (●) mol $l^{-1}$.

dance with the existence of the complexes $CuQ^{2+}$ and $CuQ_2^{2+}$, the stability constant logarithms being $10.6 \pm 0.3$ and $14.6 \pm 0.4$. These values are slightly higher than the literature data, which may be explained by the influence of high ionic strength.

The characteristics of Cu(II) complexes obtained from the polarographic data were in agreement with the general behaviour of these Cu(II) solutions. The solutions become turbid and $Cu(OH)_2$ precipitates as the pH increases to over 5.9, the Cu(II) and Quadrol concentration being $5 \times 10^{-3}$ mol $l^{-1}$. The calculations using Cu(II)–Q complex stability constants showed that the concentration of free copper ions at pH 5.9 indeed exceeds the value allowed by the $Cu(OH)_2$ solubility product.

### 3.3. Solutions at pH > 8

A sharp increase in Cu(II) complexation was observed at pH > 8, i.e. when increasing the pH of the solutions from 8 to 10 the $E^r_{1/2}$ became more negative by approximately 300 mV. This means that the concentration of free Cu(II) ions reduces by approximately 10 orders of magnitude (Fig. 3). A sharp increase in the Cu(II)–Quadrol complex stability at pH > 8 may be related to the substantial changes in the structure of the complexes. The available experimental data are not sufficient for adequate estimation of Cu(II) complex species in the pH region 8–10.

With a further increase in solution alkalinity (pH > 10), $\Delta E^r_{1/2}$ shifts to more negative values (Fig. 2(b)), although the equilibrium unprotonated Quadrol concentration is actually constant in these solutions. This fact could be accounted for by participation of a new ligand

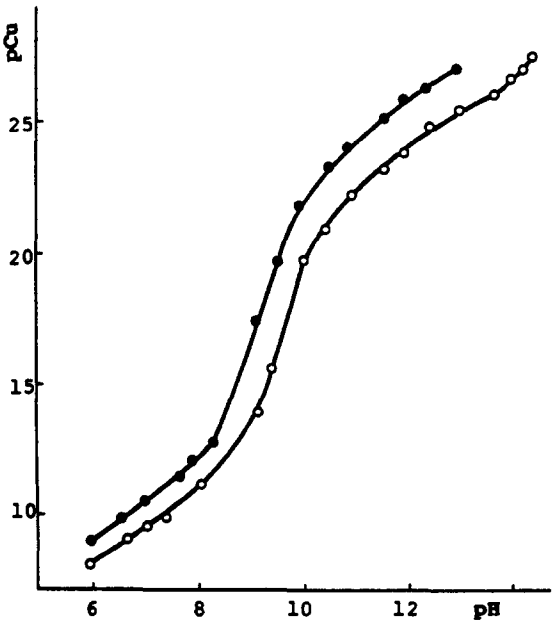

Fig. 3. Dependence of pCu on pH. Cu(II) concentration is $5 \times 10^{-4}$ mol $l^{-1}$, Quadrol concentrations are $5 \times 10^{-3}$ (○) and $5 \times 10^{-2}$ (●) mol $l^{-1}$

(namely, $OH^-$ ions) in the complex formation. Analysis of the data obtained shows that copper hydroxy complexes with two $OH^-$ groups (with increase in pH of one unit the $\Delta E^r_{1/2}$ becomes more negative by 58 mV) and one or two Quadrol molecules (at the same pH of the solution and a 10-fold higher Quadrol concentration, $\Delta E^r_{1/2}$ becomes more negative by about 50 mV) may be formed in this system.

The calculations using the LS technique indicated the presence of two kinds of hydroxy complexes in the system, namely $CuQ(OH)_2$ and $CuQ_2(OH)_2$. Their stability constant logarithms are $26.9 \pm 0.5$ and $29.1 \pm 0.3$ respectively.

Polarographic data in solutions at pH > 13 (up to 3 mol $l^{-1}$ NaOH) showed that the complex $CuQ_2(OH)_2$ dominated (at a total concentration of Quadrol of over 0.01 mol $l^{-1}$) under these conditions. In such highly alkaline solutions, Cu(II) complexes with Quadrol do not transform to tetrahydroxycuprate(II) $Cu(OH)_4^{2-}$ as occurs for Cu(II) complexes with EDTA, tartrate and NTA. This is in agreement with the value of the stability constant of $Cu(OH)_4^{2-}$: $\log \beta = 15.5$ [9].

### 3.4. Distribution of Cu(II) complexes

As follows from the analysis of polarographic data, we were not able to describe Cu(II) complex formation with Quadrol by one set of complex species over the range of solution pH values investigated. Therefore, we can only discuss the complex distribution in two separate pH regions: at pH = 5–8 and at pH > 10.

The calculations of copper ion distribution among the complexes showed that at pH 5–6 the $CuQ^{2+}$ complex predominates. With rising pH it converts to $CuQ_2^{2+}$, which predominates at pH 7–8. In alkaline solutions at pH > 10, a dihydroxy complex $CuQ_2(OH)_2$ is found to predominate, and at a total Quadrol concentration higher than 0.01 mol $l^{-1}$ (Fig. 4). The complex $CuQ(OH)_2$ predominates in solution only at low Quadrol concentrations.

It should be noted that according to our polarographic data the hydroxy Cu(II) complexes with Quadrol of high stability do not exist at pH < 8, although the formal calculation would show the presence of $CuQ(OH)_2$ at pH values as low as 7. The abrupt increase in Cu(II) complexation at pH > 8 (Fig. 3) indicates some changes not only in Cu(II) complex structure, but apparently also in ligand molecule structure, and new complex formation equilibria appear at pH > 8.

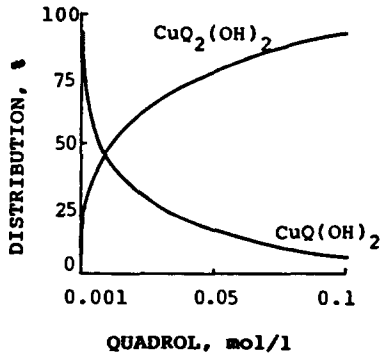

Fig. 4. Distribution of copper(II)–Quadrol complexes at different Quadrol concentrations. The total Cu(II) concentration is $0.5 \times 10^{-4}$ mol $l^{-1}$, at pH 12.0.

A similar situation is observed in the copper(II)–tartrate system: according to complex stability data [10,11], the hydroxy complex $CuTart_2(OH)_2^{4-}$ should predominate at a wide range of pH values (7–14), but it was detected by EPR techniques only in alkaline solutions at pH > 11 [12].

The newly obtained data on copper(II) and Quadrol complexes in alkaline solutions show that they are among the most stable Cu(II) complexes under these conditions. The pCu values are much higher than 20 at pH > 10 (Fig. 3), and this not only prevents the formation of $Cu(OH)_2$, but also enables the existence of rather concentrated alkaline Cu(II) solutions in the presence of Quadrol. Therefore, the use of Quadrol in electroless copper plating solutions is quite natural. The better technological parameters of these solutions compared with other practically used electroless plating solutions containing tartrate or EDTA are apparently related to the higher stability of Cu(II) complexes with Quadrol.

# Dissolved oxygen removal from aqueous media by the chromatomembrane method

L.N. Moskvin *, O.V. Rodinkov, A.N. Katruzov, G.L. Grigor'ev, S.N. Khromov-Borisov

*Department of Chemistry, St. Petersburg State University, Petrodvorets, Universitesky pr. 2, 198804 St. Petersburg, Russia*

Received 11 November 1994; revised 3 May 1995; accepted 5 May 1995

**Abstract**

The possibilities of the new chromatomembrane method in the removal of oxygen dissolved in water are studied. The scheme of the water deoxygenation process is determined. The new reagent-free method allows production of water with oxygen content at the level of a few ppb.

*Keywords:* Oxygen removal; Chromatomembrane

## 1. Introduction

The elaboration of efficient methods for the removal of dissolved oxygen from aqueous solutions is one of the preparative problems in chemistry [1]. Chemical deoxygenation methods are based upon the introduction of strong reducing agents into aqueous medium to fix the amount of dissolved oxygen. These methods are of limited use and they cannot satisfy strict requirements as to the purity of the water obtained. The possibilities of membrane methods for mass-exchange processes in the liquid–gas system are limited by the slow rates of membrane diffusion. The most common methods for removal of dissolved gases (boiling, purging with inert gas) are based upon the redistribution of gaseous components in the liquid–gas system. Their efficiency is also insufficient in many cases. With optimal design of the corresponding equipment, the residual oxygen content in water is 900 ppb for boiling and 200 ppb for bubbling [1].

The conceptually new chromatomembrane principle for the realization of mass-exchange processes in liquid–liquid and liquid–gas systems [2,3] opens up new possibilities in the removal of dissolved gases from aqueous solutions.

The chromatomembrane method of interphase exchange is based upon capillary effects that occur within a porous hydrophobic matrix [2]. It is possible to pass flows of two phases simultaneously through the porous medium when there are two types of pores that substantially differ in size. The aqueous solution, which does not wet the surface of the hydrophobic material, fills the macropores of the biporous matrix and moves within them. The gas phase moves within the micropores, which are inaccessible to the aqueous phase because of capillary forces. In order to avoid entry of the gas phase into the macropores, the aqueous phase pressure is maintained higher than the pressure of the gas phase throughout the mass-exchange space. To provide a separate inlet and outlet for flows of both phases, the gas phase enters the mass-exchange space through microporous hydrophobic membranes. The membranes are nonpermeable to the aqueous phase, which goes immediately into the

*SSDI* 0039-9140(95)01636-8

biporous medium. So, the chromatomembrane method provides continuous isolation of volatile admixtures from aqueous solutions while combining the main advantages of chromatographic (high efficiency of the mass-exchange process) and membrane (continuous regime) separation methods.

The scope of the present work was to develop a chromatomembrane method for the deoxygenation of aqueous solutions and to estimate its prospects for the production of water with low oxygen content.

## 2. Experimental

A scheme of the experimental device is shown in Fig. 1. The aqueous sample of known oxygen content is passed with a certain flow rate through the regulatory valve (1) and manifold (2) into the mass-exchange layer (3) of the chromatomembrane cell (4), and then to waste. Simultaneously, the extracting gas of known oxygen content is passed by regulatory valve (5) and manifold (2) with a certain flow rate through the microporous membranes (6) and mass-exchange layer (3). To determine the depth of deoxygenation, the oxygen content in aqueous solution at the outlet of the chromatomembrane cell was monitored by means of gas chromatography with a common thermal conductivity detector and preconcentration stage. The dissolved oxygen was preconcentrated and extracted into a gas phase by means of liquid–gas chromatography [4]. This method allows detection of the dissolved oxygen to within 10–10 000 ppb, with a relative error of less than 20%.

The experimental chromatomembrane cells were made of polytetrafluoroethylene (PTFE). The cells had membranes of 0.8 mm thickness with an average pore size of about 1 μm. The

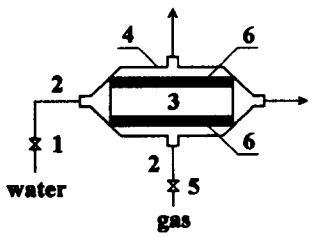

Fig. 1. Scheme of the experimental device: (1) regulatory valve for aqueous sample supply; (2) manifold; (3) mass-exchange layer; (4) case of the chromatomembrane cell; (5) gas regulatory valve; (6) microporous membrane.

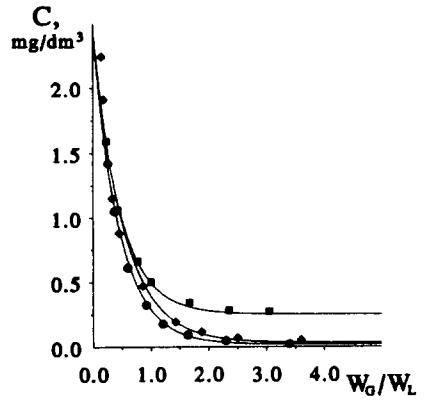

Fig. 2. Relationship between $O_2$ content in the outlet aqueous solution ($C$) and the ratio of volume rates ($W_G/W_L$). Aqueous sample flow rate $W_L = 20\ cm^3\ min^{-1}$. The mass-exchange layer dimensions of the cell are 5 × 4 × 1 cm. Initial oxygen content in the extracting gas: (■) 8.7 mg $dm^{-3}$; (◆) 0.85 mg $dm^{-3}$; (●) <0.05 mg $dm^{-3}$.

micropores within the mass-exchange layer are of the same size. The average radius of the macropores is 0.5–3.0 mm. The dimensions of the mass-exchange layer are presented hereafter in the form "length × width × height". The length is measured along the aqueous phase flow, the height being measured in the direction of the gas passage. The mass-exchange units have a hermetic case of PTFE (about 1 cm thickness) that prevents oxygen diffusion from ambient air. The cells in this study allow variation of the aqueous phase flow within the 0–350 $cm^3\ min^{-1}$ range and of the extracting gas flow within the 0–800 $cm^3\ min^{-1}$ range.

## 3. Results and discussion

Two main factors determine the degree of the chromatomembrane deoxygenation: the ratio of the volume rates of gas $W_G$ and aqueous solution $W_L$ flowing through the chromatomembrane cell, and the oxygen content in the extracting gas $C_G$ (Fig. 2). In the case of low $W_G/W_L$ values, the oxygen content in the outlet aqueous solution $C$ is virtually independent of the oxygen content in the extracting gas. The former will decrease exponentially with an increase in the $W_G/W_L$ ratio. In the limiting case, with a sufficiently high value of $W_G/W_L$, the oxygen content in the outlet aqueous solution is related to its content in the extracting gas flow simply by

$$C = C_G/K \quad (1)$$

where $K$ is the distribution coefficient of the component for the liquid–gas system, i.e. the ratio of the oxygen equilibrium concentrations in the gas and in the liquid.

The latter gives evidence of the high efficiency of mass exchange within the chromatomembrane cells. This is sufficient to obtain the ultimate possible purification of water from oxygen with its given content in the extracting gas.

To predict the degree of removal of dissolved gases by means of the chromatomembrane method, one can proceed from common features of the chromatomembrane process and continuous gas extraction (stripping). The same process of distribution of volatile components within a liquid–gas system forms the basis for both techniques. Various models of stripping and their mathematical description are discussed in detail by Vitenberg and Ioffe [5]. The high efficiency of mass exchange inherent in the chromatomembrane process allows us to assume an instant equilibration between the total volume of the liquid phase and the total volume of the gas phase in the system. Hence, we chose the model of stripping that assumes thermodynamic equilibrium between the liquid phase and gas bubbles passing through it, and also between the liquid phase and the gas phase above the solution. The process in this case is described with the equation proposed by Wahlroos [6,7] for the measurement of liquid–gas partition coefficients:

$$C_G^V = C_G^0 \exp\left(\frac{-V}{V_L/K + V_G}\right) \quad (2)$$

where $C_G^V$ is the component concentration in the gas phase after passing a gas volume $V$ through the liquid, $C_G^0$ is the initial component concentration in the gas phase, and $V_G$ and $V_L$ are the geometric volumes of the gas and liquid phases within the chromatomembrane cell respectively. It is important to note that we use in this article the distribution coefficient that is characteristic of extraction systems, whereas the reciprocal coefficient is more common in the description of head-space analysis.

Under the equilibrium conditions, the component concentration in the liquid is related to its concentration in the gas phase by the ratio $C = C_G/K$. Hence, we may transform Eq. (2) to

$$C = C^0 \exp\left(\frac{-V}{V_L/K + V_G}\right) \quad (3)$$

where $C^0$ is the component concentration in the liquid before passing the gas through.

A certain portion of the component will pass immediately into the gas phase present in the system before the stripping starts. From the equation of material balance

$$C_L V_L = C^0 V_L + K C^0 V_G \quad (4)$$

we obtain

$$C^0 = \frac{C_L}{1 + K V_G/V_L} \quad (5)$$

where $C_L$ is the initial concentration of the component in the liquid sample before contact with the gas phase. Combining Eqs. (5) and (3) we obtain, after simple transformations,

$$C = \frac{C_L}{1 + K V_G/V_L} \exp\left[\frac{-V}{V_L(1 + K V_G/V_L)}\right] \quad (6)$$

In the chromatomembrane process, the ratio of purging gas volume $V$ to the volume of liquid $V_L$ is equivalent to the ratio of the volume rates of liquid and gas phase flows through the chromatomembrane cell $W_G/W_L$. Hence, we can modify Eq. (6) to the form

$$C = \frac{C_L}{1 + K V_G/V_L} \exp\left[\frac{-W_G}{W_L(1 + K V_G/V_L)}\right] \quad (7)$$

where $C$ and $C_L$ are the component concentrations in the liquid phase at the outlet and at the inlet of the chromatomembrane cell respectively.

When the concentration of the component to be removed is not zero in the purging gas, one should take into account its contribution by means of Eq. (1). Finally, we derive an equation that allows us to predict the depth of removal of dissolved gases by the chromatomembrane method:

$$C = \frac{C_L}{1 + K V_G/V_L} \exp\left[\frac{-W_G}{W_L(1 + K V_G/V_L)}\right] + \frac{C_G}{K} \quad (8)$$

When the $V_G/V_L$ ratio is in the 0.3–1.0 range, deoxygenation of water from saturation to the 50–60 $\mu g\, dm^{-1}$ level is reached with a $W_G/W_L$ ratio of 2:1 or more. This is evident from Eq. (8) and is proved by the experimental data (see Fig. 2 and Table 1).

Comparison of the deoxygenation efficiency at chromatomembrane cells with different geometric parameters and for various rates of phase flows (Table 1) gives evidence that the degree of oxygen removal depends weakly on

Table 1
Effect of volume rates of aqueous ($W_L$) and gas ($W_G$) flows on the efficiency of chromatomembrane deoxygenation for distilled water and pure nitrogen. The water is saturated with atmospheric oxygen. The residual oxygen content in reagent-grade nitrogen is below 20 μg dm$^{-3}$. The mass-exchange layer dimensions of the three cells are: (A) 5 × 20 × 1 cm; (B) 5 × 5 × 4 cm; (C) 1 × 2 × 3 cm.

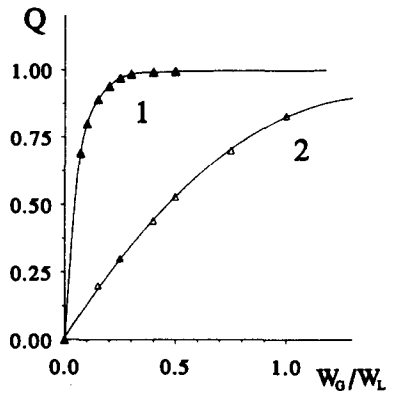

Fig. 3. Relationship between the degree of extraction of dissolved oxygen ($Q$) and the ratio of volume rates ($W_G/W_L$) of extracting gas and aqueous sample flows. (1) Chromatomembrane method. (2) Countercurrent gas extraction. Aqueous sample flow rate 10 cm$^3$ min$^{-1}$. The inner dimensions of the mass-exchange cell and extractor are 5 × 4 × 1 cm. The extracting gas is of the same purity.

the absolute rates, but is determined by their ratio to a crucial extent. When raising both phase flows, even a marked increase in the degree of deoxygenation takes place at the expense of a decrease in the $V_G/V_L$ value (see expression 8). It can be deduced from this that when using the chromatomembrane method, equilibrium between the phases is reached so rapidly that this is not the factor limiting the process efficiency.

The latter is one of the main advantages of the chromatomembrane method. In the common bubbling technique, the efficiency of removal of volatile components depends on the purge rate and, starting from rather low extracting gas rates, this efficiency decreases with an increase in rate. The performance of the chromatomembrane method is much higher for high rates of flow. This is obvious from the comparative results of dissolved gas extraction in the chromatomembrane cell and in a countercurrent gas extractor of equal dimensions (Fig. 3). We can estimate the performance of the method with the value of 10 dm$^3$ min$^{-1}$ per 1 dm$^3$ of mass-exchange cell volume with an extracting gas consumption of 2–3 dm$^3$ per 1 dm$^3$ of purified water while producing water with an oxygen content below 20 ppb.

The values obtained in the present work of residual oxygen content in purified water at the 20 ppb level are not the limiting ones. The pattern of relationships between the degree of deoxygenation and the process parameters proves unambiguously that this level can be lowered when using sufficiently pure extracting gas.

# pH-metric studies on ternary metal complexes of some amino acids and benzimidazole

M.T. El-Haty *, A.H. Amrallah, R.A. Mahmoud, A.A. Ibrahim

*Chemistry Department, Faculty of Science, Aswan, Egypt*

Received 22 November 1994; revised 28 February 1995; accepted 8 May 1995

**Abstract**

The stability constants of binary and ternary complexes of copper(II) and nickel(II) with some amino acids (D-histidine, DL-serine, lysine) as primary ligands and benzimidazole as a secondary ligand were determined pH-metrically. The study was conducted in 10% (v/v) ethanol–$H_2O$ medium and at an ionic strength of 0.1 mol $dm^{-3}$ $NaNO_3$ at $20 \pm 1$°C. Values of $\Delta \log K$ were discussed on the basis of statistical considerations and the nature of the species formed. The stability of the binary and mixed ligand complexes are discussed in terms of the molecular structure of benzimidazole and the amino acids as well as the nature of the metal ion.

*Keywords:* Amino acids; Benzimidazole; pH-metric study; Ternary metal complexes

## 1. Introduction

Metal complexes with imidazole compounds are of great interest with respect to their biological applications as imidazole occurs in purine and the amino-acid histidine [1]. The study of mixed ligand complexes has been receiving considerable attention recently. Although several studies have been made on the use of amino acids in ternary complex formation [2–4], results on ternary complexes containing amino acids and benzimidazole are still scarce.

In the present paper, a systematic study on complex formation between the metal ions Cu(II) and Ni(II), and benzimidazole and some amino acids namely D-histidine, DL-serine and lysine, has been carried out using the potentiometric titration technique. This study is concerned with the formation and stability of the ternary complexes in relation to those of the binary complexes.

## 2. Experimental

### 2.1. Materials and solutions

Analytical grade metal salts $Cu(NO_3)_2 \cdot 3H_2O$ and $NiCl_2 \cdot 6H_2O$ were used. The benzimidazole as well as the amino acids (D-histidine, DL-serine and lysine) used were A.R. grade, BDH products. Standard solutions (0.01 mol $dm^{-3}$) of benzimidazole (B) and the metal salts were prepared by dissolving the quantity required in absolute ethanol. Amino acid (A) NaOH, $NaNO_3$ and $HNO_3$ solutions were dissolved in $CO_2$-free bidistilled water.

### 2.2. Potentiometric titrations

Numerous titrations with a relatively highly concentrated standard, carbonate-free sodium hydroxide solution of the parent ($M^{2+}$–A) and/or the B mixture in a 1:5:5 molar ratio ($1 \times 10^{-3}$ mol $dm^{-3}$ of each) were carried out at $20.0 \pm 0.5$°C and in 10% (v/v) ethanol–$H_2O$ media in order to overcome the weak solubility

*SSDI* 0039-9140(95)01641-4

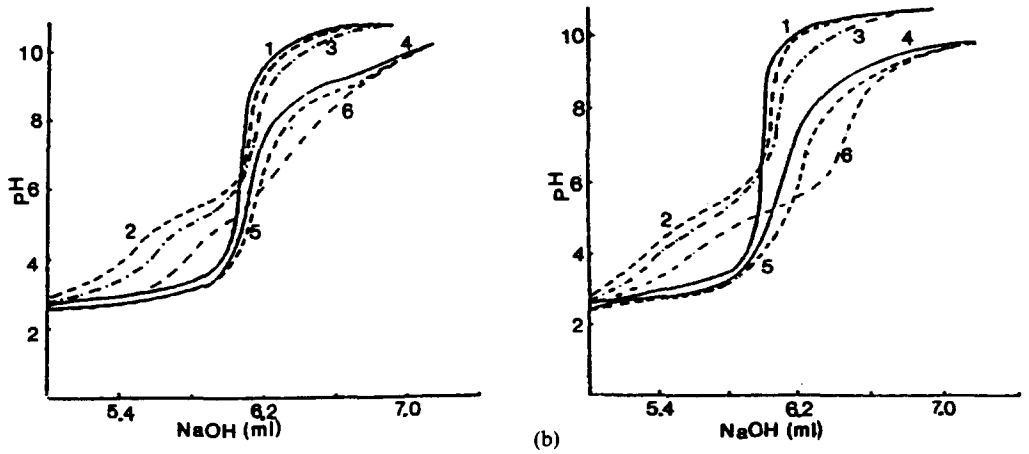

Fig. 1. Titration curves for the ternary complexes (1:1:1) at 20 °C and at $I = 0.1$ mol dm$^{-3}$ $NaNO_3$ ([NaOH] = 0.08 mol dm$^{-3}$). (a) Serine–benzimidazole–Ni(II); (b) lysine–benzimidazole–Cu(II). Curve 1, 0.01 mol dm$^{-3}$ $HNO_3$ + 0.1 mol dm$^{-3}$ $NaNO_3$, curve 2, solution (1) + $1.0 \pm 10^{-3}$ mol dm$^{-3}$ benzimidazole; curve 3, solution (2) + $2.0 \times 10^{-4}$ mol dm$^{-3}$ metal ion; curve 4, solution (1) + $1.0 \pm 10^{-3}$ mol dm$^{-3}$ amino acid; curve 5, solution (4) + $2.0 \times 10^{-4}$ mol dm$^{-3}$ metal ion; curve 6, solution (5) + $1.0 \times 10^{-3}$ mol dm$^{-3}$ benzimidazole.

of the studied systems in pure aqueous medium. The ionic strength and the total volume were kept constant at 0.1 mol dm$^{-3}$ $NaNO_3$ and 50 ml, respectively. Purified nitrogen gas was passed into the solutions before and during the titrations. Multiple titrations were carried out for each system. pH-metric measurement were performed using an Orion 601 Digital Research pH-meter with a glass calomel electrode assembly, accurate to 0.005 unit. The solutions were titrated according to the following scheme: 1, $HNO_3$; 2, $HNO_3 + B$; 3, $HNO_3 + B + M^{2+}$; 4, $HNO_3 + A$; 5,$HNO_3 + A + M^{2+}$; 6, $HNO_3 + B + A + M^{2+}$.

The pH-meter readings were corrected according to the Douheret procedure [5]. The pH-meter reading in the 10% (v/v) ethanol–$H_2O$ mixture, pH($R$), differs by an amount $\delta$ from the corrected reading in aqueous medium, pH*, according to the equation $pH^* = pH(R) - \delta$. The $\delta$ value in 10% (v/v) ethanol–$H_2O$ as reported to be 0.02 [5]. Accordingly the presence of 10% ethanol–$H_2O$ has a minor influence on the protonation or complex stability constants obtained.

## 3. Results and discussion

### *3.1. Stability constants of the binary metal complexes*

Fig. (1) represents a set of constructed titration curves for the free and complexed ligands according to the sequence described in the experimental section. In all the ternary systems, the amino acids are regarded as primary ligands and benzimidazole (B) as secondary ligand. The protonation constants have been determined under our experimental conditions using the Irving–Rossotti method [6]. The values obtained (Table 1) are more or less in good agreement with those reported earlier [7–13]. Examination of the titration curves in the presence of the metal ions Cu(II) and Ni(II) indicates that the addition of the metal ion to the ligand solutions causes a decrease in the pH value. This shows that the complexation reaction proceeds by the replacement of protons from such ligands. Generally, complex formation starts in the pH range 3.5–6.5 in the $M^{2+}$–A binary system and 3.7–5.3 in the $M^{2+}$–B binary system. It is worth mentioning that there is no precipitation during the titrations, ruling out the possibility of hydrolysis of the studied metal ions in the presence of excess ligand. The pH-metric titration curve for histidine in the presence of the metal ions exhibits two inflections corresponding to the consumption of 2 mol of NaOH. This is indicative of the liberation of two protons from the histidine molecule on complexation. In the case of serine and lysine, the complex titration curve (Figs. 1a and 1b, curve 5) shows one inflection at $a = 2$, due to the liberation of two protons corresponding to the simultaneous formation of 1:1 and 1:2 complex species (where $a$ is the number of moles of alkali added per mole of amino acid). This is clearly due to coordination

[b] The value determined at 25 °C.
[c] Refs. [7–13].

of the carboxylate group and the α-nitrogen atom of the amino acid to the metal ion leading to the formation of a five-membered chelate ring of 1:1 and a two-mentioned chelated ring of the 1:1 and the 1:2 metal–amino acid chelates, respectively.

The complex formation of benzimidazole, B, with the metal ions proceeds via the replacement of a proton of the protonated pyridyl nitrogen atom of the benzimidazole moity. Thus, the inflection observed in the benzimidazole–metal ion titration curve is interpreted on the basis of competing reactions of the metal ions and protons with benzimidazole. Hence, metal complex formation is favoured instead of the protonation reaction. The liberation of a proton from the reaction of the metal ions with $^{+}$HB consumes 1 mol of NaOH.

These equilibria can be represented as follows:

$$M + {}^{+}HB \rightleftarrows MB + H^{+} \quad K^{M}_{MB} = [MB]/[M][B] \tag{1}$$

$$\log K^{M}_{MB} = \log [MB] - (\log [M] + \log [B]) \tag{2}$$

$$MB + {}^{+}HB \rightleftarrows MB_2 + H^{+} \tag{3}$$

$$K^{MB}_{HB_2} = [MB_2]/[MB][B]$$

$$\log K^{MB}_{MB_2} = \log [MB_2] - (\log [MB] + \log [B]) \tag{4}$$

Similarly, for amino acids

$$\log K^{M}_{MA} = \log [MA] - (\log [M] + \log [A]) \tag{5}$$

$$\log K^{MA}_{MA_2} = \log [MA_2] - (\log [MA] + \log [A]) \tag{6}$$

The overall equilibrium constants for the binary complexes formed ($\log \beta = \log K^{M}_{MB} + \log K^{MB}_{MB_2}$) are calculated by using standard procedures based on the calculation of the average number of ligands bound per metal ion, $\bar{n}$, and the free ligand exponent, pL. From the titration curves 2,3 and 4,5 in Figs. 1a and 1b using the Irving and Rossotti method [6], the formation constant values for different binary chelates were obtained (Table 2).

By applying the equation $\bar{n}/\{(1-\bar{n})[L]\} = \beta_1 + 2 - \bar{n}/(1-\bar{n})\beta_2[L]$ for the subject binary systems, the best linear fit for the chelates are obtained.

### 3.2. Stability constants of the ternary metal chelates

Fig. 1 (as representative) shows typical pH-metric titration curves for the different $M^{2+}$–A–B ternary complexes studied at 20°C and at an ionic strength of 0.1 mol dm$^{-3}$. It is worth mentioning that the different ternary metal chelates show no precipitation; thus they do not undergo hydrolysis under the experimental conditions, even in the high pH region. This behaviour may be explained on the basis that the electron density of the metal–ligand bonds in ternary chelates is redistributed in such a way that the ternary chelates are more polar than the binary chelates and hence are not easily hydrolyzed in the high pH region.

Examination of the curves obtained for the ternary systems reveals that these curves overlap the binary $M^{2+}$–amino acid complex solution curves (curve 6 in Fig. 1) at low pH values. This indicates that the benzimidazole does not participate in ternary complex formation at lower pH values. At higher pH values (5.5–7.1 in the case of the $M^{2+}$–histidine–B systems, 5.7–6.5 in the case of the $M^{2+}$–serine–B systems and 5.9–7.5 in the case of the $M^{2+}$–lysine–B system, the involvement of benzimidazole in the $M^{2+}$ –A–B ternary complex formation begins. This is indicated by the presence of a second buffer region in the ternary titration curves which is below the

buffer region in which the binary complexes are formed.

Further evidence for the formation of mixed ligand complexes (MAB) from the corresponding binary MA and MB complexes was provided by comparing the mixed ligand titration curves with a composite curve drawn theoretically by adding the horizontal distance of the MA curve to the titration of the free ligand B. A deviation of the composite curve from the mixed-ligand titration curve is observed in each case studied. This observation provides evidence for the formation of mixed ligand complexes.

Generally, the shape of the complex titration curves suggest the formation of a 1:1 MA complex at lower pH values than for a 1:1 MB complex, and the MA species do not hydrolyze even at higher pH values. This indicates that the amino acids may be considered as primary ligands, and benzimidazole as a secondary ligand.

Further, the titration curves of the ternary complexes (curve 6 in Figs. 1a and 1b) exhibit two inflections at $m = 1$ before the acid curve and at $m = 1$ after the acid curve (where $m$ is the number of moles of alkali added per mole of metal ion), and then are superimposed over the MA binary complex titration curves at higher pH values. This indicates that only 1:1:1 mixed ligand complex species are formed in all the systems studied. Also, the titration curves for the 1:1:1 ternary complexes are slightly above the $M^{2+}$–amino acid titration curves at lower pH values, then are superimposed and are consequently moved below them. This indicates the formation of some 1:1:1 MAB complexes after completing the formation of the 1:1 MA complex. Such an observation has not been noted by Gergely et al. [14], for the ternary complexes of amino acids.

The stepwise complex formation in the ternary complex reaction can be represented by the following equilibria

$$M + xA \rightleftarrows MA_x \quad (7)$$

$$MA_x + yB \rightleftarrows MA_xB_y \quad (8)$$

(The charges are omitted for the sake of simplicity.).

The stability constants of the ternary metal ion complex systems can be represented by the following possible complexation equilibria

$$M + A + B \rightleftarrows MAB \quad (9)$$

$$\beta^{M}_{MAB} = [MAB]/[M][A][B]$$

$$\log \beta^{M}_{MAB} = \log [MAB] - (\log [M] + \log [A] + \log [B]) \quad (10)$$

Since

$$\log [M] + \log [A] = \log [MA] + \log K^{M}_{MA} \quad (11)$$

by

$$\beta^{M}_{MAB} = \log [MAB] - \log [MA] + \log K^{M}_{MA} - \log [B] \quad (12)$$

$$MB + A \rightleftarrows MBA \quad (13)$$

$$K^{MB}_{MBA} = [MBA]/[MB][A] \quad (14)$$

$$\log K^{MB}_{MBA} = \log [MBA] - (\log [MB] + \log [A]) \quad (15)$$

Similarly

$$MA + B \rightleftarrows MAB \quad K = [MAB]/[MA][B] \quad (16)$$

$$\log K^{MA}_{MAB} = \log [MAB] - (\log [MA] + \log [B]) \quad (17)$$

The overall stability constant $\beta^{M}_{MAB}$, which is experimentally determined, is connected with $K^{MA}_{MAB}$ and $K^{MB}_{MBA}$ by the equations

$$\log \beta^{M}_{MAB} - \log K^{M}_{MA} = \log K^{MA}_{MAB} \quad (18)$$

and

$$\log \beta^{M}_{MBA} - \log K^{M}_{MB} = \log K^{MB}_{MBA} \quad (19)$$

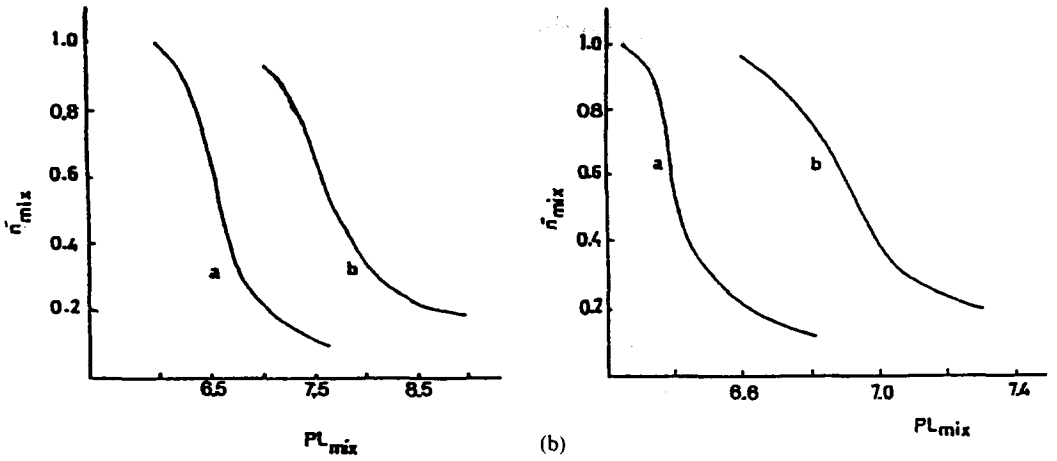

Fig. 2. $\bar{n}_{mix}$–$pL_{mix}$ relationships for the metal ion–A–B ternary complexes. (a) Serine–benzimidazole–metal ion; (b) lysine–benzimidazole–metal ion. Curve a, Ni(II); b, Cu(II).

The formation constants of the ternary complexes were calculated using a modified Irving–Rossotti titration technique [15]. The experimental $\bar{n}_{mix}$–$pL_{mix}$ curves (Fig. 2 is representative) are used to evaluate the stability constant of the ternary system.

Examination of the stability constant values given in Table 3, indicates that Eq. (18) is favoured instead of Eq. (19). This confirms the assumption that the amino acids under study act as primary ligands in these systems.

The stability of mixed ligand complexes is conveniently characterized by comparing the differences in stabilities ($\Delta \log K$) of the binary and ternary complexes. The values of $\Delta \log K$ can be calculated for the reaction of the secondary ligand (B) either with the metal ion–primary complex ($MA + B \rightleftarrows MAB$) or with the free metal ion ($M + B \rightleftarrows MB$); hence, $\Delta \log K = \log K^{MA}_{MAB} - \log K^{M}_{MB}$. The two equilibria above represent the overall equilibrium $MA + MB \rightleftarrows MAB + M$, and hence

$$\Delta \log K = \log \beta_{MBA} - (\log K_{MA} + \log K_{MB}) \quad (20)$$

Generally, the results indicate that $K_1 > K_2$. This is due to the hydrated metal ion being available for binding the first ligand to the metal ion, rather than the second. The addition of ligand B to MA should also display the same trend, i.e. $\Delta \log K$ would be negative generally between $-0.5$ and $-2.0$ [16–18] depending on the geometry of the complex. A positive value of $\Delta \log K$ suggests a significant stabilization of the ternary complex.

The other approach commonly used to quantify the apparent stabilization of ternary complexes is based on the disproportionation constant, $X$, [19,20] as defined by the equation $MA_2 + MB_2 \rightleftarrows 2\,MAB$; hence

$$X = [MAB]^2/[MA_2]\,(MB_2] \quad (21)$$

by

$$X = 2 \log \beta^{M}_{MAB} - (\log \beta^{M}_{MA} + \log \beta^{M}_{MB}) \quad (22)$$

$$\log X = (\log K^{MA}_{MAB} - \log K^{MB}_{MB_2}) + (\log K^{MB}_{MBA} - \log K^{MA}_{MA_2}) \quad (23)$$

For statistical reasons, the expected value for $\log X$ for all geometries is $-0.6$ [18,20].

| $\log X$ | $+0.6$ | $+0.57$ |

[a] At 20 °C, $I = 0.1$ mol dm$^{-3}$, and in 10% (v/v) ethanol–water medium.

The values of $\Delta \log K$ and $\log X$ were calculated and they are presented in Table 3. Based on the above binary and ternary complex stability constant values, the following conclusions could be drawn.

(a) The overall stability constant values of the same metal ion binary or ternary complexes decrease according to the following order: M–histidine > M–serine > M–lysine; M–histidine–B > M–serine–B M–lysine–B. (The charges are omitted.) This behaviour can mainly be explained in terms of the decrease in basicity of the amino acid in the same direction.

The high stability of the histidine complexes indicates that it acts as a tridentate ligand, coordinated through the carboxylic oxygen, amino nitrogen and imino nitrogen atoms of the imidazole ring [21]. For serine, the position of the three donor groups renders them sterically unfavourable for effective tridentate coordination. This is in agreement with the lower stability of its complex than that of histidine–metal complexes.

Lysine behaves as a bidentate ligand and coordinates through adjacent carboxylic and amino groups, thus forming a five-membered chelate ring. The coordination of the second amino group is excluded, due to steric hindrance caused by the lysine chain length.

(b) A comparison of $\log K^{MA}_{MAB}$ and $\log K^{MB}_{MBA}$ for all the studied systems with those of the 1:1 and 1:2 binary complexes of the secondary ligand reveals that the stability constants of the ternary chelates are greater than those of the 1:1 but less than those of the 1:2 binary systems. This means that the ligands under study prefer to form the ternary complexes MAB rather than the binary complexes MA or MB. These observations can be interpreted by assuming the existence of $M \rightarrow L\pi$ bonding due to back donation of electrons from the metal $\pi$ orbitals. This behaviour may reduce the charge and electronegativity of the metal ions used in this species as compared to that of the hydrated metal ions [15].

(c) For all the systems under study, the $\Delta \log K$ values are generally negative in accordance with statistical expectations [22], where the statistical, steric and electrostatic factors resulted in lower stability constants for the ternary complexes as compared with the corresponding binary systems. The negative $\Delta \log K$ values confirm the formation of ternary complexes. This also demonstrates that the ternary chelates show significant instability. The absence of stabilization is compatible with the explanations given by Sigel et al. [23–25] for the possible stabilization of ternary complexes. Based on the fact that $\Delta \log K$ values depend on the coordination number of the metal ion and the ligands [26,27], the change in the $\Delta \log K$ values obtained may be attributed to the change in the geometry of the metal complex. For square planar complexes with bidentate ligands, the $\Delta \log K$ value is $-0.6$ units. For a regular and distorted octahedral geometry, $\Delta \log K$ values are $-0.4$ and $-0.9$ units, respectively [17].

(d) The $\log X$ values obtained for the ternary chelates are, in general, found to be in the range of the statistically expected $\log X$ values (0.6) [18,20]. A critical study of $\log X$ values reveals that for the Ni(II) chelates, the $\log X$ values are smaller than 0.6, indicating that the binary chelates are favoured over the corresponding ternary chelates.

(e) The stability constants of both Cu(II) binary and ternary chelates are higher than those of the Ni(II) complexes; this is due to the smaller size of Cu(II). This behaviour is in line with the stability order of Irving and Williams [28].

Received 24 November 1994; revised 27 February 1995; accepted 8 May 1995

**Abstract**

A sensitive, simple, rapid and precise method for the simultaneous determination of fosinopril (FOS) and hydrochlorothiazide (HCT) in pharmaceutical formulations is presented. These active ingredients are extracted in aqueous solution and measured by multiwavelength UV spectrophotometry using the program QUEST. HCT acts as an internal standard to verify the accuracy of the analysis. Some aspects of the chemical, spectroscopic and thermoanalytical behaviour of FOS are also reported.

*Keywords:* Fosinopril; Hydrochlorothiazide; UV-spectrophotometry

## 1. Introduction

Fosinopril (FOS), (4s)-4-cyclohexyl-1-[[[(*RS*)-2-methyl-1-(propionyloxy)propoxy](4-phenylbutyl)phosphinyl]acetyl]-L-proline, sodium salt (SQ28555), is the first member of a new chemical class of angiotensin converting enzyme (ACE) inhibitors [1,2], which is equipotent to captopril as an inhibitor of pressor response, but it has a longer effect [3,4]. During or following absorption, FOS, a prodrug, is hydrolyzed [5] to the active diacid (SQ27519), (see Form 1).

In tablet formulations, FOS is usually combined with a diuretic agent [6], such as hydrochlorothiazide (HCT).

In the literature, a high-performance liquid chromatographic (HPLC) method is described to evaluate the purity of FOS [7], but no methods are reported for its determination in pharmaceutical formulations when other ingredients are present.

UV-visible spectrophotometry is an instrumental technique suitable for multicomponent analysis, because generally the procedures involve neither complicated and time-consuming sample treatments nor the need for special reagents. Only processing of the spectrophotometric data for the mixture solution by means of an adequate software package is required. However, it should be emphasized that the accurate resolution of a mixture with multiwavelength computational programs requires the prior knowledge of the components actually present and of their contribution to the mixture absorbance. In fact, the occurrence of a component scarcely contributing to the overall absorbance may result in significant deviations, and very good fits between experimental and calculated spectra do not necessarily reflect

the accurate resolution of the mixture. For this reason, it is essential to check if a mixture may be analyzed by this method, find the best experimental conditions, and provide for a final verification of the results.

The aim of our studies was to solve these problems for FOS and HCT mixtures and to propose a simple and rapid method for their simultaneous determination in pharmaceutical formulations.

## 2. Experimental

### 2.1. Instruments

The thermal measurements were carried out using a Perkin-Elmer TGS-2 thermal analyzer and a DSC-4 differential scanning calorimeter connected to a model 3700 Data Station equipped with a software package. Thermogravimetry (TG) and differential scanning calorimetry (DSC) runs were made on samples of about 1 mg, in a stream of nitrogen or oxygen (flow rate, 50 ml $min^{-1}$). The heating rate was 10°C $min^{-1}$.

IR spectra were recorded using a Perkin-Elmer 1760 FT-IR spectrometer.

UV spectra were acquired on a Perkin-Elmer 320 UV-vis spectrophotometer furnished with 1 cm quartz cells and connected to the Data Station equipped with software packages "CDS-13", for the mathematical treatment of the spectra, and "QUEST" which performs a least-squares best fit for multicomponent analysis of the mixture spectrum.

Millipore filtering apparatus fitted with 0.45 μm membrane disks (HAWPO2500) and class A glass apparatus as used.

### 2.2. Materials

Distilled, deionized water was used throughout.

Tablets: each tablet contains 20.32 mg of FOS sodium salt, and 12.27 mg of HCT, and tablet excipients are lactose, polyvinylpyrrolidone, sodium stearylfumarate, sodium croscaramellose and a dye mixture. All were a gift from Bristol-Myers Squibb (Anagni, Italy).

### 2.3. Analytical techniques

#### 2.3.1. Preparation of normalized standard curves

A standard aqueous solution of FOS was prepared by weighing, and working solutions were prepared by appropriate dilution in water to obtain final concentrations of this component giving absorbance readings in the range 0.5–1.5 [8]. Because the reliability of the mixture resolution depends primarily on the accuracy of the spectral data of the pure components used as a reference in resolving the mixture, a standard spectrum of FOS was obtained by recording the spectra of five different working solutions, normalizing them at a concentration of 10 mg $l^{-1}$ and then averaging the obtained spectra to give a single spectrum.

This procedure was used also for HCT. The spectra of the excipients were obtained more simply by scanning the aqueous solutions pre-

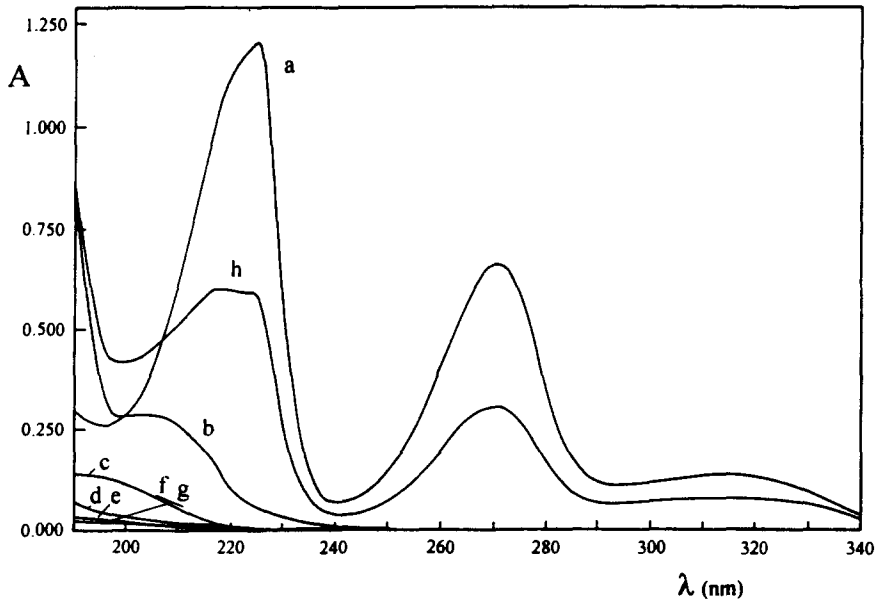

Fig. 1. Curve a, UV absorption spectra of hydrochlorothiazide; curve b, fosinopril sodium; curve c, PVP; curve d, lactose; curve e, dye mixture; curve f, sodium stearylfumarate; curve g, sodium croscaramellose; curve h, tablet aqueous solutions.

pared by dissolving an appropriate quantity of each component, and filtering when necessary.

*2.3.2. Simultaneous determination of FOS and HCT in tablets*

The average weight of a tablet was determined by weighing at least 10 tablets.

One or more tablets were finely powdered, and a portion of about 0.3 g of the powder was weighed accurately and 25 ml of water were added. The mixture was stirred gently for about 15 min at room temperature and then filtered on a 0.45 μm membrane filtering disk, collecting the solution in a dry Erlenmeyer flask.

Of this solution, 1 ml was diluted with water to 10 ml. This sample solution was analyzed by UV spectrophotometry. The mixture spectra were resolved using a computational program (QUEST).

The content (in milligrams per tablet) of FOS and HCT may be calculated by use of the following formula

$$\text{Content in milligrams} = \frac{amf}{c}$$

where $a$ is the concentration (mg $l^{-1}$) of the analyte in the final solution; $m$ is the weight (mg) of a tablet; $f$ is the dilution factor (25/100); and $c$ is the weight (mg) of the assay portion.

## 3. Results and discussion

### *3.1. Analytical behaviour of HCT and FOS*

The chemical and spectroscopic behaviours of HCT are common knowledge, so our study was limited to verify its solubility in water and the UV absorbance spectrum of its aqueous solution. As is shown in Fig. 1, curve a, there are three absorption bands with maxima at 315 nm ($\varepsilon = (3.10 \pm 0.03)\ 10^3\ l\ mol^{-1}\ cm^{-1}$), 271 nm ($\varepsilon = (1.91 \pm 0.02)\ 10^4\ l\ mol^{-1}\ cm^{-1}$) and 226 nm ($\varepsilon = (3.60 \pm 0.02)\ 10^4\ l\ mol^{-1}\ cm^{-1}$).

FOS sodium salt has been less studied as an analytical species, and we thought it convenient to investigate its chemical, spectroscopic and thermoanalytical behaviour.

FOS sodium salt is a white powder fairly soluble in methanol and water. Its aqueous solution is stable for several hours, but, on adding sodium hydroxide, FOS is hydrolyzed to the corresponding diacid. However, FOS precipitates as the protonated form on adding hydrochloric acid.

The UV spectrum of the aqueous solution (Fig. 1, curve b) shows only one absorption band with the maximum at 206 nm ($\varepsilon = (1.67 \pm 0.02)\ 10^4\ l\ mol^{-1}\ cm^{-1}$).

The IR spectrum (KBr disc) is presented in Fig. 2, showing the characteristic function of grouping of FOS.

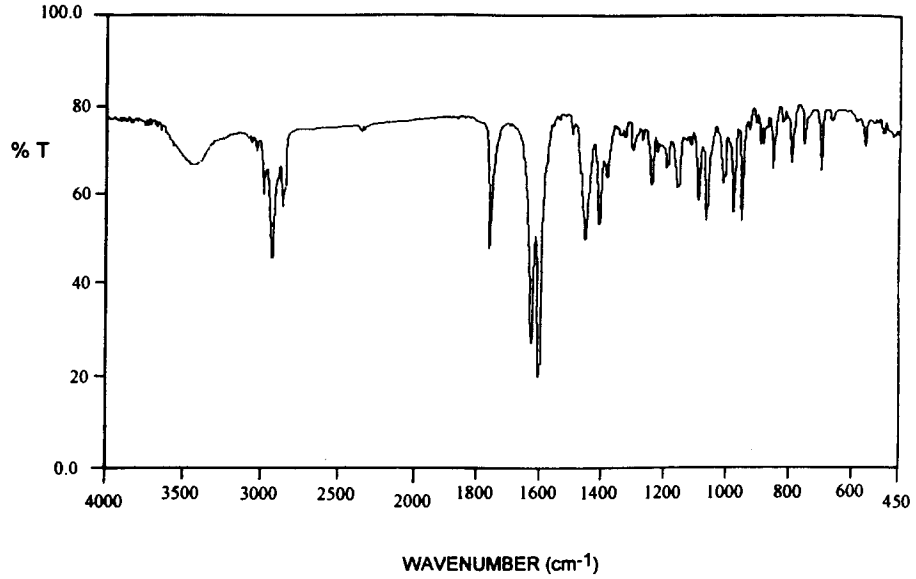

Fig. 2. IR spectrum (KBr disc) of fosinopril sodium.

TG analysis in a dynamic nitrogen atmosphere shows that FOS is stable up to about 200°C and then it decomposes in at least three steps giving a constant final residue at 550°C that consists mainly of $(NaPO_3)_x$ (calculated 17.41%; found, 16.1%).

The DSC curve shows two overlapping peaks in the temperature range 190–202°C; the first, endothermic peak, is connected with the melting of the compound, and the second, exothermic peak, with its first decomposition step. In an oxygen atmosphere the thermal decomposition takes place in an almost identical temperature range.

### *3.2. Content determination of FOS and HCT simultaneously in their tablets*

From the spectra of the aqueous solutions of the components of each tablet (Fig. 1, curve h), the optimum wavelength range for the analysis (240–210 nm) was established and justified away from the interfering species. Satisfactory results were obtained using standard solution spectra of FOS and HCT and only two blank solution spectra (lactose and PVP). The other excipients do not interfere because they are almost insoluble in water, and the small amount of absorption in the measurement range is compensated by the other blank solutions.

The results of eight replicate determinations of FOS and HCT in tablets demonstrate that the method is quite precise (relative standard deviations were 0.01 and 0.03 for FOS and HCT, respectively).

To test the quantitative recovery of both active ingredients, the technique of spiked samples was applied: known amounts of FOS and HCT were added to a powdered tablet and the mixtures were analyzed following the procedure described. The overall results are collected in Table 1.

## 4. Conclusions

The proposed spectrophotometric method for the simultaneous determination of FOS and HCT in tablets is easily carried out and rapid, requiring only few minutes to prepare the samples and to measure the absorbances. In spite of this, the method is sensitive, accurate and precise. However, to avoid unexpected interferences, it might be convenient to add an internal standard to the analyzed mixture. Comparing the amount found with the added amount of standard species, it is possible to verify the accuracy of the analysis. In the proposed method, HCT acts as an internal standard because it may be determined by measuring the mixture absorbance at a fixed wavelength. In fact, at 271 nm only HCT absorbs (Fig. 1, curve a) and these results should be in agreement with those found by multiwavelength analysis.

Table 1
Determination of FOS and HCT in tablets and in spiked samples [a]

| Sample [b] | FOS found [c] (mg per tablet) | | | | | | HCT found [c] (mg per tablet) | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | a | Recovery (%) | b | Recovery (%) | c | Recovery (%) | a | Recovery (%) | b | Recovery (%) | c | Recovery (%) | d | Recovery (%) |

Received 13 February 1995; revised 12 May 1995; accepted 12 May 1995

**Abstract**

A rapid electroanalytical method for the determination of residual styrene in polystyrene is described. The sample of polymer was dissolved in toluene and, following the addition of 10% DMF and electrolyte, a square-wave voltammogram was recorded at a gold microdisc electrode (radius, 6 μm). A standard addition technique was used to relate the peak current to the styrene concentration in solution and, hence, the styrene content of the polymer. The method gave results which are similar to those of the accepted standard procedure. It does not, however, require the precipitation of the polymer and hence is quicker and more convenient.

## 1. Introduction

The determination of residual monomer in polymers used for food packaging is a routine test since leaching of the monomer into the foodstuff is known to degrade the taste and is a potential toxic hazard. This paper describes a rapid procedure for the determination of styrene in polystyrene; in contrast to the standard procedure [1], where it is necessary to precipitate the polystyrene before the determination of the styrene in solution by gas chromatography, no treatment of the solution is necessary before the analytical determination. The method is based on the measurement of the electrochemical response for styrene [2]. In the development of the method, it was necessary to define a medium (a) in which polystrene is readily soluble, and (b) where good quality electrochemical responses could be obtained. In fact, polystyrene is insoluble in most of the solvents generally used for electrochemistry. The medium selected, 90% toluene/10% *N,N*-dimethylformamide (DMF) would normally be considered a very poor one for electrochemistry and the procedure is entirely dependent on the use of an ultramicroelectrode, which, in this work, is a gold microdisc of radius 6 μm. It is only during the past decade that the properties and advantages of ultramicroelectrodes have been widely recognized [3]. Here, the key property is the ability to obtain high quality responses in a medium of high resistance. The analytical measurement used square-wave voltammetry which led to a well-defined and easily measured peaked response.

## 2. Experimental

Both the linear potential sweep and square-wave voltammetry experiments were carried out using a potentiostat/galvanostat EG&G PAR 273. The data acquisition and treatment was performed using a LVM 486, 33 MHz computer, using the PAR software M270, version 3.00. The voltammograms were plotted on a Roland plotter, type DXY-980A.

All experiments were carried out in a two-electrode cell. The working electrode was a gold microdisc with a radius of 6 μm. The radius was checked by measuring the steady-state diffusion-controlled current for a known concentration of ferrocene in acetonitrile containing $Bu_4NClO_4$ [4]. The electrode was first polished with fine emery paper and then on a polishing cloth with 0.3 and 0.05 μm alumina (Buehler) with a polishing machine (Buehler, Ecomet 3); afterwards, it was washed with water and dried before use. Prior to each experiment, the electrode was polished with 0.3 μm alumina, rinsed with water, wiped on a clean, wet polishing cloth, rinsed again and dried. The reference/counter electrode was a Radiometer, model 401, saturated calomel electrode (SCE) and all potentials are quoted versus the SCE.

All solutions were prepared with the highest grade chemicals available in high purity toluene/DMF mixtures, previously dried with Prolabo alumina, size 2–5 mm. The supporting electrolytes used were $Bu_4NClO_4$ and $Bu_4NBF_4$. The first was available in high purity and the second was prepared by mixing aqueous solutions of $NaBF_4$ and $Bu_4NHSO_4$.The product in each case was recrystallized in methanol/water and dried under vacuum.

Experiments were conducted at room temperature, and all solutions were degassed with a fast stream of argon prior to the experiments.

## 3. Results

### 3.1. The selection of the medium

Polystyrene is most readily soluble in aromatic hydrocarbon solvents such as toluene and ethylbenzene. Hence, the objective was to use a medium with a high content of one of these solvents. Peña et al. [5] have studied a model electrode reaction, the oxidation of ferrocene in toluene/acetonitrile solutions using ultramicroelectrodes; they reported that the addition of a small percentage of the aprotic solvent to toluene led to a large improvement in the quality of the electrochemical responses. They also concluded that the addition of an electrolyte, e.g. 0.1 mol $dm^{-3}$ $Bu_4NBF_4$, was essential in media with a high percentage of toluene. We have carried out a wide range of experiments with styrene in toluene/DMF mixtures which will be reported elsewhere [6] but, in general, our conclusions are the same.

Fig. 1 shows current vs. potential curves for the reduction of styrene in different concentrations at a gold microdisc electrode (radius, 6 μm) in 90% toluene/10% DMF containing 0.1 mol $dm^{-3}$ $Bu_4NBF_4$ and deoxygenated with a fast stream of dry argon. It can be seen for each concentration that well-formed reduction waves are observed with $E_{1/2} \approx -2.51$ V vs. SCE; the waves are steep with $E_{3/4} - E_{1/4} \approx -110$ mV. Most importantly for analysis, there is a good plateau current extending over a potential range of a few hundred millivolts before reduction of the solvent/electrolyte commences (in fact, dissolved polystrene showed slightly more complex behaviour, see below). The height of the waves are proportional to the styrene concentration. In fact, the limiting current, $I_L$, at a microdisc electrode is given by the equation

$$I_L = 4nFDcr$$

where $n$ is the number of electrons involved in the reduction, $F$ is the Faraday constant, $D$ is the diffusion coefficient of styrene, $c$ is the concentration of styrene and $r$ is the radius of the microdisc. The $I_L$(A) vs. $c$ (mol $cm^{-3}$) plot is linear and is represented by the equation (correlation coefficient, 0.997)

$$I_L = 7.67 \times 10^{-6} c + 0.91 \times 10^{-10}$$

whose slope leads to a value of $4.0 \times 10^{-5}$ $cm^2$ $s^{-1}$ for $nD$, consistent with $n = 2$ [2] and $D = 2.0 \times 10^{-5}$ $cm^2$ $s^{-1}$.

The voltammograms for the dissolved polystyrene were not always the same quality as those for styrene. The plateaux were often slop-

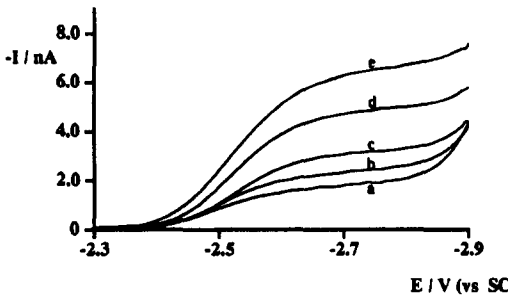

Fig. 1. Current–potential curves for the reduction of styrene in different concentrations at a gold microdisc electrode (radius 6 μm) in 90% toluene/10% DMF, containing 0.1 mol $dm^{-3}$ $Bu_4NBF_4$. Curve a, $2.0 \times 10^{-4}$ mol $dm^{-3}$; curve b, $3.0 \times 10^{-4}$ mol $dm^{-3}$; curve c, $4.0 \times 10^{-4}$ mol $dm^{-3}$; curve d, $6.0 \times 10^{-4}$ mol $dm^{-3}$; curve e, $8.0 \times 10^{-4}$ mol $dm^{-3}$.

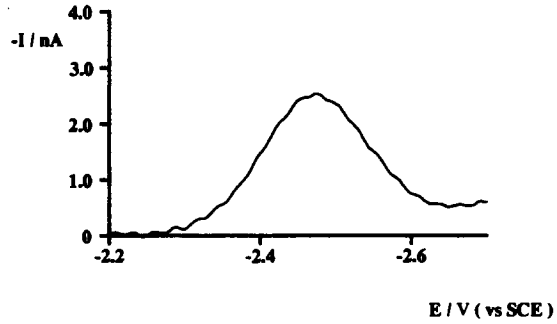

Fig. 2. Square-wave voltammogram of styrene ($3.0 \times 10^{-4}$ mol dm$^{-3}$) in 90% toluene/10% DMF, containing 0.1 mol dm$^{-3}$ $Bu_4NBF_4$ at a gold microdisc (radius, 6μm). (Square-wave amplitude, 2 mV; step height, 60 mV; frequency, 100 Hz.)

ing and sometimes the slow scan voltammetry showed a drawn out wave perhaps arising from a second overlapping reduction wave at slightly more negative potentials. This suggests that polystyrene may contain species other than styrene reducible at very negative potentials. The specificity essential for the determination of styrene in polystyrene could, however, readily be obtained by using square-wave voltammetry. Square-wave voltammetry is recognised to give much better resolution between overlapping reduction processes and converts the wave response into a peak [7]. The theory of square-wave voltammetry has been applied to ultramicroelectrodes by Osteryoung and O'Dea [8] and it has been shown that the peak current is given by

$$I_p = nFAc(D/\pi t_p)^{1/2}\Psi_p$$

where $t_p = \tau/2$ is the pulse width, $\tau$ being the period of the square wave, and $\Psi_p$ is the dimensionless current given by

$$\Psi_p = 0.846/\lambda + 0.750 + 0.177\exp(-1.13/\lambda)$$

where $\lambda = r/2(Dt_p)^{1/2}$

Fig. 2 shows a square-wave voltammogram of styrene ($3.0 \times 10^{-4}$ mol dm$^{-3}$) in 90% toluene/10% DMF containing 0.1 mol dm$^{-3}$ $Bu_4NBF_4$, at a gold microdisc electrode. A well-defined peak is observed at a potential of −2.49 V vs. SCE. A range of square-wave voltammograms was recorded for concentrations of styrene between 2.0 and $8.0 \times 10^{-4}$ mol dm$^{-3}$ and, as expected, a good linear relationship was found between the peak current and the concentration, given by the equation coefficient, 0.994)

$$I_p = 4.70 \times 10^{-6}c + 6.93 \times 10^{-10}$$

where $I_p$ is amps and $c$ is in mol dm$^{-3}$.

### 3.2. Analytical procedure

The sample of polystyrene (approximately 2 g) was dissolved in about 20 cm$^3$ of toluene using an ultrasonic bath. After complete dissolution (1 h), $Bu_4NBF_4$ (approximately 0.8 g) was added as a solid together with 2.5 cm$^3$ of DMF. When the electrolyte was fully dissolved, the solution was made up to 25 cm$^3$ with toluene in a volumetric flask. A 5 cm$^3$ portion of this solution was transferred to a simple electrochemical cell equipped with the polished gold microdisc electrode and a saturated calomel counter/reference electrode. Alumina was added to adsorb any water present and the oxygen was removed from the solution in a fast stream of argon. A square-wave voltammogram of the unstirred solution was then recorded at room temperature. A standard addition technique was employed to establish the relationship between the peak current and the styrene concentration in solution because it was considered likely that the presence of polymer in solution would cause a change in the viscosity and therefore in the diffusion coefficient of styrene. Several 3 μl additions of a solution containing styrene (0.30 mol dm$^{-3}$) in 90% toluene/10% DMF containing 0.1 mol dm$^{-3}$ $Bu_4NBF_4$ were made, and a square-wave voltammogram was recorded after each addition. Fig. 3 presents the voltammograms, not corrected for the background current, obtained for a sample of polystyrene BP(HIPS), and Fig. 4 shows the corresponding

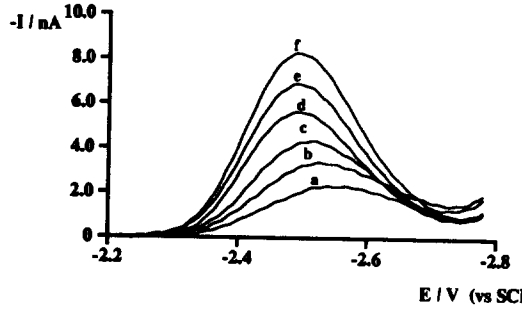

Fig. 3. Square-wave voltammograms of styrene in polystyrene BP(HIPS), (2.02 g in 25 cm$^3$) in 90% toluene/10% DMF, containing 0.1 mol dm$^{-3}$ $Bu_4NBF_4$ at a gold microdisc (radius 6 μm). (Square-wave amplitude 2 mV; step height, 60 mV; frequency, 100 Hz.) Addition to 5 cm$^3$ of sample solution were (a) 0 mol, (b) 0.9 μmol, (c) 1.8 μmol, (d) 2.7 μmol, (e) 3.6 μmol, (f) 4.5 μmol.

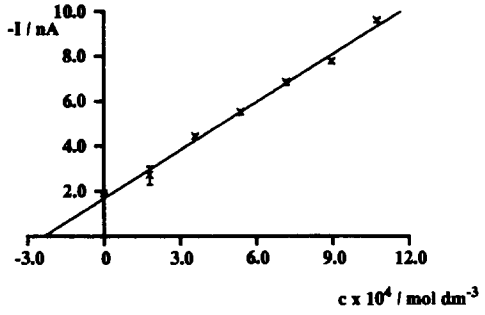

Fig. 4. Plot of square-wave peak current vs. concentration in the standard addition method for the sample of polystyrene BP(HIPS) in 90% toluene/10% DMF, containing 0.1 mol $dm^{-3}$ $Bu_4NBF_4$, as presented in Fig. 3. Each error bar represent twice the standard deviation of six determinations.

$I_p$ vs $c$ plot. A "tangent subtraction" on the computer was used to correct for background currents which were found to be more significant for dissolved samples of polystyrene than for solutions of pure styrene in the medium. In this subtraction method, a baseline was drawn between the response at the start of the peak and the minimum in the response negative to the peak; this peak height was then measured subtracting the baseline response at the peak potential. Using this measurement procedure, it can be seen that there is a good linear relationship (with a correlation coefficient of 0.998) between peak height and styrene concentration. The error bars on the figure are twice the standard deviation of six determinations. Another effect of the increased background current in the sample solution is the shift in peak potential to more positive potentials with increasing styrene concentration. This shift is not seen with solutions prepared from styrene. The origin of this background current is not clear and certainly no peaks could be defined in the square-wave voltammetry. They could arise from trace amounts of electroactive plasticizers, stabilizers, antioxidants or other additives in the polymer. It will be seen below that they are not a problem when the analysis was done by square-wave voltammetry. The errors were more significant when the analysis was based on the limiting current from steady-state voltammetry. The preference for square-wave voltammetry is not surprising since it is well known that techniques which give a "differential" response improve selectivity significantly [9].

### *3.3. Typical analyses*

The procedure described above has been used to determine the residual styrene content of four samples of polystyrene; three were commercial samples and the other a pot manufactured for Portuguese yogurt. The analyses for all four samples were straightforward and no interferences or complications were observed. The results from these analyses are reported in Table 1 along with analyses carried out by two commercial laboratories using the standard gas chomatographic method.

It can be seen that the results compared well especially since results from the standard procedure are normally only quoted to one significant figure. It should also be noted that the specification for polystyrene used in food packaging requires the residual styrene to be below 0.1%.

## 4. Discussion

The analytical procedure described in this paper has been shown to lead to estimates for the residual styrene content of polystyrene which compare well with the accepted standard procedure based on gas chromatography. It is, however, more rapid since it is not necessary to precipitate the polymer from solution before the analytical determination and it is much quicker to record the square-wave voltammogram than a chromatogram. It should be emplasized that the electroanalytical approach is only feasible because of the use of an ultramicroelectrode. It would not be possible to employ a traditionally sized electrode in a medium compatible with facile dissolution of the polymer. The application of ultramicroelectrodes in analysis has, in recent years, proved a fruitful innovation and they have been applied in several diverse analytical procedures [9]. The application of square-wave voltammetry was also found to improve the analytical procedure significantly. For a routine method, the equipment could be simplified substantially. The cell could be an enclosed beaker and the counter/reference electrode could be copper, aluminium or another metal (although there would, of course, be a shift in the peak potential). It would also be possible to write simple software for a microcomputer which controls the experiment, applies the potential/time function and analyzes the response to give the styrene content of polystyrene.

Table 1
Comparison of the results for the analyses of residual styrene in polystyrene by the new electroanalytical method and the standard procedure

| Sample | % Styrene by electrochemical method | % Styrene by gas chromatography [a] |
|---|---|---|
| BP | 0.031 ± 0.002 | 0.024 |
| BASF | 0.026 ± 0.004 | 0.032 |
| HCC | 0.021 ± 0.002 | 0.028 |
| Yogurt pot | 0.026 ± 0.004 | 0.024 |

[a] Each analysis was carried out by the Instituto Nacional de Engenharia e Tecnologia Industrial and Centro Nacional de Embalagem. Errors vary between 0.001 and 0.004%.

# Determination of cadmium in biological and environmental samples by slurry electrothermal atomic absorption spectrometry

L.C. Robles, A.J. Aller *

*Department of Biochemistry and Molecular Biology, University of León, E-24071 León, Spain*

Received 29 November 1994; revised 22 February 1995; re-revised 15 May 1995; accepted 17 May 1995

**Abstract**

The retention of cadmium by the bacteria *Escherichia coli* and *Pseudomonas putida* was optimized in order to develop a rapid and selective preconcentration method for cadmium from biological and environmental samples prior to determination by electrothermal atomic absorption spectrometry. Living and lyophilized cells for both bacteria were used, but the method using dead cells shows better analytical capabilities. Cadmium from aqueous solutions is easily retained on the outer membrane of both bacteria in the pH range 4–10, although the selected working pHs for *E. coli* and *P. putida* were 5 and 9, respectively. Cadmium retained by the bacteria was dispersed in 3.5 M nitric acid and the slurry was introduced directly into the graphite tube. The best sensitivity and detection limit were obtained for *E. coli* (0.03 ng $ml^{-1}$ and 0.04 ng $ml^{-1}$ respectively, in the absence of any chemical modifier). A strong spectral interference from nickel chloride was found and methods to overcome it were developed. The proposed extraction procedure was tested by the determination of cadmium in different standard biological and environmental samples.

## 1. Introduction

At present, there is great interest in clarifying the role of toxic elements in the development and evolution of certain illnesses. This interest is an obvious result of the improved prevention of acute poisoning. In addition, an increased awareness concerning chronic exposure is absolutely essential because such exposure may play a role in the causation of diseases with a multifactorial etiology.

Cadmium is one of the most toxic elements for animals and man. It is a ubiquitous and biologically non-essential element, being also classified as a class B and borderline element. Industrial exposure to cadmium can be the origin of acute and chronic toxicity in man. Low-level long-term exposure to cadmium seems to be associated with abnormally high hypertension, being related to renal sodium retention or to a direct effect on vascular smooth muscle [1]. The way of entry into the organisms can be by either inhalation or ingestion. Ingestion is related to severe gastroenteritis and inhalation to fatal pulmonary edema. The assimilation route of this element is similar to that of copper, zinc and manganese, being stored in the protein metallo-thionein [2]. An additional problem of cadmium toxicity is its accumulative character because about 30 mg can be accumulated during a lifetime. The main sources of cadmium are the food chain and the environment. From the analytical point of view, a problem emerges because con-

* Corresponding author

*SSDI* 0039-9140(95)01648-1

centrations of this element in biological and environmental samples are usually below the detection limits of the most sensitive techniques.

Cadmium has been successfully determined by different techniques: neutron activation analysis [3], atomic fluorescence spectrometry [4], flame atomic absorption spectrometry [5] and inductively coupled plasma-atomic emission spectrometry [6]. However, one of the most sensitive techniques for the determination of cadmium is electrothermal atomization atomic absorption spectrometry (ETAAS). Although some methods have been developed for the determination of cadmium either directly or with minimum sample manipulation in complex matrices (urine [7,8], seminal fluid [9], cigarettes [10]), many problems arising in the determination of cadmium by ETAAS have derived both from losses by vaporization prior to atomization and matrix interferences [11]. To solve these problems, different chemical modifiers [12–15] are currently used, in combination with metallic or metal-impregnated graphite platforms or tubes as atomizers [16–19]. However, different separation/preconcentration procedures have also been used to isolate cadmium from interferent matrices [11].

Some recently developed procedures for the identification and determination of cadmium use different biological systems. Thus, the crayfish, *Cambarus bartoni (Fab.) (Decapoda, Crustacea)* has been used as a reliable indicator of the presence of cadmium in the fresh water ecosystem [20]. The yeast *Saccharomyces cerevisiae* was immobilized on controlled pore glass and used in flow injection-atomic absorption spectrometry for the preconcentration of cadmium and other metals [21]. However, the most commonly used microoganisms in these tasks are algae. Cadmium ions have been preconcentrated from dilute solutions and marine reference samples by using different algae strains, *Stichococcus bacillaris* [22–24], *Chlorella pyrenoidsa* [24], *Chlamydomonas reinhart* [24,25], and *Selenestrum capricornutum* [26,27]. On the other hand, the outer membrane of bacteria displays many functional groups that can be used to retain some toxicological or precious metals. Analytical capabilities of the bacteria *Escherichia coli* (K-235) and *Pseudomonas putida* have been tested recently for gold [28] and beryllium [29]. In this paper, we will use these bacterial cells, *E. coli* and *P. putida*, to develop a preconcentration procedure for cadmium from biological and environmental samples prior to determination by slurry ETAAS.

## 2. Experimental

### 2.1. Apparatus and measurements

The experiments were carried out using a Thermo Jarrel Ash atomic absorption spectrophotometer SH 11 equipped with a heated graphite atomizer, model CTF-188, and the Smith–Hieftje background correction system. The operating parameters used were as follows: wavelength, 228.8 nm; a cadmium hollow cathode lamp, Visimax II, was used under the recommended conditions; slitwidth, 1 nm. Standard, uncoated, rectangular graphite tubes and standard pyrolytic graphite-coated platforms were used for platform atomization. An Epson 118 recorder was used. Solutions were injected into the graphite atomizer by means of the Fastac automatic aerosol deposition system, and argon (99.995% purity) served as the purge gas. The temperature programme used is shown in Table 1. The solution (10 μl) was injected into the atomizer at 150°C. Three replicate determinations based on both integrated absorbances (PA) and peak height (PH) were used for each measurement.

A Mettler AE 240 semimicro analytical balance (sensitivity, ±0.01 mg) was used for weighing the samples. The slurry was maintained during sample introduction into the atomizer using a Brasonic sonicator (model B-5). A pH meter (Crison model Digit 505) was used to measure the acidity of the aqueous phase. Potentiometric measurements were made with a radiometer automatic titrator (Mettler DL 25) (accuracy, ±0.1 mV) equipped with a combined platinum ring electrode (Mettler DM 140).

### 2.2. Reagents, preparation of cells and procedures

Cadmium stock solution (1000 μg $ml^{-1}$ Cd) was prepared by dissolving a suitable amount of cadmium oxide of the highest quality (Suprapur, Merck) in the smallest quantity of nitric acid then adding the appropriate volume of demineralized water. The test solutions were prepared by appropriate dilution of the stock solution immediately prior to their use. The

Table 1

The sampling time was 10 s, and the sampling volume was 10 µl.
[a] Values used to remove the interference from the nickel chloride.

inorganic acids and other chemicals used in this study were of the highest quality (Suprapur, Merck). Distilled, deionized water was used for the preparation of samples and standards. The TSA medium was obtained from Merck and the TSB from Biolife.

The preparation of the bacterial cells is a key stage in the retention procedure of metals, because the membrane composition changes with modification of those variables, affecting the cultivation process. Thus, the amount and type of fatty acids and phospholipids vary with temperature, growing medium, cultivation time [30–32], etc. Therefore, strict control in all stages of the preparation of the cells is needed. Cells were prepared as described elsewhere [28,29]. The retention efficiency was measured directly on the biomass. Glass (Pyrex) beakers were used in all measurements.

### 2.3. Procedure for the separation of cadmium

A 25 mg amount of biomass was added to 25 ml of cadmium solution at the corresponding pH. After 20 min stirring time, the biomass was separated by centrifugation (12 400*g*). The Cd–biomass pellet was treated with a 4 ml volume of 3.5 M nitric acid solution in order to prepare the slurry. The slurry was ultrasonically destabilized during sampling. The amount of cadmium sorbed by the biomass was deduced by determining the content of cadmium in either the slurry introduced into the graphite tube or in the supernatant solution after separation of the biomass. The solution pH was adjusted by using $HNO_3$ and NaOH solutions as necessary.

### 2.4. Sample treatment

National Institute of Standards and Technology (NIST) standard reference materials SRM 1577b bovine liver, SRM 1567a wheat flour and SRM 1568a rice flour were digested in triplicate with nitric acid. The digests were obtained by decomposing 0.2 g of bovine liver, and 4 g each of the dry powder sample materials wheat flour and rice flour with 10.0 ml of 1:1 (v/v) nitric acid. The solutions were evaporated to near dryness at 155 °C and the volumes made up to 25 ml with 0.05 mol $l^{-1}$ nitric acid. Prior to the determination of cadmium, the digests of bovine liver and wheat flour were diluted to 100 ml with 0.01 mol $l^{-1}$ nitric acid.

Air-dried coal fly ash SRM 1633a was ground to pass through a number 60 (250 µm) sieve and then ashed at 750°C to remove carbonaceous material. A 0.5 g sample of coal fly ash was digested in triplicate with 10 ml of hydrochloric acid ($d = 1.19$; 37.9% (w/w)) and 20 ml of nitric acid ($d = 1.42$, 69.8% (w/w)) to near dryness. A 20 ml amount of perchloric acid ($d = 1.53$; 60% (w/w)) was then added, and the sample was allowed to evaporate to dryness. A mixture of 10 ml of hydrofluoric acid ($d = 1.13$; 40% (w/w)) and 1 ml of sulfuric acid ($d = 1.84$, 96% (w/w)) was then added and the sample was again heated to dryness. The residue was dissolved in water and transferred quantitatively to a 100 ml volumetric flask.

## 3. Results and discussion

### 3.1. Sorption of cadmium

The best retention for cadmium (1 ng $ml^{-1}$) was obtained in the pH range 4.0–10.0 for both *E. coli* and *P. putida* (Fig. 1). However, the retention capacity (defined as the amount of cadmium retained on a percentage basis of the total cadmium in the original solution) for *P. putida* is nearly constant over the whole optimum pH interval, while for *E. coli* the

maximum retention occurs at a pH of 5.0. The selected working pHs for the following experiments were 5.0 and 9.0 for *E. coli* and *P. putida*, respectively. This versatility in the retention pH of cadmium using dead cells shows an advantage with respect to living cells because the latter can only work at a fixed pH (the pH of the culture medium). An advantage of the lyophilized bacterial cells is based on the fact that the useful retention pH is extended to acidic pH (3.5) and basic pH (11) compared with other extractants, such as algae (immobilized *Selenestrum capricornutum*: pH 9 and retention decreases strongly at higher and lower pH values [27] yeast immobilized *Saccharomyces cerevisiae*: pH above 6.5 [21], resins (7-dodecenyl-8-quinolinol: pH above 6) [33], and cyanobacteria (immobilized *spirulina platensis*: pH above 6.5 [34].

Two types of functional groups (Lewis bases (>CO, –COOH, –OH, etc.) at low pH and Lewis acids ($-NH_2$) at basic pH seems to be involved in the binding of cadmium, mainly for the bacterium *E. coli*, as a result of the data shown in Fig. 1, because the maximum retention capacity differs with the pH of the medium. At very strong acid (below 4–5) or basic (above 9–10) pHs, cadmium is not retained by the membrane wall because acidic functional groups are strongly protonated or cadmium in solution is bound to hydroxyl groups, respectively. It is also possible to conclude that these bacterial surfaces have a number of basic functional groups smaller (*E. coli*) or larger (*P. putida*) than the corresponding ones for the acidic functional groups, or alternatively, basic functional groups would have an affinity for cadmium smaller or larger than that of the corresponding acidic groups.

At the selected retention pH, the binding process shows typical two-phase kinetics (Fig. 2) where an initial period of rapid uptake occurs within minutes, followed by a period of slow, constant uptake over many minutes. This process seems to be much more true for *P. putida* than for *E. coli* and it can be explained by the cadmium ions binding first to the functional groups with the highest affinity (or accessibility) and subsequently to groups with lower affinity (or accessibility).

The maximum uptake was achieved in 20 min for *E. coli*, but the retention of cadmium by the bacterium *P. putida* went on for longer periods of time (Fig. 2). When a steady state is obtained (after 25 min), the percentage of cadmium retained is about 80.0% for both bacteria. However, for shorter periods of time, cadmium is retained more quickly by the bacterium *P. putida* than by *E. coli*, while for longer periods of time (60 min) the retention capacity for *P. putida* increases slowly (85.85%) and for *E. coli* decreases (77.24%). In conclusion, the bacterium *E. coli* has a slightly lower retention capacity for the cadmium ion compared with that obtained for the *P. putida*. The percentage of metal adsorbed by these bacteria is higher than that shown by the algae at pHs buffered at 5.5–6.5: *Stichococcus bacillaris* (35–53% depending on cadmium concentration, 0.1–4 mg $l^{-1}$), *Chlorella pyrenoidsa* (20–60%), and *Chlamydomonas reinharti* (20–35%) [24]. However, using the algae *Stichococcus bacillaris* (200 mg $l^{-1}$) and a higher cadmium concentration (144 mg $l^{-1}$), the cadmium recovery increases to 100% at neutral pH [23].

Using living cells, the removal of the cadmium ions from the solutions depends not only on the uptake rate, but also on the growth rate of the bacterial cells, because the number of cells increases during cultivation. Therefore we found only the maximum retention of cadmium. However, the retention of cadmium by living cells is always lower than when using lyophilized cells, probably due to some resistance mechanisms developed by the cells during their growth [35]. This represents a second advantage of the use of the lyophilized cells and, consequently, these cells will be the main tools used in the following experiments.

The retained cadmium increases with sample volume for a constant concentration of cadmium (0.1 ng $ml^{-1}$), but to a lesser extent than expected because the slope of the straight line

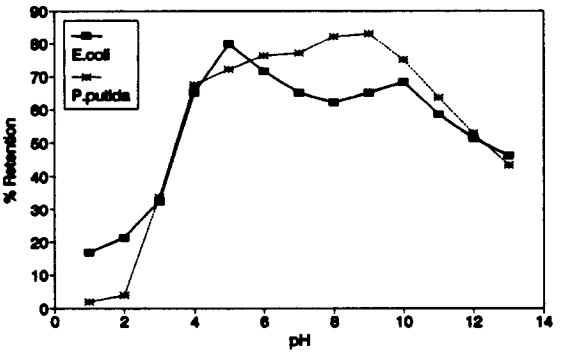

Fig. 1. Effect of pH on the retention of cadmium (1 ng $ml^{-1}$) by the lyophilized bacterias (25 mg) in 25 ml of solution (integrated absorbances by slurry platform atomization).

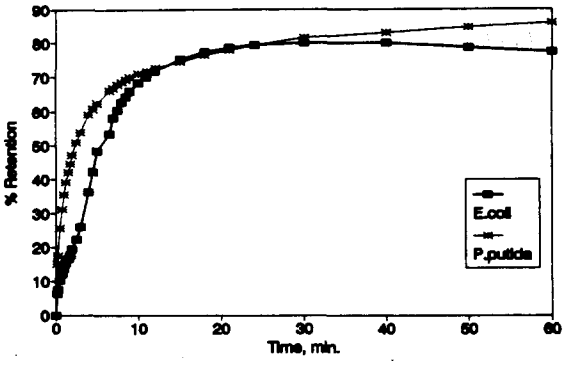

Fig. 2. Kinetics of cadmium (1 ng ml$^{-1}$) uptake by the outer membrane of lyophilized *E. coli* and *P. putida* (50 mg of cells in 50 ml of solution).

obtained by plotting absorbance versus sample volume is below unity. This suggests that in order to obtain the best uptake capacity of cadmium for increasing sample volume, it is necessary to use larger retention (stirring) times. On the other hand, no increase is obtained when the total amount of cadmium is maintained constant.

### *3.2. Mechanism of cadmium adsorption at the selected pHs*

The adsorption isotherms for cadmium show Langmuir shapes mainly for *E. coli* (Fig. 3), suggesting that the earlier retained cadmium ions do not affect the sorption of the neighbouring binding sites and the following cadmium-adsorbed species (Table 2). However, an anti-Langmuirian profile might exist at higher concentrations for *P. putida*, suggesting that the species adsorbed are favoured by those previously retained. This last result agrees well with the adsorption studies obtained using algae as extractants, where isotherms for cadmium have always shown general anti-Langmuirian shapes [24].

Adsorption studies [36] can usually be described by either the Freundlich isotherm ($s = K_F c^{1/n}$) or the Langmuir isotherm ($1/a = (1/a_m K_L)(1/c) + 1/a_m$). Both adsorption isotherms establish a relationship between the amount of metal adsorbed ($s$ is in nanograms per gram, $a$ is in milligrams per gram) by the bacteria and the concentration of metal in solution ($c$ is in nanograms per millilitre for the Freundlich isotherm and milligrams per litre for the Langmuir isotherm). The high values of the constants $K_F$ and $1/n$ show a high adsorption ability, while the parameters $a_m$ and $K_L$ represent the amount (mg) of metal adsorbed at saturation and the equilibrium constant of the adsorption process, respectively. The values of these parameters in Table 2 show a quite high ability of these bacterial cells to be used for preconcentration of cadmium. The Langmuir plot ($1/a$ vs. $1/c$) for both bacteria shows a straight line which represents the existence of only one functional group responsible for the retention of cadmium at the selected working pH. These results permit us to use a unique formation constant to describe the Cd–membrane bond in the concentration range studied (0.1–100 ng ml$^{-1}$ Cd). In contrast, results from the paper by Holcombe and co-workers [24] show two slopes in the Langmuir plot, although for a different concentration range (0.1–4 mg l$^{-1}$ Cd).

The mechanism of cadmium adsorption at the best retention pH for each bacterial membrane can be explained, as for other elements, on the basis of the chemical bond. In order to obtain an explanation of this adsorption mechanism, different experiments were carried out in which variations in the pH of a solution were recorded for the experimental cases shown in Table 3. Firstly, by adding lyophilized bacteria (50 mg) to water (50 ml) at the corresponding pH (case (i) in Table 3) we can deduce the amount of protons retained or liberated by the cells; secondly, if bacterial cells (50 mg) are added to a cadmium (1 ng ml$^{-1}$) solution (50 ml) (case (ii) in Table 3), the pH variation is also due to the influence of cadmium on the retention process; and thirdly, when a cadmium solution (10 ml) is added to an aqueous solution of cells (50 mg bacteria per 40 ml of solution) at the corresponding pH (cases (iii) in Table 3), the variations of pH are due to the retention of cadmium.

From the results of the first case (case (i) in Table 3), we can deduce that the bacterium *E. coli* in contact with water at pH 5.0 retains protons in an amount similar to that at which the *P. putida* at pH 9.0 retains hydroxyl groups. As a result of this, we can assume that the retention mechanism of protons by *E. coli* and of hydroxyl groups by *P. putida* seems to be similar. Therefore the charge of the overall membrane will be positive for *E. coli* (at pH 5.0) and negative for *P. putida* (at pH 9.0). For the second case, Fig. 4 shows the variation of solution pH during the retention process for cadmium by the bacteria. Data in Table 3 (case (ii)) were derived from Fig. 4 for a time interval

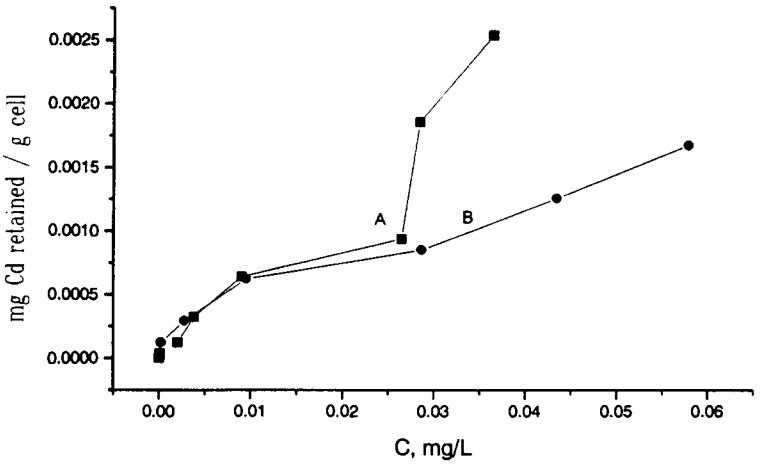

Fig. 3. Adsorption isotherm of cadmium for *P. putida* (curve A) and *E. coli* (curve B). Data shown were obtained by measuring the amount of cadmium in the supernatant solution and represent the average of three experiments with a repeatability of 3.5%.

of 20 min. The opposite trend in the variation of pH with both bacteria means that different types of ions are released from the bacterial membrane during the retention of cadmium. From Fig. 4 it is logical to think that hydroxyl groups should be released (directly or indirectly through the retention of protons) to the solution from the *E. coli* wall (at the retention pH of 5.0), while protons seems to be the most plausible ions liberated (directly or indirectly through the retention of hydroxyls groups) from the *P. putida* membrane (at pH 9.0). For this second case, the variation of pH (ΔpH) for *E. coli* ($\Delta pH_{E.\ coli} = 1.6$) is larger than that obtained for *P. putida* ($\Delta pH_{P.\ putida} = 1.1$; (Fig. 4); case (ii) in Table 3), while in the third case, the addition of cadmium to the bacterial suspension shows a smaller variation of pH of the medium (cases (iii) in Table 3).

These differences suggest that the retention mechanism of cadmium ions differs for each bacterium, being also in agreement with the results obtained for the retention rates (Fig. 2). The pH variations suggest that a proton (or hydroxyl group)–cadmium interchange process can occur, but this mechanism must not necessarily be the only process present because an alternative explanation based on conformational changes of the outer membrane components can also be assumed. In this case, any change in the structural conformation of the outer membrane components causes inner functional groups to be displayed to the aqueous environment, so retaining additional protons from solution.

Changes in the structural conformation of the membrane are suggested because it is possible to derive from Table 3 that the number of protons (or hydroxyl groups) liberated per cadmium ion retained is very high. Differences in these values for both bacteria suggest that different conformational changes occur in both bacterial membranes at the appropriate pH. It is reasonable to think that bacterial membranes in contact with the solution display their negative groups to the surrounding environment at low pH (5.0) and positive functional groups at basic pH (9.0). Cadmium ions would be bound to the negative charges of the membrane, changing their structural conformation in a different way depending on the solution pH.

### *3.3. Determination of Cd by slurry ETAAS*

The retention process was adapted to develop a procedure for the determination of cadmium by ETAAS. In this stage, those factors affecting the atomic absorption signal of cadmium were evaluated. These are the slurry characteristics (the washing acid concentration and slurry concentration), interferences from other elements and some instrumental parameters.

*Slurry characteristics*

Although the Cd–biomass pellet is introduced into the graphite tube as a slurry, we have found better atomic absorption signals for cadmium when the Cd–biomass slurry is treated with nitric acid solution. Therefore we use different concentrations of nitric acid in

order to obtain the best atomic absorption signal. Different concentrations of nitric acid could be used successfully (Fig. 5) at each retention pH, but the best results were obtained using a 3.5 M nitric acid solution at the selected retention pH. The 3.5 M nitric acid acts as a digestion agent, breaking or destroying organic compounds of the biomass, releasing in part the Cd ions under ultrasonic agitation. This total or partial release of cadmium from the biomass would also explain high cadmium values for the slurry in comparison to the supernatant solution. However, another role can also be attributed to $HNO_3$ in the slurry sample. Nitric acid acts also as a modifier because the sensitivity of the determination of cadmium is higher when the slurry is prepared with 3.5 M nitric acid than with the water-prepared slurry. The nitric acid-prepared slurry shows a sensitivity 1.22 (PH) and 1.18 (PA) times better for *E. coli* and 1.12 (PH) and 1.07 (PA) times better for *P. putida* than the water-prepared slurry. These results suggest that the 3.5 M nitric acid favours mainly the atomization rate of the cadmium. This nitric acid concentration was used in all experiments, even when working with living cells.

The washing time over intervals up to 38 h (using 4 ml of 3.5 M nitric acid every time) does not show a strong effect on the atomic absorption signal of cadmium (0.1 ng $ml^{-1}$) by ETAAS. Hence, a time interval of 20 min was selected in all experiments. We have also explored the possibility of determining cadmium in either the biomass pellet by the slurry sampling or in the supernatant after separation by centrifugation. However, higher absorbances for cadmium were obtained using the slurry sampling, suggesting the participation of the biomass on the atomization of cadmium. It is possible that, like other elements, organic matter acts as a chemical modifier. When cadmium was determined in the supernatant, a different behaviour for *E. coli* and for *P. putida* was noted, although results from the pellets were similar. Results from the analysis of supernatant show that for the *P. putida*, cadmium seems to be liberated for short time intervals, but it seems to be again retained for larger washing times. This can be due to the destruction (denaturation) of the macromolecular assembly of the cell walls for long washing times, providing soluble organic molecules with a high complexation capacity for cadmium. The behaviour of *E. coli* seems to be a little more irregular.

Table 2
Parameters of the adsorption isotherms

| Parameter | Bacteria | |
|---|---|---|
| | *E. coli* | *P. putida* |
| Freundlich's isotherm | | |
| $K_F$ (ng $g^{-1}$) | 101.95 | 108.09 |
| $1/n$ | 0.71 | 0.80 |
| Correlation coefficient | 0.97769 | 0.98474 |
| Langmuir's isotherm | | |
| $K_L$ | 678.68 | 737.22 |
| $a_m$ (mg $g^{-1}$) | $5.7 \times 10^{-4}$ | $5.1 \times 10^{-4}$ |
| Correlation coefficient | 0.98985 | 0.99712 |

The retention of cadmium can increase with bacterial mass. However, this behaviour might not necessarily be observed in the atomic absorption signal of cadmium. This is because cadmium is introduced into the graphite tube as a slurry, and biomass affects the atomization path of cadmium as was noted before, or it can even alter the sample introduction stage because the concentration of cells in the slurry sample increases with the amount of cells, making difficult the aspiration of the slurry by clogging the aspiration capillary. The cadmium absorbances increase gradually with the bacterial mass used in the retention process. This effect is mainly due to a clogging of the aspiration capillary of the Fastac sample introduction system, which occurs using amounts of *E. coli* above 20 mg (Fig. 6). From this figure we can conclude that the bacterial mass favours the atomization of cadmium. As a result of this, we can deduce that the maximum *effective* uptake capacity, defined as the amount of cadmium retained by a mass unit of the bacterial cells corresponding to the maximum atomic absorption signal of cadmium when it is introduced as slurry, was about 0.1 ng of cadmium per milligram of bacteria for both bacteria. As it is logical, this value represents an amount of cadmium a little lower than that derived from the Langmuir isotherm for the amount adsorbed at saturation ($a_m$) (Table 2).

*Effect of other elements*

Different elements could compete with cadmium during the retention process at the wall sites, showing interference effects on the final stage of the determination of cadmium by ETAAS. Thus, a ten-thousandfold concentration (1 μg $ml^{-1}$) of the following ions: Ag(I), Al(III), Au(III), Be(II), Bi(III), Ca(II), Ce(IV),

Table 3
Variation of pH ($\Delta pH = pH_{initial} - pH_{final}$) during the retention process for a time interval of 20 min

| System | *E. coli* | | | *P. putida* | | |
|---|---|---|---|---|---|---|
| | $pH_{initial}$ | $pH_{final}$ | ΔpH | $pH_{initial}$ | $pH_{final}$ | ΔpH |
| (i) $H_2O \leftarrow$ Bacteria | 5.10 | 6.50 | −1.40 | 9.00 | 7.56 | 1.44 |
| (ii) $H_2O$ + Cd [a] ← Bacteria | 5.10 | 6.70 | −1.60 | 8.75 | 7.65 | 1.10 |
| (iii) $H_2O$ + Bacteria ← Cd [a] | 5.05 | 5.14 | −0.09 | 9.03 | 8.76 | 0.27 |
| (iii) $H_2O$ + Bacteria ← Cd [b] | 5.05 | 5.23 | −0.18 | 9.02 | 8.85 | 0.17 |

[a] For cadmium solutions of concentration 1 ng $ml^{-1}$.
[b] For cadmium solutions of concentration 50 ng $ml^{-1}$ in the final volume.

Co(II), Cr(VI), Cu(II), Fe(III), Hg(II), K(I), Mn(VII), Na(I), Nb(IV), Pd(II), Se(IV), Sr(II), Te(IV), Th(IV), Ti(III), Tl(I), V(V), Zn(II) and Zr(IV) do not interfere (below 5%) in the cadmium ETAAS determination using either *E. coli* or *P. putida* for preconcentration (Fig. 7). Only La(III) and Ni(II) using *E. coli* and Ni(II), and to a lesser extent, Mg(II), using *P. putida* increase the atomic absorption of cadmium. However, increased interferences are obtained for Ni(II), Pd(II) and Zr(IV) using *E. coli*, and Ni(II), Co(II), Pd(II), Sr(II) and Zr(IV) using *P. putida* at higher concentrations (100 μg $m^{-1}$) of these elements.

The interference effects depend on the selected parameter (integrated absorbances or peak heights) used for the measurements, the bacterial cells, the concentration level of interfering elements and the counterion present. Therefore, using peak height measurements, interferences are qualitatively and quantitatively different to those obtained using integrated absorbances for both bacteria. Thus, some elements (Cr) affect only the peak heights, but others (Co, Ni, Pd, Zr) affect both peak heights and integrated absorbances. This suggests that metal concomitants are retained

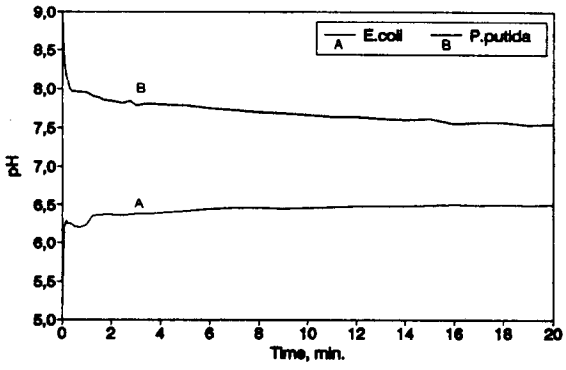

Fig. 4. Variation of pH during the retention of cadmium (lyophilized cells). These results were obtained on a continuous basis using potentiometric measurements.

together with cadmium and affect the atomization or the atomization rate of cadmium. In the same way, Ti and Cr, and, to a less extent Zr (at a 1 μg $ml^{-1}$ concentration) do not affect the integrated absorbances of cadmium but they increase the peak height of the atomic absorbance of cadmium using *E. coli*. This reflects a positive contribution of these elements upon the atomization rate of cadmium. This effect seems not to be dependent on the counterion because Cr was prepared in the absence of chlorides, while Ti was dissolved from titanium trichloride. However, using *P. putida*, this effect is mainly observed for Cr and Zr. This is probably due to the fact that the retention of Ti ions by the bacterium *P. putida* takes place to a lesser extent.

Interferences from the same concomitant differs with the bacterial cell used (La, Mg, Ti), suggesting a different participation (as an organic chemical modifier?) of the biomass in the atomization mechanism of cadmium or alternatively a different behaviour during the retention process. Interferences also vary with the concentration of the concomitant metals, and similar results to those obtained above were also found for both bacteria working at a higher concentration of the concomitant elements (100 μg $ml^{-1}$). A few elements interfere more at lower concentrations than at higher concentrations (La for *E. coli* and Mg for *P. putida*). This reflects either the existence of an antagonistic/synergistic effect with the retention of cadmium, or the presence of concomitant metals in the graphite tube, modifying the atomization path of cadmium.

The strongest interference effect arises from the presence of nickel at concentrations above 100 ng $ml^{-1}$. The interference of nickel shows a particular behaviour because its interference effect is only present when the original sample solution contains nickel as chloride but not as

nitrate. Using nickel chloride as interferent, the peak height of the atomic absorption signal of cadmium grows with the $NiCl_2$ concentration in the original sample solution, but the integrated absorbance increases much more. The interference of this element was studied to a greater extent, assuming that the enhanced interference effect can be explained on the basis of the following factors: (i) a synergistic effect on the retention of cadmium by the bacterial wall; (ii) a positive effect on the atomization of cadmium; or (iii) spectral interference.

In order to understand the positive interference of nickel, cadmium solutions without biomass were introduced into the graphite tube together with either nickel chloride or nickel nitrate, and solutions containing increased amounts of these salts were vaporized separately. The following considerations can be outlined concerning the interference of nickel: (i) the atomic absorption signal of cadmium increases with concentration of nickel chloride; (ii) no interference effect on the atomic absorption signal of cadmium in the presence of increased concentrations of the nickel nitrate exists; (iii) similar positve peaks to those reported in the presence of cadmium were obtained with increasing concentrations of the nickel chloride alone; (iv) a flat signal was obtained with increasing concentration of the nickel nitrate alone; (v) positive interferences appear again if nickel nitrate solutions (alone or together with cadmium) are vaporized in the presence of HCl. This indicates that the positive influence of nickel is due to the simultaneous presence of both the chloride and the concomitant metal. This also suggests that $Cl^-$ ions are retained together with the Ni and Cd ions by the cells used as sorbents. This interference effect appears even when the metal–biomass pellet is washed with nitric acid solution before introduction into the atomizer.

We explored different ways of overcoming this interference by using palladium and magnesium salts as chemical modifiers, by employing living cells as an extractant for cadmium, and by varying the temperature programme. The interference of Ni ($10\ \mu g\ ml^{-1}$) on the atomic absorption of cadmium ($26\ ng\ ml^{-1}$) was not completely overcome by adding Pd-based or Mg-based chemical modifiers at concentrations between 20 and $1000\ \mu g\ ml^{-1}$. We also explored the possibility of using living cells to separate cadmium from the nickel chloride solution. Therefore two sets of experiments were developed using bacterial cells grown together with, and in the absence of, cadmium with increasing concentrations of nickel as the chloride or the nitrate. Stronger interferences were also obtained as the nickel chloride concentrations increased. However, for nickel concentrations of $100\ \mu g\ ml^{-1}$ and above, the bacterial cells did not grow. The retention of the nickel and chloride ions by bacterial cells was clearly demonstrated, because these microorganisms, cultured in the presence of nickel chloride but without cadmium, also show a strong positive peak which increases as the nickel chloride concentration increases. A very small positive peak was also obtained when the cells were grown in a nickel nitrite solution, probably due to the presence in the culture medium of small amounts of chlorides. For the third approach, however, the interference of nickel was avoided using a higher temperature programme (Table 1). There is a relationship between interference and temperature, suggesting that the interfering species were simple molecules, probably NiCl or $NiCl_2$ molecules. The production of the nickel chloride molecules in the gas phase has been previously reported [38,39]. On the other hand, theoretical support for this assumption was also obtained [40]; it was shown [40] that the nickel chloride is stable in an argon atmosphere on the graphite surface to 630°C.

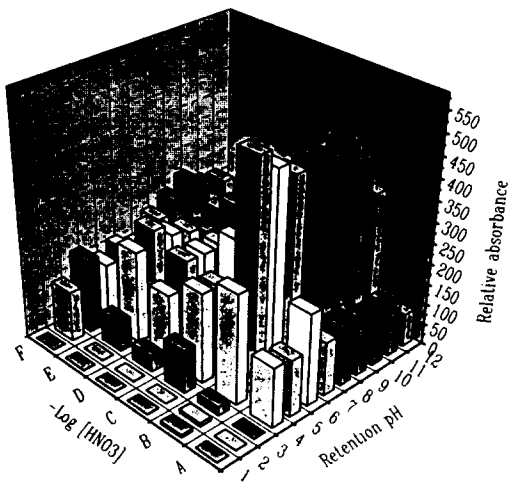

Fig. 5. Simultaneous effect of the retention pH and the washing nitric acid concentration ($mol\ l^{-1}$) on the atomic absorption signal of cadmium for *E. coli* ($-\log [HNO_3] = -0.86$ (A); $-0.56$ (B); 0.0 (C); 1.0 (D); 2.0 (E); 3.0 (F)). (integrated absorbances). Similar results were obtained for *P. putida*. The relative absorbance is the integrated absorbance multiplied by a factor of 1000.

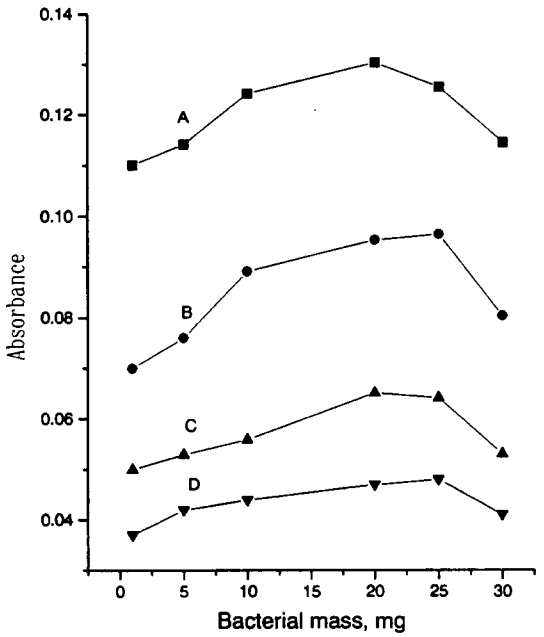

Fig. 6. Effect of biomass on the atomic absorption signal of cadmium (curves A, B) without and (curves C, D) with the extraction stage (nitric acid treatment). A and C, Cd–*E. coli* slurry; B and D, Cd–*P. putida* slurry.

In conclusion, the cause of this interference would be spectral, where a strong absorption from nickel chloride exists. These nickel species would exhibit a strong molecular absorption at the cadmium wavelength during the low-current pulse of the hollow cathode lamp used for the Smith–Heeftje background correction system of the spectrophotometer. However, the $NiCl_2$ could also show a small positive contribution in the atomization of cadmium owing to a partial hydrolysis of the nickel chloride [37] during the pyrolysis stage, seemingly a nickel chemical modifier. As a general rule, main interferences resulted from those concomitants used as chlorides, except Sr(II) and Cr(VI) which were prepared from the nitrate and potassium dichromate, respectively.

*Effect of some instrumental parameters on the atomization of cadmium*

The effect of some instrumental parameters (platform atomization, gas flow) upon the atomization of cadmium were studied for both bacteria.

*Platform atomization*

The rectangular graphite tubes described in the experimental section can be used in a vertical or horizontal manner. The two modes of the platform atomization differ in the orientation of the platform relative to the sample introduction jet. In addition, different heating rates can be experienced by the platform for the two modes. The atomic absorption signals of cadmium are very similar in each case, although showing some peculiarities (Fig. 8). Using horizontal platform atomization, atomic absorption peaks of cadmium appear at later times, showing also wider peaks. On the other hand, a second peak at the appearance time of 0.2 s appears in the atomic absorption peak profile of cadmium for concentrations of 1 ng $ml^{-1}$ (vertical platform) and 10 ng $ml^{-1}$ (horizontal platform) in the original aqueous solution. These results suggest that cadmium species are simultaneously vaporized from both the tube wall and the platform surface. Vaporization from the tube wall is more pronounced when using the platform in a vertical manner, probably due to the fact that the aerosol sample introduced into a graphite tube is deposited to a large extent on the tube wall. This does not happen using aqueous solutions because the atomic absorption signal of cadmium appears earlier, overlapping the first peak.

*Gas flow*

The influence of the purge gas flow during atomization was also studied using the *E. coli* slurry (Fig. 8) and the results can be summarized as follows. When the gas flow is "off" (i) the appearance time of the cadmium atoms is always 1 s; (ii) an increased peak width is obtained, (iii) the declining part of the peak continues on for longer times; and (iv) the appearance of a second peak is observed at 0.2 s for 10 ng $ml^{-1}$ Cd (in the original sample solution). When the gas flow is "on'," (i) the appearance time of the cadmium atoms is always 0.8 s; (ii) a smaller peak width is obtained; (iii) symmetrical peaks occur; and (iv) a smaller integrated absorbance is seen (Fig. 8B). From these results we can conclude that the presence of the purge gas flow during the atomization stage contributes to the desorption of cadmium species from the graphite surface as well as to the expulsion of cadmium atoms outside the tube. Cadmium is also vaporized as free atoms at low temperatures. Interactions between cadmium and graphite occur more strongly and the sensitivity is increased if the gas flow is "off". The results obtained from aqueous solutions show only one peak in the absorbance–time profile of cadmium at 0.2 s, and the sensitivity is a little lower than that obtained

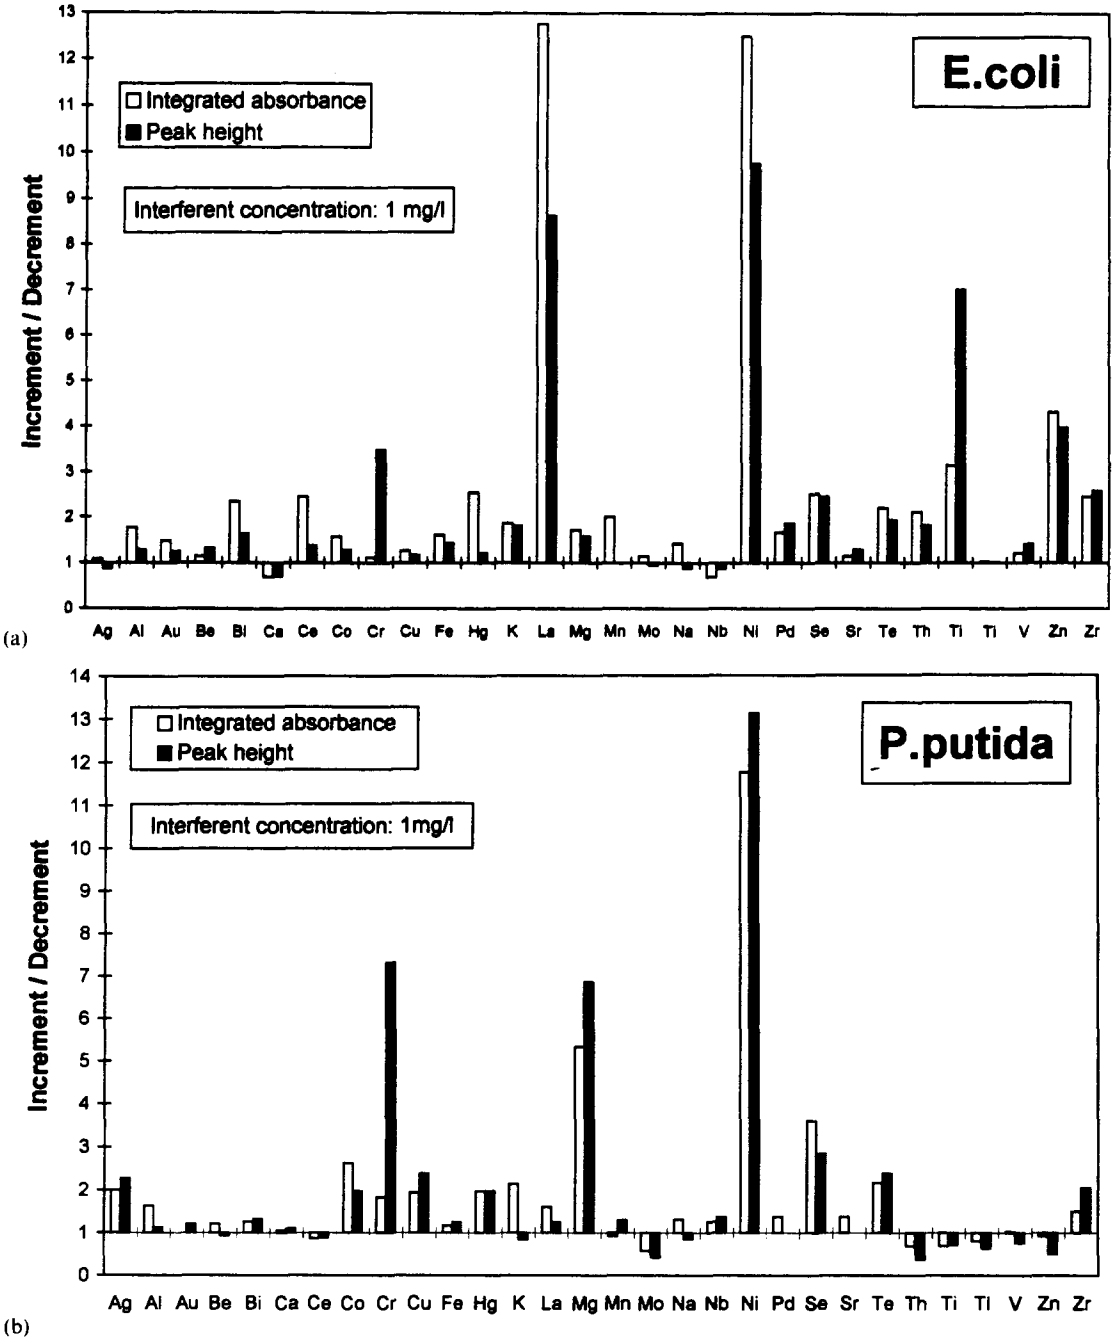

Fig. 7. Interferences of different elements (1 μg $ml^{-1}$) on the retention/determination of 0.1 ng $ml^{-1}$ Cd in the original sample for (a) *E. coli* and (b) *P. putida*.

from slurry atomization. This suggests that bacterial cells delay, simultaneously favouring, the atomization process of cadmium.

*Figures of merit*

The analytical characteristics (Table 4) show both that these bacterial cells were effective at preconcentrating small amounts of cadmium and that it is possible to determine cadmium by slurry ETAAS in the presence of an organic matrix. Beneficial effects were derived by using bacterial cells not only in the extraction step but also in the atomization process, because the introduction of cadmium together with the biomass into the graphite tube favours its atomization.

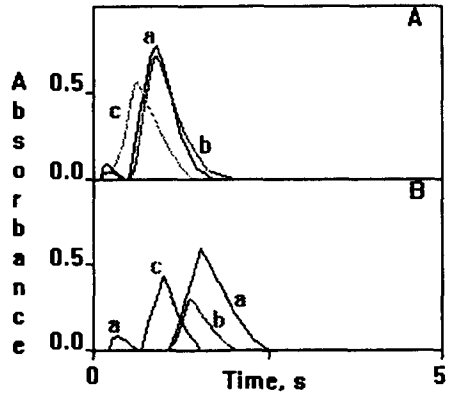

Fig. 8. Atomic absorption peak profile of cadmium (0.625 ng) for (A) vertical and (B) horizontal platform atomization. (A) curve a, *E. coli*; curve b, *P. putida*; curve c, aqueous solution. (B) curve a, *E. coli*; curve b, *P. putida*; curve c, the same as for curve a but with the gas flow "on". The gas flow was "off" always except in B, curve c.

The blank level of cadmium from the biomass against water was 0.005 AU and it was compensated for in the determination of the samples by setting the "zero" of the instrument for a biomasss slurry without cadmium. Calibration graphs were constructed by treating cadmium standards in the same way as the sample according to the procedures described in the experimental section. The sensitivity represents the slope of the analytical calibration graph of absorbance versus concentration (ng $ml^{-1}$) obtained by linear regression. Limits of detection found in this paper (Table 4) are similar to (0.05 ng $ml^{-1}$ [27], 0.06 ng $ml^{-1}$ [33]) or even better than (0.2 ng $ml^{-1}$ [21], 0.4 ng $ml^{-1}$ [34], 0.6 ng $ml^{-1}$ [41]) those reported in other work for different extractants.

The preconcentration factor was defined as the ratio between the volume of the initial sample and the final volume obtained after the extraction step. As the first aim of this paper was not to find a high preconcentration factor, a comparison with the very high concentration factors found in other work [33,42] using immobilized resins is unreliable. The AAS signal obtained on the direct injection of an aqueous cadmium solution compared with the obtained on the injection of a cadmium–pellet slurry of the same cadmium concentration (1 ng $ml^{-1}$) was termed the atomization factor. The atomization factor is the result of the simultaneous positive contribution of $HNO_3$ and the biomass to the atomization of cadmium. As the positive contribution factor ($f_a$) of $HNO_3$ was derived previously (see the section on slurry characteristics (3.3)) from the values of the atomization factors ($F_A$) shown in Table 4, we can derive the positive contribution factor of the biomass ($f_b$), because $F_A = f_a f_b$. From the results found for $f_b$, 1.81 (PA) and 2.38 (PH) for *E. coli* and 2.52 (PA) and 1.43 (PH) for *P. putida*, we can conclude that the biomass shows a positive effect larger than does the nitric acid. The enhancement factor of Table 4 was derived by comparing the AAS signal obtained on direct injection with that obtained after preconcentration and treatment with the appropriate volume and concentration of the nitric acid solution. The enhancement factors obtained were good for both bacteria.

The repeatability varies from 2.45 to 4.50% for cadmium concentrations between 0.5 and 12.5 ng $ml^{-1}$, but the best relative standard

Table 4
Figures of merit

| Parameter | Aqueous solution, PA(PH) | Lyophilized bacteria | | Living cells |

| Coal fly ash SRM 1633a | $1.00 \pm 0.15$ | $0.988 \pm 0.030$ | $1.005 \pm 0.033$ |

[a] The errors represent two standard deviations.

deviation was obtained for a cadmium concentration of 1 ng $ml^{-1}$ for both bacteria (Table 4). The accuracy of this procedure was tested by replicate determinations of cadmium in different standard samples, and the measured cadmium concentrations compared well with the certified values (Table 5). The blank levels of the NIST standard reference samples were estimated by parallel experiments applying the same separation procedure to 100 ml of Milli-Q water with the same amount of cadmium. These values represent 0.005 AU for the digestion procedure for the biological samples and 0.010 AU for the digestion procedure for the coal fly ash sample.

## 4. Conclusions

From this study we can conclude that the bacteria *E. coli* and *P. putida* show similar analytical possibilities when they are used to separate and preconcentrate cadmium from complex biological and environmental samples. The retention process for both bacteria shows higher efficiency over a wide pH interval, and the procedure for the retention/determination of cadmium exhibits good analytical sensitivity and excellent specificity.

Received 14 March 1995; revised 30 May 1995; accepted 31 May 1995

**Abstract**

A preparative supercritical fluid extraction system is described and was used with supercritical carbon dioxide to extract the active insecticide components pyrethrin I (PI) and pyrethrin II (PII) successfully from pyrethrum flower. A high-performance liquid chromatography method was developed and was used to separate and analyze the supercritical carbon dioxide extracts. Extraction efficiencies under several different extraction conditions were examined. Under the conditions examined, the most effective extractions of PI and PII ($140 \pm 18$ mg and $55 \pm 9$ mg per 100 g of dry pyrethrum flower powder) were performed at 40°C and 1200 psi. The results showed that extraction efficiencies of supercritical carbon dioxide are much better than those of *n*-hexane for pyrethrins I and II. During the extraction process, the most efficient extraction period was the first 3 h of the experiment.

*Keywords:* High-performance liquid chromatography; Insecticides; Preparative supercritical fluid extraction; Pyrethrin I; Pyrethrin II; Pyrethrum flower

## 1. Introduction

Natural pyrethrum insecticides that contain six similar pyrethrins have been prepared from the organic solvent extracts of pyrethrum flowers [1,2]. Pyrethrins have been used for the control of insects on animals in the house and on plants in agriculture for many years [3,4]. They possess exceptionally high selectivity ratios (mammalian oral $LD_{50}$/insect topical $LD_{50}$) compared to other classes of insecticides. Selectivity ratios for pyrethrins are generally greater than 1000, whereas those for members of other insecticide classes, e.g. organochlorines, organophosphorus, and carbamate, are typically less than 100 [5,6]. Therefore, the use of natural pyrethrum insecticides has increased tremendously [7]. In recent years, since people are now more concerned about environmental contamination and vertebrate toxicity, scientists are searching for new extraction techniques for pyrethrins to replace conventional solvent extraction.

Supercritical fluid extraction (SFE) has proved to be an effective technique for the extraction of flavors and active ingredients from plant materials [8–10], polyaromatic hydrocarbons from contaminated soil [11,12], and pyrethrins from pyrethrum flowers [13]. Supercritical carbon dioxide has been used as primary solvent for SFE, because it has no toxicity and a relative low critical temperature (31°C) and pressure (1070 psi). Supercritical carbon dioxide is an excellent solvent for non-

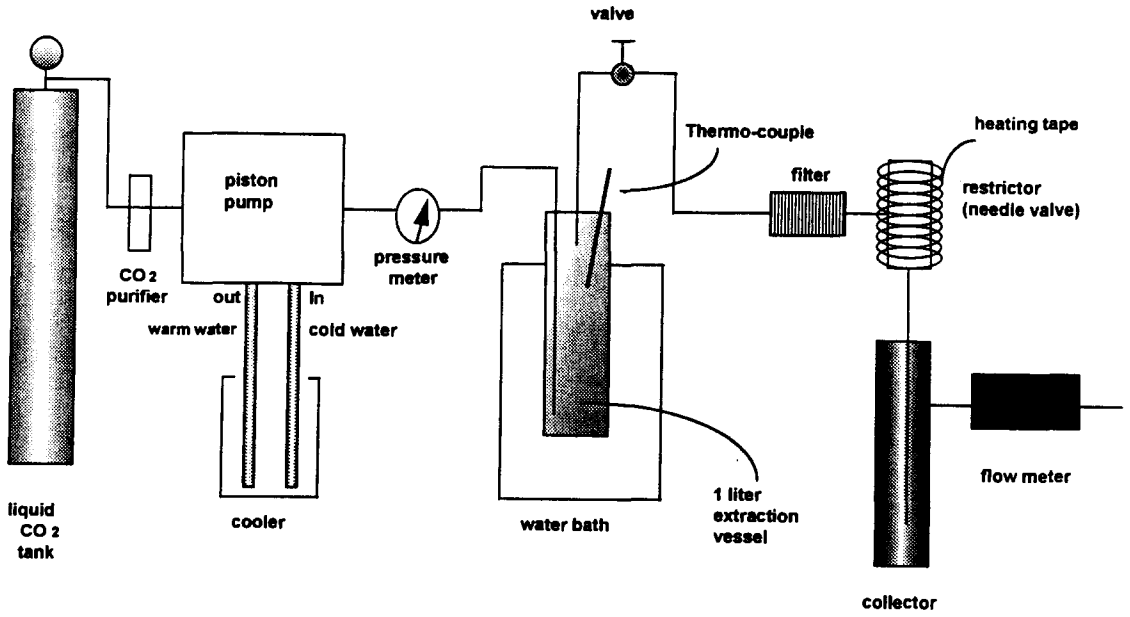

Fig. 1. The configuration of the SFE system used in this study.

polar organics because its solvating power and polarity can be controlled and adjusted by changing the temperature and pressure and by adding organic modifiers [14,15].

Dried pyrethrum flowers contain about 1–2% of natural pyrethrins by weight. Natural pyrethrins include pyrethrin I (PI), pyrethrin II (PII), jasmolin I (JI), jasmolin II (JII), cinerin I (CI), and cinerin II (CII) [12]. Among these six active ingredients, PI and PII are the major components and PI is the most potent one [7,16]. Therefore, the purpose of this investigation was to examine the usefulness of SFE for the extraction of PI and PII from pyrethrum flower powder; moreover, for comparison purposes, organic solvent extraction was performed and evaluated. In addition, an HPLC method was developed to determine the amount of PI and PII in the exctracts.

## 2. Experimental

### 2.1. Reagents

Carbon dioxide was purchased from Chin-Fong Hong (99.999%; Taipei, Taiwan, ROC). Dry pyrethrum flower was purchased from S.A. Pyrethrum Company, Ltd. (Landsberg, South Africa). HPLC-grade *n*-hexane was obtained from J.T. Baker Inc. (New Jersey, USA). Deionized water was collected from a Milli-Q water purification system (Millipore Corp., Massachusetts, USA). HPLC-grade anhydrous dichloromethane was purchased from Mallinckrodt Chrom AR (Germany). Saturated dichloromethane was prepared by shaking dichloromethane with Milli-Q water (80:20, v/v) for 15 min, letting the mixture stand for 10 min, and then discarding the aqueous portion. Pyrethrin standard was obtained from Riedel-deHaën AG (Germany). The composition of this standard is 26.8% of PI, 19.9% of PII, 1.4% of JI, 1.1% of JII, and a trace amount of CII. The standard (250 mg) was dissolved in 50 ml of *n*-hexane then dispensed into five 10 ml light-shield bottles and stored in a refrigerator.

### 2.2. Supercritical fluid extraction

A supercritical extraction system with a 1 l extraction vessel was self-assembled as shown in Fig. 1. A $CO_2$ purifier from J&W (model 300 – 1, California, USA) was used. A dual piston pump was used to increase the pressure in the system (LCD Corp., model 2396-89, Florida, USA), a 1 l extraction vessel was purchased from Zaar Tech. Inc. (Chicago, IL, USA), and a water bath was used to maintain the extraction temperature. A strainless steel in-line filter (part no. 2F-F4L, Parker-Hannifin Corp., Alabama, USA) was used to prevent clogging of the restrictor. A needle valve

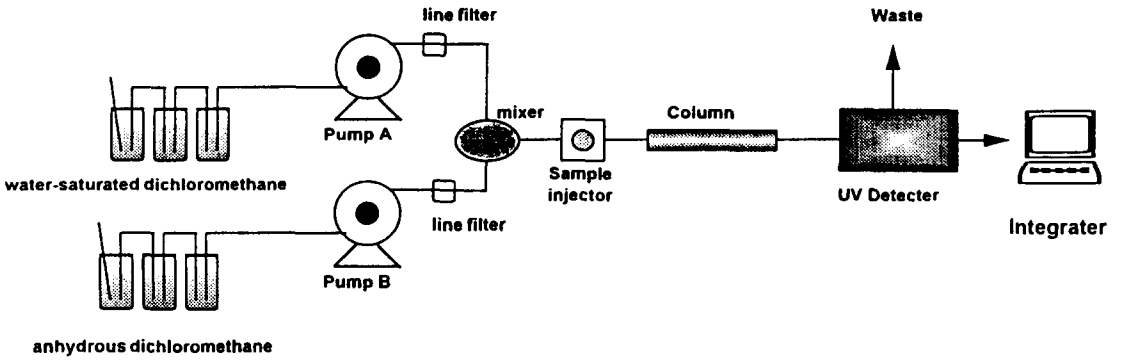

Fig. 2. Schematic of the semi-closed solvent delivery system and HPLC apparatus used in this study.

(Micrometering valve, part no. 30048-12, Autoclave Engineering Corp., Pennsylvania, USA) wrapped with a heating tape was used as a restrictor.

It has been demonstrated that the thermolabile PI and PII could be extracted without decomposition in the temperature range from 20 to 40°C [9]. Since the critical temperature of $CO_2$ is 31°C, the extraction temperature was fixed at 40°C in order to prevent PI and PII decomposition and to keep $CO_2$ in the supercritical phase. Four different extraction pressures were used: 1200, 2000, 2800 and 3600 psi. Each pressure was repeated at least three times. The outlet flow rate of atmospheric $CO_2$ during extraction was set at 3 l $min^{-1}$. About 200 g of dry ground pyrethrum flower powder were used in each SFE extraction. The extraction outlet was inserted into a flask containing 100 ml of *n*-hexane for trapping the crude extracted materials. Since some *n*-hexane evaporates during the collection period, additional *n*-hexane was added to maintain an adequate amount of the trapping solvent. After each extraction, *n*-hexane was added to the extraction flask to a total of 100 ml.

### 2.3. Organic solvent extraction

A 50 g portion of dry ground pyrethrum flower powder and 200 ml of *n*-hexane were placed in a flask wrapped with aluminum foil. After 5 h of continuous stirring at room temperature with a magnetic stirrer, the flask was refrigerated overnight, and the solution was then filtered. The filtered solution was stored in a light-shield bottle which was kept in a refrigerator. A 50 µl portion of the *n*-hexane extract was injected for HPLC analysis. All the above procedures were repeated three times on different days.

### 2.4. Chromatographic analysis

A Dionex 4000i chromatography system with a UV detector (California, USA) was used for HPLC analysis. The analytical separation was achieved on a 300 mm × 3.9 mm i.d. µ-Porasil column (Waters Association, Massachusetts, USA) with a mixture of 40% water-saturated dichloromethane and 60% anhydrous dichloromethane (v/v) as mobile phase. A Spectra-Physics (model 4400) data jet integrator (California, USA) was used for data acquisition and recording. The HPLC flow rate was 0.8 ml $min^{-1}$. A 2 ml portion of the SFE extract was combined with *n*-hexane to give a 100 ml solution, and 50 µl aliquots were then injected into the HPLC system for quantitative analysis.

A semi-closed solvent delivery system (shown in Fig. 2) was used to minimize the evaporation of the mobile phase during analysis. This system consisted of three identical solvent reservoirs placed in series, with only the reservoir furthest from the pump vented to the air, while the others were totally closed. Details of the chromatography data will be discussed in the following section.

## 3. Results and discussion

The relatively long analysis time required by published HPLC methods for the analysis of pyrethrins makes them less desirable [17,18]. We developed a rapid and reliable method. An evaluation of the effect of different mobile phase compositions on the retention times of PI and PII is summarized in Table 1. Results

Table 1
Retention times of PI and PII for different mobile phase compositions

| Water-saturated dichloromethane (%, v/v) | Anhydrous dichloromethane (%, v/v) | Retention time (min) | |
|---|---|---|---|
| | | PI | PII |
| 0 | 100 | 53.66 | 71.50 |
| 25 | 75 | 15.18 | 78.08 |
| 40 | 60 | 9.00 | 16.64 |
| 50 | 50 | 7.08 | 10.3 |
| 75 | 25 | 6.09 | 9.41 |

show that the retention times of PI and PII decreased as the amount of water-saturated dichloromethane increased. Adequate separation of each component was achieved by using a mixture of 40% water-saturated dichloromethane and 60% anhydrous dichloromethane (v/v) as mobile phase. The chromatogram is shown in Fig. 3, and the retention times of PI and PII with this mobile phase composition were approximately 9.0 min and 16.5 min, respectively. Furthermore, good linearity ranges were observed from 0.7 to 214 mg $L^{-1}$ for PI ($r^2 = 0.999$) and from 0.9 to 151 mg $L^{-1}$ for PII ($r^2 = 0.999$), respectively.

The total amounts of PI and PII extracted at various pressures by SFE are shown in Fig. 4. The extracted amount described in this figure has been normalized to 100 g of dry pyrethrum flower powder. At 40°C, the best extraction efficiencies for PI and PII were observed at

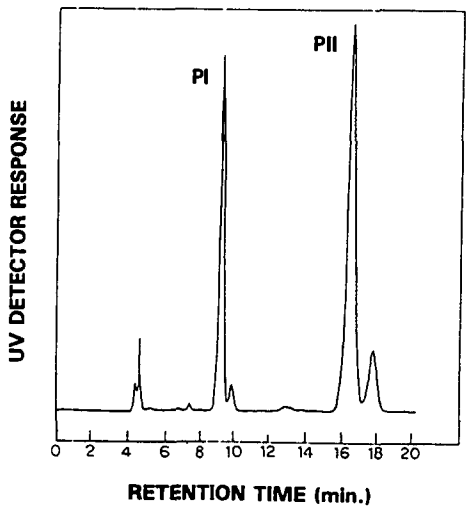

Fig. 3. Chromatogram of a standard. (Mobile phase flow rate; 0.8 ml $min^{-1}$; injection volume 50 µl. The UV detector was set at 254 nm.) PI is pyrethrin I and PII is pyrethrin II.

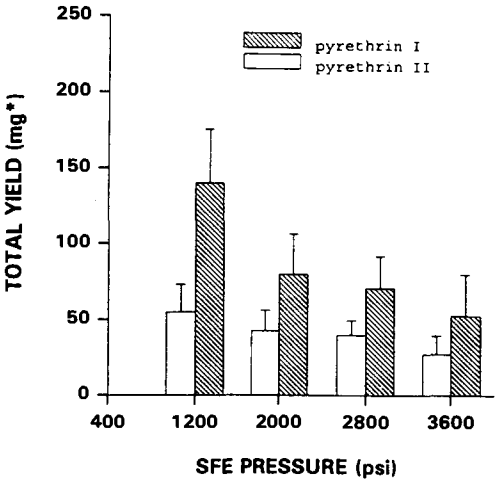

Fig. 4. Effect of SFE extraction pressure on the total yields of PI and PII. The values are the mean ± the standard error of the mean (SEM). The asterisk denotes milligrams of extract per 100 g of dry pyrethrum flower powder.

1200 psi (140 ± 18 mg and 55 ± 9 mg per 100 g of sample). This might be attributed to a low density and a high diffusivity of supercritical carbon dioxide at low pressure. As the extraction pressure increases from 1200 to 2000 psi, the density of supercritical carbon dioxide increases from 0.337 to 0.768 g $ml^{-1}$. As a result, the SFE extraction efficiencies for PI and PII decrease significantly. However, there is much less change in the extraction efficiency when the pressure is increased from 2000 to 3600 psi since the density of supercritical carbon dioxide increase to a lesser extent (0.768–0.885 g $ml^{-1}$) from 2000 to 3600 psi.

For comparison purposes, *n*-hexane extraction was performed and the total amounts of PI and PII extracted were 70 ± 8 mg and 39 ± 7 mg per 100 g of pyrethrum flower powder, respectively. This study demonstrated that SFE has a much better extraction efficiency than of *n*-hexane extraction, with 100% and 41% enhancement for PI and PII, respectively.

Fig. 5 shows SFE extraction kinetics of PI and PII from pyrethrum flower powder samples at 40°C and 1200 psi. The results indicate that the extraction of PI and PII from pyrethrum flower powder is most effective during the first 3 h; the extraction rate decreased significantly after 3 h.

## 4. Conclusion

Supercritical carbon dioxide extraction has been shown to be an effective technique for the

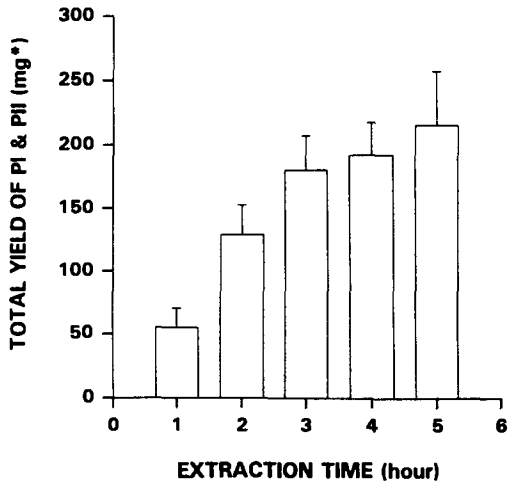

Fig. 5. Detection of the total yield of PI and PII in the SFE collector vs. extraction time. Values are the mean ± SEM. The asterisk denotes milligrams of extract per 100 g of dry pyrethrum flower powder.

extraction of pyrethrins from pyrethrum flower powder. For the temperature and pressure range examined, the most effective extraction conditions are 40°C and 1200 psi. Compared with the *n*-hexane extraction method, there is significant enhancement in extraction efficiencies for PI and PII by using SFE.

An HPLC method was developed and has been used successfully to separate the extracts. A semi-closed solvent delivery system was used to eliminate the mobile phase evaporation problem. Adequate separation of each component was achieved by using a mixture of 40% water-saturated dichloromethane and 60% anhydrous dichloromethane (v/v) as mobile phase. In addition, excellent linearity ranges for PI and PII were achieved.

We are currently studying the effectiveness of SFE extracts as insecticides. The initial test data indicate that the extract obtained by the SFE method is as effective as that obtained using the *n*-hexane extraction method.

# Chemiluminometric flow-injection method for determination of free L-malate in wine with co-immobilized malate dehydrogenase/NADH oxidase

Nobutoshi Kiba *, Junko Inagaki, Motohisa Furusawa

*Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan*

Received 21 March 1995; revised 2 June 1995; accepted 2 June 1995

**Abstract**

A flow-injection system with a co-immobilized malate dehydrogenase/reduced nicotineamide adenine dinucleotide (NADH) oxidase reactor and a chemiluminometer is described for the determination of free L-malate in wine. Malate dehydrogenase and NADH oxidase were co-immobilized on poly(vinyl alcohol) beads and packed into a stainless-steel column (5 cm × 4 mm i.d.). The hydrogen peroxide produced was detected chemiluminometrically via a luminol–hexacyanoferrate(III) reaction. The calibration graph was linear from $3 \times 10^{-7}$ M to $2.5 \times 10^{-4}$ M (the linear correlation coefficient was 0.9998); the detection limit (signal-to-noise ratio, 3) was $8 \times 10^{-8}$ M. The sample throughput was 30 $h^{-1}$ without carryover. The reactor was renewed every 2 weeks.

*Keywords:* Chemiluminescence; Flow injection; Co-immobilized enzyme reactor; Malic acid; Wine

## 1. Introduction

L-Malic acid affects the sensory characteristics of wines and its content is associated with microbial changes during aging and handling.

Enzymatic flow-injection (FI) methods for the specific determination of L-malate in wine have been developed using L-malate dehydrogenase (EC 1.1.1.37; MDH) [1–6]. Since the equilibrium constant [7] for the reaction catalyzed by MDH [L-malate + nicotineamide adenine dinucleotide ($NAD^+$) = oxaloacetate + reduced nicotineamide adenine dinucleotide (NADH) + $H^+$] is $6 \times 10^{-13}$, hydrazine is added to the carrier at a relatively high concentration to shift the reaction equilibrium toward oxaloacetate production through hydrazone formation [4]. However, hydrazine, which is carcinogenic [8], is not suitable for use in routine assays. Almuiabed et al. [6] developed a hydrazine-independent assay for malate, in which a higher pH (11.0) and a higher concentration of $NAD^+$ (3.6 mM) are used to shift the enzymatic reaction in the direction of oxaloacetate. The method is unsuitable for use in routine analysis because controlled-pore glass, which was used as a support for the covalent attachment of MDH, is unstable in alkaline solution [9]. Aspartate aminotransferase (EC 2.6.1.1; AAT) [10] and oxaloacetate decarboxylase (EC 4.1.1.3; OXD) [11] were used as trapping enzymes to shift the equilibrium of the MDH reaction in the direction of oxaloacetate.

In this work, NADH oxidase (NAOD) was used as a trapping enzyme, which catalyzes the oxidation of NADH with the production of hydrogen peroxide in the presence of molecular oxygen as an electron acceptor (NADH + $O_2$ +

* Corresponding author. Fax: (81) 552-20-8568.

*SSDI* 0039-9140(95)01660-0

$H^+ = NAD^+ + H_2O_2$]. The NAOD was co-immobilized with MDH onto poly(vinyl alcohol) beads. The NADH produced by the MDH reaction is removed by the NAOD reaction with concomitant formation of hydrogen peroxide.

FI systems with immobilized oxidase reactors and the chemiluminometric detection of $H_2O_2$ with luminol were used for rapid and sensitive determination of the substrates [12–15]. Unfortunately, the high pH (pH 10–11) required for efficient light production is not compatible with most oxidase reactions. A problem with such enzyme-coupled chemiluminometric FI systems is that a two-storage buffer sequence must be employed. A simple chemiluminometric FI system for the determination of substrates for dehydrogenases can be achieved by coupling a co-immobilized dehydrogenase/NAOD reactor with luminol chemiluminescent detection of $H_2O_2$.

In the present investigation we have developed a FI system for the chemiluminometric determination of L-malate with a co-immobilized MDH/NAOD reactor, in which enzymatic reactions and the luminol reaction were performed in the same buffer system (0.3 M carbonate buffer (pH 10.0)); in this system the pH mismatch problem previously encountered in coupled enzymatic luminol chemiluminometric detection systems can be eliminated. The method was adapted to the assay of wines.

## 2. Experimental

### 2.1. Chemicals and reagents

MDH (from *Thermus* sp., type III, 120 U $mg^{-1}$) and NAOD (EC number not assigned, from *Bacillus megaterium*, 50 U $mg^{-1}$) were obtained from the Amano Pharmaceutical Co. (Nagoya) and Asahi Kasei (Tokyo), respectively. The activity for MDH was evaluated from the increase in absorbance at 340 nm with L-malic acid and $NAD^+$ at pH 9.0 at 40°C. For NAOD it was estimated from the decrease in absorbance at 340 nm with NADH as substrate at pH 9.0 at 40°C. $NAD^+$ (free acid; 96%) and NADH (98%) were from Khojin (Tokyo). Poly(vinyl alcohol) beads (GS-520, 13 μm) and nylon beads (A-1030, 100–150 mesh) were purchased from Showa Denko (Tokyo) and Unitika (Osaka), respectively. The purity of L-malic acid, which was obtained from Sigma, was tested by the enzymatic method [16]. All other chemicals were of analytical-reagent grade.

A carbonate buffer (pH 10.0) consisting of 0.3 M sodium carbonate–0.3 M sodium hydrogen carbonate was used. A potassium hexacyanoferrate stock solution (150 mM) was prepared and diluted fivefold with water before use. $NAD^+$ solution (1.5 mM $NAD^+$ in 0.01 M phosphate buffer (pH 7.0)) was prepared daily. Luminol solution (3.0 mM luminol in 0.3 M carbonate buffer (pH 10.0)) was prepared and stored for 3 days in a refrigerator before use [12,17]. By means of the incubation, the background chemiluminescence emitted on admixing with the luminol solution and potassium hexacyanoferrate solution reduced to about one-half of its initial value, for unknown reasons.

Nylon beads were packed into a stainless-steel column (2 cm × 4 mm i.d.) having a needle for injection, with use of the dry-packing method (nylon cartridge). The cartridge was used for filtration and removal of polyphenols and dyes.

### 2.2. Preparation of the co-immobilized enzyme reactor

MDH and NAOD were immobilized simultaneously onto the poly(vinyl alcohol) beads. The beads were aminated with epichlorohydrine and ammonia water; the procedure was similar to that described previously [18]. The aminated beads were packed into a stainless-steel column (5 cm × 4 mm i.d.) and activated with 2.5% glutaraldehyde in 0.1 M phosphate buffer (pH 7.0). Enzyme solution (5 mg MDH (600 U) and 5 mg NAOD (250 U) in 10 ml of 0.1 M phosphate buffer (pH 7.0)) was circulated through the column for 6 h at a flow rate of 0.2 ml $min^{-1}$. The time course of the immobilization process for NAOD was monitored by use of a spectrophotometer (Jasco Uvidec-100-VI) equipped with a flow-through cell at 380 nm. The NAOD was immobilized with a 82% yield. The reactor was washed with the NAD solution and stored in a refrigerator when not in use.

### 2.3. FI system and procedure

A schematic diagram of the system is shown in Fig. 1 The system consisted of four piston pumps (Hitachi L-6000), an injection valve

(Sanuki SVI-6M2) equipped with a 50 µl loop, a reactor, a luminometer (Soma S-3400) with a flow-through cell (100 µl) connected to a signal cleaner (SIC SC77) and a recorder (TOA FBR-251A). The reactor was maintained at 40°C.

Wine (about 3 ml) was placed in a glass syringe. A nylon cartridge was fitted at the tip of the syringe, and the first 1 ml was discarded, after which 500 µl of filtrate were diluted two-hundredfold with water. An aliquot (50 µl) was injected into a carrier stream. The cartridge was renewed for each sample.

The results obtained by the present method were compared with those obtained by use of an F-kit (Boehringer Mannheim) with soluble MDH and AAT.

A, $NAD^+$ solution (0.3 ml $min^{-1}$); B, carbonate buffer (0.3 ml $min^{-1}$); C, 30 mM potassium hexacyanoferrate solution (0.3 ml $min^{-1}$); D, 1.5 mM luminol in 0.3 M carbonate buffer (pH 10.0) (0.3 ml $min^{-1}$); P1, P2, P3 and P4 pumps; S, injector with a 50 µl loop; ER, co-immobilized enzyme reactor; WB, water bath; MC, mixing coil; G, luminometer with flow-through cell (100 µl); SC, signal cleaner; R, recorder; W, waste.

## 3. Results and discussion

### *3.1. Properties of co-immobilized MDH/NAOD*

In order to determine the optimum operating parameters for chemiluminometric FI determination of L-malate using a co-immobilized MDH/NAOD reactor, the system shown in Fig. 2 was used and a series of investigations was first conducted in order to determine the influence of pH, temperature and $NAD^+$.

The effect of pH on the activity of the reactor was studied in the pH range 9.0–10.5 by injecting 10 µM L-malate (50 µl). The optimum pH for the reactor was about 10.0, as shown as Fig. 3. The activity of the reactor at different temperatures was examined over the range 40–50°C. The reactor exhibited maximum activity at 50°C, as shown in Fig. 3. The water bath was thermostated at 40°C to prolong the lifetime of the reactor. The effect of $NAD^+$ concentration on peak height was examined over the range 0.2–6 mM at an L-malate concentration of 500 µM. The optimum $NAD^+$ concentration was about 1.0 mM; for the MDH reaction lower $NAD^+$ concentrations are undesirable for the formation of NADH, and at higher concentrations the equilibrium of the reaction is shifted to the right. However, for the NAOD reaction, higher $NAD^+$ concentrations are undesirable for the production of

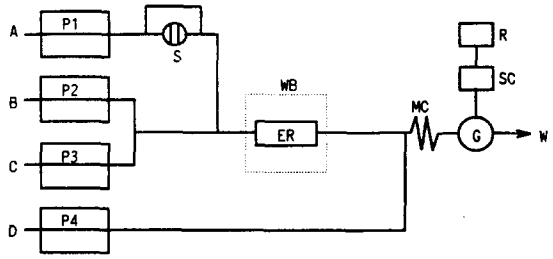

Fig. 1. Schematic diagram of chemiluminometric flow-injection system for the determination of L-malate with a co-immobilized malate dehydrogenase/NADH oxidase reactor. A, $H_2O$ (0.3 ml $min^{-1}$); B, 1.5 mM $NAD^+$ in 0.01 M phosphate buffer (pH 7.0) (0.3 ml $min^{-1}$); C, 3.0 mM luminol in 0.3 M carbonate buffer (pH 10) (0.3 ml $min^{-1}$); D, 30 mM potassium hexacyanoferrate solution (0.3 ml $min^{-1}$); $P_1$, $P_2$, $P_3$ and $P_4$, pumps; S, injector with a 50 µl loop; ER, co-immobilized enzyme reactor (5 cm × 4 mm i.d.); WB, water bath thermostatted at 40°C; MC, mixing coil (100 cm × 0.5 mm i.d.); G, luminometer with a flow-through cell (100 µl); SC, signal cleaner; R, recorder; W, waste. All connecting tubing (0.5 mm i.d.) was of Teflon.

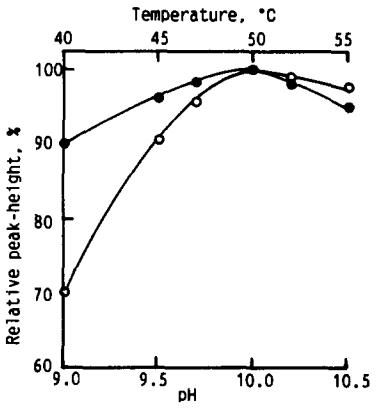

Fig. 3. Effects of pH and temperature on the response. ○, Effect of pH on the enzyme reactions; ●, effect of temperature on the enzyme reactions. The FI system shown in Fig. 2 was used. The concentrations of $NAD^+$, luminol and potassium hexacyanoferrate were 1 mM, 1.5 mM and 30 mM, respectively. All values were within 0.6% of the relative standard deviation ($n = 6$).

$H_2O_2$. A $NAD^+$ solution of 1.5 mM was used in this system; as shown in Fig, 1, since the solution is diluted threefold with the luminol solution and carrier stream, the $NAD^+$ concentration in the reactor is 0.5 mM.

The influence of luminol concentration on the peak height was studied from 0.3 to 12 mM, using the system shown in Fig. 1. The reactor exhibited a maximum response at 9 mM, but the inactivation of the reactor commenced at above 4.5 mM. The response for $H_2O_2$ increased linearly with increase in luminol concentration when the reactor was omitted. A luminol solution of 3 mM was used in this system; the luminol concentration in the reactor is 1 mM.

The operational stability of the reactor was evaluated over a period of 6 weeks. The reactor was used for 4 h per day (120 injections of 300 μM L-malate solution containing 15 mM ethanol) and then washed with the $NAD^+$ solution and stored in a refrigerator when not in use. The activity decreased slowly to 82% of the initial value after 6 weeks (5000 injections). When the daily washing procedure was eliminated, the activity decreased rapidly to 32% of the initial value after 5 days.

The chemiluminescence intensity–time variation was measured by changing the flow rates of the reactor eluent and the potassium hexacyanoferrate solution, using the smaples containing only $H_2O_2$. During the experiments the flow rate ratio of the eluent and the solution was kept at 3:1. Maximum response was obtained about 10 s after the mixing of the solutions. The peak height was measured by changing the flow rates of the $NAD^+$ solution, the luminol solution and the carrier stream, keeping the flow rate ratio of the solutions at 1.0. The peak height decreased linearly from 0.3 to 1.2 ml $min^{-1}$ for the total flow rate. The peak height at 0.3 ml $min^{-1}$ was about 1.6 times that at 1.2 ml $min^{-1}$ and the half peak width for the former was 1.9 times that of the latter. A total flow rate of 0.9 ml $min^{-1}$ (0.3 ml $min^{-1}$ each) was selected, as a compromise between sensitivity (peak height) and sample throughput; at this flow rate, the sample throughput was 30 $h^{-1}$. On the basis of these results, the flow rate of the potassium hexacyanoferrate solution selected was 0.3 ml $min^{-1}$; since the total flow rate was 1.2 ml $min^{-1}$ at the flow through cell, a mixing coil of 100 cm × 0.5 mm i.d. was used.

The influence of reducing substances on the peak height for malate (50 μM) was measured over the range 5–50 μM. The presence of equimolar amounts of sodium ascorbate and sodium sulfite depressed the peak height to 97% and 96%, respectively. Under the same conditions, the peak height did not change with the presence of 1 mM concentrations of carboxylates such as tartrate, citrate, lactate, succinate and acetate, and of ethanol up to 30 mM. The relative activities for L-malate and D-malate were 100 and 2, respectively.

### 3.2. Calibration

Under the conditions shown in Fig. 1, the plot of peak height against malate concentration was linear from 0.3 to 250 μM. The least-squares calibration equation for malate was $Y = 0.7085x + 5.6464$, where $Y$ is log(peak height (cm)) and $x$ is log(malate concentration (M)), with a linear correlation coefficient of $r = 0.9998$ (15 data points). In the reactor malate reacted in 48% yield. Below a concentration of 0.3 μM a concave graph was obtained, and above a concentration of 300 μM the graph was convex. The relative standard deviation (R.S.D.) for seven replicate injections of 100 μM malate was 0.54%. The R.S.D. ($n = 7$) for 100 μM malate in the system shown in Fig. 2 was 1.4% because of incomplete mixing of the luminol solution with the reactor eluent.

The lower limit of detection (signal-to-noise ratio = 3) was $8 \times 10^{-8}$ M (0.5 ng in a 50-μl injection).

### 3.3. Application

The method was applied to the determination of the free L-malate content in wines.

### 3.4. Recovery

First, a recovery test was performed by using a red wine sample which was supplemented with L-malate to give a final concentration of 45.5 mM. The results that had poor recoveries were obtained by subjecting wine samples that were merely diluted, without filtration through the nylon cartridge. These results are probably due to the presence of sulfites which are attached to dyes and polyphenols in wine; they react with the $H_2O_2$ produced in the reactor. Good results were obtained after removal of

Table 1
Recovery of L-malate added to red wine using the present method [a]

| Added (mM) | Recovered [b] (mM) | Recovery (%) |
|---|---|---|
| 5.00 | 4.92 ± 0.03 | 98 |
| 10.0 | 9.90 ± 0.06 | 99 |
| 15.0 | 15.2 ± 0.1 | 101 |
| 20.0 | 20.1 ± 0.1 | 101 |
| 25.0 | 25.0 ± 0.1 | 100 |
| 25.0 [c] | 18.5 ± 0.4 | 74 |

[a] Values corrected for L-malate (16.5 mM) already present in wine.
[b] Mean ± standard deviation. The values are the means of nine determinations.
[c] sample without filtration through nylon cartridge.

the compounds with the nylon cartridge (Table 1). The recovery was in the range 98–101%.

### 3.5. Precision and reproducibility

Red wine was repeatedly analyzed over a period of 3 weeks with use of the reactor. The reactor was used for the analysis of 90 samples per day and standards were measured at 30-sample intervals, in order to correct the variation of conversion efficiency. The reactor was renewed every 2 weeks. This method gave precise and reproducible results; for red wine containing 6.72 mM, the within-day R.S.D. was 0.51% and the day-to-day R.S.D. was 0.97%.

### 3.6. Comparison with a reference method

The results ($n = 23$: 12 red wines, from 3.71 to 41.8 mM; 11 white wines, from 15.6 to 45.2 mM) were compared with those obtained by use of an F-kit (Boehringer Mannheim) with soluble MDH and AAT. The results are summarized in Fig. 4. The calculated linear regression and correlation coefficient were $y = 0.9993 - 0.0029$ and $r = 0.9999$, respectively.

## 4. Conclusion

The flow-injection system with a co-immobilized MDH/NAOD reactor and chemiluminometic detection is useful for the sensitive and reliable measurement of L-malate in wine. Compared with fluorimetric FI methods utilizing co-immobilized MDH/AAT [9] and MDH/OXD [10], the $NAD^+$ concentration is about half and the sensitivity is two-times higher. The high sensitivity of luminescence allows the drawback of rather low conversion efficiency to be overcome. The co-immobilized MDH/NAOD reactor is stable enough to permit the measurement of more than 1000 samples.

# Short communication

# Uses of antimony pentachloride for thermometric determination of urea in acetic anhydride

Turgut Gündüz*, Esma Kılıç, Orhan Çakırer

*Department of Chemistry, Faculty of Science, University of Ankara, Ankara, Turkey*

Received 19 January 1995; revised 3 May 1995; rerevised 31 May 1995; accepted 1 June 1995

*Keywords:* Antimony pentachloride; Thermometric analysis; Urea

## 1. Introduction

Recently we have reported a potentiometric method for the titration of urea with perchloric acid in acetic anhydride as solvent [1]. Subsequent to this report, we also have titrated urea thermometrically with antimony pentachloride in the same solvent and have obtained very identical results to those obtained in the previous work.

## 2. Experimental, results and discussion

The antimony pentachloride used in this titration was purchased from Merck (99% purity) in small ampules and was used without further purification. In order to prepare a solution of this compound, an ampule was cooled to approximately 4°C [2,3]. The ampule was then opened and its contents were decanted immediately into a 50.0 ml volumetric flask containing about 25 ml of purified 1,2-dichloroethane [2]. The volumetric flask was then weighed accurately. Since the flask together with its contents had been weighed before the antimony pentachloride was decanted into the flask, the difference between the weights was taken to be the mass of the antimony pentachloride. The flask containing the antimony pentachloride solution was shaken vigorously and then left for 2 h to attain thermal equilibrium. Subsequent to this process the flask was filled to the red line and was then stoppered. The solution prepared in this way was stored as stock solution. By taking the required amount of solution from this stock solution, a 0.2 M antimony pentachloride solution was prepared and standardized against 1,3-diphenylguanidine.

The 1,3-diphenylguanidine was purchased from Fluka (99.5% purity) and was recrystallized twice from pure dry toluene, then dried at 100°C for 2 h (m.p., 148°C). A compound dried in this way is one of the best primary standards for non-aqueous-medium acids [4].

Urea was purchased from Fisher Scientific (99.5% purity) and was recrystallized three times from absolute ethanol. In addition, the compound was analyzed five times by the Kjeldahl method in order to determine its percentage purity; this was found to be 99.3%. This latter was accepted to be the true value. A 0.0200 M stock solution was prepared from this compound in acetic anhydride and was used in the titrations.

Acetic anhydride was purchased from Merck (99.8% purity) and was used without further purification.

Titrations were carried out in a fume cupboard made heat-proof with blown polystyrene sheeting. Its small window was left unisolated in order to view the whole titration assembly and to operate it properly, (see Fig. 1). The

* Corresponding author.

*SSDI* 0039-9140(95)01661-9

assembly was simple and consisted of (i) a small Dewar flask with a capacity of 30 ml; (ii) a tin-tipped semi-microburette with a reservoir; (iii) a Beckmann and two good-quality thermometers; and (iv) a good-quality magnetic stirrer. The Dewar flask was placed in a beaker with a capacity of 250 ml, and the walls of the Dewar flask were insulated from the walls of the beaker with blown polystyrene sheeting. The beaker was also insulated from the magnetic stirrer with blown polystyrene sheeting.

The Dewar flask was covered with a blown polystyrene lid suitably pierced to hold the Beckmann thermometer and the tin-tipped semi-microburette with a reservoir holding the titrant. On top of the reservoir was placed U-tubing filled with anhydrous calcium chloride in order to prevent moisture entering. The Beckmann thermometer was immersed in the urea solution to a definite depth in each titration, and enabled temperature changes to be read to within 0.001°C. The tin-tipped semi-microburette enabled the volume of the titrant solution to be read to within 0.01 ml. Except for the graduated parts and the tap, the semi-microburette was also insulated with blown polystyrene sheeting in order to prevent heat exchange with the operator during the titration (see Fig. 1). Two thermometers were used to measure the ambient temperature of the whole assembly and to measure the temperature of the titrant in the reservoir. Both thermometers were able to read the temperature to within 0.01°C.

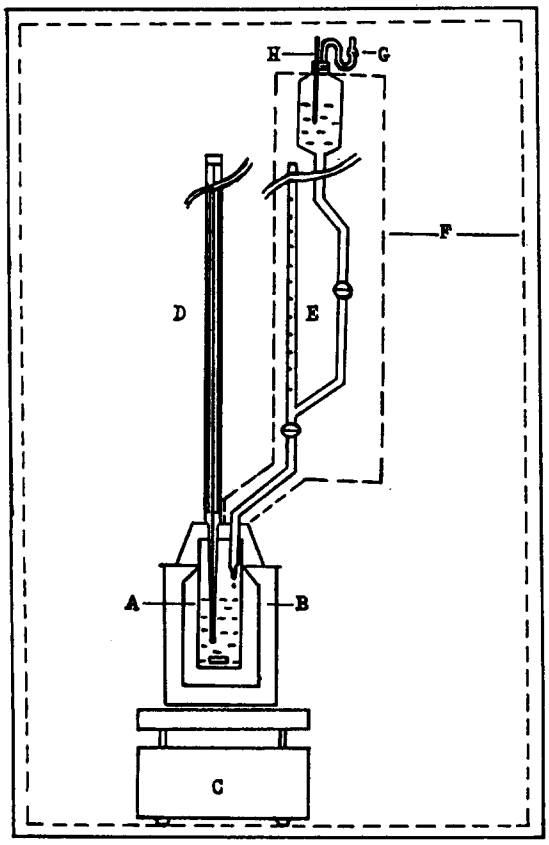

Fig. 1. Thermometric titration assembly: A, Dewar flask; B, blown polystyrene insulation layer; C, magnetic stirrer; D, Beckmann thermometer; E, microburnette and its reservoir; F, blown polystyrene insulation layer; G, tubing filled with dry calcium chloride to keep the titrant dry; H, a sensitive thermometer to read the temperature of the titrant.

Stock 0.0200 M urea solution was kept in the insulated fume cupboard to keep it in thermal equilibrium with the titrant. The sample volumes of the urea solution placed in the Dewar flask are 15.0 ml and the solutions were magnetically stirred during the addition of titrant. Addition of the titrant was performed discontinuously, and the amount of the solution added at a time was 0.25 ml. After each addition of titrant, the solution was allowed to attain thermal equilibrium for at least 1 min and then the corresponding temperature increase was determined by use of the Beckmann thermometer. Each temperature reading was repeated three times and the mean of these was taken as the temperature increase for each addition. The temperature increases were rather large to be monitored accurately by the Beckmann thermometer. One titration run was completed in about 25 min. A titration curve for each urea sample was drawn and the endpoint of titration was then fixed. One of the titration curves is presented in Fig. 2 as an example.

Five accurately weighed 1,3-diphenylguanidine samples, each dissolved in 10 ml of acetic anhydride, were titrated with approximately 0.2 M antimony pentachloride solution, and the true concentration of the antimony pentachloride was then calculated and was found to be 0.2070 M. Seven urea samples from the 0.0200 M solution were then taken and titrated with 0.2070 M antimony pentachloride solution. The mean value of the recovery of urea was 99.8% and the relative standard deviation was 0.2%. This result clearly shows that the thermometric method proposed is very suitable for the titration of urea.

In addition, we also have titrated eleven aliphatic and aromatic amines including tri-*n*-

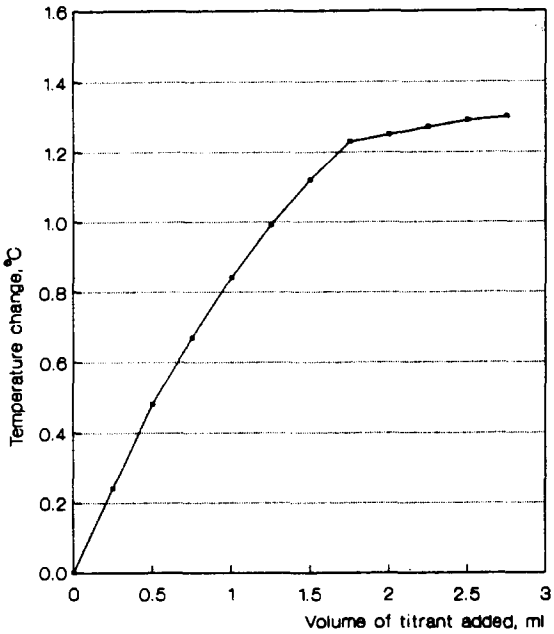

Fig. 2. Thermometric titration curve of a urea sample with antimony pentachloride in acetic anhydride, at 20 ± 1°C.

butylamine, piperidine and aniline with antimony pentachloride in 1,2-dichloroethane as solvent, and have obtained recoveries for tri-*n*-butylamine of 98.2%, for piperidine of 97.5% and for aniline of 98.5%. The relative standard deviations of these are, respectively, 0.2%, 0.4% and 0.2% [5]. The concentrations of the amines were approximately 0.02 M and the concentration of the titrant was 0.2070 M. The changes in temperature during the titrations of these compounds were 0.85–1.10°C. This obviously shows that antimony pentachloride, as a Lewis acid, has no steric hindrance in an appreciable amount. Therefore the use of antimony pentachloride as a Lewis acid titrant can be extended further to the thermometric titration of other compounds containing a basic side or sides.

We believe that the coordinate covalent bond is formed between antimony pentachloride and urea as follows

$$Cl_5Sb \leftarrow OC(NH_2)_2$$

As is well known, antimony pentachloride forms a strong coordinate covalent bond with oxygen [6,7].

Review

# Enzyme catalysis in organic solvents: a promising field for optical biosensing

M.E. Díaz-García *, M.J. Valencia-González

*Department of Physical and Analytical Chemistry, University of Oviedo, c/ Julián Clavería 8, E-33006 Oviedo, Spain*

Received 14 November 1994; revised 28 March 1995; accepted 28 March 1995

**Abstract**

The ability of enzymes to work in non-aqueous media offers new and almost unexploited possibilities for the development of new optical biosensors. The advantages of performing biocatalytic reactions in non-aqueous media are discussed in relation to their possible application in optical biosensor design. Attention is focused on the factors that influence enzymatic catalysis in organic solvents, including the role of enzyme-associated water, criteria for solvent selection and the alteration of enzyme specificity. Recent examples of relevant applications and future prospects of organic-phase optical biosensing are discussed.

*Keywords:* Optical biosensing; Organic phase enzymatic catalysis

## 1. Introduction

A biochemical sensor is an analytical device comprising a biological recognition element (enzyme, receptor, antibody or microbe) in intimate contact with a physicochemical transducer (electrochemical, optical, mass, thermal) which is capable of converting the particular biochemical event into a continuous signal which is proportional to the concentration of a specific chemical or group of chemicals.

Enzymes were the first biological components employed in optical biosensors [1] and remain by far the most commonly used elements. Enzymes possess extremely high catalytic activity and unique substrate specificity. It is these merits that make the application of enzymes in optical sensing devices extremely promising. Conventional enzymatic methods have been conducted in aqueous solutions mainly due to the preconceived idea that an aqueous environment is optimal to maintain the native, catalytically active enzyme conformation for binding and catalysis. This notion is not completely true. Many enzymes (or multienzyme complexes) such as lipases, estearases, dehydrogenases and those responsible for xenobiotic metabolism, function in natural hydrophobic environments, usually in the presence of or immobilized to a membrane [2]. The water concentration in the proximity of these enzymes is significantly less than 55.5 M, the bulk water concentration in aqueous environments.

The activation of enzymes in organic solvents is a noteworthy achievement in the fields of enzymology and organic chemistry. Many enzymes were shown to be catalytically active in a wide variety of different organic solvents [3–7], their catalytic efficiency in organic media being comparable to that in water. From an analytical viewpoint there are numerous potential advantages in carrying out enzymatic reactions in organic media as opposed to aqueous solutions: (i) efficient catalysis may be achieved with substrates poorly soluble in water; (ii) undersirable side reactions in organic media as well as substrate and product inhibition may be

* Corresponding author.

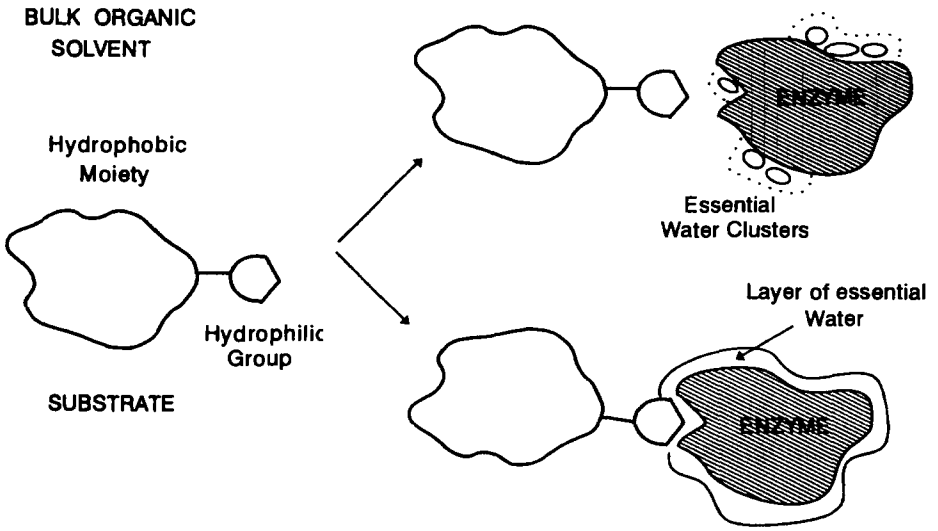

Fig. 1. Grossly simplified representation of enzymatic catalysis in organic solvents.

reduced; (iii) thermal stability of the enzymes is enhanced; (iv) immobilization is often unnecessary as enzymes are insoluble in organic solvents; (v) if immobilization is desired, adsorption onto non-porous surfaces is satisfactory as enzymes are unable to desorb from these surfaces in non-aqueous media; (vi) microbial contamination is eliminated; and (vii) recovery and reuse of the enzyme is easier.

At present, various organic-phase enzymatic electrodes have been developed for monitoring some water-insoluble substrates [8–11]. However, little or no attention has been paid to the development of optical sensing schemes based on biocatalysis in organic media despite the variety of optical transduction methods suitable for sensing applications. This article is intended to bring this methodology to the attention of analytical chemists by discussing the basic principles of organic-phase enzymology and giving specific examples of optical biosensing in organic solvents that open up promising analytical prospects in the field.

## 2. Role of water

In an aqueous environment, the folding of an enzyme is driven by the tendency of hydrophobic amino acid residues to be excluded from water and confined to the interior of the protein molecule. In turn, the charged and hydrophilic residues are exposed to the aqueous solvent. When water is replaced by an organic solvent, not only the tertiary structure but also the secondary structure such as the alpha helix and the beta structure may be distorted.

In order to ensure a catalytically active enzyme conformation in organic media the enzyme molecule must have a definite hydration shell [12,13] to separate the solvent from contact with the protein surface. Water is essential for enzyme catalysis because of its contribution to all non-covalent bonding and to the hydrogen bonds of the protein structure: however, the appropriate amount of water necessary for enzyme activity in organic media has been the subject of numerous discussions and papers [14–16]. Zaks and Klibanov [15] examined three model enzymes, polyphenol oxidase, alcohol dehydrogenase and alcohol oxidase, in solvents of different hydrophobicities and water contents. They showed that the enzyme activity was related to the amount of water bound to the protein and not to the concentration of water in the organic solvents. Water bound to those enzymes in organic solvents could not form a true water layer coverage but rather a few clusters probably around charged and polar regions on the ezyme surface. Taking into account that water is required absolutely for the catalytic function of enzymes in organic solvents, that "wet" immediate microenvironment of the enzyme could be considered as the region through which the enzymatic reaction should proceed. The situation is schematically presented in Fig. 1.

Although the presence of essential bound water remains a necessary condition for the retention of enzyme catalytic activity and stability in non-aqueous solvents, there have been

studies [17–20] in which some enzymes, such as erythrocuprein, porcine pancreatic lipase, subtilisin or xanthine oxidase, have been shown to retain catalytic activity in truly anhydrous organic solvents (dimethyl sulphoxide, formamide, pyridine or dimethylformamide). The molecular mechanisms protecting the enzyme conformation and catalytic properties in these dry organic solvents still remain unclear.

## 3. Criteria for solvent selection

The selection of a suitable solvent is crucial because it may affect enzymatic catalysis in different ways. Firstly, the solvent can inactivate the enzyme by directly interacting with it: the solvent may alter the native conformation of the enzyme by penetrating into the hydrophobic core of protein thus disrupting hydrogen bonding and hydrophobic interactions and leading to reduced activity and stability [21]. This situation is particularly important with soluble enzymes in biphasic systems (water/water-immisicible organic solvent) and aqueous systems with low concentrations of water-miscible organic solvents. In contrast, the insolubility of enzymes in monophasic organic solvents prevents the enzyme from severe distortion of its conformational stability. In fact, many enzymes in monophasic organic media are known to retain their native conformation even after vigorous vortexing [14]. An additional stabilization of the enzyme could also be due to a "cage effect": enzyme molecules inside the protein particle would be tightly squeezed from all sides by surrounding molecules, resembling an immobilized state that should favour increased conformational stabilities [22].

Another way in which solvents affect enzymatic activity is by interacting directly with the essential water around the enzyme molecule [23]. Although this interaction may not affect the enzyme itself, it does have implications for catalysis. Highly polar solvents are capable of thirstily absorbing water and stripping the hydration shell from the enzyme, entailing the loss of catalytic properties. Conversely, hydrophobic solvents are less able to pull away or distort the hydration shell and hence are less likely to affect catalytic activity.

It is important to note that although this solvent effect holds true for most enzymes, there are some notable exceptions, as we have seen before. Xanthine oxidase [18], porcine pancreatic lipase [19] and subtilisin [20] still function when suspended in some water-miscible solvents. One possible explanation of this fact is that these enzymes are capable of retaining their hydration shell so tightly that even hydrophilic solvents cannot usurp the water [19]. Such enzymes are active in both hydrophobic and hydrophilic solvents. Although our understanding of the effects of organic solvents on enzyme activity and stability is growing, the choice of the suitable solvent is not straight forward and, recently, some general empirical rules have been formulated for the optimization of biocatalytic activity in different organic solvents [15]. The parameter $P$ (the partition coefficient of the solvent between octanol and water) was introduced as a quantitative measure of solvent polarity [24,25]. Generally, the enzymatic activity is low in polar solvents having $\log P < 2$, is moderate in solvents having $\log P = 2–4$ and is high in apolar solvents having $\log P > 4$ (see Table 1).

Another consideration for solvent selection is the solubility of substrate and product in the media [26]. For example, sugars are soluble only in hydrophilic water-miscible solvents such as pyridine or dimethylformamide. The use of water-immiscible solvents is impractical for enzyme-catalysed sugar oxidation as there would be no interaction between the insoluble sugar and insoluble enzyme. In a similar way, compatibility of the enzymatic reaction products with the solvent is crucial. Polar products tend to remain in the water shell surrounding the enzyme and this could cause inhibition or undergo undesirable side reactions. This situation was found in the catalysis of phenols by

Table 1
Log $P$ values of some organic solvents [a]

| Solvent | Log $P$ | Solvent | Log $P$ |
|---|---|---|---|
| Dimethyl sulphoxide | −1.30 | Dipropyl ether | 1.90 |
| Dioxane | −1.10 | Chloroform | 2.00 |
| Methanol | −0.76 | Heptanol | 2.40 |
| Acetonitrile | −0.33 | Toluene | 2.50 |
| Ethanol | −0.24 | Xylene | 3.10 |
| Propanol | 0.28 | Hexane | 3.50 |
| Tetrahydrofuran | 0.49 | Decanol | 4.00 |
| Butanol | 0.80 | Heptane | 4.00 |
| Cyclohexanone | 0.96 | Octane | 4.50 |
| Hexanone | 1.30 | Dodecanol | 5.00 |
| Phenol | 1.50 | Dibutylphthalate | 5.00 |
| Cyclohexanol | 1.50 | Undecane | 6.10 |
| Hexanol | 1.80 | Tetradecane | 7.60 |
| Benzoic acid | 1.90 | Butyl oleate | 9.80 |

[a] Data taken from Ref. [25].

polyphenol oxidase in hexane [5], the polar quinone products are insoluble in hexane and rapidly polymerize in the water environment around the enzyme, giving rise to its incativation. In the more polar chloroform, products (quinone, catechol) favourably partition into the bulk solvent and do not inactivate the enzyme [5,27].

This is not the only example. A similar situation was observed in the oxidation of benzyl alcohol by alcohol oxidase in non-aqueous solvents [28]. Benzaldehyde, the reaction product, partitions differently between the water bound to the enzyme and the organic medium depending on the solvent chosen. For example, using hexane benzaldehyde was favourably partitioned into the aqueous enzyme environment giving rise to alcohol oxidase inhibition. However, using toluene the product was efficiently solubilized in the organic phase, so minimizing benzaldehyde inhibition of alcohol oxidase.

Another interesting practical problem concerns the effect of the reaction pH. All enzymatic reactions in water are strongly pH dependent. In organic solvents, a difficulty stems from the fact that one cannot reliably use a glass electrode; even if this could be done in the vicinity of the enzyme, no reliable value could be obtained because for this "special" aqueous environment no pH calibration is available. Quoting Klibanov [19], an enzyme "remembers" the pH of the aqueous solution from which it was last recovered. In an aqueous buffer solution the enzyme's ionogenic groups acquire the corresponding ionization state, which then remains unchanged in organic solvents as well as in the solid state. Moreover, the buffering capacity of the aqueous microenvironment can be controlled by the enzyme itself. Therefore, it is often worthwhile to employ enzymes that have been lyophilized or precipitated from an appropriate pH (and buffer) before use [29].

Other criteria that should be taken into account in the selection of organic solvents for developing optical biosensors include compatibility with the optical transducer, toxicity flammability, waste disposal and cost.

## 4. Enhancement of thermal stability

In aqueous media at high temperatures, enzymes inactivate due to both alterations in the primary structure of the molecule and unfolding of the enzyme molecule [30,31]. The chemical and structural changes that result in irreversible thermal inactivation all require water. Therefore, if enzymes are placed in an essentially water-free solvent, it should be possible to enhance the thermostability. In fact, it has been confirmed by Zaks and Klibanov [32] who showed that porcine pancreatic lipase in aqueous solutions at 100°C was completely inactivated within seconds. Conversely, in a dry tributyrin–heptanol mixture the lipase had a half-life at 100°C of 12 h. Furthermore, at this temperature the enzyme is 10 times more active than at 20°C. Reslow et al. [33] ($\alpha$-chymotrypsin dried onto glass beads) and Zaks and Klibanov [15,32] (crude lipase powder, lyophilized pure $\alpha$-chymotrypsin and subtilisin) agree that thermal stability increases with solvent hydrophobicity. However, for any given solvent, adding water (less than 1%) reduces enzyme half-life. This result has been interpreted as an increased enzyme flexibility due to the higher water content [34].

Biosensors, in general are operated at optimum temperatures for the biocatalytic reaction to proceed rapidly and sensitively, although such a condition could not be optimum for wide applicability. The enhanced thermal stability of enzymes in non-aqueous media is an important advantage from an analytical point of view because it extends the temperature range in which a given optical biosensing device is analytically useful.

## 5. Alteration of enzyme specificity

There exists the possibility that enzyme specificity may be altered by the presence of an organic solvent by modifying the active site conformation. Elimination of bulk water results in conformational rigidity [22] and the inability to accommodate a given substrate. For example, "wet" porcine pancreatic lipase can accept a broad range of substrates of varying sizes, which suggests that the protein backbone of lipase is flexible and can adopt a variety of conformations to accommodate substrate molecules. However, the "dry" enzyme does not react with bulky substrates, presumably due to its now rigid active site not being able to open up to accommodate them [4].

Also, organic solvents may affect the binding of substrates to the active site by altering the apparent $K_m$ values. For instance, in aqueous

solutions chymotrypsin hydrolyses non-polar amino acid substrates. The driving forces of enzyme–substrate binding are the hydrophobic interactions operative in aqueous media; hydrophobic substrates are "expelled" from water into the enzymatic active centre [14]. In non-polar organic media, this partitioning is reduced and the apparent $K_m$ increases [35]. Therefore, in water the catalytic efficiency ($k_{cat}/K_m$) of *N*-acetyl-L-phenylalanine ethyl ester hydrolysis is nearly 100 times higher than with the ethyl ester of *N*-acetyl-L-histidine because of the lipophilicity of the former substrate. In octane the substrate specificity is reversed and the histidine derivative becomes a markedly better substrate than phenylalanine.

Such specificity shifts could have significant implications on the development of optical biosensing devices for compounds for which enzyme-catalysed reactions are not feasible in water. For example, lipase — the most studied enzyme in organic media — can catalyse, in organic media of lower water concentrations with low water activities, a variety of reactions including transesterification, esterification, aminolysis, thiotransesterification oximolysis and acyl exchange [6,36]. In water, these reactions are almost completely suppressed by hydrolytic processes.

Some enzymes in non-aqueous media exhibit very high stereospecificity. The preferred interaction of the enzyme with one of the two enantiomers is due to several geometric factors and differences in the binding energy [37] and this fact could be used in the development of optical biosensors to recognize optical isomers.

## 6. Enzyme immobilization

In order to develop an efficient and effective optical biosensor it is required that the enzyme is in close proximity with the optical transducer. On the other hand, to preserve the integrity and activity of enzymes in organic solvents it is necessary to fix the conformation of the catalytically active enzyme to the increase rigidity.

Enzyme immobilization has proved to be an extremely powerful approach to fulfill the above requirements. Various methods are available to immobilize enzymes: entrapment within a support (membrane, gel, microcapsule), physical adsorption, cross-linking between molecules and covalent binding [38].

Due to the insolubility of the enzymes in organic solvents, simple adsorption on a solid support is often sufficient. Adsorption is used here in its broadest sense to cover all the processes by which enzymes are held at the phase boundary by non-covalent forces. The adsorption of enzymes onto solid phases can be achieved by using finely divided particles or macroporous structures with large surface areas [5]. There is easy availability of good, ready-made support materials, such as ion exchangers [39], alumina [8], polymeric gels [40] and, especially, glass porous beads [41]. The bound enzyme will have no propensity to desorb from the surface and facile immobilization is feasible by impregnation of the support with an aqueous solution of enzyme, without the cumbersome covalent cross-linking or entrapment procedures required in conventional aqueous-based systems. Moreover, organic solvents may attack the covalent binding of enzymes to the support.

The support was regarded as inert and without influence on the kinetic behaviour of the enzyme. However, an important aspect of immobilized enzymes in organic solvents is the possibility of the support to alter the microenvironment close to the enzyme [42,43]. Hydrophilic supports such as calcium alginate are compatible with enzymes and can be used to increase the level of enzyme hydration, avoiding the formation of a separate aqueous phase in the organic solvent. On the other hand, extremely polar supports may limit the rate of mass transfer of hydrophobic substrates to the enzyme layer. This fact should cause apparent $K_m$ values to increase and the enzyme catalytic efficiency to decrease. Hydrophobic supports such as polyurethanes [44] overcome the latter problem but are less compatible with hydrophilic enzymes. An elegant solution to obtain optimal hydrophilicity/hydrophobicity matching between reagents and the support matrix has been devised by the use of gels based on photopolymerizable resins and urethane macromonomers by varying the ratio between hydrophilic and hydrophobic moieties in the monomer molecules [45].

In order to quantify the support influence and to derive general rules to predict the performance of the enzyme in organic solvents using specific supports, the concept of aquaphilicity has been introduced [46]. Aquaphilicity is a measure of how the water in a volume of water-saturated diisopropyl ether is parti-

Table 2
Examples of recent applications of organic-phase enzyme electrodes

| Enzyme | Solvent | Analyte | Detector | Detection limit (mM) | Ref. |
|---|---|---|---|---|---|
| Horseradish peroxidase | Dioxane | Hydrogen peroxide | Carbon electrode | 10 | [47] |
| | Ethanol | Organic peroxides | Carbon microelectrode | 1 | [48] |
| | Acetonitrile | Hydrogen peroxide | Carbon electrode[a] | 0.0003 | [49] |
| Tyrosinase | Ethanol | Phenols | Carbon microelectrode | 0.7 | [48] |
| | Acetonitrile | Phenols | Carbon electrode[a] | 0.0001 | [49] |
| | Various | Phenols | Oxygen electrode | 0.0002 | [50,51] |
| | Acetonitrile | Moisture | Carbon electrode | 0.072% (v/v) | [52] |
| Vegetal tissues | Choloroform | Phenols | Graphite electrode | 0.03 | [53] |
| Cholesterol oxidase | Hexane/chloroform | Cholesterol | Oxygen electrode | – | [8] |
| Laccase | Alcohols | Hydroquinone | Glassy carbon electrode | 0.0006 | [10] |
| Glucose oxidase | Acetonitrile/water | Glucose | Glassy carbon electrode | – | [54] |

tioned between the ether phase and a fixed amount of dry support. The higher the aquaphilicity of the support, the greater its tendency to sequester water from the ether phase, thus leaving less for enzyme hydration and thereby decreasing its activity.

## 7. Current and potential analytical applications

The analytical applications of enzymes in organic solvents centre around the development or organic-phase enzyme electrodes. Table 2 summarizes some of the recently reported examples of applications. Apart from isolated enzymes, whole cell preparations from plant sources have been proposed as biocatalytic materials for the construction of biosensors. Plant-tissue-based biosensors are constructed by physically retaining a thin slice of the tissue at the surface of a detection element using a porous membrane. An example is the phenol sensor [53] when a thin slice of mushroom or banana is held at the surface of a graphite disc electrode (see Table 2).

Flow measurements of enzyme inhibitors and trace water in non-aqueous media represent attractive and novel applications of organic-phase enzyme electrodes. Inhibition of tyrosinase and horseradish peroxidase (HRP) in acetonitrile by thiourea, benzoic acid and other poorly water-soluble inhibitors can be indirectly monitored from the decrease of the flow-injection peak of the phenol substrate, used as the maximum reference signal [55]. A wide variety of inhibitors with poor water solubility (pesticides, PAHs, drugs) could be measured based on inhibitor biosensors in organic media. Also, a tryosinase electrode has been used to measure water in an organic solvent [56]. Here, the influence of low levels of water on the rate of the biocatalysed phenol oxidation can be related to the water concentration. This indirect biosensing approach, pioneered by Wang and Reviejo [56], is an attractive alternative to the Karl-Fisher titration method.

While most of the recent advances in organic-phase enzyme biosensors have been made using electrochemical detection techniques, there have been very scarce efforts to use optical sensing approaches. A number of optical transducing mechanisms and sensing designs are potentially available for application in organic-phase biosensing. Parameters such as oxygen, $CO_2$, hydrogen peroxide or pH are commonly detected in biocatalytic reactions and, for them, a wide choice of spectrophotometric methods and/or sensors (absorbance, reflectance, fluorescence, room-temperature phosphorescence and chemi/bioluminescence) are feasible. However, most, if not all, have yet to realize their full potential for developing optical organic-phase biosensing approaches.

Up to now, the physical combination of immobilized enzymes and optical transducers to form selective detection devices in the organic phase has followed three main approaches (see Fig. 2):

(i) Enzyme reactor–optical detection systems, where the biochemical event produced in an enzymatic reactor in a flow system is followed by directly monitoring either production or consumption of a chromophore. Braco et al. [57] reported the first example of this type of biosensing in organic media for cholesterol analysis. The system, previously studied by Ka-

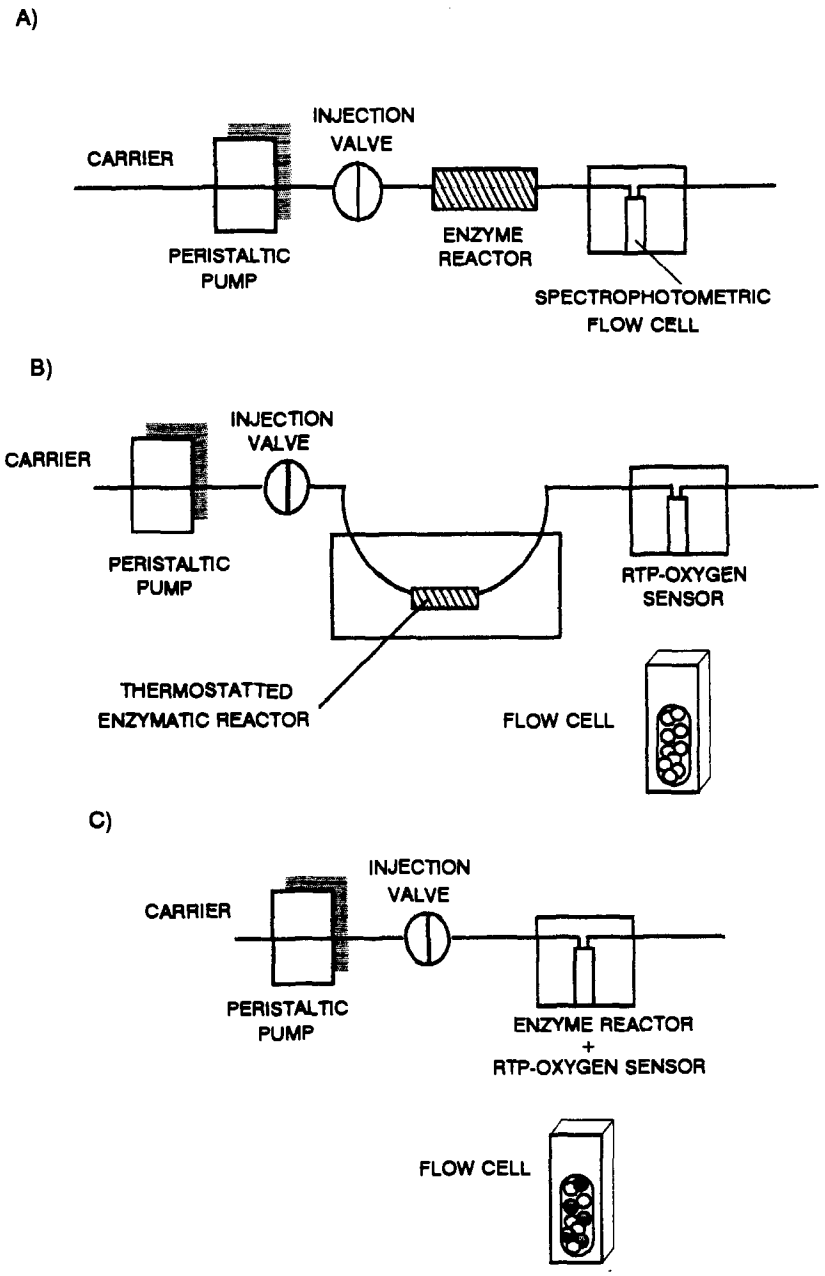

Fig. 2. Different approaches for organic-phase optical biosensing. (A) Enzyme reactor–optical detection system. (B) Enzyme reactor–optical sensor system. (C) Flow-through enzyme optosensing.

zandjian et al. [14] using a batch approach, used a non-covalently immobilized cholesterol oxidase (COD) and HRP reactor operating in toluene. Cholesterol is first oxidized by molecular oxygen in a COD-catalysed reaction, releasing stoichiometrically equivalent hydrogen peroxide, which is, in turn, converted to water by HRP in oxidizing *p*-anisidine (chromogenic indicator substrate) yielding a coloured product which was monitored at 458 nm by means of a flow-cell UV–vis detector. The strategy developed combines the remarkable benefits offered by enzymology in organic solvents and the advantages inherent to flow injection methods.

(ii) Enzyme reactor–optical sensor systems, where the enzyme is immobilized in a reactor preceding an optical sensor in a flow system. A COD reactor–room-temperature phosphorimetric sensor system, operating in a chloroform–hexane mixture for use in a flow-injection system has been developed [58]. Oxygen consumption during the enzymatic choles-

Table 3
Comparative analytical performance characteristics for optical biosensing of cholesterol in organic media

| Conditions/ performance characteristics | Enzyme reactor–optical detection | Enzyme reactor–RTP sensor | | Flow-through enzyme optosensing |
|---|---|---|---|---|
| Temperature (°C) | 25 | 35 | 25 | 25 |
| Detection limit (M) | $10^{-6}$ | $5 \times 10^{-5}$ | $1.4 \times 10^{-4}$ | $3 \times 10^{-4}$ |
| Linear range (M) | Up to $2 \times 10^{-4}$ | Up to $4 \times 10^{-3}$ | More than $10^{-2}$ | Up to $10^{-2}$ |

terol oxidation was followed via the changes in the room-temperature phosphorescence (RTP) of an oxygen-sensitive metal chelate immobilized on an anion exchange resin packed into a conventional flow-through cell [59,60]. This work has opened the door for similar analytical sensor devices to measure other poorly water-soluble analytes such as bilirubin, fatty and other carboxylic acids, aldehydes, etc. for which suitable oxidases are available.

(iii) Flow-through enzyme optosensing, where the immobilized enzyme is in close proximity to the optical sensing phase in a flow configuration. A flow-through cholesterol RTP biosensing device using the optical sensing basis mentioned above illustrated this latter point [58]. The immobilized COD glass beads and the RTP sensing beads were mixed and packed into the small space of a flow-through cell. Although the detection limit for cholesterol working at room temperature was twice higher than that obtained with the reactor–room-temperature phosphorimetric sensor approach, a strict comparison among the systems cannot be made because reactors are generally designed with an excess of reagent (large reactor volume), whereas the flow-through approach offers a limited surface for the enzyme reaction to take place.

The immobilized COD glass beads and the RTP sensing beads mixture could be placed on the common end of the bifurcated optical fibre in order to develop an organic-phase optrode. Work in this direction using fluorescence and RTP sensing materials for oxygen is currently in progress in our laboratory.

Some important analytical features of these systems are listed in Table 3.

While the concept of organic-phase optical biosensing (OPOB) is presented here within the framework of on-line cholesterol analysis, the approach may have a bright future in several fields, due not only to the several important advantages accrued from enzymology in organic media but also from the use of fibre-optic chemical sensors [61]. On the other hand, sample pretreatment can be eliminated or minimized, which is extremely attractive in some instances for continuous monitoring purposes. For example, a field in which OPOB could find important applications is food technology and food testing, with its many challenging water-insoluble samples. Frequently performed analyses are of aldehydes or phenol in fats and oils, cholesterol or lactose in butter and margarines, quality of edible oils monitoring, etc. Temperature abuse detection is another area in which OPOB may find an application. The monitoring of temperature maintenance is important in the transport of chilled or frozen foods and pharmaceuticals and other heat-sensitive materials. A prototype of a device was developed which relies on the low catalytic activity of peroxidase in a solid solvent (hexadecane at 4 °C) to reliably, accurately and irreversibly detect temperature abuse [62]. Once the temperature rises above the melting point of the solvent, the peroxidase quickly catalyses the oxidation of *p*-anisidine and colour is produced. Adequate mixing of various hydrocarbons allows the melting point of the solvents to be varied.

Another area in which OPOBs could be used is clinical diagnostics. Poorly water-soluble analytes such as cholesterol or bilirubin are amenable to detection using the approach. An area of growing importance is the monitoring of the quality of water and effluents. The determination of water contaminants such as fat-soluble biodegradable pesticides, phenol and other organic contaminants may be made possible by the implementation of OPOBs. In most cases, an organic extraction will be necessary in order to preconcentrate the organic contaminant.

The pharmaceutical industry is another area in which OPOBs could make a significant contribution as many pharmaceutical products are not readily dissolved in aqueous media. For example, of interest are steroids and steroid-based drugs production or peroxide bleaching agents in cosmetic products. One of the most valuable features of some enzymes in non-aqueous media is their ability to discriminate between enantiomers of racemic substrates and, therefore, could be used to determine optically active (chiral) products in pharmaceuticals.

Other opportunities come from the petrochemical industry, where many analytes such as alcohols, aldehydes and esters could be analysed in an organic phase using suitable enzymes. However, in this industry, environmental conditions are generally too harsh (high temperature and/or pressure) for the immobilized biocatalyst and/or the optical transducer to work effectively. The operation may be limited to an automated off-line arrangement.

Future research is likely to solve the critical issues of optical sensor stability in organic solvents, ease of fabrication and calibration. Although the basic technology is straightforward, each application requires customized engineering to produce optical biosensing devices with the expected capabilities.

Enzymatic catalysis has recently been extended to the gas phase and some enzyme-based sensors for use in the gase phase are at present under development. For example, an alcohol-oxidase-based sensor for the analysis of ethanol in air has been developed [63] and is attractive for breathalyser analysis. Alcohol oxidase and catalase (to prevent $H_2O_2$-based inactivation of the alcohol oxidase) were codeposited onto cellulose particles and the reaction was followed in situ by oxidation of a chromogen. In another approach, Barzana et al. [63] also described a method for detecting harmful organic vapours using solid state enzymes. The fact that enzymes retain their catalytic activity in an almost dry state has interesting implications for the development of fibre-optic-mediated biosensors. Fiber optic chemical sensors for the measurement of oxygen, ammonia or carbon dioxide could be coupled with solid state enzymes in the gaseous phase to produce a biosensor. We have begun to explore the suitability of this new optical biosensor scheme for alcohols using an RTP sensor based on a xanthene dye.

Enzymatic catalysis in organic media is an exciting field capable of revolutionizing analytical technology in disciplines as diverse as veterinary medicine, agriculture, bioprocessing, clinical biochemistry and defence. The use of new biocatalysts in organic media — either through protein and antibody engineering or recent isolation — could also open up new areas of research. Future prospects and opportunities of organic-phase biosensing (in the context of electrochemical and other transducers) have recently been discussed by Saini et al. [9] and Wang et al. [11].

## 8. Conclusions

The development of organic-phase optical biosensing is still very much at the basic research stage. From a practical standpoint the ability to easily immobilize and retain the activity of enzymes within an organic solvent should find many applications in optical biosensor technology, e.g. via the use of sensitive optical detection techniques and/or via the use of multienzyme systems. On the other hand, the possibility of finding or inducing new biocatalysts (enzymes or antibodies) tailored to a particular analytical need could also open up new areas of research and application. From a basic point of view several fundamental issues remain unresolved: the parameters that govern enzymatic activity in non-aqueous media must be addressed, the role of water and the nature of the organic solvent on the biocatalyst must be fully understood, a mechanistic and kinetic description of enzymatic catalysis in organic solvents is needed, etc. Biocatalysts in non-aqueous media thus open up another promising horizon for basic study and the application of biochemical analysis. We hope this overview stimulates fresh ideas and new approaches that will aid progress in this exciting field.

# Salicylate-selective electrode based on lipophilic tin(IV)phthalocyanine

Jun-Zhong Li, Xin-Yu Pang, De Gao, Ru-Qin Yu *

*Department of Chemistry and Chemical Engineering, Hunan University, Changsha, 410082, People's Republic of China*

Received 22 July 1994; revised 6 September 1994; accepted 8 May 1995

**Abstract**

A new PVC membrane electrode based on lipophilic (2,9,16,23-tetra-*tert*-butylphthalocyanine)tin(IV) dichloride which demonstrates excellent selectivity and fast response toward the salicylate ion is described. The membrane electrode displayed a linear response for salicylate in the concentration range $10^{-5}$–0.1 M and exhibited an antiHofmeister pattern, with high selectivity for salicylate compared with lipophilic inorganic and biologically important organic anions. The electrode was successfully applied to the determination of salicylate in pharmaceutical preparations and biological samples.

## 1. Introduction

The conventional anion-selective electrodes based on quaternary ammonium or phosphonium salts are essentially non-selective because the selectivity is determined by the hydration energy and the relative solubility of the individual anions in the solvent mediator, i.e. the electrodes always display the so-called Hofmeister sequence [1,2]. Recently, electrodes using plasticized poly(vinyl chloride) (PVC) membranes incorporating derivatives of vitamin $B_{12}$ [3], the porphyrin complexes of Co(III) [4], Sn(IV) [5], In(III) [6], Mn(III) [7], organometallic compounds such as organotin [8] or organomercury [9] compounds as well as Schiff's base complexes have been reported. Many of them showed potentiometric anion-selectivity sequences which were derived from the Hofmeister pattern. The mechanism for the selectivity obtained is believed to be based on the coordination of the analyte ions with the respective metal atoms involved in the carrier molecules. The work reported here extends this concept with the development of a new salicylate-selective membrane electrode based on the tin(IV)–phthalocyanine complex, $TTBPcSnCl_2$.

Salicylate and its analogues such as acetylsalicylate (aspirin) are commonly used as effective analgesics. Despite their utility as pain relievers and antipyretics, salicylate derivatives can be quite toxic if taken in large doses. The most widely used spectrophotometric method [10] for determining "total" salicylate is rather tedious and exhibits poor selectivity. With the wide use of aspirin, there is an increasing need for measurement of "free" salicylate in biological samples such as urine and serum. Polymeric membrane electrodes for salicylate measurements have been proposed previously [11]. Since these earlier probes were based on dissociated ion exchangers such as quaternary ammonium or phosphonium salts, they lacked adequate selectivity for salicylate over a number of phisiologically important anions such as chloride and lactate. A salicylate-selective electrode useful in the analysis of biological samples were reported by Meyerhoff and co-workers [5] using tetraphenylporphyrin-tin(IV) dichloride as the carrier. The electrode, unfortunately, possessed a relatively long response time (2–10 min to reach 90% of equi-

*SSDI* 0039-9140(95)01639-2

librium). This drawback prompted us to develop a new salicylate-selective electrode with a rapid response as well as a high selectivity. The metal phthalocyanines, with a structure similar to the metal porphyrins, neverthlesss exhibit properties different from the latter, probably owing to the difference in, say, the "hole" size [12]. In addition, the metal phthalocyanines are more easily obtained and chemically stable than the metal porphyrins. This paper describes a new lipophilic phthalocyaninetin(IV) based salicylate sensor with a relatively high selectivity over common inorganic and organic anions, rapid response time, and wide linear range. The proposed membrane electrode provides an alternative useful device for measuring salicylate in pharmaceutical preparations and physiological samples.

## 2. Experimental

### 2.1. Reagents and chemicals

All potentiometric measurements were carried out in phosphate buffer solutions. Aqueous solutions were prepared with doubly distilled water. Tetrahydrofuran (THF), high molecularweight poly(vinylchloride) (PVC), potassium tetraphenylborate (KTPB), dinonyl sebacate (DNS), and *n*-dibutyl phthalate (DBP) were obtained from Shanghai Chemicals Co. Chemicals used for the synthesis were of reagent grade quality and were used without further purification.

### 2.2. Preparation of (2,9,16,23-tetra-tert-butylphthalocyanine)tin(IV) dichloride (TTBPcSn(IV), Fig. 1)

The synthesis based on the literature [13] was modified as follows. A finely powdered mixture of 2.9 g (48.5 mmol) of urea (water-free), 235 mg (4.5 mmol) of ammonium chloride, 575 mg (2.5 mmol) of stannous chloride and 34 mg (0.03 mmol) of ammonium molybdate was mixed thoroughly with 1.8 g (8.1 mmol) of 4-*tert*-butylphthalic acid prepared according to Hanack et al. [14]. The mixture was heated at 180 °C and kept at this temperature for 30 min. The temperature was then increased to 200 °C and maintained for 4 h. The crude product was boiled for 1 h in 1 mol $l^{-1}$ HCl, filtered, and washed with water until the filtrate was neutral. The product obtained was further purified by dissolving in $CHCl_3$ and the resulting solution was chromatographed using a silica gel column with elution with a mixture of $CHCl_3$ and $CH_3OH$ (8:1 v/v). The eluted solution was evaporated under reduced pressure, and a blue solid was obtained. Analysis: calculated for $C_{48}H_{48}N_8SnCl_2$(Mr., 926.62); C, (62.16%) H (5.18%); N (12.08%); found: C (62.61%); H (5.47%); N (11.95%).

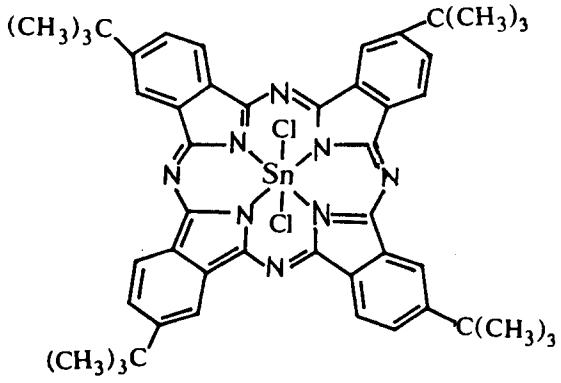

Fig. 1. Structure of the carrier studied.

### 2.3. Apparatus

Potentiometric and pH measurements were made with use of a model PHS-10A digital Ionnalyzer (Xiaoshan). The cells used for millivolt measurements were of the following type: $Hg/Hg_2Cl_2$(s), KCl(saturated)|sample solution‖PVC membrane‖NaSal(0.001 M), KCl(0.1 M), AgCl/Ag. The cell potentials were measured at room temperature (10 °C). The solutions were buffered with 0.05 mol $l^{-1}$ phosphate and adjusted to the required pH with KOH.

### 2.4. Electrode preparation and handling

The PVC membrane electrodes were fabricated from various carriers and assembled according to Thomas and co-workers [15,16]. The membrane composition was 2 wt.% TTBPcSn(IV), 31 wt.% PVC and 67 wt.% DNS. The Aliquat-336 membranes were prepared with 7 wt.% Aliquat, 30 wt.% PVC and 63 wt.% DBP. Before use, the electrodes were conditioned in 0.01 mol $l^{-1}$ NaSal solutions for 2 h. When not in use, the electrodes were stored in $10^{-4}$ mol $l^{-1}$ NaSal solutions at room temperature and protected from the ambient light to prevent any possible photodecomposition of the ionophores as a precautionary measure, although during a period of at least 1 month

there was no detectable change of the electrode characteristics.

### 2.5. Determination of EMF response and selectivity of the membranes

Anion selectivity coefficients, $\log K^{pot}_{Sal,anion}$, were determined in 0.1 M solutions of the corresponding sodium salts by the separate solution method [17]. The solutions were buffered with 0.05 M phosphate adjusted with KOH to pH 5.5. Concentrations were used rather than activities due to uncertainties in estimating the ionic strengths of zwitterion background electrolytes. The concentration of the dissociated anions of weak acids in the test solutions was calculated using the Henderson–Hasselbalch equation. The pH response curve of the salicylate-membrane electrode was obtained by titrating 0.05 M phosphoric acid with small aliquots of KOH, while simultaneously monitoring the pH of the sample solution with a combination glass pH electrode.

### 2.6. A.c. impedance experiments

The a.c. impedance spectra of the electrode membrane containing TTBPcSn(IV) were recorded with use of a PAR M368-2 system (EG & G Princeton Applied Research, USA) in 0.05 mol $l^{-1}$ phosphate at pH 5.5. The frequency range used was $10^5$–0.01 Hz (at 10 °C). The a.c. amplitude was 5 mV.

### 2.7. UV-Vis absorption spectra

Spectra of the chloroform phase obtained by shaking a solution of the TTBPcSn(IV) complex in $CHCl_3$ with water (pH 5.5) or with 0.1 mol $l^{-1}$ NaSal for 30 min were recorded on a PE Lamada 17 spectrophotometer (Perkin-Elmer).

### 2.8. Determination of salicylate in aspirin tablets and urine

Tablets of aspirin (Central South Pharmaceutical Co., Hunan) were finely powdered and treated according to the procedure described by Choi and Fung [11]. A standard additions method was employed to evaluate the concentration of salicylate. A standard procedure for the assay of soluble aspirin tablets [18] was used as the reference method.

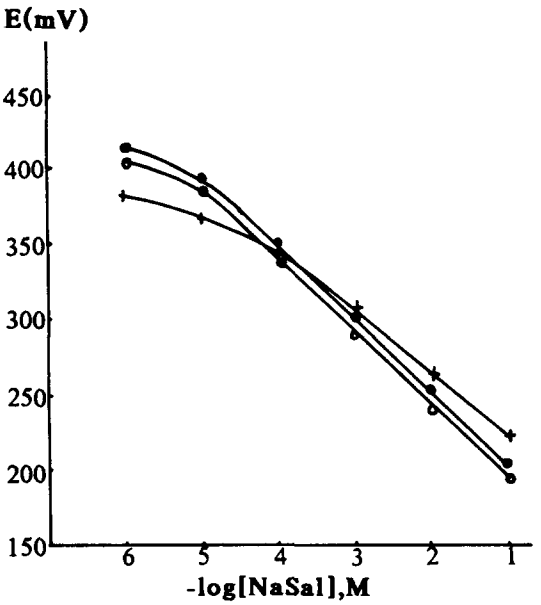

Fig. 2. Potentiometric response curves of the electrode at various pH values in 0.05 mol $l^{-1}$ phosphate buffer. ●, pH 5.5; ○, pH 6.2; +, pH 7.2.

Recovery experiments were undertaken on urine samples drawn from healthy persons not taking aspirin. Urine samples (5 ml) were diluted with 0.05 mol $l^{-1}$ phosphate buffer (pH 5.5) to the appropriate volume and the standard additions method was used to obtain the salicylate concentration which was compared with the results obtained by the conventional colorimetric method [10].

## 3. Results and discussion

### 3.1. Potentiometric response

The calibration curves of the electrode incorporating TTBPcSn(IV) are shown in Fig. 2. The electrode showed a linear potentiometric response over a wide concentration range of $1 \times 10^{-5}$–0.1 mol $l^{-1}$ salicylate (with a slope of −50– −54 mV per decade at room temperature, 10 °C) in 0.05 mol $l^{-1}$ phosphate buffer solution, pH 5.5. The limit of detection was determined to be $7 \times 10^{-6}$ mol $l^{-1}$ salicylate. The standard deviation of the potential readings was 0.8 mV when the electrode pair was dipped alternately into $10^{-3}$ and $10^{-2}$ M NaSal solutions.

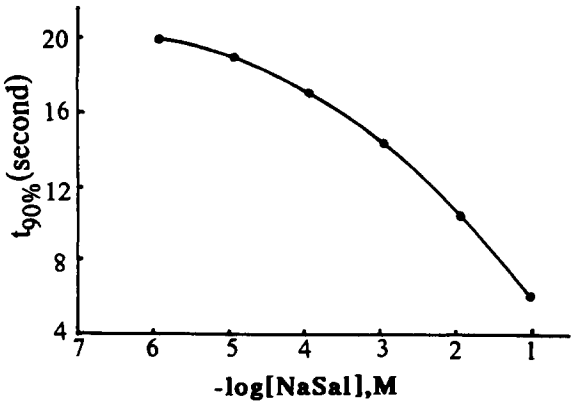

Fig. 3. The $t_{90\%}$ response time of the electrode as a function of sample salicylate concentration in phosphate buffer, pH 5.5.

### 3.2. Response time

For analytical applications, the response time of a sensor is an important factor. With a salicylate-selective electrode based on tetraphenylporphyrintin(IV), $t_{90\%}$ values of 2–10 min have been reported, depending on the concentration of salicylate tested, and the relatively long response time was ascribed to the exchange between salicylate and the axial coordination anions. For the membrane electrode containing TTBPcSn(IV), the $t_{90\%}$ was determined to be 20–6 s from lower to higher salicylate concentrations, which is similar to those observed with classical ion-exchange membrane electrodes (see Fig. 3). It seems that the compound $TTBPcSnCl_2$ could act as a charge carrier in the membrane after exposure to the test solutions. In fact, in UV-Vis spectroscopic experiments as described in the experimental section 2.7, the TTBPcSn(IV) complex in $CHCl_3$, after shaking with a phosphate buffer, showed a change in the absorption spectra (see Fig. 4). This spectral change is thought to have originated from the axial coordination of either $H_2O$ or $OH^-$ ions at the fifth and/or sixth coordination positions, that is to say, the substitution of $H_2O$ or $OH^-$ ions with salicylate ions. It was noticed that the equilibration time in such spectroscopic experiments was relatively fast compared with the time observed in a similar spectroscopic experiment for tetraphenylporphyrintin(IV) (3–4 days) [19]. It seems that the kinetic rate for axial ligand-exchange on TTBPcSn(IV) is faster than that of tetraphenylporphyrintin(IV); this may be associated with the relatively short response time of the TTBPcSn(IV)-based electrode compared with the tetraphenylporphyrintin(IV)-based electrode.

### 3.3. Effect of pH

The pH response profiles for TTBPcSn(IV) were examined by titrating 0.05 mol $l^{-1}$ phosphoric acid with KOH (Fig. 5). Similar to the electrodes based on metal porphyrins and other organometallic compounds, the TTBPcSn(IV)-based membrane also exhibits pH sensitivity, possibly as a consequence of the tendency of the central metal atom to form oxides and, or hydroxides at moderate or high pH values. For metal-phthalocyanine based membrane electrodes, this might be explained by the coordination of water molecules or hydroxyl groups as axial ligands to the central metal atoms. The calibration curves for the TTBPcSn(IV)-based

| Iodide | −2.58 | −3.58 | 0.14 |
| Citrate | −3.36 | −3.48 | −1.61 |
| Acetate | −3.31 | −3.42 | −2.31 |
| Lactate | −1.29 | −1.64 | −2.01 |
| Benzoate | −0.76 | −1.12 | −1.11 |

[a] The membrane composition is the same as that described in the experimental section with the addition of about 0.1 wt.% KTPB.

electrode at different pH values are shown in Fig. 2. There is no obvious difference between the calibration curves for the electrode at pH 5.5 and pH 6.2 due to the relatively weak pH response of the TTBPcSn(IV)-based electrode. (At pH values below 5.5 a significant fraction of salicylate changes to the protonated form which is not detected by the electrode.) At pH 7.2, on the other hand, owing to the increased interference of the hydroxide ions, the detection limit of the electrode for salicylate deteriorates.

### 3.4. Selectivity of the electrode

The potentiometric selectivity coefficients for membranes containing different carriers are shown in Table 1. For comparison, the selectivity data for a conventional salicylate electrode based on Aliquat-336s are also presented. The TTBPcSn(IV)-based membrane displayed substantially improved selectivity for salicylate over common inorganic and biologically important organic anions. Most of these ions would be expected to interfere seriously with classical anion-exchanger-type membrane sensors. It is evident that the binding constant between tin and the salicylate anion is much higher than those for most other anions; the relatively high electron density around the central tin atom of TTBPcSn(IV) would weaken the coordinating ability of this atom. The selective bonding of the salicylate ion is thought to be the origin of the high selectivity of the

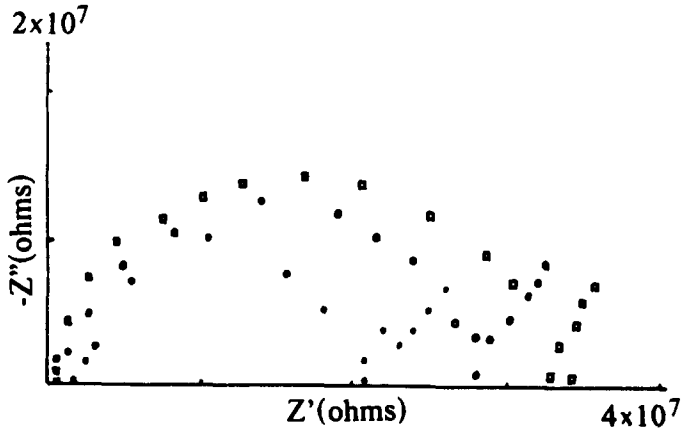

Fig. 6. The a.c. impedance of the membrane incorporating TTBPcSn(IV) after conditioning for 2 h in (●) $10^{-1}$ mol $l^{-1}$ NaSal solution, (○) $10^{-3}$ mol $l^{-1}$ NaSal solution, and (□) $10^{-5}$ mol $l^{-1}$.

[b] Single measurement.

TTBPcSn(IV)-based electrode of salicylate over other anions. It is of particular significance that the electrode displayed a very high selectivity over chloride, making possible the use of the electrode for the determination of salicylate in biological samples. The selectivity of this salicylate-sensitive TTBPcSn(IV)-based electrode relative to perchlorate and thiocyanate is somewhat worse than that of the Sn(IV)–porphyrin system, as reported by Meyerhoff and coworker [9].

Recently, Schaller et al,[20] and Bakker et al, [21] have demonstrated independently that for anion ionophores which operate via a charged carrier mechanism, the addition of small amounts of negative sites in the membranes will benefit the selectivity of electrodes. To check whether it is possible to further improve the selectivity of the TTBPcSn(IV)-based electrode, a small amount of potassium tetraphenylborate (KTPB) was added to the membrane. The selectivity coefficients of such a membrane incorporating KTPB are also shown in Table 1. The selectivity of the resulting electrode over other anions, especially perchlorate and thiocyanate, is really slightly improved. On the other hand, according to the theoretical models that predict the effects of lipophilic anion sites on the selectivity of membranes [20–21], it also demonstrates that the membrane incorporating TTBPcSn(IV) is operating via a charged carrier mechanism.

### 3.5. A.c. impedance spectra

The a.c. impedance spectra of the membrane incorporating TTBPcSn(IV) were recorded after conditioning in salicylate solutions for 2 h. Well-defined semicircles at high frequency and Warburg impedance at low frequency intervals were observed (see Fig. 6). The bulk resistance increased with the decrease in the concentration of aqueous salicylate solutions, indicating that the transfer process of salicylate across the solvent polymeric membrane was controlled by the diffusion process. It is interesting to notice that according to the cyclic voltammetric experiments of Nakamura et al. [22], a phthalocyaninecobalt-immobilized polymer membrane also showed facilitated transfer of some anion species.

### 3.6. Analytical applications

The high selectivity for salicylate over common inorganic and organic anions as well as the lower detection limit of the TTBPcSn(IV)-based electrode made it possible to determine salicylate in pharmaceutical preparations and biological samples. The electrode was employed for the assay of aspirin. The salicylic acid produced by the hydrolysis of acetylsalicylic acid was determined as described in the experimental section. The result obtained was 44.80 ± 0.34% (by weight, $n = 5$), which was in fair agreement with that of the pharmacopoeia method (44.67 ± 0.29%; $n = 5$).

A more detailed evaluation of the electrode method for determining salicylate in urine was carried out. Recovery studies with salicylate-spiked urine yielded recoveries ranging from 95 to 104% as shown in Table 2. The results obtained by the electrode method were in agreement with those of the colorimetric procedure. The new TTBPcSn(IV)-based electrode seemed to provide a nice alternative device for the direct determination of salicylate in biological samples.

# Preparation and characterization of a new enzyme electrode based on solid paraffin and activated graphite particles

C. Petit, A. Gonzalez-Cortes, J-M. Kauffmann *

*Free University of Brussels, Institute of Pharmacy, Bd. Triomphe, Campus Plaine, CP 205/06, 1050 Brussels, Belgium*

Received 28 March 1995; accepted 15 May 1995

**Abstract**

A new electrochemical biosensor was developed by incorporating an enzyme into a solid-paraffin–graphite-particle matrix. Tyrosinase served as model enzyme and the biosensor response was characterized with respect to its response to dopamine. The influence of different experimental parameters (tyrosinase loading, flow rate, oxygen dependence, pH, etc.) was investigated in order to optimize the biosensor performance. The electrode response was fast, reversible and linear in a large concentration domain (0.1 μM–1 mM). The enzyme–solid paraffin carbon paste electrode (CPE) showed markedly improved stability in flow injection analysis compared to the classical liquid paraffin–graphite-based biosensors. The biosensor allowed a sampling rate of 79 samples per hour, the repeatability of the injections was improved with respect to the classical CPE with a relative standard deviation of 2.2% ($N = 63$), and the detection limit for dopamine was 50 nM. The biosensor response to some phenol and catechol derivatives was also investigated.

## 1. Introduction

Amperometric biosensors are increasingly of considerable interest for monitoring analytes in flowing streams in pharmaceutical and environmental analysis [1–5]. The immobilization of a biological component in a water-insoluble matrix such as carbon paste (graphite + liquid paraffin) is currently extensively used for the development of amperometric biosensors [3–6]. Interestingly, the carbon paste electrode (CPE) exhibits a low background current compared to other solid electrodes [7], and enzyme-modified CPEs show fast responses due to the proximity of the biocatalyst–graphite particles. The electrode may be additionally mixed with a catalyst (redox mediator [8–12], metal particles [13–16]) and the biocatalyst is protected by the hydrophobic matrix of the electrode [17]. The enzyme loading may be important, allowing high rates of substrate conversion. However, applications under hydrodynamic conditions are limited by the instability of such biosensors [3,8], due in part to the poor mechanical strength of the paste [18] giving rise to enzyme leakage along with progressive erosion of the electrode surface [8,19]. Several interesting strategies have been considered for improving these so-called bulk-modified enzyme electrodes by using carbon composite matrixes such as epoxy [20–22], Kel-F [23], silicone grease [2], PVC [24], or Teflon [25] as binders, by stretching a dialysis membrane over the electrode [13,17,26], by chemically modifying the enzyme [27], or by chemically attaching the enzyme to the graphite particles [28]. In our

*SSDI* 0039-9140(95)01645-7

preliminary work, we described the preparation of a new solid paraffin-based carbon paste electrode (SCPE) for the development of an enzyme-immobilized electrode [29]. By studying the latter under hydrodynamic conditions (how injection analysis (FIA)), it appeared that the solid paraffin improved remarkably the mechanical stability of the biosensor, and the reproducibility and repeatability of the results compared to a liquid paraffin-based biosensor. We report here the characterization and properties of a tyrosinase-immobilized solid CPE (SCPE) by studying phenol and catechol derivatives and dopamine as model compounds in FIA and batch experiments. Tyrosinase (polyphenoloxidase) has already been used extensively for biosensor preparation [2,9,22,26, 28,30–34]. The enzyme is known to catalyze the oxidation of phenolic compounds via hydroxylation in the presence of molecular oxygen to catechol and finally to the corresponding *o*-quinone. The latter can be monitored amperometrically at −0.2 V vs. a saturated calomel electrode (SCE) and quantitatively related to the concentration of phenol or catechol derivatives [30–32]. A tyrosinase-immobilized CPE has been extensively studied by Ortega et al. [28,32] and the results have shown the high instability of the paste under hydrodynamic conditions, e.g. in HPLC [32]. Here, the electrochemical detection of quinones occurs at low potentials; this reduces the magnitude of the background current and minimizes the risks of interferences by uric acid, ascorbic acid and acetaminophen [33,35].

## 2. Experimental

### 2.1. Apparatus

*FIA experiments*

The experimental set-up consisted of an analytical pump (Perkin-Elmer, series 10, liquid chromatograph) with a sample injector of volume 20 µl, connected to the detector by a conduit of 40 cm length (Peek tubing, 0.03 cm i.d.).

The wall-jet configuration consisted of a large volume cell [36] containing the reference electrode (SCE); the enzyme electrode and a stainless-steel chromatographic tube as auxiliary electrode completed the cell. An applied potential of −0.2 V was maintained with a Bruker E 230 LC potentiostatic detector. The surface of the biosensor was positioned at a distance of 1 mm in front of the impinging jet.

A flow-through cell of thin layer design was also employed to check for the oxygen dependence of the biosensor. It was positioned within the FIA experimental set-up outlined above. The detection cell (BAS) housed the enzyme electrode (dual electrode, 3 mm in diameter), an Ag/AgCl (3 M NaCl) reference electrode (BAS) and a stainless-steel block as auxiliary electrode. The potential was controlled by a BAS LC 4B amperometric detector. The current output was displayed on a Kipp and Zonen $Y-t$ recorder.

Samples for injection were prepared using the carrier solution.

*Batch experiments*

Amperometric measurements were performed with use of a 20 ml cell containing the working electrode, an SCE as reference electrode and a glassy carbon electrode as the auxiliary electrode. The applied potential was maintained with a Bruker E 230 LC potentiostatic detector. A magnetic stirrer and a stirring bar provided convection. The current output was displayed on a Kipp and Zonen recorder.

Voltammetric measurements were performed with use of a Bioanalytical system (BAS) model CV 27 voltammetric analyzer connected to a 7090A Hewlett Packard printer.

All measurements were made at room temperature (22 ± 1°C).

### 2.2. Reagents

All chemicals were of analytical grade (Merck or Sigma) and were used as received. Stock solution of dopamine, catechol and phenol derivatives were prepared in nitrogen-deaerated phosphate buffer solutions. The latter were prepared from sodium dihydrogen phosphate and the pH was adjusted to the desired value by $H_3PO_4$ or NaOH. Deionized water was used for preparing the solutions. Graphite particles (diameters 10–100 µm) were cleaned by lixiviation with acetone, then activated with aqua regia and thoroughly rinsed with water to neutral pH and finally dried at 400°C for 4 h. The carbon paste electrode (CPE) was prepared by using commercial carbon pastes from Metrohm (E.A.207c), namely type A, consisting of 76% graphite and 24% liquid paraffin, and type B having 66% graphite and 34% liquid paraffin. Tyrosinase EC 1.14.18.1 (tyrosinase activity, 3900 U $mg^{-1}$ solid; polyphenol oxidase activity, 84 000 U $mg^{-1}$ solid; catechol oxidase ac-

tivity, 400 000 U $mg^{-1}$ solid) was purchased from Sigma as a lyophilized powder.

### 2.3. Electrode preparation

The solid carbon paste electrode (SCPE) was prepared by melting paraffin wax for 15 min in a mortar thermostated in a water bath, at a temperature close to its melting point (46–48°C) in the presence of graphite particles in the ratio 34:66 (m/m). The mortar was removed from the water bath and the paste was thoroughly mixed and crushed with a pestle.

For the enzyme-immobilized paste preparation, and in order to achieve optimum responses and reproducibility between pastes the dry enzyme powder was added by direct admixing with the carbon paste [32].

*Metrohm carbon paste electrode (EMCPE) types A and B*

The enzyme tyrosinase was mixed homogeneously with the Metrohm carbon paste (MCPE) in a mortar (5% (m/m)) at room temperature.

*New solid carbon "paste" electrode (ESCPE)*

The paraffin wax was melted in a mortar thermostated in a water bath at a temperature close to its melting point (46–48°C). The mortar was then removed from the bath and the lyophilized tyrosinase was added and thoroughly mixed. Subsequently, the graphite particles were added and mixed with a glassy spatula to obtain a prehomogeneous paste. The final "solid paste" was obtained by crushing with a pestle in the mortar. A portion of this mixture was packed into the Teflon body of the electrode (1 mm i.d.). Before the measurements, the new enzyme electrode was smoothed to a mirror finish using a clean paper card.

## 3. Results and discussion

The hardness of the ESCPE greatly minimized the leakage of the enzyme into the solution compared with a tyrosinase–MCPE. This was confirmed in batch conditions by dipping the enzyme-modified electrode (5% (m/m)) into a 20 ml cell containing 0.1 M phosphate buffer (pH 7.0) during 22 h under mild stirring. The presence of solubilized tyrosinase was demonstrated by the addition of catechol ($10^{-4}$ M) to the solution and monitoring the *o*-quinone produced by amperometric reduction using an MCPE. No reduction current was observed in the solution which contained the ESCPE, in contrast to the result obtained with the solution which contained the EMCPE type A.

### 3.1. Influence of flow rate

The dependence of the peak height upon the flow rate of the carrier (0.1 M phosphate buffer (pH 7.0)) was investigated in the range 0.3–2 ml $min^{-1}$ using the ESCPE by injecting a 34 μM dopamine solution into the FIA wall-jet system. A nearly exponential decrease of the signal was observed on increasing the flow rate in accordance with literature data [28, 32] which showed that the enzymatic conversion is limiting the response. It should be noted that at a flow rate of 1.0 ml $min^{-1}$, the response obtained represented approximately 55% of the response achieved at 0.3 ml $min^{-1}$. The latter flow rate was used for further experiments.

### 3.2. Influence of pH

The optimum pH for the ESCPE was determined in 0.1 M phosphate buffer in the pH range 5–9 using a 12 μM solution of dopamine. Experiments were carried out with the FIA system (wall-jet configuration) and the batch set-up (100% steady state). As shown in Fig. 1, curves A and B, similar behaviour was observed, with a maximum response at pH 7.0 in accordance with literature data on tyrosinase immobilized in a polypyrrole matrix [34], in a CPE [28,32], and in a graphite–epoxy composite electrode [23].

### 3.3. Influence of buffer concentration

The ESCPE response was investigated in the FIA system (wall-jet configuration) by varying the phosphate buffer concentration between 0.01 and 0.2 M at pH 7.0. The response decreased by approximately 50% from 0.01 to 0.1 M, then it stabilized to reach a plateau at 0.1 M. The response was quasi-independent of buffer concentration between 0.1 and 0.2 M. Further experiments were performed using a 0.1 M pH 7.0 buffer concentration.

### 3.4. Influence of temperature and enzyme loading

In order to check for the risk of enzyme degradation by heat, the influence of the tem-

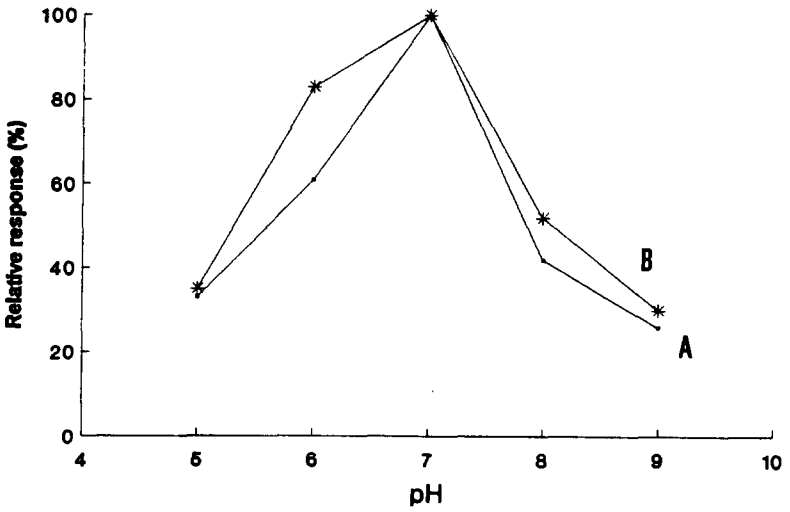

Fig. 1. Relative response of the ESCPE as a function of pH. Experimental conditions were optimized (see details in text). Curve A, FIA systems; curve B, Batch set-up.

perature during the paste preparation was investigated at 48, 58, and 68°C. No significant difference in the responses was observed (within experimental error) in this temperature range. The response of the biosensor (5.4 μM dopamine injection) increased non-linearly by raising the enzyme loading, e.g. 0.31 nA, 0.95 nA, and 2.2 nA at 2%, 5% and 8% (m/m), respectively. The second paste composition was selected in this study as it showed a better background current stability than the 8%, (m/m) loading. Using the latter, the background current was stable for 2 h then it started to increase gradually. This may be related to a higher hydrophilicity (inferred from an initially higher background) of the electrode surface, dissolution of the enzyme and progressive erosion of the electrode surface.

### 3.5. ESCPE stability in FIA

The operational stability of the ESCPE (5% (m/m)) and the tyrosinase–MCPE types A and B (5% (m/m)) were compared by repetitive injections of a 9.2 μM dopamine solution. As shown in Figs. 2A and 2B, a progressive increase of the background current and a peak current decrease with time were observed for the tyrosinase–MCPE types A and B compared to the ESCPE. As expected, the enzyme electrode with a higher graphite loading i.e. EMCPE type A (Fig. 2A), showed dramatic behaviour under hydrodynamic conditions due to its lower mechanical strength. For identical electrode compositions with respect to the binder:graphite:enzyme ratio, the ESCPE showed a markedly improved behaviour compared with the EMCPE type B (Figs. 2C and 2B, respectively). Note also that the initial response at the EMCPE were four times higher than at the ESCPE. This suggested that a larger amount of tyrosinase was spread over the tyrosinase–MCPE surface than over the ESCPE, but progressive dissolution of the enzyme (peak decrease) and gradual erosion (background increase) of the EMCPE types A and B limited their applicability. The ESCPE maintained 100% and 90% of its initial FIA response after 12 h and 24 h of continuous use, respectively. The long-term storage stability of the solid paste at 5°C was determined by studying the response of the ESCPE (injection of 12 μM dopamine in FIA). The ESCPE showed 69% of its initial response using a 65-days-stored solid paste.

The background current at the ESCPE was stabilized within 30 min following the application of the potential under the FIA optimal conditions.

### 3.6. Influence of oxygen

In the wall-jet configuration, the ESCPE response was not significantly affected when the carrier was permanently deaerated by nitrogen. This might be explained by the presence of traces of oxygen absorbed and entrapped in the ESCPE [19]. The oxygen non-dependence was also observed when using the FIA thin-layer configuration. The presence of entrapped oxy-

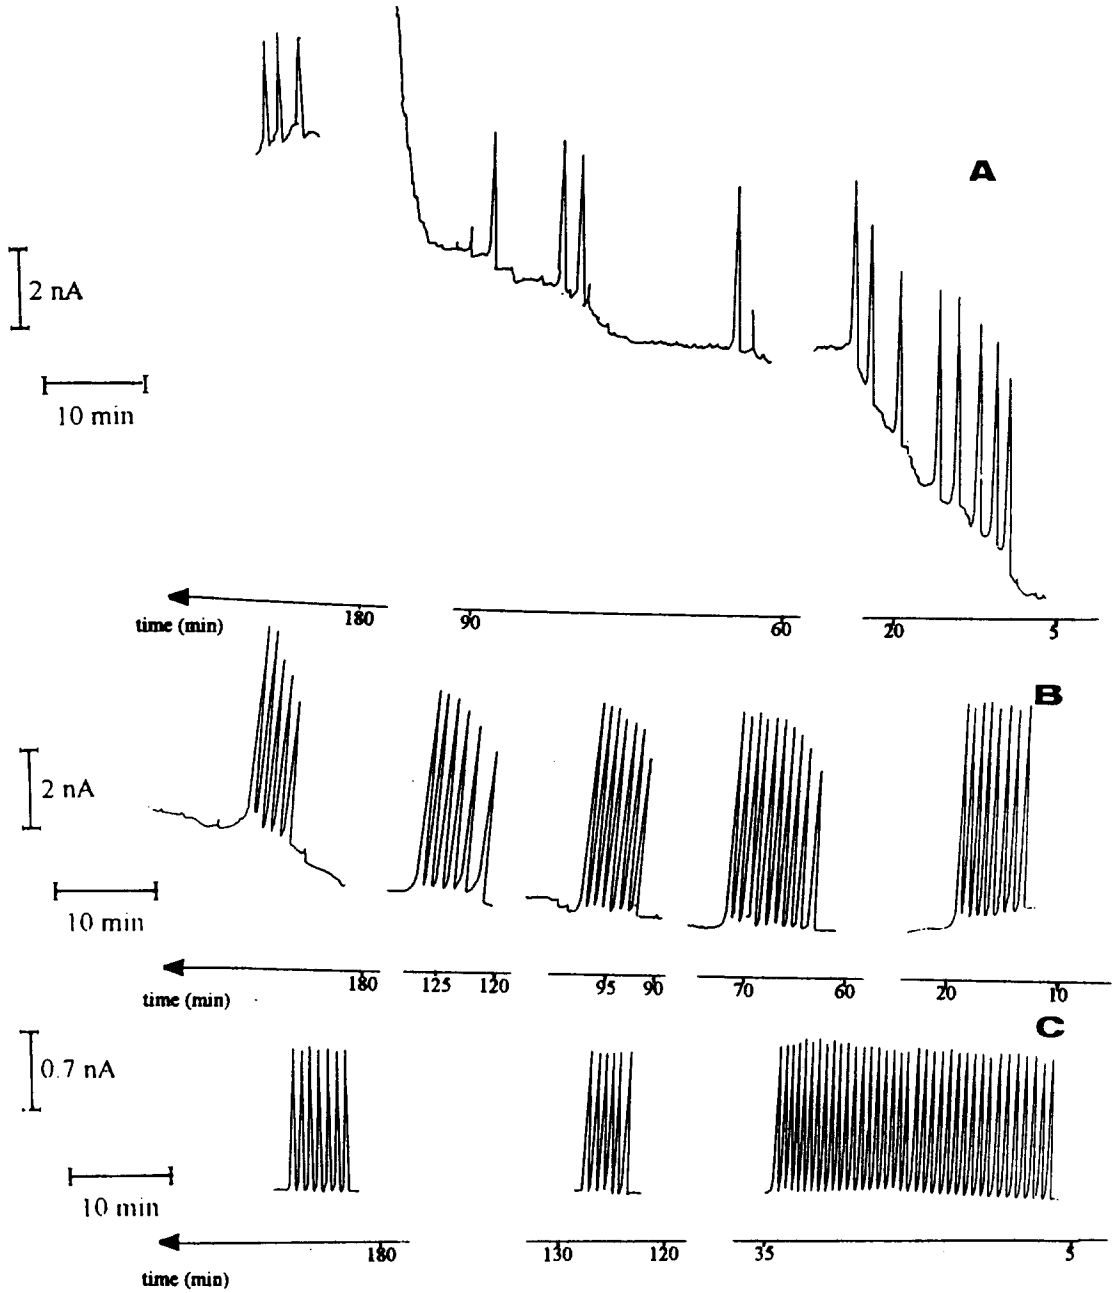

Fig. 2. Typical amperometric recordings in FIA. (Dopamine concentration, 9.2 μM; injection loop, 20 μl; 0.1 M phosphate buffer (pH 7.0); flow rate, 0.3 ml $min^{-1}$, $E_{app} = -0.2$ V vs. SCE.) (A) Metrohm CPE (type A)–tyrosinase 5% (m/m); (B) Metrohm CPE (type B)–tyrosinase 5% (m/m); (C) solid CPE–tyrosinase 5% (m/m).

gen was inferred from the broad reduction peak observed (in the negative potential range below −0.34 V) in the cyclic voltammetric curves recorded in nitrogen-degassed 0.1 M phosphate buffer (pH 7.0) at MCPE types A, B and the SCPE (figures not shown).

In FIA, using the wall-jet configuration under optimum conditions (flow rate, 0.3 ml $min^{-1}$; 0.1 M in phosphate buffer (pH 7.0)) the reproducibility (calculated by studying dopamine injections at two different concentrations, 3.6 μM and 5.4 μM) for different electrode surfaces ($N = 5$) was 5.1%. The ES-CPE showed a linear response (FIA wall-jet system) in the concentration range 0.1 μM–1 mM; $Y = 0.151x - 0.617$ where $Y$ is in

nanoamps and $x$ is in micromoles; and with a linear correlation coefficient of $r = 0.997$ (eight data points). The detection limit (signal-to-noise ratio, 3) was 50 nM. The calculated repeatability of several injections ($N = 63$) corresponded to a relative standard deviation (RSD) of 2.2%. The electrode response was fast, with a half-peak value of 23 s corresponding to a sampling frequency of 79 injections per hour.

It was of interest to compare the sensitivity for dopamine of the new biosensor with the results obtained by the direct oxidation of dopamine at the SCPE at a potention of +0.6 V vs. SCE. At the latter potential, the linear domain range was from 0.2 μm to 1 mM and the detection limit was 40 nM, but the responses were less reproducible (RSD, approximately 5%) and less selective due to the relatively high applied potential.

Trends in sensitivity taking into consideration other related molecules were established by studying the relative response for four phenol and catechol derivatives (taking the dopamine sensitivity as 100%). A calibration graph was obtained for each molecule investigated in the FIA system (wall-jet), using a flow rate of 1 ml $min^{-1}$. The results reported in Table 1 are in accordance with those reported by Ortega et al. for a tyrosinase–CPE [28]. The high response towards catechol may be attributed to the high catechol oxidase activity of the enzyme (see reagents). Differences in sensitivity among the catechols (catechol > dopamine > noradrenaline) are likely to be due to differences in the $K_m$ values of the catechol oxidase [37].

With respect to the possible use of the electrode in liquid chromatography, the ESCPE behaviour was tested in aqueous hydro organic media (methanol–buffer or acetonitrile–buffer) in the FIA system. On repetitive injections ($N = 23$) of a $6.5 \times 10^{-4}$ M dopamine solution, the response decrease slightly but continuously, using both the acetonitrile (10% (v/v)-containing and methanol (10% (v/v)))-containing carriers. The initial response was reduced by approximately 12% after 23 injections. A slightly more rapid decrease in response was observed in the acetonitrile-containing carrier. By raising the acetonitrile content to 40%, the intensity of the current dropped by 75% of its initial value within 2 h of use. Using a 40:60 (v/v) methanol–0.1 M phosphate buffer (pH 7.0), the intensity of the response (intermittent injections) was stable for 8 h. Further studies were carried out using 10:90 (v/v) methanol–buffer. Reproducible results (RSD, 1.8%; $N = 14$) were observed by allowing a waiting time of 5 min between each injection. A calibration graph was obtained in the concentration range 2.5 μM–1.8 mM; $Y = 0.026x + 0.232$, where $Y$ is in nanoamps and $x$ is in micromoles; $r = 0.9992$; with a detection limit of 1 μM.

Despite its gradual loss in sensitivity, the biosensor response was regenerated to 85% of its initial value by allowing a phosphate buffer carrier to flush over the biosensor for 1 h.

Table 1
Relative responses (slopes of the calibration curves) in the FIA wall-jet system of the tyrosinase–solid carbon paste electrode towards various substrates

| Compound | Slope (%) |
|---|---|
| Dopamine | 100 |
| Catechol | 680 |
| Phenol | 380 |
| L-Tyrosine | 51 |
| Noradrenaline | 23 |

## 4. Conclusion

The immobilization of an enzyme such as tyrosinase in solid paraffin in the presence of graphite particles appeared to be a judicious way of preparing electrochemical (micro) biosensors showing high stability and rapid response rates suitable for hydrodynamic applications. The detection limits were as good as those obtained at the enzyme-carbon paste electrode i.e. 40 nM, but the reproducibility of the response and the stability of the probe in aqueous organic media were considerably improved. Possible application of this new "robust" enzyme electrode may be considered in on-line phenol (and derivatives) monitoring, in "in vivo" sensing or as a detector in HPLC analysis.

Received 28 March 1995; revised 5 May 1995; accepted 15 May 1995

**Abstract**

Strip-type, preconcentrating/voltammetric sensors, prepared by incorporating a cation-exchange resin within screen-printed carbon inks, are described. Such single-use strips combine the efficient electrostatic accumulation of heavy metals with the use of "mercury-free" surfaces. The uptake of copper(II) from dilute solutions (under open circuit conditions) is followed by voltammetric measurements in a separate blank solution. Various experimental variables have been optimized to yield low detection limits (e.g. 0.5 $\mu g\,l^{-1}$ with 10 min accumulation) and good reproducibility (relative standard deviation, 2%). The applicability to assays of drinking water is demonstrated.

*Keywords:* Cation-exchanger-modified surface; Trace copper; Voltammetric sensors

## 1. Introduction

There is a growing need for decentralized testing of trace metals in connection with environmental field screening or near-patient clinical diagnosis [1]. The remarkable sensitivity of electroanalytical procedures, coupled with their compact instrumentation and low-power requirements, make them very attractive for the task of on-site metal analysis. Particularly useful are single-use sensor strips based on screen-printing technology. Such thin film microfabrication capability allows the mass production of highly reproducible, and yet extremely inexpensive disposable electrode strips [1–3]. Useful metal sensors have thus been developed based on the coupling of screen-printed electrodes with highly sensitive electrochemical stripping procedures [1,4]. Voltammetric and potentiometric stripping operations of these disposable electrodes offer reliable and yet convenient quantitation of heavy metals down to the nanomolar concentration level. One concern related to the field application and disposal of stripping-based screen-printed electrodes is their reliance on mercury-coated surfaces. The development of "mercury-free" metal sensors thus represents a challenging and important task.

This paper describes the performance of a cation-exchanger-based single-use sensor for heavy metals. While chemically modified screen-printed electrodes have been reported previously in connection with electrocatalytic modifiers [2,5], no reports are available on analogous tailoring of screen-printed electrodes with preconcentrating agents. The preconcentration/voltammetric strategy enjoys remarkable sensitivity [6], and its coupling to screen-printing technology holds great promise

for on-site metal analysis. Preconcentrating modified electrodes also allow the use of medium-exchange procedures, i.e. the removal of the sensor from the sample matrix and potential interferences. In the present study, a cation-exchanger resin, Dowex 50W-X8, was dispersed within a commercial carbon ink prior to the screen-printing process. The ability of this cation exchanger to rapidly collect metal ions from dilute solutions was demonstrated earlier in connection with modified carbon paste electrodes [7–9]. Similarly, as will be illustrated in the following sections, this resin modifier retains its attractive electrostatic accumulation behavior upon incorporation within printing carbon inks, and the resulting screen-printed preconcentrating electrode offers convenient quantitations of trace copper, lead and cadmium.

## 2. Experimental

### 2.1. Apparatus

All voltammetric experiments were carried out using an EG&G PAR Model 264A voltammetric analyzer, in connection with an EG&G PAR Model 0073 $X-Y$ recorder. Measurements were performed in a 10 ml electrochemical cell (BAS, Model VC-2). The working electrode strip, reference electrode (Ag/AgCl, Model RE-1, BAS) and platinum wire auxiliary electrode joined the cell through holes in the Teflon cover.

pH measurements were carried out using a Beckman Φ12 pH/ISE meter, in combination with a Beckman combined pH electrode (No. 39 831).

### 2.2. Screen-printing fabrication

A semiautomatic screen printer (Model TF-100, MPM Inc., Franklin, MA) was used for fabricating the working electrode strips. The modified inks were prepared by thoroughly mixing the appropriate amounts of commercial carbon ink (product no. G-488 [1], Ercon, Waltham, Ma) with the solid cation exchanger Dowex 50W-X8 ($H^+$ form, 20–50 mesh (Fluka)) in a porcelain mortar. Prior to mixing, the cation exchanger was ground in a mortar to a very fine powder. A group of ten electrodes was printed onto the alumina ceramic plate (1.33 in × 4.00 in) through a pattern stencil. Each electrode consisted of a $1.5 \times 30\ mm^2$ area. After letting the electrodes dry at room temperature, a layer of insulator was placed onto part of the printed ink, leaving a defined $1.5 \times 5\ mm^2$ working-electrode area.

### 2.3. Reagents

All solutions were prepared with deionized or nanopure water (for experiments using very low concentrations of copper). The disodium salt of ethylenediaminetetraacetic acid (EDTA) and dipotassium hydrogen phosphate were received from Fisher, while potassium dihydrogen phosphate was obtained from Aldrich. Chemicals were used as received. Standard solutions of copper, antimony, bismuth, cadmium, iron, mercury, lead, silver and zinc ($1000\ mg\ l^{-1}$) were purchased as standards for atomic absorption from Aldrich, and were diluted with nanopure water prior to use. The ground water sample was collected at Hanford site (Richland, WA), while the drinking water was sampled at the NMSU laboratory (Las Cruces). Both samples could be used after adjustment of the pH with nitric acid (Fisher) without further treatment.

### 2.4. Procedure

Both unmodified and modified screen-printed electrodes were used without further pretreatment.

*Preconcentration*

For the accumulation of copper, the electrode was exposed to the stirred sample solution (10 ml of double-distilled water, pH 5.7) containing copper(II) for the required time. After the preconcentration period, the electrode was removed, rinsed with water, placed into the voltammetric cell and connected to the polarograph.

*Voltammetry*

The supporting electrolyte for the voltammetric measurements was phosphate buffer (0.005 M; pH 5.7). Cyclic voltammograms (CV) were recorded with a scan rate of $50\ mV\ s^{-1}$; the scan was initiated at +0.6 V and then switched in direction at −0.6 V. All quantitative measurements were performed in the differential pulse mode (DPV). The initial potential was −0.4 V; the final potential was +0.3 V. An equilibration time of 15 s with the

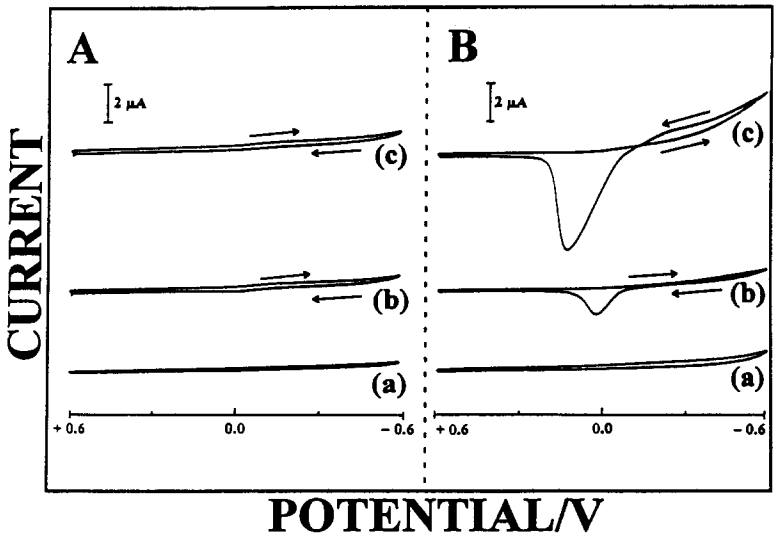

Fig. 1. Cyclic voltammograms for copper, preconcentrated at (A) plain and (B) modified screen-printed electrodes: (curves a) 0 ppm, (curves b) 1 ppm and (curves c) 4 ppm of copper in the sample solution, respectively. (Scan rate, 50 mV $s^{-1}$; supporting electrolyte, 0.005 M phosphate buffer, (pH 5.7). Medium exchange technique: accumulation time, 1 min; pH of the sample solution, 5.7. Modifier (Dowex 50W-X8) loading (B), 5% (w/w).)

initial potential applied was required to obtain complete reduction of copper(II) to copper(0). The pulse height was 50 mV and the scan rate was 20 mV $s^{-1}$ with an increment of 4 mV per data point. The current range was set according to the concentration of copper.

*Regeneration*

Following the voltammetric quantitation, the strip was immersed in a well-stirred aqueous solution of EDTA (0.1 M) for 15 s. After careful rinsing with water, the blank voltammogram was recorded.

## 3. Results and discussion

Solid cation exchangers have not been employed for the modification of screen-printed electrodes. The finely ground Dowex 50W-X8 particles, admixed thoroughly within the carbon ink, retain their attractive uptake properties following the screen-printing process. Fig. 1 compares the voltammetric response of the (A) plain and (B) modified screen-printed strips, following accumulation from copper solutions and transfer to a blank solution. As can be clearly seen, accumulation of copper takes place only when modified screen-printed electrodes are used, resulting in a rather small and broad cathodic wave corresponding to the reduction of copper(II) to copper(0) at a potential of about −0.1 V (vs. Ag/AgCl), and in a very sharp and well-defined reoxidation (stripping) signal at +0.1 V; the anodic peak shifts to more positive potentials with increasing copper concentration. No distinctive copper peaks are observed with unmodified screen-printed electrodes.

The irreversible character of the reduction of copper(II) is in contrast to its behavior at Dowex-50W-X8-modified carbon paste electrodes [8]. In this latter case the reduction of copper(II) yielded a sharp signal, which was exploited for DPV quantitation. As only the copper reoxidation yielded a defined response at the modified screen-printed electrodes, this signal was exploited for all further investigations. For quantitation purposes, the accumulated copper is first reduced to the metallic state during the equilibration step (at the initial potential of −0.4 V), and then reoxidized upon scanning in the anodic direction. An equilibration time of 15 s was found to be sufficient to ensure complete reduction of the accumulated copper prior to measurement. The ion-exchange accumulation and measurement processes may be described by the following equations

Accumulation:

$$2[RSO_3^- H^+]_{surf} + [Cu^{2+}]_{sol} \leftrightarrow [(RSO_3^-)_2 Cu^{2+}]_{surf} + 2H^+_{sol} \quad (1)$$

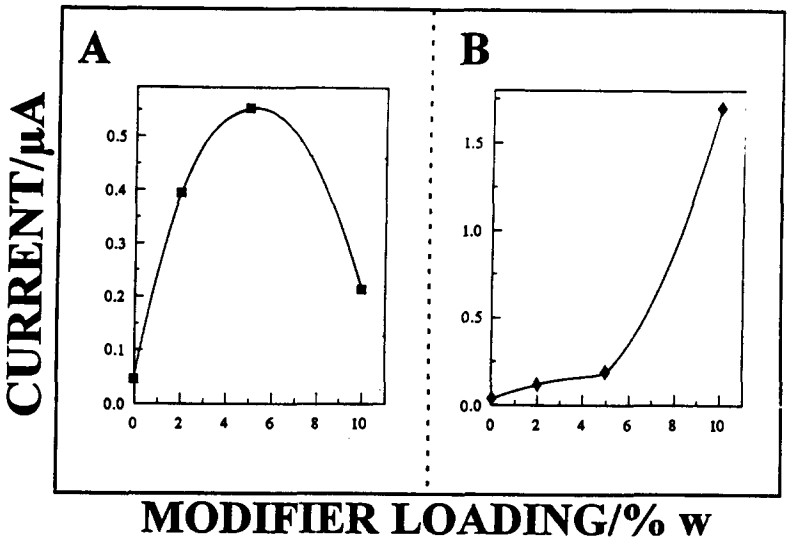

Fig. 2. Effect of modifier loading on the (A) peak and (B) background current. (Differential pulse voltammetry: potential, −0.4–+0.3; scan rate, 20 mV $s^{-1}$. Medium exchange technique: 100 ppb copper; 1 min accumulation time. Other conditions as in Fig. 1).

Equilibration (−0.4 V)

$$[(RSO_3^-)_2Cu^{2+}]_{surf} + 2H^+_{sol} + 2e^- \leftrightarrow 2[RSO_3^-H^+]_{surf} + [Cu^0]_{surf} \quad (2)$$

Measurement (−0.4– + 0.3 V)

$$[Cu^0]_{surf} \leftrightarrow [Cu^{2+}]_{sol} + 2e^- \quad (3)$$

The removal of accumulated copper residues after the voltammetric measurement is essential for the repeated use of the electrode strips. Such cleaning is possible by exposure of the electrode to solutions of EDTA or KCN. As screen-printed electrodes are aimed mainly for on-site environmental applications, the use of KCN as the regeneration agent was considered to be less favorable. A 15 s immersion of the electrode in a 0.1 M EDTA solution was sufficient for complete regeneration of the surface, without loss of analytical performance. Reproducible repetitive runs require recording of the blank voltammogram after each regeneration procedure, probably to remove complexed copper from the electrode surface, and to return the cation exchanger to its "active" form. Careful rinsing of the electrode after exposure to the regeneration solution was found to be extremely important in order to avoid contamination of the sample or measurement solutions with EDTA.

The loading of the resin modifier within the ink has a profound effect on the performance of the modified screen-printed electrode strips. Higher surface loadings normally result in a higher accumulation capacity, but also in larger background currents. In order to optimize the composition of the modified electrodes, strips were prepared with various loadings of the resin modifier. Similar to the trend obtained with Dowex-40W-X8-modified carbon paste electrodes [8] it was found that the exchange capacity increased up to a modifier loading of 5% (w/w), but decreased with higher modifier loadings accompanied by a drastic increase of the background current for loadings greater than 5% (Fig. 2). Screen-printed electrodes with a modifier loading of 5% (w/w) were thus found to yield the optimum signal-to-background ratio.

While screen-printed electrodes are mainly designed for "one-shot" applications, the Dowex-modified strips are also found to yield high stability and reproducibility after regeneration. They can be used throughout several days, without deterioration of the analytical performance. No special pretreatment is necessary when using freshly prepared strips, and the copper signals attain a constant height after two preliminary accumulation/measurement/regeneration cycles, yielding a relative standard deviation of less than 2% for 10 consecutive measurements. The variability between different electrodes is also good. A relative standard deviation of 5% was calculated for the response of 100 μg $l^{-1}$ Cu at five different electrodes (accumulation time of 1 min).

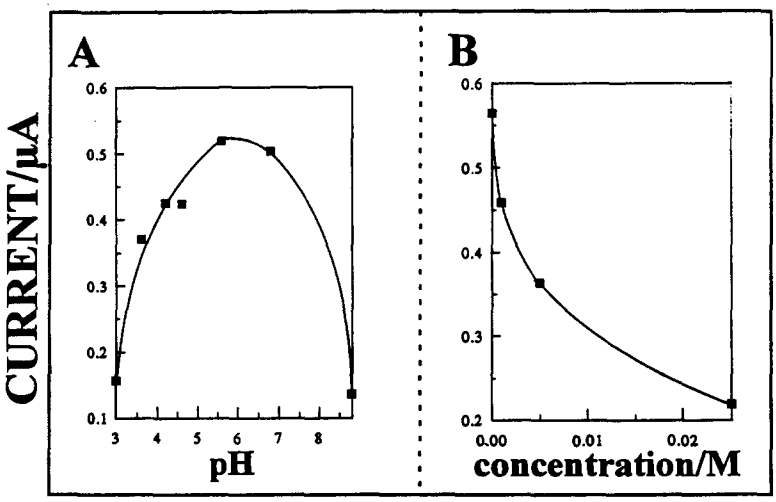

Fig. 3. Effect of (A) pH and (B) ionic strength on the peak current (5% (w/w) modified screen-printed electrode; (B) pH 5.7; other conditions as in Fig. 2).

Experiments were performed to explore the optimum conditions for the accumulation/measurement procedure. When varying the differential pulse scan rate between 10 and 100 mV $s^{-1}$, it was found that a scan rate of 20 mV $s^{-1}$ provided the optimum ratio between peak height and peak shape. Lower scan rates resulted in much smaller peak currents, whereas with higher rates, broadening of the peaks took place, without any gain in peak height.

Parameters which influence the analytical performance of preconcentration strip electrodes to a great extent are the composition and pH of the measurement and sample solutions. As for the supporting electrolyte (for the measurement solution), it was found in preliminary investigations that both non-complexing potassium nitrate and phosphate buffer are suitable electrolytes for the modified screen-printed electrodes. Similar results were obtained when modified carbon paste electrodes were used [8]. However, as the pH of the measurement solution had a great influence on the peak current of the copper reoxidation signal in the range between 6 and 8, and to ensure constant pH, phosphate buffer was chosen as the supporting electrolyte. The optimum pH for the measurement step was found to be 5.7, in conjunction with a phosphate buffer concentration of 0.005 M. The influence of dissolved oxygen was investigated with respect to the applicability of the Dowex-modified electrodes in field analysis. It was found that removal of oxygen by purging nitrogen through the solution results in slightly higher peak currents (approximately 5%), but did not alter or improve the general voltammetric behavior. Therefore, this procedure is not necessary for improving the results.

Even more important than the measurement solution are the composition and pH of the sample solution as they directly effect the accumulation step. Fig. 3A displays the dependence of the peak current on the pH of the sample solution. As can be seen, the pH has a great influence on the accumulation behavior. At high concentrations of hydronium ions, the equilibrium of Eq. (1) is shifted to the left-hand side, in favor of the binding of hydronium ions to the sulfonic acid groups of the cation exchanger. On the other hand, the presence of high levels of hydroxide ions may lead to ion pairs with copper, which is no longer acessible for accumulation. Additionally, it is possible that the pH influences the accumulation capacity of the cation exchanger itself. A pH of 5.7 thus offers an optimum accumulation of copper. The pH had to be kept constant throughout a whole series of measurements, and was monitored periodically (after five consecutive accumulation/measurement cycles).

As can be seen from Fig. 3B, an increase of the ionic strength of the sample solution leads to a rapid decrease of the peak current, due to competition by coexisting cations of the electrolyte solution for the surface cation-exchanger sites.

As expected for preconcentration electrodes, the response of the sensor strip is strongly dependent upon the accumulation time. Fig. 4 shows the dependence of the peak current on

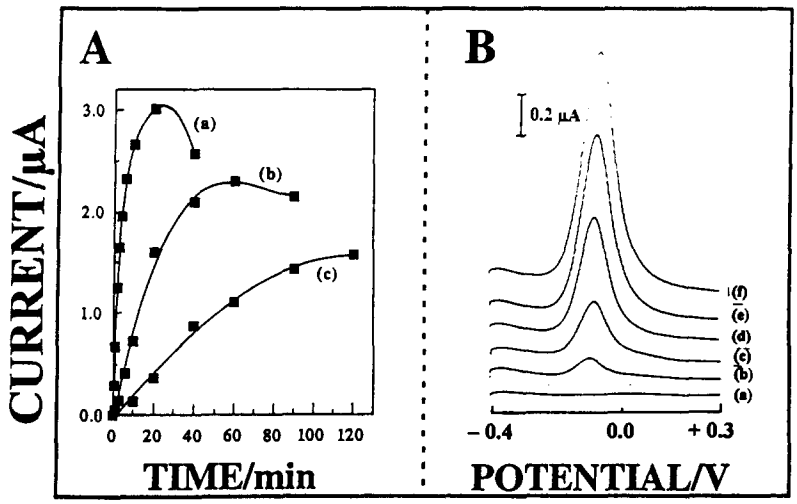

Fig. 4. (A) Dependence of the peak current on the accumulation time; (B) the resulting differential pulse voltammograms. (A) Copper concentrations: (curve a) 100 ppb; (curve b) 10 ppb; (curve c) 1 ppb. (B) Copper concentration, 10 ppb; accumulation times: (curve a) 0 min; (curve b) 3 min; (curve c) 5 min; (curve d) 8 min; (curve e) 12 min; (curve f) 15 min. Other conditions as in Fig. 3.

the preconcentration time for three different copper concentrations (Fig. 4A), as well as the corresponding differential pulse voltammograms for 10 ppb of copper with increasing times. The curves for 100 and 10 ppb of copper in Fig. 4A display an initial linear increase of the peak current with increasing preconcentration times, followed by a leveling off, indicating saturation of the modifier functionalities with copper ions; a slight decrease is observed at very long accumulation times. The corresponding curve for the 1 ppb copper level exhibits a linear increase of up to 60 min preconcentration time, followed again by a horizontal region. There is no deterioration of the peak shape with very long accumulation times, as can be seen from the response of Fig. 4B. Notice also the well-defined response for 10 ppb copper (even at short times of 3–5 min curves b, and c), and the low background current. As expected, the linear range is wider when lower copper concentrations are used, as saturation effects occur only with longer preconcentration periods. The results obtained in this study indicate that the exchange between the copper and the hydronium ions bound to the surface of the modified screen-printed electrode takes place rather slowly.

The lowest achievable limit of detection depends on the preconcentration time used. For a preconcentration period of 10 min, copper levels as low as 0.5 ppb can be determined with high precision (relative standard deviation (RSD), 2%). The detection limit could be even further reduced with longer preconcentration times (although such periods are not practical).

An additional study was carried out to assess the accumulation behavior in quiescent (unstirred) solutions, with the prospect of placing sample drops on these modified screen-printed electrode strips, as is common for stripping assays of lead in urine and drinking water [4]. Experiments showed that the resulting peak currents were approximately five times lower without stirring than with stirring, but that the peak shape was not altered at all. Due to the overall remarkable sensitivity, low parts-per-billion concentrations can be measured for quiescent solutions. The dependence on the preconcentration time without stirring displayed a wider linearity than with stirring, as saturation can be obtained only for very long preconcentrations periods.

As expected for ion-exchange equilibria, the amount of collected ions is related to their solution concentration (as long as saturation effects are not observed). Fig. 5 shows the dependence of the peak current on the concentration of copper in the sample solution, for a 2 min accumulation time. The peak current increases linearly with increasing copper concentration of up to 110 ppb, and then starts to level off, reaching a constant value at 400 ppb, indicating saturation of surface functionalities.

Several other metal ions were examined with respect to their influence on the copper response (50 ppb; 1 min accumulation time). Due to the nature of the electrostatic accumulation

process, interferences from these cations, present in the sample soluution, are expected. However, it was found that at the same concentration level (50 ppb) only Pb(II) interfered strongly, leading to a decrease of the copper signal by 40%; in contrast, Sb(III), Zn(II), Bi(III), Cd(II), Ag(I), Hg(II) and Fe(III) had no or very little effect (less than 10%). A less than 10% change in peak height was observed in the presence of a tenfold excess of Sb(III), Zn(II), Bi(III), Cd(II) and Fe(III). A tenfold excess of Pb(II) and Ag(I) decreased the peak height by 50%, the latter yielding a second peak at about +0.2 V, and an increased background current at the beginning (around −0.4 V). Strong interference was found only for a tenfold excess of mercury.

To investigate the practical applicability, the new strips were employed for the determination of copper in drinking and ground water samples. Fig. 6 displays the results for the drinking water sample. An accumulation time of 2 min was sufficient to yield a defined copper signal for the sample (curve a), as well as for successive standard additions of 10 ppb (curves b–e). A copper value of 12 ppb was estimated based on the resulting standard addition plot. It can clearly be seen that the presence of coexisting inorganic or organic compounds does not affect the shape of the copper signal, and no overlap with other peaks occurs. The

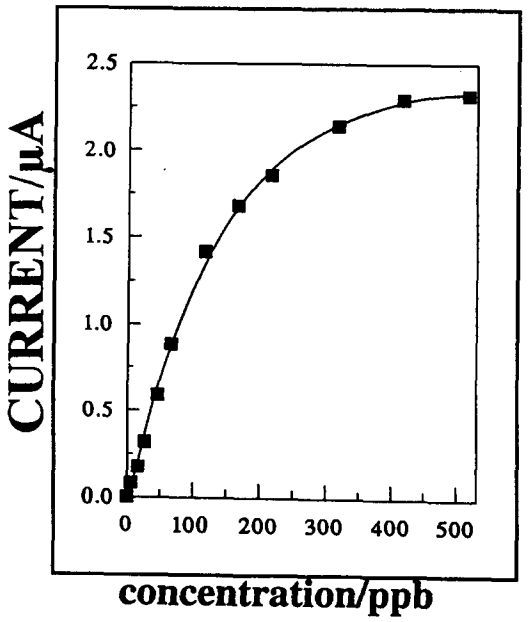

Fig. 5. Dependence of the peak current on the concentration of copper in the sample solution. Accumulation time, 2 min; other conditions as in Fig. 3.

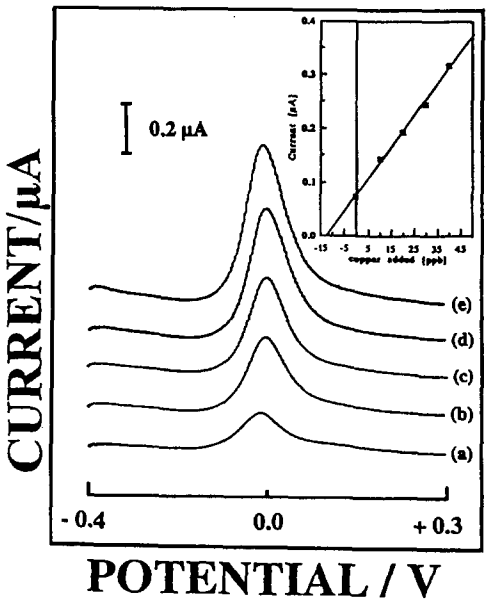

Fig. 6. Assay of drinking water sample. Response for the sample (curve a), as well as for subsequent additions of (curve b) 10 ppb, (curve c) 20 ppb, (curve d) 30 ppb, (curve e) 40 ppb copper (accumulation time, 2 min; other conditions as in Fig. 3). Also shown (inset) is the resulting standard addition plot.

absolute peak currents are slightly lower than those in pure sample solutions, but the precision of the determination is quite high.

In the case of groundwater, a 5 min preconcentration time had to be employed, as the amount of copper was very low (1 ppb). Due to a higher content of interfering substances in the ground water samples, additional peaks, as well as higher background currents, were observed. However, as these additional peaks did not overlap with the copper reoxidation signal, quantitation was possible.

Finally, attempts were made to employ the Dowex-modified screen-printed electrodes in the simultaneous analysis of several metal ions. Fig. 7 displays differential pulse voltammograms for subsequent additions of cadmium, lead and copper to the sample solution, using 2 min preconcentration. Although the conditions had been optimized only for the accumulation of copper, defined oxidation signals are observed for cadmium (at a potential of −0.9 V) and lead (−0.6 V). These peaks increase linearly upon increasing concentration of these metal ions. The peaks are well-separated, with no obvious interference.

In conclusion, the results presented above demonstrate that modified screen-printed electrodes, prepared by direct admixing of the

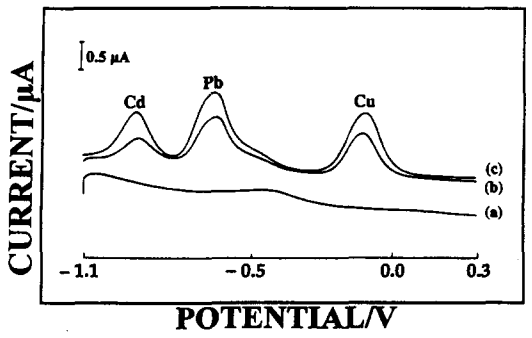

Fig. 7. Simultaneous differential pulse voltammograms for cadmium, lead and copper. Potential, −1.1–+0.3 V; 2 min accumulation time; curve (a) blank; (curve b) 50 ppb Cu, 100 ppb Cd and 100 ppb Pb; (curve c) 100 ppb Cu, 200 ppb Cd and 200 ppb Pb. Other conditions as in Fig. 3.

cation exchanger to the carbon ink prior to the screen-printing process, allows efficient preconcentration of copper(II) ions before voltammetric measurement. High precision and very low detection limits in the nanomolar region can be obtained with short preconcentration times. The modified screen-printed electrode strips provide a useful tool for multielement analysis of metal ions analogous to stripping-based sensors (but without a mercury coating). Future attention will be given to adopting these screen-printed strips for the on-site field screening of environmentally important trace metals. Even though the concept is presented in the context of the Dowex cation exchanger, a number of other sensors based on non-electrolytic preconcentration schemes can be visualized. For example, a new "one-shot" sensor for nitrite was recently developed in our laboratory based on admixing a liquid anion exchanger with carbon inks [10].

***Encapsulation and Controlled Release***, edited by D.R. Karsa and R.A. Stephenson, The Royal Society of Chemistry, Cambridge, 1993, viii + 178 pp., £37.50. ISBN 0-85186-615-8.

This book is based on a symposium organised by the North West Region of the Industrial Division of the Royal Society of Chemistry and the Water Soluble Polymers Sector Group of the British Association for Chemical Specialities at UMIST, Manchester, UK on 14–15 October 1992. It is classified as specialist publication No. 138 by the RSC.

The contents consist of 15 papers by industrial and academic researchers from not only the UK but also from Germany, Italy, Denmark, Belgium, the Netherlands and USA. As expected, the majority of topics are related to drug delivery but there are also papers on pesticides, flavours and fragrances, inorganic pigments ($TiO_2$) and enzyme encapsulation.

The multi-disciplinary approach required for this subject area is apparent in this publication but, as it is aimed at chemists, the biological aspects related to release of drugs are kept somewhat in the background. It is mainly the technology of producing microspheres, microparticles and nanoparticles and the use of biodegradable/non-biodegradable polymers that is covered here. Of course, much information in this field is commercially sensitive as teaching old drugs new tricks can be very profitable. This is borne out in the text where most papers are clear and complete whilst a few leave you feeling that some details are missing, perhaps requiring a visit to the patent literature. The paper on the infusion of drugs into polymers, for example, is intriguing but is one of only two presentations which lacks references.

Most of the papers are general rather than specific and are therefore very useful introductions to this area. For example, Industrial Microencapsulation—Polymers for Microcapsule Walls by C.A. Finch, Encapsulation and Controlled Release of Flavours and Fragrances by H.C. Greenblatt et al., and Biodegradable Microspheres for Controlled Drug Release by T.L. Whateley (who is, incidentally, the editor of the Journal of Microencapsulation) are excellent summaries of methods and materials. I also enjoyed reading—and benefited from—the papers on Nanoparticles by J. Kreuter and Softgels by K. Hutchinson.

A useful subject index is provided and the various fonts and print sizes do not detract from the quality of the contributions. Indeed all the papers should be of interest to those involved in the expanding field of controlled release technology and this is certainly a book that I recommend to those working in this area.

***Flame Spectrometry in Environmental Chemical Analysis—A Practical Guide***, by M.S. Cresser, The Royal Society of Chemistry, Cambridge, 1994, x + 108 pp., £29.50. ISBN 0-85186-734-0.

Every once in a while being asked to review a book can be a real pleasure and for me this was the case on this occasion. All too often authors are tempted to over-play their pet topics, resulting in the omissions in other often relevant areas, and a resultant imbalance in the final text. Thus such books tend to miss the mark with respect to their target audience. This book however is exactly what its title implies—a practical guide to flame spectrometry and its use in environmental analysis. It is written in a style ideally suited to students and non-specialists who want a no-frills approach, but at the same time want to fully understand what they are doing and what is happening when they use the instrumentation. Thus this book addresses the essential components of flame AAS, AES and AFS instruments, instrumental optimisation and useful techniques to aid analysis such as hydride generation and the use of discrete

sampling devices, all from a user standpoint. The author deliberately avoids specialist theory but uses the first chapter to provide an overview of the subject area to underpin the rest of the book.

Having described the instrumentation the remaining five chapters in the book are devoted to practical analysis. There is a useful chapter on sample preparation and a chapter on interferences and how to overcome them, including a section on background correction in AAS. There is also a chapter which looks at the practical problems of determining individual elements. This chapter has 28 elements listed in turn and a small section on speciation and hybrid techniques. The last two chapters in the book discuss quality control, error detection, the use of reference materials and safety.

The style of this book makes it easy and indeed enjoyable to read, and the 101 pages of text are full of advice and guidance. Clearly some areas are not covered in minute detail—that is not the aim of the book. However there are references throughout, conveniently located at the foot of the page, to aid access to further reading if required. I would warmly recommend this book, although disappointingly it is only available in hardback at the present time and thus possibly beyond the pockets of those who would benefit most from owning a personal copy.

***Undergraduate Instrumental Analysis***, 5th edn., by J.W. Robinson, Dekker, New York, 1994, xxiii + 858 pp., US$65.00. ISBN 0-8247-9215-7.

This is an extensive book (over 800 pages) which has been revised and expanded for the fifth edition. The layout is good and the majority of the diagrams are clearly drawn. At the end of each chapter there are up-to-date references and further readings, some suggested experiments and, as would be expected in an American book, plenty of problems to test the students' understanding. An introductory chapter on 'The Concepts of Analytical Chemistry' is followed by eleven chapters on the various spectrometric techniques plus chapters on chromatography, thermal analysis, surface analysis and electrochemistry. The emphasis is on spectrometry (over 70 percent of the book) so that the whole of chromatography is covered in only 80 pages whereas the infrared and mass spectrometry chapters are both longer. Consequently, the very important techniques of gas and high performance liquid chromatography (particularly the latter) receive insufficient coverage in depth, and high performance capillary electrophoresis, a technique of rapidly-growing importance, is not mentioned at all.

The balance of the material between theory, instrumentation and applications within each chapter is generally good but the treatment of some important topics is too superficial, e.g. the very brief section on the statistical assessment of quantitative data, the causes of curvature in Beer's Law plots, chemical shift, spin–spin splitting and 2-D techniques in nuclear magnetic resonance spectrometry, and the whole of high performance liquid chromatography. In the section of potentiometry, the fluoride ion-selective electrode, one of the best and most widely-used, is dismissed in two lines and gas-sensing electrodes are omitted altogether.

As the book is written for American undergraduates, much of the material is rather basic and possibly more appropriate for first and perhaps second year students taking degree courses in the UK and Europe. The content is variable in quality and although it contains many useful tables of comparative data, particularly on the sensitivities of various analytical techniques, it is most unfortunate that in 1995 'cps' is used instead of Hertz, 'Gauss' instead of Tesla and 'micrometer' in preference to wavenumbers in discussing infrared spectra. Whilst I cannot wholeheartedly recommend this book for the reasons outlined above, there is much useful material in it that is suitable for introductory courses in analytical chemistry.

This is an extensive book (over 800 pages) which has been revised and expanded for the fifth edition. The layout is good and the majority of the diagrams are clearly drawn. At the end of each chapter there are up-to-date references and further readings, some suggested experiments and, as would be expected in an American book, plenty of problems to test the students' understanding. An introductory chapter on 'The Concepts of Analytical Chemistry' is followed by eleven chapters on the various spectrometric techniques plus chapters on chromatography, thermal analysis, surface analysis and electrochemistry. The emphasis is on spectrometry (over 70 percent of the book) so that the whole of chromatography is covered in only 80 pages whereas the infrared and mass spectrometry chapters are both longer. Consequently, the very important techniques of gas and high performance liquid chromatography (particularly the latter) receive insufficient coverage in depth, and high performance capillary electrophoresis, a technique of rapidly-growing importance, is not mentioned at all.

The balance of the material between theory, instrumentation and applications within each chapter is generally good but the treatment of some important topics is too superficial, e.g. the very brief section on the statistical assessment of quantitative data, the causes of curvature in Beer's Law plots, chemical shift, spin–spin splitting and 2-D techniques in nuclear magnetic resonance spectrometry, and the whole of high performance liquid chromatography. In the section of potentiometry, the fluoride ion-selective electrode, one of the best and most widely-used, is dismissed in two lines and gas-sensing electrodes are omitted altogether.

As the book is written for American undergraduates, much of the material is rather basic and possibly more appropriate for first and perhaps second year students taking degree courses in the UK and Europe. The content is variable in quality and although it contains many useful tables of comparative data, particularly on the sensitivities of various analytical techniques, it is most unfortunate that in 1995 'cps' is used instead of Hertz, 'Gauss' instead of Tesla and 'micrometer' in preference to wavenumbers in discussing infrared spectra. Whilst I cannot wholeheartedly recommend this book for the reasons outlined above, there is much useful material in it that is suitable for introductory courses in analytical chemistry.

***Interfacial Design and Chemical Sensing***, T.E. Mallouk and D.J. Harrison, ACS Symposium Series 561, American Chemical Society, Washington, DC, 1994, xi + 338 pp. ISBN 0-8412-2931-7.

Interfacial Design and Chemical Sensing contains 27 papers from a symposium at the August 1993 American Chemical Society meeting. The papers are organized into three separate categories: New Materials, Structurally Tailored Interfaces and Chemical Sensor Designs.

The New Materials category includes papers on subjects from zeolite synthesis to devices in which dye absorption and polymer oxidation are observed through their effect on high temperature superconductors. Some of the new materials are designed to offer new approaches to selectivity, e.g. synthetic zeolites and metal phosphonate thin films with molecular voids of known dimensions. Other goals are to increase the effective surface area of sensors and to prepare membranes with photogated ion channels.

The papers in the Structurally Tailored Interfaces are more focused towards a particular goal. Several papers involve systems in which a host–guest binding event modifies the permeability of a thin layer on the surface of an electrode. Other topics range from a study of nucleation and growth of molecular crystals on molecular interfaces to the preparation of ordered monolayers by molecular beam epitaxy.

The papers in the Chemical Sensor Designs section described the actual preparation of sensor systems. It includes papers on the use of chemical modified electrodes, interfaces for acoustic wave devices and micromachined chemical systems. Even in this section the emphasis is on illustrating sensor concepts rather than on solving particular problems.

Despite the diversity of topics, it is possible to make several generalizations about this book. Throughout, the quality of the science is high. There is a strong emphasis on preparing thin films of known structure and then characterizing the properties of these films. While many different types of films are described, self-assembled monolayers and Langmuir–Blodgett films are common to many of the papers in the first two sections. The most common characterization methods are electrochemistry and atomic force microscopy. Interestingly, the emphasis shifts to polymer films in the Chemical Sensor Design section, an indicator perhaps that polymer films remain the most practical for actual sensors at this point in time.

The emphasis throughout is on new materials and concepts.

***Medicinal Chemistry—Principles and Practice***, edited by F.D. King, The Royal Society of Chemistry, Cambridge, 1994, xxiv + 314 pp., £39.50, Softback. ISBN 0-85186-494-5.

As a member of a pharmaceutical department I was particularly interested in reviewing this book as many of the topics covered are of direct relevance to activities in the pharmaceutical industries. Indeed much of the content is provided by UK authors from Zeneca, SmithKline Beecham, Glaxo, Fisons, etc. and is directed at graduate chemists—primarily synthetic chemists who have just started their careers in industry. The book represents the lectures delivered at the 7th RSC Medicinal Chemistry School held in 1993 at the University of Kent, Canterbury, UK.

There are 19 chapters in the book and each one is written by a different author. There is no stated intention to group these chapters into sections but the editor has, I believe, arranged them in a logical order which takes the reader through some of the basic concepts and ends with several examples of case histories.

The first 6 chapters concentrate on biochemical aspects: drug-receptor interactions, signal transduction and second messengers, enzyme inhibitors, biological evaluation, pharmacokinetics, and drug metabolism. These subjects should have been previously covered by biochemists, pharmacologists and pharmacists but perhaps not by graduate chemists. Bibliographies and details of further reading related to these chapters also help the chemist come to grips with these topics.

Hopefully, the chemist will feel more at home with the next three chapters: physiochemical properties and drug design, quantitative structure-activity relationships, and use of computational chemistry techniques. Again, space permits only an overview of these subjects.

The next chapter on patent medicine is excellent and is complimented by the ingredient most welcomed by students young and old—humour. The following chapter on molecular biology, which gives a brief overview of gene cloning, is most appropriate to any modern text on medicinal chemistry.

Finding a starting point is the basis of the next three chapters which are entitled: devising a research strategy, past approaches to discovering new drugs, and bioisosteres, conformational restriction and pro-drugs. Chapters on specific case histories follow and conclude with a chapter on drug development. There are various appendices and a subject index.

***A spreadsheet workbook for quantitative chemical analysis***, By R. de Levie, McGraw-Hill, New York, 1992, approx. 170 pp., spiral bound. ISBN 0-07-016274-3.

This workbook begins with a brief introduction to the use of a spreadsheet, in this case Quattro Pro. In the rest of the book, instructions are given for entering chemical calculations into the spreadsheet; at first, in some detail, but later, just in outline, as the student is assumed to be become more familiar with the software. The topics covered include acid–base equilibria (simple and more complicated), acid–base titrations, logarithmic concentration diagrams for calculation of pH, complexation equilibria, extraction equilibria, precipitation equilibria, electrochemical equilibria, redox titrations, activity effects, curve-fitting, differentiation, integration, and finding roots.

Much of the treatment is rather detailed, and in the UK would probably be considered suitable for use in postgraduate rather than undergraduate courses, because it would be difficult to provide enough computer time for an undergraduate class to work through all the material. It will be a valuable resource for postgraduate students–I would have found it invaluable for my own Ph.D. work, in which I made use of the textbooks referred to by this author.

It is a problem of books that utilize computer packages that they very quickly become dated. This book is no exception, particularly because the past two years have seen *Windows* applications virtually take over the DOS ones. Students find the new *Windows* spreadsheets (such as *QP for Windows*) to be very much easier to use than their DOS predecessors, so Chapter 1 will soon be seen as out-of-date. However, since much of the rest of this book consists of chemistry and chemical equations, it should remain of value for use with other spreadsheet packages.

# Binding of cadmium to Laurentide fulvic acid. Justification of the functionalities assigned to the predominant acidic moieties in the fulvic acid molecule

Andrew S. Mathuthu [a], James H. Ephraim [b,*]

[a] *Department of Chemistry, University of Zimbabwe, P.O. Box MP 167, Mount Pleasant, Harare, Zimbabwe*
[b] *Department of Water and Environmental Studies, Linköping University, S-581 83, Linköping, Sweden*

Received 26 January 1995; revised 10 April 1995; accepted 11 April 1995

**Abstract**

The binding of cadmium to a fulvic acid (FA) extracted from peat was studied as a function of pH (4–8), ionic strength (0.01 and 0.10 M $NaNO_3$) and ratio of fulvic acid to metal ion concentrations (FA/Cd = 8, 4, and 2). An overall complex formation function of approximately $10^{3.14}$ was determined to enable comparison with previous studies. Additionally, literature values of complex formation constants were employed to describe the interaction between Cd(II) and the individual acidic sites. A good prediction of the experimental results is considered as a justification of the functionalities assigned to the predominant acidic sites in the fulvic acid molecule.

*Keywords:* Cadmium; Fulvic acid; Functionalities

## 1. Introduction

The importance of humic substances in terrestrial and aquatic environments is measured by the role they play in the mobility and distribution of metal ions and low-molecular weight organics. Even though many papers have been published on the binding of metal ions by humic substances, there is still a lack of complete understanding of the metal–humate equilibrium, primarily because of inadequate characterization of the humic substance molecule as a ligand. Earlier studies involving humic substances were carried out by agronomists and soil scientists, but recently the solution chemistry of these natural organic acids has aroused the interest of researchers from different disciplines [1–9]. The complicating factors influencing the solution chemistry of these natural organic acids have been hypothesized to be the functional group heterogeneity and the heterogeneity in the molecular size and shape leading to ionic strength effects [1,2,5–8]. Our earlier adaptation of the Gibbs–Donnan-based model to humic substances has prompted research into the identification of acidic functionalities in the fulvic acids, e.g. moieties with $pK_a \leqslant 3$ [9].

Despite the consensus among researchers that natural organic acids (humic substances) are heterogeneous with respect to both molecular weight and functional group, descriptions of metal interactions with these substances have failed to take such characteristics into consideration. Some recent metal–humate interaction papers have considered the functional group heterogeneity using the discrete ligand model and the continuous distribution model [2–8]. In an earlier paper [10], the dissociation properties of Laurentide fulvic acid have been described following the Gibbs–Donnan-based approach [1] and identifying the predominant

* Corresponding author.

*SSDI* 0039-9140(95)01627-9

acidic sites. Such a consideration draws criticism from various schools which believe that a continuous distribution approach must be employed. However, we are guided by the philosophy that in the formation of a stable compound, a limited number of vectors converge to form the product; thus, the overall properties may be described by considering the most predominant components of the material. In this paper, the binding of Cadmium by a well-characterized soil fulvic acid is described by employing the functional groups identified in an earlier acid–base analysis, and the stability constants reported in the literature for the complex formation between Cd(II) and the monomeric acid envisaged to resemble the functional group in the fulvic acid molecule. In order to facilitate a comparison of our results with earlier work, an overall complex formation function had additionally been computed for the Cd–fulvate systems studied.

## 2. Experimental

### 2.1. Chemicals and materials

Analytical grade chemicals, $Cd(NO_3)_2$, $HNO_3$, $NaNO_3$, were employed for the preparation of all reagents. The fulvic acid, extracted from peat, was obtained from the Department of Chemistry, Concordia University at Montreal, Canada [11]. Potentiometric titrations of the fulvic acid have been performed and the predominant sites responsible for the observed acidic behaviour have been proposed [12]. The analytical concentrates used to prepare NaOH, which was employed to obtain a range of pH values, and $NaNO_3$, which was used to alter bulk electrolyte concentrations, were purchased from J.T. Baker Chemicals.

### 2.2. Methods

Two approaches were used in the ion-selective electrode technique employed in the study. In the first approach, starting with an initial ratio of fulvic acid (FA) to metal ion, the proton and metal ion concentrations were determined after each addition of NaOH. The concentration of fulvic acid employed in the studies was fixed at 100 ppm ($7.6 \times 10^{-3}$ M), while a range of metal ion concentrations ($9.8 \times 10^{-5}$–$4.0 \times 10^{-4}$ M) was used. In the second approach, the initial degree of dissociation of the FA was fixed, and the ratio of metal to FA was changed by stepwise addition of metal ion. The equilibrium concentrations of both proton and metal ions were measured with the appropriate electrode at each addition of metal ion. Details of the experimental procedure are described elsewhere [13,14].

## 3. Heterogeneity considerations

A heterogeneous ligand like fulvic or humic acid could potentially bind metal ions both with and without the release of protons. The extent of proton release is a direct function of the $pK_a$ of the acid and the free energy of complex formation, $\Delta G$. The overall equilibrium may, however, be described by considering each acid site to be involved in a one-to-one complexation mode with the metal as follows:

$$S_i + M \rightleftharpoons S_iM \tag{1}$$

This representation implies that at equilibrium, each active site, $S_i$, reacts with the metal ion, M, to yield a complex, $S_iM$. All species are in equilibrium with each other, their relative concentrations determined by their respective free energy of formation, $\Delta G_{SiM}$. It is necessary to note that in such a consideration, site-to-site interactions have not been incorporated because there is no available method for their determination.

For a given initial concentration of metal ions, $M_T$, the fraction of metal bound, $\theta_M$, is given by

$$\theta_M = \frac{\sum M_{b_i}}{M_T} = \frac{\sum \beta_i A_i}{1 + \sum \beta_i A_i} \tag{2}$$

where $\beta_i$ is the complex formation constant (equivalent $l^{-1}$) for each site and $A_i$ is the concentration (equivalent $l^{-1}$) of the ionised form of each acid site. At each experimental pH, if the metal ion content is determined simultaneously, $\theta_M$, may be calculated and $A_i$ for the individual site may also be estimated via the application of the unified physicochemical approach [1,15], where four to five predominant acid sites are conceptualized. In the presence of metal ions, material balance considerations allow the following to be written for each site:

$$Ha_{i,T} = A_{i,f} + HA_i + A_{i,b} \tag{3}$$

Table 1
Site characterization of Laurentide fulvic acid and stability constants employed to predict Cd(II) binding to the envisaged sites (see Ref. [12])

| Site | $pK_a$ | Abundance | Functionality | Stability constant |
|---|---|---|---|---|
| I | 1.7 | 0.320 | -COOH | 25 |
| II | 3.0 | 0.210 | -COOH | 25 |
| III | 4.0 | 0.204 | -COOH | 25 |
| IV | 5.1 | 0.140 | -OH | $10^{3.83}$ |
| V | 6.5 | 0.126 | -OH | $10^{5}$ |

where $HA_{i,T}$ and $HA_i$ are the respective concentrations (equivalent $l^{-1}$) of the total titratable and the protonated form of the acid site at equilibrium, $A_{i,f}$ is the ionised form of the acid at equilibrium and $A_{i,b}$ is the bound form of the acid site. Rearrangement of Eq. (3) yields

$$A_{i,f} = \left( \frac{HA_{i,T}}{1 + \frac{H}{K_i} + \beta_i M_f} \right) \quad (4)$$

where $K_i$ is the dissociation constant of the acid site, $\beta_i$ is the complex formation constant for reaction in Eq. (1), $M_f$ is the free metal ion concentration and $H$ is the proton concentration. Incorporation of Eq. (4) into Eq. (2) yields Eq. (5), where $f_i$ is the fraction of the $i$th site and $HA_T$ is the total concentration of titratable acid in the system:

$$\left[ \frac{\theta_M}{(1-\theta_M)} \right] \frac{1}{HA_T} = \sum_{i=1}^{n} \left( \frac{\beta_i f_i}{1 + \frac{H}{K_i} + \beta_i M_f} \right) \quad (5)$$

Note that $HA_{i,T}$ and $HA_T$ are related as follows:

$$HA_{i,T} = f_i HA_T \quad (6)$$

The left-hand-side (LHS) of Eq. (5) is obtainable from experimental values and thus designated as experimental, while the right-hand-side (RHS) of the equation is obtained using literature values of $\beta_i$ [16] and $f_i$ obtained from fitting potentiometric titrations (see Table 1). The complexation constant for the interaction between Cu(II) and monomeric acids is directly related to the $pK_a$ of the acid [16,17]. The absence of such a linear relationship has motivated the use of a single complex formation constant of 25 for the interaction between Cd(II) and the -COOH moieties. The acid site IV is considered to mimic an enolic -OH which, via tautomerism, resembles an acetylacetone. The value of $10^{3.83}$ reported for $Cd^{2+}$–acetylacetone complexation constant has been employed. Acid site V has been envisaged to resemble a kojic acid arrangement, i.e. an -OH group in an ortho position to a carbonyl group. The complex formation constant of $10^{5.0}$ has thus been employed in this exercise.

## 4. Results

In the first experimental approach, where standard alkali was added to an initial ratio of fulvic acid to metal ion, the binding of Cd(II) by Laurentide fulvic acid, presented in Fig. 1, followed the pattern which may be summarized as follows. The fraction of metal ion bound generally:

(1) increased with an increase in pH for all FA/Cd(II) ratios;

(2) increased with a decrease in ionic strength for the same FA/Cd(II) ratio;

(3) increased with an increase in FA/Cd(II) ratio at the same ionic strength.

The increase in the fraction of metal bound with an increase in pH for all systems has been attributed to an increase in ionization of the fulvic acid molecule. Such an ionized species, $A^-$, is considered to be involved in binding with the $Cd^{2+}$ ion. It must be noted, however, that the fraction of Cd(II) bound in the pH range of 4–8 reaches a maximum of 0.7, as compared to the case of Cu(II) binding which reaches a maximum of 1 at pH values as low as 5 [17].

The increase in fraction of Cd(II) bound with a decrease in ionic strength for the same FA/Cd(II) ratio may be explained by the electrolyte screening effect being minimal at lower ionic strength and increasing with an increase in ionic strength. Such an increase in screening leads to the effect of low binding at higher ionic strength. In Fig. 1, using the same FA/Cd(II) ratio of 4, a decrease in ionic strength from 0.100 M $NaNO_3$ to 0.010 M yielded a

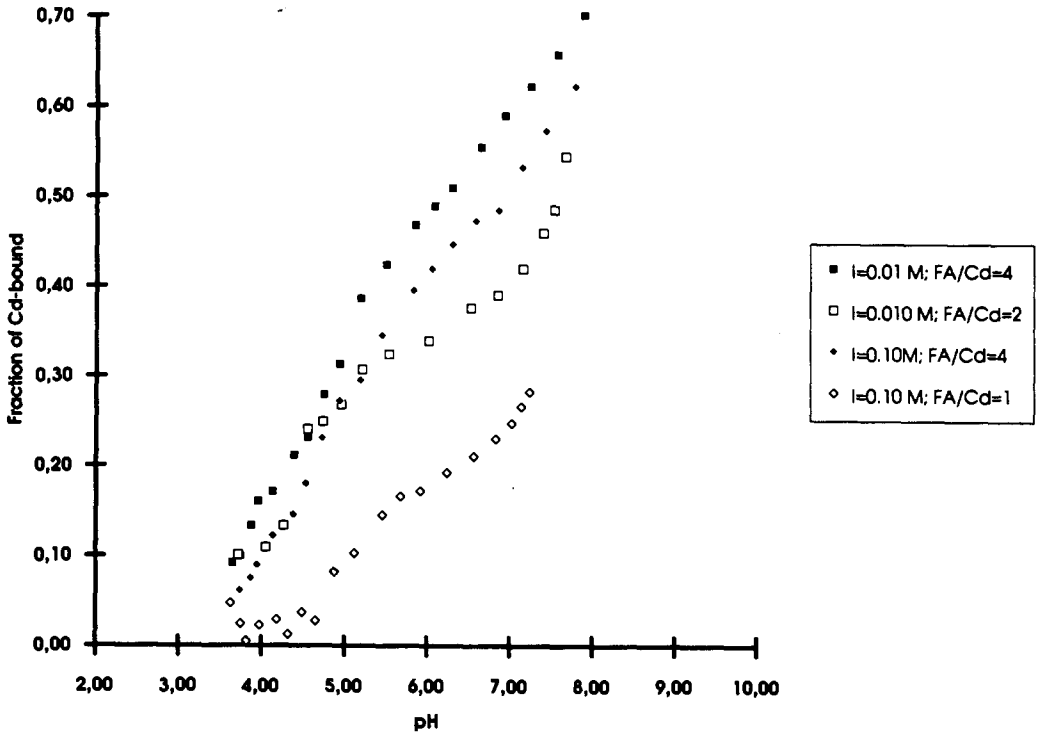

Fig. 1. The fraction of Cd(II) bound as a function of pH, ionic strength and the initial ratio of FA/Cd(II) for the system where aliquots of standard base were added to an initial fixed ratio of FA/Cd(II).

pH-insensitive increase of approximately 0.07 in the fraction of Cd(II).

The increase in the fraction of Cd(II) bound with an increase in FA/Cd(II) ratio is explicable by the argument that more ligands are available to effect more binding. However, a decrease in FA/Cd(II) ratio (especially with Cd(II) concentrations approaching that of fulvic acid) may induce considerable aggregation in the fulvic acid molecule [18]. That this may be the situation can be inferred from the characteristically different shape of the plots in Fig. 1 in cases where the amount of Cd(II) is increased. At an ionic strength of 0.01 M $NaNO_3$, an increase in the FA/Cd(II) ratio from 2 to 4 yielded a pH-dependent increase in the fraction of Cd(II) bound which ranged from 0.06 to 0.20 in the pH range of 4–7 (Fig. 1). At an ionic strength of 0.10 M $NaNO_3$, an increase in the FA/Cd(II) ratio from 1 to 4 yielded a similar pH-dependent increase in the fraction of Cd(II) bound, which ranged from 0.08 to 0.29 in the pH range of 4–7. The results of the second experimental approach (addition of metal ion to FA at a defined initial degree of ionization) showed similar effects of ionic strength and ratio of FA/Cd(II) on the binding pattern (Fig. 2). The fraction of metal bound decreased with an increase in the total amount of cadmium. For the same amount of cadmium added, the higher the pH, the higher the fraction of metal bound. The inverse relationship between ionic strength and the fraction of metal bound is additionally illustrated.

The results of Cd(II) binding to Laurentide fulvic acid obtained as a function of pH have been analyzed via the resolution of an overall complex formation function (Table 2) to allow comparison with previous results [19–24]. The overall complex formation function, $\beta_{ov}$, was estimated by the following equation:

$$\beta_{ov} = \frac{\sum M_b}{M_f \gamma_{M^{z+}} \sum A^-} \quad (7)$$

where $\Sigma M_b$ is the total amount of metal bound, $M_f$ is the free metal ion concentration, $\gamma_M$ is the activity coefficient of the metal ion, and $\Sigma A^-$ is the total amount of the ionized form of the fulvic acid. The activity coefficients yielded $\log \beta_{ov}$ values (3.3–3.2) essentially equivalent for the system at 0.01 and 0.10 M $NaNO_3$ bulk electrolyte concentrations. The only deviation was the lower value (2.69) obtained at an ionic strength of 0.10 M $NaNO_3$ when the Cd(II) concentration was slightly higher than the fulvic acid concentration. These values reported in Table 2 are significantly lower than earlier reported constants for

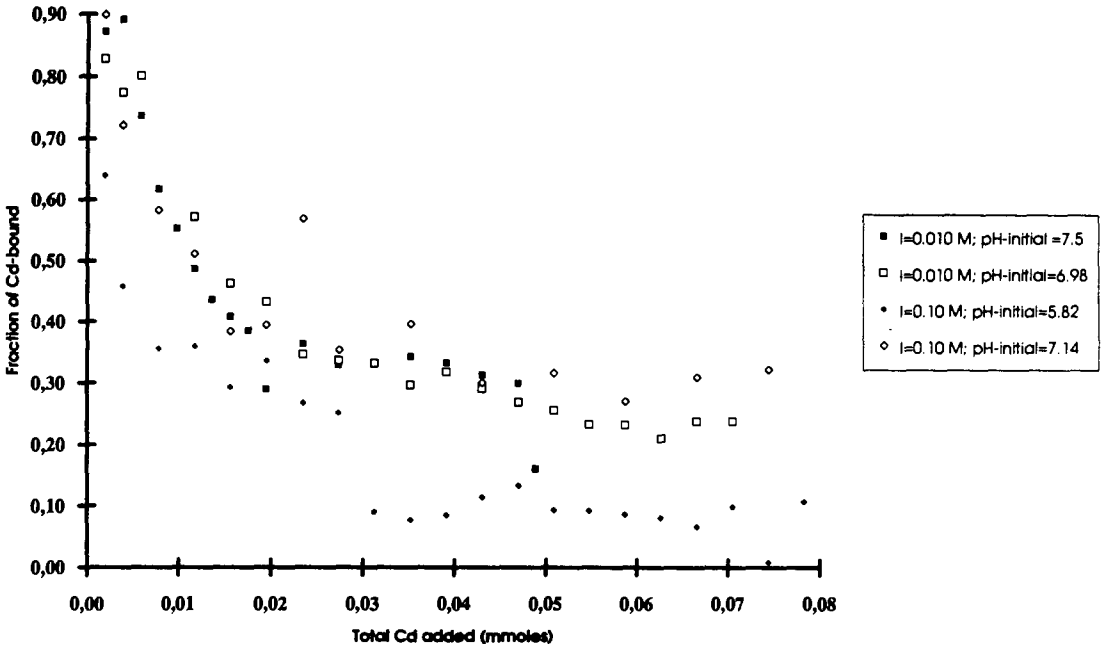

Fig. 2. The fraction of Cd(II) bound as a function of total Cd(II) added, pH and ionic strength for the system where Cd(II) was added to a fixed initial degree of neutralization (pH) of the fulvic acid.

Cd(II) binding [19,21], but are in good agreement with others [20,22].

### 4.1. Heterogeneity considerations

The use of stability constants to describe the complex formation between Cd(II) and the proposed functional group in the fulvic acid molecule (Table 1) has allowed a comparison of the RHS of Eq. (5) (model computed) to the LHS of the equation (experimental). The results of such an exercise are shown in Figs. 3 and 4. It should be noted that the object of the exercise has not been to fit the LHS with the RHS by adjusting parameters. Rather, it has been the goal to describe how best the experimental data are described using literature values of stability constants considered to mimic the interaction of Cd(II) with the acidic moieties postulated to be present in the fulvic acid molecule.

The results shown in Figs. 3 and 4 give testimony that the envisaged functionality given to the predominant acidic sites in the fulvic acid molecule is reasonable. In Fig. 3(a), the binding of cadmium to Laurentide FA in 0.010 M $NaNO_3$ at two different ratios of FA/Cd is reasonably predicted by the use of the literature values of complex formation constants. In Fig. 3(b), the model computed parameters appear larger than the experimental values for the Cd(II)–FA system at an ionic strength of 0.100 M $NaClO_4$. However, the pattern of the experimental values as a function of pH is closely followed by the model computed values. In Figs. 4(a) and 4(b), the results of the model computed comparison with the experiment for the system where Cd(II) was added to fulvic acid at a defined initial degree of neutralization are shown. At both ionic strengths and for all the different initial pH values, the model computed values (RHS of

Table 2
Resolved overall complex formation function for the interaction between Laurentide fulvic acid and cadmium

| No. | FA (mmol $ml^{-1}$) | Cd (mmol $ml^{-1}$) | $I(NaNO_3)$ | pH range | $\log \beta_{ov}(M^{-1})$ |
|---|---|---|---|---|---|
| 1 | $7.69 \times 10^{-4}$ | $1.96 \times 10^{-4}$ | 0.010 M | 3.6–7.9 | $3.28 \pm 0.30$ |
| 2 | $7.69 \times 10^{-4}$ | $3.92 \times 10^{-4}$ | 0.010 M | 3.7–7.7 | $3.24 \pm 0.20$ |
| 3 | $7.69 \times 10^{-4}$ | $1.96 \times 10^{-4}$ | 0.100 M | 3.7–7.8 | $3.36 \pm 0.33$ |
| 4 | $7.69 \times 10^{-4}$ | $7.83 \times 10^{-4}$ | 0.100 M | 3.6–7.2 | $2.69 \pm 0.50$ |

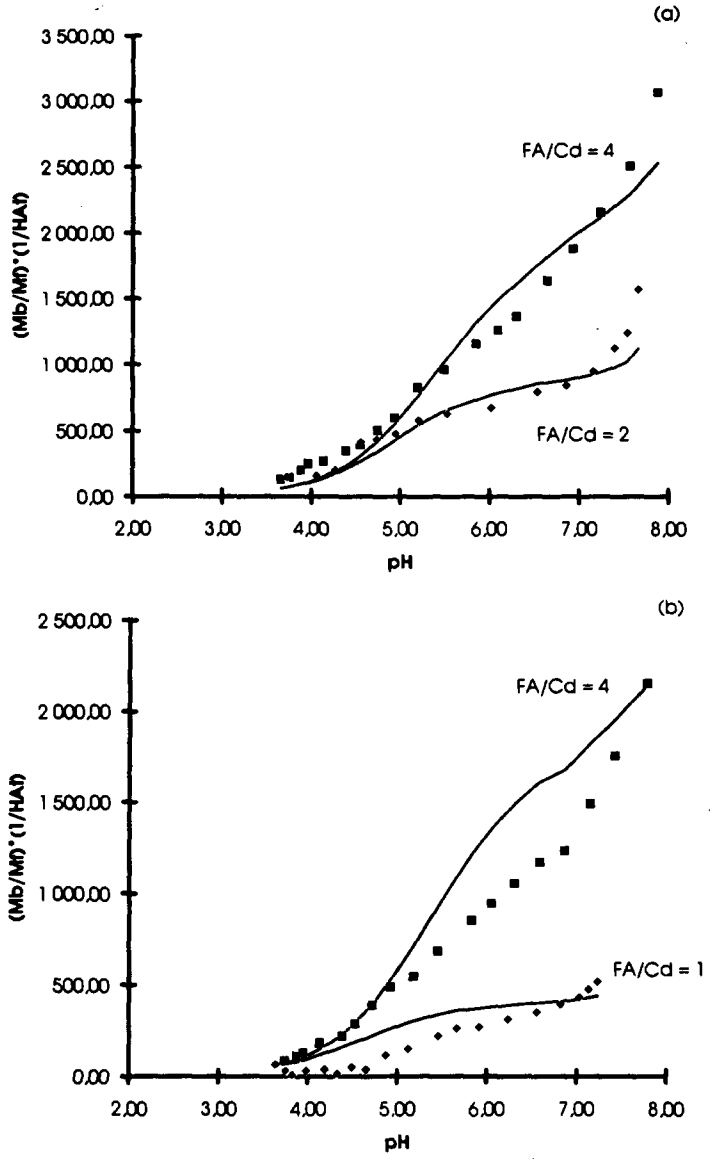

Fig. 3. Comparison of model predicted (RHS of Eq. 5) and experimental (LHS of Eq. 5) values for the Cd(II)–fulvate system where aliquots of base were added to an initial fixed ratio of FA/Cd(II). The model predicted values are designated by the continuous line. (a) $I = 0.010$ M $NaClO_4$; (b) $I = 0.100$ M $NaClO_4$. The ratios of FA/Cd(II) are the same as in Fig. 1.

Eq. 5) compare reasonably well with the experimental values (LHS of Eq. 5). It should be noted that it has not been the objective to fit the experimental values, otherwise the stability constants in Table 1 would have been changed until a perfect fit was obtained between the model computed and the experimental values.

## 5. Discussions and conclusions

The binding of Cd(II) to Laurentide fulvic acid has been described by considering the most predominant oxygen-containing functional groups postulated to be present in the fulvic acid molecule [10]. The description of metal–humate interactions by estimating the binding due to the most predominant functional groups existent in the humic substance molecule is considered to be a better treatment of the system than considering the humic substance as a "black-box" ligand with some average affinity. The complex formation constant reported for the binding of Cd(II) to the monomeric oxygen-containing functional group has thus been utilized to describe the

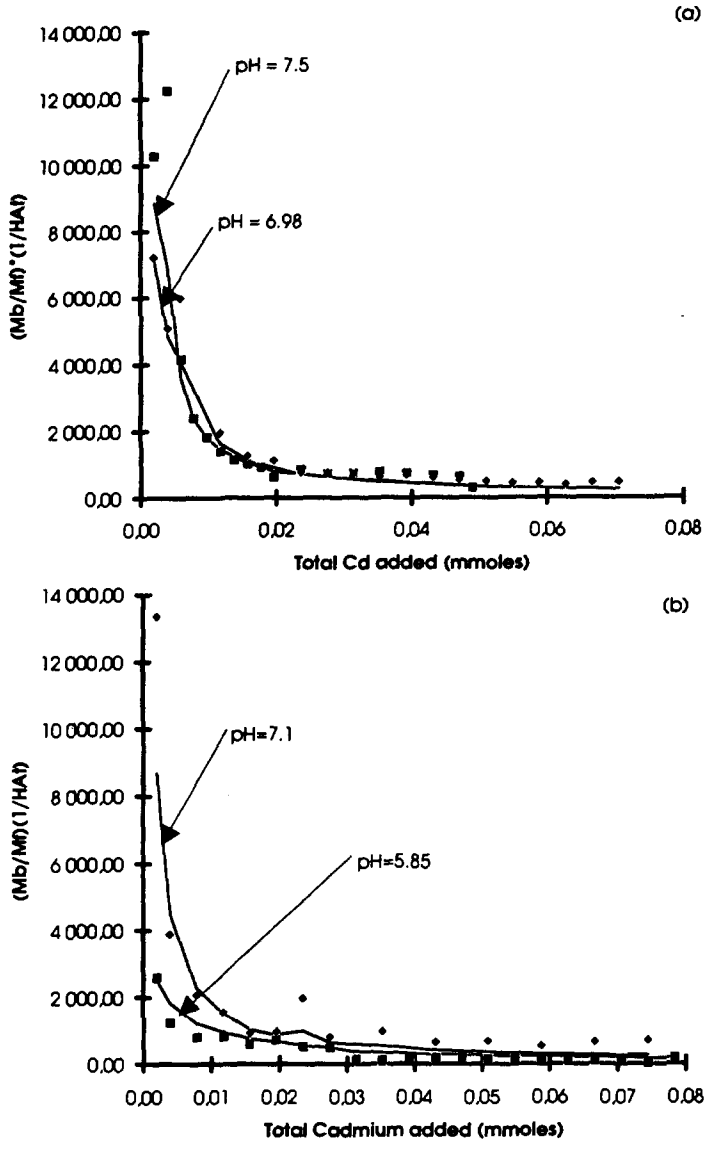

Fig. 4. Comparison of model predicted (RHS of Eq. 5) and experimental (LHS of Eq. 5) values for the Cd(II)–fulvate system where aliquots of standard Cd(II) were added to a fulvic acid solution at an initial fixed pH. The model predicted parameter is designated by the continuous line. (a) $I = 0.010$ M $NaClO_4$; (b) $I = 0.100$ M $NaClO_4$. The initial pH values are the same as in Fig. 2.

experimentally observed complexation. The good prediction of the experiment by the model is considered to justify the hypothesized functionality in the fulvic acid molecule. The novelty of the approach is the possibility it provides for the design of experimental techniques towards the identification of the total functional group heterogeneity in the humic substances [9,25]. It should be noted that the approach does not rely on the luxury of just fitting experimental data, but rather places emphasis on chemical-based verification of the proposed functional group. With this philosophy, it may be stated that the proposed functional groups in the Laurentide fulvic acid are reasonable (Figs. 3 and 4).

# Magnetic field effects-polarization-resonant synchronous fluorescence spectrometry for simultaneous analysis of polynuclear aromatic hydrocarbons in mixtures

Yong Zhang [a,*], Yaxian Zhu [b], XiongZhi Xue [a], Xianzhi Huang [b]

[a] *Environmental Sciences Research Center, Xiamen University, Xiamen, 361005, People's Republic of China*
[b] *Department of Chemistry, Xiamen University, Xiamen, 361005, People's Republic of China*

Received 27 December 1994; revised 24 April 1995; accepted 26 April 1995

**Abstract**

The level and undulation of scattered light can be effectively suppressed by magnetic field effects-polarization-resonant synchronous fluorescence spectrometry. The established technique was used for simultaneous determination of a sample mixture containing fluorene, acenaphthene, anthracene, benzo-[a]-pyrene (B-[a]-P) and perylene. The detection limits were 0.23, 7.90, 0.13, 1.10, 0.0083 ng $ml^{-1}$ for fluorene, acenaphthene, anthracene, B-[a]-P and perylene, respectively. The relative standard deviations were less than 5%.

## 1. Introduction

Polynuclear aromatic hydrocarbons (PAHs) are widespread in the atmosphere, water, the earth, plants, as well as animals and their products. Because this class of compounds contributes to carcinogenicity [1], chemists and environmental researchers have been searching for effective techniques to control and monitor them. PAHs have been extensively studied by luminescence spectrometry. Synchronous fluorescence spectrometry (SFS), introduced by Lloyd [2], has been applied to the multicomponent analysis of PAHs [3–5]. Constant-energy synchronous fluorescence spectrometry (CESFS) was first described by Inman and Winefordner [6,7], and has also been applied to PAH analysis [8–11].

Derivative fluorescence spectrometry was first reported by Green and O'Haver and has since been developed [12–14]. However, the application of this technique to constant-wavelength synchronous fluorescence spectrometry (CWSFS) was still in its developing stage [15–20]. As a successful example, derivative techniques have been combined with CWSFS to analyze PAH mixtures by Vo-Dinh [21] and Romanovskaya and Chibisov [22]. A combination of the derivative technique and CESFS for the further elimination of Raman scattering interference was suggested [23], and was used to analyze multicomponent mixtures by Li et al. [24,25]. This combination technique was adopted by variable-angle synchronous fluorescence spectrometry and applied to binary mixture analysis [26].

Successful research projects in CWSFS have used an organized medium (such as micellar solution) for multicomponent analysis of PAHs [27–31]. However, the established methods were used for simultaneous analysis of not more than four components, and focussed only on the sensitivity. It has been reported that every component would give a very narrow peak for resonant synchronous fluorescence spectra (RSFS) in supersonic jet resonant synchronous fluorometry. This implies that a good selectivity would be achieved with $\Delta\lambda = 0$ [32]; however, this sensitivity would be greatly decreased by the scattered light interference.

In this study, fluorene, acenaphthaene, anthracene, benzo-[a]-pyrene (B-[a]-P) and perylene were selected as model compounds for the evaluation of the recently established technique magnetic field effects-polarization-resonant synchronous fluorescence spectrometry (MFEPRSFS); the proposed technique can be conveniently used to effectively suppress the scattered light interference, while simultaneously analyzing the model compounds.

## 2. Experimental

### 2.1. Reagents

Fluorene, acenaphthene, anthracene, B-[a]-P and perylene were products of Aldrich. Stock standard solutions were prepared by dissolving them in distilled ethanol.

### 2.2. Apparatus

All spectra were obtained on a Hitachi 650-10S spectrofluorometer equipped with a polarization device, and including a home-made cell holder and a 1 cm quartz cell; a $CT_7$ Teslarmeter was purchased from The Fourth Electrometer Factory of Shanghai. The magnetic field was generated by two sets of magnets. The experimental devices are shown in Fig. 1. Fig. 1(a) shows the device for normal fluorescence determination; Fig. 1(b) shows the device combining polarization and normal fluorescence (the excitation polarizer and emission polarizer were oriented vertically); Fig. 1(c) illustrates the magnetic field applied with the device in Fig. 1(b), the magnetic field strength on the light path being about 70 mT.

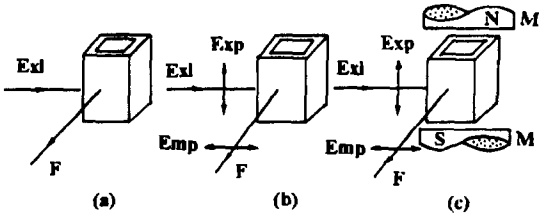

Fig. 1. Schematic diagram of the sample cell setup used for: (a) general fluorometry; (b) polarization fluorometry; (c) MFEs-polarization fluorometry. Exl, Exp, Emp, F and M are abbreviations for excitation light, excitation polarizer, emission polarizer, fluorescence and magnets, respectively.

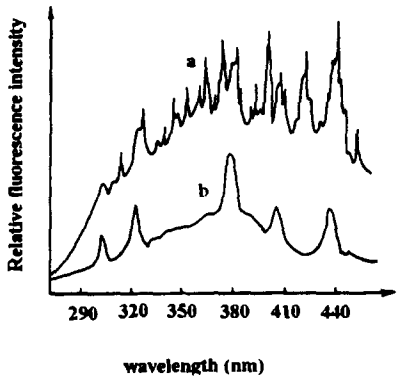

Fig. 2. (a) Resonant synchronous fluorescence spectra of the mixture solution; (b) MFEs-polarization-resonant synchronous fluorescence spectra of the mixture solution. The concentrations of fluorene, acenaphthene, anthracene, B-[a]-P and perylene were 10.0, 100.0, 10.0, 10.0 and 1.0 ng $ml^{-1}$, respectively.

### 2.3. Procedures

The prepared mixtures of fluorene, acenaphthene, anthracene, B-[a]-P and perylene were transferred into the 1 cm quartz cell. The cell was covered and then inserted into the cell holder. Both the excitation and emission slits were set at 5 nm. The "sensitivity" switch was set at a suitable position. The interval between emission wavelength and excitation wavelength was kept at zero ($\Delta\lambda = 0$). After applying external magnetic field effects (MFEs) to the sample cell for 10 min, resonant synchronous scanning within the spectral region of interest was carried out while the excitation polarizer and emission polarizer were vertically orientated, and MFEs were presented. The MFEPRSFS spectra of the PAHs being tested were recorded as illustrated in Fig. 2(b).

Ten mixed samples, as listed in Table 1, were prepared for the calibration measurements. In order to keep the light intensity of MFEPRSFS and RSFS at about the same level, all the MFEPRSFS spectra were obtained with an instrumental sensitivity set at a higher scale than that for RSFS. For MFEPRSFS spectra, the analytes were quantified by peak height after correcting for the background.

## 3. Results and discussions

### 3.1. RSFS and MFEPRSFS of fluorene, acenaphthene, anthracene, B-[a]-P and perylene

The standard solutions of fluorene, acenaphthene, anthracene, B-[a]-P and perylene in

| 9 | 18.0 | 180.0 | 18.0 | 13.5 | 1.35 |
| 10 | 20.0 | 200.0 | 20.0 | 15.0 | 1.50 |

ethanol were analyzed and their RSFS recorded. The results demonstrate that RSFS fluorescence peaks for the five components were located at 305, 325, 380, 407 and 438 nm, respectively, whether the MFEs were applied or not.

In the previous study, it was found that the undulation of scattered light interference caused by solvent ethanol in resonant synchronous spectrofluorometry could be suppressed by MFEs [33]. It was also reported by our research group recently that the total level of scattered light could be restricted by the polarization technique [34]. In this study, a combination of the above two techniques with RSFS was used to improve the detection limits of the PAHs being tested.

In the proposed MFEPRSFS technique, the magnetized time for suppressing the undulation of scattered light interference should be optimized. Magnetized times from 0 to 15 min were investigated; it was found that for most of the test pure hydrophilic solvents, 5 min was sufficient when the magnetic field strength was about 70 mT [33]. The magnetized time selected in this study was 10 min.

A polarizer was placed in each of the excitation and the emission light paths. The observing polarizer was orientated perpendicular to the direction of the excitation polarizer. Polarized light was produced when the exciting light passed through the excitation polarizer. The sample molecules were excited by polarized light to produce a weakly polarized fluorescence signal. In contrast, the scattered light was totally depolarized. When all emissions reached the emission polarizer, only the fluorescence signal and a small portion of scattered light with the same orientation as that of the fluorescence were allowed to pass through the emission polarizer and reach the detector. The total level of scattered light interference could thus be suppressed by 95–98%.

It is well known that taking advantage of band-narrowing effects can improve the selectivity in synchronous spectrofluorometry for analyzing PAHs [35,36]. However, if the selected $\Delta\lambda$ value is not large enough, the scattered light interference can be serious. It is difficult to obtain high sensitivity and good selectivity at the same time with CWSFS alone. Excellent sensitivity and selectivity can be achieved with the proposed MFEPRSFS technique which combines polarization, MFEs, and CWSFS. The total level and undulation of scattered light interference was effectively restricted owing to the utilization of the polarization, MFEs with CWSFS together.

Fig. 2 shows the RSFS and MFEPRSFS spectra for the mixture of fluorene, acenaphthene, anthracene, B-[a]-P and perylene. Curve (a) is the normal RSFS spectra. It was difficult to distinguish the fluorescence signal from the noise in curve (a). Curve (b) was obtained with the proposed MFEPRSFS technique. The scattered light interference caused by the solvent was eliminated, resulting in an effectively reduced fluorescence background and a greatly enhanced signal-to-noise ratio. Each fluorescence signal of the five components appeared to be smooth and clear. The detection limits for fluorene, acenaphthene, anthracene, B-[a]-P and perylene were improved. The reported results for fluorene, acenaphthene, anthracene and perylene in Ref. [34] were 1.1, 10.0, 1.8 and 0.26 ng ml$^{-1}$ respectively, with the polarization technique only. The experimental results obtained by MFEPRSFS were 0.23, 7.9, 0.13 and

Table 2
Data of analytical merit

| PAH | Calibration [a] $I = aC + b$ | $r$ | Blank signal [b] | | Detection limit (ng ml$^{-1}$) | RSD (%) [c] ($n = 11$) |
|---|---|---|---|---|---|---|
| | | | Mean | SD | | |
| Fluorene | $I = 1.32C$-0.15 | 0.995 | 0.1 | 0.10 | 0.23 | 4.5 |
| Acenaphthene | $I = 0.14C$-0.90 | 0.998 | 0.3 | 0.37 | 7.90 | 4.9 |

| Perylene | $I = 39.73C$-1.61 | 0.997 | 0.2 | 0.12 | 0.0083 | 4.7 |

[a] $I$ = relative fluorescence intensity; $C$ = concentration in ng ml$^{-1}$; $a$ and $b$ are constants.
[b] The instrument sensitivity scale was set at the same as that in the blank measurement. SD represents the standard deviation blank measurement.
[c] Relative standard deviation for the mixtures containing 10.0 ng ml$^{-1}$ fluorene, 80.0 ng ml$^{-1}$ acenaphthene, 10.0 ng ml$^{-1}$ anthracene, 10.0 ng ml$^{-1}$ B-[a]-P and 0.5 ng ml$^{-1}$ perylene.

Table 3
Results of recovery experiments

| PAH | Known (ng ml$^{-1}$) | Added (ng ml$^{-1}$) | | Found (ng ml$^{-1}$) | | Recovery (%) | |
|---|---|---|---|---|---|---|---|
| | | A | B | A | B | A | B |
| Fluorene | 7.9 | 5.0 | 10.0 | 12.6 | 18.0 | 97.9 | 100.6 |
| Acenaphthene | 82.2 | 50.0 | 100.0 | 129.3 | 176.5 | 97.9 | 86.8 |
| Anthracene | 10.1 | 5.0 | 10.0 | 15.1 | 20.7 | 100.0 | 103.1 |
| B-[a]-P | 9.0 | 3.0 | 6.0 | 12.2 | 14.9 | 101.4 | 99.3 |
| Perylene | 0.50 | 0.30 | 0.50 | 0.76 | 1.0 | 95.2 | 101.0 |

0.0083 ng ml$^{-1}$, respectively. For perylene, the detection limit was about 30 times lower than that reported in Ref. [34]. In this work, however, the detection limit of B-[a]-P was somewhat higher than that reported in Ref. [31]. This was due to $\Delta\lambda = 0$ selected in MFEPRSFS scanning; the obtained synchronous fluorescence intensity corresponded only to the 0–0 band transition. The 0–0 band transition for B-[a]-P, however, is not the strongest transition band. Therefore, with $\Delta\lambda = 0$, the selectivity was enhanced but the sensitivity was reduced. In Ref. [31], the $\Delta\lambda$ value selected by the author was 42 nm. This value was nearly equal to the difference between the maximum emission and the maximum excitation of B-[a]-P in conventional fluorescence spectra. Under that condition, the sensitivity was higher but the selectivity was rather poor.

### 3.2. Data of analytical merit

With MFEPRSFS, one fluorescence peak corresponded to one component in the mixture and the peak height was measured for quantitative analysis. The analytical data are summarized in Table 2. Comparing the results listed in Table 2 with those in Ref. [34], the detection limit of each component was improved to a different degree based on the spectral properties of the different compounds and the instrumental parameters.

### 3.3. Recovery experiment

Standard solutions of the five test PAHs were mixed to prepare the mixture sample. The recovery experiment was carried out and the results are listed in Table 3.

The study demonstrated that the proposed technique has the advantages of being simple, easy, selective, sensitive and almost free of interference from the scattered light. The proposed technique can be used for simultaneous PAH analysis and other multicomponent analysis.

# Evaluation of a magnetically coupled microcavity hollow cathode discharge for atomic emission spectroscopy

A.R. Raghani, M.A. Bolshov[1], B.W. Smith, J.D. Winefordner*

*Department of Chemistry, University of Florida, Gainesville, Florida 32611, USA*

Received 27 March 1995; revised 28 April 1995; accepted 29 April 1995

**Abstract**

A magnetically coupled microcavity hollow cathode discharge device was evaluated for its analytical potential as a boosted atomic emission source. A magnetic field using an electromagnet was applied perpendicular to the axis of the microcavity hollow cathode. The intensity of the atomic emission of copper, aluminum and the ionic emission of magnesium increased with increasing magnetic field until it reached a maximum. A further increase in the field strength did not lead to an enhancement of these emissions. The attainment of the maxima was attributed to the increase in the electron temperature and radial diffusion of the electrons from the center of the microcavity axis. Electron temperatures in the presence of the magnetic field calculated based on the semicorona model were shown to be proportional to the square of the reduced field strength. Further, these maxima were correlated to the energies of the upper levels of the transition studied.

*Keywords*: Atomic emission spectroscopy; Electron temperature; Magnetic field effects; Microcavity hollow cathode

## 1. Introduction

Hollow cathode discharge devices (HCDs) have been employed for many years as a source in atomic absorption, fluorescence and emission spectroscopy. In atomic emission spectroscopy, they have found applications where a solid sample is used as a cathode or a liquid sample is deposited on the cathode and its residue is analyzed. However, the output of the emission intensity is lower than in most of the other atomic emission techniques. There are various ways by which enhancement of the emission intensity is possible, including the application of external fields such as microwaves [1,2], radiofrequency [3,4] magnetic field [5,6] or by pulsing the discharge [7] or using an auxiliary discharge [8]. Another mode of boosting the emission intensity is by modifying the geometry of the hollow cathode. Examples of this include the conical-bottom hollow cathode [9] or the microcavity hollow cathode [10]. Microcavity hollow cathodes typically have a diameter less than 2 mm and a depth less than 10 mm.

Microcavity hollow cathodes have been applied in the trace analysis of subnanoliter volume liquid samples for the determination of elements of physiological importance [11,12]. Recently, in our laboratory we have successfully demonstrated the analytical potential of a microcavity HCD for the analysis of microliter volumes of liquid samples by constructing a

miniature quartz glow discharge chamber with a volume less than 100 ml [13]. Excellent detection limits for lead and copper ( 210 fg and 10 pg, respectively) were obtained.

There have been numerous reports on the study of the influence of a magnetic field on the HCD using conventional-diameter hollow cathodes. Rudnevsky and Maksimov [14] arranged the magnetic field parallel and perpendicular to the cathode axis and obtained an about an order of magnitude improvement in the detection limit. In order to further improve upon the sensitivity of this device, we have investigated the influence of a magnetic field on the microcavity hollow cathode discharge, which is the basis of this report.

## 2. Experimental

The experimental set-up for atomic emission is given in detail elsewhere [13]. The set-up was modified for this study and only a brief account is presented here. Microcavity hollow cathodes 1.5 mm in diameter and 6 mm in depth were machined from high purity metals. For the magnesium studies, NIST standard reference material 124b was used, which contains 4.54% magnesium in aluminum alloy. The cathodes were then secured using epoxy adhesive in a quartz inner tapered joint. A glow discharge chamber was made from a quartz outer tapered joint with an optical quality window fused at one end of the joint. A stainless steel anode wire, 2 mm in diameter, was sealed inside this chamber. The outer tapered joint contained an inlet and an outlet for the flow of the fill gas and a vacuum connection. The inner joint with the electrode and the outer joint formed a demountable assembly which held the tight vacuum necessary for low pressure discharges. Argon gas was used as the fill gas and its pressure inside the chamber was maintained at 1 Torr. An electromagnet (Anac, model 3470) was used for the application of the magnetic field and the field strength was varied by changing the coil current of the magnet. Magnetic field measurements were carried out using a gaussmeter probe (Bell, Inc., model 640). The microcavity HCD was placed between the two poles of the magnet, and the field was applied perpendicular to the axis of the microcavity (see Fig. 1). The poles were brought as close as possible to the chamber in order to obtain maximum interaction of the magnetic field with the discharge.

The emission from the microcavity was focused on the entrance slit (slit width, 10 $\mu$m; slit height, 4 mm) of a 1 m focal length grating spectrometer (reciprocal linear dispersion of 0.02 nm $mm^{-1}$) equipped with a photodiode-array detector with a spectral range of 20 nm. The diode-array pixel height was 3 mm. Therefore each observed spectral line intensity repre-

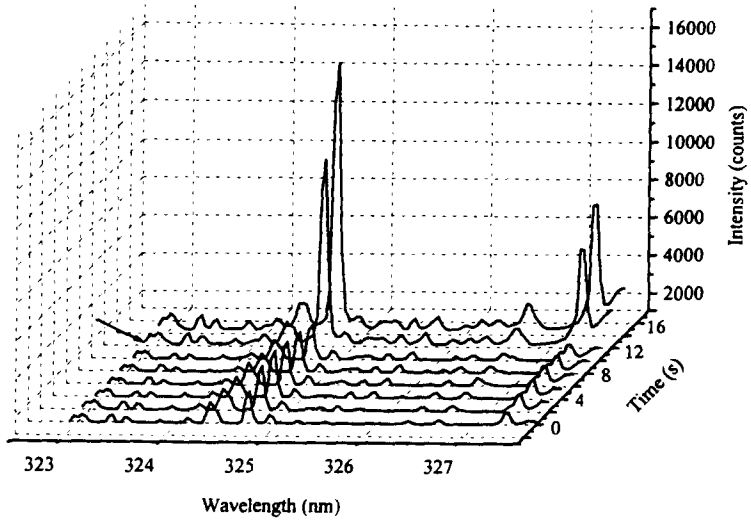

Fig. 2. Temporally resolved emission spectra of a solution containing 100 ng of copper residue in the aluminum microcavity hollow cathode (arrow indicates the point at which the magnetic field was turned on).

sents an average intensity over a thin vertical slice of the discharge. The horizontal spatial resolution is about 50 $\mu$m which was chosen as the measurement increment. Data were acquired with a personal computer and data acquisition software (OSMA I-120, Princeton Instruments, Inc., Trenton, NJ, USA).

Radial profiles of the atomic emission from the microcavity were obtained by moving the lens at 50 $\mu$m increments across the diameter of the microcavity using an $x$–$y$ translator and focusing the image on the slit of the monochromator.

## 3. Results and discussion

Application of the magnetic field resulted in a very intense positive column and the negative glow was seen to further penetrate inside the microcavity. The emission from the inside of the microcavity was brighter in the presence of the magnetic field. Fig. 2 shows the temporally resolved emission spectra of a solution containing 100 ng of copper deposited in an aluminum microcavity. The discharge current was 38 mA at an argon pressure of 1 Torr. Since we used a photodiode- array detector with a 20 nm spectral window, we could simultaneously observe the two resonance lines of copper at 324.75 and 327.40 nm. At the beginning of the discharge (0 s in Fig. 2), no magnetic field was applied, and the line at 324.75 nm had a good signal-to-background (S/B) ratio whereas the line at 327.40 nm had a poor S/B ratio. As soon as the field was turned on (as shown by the arrow in Fig. 2), the intensity of the line at 324.75 nm increased by up to four times and the emission line at 327.40 nm began to appear well above the background. Similar results were reported by Rudnevsky and Maksimov [14] for the magnetically boosted HCD of conventional dimensions. The precision of our measurements was, however, about 30% for solution analysis. In order to optimize experimental conditions such as magnetic field strength, current and pressure, we studied the effect of the magnetic field on solid samples before further evaluation of solution sample residues.

Fig. 3 shows the enhancement of the atomic emission of copper from the copper microcavity for the two lines at 324.75 and 327.40 nm with increasing magnetic field strength. The emission intensity increased by a factor of about two up to a magnetic field of 2500 G, and further increase in the magnetic field resulted in a decrease in the emission intensity. The background emission was unaffected by the magnetic field. The precision (percentage relative standard deviation) for these measurements was less than 2%. A possible mechanism involved the negative glow inside the microcavity being pushed towards the inside walls of the microcavity as the magnetic field is increased further, as reported by Pavlovic and Dobrosavljevic [15]. As a consequence, there would be a reduction in the intensity at the center of the microcavity at higher field strengths. However, this possibility was ruled out by measuring the radial profiles of the

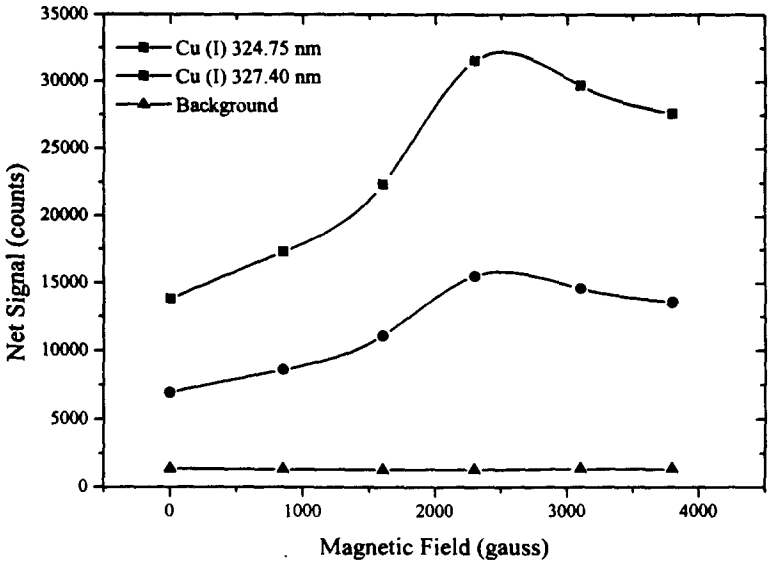

Fig. 3. Effect of magnetic field on copper emission at 324.75 and 324.40 nm from a copper microcavity hollow cathode.

copper microcavity emission at 324.75 nm at different field strengths. The results are shown in Fig. 4. The intensity of the emission is maximum at the center of the microcavity at all magnetic field values, indicating that there is no localization of the negative glow near the inside walls of the microcavity. Atomic emission from an aluminum microcavity hollow cathode was also observed under identical discharge conditions to those used for the copper emission study; the results are shown in Fig. 5. Once again, as with the copper emission, there was an increase and then a decrease in the atomic emission intensity of the aluminum lines at 394.15 and 396.40 nm as the magnetic field was increased. The background was again constant over the range of magnetic field strengths. A similar study was conducted for magnesium ion lines by observing the emission from the microcavity hollow cathode made from an NIST sample of aluminum containing 4.54% magnesium. The results for magnesium ion emission for the lines at 279.55 and 280.27 nm, shown in Fig. 6, exhibit the same trends as for copper and aluminum. Somersan and Popovici [16] studied the effect of a magnetic field on the atomic emission of lead at 405.78 nm using different fill gases; the emission intensities did not change much after reaching a maximum. However, no theoretical explanation was given. Rudnevsky et al. [17] have studied residues of the alkali metals deposited in an HCD in a magnetic field; they also observed a similar pattern. A reduction in the molecular emission background of CN was observed with increasing magnetic field strength. However, in our case, the background was fairly constant near the emission lines of all the three elements.

Hollow cathode discharges are known to show self-absorption, and the decrease in the emission intensity for the analytes studied here may be due to an increased sputtering rate with increasing magnetic field. However, on studying the effect of magnetic field strength on argon ion emission at 404.29 nm (see Fig. 7), a steady decrease in the emission intensity with magnetic field strength was observed. This implies that there is no increase in the ionization of the argon gas with increasing magnetic field. In other words, it is possible that there is no increase in the sputtering rates with increasing magnetic field strengths at an argon pressure of 1 Torr.

Sen et al. [18] observed the variation of the spectral emission intensities of helium, hydrogen and mercury as fill gases in glow discharges as a function of magnetic field strength, and they reported similar variations in emission with increasing magnetic field for the atomic lines of the fill gases used. The attainment in the emission maxima was attributed to two discharge-related factors that are simultaneously influenced by the applied magnetic field; these factors are electron temperature and the electron number density along the axis of the discharge [18]. It was assumed in their studies that the excitation mechanism was mostly by electron impact [19]. The electron

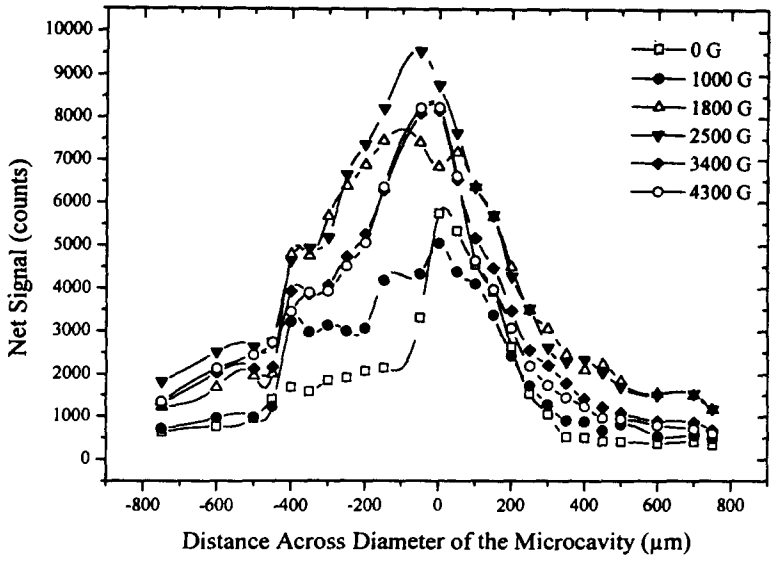

Fig. 4. Radial profiles of atomic emission from a copper microcavity at different magnetic field strengths.

temperature increases with magnetic field, whereas there is a radial diffusion of electrons from the axis of the discharge with increasing magnetic field. In order to confirm that a similar argument can be used to justify the trend observed in our case for the sputtered materials, the following mechanism is speculated.

The electron temperature in a magnetic field, $T_{eB}$, is related to the electron temperature without a magnetic field, $T_e$ as follows [18]

$$T_{eB} = T_e\left(1 + C_1\frac{B^2}{P^2}\right)^{1/2} \quad (1)$$

where $B$ is the magnetic field strength (G), $P$ is the pressure (Torr) and $C_1$ is a constant (Torr$^2$ G$^{-2}$) dependent on the fill gas which is given by

$$C_1 = \left(\frac{eL}{mv_r}\right)^2 \quad (2)$$

where $e$ is the electronic charge (C), $L$ is the electron mean free path (m) at a pressure of 1 Torr, and $v_r$ is the random velocity of the electron (m s$^{-1}$).

The electron number density, $n_{eB}$ (cm$^{-3}$) along the axis of the microcavity HCD in the presence of the magnetic field is given as [20]

$$n_{eB} = n_e\exp\left(-\frac{eEC_1^{1/2}rB}{2kT_eP}\right) \quad (3)$$

where $n_e$ is the electron density (cm$^{-3}$) in the absence of a magnetic field and $E$ is the axial electric field per centimeter (V cm$^{-1}$). This equation implies that there is a reduction in the electron number density at a distance $r$ from the axis due to the presence of the magnetic field.

The intensity of the emission arising from a transition $j \rightarrow i$, for an optically thin semicorona plasma, in the absence of magnetic field, is given by [20]

$$I_{ji} = n_e n_a\left(\frac{hlv_{ji}}{4\pi}\right)\chi_{gj}\left(\frac{A_{ji}}{\sum_{m<j} A_{jm}}\right)\exp\left(-\frac{U_j}{kT_e}\right) \quad (4)$$

where $h$ is Planck's constant (J s), $l$ is the path length (cm), $n_a$ is the number density of the analyte atoms or ions in the ground state (cm$^{-3}$), $A_{ji}$ is the Einstein coefficient of transition probability (s$^{-1}$), $\Sigma_{m<j} A_{jm}$ is the summation of all the transition probabilities between the upper and the lower levels, $\chi_{gj}$ is the collisional excitation rate coefficient from the ground state $g$ to the excited state $j$ (cm$^{-3}$ s$^{-1}$), $U_j$ is the energy of the upper level (eV), and $v_{ji}$ is the frequency of the emitted radiation (s$^{-1}$).

In the presence of a magnetic field, $I_{ij}$ is given by [20]

$$(I_{ji})_B = n_e n_a\left(\frac{hlv_{ji}}{4\pi}\right)\chi_{gi} \times \exp\left(-\frac{eEC_1^{1/2}rB}{2kT_eP}\right)\left(\frac{A_{ji}}{\sum_{m<j} A_{jm}}\right)_B \times \exp\left(-\frac{U_j}{kT_{eB}}\right) \quad (5)$$

Taking the ratio of Eqs. (4) and (5) and substitution for $T_{eB}$ from Eq. (1) and maximizing the result with respect to $B$ gives

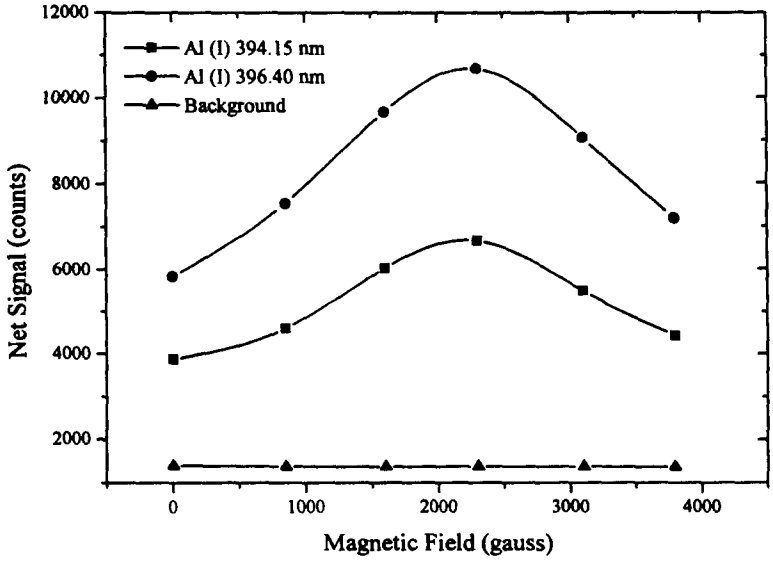

Fig. 5. Effect of magnetic field on aluminum emission at 394.15 and 396.40 nm from an aluminum microcavity hollow cathode.

$$e^2E^2r^2 = 4C_1B_{max}^2U_j^2\left[P^2\left(1 + C_1\frac{B_{max}^2}{P^2}\right)^{-1}\right] \quad (6)$$

For a particular gas, we deduce that $B_{max}U_j(1 + C_1B_{max}^2/P^2)^{-1/2}$ is almost a constant. There is some degree of uncertainty involved in the theoretical calculation of the value for $B_{max}$ using Eq. (6) since the values of $E$ and $r$ are not precisely known. Therefore, it will suffice to prove that for a given set of emission lines for a particular element

$$B_{max}U_j(1 + C_1B_{max}^2/P^2)^{-1/2} = C_2 \quad (7)$$

where $C_2$ is a constant. In order to calculate $C_1$ from Eq. (2), one has to know the collision cross-section of electrons and fill gas atoms to calculate the mean free path. Since the collision cross-section depends on the energy of the electron and that of the gas atoms, its precise determination is difficult. Sadhya and Sen [20] proposed a method for calculating the value of $C_1$ from Eq. (1 by plotting the electron temperature in a magnetic field at various field strengths, the slope of which gives $C_1$. Further-

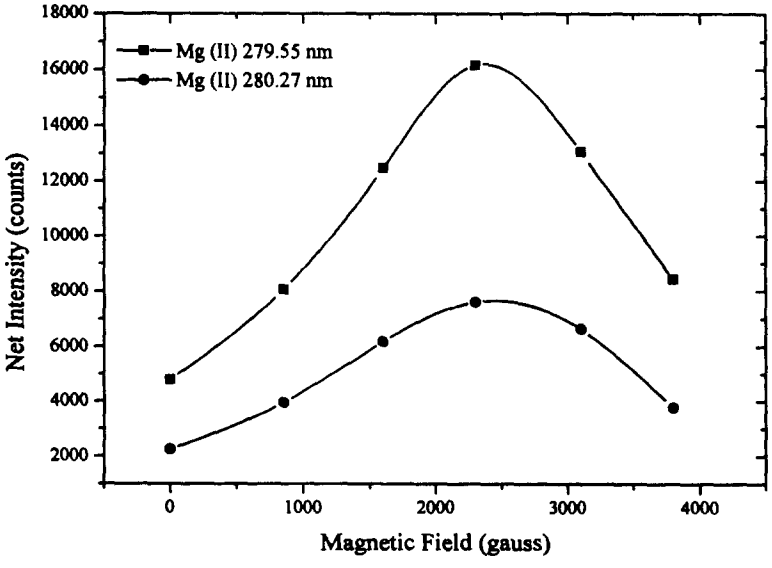

Fig 6. Effect of magnetic field on magnesium ion emission at 279.55 and 280.27 nm from an NIST standard aluminum alloy microcavity hollow cathode. (This standard contains 4.54% magnesium).

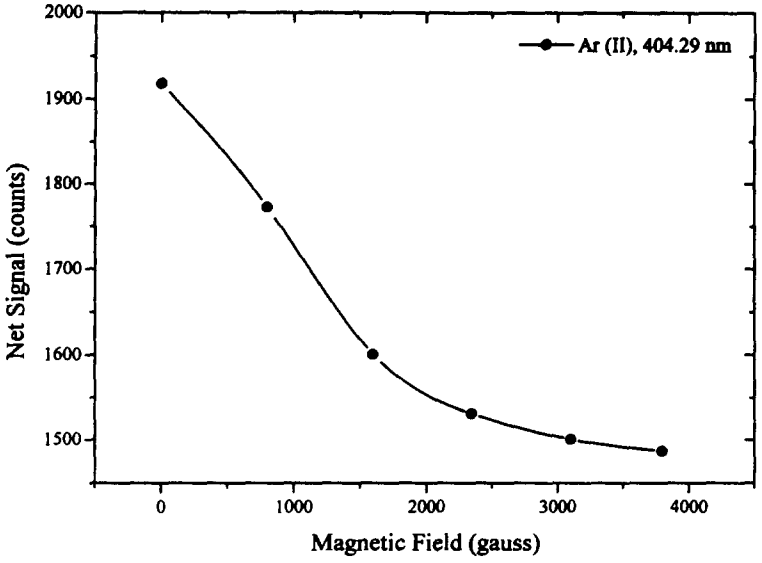

Fig. 7. Effect of magnetic field on argon ion emission at 404.29 nm.

more, the electron temperature $T_e$ without the magnetic field was calculated from the intensity ratio of two lines assuming the gas was in local thermodynamic equilibrium (LTE). Since a low pressure discharge is not in LTE, a semicoronal equilibrium was assumed to prevail inside the discharge [19].

Assuming another transition $k \rightarrow i$ and taking the ratio of the intensity of the two lines gives

$$kT_e = (U_k - U_j)/\ln\left(\frac{I_{ji}\lambda_{ji}{}^3 f_{ik}}{I_{ki}\lambda_{ki}{}^3 f_{ij}}\right) \quad (8)$$

assuming the excitation rate coefficients $\chi_{gj}$ and $\chi_{gk}$ are the same due to the similarity of excited states $g$ and $j$. When the magnetic field is applied

$$\frac{1}{T_e} - \frac{1}{T_{eB}} = \frac{k}{(U_k - U_j)} \ln\left[\frac{(I_{ki})_B (I_{ji})}{(I_{ji})_B (I_{ki})}\right] \quad (9)$$

where $f_{ij}$ and $f_{ik}$ are the oscillator strengths (dimensionless) of the respective transitions and $T_{eB}$ is the electron temperature in the presence of the magnetic field. It is important to note that this equation is valid only for those emission lines which have the same

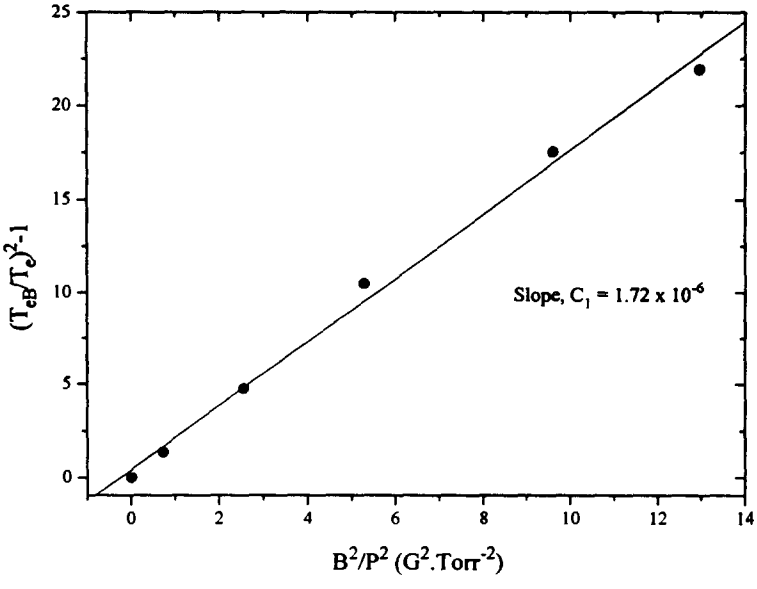

Fig. 8. Effect of magnetic field on the electron temperature.

ground states because the statistical weights of the ground state are also affected by the applied magnetic field as a result of Zeeman splitting. The ratio of the statistical weights in the presence of the magnetic field is unity if the two ground levels are the same. We selected two resonance lines of copper (324.70 and 327.40 nm) for the calculation of electron temperatures both with and without the magnetic field using Eqs. (8) and (9). A plot of $(T_{eB}/T_e^2) - 1$ versus $B^2/P^2$ (where $B/P$ is known as the reduced magnetic field) is shown in Fig. 8. It is evident from this plot that the electron temperature is constantly increasing with applied magnetic field strength (where pressure is kept constant). The value of the slope of this plot, which corresponds to $C_1$, gives $1.72 \times 10^{-6}$ for argon which is in the same range calculated for helium by Sadhya and Sen [20]. Table 1 lists the values of the constant in Eq. (7). As can be seen from Table 1, for a particular element, the value of $C_2$ is almost constant. Therefore, the closer the energies of the upper levels of the lines of a particular element, the closer are the maxima of the emission intensities that occur when the field strength is increased as seen in Figs. 3, 4 and 6. For all three elements chosen in this study, $B_{max}$ values are nearly the same for a given element. For example, aluminum has the same energy of the upper levels for both lines at 394.40 and 396.15 nm and shows maxima for these lines at 2300 G.

## 4. Conclusions

It can be concluded that the two-field dependent factors, electron temperature and radial diffusion of the electron, are both acted upon simultaneously and opposite to each other by the applied magnetic field. The electron temperature increases with magnetic field, whereas there is an increase in radial diffusion of the electron with increasing magnetic field. Therefore, a maximum in emission intensity does occur at a certain field strength and this maximum is dependent upon the energy of the upper state of the analytical line. Since there is no substantial advantage of using a very high magnetic field strength, it might be appropriate to use permanent magnets which tend to have sufficient field to produce the positive effect of magnetic field on atomic emission intensity [21]. Use of a permanent magnet will facilitate a compact discharge design. We are currently developing a compact magnetically boosted glow discharge device using permanent magnets for the analysis of residues of microliter volume liquid samples.

Table 1
Relationship between intensity maxima and energy of upper level

| Analyte | Wavelength (nm) | Energy of the upper level (eV) | $B_{max}$ [a] (G) | $C$ (G eV) |
|---|---|---|---|---|
| Cu(I) | 324.75 | 3.817 | 2500 | 2784 |
| Cu(I) | 327.40 | 3.786 | 2500 | 2761 |
| Mg(II) | 279.55 | 4.434 | 2400 | 3222 |

# Determination of calcium, magnesium and zinc in unused lubricating oils by atomic absorption spectroscopy

A.P. Udoh

*Department of Chemistry and Biochemistry, University of Uyo, Uyo, Akwa Ibom State, Nigeria*

Received 20 June 1994; revised 3 May 1995; accepted 5 May 1995

**Abstract**

Varying concentrations of lanthanum and strontium were added to solutions of ashed unused lubricating oils for the determination of calcium, magnesium and zinc content using flame atomic absorption spectrophotometry. At least 3000 $\mu g\ g^{-1}$ of lanthanum or strontium was required to completely overcome the interference of the phosphate ion, $PO_4^{3-}$, and give peak values for calcium. The presence of lanthanum or strontium did not cause an appreciable increase in the amount of magnesium and zinc obtained from the analyses. The method is fast and reproducible, and the coefficients of variation calculated for the elements using one of the samples were 1.6% for calcium, 3.5% for magnesium and 0.2% for zinc. Results obtained by this method were better than those obtained by other methods for the same samples.

*Keywords:* Calcium; Magnesium; Zinc; Lubricating oils; Atomic absorption spectroscopy

## 1. Introduction

Lubricating oils are employed to separate metallic surfaces in mechanical systems. The performance characteristics of these oils are usually improved by the incorporation of additives which contain one or more of the following elements — phosphorus, barium, calcium, magnesium, zinc, antimony, nickel, boron, cadmium, chromium, mercury, molybdenum, selenium and tin [1–3]. A rapid and accurate analytical procedure is needed for routine analysis of these elements in order to provide proper control of plant blending operations. The American Society for Testing and Materials [4] recommended ashing at 650–700°C. The institute of Petroleum [5–7] also recommended ashing at 550°C until the ash is free of all visible traces of carbon. Udoh et al. [8] observed that with lubricating oils marketed in Nigeria, complete oxidation of carbon was not possible at any of these standard temperatures. This could perhaps account for the need to filter the solution in the above cases. Suspecting that incomplete oxidation of carbon may lead to lower values for the added elements, Udoh et al. [8] designed a series of experiments that led to the recommendation of an ashing temperature of $900 \pm 50$°C.

There are a number of methods which can be used to determine the above elements in solubilised ash. These include titrimetry, emission spectroscopy [1,9] and chemical analysis [4–7]. Such methods are laborious and impractical, especially when large numbers of samples are involved. The Institute of Petroleum [10] recommended an atomic absorption spectrometric analysis of the unused oil for barium, calcium, magnesium and zinc after dilution with white spirit, but this method is not suitable for lubricating oils that contain viscosity index improvers. Other organic solvents can be used, but they pose a lot of difficulties [11] and the

*SSDI* 0039-9140(95)01634-1

results obtained depend on the type of organometallic compound used for calibration [12]. Such difficulties were believed to be overcome by the use of oxygenated solvents and mixed solvent systems, but flame problems are still common even though they allow for the application of aqueous inorganic salt standards which make the analyses cheaper.

Surprisingly, with the ready availability of flame atomic absorption spectrophotometers (using an air–acetylene flame), no method has been described to apply this facility using aqueous standard and the inorganic ash, perhaps owing to the common interference of phosphorus in the determination of the alkaline earth metals by flame absorption. This interference by phosphorus in inorganic systems is usually overcome by the addition of lanthanum or strontium solution. Varying concentrations of lanthanum in the final solution have been recommended when analysing different classes of materials [13–16]. To my knowledge, none has yet been recommended as being adequate for the determination of these elements in the ashed lubricating oils. If the interference due to phosphorus in the ashed oil is overcome, its incorporation into the above-mentioned procedure [8] can provide a rapid method for routine analysis, perhaps with more quantitative results than from direct dilution with organic solvents or chemical analysis.
This paper describes how the interference from phosphorus is overcome, and recommends a cheaper and reliable procedure for routine analysis of unused lubricating oils.

## 2. Experimental

### 2.1. Reagents and apparatus

All the reagents were of analytical grade. Doubly-distilled water was used to prepare all the solutions. Stock (1000 $\mu g\ g^{-1}$) Ca, Mg and Zn was prepared from carbonate (Ca), sulphate (Mg) and oxide (Zn), stored in polythene bottles and diluted appropriately to obtain working solutions. 10 000 $\mu g\ g^{-1}$ of lanthanum (as nitrate) and strontium (as chloride) was added to the sample solutions as buffer to overcome the interference of the phosphate ion.

A Gallenkamp muffle furnace with a temperature range of 0–1000°C was used for ashing. A Unicam AA919 atomic absorption/flame emission spectrophotometer equipped with a premix chamber and a 10 cm single element hollow cathode lamps as sources was used for the analysis.

### 2.2. Lubricating oil samples

The samples analysed were purchased from producing companies as sold at their appropriate stations in Nigeria. All samples were stored in polythene bottles and were assigned numbers to differentiate between them in this work. Both premium quality SAE 20/50 and medium quality SAE 40 were used. A detailed list is presented in Table 1. All the samples are highly viscous and amber coloured, except sample 9 which is reddish.

### 2.3. Effects of varying the concentrations of lanthanum and strontium on the recovery of calcium and magnesium

10.0 g of sample 2 was weighed into different porcelain evaporating dishes, ashed, solubilised and concentrated as described below. Varying concentrations of lanthanum and strontium solution were added to the resulting solutions, and the volumes made up to 20.0 $cm^3$. The amounts of calcium and magnesium in each case were determined. The results of duplicate determinations are presented in Table 2.

### 2.4. Recommended procedure

10.0 g [4] of the lubricating oil was weighed into a 100 $cm^3$ capacity evaporating dish and heated gently with a bunsen flame until it ignited. The flame was removed and the oil allowed to burn until a coke residue was

formed. Heating with the flame was recommenced until all volatile matter had been driven off. The evaporating dish was then transferred to a muffle furnace set at $900 \pm 50$ °C [8] and heated until the ash was free from all visible traces of carbon. This occurred about 3 h after the attainment of the above temperature. The evaporating dish was removed from the furnace and allowed to cool. The residue was treated with 20.0 $cm^3$ of 6 M hydrochloric acid and the solution concentrated on a steam bath to about 5.0 $cm^3$. The solution was transferred quantitatively to a 20.0 $cm^3$ volumetric flask. 6.0 $cm^3$ of 10 000 $\mu g\ g^{-1}$ lanthanum or strontium solution was added and the solution diluted to the mark with water.

The resulting solution was used for the determination of the elements using atomic absorption. A blank solution was also prepared.

### 2.5. *Evaluation of the procedure*

The reproducibility of the procedure was established by applying the proposed procedure six times in turn to sample 1 and determining the elements of interest. The reproducibility in the determination of the various determinant elements is appropriately discussed.

In a comparison of methods, some samples were prepared in duplicate and analysed for calcium, magnesium and zinc using other approaches (precipitation as oxalate followed by titration with $KMnO_4$ solution for Ca, precipitation as 8-hydroxyquinaldinate for Mg, and titration with EDTA for Zn) and the results compared with those obtained for the same samples using the recommended procedure. The data are presented in Table 3.

## 3. Results and discussion

The concentrations of calcium obtained continued to increase with the concentration of either lanthanum or strontium until a peak concentration was obtained, at a lanthanum or strontium concentration of 3 000 $\mu g\ g^{-1}$. Once reached, the peak value remained virtually constant when higher concentrations of lanthanum or strontium were applied. Plotted against increasing concentration of lanthanum or strontium, the concentration of calcium increased linearly to the peak value and thereafter mainted a plateau up to a lanthanum or strontium concentration of 5000 $\mu g\ g^{-1}$. Although the results of Table 2 relate to sample 2, the same trend was observed for the other samples. Table 2 also shows that an increase in the concentration of lanthanum or strontium did not give a corresponding increase in the concentration of magnesium and that all the magnesium was recovered with or without the addition of lanthanum or strontium. Generally, magnesium is not known to be affected by interference due to the phosphate ion, $PO_4^{3-}$.

The recommended procedure gives highly reproducible analysis for unused lubricating oils. Replicate analysis of sample 1 gives the following results — calcium $1648 \pm 26$, magnesium $1620 \pm 57$ and zinc $1160 \pm 2\ \mu g\ g^{-1}$. Table 2 also shows that the results obtained from the procedure are more enhanced for calcium than those obtained from gravimetry, and also that the same sample solution gives comparatively good results for magnesium and zinc. Statistical analysis shows that the new AAS method is free from determinate error at 95% probability. The differences in results between the new AAS

[a] Average of duplicate determinations.

method and other conventional approaches could be attributed to the reduced sensitivity of the other methods for calcium and magnesium. Comparable results are obtained for zinc in most of the samples. It must be noted that the sample solution is a complex matrix and the effects of the presence of many other unknown ions interfere with the sensitivity of the conventional methods, leading to a positive or negative influence on the values obtained. Although comparable results are obtained for zinc from titration and the new method, this element alone cannot be determined by titration and the others by AAS when all of them can be determined very fast by AAS.

The procedure presented in this article offers many advantages over other approaches hitherto described. It reduces the analysis time, and the same sample solution can be used to determine all the additive elements included in this work instead of preparing the sample separately for the determination of each element as in the Institute of Petroleum Methods. It overcomes all the problems posed by the use of organic solvents for direct dilution. The procedure employs the use of aqueous inorganic salt standards, thereby freeing the results form dependence on the type of organometallic salt used for calibration. Also, a larger number of samples can be handled simultaneously.

## 4. Conclusion

Additive elements in lubricating oils have hiterto been determined by atomic absorption spectrophotometry after dilution with organic solvents or by chemical analysis of the solubilised ash. This article has demonstrated that the problems encountered in other approaches are easily overcome by the procedure described herein. The method is accurate and fast, and particularly suitable for progressive monitoring of plant blending operations.

## Acknowledgement

I am grateful to the University of Uyo Research Committee for funding this research. I am also grateful to Roberta Mbale Eta and Mfon Johnson Atang for helping to carry out the analysis.

# Luminescence determination of europium microquantities after its preconcentration on polyurethane foam

S. Beltyukova *, G. Balamtsarashvili

*A.V. Bogatsky Physico-Chemical Institute of the National Academy of Sciences of Ukraine, 86 Chernomorskaya Doroga, 270 080, Odessa, Ukraine*

Received 12 December 1994; revised 4 April 1995; accepted 24 April 1995

**Abstract**

Sorption of the mixed-ligand complexes of europium(III) with thenoyltrifluoroacetone (TTA) and 1,10-phenanthroline (Phen) on polyurethane foam (PUF) has been studied by a luminescence method. The optimum conditions of sorption have been found. The sorbate composition on PUF has been determined (the Eu:TTA:Phen ratio was 1:3:1). Luminescence spectra of the europium complexes in solution and on PUF at 77 K have been investigated. It was concluded that the character of the $Eu^{3+}$ coordination both in solution and on the sorbent is the same. Stability constants for the complexes in solution ($\lg K = 8.4$) and on the sorbent ($\lg K = 5.5$) have been calculated. The decrease of the stability of the complex on PUF is explained by the deformation of the complex molecule in the sorbent phase. Sorption coefficients for europium (245) and scandium (2.35) and the coefficient of selectivity for europium in $Sc_2O_3$ (102.3) have been determined. A method for the sorption–luminescence determination of europium in $Sc_2O_3$ with a lower limit of contents determined of $1 \times 10^{-6}$% has been developed.

*Keywords:* Europium; Polyurethane foam; Luminescence determination; Preconcentration

## 1. Introduction

Over the past years, polyurethane foam (PUF) has been used successfully in analytical chemistry for the determination of different elements. The sorption of a large quantity of transition, rare earth and toxic elements on PUFs with the aim of their further determination in the eluate or directly on the sorbent by one of the spectroscopic methods, has been reported [1–3].

Only the selective separation of cerium(III) on PUF modified with tri-*n*-butyl phosphate and thenoyltrifluoroacetone [4] or di(2-ethylhexyl) phosphoric acid [5], as well as the luminescence determination of yttrium immobilized on PUF as complexes with quinosol [6] have been described.

In this paper, the sorption of europium from a solution of its mixed-ligand complex with thenoyltrifluoroacetone (TTA) and 1,10-phenanthroline (Phen) on solid PUF has been studied, and the possibility of application of the luminescence properties of the sorbate to the determination of europium in scandium oxide has been demonstrated. Use of the sorption of europium allowed us to carry out its preconcentration as well as to eliminate factors which cause the non-radiative loss of excitation energy (to increase the rigidity of the system, to decrease the thermal motion of molecules, and to decrease the free rotation of ligand fragments).

## 2. Experimental

### 2.1. Reagents

Solutions of lanthanide chlorides (0.1 mol $l^{-1}$ and 1 mg $ml^{-1}$) were prepared by dissolution of the corresponding oxides in HCl. The solutions were then evaporated to the wet salts, which were then diluted with water.

The concentration was determined by complexometric titration with Arsenazo I [7]. Solutions of mixed-ligand complexes were prepared according to a literature procedure [8]. Industrial PUF, mechanically pounded to a grain size of 1 mm, was used as the sorbent. The pounded sorbent was treated with 1 M HCl and ethanol and was dried in air.

### 2.2. Apparatus

The pH values of the solution were measured using a pH-meter pH-340. The luminescence spectra of europium were recorded in the region of the $^5D_0 \rightarrow {}^2F_2$ transition (520–630 nm) using an СДЛ-2 spectrometer. The excitation source was a ДКсЭл-1000-5 ultrahigh pressure xenon discharge lamp (power, 1000 V; luminour flux, 32 klm).

### 2.3. Procedure

Sorption was studied under static conditions. The sorbent weight was equilibrated by shaking with 10 ml of a solution of known composition. Equilibrium was controlled by the luminescence of the equilibrium solution.

## 3. Results and discussion

### 3.1. Optimum conditions for sorption

As can be seen in Fig. 1, complete sorption of europium from a solution of the thenoyltrifluoroacetone and 1,10-phenanthroline complex is observed in 10 min. The decrease in luminescence intensity ($I_{lum}$) of the europium sorbate after sorption (10 min) could be connected with the fact that on increase in the sorption time, the sorption of unbound ligands (TTA and Phen) increases and this could lead to a concentration quenching of europium luminescence in the sorbate. Sorption of the europium mixed-ligand complex on PUF is observed over the pH range 7–9, i.e. in the region of existence

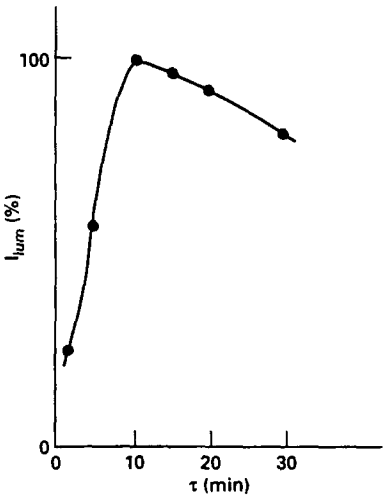

Fig. 1. Dependence of $I_{lum}$ of europium on the sorbent on sorption time ($C_{Eu} = 1 \times 10^{-6}$ mol $l^{-1}$).

of the complex in solution. The highest luminescence intensity of europium on PUF is observed at pH 8 (Fig. 2). The required value of the pH in solution was obtained with urotropine (0.5 ml of a 40% solution) as buffer.

A study of the dependence of the sorption of europium on the amount of complexing substance in solution has shown that a one-hundred to two-hundred fold excess of the reagents (TTA and Phen) is necessary for obtaining the maximum $I_{lum}$ value (Fig. 3). The large excess of the reagents might be due to the additional sorption of unbound ligands on PUF. The choice of the optimum amount of PUF shows that the highest $I_{lum}$ of europium is observed with a sorbent addition of 40 mg (at $C_{Eu} = 1 \times 10^{-5}$ mol $l^{-1}$) (Fig. 4).

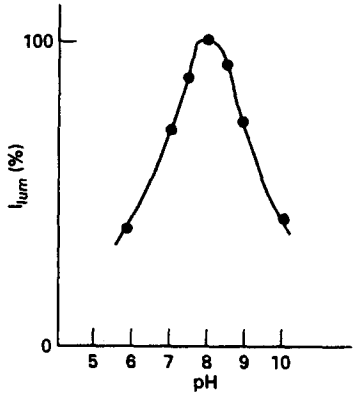

Fig. 2. Dependence of $I_{lum}$ of the europium sorbate on the pH of the solution ($C_{Eu} = 1 \times 10^{-6}$ mol $l^{-1}$).

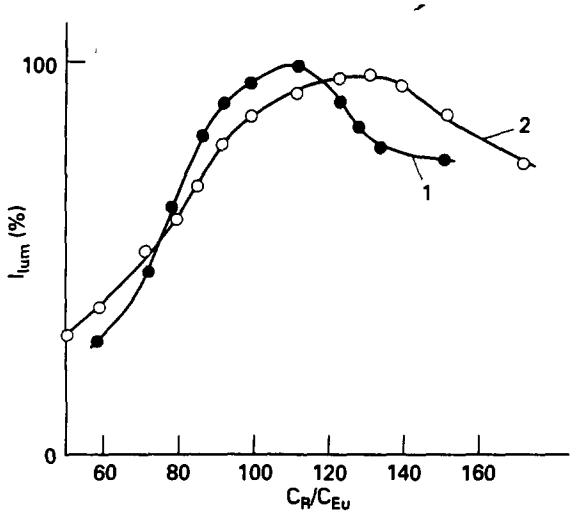

Fig. 3. Dependence of $I_{lum}$ of the europium sorbate on the amount of TTA (curve 1) and Phen (curve 2) in solution ($C_{Eu} = 1 \times 10^{-5}$ mol $l^{-1}$).

### 3.2. Influence of solvent

Values of $I_{lum}$ of the europium complex on PUF in the presence of series of solvents (20% vol.) with different donor–acceptor properties are summarized in Table 1.

As can be seen in the table, the highest $I_{lum}$ value of europium is observed with dimethylformamide and increases threefold. The influence of the electric field of the solvent on the 4f shell of the lanthanide ion has previously been reported [9,10] for the solutions of some complexes of europium and terbium and is exhibited in the dependence of the $I_{lum}$ of these ions on the permittivity of the solvent. However this influence is not observed for sorbates. A dependence of the $I_{lum}$ of europium on the sorbent on the different parameters characterizing the solvent donor–acceptor ability, such as the solvation energy, the acceptor ability, the relative coordination force, and the general base is also not observed.

The influence of the character of the solvent on the $I_{lum}$ of europium in solution and on the sorbent is different. If the $I_{lum}$ in the solution is maximal for water–alcohol solutions, then the $I_{lum}$ on PUF in the presence of these solvents is low. It could be supposed that, in this instance, the solvent influences the sorption ability of the complex. However, the $I_{lum}$ of europium in solution after sorption is low; for example, sorption in the presence of dimethylformamide is 100% and in the presence of ethanol is 87%. On the one hand, it is evident that solvation of the complex molecules by alcohols reduces the total energy of the solvate–sorbate interaction; on the other hand, the sorbating molecules of the solvent definitely influence the processes of non-radiative energy transfer of the electron excitation of the complexes on the sorbates.

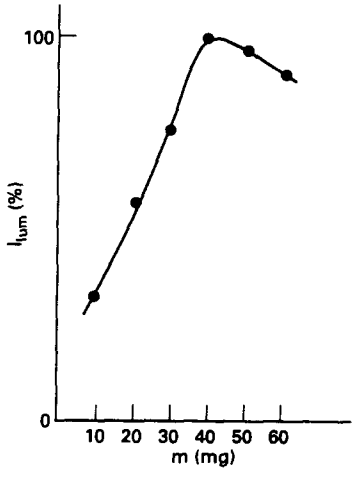

Fig. 4. Dependence of $I_{lum}$ of the europium sorbate on the amount of sorbent ($C_{Eu} = 1 \times 10^{-5}$ mol $l^{-1}$).

### 3.3. Influence of surfactants

The influence of surfactants on the $I_{lum}$ of europium in the mixed-ligand complexes with TTA and Phen (or TOPO) has been reported by many authors [11]. The use of micellar media allows the detection limit of europium to be significantly decreased. Hence, it was interesting to follow the influence of the surfactants on the $I_{lum}$ of sorbed europium on the solid matrix. The sorption of europium was carried out from solutions of mixed-ligand complexes into which different surfactants were introduced. The results obtained are summarized in Table 2. As can be seen, the highest $I_{lum}$ of europium on PUF is observed for the sorption in the absence of surfactants. The introduction of surfactants decreases in either degree the luminescence intensity on the sorbent. Hence, it can be supposed that, in any given instance, a decrease in the degree of sorption and the decrease in the $I_{lum}$ on the sorbent results from solubilization of the complex in solution. The luminescence intensity of the solutions in the presence of surfactants remains fairly high after sorption. This fact testifies in favour of the above supposition.

Table 1
The dependence of the $I_{lum}$ of europium sorbates and solutions of europium and TTA and Phen complexes on the nature of the solvent

| Solvent | $\varepsilon_{Dp}$ | $I_{lum}$ europium (%) | |
|---|---|---|---|
| | | Sorbent | Solution |
| Water | 80.31 | 29 | 100 |
| Dimethylsulfoxide | 48.9 | 75 | 83 |
| Dimethylformamide | 37.6 | 100 | 59 |
| Methanol | 33.6 | 35 | 148 |
| Ethanol | 24.5 | 46 | 162 |
| Propanol | 20.75 | 15 | 135 |

### *3.4. Determination of the degree of sorption and the sorbate composition*

The degree of sorption of europium on PUF was determined by carrying out the sorption under the optimum conditions. The sorbent was dried, burnt in a muffle furnace, the residual ashes were dissolved, and the europium content was determined with Arsenazo III as previously described [7]. The degree of europium sorption in the presence of cetyltrimethylammonium bromide, OC-20 and Triton X-100 were 60%, 20% and 16.6%, respectively, i.e. a significantly higher solubilization of the europium complex in non-ionic surfactants (OC-20, Triton X-100) led to a lower degree of sorption in their presence. Europium forms a complex with TTA and Phen in water–organic media and extracts. The ratio of the components (Eu:TTA:Phen) is 1:3:1. The application of the method of limited logarithms has shown that the sorbate composition corresponds to the composition of the complex in solution.

Europium sorbates exhibit an intensive luminescence which exceeds by two orders the $I_{lum}$ of europium in solutions of the same complex. The distribution of radiation energy on the $^5D_0 \rightarrow {}^7F_j$ (where $j = 1, 2$) transitions and on the separate lines within the transition is approximately equal for the sorbate and a solution of the complex at 77 K (Fig. 5). The major part of the radiative energy in the sorbate is on the line of the $^5D_0 \rightarrow {}^7F_2$ electric-dipole transition. It is known that the intensity of the lines corresponding to the $^5D_0 \rightarrow {}^7F_1$ magnetic-dipole transition is lower than the intensity of the line of the $^5D_0 \rightarrow {}^7F_2$ electric-dipole transition by one order of magnitude. The $\Delta F_{1,2}$ magnitudes, which are recorded in the low temperature luminescence spectra, are sensitive indicators of the $Eu^{3+}$–coordinated ligands interaction. The splitting of the Stark components $^7F_j$ for sorbates and complexes in solution are similar; this could testify to the identical character of the coordination of the europium ion in solution and on the sorbent.

Table 2
The dependence of the $I_{lum}$ of europium in solution of complexes with TTA and Phen in the sorbates on the nature of the surfactants

| Surfactant | $I_{lum}$ of europium in solution before sorption (%) | $I_{lum}$ of europium on PUF (%) |
|---|---|---|
| None | 32 | 100 |
| Cetyltrimethylammonium | 52 | 42 |
| Cetylpyridinium bromide | 21 | 38 |
| Aethonium | 34 | 11 |
| OC-20 | 53 | 51 |

| Tetramethylammonium bromide | 21 | 39 |
| Tetrabutylammonium bromide | 20 | 37 |
| Lauryl sulphate | 30 | 12 |

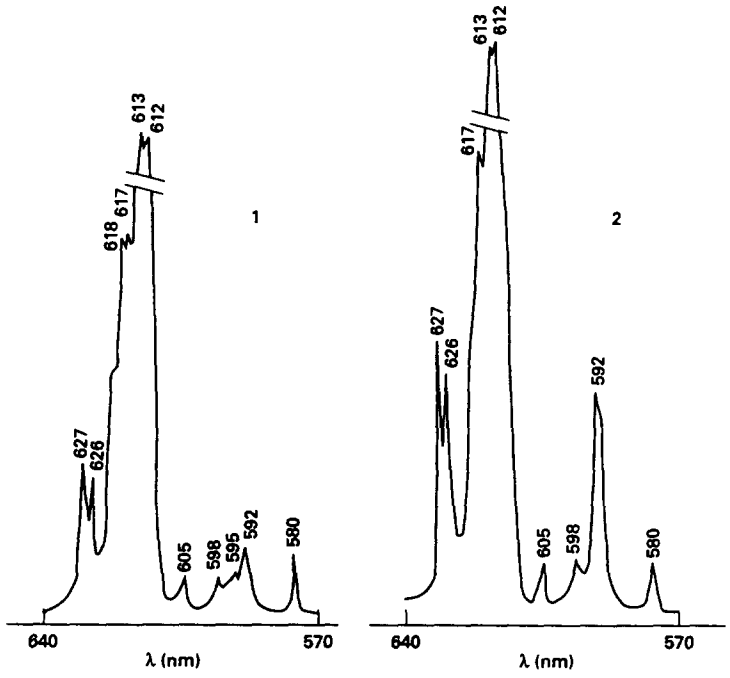

Fig. 5. Luminescence spectra of a mixed-ligand complex of europium with TTA and Phen (spectrum 1) in solution and (spectrum 2) on the sorbent at 77 K.

### 3.5. Stability of the complexes in the sorbates

A mathematical model describing similar systems [12] has been applied to the stability evaluation of the obtained complexes on polyurethane foam. According to this model, the inverse magnitude of the metal concentration on the sorbent ($Y$) and the inverse magnitude of its equilibrium concentration ($X$) in solution are bound by the rectilinear dependence

$$I/Y = A_1(I/X) + A_0$$

where $A_1$ and $A_0$ are coefficients of this equation. The stability constant of the europium complex on the sorbent, $K_{stab} = A_0/A_1$.

Stability constants of the complex in solution were calculated for comparison purposes. The least-squares method has been applied in the calculations in both instances. Correlation coefficients of the linear equations are within the limits 0.95–0.98. The obtained results show that the stability of the complexes on the sorbent (lg $K = 5.5$) is lower than that in solution by several orders (lg $K = 8.4$). This could be connected with the fact that the fixed on matrix ligands take place in complexing in the sorbate instance. If all the ligands can take the necessary geometric configuration in solution, then this is connected with the additional energy expenditure in the sorbent layer. This energy is needed for the taking up of the necessary geometric position by the attached ligand groups, i.e. to deform the natural position of the attached ligands as well as the matrix itself [14]. Deformed complex, which is attached to the matrix, has a lower stability.

### 3.6. Possibility of analytical application of the sorbate

The high luminescence intensity of sorbates of europium phenanthrolinethenoyltrifluoro-acetonate may be used to develop methods for the determination of europium in lanthanide oxides with much lower detection limits, i.e. of the order of $n.10^{-6}$–$n.10^{-7}$%. At present, the analysis of lanthanide oxides as well as scandium oxide is very actual. It is known that differences between the formation conditions and the stability of the europium and scandium complexes with TTA are applied in the separation by extraction of these elements. Thus, scandium is extracted by benzole from more acidic solutions ($pH_{1/2(Sc)}$ 0.5) than europium ($pH_{1/2(Eu)}$ 2.9). The extraction constants of these elements (lg $K(Sc) = -0.77$, lg $K(Eu) = -7.9$ [13]) are also different. It could be supposed that, by analogy

with the extraction processes, the differences in the properties of the complexes are intensified on sorption. Hence, the determination of europium in the presence of large amounts of scandium will be possible. It has been established that the degree of sorption of scandium from solutions in the presence of both TTA and Phen under optimum conditions for the sorption of europium on PUF is 50%.

Sorption coefficients for europium and scandium are 245 and 2.35, respectively. The selectivity coefficient for europium in scandium oxide is 102.3. hence, it may be concluded that application of PUF allows the detection limit of europium in scandium oxide to be reduced.

### *3.7. Method of determination*

The scandium oxide to be analyzed is dissolved in HCl, the solution is evaporated to the wet salts, and the residue is dissolved in distilled water. Samples of the solution to be analyzed are placed in three beakers; the solution contains 50–100 μg of scandium oxide. Different amounts of a solution of europium chloride are added to two of the beakers. To each beaker are then added 0.5 ml of 0.5% TTA, 0.15 ml of 3% Phen, 2 ml of dimethylformamide, and 0.5 ml of 40% urotropine. The solution is diluted to 10 ml with water, 40–50 mg of PUF are added, and sorption is carried out for 10 min. The sorbent is filtered, washed with distilled water and dried in air. Luminescence spectra are recorded using the СДЛ-2 spectrometer (or any other spectrometer) at $\lambda = 612$ nm. The europium content of the sample solution and of the sample with additions is calculated using the additions method in accordance with the size of the luminescence peak. The accuracy of the analysis has been tested by the additions method and by varying the sample additions. The europium content in the samples of scandium oxide to be analyzed according to the certified data is below $1 \times 10^{-4}$%. Additions of europium (0.002 and 0.005 μg) to aliquots of $Sc_2O_3$, carried out for all analyses, are 0.0019 μg and 0.0051 μg at $n = 5$, $P = 0.95$ and $S_r = 0.06$ and 0.05, respectively.

As the data show, the developed methods allow europium to be determined in scandium oxide with satisfactory accuracy and reproducibility.

The detection limit of europium, i.e. $1 \times 10^{-6}$%, was calculated according to the $3\sigma$-criterion.

**Abstract**

Direct-current cyclic voltammetry is used to investigate the suitability of some ferrocene derivatives such as ferrocenecarboxylic acid, ferroceneacetic acid and ferrocenemethanol as mediators for ascorbic acid oxidation in aqueous solutions with low pH. The ascorbic acid coupled catalytically to three ferrocene derivatives exhibiting homogeneous second-order rate constants $k_s$, in the range $7.36 \times 10^5$–$1.23 \times 10^7$. The catalytic oxidation peak current was linearly dependent on the ascorbic acid concentration and the linearity range obtained in the presence of ferrocenecarboxilic acid, having the largest second-order rate constant, was $5 \times 10^{-5}$–$1.5 \times 10^{-3}$ M. The catalytic effect of the ferrocene derivatives on the electrochemical oxidation of ascorbic acid reduced the oxidation potential of ascorbic acid, resulting in the separation of the overlapping voltammograms of ascorbic acid and dopamine at the glassy carbon electrode in a mixture. This allowed the determination of ascorbic acid in the presence of dopamine. The calibration graph obtained by linear sweep voltammetry for ascorbic acid in the presence of dopamine of fixed concentration is linear in the range $5 \times 10^{-5}$–$1.5 \times 10^{-3}$ M. In a similar manner, dopamine is determined in the presence of a high concentration of ascorbic acid, up to 100 times that of dopamine, using ferroceneacetic acid as the most suitable mediator for this purpose.

## 1. Introduction

Ascorbic acid (vitamin C) is a hexuronic acid with $pK_a$ values of 4.17 and 11.5. In biological solutions at neutral pH it exists primarily as the monohydrogen ascorbate anion. Ascorbic acid/ascorbate is a vital component in the diet of humans. Ascorbate is the agent which prevents scurvy and is known to take part in several biological reactions. Ascorbate is possibly the primary antioxidant in human blood plasma and is present in mammalian brain in the presence of several neurotransmitter amines including dopamine, epinephrine and norepinephrine. In addition, ascorbic acid is found in high concentration in some fruits and foods together with vasoactive amines such as dopamine.

Many of the fundamental studies on ascorbic acid oxidation have examined the reaction at metal electrodes. It is now established that the oxidation of ascorbic acid (1) at low pH proceeds via two consecutive one-electron pro-

* Corresponding author.

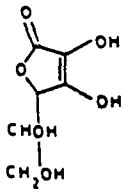
*SSDI* 0039-9140(95)01638-4

TAL 42-12-0

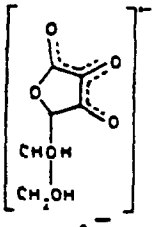
cesses involving the participation of a radical anion intermediate (2) (the latter being confirmed from electron paramagnetic resonance spectroscopy [1], to form dehydro-L-ascorbic acid (3). The latter species subsequently undergoes a hydration reaction characteristic of carbonyl groups to form the final electroinactive product (4). Consequently the overall reaction can be classified as an EC process:

$$AH_2 - 2e \rightarrow A + 2H^+ \quad E \quad (1)$$

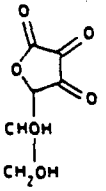
$$A + H_2O \rightarrow B \quad C \quad (2)$$



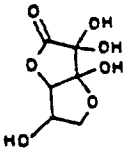
$AH_2$
(1)



A
(2)



A
(3)



B
(4)

Note also that at pHs between the first and second $pK_A$ values ($4.17 < pH < 11.5$), the oxidation process will only involve the loss of a single proton owing to the fact that ascorbic acid will be of the form $AH^-$.

The selective amperometric determination of ascorbic acid is of much current interest. In samples with low pH, it is almost too difficult to determine this compound electrochemically by direct oxidation on a conventional electrode because of fouling by the oxidation products. A carbon electrode, when subjected to an appropriate pretreatment procedure, exhibits minimal propensity for surface fouling. However, the kinetics of electron transfer are quite sluggish. This last characteristic of electrochemical irreversibility means that ascorbic acid will be oxidized only at potentials considerably removed from its standard redox potential. It has been demonstrated [2] that ascorbic acid can undergo mediated oxidation via a homogeneous process by electrogenerated hexacyanoferrate (III). In addition, some chemically modified electrodes with various active mediators immobilized at the electrode surface for the mediated oxidation of ascorbic acid in acidic solution have been used [3–7].

This paper describes the suitability of some ferrocene derivatives as mediators for the mediated oxidation and determination of ascorbic acid in aqueous solutions with relatively low pH values. The homogeneous second-order rate constants ($k_s$) for the interaction between ascorbic acid and electrogenerated ferricinium derivatives are determined by cyclic voltammetry. In view of the fact that normally it is difficult to obtain separate voltammetric waves for ascorbic acid and dopamine in the presence of each other, mainly when ascorbic acid is present at high concentration [8,9] the ability of the mediators to promote the voltammetric resolution of ascorbic acid and dopamine is investigated.

## 2. Experimental

### 2.1. Reagents and chemicals

The solvent used for the electrochemical studies was doubly distilled water. Lithium perchlorate from Fluka was used as supporting electrolyte. The ferrocene derivatives were from Janssen and were used without further purification. All other reagents were of analytical grade. The solutions were bubbled with nitrogen gas (99.99%) and were kept under a nitrogen atmosphere during the electrochemical experiments.

### 2.2. Instrumentation

The electrochemical experiments were carried out using the EG&G potentiostat/galvanostat model 273 coupled with an IBM personal computer connected to an Epson model FX-850 printer. A conventional three-electrode cell with a calomel electrode as the reference electrode, a platinum wire as the auxiliary electrode and a glassy carbon disk as the working electrode ($A = 0.126\ cm^2$; obtained from EG&G) as used. A pH-meter, model 654 (from Metrohm), was also used.

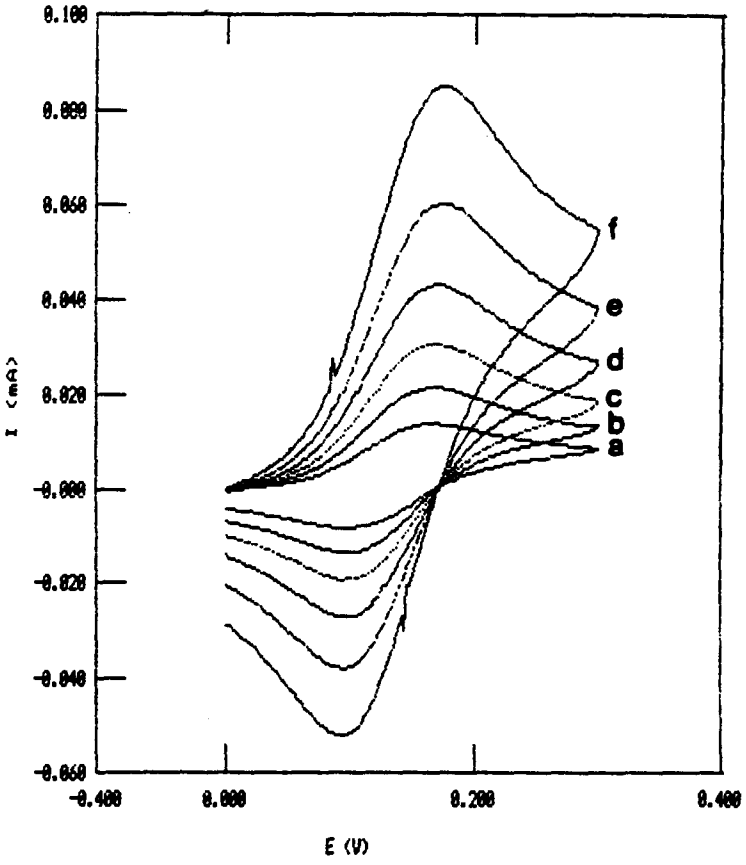


Fig. 1. Cyclic voltammograms of 2 mM ferroceneacetic acid in 0.5 M acetic buffer + 0.1 M $LiClO_4$ at pH 5, using a glassy carbon working electrode, at scan rates of (curve a) 20 mV $s^{-1}$, (curve b) 50 mV $s^{-1}$, (curve c) 100 mV $s^{-1}$, (curve d) 200 mV $s^{-1}$, (curve e) 400 mV $s^{-1}$, and (curve f) 800 mV $s^{-1}$.

## 3. Results and discussion

### 3.1. Electrochemistry of mediators

It has been demonstrated that the optimum characteristics for mediators that can be used in the catalytic electrochemical reaction of substrate include reversible electrochemistry at the electrode surface and rapid reaction with the substrate. The reversibility of ferrocene/ferricinium derivative systems used as mediators in this study was examined by cyclic voltammetry. Cyclic voltammograms for ferroceneacetic acid are shown as examples in Fig. 1 and a summary of electrochemical data for the mediators obtained at the glassy carbon electrode is presented in Table 1. As can be seen in the table, the peak separation potentials $\Delta E_p$ are consistent with an almost reversible oxidation process for the mediators.

### 3.2. Mediated oxidation of ascorbic acid

Previously, $Fe(CN)_6^{4-}$ was shown to be able to electrocatalyze the oxidation of ascorbic acid via a homogeneous process when the ferrocyanide is present in the dissolved form

Table 1
Heterogeneous rate constants for ferrocene derivatives at the glassy carbon electrode

| Ferrocene derivative | $E^a_{1/2}$ (mV) | $\Delta E^b_p$ (mV) | $k^c_0$ (cm $s^{-1}$) |
|---|---|---|---|
| Carboxylic acid | 300 | 74 | $1.6 \times 10^{-2}$ |
| Acetic acid | 139 | 64 | $7.4 \times 10^{-2}$ |
| Methanol | 180 | 70 | $2.0 \times 10^{-2}$ |

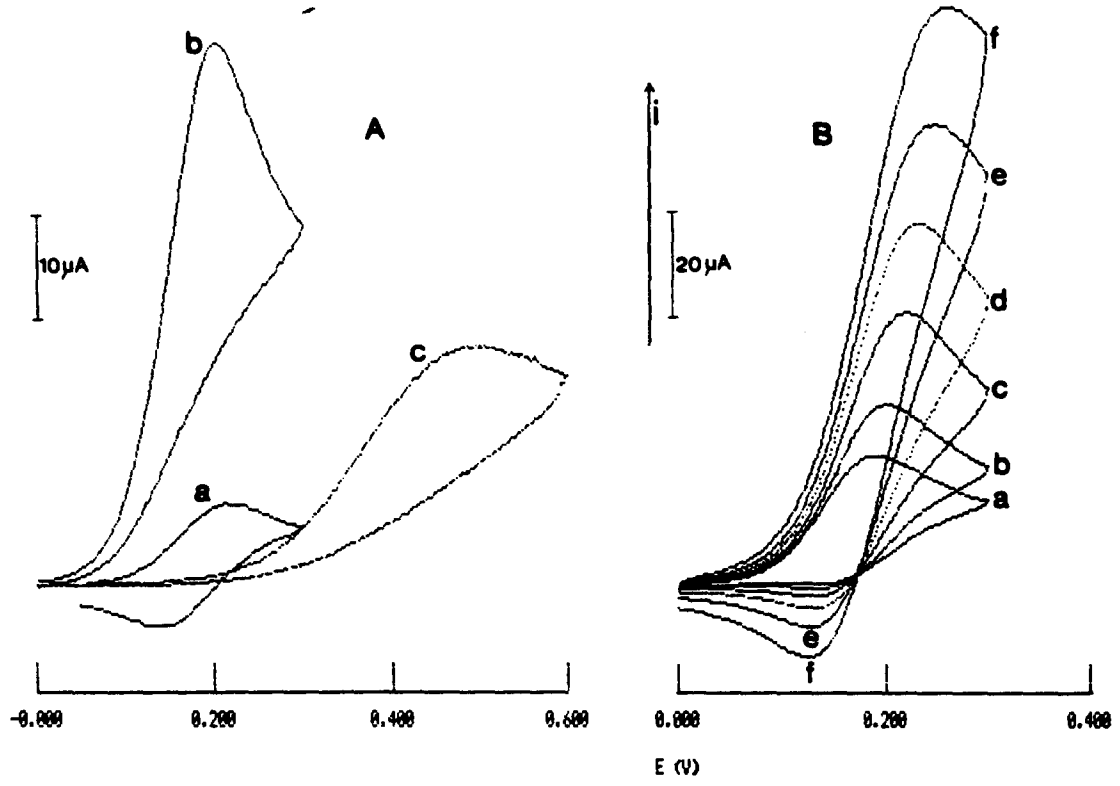

Fig. 2. (A) Cyclic voltammograms of (curve a) saturated ferrocenemethanol in 0.5 M glycine buffer + 0.1 M $LiClO_4$ at pH 4, (curve b) a + 5 mM ascorbic acid, and (curve c) 5 mM ascorbic acid in a buffer solution of pH 4; scan rate, 5 mV $s^{-1}$. (B) catalytic oxidation of 1 mM ascorbic acid at scan rates of (curve a) 10 mV $s^{-1}$; (curve b) 20 mV $s^{-1}$; (curve c) 50 mV $s^{-1}$; (curve d) 100 mV $s^{-1}$; (curve e) 200 mV $s^{-1}$ and (curve f) 400 mV $s^{-1}$. Solution conditions as in (A).

[2]. Accordingly, we decided to examine the ability of ferrocene derivative mediators compared with ferrocyanide to catalyze the ascorbic acid oxidation.

Typical examples of cyclic voltammograms obtained for a saturated ferrocenemethanol solution and for $5 \times 10^{-3}$ M ascorbic acid solutions in the presence and absence of ferrocenemethanol at pH 4 are shown in Fig. 2A. As can be seen in this figure (curve c), the oxidation of ascorbic acid in the absence of mediator occurred irreversibly with a peak potential of almost 0.5 V vs. SCE, while in the presence of ferrocenemethanol as the mediator, its oxidation appeared at the potential of the mediator (curve b); the anodic peak current of the mediator was greatly increased over that normally observed just for the mediator redox couple, while the corresponding cathodic wave was substantially depressed on the reverse voltage scan (curve b). This behaviour is typical of that expected for mediated oxidation. The cyclic voltammograms shown in Fig. 2B for the ascorbic acid–ferrocenemethanol couple at various potential scan rates reveal that the catalytic effect of the mediator appeared even at high scan rates of up to 100 mV $s^{-1}$ (curves a–d), due to a considerable catalytic reaction rate. The other ascorbic acid–ferrocene derivative couples showed a similar behaviour at the appropriate solution pH.

### 3.3. Optimization of the solution pH

Cyclic voltammograms obtained for the solutions containing ascorbic acid and the ferrocene derivative mediators in strongly acidic media showed that ascorbic acid did not couple catalytically with the ferrocenes. Therefore, optimization of the solution pH for each ferrocene–ascorbic acid couple was necessary in order to obtain the catalytic couple. The study of the pH effect was carried out with the aid of two different buffers and the cyclic voltammograms are shown in Fig. 3. The optimum pH values obtained for the carboxylic acid, methanol and acetic acid ferrocene derivatives were 4, 4 (0.5 M glycine buffer) and 5 (0.5 M acetic buffer), respectively.

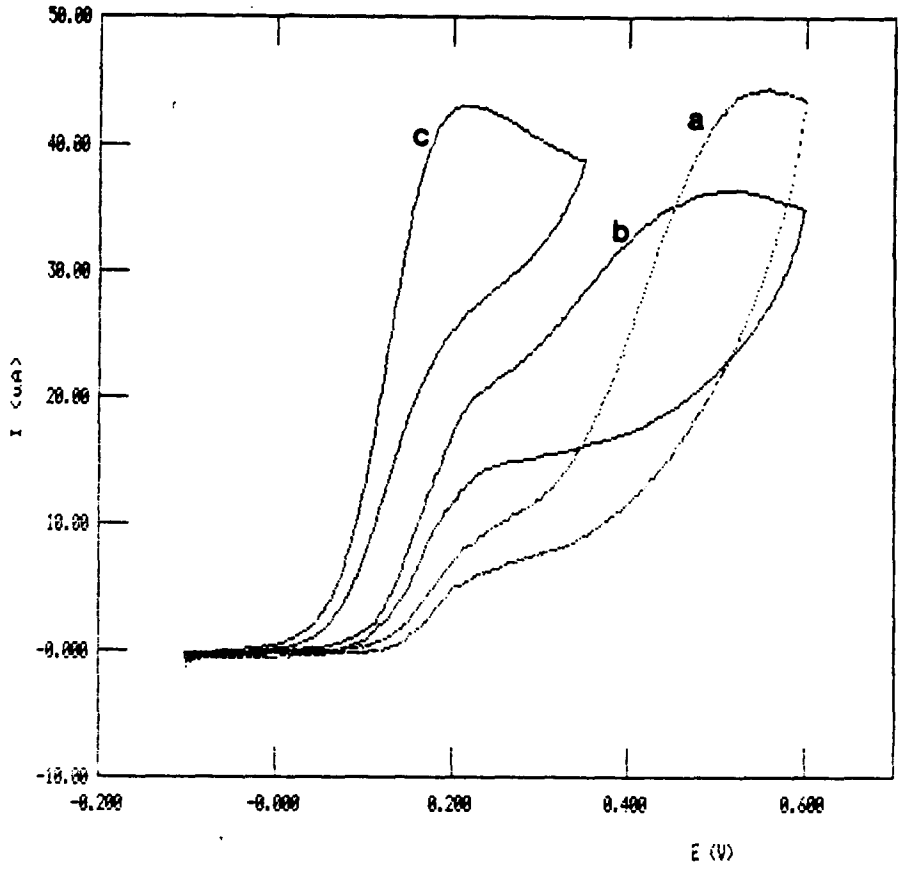

Fig. 3. Cyclic voltammograms of 10 mM ascorbic acid in the presence of 1 mM ferroceneacetic acid at (curve a) pH 2 (0.5 M glycine buffer) (curve b) pH 3 (0.5 M glycine buffer) and (curve c) pH 5 (0.5 M acetic buffer). In all cases 0.1 M $LiClO_4$, was used as the supporting electrolyte. The scan rate was 5 mV $s^{-1}$.

### 3.4. Evaluation of catalytically coupled reaction rates

The theory of stationary electrode voltammetry developed by Nicholson and Shain [10] can be used to analyze a catalytically coupled reaction. The reaction scheme can be described as

$$R - e^- \rightleftharpoons O \qquad Z + O \xrightarrow{k_f} R$$

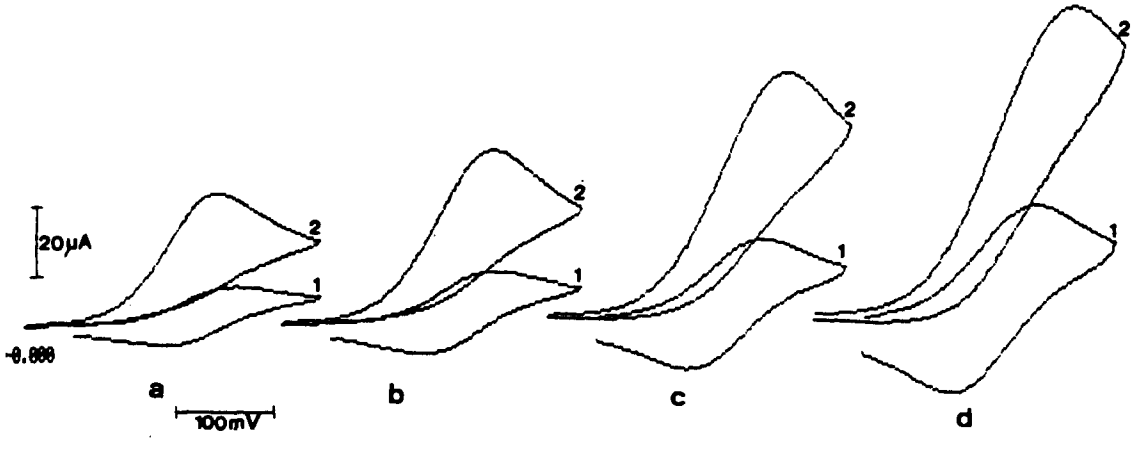

Fig. 4. Cyclic voltammograms of saturated ferrocenemethanol in 0.5 M glycine buffer + 0.1 M LiClO at pH 4 (curves 1; $i_p = i_D$) and 1 + 2 mM ascorbic acid (curves 2; $i_p = i_K$) at a scan rate of (a) 10 mV $s^{-1}$, (b) 20 mV $s^{-1}$, (c) 50 mV $s^{-1}$ and (d) 100 mV $s^{-1}$.

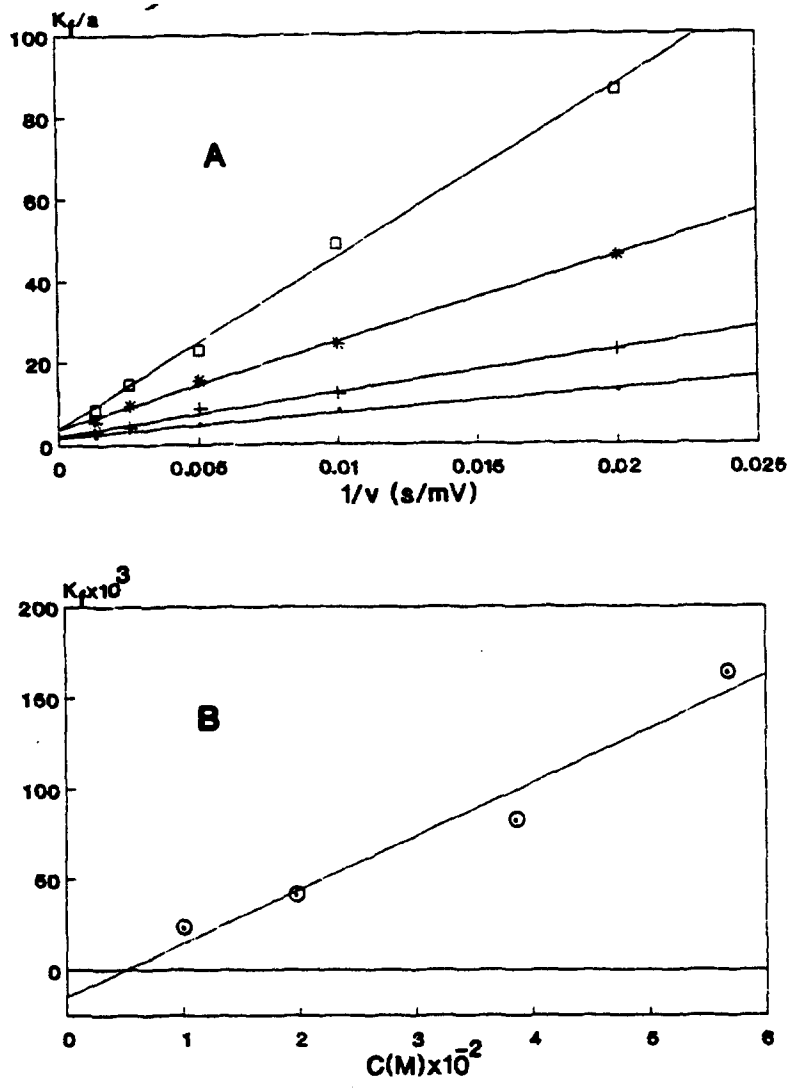

Fig. 5. (A) Kinetic parameter $k_f/a$ as a function of $1/v$ for the interaction between 2 mM ferroceneacetic acid and (●) 9.9 mM, (+) 19.6 mM, (•) 38.5 mM, or (□) 56.6 mM ascorbic acid in acetic buffer (pH 5) at 25 °C. (B) Pseudofirst-order rate constant $k_f$ (calculated from (A)) as a function of the ascorbic acid concentration.

where R and O represent the respective reduced and oxidized forms of the mediators, Z represents ascorbic acid, and $k_f(=k[Z])$ is the pseudofirst-order rate constant. Using experimental values of $i_K/i_D$, the ratio of the kinetically controlled current (in the presence of ferrocene) to the diffusion-controlled current (in the absence of ferrocene) (Fig. 4), a value of $k_f/a$ for each ascorbic acid–ferrocene couple can be derived from the working [10] curve ($i_K/i_D$ vs. $(k_f/a)^{1/2}$, where $a = nFv/RT$, $v$ being the scan rate (V s$^{-1}$). A plot of $k_f/a$ vs. $1/v$ at each ascorbic acid concentration under pseudofirst-order conditions should be linear, with a slope of $RTk_f/nf$ (Fig. 5A). This procedure allows the pseudofirst-order rate constant to be obtained independently of the scan rate. A plot of $k_f$ vs. ascorbic acid concentration is also linear with a slope equal to the second-order homogeneous rate constant $k_s$ for the reaction between the ferricinium derivatives and ascorbic acid (Fig. 5B). The rate constants for the mediators used in this study were determined by the method mentioned above with the ascorbic acid concentration expressed in moles per litre (Table 2).

## 4. Analytical aspects

### 4.1. Determination of ascorbic acid

Linear sweep voltammetry (LSV) of ascorbic acid at a glassy carbon electrode, using fer-

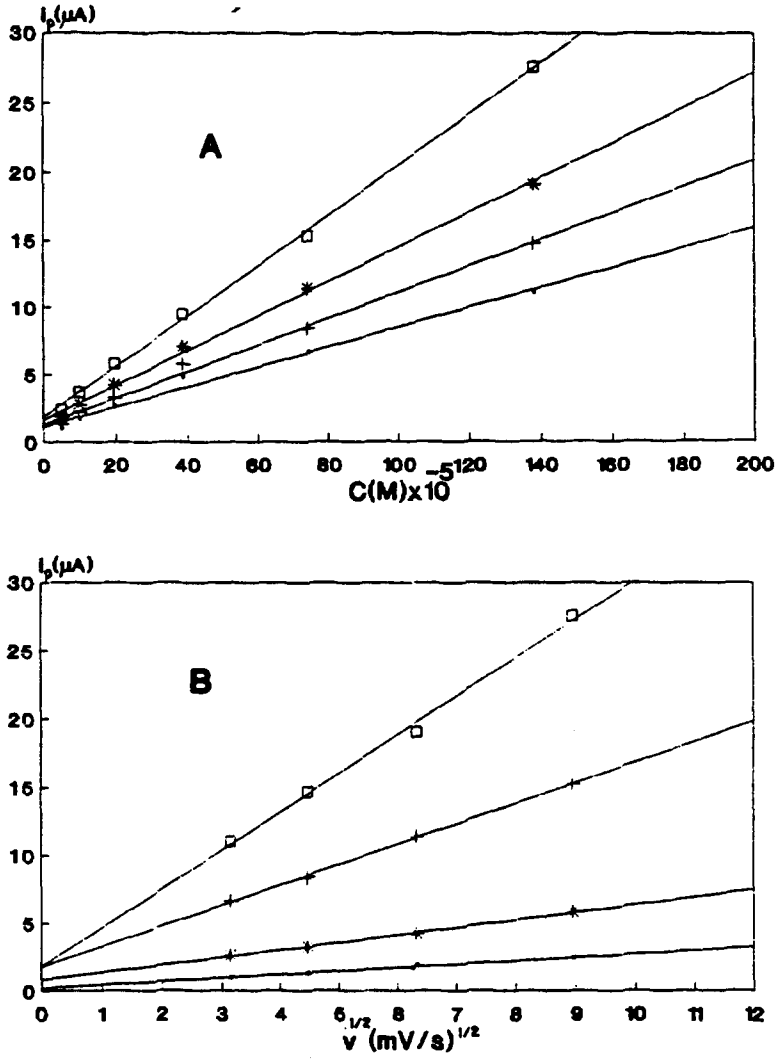

Fig. 6. (A) Dependence of the peak current on the concentration of ascorbic acid at pH 4 for different scan rates: (●) 10 mV s$^{-1}$; (+) 20 mV s$^{-1}$; (*) 40 mV s$^{-1}$; (□) 80 mV s$^{-1}$. The mediator was 0.1 mM ferrocenecarboxylic acid; (B) Dependence of the peak current on the square root of the scan rate for different ascorbic acid concentrations: (●) 4.98 × 10$^{-5}$ M; (*) 1.96 × 10$^{-4}$ M; (+) 7.41 × 10$^{-4}$ M; (□) 1.38 × 10$^{-3}$ M. Solution conditions as in (A)

rocenecarboxylic acid as a convenient mediator, showed that the mediated oxidation current was linearly dependent on the substrate concentration and the square root of the applied potential scan rate (Figs. 6A and 6B). Fig. 6B indicates that the current is diffusion-controlled and the effect of slow charge-transfer kinetics is not apparent. The calibration graph was linear in the range $5 \times 10^{-5}$–$10^{-3}$ M with a correlation coefficient of 0.999. The detection limit, taken as the concentration that gave a signal equal to three times the standard deviation of the blank signal, calculated from the calibration graph, was $2 \times 10^{-5}$ M. Thus the catalytic oxidation of ascorbic acid can readily be applied to the determination of ascorbic acid.

Table 2
Homogeneous second-order rate constant ($k_s$) for the interaction between ascorbic acid and the ferrocene derivatives, determined by cyclic voltammetry

| Ferrocene derivative | $k_s$ (l mol$^{-1}$ s$^{-1}$) | $t$ (°C) | pH |
|---|---|---|---|
| Carboxylic acid | $1.23 \times 10^7$ | 25 | 4.0 |
| Acetic acid | $2.96 \times 10^6$ | 25 | 5.0 |
| Methanol | $7.36 \times 10^5$ | 25 | 4.0 |

### 4.2. Determination of ascorbic acid in the presence of dopamine

Fig. 7, curve a shows that the differential pulse voltammograms of ascorbic acid and dopamine of equal concentration were overlap-

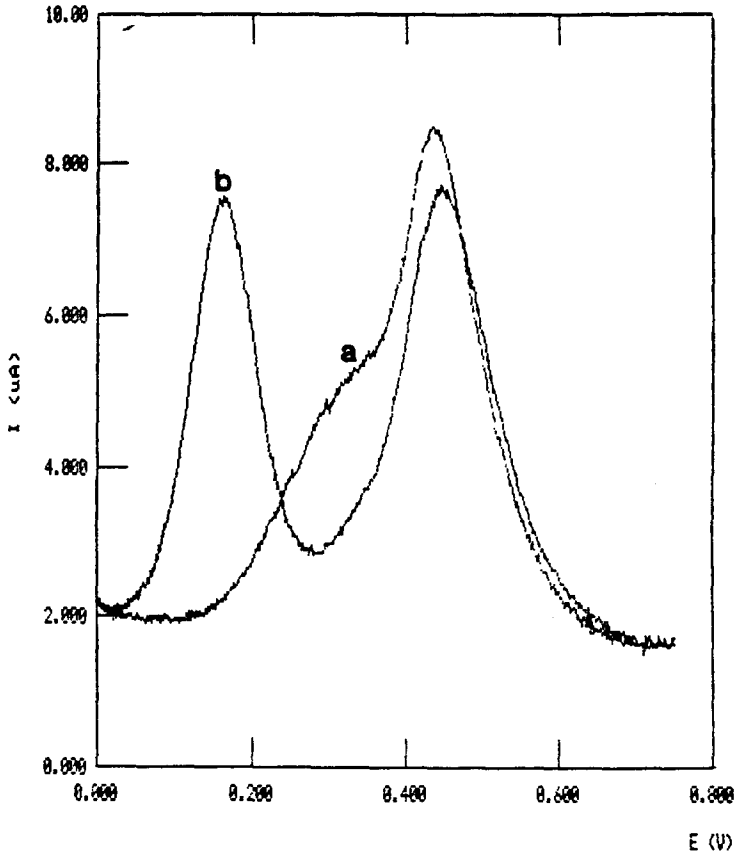

Fig. 7. Differential pulse voltammograms of 0.5 mM ascorbic acid and 0.5 mM dopamine obtained in 0.5 M glycine buffer + 0.1 M $LiClO_4$ at pH 4 in (curve a) the absence and (b) the presence of ferrocenemethanol. Scan rate, 5 mV $s^{-1}$; pulse amplitude, 50 mV; pulse time, 25 ms.

ping, while two distinct differential pulse voltammograms were obtained in the presence of the ferrocene derivative mediators (Fig. 7, curve b) due to the mediated oxidation of ascorbic acid at a sufficiently negative potential. The separation between the two peak potentials for these compounds was the largest in the presence of ferrocenemethanol, and is large enough (about 300 mV) to allow the determination of ascorbic acid in a mixture. However the calibration graph obtained by differential pulse voltammetry was not linear in the concentration range below $5 \times 10^{-4}$ M ascorbic acid. As seen in Fig. 8A, a relatively large separation between the two peaks was observed by linear sweep voltammetry at a stationary glassy carbon electrode under the same solution conditions; therefore the identification and determination of ascorbic acid in the presence of dopamine is feasible. Linear sweep voltammetric peak currents were found to vary linearly with the concentration of ascorbic acid between $5 \times 10^{-5}$ and $1.4 \times 10^{-3}$ M, with a correlation coefficient of 0.996 (inset Fig. 8B).

### *4.3. Determination of dopamine in the presence of a high concentration of ascorbic acid*

One factor that is of importance when applying ascorbic acid catalytically coupled mediators is the ability to separate or resolve voltammetric waves of ascorbic acid and dopamine in a mixture, because it is normally difficult to obtain separate voltammetric waves for these compounds in the presence of each other, largely when ascorbic acid is present at high concentration [8,9].

The voltammetric response of dopamine is hindered by electroactive species, mostly ascorbic acid, which are present at a substantially higher concentration than dopamine. In order to resolve this problem, i.e. to introduce specificity, we have carried out the catalytic oxidation of ascorbic acid using a high concentration of mediator. This may be achieved by the use of ferroceneacetic acid "having both the desired solubility and the catalytic ability" as the most suitable mediator for the mediated oxidation of ascorbic acid at high concentration, at a suffi-

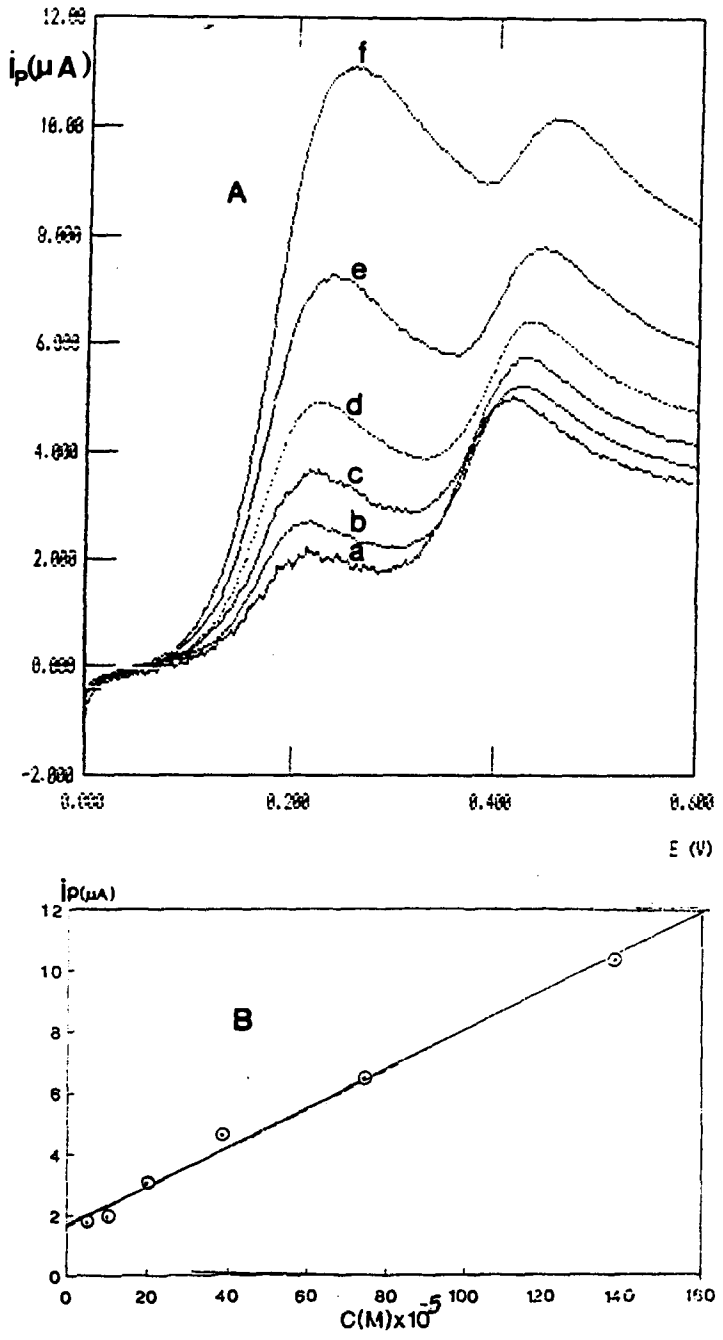

Fig. 8. (A) Linear sweep voltammograms of ascorbic acid of various concentrations: (curve a) $4.98 \times 10^{-5}$ M; (curve b) $9.9 \times 10^{-5}$ M; (curve c) $1.96 \times 10^{-4}$ M; (curve d) $3.85 \times 10^{-4}$ M; (curve e) $7.4 \times 10^{-4}$ M; (curve f) $1.38 \times 10^{-3}$ M; in the presence of dopamine with a fixed concentration of $5 \times 10^{-4}$ M. (B) Plot of linear sweep voltammetric peak current (shown in (A)) vs. the ascorbic acid concentration. Solution conditions: pH 4 (0.5 M glycine buffer), 0.1 M $LiClO_4$, ferrocenemethanol (saturated). Scan rate, 5 mV $s^{-1}$.

ciently lower positive potential compared with that of dopamine oxidation (Fig. 9A). The figure shows that in spite of the fact that the concentration of ascorbic acid is 100 times higher than that of dopamine, a distinct anodic wave associated with the oxidation of dopamine is observed at 0.45 V. As seen in Fig. 9B, differential pulse voltammetric peak currents for dopamine in the presence of ascorbic acid of a fixed concentration vary linearly with concentration (the correlation coefficient was 0.998) between $2 \times 10^{-4}$ and $1.4 \times 10^{-3}$ M. The LSV technique was less sensitive.

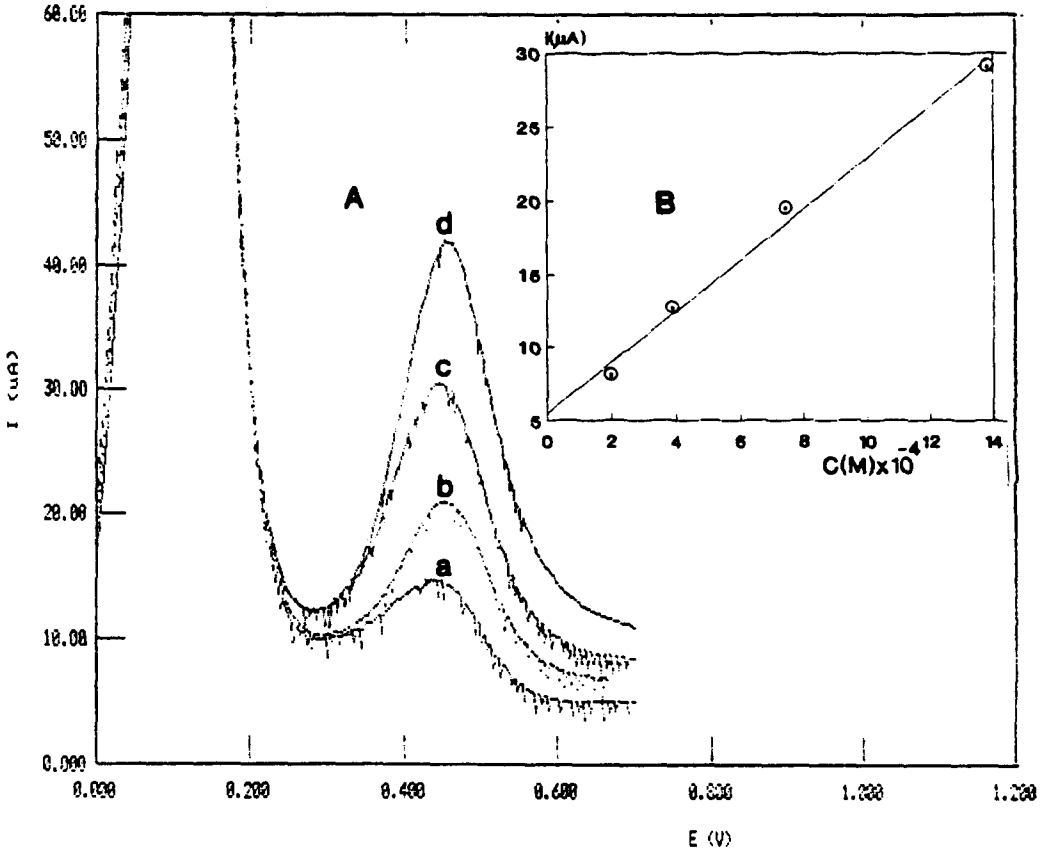

Fig. 9. (A) Differential pulse voltammograms of dopamine of various concentrations: (curve a) $1.96 \times 10^{-4}$ M; (curve b) $3.85 \times 10^{-4}$ M; (curve c) $7.41 \times 10^{-4}$ M; (curve d) $1.38 \times 10^{-3}$ M; in the presence of ascorbic acid with a fixed concentration of $2 \times 10^{-2}$ M. Solution conditions: $5 \times 10^{-3}$ M ferroceneacetic acid, 0.1 M $LiClO_4$ and pH 5 (0.5 M acetate buffer). Scan rate, 10 mV $s^{-1}$; pulse amplitude, 50 mV; pulse time, 25 ms. (B) Plot of differential pulse voltammogram peak current shown in (A) vs. the dopamine concentration.

## 5. Conclusion

Some ferrocene derivatives, soluble in acidic aqueous solutions, exhibit reversible electrochemistry at the glassy carbon electrode. Carboxylic, acetic and methanol ferrocene derivatives can act as mediators in the electrocatalytic oxidation of ascorbic acid. The analysis of catalytically coupled reactions between electrogenerated ferricinium derivatives and ascorbic acid reveals that the highest second-order rate constant ($k_s$) belongs to ferrocene monocarboxylic acid. In the presence of the ferrocene mediators, the catalytic peak currents are linearly dependent on the ascorbic acid concentration for various potential scan rates. The mediated oxidation of ascorbic acid in the presence of ferrocenemethanol as the most convenient mediator occurred at a sufficiently less positive potential than for dopamine oxidation and allowed the determination of ascorbic acid in a mixture. Dopamine can be determined in the presence of ascorbic acid of a fixed concentration 100 times higher than that of dopamine, using ferroceneacetic acid as a suitable mediator for this purpose.

**Abstract**

The application of probe ion fluorimetry has succeeded in the microdetermination of six aminoglycoside antibiotics: neomycin, streptomycin, gentamicin, tobramycin, amikacin and kanamycin as sulfate salts in pure form and in some pharmaceutical preparations. The method is based on the reaction of $Eu^{3+}$ ions with aminoglycosides through amino and hydroxy groups. Such interactions enhance the intensity of the 616 nm fluorescence emission of the $Eu^{3+}$ ion. The fluorescence at 592 nm comes from a non-hypersensitive transition and is not affected by the ligand which is bound to the probe ions. The intensity ratio $R$, defined as $I_{592}/I_{616}$ was used to determine the amount of free and bound europium ions. A linear relationship between bound europium ions and aminoglycoside was found within the concentration ranges 20–100 ppm for neomycin, 5–60 ppm for streptomycin, and 10–70 ppm for gentamicin, tobramycin, amikacin, and kanamycin as sulfate salts. The percentage recoveries ranged from 99.22 to 101.07, with standard deviations ranging from $\pm 1.5$ to $\pm 4.38$. The relative stability constants ranged from $5 \times 10^3$ to $2 \times 10^4$. The optimum reaction conditions were studied and the results obtained compared favourably with the fluorimetric method using fluorescmine reagent.

## 1. Introduction

Numerous procedures are available for the determination of aminoglycoside antibiotics such as spectrophotometry [1–4], densitometry [5], fluorimetry [6,7], polarography [8], gas chromatography [9], radioimmunoassay [10], HPLC [11,12], MS [13], and NMR [14]. Many of these methods have been reviewed [15–19]. The official methods usually involve microbiological procedures [20–22].

Lanthanide ion probe spectrofluorometry (LIPS) was introduced in 1979 by Horrocks and Sundnick [23]. This technique employs two emission lines of $Eu^{3+}$ located at 592 nm and 616 nm. The 616 nm emission line is produced by a hypersensitive transition [24], $^5D_0 \rightarrow {}^7F_2$, which is normally a forbidden transition, but interaction with ligands makes the transition allowed and enhances the intensity of its emission. The fluorescence at 592 nm comes from a non-hypersensitive transition and is not affected by the ligand which is bound to the probe ion [25]. Thus, the ratio of these intensities can be used to determine free and ligated $Eu^{3+}$.

The applications of probe ion spectroscopy in pharmaceutical analysis are limited in spite

of the availability of the method for the determination of many pharmaceutical compounds. Europium ions have been used for the fluorimetric determination of tetracycline [26,27], diclofanec sodium [28] and theophylline [29] in blood serum and in pharmaceutical preparations. In this article, we describe a spectroscopic method for the determination of aminoglycoside antibiotics in pure form and in pharmaceutical formulations using the LIPS spectrofluorometric technique.

## 2. Experimental

### 2.1. Apparatus

A Lambda Physic EMG 102 XeCl excimer laser and a FL 3002 tunable dye laser were used in tandem to supply a high intensity tunable source. The average output of the XeCl excimer was 1.6 W (10 Hz repetition rate) at 308 nm. A tunable ultraviolet emitting dye laser was used to provide an excitation source of 394.3 nm, which corresponds to a resonant absorption transition of the Eu metal ions. The Eu fluorescence was collected and frequency analyzed with a Spex 1877 triple monochromator. The fluorescence was detected by a charge coupled detector (ccd 9000 Photometric Ltd.). The recorded curves were fitted with Lab Calc (Galactic Software) using a gaussian model. The areas under the two peaks at 592 nm and 616 nm were integrated and the ratio of the two peaks was taken as the $R$ value of the sample.

### 2.2. Materials

Neomycin sulfate, streptomycin sulfate, gentamicin sulfate, tobramycin sulfate, amikacin sulfate and kanamycin sulfate were obtained from Sigma and the various dosage forms from commercial sources. Europium(III) chloride was from Aldrich. Hydrochloric acid, chloroform and ammonia solutions were Baker analyzed reagents.

### 2.3. Reagents

All chemicals were analytical reagent grade. The following reagents were used:

(1) Stock solutions of aminogycosides were freshly prepared as 0.5 mg $ml^{-1}$ in deionized water.

(2) $1E^{-4}$ M, $1E^{-5}$ M and $2.5E^{-5}$ M $Eu^{3+}$ ion solutions were prepared by dissolving an appropriate amount of europium chloride hexahydrate in 1 l of deionized water, and adjusting to pH 5.5 using hydrochloric acid solution.

(3) Aqueous solutions of pH 2, 5.5, 8, and 10 were prepared by serial dilution of hydrochloric acid and sodium hydroxide with deiionized water, and pH adjustment hydrochloric acid solution or sodium hydroxide solution using a Fisher pH meter.

### 2.4. Procedure

*A. Calibration lines*

An aliquot volume of standard aminoglycoside antibiotic solution equivalent to 0.2–1.0 mg neomycin sulfate, 0.05–0.6 mg streptomycin sulfate, and 0.1–0.7 mg gentamicin sulfate, tobramycin sulfate, amikacin sulfate and kanamycin sulfate was transferred into a 10 ml calibrated flask. 1 ml of $2.5E^{-5}$ M $Eu^{3+}$ solution was added to the neomycin sulfate and streptomycin sulfate, 1 ml of $1E^{-4}$ M $Eu^{3+}$ solution was added to the gentamicin sulfate and tobramycin sulfate, and 1 ml of $1E^{-5}$ M $Eu^{3+}$ solution was added to the amikacin sulfate and kanamycin sulfate. 2 ml of a hydrochloric acid solution of pH 5.5 was added and brought to volume with deionized water. The fluorescence was measured from 576 to 633 nm (excitation at 394.3 nm). The curves were integrated using a gaussian model and the area under the two peaks at 592 nm and 616 nm was taken as the $R$ value of the sample.

*B. For injections*

An accurate volume of the mixed contents of three vials, equivalent to 10 mg of drug, was transferred into a CM (carboxylic acid) ion exchange resin column [10,31] loaded with water–hydrochloric acid solution pH 2, and then eluted with 25 ml of water–hydrochloric acid solution pH 2. The column was washed with 25 ml of pH 7 deionized water. The elution and washing water were discarded. Aminoglycoside was eluted using 30 ml of aqueous pH 11 solution and 10 ml of deionized water into a 50 ml calibrated flask. The solution was mixed well and its pH adjusted to about 5.5 using hydrochloric acid solution; it was brought to volume with deionized water. 2 ml of this solution was assayed as described in the previous section.

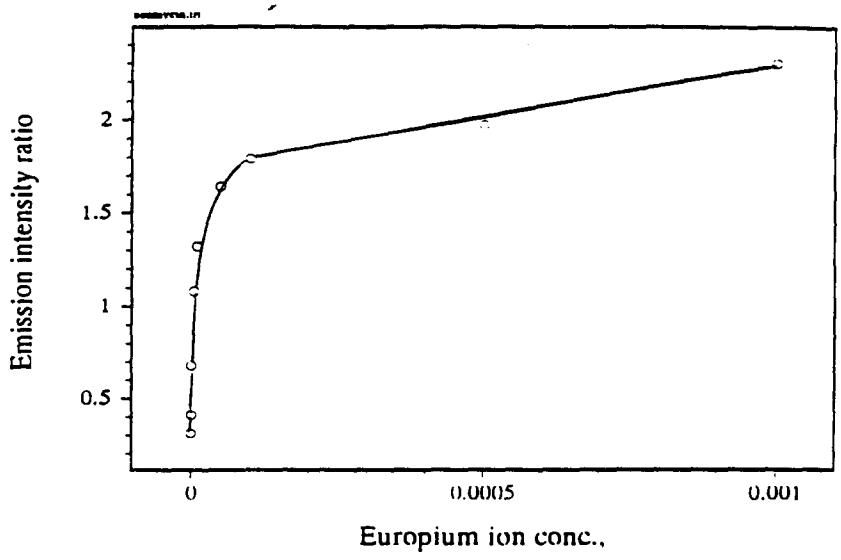

Fig. 1. Effect of $Eu^{3+}$ ions on the emission ratio of $1 \times 10^{-4}$ M neomycin sulfate.

*C. For tablets*

Twenty tablets were weighed and powdered. To the quantity of powder equivalent to 500 mg was added 10 ml of deionized water, and the mixture sonicated for 20 min. It was then filtered into a 100 ml calibrated flask, the powder washed three times each with 5 ml water, and the combined filtrate mixed well and brought to volume with deionized water. 2 ml of the filtrate was transferred into a CM ion exchange column and the procedure was completed as described in the previous section.

*D. For ointment*

The contents of two bottles of ointment were weighed and mixed. A quantity of ointment equivalent to 20 mg of drug was transferred into a separating funnel, and 50 ml of ether was added. Gentamicin was extracted three times with pH 8 water. The pH of the extract was adjusted to pH 5.5 using hydrochloric acid solution and brought to volume (100 ml) with deionized water. 2 ml of this solution was assayed as described in Section 2.4 A.

## 3. Results and discussion

### *3.1. Lanthanide ion probe*

In a study of any probe, the most fundamental and necessary characteristic is the ability to determine quantitatively the concentration of the free and bound metal ions simultaneously.

The use of lanthanide ions as fluorescent probes has been well documented [32]. The europium metal ion has been the lanthanide of choice in most applications and its spectral features are widely documented [33]. This speciation information is uniquely encoded in the experimental $Eu^{3+}$ profile. Fig. 1 shows a typical spectral titration plot of $Eu^{3+}$ using $1E^{-4}$ M aminoglycoside (neomycin sulfate). In the early stages of the titration process there is only a small amount of fluorescent metal probe ion compared to the available binding sites, and hence the majority of metal ions are bound to the ligand. Consequently, the hypersensitive emission band at 616 nm is larger than the non-hypersensitive band at 592 nm, and the intensity ratio $R$ is small and close to the lower limit value, $L_S$. As the titration progresses the relative amount of total bound species gradually increases. Consequently, the intensity ratio, $R$, gradually increases as more metal ions are added to the system. At the end of titration the ratio $R$ is close to its upper limit value, $L_B$, and the concentration of $Eu^{3+}$ is much greater than the concentration of ligand. The optimum concentration of $Eu^{3+}$ ions in a such study is that required to produce a ratio value $R$ between $L_S$ and $L_B$. A ratio value of around unity has been shown to be the most sensitive for this type of measurement [25,34]. All the aminoglycoside antibiotics behave similarly to neomycin sulfate, except in the amount of $Eu^{3+}$ ions added which is due to the differences in the molecular weights.

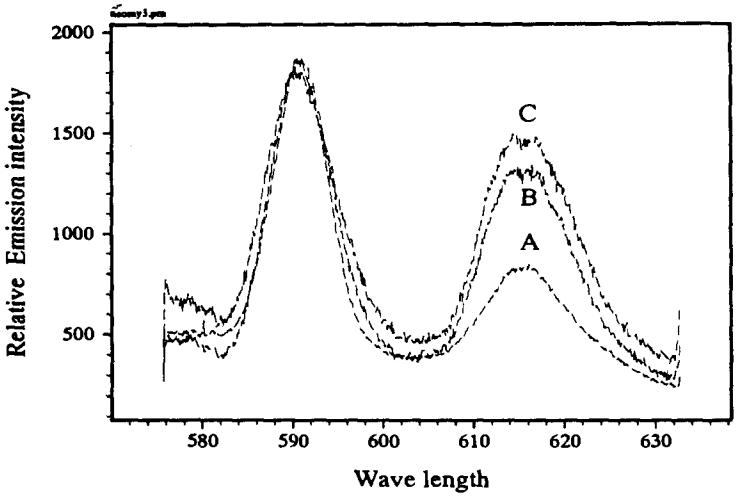

Fig. 2. Emission spectra of 1 ml of $2.5E^{-5}$ M of europium ions: (A) without neomycin sulfate; (B) in the presence of 600 μg neomycin sulfate; and (C) in the presence of 900 μg neomycin sulfate, in a total volume of 10 ml.

Suitable $Eu^{3+}$ ion concentrations for such a study were found to be $2.5E^{-5}$ M Eu(III) ions for the determination of neomycin sulfate and streptomycin sulfate, $1E^{-5}$ M $Eu^{3+}$ for the determination of gentamicin sulfate and tobramycin sulfate, and $1E^{-4}$ M $Eu^{3+}$ for the determination of amikacin sulfate and kanamycin sulfate. Fig. 2 shows emission spectra of $Eu^{3+}$ ions in the presence and absence of neomycin sulfate.

### 3.2. *Effect of buffer and pH*

Fig. 3 shows that the complexes formed were pH dependent and must be controlled between pH 5 and 6. Acidic buffers such as acetate, phosphate, MOPS, MES and THAM buffer systems were not suitable in such a study owing to the formation of europium salts or complexes which interfered with the measurement; such observations have been made in our laboratory [25]. At a pH below 5, the competition between the proton and $Eu^{3+}$ will decrease the formation of Eu–aminoglycoside complex, and in neutral solution $Eu(OH)^{2+}$ is formed which interferes with the measurement. Adjusting the initial pH of the $Eu^{3+}$ solution to pH 5.5 and using 2 ml of aqueous hydrochloric acid solution at pH 5.5 kept the pH of the mixtures between 5 and 6.

### 3.3. *Molar ratio*

Eu is bound with aminoglycoside in a 1:1 molar ratio. Fig. 4 shows the spectroscopic titration of 1 ml of $1 \times 10^{-4}$ M neomycin sulfate with $1 \times 10^{-4}$ M $Eu^{3+}$ ions.

### 3.4. *Effect of time and temperature*

The complex formation between $Eu^{3+}$ ions and aminoglycoside was almost instantaneous, as a stable ratio was produced within 5 min and the complexes were stable for at least 24 h. Temperature had little effect on the complex formation and its stability, so the reaction was carried out at ambient temperature.

### 3.5. *Effect of ionic strength*

Ionic strength is a factor that sometimes cannot be neglected. The effect of ionic strength on the spectral titration plot was studied by varying the concentration of the background electrolyte, sodium chloride. The choice of sodium chloride was based on the fact that the $Na^+$ ion is very weakly bound, if at all, to the aminoglycoside binding sites, and $Cl^{-1}$ is already in the system as a counter ion that comes from dissolving $EuCl_3$. Three titration plots correspond to 0.0, 0.01 and 0.1 M sodium chloride added as background electrolyte. The addition of background electrolyte will decrease the total concentration of bound species of the probe ion. It should be emphasized here that this decrease is not due to the competition effect of sodium ion (similar to proton competition) to occupy the same set of aminoglycoside sites, but purely due to electrostatic forces as previously reported with humic acid substances [34].

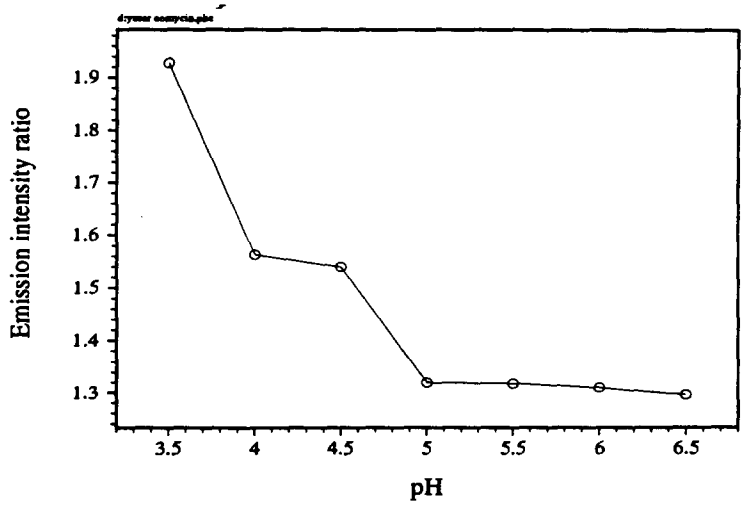

Fig. 3. Effect of pH on emission ratio of 50 μg ml$^{-1}$ neomycin sulfate and 1.00 ml of 2.5E$^{-5}$ M $Eu^{3+}$ ions.

## 4. Performance characteristics

The investigated aminoglycosides possess amino and hydroxy groups which can form complexes with metal ions. Evangelista and Schapoval [1] have determined these compounds by spectrophotometric determination of their blue complexes with copper ions at 634 nm.

Aminoglycoside antibiotics complex $Eu^{3+}$ ions, and such ligation leads to a hypersensitive transition of $Eu^{3+}$ ions, and such ligation leads to a hypersenstive transition of $Eu^{3+}$ ions, $^5D_0 \rightarrow {}^7F_2$ (616 nm). These hypersensitive transitions are specific absorption or emission transitions of lanthanide ions that are extremely sensitive to ligation. The intensity of a hypersensitive transition is enhanced in the metal–ligand complex relative to that transition in aquo ions. Experimentally, this is observed by making the concentration of $Eu^{3+}$ ions small relative to the aminoglycoside concentration, so that the majority of the metal ions are complexed with aminoglycosides. Such effects are most obvious from the observation of several emissions of $Eu^{3+}$ ions with neomycin sulfate concentrations (Fig. 2). The absolute emission intensity is not important here as we are concerned only with the change in the integrated emission ratio $R$ ($I_{592}/I_{616}$) due to the aminoglycoside antibiotics. These $R$ values decrease upon the addition of antibiotics owing to the enhanced emission at 616 nm relative to the emission at 592 nm. The 592 nm emission is not effected by ligation.

Susetyo and co-workers [25,35] have developed a statistical model for the distribution of binding sites in humic acid. This model was applied to study the spectral titration plot generated by lanthanide ion probe spectroscopy. They expressed the free and bound $Eu^{3+}$ ions as a function of experimental parameters. The free $Eu^{3+}$ ions could be expressed as

$$M = \frac{C_M L_B (R - L_S)}{R(L_B - L_S)} \quad (1)$$

where $M$ is the concentration of free metal ions, $C_M$ is the total concentration of metal added, $L_B$ is the ratio of the two Eu peaks at 592 nm and 616 nm when the concentration of $Eu^{3+}$ was very large with respect to ligand concentration, and $L_S$ is the ratio when the $Eu^{3+}$ concentration was very small with respect to the ligand concentration. Table 1 shows $L_B$ and $L_S$ for each aminoglycoside. $R$ is the ratio $I_{592}/I_{616}$ of the free and bound metal species which was quantitatively determined from the experimentally observed parameters.

The bound $Eu^{3+}$ ion concentration could be expressed as

$$ML = C_M - M \quad (2)$$

Calibration lines were calculated by plotting $ML$ against the concentration of aminoglycoside. It was found that there was a linear relation between the concentration of aminoglycoside and the concentration of bound $Eu^{3+}$ ions within the ranges shown in Table 1, with standard deviations from 4.338 to 1.50 ppm.

Table 1 also shows regression equations and correlation coefficients of aminoglycosides us-

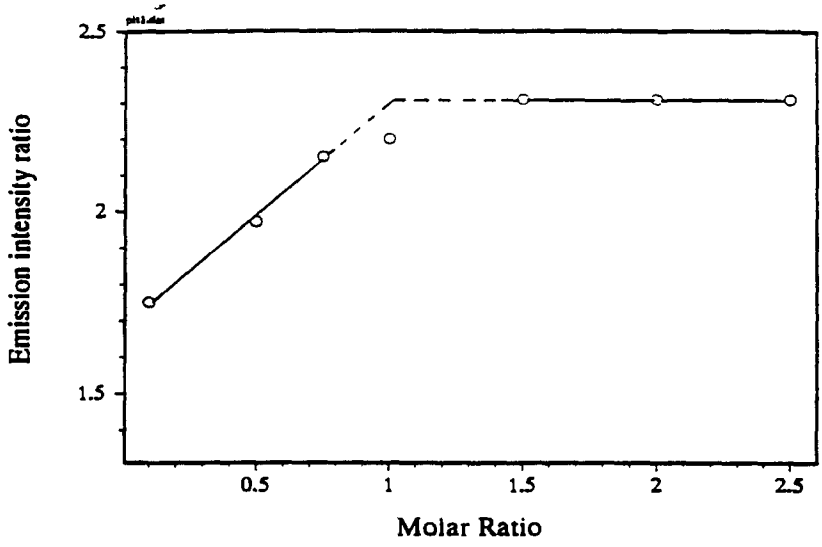

Fig. 4. Spectroscopic titration of 1 ml of $1 \times 10^{-4}$ M neomycin sulfate with $1 \times 10^{-4}$ M $Eu^{3+}$ ions.

ing the proposed method. This has proved to be an accurate method for the determination of aminoglycosides. As compared with conventional organic fluorescent probes [6,7], fluorescent lanthanide chelates can offer several advantages. They have narrow-banded emission lines well distinguished from any disturbing background. Chelates have exceptionally wide Stokes' shifts, over 200 nm, while with fluorescamine it is only 50–70 nm. In addition to spectral resolution, their emission can be distinguished from any organic background interference owing to the very long fluorescence decay time ($\sim 110$ μs) associated with $Eu^{3+}$ fluorescence which makes them an ideal choice for a fluorimetric system [36].

Table 2 shows the assay results of aminoglycosides by the proposed method and fluorescamine fluorimetric methods [6]. The proposed method, when compared to the official microbial assays, offers advantages with regards to rapidity, simplicity and precision, so we compared these results to the fluorimetric method using fluorescamine. The calculated student's $t$ and variance ratio $F$ tests were less than the respective tabulated one at $P = 0.05$, so the results obtained by the proposed method have proved to be in good agreement with those obtained by the reference fluorimetric method.

Results of the determination of aminoglycosides in different dosage forms by the probe

Table 1
Regression data, correlation coefficients, stability constants of Eu–aminoglycoside complexes, concentrations of Eu used for calibration, and concentration ranges of aminoglycoside antibiotics determined by the proposed spectroscopic probe ion method

| Aminoglycoside sulfate salt | Regression data [a] | | | | | Conc. [b] range | $L_B$ | $L_S$ |
|---|---|---|---|---|---|---|---|---|
| | $C_0$ | $C_1$ | $r$ | $k$ | $C_M$ | | | |
| Neomycin | $3.59E^{-8}$ | $4.77E^{-9}$ | 0.99681 | $2.1E^{4}$ | $2.5E^{-5}$ | 20–100 | 2.30 | 0.31 |
| Streptomycin | $1.08E^{-9}$ | $1.91E^{-8}$ | 0.99983 | $1.3E^{4}$ | $2.5E^{-5}$ | 5–60 | 2.30 | 0.31 |
| Gentamicin | $4.78E^{-7}$ | $2.82E^{q-8}$ | 0.99086 | $3.1E^{3}$ | $1.0E^{-4}$ | 10–70 | 2.55 | 0.61 |
| Tobramycin | $7.12E^{-7}$ | $4.29E^{-8}$ | 0.99892 | $2.5E^{3}$ | $1.0E^{-4}$ | 10–70 | 2.55 | 0.61 |
| Amikacin | $1.13E^{-7}$ | $2.48E^{-9}$ | 0.99857 | $3.5E^{3}$ | $1.0E^{-5}$ | 10–70 | 2.17 | 0.47 |
| Kanamycin | $1.11E^{-7}$ | $3.52E^{-9}$ | 0.99935 | $5.7E^{3}$ | $1.0E^{-5}$ | 10–70 | 2.17 | 0.47 |

$C_0$ is the intercept, $c_1$ is the slope, $r$ is the correlation coefficient, $K$ is the stability constant of the Eu–aminoglycoside complex, $C_M$ is the molar concentration of $Eu^{3+}$ ions used for calibration, $L_B$ is taken to be the ratio of the two $Eu^{3+}$ peaks in the absence of aminoglycoside, $L_S$ is taken to be the ratio when the $Eu^{3+}$ concentration was very small with respect to a large ligand concentration.

[a] Average of at least seven triplicate determinations within the concentration range.

[b] Concentration ranges were calculated in ppm.

Table 2
Assay results of aminoglycoside antibiotics in bulk using the proposed method and the reference method [6]

| Aminoglycoside sulfate salt | % Recovery [a], ±SD | |
|---|---|---|
| | Proposed method | Reference method [b] |
| Neomycin | 100.16 ± 1.05<br>$t$ = 0.175 (2.179) [c] | 100.04 ± 1.48<br>$F$ = 1.987 (4.28) [c] |
| Streptomycin | 98.61 ± 3.57<br>$t$ = 0.421 (2.179) [c] | 99.25 ± 1.86<br>$F$ = 3.684 (4.28) [c] |
| Gentamicin | 100.82 ± 2.30<br>$t$ = 1.660 (2.179) [c] | 99.00 ± 1.82<br>$F$ = 1.689 (4.28) [c] |
| Tobramycin | 100.26 ± 2.23<br>$t$ = 0.481 (2.179) [c] | 99.68 ± 2.28<br>$F$ = 1.045 (4.28) [c] |
| Amikacin | 98.81 ± 4.52<br>$t$ = 0.500 (2.179) [c] | 97.82 ± 2.66<br>$F$ = 2.875 (4.28) [c] |
| Kanamycin | 100.19 ± 1.50<br>$t$ = 0.956 (2.179) [c] | 99.14 ± 2.49<br>$F$ = 2.756 (4.28) [c] |

[c] Values in parentheses are theoretical values at $P = 0.05$.

ion method and the fluorescamine fluorimetric method are presented in Table 3. The proposed procedure was selectivity enhanced by an ion exchange resin resolution of the interferences, since it is well known that $Eu^{3+}$ ions are strongly bound by charged oxygen donor atoms such as carboxylic or phenolic groups [29]. Ingredients other than aminoglycosides, such as additives, stabilizers and antioxidants of tablets, ampoules and ointments, are removed by this procedure and do not interfere with the recommended method. They were separated from aminoglycosides in an ion exchange resin (carboxylic acid resin) by aqueous buffer at pH 2 [30,31]. The proposed procedure is as sensitive as the fluorescamine fluorimetric method [6], and gives good agreement with it. The proposed method is simpler and more rapid, and the reaction products are more stable than for conventional fluorometric methods. Moreover, the determination bound $Eu^{3+}$ using the relative intensity ratio $R$ as a function of the concentration of aminoglycoside antibiotics is more reliable, and has less experimental error (about ±5%), than that using the absolute emission intensity in conventional organic fluorescent methods. In conventional organic fluorometric methods the absolute emission value is strongly effected by many systemic errors due to blank and analyte interferences. Moreover, the absolute emission intensity is highly dependent on the intensity of the excitation source, the quantum yield of the complexes which is low compared to the $Eu^{3+}$-complex (≈0.18) [37], and the detector used for the measurement rather than the fluorescence of the analyte [30]. Thus, the proposed procedure can be used for routine analysis and quality control of aminoglycosides in pharmaceutical preparations.

Table 3
Assay results of aminoglycoside antibiotics in some pharmaceutical preparations by the proposed method and the reference method

| Drug | % Recovery, ±SD [a] | |
|---|---|---|
| | Proposed method | Reference method [b] |
| Neomycin Tablets 500 mg (Memphis Co., Egypt) | 100.99 ± 0.36 | 98.98 ± 2.16 |
| Gentamicin Oint., 0.1% (Memphis Co., Egypt) | 104.74 ± 1.6 | 97.54 ± 1.98 |
| Gentamicin Amp. 20 mg (Memphis Co., Egypt) | 101.22 ± 2.39 | 98.23 ± 1.71 |

[b] Fluorometric determination of aminoglycoside antibiotics using fluorescamine [6].

## 5. Conclusion

From the foregoing discussion, the $Eu^{3+}$ probe ion fluorimetric technique has been applied to the determination of six aminoglycosides in pure form and in pharmaceutical preparations. Ion exchange was carried out for resolution of aminoglycoside antibiotics from other additives such as EDTA, sodium citrate, phenol, and other injection and tablet additives.

# Lead determination at the ppb level using stopped-flow FIA

Mingshu Li, G.E. Pacey *

*Department of Chemistry, Oxford, OH 45056, USA*

Received 16 January 1995; revised 12 May 1995; accepted 12 May 1995

**Abstract**

A flow-injection-based kinetic method for the determination of lead ions was developed. In this method, resazurin was reduced to resorufin by sulfide and lead ions. The method has a detection limit of 1 ppb with a relative standard deviation of 5.2% at the 20 ppb level. Interferences can be removed by prior extraction.

*Keywords:* Flow injection analysis; Kinetic methods; Lead determination; Resazurin; Water analysis

## 1. Introduction

Adverse health effects from exposure to lead are now recognized to be among industrialized society's most significant health problems [1]. Drinking water is the major source of lead exposure for the general population. Lead seldom occurs naturally at a level higher than 5 $\mu g\,l^{-1}$ in surface water supplies such as rivers and lakes [2]. Lead enters drinking water primarily as a result of the corrosion, or wearing away, of materials containing lead in the water distribution system and household plumbing [3]. USEPA has set strict regulations on lead concentrations in drinking water. Effective from December 1992, the maximum permissible concentration of lead in drinking water is 50 $\mu g\,l^{-1}$ [3]. EPA requires "lead action" if the concentration of the lead exceeds 15 $\mu g\,l^{-1}$ in more than 10% of tap water samples collected during any monitoring period [3]. Improved, more-cost-effective automated methods for lead determinations are needed.

Current lead determinations at the ppb–ppm levels [4–10] are performed using preconcentration techniques followed by atomic absorption spectrophotometry (AAS) with reported detection limits from 0.08 [11] to 1 $\mu g\,l^{-1}$. Unfortunately, these methods are problematic when a large number of samples have to be determined, since the preconcentration step is usually too labor- and time-consuming.

Other techniques used for lead determinations include isotope dilution GC–MS [12], flow-injection Donnan dialysis–inductively coupled plasma-atomic emission spectrometry [13,14], anodic stripping voltammetry [15–17], potentiometry [18], laser atomic fluorescence spectrometry [19,20], the flow injection analysis (FIA)-based crown ether dicyclohexyl-18-crown-6 extraction method [21], the FIA-based 4-(2-pyridylazo)resorcinol (PAR) complex method [22], and the FIA-based 5,10,15,20-tetra(4-*n*-sulfoethylpyridinium)porphyrin (T(4-sp)p method [23]. Kinetic methods include catalytic persulfate oxidation of hematoxylin [24] and reduction of resazurin by sodium sulfide [25].

Given the variety of techniques and methods that exists, there is not much point in develop-

* Corresponding author. Fax: (513)529-7284.

*SSDI* 0039-9140(95)01644-9

ing another method unless it can yield a significantly higher sampling frequency, lower detection limit, and easier operation without preconcentration. An FIA-spectrophotometric-based method is suggested. Therefore, the objective of this research was to develop a simple, reliable FIA method for lead ion determination in water without preconcentration with a detection limit of 1 ppb and a relative standard deviation of less than 10% at the 20 ppb level. Resazurin chemistry with sufilde using lead ions as the catalyst was investigated for this work [25].

## 2. Experimental

### 2.1. Reagents

All reagents were reagent grade and the water was deionized triply distilled with 18 megohm–cm resistance.

A resazurin stock solution was prepared by dissolving 0.1000 g of resazurin (Aldrich Chemical Company, Inc.) into 100 ml of water. The working resazurin solutions were made by appropriate dilution of the stock solution, which was stable for several months.

The sodium sulfide stock solution was made by dissolving 20 g of sodium sulfide (Fisher Scientific) in 100 ml of water. This solution had to be freshly prepared daily. The working sodium sulfide solutions were made by diluting the stock solution appropriately.

The stock sodium hydroxide solution was prepared by dissolving 200 g of sodium hydroxide in 1000 ml of water.

All three reagent solutions were heated in a hot-water bath for 30 min and were cooled to room temperature before use.

A 1% nitric acid solution was prepared by diluting 10 ml of high-purity (low metal content) nitric acid to 1 l with water.

Phosphate buffer solution was prepared by dissolving 3.4 g of monobasic potassium phosphate in 100 ml of water and adjusting the solution pH to 7 by adding sodium hydroxide.

Dimethylglyoxime solution was prepared by dissolving 0.1000 g of dimethylglyoxime (Fisher Scientific) in 100 ml of absolute ethanol.

A quinolin-8-ol–chloroform extraction solution was prepared by dissolving 14.5 g of quinolin-8-ol in 1 l of chloroform.

An aqueous lead standard stock solution was prepared by dissolving 1.5985 g of lead nitrate (Fisher Scientific) with 20 ml of concentrated nitric acid and diluting to 1 l. Working solutions were prepared by appropriate dilution of the stock solution.

### 2.2. Equipment

The manifold used for lead determination is shown in Fig. 1. All tubing was 0.5 mm i.d. Teflon and all pumping tubes were Tygon. A Tecator model 5020 flow injection analyzer was used throughout the investigation.

The detector was a Waters 991 M photodiode-array spectrophotometer controlled by a Millennium 2010 chromatography manager computer software system. The detecting system was able to scan the spectra between 200 and 800 nm and measure the absorbance at the desired wavelength and time. For a specific peak, it was able to provide peak height or area.

### 2.3. Glassware

All the glassware was cleaned with detergent, rinsed with tap water followed by distilled water, soaked overnight in a nitric acid (1:2, v/v) bath, carefully rinsed with a small amount of Norchromix (15% in concentrated sulfuric acid), then rinsed with distilled water and finally with triply distilled deionized water.

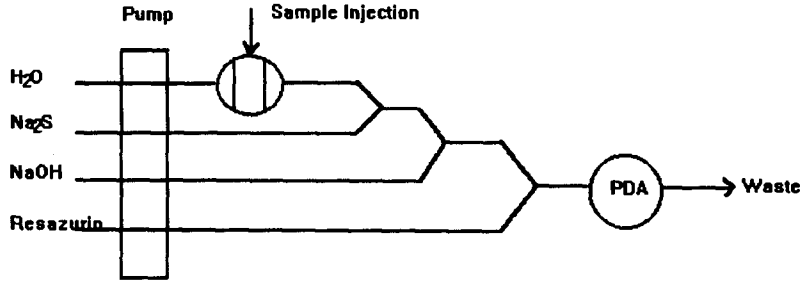

Fig. 1. Diagram of flow injection manifold used in this investigation.

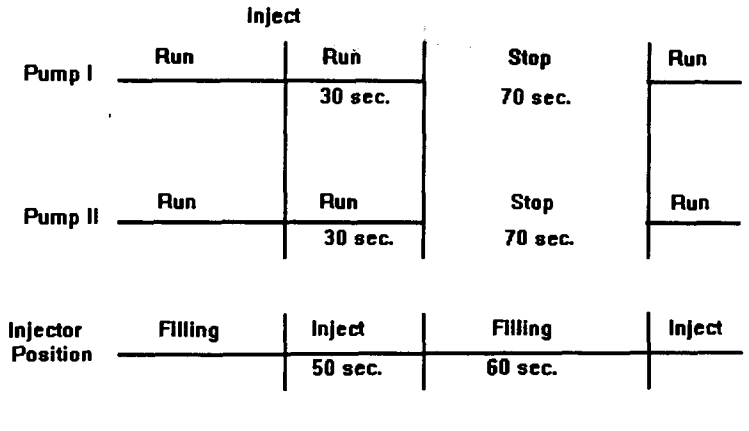

Fig. 2. Timing of cycles in the lead method.

### 2.4. Procedures

For samples that do not contain interferents, the sample is injected directly into the FIA manifold. If interferences are anticipated, a 50 ml sample is added to a 250 ml Erlenmeyer flask which contained 2 ml of pH 7 phosphate buffer solution. To this mixture are added the appropriate reagents for removing the interferences.

Before pumping reagents, the FIA system was cleaned by pumping 1:4 hydrochloric acid solution through the FIA manifold for about 5 min and then deionized distilled water for another 5 min. The run-stop times for pump I and pump II were set as indicated in Fig. 2(a) and sample loading and injecting times for the valve were as indicated in Fig. 2(b).

The FIA system pumped the reagents through the manifold shown in Fig. 1 and the computer started collecting data before the reagents reached the detector in order to obtain the baseline absorbance. The sample solutions were injected when the resazurin absorbance was at a maximum and stable, usually between 2.500 and 3.000 au. The absorbance changed observed for a 100 ppb lead sample was about 2.000–2.500 au using a stopped-flow period of 70 s. At least three injections were made for every sample solution. The decrease (negative peak) in the absorbance at 608.2 nm was monitored and the peak area measured. The peak area was converted to the lead ion concentration using a calibration curve.

A calibration curve was obtained by injecting 0, 10, 20, 40, 60, and 100 ppb lead standard solutions. These standard solutions were prepared in 50 ml volummetric flasks, adding 5 ml of 1% nitric acid to each, then 0.0, 0.5, 1.0, 2.0, 3.0, and 5.0 ml of the lead working solution (1 ppm), and diluting to the mark with water. At least three injections were also made of the standard solutions. The average values of the peak areas were used for the calibration.

For interferents that can be eliminated by the dimethylglyoxime procedure, 2 ml of dimethylglyoxime–alcohol solution and 15 ml of chloroform were added to the buffered sample. After extraction, the chloroform phase was separated and the aqueous phase was injected into the FIA manifold. For the interferents removed by quinolin-8-ol, 15 ml of quinolin-8-ol–chloroform solution were added to the buffered sample. After extraction, the chloroform phase was separated and the aqueous phase was injected into the FIA manifold. In extreme cases, both procedures may be needed. If the aqueous phase formed precipitates, they were filtered (Whatman; qualitative; #1) and then used for the determination. Although this part of the procedure was not automated, FIA-based extractions have been demonstrated.

A comparison of this new method with the standard dithizone method was performed. All

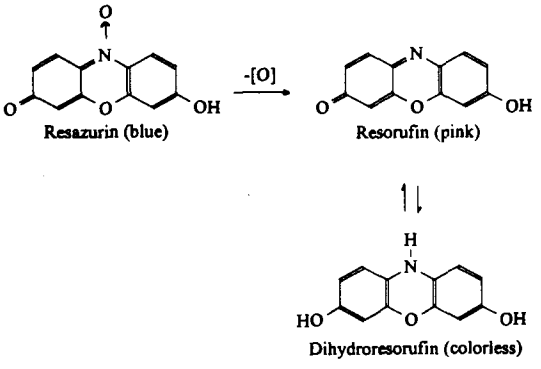

Fig. 3. The resazurin reduction reaction.

reagents and procedures for the lead ion determination with the dithizone standard method were prepared and followed as described elsewhere [2].

Sampling procedures for tap water comprised allowing the water to run for 15 min at the maximum flow rate before collecting a sample. A 1 l polypropylene bottle was rinsed with three 20 ml portions of sample before collecting the final sample. The collected sample has 1 ml of high-purity concentrated nitric acid added before mixing thoroughly.

## 3. Results and discussion

Resazurin is reduced by sulfide in alkaline solution to resorufin, Fig. 3. The first step is irreversible and proceeds very slowly without catalyst, but the second step is reversible and is reported to be fast [25]. In the presence of trace amount of lead, the reduction rate of the first step increases significantly. This catalytic effect is the bases for this work.

The absorption spectra of resazurin and resorufin exhibit a decrease in the absorbance at 608 nm (decrease in concentration of resazurin). In order to find the optimum conditions, the concentration of all reagents, the temperature and the basicity on the reaction rate was optimized.

The rate of the reaction is related to the sulfide concentration. However, since the sulfide concentration is kept constant in every determination and only a reduction of the resazurin concentration is observed, the effect of the sulfide concentration on the detected absorbance can be treated as a constant; therefore

$$dx/dt = \chi C_k^0 \pi_c$$

is a generalized equation for the rate of catalytic reactions, where $\chi$ is catalytic coefficient and $\pi_c$ is the combined concentrations of all reagents and $C_k^0$ is the lead concentration. To derive the integrated form of this equation, the approximate order of the reaction needs to be determined. Three possible orders, zero order, first order and second order were tested using the FIT program.

$$x = k_1[Pb^{2+}]t \quad \text{(zero order)}$$

$$\ln[\alpha/(\alpha - x)] = k_2[Pb^{2+}]t \quad \text{(first order)}$$

$$1/\alpha - 1/(\alpha - x) = k_3[Pb^{2+}]t \quad \text{(second order)}$$

where $\alpha$ is initial concentration of resazurin, and $x$ is the concentration of resazurin at time $t$.

The line equations and the correlation coefficients for the fitted data for the zero-

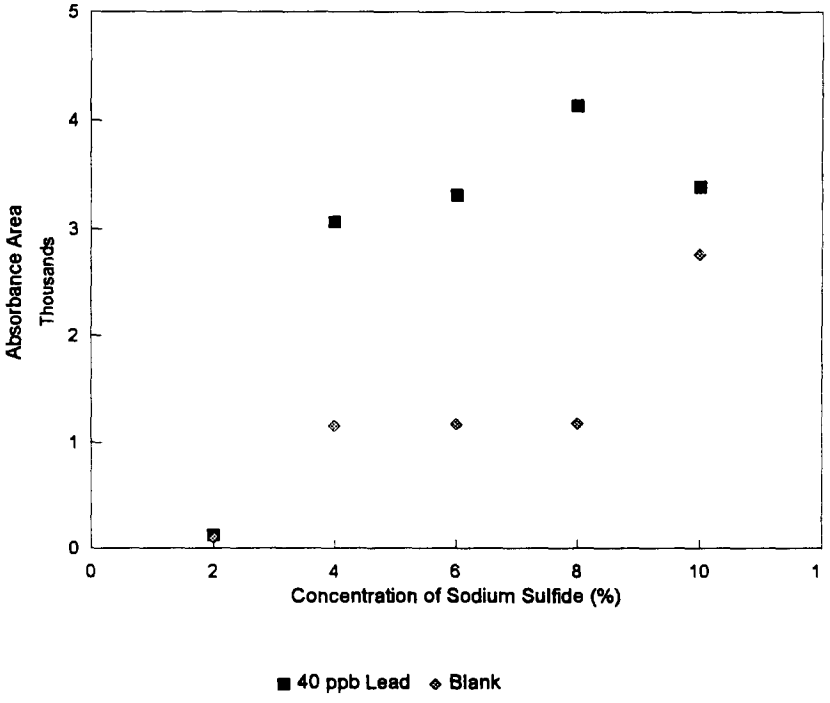

Fig. 4. Absorption spectra of resazurin and resorufin.

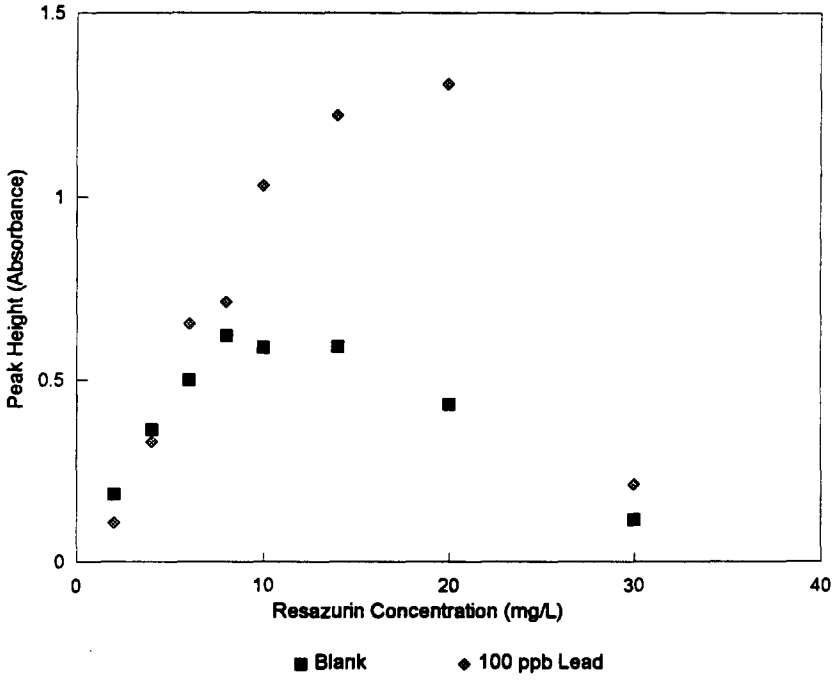

Fig. 5. Optimization of the resazurin concentration.

order, first-order and second-order reactions are: area = 2725 + 51020[$Pb^{2+}$], $r^2 = 0.9988$; area = 8.0787 + 7.4466[$Pb^{2+}$], $r^2 = 0.9805$; and area = $2.9474 \times 10^{-4} - 1.2747 \times 10^{-3}$ [$Pb^{2+}$], $r^2 = 0.9108$, respectively. Although the data are insufficient to draw a definitive conclusion, it is clear that the reaction is not second order [26]. With a correlation coefficient of 0.9988, the results suggest that the reaction may be zero order. The first-order equation also demonstrated a good fit. However, for the determination of low lead levels, the assumption that the reaction rate is zero order is acceptable. The high intercept for zero order is indicative of the presence of some uncatalyzed reaction [27].

The effect of temperature on the reaction rate was studied at 22 °C (room temperature) and at 55 °C. With an increase in temperature, the reaction rate for both catalyzed and uncatalyzed reactions (zero lead concentration) increased. The increase in reaction rate is higher for the uncatalyzed reaction than for the catalyzed reaction. This is a major disadvantage for trace ion analysis. Therefore, a temperature higher than room temperature is not recommended unless there is a way to suppress the reaction rate for the uncatalyzed reaction.

One interesting and unexplained observation is that when the reagents were heated for 30 min in a hot-water bath, then cooled and used, the amount of uncatalyzed reaction was reduced by a factor of 10. Similar results were found by Safavi et al. [28] in their research on selenium determination based on the reduction of resazurin by sulfide. They claimed that heating the mixture of reagents and cooling them down to room temperature increased the catalyzed reaction and stabilized the uncatalyzed reaction. The detection limit was reduced by one order of magnitude in their work. This is not just a degassing step, since purging the reagents with helium or nitrogen did not produce the same results.

The concentration of sulfide ions had a very close relationship with the rate of reaction. Fig. 4 shows this relationship. When the concentration of sodium sulfide increased from 2 to 4%, the integrated absorbance area jumped from $1.194 \times 10^6$ to $30.288 \times 10^6$ for the catalyzed reaction, while the increase for the uncatalyzed reaction was from $0.876 \times 10^6$ to $1.420 \times 10^6$. For a concentration increase from 4% to 10%, the increase in absorbance area for both the catalyzed and the uncatalyzed reactions was not as significant. At higher sulfide concentrations, the rate of the uncatalyzed reaction still increased while the rate of the catalyzed reaction was relatively stable. Therefore, 4% sodium sulfide solution was selected for its high sensitivity and relatively low blank absorbance.

The sodium sulfide solution was unstable overnight. On standing in contact with air, the

sulfide ion in solution was oxidized. Therefore, the reagent needed to be kept in a refrigerator and filtration was needed when the solution was not clear.

It was reported that the concentration of resazurin had no effect on the reaction rate of both catalyzed and uncatalyzed reactions in the range 12–60 mg $l^{-1}$ [25]. It was found in this research that there were maximum rates for both catalyzed and uncatalyzed reactions as the concentration of resazurin changed from 2 to 30 mg $l^{-1}$. Fig. 5 shows the influence of the resazurin concentration on the rate of reaction. The reaction rate of uncatalyzed reaction was stable when the concentration of resazurin was in the range 8–14 mg $l^{-1}$ while the rate of the catalyzed reaction reached a maximum at a resazurin concentration of 10 mg $l^{-1}$. Therefore, 10 mg $l^{-1}$ was chosen for the resazurin concentration which would produce a baseline absorbance ($A_0$) of about 2.50 and $A_0 - A$ of about 1.50 for a 100 ppb lead standard solution.

Because of the instability of sodium sulfide in acidic media and its adverse effect on the stability of the blank, the effect of acidity on the catalysis mechanism was not studied. Only the effect of base was investigated. Fig. 6 shows the results of this investigation. It was observed that with an increase of sodium hydroxide concentration from 0.1 to 8 M, the reaction rates of both catalyzed and uncatalyzed reactions were increased. However, when the concentration of sodium hydroxide was 4–6 M, the area difference for the blank and at the 200 ppb level reached a maximum and remained constant. With a sodium hydroxide concentration higher than 6 M, the system was not stable and the reproducibility was poor. Therefore, a sodium hydroxide concentration of 5 M was selected.

The reason for operating a FIA system in the stopped-flow mode is to increase the measurement sensitivity by increasing the residence time, and therefore the conversion of the measured species. The rate of the resazurin–sulfide reaction under investigation was relatively slow. It was impossible to detect the catalytic effect of trace levels of lead with continuous-flow FIA. Stopping the flow to ensure sufficient time for the reaction was necessary. Fig. 7 shows the relationship between stopping time and sensitivity. It was found that with longer stopping times, the sensitivity increases and the linear range decreases. For lead concentrations higher than 100 ppb, stopping for 15 s provided sufficient sensitivity, with straight-line correlations between 1 and 1000 ppb tested. For the samples with lead concentrations below 100 pbb, which is the case for drinking water, longer stopping times were needed. A

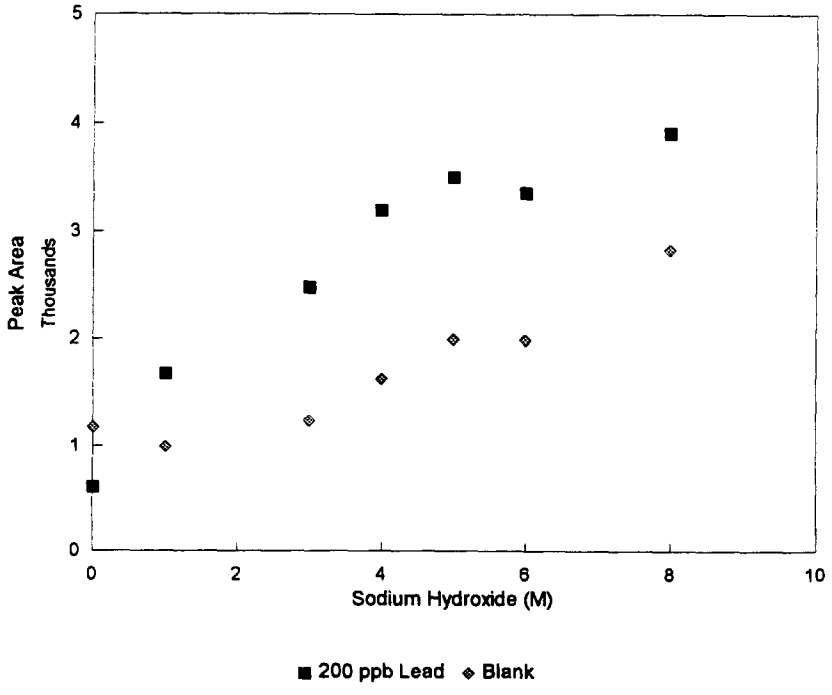

Fig. 6. Optimization of the pH.

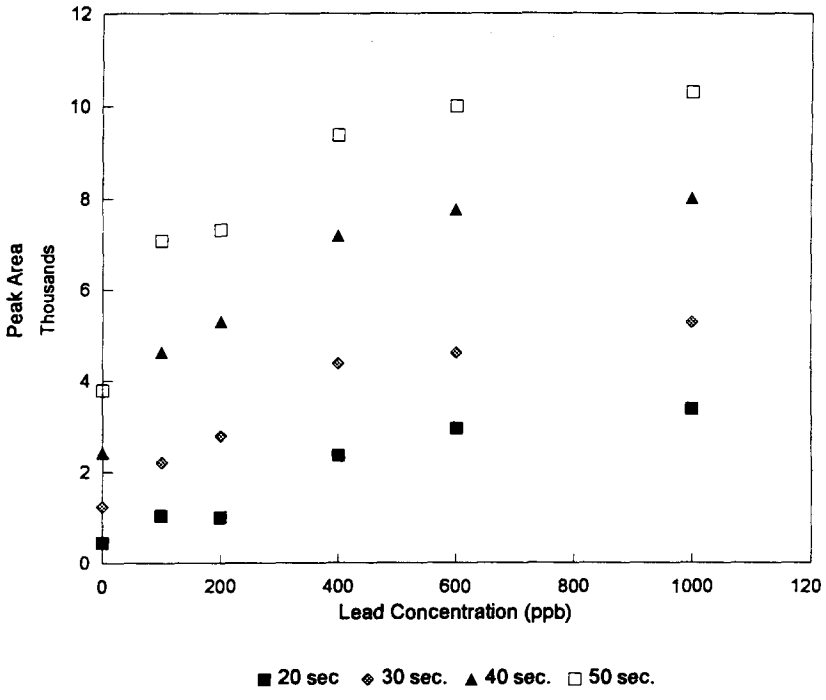

Fig. 7. Optimization of the time.

stopping time of 70 s was selected since it provided high sensitivity and a good linear range.

Since the determination of 1 ppb of lead was the objective of this work, a very small amount of sample dispersion is desired. However the peak must reach a wide enough plateau to allow for a reproducible stopping point. In order to have the smallest dispersion possible, the following experiment was conducted. With the manifold in fig. 1, the ideal dispersion coefficinet would be 3.10, that is, when the sample is used as the carrier stream and there is only dilution from mixing with reagents. A small sample volume would produce too large a dispersion coefficient, e.g. a 9.80 µl sample injection volume gave a dispersion coefficient as large as 5.14 and a large sample volume would reduce the sample throughput. Small sample volumes produce narrow peaks. On increasing the injection volume to 100 µl, the dispersion coefficient was reduced to 3.72 and the peak had a 26.4 s plateau. The peak started at 10.2 s after injection, after 22 s the peak platform formed and lasted for 26.4 s, and the peak returned to baseline in 30 s. Therefore, a volume of 100 µl was selected and run–stop modes for pump I and pump II, and injection and filling times for the injector were established. The sample throughput of the system was 30 injections per hour.

The computer system employed in this work was able to provide information concerning the peak height, area, and its slope. Both height and area were proportional to the lead concentration, but the linear range and precision were different. The peak height was a good representation of the lead concentration for a short stopping time (such as 7 s) for concentrations higher than 100 ppb. With a longer stopping time, the linear range was limited and the precision was poor. Area measurement gave better precision and the calibration lines were linear up to 1000 ppb for all the stopping times. Therefore, area measurements were used for this method.

In order to demonstrate the selectivity of the method, 36 anions and metal ions were tested, as listed in Table 1. The tolerance limit of each foreign ion was taken as the amount of added ion causing less than a $\pm 3\%$ error in the measured parameter for 10 ppb of lead. As can be seen from Table 1, most of the ions tested did not interfere, even when present in 200–2000-fold excess over the lead concentration.

The most severe interferents, copper(II) and cadmium(II), exhibited a positive interfering effect at concentrations higher than 0.25 ppm. Cobalt(II), vanadium(V), bismuth(III), and tin(II) showed a positive interfering effect at concentrations above 1 ppm. Zinc(II) at the 2 ppm level showed a negative effect. Nickel(II) at the 5 ppm level and 10 ppm of iron(III) gave

Table 1
Interfering ion tolerance limits

| Ions tested | Tolerance limit ($mg\,l^{-1}$) | Tolerance limit after removal ($mg\,l^{-1}$) |
|---|---|---|
| $Cu^{2+}$, $Cd^{2+}$ | 0.25 | 10 |
| $PO_4^{3+}$, $SO_3^{2+}$, | $8.0 \times 10^3$ | – |
| $Co_3^{2-}$, $F^-$, $Cl^-$, $I^-$ | $5.0 \times 10^3$ | – |
| $Br^-$ | $1.6 \times 10^3$ | – |
| $SO_4^{2-}$ | $3.8 \times 10^3$ | – |
| $SCN^-$ | 1000 | – |
| EDTA, $La^{3+}$, $Mg^{2+}$, $CrO_4^{2-}$ | 50 | – |
| $Ca^{2+}$ | 400 | – |
| $Ba^{2+}$ | 200 | – |
| $Hg^{2+}$, $Al^{3+}$, $Hg^+$, $Te^{4+}$ | 100 | – |
| $Zn^{2+}$, $Pd^{2+}$ | 2 | 20 |
| $Fe^{3+}$, $Fe^{2+}$ | 10 | 200 |
| $Cr^{3+}$, $Sb^{3+}$ | 10 | – |
| $As^{3+}$, $Tl^+$ | 20 | – |
| $Se^{4+}$, $Ag^+$ | 3 | – |
| $Co^{2+}$, $V^{6+}$, $Sn^{2+}$, $Bi^{3+}$ | 1 | 20 |
| $Ni^{2+}$ | 5 | 100 |

a positive interference. The interfering effects of $Cu^{2+}$, $Ni^{2+}$, $Zn^{2+}$ and $Co^{2+}$ ions were removed by extracting their complexes with dimethylglyoxime into chloroform at pH 7. The addition of 0.1 M quinolin-8-ol to the test solution and extraction with chloroform successfully removed the interferences of $Bi^{3+}$, $cd^{2+}$, $Fe^{3+}$, and $V^{5+}$ ions. Adding 0.01 M ammonium thiocyanate to the sodium hydroxide solution also prevented the interference of $Fe^{3+}$ ions. The tolerance limits of these interfering ions after their removal are also listed in Table 1. A calibration curve of 1–100 ppb lead was determined from the mean of three measurements at each point. The correlation coefficient of the regression line was 0.9992 and the fitted linear equation of the curve was

$$\text{Area} = 1552.8 + 88.54\,[Pb^{2+}]$$

The standard deviation of the blank measurement of peak area ($n = 15$) was 29.35 and the limit of detection at the 99% confidence level ($3\sigma$) was 0.994 ppb. The limit of quantification with $10\sigma$ was 3.6 ppb. The relative standard deviation (RSD) at the 20 ppb level (the area was measured and the stopping time was 70 s) was 5.2% and at the 200 ppb lead level (the peak height was measured and the stopping time was 12 s) was 3.37% ($n = 15$).

Samples were collected and both this method and the standard dithizone method were used to determine lead concentrations. The results in Table 2 are in good agreement with each other. Additions of 20, 40 and 60 ppb lead were made to sample A and the total lead was determined. The recoveries ranged from 98.1 to 103.5%.

## 4. Conclusions

The results of the sample analyses were in good agreement with those of the standard dithizone method. The resazurin method provided a simple and reliable determination of lead in tap water without preconcentration. Minimal interferences were removed by a simple solvent extraction procedure. The method meets the need for a detection limit of 1 ppb and a relative standard deviation of 5.2% at the 20 ppb lead level. The developed method has the potential to be applied to the determination of trace amount of lead in drinking water for regular lead monitoring.

# Equilibrium reactions network for the *cis*- or *trans*-bis(pyrazine)tetraammineruthenium(II/III) and ruthenium(II/III)–EDTA complexes

Henrique E. Toma *, Rosana L. Sernaglia

*Instituto de Química, Universidade de São Paulo, Caixa Postal 26077, CEP 05599-970 São Paulo, SP, Brazil*

Received 8 February 1995; revised 16 May 1995; accepted 17 May 1995

**Abstract**

The elecrochemical and spectroelectrochemical behavior of the binuclear and trinuclear complexes generated from the association of *cis*- or *trans*-$[Ru(NH_3)_4(pz)_2]^{3+/2+}$ (where pz represents pyrazine) and $[RuEDTA(H_2O)]^{2-/-}$ complexes has been investigated in aqueous solution. Based on two sets of spectrophotometrically determined equilibrium constants and on the formal redox potentials, the complex network of equilibrium reactions involving mixed valence species has been elucidated.

*Keywords:* Bis(pyrazine)tetraammineruthenium(III) complexes; Electrochemical behavior; Equilibrium constants; Equilibrium reactions; Redox potentials; Ruthenium(II/III)–EDTA complexes; Spectrochemical behavior

## 1. Introduction

Polymetallic complexes exhibiting redox active groups are particularly interesting as electron-transfer mediators in molecular devices and in multielectron transfer catalysis [1–8]. A typical compound displaying a strong electrocatalytic response in the reduction of molecular oxygen has been obtained by the association of four $[Ru^{III/II}EDTA]^{-/2-}$ complexes to the *meso*-tetrapyridylporphyriniron(II) species [2]. The binding of the $[Ru^{III}EDTA]^-$ complex to multibridged species is a rather simple way of obtaining polymetallic systems; however, in the absence of a large excess of the ruthenium complex a complicated network of equilibrium reactions can result. An interesting case, involving a double bridging $[Ru(NH_3)_4(pz)_2]^{2+}$ where pz represents pyrazine in the presence of $[Ru^{III}EDTA]$ ions, is reported here. This work deals with the determination of equilibrium and electrochemical parameters, providing a good example of the elucidation of a complex network of equilibrium reactions.

## 2. Experimental

The $[Ru(HEDTA)(H_2O)]$ and *cis*-, *trans*-$[Ru(NH_3)_4(pz)_2](PTS)_2$ complexes (where PTS represents the *p*-toluenesulfonate ion) were prepared and characterized as previously reported in the literature [9–12]. The binuclear and trinuclear mixed complexes were studied in aqueous solution, under an argon atmosphere, at pH 4.7, in 0.10 M acetate buffer. The cis and trans trinuclear compounds have also been isolated and characterized in the solid form, for comparison purposes. The procedure consisted

* Corresponding author. Fax: (55)11-815-5579; E-mail: HENETOMA@QUIM.IQ.USP.BR

*SSDI* 0039-9140(95)01646-5

of mixing stoichiometric amounts of the complexes in aqueous solution, and precipitating with acetone. The solids precipitated were collected on a filter, washed with acetone and dried under vacuum. Elemental analyses were carried out by the Microanalytical Laboratory of the University of São Paulo. Calculated for *cis*-$[Ru(NH_4)_4\{pzRuEDTA\}_2] \cdot 12H_2O$: C, 25.4; N, 12.8; H, 5.3. Found: C, 25.4; N, 12.7; H, 4.1. Calculated for *trans*-$[Ru(NH_3)_4\{pzRuEDTA\}_2] \cdot 5H_2O$: C, 28.0; N, 14.0; H, 4.7. Found: C, 28.0; N, 14.1; H, 4.4.

Cyclic voltammetry was carried out using a Princeton Applied Research Corp. model 173 potentiostat and model 175 universal programmer. A glassy carbon working electrode and a platinum wire auxiliary electrode were employed for the measurements versus an Ag/AgCl (1 M KCl) reference electrode ($E^0 = 0.222$ V versus SHE) [13]. When mentioned in the text, reversible behavior of the voltammetric waves has been proposed, considering, simultaneously, (a) the separation of the anodic and cathodic peaks, typically in the 60–70 mV range; (b) their similar intensities; and (c) the linear response of the peak currents versus the square root of the scan rates.

The electronic spectra were recorded on a Hewlett-Packard model 8452-A diode-array spectrophotometer, or on a Guided-Wave model 260 fiber-optics instrument. Spectrophotometric titrations of the cis and trans complexes, $3.9 \times 10^{-5}$ M and $2.6 \times 10^{-5}$ M, respectively, with 0.42 M $[Ru^{III}EDTA(H_2O)]^-$ were carried out using a quartz cuvette (1 cm pathlength) attached to a cylindrical reservoir. An ultraprecision Gilmont micrometer syringe ($\pm 0.0001$ ml) was employed in the experiments. Spectroelectrochemical measurements were carried out using the potentiostat in parallel with the diode-array spectrophotometer. A three-electrode system was designed for a quartz cell of 0.025 cm internal optical pathlength. A gold minigrid was used as a transparent working electrode, in the presence of a small Ag/AgCl (1 M KCl) reference electrode and a platinum auxiliary electrode. Because of the semi-infinite diffusion conditions employed, the measurements were carried out after the decay of the Faradaic currents and the stabilization of the spectra (about 3 min). The reversibility of the spectroelectrochemical behavior was evaluated based on the regeneration of the initial spectra after returning the applied potential to the starting point, and on the analysis of the Nernst plots.

## 3. Results and discussion

### 3.1. Spectrophotometric titrations

The $[Ru^{III}EDTA(H_2O)]^-$ complex is the major species [11] generated from the dissolution of $[Ru^{III}HEDTA(H_2O)]$ in aqueous solution in the pH range 3.0–6.5. This ion undergoes a rapid substitution of the labile water molecule in the presence of *N*-heterocyclic ligands, such as pyrazine, pyridine and related species [11,14] yielding the corresponding substituted complexes. The products containing *N*-heterocyclic ligands display weak absorption bands in the visible region and, in general, are not suitable for spectrophotometric studies. In the case of the *cis*- and *trans*-$[Ru(NH_3)_4(pz)_2]^{2+}$ complexes, the binding of $[Ru^{III}EDTA]^-$ groups at the pyrazine bridging ligands can easily be monitored, since it leads to pronounced changes in the ruthenium(II)-to-pyrazine charge transfer (MLCT) bands, as illustrated in Figs 1A and 2A. The $Ru^{III}$ ions are expected to act as electron withdrawing groups at the pyrazine ring, lowering the energies of the $\pi^*$ orbitals and shifting the MLCT bands from 398 nm ($\log \varepsilon = 4.08$), and 474 nm ($\log \varepsilon = 3.94$) (cis) and 486 nm ($\log \varepsilon = 4.34$) (trans) in the starting complexes to 424 nm ($\log \varepsilon = 4.08$), 537 nm ($\log \varepsilon = 4.28$) (cis) and 558 nm ($\log \varepsilon = 4.59$) (trans) in the trinuclear species. The absorption band at 424 nm in the cis trinuclear complex is masked by absorption of the excess $[Ru^{III}HEDTA(H_2O)]^-$ in Fig. 1A; however, it can be detected spectroelectrochemically (see Fig. 4A) or in the absorption spectrum of the solid complex.

Typical spectrophotometric titration plots for the cis and trans isomers can be seen in Figs. 1B and 2B, respectively. The lack of inflection in the spectrophotometric plots indicates the existence of overlapping equilibrium reactions. Two successive reactions (1) and (2) have been considered in this work

$$Ru^{III} + LRu^{II}L \overset{K_{32}}{\rightleftharpoons} Ru^{III}LRu^{II}L \quad (1)$$

$$Ru^{III}LRu^{II}L + Ru^{III} \overset{K_{323}}{\rightleftharpoons} Ru^{III}LRu^{II}LRu^{III} \quad (2)$$

where $Ru^{III}$ refers to $[Ru^{III}EDTA(H_2O)]^-$, $LRu^{II}L$ refers to $[Ru^{II}(NH_3)_4(pz)_2]^{2+}$, and the subscripts in $K_{32}$ and $K_{323}$ represent the oxidation states of the ruthenium ions as they appear in the formulas.

The calculation of the equilibrium constants $K_{32}$ and $K_{232}$ from the spectrophotometric data

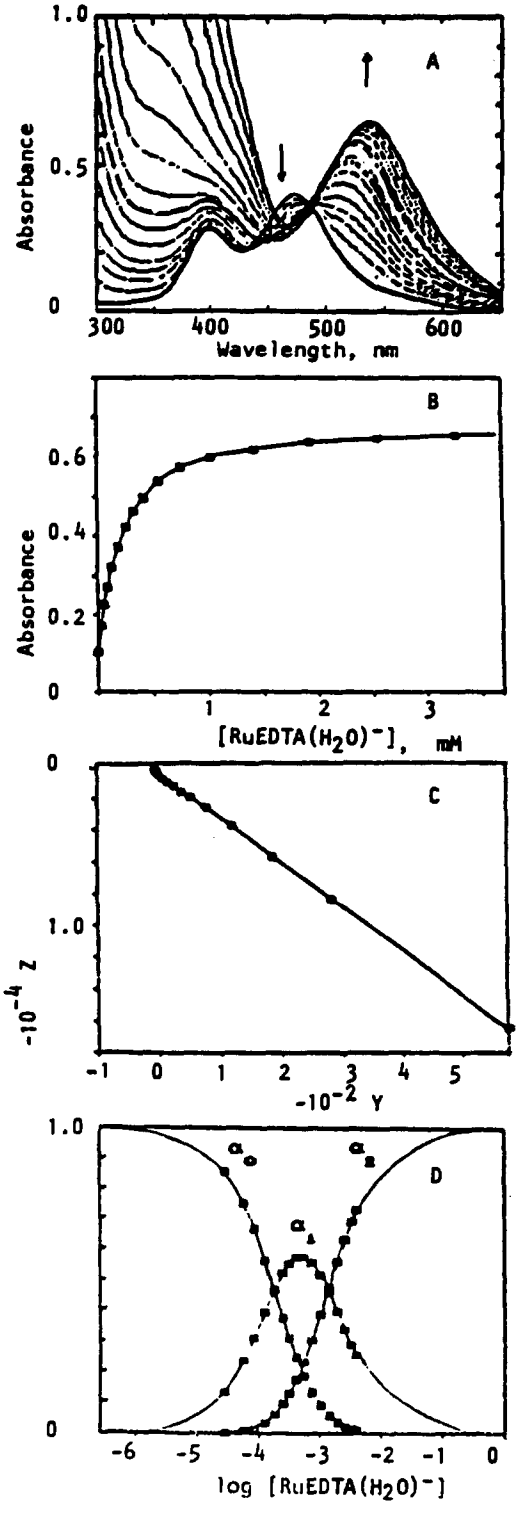

Fig. 1. (A) Spctrophotometric titration of *cis*-$[Ru(NH_3)_4(pz)_2]^{2+}$ ($3.9 \times 10^{-5}$ M) with $[Ru^{III}EDTA(H_2O)]^-$, at pH 4.7, in 0.10 M acetate buffer; (B) absorbance plot ($\lambda = 537$ nm); (C) linear regression analysis of $Z$ versus $Y$ (see text); (D) plots of the distribution functions for the starting complex ($\alpha_0$) and the binuclear ($\alpha_1$) and trinculear ($\alpha_2$) species (solid line represents the theoretical curves).

can be carried out using the general method proposed by Yatsimirskii [15] based on a successive extrapolation procedure. An alternative method has been proposed by Toma and Morino [16] and is based on the linearization of the general Eq. (3) for $\varepsilon_i = A/[Ru_T]$, where $A$ is the measured absorbance, and $[Ru_T]$ is the total Ru(III)–EDTA concentration. Under the conditions of this work, $[Ru^{III}]$ is in large excess over $[LRu^{II}L]$, and is practically equivalent to $[Ru_T]$.

$$\varepsilon_i = \frac{\varepsilon_{LRuL} + \varepsilon_{32}K_{32}[Ru^{III}] + \varepsilon_{323}K_{323}[Ru^{III}]^2}{1 + K_{32}[Ru^{III}] + K_{32}K_{323}[Ru^{III}]^2} \quad (3)$$

This equation can be rearranged as

$$\frac{(\varepsilon_i - \varepsilon_{LRuL})}{(\varepsilon_i - \varepsilon_{323})}[Ru^{III}]^2 = -K_{32}K_{323} - K_{32}\frac{(\varepsilon_i - \varepsilon_{32})}{(\varepsilon_i - \varepsilon_{323})}[Ru^{III}] \quad (4)$$

or

$$Z = -K_{32}K_{323} - K_{32}Y \quad (5)$$

In this method, $\varepsilon_i$ is calculated for each $[Ru^{III}]$ concentration and the extinction coefficients for the starting and final species, $\varepsilon_{LRuL}$ and $\varepsilon_{323}$, are previously known. By means of an iterative least-squares analysis, it is possible to find values of the extinction coefficients for the binuclear complex ($\varepsilon_{32}$) which give the best fit for the linear Eqs. (4) or (5), and simultaneously determine the equilibrium constants $K_{32}$ and $K_{323}$. The best values for $\varepsilon_{32}$ were $13.9 \times 10^3$ $m^{-1}\,cm^{-1}$ (537 nm) and $28.0 \times 10^3$ $M^{-1}\,cm^{-1}$ (558 nm) for the cis and trans isomers, respectively, leading to the linear plots shown in Figs. 1C and 2C. The corresponding equilibrium constants, $K_{32}$ and $K_{323}$, for the cis and trans complexes were $(5.6 \pm 0.1) \times 10^3$ $M^{-1}$ and $(7.3 \pm 0.9) \times 10^2$, and $(5.2 \pm 0.1) \times 10^3$ $M^{-1}$, and $(1.5 \pm 0.2) \times 10^3$ $M^{-1}$, respectively. Similar results were obtained by means of the Yatsimirskii method, e.g. $(5 \pm 1) \times 10^3$ $M^{-1}$ and $(6 \pm 1) \times 10^2$ $M^{-1}$, and $(5 \pm 1) \times 10^3$ $M^{-1}$ and $(1.3 \pm 0.6) \pm 10^3$ $M^{-1}$, respectively; however, the precision was much smaller because of the many successive non-linear extrapolations involved.

### 3.2. Cyclic voltammetry

Typical cyclic voltammograms for the cis and trans isomers in the presence of $[Ru^{III}EDTA(H_2O)]^-$ ions are shown in Figs. 3A and

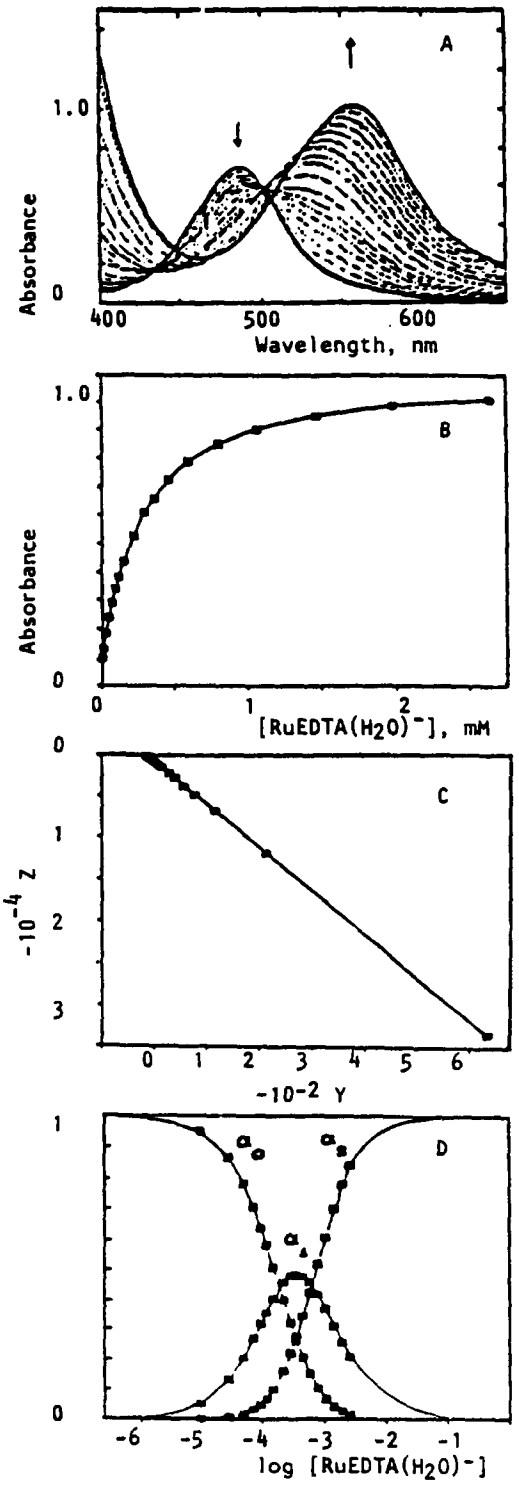

Fig. 2. (A) Spectrophotometric titration of *trans*-$[Ru(NH_3)_4(pz)_2]^{2+}$ ($2.6 \times 10^{-5}$ M) with $[Ru^{III}EDTA(H_2O)]^-$, at pH 4.7, in 0.10 M acetate buffer; (B) absorbance plot ($\lambda = 558$ nm); (C) linear regression analysis of $Z$ versus $Y$ (see text); (D) distribution plots for the starting complex ($\alpha_0$) and the binuclear ($\alpha_1$) and trinuclear ($\alpha_2$) species (solid line represents the theoretical curves).

3B, respectively. The starting *cis*- and *trans*-$[Ru^{II}(NH_3)_4(pz)_2]^{2+}$ complexes exhibit a reversible wave at $E^{0'} = 0.88$ V and 0.81 V, associated with the $Ru^{III/II}$ redox couples (25 °C; 0.10 M KCl). Under the same experimental conditions, the $[Ru^{III}EDTA(H_2O)]^-$ complex exhibits $E^{0'} = -0.01$ V. The binding of the $[Ru^{III}EDTA]^-$ ion to the *cis*- and *trans*-$[Ru^{II}(NH_3)_4(pz)_2]^{2+}$ complexes gives rise to a new, reversible wave at 0.27 V, ascribed to the $[Ru^{III/II}EDTA(pz)]^{-/2-}$ moieties, and is accompanied by an increase, up to 100 mV, in the $E^{0'}$ values for the $[Ru^{III/II}(NH_3)_4(pz)_2]^{3+/2+}$ group. These results reflect the influence of $\pi$-backbonding effects through the $Ru^{II}$–pz bonding, induced by the attached $[Ru^{III}EDTA]^-$ groups. The $E^{0'}$ values are shown in Table 1.

The corresponding $E^{0'}$ values for the cis and trans trinuclear complexes, e.g. 0.98 V and 0.91 V, were evaluated from measurements obtained in the presence of a large excess of $[Ru^{III/II}EDTA(H_2O)]^{-/2-}$ species (above 6 mM) to ensure that the formation of products is more than 90% complete. In this case, the voltammograms obtained starting from a cathodic scan were practically identical to those obtained by scanning the potentials in the opposite direction. Unfortunately, under such conditions, the background currents increase very rapidly near the positive limit of the aqueous solvent, and the voltammograms become distorted above 0.9 V, as one can see in Fig. 3. On the other hand, in the negative region, there is a very strong peak associated with the excess of $[Ru^{III/II}EDTA(H_2O)]^{-/2-}$ species (not shown in Fig. 4).

The $E^{0'}$ values for the cis and trans binuclear complexes, i.e. 0.94 V and 0.87 V, were estimated from the measurements carried out using a 1:1.1 molar ratio, coinciding with the maximum in the distribution curves of Figs. 1D and 2D. The peak positions were not sensitive to the initial scan direction. Because of the presence of 25% of the mononuclear and trinuclear species, the voltammograms were slightly broader than for a single species; however the peak positions should reflect the major contribution of the binuclear complexes as the main species in solution. This conclusion is supported by simulation or deconvolution analysis, considering three reversible, monoelectronic waves, exhibiting 1:2:1 intensities, separated by 50 mV. On the other hand, it should be noted that measured $E^{0'}$ values coincide with the estimated values, based on the arithmetic average of the

formal redox potentials for the mononuclear and trinuclear complexes.

### 3.3. Spectroelectrochemistry

Spectroelectrochemical measurements for the cis and trans trinuclear complexes are shown in Figs. 4 and 5. The totally reduced species, $Ru^{II}LRu^{II}LRu^{II}$, exhibit very strong absorption bands in the visible region, which can be deconvoluted in its three bands at 420 nm (3.70), 490 nm (4.36) and 590 nm (4.54) for the cis isomer, and into two bands at 530 nm (4.43) and 600 nm (4.81), for the trans species. The high energy bands correlate with the MLCT bands observed for the *cis*- and *trans*-$[Ru^{II}(NH_3)_4(pz)_2]^{2+}$ complex. The low energy bands can be ascribed to Ru-to-pyrazine charge-transfer transitions in the energy bands can be ascribed to Ru-to-pyrazine charge-transfer transitions in the $[Ru^{II}EDTA$–pyrazine$]^{2-}$ moiety, since their intensities depend on the number of [$Ru^{II}$EDTA] groups and undergo complete decay after their oxidation at 0.4 V. The spectroelectrochemical measurements were also extended to the near-infrared region (2200 nm), with no evidence of intervalence transfer bands with $\varepsilon > 100\ M^{-1}\,cm^{-1}$.

The [$Ru^{III\,II}$EDTA] moieties display a typically reversible response, allowing very accurate spectroscopic measurements as a function of the applied potentials. The corresponding Nernst plots exhibit a small inflection, with two parallel lines displaying a slope of 0.059. These results can be interpreted in terms of two successive, reversible, monoelectronic processes exhibiting very close $E^0$ values, here denoted $E^0_{323,223}$ and $E^0_{223,222}$ (Table 1).

$$Ru^{III}LRu^{II}LRu^{III} \underset{E^0_{323,223}}{\overset{+e}{\rightleftharpoons}} Ru^{II}LRu^{II}LRu^{III} \underset{E^0_{223,222}}{\overset{+e}{\rightleftharpoons}} Ru^{II}LRu^{II}LRu^{II} \quad (6)$$

The difference in the successive $E^{0'}$ values is smaller than 30 mV, indicating a negligible interaction between the peripheral $[Ru^{II}EDTA]^{2-}$ and $[Ru^{III}EDTA]^-$ groups in the mixed valence $[Ru^{II}LRu^{II}LRu^{III}]$ complex.

In contrast to the $[Ru^{II}EDTA]^{2-}$ groups, the electrochemical oxidation of the $[Ru^{II}(NH_3)_4(pz)_2]^{2+}$ center proceeded in an irreversible way in the time scale of the spectroelectrochemical measurements. The measurements varied systematically as a function of time, and the starting spectrum was not completely recovered after returning the potential to the initial value. In this case, the $E^0$ values were obtained from the cyclic voltammograms.

### 3.4. Thermodynamic network

Based on the equilibrium constants and $E^{0'}$ values determined in this work, the following thermodynamic scheme can be elaborated and solved

$$\begin{array}{ccccc} Ru^{II} + LRu^{II}L & \overset{K_{22}}{\rightleftharpoons} & Ru^{II}LRu^{II}L(+Ru^{II}) & \overset{K_{222}}{\rightleftharpoons} & Ru^{II}LRu^{II}LRu^{II} \\ & & \downarrow E^0_{3/2} & & \downarrow E^0_{223/222} \\ \downarrow E^0_{3/2} & & Ru^{II}LRu^{II}L\ (+Ru^{III}) & \overset{K_{223}}{\rightleftharpoons} & Ru^{II}LRu^{II}LRu^{II}LRu^{III} \\ & & \downarrow E^0_{32/22} & & \downarrow E^0_{323/223} \\ Ru^{III} + LRu^{II}L & \overset{K_{32}}{\rightleftharpoons} & Ru^{III}LRu^{II}L(+Ru^{III}) & \overset{K_{323}}{\rightleftharpoons} & Ru^{III}LRu^{II}LRu^{III} \\ \downarrow E^{0'}_{3/2} & & \downarrow E^0_{33/32} & & \downarrow E^0_{333/323} \\ Ru^{III} + LRu^{III}L & \overset{K_{33}}{\rightleftharpoons} & Ru^{III}LRu^{III}L(+Ru^{III}) & \overset{K_{333}}{\rightleftharpoons} & Ru^{III}LRu^{III}LRu^{III} \end{array} \quad (7)$$

For each square cycle, the equilibrium constants $K_i$ and $K_j$ are related to $E^0_i$ and $E^0_j$ by the free energy relationship

$$nFE^0_i + RT \ln K_i = +nFE^0_j + RT \ln K_j \quad (8)$$

$$\frac{K_j}{K_i} = 10^{(E_i - E_j)/0.0591} \quad (9)$$

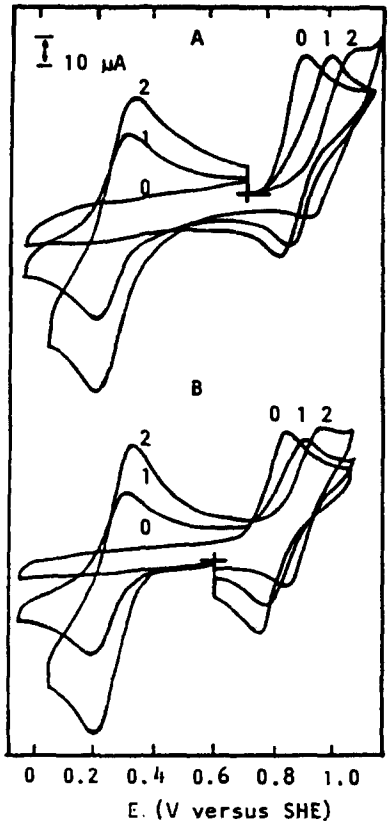

Fig. 3. Cyclic voltammograms of the (A) *cis*- and (B) *trans*-$[Ru(NH_3)_4(pz)_2]^{2+}$ complexes (1.0 mM) (voltammogram 0), and of the binuclear (voltammogram 1) and trinuclear (voltammogram 2) species, generated in the presence of 1.1 μm and 6.0 mM $[Ru^{III}EDTA(H_2O)]^-$, respectively (0.10 M KCl; glassy carbon disc electrode (0.20 $cm^2$); 100 mV $s^{-1}$; 25 °C.

where $n$, $F$, $R$ and $T$ have the conventional meaning. This equation is extremely useful since, from the known values of $K_i$, $E^0_i$ and $E^0_j$, one can readily calculate $K_j$ [17]. The thermodynamic cycle requires that the redox potentials correspond to those of the initial and final states. Therefore, in the measurements of $E^0_j$ it is important to ensure that the formation of the products in the square cycle is complete, as we have pursued in this work. This means that $K_i[\text{complex}_i] \gg 1$ and $K_j[\text{complex}_i] \gg 1$; otherwise a concentration-dependent equation should be employed, e.g.

$$E^{0'}_j = E^0_i + (RT/F) \ln\{(K_i[\text{complex}_i] + 1) / (K_j[\text{complex}_i] + 1)\}$$

In our case, the thermodynamic constants and $E^0$ values were replaced by the conditional equilibrium constants and formal redox potentials, $E^{0'}$. This procedure is normally adopted, since the electrochemical measurements require the use of supporting electrolytes, and the activity coefficients for the oxidized and reduced species are not expected to differ appreciably at high, constnat, ionic strengths.

Starting from the spectrophotometrically determined $K_{32}$ and $K_{323}$ constants, it is possible to solve four associated free energy cycles, i.e.

$$\log(K_{33}/K_{32}) = (E^{0''}_{3/2} - E^{0'}_{33/32})/0.0591 \quad (10)$$

$$\log(K_{333}/K_{323}) = (E^{0'}_{33/32} - E^{0'}_{333/323})/0.0591 \quad (11)$$

$$\log(K_{22}/K_{32}) = E^{0'}_{32/22} - E^{0'}_{3/2})/0.0591 \quad (12)$$

$$\log(K_{223}/K_{323}) = (E^{0'}_{323/223} - E^{0'}_{32/22})/0.0591 \quad (13)$$

Based on the calculated $K_{223}$ values, another cycle can be solved

$$\log(K_{222}/K_{223}) = (E^{0'}_{223/222} - E^{0'}_{3/2})/0.0591 \quad (14)$$

The complete set of equilibrium constants calculated in this way can be seen in Table 1,

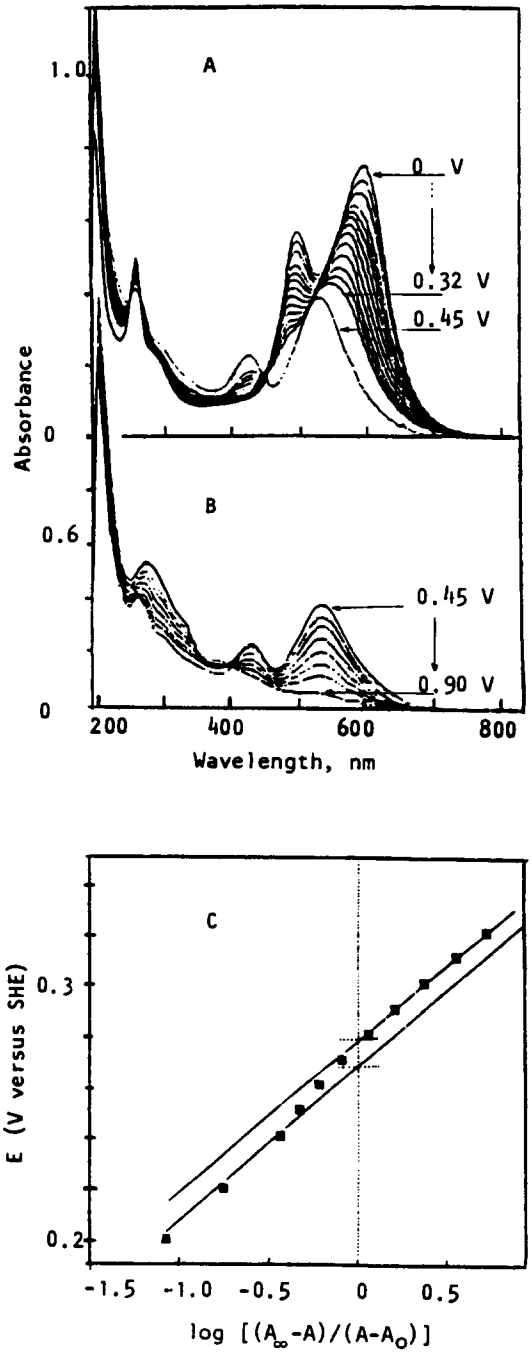

Fig. 4. Spectroelectrochemical behavior of the trinuclear complex, *cis*-$[Ru(NH_4)_4\{(pz)RuEDTA\}_2]$, 1.0 mM in the presence of 6.0 mM $[Ru^{III}EDTA(H_2O)]^-$, and 0.1 M KCl, showing the oxidation of (A), the $[Ru^{II}EDTA(pz))]^{2-}$ moiety (A) and (B) the $[Ru^{II}(NH_3)_4(pz)_2]^{2+}$ moiety, and (C) the Nernst plot employed for the evaluation of $E^0_{223,222}$ and $E^0_{323,223}$.

along with the corresponding $E^{0'}$ values. Because of the errors involved in the $E^{0'}$ measurements and of the small variation in the activity coefficients, the results should be regarded as good estimated values of the equilibrium constants, in the absence of thermodynamic data extrapolated to infinite dilution.

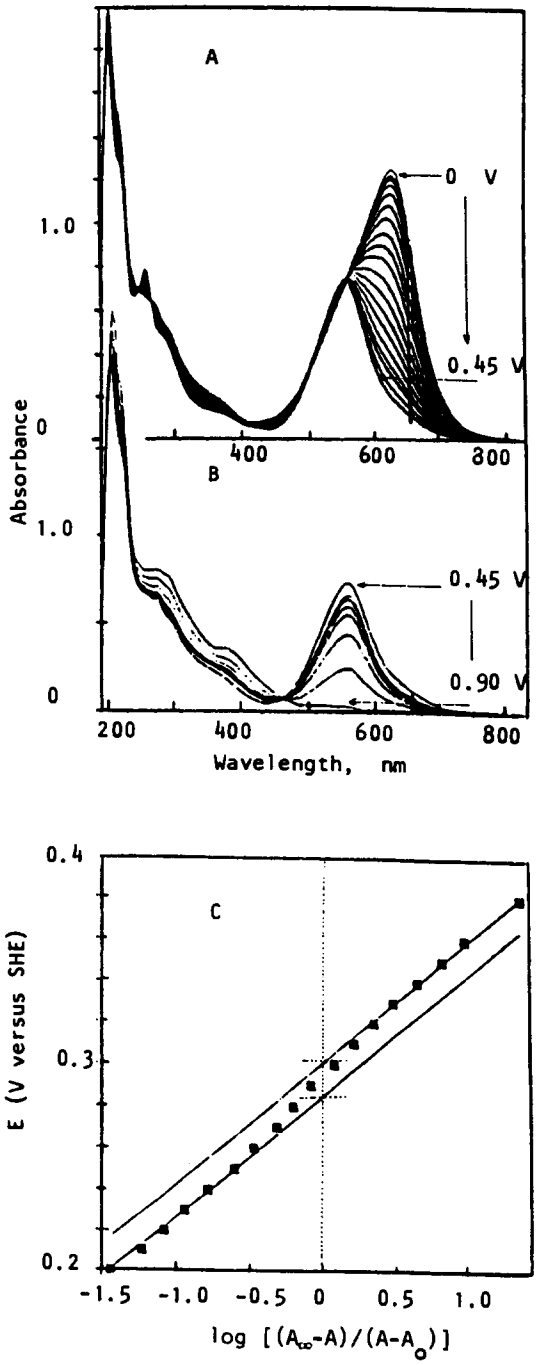

Fig. 5. Spectroelectrochemical behavior of the trinuclear complex, *trans*-$[Ru(NH_4)_4\{(pz)RuEDTA\}_2]$, 1.0 mM, in the presence of 6.0 mM $[Ru^{III}EDTA(H_2O)]^-$, 0.1 M KCl, showing the oxidation of moiety (A) the $[Ru^{II}EDTA(pz)]^2$ and (B) the $[Ru^{II}(NH_3)_4(pz)_2]^{2+}$ moiety, and (C) the Nernst plot employed for the evaluation of $E^0_{223/222}$ and $E^0_{323/223}$.

## 4. Conclusion

This work has shown that based on the determination of the redox potentials and of two successive equilibrium constants, the complete network of association reactions for the *cis*- and *trans*-$[Ru(NH_3)_4(pz)_2]^{3+/2+}$ + $[RuEDTA(H_2O)]^{-/2-}$ complexes can be elucidated.

From the data in Table 1, one can see that the $[Ru^{II}EDTA]^{2-}$ ion exhibits a remarkable affinity for the pyrazine bridging ligands, leading to the formation of very stable binuclear and trinuclear species. In comparison with the corresponding $[Ru^{III}EDTA]^{-}$ complexes, the difference of six orders of magnitude in the stability constants is consistent with strong backbonding interactions in the [$Ru^{II}$EDTA–pyrazine] moiety.

Except for the *trans*-$[Ru^{II}LRu^{II}LRu^{II}]$ complex, successive equilibrium constants decrease systematically according to statistical behaviour, for instance $K_{32} > K_{323}$ and $K_{33} > K_{333}$. In the case of the *trans*-$[Ru^{II}LRu^{II}LRu^{II}]$ complex, $K_{22} < K_{222}$ indicates a cooperative effect associated with the backbonding interactions in the complex. This is not observed in the cis isomer, presumably because of its greater susceptibility to steric hindrance effects.

Received 3 October 1994; revised 10 January 1995; accepted 18 May 1995

**Abstract**

The protonation constants of ten Schiff's bases synthesized by the condensation of 2-hydroxy-1-naphthaldehyde with aniline and *o*-, *m*-, and *p*-substituted methylanilines, ethylanilines and methoxyanilines in various dioxan–water mixtures have been determined potentiometrically using an electrode system calibrated in concentration units of the hydrogen ion. The influence of substituents in the molecular structure on the protonation constants is discussed. The log $K_2$ values relating to the protonation of imine nitrogen atoms are in accordance with the Hammett relationship for all solvent compositions. A reverse relationship is observed between log $K_2$ for all Schiff's bases and the mole fraction of dioxan. However, the log $K_1$ values corresponding to the protonation of naphtholate O-ions have been found to increase with the increase in concentration of dioxan. Both electrostatic and non-electrostatic contributions influencing these constants are briefly discussed.

*Keywords:* Dioxan–water mixture; 2-Hydroxy-1-naphthalideneanilines; Potentiometry; Protonation constants; Schiff's bases; Solvent effect; Substituent effect; Titrimetry

## 1. Introduction

Among different physicochemical properties of organic compounds, protonation constants determined in mixed solvents provide an important basis for speculation about whether solvent and substituent effects influence their acidity or basicity. Knowledge of equilibrium data also facilitates the design of new separation and analytical procedures such as acid–base titration, complex formation and solvent extraction. In a continuation of our previous work [1–3] on various protonation equilibria in water–organic solvent mixtures, the present work reports the protonation constants of substituted 2-hydroxy-1-naphthalideneanilines (I) in different water–dioxan mixtures. There have been a number of publications on the protonation constants of 2-hydroxy-1-naphthalideneanilines in mixed solvents but no systematic reports dealing with these Schiff's bases in dioxan–water mixtures have appeared so far [4–10].

In addition, the results obtained in the present paper have been compared with those for salicylideneanilines in dioxan–water mixtures in order to gain a better understanding of solute–solvent interactions and structural variations. Such studies are now being conducted in our laboratories and will be reported later.

where R is H (2-hydroxy-1-naphthalideneaniline; used as a reference), 2-$CH_3$ (2-hydroxy-1-naphthalidene-2-methylaniline), 3-$CH_3$ (2-hydroxy-1-naphthalidene-3-methylaniline), 4-$CH_3$ (2-hydroxy-1-naphthalidene-4-methylaniline), 2-$C_2H_5$ (2-hydroxy-1-naphthalidene-2-ethylaniline), 3-$C_2H_5$ (2-hydroxy-1-naphthalidene-3-ethylaniline), 4-$C_2H_5$ (2-hydroxy-1-naphthalidene-4-ethylaniline), 2-$OCH_3$ (2-hydroxy-1-naphthalidene-2-methoxyaniline), 3-$OCH_3$ (2-hydroxy-1-naphthalidene-3-methoxyaniline), 4-$OCH_3$ (2-hydroxy-1-naphthalidene-4-methoxyaniline).

## 2. Experimental

### 2.1. Materials

The 2-hydroxy-1-napthalideneanilines were prepared by the condensation of 2-hydroxy-1-naphthaldehyde with aniline and 2-methylaniline, 3-methylaniline, 4-methylaniline, 2-ethylaniline, 3-ethylaniline, 4-ethylaniline, 2-methoxyaniline, 3-methoxyaniline and 4-methoxyaniline. The purity of these compounds was confirmed by a non-aqueous titrimetric method. Stock solutions of Schiff's bases were prepared in dioxan purified by the method given in Ref. [11]. 2-Hydroxy-1-naphthaldehyde and all anilines were purchased from Merck. The water used was deionized water redistilled twice, once over alkaline $KMnO_4$ and then in an all-glass still, and was stored under nitrogen. Standard solutions of perchloric acid and sodium hydroxide were prepared as described elsewhere [1].

### 2.2. Procedure

The study was performed by potentiometric measurement of the hydrogen ion concentration at $25.0 \pm 0.1$°C and under a nitrogen atmosphere in water–dioxan mixtures containing 30, 40, 50, 60 and 70% dioxan (v/v). Ionic strengths of the media were maintained at 0.1 M using sodium perchlorate (Merck).

For each solvent mixture, the pH-ionmeter (Orion 940), fitted with a combined pH electrode (Ingold) containing a filling solution of 0.01 M NaCl–0.09 M $NaClO_4$ as calibrated in concentration units of the hydrogen ion as described previously, using a standard solution of sodium hydroxide as the titrant prepared in the corresponding solvent mixture [1]. The preparation of the test solutions for the potentiometric measurements and the procedure employed for the estimation of new protonation constants have been described in Ref. [1]. All test solutions were freshly prepared before taking the measurements. Computations were carried out with the software termed pKAS, which handles protonation constants with a high degree of efficiency [12,13].

## 3. Results and discussion

The stoichiometric protonation constants of Schiff's bases derived from 2-hydroxy-1-naphthaldehyde and substituted anilines in dioxan–water mixtures at 25°C are tabulated in Table 1.

The log $K_1$ values correspond to the protonation equilibrium of naphtholate O-ions and log $K_2$ to the imine nitrogen atom. These equilibria are $L^- + H^+ \leftrightarrow HL$ and $L + H^+ \leftrightarrow H_2L^+$, respectively. The magnitudes of the differences between log $K_1$ and log $K_2$ values for all Schiff's bases show that the protonation nitrogen atom and naphtholic hydrogen atom are completely dissociable in separate steps.

It is interesting to compare the protonation constants of 2-hydroxy-1-naphthalideneanilines with those of salicylideneanilines reported in our previous paper [1]. It is seen that both the log $K_1$ and the log $K_2$ values of naphthalideneanilines (NA) studied are lower than those of the corresponding salicylideanilines (SA) for each dioxan–water mixture. This result can be attributed to the fact that the electron densities of nitrogen atoms and $O^-$ ions in the case of naphthalideneanilines are smaller because of the higher electron withdrawing tendency of the naphthaline ring compared with the benzene ring. One can think that these values obtained for the protonation constants of the NA and SA can also be explained by comparing the conformational structures of these compounds. Both SA and NA can exist in two planar conformations, one of which has an intramolecular hydrogen bond. The hydrogen-

bonded conformation will be more probable for the NA due to the steric effect of the C8 atom and its attached hydrogen atom. Thus, in the case of NA, the electron density of the hydrogen acceptor imine nitrogen atom decreases and the observation of lower $\log K_2$ values for the NA derivatives compared with those of the corresponding SA derivatives can be explained in terms of their stereochemistry. However, when it comes to $\log K_1$ values, in NA, where an intramolecular hydrogen bonded structures formed by the protonation $O^-$ ion is more probable, one would have expected that the $\log K_1$ values should have been higher than those of SA, contrary to experimental findings. However, the fact that the differences between the $\log K_2$ values of naphthalideneanilines and the corresponding salicylideneanilines decrease with the increasing mole fraction of dioxan suggests that solute–solvent interactions as well as inductive effects are also of importance in the determination of the numerical values of the protonation constants of Schiff's bases.

The protonation constants given in Table 1 are considered in more detail in order to gain more information about the specific effects of the substituents and the effect of the solvent composition on the basicities of the Schiff's bases.

### 3.1. Substituent effect

The variation of the $\log K_2$ values of naphthalideneanilines shows that substitution on the aniline component influences the electron density at the imine nitrogen atom. When the basicities of alkyl derivatives with differing substitution patterns are compared, the order 2-R < reference < 3-R < 4-R (where R is $CH_3$ and $-C_2H_5$) is found in all solvent mixtures. This order can be used as an indication of the extent of the contributions of the alkyl groups to the basicity of the azomethine nitrogen atom. Furthermore, electronic and steric effects of the alkyl groups can also be inferred. Methyl and ethyl groups are capable of releasing electrons by a resonance mechanism and are best able to stabilize a positive center when positioned ortho or para to it. This effect is known as hyperconjugation [14]. If the hyperconjugation was only the effect on the basicity of the azomethine nitrogen atom, the 2-R derivatives would also be more basic than the reference. The fact that the reference is more basic than the 2-R derivatives indicates that the steric effect is dominant over the resonance effect in the case of ortho substitution. The 4-R derivative is more basic than the 3-R derivative. This is in agreement with the prediction that the *p*-alkyl group will contribute more to the electron density of the azomethine group than the *m*-alkyl group.

Considering the reported values of $\log K_2$ of the methyl- and ethylnaphthalideneanilines with the same pattern of substitution, it is observed that the value for each ethyl derivative is slightly smaller than those for the methyl analogs regardless of the medium. In addition, it is found that the orders obtained for the alkyl derivatives of naphthalideneanilines are similar to those of salicylideneanilines in all dioxan–water mixtures [1]. However, as regards the order of the basicities for the methoxy derivatives of naphthalideneanilines, we have found different orders from those obtained for the methoxy derivatives of salicylideneanilines in all the media investigated [1,2]

For naphthalideneanilines

$$3\text{-}OCH_3 < 2\text{-}OCH_3 \leq \text{Reference} < 4\text{-}OCH_3$$

For salicylideneanilines

$$3\text{-}OCH_3 < \text{Reference} < 2\text{-}OCH_3 < 4\text{-}OCH_3$$

The fact that the 2-methoxy derivatives of naphthalideneanilines, in contrast to salicylideneanilines, are slightly less basic than the reference reveals that the steric effect of the methoxy group is more pronounced in the case of the naphthalideneanilines compared to the salicylideneanilines.

In agreement with the observations obtained in our previous work on salicylideneanilines [1,2], any regularity between the $\log K_1$ values and the type and position of the substituents was also not found for naphthalideneanilines in the present study. This lack of regularity is further evidence supporting the lack of significance of electronic effects of the substituents located far from the reaction sites.

Although almost every kind of organic reaction has been treated via the Hammett equation or its extended form in various water–organic solvent mixtures [15–19], any study related to the protonation of Schiff's bases in dioxan–water mixtures is yet to appear in the literature. It is of interest to examine the question whether the Hammett equation can be used to predict the effect of substituents on the basicity of 2-hydroxy-1-naphthalideneaniline in dioxan–water mix-

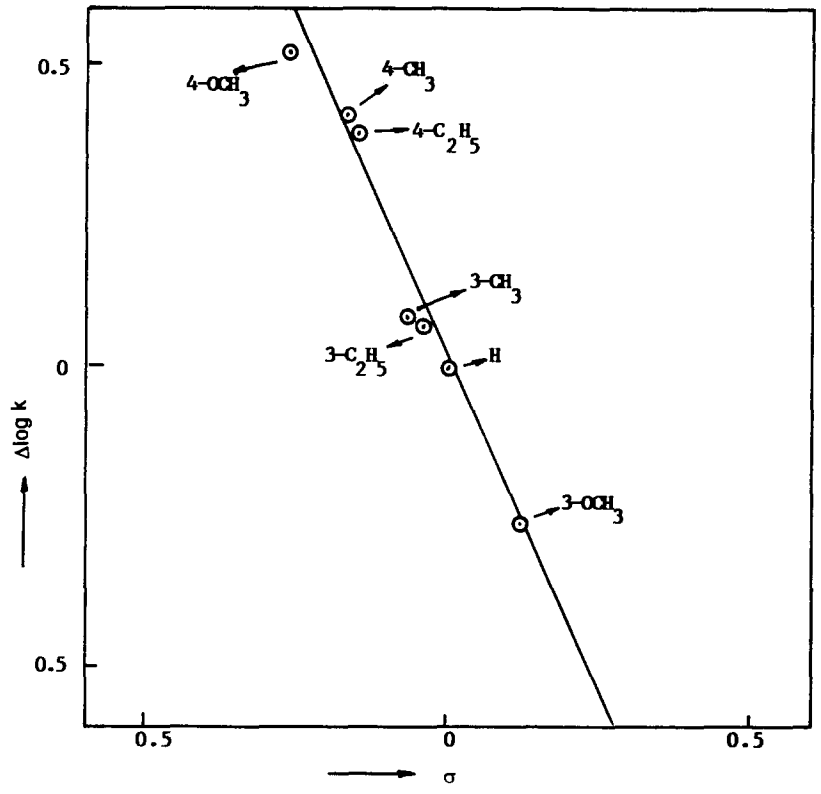

Fig. 1. Plot of $\Delta \log k$ of substituted 2-hydroxy-1-naphthalideneanilines against the Hammett substituent constants ($\sigma$) in 40% dioxan–60% water.

tures. The plots of the $\Delta \log k$ values, i.e. $\log K_2 - \log K_{2(\text{Ref.})}$ for the substituted naphthalideneanilines against the Hammett substituent constants ($\sigma$) are obtained for each dioxan–water mixture studied and the plot for 40% dioxan–60% water is given in Fig. 1 as an example. The equations of the best straight lines through the points are given in Table 2 together with their regression coefficients. From these results, it can be concluded that the Hammett equation, to a reasonable approximation, represents the effects of substituents on the protonation reaction of the imine nitrogen atoms 2-hydroxy-1-naphthalideneanilines in dioxan–water mixtures. Although one can claim that it may not be proper to make any conclusive remarks about the applicability of the Hammett equation, considering that the range of substituent types investigated in this study was not too large and all the substituents were electron donors in nature, a similar observation made in our previous study [2], in which the effect of seven electron donor and acceptor substituents upon salicylideneanilines having similar structures to naphthalideneanilines was investigated, supports our above conclusion regarding the applicability of the Hammett equation to naphthalideneanilines.

Table 2

Furthermore, we attempted to examine the question whether the extended Hammett equation proposed by Hoefnagel and Webster [16] for use in water–organic solvent mixtures covers the experimental data better. We observed that this equation could no longer give any improvement for the substituted naphthalideneanilines in dioxan–water mixtures.

### 3.2. Solvent effect

The numerical $\log K_2$ values for ten naphthalideneanilines determined in dioxan–water

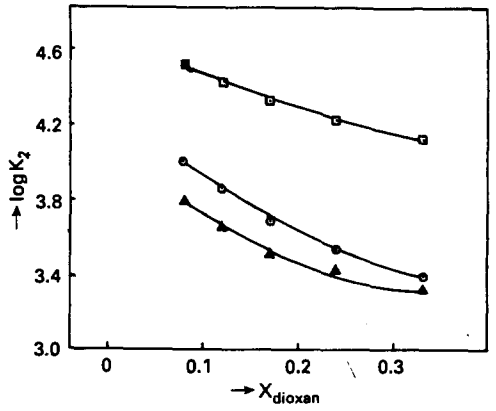

Fig. 4. Variations of $\log K_2$ values of methoxy-substituted Schiff's bases with the mole fraction of dioxan ($x_{dioxan}$). ⊙, 2-$OCH_3$; △, 3-$OCH_3$; ⊡, 4-$OCH_3$.

mixtures decrease with increasing dioxan content in the solvent mixture as shown in Figs. 2–4. For all Schiff's bases studied, it is observed that the relationships are linear over the range of dioxan mole fractions from 0.08 to 0.24. However, $\log K_2$ values at a mole fractionof dioxan of 0.33 are slightly higher than those expected from the linear trend. The linear equations and the related regression coefficients are listed in Table 3. This linear variation is very similar to that found for salicylideneanilines in the same media [1]. This observation is not surprising as the molecular species HL would be solvated better than the ionic species $H_2L^+$ in the solvent mixture rich in dioxan. The fact that an increase in $\log K_2$ values appeared at $x_{dioxan} = 0.33$ suggests that these values may pass through a minimum as the water content becomes low. Such deviations of linearity are characteristic of the dissociation of the charged acids in a number of mixed solvent media and can satisfactorily be explained by differences in solvent stabilization of the species $H^+$ and $H_2L^+$, resulting from the marked preference of the proton for water [20,21]. It may also be caused by ignoring the variation of the dielectric constant of the solvent molecules in the vicinity of an ion that can arise from preferential solvation of the solute by water or an organic component of the solvent mixture [14,22,23]. We have also observed similar behaviors for both salicylideneanilines and pyridines in aqueous ethanol [2,3]. It can thus be said that the nature of the solvent effects on the protonation of the imine nitrogen atoms of Schiff's bases is as expected from that of the uncharged bases in mixed solvent media.

When the variation of $\log K_1$ values of the phenolic moiety of Schiff's bases with solvent composition is examined, it is found that the

[a] Regression coefficient.
[b] Standard deviation of the regression line.

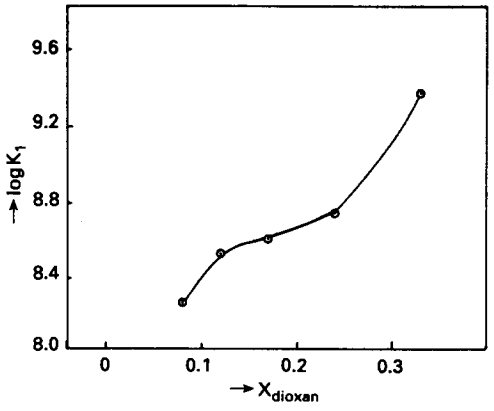

Fig. 5. Variations of $\log K_1$ values of 2-hydroxy-1-naphthalidene-4-ethylaniline with the mole fraction of dioxan ($x_{dioxan}$).

general trends of the curves obtained are qualitatively similar. All the curves increase as the mole fraction of dioxan increases up to 0.24, above which they rise rapidly, as seen in the example given in Fig. 5 for 2-hydroxy-1-naphthalidene-4-ethylaniline. In an attempt to assess more clearly the electrostatic contributions to the solvent effect on protonation, $\log K_1$ values are plotted as a function of the reciprocal of the dielectric constants ($1/\varepsilon$) of the mixed solvent. Fig. 6 shows such a plot. It is evident that a straight line is not obtained, as would be expected if the simple Born's model were an adequate representation of solvent effects on the protonation constants of uncharged acids such as phenols [21,24,25]. This observation may be explained by the existence of a non-electrostatic contribution to the variation in $\log K_1$ with increasing dioxan content which is a result of selective interactions between the molecular or anionic form of the Schiff's base and the preferred species of solvent molecules. In the related equilibrium, the HL species

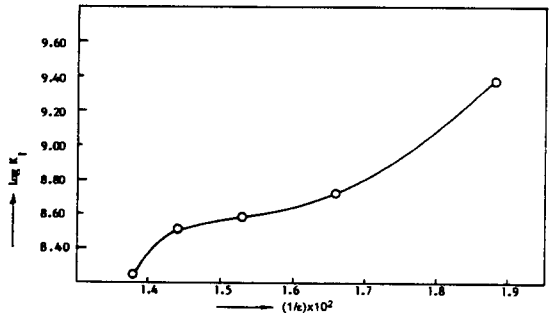

Fig. 6. Variations of $\log K_1$ values of 2-hydroxy-1-naphthalidene-4-ethylaniline the reciprocal of dielectric constants ($1/\varepsilon$) of dioxan–water mixtures.

would be solvated better than the $L^-$ species in solvents containing a higher concentration of dioxan, whereas the opposite would be true for a solvent rich in water, and thus the $\log K_1$ values would be expected to increase as observed with increase of dioxan concentration. The steep increase of the $\log K_1$ values at $x_{dioxan} = 0.33$ may be connected at least partially with a change in the effective dielectrc constant in the cibotactic region [14]. Thus, our results for Schiff's bases in the present and previous work [1,2] support the hypothesis that solute–solvent interactions of a non-electrostatic nature play an important role in controlling acid–base processes in the mixed solvents.

# Inorganic tin(II) determination by FIA with amperometric detection of its oxinate complex

K. Boutakhrit, Z.P. Yang, J.-M. Kauffmann *

*Institute of Pharmacy, Free University of Brussels, Campus Plaine CP 205/6, 1050 Brussels, Belgium*

Received 6 March 1995; revised 18 May 1995; accepted 19 May 1995

**Abstract**

A highly selective, rapid and direct amperometric method, based on the formation of a complex between tin(II) and 8-hydroxyquinoline (oxine), has been developed for the determination of trace levels of tin(II) using flow injection analysis. Tin(II) electro-oxidation was catalyzed by oxine; its oxidation peak occurred at +0.05 V vs. Ag/AgCl at a glassy carbon electrode in 0.1 mol $l^{-1}$ acetate buffer (pH 6). A linear relationship was obtained between the peak current and the tin(II) concentration in the range 0.25–20 μmol $l^{-1}$. The detection limit was 0.1 μmol $l^{-1}$ and the relative standard deviation calculated by the injection of a 10 μmol $l^{-1}$ tin(II) solution was 5% ($n = 20$). Optimization of several experimental parameters has been carried out and the influence of numerous cations and possible interfering molecules encountered in radiopharmaceuticals and in dental gels has been investigated. The method was applied to the determination of tin(II) in dental gels.

*Keywords:* Amperometric detection; Dental gel; Flow injection analysis; 8-Hydroxyquinoline; Tin(II) determination

## 1. Introduction

Tin occurs in trace amounts in most foods and in larger amounts in canned foods [1]. A rapid, selective and quantitative assay for inorganic tin(II) used as a reducing agent for radioactive $^{99m}$Tc(VII) would be very desirable in the quality assurance control of radiopharmaceutical "kits". Tin (II) fluoride is used in gel formulations for the treatment of dental surfaces. However, on standing, tin(II) is oxidized and the gel loses its activity. Actually, the determination of tin(II) in the presence of tin(IV) is of considerable interest.

Many techniques have been described for the determination of total tin after conversion to tin(II) or tin(IV), such as atomic absorption spectrometry [2–6], fluorimetry [7], spectrophotometry [8–14], polarography [15–19] and anodic stripping voltammetry [20–25]. Tin, when present in appreciable amounts, can be determined by gravimetry or oxidative volumetry with potentiometric detection [26–29] or by complexometry [27]. Few methods allow the determination of tin(II) in the presence of tin(IV); they are generally complex, insensitive, and time-consuming. Tin(II) is the least favourable cation for analytical investigations; it is not only readily oxidized by air [30] ($E_0$(Sn(II)/Sn(IV) ≈ +0.15 V vs. NHE), but it also precipitates and forms basic oxides above pH 2 [31].

The compound 8-Hydroxyquinoline (oxine; 8-quinolinol) is a well-characterized reagent

* Corresponding author.

*SSDI* 0039-9140(95)01650-3

that reacts with more than 60 metal ions to form complexes whose aqueous phase formation constants range from about $10^4$ ($Ba^{2+}$) to $10^{38}$ ($Fe^{3+}$) [32]. It is a useful reagent for the extraction, separation and spectrophotometric detection of metal ions [33]. Oxine (HOx) has been extensively applied to the polarographic [34–37] and adsorptive stripping voltammetric [38–41] determination of trace metals using mercury electrodes. The latter, however, are quite unstable under hydrodynamic conditions. Recently, Cai and Khoo [42] determined aluminium(III) at trace levels in water samples by differential pulse adsorptive stripping voltammetry based on the oxidation of the aluminium(III)–HOx complex at a glassy carbon electrode at +0.88 V vs. $Ag/Ag^+$. The complexation kinetics were fast; however, numerous other metals interfere since they show, once complexed by oxine, an oxidation peak close to the aluminium(III)–oxine oxidation peak [42]. In a project devoted to tin(II) analysis, we discovered that the oxidation of tin(II) at solid electrodes was catalyzed thanks to its complexation by oxine and occurred at a potential close to +0 V vs. $Ag/Ag^+$ [43]. In the present work, flow injection analysis (FIA) with amperometric detection was used for the rapid and selective determination of tin(II). A study of the possible interferences present in radiopharmaceutical kits and its application to tin(II) analysis in a dental gel formulation is illustrated.

## 2. Experimental

### 2.1. Apparatus

Voltammetric measurements were made with a BAS CV 27 electrochemical analyzer and a three-electrode cell coupled to a HP 7090A recorder. A 3 mm diameter glassy carbon electrode (BAS), a platinum wire and an Ag/AgCl (3 M NaCl) electrode (BAS), served as working, auxiliary and reference electrodes, respectively. The other working electrodes used were a dual carbon paste electrode (BAS; diameter, 3 mm) prepared from standard paste (Metrohm Ea 207c) and a carbon paste electrode bulk modified by 8-hydroxyquinoline (5% (m/m)). The flow system consisted of a pump (Hiload™ pump P-50) used to deliver the carrier, and a rotary valve with a 20 µl loop for sample injection. The reaction coil was 50 cm × 0.02 cm i.d. Peek tubing connected to a thin-layer electrochemical cell (BAS; LC-CC5 dual glassy carbon working electrode 2 × 3 mm in diameter). The electrode potential was adjusted by means of a potentiostat (BAS; LC-4B). Amperometric currents were recorded using a $Y-t$ recorder (Kipp & Zonen, type BD 41). The pH measurements were made with a Tacussel Mini 80 pH meter.

### 2.2. Reagents

All chemicals were of analytical grade. Tin(II) chloride dihydrate was from Merck. Oxine (HOx), 8-hydroxyquinoline-5-sulfonic acid hydrate, 8-hydroxyquinoline-7-iodo-5-sulfonic acid, and 8-hydroxyquinoline-*N*-oxide were obtained from Aldrich. Methylene diphosphonic acid (medronic acid), (α, D)-glucoheptonic acid and gentisic acid were from Sigma, pentetic acid (Schuchardt München), dimercaptosuccinic acid (DMSA) and 4-aminobenzoic acid were from Aldrich. A standard solution of tin(II), prepared in nitrogen-deaerated HCl, was titrated iodometrically [44,45]. A fresh solution (0.01 mol $l^{-1}$) was prepared daily and kept in the dark before use. Tin(IV) and other metal ion solutions were prepared by dissolution of the corresponding salts in 0.1 mol $l^{-1}$ HCl. A stock solution (0.01 mol $l^{-1}$) of oxine was prepared in methanol and protected from light by storage in a dark glass bottle. A 0.1 mol $l^{-1}$ acetate buffer (pH 6) served as the carrier and for solution dilution. It was prepared by sodium acetate trihydrate dissolution in demineralized double-distilled water and the pH was adjusted to 6 with 0.1 mol $l^{-1}$ HCl solution.

### 2.3. Analytical procedure

The amperometric signal was obtained by holding the electrode at +0.15 V vs. Ag/AgCl. The carrier flow rate was 1 ml $min^{-1}$. Several media were tested for the tin(II) stock solution preparation, namely acetonitrile [46], DMSO [47], DMF [48], glycerol and polyalcohols [48–50], but better repeatability of the tin(II)–oxine response was obtained using 1 mol $l^{-1}$ HCl. The tin(II)–oxine complex was prepared by adding aliquots (less than 100 µl) of the deaerated tin(II) stock solution to 10 ml of 0.1 mol $l^{-1}$ acetate buffer (pH 6) containing 0.25 mmol $l^{-1}$ oxine (the latter was the blank). After standing for 1 min, the tin(II)–oxine solution was injected into the FIA system. It

should be mentioned that the pH of the injected solution was lower than the carrier pH, at worst by approximately 0.3 pH units. The blank response was low, and its magnitude, i.e. 2 nA, was subtracted from the tin(II)–oxine response. The tin(II)–oxine solutions were prepared just before injection. Before each set of experiments (i.e. daily), the glassy carbon working electrode (GCE) was polished with 0.01 μm alumina slurry on a polishing cloth (BAS).

## 3. Results and discussion

### 3.1. Linear scan voltammetry

A linear scan voltammogram (LSV) of 0.1 mmol $l^{-1}$ tin(II) (Fig. 1, curve a) in 0.1 mol $l^{-1}$ acetate buffer (pH 6) showed an oxidation process starting at +0.15 V and spread over a large potential range (from +0.15 to +0.6 V). The broad shape of the curve was not very useful from an analytical point of view (in terms of sensitivity and selectivity). The linear scan voltammogram of 0.2 mmol $l^{-1}$ oxine in 0.1 mol $l^{-1}$ acetate buffer (pH 6) showed one well-defined oxidation peak (P1) at +0.58 V (Fig. 1, curve b). On the addition of tin(II) (0.05 mmol $l^{-1}$), P1 decreased and two new oxidation peaks appeared, one (P2) located at a less positive potential (+0.05 V) and the other (P3) at a more positive potential than P1 (+1.13 V) as shown in Fig. 1, curve c. Subsequent additions of tin(II) lead to an increase in the peaks P2 and P3 and a decrease in peak P1. On the addition of tin(IV), P1 decreased and the oxidation peak P3 increased (not shown). As reported previously [43], peak P2 corresponded to the oxidation of tin(II) catalyzed by oxine and P3 corresponded to the oxidation of the oxinate complexed to tin(IV). At this point in the work, it is interesting to note that an electrode held at +0.15 V will not sense oxine or tin(II), but will sense the tin(II)–oxine complex.

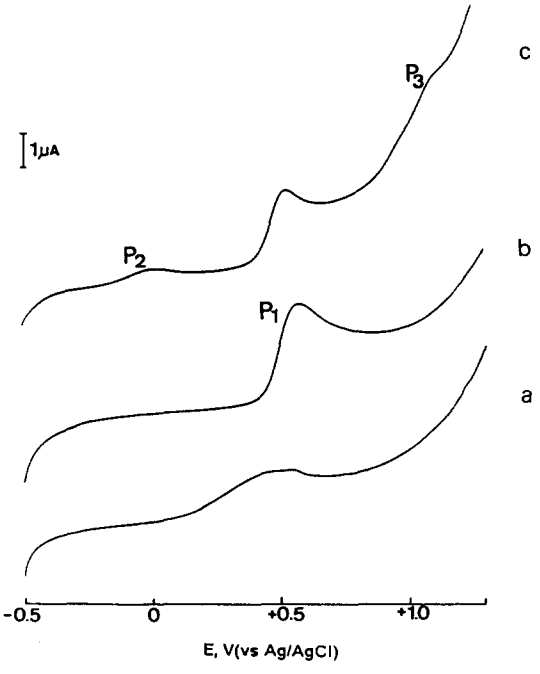

Fig. 1. Linear-scan voltammograms at the glassy carbon electrode in 0.1 mol $l^{-1}$ acetate buffer (pH 6). (Curve a) buffer + 0.1 mmol $l^{-1}$ tin(II); (curve b) buffer + 0.2 mmol $l^{-1}$ HOx, P1 is at +0.58 V; (curve c) buffer + 0.2 mmol $l^{-1}$ HOx + 25 μmol $l^{-1}$ tin(II), P2 is at +0.05 V, P3 is at +1.13 V. (Scan rate, 20 mV $s^{-1}$.)

Several molecules structurally related to oxine have also been investigated as possible complexing agents for tin(II) catalytic oxidation (see experimental section), but oxine was found to give the best signal in terms of peak shape and ease of oxidation [43].

### 3.2. Optimization of Sn(II)–HOx formation

*Effect of HOx concentration*

The intensity of the tin(II)–HOx peak (P2) was measured by LSV in acetate buffer (pH 6) as a function of the HOx concentration in the presence of 50 μmol $l^{-1}$ tin(II) (Fig. 2). The peak height increased linearly on raising the HOx concentration from 20 to 50 μmol $l^{-1}$ (slope 1) and from 50 to 80 μmol $l^{-1}$ (slope 2); it remained constant beyond 80 μmol $l^{-1}$ oxine (i.e. the complete complexation of tin(II)–HOx was attained). From the structure of the isolated and spectroscopically characterized (NMR, Mössbauer, IR) tin(II)–oxine, and in accordance with the UV-vis spectroscopic data [51], our results suggested that complexes with stoichiometries of 1:1 tin(II)/HOx (slope 1) and 1:2 tin(II)/HOx (slope 2) were formed, respectively.

*Influence of pH*

The solution pH may influence the distribution both of tin(II) [31] and of the HOx species ($pKa_1 = 4.9$; $pKa_2 = 9.8$) [52]. In the pH range 5–9, HOx existed mainly in its neutral form. At pH values above 8.8 and below 5.9, HOx was converted to the phenolate $C_9H_6NO^-$ ion

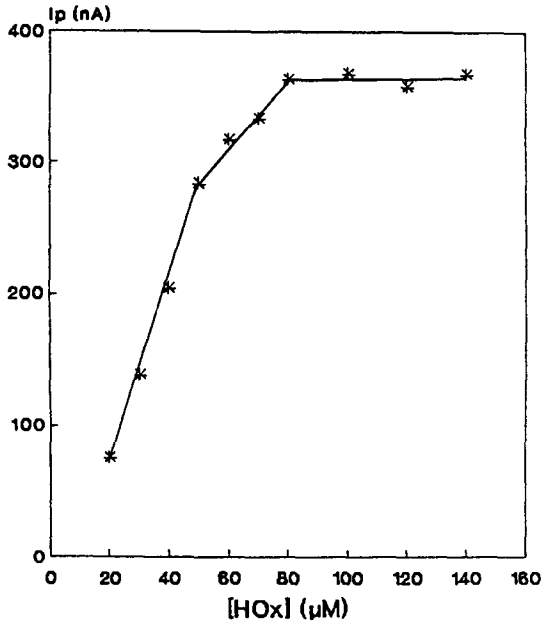

Fig. 2. Peak current (LSV) of tin(II)–HOx as a function of the HOx concentration. ($C_{Sn(II)} = 50$ μmol $l^{-1}$; 0.1 mol $l^{-1}$ acetate buffer (pH 6).)

and the oxinium $C_9H_6N^+OH$ cation, respectively. The peak height of the tin(II)–HOx complex, studied by LSV, was constant in the pH range 5–7, whereas at lower or higher pH values it diminished (Fig. 3). This indicated that the complexation was complete in the pH

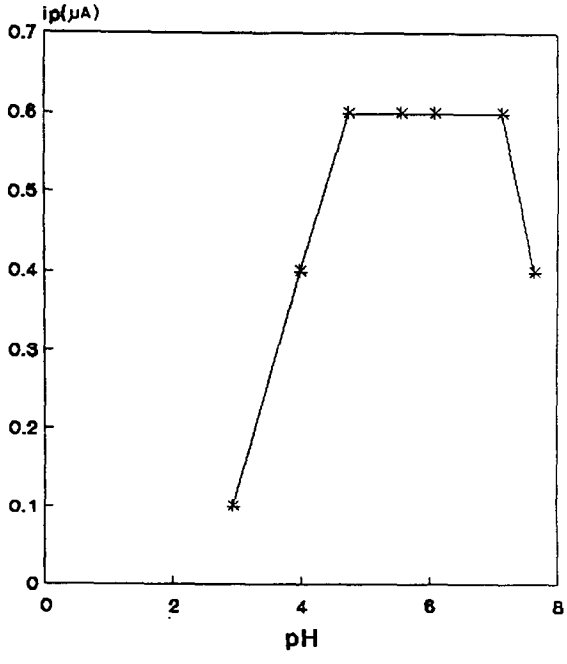

Fig. 3. Peak current (LSV) of tin(II)–HOx as a function of pH (acetate adjusted with HCl or NaOH). ($C_{Sn(II)} = 50$ μmol $l^{-1}$; $C_{HOx} = 0.1$ mmol $l^{-1}$. Scan rate, 20 mV $s^{-1}$.)

range 5–7 i.e. where oxine existed in its neutral form. Below pH 5, the protonation of oxine inhibited tin(II)–HOx formation and above pH 7, formation of the complex $Sn(OH)_3^-$ may occur [31,51]. We note also that the tin(II)–HOx peak (P2) shifted to less positive values by raising the pH from 2 to 5 and it became pH independent in the range 5–8. Several electrolytes have been tested, namely NaOAc–HCl, $NH_4OAc$, $NH_4Cl$–$NH_3$, $NaH_2PO_4$–$Na_2HPO_4$ and $H_4Cit$–$Na_3HCit$ (all at a concentration of 0.1 mol $l^{-1}$ and at pH 6). The oxidation peak shape (intensity and potential) of the tin(II)–HOx complex was found to differ significantly depending on the electrolyte used. In phosphate buffer, a 40% peak decrease was observed compared with the peak obtained in acetate buffer, a phenomenon likely to be due to competition between phosphate and oxine for tin(II) complexation. In subsequent work, a pH 6 NaOAc–HCl buffer was selected because of a better peak sensitivity and buffering capacity (acetate is also a weak competitor for tin(II) complexation).

### 3.3. Flow injection analysis of tin(II)

*Stability of the tin(II)–HOx complex*

Solutions of tin(II) (10 μmol $l^{-1}$) in the presence of 0.2 mmol $l^{-1}$ oxine at pH 6 were injected into the FIA set-up, the electrode being held at +0.15 V (see experimental section). Experiments were performed in the presence and in the absence of dissolved oxygen in the sample and the carrier. The FIA response was reproducible for the first 10 min following the preparation of the complex, then a gradual current decrease was observed with a loss of 25% of the peak height after 20 min of standing. Since no significant difference was observed in the presence or absence of dissolved oxygen, the decline in the response may most likely be attributed to the poor solubility of the metal–oxinate complex (between 1 nmol $l^{-1}$ and 1 μmol $l^{-1}$) [53]. From these results we may infer that the linear scan voltammetric determination of tin(II)–oxine, using the standard additions method, would be inappropriate due to the length of the procedure. With use of FIA, the total analysis time was reduced to 3 min per sample.

*Choice of the working electrode*

In LSV, the GCE needed resurfacing by manual polishing after each scan in order to

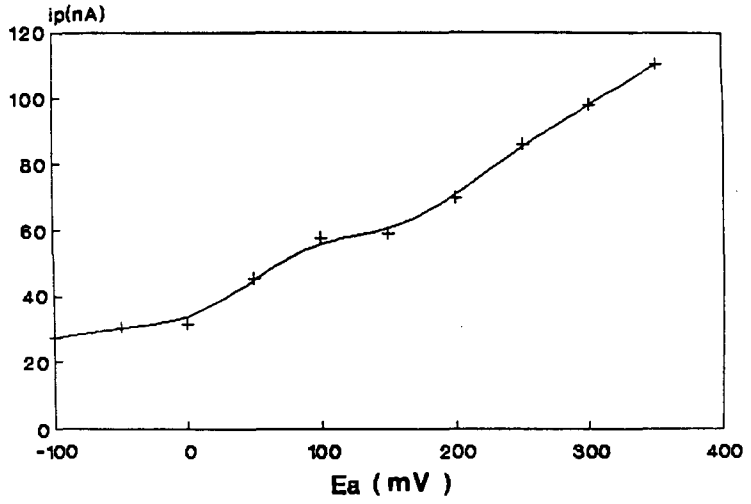

Fig. 4. Hydrodynamic voltammogram of 50 μmol $l^{-1}$ tin(II) (carrier, 0.1 mol $l^{-1}$ acetate buffer (pH 6); flow rate, 1 ml $min^{-1}$).

remove adsorbed products due to tin(II)–HOx oxidation. In FIA, the electrode was renewed daily since fouling was minimized due to reduced contact time and thanks to the washing out effect exerted by the carrier flow. A comparative study of several working electrodes has been carried out. The slope of the calibration graph obtained in FIA at the GCE was seven and three times higher than at the carbon paste electrode (CPE) and oxine-modified CPE, respectively.

*Effect of the applied potential and flow rate*

As reported in Fig. 4, the hydrodynamic voltammogram (HDV) of the tin(II)–HOx complex (10 μmol $l^{-1}$) at the GCE showed an almost sigmoidal curve, indicating a diffusion-controlled process. In order to achieve good signal stability and sensitivity, an applied potential of +0.15 V was selected. The FIA response of the injected tin(II)–HOx complex (10 μmol $l^{-1}$) increased linearly upon raising the flow rate to 0.7 ml $min^{-1}$; it remained constant beyond this value. A flow rate of 1 ml $min^{-1}$ was selected for further studies.

*Analytical characteristics*

Actually, the FIA experiments may be performed as described above (see experimental section) or by using a carrier containing the complexing agent, provided that the complexation is fast. The latter procedure consisted of using a 0.1 mol $l^{-1}$ acetate buffer carrier at pH 6 containing oxine (0.25 mmol $l^{-1}$) and injecting the tin(II) sample just after its preparation in the acetate buffer. Both procedures have been shown to be suitable for tin(II) determination, with no significant differences in terms of sensitivity. A linear relationship was observed between the amperometric signal and tin(II) concentrations between 0.25 and 20 μmol $l^{-1}$; $Ip$ (nA) = 10.1 × [$Sn^{2+}$] (μmol $l^{-1}$) + 2.98 ($r$ = 0.998). Typical FIA responses as a function of tin(II) concentration are shown in Fig. 5. The repeatability was studied by serial injections of a 10 μmol $l^{-1}$ tin(II)–HOx solution and the relative standard deviation was 5% ($n$ = 20). The detection limit (three times the standard deviation of the blank) was 0.1 μmol $l^{-1}$ by FIA and 10 μmol $l^{-1}$ (signal-to-noise ratio, 3) by LSV.

*Interferences*

In the amperometric tin(II)–HOx determina-

tion, provided that there was an excess of oxine, the cations investigated did not interfere at the applied potential because, once complexed by oxine, they showed no response (Ca, Cd, Cr, Mg, Pb, Zn) or an oxidation peak P3 at a high positive potential (Al, Co, Cu, Fe, Mn, Ni, Sn(IV)) (Table 1) [41]. The influence of different molecules which may be present in radiopharmaceutical kits along with tin(II) has been studied. As shown in Table 2, except for DMSA and ascorbic acid (AA), the molecules were not electroactive at +0.15 V. The effect of these molecules on the tin(II)–HOx peak is also shown in Table 2. It appeared that in addition to AA and DMSA interference, radiopharmaceutical kits containing molecules which form strong complexes with tin(II), such as medronic acid, 4-aminobenzoic acid and pentetic acid gave rise to a decrease in the tin(II)–HOx peak. The interference of AA, however, could be avoided by injecting the sample in the absence (AA response) and in the presence of oxine (AA + tin(II)–HOx response) and subtracting the signals.

*Application*

The method was applied to the determination of tin(II) by analyzing two lots of dental gel formulation (gel composition: sorbitol, water, hydrated silica, PEG-32, sodium lauryl sulfate, xanthum gum, stannous pyrophosphate, flavour, titanium dioxide, zinc citrate, sodium fluoride, sodium saccharin). The sample was dissolved in 1 mol $l^{-1}$ deaerated HCl and sonicated for 5 min. Samples were clarified by standing and the supernatant was injected after passage through a 0.45 μm filter. Two samples have been analyzed (5 assays per sample, 5 injections per assay). The tin(II) results were obtained by reference to the calibration curve and were in good agreement with results obtained by iodatometry [44,45] (Table 3). The calculated $t$ and $F$ values did not exceed the theoretical values (Table 4). From the obtained data, it

**Abstract**

Indirect thermo-optical detection for capillary electrophoresis is described first. A 20 mW helium–neon laser (632.8 nm) was used to provide the pumping beam and a 2 mW helium–neon laser (632.8 nm) supplied as the probe beam; Methylene Blue dye was used as a background absorber. The addition of ethanol to the background electrolyte solution can be performed to reduce adsorption of Methylene Blue onto the capillary wall. The detection method was applied to the detection of amino acids separated by capillary electrophoresis. The detection limit for lysine was $5 \times 10^{-6}$ mol $l^{-1}$ (signal-to-noise ratio, 2).

*Keywords:* Amino acids; Capillary electrophoresis; Indirect-optical detection; Methylene Blue

## 1. Introduction

Capillary electrophoresis (CE) is a highly efficient microvolume separation technique that can be applied to the separation of a variety of compounds, including proteins, peptides, DNA fragments, pharmaceuticals, inorganic ions and organic compounds [1]. The detection methods used in CE mainly include UV absorbance detection [2], fluorescence detection [3], electrochemical detection [4], laser interference refractive index detection [5], thermo-optical detection [6], etc. However, many compounds do not inherently possess the necessary characteristics for sensitive detection, indirect detection can be used as a more universal method for non-absorbing analytes (non-fluorescent and electrochemically inactive analytes) after CE separation. The possibilities for indirect laser-induced fluorescence detection have been studied by Yeung [7]. He used the latter detection method in the separations of amino acids, nucleotides, proteins, sugars and inorganic ions. Olefirowicz and Ewing [8] first demonstrated the use of indirect amperometric detection with CE and reported the successful separation of amino acids and dipeptides. Indirect UV absorbance detection has been used extensively to detect inorganic ions, organic acids, amino acids, etc. [9]. However, the detection limit for indirect UV absorbance detection is limited by a short light path in the UV absorbance detector.

Crossed-beam thermo-optical detection provides very small volumes, typically on the order of a few picoliters. The sensitivity of this method is almost unrelated to the light path. The thermal lensing and the thermo-optical interference approach were used in the crossed-beam thermo-optical method. Since the internal diameter of the capillary is small, the thermal lensing approach is difficult to use in CE. The interference detection technique has been widely employed in the crossed-beam thermo-optical detection method for CE. In thermo-optical detection, the two laser beams

*SSDI* 0039-9140(95)01653-8

are located perpendicular to each other and in a plane orthogonal to the capillary tube. When the analyte passes through the detection window, absorbance by the analyte will generate a temperature rise in the buffer. Since the refractive index of almost every substance changes with temperature, absorbance of the pumping beam results in a refractive index change within the buffer that can be detected as a change in the intensity of the probe beam. Yu and Dovichi [10,11] exploited the high intensity and focusing ability of a laser to construct a thermo-optical detection system, which was used to detect derived amino acids after CE separation. The detection limit for glycine was 42 attomol. But thermo-optical detection is relative to the molar absorption coefficient of the analytes, the detector cannot be used directly to detect non-absorbing analytes.

In this paper, an indirect thermo-optical detection method for detecting native amino acids after CE separation is first described. In the CE detector, Methylene Blue was used as a background absorber, and the addition of ethanol to the background electrolyte solution (BGES) can reduce the adsorption of Methylene Blue onto the capillary wall and enhance the detector signal.

## 2. Experimental

### 2.1. Instrumentation

The capillary electrophoresis system was constructed in the laboratory [5], and was similar to that described previously by Jorgenson and Lukacs [12]. A high-voltage d.c. power supply (0–30 kV; made in Shanghai, China) was employed to provide a high voltage. The capillary used was of uncoated fused-silica, 75 μm in i.d. (Yongnian Optical Fiber Factory), and 59 cm in length (48 cm to the detector). A 1 cm length of the polymer coating was carefully scraped; this was used as the window of the detector. The indirect thermo-optical detection system is shown in Fig. 1, and is similar to that described by Yu and Dovichi [10]. A 20 mW helium–neon laser (M1000 mode; made at the Shanghai Institute of Laser Technology) provided the pumping beam, and a 2 mW helium–neon laser (TEMOO mode; made at the Shanghai Institute of Laser Technology), provided the probe beam. Other detector components included a lock-in amplifier (ND240 mode; Nanjin University Instrument Factory), a chopper (194A mode, EG&G, USA), a photodiode (Wuhan University semiconductor factory), and lens (3) and lens (6) ($f = 9$ mm). A recorder (Dahua instrument factory; Shanghai) was used to record the electropherograms of the analytes.

### 2.2. Chemicals

Lysine, alanine and isoleucine were purchased from Sigma Co. Other chemicals were of analytical reagent grade (Shanghai Chemical Co.). Water was double-distilled. Samples were dissolved in the BGES.

### 2.3. Experimental procedure

Alignment of the optical system was performed by filling the capillary with BGES containing Methylene Blue. The positions of the two lenses were adjusted so that the beams were both focused onto the capillary, this required an iterative process to ensure maximum overlap between the pumping and probe laser beams. The probe beam was aligned first. The position of the focused lens was adjusted carefully to obtain a high-contrast interference pattern in the forward direction of the probe beam. Subsequently, the pumping beam was focused onto the capillary until maximum overlap between the pumping and probe beams and minimum light scattering of the pumping beam at the point of detection were achieved; this generated the maximum signal. Once this

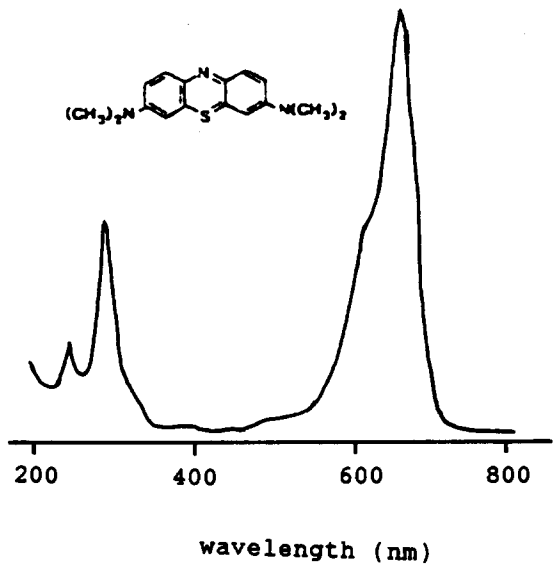

Fig. 2. The structure and spectrum of Methylene Blue. (Buffer, $2.5 \times 10^{-3}$ mol $l^{-1}$ $H_3PO_4$ + 20% ethanol; concentration of Methylene Blue, $10^{-5}$ mol $l^{-1}$).

was achieved, all optical components were fixed. In indirect detection, the power of the pump laser beam was 20 mW and its modulated frequency was 12 Hz. CE was performed as below.

A new capillary was rinsed with 0.1 mol $l^{-1}$ sodium hydroxide, double-distilled water and BGES, in the appropriate order. The capillary was filled with BGES by the hydrostatic method. The high-voltage output and the ground were connected to platinum electrodes, which were placed in 6 ml electrolyte reservoirs. The ends of the fused silica capillary were dipped in both reservoirs, completing the circuit. The sample solution was introduced by siphoning at a given height. The electrophoresis was performed at constant voltage. A recorder was used to record the electropherograms of the analytes.

## 3. Results and discussion

### 3.1. Choice of background absorber

In indirect thermo-optical detection, a helium–neon laser (632.8 nm) was used to provide a pumping beam. Experiments showed that the absorption wavelength of Methylene Blue can match that of the helium–neon laser beam. The structure and spectrum of Methylene Blue are shown in Fig. 2. The molar absorption coefficient of the absorber at 633 nm is about $5 \times 10^4$ l mol$^{-1}$ cm$^{-1}$.

In acidic buffer, adsorption of Methylene Blue onto the capillary surface was noted by Higashijima et al. [13]. In the experiments, we found that the addition of ethanol to BGES can reduce the adsorption of the capillary surface. The results are shown in Fig. 3. The increase in the concentration of ethanol was beneficial, leading to an improvement in the peak shape of Methylene Blue. This phenomenon can be attributed to the fact that ethanol can limit the dissociation of silanol on the capillary surface and the adsorption of Methylene Blue. Meanwhile, ethanol also enhanced the Methylene Blue detection signal, because $dn/dT$ of ethanolic solutions is larger than that of water solutions; this was beneficial for the improvement of sensitivity in indirect thermo-optical detection.

### 3.2. Indirect detection

The indirect thermo-optical detection of amino acids was accomplished by the addition of cationic absorber, Methylene Blue, to the BGES. When the capillary was filled with BGES containing Methylene Blue, a constant background thermo-optical signal was produced in the detection system. Due to the need to maintain charge neutrality of the sample zone in CE, Methylene Blue in BGES was displaced by cationic analytes when they passed by the detection window. The displacement lead to a decrease in the background signal. As a result, negative peaks were expected in the electropherogram. Fig. 4 shows an electropherogram of amino acids in a phosphoric

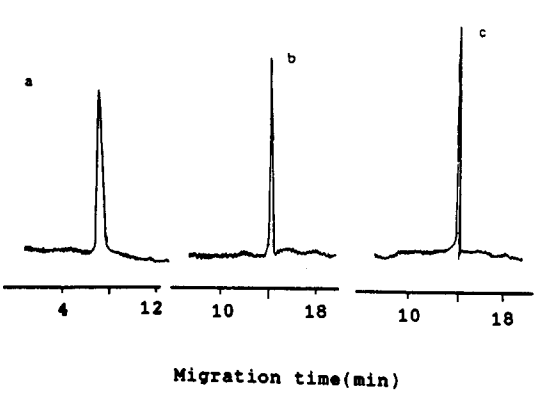

Fig. 3. Electropherogram of Methylene Blue. Buffer a, $2.5 \times 10^{-3}$ mol $l^{-1}$ $H_3PO_4$; buffer b, $2.5 \times 10^{-3}$ mol $l^{-1}$ $H_3PO_4$ + 20% ethanol; buffer c, $5 \times 10^{-3}$ mol $l^{-1}$ $NaH_2PO_4$ + 40% ethanol, 19 kV; sample, $10^{-4}$ mol $l^{-1}$ Methylene Blue.

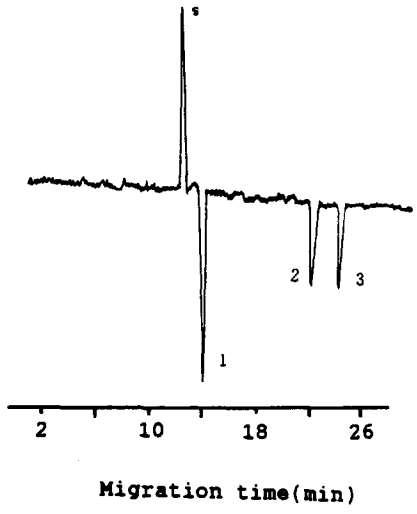

Fig. 4. An electropherogram of amino acids. Electrophoretic conditions: buffer, $2.5 \times 10^{-3}$ mol $l^{-1}$ $H_3PO_4$ + 20% ethanol + $10^{-4}$ mol $l^{-1}$ Methylene Blue; 19 kV. s, System peak; 1, lysine ($5 \times 10^{-5}$ mol $l^{-1}$); 2, alanine ($10^{-4}$ mol $l^{-1}$); 3, isoleucine ($10^{-4}$ mol $l^{-1}$).

acid–ethanol–Methylene Blue buffer. In this buffer, both the amino acids and the Methylene Blue possessed positive charges; the amino acids were detected by the indirect thermo-optical method. The migration time of the first peak(s) in the electropherogram corresponded with that of Methylene Blue. Of three amino acids, the peak height of lysine was the largest since its mobility was nearest to that of Methylene Blue and it had the highest displacement ratio.

### 3.3. Linearity and detection

In CE analyses, the reproducibility depends on factors such as sampling, temperature, voltage, and position of the probe aperture in the thermo-optical detector. The effects of the above-mentioned factors can be reduced by using the internal standard method [14]. Fig. 5 shows an electropherogram of tetrabutylammonium bromide and lysine. In phosphate–ethanol–Methylene Blue buffer, the two compounds exhibited good peak shapes. Fig. 6 illustrates the relationship between relative peak height and the concentration of lysine using tetrabutylammonium bromide as internal standard. When the concentration of lysine was below $10^{-4}$ mol $l^{-1}$, the equation for the calibration curve was $h = 1.04 \times 10^{-4} C - 3.85 \times 10^{-6}$ (where $h$ is the relative peak height and $C$ is the concentration of lysine; $r = 0.9994$). The detection limit for lysine was $5 \times 10^{-6}$ mol $l^{-1}$ (signal-to-noise ratio, 2).

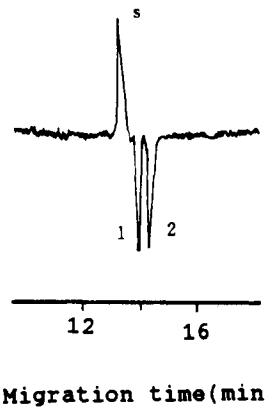

Fig. 5. An electropherogram of lysine and tetrabutylammonium bromide. Electrophoretic conditions: buffer, $56 \times 10^{-3}$ mol $l^{-1}$ $NaH_2PO_4$ + 40% ethanol + $10^{-4}$ mol $l^{-1}$ Methylene Blue; 19 kV. s, System peak; 1, lysine ($2.5 \times 10^{-3}$ mol $l^{-1}$); 2, tetrabutylammonium ($2.5 \times 10^{-5}$ mol $l^{-1}$).

## 4. Conclusions

In the present work, we have demonstrated indirect thermo-optical detection for CE. With Methylene Blue added to BGES as an absorber, three amino acids were separated on a home-made CE system with indirect thermo-optical detection. Since the conditions in our laboratory were limited, in indirect thermo-optical detection, helium–neon lasers (632.8 nm) were used to provide both the probe beam and the pumping beam. If the probe beam is supplied by another laser, such as an argon ion laser, the detection limit in indirect thermo-optical detection can be further improved due to

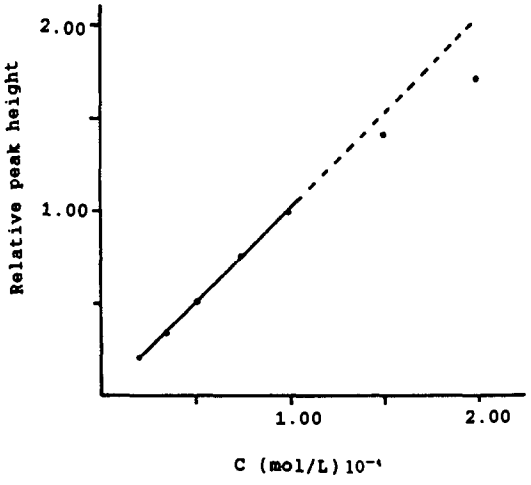

Fig. 6. Calibration curve of lysine. Conditions as in Fig. 5. Internal standard, tetrabutylammonium bromide ($10^{-4}$ mol $l^{-1}$).

a decrease in the effects of light scattering from the probe beam. Future work will investigate possible improvements to the detection sensitivity including the use of highly stable lasers, and the improvement of the optical configuration in the indirect thermo-optical detector to decrease the detector noise, leading to an enhancement of the signal-to-noise ratio.

# Studies on $\beta$-type reaction and kinetics of lanthanides with *p*-bromochloroarsenazo

Jinzhang Gao *, Fei Zha, Hui Chen, Jingwan Kang

*Institute of Chemistry, Northwest Normal University, Lanzhou 730070, China*

Received 16 January 1995; revised 15 May 1995; accepted 23 May 1995

**Abstract**

The reaction behaviour of the $\beta$-type chelates of lanthanide ions ($Ln^{3+}$) with *p*-bromochloroarsenazo (4-CAsA-pB) in 0.01 mol $l^{-1}$ $HClO_4$ solution has been studied systematically by a spectrophotometric method. All the lanthanide ions can form $\beta$-type chelates with *p*-bromochloroarsenazo. The maximum absorption wavelength is in the range 727–731 nm, the molar absorptivities are about $6.0 \times 10^4$–$9.0 \times 10^4$ $cm^2$ $mol^{-1}$, the composition ratio of $Ln^{3+}$ ions with 4-CAsA-pB is 1:2 and the actual combining ratio is 2:4. The optimum acidity range ($\Delta$pH value) of the formation of $\beta$-type chelates has been obtained. Kinetic parameters, such as the reaction order and rate constants, have also been studied and a formation mechanism for the $\beta$-type chelates has been proposed.

*Keywords:* Absorption spectra; $\beta$-Type chelates; *p*-Bromochloroarsenazo; Kinetic parameters; Lanthanides

## 1. Introduction

The interaction between lanthanide ions and some 2,7-bis(arylazo) derivatives of chromotropic acid, which form chelates that have high molar absorptivities in the 700–800 nm region, has been for a long time, of interest to analysts [1,2]. Many authors [3–7] have reported that these reactions can be used for the determination of trace amounts of light lanthanide elements in the presence of heavy lanthanide elements. Some authors [7,8] have presented the kinetics and mechanisms of the formation of $\beta$-type chelates. However, information concerning the reaction behavior of arsenazo-type reagents which contain an axochromic group in the benzyl ring linked to the analytic group is still sparse.

Therefore, as part of a systematic study, in this paper we describe the $\beta$-type chelates of lanthanide ions with *p*-bromochloroarsenazo (a new non-symmetric azo-type reagent; see Scheme 1). We determine the composition ratio and the actual combining ratio, investigate the optimum acidity range ($\Delta$pH value) of the formation of $\beta$-type chelates, the reaction order and the rate constants, and propose a process for the formation of the $\beta$-type chelates.

$T = 288$ K.

## 2. Experimental

### 2.1. Apparatus

The absorption is measured by means of a U-3400 spectrophotometer (Hitachi, Japan) at a constant temperature controlled by a model 501 Super Thomostat (Shengzhen, China). The acidity is determined by means of a model pHS-3C meter (Zhejiang, China).

### 2.2. Reagents

Standard solutions of the lanthanide(III) ions were prepared by dissolving their corresponding oxides, which were of spectral purity, in hot perchloric acid (adding hydrogen peroxide when dissolving $CeO_2$), then evaporating the excess acid and diluting with redistilled, deionized water to a given volume. The *p*-bromochloroarsenazo was provided as a gift by Professor Bincai Wu, Department of Chemistry, East China Normal University, and was used without further purification (more than 94% pure). The other reagents were all analytical grade, and all solutions were prepared with redistilled, deionized water.

### 2.3. Procedure

(1) Preparation of the complex solution involved adding 3.0 ml of $1.0 \times 10^{-4}$ mol $l^{-1}$ *p*-bromochloroarsenazo (4-CAsA-pB) to a 25 ml calibrated flask which contained 1.0 ml of a $1.0 \times 10^{-4}$ mol $l^{-1}$ solution of the lanthanide ion and requisite amounts of 0.01 mol $l^{-1}$ $HClO_4$ solution or 0.02 mol $l^{-1}$ NaOH solution (the resultant pH of the final solution is shown in Table 1), diluting to the mark with water and allowing to stand overnight. The absorption was then measured in a 1.0 cm cell against a reagent or water blank.

(2) Determination of the rate constants for the formation of the β-type chelates involved adding 2.0 ml of $1.0 \times 10^{-4}$ mol $l^{-1}$ 4-CAsA-pB to a 25 ml calibrated flask which contained 1.0 ml of a $1.0 \times 10^{-4}$ mol $l^{-1}$ solution of the lanthanide ion and 2.0 ml of 0.01 mol $l^{-1}$ $HClO_4$ at a constant temperature, diluting to the mark with water, mixing well rapidly, then immediately measuring the variation of absorption with the time in the kinetic system, with use of the U-3400 spectrophotometer.

## 3. Results and discussion

### 3.1. Absorption spectra

The β-type reactions of 14 lanthanides with 4-CAsA-pB in 0.01 mol $l^{-1}$ $HClO_4$ solution (pH 3.40–3.70) were studied and the results are given in Fig. 1. All the lanthanide ions form

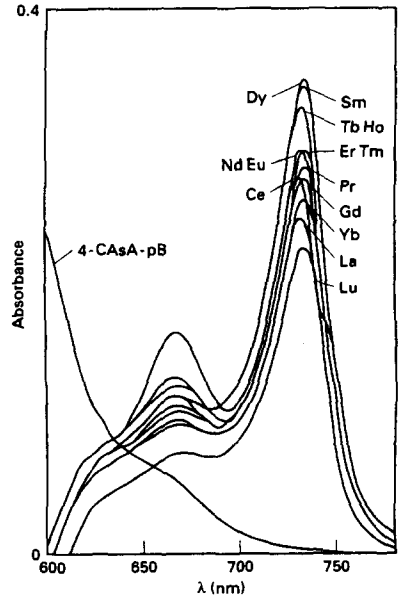

Fig. 1. The absorption spectra of β-type chelates of $Ln^{3+}$ ions with 4-CAsA-pB. ($C_{Ln^{3+}} = 4.0 \times 10^{-6}$ mol $l^{-1}$; $C_{4\text{-CAsA-pB}} = 1.2 \times 10^{-5}$ mol $l^{-1}$; pH 3.40–3.70; $HClO_4$; $T = 296 \pm 0.3$ K; against reagents.)

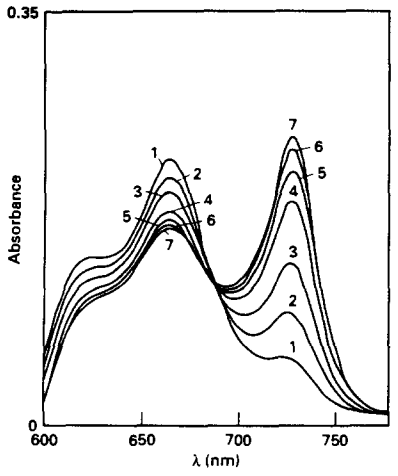

Fig. 2. Absorption scans of $\beta$-type chelates with respect to time for the system $Eu^{3+}$ with 4-CAsA-pB. ($C_{Eu} = 4.0 \times 10^{-6}$ mol $l^{-1}$; $C_{4\text{-CAsA-pB}} = 1.2 \times 10^{-5}$ mol $l^{-1}$; pH $3.40 \pm 0.1$; $T = 296 \pm 0.3$ K). Curve 1, 2.0 min; curve 2, 5.0 min; curve 3, 10.0 min; curve 4, 20.0 min; curve 5, 30.0 min; curve 6, 40.0 min; curve 7, 50.0 min.

homonuclear $\beta$-type chelates with 4-CAsA-pB, the maximum absorption peaks of which shift from 727 nm to 731 nm with increasing atomic number of the lanthanides, and the absorptivities correspondingly vary from $6.0 \times 10^4$ to $9.0 \times 10^4$ $cm^2$ $mol^{-1}$.

Results from continuous scanning of the absorption with respect to time show that there is a transformation from $\alpha$-type to $\beta$-type chelates (see Fig. 2 for the system of $Eu^{3+}$ ions with 4-CAsA-pB. A similar transformation was observed for the other lanthanides). During the transformation process, the absorption of the $\alpha$-type chelates decreased while the absorption of the $\beta$-type chelates increased. The $\beta$-type chelates were stable for at least 12 h after the transition of the $\alpha$-type chelates to the $\beta$-type had reached equilibrium (for each lanthanide system, the time of equilibrium was different). However, on standing for more than 48 h, the absorbance decreased and a blue precipitate appeared.

### *3.2. Determination of the optimum acidity range (ΔpH value) of the formation of the β-type chelates*

As is known, the acidity of the solution plays an important role in the formation of the $\beta$-type chelates. We systematically determined the optimum acidity range (ΔpH value) for the formation of the $\beta$-type chelates of the lanthanide ions with 4-CAsA-pB. The results are listed in Table 1. The determination showed that the optimum acidity range is different for each of the lanthanide systems; the ΔpH value is extended with increasing atomic number of the lanthanides and these changes can be divided into three groups: for La to Eu, the ΔpH value is about 0.5–0.7, for Ga to Er, the ΔpH value is about 1.0–1.1, and for Tm, Yb, Lu, the ΔpH values are about 3.1, 3.3 and 3.4, respectively. The conclusions are similar for the system of lanthanides with *p*-bromochlorophosphonazo [9].

It is worth noticing that there is some definite relationship between the optimum acidity range for the formation of $\beta$-type chelates and the deprotonation constants of the analytic functional group $-AsO_3H_2$. The minimum and maximum pH values ($pH_1$, $pH_2$) are almost approximately $pk_3$, $pk_4$ if we consider the influence of some lanthanide characteristics (i.e. the atomic number, the ionic radius, etc.). That is to say, the optimum acidity range is influenced by the deprotonation constants of the $-AsO_3H_2$ group and some lanthanide characteristics.

### *3.3. Investigation of the composition ratio and the actual combining ratio of the β-type chelates*

Using the continuous variation method [10] and the equilibrium shift method [11], we investigated the composition ratio of the $\beta$-type chelates of lanthanide ions with 4-CAsA-pB

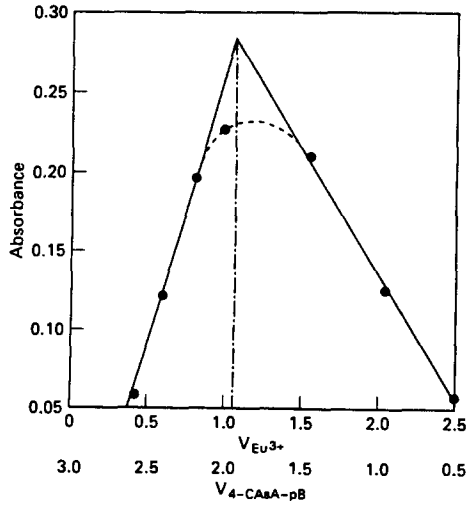

Fig. 3. Investigation of the composition of $\beta$-type chelates by the continuous variation method. (Eu; wavelength $\lambda = 728.5$ nm; pH 3.20–3.40; $T = 296 \pm 0.3$ K.)

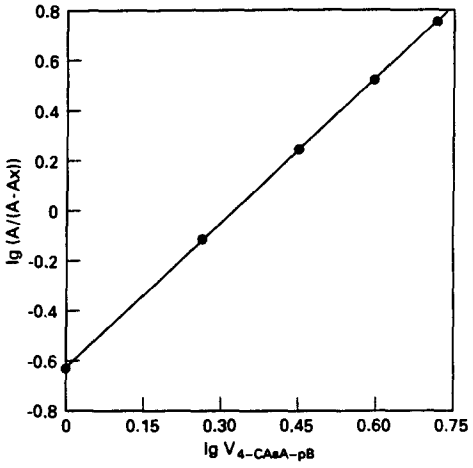

Fig. 4. Investigation of the composition of $\beta$-type chelates by the equilibrium shift method. (Eu; $\lambda = 728.5$ nm; pH 3.20–3.40; $T = 296 \pm 0.3$ K.)

(see Figs. 3 and 4 for Eu; similar results are obtained for other lanthanide systems). The composition ratio, $Ln^{3+}$:4-CAsA-pB was found to be 1:2. Furthermore, the actual combining ratio of the $\beta$-type chelates is insured to be 2:4 by a graphical method involving the dilution effect model [12,13] (see Figs. 5 and 6 for Ce; similar results are obtained for the other lanthanide systems). These investigations show that the $\beta$-type chelates of lanthanides with 4-CAsA-pB are polymers.

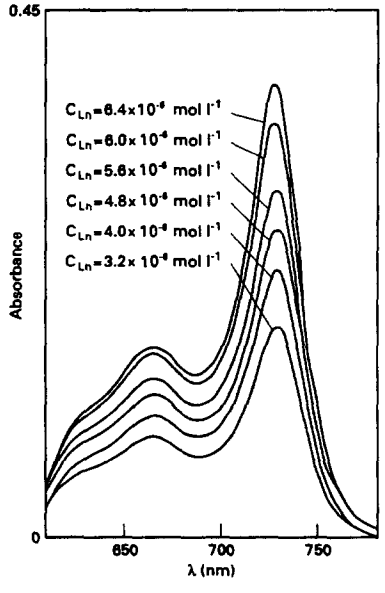

Fig. 5. Dilution absorption spectra of $\beta$-type chelates in the system $Ln^{3+}$ with 4-CAsA-pB. (Ce; the Ln: 4-CAsA-pB ratio is 1:2; $T = 296 \pm 0.3$ K.)

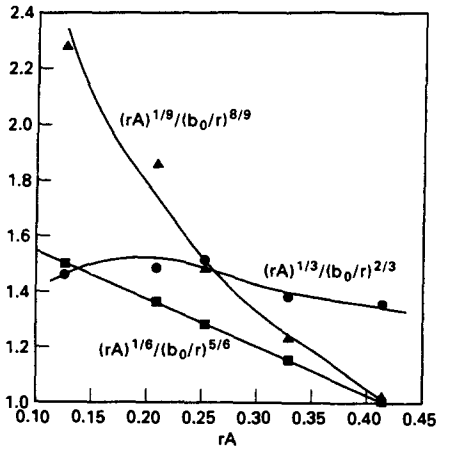

Fig. 6. Actual combining ratio of $\beta$-type chelates. (Ce; $\lambda = 727.8$ nm; $T = 296 \pm 0.3$ K.)

### 3.4. The kinetics of $\beta$-type chelates

From the absorption spectra of $Ln^{3+}$ with 4-CAsA-pB (see Fig. 1) we know that $\lambda_\beta = 727–731$ nm, $\lambda_\alpha = 662–665$ nm, $\lambda_{4\text{-CAsA-pB}} = 572$ nm, $\Delta\lambda_\alpha = 90–92$ nm, $\Delta\lambda_\beta = 155–159$ nm and $\Delta\lambda_{\alpha,\beta} = 65–67$ nm, so there is no influence on the scan of the absorption of the $\alpha$-type chelate and the $\beta$-type chelate with respect to time. Fig. 2 shows the conversion of $\alpha$-type chelates to $\beta$-type chelates, and the reaction order determination is shown in Fig. 7. It is concluded that the conversion from $\alpha$-type chelates to $\beta$-type chelates in 0.01 mol $l^{-1}$ $HClO_4$ is a second-order reaction. Using the same graphical method, we investigated the rate constants for the $\beta$-type conver-

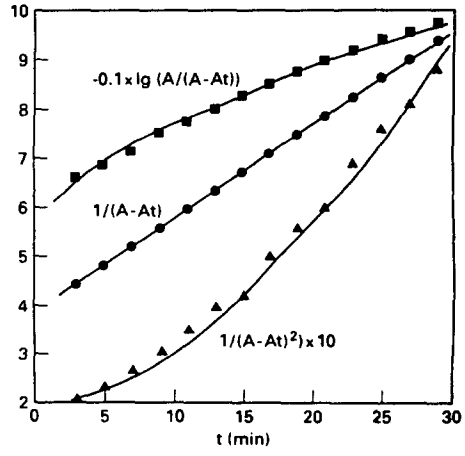

Fig. 7. The reaction order of $\alpha$-type chelates conversion to $\beta$-type chelates. ($C_{Eu^{3+}} = 4.0 \times 10^{-6}$ mol $l^{-1}$; $C_{4\text{-CAsA-pB}} = 8.0 \times 10^{-6}$ mol $l^{-1}$; $\lambda = 728.5$ nm; $T = 296 \pm 0.3$ K; pH $3.40 \pm 0.1$.)

Table 2
Rate constants for the $\alpha$-type to $\beta$-type conversion reaction for the system $Ln^{3+}$ with 4-CAsA-pB

| Reaction rate | $Ln^{3+}$ ion | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | La | Ce | Pr | Nd | Sm | Eu | Gd | Tb | Dy | Ho | Er | Tm | Yb | Lu |
| $k$ ($m^3 mol^{-1} s^{-1}$) | 0.31 | 0.33 | 0.69 | 1.02 | 21.2 | 23.0 | 20.8 | 25.9 | 28.0 | 30.1 | 31.2 | 14.0 | 46.4 | 21.9 |

$T = 296 \pm 0.3$ K; pH $3.56 \pm 0.2$.

Table 3
The influence of acidity on the reaction rate of $\beta$-type chelates in the system $Eu^{3+}$ with 4-CAsA-pB

| Reaction rate | pH | | | | | |
|---|---|---|---|---|---|---|
| | 3.03 | 3.07 | 3.14 | 3.28 | 3.56 | 4.23 |
| $k$ ($m^{-3} mol^{-1} s^{-1}$) | 19.56 | 19.79 | 32.48 | 25.78 | 23.84 | 16.81 |

$T = 298 \pm 0.3$ K.

sion from the $\alpha$-type reaction in the system of lanthanide ions with 4-CAsA-pB at $T = 296 \pm 0.3$ K and pH $3.56 \pm 0.2$. The results listed in Table 2 show that the rate constants increased with increasing atomic number of the lanthanides and that the rate constants for light rare earth elements and heavy rare earth elements are very different.

We also studied the influence of acidity and temperature on the reaction rate in the system $Eu^{3+}$ with 4-CAsA-pB. The results are listed in Tables 3 and 4. The reaction rate increased with increasing acidity at $298 \pm 0.3$ K. However, if the pH is below 3.07, the reaction rate decreased. It also increased with increasing temperature at pH $3.60 \pm 0.2$ when the temperature is below 303 K. Otherwise, it decreased.

### *3.5. Proposed mechanism of the formation of $\beta$-type chelates*

The conclusion of the transformation from $\alpha$-type chelates to $\beta$-type chelates has been reported as a deprotonation process, in which the ligand loses one proton and forms a "Z"-type chelate in the system of heavy rare earth elements [8]. As the structure of 4-CAsA-pB and its reaction behaviour with lanthanide ions is different, we have suggested another mechanism for the formation of $\beta$-type chelates for the system 4-CAsA-pB with lanthanide ions. Usually, the structure of 4-CAsA-pB in acidic solution is as presented in Scheme 2 [14]. The hydrogen bond makes the –N=N– group more stable and it also decreases the deprotonating ability of the –OH group linked to the naphthyl ring. The dissociation pathway of azo-type reagents also shows that the deprotonating ability of –OH groups linked to the naphthyl ring in acidic solution is very weak [14]. In contrast, the deprotonating ability of the $-AsO_3H_2$ group is increased on decreasing the electronic clouds around the oxygen atom in the $-AsO_3H_2$ group by adding a strong electronic acceptor (–Cl) onto the benzyl ring linked to the $-AsO_3H_2$ group. Therefore, in highly acidic solution, the coordinating ability of the $-AsO_3H_2$ group is greater than that of the –N=N– group and the –OH group linked to the naphthyl ring. The probable coordination pattern may be lanthanide ions combining with oxygen atoms in the $-AsO_3H_2$ group and forming a bridging bond between the lanthanide atoms and the oxygen atoms (see Scheme 3 for its structure).

## 4. Conclusion

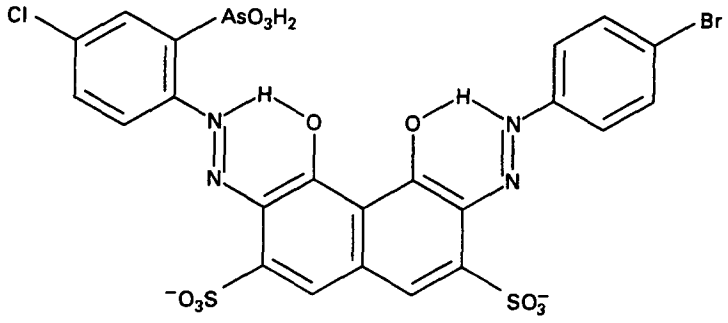
According to the above results, the following conclusions may be drawn. The 4-CAsA-pB reagent forms sensitive $\beta$-type chelates with all the lanthanide ions. The optimum acidity range of the formation of the $\beta$-type chelates ($\Delta$pH value) is extended with increasing atomic number of the lanthanides. There is a definite relationship between the optimum acidity and the deprotonation constants of the $-AsO_3H_2$ groups.

Table 4
The influence of temperature on the reaction rate of $\beta$-type chelates in the system $Eu^{3+}$ with 4-CAsA-pB

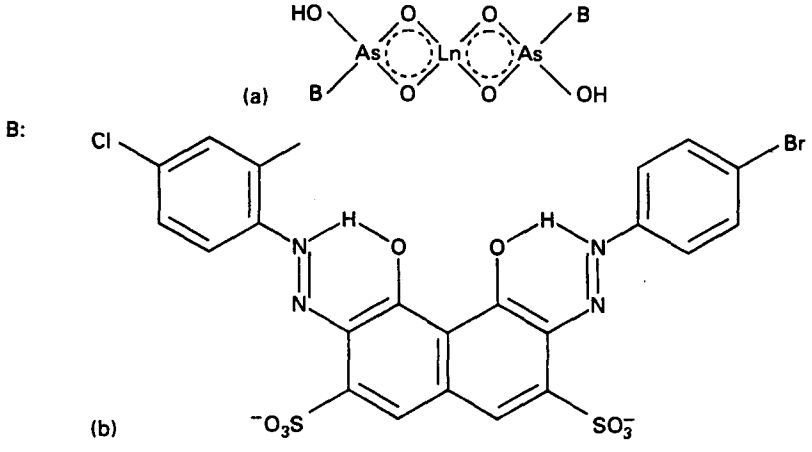
| Reaction rate | Temperature (K) | | | | | |
|---|---|---|---|---|---|---|
| | 286 | 291 | 296 | 299 | 303 | 306 |
| $k$ ($mmol^{-1}\,s^{-1}$) | 11.24 | 16.45 | 18.90 | 20.24 | 15.74 | 13.51 |

pH $3.60 \pm 0.2$.

Scheme 2. The structure of 4-CAsA-pB in the acidic solution



Scheme 3. The structure of the β-type chelates of $Ln^{3+}$ with 4-CAsA-pB



The $\beta$-type chelates are polymers formed from $\alpha$-type chelates. The formation procedure is a second-order reaction and the reaction rate increases with increasing atomic number of the lanthanides. The influence of acidity and temperature on the reaction rate is such that, over a defined range, the reaction rate is increased with increasing temperature and acidity.

# Spectrophotometric determination of scandium based on the cocoloration effect in scandium–cerium–*p*-acetylchlorophosphonazo (CPApA) system

Chung-Gin Hsu*, Shuang-Cheng Liu, Jiao-Mai Pan

*Department of Chemistry, East China Normal University, 3663 Zhong Shan Road(N), Shanghai 200062, People's Republic of China*

Received 27 March 1995; revised 30 May 1995; accepted 31 May 1995

**Abstract**

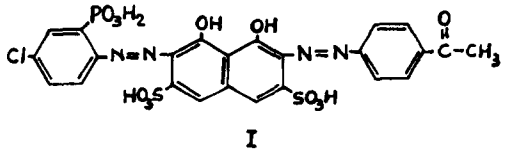
Scandium in the presence of cerium(III) forms, with *p*-acetylchlorophosphonazo (CPApA), a heteropolynuclei ternary $\beta$-complex of scandium–cerium–CPApA. The complex gives a very sensitive reaction for scandium with a molar absorptivity of $\varepsilon_{Sc} = 2.29 \times 10^5\,l\,mol^{-1}\,cm^{-1}$ due to the cocoloration effect. Most foreign ions can be tolerated in considerable amounts. The optimum conditions and the mechanism of the complex formation reaction are discussed. A simple method is proposed for the determination of scandium in alloys, with satisfactory results.

*Keywords:* Cocoloration effect; Scandium–cerium–*p*-acetylchlorophosphonazo complex; Spectrophotometry

## 1. Introduction

$\beta$-type complex formation reactions [1,2] of rare earths with asymmetric derivatives of chromotropic acid containing the *o*-phosphono-*o'*-hydroxyazo functional group have been widely used for the determination of rare earth elements [3,4].

*p*-Acetylchlorophosphonazo [5] (CPApA; I), one of the reagents synthesized in our laboratory, has been employed to determine total rare earths [5] and cerium subgroup rare earths [6].



I

Usually, the $\beta$-complex reaction is accompanied by a cocoloration effect [7–9]. It was found that CPApA gave a sensitive $\beta$-reaction with scandium in acidic medium, and the sensitivity of the reaction would be greatly enhanced in the presence of rare earth elements. In this paper, we studied the spectrophotometric characteristics and the mechanism of the cocoloration effect of the scandium–cerium–CPApA system. From the results, a sensitive method has been developed for the determination of scandium in alloys.

## 2. Experimental

### 2.1. Reagents

A standard stock solution of scandium was prepared by dissolving scandium oxide (Spec-

* Corresponding author.

*SSDI* 0039-9140(95)01658-9

pure; Johnson Matthey) in hydrochloric acid (1 + 1), evaporating the excess acid and diluting with hydrochloric acid (1 + 100) to a given volume. The solution was standardized by EDTA titration with Xylenol Orange as indicator. The working standard solution was prepared by diluting as required with hydrochloric acid (1 + 100).

A standard solution of cerium(III) was prepared as described previously [10].

*p*-Acetylchlorophosphonazo (CPApA) solution (0.04%) was prepared by dissolving 0.04 g of CPApA in 100 ml of water. CPApA was synthesized as described in the previous work [11].

Other reagents were of analytical-reagent grade.

### 2.2. Apparatus

Absorption spectra and absorbances were recorded and measured with use of a Beckman DU-7HS spectrophotometer and a model 752 spectrophotometer (Shanghai Analytical Instruments). A constant temperature was maintained by using a model CS-501 ultrathermostat.

### 2.3. Procedures

*(A) General procedure*

To 2–8 μg of scandium in a 25 ml calibrated flask, add 25 μg of cerium(III), 1 ml of 3 M hydrochloric acid, and adjust the volume to about 10 ml with water. Add 3.5 ml of 0.04% CPApA and mix well. After allowing to stand for 30 min, dilute to the mark with water. Measure the absorbance at 722 nm in a 1.0 cm cell against a reagent blank.

*(B) Procedure for kinetic study*

Under a constant temperature in a 25 ml calibrated flask, add 5 μg of scandium, 1 ml of 3 M hydrochloric acid, and adjust the volume to about 20 ml with water, add 1.5 ml of 0.04% CPApA, dilute to the mark with water and measure the absorbance at 722 nm in a 1.0 cm cell against a reagent blank without standing.

*(C) Procedure for the determination of scandium in alloys*

To 1.5 g of the sample, add 10 ml of aqua regia (1 + 1), heat to decompose the sample and evaporate almost to dryness. After cooling to room temperature, dissolve the residue in water, transfer the solution into a 100 ml calibrated flask, and dilute to the mark with water. Place 1.0 ml (or another appropriate aliquot) of the resultant solution in a 25 ml calibrated flask, then add 2.0 μg of scandium, and follow the general procedure for the determination of scandium.

## 3. Results and discussion

### 3.1. Absorption spectra

As shown in Fig. 1, the $\alpha$-complex of cerium–CPApA exhibits an absorption peak at 678 nm (curve 2), whereas the $\beta$-complex of scandium–CPApA gives a maximum absorption at 722 nm (curve 3). However, in the presence of cerium(III), a hetero-polynuclei ternary complex of scandium–cerium–CPApA is formed, which greatly enhances the absorption at 722 nm (curve 4) due to the cocoloration effect [7–9,12–14].

### 3.2. Optimum conditions for complex formation

CPApA forms a ternary complex with the mixture of scandium and cerium(III) in acidic medium. In 0.08–0.24 M hydrochloric acid (Fig. 2) and $1.3–1.8 \times 10^{-5}$ M CPApA, the complex gives the highest and a constant absorbance. The temperature at 10–30 °C does not influence the color development.

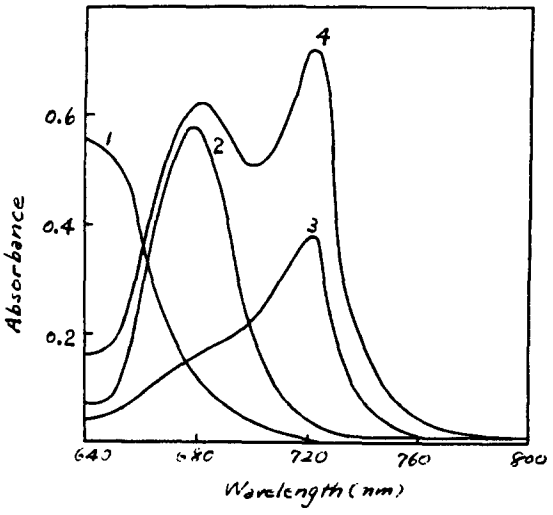


Fig. 1. Absorption spectra of CPApA and its complexes. Curve 1, CPApA vs. water; curve 2, cerium–CPApA; curve 3, scandium–CPApA; curve 4, scandium–cerium–CPApA vs. reagent blank (scandium, 5 μg; cerium, 25 μg; CPApA, $1.55 \times 10^{-5}$ M; HCl, 0.12 M).

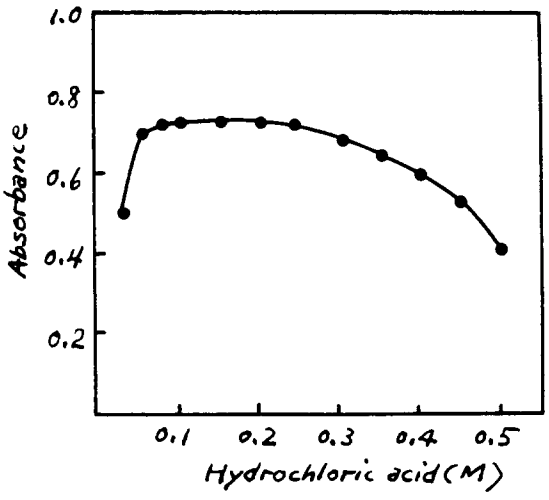

Fig. 2. Effect of acid concentration on the scandium–cerium–CPApA complex (wavelength $\lambda = 722$ cm; other conditions as for Fig. 1).

The reaction rate of $\beta$-complex formation in the scandium–cerium–CPApA systems is slow: maximum absorbance will be obtained after 3 h; however the reaction can be completed within 30 min if a smaller volume (10–15 ml) is used owing to the higher concentrations of the reactants; the solution is then diluted to 25 ml with water in the calibrated flask. The complex once formed will be stable for at least 3 h.

### 3.3. Analytical characteristics of the reaction

The calibration graph prepared by plotting absorbance vs. concentration of scandium was linear over the range 2–8 μg of scandium in 25 ml of solution. For convenience and for the determination of less than 2.0 μg of scandium, a standard addition–deduction method [3,15] was used; i.e. 2.0 μg of scandium were added to each of the standard solutions to construct a calibration graph (starting from 0 μg on the abscissa). For sample analysis, 2.0 μg of scandium were also added to each of the sample solutions; the scandium contents could then be determined directly from the calibration graph.

The straight-line equation obtained by a least-squares treatment ($n = 7$) was $A = 0.204C - 0.286$ ($r = 0.9980$), where $A$ is the absorbance recorded, $C$ is the concentration (number of micrograms of scandium in 25 ml of solution), and $r$ is the correlation coefficient. The apparent molar absorptivity for scandium was found to be $2.29 \times 10^5$ l mol$^{-1}$ cm$^{-1}$. Ten replicate analyses of a test solution containing 5 μg of scandium gave a coefficient of variation of 0.73%.

### 3.4. Effect of foreign ions

A solution containing 3 μg of scandium and various amounts of 37 possible accompanying ions were prepared, and procedure A was followed for the determination of scandium. As shown in Table 1, most of the ions do not interfere with the determination (maximum 5% error); 1.5- to 3-fold amounts of rare earths, uranium(VI), iron(III), titanium and zirconium are tolerated, as well as more than 10 mg magnesium, iron(II), copper and zinc. This property can be utilized to create a satisfactory method for the determination of scandium in these metals and their alloys without separation.

### 3.5. Composition of the complex

The molar composition of the scandium–cerium–CPApA complex was determined by the mole ratio method [16]. According to the conditions described in procedure A, the molar ratios of scandium to cerium(III) in a series of solutions were varied while CPApA was present in excess. An intersection point occurred when

Table 1
Tolerance limits (maximum 5% error) for foreign ions in the determination of 3 μg of scandium

| Foreign ion | Tolerance limit (μg) |
|---|---|
| Cu(II) | 60 000 |
| Zn(II) | 50 000 |
| $NH_4$(I) | 20 000 |
| Fe(III)[a] | 10 000 |
| Mg(II) | 10 000 |
| Mn(II) | 5000 |
| Sb(III) | 2000 |
| Ca(II) | 1500 |

| Bi(III) | 50 |
| Ti(IV), Zr (IV) | 10 |
| La(III), Y(III), Ce(IV), U(VI), Fe(III) | 5 |
| Phosphate | 150 000 |
| Sulphate, ascorbate | 50 000 |
| Citrate | 40 000 |
| Nitrate, tartrate | 20 000 |
| Oxalate | 5000 |
| EDTA | 1500 |

[a] In the presence of 50 mg of ascorbic acid.

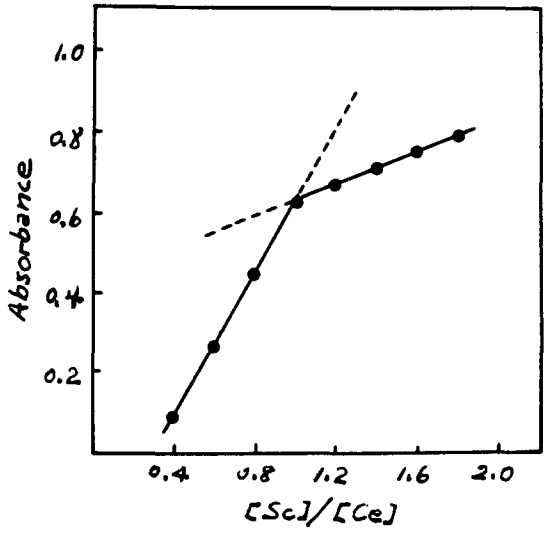

Fig. 3. Molar ratio of scandium to cerium in the ternary complex ($\lambda = 722$ nm; cerium, $4.4 \times 10^{-6}$ M; CPApA, $1.55 \times 10^{-5}$ M; HCl, 0.12 M).

[Sc]/[Ce] = 1 (Fig. 3). Similarly, the concentrations of CPApA were varied; when the mole ratio of scandium to cerium was fixed at 1, the intersection point was at [CPApA]:[Sc] = 2:1 (Fig. 4). Thus, the molar composition of the polynuclei ternary complex was estimated to be scandium:cerium:CPApA = 1:1:2.

### 3.6. Kinetic study and the mechanism of the complex formation

The formation of a hetero-polynuclei complex is often based on the formation of a homo-polynuclei complex [8,9]. In order to

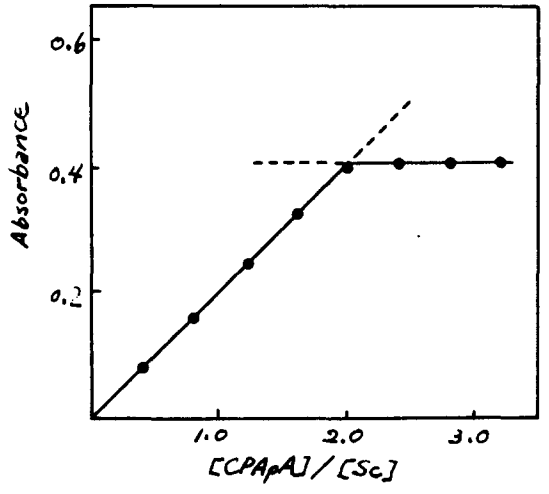

Fig. 4. Molar ratio of CPApA to scandium in the ternary complex (scandium, cerium, $2.70 \times 10^{-6}$ M; other conditions as for Fig. 3).

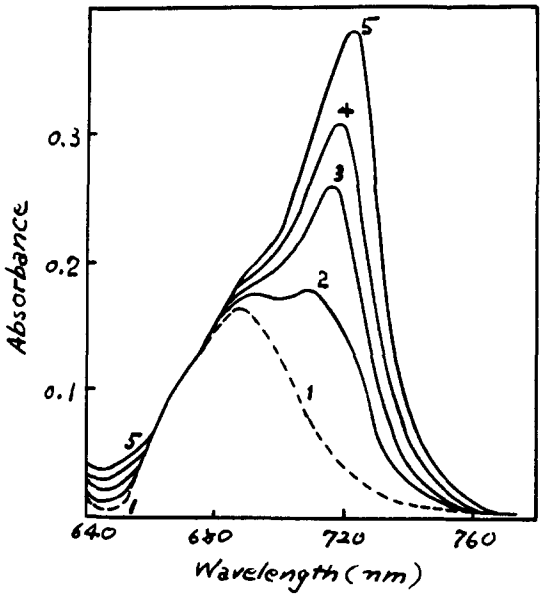

Fig. 5. Absorption spectra of the scandium–CPApA complex at (curve 1) 0 min; (curve 2) 5 min; (curve 3) 10 min; (curve 4) 20 min; (curve 5) 30 min (scandium, $4.44 \times 10^{-6}$ M; CPApA, $6.64 \times 10^{-6}$ M; HCl, 0.12 M; $T = 288$ K).

study the mechanism of the formation of the scandium–cerium–CPApA ternary complex, it is required that the nature of the scandium–CPApA binary complex be understood.

The absorption spectra of the scandium–CPApA complex are shown in Fig. 5. At the beginning of the reaction, an $\alpha$-type complex of scandium–CPApA is formed, with maximum absorption at 687 nm. After standing, the absorption peak will be gradually shifted to a longer wavelength (722 nm) and a $\beta$-type complex is then formed.

Under the conditions described in procedure B, $\log(A_{max} - A_t)$, $1/(A_{max} - A_t)$ and $1/(A_{max} - A_t)^2$ were plotted respectively versus $t$, where $A_{max}$ is the maximum absorbance and $A_t$ is the absorbance at the denoted time. As shown in Fig. 6, the linear relationship between $1/(A_{max} - A_t)$ and $t$ indicates that the transformation reaction of the $\alpha$-complex to the $\beta$-complex is a second-order reaction. The rate constant $K$ obtained from slope of the straight line is $1.72 \times 10^{-1}$ mol$^{-1}$ l min$^{-1}$.

Both the molar compositions of the $\alpha$-complex and the $\beta$-complex of scandium–CPApA were ascertained by the Asmus method [17], and the mole ratio and slope ratio [18] methods. All three methods indicated that the metal-to-ligand ratios of these two complexes were all 1:1. In considering the order of the

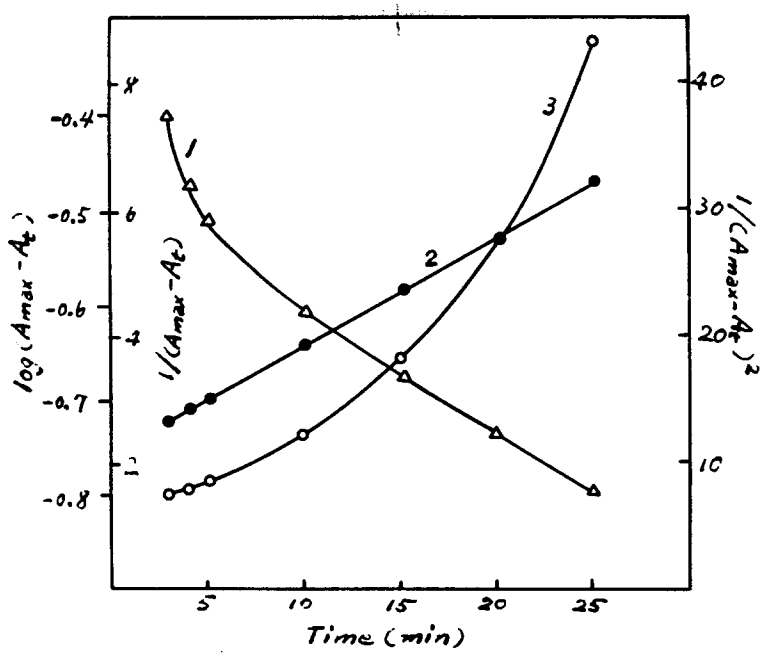

Fig. 6. Determination of the reaction order of the formation of the $\beta$-complex of scandium–CPApA ($\lambda = 722$ nm; other conditions as for Fig. 5). Curve 1, $\log(A_{max} - A_t)$ vs. $t$; curve 2, $1/(A_{max} - A_t)$ vs. $t$; curve 3, $1/(A_{max} - A_t)^2$ vs. $t$.

reaction, the $\beta$-complex of scandium–CPApA will be a dimer, i.e. $Sc_2(CPApA)_2$.

According to the experimental results, the complex formation reaction proceeded as follows.

(a) The $\alpha$-complexes of CPApA with scandium and cerium(III) are formed instantly at first (Eqs. (1) and (2)) (the charges on the ions are omitted for convenience).

$$Sc + CPApA \rightarrow Sc(CPApA) \quad (1)$$

$$Ce + 4CPApA \rightarrow Ce(CPApA)_4[6] \quad (2)$$

(b) Two molecules of the $\alpha$-complex of scandium–CPApA combine together to form one molecule of the $\beta$complex (Eq. (3)).

$$2Sc(CPApA) \rightarrow Sc_2(CPApA)_2 \quad (3)$$

[a] Approximate.

(c) Finally, the $\beta$-complex of scandium–cerium–CPApA is formed by the reaction between the $\beta$-complex of scandium–CPApA and the $\alpha$-complex of cerium–CPApA (Eq. (4))

$$Sc_2(CPApA)_2 + 2Ce(CPApA)_4 \rightarrow 2Sc\text{–}Ce\text{–}(CPApA)_2 + 6CPApA \quad (4)$$

in which cerium(III) replaces one atom of the scandium in $Sc_2(CPApA)_2$, with the formation of two molecules of Sc–Ce–$(CPApA)_2$, and the absorbance of the ternary complex will be increased markedly.

### 3.7. Determination of scandium in alloys

Synthetic samples were prepared by introducing known amounts of scandium to standard samples of copper, zinc, and magnesium alloys [19], and the scandium contents were determined by using procedure c. The results obtained (Table 2) indicate that the method is reliable and accurate.

## 4. Conclusions

The present method, based on the formation of the scandium–cerium–*p*-acetylchlorophosphonazo(CPApA) complex, for the spectrophotometric determination of scandium in alloys is simple, accurate and reliable.

Compared with the spectrophotometric methods conventionally used for determination (Table 3), in terms of sensitivity, the described method is superior to the other methods except for that utilizing the scandium–Chrome Azurol S–*N*-dodecyldimethylaminoacetic acid systems. However, the latter suffers serious interferences from iron and aluminium.

Under the experimental conditions employed, 10 mg or more of magnesium, iron, copper and zinc do not interfere, and 0.5 mg of aluminum are tolerated. This gives the described method an advantage over the other methods.

**Abstract**

The reagent 3,8,13,18-tetramethyl-21*H*,23*H*-porphine-2,7,12,17-tetrapropionic acid or coproporphyrin-I (CPI) was used for the spectrophotometric determination of copper(II) and cobalt(II) in the presence of pyridine and imidazole catalysts. Optimum conditions were investigated and the methods were applied to the determination of parts per billion levels of copper(II) and cobalt(II). The Sandell sensitivities of the recommended procedures were 0.568 μm $cm^{-2}$ and 0.464 μg $cm^{-2}$ (for $A = 0.001$) for copper and cobalt, respectively. The relative standard deviations were 2.0% for copper and 1.0% for cobalt. The kinetics of the reaction of CPI with copper(II) and cobalt(II) in the presence of the catalysts and the influence of the temperature were studied, and their kinetic constants determined.

The influence of light on the photodecomposition of CPI was also studied.

*Keywords:* Copper(II); Cobalt(II); Spectrophotometry; Coproporphyrin-I

## 1. Introduction

Porphyrins have been extensively studied because of their biological importance and analytical applications. Particular attention has been given to the analytical use of porphyrins for spectrophotometric determinations of several metal ions, because they form very stable complexes with very high molar absorptivity (on the order of several hundred-thousands in a 400–500 nm field, the so-called Soret band). However, porphyrins have the disadvantage that the incorporation reaction of the metal ion into the porphyrin ring is generally very slow and must be accelerated by using several catalysts [1], or by metal exchange reactions [2,3]. In many cases, porphyrins have found analytical applications for the determination of several metal ions at the parts per million level [1,4–8].

It has been also observed that porphyrins undergo photoreduction reactions with the formation of stable photoproducts [9,10] that may play an important role in cancer therapy [11].

In this paper, a series of spectrophotometric studies on coproporphyrin-I (CPI) is described in order to verify its possible use for the determination of metal ions. The influence of light on CPI and on CPI complexes and the equilibria between CPI and copper(II) or cobalt(II), and the influence of several catalysts on the reaction rate are studied. A simple method for the spectrophotometric determination of copper(II) and cobalt(II) at the parts per billion level is developed.

## 2. Experimental

### 2.1. Reagents

All reagents were of analytical grade and were used without further purification. All the solutions were prepared with distilled, demineralized water.

#### 2.1.1. CPI solution

A $2.8 \times 10^{-4}$ M stock solution was prepared by dissolving 102.1 mg of CPI dihydrochloride in 500 ml of 7.2 mM sodium hydroxide solution, and diluting with water.

#### 2.1.2. Standard copper(II) and cobalt(II) solutions

Stock aqueous solutions containing about 0.4 mmol of $CuCl_2$ or $CoCl_2 \cdot 6H_2O$ per litre, and sufficient acid to prevent precipitation, were prepared. The stock solutions were standardized by inductively coupled plasma (ICP) determinations.

### 2.2. Apparatus

A Hewlett-Packard 8452 A diode-array spectrophotometer with a 1 cm quartz cell connected to a Lauda K2R thermostat was used for the absorbance measurements.

A Metrohm 655 pH meter was used for pH measurement.

An inductively coupled plasma Jobin Yvon JY 24R instrument was used for the metal solution standardization.

A 150 W Osram xenon lamp was used for the photochemical reaction study.

### 2.3. Recommended procedures

#### 2.3.1. Photometric measurements

Ten sample solutions containing from $3 \times 10^{-6}$ M to $2 \times 10^{-5}$ M of CPI at pH ranging from 1 to 13, previously degassed with a nitrogen flow, were illuminated with UV-Vis radiation by use of a xenon lamp with interference filters. An infrared absorbing glass and a water cell were placed in the light path and the absorbance was measured every 5 min in the range from 200 to 800 nm in a 10 mm cell, against a blank.

#### 2.3.2. Kinetic measurements

In 10 ml volumetric flasks were placed from 0.1 to 0.6 ml of the standard solution of CPI, and from 0 to 5 ml of the stock solution of the metals, followed by over 2.5 ml of 4 M imidazole or pyridine solution. The pH of these solutions was adjusted to 8 by the addition of perchloric acid, and the solutions were brought to volume with water. The ionic strength was maintained constant at 0.2 M with sodium perchlorate. The absorbance–time curves of the solutions were obtained by measuring the absorbance every 2 min at 414 nm for the cobalt complex, and at 380 nm for the copper complex in a 10 mm cell against a blank, at temperatures ranging from 20 to 40 °C.

#### 2.3.3. Spectrophotometric titration

Ten samples, containing about 0.1 μg $ml^{-1}$ of cobalt(II) or copper(II), and sufficient $NaClO_4$ and $HClO_4$ to adjust the ionic strength to 0.2 M and the pH to 8, were titrated with a $2.8 \times 10^{-4}$ M CPI solution. After each addition, the solutions were heated in a water bath at 80 °C (with catalysts) or at 90 °C (without catalysts), for 10 min. They were then cooled in cold water, and the absorbances were measured at 414 nm or 380 nm, respectively, in a 10 mm cell thermostatted at 20 °C, against a blank.

#### 2.3.4. Calibration curve method

Calibration curves were obtained by mixing increasing quantities of cobalt(II) or copper(II) (from 35 to 128 ppb) with a slight excess of CPI at pH 8 and ionic strength 0.2 M. Each solution was heated in a water bath at 90 °C for 10 min. After cooling in cold water, the absorbance was measured at 414 nm or 380 nm, respectively, in a 10 mm cell thermostatted at 20 °C, against a blank.

## 3. Results and discussion

### 3.1. Photometric measurements

An aqueous solution of CPI with pH 8 and ionic strength 0.2 mol $l^{-1}$ was deep pink and displayed absorption maxima at 372 nm (Soret band; $\varepsilon = (1.16 \pm 0.02) \times 10^5$ and at 500, 538 and 558 nm, and a shoulder at about 606 nm. The illumination with light of degassed solutions of CPI at pH 5–13 caused the formation of a stable and colourless photoproduct. In Fig. 1 are presented (curves (a)) spectra of CPI, showing an absorbance decrease as a function of time due to exposure to light. The spectrum of the photoproducts has absorption maxima

at 220 and 264 nm, and a shoulder at around 380 nm (see Fig. 1, curve (b)). The photoreaction may be represented by the equation

$$CPI + h\nu \rightarrow \text{photoproduct}$$

the corresponding kinetic equation of which was

$$-\frac{d[CPI]}{dt} = k[CPI] \quad (1)$$

where $k_1$ is the first-order rate constant.

The plots of ln(1/[CPI]) versus the exposure time, measured at two different wavelengths, give good straight lines, the slopes of which represent the first-order rate constant. The two values obtained are in good agreement: $k_{372} = (4.39 \pm 0.01) \times 10^{-6}\ s^{-1}$; $k_{388} = (4.50 \pm 0.02) \times 10^{-6}\ s^{-1}$.

No photoreaction has been observed, either in acidic solution or in the presence of metal ions.

### 3.2. Absorption spectra of the complex

In the presence of an excess of metal, the absorption spectra of metal–CPI complexes gave absorption maxima at 414 nm (Soret band; $\varepsilon = (1.01 \pm 0.05) \times 10^5$ with pyridine and $\varepsilon = (1.95 \pm 0.03) \times 10^5$ with imidazole) for cobalt (Fig. 2, curve (a)) and at 380 nm (Soret band; $\varepsilon = (1.12 \pm 0.01) \times 10^5$ with pyridine and $\varepsilon = (2.03 \pm 0.02) \times 10^5$ with imidazole) for copper (Fig. 2, curve (b)).

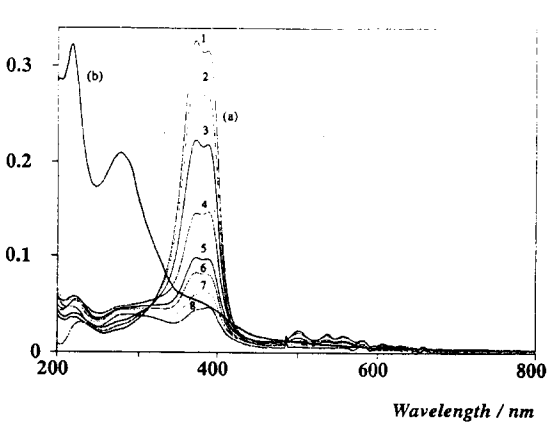

Fig. 1. Curves (a), absorption spectra of CPI ($2.2 \times 10^{-6}$ M; pH 8; ionic strength, 0.2 M) after: (spectrum 1) 0 min; (spectrum 2) 5 min; (spectrum 3) 10 min; (spectrum 4) 15 min; (spectrum 5) 20 min; (spectrum 6) 35 min, (spectrum 7) 40 min, (spectrum 8) and 45 min of light exposure. Curve (b), spectrum of the photoproducts obtained after the light exposure of CPI (absorbance × 5).

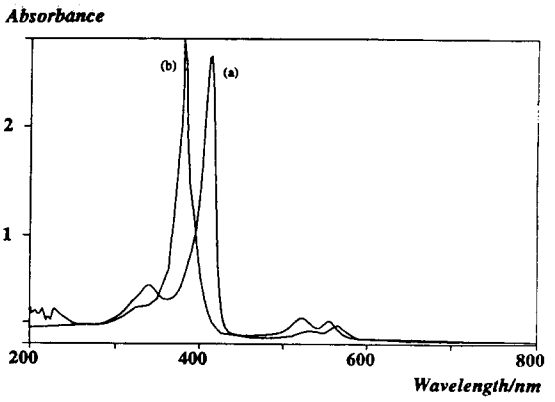

Fig. 2. The absorption spectra of (curve (a)) the cobalt–CPI ($1.34 \times 10^{-5}$ M) complex and (curve (b)) the copper–CPI ($1.38 \times 10^{-5}$ M) complex at pH 8, an ionic strength of 0.2 M, and with imidazole as catalyst.

### 3.3. Composition of the complex

The stoichiometry of the reactions in the copper–CPI and cobalt–CPI systems has been determined by applying the mole ratio method; the ratio was 1:1 in both cases (Fig. 3).

### 3.4. Reaction rate for the formation of the complex

The rate of formation of CPI complexes with metal ions was generally very slow. In order to increase the reaction rate, we carried out measurements in the presence of a catalyst at 20 °C or at higher temperatures in the absence of catalyst. By using pyridine or imidazole as catalysts, an increase in the reaction rate of about 10 times with respect to the uncatalyzed reaction was observed. The reaction rates depended on the pH, and a maximum value was reached at about pH 8. Measurements carried

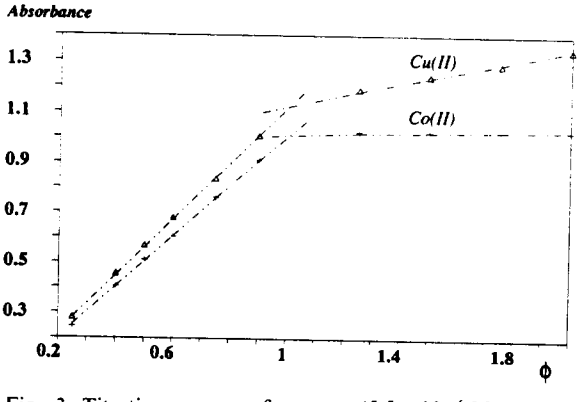

Fig. 3. Titration curves of copper ($5.5 \times 10^{-6}$ M) and cobalt ($5.1 \times 10^{-6}$ M) by CPI at pH 8, ionic strength 0.2 M, with imidazole as catalyst ($\phi$ indicates the CPI: metal ion ratio).

Table 1
First- and second-order kinetic constants for copper and cobalt complexes with different catalysts at 20°C

| Catalyst | Cu(II) | | Co(II) | |
|---|---|---|---|---|
| | $k_1$ ($s^{-1}$) | $k_2$ ($l\ mol^{-1}\ s^{-1}$) | $k_1$ ($s^{-1}$) | $k_2$ ($l\ mol^{-1}\ s^{-1}$) |
| Pyridine | $(5.05 \pm 0.02) \times 10^{-2}$ | $26.85 \pm 1.01$ | $(5.14 \pm 0.03) \times 10^{-2}$ | $23.81 \pm 3.12$ |
| Imidazole | $(4.69 \pm 0.01) \times 10^{-2}$ | $24.88 \pm 0.94$ | $(1.45 \pm 0.02) \times 10^{-2}$ | $18.22 \pm 2.93$ |

Copper(II) and cobalt(II), $4 \times 10^{-6}$–$2 \times 10^{-4}$ M; CPI, $2.8 \times 10^{-6}$–$1.68 \times 10^{-5}$ M; pyridine and imidazole, 1 M; ionic strength, 0.2 M ($NaClO_4$).

out in the presence of a large excess of metal (1:100 relative to CPI) at pH 8 and in the presence of a catalyst at 20 °C have shown that the reactions were completed within 30 min, and followed first-order kinetics, the rates of which may be represented by the equation

$$-\frac{d[CPI]}{dt} = k_1[CPI] \quad (2)$$

where $k_1$ is the conditional rate constant, involving the concentration of hydrogen ions, cobalt or copper.

The plots of $(1/C_L) \ln[(A_0 - A_\infty)/(A_t - A_\infty)]$ versus $t$ (where $A_0$, $A_t$ and $A_\infty$ denote the absorbances of the system at times 0, $t$, and infinity, respectively) give good straight lines, the slopes of which represent the conditional rate constants. Measurements carried out under the same conditions as described above, but in the presence of a small excess of metal (1:5 relative to CPI), showed second-order kinetics, corresponding to the equation

$$-\frac{d[CPI]}{dt} = k_2[M][L] \quad (3)$$

where $k_2$ is the second-order rate constant, involving only the hydrogen ion concentration.

The plot of $[1/(C_M - C_L)] \ln([M]/[L])$ versus $t$ (where $C_M$ and $C_L$ denote the metal and ligand concentration, respectively $[M] = C_M - C_L[(A_0 - A_t)/(A_t - A_\infty)]$ and $[L] = C_L[(A_t - A_\infty)/(A_0 - A_\infty)]$) gave a straight line, the slope of which provided the value of $k_2$. All the results are summarized in Table 1.

Measurements performed under the same conditions but without a catalyst, at temperatures ranging from 20 to 40 °C, showed an increase in the reaction rate of about 0.2 times per degree. At 20 °C, the catalyzed reaction rate is about half that of the uncatalyzed reaction at 40 °C. Plots of $\ln k_1$ against $1/T$ at different wavelengths allowed the determination of the activation energy according to the relationship $\ln k = \ln A - E_a/RT$. The mean value for the cobalt complex was $(4.9 \pm 0.1) \times 10^4\ J\ mol^{-1}$.

### 3.5. Spectrophotometric titration

These titrations have given well-defined curves. A typical plot is shown in Fig. 3. The equivalence point is in accordance with the formation of a 1:1 complex. Using this method, amounts of copper and cobalt in the range $10^{-7}$–$10^{-5}$ M can be determined with relative standard deviations of 2.0% and 1.0%, respectively.

### 3.6. Calibration curve method

Calibration curves obtained according to the procedure described give good straight lines, the equations of which were

$$\text{Amount of Cu} = 0.568(A_0 - A)$$

$$\text{Amount of Co} = 0.464(A_0 - A)$$

where copper and cobalt are in units of micrograms per millilitre, and $A_0$ and $A$ are the absorbances of the reagent blank and the sample, respectively. Minimum detectable amounts in the copper and cobalt determinations were on the order of parts per billion, with a sensitivity for the 0.001 absorbance (Sandell index [7]) of 0.568 $\mu g\ cm^{-2}$ for copper(II) and 0.464 $\mu g\ cm^{-2}$ for cobalt(II). The sensitivity for the copper(II) determination is eight times greater than the sensitivities of the bathocuproine, cuprizon, sodium diethyl dithiocarbamidate methods, and is comparable with that of the diphenylcarbazide method [12–16]. For the cobalt(II) determination, the sensitivity is ten times greater than those obtained using a nitroso-R salt and 2-nitroso-1-naphthol, is four times greater than when using 1-nitroso-2-naphthol, and is twofold greater

than that obtained for the 1-(2-pyridylazo)resorcinol methods [12,15].

### 3.7. Effect of foreign ions

Solutions containing 0.1 mg $l^{-1}$ of copper(II) or cobalt(II) and varying concentrations of several ions metals were analyzed in order to ascertain whether they interfered with the determinations. Mn(II), Zn(II), Ni(II), Pb(II), Cr(II), Fe(III), Mg(II), Ca(II), Sr(II) and Ba(II) did not interfere up to 100 mg (about a one-thousandfold excess). Pd(II), Fe(II) and Hg(II) interfered in the determination. The interference of Pd(II) was removed by the addition of 0.01 M potassium iodide solution, while the interference of Fe(II) was removed by preliminary oxidation to Fe(III). Hg(II) reacted quickly with the CPI and its interference was avoided by the addition of hydroxylamine.

## 4. Conclusions

The illumination of CPI using a UV-Vis light source caused the formation of stable and colourless photoproducts with absorption bands at 220 and 264 nm at pH above 6. In contrast in acidic solutions, and in the presence of metal ions, CPI did not photodecompose. This fact suggests that the photoreaction begins inside the CPI ring in the absence of crowding. The porphyrin ring can be reduced by photochemical or chemical action, giving phlorin, displaying absorption maxima at 400 and 735 nm, porphomethene (500 nm) and porphyrinogen (about 200 nm). The photoreduction proceeds through distinct stages; the third stage (porphyrinogen) is a completely colourless compound that could be reached only with several reducing agents [18]. The photoreduction can concern the $2\beta$ bonds of the pyrroles (absorption maxima at about 650 nm) [19] with the formation of chlorine. The product obtained on irradiation of CPI exhibited the characteristic band of porphyrinogens, therefore this product is the most favourable in this phototransformation. The phototransformation rate was very slow with respect to the complexation reaction rate, in such a way that it did not influence the determination of the kinetic complexation constants and the metal ions.

The Soret bands of CPI and its metal complexes at pH 8 were located at 372 and 414 nm (Co(II)) and 380 nm (Cu(II)). In the analytical determination of cobalt(II), the distance of the complex from the CPI band was sufficient for an easy determination of the absorbance peak, while in the Cu(II) determination, a gaussian decomposition of the peaks was necessary. The application of these direct reactions was impractical because of their small reaction rates even in the presence of catalysts. Actually, after each addition of titrant (CPI), it was necessary to wait at least 10 min for completion of the reactions. Because of the very large absorptivities of CPI and its complexes, after the equivalence point the measured absorbances were proportional to the difference between the absorptivities of CPI and the metal complexes. This influence on the titration curves was more evident for copper than for cobalt (due to the smaller distance between CPI and the peaks of the complex); however, this fact does not influence the titration end point (Fig. 3). This method presents several advantages compared with common titrants, because it forms extremely stable metal complexes with a molar ratio of 1:1 and with a very large molar absorptivity, as well as, high sensitivities, greater than or comparable with those obtained with other ligands.

The calibration curve method was more practical than the titration method because although it was an equally sensitive technique, it was less time consuming. In conclusion, CPI may be considered as a suitable titrant for the determination of several metals despite the low reaction rate observed. Trace amounts of copper or cobalt ions may be directly determined by spectrophotometry with sensitivities of $0.568 \times 10^{-3}$ μg $cm^{-2}$ and $0.464 \times 10^{-3}$ μg $cm^{-2}$ for copper and cobalt, respectively.

**Abstract**

Humic materials extracted from tree leaves of chestnut (*Castanea sativa*), eucalyptus (*Eucalyptus globulus*) and oak (*Quercus robur*) were analyzed by performing conductimetric titrations. Values between about 84 and 236 $\mu S\,cm^{-1}$ for the molar conductivity and between 0.42 and 0.74 for the charge distribution parameter were obtained when the concentrations of the extract are increased from 40 to 100 $mg\,l^{-1}$. These variations were explained by using the counterion condensation theory, and the distance between the charged groups of the polyions, the volume of the counterion condensation and the Debye–Hückel potential were also calculated.

*Keywords:* Conductimetry; Humic acids; Leaf extract

## 1. Introduction

The organic matter of soils is constituted mainly from humic materials (humic acids (HA) and fulvic acids (FA)), polyelectrolyte compounds which play an important role in the behaviour of metals in soils and aquatic environments, due to their ability to complex metal ions. On the other hand, these humic materials are formed by microbial degradation and percolation of water through leaves and other organic litter, so a knowledge of the behaviour and structural properties of leaf extracts in solution may be of interest in understanding the chemical behaviour of humic materials.

In order to study these polyelectrolyte materials in solution, many different techniques (i.e. potentiometry, dialysis, fluorescence spectroscopy, etc.) have been used. Conductimetric titrations are an important tool in the study of these types of compounds, because they provide information on association phenomena and on the nature and behaviour of charged groups [1–11]. However, interpretation of the experimental results has been difficult. The development of the condensation theory [12] was an important advance in the explanation of the polyelectrolyte properties of solutions [13–16], and recently van Leeuwen et al. [17] summarised existing theories of association phenomena and reviewed the literature relating to conductimetric analysis of polyelectrolyte systems. These authors stressed the difficulty of understanding the concentration dependence of the conductivity of polyelectrolyte solutions.

TAL 42:12-H

In the present work, the influence of concentration on the conductimetric analysis of the extracts obtained from leaves of three types of trees common in the forests of the Galician country (N.W. Spain), i.e. oak, eucalyptus and chestnut, when titrated with alkali metal hydroxides, is reported. The parameters relating to the "condensation" of counterions (i.e. the line charge density, $\xi$, and the Debye–Hückel potential, $\psi(a)$) and the volume of the zone of the counterion condensation, $V_p$, are calculated.

## 2. Experimental

All reagents were p.a. or similar, and were used without further purification. Carbon-dioxide-free deionised water with resistivity 20 MΩ cm or above was used.

The solutions of the metal ions ($Li^+$, $Na^+$ and $K^+$) were prepared by dilution of stock solutions of their respective hydroxides. Their concentrations were determined by titration with standardised HCl.

The extracts of oak, chestnut and eucalyptus were obtained from leaves collected in different forests of Galicia, and were extracted by using the standard procedure recommended by the IHSS for FA [18,19]. For this purpose, the leaves were dried in air, shaken with 2 M hydrochloric acid solution diluted with water to pH approximately 2, concentrated on Amberlite XAD-8 resin, transformed to their acidic form using cation-exchange resin (Merck ion exchanger I) and freeze-dried. The yield of the process was about 0.3% (w/w).

A CRISON microCM 2101 conductimeter, equipped with a platinum cell (nominal constant 1) and calibrated with a 0.01000 M KCl solution, was used to obtain the conductance of the FA solutions.

In the experiments, 50 ml of diluted salt-free solutions of the extracts (concentrations, 40, 60, 80 and 100 $mg^{-1}$, except for oak because its 100 $mg\,l^{-1}$ solutions were unstable), were introduced into a thermostatted cell (298.0 ± 0.1 K) until thermal equilibrium was reached, and were titrated with metal hydroxide (approximately 0.018 M, in steps of 25 μl) with a CRISON μBUR 2031 burette. Prior and during the titrations the samples were purged and stirred with $CO_2$-free dry air. The conductance values were recorded after stabilisation (conductance variations of 0.1 μS cm or less per 2 min) and average values of three repeated experiments (the differences were less than 0.2 μS cm) were used in the calculations.

## 3. Calculations

The interpretation of the conductimetric behaviour of polyelectrolyte systems is not easy and different theories attemtping to explain it have been published [17]. Of these, the line charge model seems the most interesting, because of the good correlation of predictions with the experimental results and the relatively large number of parameters which can be calculated from the experimental data.

The basic starting point for understanding the conductimetric curves of polyelectrolyte systems is the expression for the molar conductivity (Λ) of a solution which contains only polyions p and their respective counterions

$$K = f(\lambda_c + \lambda_p)C_p$$

$$\Lambda = f(\lambda_c + \lambda_p) \quad (1)$$

where $K$ is the conductance of the solution, $C_p$ is the molar concentration of deprotonated groups of the polyion, Λ is the molar conductivity ( $= K/C_p$ [17]), $\lambda_c$ is the conductivity of the counterions, $\lambda_p$ is the conductivity of the polyion and $f$ ($= 1 - \theta$, where $\theta$ is the fraction of countercharges bounded to the polyion) is a charge distribution parameter which can be related to the fraction of free counterions. The molar conductivity is calculated from the experimental plots of the conductance of the polyelectrolyte solutions vs. the amount of metal hydroxide added in the zone where the concentrations of $H^+$ and $OH^-$ are not great [20]. This equation can be modified [21] to consider $\lambda_c^0$ (the conductivity of the counterions in pure solvent, available from the literature), instead of $\lambda_c$

$$\Lambda = f(\lambda_c^0 + \lambda_p) \quad (2)$$

Eq. (2) expresses the fact that Λ is proportional to $\lambda_c^0$ and, if linear plots are obtained [22], the slope and intercept of the plot of Λ vs. $\lambda_c^0$ for different monovalent cations allows the calculation of $f$ and $\lambda_p$ [23].

On the other hand if it is assumed that the polyion can be considered as a long cylinder with a sufficiently high charge density (due to the presence of a large amount of deprotonated groups in different sites), Manning [13,21] found the following relationships between $f$

and a dimensionless line charge density $\xi$ ($\lambda_p$-dependent; see also Eqs. (7) and (9))

$$f = 0.866|z|^{-1}\xi^{-1} \quad (\xi \geqslant |z|^{-1}) \tag{3}$$

$$f = 1 - \frac{0.55\xi^2}{\pi + \xi} \quad (\xi \leqslant |z|^{-1}) \tag{4}$$

where $z$ is the charge of the cation (Eq. (4) holds for $|z| = 1$ only). On the other hand, $\xi$ is related to the average spacing between charged sites of the polyion, $l$

$$\xi = \frac{l_B}{l} \tag{5}$$

where $l_B$ is the Bjerrum length, defined as

$$l_B = \frac{e^2}{4\pi\varepsilon\varepsilon_0 kT} \tag{6}$$

where $\varepsilon\varepsilon_0$ is the permitivity of the solution. From Eqs. (3)–(6), $\xi$ and $l$ values can be estimated from $f$.

Moreover, if the relaxation effect is considered [21], the following relationship between $\lambda_p$, $\lambda_c^o$, the radius of the cylinder, $a$, and a reciprocal screening length, $\kappa_D$, can be obtained

$$\lambda_p = \frac{0.866H\lambda_c^0 \ln|\kappa_D a|}{|z|\lambda_c^0 + 0.134H \ln|\kappa_D a|} \tag{7}$$

In this expression, $H$ is a standard electrophoretic mobility factor defined by

$$H = \frac{4\varepsilon\varepsilon_0}{3\eta} RT \tag{8}$$

$\eta$ is the viscosity of the polyelectrolyte solution, and $\kappa_D$ can be calculated from

$$\kappa_D^2 = \frac{F^2 C_p}{\varepsilon\varepsilon_0 RT\xi} \tag{9}$$

In the same way, a relationship can be obtained for the electrostatic potential at the surface of the cylinder of radius $a$ ($\Psi(a)$), due to the presence of the counterions ($|z| = 1$ only)

$$\psi(a) = \frac{2kT \ln|\kappa_D a|}{e} \tag{10}$$

Finally, when $\xi$ exceeds unity, the volume of the zone of counterion condensation, $V_p$, (in cubic centimetres per mole if $l$ is expressed in Angströms) can be related to $\xi$ by the equation [24]

$$V_p = 41.1(\xi - 1)l^3 \tag{11}$$

## 4. Results and discussion

The titration curves of polyelectrolyte solutions with metal hydroxides show three different regions (in Fig. 1 a set of typical experimental titration curves at different extract concentrations is presented as an example): (a) the initial part of the curve, where the conductivity decreases down to a minimum, which can be attributed to the neutralisation of free $H^+$ ions by added metal hydroxide; (b) the region after the minimum, where the conductivity increases slowly due to an increase in both negatively charged groups on the polyelectrolyte molecules and the concentration of free metal ions; and (c) the final part, where a larger slope is obtained due to an increase in the concentration of free metal hydroxide.

Of these three regions, the second (where the concentrations of $H^+$ and $OH^-$ ions are low) is the most important for performing the calculations of the conductimetric parameters of polyelectrolytes, because the conductivity depends only on the fraction of free counterions, and on the molar conductivities of the counterion in the pure solvent and the polyion. Therefore, application of Eqs. (1) or (2) allows the calculation of $f$ and $\lambda_p$. These equations predict that the plots of $K$ vs. $C_p$ have an intercept equal to zero; if this is not the case, the $K$ values must be corrected by subtracting the value of $K$ obtained by extrapolation of $OH^-_{added}$ to zero. Values for $\lambda_p$ and $f$ in that region of the curves for the three extracts analysed, obtained by using Eq. (2), are sum-

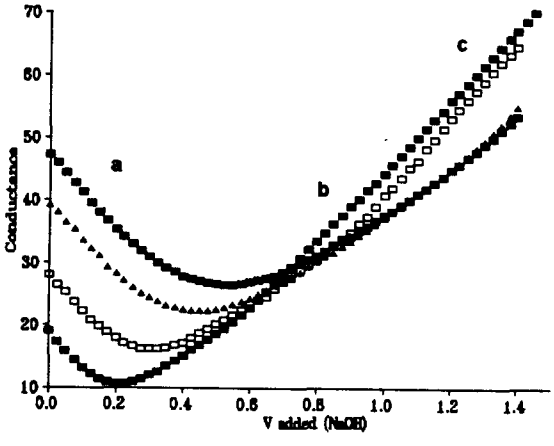

Fig. 1. Variation of the conductance ($\mu S\ cm^{-1}$) of eucalyptus extract solutions (of concentrations (■) 40 mg $l^{-1}$, (□) 60 mg $l^{-1}$, (▲) 80 mg $l^{-1}$ and (⊠) 100 mg $l^{-1}$) when titrated with NaOH. For an explanation of the a, b and c regions, see the text.

Table 1
Parameters obtained from the conductimetric titration of eucalyptus, chestnut and oak

[a] Values not available (see text).

marised in Table 1 (statistical treatment of the plots showed that the above-mentioned corrections were not required).

The results show that an initial decrease of $\lambda_p$ occurs when the concentration of the extract rises until a minimum is reached (at about 60–80 $mg\,l^{-1}$, depending on the extract). The eventual increase in $\lambda_p$ (and related variables) can be attributed to changes in the conformational structures of the polyelectrolyte molecules. These results are in agreement with the theoretical decrease of $\lambda_p$ when the number of deprotonated groups of polyelectrolyte increases [17], due to an increment in the polyion radius and a consequent decrease in $\xi$. As $f$ and $\xi$ are inversely related (Eqs. (3) and (4)), a parallel increase in the fraction of conductimetrically free counter ions is also observed.

From the calculated $f$ values, the line charge density, $\xi$, and the distances between charged groups ($l$) were estimated using Eqs. (3)-(6). The values obtained (also listed in Table 1) fall in the range 3.4–6.4 Å, and are similar to published values for similar systems [24,25], which confirms the polyelectrolyte nature of the extracts. As for $f$, an increment in the $l$ values is observed when the concentration increases, in agreement with an increase in the viscosity values (obtained in salt-free solutions of the extracts) with concentration (the viscosity increases up to 60–80 $mg\,l^{-1}$, but a marked decrease is observed at the highest concentration [25] and this suggests an unscrolling of polyelectrolyte molecules in the concentration range from 40 to 60–80 $mg\,l^{-1}$ and a later scrolling due to changes in their conformation.

From $\lambda_p$ and $\eta$, values of $\psi(a)$ and $V_p$ were estimated using Eqs. (10) and (11). An initial decrease in the Debye–Hückel potential when the concentration increases is obtained; this can be attributed to the enlargement of the extract molecules, in good agreement with the $l$ and $f$ variations calculated before, and with others reported for FA [26]. On the other hand, no definite trend was found for the $V_p$ values, due to the small influence of the counterions on the size of the condensation volume.

When the parameters calculated for the three different extracts are compared, significant differences appear for the eucalyptus at the higher concentrations analyzed. The $f$ and $l$ values are higher than for the other two extracts, showing that the distance between groups is larger and a higher number of counterions are conductimetrically free. This behaviour is in agreement with the less acidic nature of the eucalyptus extract, determined previously [27].

## Acknowledgment

The authors acknowledge the concession of an Acción Integrada Hispano–Portuguesa for the development of this work to the Ministerio de Asuntos Exteriores of Spain and the Conselho de Reitores das Universidades Portuguesas of Portugal.

# High-performance liquid chromatographic determination of uranium using solvent extraction and bis(salicylaldehyde) tetramethylethylenediimine as complexing reagent

M.Y. Khuhawar*, S.N. Lanjwani

*Institute of Chemistry, University of Sindh, Jamshoro, Sindh, Pakistan*

Received 23 January 1995; revised 22 May 1995; accepted 12 June 1995

**Abstract**

The reagent bis(salicylaldehyde)tetramethylethylenediimine has been used for the determination of dioxouranium(VI), based on complexation in aqueous solution at pH 6, followed by extraction in chloroform and HPLC determination on a Hypersil ODS (3 μm) column. The complex was eluted with the ternary mixture methanol–acetonitrile–water (40:30:30, v/v/v), with UV detection at 260 nm. Oxovanadium(IV), iron(III), copper(II), cobalt(II), nickel(II) and palladium(II) were completely separated and did not interfere in the determination of uranium. The linear calibration range and detection limits have been obtained. The method has been applied to the determination of uranium together with copper, iron and nickel in mineral ore samples.

*Keywords:* Bis(salicylaldehyde)tetramethylethylenediimine; Complexation; Dioxouranium(VI); HPLC; Solvent extraction; Uranium determination

## 1. Introduction

A number of analytical methods are reported for the determination of uranium, including spectrophotometry, spectrofluorimetry and inductively coupled plasma-atomic emission spectrometry. The methods generally involved prior separation using ion exchange or solvent extraction techniques [1–3]. High-performance liquid chromatography (HPLC) methods for the determination of uranium have also been reported, based on ion exchange, ion pair or ion chromatography and post column derivatization using Arsenazo III or 4(2′-pyridylazo)resorcinol [4–11]. Casoli et al. [12] have used 2,6-diacetylpyridine-bis-(benzoylhydrazone) for solvent extraction, and reversed phase HPLC for the determination of uranium. Main and Fritz [13], after complexing uranium with the bis(quaternary ammonium hydrazones) of 2,6-diacetylpyridine, have determined the uranium complexes chromatographically. Fuping et al. [14] have studied the retention behaviour of α-hydroxyisobutyric acid complexes of thorium and uranium by reversed-phase (RP) HPLC.

The reagent bis(salicylaldehyde)tetramethylethylenediimine ($H_2SA_2Ten$) has been used for the determination of copper and nickel in metal alloys using gas chromatography and normal phase HPLC [15], oxovanadium(IV) in crude petroleum oils using normal phase HPLC [16], and cobalt and iron in pharmaceutical preparations using RP HPLC [17]. In the present work, the selective reaction of $H_2SA_2Ten$

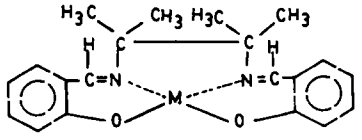

Fig. 1. Structural diagram of the metal–$H_2SA_2Ten$ complex.

(Fig. 1) with a limited number of metal ions (copper(II), nickel(II), cobalt(II), cobalt(III), iron(II), iron(III), palladium(II), platinum(II), manganese(II), oxovanadium(IV) (VO(II)) and dioxouranium(VI) ($UO_2$(II)) [15–19]) combined with simple isocratic RP-HPLC has been used for the determination of uranium.

## 2. Experimental

The reagent $H_2SA_2Ten$ and its copper(II), nickel(II), palladium(II), iron(III), oxovanadium(IV) and dioxouranium(VI) complexes were prepared as reported earlier [15–18].

### *2.1. Solvent extraction of dioxouranium(VI)*

An aliquot of a solution (1–10 ml) containing uranium (0–200 μg) was transferred to a well-stoppered test tube. Sodium acetate–acetic acid buffer (pH 6; 2 ml) and reagent solution (1.5 ml; 1% (w/v) in ethanol) were added. The mixture was warmed on a water bath for 10 min, and after cooling, chloroform (2 ml) was added. The layers were mixed well and 1 ml of the extract was transferred to a sample vial. The solvent was removed and the complex was redissolved in 1 ml of methanol. Portions of the solution (1–5 μl) were injected on to a column (150 mm × 4.6 mm) of Hypersil ODS (3 μm) and the complex was eluted with a ternary mixture of methanol–acetonitrile–water (40:30:30, v/v/v) with a flow rate of 0.5 ml $min^{-1}$. Detection (UV) was performed at 260 nm.

### *2.2. Analysis of uranium in mineral ore samples*

Samples (1) 38834 (0.5 g), (2) 38842 (0.5 g), (3) 38835 (0.2 g), (4) 388496 (0.2 g) and (5) 38850 (0.2 g) were transferred to beakers and hydrochloric acid (60 ml; 37%) and nitric acid (20 ml; 65%) were added. The contents of the beaker were heated gently on a hot plate and when most of the acids had evaporated, nitric acid (20 ml; 65%) was added. The beaker contents were again heated to near dryness and the residues were dissolved in nitric acid (0.1 N). The solutions were filtered and the volumes was adjusted to 25 ml. The solution (10 ml) resulting from sample 1 or those (5 ml) resulting from samples 2, 3, 4 and 5 were transferred to well-stoppered test tubes and the pHs were adjusted to 5–6. The procedure described in section 2.1 was then followed.

### *2.3. Analysis of uranium using standard addition technique*

To sample 38842 (0.2 g) were added 40, 80, 120, 160 and 200 μg of uranium, and the procedure described in section 2.2 was then followed.

### *2.4. Simultaneous extraction of copper(II), nickel(II), iron(II) and dioxouranium(VI)*

To a solution (5 ml) containing (0–200 μg) of copper, nickel, iron and uranium were added the reagents, and that procedure described in section 2.1. was followed. The aqueous phase was transferred to a volumetric flask (10 ml), and the volume was adjusted to 10 ml. The amount of copper, nickel and iron remaining in the aqueous phase was determined using atomic absorption spectrophotometry.

### *2.5. Simultaneous extraction and determination of copper(II), nickel(II), iron(II) and dioxouranium(VI) in mineral ore samples*

The mineral ore samples (1 g) were transferred to beakers and the analytical procedure described in section 2.2 was followed. The final volume was adjusted to 50 ml. An aliquot of the solution (0.1–25 ml) was taken and the volume was adjusted to 10 ml. The procedure described in section 2.1 was then followed.

The mineral samples (sandstone house reference standards) were obtained from the Atomic Energy Minerals Centre, Lahore, and uranyl nitrate (BDH Chemicals Ltd.) was used for the preparation of a uranium standard solution (1 mg $ml^{-1}$).

HPLC studies were carried out with use of a Hitachi 655A liquid chromatograph connected

to a variable wavelength UV monitor, a Rheodyne 7125 injector and a Hitachi Chromato integrator D-2500.

A column (150 mm × 4.6 mm i.d.) of Hypersil ODS (3 μm) (Shandon, USA) was used throughout the study. Spectrophotometric studies were carried out with use of a Hitachi 220 spectrophotometer. A Varian Spectr AA 20 atomic absorption spectrophotometer with an air–acetylene nebulizer was used.

## 3. Results and discussion

The reagent $H_2SA_2Ten$ forms a neutral complex with dioxouranium(VI), which is easily extractable into chloroform ethyl acetate and methyl isobutyl ketone (MIBK). The absorbtion maximum for the complex is at 470 nm and Beer's law is obeyed at a final concentration of 2–20 μg $ml^{-1}$ in chloroform. The effect of pH on the extraction of dioxouranium(VI) was investigated spectrophotometrically. It was observed that dioxouranium(VI) is extracted in the pH range 3–9, but optimal extraction was observed at pH 6.

The uranyl complex was easily eluted from the Hypersil ODS column, but optimal separation from an excess of the reagent occurred when elution was effected with a ternary mixture of methanol–acetonitrile–water (40:30:30, v/v/v) (Fig. 2). Copper(II), cobalt(II), nickel(II), iron(III), palladium(II) and oxovanadium(IV) complexes of $H_2SA_2Ten$, when present together, eluted separately from the uranyl complex and did not interfere in the uranium determination. However complete separation between dioxouranium(VI), oxovanadium(IV), palladium(II), nickel(II), cobalt(II), iron(II) and copper(II) was observed when isocratic elution was performed with methanol–acetonitrile–water (70:10:20, v/v/v) (Fig. 3).

Linear calibration of uranium was obtained with 0–100 μg $ml^{-1}$ of the extract by plotting the average peak height ($n = 3$) versus concentration. The coefficient of correlation ($r$) was 0.998. The detection limit measured at least three times the background noise was 2.5 μg $ml^{-1}$, corresponding to 12.5 ng per injection. The test solutions were analyzed for content of uranium, and a relative percentage error within 0–4.2% was found. The effects of aluminium(III), chromium(VI), manganese(II) and zinc(II) on the extraction of uranium were examined. Aluminium(III), manganese(II) and zinc(II) decreased the percentage extraction of uranium. Aluminium was masked with ammo-

nium fluoride (1 ml; 1% (w/v)) and manganese(II) and zinc(II) could be tolerated at a concentration similar to that of uranium. The mineral samples were analyzed for content of uranium (Table 1), and the values obtained showed coefficients of variation (C.V) within 2.7–4.6%, which is 5.0–7.3% lower than the expected values. Sample 2 (38842) was also analyzed by the standard addition method and the results obtained (395 $\mu g\ g^{-1}$ with a C.V. of 3.5%) was close to the previously obtained value. It may be suggested that the complexation extraction and HPLC determination are quantitative, but slightly low results (5–7.3%) could be attributed to a low dissolution efficiency of uranium in hydrochloric acid–nitric acid from sandstone.

Finally, it was observed that the mineral samples contained copper, iron and nickel,

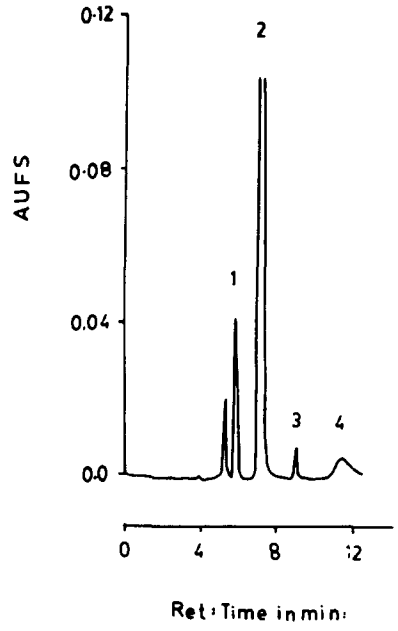

Fig. 4. Simultaneous HPLC determination of chelates of (peak 1) dioxouranium(VI) (peak 2) iron(III), (peak 3) nickel(II), (peak 4) copper(II) in sample no. 38842,on a column (150 mm × 4.6 mm i.d.) of Hypersil ODS (3 μm), with elution with methanol–acetonitrile–water (40:40:20, v/v/v) at a flow rate of 0.8 ml $min^{-1}$ and with detection at 260 nm.

which were simultaneously extracted with uranium. The transfer of metals from the aqueous to the organic phase was examined. The metal ions remaining in the aqueous phase were determined using atomic absorption spectrophotometry. It was observed that 92%, 93% and

| | | Cu | 22(4.8) | 20(1.8) |
| | | Fe | 49000(2.0) | 49400(0.5) |

[a] Coefficients of variation (%) are given in parentheses.

94% of copper, nickel and iron were transferred with C.V.s of 1.54%, 2.86% and 0.86%, respectively, using a single extraction. Thus an attempt was made to determine copper, iron and nickel together with uranium using HPLC (Fig. 4). The same extraction procedure was used as for uranium. The results in Table 2 indicate a close correlation between the amounts obtained by HPLC and atomic absorption spectrophotometry. Coefficients of variation obtained by HPLC were 2.0–6.6%, compared to 0.5–5.0% by atomic absorption spectrophotometry.

## 4. Conclusions

A simple HPLC method has been used for the determination of uranyl, based on pre-column derivatization and using $H_2SA_2Ten$ as complexing reagent. The method has been used for the determination of uranium together with copper, iron and nickel in mineral samples after acid dissolution.

## Acknowledgements

Dr. Fazal-Ur-Rehman, CSO, and the Director, Atomic Energy Mineral Centre, Lahore are acknowledged for providing us with five house reference standards for use in the development of the HPLC method.

# Electrochemical approach to monitoring metal exchange reaction of acetylacetonate complexes with cadmium, copper and zinc ions

Ryoko Fujiyoshi *, Meiseki Katayama

*Faculty of Engineering, Hokkaido University, Sapporo 060, Japan*

Received 14 April 1995; revised 8 June 1995; accepted 13 June 1995

**Abstract**

Metal exchange reactions of acetylacetonate complexes with Cd(II), Cu(II) and Zn(II) ions were investigated by using cadmium and copper ion selective electrodes. Changes in the electrode potential and pH of the solutions were monitored upon adding the pertinent metal Zn(II) of the acetylacetonate (AA) complexes. In the reverse system in which a stable Cu–AA complex exists in the solution prior to adding a secondary metal ion (Cd(II) or Zn(II)), no Cu(II) was replaced by either ion. In the systems containing Cd(II) and Zn(II) as a complexed form with AA or as free ions, the exchange reactions were not explained by considering the equilibrium stability constants of the Cd–AA and Zn–AA complexes.

*Keywords:* Acetylacetonate complexes; Cadmium(II) ions; Copper(II) ions; Electrochemistry; Ion selective electrodes; Metal exchange reactions; Zinc(II) ions

## 1. Introduction

Speciation studies of trace elements in the natural environment have been carried out extensively to elucidate the fates and bioavailability of toxic pollutants [1–3]. Several methods are used for these purposes, which can be classified into three categories: thermodynamic (and kinetic) calculations, direct analysis of environmental samples (including in situ analysis), and model experiments (experimental simulations in the laboratory). The individual methods and their appliations strongly depend on the nature of the medium to be analyzed, and on the different physicochemical forms to be determined. The electrochemical approach is one of the promising methods for this purpose [4]. The accuracy and sensitivity are sometimes not sufficient to deal with most natural water systems. The solution pH may be another limiting factor for ion selective electrode (ISE) measurements. However, in some cases, in which the concentration of the element of interest is rather high, e.m.f. measurement can be applied to environmental monitoring.

The purpose of the present study is to elucidate the possibility of evaluating exchange reactions of metal complexes by using ion selective electrodes. As a preliminary example, metal exchange reactions of well-known acetylacetonate (AA) complexes have been investigated using cadmium and copper electrodes. The authors try to find unknown exchange reactions in the natural environment through certain metal complexes with known stability constants.

## 2. Experimental

### 2.1. Reagents and solutions

All chemicals used in this study were purchased from Wako Pure Chemical Industries and were of analytical reagent grade.

Standard solutions of Cd(II), Cu(II) and Zn(II) were prepared by dissolving the pertinent metals (99.9% purity) in a small amount of concentrated $HNO_3$. An aqueous solution of acetylacetone was prepared from direct dilution of the reagent.

### 2.2. Procedure

The free ion concentration of Cd(II) or Cu(II) in the solution was measured by using an ion analyzer (Orion Model EA940) with a cadmium ion selective electrode (Orion Model 9448BN) or a copper ion selective electrode (Orion Model 9429BN), an Ag/AgCl double-junction reference electrode (Orion 900200) and an automatic temperature compensation probe (Orion 917001). The solution pH was also monitored with a pH meter (Horiba D12).

Calibration was carried out within the linear working range ($10^{-7}$–$10^{-5}$ M) for individual metal ions (Cd(II) or Cu(II)) to obtain a characteristic slope in the pertinent e.m.f. measurement. Factors affecting the electrode potential are temperature, pH, ionic strength and also ionic and/or non-ionic species coexisting in the solution. The experimental conditions in this study were set as follows: temperature, $20 \pm 0.1$°C; pH 4–5; $I = 0.01$ M (with $NaNO_3$). The linearity of the electrode potential for both the cadmium and the copper electrodes was examined in the concentration range from $10^{-7}$ to $10^{-5}$ M. The reproducibility of the calibration curve was carefully checked before and after the experiment. The effects of coexisting ions on the electrode potential were evaluated by changing the amount of pertinent salts added to the solution of constant ionic strength.

## 3. Results and discussion

In order to elucidate the ISE response to the acetylacetonate complexation of Cd(II) and Cu(II), titration curves of these ions were obtained by using cadmium and copper electrodes. Figs. 1 and 2, respectively, show the

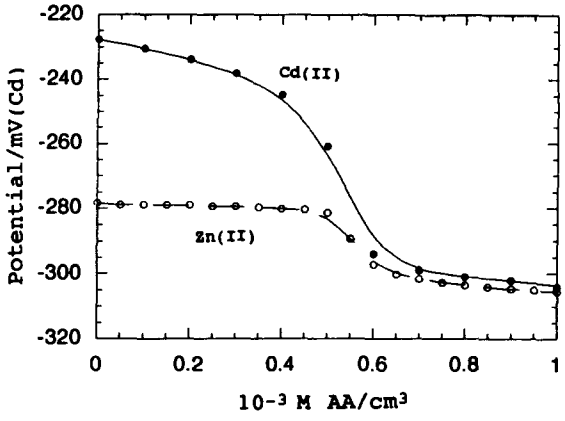

Fig. 1. Titration curves of Cd(II) and Zn(II) solutions with $10^{-3}$ M AA aqueous solution monitored with a cadmium selective electrode. ●, $5.0 \times 10^{-6}$ M Cd(II); ○, $5.0 \times 10^{-6}$ M Zn(II).

results for Cd–AA and Cu–AA systems, in which the concentration of each metal ion was adjusted to $5 \times 10^{-6}$ M at pH 5 and $I = 0.01$ M initially. An aqueous solution of AA ($10^{-3}$ M) was used as a titrant. Considering the acid dissociation constants of acetylacetone ($pK_a = 8.9$), [5] virtually all AA in aqueous solution is in the neutral form, i.e. AAH at pH 5. The suitable pH range for ISE measurement is restricted by hydroxide formation for both Cu(II) and Cd(II), which is not detected by an ISE. Under the experimental conditions specified in this study, the complexation at pH 5 is fast enough to monitor a change in the e.m.f. of the solution electrochemically. Proton exchange is supposed to occur simultaneously in the AA complexation at pH 5.

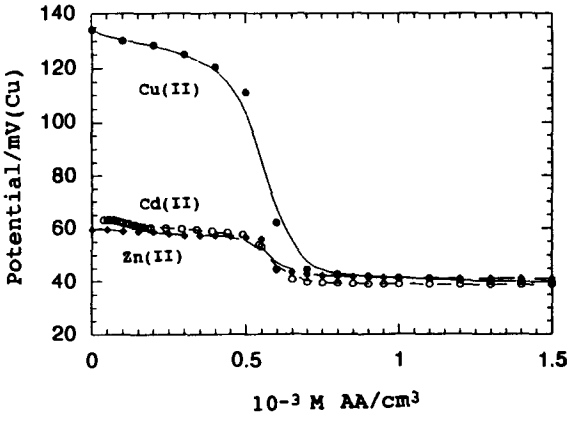

Fig. 2. Titration curves of Cd(II), Cu(II) and Zn(II) solutions with $10^{-3}$ M AA aqueous solution monitored with a copper selective electrode. ○, $5.0 \times 10^{-6}$ M Cd(II); ●, $5.0 \times 10^{-6}$ M Cu(II); ◆, $5.0 \times 10^{-6}$ M Zn(II).

Table 1
Electrode response to the ion (M') present in the solution at 20°C, pH 5 and $I = 0.01$

| Electrode | Ion (M') | Selectivity coefficient[a] | Concentration ($\times 10^{-7}$ M) |
|---|---|---|---|
| Cadmium | Cu(II) | $10 \sim 35$[b] | 1–10 |
| | Zn(II) | $10^{-2}$ | 1–50 |
| Copper | Cd(II) | $10^{-2}$ | 1–50 |
| | Zn(II) | $10^{-2}$ | 1–50 |

[a] The selectivity coefficient was obtained by the mixed solution method with both fixed primary ion and fixed interference.

[b] The value was not constant but increased with increasing amount of Cu(II) ion present in the solution.

The absolute value of the e.m.f. after the endpoint of a titration is known to be dependent on the type of complexing agent in the solution, its concentration and pH [6]. The endpoints obtained in both systems correspond to the formation of a stoichiometric 1:1 complex of metal-acetylacetonate. Figs. 1 and 2 also show the results of the titration of Zn(II) with AA using a cadmium electrode and also of Zn(II) and Cd(II) using a copper electrode, respectively. The endpoints on the curves also suggest the formation of a 1:1 complex of the metal-acetylacetonates. Any metal species other than free ions are not detected by the ISE measurements. The acetylacetonates of Cd(II), Cu(II) and Zn(II) are supposed to be 1:2 (metal:AA) with respect to chemical composition under the present experimental conditions.

The effects of Zn(II) ions on the ISE potential of the cadmium electrode, and Zn(II) or Cd(II) ions on that of the copper electrode were investigated separately by using the mixed solution method with both a fixed primary ion and fixed interference [7].

Table 1 lists the response of both cadmium and copper electrodes to the ions (M') present in the solutions. The presence of Zn(II) ions and also Zn(II) and Cd(II) ions ($5 \times 10^{-6}$ M or lower) did not affect the electrode potential significantly on using the cadmium electrode and copper electrode, respectively [8]. Cd(II) ions in the solution do not interfere in the ISE measurement of Cu(II) ions with the copper electrode. The most striking effect appeared to be on the e.m.f. measurement of the Cd(II) ions in the solution containig cupric ions. The selectivity coefficients of the cadmium electrode was not constant but increased with increasing amount of Cu(II) ions in the solution ($10^{-7}$ M < Cu(II) < $5 \times 10^{-6}$ M).

The metal exchange reaction was then investigated by titrating a solution containing a known amount of primary metal–AA complex ($5.0 \times 10^{-6}$ M) with a standard solution of a secondary metal ion ($10^{-4}$ M). The following systems were examined

(a) $CdAA_2$ + Cu(II) (Cu)
(b) $ZnAA_2$ + Cu(II) (Cu)
(c) $CdAA_2$ + Zn(II) (Cd)
(d) $ZnAA_2$ + Cd(II) (Cd)
(e) $CuAA_2$ + Cd(II) (Cd)
(f) $CuAA_2$ + Zn(II) (Cu)

where the element in parenthesis refers to the ISE used in the system.

Fig. 3 shows the results of two typical examples, systems (b) and (e), where the ISE potential (mV) of the copper electrode is plotted against the logarithmic concentration (M) of Cu(II) ions added to the solution. The calibration curve for Cu(II) is shown together with the titration curves. As shown in the figure, metal exchange is clearly observed between Zn(II) of the Zn–AA complex and the added Cu(II) ions (System (b)). In contrast, the Cd(II) ion does not replace the Cu(II) of the $CuAA_2$ complex appreciably (System (e)).

From a set of data for e.m.f. measurements from the metal exchange reactions, the per cent exchange of a primary metal ion bound by AA was calculated as a function of the secondary metal concentration in the systems listed above. Figs. 4 and 5 give the results. As shown in Fig. 4, Cd(II) and Zn(II) bound with AA are easily replaced with Cu(II) ions under the experimental conditions specified in this study.

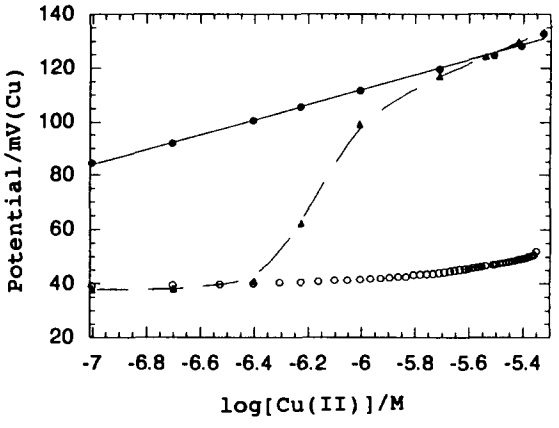

Fig. 3. Change in ISE potential as a function of Cu(II) concentration monitored with a copper selective electrode. ●, Calibration curve; ▲, system (b) ($ZnAA_2$ + Cu(II)); ○, system (e) ($CuAA_2$ + Cd(II)). The initial concentrations of $ZnAA_2$ and $CuAA_2$ in the solution were adjusted to be $5 \times 10^{-7}$ M and $5 \times 10^{-6}$ M, respectively.

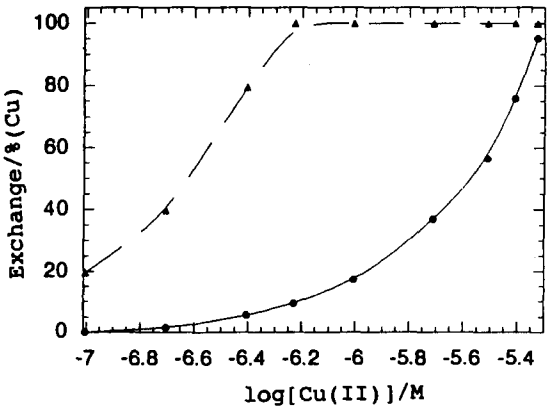

Fig. 4. Per cent exchange of metal–acetylacetonate as a function of Cu(II) concentration in the solution. ●, System (a) ($CdAA_2$ + Cu(II)); ▲, system (b) ($ZnAA_2$ + Cu(II)). The initial concentrations of $CdAA_2$ and $ZnAA_2$ in the solution were adjusted to be $5 \times 10^{-6}$ M and $5 \times 10^{-7}$ M, respectively.

The behavior of Cu(II) in the metal exchange reaction of the AA complex may be explained by considering the large stability constant (log $\beta = 23.7$) of $CuAA_2$. The stability constants (log $\beta$) of $ZnAA_2$ and $CdAA_2$ are reported to be 17.6 and 14.5, respectively at 25°C [9]. It is thus supposed that metal exchange will easily proceed in the system (c). However, as shown in Fig. 5, no exchange occurs before the point on the curve at which an equal concentration of Zn(II) ions to the Cd(II) are added to the $CdAA_2$ solution. After this point, Zn(II) ions begin to replace Cd(II) of $CdAA_2$ to form the Zn–AA complex.

Fig. 5 also shows the result in system (d).

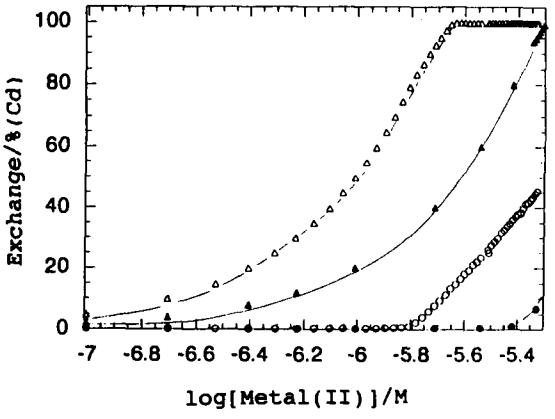

Fig. 5. Per cent exchange of metal–acetylacetonate as a function of titrant (AA complex) concentration in the solution. System (c) ($CdAA_2$ + Zn(II)): ○, $2.0 \times 10^{-6}$ M; ●, $5.0 \times 10^{-6}$ M. System (d) ($ZnAA_2$ + Cd(II)): △, $2.0 \times 10^{-6}$ M; ▲, $5.0 \times 10^{-6}$ M. The initial concentrations of both $CdAA_2$ and $ZnAA_2$ in the solution were adjusted to be $2 \times 10^{-6}$ and $5 \times 10^{-6}$ M.

Table 2
Per cent exchange of $M-AA_2$ in the mixed solutions (equilibrium experiments)

| System | Concentration ($\times 10^{-6}$ M) | | Exchange (%) |
|---|---|---|---|
| | $M-AA_2$ | M′ | |
| (c) | 2.0 | 2.0 | 13.0 |
| | | 5.0 | 45.3 |
| | | 10.0 | 100 |
| (d) | 2.0 | 2.0 | 90.2 |
| | | 5.0 | 100 |
| | | 10.0 | 100 |

The exchange is unlikely to occur appreciably in this system because of a three orders-of-magnitude difference between the overall stability constants of $ZnAA_2$ and $CdAA_2$. However, as shown in the figure, the per cent exchange of $ZnAA_2$ increases with increasing amount of Cd(II) ions added to the solution. All the Zn(II) bound with AA has been replaced by Cd(II) ions at a point on the curve in which the concentration of Cd(II) ions equals that of Zn(II).

In order to check that the equilibrium consideration is applicable to the results from the titration experiments in systems (c) and (d), the potential of the cadmium electrode was measured in the mixed solutions with known amounts of $CdAA_2$ (or $ZnAA_2$) and Zn(II) ions (or Cd(II) ions) at 20°C. Table 2 shows the per cent exchange of $MAA_2$ obtained from serveral solutions for each system. The results are in agreement with those of the titration experiments.

These facts suggest that the metal exchange in the AA complex does not always proceed according to the stability constants of the pertinent acetylacetonates. This seems particularly to be the case when the difference in the stability constants between primary and secondary metal complexes is not large.

The present authors have studied metal and/or ligand exchange reactions of several metal complexes including porphyrins by using the radiotracer technique [10,11]. The degree of exchange in any of the systems studied previously could be evaluated from the stability constants of each complex.

The applicability of various exchange reactions to natural systems should be further investigated not only by the radiotracer technique, but by another technique, such as ISE measurements.

## 4. Conclusion

Cadmium and copper ion selective electrodes were used to monitor free ion concentrations of Cd(II) and Cu(II) in the metal exchange reaction of acetylacetonate complexes with Cd(II), Cu(II) and Zn(II) ions at 20°C, pH 4–5 and $I = 0.01$ M. In some cases in which Cu(II) is included in the system, the exchange reaction proceeds according to the differences in the stability constants of the metal acetylacetonates. However, in the systems in which Zn(II) and Cd(II) are held in the complex form with AA or as added free ion, respectively, the Zn–AA complex with the higher stability constant releases Zn(II) ions to be Cd–AA complex through titrating Cd(II) ions to the solution.

Further studies on metal exchange reactions are now being undertaken using a radiotracer technique.

**Abstract**

The separation of silver from a uranium matrix has been carried out using Cyanex-471X (triisobutylphosphine sulphide) in xylene. The effects of various parameters such as the Cyanex-471X concentration, the nitric acid molarity, the contact time and the nitrate ion concentration on the extraction of silver have been studied. The silver metal ion species extracted into the organic phase was found to be $Ag(NO_3)\cdot 2S$ (where S is Cyanex-471X). The stripping of silver into an aqueous medium was carried out with 5% $NaHSO_3$, followed by its determination using ICP-AES.

*Keywords:* Chemical separation; Cyanex-471X; Extraction; ICP-AES; Silver determination; Silver nitrate; Triisobutylphosphine sulphide; Uranium matrix

## 1. Introduction

In view of the significantly high value of the thermal neutron absorption cross-section for silver, it is considered to be one of the metallic elements to be specially monitored in the chemical quality control of nuclear fuel materials. Inductively coupled argon plasma-atomic emision spectrometry (ICP-AES) has less tolerance for dissolved solids and can generate spectral interferences from uranium/plutonium in the determination of analytes. In order to improve the overall analytical performance, it is, therefore, essential to chemically separate the major matrix from the analytes or to separate the analyte metal ion selectively before ICP/AES determination. A highly selective solvent extraction technique has been developed for the separation of silver from uranium/plutonium.

Metal ions such as gold, silver, mercury, copper and palladium (all classified as "soft acids") are selectively extracted by reagents containing sulphur and phosphorus ("soft bases") as donor atoms [1–5]. Cyanex-471X (triisobutylphosphine sulphide) developed by the American Cynamid Co., has been used successfully [6–10] in the extraction of palladium, mercury, rhodium, gold and silver.

This paper describes the extraction of silver from a uranium matrix using 0.1% Cyanex-471X in xylene, from $HNO_3$ medium. The effect of various parameters on the extraction of silver has also been studied.

## 2. Experimental

### 2.1. Apparatus

A Jarrell-Ash 0.75 M (Mark III: Atomcomp 1100 series) direct reading spectrometer equipped with d.c. arc and ICP excitation sources was used. The spectrometer consists of 48 analytical channels covering 33 elements and a monochromator as a variable wavelength channel. The data acquisition and processing are carried out with an IBM-compatible computer. A high-purity germanium (HPGe) detec-

tor with a multichannel analyser was used for checking the purity of the $^{110m}Ag$ tracer by recording its gamma energy spectrum. Gross gamma counting of $^{110m}Ag$ was carried out with a gamma scintillation counter using a NaI(Tl) detector (Harshaw, UK, 3 × 3 well-type, type no. 12 SW 12-W 3).

### 2.2. Preparation of standards and samples

All the reagents ($HNO_3$, xylene, $NaNO_3$, $NaHSO_3$) were A.R. grade. Preanalysed high-purity $U_3O_8$ was used for the preparation of the synthetic samples. A radioactive tracer of $^{110m}Ag$ ($\beta$-active; Board of Radiation and Isotope Technology (BRIT), Department of Atomic Energy (India)) was used to monitor the extraction of silver radiometrically. Cyanex-471X was used directly to extract silver in nitric acid medium. Stripping of silver into the aqueous phase was carried out with $NaHSO_3$ solution.

Spec-pure $AgNO_3$ (Johnson Matthey, UK) was dissolved in 0.3 M $HNO_3$ to prepare a stock solution of concentration 1 $mg\ ml^{-1}$. A soluiton of 100 $\mu g\ ml^{-1}$ was prepared in order to optimize the experimental parameters for silver (328.1 nm). A 20 $\mu g\ ml^{-1}$ solution and the reagent blank were used as high-concentration and low-concentration standards for two-point standardisation. The $U_3O_8$ matrix was dissolved in $HNO_3$ in order to prepare a 1 $mg\ ml^{-1}$ uranium stock solution. A 100 $\mu g\ ml^{-1}$ uranium solution was used for the optimisation of the analytical signal for uranium at the 409.01 nm line. The reagent blank and a 10 $\mu g\ ml^{-1}$ uranium solution served as low- and high-concentration standards in a two-point standardisation programme for the monitoring of uranium in the chemically separated silver solution.

### 2.3. Procedure

*Kinetics of silver extraction*

The extraction kinetics of $^{110m}Ag$ were studied by mixing 1.0 ml of 2.5 M $HNO_3$ containing silver tracer with an equal volume of 0.1% Cyanex-471X in xylene and equilibrating by slow rotation (40 rev $min^{-1}$) in a water bath at 25 ± 0.1°C for 0.5–60 min. The solutions were centrifuged and the organic and aqueous phases were separated for radioassay.

*Extraction of $^{110m}Ag$ by Cyanex-471X*

Initial experiments on silver extraction were carried out in aqueous medium without any uranium. Different sets of experiments were performed by varying the Cyanex-471X, $HNO_3$, $NO_3^-$ ion and carrier $Ag^+$ concentrations.

The range of variation for each of the above parameters is given in Table 1. After equilibration, the phases were centrifuged, separated and radioassayed.

*Silver removal from the loaded organic phase*

Silver was extracted by 0.1% Cyanex-471X solution from 2.5 M $HNO_3$ (containing $^{110m}Ag$) and the organic phase was separated. To 1 ml of the loaded organic phase, equal volumes of 1–5% $NaHSO_3$ solution was added. After shaking and centrifuging, the phases were separated and assayed for the $^{110m}Ag$ activity.

Once the experimental parameters were optimised, silver was separated from the uranium matrix. $U_3O_8$ (100 mg) was dissolved in 2.5 M $HNO_3$ to which a known amount of $^{110m}Ag$ tracer was added. The solution was extracted using 0.1% Cyanex-471X in xylene. Both the organic and aqueous phases were separated and assayed for the $^{110m}Ag$ activity to assess the efficiency of extraction.

Two synthetic samples were also prepared by adding known amounts of silver to uranium. Silver was extracted with 0.1% Cyanex-471X in xylene with a 1 min contact time. Silver was removed from the organic phase uisng a 5% $NaHSO_3$ solution.

The ICP-AES method was standardised for the determination of silver stripped into the $NaHSO_3$ solution. Initially, the experimental parameters (argon gas flow rates, signal integration time, viewing positions) were optimised using 100 μg ml$^{-1}$ silver solution. The optimised parameters were then used to carry out a two-point standardisation with 0.3 M nitric acid as the low-concentration standard and 20 μg ml$^{-1}$ solution as the high-concentration standard. Since uranium is not covered by the 48 analytical channels available from the polychromator, the U 409.01 nm line was monitored on the variable wavelength channel. The experimental parameters were optimised using 100 μg ml$^{-1}$ uranium solution. A two-point standardisation was carried using 0.3 M nitric acid as the low-concentration standard and 20 μg ml$^{-1}$ solution as the high-concentration standard. The synthetic samples from which silver was separated were analysed for silver and traces of uranium.

## 3. Results and discussion

The kinetics of extraction of $^{110m}Ag$ by Cyanex-471X has shown that the equilibrium is attained in about 1 min (Fig. 1). The extraction dependence of silver on the Cyanex-471X concentration is shown in Table 2. At 0.1% or above, the extraction is quantitative. The equilibrium for the extraction of silver in the organic phase is

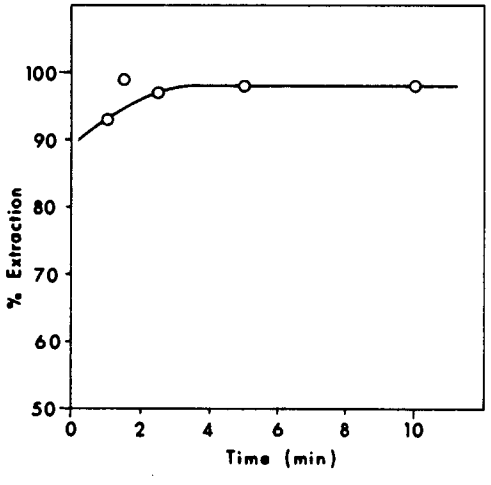

Fig. 1. Plot of percentage extraction vs. time for Ag(I) in 2.5 M $HNO_3$ at a 0.1% Cyanex concentration.

$$Ag_a^+ + NO_3^- + mS_o \overset{K}{\rightleftharpoons} (AgNO_3 \cdot mS)_o$$

where subscripts a and o represent the aqueous phase and organic phase, respectively, and S signifies Cyanex-471X.

$$K = \frac{[AgNO_3 \cdot mS]_o}{[Ag^+]_a [NO_3^-]_a [S]_o}$$

The distribution ratio ($D$) can be represented by

$$D = \frac{[Ag]_o}{[Ag]_a} = \frac{[AgNO_3 \cdot mS]_o}{[Ag^+]_a}$$

$$K = \frac{D}{[NO_3^-]_a [S]^m}$$

$$\log K = \log D - \log[NO_3^-]_a - m \log[S]_0$$

$$\log D = \log K + \log[NO_3^-]_a + m \log[S]_o$$

Log $D$ was plotted against the logarithm of the Cyanex-471X and the nitrate ion concentrations. Fig. 2 shows a plot of log $D$ vs. log [Cyanex-471X] in 2.5 M nitric acid. The slope is $1.9 \pm 0.1$ suggesting that two molecules of Cyanex-471X are attached to the silver atom. Fig. 3 shows a plot of log $D$ vs. log [$NO_3^-$]; a straight line with a slope of 1.2 suggests that the complex species extracted is $AgNO_3 \cdot 2S$. The free $NO_3^-$ ion concentration was calculated by applying a correction for the dissociation of $HNO_3$.

Table 3 shows the effect of nitric acid molarity on the extraction of silver using 0.1%

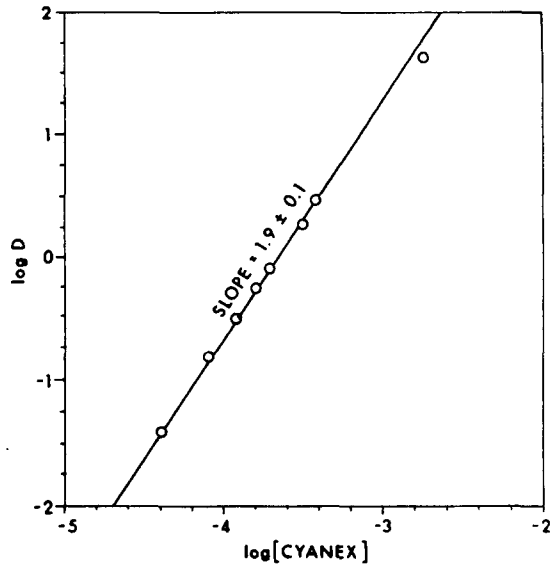

Fig. 2. Plot of log $D$ vs. log[Cyanex] for Ag(I) in 2.5 M $HNO_3$.

Cyanex-471X. With an increase in nitric acid concentration, the extraction of silver increases and becomes almost constant above 4 M.

The loading effect of silver was studied by adding increasing amounts of silver carrier ranging from 1 to 20 μg $ml^{-1}$. Extractions were carried out from 2.5 M $HNO_3$ using 0.05% Cyanex-471X in xylene. Up to 20 μg $ml^{-1}$ silver, the extraction is found to decrease. However, with increased concentration of Cyanex-471X (0.1%) a quantiative extraction of silver up to 50 μg $ml^{-1}$ can be achieved (Table 4).

Table 5 shows the effect of $NaHSO_3$ concentration on the stripping of silver from the organic to the aqueous medium. Silver could

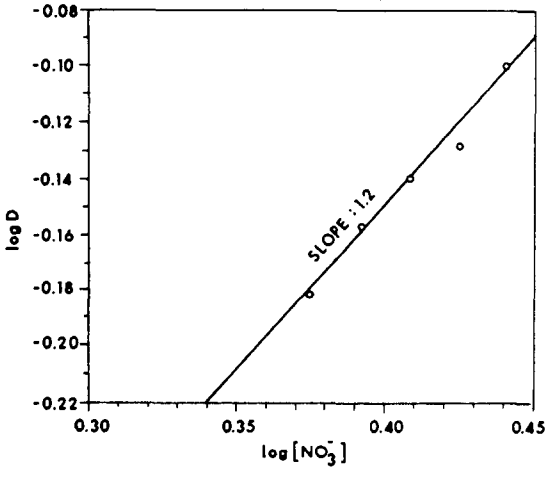

Fig. 3. Plot of log $D$ vs. log[$NO_3^-$] for Ag(I) at a concentration of 0.005% Cyanex in xylene.

| 4.0 | 98.8 |
| 5.0 | 99.0 |

be stripped to the extent of about 94% into the aqueous medium in a single contact with about a 5% solution of $NaHSO_3$. Since a high concentration of $NaHSO_3$ is used for the stripping of silver which is then determined by ICP-AES, the interference of sodium ions on the determination of silver has also been studied. A $NaHSO_3$ solution at a 5% concentration was nebulised in the ICP and the analytical signal was monitored on the silver channel. The concentration of silver recorded was of the order of the blank. Thus the $NaHSO_3$ concentration was optimised at 5%.

The uranium spectrum gives rise to spectral interference for most analyte elements in ICP-AES. Therefore, the presence of uranium in the silver solution after its chemical separation using Cyanex-471X as extractant was monitored. Uranium up to 10 μg $ml^{-1}$ did not interfere in the determination of silver; however, the coextracted amount of uranium in the present work was found to be below 0.5 μg $ml^{-1}$ in all the samples.

Optimised ICP-AES experimental parameters are tabulated in Table 6. The detection limit for silver is 0.2 ppm and it is based on the

$\bar{X}+3\sigma$ concept ($\bar{X}$ being the average blank signal). The detection is limit calculated by repetitive analyses of the blank. The precision of the determinations is based on ten replicate analyses of synthetic samples. The amounts of silver determined in the synthetic samples were in good agreement with the added amounts. The analytical data obtained are given in Table 7.

Due to the non-availability of suitable reference standards/samples, two uranium samples were prepared synthetically by the addition of silver at the 0.5 and 2.5 ppm levels. These samples, after chemical separation, were analysed by electrothermal atomisation—atomic absorption spectrometry (ETA-AAS) in order to provide an independent check on the recovery of silver. Further, these samples were also analysed by the ICP-AES technique using the optimised procedure. The results of these analyses are included in Table 8, and show good agreement for the estimates of silver in the two samples obtained by these methods and also with their added contents.

Concentration corresponding to signal equal to $\bar{X}+3\sigma$.

In conclusion, silver can be separated selectively and quantitatively at trace level concentrations from a uranium matrix using Cyanex-471X extractant in xylene. Silver can then be back-extracted with a 5% $NaHSO_3$ solution. The detection limit for silver in the ICP-AES determination is 20 μg $g^{-1}$ based on a 100 mg uranium sample aliquot. The developed method is suitable for the analysis of nuclear fuel samples.

## Acknowledgements

# Use of cerium oxide ($CeO_2$) as a packing material for the chromatographic separation of $C_{60}$ and $C_{70}$ fullerenes

Yoshifumi Akama

*Department of Chemistry, Faculty of Science and Engineering, Meisei University, Hodokubo, Hino, Tokyo 191, Japan*

Received 4 March 1995; revised 13 June 1995; accepted 16 June 1995

**Abstract**

Cerium oxide ($CeO_2$) was tested as a packing material in liquid chromatography for the separation of $C_{60}$ and $C_{70}$ fullerenes. The separation of $C_{60}$ and $C_{70}$ fullerenes could be achieved within 20 min by using pure *n*-hexane as the mobile phase. Furthermore, some higher fullerenes could also be separated in less than 40 min. The peak area was reproducible to a large extent. The separation of fullerenes by liquid chromatography on $CeO_2$ is shown to be an effective method for their isolation in large amounts. The column efficiency of the $CeO_2$ column was compared with commercial silica gel and ODS columns. The main advantage of the $CeO_2$ column is its ability to separate large amounts of fullerenes ($C_{60}$ and $C_{70}$) in toluene.

*Keywords:* $C_{60}/C_{70}$ fullerene mixtures; Cerium oxide; Column packing material; Fullerenes; High performance liquid chromatography

## 1. Introduction

The physical and chemical characterization of fullerenes have been actively investigated by NMR, IR, mass spectrometry and other spectroscopic techniques.

The purification of the spherical carbon clusters termed fullerenes is an area of increasing importance in chemical and physical testing. However, it is difficult to produce sufficient quantities of high-purity fullerenes to evaluate the possible applications due to their limited solubility in organic solvents. Therefore, there is a need for the development of an efficient separation technique for fullerenes. Until now, many attempts have been made to develop a technique for the separation of fullerenes and their derivatives by column chromatography, e.g. $C_{18}$ reversed-phase [1], silica-gel [2], alumina [3], Pirkle [4], CPS [5], graphite [6], PYE silica [7], multilegged phenyl group bonded silica [8]. Some techniques [9,10] have also been developed for the large-scale purification of fullerenes. While most separation techniques so far utilized are straightforward at the analytical level, they are not suitable for the large-scale purification of fullerenes.

We have recently demonstrated that the polycyclic aromatic hydrocarbons can be effectively separated on a $CeO_2$ stationary phase using *n*-hexane as the mobile phase. As an extension of this work, we have proposed the use of a $CeO_2$ column for the separation of $C_{60}$ and $C_{70}$ fullerenes. For the large-scale separation of $C_{60}$ and $C_{70}$ fullerenes, the $CeO_2$ column was clearly effective compared with the commercial silica gel and ODS columns.

## 2. Experimental

Commercial $CeO_2$ (about 10 g), which was purchased from Soekawa Chemical Co. Ltd., was pretreated before use as a column packing

*SSDI* 0039-9140(95)01667-8

material by suspension in ethanol with mixing for 1 min, then allowed to stand for 10 min. The supernatant was discarded in order to remove any small particles. This procedure was repeated in five times. The pretreated $CeO_2$ with a mean particle size of 5 μm was slurried in 15 ml of ethylene glycol. This mixture was forced into a stainless steel tube (4.6 mm × 135 mm) over a period of 60 min using pure ethanol as the packing solvent, at a constant pressure of 550 kg $cm^{-2}$. However, optimization of the packing is difficult because no satisfactory slurrying solvent has been found. The column was then used as a normal phase support using *n*-hexane as the mobile phase. The stock solutions of $C_{60}$ and $C_{70}$ fullerene standards are prepared by dissolution in toluene due to the higher solubility of the fullerenes. The working standards were prepared by appropriate dilution with toluene or *n*-hexane from the stock solution. The analytical HPCL system consisted of an 880-PU pump, and an 875-UV spectrophotometric detector (both from JASCO, Tokyo), a Rheodyne model 7125 injector with a 20 μl injection loop and a Shimadzu model CR4A Chromatopac integrator. A Personal Pump NP-AX-15 (Nippon Seimitsu Kagaku Co. Ltd., Tokyo) was used for the packing of $CeO_2$ into the stainless steel tube. The mobile phase was 100% *n*-hexane and the flow rate was 1.0 ml $min^{-1}$. The detector was operated at 350 nm and the injection volume was 20 μl. Quantitation was carried out by determination of the peak area.

## 3. Results and discussion

Fig. 1 shows the grain distribution of $CeO_2$ which was untreated (Fig. 1(a)) and pretreated (Fig. 1(b)) with ethanol prior to packing in the column as mentioned in the experimental section. The mean grain size of $CeO_2$ was reduced to approximately 5 μm by the ethanol treatment. The variation in the grain size after the treatment is due to the disentanglement of the ground $CeO_2$ by mixing with ethanol. Further, ethanol washing leads to a narrowed distribution of $CeO_2$ particle sizes, as shown in Fig. 1(b). This result is also clear by a comparison of the scanning electron microscope pictures of treated and untreated $CeO_2$.

The preparative $CeO_2$ column was applied to the fullerenes ($C_{60}$ and $C_{70}$) to evaluate their chromatographic separation. Typical chromatograms of the fullerenes obtained using $CeO_2$, ODS and silica gel columns are illustrated in Fig. 2. It appears that good resolution of $C_{60}$ and $C_{70}$ fullerenes can be achieved in a short time by using the $CeO_2$ column and pure *n*-hexane as the elution solvent. We also found that $C_{60}$ and $C_{70}$ fullerenes can be widely separated; the smaller $C_{60}$ fullerene is eluted before the $C_{70}$, followed by the higher fullerenes. No other solvents examined (methanol, ethanol, ethyl acetate and toluene) effected separations as efficiently as pure *n*-hexane. The use of these solvents as mobile phases results in virtually no retention of $C_{60}$ and $C_{70}$ fullerenes on $CeO_2$. The $CeO_2$ is stable over a wide pH range; however, water or water/organic solvent mixtures cannot be used as the mobile phase.

Surprisingly, effective separation of the fullerenes has been obtained when about 30 ml of $CHCl_3$ or $CCl_4$ are passed through the column at a flow rate of 1.0 ml $min^{-1}$ prior to the use of *n*-hexane as the mobile phase. A similar separation effectiveness has also been observed for polycyclic aromatic hydrocarbons (PAHs) [11]. Thus, the decline in efficiency of the separation due to repetitive use is improved by passing these solvents through the column.

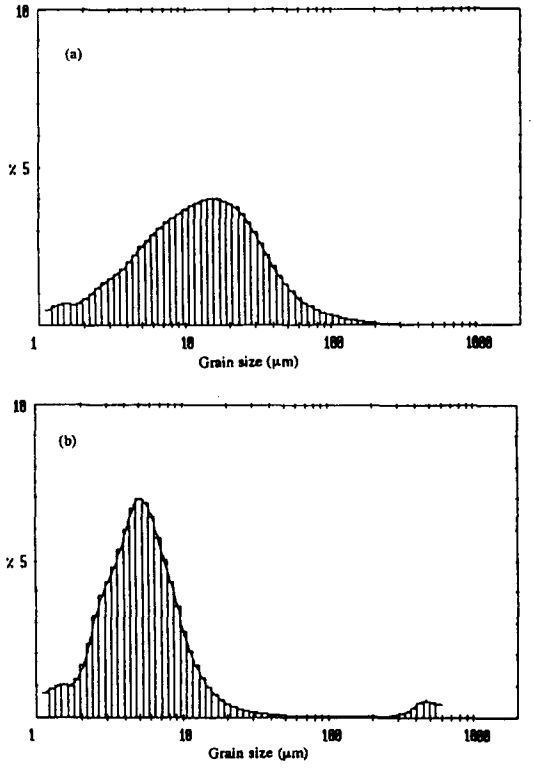

Fig. 1. The distribution curves of grain size of $CeO_2$ used in this experiment. (a) Treated with ethanol; (b) untreated.

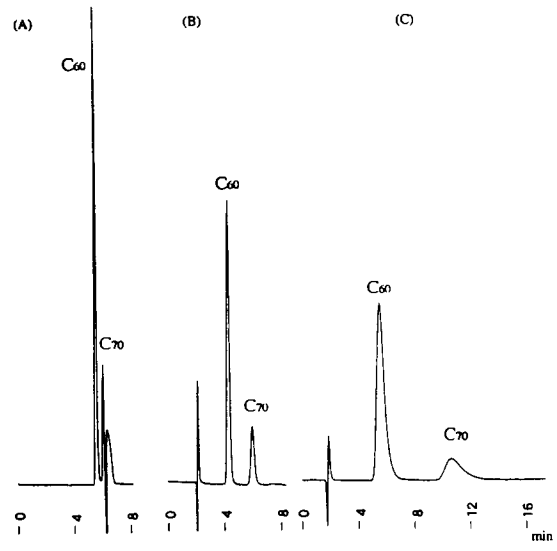

Fig. 2. Separation of fullerenes on a $CeO_2$ column. Chromatographic conditions: mobile phase, *n*-hexane; sample, 8 μg ml$^{-1}$ $C_{70}$; column, (A) Finepak SIL (4.6 mm × 250 mm), (B) Chemcosob 5-ODS-UH (4.6 mm × 150 mm), (C) cerium oxide (4.6 mm × 125 mm); injection volume, 20 μl; flow rate, 1.0 ml min$^{-1}$; detection, UV at 350 nm; attenuation, 4.

This result indicates that the surface of $CeO_2$ may be activated by these solvents; however, further work may be required to understand the origin of these solvent effects.

The retention mechanism of the fullerenes on the $CeO_2$ phase is due to the adsorption contribution, similar to the mechanism of PAH retention on alumina. The fullerenes, which have many π-electrons, strongly interacted with the cerium atom on the surface of the adsorbent. It is expected that a difference in the number of π-electrons will lead to different interactions with $CeO_2$; thus the $C_{60}$ and $C_{70}$ compounds can be separated on this basis. A similar retention mechanism may be applied to the other rare earth oxides when separating the fullerenes or PHAs. However, the separation of the fullerenes could not be performed using $La_2O_3$, $Gd_2O_3$ and $CeO_2$, which have particle sizes below about 1 μm. These results were mainly due to packing difficulties or ease of water adsorption caused by fines. In this study, $CeO_2$ (about 5 μm) was used as a packing material because of its excellent separation capability, and the cost of $CeO_2$ is lower than that of the other rare earth oxides. The column efficiencies for the fullerenes were approximately 500 theoretical plates for the 5 μm $CeO_2$ employed. In general, large-scale purifications of fullerenes are difficult due to their insolubility [12] in organic solvents.

In this study, about 7 mg of a 8:2 $C_{60}/C_{70}$ mixture in 2 ml of toluene solution can be successfully separated, per 20 μl injection, on the preparative $CeO_2$ column, as shown in Fig. 3. Further, it was found that some higher fullerenes could be separated in less than 40 min. Separations of fullerene solutions of concentration 1 and 0.1 mg ml$^{-1}$ are also illustrated in Fig. 4. Fig. 3 shows that the $CeO_2$ column is superior to the silica gel or ODS columns for the resolution of a high concentration of fullerenes. This discrepancy is likely to be associated with many adsorption sites on the surface of a $CeO_2$ particle; this allows a strong interaction between the fullerenes and the Ce(IV) atoms. Consequently we infer that the loading capacity for this material is much greater than that of ODS or silica gel. The loading capacity and column efficiency are very important for both analytical and preparative-scale chromatography, since it is desirable to have a large capacity and a good separation.

The economics of this large-scale chromatographic process for the purification of fullerenes are worth noting. The enhancement of the productivity of fullerenes will be dramatically improved by using a column with a large inner diameter and a longer length. The $CeO_2$ column was found to be quite stable under the conditions used in this study. The reproducibilities of the peak areas were tested by repeated injections (20 replicate injections) of the fullerene standard solution ($C_{60}$, 40 μg ml$^{-1}$; $C_{70}$, 10 μg ml$^{-1}$). The relative standard deviations were 1.4% and 7.7% for the $C_{60}$ and the $C_{70}$, respectively. However, the $CeO_2$ column possesses weakness, in the lack of peak retention reproducibility.

In conclusion, a $CeO_2$ column with high separation efficiency has been developed. The fullerenes ($C_{60}$ and $C_{70}$) could be satisfactorily separated in less than 20 min. The separation of large amounts of $C_{60}$ and $C_{70}$ fullerenes using the $CeO_2$ column was more efficient than with silica gel or ODS columns. The best separation was obtained when $CHCl_3$ or $CCl_4$ was passed through the column prior to use. The retention is probably related to the interaction between the $CeO_2$ and the π-electrons of the fullerene. The main potential use of the $CeO_2$ column is for the separation of fullerenes in large-scale purification. If a large column had been used for the separation, a large amount of fullerenes would be obtained.

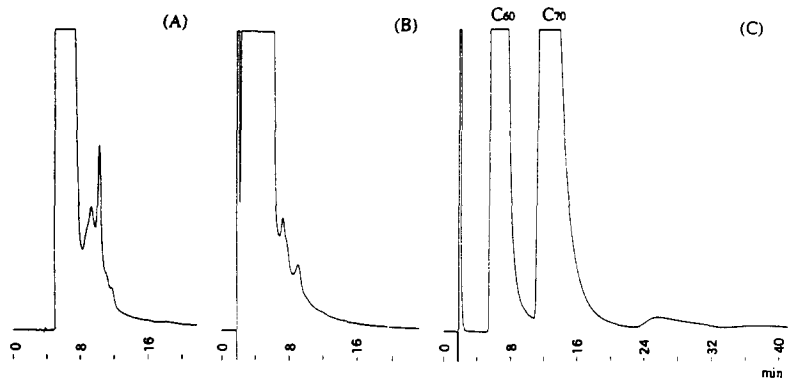

Fig. 3. Separation of fullerenes on a $CeO_2$ column. Chromatographic conditions: sample, 7 mg fullerene in 2 ml toluene (about 80% $C_{60}$, 20% $C_{70}$ and a trace amount of higher fullerenes); column, (A) Finepak SIL (4.6 mm × 250 mm), (B) Chemcosob 5-ODS-UH (4.6 mm × 150 mm), (C) cerium oxide (4.6 mm × 125 mm); attenuation, 5. The other experimental conditions are as in Fig. 2.

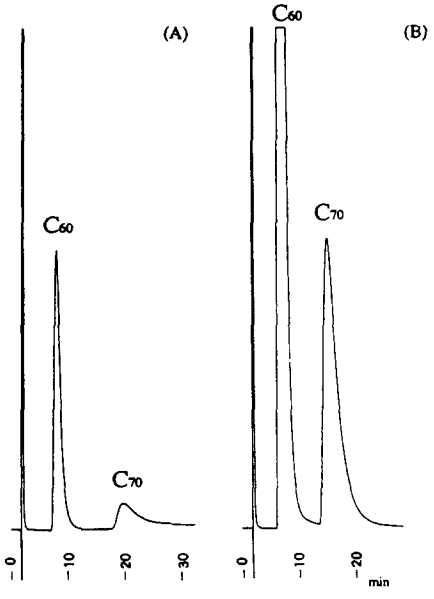

Fig. 4. Separation of $C_{60}$ and $C_{70}$ fullerenes on a cerium oxide column. (A) 0.1 mg $ml^{-1}$ solution of fullerenes ($C_{60}$, 0.08 mg $ml^{-1}$; $C_{70}$, 0.02 mg $ml^{-1}$) in toluene. (B) 1.0 mg $ml^{-1}$ solution of fullerenes ($C_{60}$, 0.8 mg $ml^{-1}$; $C_{70}$, 0.2 mg $ml^{-1}$) in toluene; attenuation, 5. The other experimental conditions are as in Fig. 2.

# Direct ICP-MS determination of trace and ultratrace elements in geological materials after decomposition in a microwave oven. Part II. Quantitation of Ba, Cs, Ga, Hf, In, Mo, Nb, Pb, Rb, Sn, Sr, Ta and Tl☆

J.G. Sen Gupta*, N.B. Bertrand

*Geological Survey of Canada, Ottawa, Ont. K1A OE8, Canada*

Received 24 February 1995; revised 16 June 1995; accepted 16 June 1995

**Abstract**

A new method has been developed for the rapid determination of traces of Ba, Cs, Ga, Hf, In, Mo, Nb, Pb, Rb, Sn, Sr, Ta and Tl in silicate rocks and lake, stream and river sediments. The method involved dissolution of samples in a microwave oven by heating in a pressure decomposition Teflon vessel with a mixture of $HF + HNO_3 + HCl + H_3BO_3 + EDTA$ followed by direct multielement determination using inductively coupled plasma-mass spectrometry (ICP/MS). The method is faster than conventional dissolution of samples by open vessel acid digestion and fusion and determination by instrumental methods. The accuracy and precision of the developed method were tested by replicate analyses of a number of international geochemical reference samples of established trace element contents. Satisfactory correlation with the "recommended" or "consensus" values was found and recoveries were in most cases 95–100%. New values for Ga, In, Nb and Tl in several international geochemical reference materials are first reported in this paper.

*Keywords:* Geological materials; ICP-MS; Microwave decomposition; Multielement determination

## 1. Introduction

The determination of trace and ultratrace elements in the Analytical Chemistry Section of the Geological Survey of Canada (GSC) is part of an ongoing task to establish compositions of various geological materials collected by GSC scientists for their petrological, geochemical and mineralogical studies. In the past, this task was performed by colorimetry [1,2], titrimetry, fluorimetry, atomic absorption spectrometry and optical emission spectrometry [2,3]. With the necessity of producing more data on a significantly large number of samples at lower levels, it became increasingly important to switch to modern instrumental techniques such as inductively coupled plasma-atomic emission spectrometry (ICP-AES) and ICP-MS. However, since the detection limits of ICP-MS are much superior to those of ICP-AES, the former technique gained preference in the GSC for the determination of trace and ultratrace elements in geological and environmental materials.

Details of the application of ICP-MS to geoanalysis are found in the reviews by Riddle et al. [4], Hall [5] and Falkner et al. [6]. Prior to

 Geological Survey of Canada contribution number, 61994.

* Corresponding author. Present address: 6074 Meadowglen Drive, Gloucester, Ontario, K1C 5R6, Canada.

*SSDI* 0039-9140(95)01673-2

the ICP-MS determination of trace elements in geological materials, sample solution preparation involved techniques such as (1) open vessel acid attack [7,8]; (2) fusion with sodium peroxide [9] or lithium metaborate [10,11]; (3) decomposition in a screw-top Teflon bomb with $HF + HNO_3 + HClO_4$ followed by evaporation of the excess HF with $HNO_3$ or $HClO_4$ [12,13]. These procedures are generally slow for modern ICP-MS automated instruments which can analyze samples much faster than the time needed to prepare sample solutions. There is, therefore, a need to decrease the solution preparation time in order to increase productivity.

In recent years, the microwave digestion technique for the dissolution of solid samples has gained increasing attention, as was emphasized in a review by Matusiewicz and Sturgeon [14]. Applications are also found in dissolving rocks [15] and catalysts [16].

In part I of this series, the authors [17] described a method for the direct determination of traces of Th, U and the lanthanides in geological materials by ICP-MS after the dissolution of samples by microwave digestion in a Teflon vessel using a mixture of $HF + HNO_3 + HCl + H_3BO_3$ + EDTA. The purpose of this paper is to demonstrate the effectiveness of the sample preparation procedure followed by direct ICP-MS determination for other trace elements also, such as Ba, Cs, Ga, In, Mo, Nb, Pb, Rb, Sn, Sr, Ta and Tl in rocks and sediments.

The accuracy and precision of the developed method was tested by five replicate analyses of international geochemical reference samples SY-2, MRG-1, BCR-1 and MAG-1. Several other international geochemical reference rocks and sediments were also analyzed, in triplicate or duplicate, to ascertain the accuracy. Excellent agreement with the "recommended" values was found for the majority of these samples. The developed method is fast for routine analysis, economical since it involves less chemicals and equipment for sample decomposition, and environmentally friendly because no evaporation of acids is required.

## 2. Experimental

### 2.1. Apparatus

A Perkin-Elmer/Sciex Elan model 5000 ICP-mass spectrometer equipped with an IBM PS/2 computer (model 70) and an AS-91 autosampler was used for mass spectral analysis. A Milestone microwave oven (model MLS 1200 MEGA) equipped with six 100-ml Teflon pressure decomposition vessels, a microwave digestion rotor (model HPR 10016) and a remote control panel was used for the decomposition of the samples.

### 2.2. Reagents and standard solutions

Synthetic standard solutions of elemental concentrations ranging from 20 to 100 ng $ml^{-1}$ were prepared by diluting 10 μg $ml^{-1}$ mixed high purity ICP-MS standard solutions from Delta Scientific Laboratory Products Ltd. (Mississauga, Ontario) with 3% (v/v) nitric acid. Each standard solution also contained 50 ng $ml^{-1}$ each of ruthenium and rhenium in the final volume (these acted as internal standards for ICP-MS drift control) and two drops of concentrated hydrofluoric acid (to stabilize the tantalum in solution).

A mixed solution of 0.165% ethylenediaminetetraacetic acid (EDTA) and 2% boric acid was prepared by dissolving 1.65 g of EDTA in dilute ammonia solution followed by the addition of 22 g of boric acid, heating to dissolve, mixing and diluting to 1 l with water. Deionized water prepared by reverse osmosis and ACS grade reagents were used throughout, and all solutions were stored in stoppered nalgene bottles.

### 2.3. Procedure

The sample decomposition procedure was described in detail elsewhere [17,18]. Briefly, it

[b] Used as an internal standard to correct for instrumental drift and matrix effects on Group 1 elements.

involved heating a group of six samples in pressurized Teflon vessels, each containing 0.5 g of up to 200 mesh sample and a mixture of 2.5 ml of 27 M HF, 3 ml of 16 M $HNO_3$ and 3 ml of 12 M HCl, in a microwave oven for a total period of 16 min (the power ranged from 250–1000 W). After cooling to room temperature in a water bath, each solution was mixed with 30 ml of the boric acid and EDTA mixture, and the assembled vessels were heated in the microwave oven for an additional 8 min (power ranged from 250–1000 W). The contents of the vessel were then transferred to a polypropylene tube by rinsing with 2% (v/v) nitric acid, and the volume was made up to 50 ml. For ICP-MS determination of the specified elements, an aliquot was diluted 10 times with 3% (v/v) nitric acid containing ruthenium and rhenium internal standards. The final concentrations of ruthenium and rhenium were 20 ng $ml^{-1}$ each in the diluted sample solution; these two elements corrected for matrix effects and controlled instrumental drifts during the ICP-MS measurements. A reagent blank was taken through the procedure. However, multiple blank values for the analytes were found to be negligible.

### 2.4. Multielement ICP-MS determination

Using the instrumental operating parameters of Table 1 and isotopic masses of Table 2, calibration curves were obtained with a blank and three synthetic mixed standard solutions of concentrations 20, 50 and 100 ng $ml^{-1}$ of each element. The 20 ng $ml^{-1}$ synthetic standard solution, six unknown sample solutions (each having a 1 mg $ml^{-1}$ sample concentration and ruthenium and rhenium internal standards) were then run through the autosampler. This

was followed by a repeat determination of a 20 ng ml$^{-1}$ synthetic standard solution and the determination of the concentrations of trace elements for three geochemical reference materials (AGV-1, BCR-1 and BHVO-1), the solutions of which were prepared identically to the unknown sample solutions.

The instrument software automatically performed blank subtraction, calibration, drift control and calculation of the concentrations of the elements in the standard (20 ng ml$^{-1}$), unknown sample solutions and the reference materials used as a control, and printed out the data. From the print-out of the data sheet, the

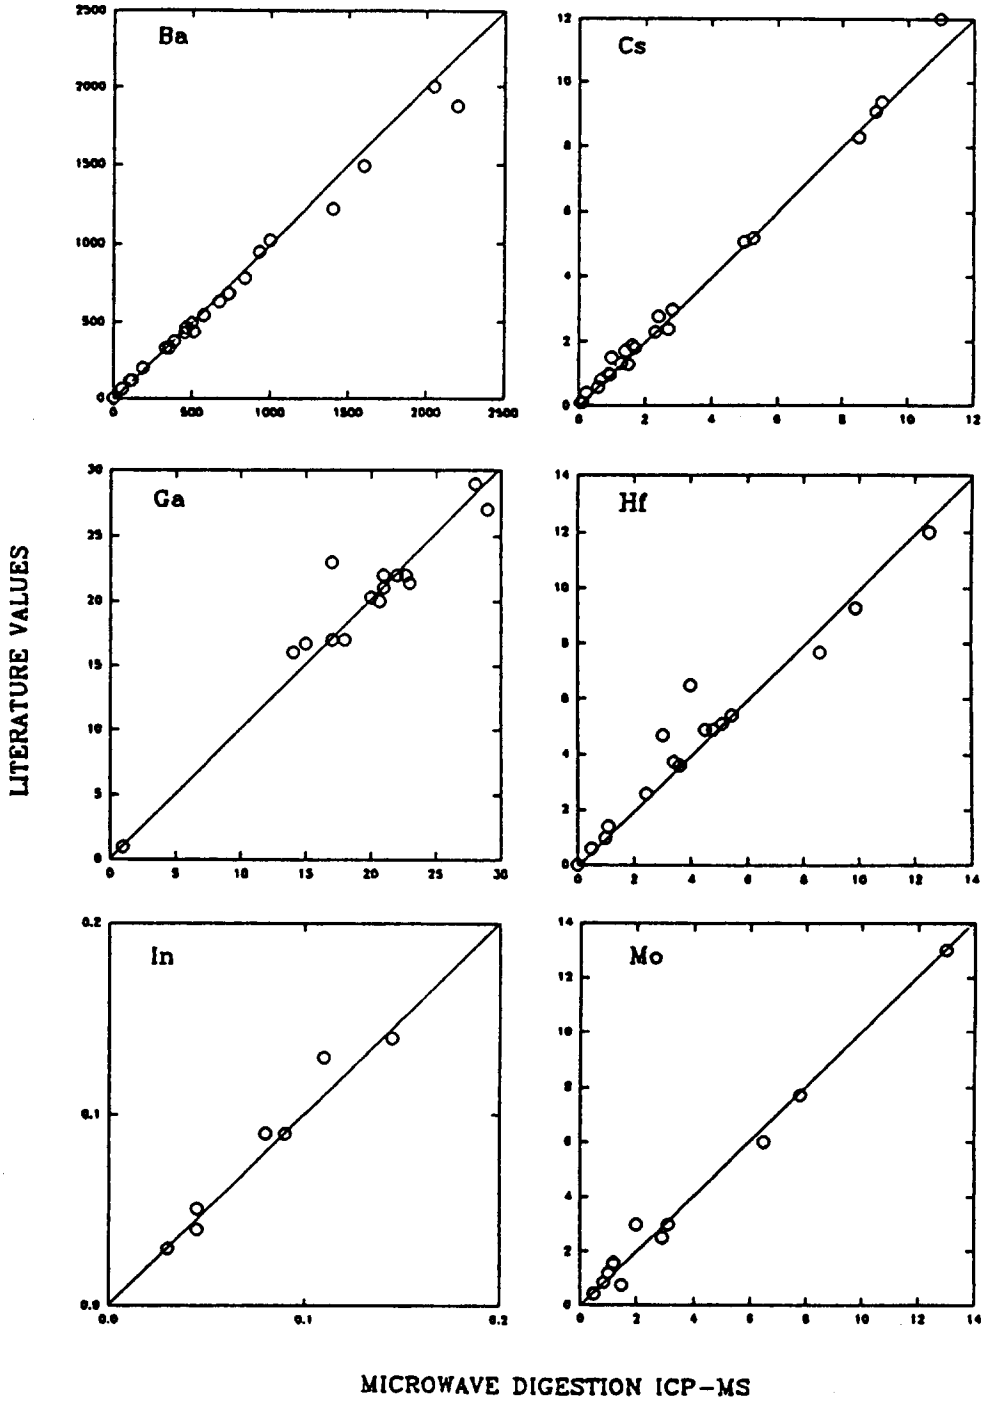

Fig. 1. (Part 1).

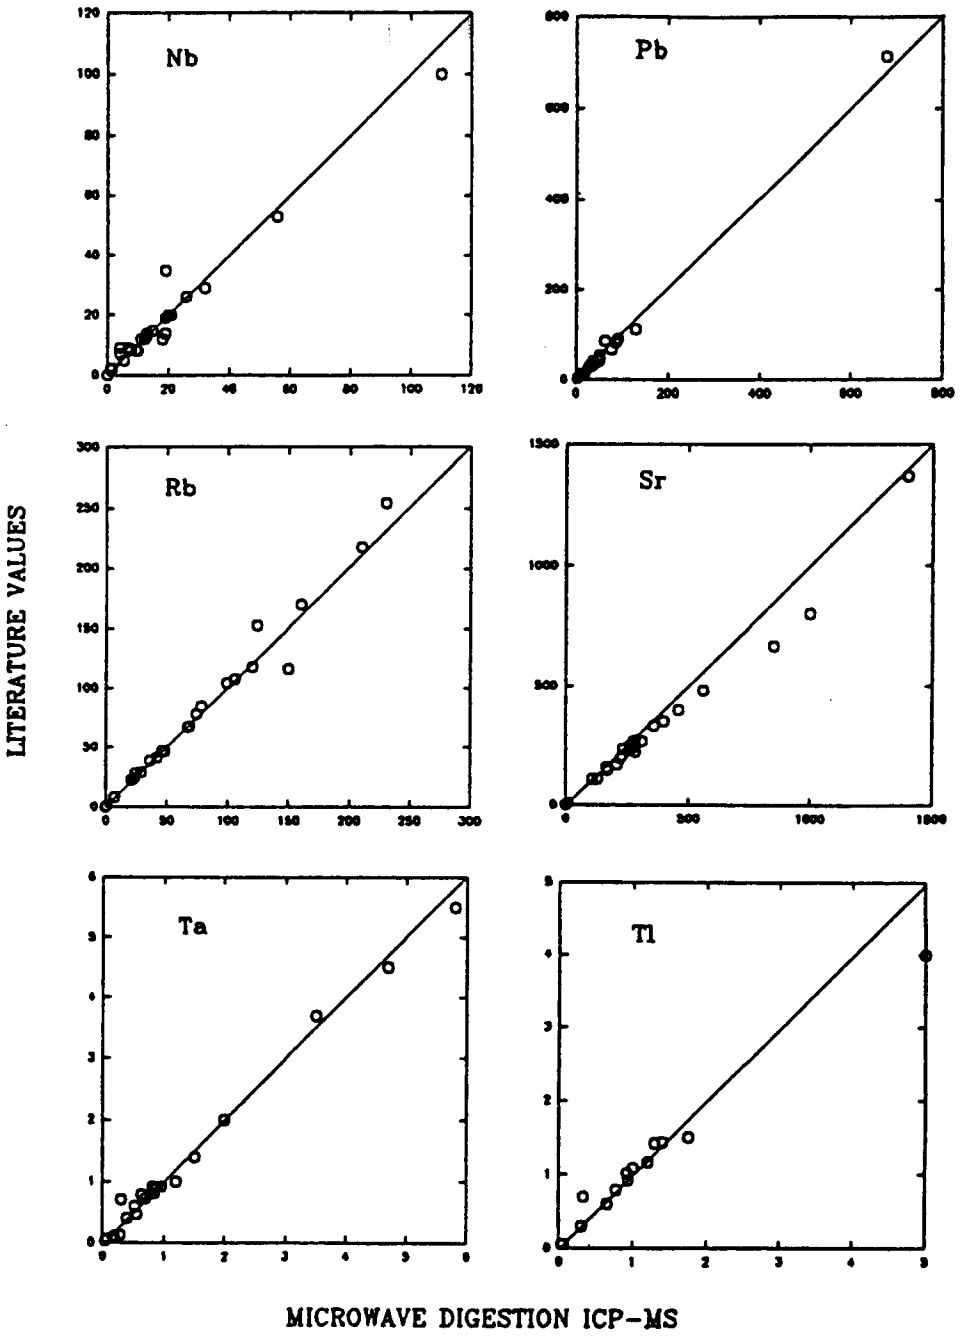

Fig. 1 (continued). Correlation plots for microwave digestion ICP-MS versus the literature values for Ba, Cs, Ga, Hf, In, Mo, Nb, Pb, Rb, Sr, Ta and Tl in some international reference samples of rocks and sediments (concentrations are given in units of micrograms per gram).

recovery of the 20 ng $ml^{-1}$ synthetic standard was checked, and if required, a correction factor (about $1 \pm 0.03$) was applied to the results for the unknown and reference materials. The results for the reference materials were first checked for their accuracy with reference to the "consensus" or "recommended" statistical ranges of literature values [19,20]. If the values for the reference materials fell within acceptable ranges, the results for the unknown samples were presumed correct for reporting purposes. In actual practice, this procedure worked well for the reference materials as well as for the unknown samples.

## 3. Results and discussion

The ICP-MS determination limits (micrograms per gram in the original rock) of this work for 13 trace elements were as follows: Cs, Hf, In, Rb, Tl (0.02); Ga, Nb, (0.10); Mo, Pb, Ta (0.20); Ba (0.5); Sn, Sr (2).

Except for strontium, ICP-MS determination limits of this work for the other elements are superior to those of ICP-AES [7,21]. Isotopic masses of the trace elements analyzed in this work were chosen in such a manner as to possess minimum isobaric interferences. In the case of $^{115}$In, the isobaric contribution of $^{115}$Sn was automatically corrected by the instrument.

Table 3 shows the accuracy and precision of the results for five replicate analyses of Canadian Certified Reference Materials Project (CCRMP) reference rocks SY-2 (syenite) and MRG-1 (gabbro), and USGS reference materials BCR-1 (basalt) and MAG-1 (marine mud), and a comparison with the literature recommended values [19,20,22–25]. For SY-2 and MRG-1 (except for somewhat lower values for lead in SY-2), agreement of the results for the other elements with the recommended values is of the order of 96–100%. However, a large standard deviation in the literature values for Mo in Sy-2 makes them uncertain compared to microwave digestion-ICP-MS (MD-ICP-MS) data. For BCR-1, there is excellent agreement of MD-ICP-MS values with the literature values [19]. For MAG-1, the MD-ICP-MS data compare well with the recommended values in the majority of cases except for niobium, where a significantly higher value was obtained in this work (compare Table 3). In Tables 4–7, MD-ICP-MS results for the specified elements for some international reference materials are given and compared with the literature values [19,20,24,26–28]. These are the USGS reference rocks andesite (AGV-1), basalt (BIR-1), diabase (DNC-1 and W-2), dunite (DTS-1), granite (G-2) and granodiorite (GSP-1), CCRMP lake sediments (LKSD-1 to 4) and stream sediments (STSD-1 to 4), National Institute of Metallurgy (South Africa) granite (NIM-G), International Working Group (France) basalt (BE-N), Institute of Geophysical and Geochemical Exploration (China) stream sediments (GSD-1, GSD-5 and GSD-6) and National Bureau of Standards river sediment (NBS 1645).

MD-ICP-MS results for AGV-1, G-2, NIM-G and BE-N represent mean and standard deviations of three or more determinations. Good agreement between MD-ICP-MS values and the literature values is found in the majority of cases (see Tables 4–7).

New values for gallium in LKSD-1 to 4 and STSD-1 to 4, for indium in BIR-1, DNC-1, W-2, LKSD-1 to 4, STSD-1 to 4, NIM-G, BE-N, GSD-1 and NBS 1645, for niobium in NBS 1645, and for thallium in W-2, LKSD-1 to 4 and STSD-1 to 4 are given in Tables 4–7. It should be pointed out that the literature values for CCRMP lake and stream sediment samples (LKSD-1 to 4 and STSD-1 to 4) are only "provisional", not certified. Therefore, more other values in these samples are needed to make a valid comparison with the results obtained in this work by MD-ICP-MS.

Where possible, the results of this work are also compared graphically with other recommended values (without the standard deviations) in Fig. 1. Most points fall on or near the 45° line supporting the accuracy of the proposed method.

From the data of Tables 4–7 and the above discussion, it can be concluded that for most common types of silicate rocks such as syenites, gabbro, granites, basalts, diabase, etc. and various water sediment samples, the MD-ICP-MS procedure would give results equally as good as those of the open vessel digestion ICP-MS method. But the advantage of the microwave digestion method lies not only in the rapidity of the sample dissolution procedure but also in the economy of reagents and equipment and the smaller amount of environmental pollution since no evaporation of excess acids is required. Approximately 30 sample solutions can be prepared by one operator in one working day by the microwave digestion method.

## Acknowldgements

The authors are indebted to J.L. Bouvier for decomposing some samples, and to K.N. De-Silva for critical reading of the manuscript.

# Determination of impurities in highly pure platinum by inductively coupled plasma-atomic emission spectrometry

Xinhua Zhang*, Huifen Li, Yufang Yang

*Institute of Precious Metals, Kunming, 650221, People's Republic of China*

Received 7 November 1995; revised 9 June 1995; accepted 19 June 1995

**Abstract**

In this work, a cyclone spray chamber system is used in conjunction with an inductively coupled plasma-atomic emission spectrometer instead of the conventional Scott-type chamber system to reduce the lower limit of detection achieved by the instrument, and an internal standard element (Y) is introduced to eliminate the effects caused by the drift in the plasma background level. An ICP-AES method for the determination of 13 impurity elements in a highly pure platinum sample has been developed. In this method, it is not necessary either to add a platinum matrix to the calibration standard or to separate and concentrate the elements to be determined in the samples. The effect of the platinum matrix on the elements to be analyzed is corrected for by a background equivalent concentration subtraction method. The determination ranges of the method are as follows: 0.00010–0.0050% for Mg, Mn, Cu, Ag, Fe and Zn; 0.00030–0.015% for Au, Ir, Ni and Pb; 0.00050–0.025% for Rh and Al; and 0.00080–0.040% for Pd. The method is simple, rapid and accurate, and can be applied to the analysis of 99.9–99.995% pure platinum.

*Keywords:* Cyclone spray chamber; ICP-AES; Impurity elements; Multielement analysis; Platinum

## 1. Introduction

In a previous paper [1], we reported the determination of 13 impurities in 99.99% pure platinum with the ICPQ-1015 direct spectrometer. When there is a demand for the analysis of samples of this metal having a higher purity, the instrument cannot meet the required lower limit of detection of impurity elements. As Browner and Boorn [2] pointed out, the sample introduction system does not always share the excellent properties of the optical and electronic components found in most modern atomic spectrometers. For this reason we introduced a cyclone spray chamber system (CSCS) [3] into the original instrument, and compared the analytical characteristics of the CSCS with those of the conventional Scott-type chamber system (STCS). Under the same operating conditions, the detection limits of the elements to be determined were reduced two- to threefold when the CSCS was used. This means that the lower limit of detection and the amount of sample used can be reduced by use of the CSCS technique. An internal standard element (Y) was introduced to eliminate the effects caused by the drift in the plasma background level [4]. Efforts were made to develop a method for the determination of 13 impurities in 99.9–99.995% pure platinum.

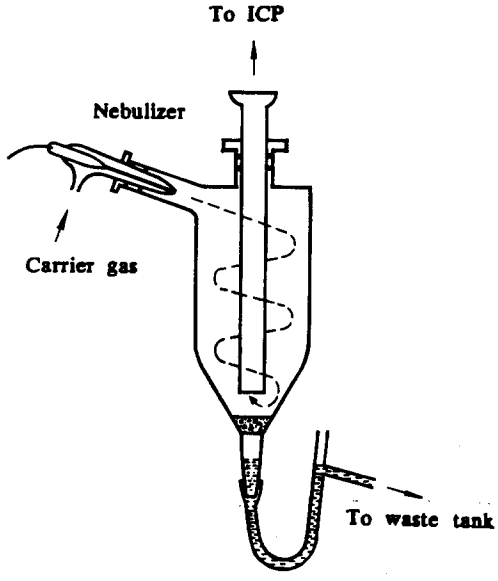

Fig. 1. Diagram of the CSCS.

## 2. Experimental

### 2.1. Apparatus

The determinations were carried out with an ICPQ-1015 direct spectrometer, a CTM-50 monochromator, and an automatic background correction unit. A diagram of the CSCS is shown in Fig. 1. The working conditions given in Table 1 were used throughout the investigation.

### 2.2. Reagents

Hydrochloric acid and nitric acid (suprapure grade), platinum metal (purity, 99.99938%), $Y_2O_3$ (purity, 99.99%), impurity elements (purity more than 99.9%), and doubly distilled water were used.

Table 2
Wavelength of analytical lines

| Element | Wavelength (nm) | Element | Wavelength (nm) |
|---|---|---|---|
| Pd | 363.469 | Cu | 324.754 |
| Rh | 343.489 | Al | 396.152 |
| Ir | 224.268 | Mg | 279.553 |
| Au | 267.594 | Mn | 257.610 |
| Ag | 328.068 | Zn | 202.548 |
| Fe | 259.940 | Pb | 220.353 |
| Ni | 231.604 | Y | 371.030 |

### 2.3. Preparation of solutions

*Calibration standard solutions*

According to the determination ranges, a set of at least three calibration standard solutions were prepared. These solutions contained 10% (v/v) hydrochloric acid, 2 μg $ml^{-1}$ of the internal standard element (Y), and different concentrations of the impurity elements to be determined, but they did not contain a platinum matrix.

*Matrix solution*

A matrix solution containing 20 mg $ml^{-1}$ of platinum was prepared; the solution also contained the same amount of hydrochloric acid and internal standard element as the calibration standard solutions.

*Sample solutions*

The platinum sample was dissolved in aqua regia and was converted to its chloro complex by repeated evaporation with hydrochloric acid. The residue was dissolved in 2 ml of 1:1 hydrochloric acid and the solution was diluted to 10 ml.

### 2.4. Analytical procedures

The wavelengths of the analytical lines used are shown in Table 2.

Firstly, the optical system of the instrument was calibrated by using a solution of any single element of a suitable concentration, and the gain (voltage) of the spectrometer photomultipliers were adjusted by using a standard solution of high concentration. Secondly, the spectral intensities of the analytes in the calibration standards were determined. Calibration curves were prepared from the spectral intensities of these analytes, and the concentrations of analytes in the sample were determined. Finally, the background equivalent concentration (BEC) at the wavelength of the analytical line for the analytes were determined with the platinum matrix solution. The above operations were controlled by a computer program, and printed results were provided automatically.

## 3. Results and discussion

### 3.1. Main characteristics of CSCS

The analytical characteristics of the CSCS and the STCS were determined and compared by using a solution containing 19 $\mu g\ ml^{-1}$ of each analyte and a blank solution, under the same conditions. The results are summarized in Table 3. In this table, $I_a$ represents the intensity of the analytical line for analyte A in a solution with concentration $C_a$, $I_b$ represents the intensity of the blank at the same wavelength as for analyte A, BEC (equal to $KI_b$), and DL (equal to $0.03C_a/I_a/I_b$) is the detection limit of the analyte A.

The ICPQ-1015 direct spectrometer is equipped with photomultipliers the gain (voltage) of which can be adjusted automatically. When the concentrations of the analyte and the operating conditions are kept constant, the gain with the CSCS is reduced by 80–100 V relative to that with the conventional STCS. This means that the CSCS works better in the target ranges of the instrument than the STCS. In other words, there are wider dynamic ranges with the CSCS than with the STCS. More aerosols, and smaller and more evenly distributed droplets are introduced from the central tube at the bottom of the chamber into the torch after the solutions are aspirated into the chamber and moved along a spiral path, which provides more opportunities for collision with the wall of the chamber, as shown in Fig. 1. Thus, the noise which originates from the fluctuation of the aerosols is also reduced, and a more stable signal is obtained. From the results obtained in Table 3, it is obvious that, when the CSCS is used, $I_a$ for a specified element is increased while the corresponding $I_b$ and BEC are decreased, and hence $I_a/I_b$ is also increased. The detection limits obtained with the CSCS are reduced two-to-threefold compared with those obtained with the STCS. In other words, the sensitivity obtained with the CSCS is increased two-to-threefold compared with those obtained with the STCS. This means that the lower limits of detection of the instrument and the amount of sample used can be reduced by

use of the CSCS technique. On the basis of the results obtained, a method has been developed for the determination of 13 impurities in 99.9–99.9955% pure platinum with the use of 20 mg ml$^{-1}$ sample solutions.

### 3.2. *Effect of platinum matrix and correction of spectral interferences*

Spectral interference is one of the most important interferences in ICP-AES. The background caused by the intense emission of the platinum matrix is the main source of interference and must be corrected for before any element can be determined.

The influence of the platinum matrix on the intensity of the analytical lines is shown in Table 4. The investigation was carried out with a solution containing 1 μg ml$^{-1}$ of each of the analytes, and 0, 10, 15, or 20 mg ml$^{-1}$ of platinum. The interference of the matrix platinum on the analyte determination was also observed by using the automatic background correction unit, with solutions containing 10 μg ml$^{-1}$ of analyte and a solution containing 20 mg ml$^{-1}$ of platinum.

From the experimental results, no spectral interferences are found among the platinum group elements. This is in agreement with the results obtained by Kibright and Tinsley [5]. Because the analytical line from the gold channel, Au 242.795 nm, suffers serious interference due to the platinum spectral line (Pt 242.804 nm), gold was determined with use of another line, Au 267.595 nm, by using the CTM-50 Monchromator. The analytical line, Ir 224.268 nm, suffers a slight interference from the spectral line of copper (Cu 224.261 nm), but can be neglected in the present work. The analytical lines of Zn, Fe, Pb and Ni suffer slight interferences from the spectral wings of the platinum lines. Because the values of these spectral wings are small and constant at a fixed concentration of platinum, they are also treated as a background. Almost no spectral lines of other analytes are influenced by the platinum matrix. It was found previously [6] that the Pb 220.350 nm spectral line suffers interference from the Pd 220.349 nm spectral line when a large amount of palladium is present, but no such interference was found with a trace amount of palladium. The analytical line, Pd 363.470 nm, suffers interference from the Ar 363.446 nm spectral line, and thus the sensitivity of palladium is reduced.

The effect of platinum on the analytes was corrected for by a BEC subtraction method. It can be formulated briefly as follows: $C_{tr} = C_{ap} - C_{eq}$, where $C_{ap}$, $V_{eq}$, and $C_{tr}$ are the apparent concentration, background equivalent concentration and true concentrations of the

[a] $C^{ad}$, concentration added.

analyte, respectively. Here, $C_{eq}$ practically includes the background, the spectral wing and even the very weak spectral line of the platinum matrix. The purity of the platinum matrix, from which the BEC values of the analyte are determined, is directly related to the reliability of the correction. The platinum matrix used in our research is a special product of our Institute, the purity of which is 99.99938%. The BEC of the matrix is almost constant; it is not necessary to determine the BEC value each time of analysis with the same batch of matrix if the analytical conditions are controlled strictly.

### *3.3. Determination ranges and results for synthetic samples*

The determination ranges are as follows: 0.00010–0.0050% for Mg, Mn, Cu, Ag, Fe and Zn; 0.00030–0.015% for Au, Ir, Ni and Pb; 0.00050–0.025% for Rh and Al; and 0.00080–0.040% for Pd.

The results for two synthetic samples are summarized in Table 5, in which the RSD (relative standard deviation) values for each sample were obtained statistically from 12 replicate determinations in four experiments during a period of 2 months.

# Direct flame atomic absorption spectrophotometric determination of alkalis in geochemical samples

Partha Chattopadhyay

*Regional Research Laboratory, Council of Scientific and Industrial Research, Bhubaneswar-751013, India*

Received 5 January 1995; revised 17 May 1995; accepted 21 June 1995

**Abstract**

Flame atomic absorption spectrometry has been used for the estimation of the alkali metal content (as $Na_2O$ and $K_2O$) in 95 reference materials with diverse matrices (including recently introduced Polish and Chinese standard samples awaiting certification through collaborative studies) using 1000 μg $ml^{-1}$ of lanthanum and 2000 μg $ml^{-1}$ of rubidium as matrix buffers for sodium and potassium, respectively. The $\pm t$ (Student's values for the samples with known recommended values (degree of freedom $n - 1 = 9$), at the 95% and 99% confidence levels) indicate that within the confidence levels 95–99% there is no statistical difference between the data presented and the reference data for most of the samples. The agreement between the reported data and the results obtained are generally good.

*Keywords:* Alkali metals; Flame atomic absorption spectrometry; Geochemicals; Potassium oxide; Sodium oxide

## 1. Introduction

Silicate rocks and minerals contain both sodium and potassium in amounts varying from less than 100 μg $g^{-1}$ in some ultrabasic rocks such as dunite and peridotite, to as much as 10% $K_2O$ or 15% $Na_2O$ in feldspar minerals. Both elements occur as major constituents of many rock-forming minerals, particularly the alkali feldspar group, and are always determined when a complete chemical analysis of a silicate rock or mineral is required. Also, very accurate data for alkali metals are required for limestone and related materials before their end use in ferrous metallurgy. Calibration of spectrochemical methods, including emission and X-ray fluorescence (XRF) spectrometry, requires the use of reference materials (RMs) that are well characterized with respect to the analytes of interest. The accuracy of the measurements is directly related to the quality of the selected RM. The quality control of products has always been a great challenge for analytical chemists. Suitable certified RMs covering a wide range of concentrations must be simultaneously processed with the unknown samples to monitor the analytical accuracy and assure the quality of the data. When the matrix of the incoming sample is not known, then the XRF method is never the preferred method. Flame atomic emission/absorption spectrometry is the most preferred technique for the measurement of the alkali metals [1–5]. One particular characteristic of metals is their low ionization potential. Indeed, the thermal energy of the flame is sufficient to cause a significant degree of ionization of alkali metals. In consequence, a reduction in the atomic absorption signal is observed, since ions exhibit a quite different spectrum from atoms. Caesium has been considered to be the favoured ionization suppressant for the determination of Na and K

*SSDI* 0039-9140(95)01676-7

[6]. Other alkali metals such as lithium and rubidium, are also used for a similar purpose. Hitherto, it was not known which of the alkali metals should be used, and to what extent (in terms of concentration) for the accurate estimation of alkali flame atomic absorption spectrometry metals (FAAS). Comparative studies on probable suppressants revealed that lanthanum and rubidium are the most effective matrix buffers for sodium and potassium respectively, in their FAAS determination [7]. The present author has shown recently that the alkali metals themselves (i.e., potassium for $Na_2O$ determination and sodium for $K_2O$ determination) are also very effective ionization buffers for alkali metal determinations in some Japanese reference materials [5]. The objective of this investigation, therefore, is to develop a standard method for the accurate determination of alkali metals in cases when reference materials have to be analyzed for certification purposes, and simultaneously, to identify a method that could offer increased reliability and wider applicability as far as the accurate estimation of the $Na_2O$ and $K_2O$ content in different geological reference samples with diverse matrices is concerned. A further aim is to contribute data on some samples which are at present either candidates for certification through a collaborative study or have "information values" only. Alkalis are better determined by flame rather than by plasma atomic emission spectrometry (AES) due to reduced sensitivities and stabilities in the much hotter plasma souce.

## 2. Analytical methods

### 2.1. Apparatus and reagents

A Varian Techtron (AA 1475) atomic absorption spectrophotometer with a deuterium arc background correction system coupled with an Epson LX-800 printer and a Varian DS-15 data station were used for the absorbance measurements. Most sensitive resonance lines for sodium (589 nm) and potassium (767.5) were chosen and an air–acetylene flame was used. Other instrumental parameters, e.g. slit width, lamp current, integration time, and burner height were as specified in the manufacturer's instructions.

To prepare a stock sodium solution of concentration 1000 μg $ml^{-1}$, dissolve 2.542 g of NaCl (GR grade; E-Merck) in water and dilute to 1 l with 1% HCl (v/v) solution. To prepare a potassium solution of concentration 1000 μg $ml^{-1}$, dissolve 1.907 g of KCl (GR grade; E-Merck) in 1% HCl solution. A lanthanum (1%) solution was prepared by dissolving 58.7 g of lanthanum oxide (Fluka) in HCl (100, 6.8 M), and making up the volume to 500 ml with distilled water. The resulting solution was diluted ten times with water only. A rubidium solution was prepared by dissolving RbCl (99.7%; Aldrich, USA) in 1% HCl solution.

### 2.2. Reference samples

Information relating to the standard reference materials (USGS; Geological Survey Suriname; Analytisk Sporelement Komite (ASK), Norway; University of Liege, Belgium; and Zentrale Geologisches Institute (ZGI), Germany) is available elsewhere [8]. For CANMET, Geological Survey of Japan (GSJ), British Geological Survey, Chinese and Polish samples, information is available in Refs. [9], [5,10], and [12], [13], [14] and [15], respectively.

### 2.3. Procedure

Weigh accurately 0.1–2.00 g samples in a platinum crucible. Moisten with about 5 ml of distilled water. Add 5–10 ml of $HClO_4$ (70%) drop wise and cover the crucible with a lid. After some time, rinse the lid into the crucible with distilled water. Evaporate the crucible contents to complete dryness on a hot plate. Cool, add 10 ml of HCl (11 M) of HF (48%) and 5 ml of $H_2SO_4$ (1:1). Heat the solution slowly on a hot plate and reduce in volume to approximately 5 ml. Add another 5 ml portion of HF (48%) and HCl (11 M). Evaporate the solution to complete dryness, until no more fumes of $SO_3$ are visible. Finally, heat the crucible strongly with a full flame until all fuming ceases. Cool, and add about 10 ml of HCl (11 M) and an equal volume of water. Evaporate to dryness on a low heat. Add 5 ml each of HCl (11 M) and $H_2SO_4$ (1:1) and 25 ml of water. Digest on a hot plate for about 15 min. Filter into a 100 ml volumetric flask (plastic; Torson, India) using Whatman no. 40 filter paper. Wash the residue with hot water (five times will suffice). Dilution, if any, should be performed using dilute acid solution (5 ml HCl (11 M) + 5 ml $H_2SO_4$ (1:1) + 90 ml distilled

water). The solution for final aspiration to the air-acetylene flame should contain 1000 μg La $ml^{-1}$ and 2000 μg Rb $ml^{-1}$ for sodium and potassium, respectively.

## 3. Results and discussion

Table 1 shows the mean ($\bar{x}$) of ten replicate analyses with the deviations ($s$), per cent relative standard deviations (%RSD) and the per cent average deviations (%Dev.) using mean and true values available in the literature. The $Na_2O$ and $K_2O$ values for limestone KH and serpentinite, respectively, are not available in the literature [8], and hence could not be compared. The potassium value for JDO-1 was consistently higher than the reported value [12]. Provisional values for the CANMET, Polish and Chinese samples are also quite good. Indeed, there are deviations for those samples along with some cases where only the "information values" are available indicating that more data are still required in order to upgrade the status of some samples from the provisional/conditional level to the certified level. For Japanese samples (JG2, JG3, JG1a, JR-1, JR-2, JB-1a, JB-2, JB-3, JGb-1, JA-1, JA-2 and JA-3) and USGS samples (G2, BIR-1 and BHVO-1) data from the present study along with recently published data [5] are presented for comparison. The recommended procedure is equally effective in both normal rock samples and in highly calcium-rich materials, in which as the previous procedure always yields high values of alkali metals in limestone and related materials, it hence cannot be adapted for certification purposes.

### 3.1. Test on reliability of statistical data

In order to test whether one set of data (with a mean $\bar{x}$) belongs to another population (with a mean $\mu$) to within a specified confidence limit, the value of Student's $t$ has been calculated from the equation $\pm t = (\bar{x} - \mu)\sqrt{n}/s$.

Table 2

[a] Value is expressed in micrograms per gram.
Where two values are given, the first (upper) value was obtained from the present work, and the second (lower) value was obtained from previous work [5].

For a population, whose mean has a value of $\bar{x}$, to have a high probability of belonging to the population with a mean value of $\mu$, the $t$-value calculated according to the above equation must be smaller than the appropriate value listed in the Student's $t$-distribution table [16]. The $\pm t$ values for $Na_2O$ and $K_2O$ of well-characterized samples [8] are shown in Table 2. When the $\pm t$ value of less than 2.262 and 3.250 (at a degree of freedom of 9) at a confidence level of 95% or 99%, respectively, there is no statistical difference between the current result ($\bar{x}$) and the reference material data mean ($\mu$).

On rearrangement, the previous equation is expressed as $\mu = \bar{x} + tsn^{1/2}$. The population means at a 95% confidence level (although of course, the $t$-test is not restricted to 95% or any other confidence limits; the 95% limits are most commonly used) for a degree of freedom of 9 are calculated from this equation and are shown in Table 2 for comparison with the true values. This is done just to calculate the error limits about a data set mean ($\bar{x}$) within which the population mean ($\mu$) must lie for a given confidence level.

The present set of data on reference samples (which are useful because they provide a mechanism for assessing the accuracy of a technique and for reaching the goal of better analyses of real samples) of varied composition involving two-step decomposition and a matrix buffer can be applied successfully to the accurate estimation of alkali metals for certification purpose and in quality control assessment.

## Acknowledgements

The Director, Regional Laboratory, Bhubaneswar, is thanked for granting permission to publish this work. Special thanks are to the authorities of the Chinese Academy of Geological Sciences and Glowny Urzard Miar, Poland for the reference samples and associated documents. Mr P.N. Sethi is thanked for excellent secretarial assistance.

**Abstract**

In the present paper, a new procedure using Pyrocatechol Violet (PCV) for the determination of tin in copper-based alloys is proposed. The use of HEDTA as masking agent allowed tin to be determined in the presence of large amounts of copper, without any separation procedure. The method is more selective than previous methods. Cetyltrimethylammonium bromide (CTAB) and Tween-20 are used to increase the stability of the system.

The method can be applied directly to an acidic solution of Sn(IV) in the range 2.0–60.0 μg with a final volume of 50 ml. The pH is adjusted to $2.0 \pm 0.2$ with glycine buffer and, after 30 min, the absorbance is measured at 660 nm. Al(III), Cd(II), Co(II), Mg(II), Ca(II), Mn(II), Ni(II) and Pb(II) do not interfere at the 500 mg level; 20 000 μg of Cu(II) and 400 μg of NaCl can be present. The interference at 100 μg of Fe(III) can be masked with ascorbic acid. Bi(III), Sb(V), Ti(IV), Mo(VI), EDTA, tartrate, citrate and iodide interfere. The proposed method was used for tin determination in several copper-based alloys and a comparison of the analytical results with certified values indicates that the procedure provides accurate and precise results.

*Keywords:* Copper-based alloys; Pyrocatechol Violet; Spectrophotometric analysis; Tin determination

## 1. Introduction

Tin is an element frequently present in copper-based alloys. However, the spectrophotometric determination of this element in these matrices is problematic because many of the reagents used also react with the copper and other elements present. Numerous procedures have been published for this determination, and normally these methods are not simple and usually require extensive and laborious steps for the separation of tin from the matrices, using procedures that involve operations such as extraction [1,2], ionic exchange [3,4], precipitation of tin as metastannic acid [5], coprecipitation of tin using copper sulfide [6], manganese dioxide [7], or beryllium hydroxide [8] and until distillation [9], the tin being separated as stannic bromide. Table 1 describes the application of some of the reagents during tin determination in copper matrices.

Pyrocatechol Violet (PCV) [10] is one of the main reagents used in the spectrophotometric determination of tin. Some procedures [11] were proposed that used gelatin to stabilize the color; however, the addition of gelatin causes the absorption band of the Pyrocatechol Violet–tin(IV) complex to become broadened and to extend to longer wavelengths. Therefore, the absorbance measurements must be made at 619 nm, and a loss of sensitivity is observed.

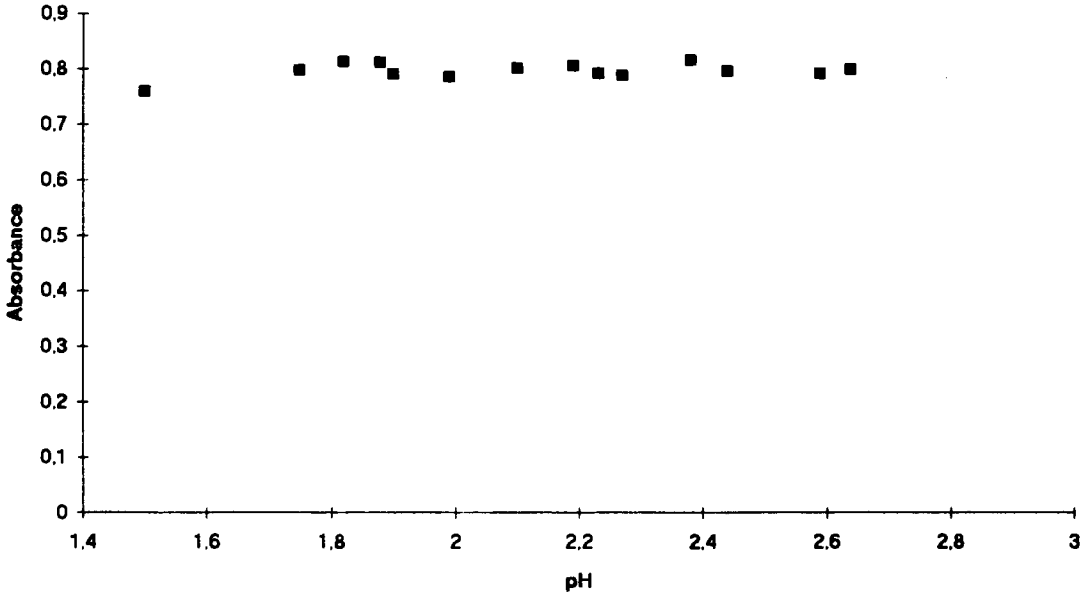

Fig. 1. Effect of the pH on the Sn(IV)–PCV system. [Sn(IV)], 50.00 μg per 50 ml; PCV amount, 1 ml; PCV solution, 0.1%.

Dagnall et al. [12], studied the effect of several surfactants in relation to an increase in stability of the Pyrocatechol Violet–tin(IV) system and found that cetyltrimethylammonium bromide (CTAB) is the most satisfactory. However, the use of this surfactant is not possible in the extraction step, because tetraalkylammonium iodide was precipitated. Pyrocatechol Violet was proposed for tin determination in bronze by Karnaukhova [3], the procedure is based on tin separation on an anionic resin in the chloride form.

In the present paper, we propose a procedure that uses PCV for tin determination in brasses and bronzes, using HEDTA as masking agent for several ions, allowing tin determination without separation. The proposed method is simple, highly selective and reproducible. A mixture of two surfactants, cetyltrimethylammonium bromide and Tween-20, increases the system stability.

## 2. Experimental

### 2.1. Reagents

All reagents were analytical grade unless otherwise stated. The tin solution (100.0 μg $ml^{-1}$) was prepared by dissolving 0.1 g of granulated tin metal (Baker) in 20 ml of concentrated sulfuric acid with heating, and dilution to 1 l with

60 ml of concentrated sulfuric acid and demineralized water. The PCV solution (0.1%) was prepared by dissolving 0.1 g in demineralized water to 100 ml. Tween-20 (1%) was prepared by dissolving 1.0 g in demineralized water to 100 ml. Glycine buffer solution (pH 2.0) was prepared with glycine solution (1.0 M) and the pH was adjusted to 2.0 with hydrochloric acid and/or sodium hydroxide solution. HEDTA solution (0.10%) was prepared by dissolving 0.10 g of *N*-(carboxymethyl)-*N'*-(2-hydroxyethyl)-*N*,*N'*-ethylenediglycine in demineralized water to 100 ml.

### 2.2. Apparatus

The absorption spectra were recorded and measured with a Varian DMS-80 spectrophotometer and an Intralab recorder using 1.0 cm cells. A 300 Analyser pH meter was used to measure the pH values.

### 2.3. General procedure

*Spectrophotometric determination of tin*

Transfer to a 50 ml volumetric flask 1.0 ml of the PCV solution, 2.0 ml of the Tween-20 solution and 2.0 ml of the CTAB solution. Mix and add a portion of tin(IV) solution containing 10–60 μg of tin, 10.0 ml of glycine buffer and 5.0 ml of HEDTA solution. Mix, and after 30 min, dilute to the mark with water and measure the absorbance at 660 nm in a 1 cm cell, using water as a blank.

Table 2
Effect of the amount of glycine buffer solution

| (M) Concentration | Absorbance |
|---|---|
| 0.04 | 0.787 |
| 0.14 | 0.786 |
| 0.20 | 0.795 |
| 0.30 | 0.796 |
| 0.40 | 0.796 |
| 0.50 | 0.797 |

## 3. Results and discussion

### 3.1. Characteristics of the reagent and the complex

The reaction of PCV with the tin(IV) cation in the presence of CTAB and Tween-20 results in a green complex with an absorption maximum at 660 nm. The PCV reagent has an absorption maximum at 441 nm. The complex without surfactants is red, with a maximum absorption at 555 nm.

### 3.2. Effect of the pH

The effect of pH on the tin(IV)–PCV system was studied and the results demonstrated that the absorbance signal is at a maximum and constant in the pH range 1.60–2.7 as can be seen in Fig. 1.

In the described procedure the use of glycine buffer at pH 2 is recommended because at this pH, the selectivity is higher. A glycine buffer

Table 3
Effect of the order of addition of reagents

| Order of addition | Absorbance |
|---|---|
| PCV + Tween-20 + CTAB + Sn(IV) + buffer + HEDTA | 0.802 |
| PCV + CTAB + Tween-20 + Sn(IV) + buffer + HEDTA | 0.796 |

| Sn(IV) + buffer + PCV + Tween-20 + CTAB + HEDTA | 0.376 |
| Sn(IV) + HEDTA + buffer + Tween-20 + CTAB + PCV | 0.019 |
| Sn(IV) + PCV + HEDTA + Tween-20 + CTAB + buffer | 0.015 |
| Sn(IV) + PCV + HEDTA + buffer + Tween-20 + CTAB | 0.011 |
| Sn(IV) + HEDTA + PCV + Tween-20 + CTAB + buffer | 0.011 |

Table 4
Effect of the amount of HEDTA on the tin(IV)–PCV system

| ($10^{-4}$ M) Concentration | Absorbance |
|---|---|
| 3.6 | 0.805 |
| 7.2 | 0.801 |
| 10.8 | 0.799 |
| 14.4 | 0.795 |

Table 5
Analytical characteristics of the procedures

| Characteristic | Value |
|---|---|
| Molar absorptivity ($l\,mol^{-1}\,cm^{-1}$) | $1.03 \times 10^5$ |
| Calibration sensitivity ($ml\,\mu g^{-1}$) | 0.867 |
| Analytical sensitivity ($ml\,\mu g^{-1}$) | 86.73 |
| Limit of detection, $C_L$; $3\sigma$ ($ng\,ml^{-1}$) | 7 |
| Limit of quantitation, $C_Q$; $10\sigma$ ($ng\,ml^{-1}$) | 25 |
| Linear dynamic range ($\mu g\,ml^{-1}$) | 0.02–1.20 |
| Coefficient of variation (%) | 1.25 |

concentration in the range 0.04–0.50 M does not affect the absorbance signal of the tin(IV)–PCV system (Table 2).

### 3.3. Effect of the order of addition of the reagents on complex formation

The order of reagent addition was studied. This is a critical stage in the reaction. The results demonstrated that the order strongly affects the complex formation, as can be seen in Table 3. The reagent and surfactants must be added before the tin(IV) or sample solution, and only after this can the pH be adjusted.

### 3.4. Effect of the HEDTA amount on the tin(IV)–PCV complex

PCV is not a selective reagent for tin determination. However, the use of HEDTA as masking agent solves this problem. The effect of the HEDTA amount on tin(IV)–PCV complex formation was studied, and the results show that it does not affect the complex formation when present at the least in the range $3.6 \times 10^{-4}$–$14.4 \times 10^{-4}$ M (Table 4). The HEDTA must be added after the formation of the complex.

### 3.5. Analytical characteristics of the method

A calibration curve was prepared according to the general procedure described in the experimental section 2.3, using water as the blank.

Beer's law was obeyed in the concentration range 0–1.20 $\mu g\,ml^{-1}$ of tin and the curve does not pass through the origin. The molar absorptivity was $1.03 \times 10^5\,l\,mol^{-1}\,cm^{-1}$ at 660 nm.

The analytical sensitivity [13], the calibration sensitivity [13], the limit of detection and the limit of quantitation [14] as well as other analytical characteristics are summarized in Table 5.

### 3.6. Effect of interfering ions

Solutions containing 50.00 μg of tin(IV) and various proportions of several cations and anions were prepared, and the general procedure was followed.

Table 6 shows interference levels during tin determination in the absence and presence of HEDTA. The main interferences are vanadium(V), molybdenum(VI), titanium(IV) and iron(III).

Iron(III) interference can be eliminated by reduction to iron(II) with ascorbic acid; 50 mg

of ascorbic acid are sufficient for masking 1000 μg of iron(III) during the determination of 50.0 μg of tin(IV).

The effect of the ionic strength on the system is negligible up to a sodium chloride concentration of 0.1 M.

### 3.7. Application

*Tin determination in copper-based alloys*

The proposed procedure was applied to tin determinations in several standards and samples of copper-based alloys.

The sample solutions were prepared using nitric and hydrochloric acids. The results are described in Tables 7 and 8, and the matrix compositions are shown in Table 9.

The results shown in Table 7 demonstrate that there is no significant difference between the certified value and the value obtained with PCV at the 95% confidence level for four different alloys.

Application of the paired $t$ test [15] in the results obtained by the PCV procedure and the ICP method (Table 8) showed that there is no significant difference between the two methods at the 95% confidence level.

## 4. Conclusions

The spectrophotometric determination of tin using Pyrocatechol Violet can be improved with the use of HEDTA as masking agent, and Tween-20 and cetyltrimethylammonium bromide as sensitizing and stabilizing agents.

This new proposed method can be used for the spectrophotometric determination of tin in copper-based alloys without carrying out a separation procedure.

# Rapid one-step derivatization of Se(VI) to a piazselenol for the spectrofluorimetric determination of selenium in biological material

Karin Johansson *, Xiaoguang Luo, Åke Olin

*Department of Analytical Chemistry, University of Uppsala, P.O. Box 531, S-751 21 Uppsala, Sweden*

Received 4 April 1995; revised 15 June 1995; accepted 15 June 1995

**Abstract**

A spectrofluorimetric method for the determination of total selenium in biological samples has been developed. After oxidative destruction, the sample is reacted with a mixture of bromide and 2,3-diamino-1,4-dibromonaphthalene ($Br_2$-DAN) without pH adjustment. Selenium(VI) is rapidly reduced by bromide to Se(IV) which then forms 4,7-dibromo-5,6-benzopiazselenol ($Br_2$-DAN-Se). The conversion of Se(VI) to $Br_2$-DAN-Se is completed in 6 min at 100°C. The piazselenol is extracted to cyclohexane and the fluorescence measured at 577 nm with excitation at 518 nm. The procedure has been validated by determinations on reference materials with selenium concentrations ranging from 4 to 1460 ng $g^{-1}$. The advantages of the method are the fast reduction of Se(VI) by hydrobromic acid and the properties of $Br_2$-DAN, which permit the piazselenol formation to be carried out in a strongly acidic medium and at high temperature. The limit of detection is 0.6 ng $g^{-1}$ as estimated by three times the standard deviation of the blank determination ($n = 7$).

The rate of reduction of Se(VI) to Se(IV) in hydrobromic acid was investigated as a function of concentration and temperature. The new kinetic data together with previous kinetic and equilibrium data for the piazselenol formation were used to model and optimize the simultaneous reduction–derivatization procedure.

*Keywords:* Selenium; Spectrofluorimetry; Biological material

## 1. Introduction

Several methods for the determination of selenium are available and those most commonly used are molecular fluorescence spectrometry (MFS) [1–6], gas chromatography with electron capture detection (GC-ECD) [7–10], atomic absorption spectrometry after hydride generation (HG-AAS) [11,12] and electro-thermal atomic absorption spectrometry (ETAAS) [13]. These methods, except ETAAS, respond only to selenium in the tetravalent state. Thus, all other forms of selenium have to be converted into Se(IV).

In the determination of total selenium in biological samples destruction of the organic material has to be accomplished in most cases. This is usually performed by treatment of the sample with strong oxidizing acids. Most commonly employed is a mixture of nitric, perchloric and sulfuric acids. Another digestion method, which avoids the hazards connected with the use of perchloric acid, is the combined wet-dry ashing procedure described by Hansson et al. [14]. After the digestion, Se(VI) is reduced to Se(IV), normally with 4–6 M hydrochloric acid [15]. If HG-AAS is used, the sample is ready for analysis. With GC-ECD or

*SSDI* 0039-9140(95)01678-3

MFS, Se(IV) is reacted with an aromatic *o*-diamine in excess to form a piazselenol that is extracted to an organic solvent before the instrumental finish. The extraction step can provide an enrichment of the analyte by up to 500 times [16].

In MFS the most commonly used reagent is 2,3-diaminonaphthalene (DAN) introduced by Parker and Harvey in 1962 [1]. However, the properties of this reagent make the analysis somewhat complicated [17]. The piazselenol formation occurs in a reaction between selenous acid and monoprotonated *o*-diamine and the reaction conditions must therefore be selected so that these species predominate in order to arrive at reasonable derivatization times [4,18]. For a biological sample, which has been digested and then reduced by hydrochloric acid, this implies that considerable pH adjustment is necessary when the DAN reagent is employed. Recently, the use of 2,3-diamino-1,4-dibromonaphthalene ($Br_2$-DAN) as a new spectrofluorimetric reagent was reported [19]. The values of acidity constants of $Br_2$-DAN make this reagent compatible with a strongly acidic medium and hence the pH adjustment is obviated. However, when the piazselenol formation is performed in a medium of hydrochloric acid, an exchange may occur of bromine with chlorine in the reagent and the piazselenol. The chlorinated piazselenol, 4,7-dichloro-5,6-benzopiazselenol ($Cl_2$-DAN-Se), has a lower fluorescence intensity than the corresponding brominated piazselenol, 4,7-dibromo-5,6-benzopiazselenol ($Br_2$-DAN-Se). Therefore, irreproducible results will be obtained when the temperature and concentration of hydrochloric acid are high, conditions that speed up the rates of the reduction and derivatization reactions to expedient values.

Hydrobromic acid has been found to be a suitable alternative to hydrochloric acid, both as a reaction medium for the derivatization with $Br_2$-DAN and as a reducing agent [19]. Few articles have reported on the use of hydrobromic acid for the reduction of Se(VI) [20,21]. This paper delineates the influence of concentration and temperature on the rate of reduction of Se(VI) with hydrobromic acid. The rapid reduction which can be achieved and the thermal stability of $Br_2$-DAN and $Br_2$-DAN-Se suggested that the usual two-step reduction–derivatization sequence could be replaced by a combined reduction–derivatization step. This simplification of the fluorimetric selenium determination has been studied and resulted in a procedure in which Se(VI) is converted to $Br_2$-DAN-Se in about 6 min.

## 2. Experimental

### 2.1. Apparatus and reagents

All fluorescence recordings were made on an Aminco SPF-500 Corrected Spectra Fluorometer as described earlier [19]. Most experiments were performed in 8 ml Pyrex glass tubes equipped with PTFE-faced screw-caps in a laboratory-built aluminum block (150 × 150 $mm^2$) with a capacity of 25 samples and placed on a 2000 W hot-plate. The temperature was regulated by an Eurotherm 904 temperature regulator (Eurotherm International, Strängnäs, Sweden).

All chemicals were of analytical grade from Merck unless otherwise stated. Milli-Q-filtrated (MQ) water (Millipore™) was used throughout. All glassware was cleaned in 7 M nitric acid and rinsed with MQ water. The standard solutions of Se(IV) and Se(VI) were prepared and analysed as described before [10,14]. The three acid mixture was composed of 65% nitric acid, 70–72% perchloric acid and 95–97% sulfuric acid in the proportions 20:5:2. $Br_2$-DAN was synthesized as described before [19]. A 2.05 mM working solution of $Br_2$-DAN was prepared by dissolving 16.2 mg of the chemical in 25 ml of methanol. The solution was stored at room temperature in the dark. It was stable for at least one week.

The reference materials were MA-B-3/TM fish tissue (IAEA, Monaco), SRM 1567 wheat flour, SRM 1577a bovine liver, RM 8433 corn bran, RM 8412 corn stalk, RM 8413 corn kernel (NIST, Gaithersburg, MD) and Seronorm 105 human serum (Nycomed AS, Oslo, Norway).

### 2.2. Kinetic experiments

*Reduction of Se(VI) by hydrobromic acid*

A solution of 1.5, 2.0 or 2.5 M hydrobromic acid (200 ml) was heated in a glass beaker on a hot plate with magnetic stirring facilities and the temperature was regulated by a sensor placed in the solution (Heidolph, Kelheim, Germany). When the desired temperature had been reached and stabilized, a small volume of a standard solution of Se(VI) was added. The

reaction was followed by measurement of the Se(IV) concentration. Part of the reaction mixture was continuously withdrawn from the beaker through Teflon tubing (0.7 mm i.d.) by pumping. The sample stream was immediately cooled and then passed through the sample loop of an injection valve before going to waste. The value was activated at regular intervals by a timer and injected the sample into a HG-AAS instrument [22] for determination of Se(IV). Concentrations were evaluated from a calibration curve determined with matrix-matched standards.

*Simultaneous reduction of Se(VI) and piazselenol formation*

To a set of 12 Pyrex test tubes a 0.95 ml portion of a solution containing 1.6, 2.1 or 2.6 M hydrobromic acid and 53 or 105 μM $Br_2$-DAN was added. The tubes were closed and placed in a thermostatted aluminum block. When the desired temperature had been reached, 50 μl of 200 ng $l^{-1}$ of Se(VI) was added. At predetermined times, a tube was withdrawn from the heating block and the reaction stopped by changing the pH to 5 by addition of a concentrated sodium phosphate solution. The tube was then stored in an ice bath. The extraction of the piazselenol was performed at room temperature with 3 ml of cyclohexane.

### 2.3. Analytical procedures

*Digestion with the three acid mixture*

Weigh 0.5–1 g of sample into a 100 ml Kjeldahl flask. Add 20 ml of the three acid mixture and a few boiling stones and place the flask in the heating stand. Boil the mixture until the sulfuric acid begins to distil. After cooling add 10 ml of 5 M sodium bromide and dilute to 25 ml with water. Transfer 2 ml of this solution to a 8 ml test tube and add 100 μl of 2.05 mM $Br_2$-DAN. Close the tube and place it in the aluminum block for 6 min at 100°C. Cool to room temperature and extract with 3 ml of cyclohexane. Rapid phase separation is obtained by spinning the test tubes.

Measure the fluorescence of the piazselenol extract at an excitation wavelength of 518 nm and emission wavelength of 577 nm.

*Digestion with magnesium nitrate–nitric acid*

Weigh about 0.1 g of dry homogeneous sample into a 8 ml Pyrex test tube. Add 0.3 g of magnesium nitrate hexahydrate, 1 ml of 14 M nitric acid and 50 μl of 12 M hydrochloric acid. Place the tube in the aluminum block and apply the following temperature programme: [(°C)/ramp time (min)/dwell time (min): 50/20/60, 85/20/100, 105/20/100, 125/20/100, 175/120/30, 225/40/30, 500/180/120]. Include an end step that allows the temperature to decrease to 100°C. Withdraw the tube from the block and add 1 ml of a solution containing 3 M perchloric acid and 0.05 M sulfamic acid. When the digestion residue has dissolved, add 1 ml of a solution containing 4 M hydrobromic acid and 2 mM hydroxylammonium sulfate and finally 100 μl of 2.05 mM $Br_2$-DAN. Close the tube and place it in the aluminum block at 100°C for 6 min. The extraction and fluorimetric measurement are then performed as described above.

## 3. Results and discussion

### 3.1. Reduction of Se(VI) in hydrobromic acid

The aim here was to find conditions for rapid reduction of Se(VI) to Se(IV) and only restricted ranges of temperature and hydrobromic acid concentration were therefore studied. For acid concentrations below about 1.5 M the reaction becomes unattractively slow even at high temperature. Concentrations (M) here and elsewhere refer to the value at room temperature for practical reasons and pH will be used freely to denote $-\log[H^+]$. The upper concentration limit was set by the proportionally large volume of hydrobromic acid (8.7 M) which had to be added. Furthermore, one of the batches of hydrobromic acid used contained an unidentified reducing agent, which lead to selenium losses at high temperatures and concentrations of the acid. Hence an upper limit of 2.5 M was chosen as a precaution against selenium losses, but a new batch of hydrobromic acid should always be tested for excessive reducing power before use. The reducing agent might have been iodide, which fairly rapidly reduces Se(VI) to Se(0) even at micromolar concentrations [23]. Losses of selenium can be avoided by the addition of small amounts of bromate. Since bromine interferes in the piazselenol reaction, free bromine must be removed after the reduction if a spectrofluorimetric finish is used.

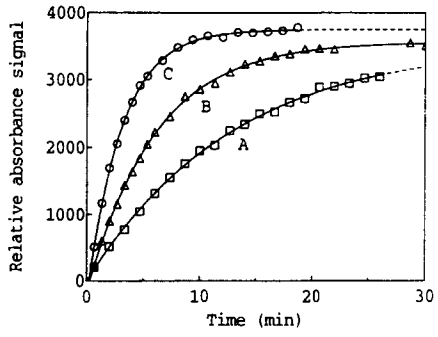

Fig. 1. Dependence of the rate of reduction of Se(VI) to Se(IV) on the concentration of hydrobromic acid at 75°C. The Se(IV) concentration is represented by the relative absorbance signal. A, 1.5; B, 2.0; and C, 2.5 M hydrobromic acid.

Representative formation curves of Se(IV) generated by reduction of Se(VI) with hydrobromic acid are shown in Figs. 1 and 2. The rate constant, $k_r$, was determined by fitting the function [15]

$$y = A - B\,e^{-k_r t} \quad (1)$$

to the data ($t$, [Se(IV)]) by non-linear regression. Experiments with different initial Se(VI) concentrations confirmed that the reaction was of first order with respect to Se(VI). The values of $k_r$ so obtained can be reproduced by

$$k_r = 2.01 \times 10^{12}[HBr]^{2.57}\,e^{-1.11 \times 10^4/T} \quad (2)$$

with $k_r$ in $min^{-1}$. Note the high power in [HBr] which leads to a rapid increase in the reduction rate with acid concentration. A strong rate dependence on concentration has been found for hydrochloric acid also [15].

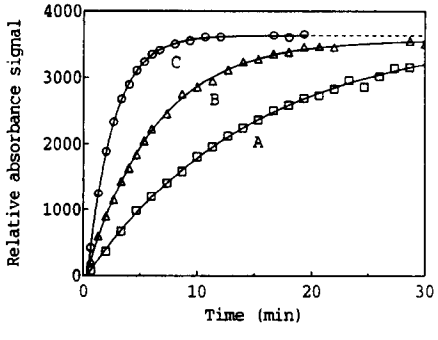

Fig. 2. Dependence of the rate of reduction of Se(VI) to Se(IV) on temperature in 2 M hydrobromic acid. The Se(IV) concentration is represented by the relative absorbance signal. A, 65; B, 75; and C, 85°C.

### 3.2. Simultaneous reduction of Se(VI) and formation of 4,7-dibromo-5,6-benzopiazselenol

The purpose of a simultaneous reduction of Se(VI) and derivatization of the Se(IV) formed to a piazselenol is to simplify the analytical procedure and diminish the analysis time. Therefore, the conditions for fast reduction and derivatization must be considered at the same time and balanced. The rate of the reduction of Se(VI) increases both with temperature and hydrobromic acid concentration as discussed in the previous paragraph and results in a complete conversion to Se(IV). The optimal conditions for the piazselenol reaction will be discussed with reference to the kinetic and equilibrium studies made previously [19]. Data needed for the calculations made in the following paragraphs were taken from this reference.

*Equilibrium considerations*

The formation of $Br_2$-DAN-Se occurs in a reaction between undissociated selenous acid and monoprotonated $Br_2$-DAN. The reaction can be represented by

$$H_2SeO_3 + Br_2\text{-}DANH^+ \underset{k_b}{\overset{k_f}{\rightleftharpoons}} Br_2\text{-}DAN\text{-}Se + H^+$$

where $k_f$ and $k_b$ are the rate constants of the forward and reverse reactions respectively. It was found that the reaction moved towards an equilibrium with incomplete conversion to the piazselenol although the ligand was in great stoichiometric excess. For biological samples the total selenium concentration seldom exceeds 1 μM, whereas the normal ligand concentration is in the range 50–100 μM, thus in a hundred fold excess. The equilibrium constant of the reaction, $\beta$, is given by

$$\beta = \frac{[Br_2\text{-}DAN\text{-}Se]_{eq}[H^+]_{eq}}{[H_2SeO_3]_{eq}[Br_2\text{-}DANH^+]_{eq}} = \frac{k_f}{k_b} \quad (3)$$

The numerical value of $\beta$ is $3 \times 10^5$ at 70°C. The $\beta$ value previously reported was $3.4 \times 10^5$, but an extended analysis of the data has resulted in the new value. The degree of conversion to the piazselenol at equilibrium, defined as $[Br_2\text{-}DAN\text{-}Se]_{eq}/[Se]_{tot}$, can be found from Eq. (3).

Fig. 3 shows the pH dependence of the degree of conversion at two ligand concentrations. As seen directly from Eq. (3) the piazselenol concentration decreases with acidity in strongly acid medium, in which $H_2SeO_3$ and $Br_2$-$DANH^+$ constitute large fractions of the total concentrations of Se(IV) and $Br_2$-DAN respectively. In less acid solution, $Br_2$-DAN is the dominating ligand species and the degree of

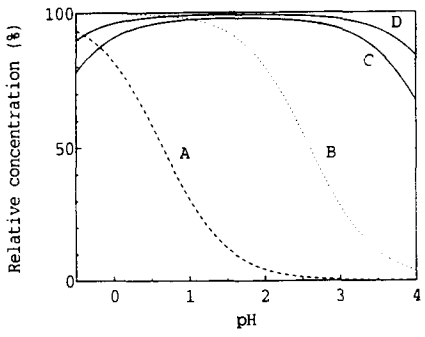

Fig. 3. Distribution diagram for Se(IV) and $Br_2$-DAN, and the calculated pH dependence of the degree of conversion of Se(IV) to the piazselenol at equilibrium for two ligand concentrations. A, fraction of the free ligand as $Br_2$-DANH$^+$; B, fraction of Se(IV) as $H_2SeO_3$; C and D, degree of conversion for 40 and 100 μM ligand respectively.

conversion is almost independent of pH until $H_2SeO_3$ starts to deprotonate. Then the equilibrium shifts to the left. Hence equilibrium considerations indicate that a reaction medium with a pH between 1 and 3 would be optimal. Note, however, that the decrease of the equilibrium concentration of the piazselenol with acidity can be counteracted by an increase of the ligand concentration. The drop in the degree of conversion with acidity is moderate at a ligand concentration of 100 μM.

*Rate considerations*

When the piazselenol reaction is run at a constant pH and a large excess of the ligand, the reaction rate follows

$$r = \frac{d[Br_2\text{-DAN-Se}]}{dt} = k_f[H_2SeO_3][Br_2\text{-DANH}^+] - k_b[Br_2\text{-DAN-Se}][H^+] \quad (4)$$

with the solution

$$[Br_2\text{-DAN-Se}] = [Br_2\text{-DAN-Se}]_{eq}(1 - e^{-kt}) \quad (5)$$

$k$ is a conditional first order rate constant defined by

$$k = k_b[H^+] + \frac{k_f[Br_2\text{-DAN}]_{tot}}{f_1 \cdot f_2} \quad (6)$$

$f_1^{-1}$ denotes the fraction of the ligand present as $Br_2$-DANH$^+$ and $f_2^{-1}$ the fraction of Se(IV) present as $H_2SeO_3$. Fig. 4 shows the variation of the rate constant with pH at 70°C and a ligand concentration of 100 μM. Clearly, the reaction rate drops rapidly with increasing pH. Hence, rapid derivatization is favoured by an increase in acidity, which, however, decreases the degree of conversion to the piazselenol.

The temperature dependence of $k$ was determined previously in 2 M hydrobromic acid and a ligand concentration of 50 μM. From these data the temperature dependence of $k_f(M^{-1}\,min^{-1})$ can be calculated as

$$\ln k_f = 23.2 - \frac{4820}{T} \quad (7)$$

This equation indicates a rapid increase in reaction rate with temperature. Thus, in order to speed up the chemical reactions the temperature should be as high as possible and a high concentration of hydrobromic acid should be used. The influence of temperature on the equilibrium constant of the piazselenol reaction has not been determined, but previous measurements indicate that equilibrium concentrations are only moderately affected by temperature, at least for high ligand concentrations.

*Computer simulations*

As guidance in the choice of proper derivatization conditions, computer simulations were performed. The three simultaneous rate equations for the reaction sequence

$$Se^{VI} \xrightarrow[(HBr)]{k_r} Se^{IV} \underset{(H^+)}{\overset{(Br_2\text{-DAN})}{\overset{k_f}{\underset{k_b}{\rightleftharpoons}}}} Br_2\text{-DAN-Se}$$

were solved subject to the condition of constant acidity and a large excess of ligand and used to study the progress of the reaction sequence for different combinations of temperature, hydrobromic acid and ligand concentrations. The pseudo first order rate constants were calculated from Eqs. (2), (3) and (6). No attempts were made to include temperature or medium corrections in the equilibrium constants.

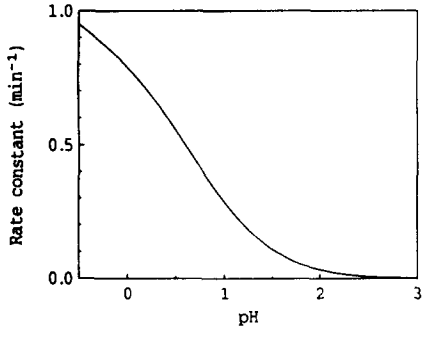

Fig. 4. The rate constant of the piazselenol formation, Eq. (6), as a function of pH at a ligand concentration of 100 μM and 70°C.

Table 1
Computer simulated reaction times for the conversion of Se(VI) to $Br_2$-DAN-Se by simultaneous reduction and derivatization as a function of temperature and the concentrations of hydrobromic acid and $Br_2$-DAN. Relative yield is the degree of conversion to the piazselenol at equilibrium and $t$ is the time needed to reach 98% of the equilibrium concentration

| [HBr] (M) | Temp. (°C) | 50 μM $Br_2$-DAN | | 100 μM $Br_2$-DAN | |
|---|---|---|---|---|---|
| | | Relative yield (%) | $t$ (min) | Relative yield (%) | $t$ (min) |
| 1.5 | 80 | 91 | 31 | 95 | 30 |
| | 90 | | 14 | | 13 |
| | 100 | | 6.3 | | 5.9 |
| 2.0 | 80 | 88 | 16 | 94 | 15 |
| | 90 | | 7.4 | | 6.5 |
| | 100 | | 3.9 | | 3.1 |
| 2.5 | 80 | 86 | 11 | 93 | 8.8 |
| | 90 | | 5.4 | | 4.1 |
| | 100 | | 3.2 | | 2.1 |

The results of the simulations are presented in Table 1, which contains the reaction time needed to reach 98% of the equilibrium concentration of $Br_2$-DAN-Se and the degree of conversion at equilibrium. The figures in the Table demonstrate the great influence of temperature and the hydrobromic acid concentration on the rate of the piazselenol formation. It can also be noted that the ligand concentration has little effect on the rate of formation of the piazselenol, which is largely governed by the rate of reduction of Se(VI). Fig. 5 shows an example of the changes in the concentrations during the progress of the reactions. Since the piazselenol formation cannot proceed faster than the reduction of Se(VI), a high temperature and concentration of hydrobromic acid should be chosen. High acid concentrations will also increase the rate of the piazselenol reaction but the equilibrium concentration of the piazselenol will decrease. However, the shift of the equilibrium position with the concentration of hydrobromic acid will not be pronounced at higher concentrations of $Br_2$-DAN. The degree of conversion, however, is limited by the solubility of the ligand, which is about 100 μM.

*Experimental tests of the computer simulations*

The computer simulations delineated appropriate conditions for fast simultaneous reduction and derivatization. These conditions were tested experimentally on standard solutions of Se(VI). Results from these tests are presented in Figs. 6 and 7 and the agreement is good between the simulated reaction times in Table 1 and the experimental findings. There was some

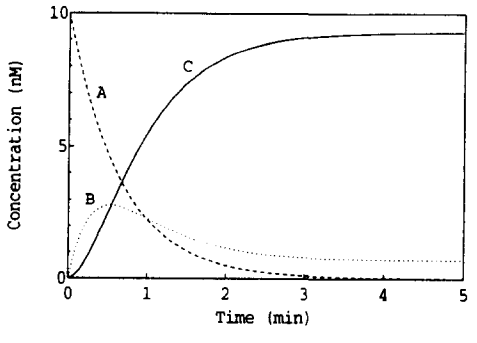

Fig. 5. Calculated concentrations during the formation of $Br_2$-DAN-Se by simultaneous reduction and derivatization at 100°C. Initial Se(VI) concentration 10 nM, ligand concentration 100 μM and hydrobromic acid concentration 2 M. A, Se(VI); B, Se(IV); C, $Br_2$-DAN-Se.

Ligand concentration 50 μM. A, 1.5; and B, 2.5 M hydrobromic acid. Drawn curves are calculated formation curves for $Br_2$-DAN-Se.

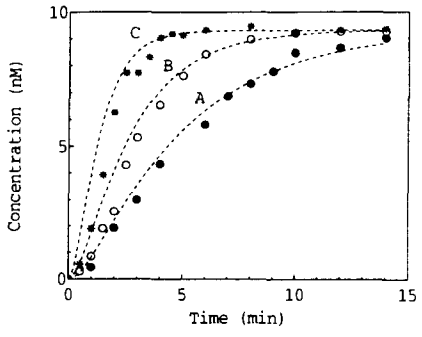

Fig. 7. Temperature dependence of the simultaneous reduction of Se(VI) and formation of $Br_2$-DAN-Se in 2 M hydrobromic acid and 100 μM $Br_2$-DAN. Experimental results. A, 77.5; B, 85; and C, 95°C (aluminum block 80, 90, 100°C). Drawn curves are calculated formation curves for $Br_2$-DAN-Se.

disagreement between the shape of the experimental formation curve and the curve calculated for the temperature of the aluminum block. The differences are caused by difficulties with the timing in the initial part of the experiments and the rather crude temperature control. The actual temperature of the reaction mixture was lower than the set temperature by 2.5–5°C. From the results of the experiments and simulations it was decided to perform the combined reduction and derivatization in 2 M hydrobromic acid and 100 μM $Br_2$-DAN at 100°C in the applications to real samples.

### *3.3. Determination of selenium in biological materials*

*Destruction by a three acid mixture*

We have previously preferred the combined wet/dry ashing method described by Hansson et al. [24] since it does not involve the use of perchloric acid. When hydrobromic acid was added to samples digested with this method, the solutions became colored yellow by bromine which was most likely generated in a redox reaction between added bromide and nitrite formed during the digestion. Bromine is beneficial in the reduction step since the $Br_2/Br^-$ redox couple stabilizes the tetravalent oxidation state of selenium, but it severely interferes in the piazselenol formation step. To avoid bromine formation, the samples were instead digested with a three acid mixture of nitric, perchloric and sulfuric acids. With this destruction method, no appearance of bromine was observed.

The selenium is present in a matrix of concentrated sulfuric acid after destruction by the three acid mixture. A study of the rate of the simultaneous reduction and derivatization at different concentrations of sulfuric acid and 2 M bromide revealed that the piazselenol formation was completed within 6 min in 1 M sulfuric acid at 100°C. It was also observed that the fluorescence signal was somewhat lower in sulfuric acid than in hydrobromic acid of the same concentration. Hence, it was decided to dilute the digested sample to 25 ml, i.e. approximately to 1 M sulfuric acid. Sodium bromide was added to a concentration of 2 M. A 2 ml portion of the diluted sample was used for the spectrofluorimetric finish. The calibration curve was established by addition of Se(VI) standards to a blank solution.

The procedure was evaluated by determinations on the following reference materials; MA-B-3/TM fish tissue (1460 μg $kg^{-1}$, 1350–1770 μg $kg^{-1}$), SRM 1567 wheat flour (1100 ± 200 μg $kg^{-1}$), SRM 1577a bovine liver (710 ± 70 μg $kg^{-1}$), Seronorm 105 human serum (90 ± 6 μg $l^{-1}$), RM 8433 corn bran (45 ± 8 μg $kg^{-1}$), RM 8412 corn stalk (16 ± 8 μg $kg^{-1}$) and RM 8413 corn kernel (4 ± 2 μg $kg^{-1}$). The results are presented in Table 2. The concentrations obtained fall within the specified concentration limits of the reference materials except for SRM 1567 and RM 8413. Low and high results respectively, for these materials have been obtained earlier [14,19,24]. Therefore, it is believed that the results are not caused by the new derivatization method.

*Destruction by wet/dry ashing*

Since access to a digestion method which does not include perchloric acid was considered of value, the previously discussed bromine problem associated with the wet/dry ashing procedure with magnesium nitrate–nitric acid was also addressed. The reaction of nitrous acid with primary amines in acidic solution can be used for the removal of nitrite. Sulfamic acid was used here, since it yields sulfuric acid and nitrogen as reaction products and no interference in the fluorescence measurement was noted. Its performance in conjunction with the present conditions was tested as follows. The reagent was added together with the perchloric acid used for the dissolution of the magnesium oxide and sample residues left after the dry ashing. Hydrobromic acid was then added and the sample was heated at 100°C for about 10 min. The presence of sulfamic acid substan-

[a] 95% non-parametric interval based on the median.
[b] $\mu g\ l^{-1}$.

tially decreased the formation of bromine. However, the bromine formation was not completely suppressed and it was observed that the concentration of bromine increased slowly with time. An increase of the concentration of sulfamic acid did not diminish the slow bromine formation. We believe that nitrite is removed by the addition of sulfamic acid and that the observed slow bromine formation is due to trace amounts of other, unidentified, species present in the digestion residue. It was also observed that the rate of the slow bromine formation, measured by spectrophotometry, was greatly dependent on the volume after dissolution of the sample. If the total volume was increased from 1 (normal volume) to 2 ml at a constant concentration of hydrobromic acid and a constant amount of sulfamic acid, the amount of bromine formed was small enough to be completely removed by the addition of 1 mM hydroxylammonium sulfate. This concentration causes insignificant reduction of Se(IV) to Se(0) at 100°C during 10 min. These findings have been exploited in the proposed analytical procedure, which was applied for the analysis of the reference materials mentioned above. The results are presented in Table 2. The agreement between the results obtained with the two digestion methods is good. As usual [19], a low result was obtained for SRM 1577a after digestion with the small scale version of the wet/dry digestion method.

The detection limit of the spectrofluorimetric method for both digestion techniques is 0.6 $ng\ g^{-1}$, as estimated by three times the standard deviation of the blank determinations ($n = 7$).

## 4. Conclusion

The simultaneous reduction and derivatization of Se(VI) using hydrobromic acid and 2,3-diamino-1,4-dibromonaphthalene as reagents simplifies the spectrofluorimetric method for the determination of selenium in biological samples. It is suitable for samples digested with the three acid method or the magnesium nitrate–nitric acid wet/dry ashing method provided that the necessary precautions against bromine formation are taken in the latter case. It is difficult to recommend one of the procedures in favour of the other as they both have their pros and cons. For laboratories with facilities that allow work with perchloric acid, the three acid procedure is probably the best choice. A scaled-down version of the present method would make it even more attractive. Finally, the short reaction times should make the combined reduction–derivatization approach well suited as part of an automated system for selenium determinations.

# Interaction of 5,7-dichloro-2-methyl-8-hydroxyquinoline with ionic micelles

J.L. Beltrán *, M.D. Prat, R. Codony

*Departament de Química Analítica, Universitat de Barcelona, Av. Diagonal, 647, 08028 Barcelona, Spain*

Received 25 January 1995; revised 21 June 1995; accepted 23 June 1995

**Abstract**

The changes in the apparent acid–base equilibria of 5,7-dichloro-2-methyl-8-hydroxyquinoline (HQ), in solutions of ionic surfactants (sodium lauryl sulphate, SLS; and cetyltrimethylammonium bromide, CTAB) were studied spectrophotometrically in 0.1 M NaCl medium at 25°C. The partition model, in which the different species involved in the equilibria ($H_2Q^+$, HQ and $Q^-$) can distribute betweeen aqueous and micellar pseudophases, was applied to account for the shifts in the apparent acidity constants. A factor analysis procedure was applied to the spectrophotometric data in order to determine the number of species in equilibrium.

The distribution constants for the different species were calculated with the SPDIS program. The proposed models for SLS and CTAB solutions were applied to simulate the apparent $pK_a$ values in these media; the satisfactory agreement between experimental and calculated values indicates that this model provides a good description of the effect of ionic surfactants on the acid–base equilibria of HQ.

## 1. Introduction

The solute–micelle interactions and the distribution of solutes between aqueous and micellar pseudophases have been studied extensively in order to explain the properties of aqueous micellar systems [1–5]. These media are used in different areas of analytical chemistry, such as the development of fluorimetric methods in order to increase their sensitivity [6,7], or in separation methods, such as micellar liquid chromatography and micellar electrokinetic capillary chromatography [8,9]. Moreover, there are separation methods based on the cloud-point of micellar solutions [10,11]. In most cases, the use of surfactant solutions is due to the ability of micelles to solubilize species, such as organic compounds and metal chelates, which are sparingly soluble in water.

The interaction of solutes with micelles leads to apparent changes in their chemical properties, such as shifts in their absorption spectra and in acid–base equilibria [12–15]. There are different models that explain these changes, such as the binding equilibria [5,16] between solute and micelle aggregates, the partition equilibria [4,16,17] of solutes between aqueous and micellar pseudophases, and the ion-exchange equilibria [18–20]. However, these different models are applied depending on the kind of micelles: the ion-exchange model is applied to explain the behaviour of charged species in solutions of ionic surfactants, whereas the partition equilibria model is applied mainly for non-ionic surfactants; the binding model can be applied for both types of surfactant.

*SSDI* 0039-9140(95)01679-1

In a previous work [21], a program (SPDIS) for the determination of distribution constants according to the partition model was developed and successfully applied to non-ionic micellar solutions. In this paper, we show that the partition model can also be used in solutions of ionic surfactants, provided that the surfactant concentration is above its critical micelle concentration, and that the concentration of background electrolyte is much higher than those of the solutes.

Here, the model was applied to the distribution equilibria of 5,7-dichloro-2-methyl-8-hydroxyquinoline (chlorquinaldol) in solutions of sodium lauryl sulphate (SLS, anionic surfactant) and cetyltrimethylammonium bromide (CTAB, cationic surfactant). The results obtained by the application of the partition model are in accordance with the observed shifts of the dissociation constants of chlorquinaldol in these media. Additionally, we determined the critical micelle concentration of CTAB in 0.1 M NaCl medium, as there are some discrepancies between the values reported in the literature.

Interest in chlorquinaldol is related to its chelating ability towards metal ions and to the analytical applications based on the micelle-enhanced fluorescence of its metal chelates [7,22,23]. Previous studies on the fluorescence properties of metal–chlorquinaldol complexes [24] showed that non-ionic and cationic micelles led to important enhancement in fluorescence, relative to hydro-organic media, whereas the effect of anionic micelles depended on the nature of the metal ion. Studies on the partition equilibria of ligand and metal chelates (now in progress) in different micellar media will provide useful information to understand the mechanism of the micellar fluorescence enhancement.

## 2. Experimental

### 2.1. Apparatus

The absorption spectra were recorded on a Beckman DU-7 single-beam spectrophotometer, using a 1.00 cm quartz cuvette. The spectrophotometer was connected to an IBM-PC via a serial interface, and the absorbance data were acquired by using the DUMOD program [25].

The measurements of surface tension were carried out on a Krüss K-12 tensiometer, equipped with a platinum–iridium plate.

The pCH values were measured with a Radiometer PHM 84 pH meter, equipped with an Orion 81-02 combined glass electrode. Calibration of the electrode was performed according to the Gran method [26].

All spectrophotometric, potentiometric and surface tension measurements were made at 25°C (±0.2°C).

### 2.2. Reagents

5,7-Dichloro-2-methyl-8-hydroxyquinoline (chlorquinaldol, Supro, Troponwerke) was recrystallized twice from ethanol solution. Fresh 0.001 M solutions were prepared daily by dissolving the reagent in 0.02 M hydrochloric acid. SLS and CTAB (both from Merck) were used without further purification, although in some experiments SLS was recrystallized from ethanol. All other chemicals were of analytical grade. Buffer solutions were prepared according to Perrin and Dempsey [27] from hydrochloric acid, formic acid, acetic acid, boric acid, sodium dihydrogenphosphate, tris(hydroxy-methyl)aminomethane and sodium hydroxide. Double distilled water was used throughout.

### 2.3. Procedures

The apparent dissociation and distribution consistants of chlorquinaldol were obtained from spectrophotometric data. Aqueous solutions, containing chlorquinaldol ($2 \times 10^{-5}$ M), surfactant and sodium chloride to adjust the ionic strength to 0.1 M were prepared. The pCH was varied by the addition of hydrochloric acid, sodium hydroxide and/or small amounts (0.002 M) of buffer solutions. The solutions were thermostated in a waterbath at 25°C; after this, the absorption spectra of the solutions were recorded over the spectral range from 220 to 450 nm, at 5 nm intervals, and the $[H^+]$ values were measured.

The critical micelle concentration (cmc) of CTAB was determined from surface tension measurements, according to the Wilhelmy method [28]. Several solutions were prepared by adding variable amounts of CTAB to volumetric flasks containing the buffer, ionic medium and chlorquinaldol (when necessary). The surface tension of the thermostated solu-

tions (25°C) was measured and the cmc obtained by plotting the surface tension versus the logarithm of CTAB concentrations.

## 3. Solute–micelle interactions

The interaction between solutes and micelles can be explained by different models: partition equilibria of species between aqueous and micellar phases, binding equilibria between solutes and micellar aggregates, or by the ion-exchange equilibria.

The interaction between the neutral species HQ and the micellar aggregates (SLS and CTAB) can be described in terms of binding or partition equilibria. The binding equilibria is defined by

$$HQ + C \rightleftharpoons HQC \quad (1)$$

where $C$ means the concentration of surfactant in micellar form: $C = C_T - \text{cmc} - [HQC]$ ($C_T$ is the total concentration of surfactant and cmc its critical micelle concentration), and HQC indicates the chlorquinaldol bound to micelles. The binding constant $K_b$ is equal to

$$K_b = [HQC]/([HQ][C]) \quad (2)$$

where the concentrations of each species are referred to the total volume of the solution.

Alternatively, the partition of the species HQ between aqueous phase and micellar pseudophase can be defined by

$$HQ_{(w)} \rightleftharpoons HQ_{(m)} \quad (3)$$

$K_D$ is the partition constant:

$$K_D = [HQ]_{(m)}/[HQ]_{(w)} \quad (4)$$

Note that in this case the subscript (w) or (m) indicates the concentration of the species in aqueous or micellar phase.

For a given system, the binding and partition constants are related to the partial molar volume of the surfactant in micellar phase ($V_\phi$):

$$K_b = K_D \cdot V_\phi \quad (\text{if } C_T \gg [HQC]) \quad (5)$$

The interaction between charged species ($Q^-$ and $H_2Q^+$) and ionic surfactants is explained in two different ways, depending on the charges of surfactant and solutes. For species with the same charge as the surfactant ($Q^-$ in SLS, or $H_2Q^+$ in CTAB), the equilibria can be described in a similar way to the distribution of neutral species, taking into account that the ionic species can be extracted as the neutral ion associates with counter ions (mainly from the background electrolyte):

$$H_2Q^+_{(w)} + Cl^-_{(w)} \rightleftharpoons H_2Q^+ \cdot Cl^-_{(m)} \quad \text{(in CTAB solutions)} \quad (6)$$

$$Q^-_{(w)} + Na^+_{(w)} \rightleftharpoons Q^- \cdot Na^+_{(m)} \quad \text{(in SLS solutions)} \quad (7)$$

In this case, we can define the extraction constant as

$$K_{EX(H_2Q^+)} = [H_2Q^+ \cdot Cl^-]_{(m)}/([H_2Q^+]_{(w)} \cdot [Cl^-]_{(w)}) \quad (8)$$

$$K_{EX(Q^-)} = [Q^- \cdot Na^+]_{(m)}/([Q^-]_{(w)} \cdot [Na^+]_{(w)}) \quad (9)$$

In the presence of a large excess of background electrolyte with respect to the solute ($C_{NaCl} = 0.1$ M, and $C_{HQ}$ about $2 \times 10^{-5}$ M in our conditions), the free concentration of sodium and chloride ions can be considered as constants. By substituting $[Q^-]_{(m)} = [Q^- \cdot Na^+]_{(m)}$ and $[H_2Q^+]_{(m)} = [H_2Q^+ \cdot Cl^-]_{(m)}$ we can obtain the conditional partition constants for these species:

$$K'_{D(H_2Q^+)} = [H_2Q^+]_{(m)}/[H_2Q^+]_{(w)} = K_{EX(H_2Q^+)} \cdot C_{NaCl} \quad (10)$$

$$K'_{D(Q^-)} = [Q^-]_{(m)}/[Q^-]_{(w)} = K_{EX(Q^-)} \cdot C_{NaCl} \quad (11)$$

For species with opposite charges to surfactant, the interaction cannot be explained by a single partition equilibria; in these cases, the systems are described by the ion-exchange model, taking into account the different ions involved in the equilibrium. To simplify, the interaction of buffer species with the surfactants will be omitted because their concentrations (about 0.002 M) are negligible compared with the background electrolyte.

As an example, the ion-exchange equilibria of $H_2Q^+$ in SLS solutions can be described as

$$H_2Q^+_{(w)} + Na^+_{(m)} \rightleftharpoons H_2Q^+_{(m)} + Na^+_{(w)} \quad (12)$$

The equilibrium constant is defined, in this case, as the selectivity coefficient:

$$K_{H_2Q^+/Na^+} = [H_2Q^+]_{(m)} \cdot [Na^+]_{(w)}/[H_2Q^+]_{(w)} \cdot [Na^+]_{(m)} \quad (13)$$

We must take into account the exchange of hydrogen ion into micellar phase as

$$H^+_{(w)} + Na^+_{(m)} \rightleftharpoons H^+_{(m)} + Na^+_{(w)} \quad (14)$$

The concentrations of $Na^+$ in aqueous and micellar phases are obtained from the mass balance of sodium ion. Let $n_{Na}$ be the total number of moles of $Na^+$ in solution, $V_w$ and $V_m$ the volumes of aqueous and micellar phases, and $V$ the total volume of the solution ($V = V_w + V_m$). The volume of the micellar pseudophase is given by $V_m = C \cdot V \cdot V_\phi$. In practice, it can be assumed that $V_m \ll V_w$, and $V \approx V_w$. Under these conditions, we can write:

$$\begin{aligned} n_{Na} &= (C_T + C_{NaCl}) \cdot V \\ &= [Na^+]_{(w)} \cdot V_w + [Na^+]_{(m)} \cdot V_m \\ &= n_{Na,w} + n_{Na,m} \end{aligned} \quad (15)$$

$$\begin{aligned} n_{Na,w} = C_{NaCl} \cdot V + \alpha \cdot C \cdot V + \text{cmc} \cdot V \\ + [H_2Q^+]_{(m)} \cdot V_m + [H^+]_{(m)} \cdot V_m \end{aligned} \quad (16)$$

$$\begin{aligned} n_{Na,m} &= n_{Na} - n_{Na,w} \\ &= C \cdot V \cdot (1 - \alpha) - [H_2Q^+]_{(m)} \cdot V_m \\ &\quad - [H^+]_{(m)} \cdot V_m \end{aligned} \quad (17)$$

where $\alpha$ is the ionization degree of the micelles, which can be considered constant for surfactant concentrations well above the cmc (typical values range between 0.15 and 0.25). By defining $R$ as the ratio of micellar volume to the total volume ($R = V_m \cdot V^{-1} = C \cdot V_\phi$), the concentration of sodium ion in aqueous and micellar phases is given by

$$\begin{aligned} [Na^+]_{(w)} = C_{NaCl} + \alpha \cdot C + \text{cmc} \\ + [H_2Q^+]_{(m)} \cdot R + [H^+]_{(m)} \cdot R \end{aligned} \quad (18)$$

$$\begin{aligned} [Na^+]_{(m)} &= (1 - \alpha) \cdot C \cdot R^{-1} \\ &\quad - [H_2Q^+]_{(m)} - [H^+]_{(m)} \\ &= (1 - \alpha) \cdot V_\phi^{-1} - [H_2Q^+]_{(m)} - [H^+]_{(m)} \end{aligned} \quad (19)$$

Under our working conditions, $C_{NaCl} \gg (\alpha \cdot C + \text{cmc} + [H_2Q^+]_{(m)} \cdot R + [H^+]_{(m)} \cdot R)$, so we can consider that the concentration of sodium ion in the aqueous phase is nearly constant, and equal to $C_{NaCl}$. Moreover, in Eq. (19), the concentrations of $H_2Q^+$ and $H^+$ in the micellar phase are negligible compared to $(1 - \alpha) \cdot V_\phi^{-1}$, and we can consider that the concentration of sodium in micellar phase is also constant. In this case the selectivity coefficient is given as

$$\begin{aligned} K_{H_2Q^+/Na^+} = [H_2Q^+]_{(m)} \cdot C_{NaCl} \cdot V_\phi / \\ \{[H_2Q^+]_{(w)} \cdot (1 - \alpha)\} \end{aligned} \quad (20)$$

Taking into account that, under our experimental conditions, the concentration of sodium chloride is constant, and that the $V_\phi$ and $\alpha$ values corresponding to surfactant micelles can also be considered constant, we can define a conditional distribution constant for the $H_2Q^+$ species in this medium, which can be related to the selectivity coefficient as

$$\begin{aligned} K'_{D(H_2Q^+)} &= [H_2Q^+]_{(m)}/[H_2Q^+]_{(w)} \\ &= K_{H_2Q^+/Na^+} \cdot (1 - \alpha)/\{C_{NaCl} \cdot V_\phi\} \end{aligned} \quad (21)$$

This treatment can also be applied to the exchange of $Q^-$ species in CTAB micellar solutions, which gives a similar definition for their conditional distribution constant.

Eqs. (13–21) show that by the simplification of the ion-exchange model (in a large excess of background electrolyte at constant concentration and surfactant concentrations above the cmc), the definitions of the equilibrium constants are very similar to those obtained by the partition model. The advantage of this model is that it can be applied to the different species in the SLS or CTAB micellar media, regardless of the kind of solute/micelle interaction or the charge of the individual species. Moreover, the partition model is easier to define, and the results obtained for a given species in different surfactants can be readily compared.

## 4. Data treatment

As noted previously, the partition of one or more species in the micelar phase leads to changes in the apparent dissociation constants of chlorquinaldol. These constants were determined by the application of the STAR program [29] to the spectrophotometric data, at the different surfactant concentrations.

For the determination of the partition equilibria of the different species we have applied a modified version of the SPDIS program [21]. This is a non-linear least-squares program, in which the equilibrium constants are refined by using the Gauss–Newton iterative algorithm, in order to minimize the sum of squared residuals ($U$) in absorbance measurements, defined as

$$U = \sum_{i=1}^{ns} \sum_{j=1}^{nw} (A_{i,j,exp} - A_{i,j,calc})^2 \quad (22)$$

where ns and nw indicate the number of spectra and the number of wavelengths respectively. $A_{i,j,exp}$ is the measured absorbance, and $A_{i,j,calc}$ the calculated absorbance, on the basis of the proposed model. The program also calculates the molar absorptivities of the guessed species at the working wavelengths. In the present version, this program can deal with up to 150 spectra, measured at 50 wavelengths.

Fig. 1 shows the different possibilities for the partition equilibria between aqueous and micellar phases. According to this model, three species could be extracted in micellar media (the neutral form, HQ, and the charged species $H_2Q^+$ and $Q^-$). In order to ascertain the "real" number of extracted species, we determined the number of species in solution by factor analysis of the absorbance data matrix, following the procedure described by Kankare [30]: by plotting the standard deviation of residuals ($S_{k(A)}$) versus the number of species (factors), and by comparing these values with the instrumental error, the number of species can be inferred. The results obtained using this procedure are compared with those obtained by the application of the SPDIS program, based on the partition model.

## 5. Results and discussion

### 5.1. Apparent $pK_a$ micellar media ($pK_a^*$)

To study the effect of SLS and CTAB in apparent acid–base equilibria of chlorquinaldol, the absorption spectra of several series of aqueous micellar solutions were recorded. In each series the surfactant concentration was kept constant, and the pCH was varied from 2 to 11. The results obtained by the application of the STAR program are summarized in Tables 1 and 2. These $pK_a^*$ values clearly show the different behaviour of chlorquinaldol in these different charge-type micellar systems. Thus, the apparent $pK_{a2}$, which involves the uncharged acid HQ and the anionic base $Q^-$, decreases by the addition of CTAB from 7.84 to 6.76, and increases to 9.28 when SLS is added. In contrast, the apparent $pK_{a1}$, which involves the equilibrium between the cationic species $H_2Q^+$ and the neutral form HQ, drastically decreases by the addition of cationic surfactant CTAB (from 3.44 to 1.32), but it increases slightly on addition of anionic surfactant SLS (to 3.93).

The $pK_a^*$ values obtained are displayed in Figs. 2a and 2b, together with those previously reported in Brij-35 micellar media. For comparative purposes, the $pK_a^*$ values are plotted against $R$ (the ratio of micellar volume to the total volume) instead of the surfactant concentration. From these figures, it can be seen that

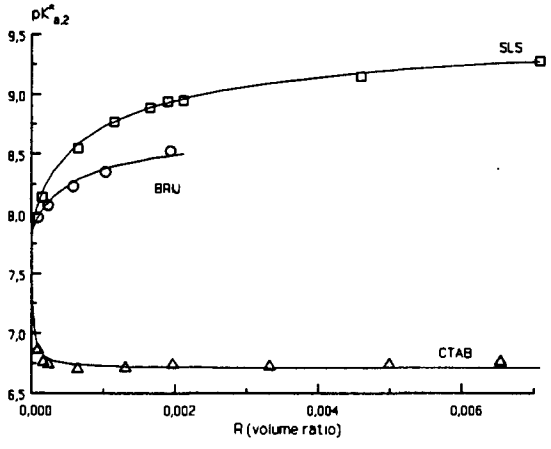
(a)



(b)

Fig. 2. Apparent dissociation constants of chlorquinaldol in micellar media. Solid lines indicate the $pK_a^*$ values calculated from the distribution constants. (Data for Brij solutions taken from Ref. [21].)

the trends observed for $pK_{a1}^*$ in CTAB solutions are similar to that observed in Brij-35 solutions, while the $pK_{a2}^*$ variation in Brij-35 is like that observed in SLS.

It should be noted that SLS or Brij-35 surfactants, at concentrations below the cmc, have no significant effect on chlorquinaldol solutions, whereas in CTAB there are marked changes in the absorption spectra and in $pK_a^*$ values, at surfactant concentrations below the cmc reported values [31] (in 0.1 M NaCl ionic medium, these values range from $2 \times 10^{-4}$ to $7.5 \times 10^{-4}$ M). Fig. 3 shows the apparent absorption spectra of the uncharged species HQ in CTAB at low surfactant concentrations (from $0.76 \times 10^{-4}$ to about $7 \times 10^{-4}$ M). Because of these apparently anomalous results, and the poor agreement between the values

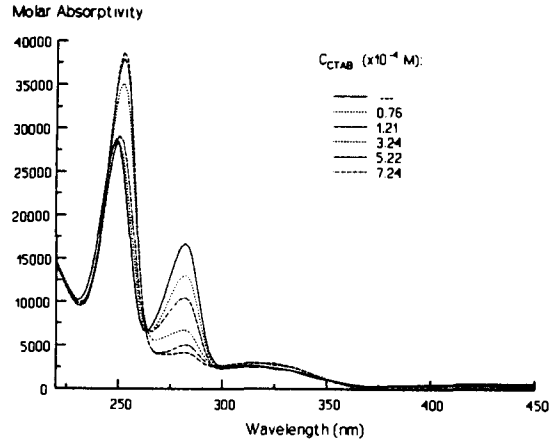


Fig. 3. Apparent absorption spectra of the neutral species HQ at different concentrations of CTAB.

reported by different authors, the cmc of CTAB was determined. The value obtained (see next section) was far below those previously reported, and in accordance with the observed effects on $pK_a^*$ values and on absorbance spectra.

### 5.2. Determination of the cmc of CTAB

The cmc of CTAB was obtained from plots of the surface tension of aqueous solutions of CTAB against the logarithm of their bulk concentration in 0.1 M NaCl solutions. The results obtained show that the presence of NaCl drastically decreases the cmc value, from $9.2 \times 10^{-4}$ M in pure water [6] to $7 \times 10^{-5}$ M (Fig. 4).

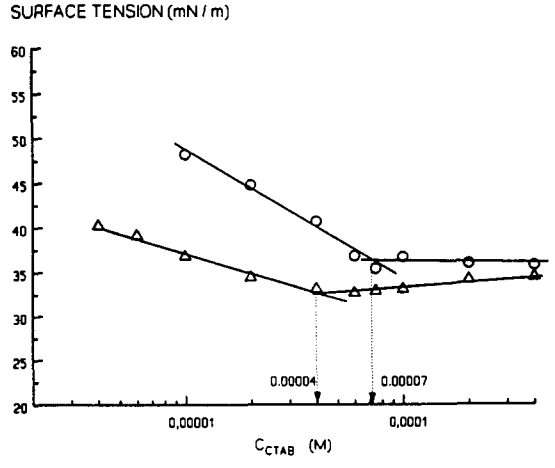

Fig. 4. Determination of the critical micelle concentration of CTAB in ○, 0.1 M NaCl medium; △, 0.1 M NaCl, with $2 \times 10^{-5}$ M chlorquinaldol in alkaline medium.

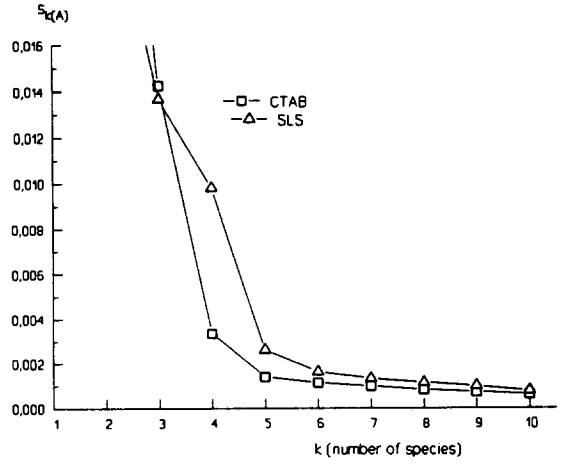

Fig. 5. Determination of the number of species in solution by factor analysis.

Because the addition of solutes can modify the cmc values, the effect of chlorquinaldol on CTAB solutions was also studied. The results indicate that there is no significant difference in the cmc of CTAB in acid and neutral solutions, whereas in alkaline medium it decreases to $4 \times 10^{-5}$ M (see Fig. 4). However, this difference has little relevance in the study of partition equilibria, as the data taken for the calculations correspond to CTAB concentrations well above the cmc.

### 5.3. Partition equilibria

For the distribution equilibria in CTAB solutions, the calculations were carried out over 140 spectra, at CTAB concentrations ranging from $3.2 \times 10^{-4}$ to $1.8 \times 10^{-2}$ M. In the case of SLS micellar media, the concentrations ranged between $6.1 \times 10^{-3}$ and $3 \times 10^{-2}$ M (100 spectra were taken). In both systems, the determination of partition constants was carried out in the spectral range between 240 and 295 nm, corresponding to the absorption maxima of the species involved.

The determination of the number of species by factor analysis of the absorbance data is displayed in Fig. 5. The comparison of the standard deviation of residuals ($S_{k(A)}$) with the instrumental error (about 0.0022 absorbance units in our experimental conditions) indicates that five and six species are needed, in CTAB and SLS solutions respectively, to obtain a standard deviation of residuals lower than the instrumental error. Taking into account that there are three species of chlorquinaldol in aqueous phase ($H_2Q^+$, HQ and $Q^-$), we conclude that there are two partition equilibria in CTAB solutions, and three in SLS solutions.

The distribution equilibria of chlorquinaldol in CTAB and SLS micellar media were studied by using the SPDIS program, according to the partition model.

The first model proposed for both surfactants included, as known parameters, the dissociation constants in water, the absorption spectra of the pure species $H_2Q^+$, HQ and $Q^-$, and the surfactant partial volume and its cmc [32,33] (0.249 l mol$^{-1}$ and $1.46 \times 10^{-3}$ M for SLS, and 0.361 l mol$^{-1}$ and $7.0 \times 10^{-5}$ M for CTAB). The model also contained the partition constants for the three species of chlorquinaldol. This assumption should be valid in the case of SLS solutions, as the results obtained by factor analysis suggested this model. In the case of CTAB solutions, only two species should be extracted according to the factor analysis results; however, this method does not indicate which species are extracted. For this reason, we included all the possibilities in the first model.

The treatment of data corresponding to SLS solutions by the program SPDIS indicates the extraction of the three chlorquinaldol species, in accordance with the model proposed. By applying the same model to CTAB solutions, it was found that the partition constant corresponding to $H_2Q^+$ species was ill-defined, giving a calculated concentration for this species less than 5% of the total chlorquinaldol in solution. Further, taking into account also the results obtained by factor analysis, this species, ($H_2Q^+_{(m)}$), was rejected from the equilibrium model.

The final results obtained by SPDIS are given in Table 3, where the partition constants are also compared with those previously obtained in Brij-35 micellar solutions. These results show that the solubilization of the neutral

Table 3
Partition constants of chlorquinaldol in different surfactants (in 0.1 M NaCl, at 25°C)

| Surfactant | log $K'_{D(H_2Q^+)}$ [a] | log $K_{D(HQ)}$ [a] | log $K_{D(Q^-)}$ [a] |
|---|---|---|---|
| Brij-35 [b] | – | 3.64(0.01) | 2.77(0.05) |
| SLS | 4.40(0.02) | 3.89(0.02) | 2.19(0.04) |
| CTAB | – | 4.25(0.02) | 5.39(0.01) |

[a] The values given in parentheses correspond to three times the standard deviation of the constants (given by the SPDIS program).

[b] After Ref. [21].

species HQ is similar for neutral and ionic surfactants (about 0.6 logarithm units as maximum difference). Otherwise, as may be expected, the extraction of ionic species is clearly favoured when a surfactant of opposite charge is used; thus, the maximum value for the partition constant corresponds to the interaction between the species $Q^-$ and CTAB micelles, followed by the $H_2Q^+$–SLS interaction.

The solubilization ability of SLS anionic micelles should be noted, as in this media the three species of chlorquinaldol can be extracted, despite the charge of the species.

With the set of partition constants given in Table 3, we calculated the theoretical apparent dissociation constants of chlorquinaldol against the volume ratio $R$, in order to evaluate the prediction ability of the partition model in the acid–base equilibria [21]. The results of this evaluation are shown in Figs. 2a and 2b (for the variation of $pK^*_{a1}$ and $pK^*_{a2}$ respectively), where the predicted apparent constants are indicated by the continuous line. The good fit obtained between the predicted and experimental values indicates that the application of the partition equilibria model provides a satisfactory description for the acid–base equilibria in micellar solutions of ionic and non-ionic surfactants.

The approaches described in this work provide several tools for the study of the micelle–solute interactions: first of all, they can be applied to ionic and non-ionic surfactants, regardless of the specific solute–micelle interactions. So the comparison of the equilibrium constants for a given system in different surfactant solutions yields a direct comparison in terms of the extent of "solute–micelle interaction" for the different species or the "ability of solubilization" of the surfactants studied. Moreover, the method is not restricted to acid–base equilibria, and it can be applied to other systems, such as the partition of single species, or metal–ligand complex formation and partition of the species formed. It should also be noted that the equilibrium constants are calculated directly from the experimental absorbance data (at different pCH and surfactant concentrations, in the full range of spectra); this feature is an important advantage over the previous methods established, in which the solute–micelle interactions are determined from the variation in the apparent $pK_a$ of the solutes. In fact, in this work, this variation is applied only for the model validation, and it is unnecessary for the calculation of the partition constants.

Furthermore, this full-spectrum approach allows the determination of the number of significant species in solution by means of factor analysis procedures. This is a useful feature for the data interpretation, as it indicates the number of equilibria to be considered in the chemical model.

# Application of microwave heating to the determination of free, combined and total sulphur in rubber

Wojciech Puacz *, Wiesław Szahun, Mariusz Kopras

*Institute of Chemistry and Technical Electrochemistry, Poznań University of Technology, ul. Piotrowo 3, 60-965 Poznań, Poland*

Received 1 March 1995; revised 24 May 1995; accepted 30 June 1995

**Abstract**

An atomic absorption spectrometry (AAS) method for the determination of total and combined sulphur in rubber and a catalytic method for the determination of free sulphur in rubber are described. The catalytic method is based on the iodine–azide reaction and is followed by an extraction of free sulphur with benzene, toluene or acetone. The catalytic determination, with the aid of gas chromatography, was performed in *N,N*-dimethylformamide after expelling the more volatile solvents used in the extraction. The calibration is linear over the range $2 \times 10^{-6}$–$3 \times 10^{-4}$ M. Before the determination of total and combined sulphur, the rubber samples were decomposed by microwave assisted heating (5 min, 110 W) in a Teflon closed vessel. After microwave heating the solution was clear and homogenous and all sulphur compounds contained in the rubber were quantitatively oxidized to sulphate. The sulphates were then precipitated as $BaSO_4$ and an excess of barium was determined by AAS. From the difference in the results of the determinations of total and free sulphur the amount of combined sulphur can be calculated, and from the difference in the determinations of total and combined sulphur the amount of free sulphur can be calculated. In the latter case the catalytic analysis is not needed.

## 1. Introduction

Sulphur is one of the most frequently used vulcanizing agents in natural rubber, synthetic rubber and mixed vulcanizates. Sulphur is used together with vulcanizing accelerators, usually containing sulphur, which, apart from their basic function (accelerating vulcanization) vulcanize themselves. Thus cross-linkings in rubber are formed by elemental sulphur as well as by sulphur from accelerators. Chemical, mechanical and elastic properties of rubber and its ageing resistance depend on the number of cross-linkings and on the amount of sulphur left after vulcanization—so-called free sulphur. In a complicated system such as rubber (containing not only sulphur and accelerators but also extenders, softeners, antioxidizers, etc.), in addition to correct proportioning of its components, a quantitative control of concentrations of different forms of sulphur in the final product is very important.

Among direct methods for sulphur determination only neutron activation and X-ray fluorescence spectrometry allow determinations at parts per billion concentration levels. Both of these methods are very complicated and the instruments are expensive. Radiometric methods, atomic and molecular emission spectrometry and atomic absorption analysis allow direct determination of sulphur and compounds of sulphur in different oxidation states but they are limited by difficulties with atomization of

*SSDI* 0039-9140(95)01680-5

sulphur, are complicated and scarcely given reproducible results. For these reasons indirect methods for determination of sulphur and its compounds are the most frequently presented in the literature.

Vulcanized rubber contains up to 3.5% of sulphur of which free sulphur usually does not exceed 0.15%. Total sulphur in rubber is determined after burning the sample in a pipe furnace [1,2], after melting it with sodium peroxide [3], after wet mineralization [4,5], by the Schöniger method after burning the sample in oxygen [6] or with the use of analyzers based on coulometric, potentiometric, conductometric or spectrophotometric techniques. Free sulphur in rubber is usually determined chromatographically [7,8]. There are also methods based on thiosulphate [9] or thiocyanate [10] formation or iodine–azide catalysis [11].

In this paper microwave energy is used for rubber mineralization and an indirect AAS method is used for total sulphur and combined sulphur determination. Rubber samples are mineralized in Teflon vessels using a high efficiency microwave digestion unit. Sulphates formed during mineralization are precipitated ($BaSO_4$) and the excess of barium is determined by atomic absorption spectrometry (AAS). Free sulphur is extracted from rubber with benzene, toluene or acetone and, after cleavage of S–S bonds in the $S_8$-ring using microwave energy, it is determined by a chromatographic method based on iodine–azide catalysis (i–a). In both cases the use of microwave energy allowed shortening and simplification of analysis and it is as a result of microwave heating that rubber mineralization (determination of total sulphur and combined sulphur) and S–S bond cleavage in the $S_8$-ring (free sulphur determination) reach 100% yields. Quantitative bond cleavage was confirmed by UV spectra before and after microwaving. To check the accuracy of the proposed method the gravimetric method for the determination of combined and total sulphur in rubber following the combustion of the sample by the Schöniger method [12] was used.

## 2. Experimental

### 2.1. Apparatus

A Varian 3700 gas chromatograph, a Beckman 1233 atomic absorption spectrophotometer, a Beckman DU 7500 single beam spectrophotometer with 10 mm quartz cells, a high efficiency microwave digestion unit (Plazmatronika Ltd, Wrocław, Poland) and a Heraeus Mikro K Oxidizer were used.

### 2.2. Reagents

All chemicals used were of analytical-reagent grade and were used without further purification. Organic solvents were taken from the same batch. Standard solutions of sulphur, 10 $\mu g\ cm^{-3}$, in benzene, toluene and acetone were prepared. The precipitating solution (barium, 500 $\mu g\ cm^{-3}$) was made by dissolving 0.8892 g of $BaCl_2 \cdot 2H_2O$ and 13.0 g of NaCl in 50 $cm^3$ of doubly distilled water, adding 500 $cm^3$ of methanol, mixing well and diluting to volume in a 1 l standard flask with water.

## 3. Procedure

### 3.1. Determination of free sulphur in rubber

Finely cut rubber (50–100 mg) was placed in a 100 $cm^3$ conical flask and 50 $cm^3$ of one of the solvents (benzene, toluene or acetone) was added. Flasks were protected from the light with aluminium foil and the solution was purged with nitrogen for 10 min directly before extraction to avoid oxidative or photolytic damage of the network structure. Free sulphur was extracted at 20°C for 18 h (benzene), 22 h (toluene) or 26 h (acetone). The solution was then decanted and the rubber was washed with two 10 $cm^3$ portions of the same solvent that was used for extraction. Combined solutions (50 $cm^3$ + 20 $cm^3$) were placed in a 200 $cm^3$ round-bottomed flask. *N,N*-Dimethylformamide (DMF) (10 $cm^3$) was added and, taking advantage of a big difference in the boiling points of DMF (153.0°C) and the solvents (benzene, 80.1 °C; toluene, 110.6°C, acetone, 56.2°C), the solvent was stripped. $NaN_3$ (3 $cm^3$, 0.20 mg $cm^{-3}$) solution in DMF was added and after making up the solution to 15 $cm^3$ with DMF the sample was microwaved in order to cleave the S–S bonds of the $S_8$-ring. The cleavage of sulphur bonds took place inside the sealed Teflon vessel of 30 $cm^3$ volume with the aid of the high efficiency microwave digestion unit for 4 min at 110 W. The vessel was then cooled (about 15 min) in a water bath

and the solution (15 $cm^3$) was divided into 2 portions: 5 $cm^3$ and 10 $cm^3$. The first one was diluted with 40 $cm^3$ ethanol and then a UV spectrum was recorded using DMF:ethanol 1:8 (v/v) as the reference solution. The spectra give information about the extent of the bond cleavage (under optimum conditions 100% cleavage was reached) and semiquantitative information about the sulphur concentration. Cleaved divalent sulphur was determined in the second part of the sample (10 $cm^3$) by a method based on i–a catalysis using gas chromatography—the nitrogen producted in the catalyzed i–a reaction was in an amount directly proportional to the divalent sulphur catalyst concentration. An analytical column with molecular sieve 5 Å and thermal conductivity detector was used. For quantitative estimation of nitrogen the peak height as well as the peak area were used [13].

### 3.2. Determination of total sulphur in rubber

Finely cut rubber (20–40 mg) was placed in a 30 $cm^3$ Teflon vessel and 5 $cm^3$ of concentrated $HNO_3$ and 0.5 $cm^3$ of 30% $H_2O_2$ were added. The closed vessel was placed in a stainless-steel jacket [14] of the apparatus for the pressure mineralization of rubber with the use of microwave energy. The exposure time was 5 min (determined experimentally) and the microwave heating power was 110 W. The vessel was then cooled (about 15 min) in a water bath and after careful opening of the vessel the sample was transferred into a 50 $cm^3$ beaker. Concentrated HCl (1 $cm^3$) was added and the beaker was heated slightly to expel the residue of $HNO_3$ left after mineralization. The sample was then transferred into a 250 $cm^3$ volumetric flask and made up to the mark with water. The solution after mineralization was homogenous, yellowish and completely clear. All forms of sulphur in the rubber were oxidized into sulphates that were determined by the indirect AAS method. In order to precipitate sulphates 3 $cm^3$ of a precipitating solution of $BaCl_2$ was added to the sample. After vigorous shaking the solution was allowed to stand for at least 8 h (usually overnight). The excess of barium was then determined, without filtration, by AAS with a nitrous oxide–acetylene flame. During aspiration of the samples into the flame it is important not to shake the samples (which would disturb the precipitate, and vitiate the determination). Sodium chloride was added to the precipitating solution to suppress ionization of barium in the nitrous oxide–acetylene flame. The measurements were carried out at $\lambda = 553.6$ nm, using band width 0.41 nm, lamp current 18 mA and nitrous oxide pressure 40 kPa, acetylene 150 kPa.

### 3.3. Determination of combined sulphur in rubber

Rubber (20–40 mg) after extraction of free sulphur was washed twice with acetone and dried in a stream of air for 90 min at 40°C. The sample was placed in a Teflon vessel and mineralized using microwaves. Sulphates formed during mineralization were determined by the AAS method given in the procedure for total sulphur determination.

### 3.4. Calculating the amount of combined sulphur in rubber

The amount of combined sulphur forming cross-linkings was calculated from the difference between the amounts of total and free sulphur.

### 3.5. Calculating the amount of free sulphur in rubber

The amount of free sulphur was calculated from the difference between the amounts of total and combined sulphur. In this case the catalytic analysis based on the i–a reaction need not be performed at all.

## 4. Results and discussion

Almost 20 h of extraction with benzene or toluene or an even longer extraction with acetone is the main drawback of free sulphur determination in rubber. Such long times are necessary for rubber swelling, solvent penetration and extraction of free sulphur. All methods of free sulphur determination known from the literature contain this long extraction step.

We tried to extract sulphur with several portions of solvent and then to determine sulphur in combined solutions. This did not allow us to shorten the extraction time because extraction of sulphur takes place after rubber swelling which is the longest step. In another attempt rubber was frozen in liquid nitrogen and then crushed. In this case we always extracted more free sulphur, probably as a result of cleavage of

sulphur bridges. Our results of free sulphur determination after extraction at boiling points of solvents performed in a flask with reflux condenser or Soxhlet apparatus also did not reflect the actual free sulphur concentration in different samples of rubber. This was because the extraction at the boiling points of the solvents used caused further vulcanization of rubber.

The completeness of the extraction of free sulphur (18, 22 and 26 h for benzene, toluene and acetone respectively) was checked by an extraction of the rubber sample with a new portion of the solvent.

Free sulphur extracted from rubber remains in DMF (after solvent stripping) as elemental, crystalline sulphur, which forms very stable ring cyclo-octasulphur $S_8$. An "opening" of the $S_8$-ring through the cleavage of the sulphur bonds makes the sulphur more reactive. Elemental sulphur, as a Lewis acid, reacts first of all as an electrophilic agent and becomes very flexible to nucleophilic attack via an $S_N2$ mechanism. Activation of sulphur by cleavage of the S–S bonds of the $S_8$-ring may be achieved only in polar solvents.

In order to achieve bond cleavage in the $S_8$-ring several nucleophilic or reducing agents (nitrite [15], azide [16], sulphite [17], cyanide [18], borohydride [19,20], triphenylphosphine [21] and others) were applied. The methods cited above have some drawbacks, such as a yield lower than 100%, long reduction time and limitation on the choice of solvent. The application of microwave heating coupled with the nucleophilic action of $N_3^-$ in DMF on the reduction of the S–S bonds in the $S_8$-ring significantly improves the cleavage procedure.

Effectiveness of microwave heating is connected with absorption of microwave energy by the compound and depends strongly on the polarity of the compound and the solvent. For this reason non-polar solvents (benzene, toluene or acetone) used for sulphur extraction from rubber were stripped. DMF, having a dielectric constant of 36.7, is a good medium for S–S bond cleavage. Due to the application of microwave heating the time needed for cleavage was reduced from hours, in the papers cited [15–21], to a few minutes in the present method. Without a minimum amount of the azide ion in the solution however, the cleavage of the sulphur bonds in the $S_8$-ring did not take place at all, even at very long times and with the highest microwave heating power. The process did not take place either when azide ion in the DMF solution was substituted by any non-nucleophilic anion, e.g. $Cl^-$, $SO_4^{2-}$, $NO_3^-$, etc.

It is very important to achieve quantitative bond cleavage because only solutions with quantitatively cleaved sulphur do not form sols when water is added. Sol formation during sulphur determination, which at low concentrations is practically invisible, always results in errors of determination. In order to control this process UV spectra of sulphur were recorded before and after microwaving. Solutions of sulphur in DMF were diluted with ethanol (DMF:ethanol 1:8, v/v) because DMF spectra cannot be analyzed in the range below 250 nm due to very high solvent absorption.

Fig. 1(a) shows spectra of elemental sulphur at different concentrations (before microwaving). Fig. 1(b) shows spectra of "cleaved sulphur" at different concentrations (after microwaving). The curves give information about the completeness of bond cleavage (i.e. whether microwaving parameters, exposure time and

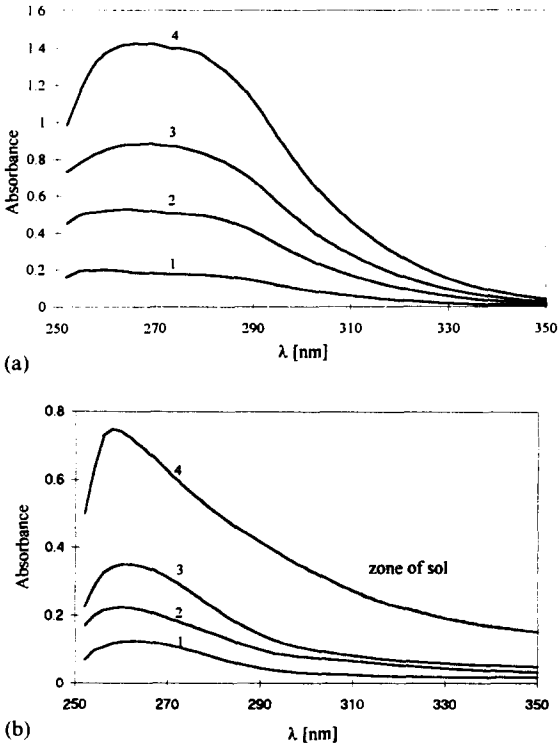

Fig. 1. (a) UV spectra of sulphur in DMF:ethanol (1:8, v/v). Curves 1, 2, 3 and 4 correspond to concentrations of sulphur of 4.0, 8.0, 12.0 and 20.0 μg cm$^{-3}$ respectively. (b) UV spectra of sulphur in DMF:ethanol (1:8, v/v) after microwave assisted heating, concentrations of sulphur (curves 1, 2, 3 and 4) as in Fig. 1(a). Sol of sulphur is formed up to 0.15 of absorbance and at $\lambda > 300$ nm, see zone of sol.

power were chosen properly) and semiquantitative information about sulphur concentration. This latter information is useful when choosing optimum concentrations of components in the i–a catalytic reaction. In Fig. 1(b) curves 1, 2 and 3 show quantitative (100%) bond cleavage. Curve 4 shows partial cleavage—it passes through the "zone of sol". As these data allow us to predict whether sulphur sol will be formed in water or not it is possible to perform microwave heating again under modified conditions (increased exposure time, increased power or both) and to not destroy the sample. $SN_3^-$ is the product of $S_8$ cleavage during microwaving with $N_3^-$.

The i–a reaction is catalyzed by divalent sulphur compounds such as sulphides, thiosulphates, thiocyanates and other R–S and R–S–H compounds. The course of the i–a reaction can be followed by a volumetric [22,23] or gas chromatographic [24,25] determination of the liberated nitrogen, by the determination of the excess iodine using amperometric [26,27] or titrimetric methods [28,29] and by thermometric [30] or enthalpimetric detection [31–34] (the i–a reaction is exothermic).

When a small amount of sulphur (−II) catalyst is added to a solution containing iodine and azide ions, a definite amount of azide is converted into nitrogen and the catalyst is destroyed and removed from the catalytic cycle, being oxidized to a higher oxidation state of sulphur, usually ultimately to sulphate or sulphonic acid:

$$I_2 + 2N_3^- \xrightarrow{S^{2-}} 2I^- + 3N_2$$

Catalytic properties of sulphur (−II) catalysts were determined by a catalytic coefficient expressed by the equation:

$$\text{catalytic coeff.} = \frac{\text{mass } N_2\text{(mg) in i–a reaction}}{\text{mass S(mg)} \times 0.436}$$

The slope of the calibration curve is a measure of the catalytic activity of sulphur (−II) compounds. The value 0.436 is the ratio of moles of nitrogen to sulphur.

In order to determine the "cleaved sulphur" calibration must be performed. Fig. 2 illustrates the calibration curve prepared according to the procedure within a range of $2 \times 10^{-6}$–$3 \times 10^{-4}$ M. As was shown $SN_3^-$ was the final product of the cleavage of S–S bonds in the $S_8$-ring, $ISN_3$ was the catalyst of the i–a reaction and sulphates are the final form of deactivated sulphur. As free sulphur extraction is

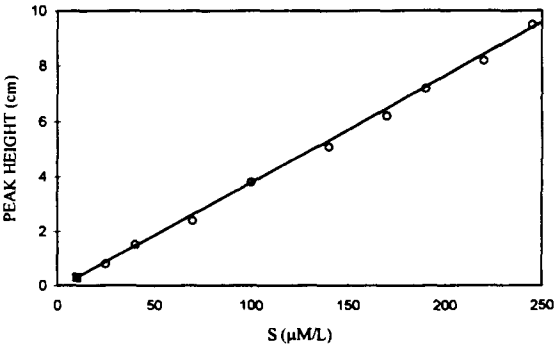

Fig. 2. Calibration graph for sulphur. ■, Reagent blank.

quantitative the precision of the catalytic method given in the Procedure section can be found for known concentrations of sulphur. Results are given in Table 1.

Sulphur was determined in rubber samples manufactured by STOMIL Poznań. Characteristics of rubber samples are given in Table 2 and results of the determinations of free sulphur as given in Table 3.

In the case of sample C, where only 0.4% of elemental sulphur was used for vulcanization, we expected that sulphur bridges would be formed quantitatively. The results do not confirm this prediction. Even in this sample small amounts of free sulphur were found. Our investigations confirm that solubility of sulphur in rubber increases with increasing temperature and, probably, in this state there is no free sulphur—the whole amount is combined. When cooling down the vulcanizate the solubility of sulphur decreases and part of the sulphur may crystallize again in the bulk of the rubber as elemental sulphur. After heating the rubber again new sulphur bridges may be formed from this sulphur. There is a dynamic equilibrium between free and combined sulphur and temperature is the most important parameter for this equilibrium.

Table 1
Results of the determination of elemental sulphur of known amount by the catalytic method

| Taken (μg) | Recovery (%) | Relative standard deviation (%) |
|---|---|---|
| 10 | 98.9 | 1.8 |

Determination of total sulphur in rubber is always preceded by mineralization of rubber. Rubber is one of the least mineralizable materials. All known methods of mineralization (1–6) are technically difficult to reproduce, time-consuming and require complex and expensive equipment. Judging by our experience we can say that application of microwave energy allows fast and quantitative mineralization of different kinds of rubber in a wide range of amounts (0.2–0.8 g). Although mineralization of rubber can be performed in a domestic microwave oven the microwave digestion unit used by us proved to be especially effective. Therefore good efficiency of mineralization of rubber using this apparatus is achieved due to a very high concentration of microwave energy in the sample and application of a self-focusing antenna arrangement which allows direct coupling of microwave energy into the pressure vessel.

Total sulphur in rubber samples A, B and C was determined by an indirect AAS method with a barium lamp and the results are given in Table 4. Earlier we used this technique to determine di-, tri- and tetrasulphides [35].

Combined sulphur in rubber, after free sulphur extraction, was determined in the same way as total sulphur and the results for rubber samples A, B and C are given in Table 5.

Because a "dynamic equilibrium" occurs in rubber between the amount of various sulphur compounds and elemental sulphur the real certified reference materials are not available. The results of the determination of total sulphur (Table 4) and combined sulphur (Table 5) obtained by the proposed AAS method are compared with a gravimetric method, which is a standard one for determining sulphate and is most frequently used to check the accuracy of

Table 4

| | 239.08 | 39.92 | 0.88 | 0.37 | 0.15 | 0.38 |

the newly developed method. We used a gravimetric method after combustion of rubber samples in oxygen by the well-known Schöniger technique.

The method proposed is simple and, as shown in Tables 4 and 5, the results are similar to those obtained by the gravimetric method. Its only drawback is the long time for $BaSO_4$ crystallization (up to 8 h), but it does not hinder serial analysis.

Results given in Tables 3–5 show that the calculated amounts of free and combined sulphur do not differ from the results of determinations by more than 6%. Therefore in determination of free, combined and total sulphur in rubber it is possible to perform only AAS determination of combined and total sulphur. In the case when only the free sulphur in rubber is determined, the catalytic method is chosen in our laboratory because it is very simple, and as accurate as AAS but less time-consuming.

## 5. Conclusions

Concentrations of free, combined and total sulphur in rubber should be controlled because mechanical and chemical properties of rubber depend strongly on these concentrations and their proportions. Application of microwave energy for mineralization of rubber and cleavage of sulphur bonds in the $S_8$-ring shortens these steps down to several minutes, simplifies the process and gives a yield of 100%. Analytical methods for determination of free (i–a catalysis with gas chromatography), total and combined sulphur (AAS) are simple, precise and inexpensive. The main drawback to this and all other free sulphur determination methods known from the literature is the long time necessary for extraction of sulphur from rubber.

**Abstract**

Two infrared spectroscopic methods, optothermal near infrared (NIR) spectroscopy and Fourier transform mid-infrared–attenuated total reflection (FTIR–ATR) spectroscopy, were applied to 24 cheese samples in order to obtain protein, fat and moisture contents. Reference values of the protein, fat and moisture contents in weight percent were obtained using standard wet chemistry analysis. Prediction correlation coefficients between 0.93 and 0.96 and standard errors of prediction between 2% and 5% were obtained using optothermal spectroscopy while the corresponding values for FTIR–ATR were 0.81–0.92 and 4–9%. Inhomogeneities in the cheeses, primarily due to the fat droplets, are probably the main reason for the differences in the error sizes. The superior results for optothermal spectroscopy are the more attractive because the instrument is easier to use than the FTIR–ATR instrument, it provides results more quickly with simpler statistical analysis and it is more compact and robust.

## 1. Introduction

Near infrared spectroscopy has been used more and more in the agricultural and food industries in recent decades. An excellent summary of the field is given by Williams and Norris [1]. In recent years it has become increasingly clear that the application of spectroscopic methods to food analysis can alleviate important problems in the processing and distribution of food and food products [2–4]. More recently the mid-infrared region has attracted considerable interest [5]. It is especially clear that quick, inexpensive, objective methods that do not require special skills on the part of the users are of greatest interest. The ideal case would be that small and medium-sized organizations could handle the spectroscopic instruments in direct connection with their food handling systems, obtaining measurement results in seconds or minutes so that processes could be adjusted and decisions taken quickly. Such smaller production units are not expected to have easy access to highly trained laboratory personnel or to be able to afford expensive and/or sophisticated equipment. Alternatively, quick methods can be used to screen large numbers of samples prior to more detailed analysis of specific samples when and where necessary. The optothermal near infrared (NIR) spectroscopic technique described here can be an appropriate method in some cases while for other applications the repeatability of the measurement results must be improved.

An example of an industry in which there is a large number of small medium-sized units processing food products is the cheese industry. There are several steps in the cheese-making process that can directly affect the amounts of fat, protein and moisture in the final products, for instance the step or steps in which the curds are separated from the whey. Further, it is known that because of its texture cheese is difficult to analyze spectroscopically using traditional methods. Fourier transform mid-infrared–attenuated total reflection FTIR–ATR and NIR optothermal analysis are two possible methods for determining fat, protein and moisture contents quickly and accurately as well as at reasonable expense to the cheese producer. Here these two methods are evaluated and the results discussed in terms of the morphology of the cheese samples.

It is known that cheeses (and other similar products) are not spatially homogeneous. For instance, the fat content in one part of a large cheese can be of the order of one percent different from that in another part of the same cheese. On another level, the cheese is very inhomogeneous on a submillimeter scale because of the relatively large fat globules. These conditions have to be taken into account in interpreting measurements of fat, protein and moisture contents of cheeses.

Fat globules in milk have diameters of the order of several microns, with wide variations [6]. The casein micelles are much smaller, of the order of 100 nm, and globular proteins are even smaller.

While there is a great deal of detailed information about the morphology of milk fat and other milk components, the situation is quite different concerning cheese, for which vanishingly little published data is available. However, it is felt that during coagulation there is no reason to expect changes in the sizes of fat globules, even if there can be damage to and surface modifications of the fat globule membrane during pasteurization before the cheese-making process. The fat globule membrane can be altered due to the acidity of the cheese starter or due to physical processing such as centrifugation or membrane processing. None of these factors is expected to reduce the sizes of the fat globules significantly. During ripening the activities of the lipases produced by the microorganisms of the starter modify the fat globule structure, increasingly changing the typical round shape of the globules. In some sufficiently aged cheeses the fat globules disappear to be replaced by aggregates of lipolized fat [7, 8]. Thus it appears that the extent of lypolysis is a prime determinant of the morphology of cheeses at the micron level. The morphologies of fresh cheeses are thus expected to be quite similar to that of the milk from which they were produced, while the aged cheeses may be somewhat less inhomogeneous on the micron scale.

## 2. The cheese samples

Twenty-four cheese samples were studied. Six samples each were obtained from sources in Portugal, UK, Denmark and Finland. They included six fresh cheeses, nine soft cheeses and nine hard cheeses. The widest possible range of cheese types was sought in order that fat, protein and moisture contents show the widest variations possible and so that cheese characteristics affecting the measurement techniques, for instance rheological and mechanical characteristics as well as morphology, be as clearly expressed as possible. However, no separate rheological, mechanical or morphological studies of the cheese samples were carried out.

## 3. Methods

### *3.1. Wet chemistry*

The wet chemistry analysis of the 24 cheese samples was carried out using standardized methods according to the Nordic Committee on Food Analysis. For each component and each cheese at least two samples were analyzed.

The protein contents were determined using the Kjeldahl method in which "The sample is digested with concentrated sulphuric acid, with the addition of potassium sulphate and copper(II) sulphate. The ammonia formed is distilled off with sodium hydroxide solution and collected in boric acid. The nitrogen content of the sample is then determined by titration with hydrochloric acid".

The fat content was determined according to the Schmid–Bondzynski–Ratslaff method in which "The sample is treated with 8 M hydrochloric acid and after addition of ethanol the liberated fat is extracted with a mixture of diethyl ether and petroleum ether. The solvent is then evaporated and the fat is weighed".

The moisture content was measured by drying the sample at 102–105°C for 16–18 h.

It is not possible to assess the accuracy and repeatability of the wet chemistry measurement results in detail. However, for six of the cheeses there are two independent evaluations of the fat contents. In each of the six cases the fat contents according to the two evaluations are different, for instance 31.4% fat and 32.5% fat for one cheese. The average absolute difference between six such pairs of samples is just over 1%. This number can be taken as an estimate of the probable repeatability of the wet chemistry measurements of protein and moisture as well as of fat.

The amount of effort required to analyze all 24 samples for protein, fat and moisture contents in this way was about 2 man weeks including all overheads and incidental costs.

### 3.2. Optothermal spectroscopy

Optothermal spectroscopy is a variation of photoacoustic spectroscopy, which has been described in the literature many times (see for instance Ref. [9]). The optothermal method itself has been described in published reports several times [10–12]. In principle the heat generated when light is absorbed by a sample is measured as a temperature change. The incident light, of the desired wavelength, is chopped at an appropriate frequency (here at 2 Hz) so that the measured temperature changes vary synchronously with the light intensity. This makes sensitive phase-locked detection possible. The wavelengths used are defined by broad bandpass filters, in this case at 1740 nm (bandwidth 75 nm), 1935 nm (bandwidth 110 nm) and 2180 nm (bandwidth 100 nm).

The sapphire surface on which the sample is placed is mounted on the top of the small self-contained optothermal instrument (external dimensions 300 mm × 260 mm × 115 mm). After selection of the appropriate filter the instrument is activated and the sample illuminated with 2 Hz chopped light for about 20 s. The average signal strength and phase are calculated for the last 15 s and the result is presented on a digital display. It is important that good thermal contact is made between the cheese sample and the sapphire as the temperature measurement is dependent on diffusion of the heat generated in the cheese sample to the thin sapphire disc. In practice sufficiently good contact is easily achieved.

The present experiments were carried out as follows. On day one a small piece (about 0.25 $cm^3$) of each cheese sample was applied to (pressed or smeared onto) the sapphire. Each piece was measured three times, first using the 1740 nm filter, then the 1935 nm filter and finally the 2180 nm filter, 20 being taken to complete a single measurement. It took less than 10 min to complete the measurements, change the filters and record the results on each piece of cheese. Application of a new piece of cheese took about 1 or 2 min. In all it took about 4 h to analyze the 24 cheese samples. The averages of the three measurements at each wavelength were then calculated. In general the standard deviation of the individual measurements was under 2% of the measured value. The procedure was repeated on day three and day five using different small pieces from the cheese samples. In the end this produced 3 × 72 data points for the 24 cheeses (one for each of the three wavelengths and each of the three days), each data point being the average of three measurements.

A separate experiment was carried out to assess the effect of poorly applied samples, that is, what the result of poor thermal contact between the cheese sample and the sapphire surface might be. As expected, poor thermal contact results in reduced signal strengths at each of the three wavelengths used. Somewhat contrary to expectations, for this poor thermal contact to become evident the cheese samples had to be very badly applied to the sapphire surface. This may be because of the low chopping frequency used, 2 Hz, for which the thermal diffusion length is more than a tenth of a millimeter in water and in excess of a millimeter in air.

### 3.3. FTIR–ATR spectroscopy

The 24 samples were also analyzed using FTIR–ATR spectroscopy. All spectra were acquired on a Spectra-Tech MONITIR system equipped with a horizontal ATR accessory with 45° zinc selenide element. The wavenumber region used was 5000–400 $cm^{-1}$, corresponding to wavelengths between 2 μm and 25 μm. To obtain the spectra 256 interferograms were added together before Fourier transformation, this process requiring about 3 min. Triangular apodization was used and the resolution was 8 $cm^{-1}$.

The ATR method is an established technique and has been described in the literature many times (see for instance Ref. [9]). It depends on the fact that even when light is totally internally reflected there is some non-radiative penetration of the electromagnetic field into the low refractive index medium, that is, the sample. Since the sample is optically absorbing the reflected light is correspondingly weaker. In the case of zinc selenide and 45° incidence the penetration depth of the light is somewhat more then a tenth of a wavelength (as measured in air) and only weakly dependent on the optical absorption. In the present case the penetration depth is between about 0.2 μm and 5 μm. A recent investigation of this technique applied to dairy cream is given by Kemsley et al. [3].

In the experiments each cheese was carefully cut open and a sample taken from the center. The sample was applied to the ATR element and spread across the entire surface using a soft spatula. The cheese was worked gently with the spatula to ensure complete coverage, the hard cheeses requiring somewhat more physical pressure than the soft ones to insure good contact with the crystal. After spectral acquisition the ATR element was cleaned with tissue followed by water, 0.2% Triton X100 and water before drying. A new single beam reference was collected before each sample was measured. The time required from completion of a measurement on a given sample to completion of the corresponding measurement on the next samle was about 10–12 min. In total the measurements on all 24 samples required about 8 h work including start up time, instrument adjustments and cleaning.

## 4. Results

The measurement results were analyzed statistically using principal component analysis and multicomponent regression techniques. The work was carried out using Unscrambler software from Camo AS, Norway. Initially the wet chemistry results (protein, fat and moisture contents) were taken as the reference data. The spectroscopic data were regressed against the wet chemistry data and calibration formulae were developed. These calibration formulae were then applied to the original spectroscopic data to produce "calculated" protein, fat and moisture contents for the cheese samples. These calculated protein, fat and moisture contents were then plotted against the corresponding wet chemistry values.

Cross validation was used to test the reliability of the calibration formulae because on considering the wide range of properties and the variations in morphological structure 24 samples is too small to be divided into calibration and prediction sets. During the cross validation procedure each sample in turn was deleted from the sample set and predicted using the calibration formula extracted from the rest of the sample set.

### 4.1. Optothermal measurements

In the case of the optothermal measurements there are three data points per sample per day, which should be enough to determine the fat, protein and moisture contents of each cheese sample. In fact, as the sum of the protein, fat and moisture contents must be near 95 wt.%, the system is slightly over-determined.

Inspection of the raw data revealed that data for one cheese sample, # 19, on day three were unusual and inconsistent with the measurement results for day one and day five. Therefore sample # 19 was deleted from the analysis.

First, a straightforward multicomponent regression using the least-squares method of optimization was applied to the data. This produced calibration formulae which were then used to calculate protein, fat and moisture contents for each cheese. The results were regressed against the wet chemistry data using simple linear regression formulae. As would be expected, the correlation coefficients, $r$, obtained in this way were rather low, around 0.85. Our conclusion is that such a straightforward least-squares approach is inappropriate in this case.

Next, more sophisticated statistical methods using Unscrambler software (mainly partial least squares, PLS1) were applied to the data, and new calibration formulae were developed. These were used to produce new calculated protein, fat and moisture contents, which were again regressed against the wet chemistry data. The results are much better than those obtained using the simple least-squares criterion. When 24 data points (less the outlier # 19) are used correlation coefficients of 0.93–0.97 are obtained.

For protein the variable protein content ranged from 6% to almost 30%, as shown in

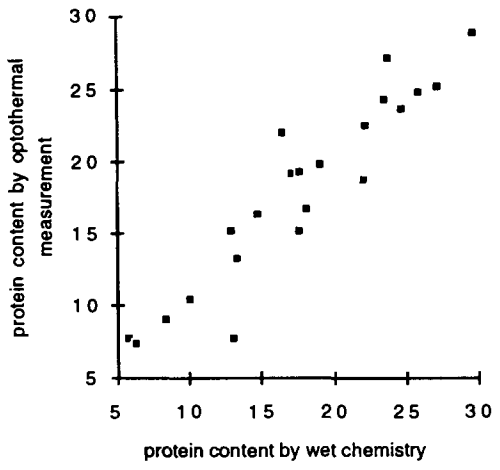

Fig. 1. Protein content (weight percent) of cheeses (sample 19 excluded) according to the optothermal method versus wet chemistry. Correlation coefficient 0.94 and standard error of prediction 2.4. The typical repeatability of the optothermal results is ±1.5 units.

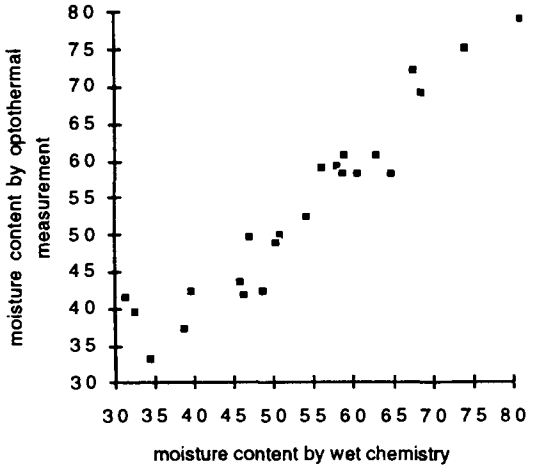

Fig. 3. Moisture content (weight percent) of cheeses (sample 19 excluded) according to the optothermal method versus wet chemistry. Correlation coefficient 0.96 and standard error of prediction 3.9. The typical repeatability of the optothermal results is ±2.5 units.

Fig. 1. Of course this is a much wider range of protein contents (and cheese types) than any ordinary producer of cheese is likely to have to deal with in a single plant. The same is true for the fat contents plotted in Fig. 2, which ranged from zero to 41%, and for the moisture contents shown in Fig. 3 which varied from just over 30% to in excess of 80%. It is entirely possible that regressions limited to certain types of cheese can produce results with less data scatter, but such sample sets were not available for this study. The repeatabilities given in the figure captions are based on comparisons between regression results for day one, day three and day five and correspond to roughly one standard deviation.

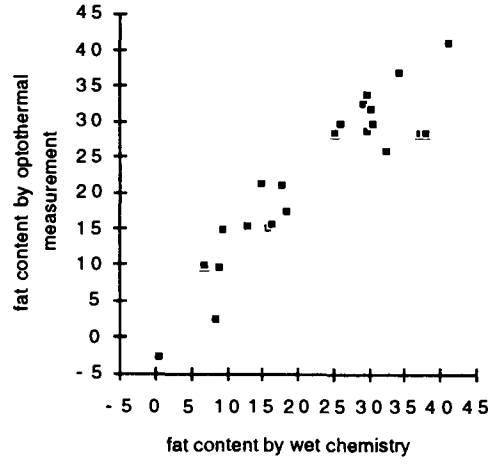

Fig. 2. Fat content (weight percent) of cheeses (sample 19 excluded) according to the optothermal method versus wet chemistry. Correlation coefficient 0.93 and standard error of prediction 4.4. The typical repeatability of the optothermal results is ±2.5 units.

Table 1 summarizes the statistical analysis results (24 cheeses in all) for both the model and the predictions. Comparison of the two indicates that the calibration formulae are quite stable. The reasons for the scatter in the data are several, of course. Among them are the following.

*4.1.1. Limited instrument reproducibility*

This is mainly due to electrical noise in the signal that the instrument analyses. The observed reproducibility of the instrument's response to a given constant input in this type of application is about 1.5% of the signal strength as estimated from over 200 groups of three measurements each on these samples. A more modern version of the instrument has better signal reproducibility.

*4.1.2. Sample application*

As noted above, variations in the thermal contact between the sample and the sapphire affect the signal strengths. For a given sample a reduction of signal strength due to a slight gap between the sample and the sapphire should affect all measurements proportionately. Typically this variation from piece to piece of the same cheese sample is about ±10% or less of the measured signal strength. The regression analysis minimizes this effect by mainly making use of the relative strengths of the signals at the different wavelengths. The effect is not com-

Table 1
Summary of statistical analysis results for optothermal data on 24 cheeses

| | Correlation of the calibration | Standard error of calibration | Correlation of the prediction | Standard error of prediction | Outliers deleted |
|---|---|---|---|---|---|
| Protein | 0.96 | 2.1 | 0.94 | 2.4 | #19 |
| Fat | 0.95 | 3.7 | 0.93 | 4.4 | #19 |
| Moisture | 0.97 | 3.4 | 0.96 | 3.4 | #19 |

pletely eliminated, however, and it is more evident with the hard cheeses than with the soft ones.

*4.1.3. Temperature variations*

The temperatures of the cheese samples on the sapphire can vary and affect the measurement results because the different absorption lines change differently with temperature. In the instrument used in this investigation this effect cannot be compensated for.

*4.1.4. Sample inhomogeneity*

Cheese samples are not perfectly homogeneous on the scale of these measurements. For wet chemistry analysis a piece of cheese of the order of 1 g is used (about 5 g for moisture, 2 g for fat and 1 g for protein), while in the optothermal analysis the sample interrogated corresponds to about 1 mg. Clearly, to obtain appropriate averages using the optothermal method several pieces from each cheese sample should be analyzed and the results averaged. The statistical data analysis above shows that this averaging procedure produces more representative values than do single measurements.

*4.1.5. Errors in wet chemistry values*

However carefully the wet chemistry measurements are carried out, there are residual errors in the results. These errors contribute to the reported data scatter when the optothermal results are plotted against the wet chemistry values.

*4.1.6. Nonlinearities*

Because of the relatively wide range of protein, fat and moisture values nonlinearities in the relationships between the optothermal measurement results and the wet chemistry data are to be expected. However, the calibration and analysis procedures are based on linear relationships only. This simplification is expected to lead to less than perfect fitting of the data.

*4.2. FTIR–ATR*

Because the diameters of the fat globules are of the same order of magnitude as the penetration depth of the light in ATR measurements relatively large variations in signal strengths from measurement are expected, the sample being inhomogeneous at this level and the total measurement volume being small.

The data were analyzed in the wavelength interval 3760–1520 $cm^{-1}$ (corresponding to 2.6–6.6 μm). First a multiplicative scatter correction (Unscrambler software) was applied to the data. Thereafter ten point averages were formed to reduce noise and the complexity of the calculations. Thus each spectrum contained 224 data points.

Application of the Unscrambler software (PLS2) produced regression formulae and predicted protein, fat and moisture contents corresponding to those for the optothermal results. For protein the result was a correlation coefficient of 0.82 and a standard error of prediction of 3.7 using six principal components. The corresponding numbers for fat and moisture are 0.78 and 0.93 for the correlations and 6.6 and 4.5 for the standard errors of prediction using eight and six principal components respectively. At this point the outliers (as "proposed" by the Unscrambler software) were deleted (for protein sample #1, for fat samples #1, #4, #9, #13, #15, #16, #21 and #22 and for moisture samples #1 and #17). The fresh cheeses are over-represented among the deleted outliers. Table 2 summarizes the statistical results where PLS2 was used for protein and moisture and PLS1 was used for fat since the number of samples was only 16. Comparison of the model and prediction results shows that the calibration formulae are unstable. Somewhat surprisingly, for this FTIR–ATR data elimination of the outliers produced somewhat lower correlation coefficients and larger standard errors of prediction. In the case of the

Table 2
Summary of statistical analysis results for FTIR–ATR data on 24 cheeses

| | Correlation of the calibration | Standard error of calibration | Correlation of the prediction | Standard error of prediction | Principal components | Outliers deleted |
|---|---|---|---|---|---|---|
| Protein | 0.97 | 1.9 | 0.81 | 4.4 | 6 | 1 |
| Fat | 0.99 | 1.4 | 0.64 | 9.1 | 8 | 8 |
| Moisture | 0.99 | 2.2 | 0.92 | 5.4 | 6 | 2 |

fat content, where eight samples were deleted, this is because the deleted samples had either very low or very high fat contents. Thus the range of fat contents was reduced by elimination of the outliers.

In both the optothermal results and the FTIR–ATR results the largest standard error of prediction is for fat and the smallest is for protein. Furthermore, for all three components the standard errors of prediction are much larger for the FTIR–ATIR results than for the optothermal results. This supports the proposition that the greatest inhomogeneities on the micron level are for the fat contents, rather than for the moisture contents or the protein contents.

Another reason for scatter in the data could be the fact that fat can preferentially adsorb to the ZnSe ATR crystal. Depending on the nature of the cheese sample this effect can be larger or smaller for different cheeses, thus introducing errors in the measurements. In contrast, there is no evidence for such preferential adsorption onto sapphire.

Other sources of error can be limited instrument reproducibility, temperature variations and errors in wet chemistry values, as discussed above in connection with the wet chemistry results.

## 5. Discussion and conclusions

The above results and analysis indicate clearly that the optothermal method is superior to the FTIR–ATR method for determining the fat, protein and moisture contents of cheeses for several reasons. For prediction the correlation coefficients are significantly higher and the standard errors much smaller for the optothermal results than for the FTIR–ATR results (before and after deletion of the FTIR–ATR outliers). It is quite possible that even better prediction accuracy would have been achieved for optothermal data had the morphological structures of the cheeses not varied so much. The measurements can be made more quickly on the optothermal instrument than on the FTIR–ATR instrument and the data analysis is far less complicated, resulting in a simple regression formula for interpreting the measurement results. Finally, we showed that the quality of sample application to the measurement surface is not as critical for the optothermal method as it is for the FTIR–ATR method. Table 3 summarizes some of the more important characteristics of the three analysis methods used in this investigation.

We found that in the statistical analysis of the optothermal data the Unscrambler software produced much more satisfactory results than did simple least-squares regressions using three variables. However, the limited number of cheese samples precluded more detailed analysis of, for instance, soft cheeses as opposed to hard cheeses or cheeses with low moisture contents as opposed to those with high moisture contents. Further, the limited repeatabilities of the measurement methods make more sophisticated statistical analysis of the present data inappropriate.

Sample homogeneity is already known to be critical for satisfactory performance of both the FTIR–ATR method and the optothermal method. To make progress in understanding the effects of sample inhomogeneity on the measurement results one has to describe the scale of the inhomogeneity in question. In the case of cheese, inhomogeneities on a micron scale are expected primarily because of the fat globules. This is the same scale as the penetration depth of the light into samples in the case of FTIR–ATR, while it is one to two orders of magnitude smaller than the penetration depth in optothermal spectroscopy at a chopping frequency of 2 Hz.

Sample inhomogeneity can also occur on large scales, of course, and it is known that the

Table 3
Summary of several important characteristics of the different analysis methods

| Characteristic | FTIR–ATR | Optothermal method | Wet chemistry |
|---|---|---|---|
| Total time to collect data on 24 cheese samples | 8 h | 4 h | 60–80 h |
| Time to complete measurement on a sample | 10–12 min | 10 min | One method per component with various calibrations and references required |
| Time to obtain a spectrum | 3 min | 3 × 20 s | |
| Calibrations, references | Clean element, remount, collect new reference | Absolute calibration against black stable over long time | Various chemicals required |
| Wavelengths/numbers resolution | 5000 $cm^{-1}$ to 400 $cm^{-1}$ at 8 $cm^{-1}$ resolution | 3 wide band filters (ca. 100 nm) at 1740, 1935 and 2180 nm | |
| Data analysis method | Unscrambler PLS2 | Unscrambler PLS1 | Component by component analysis |
| Data interpretation | Regression formulae with six to eight principal components | Regression formulae with three components | |
| Size of instrument | 60 × 45 × 25 cm ca. 30 kg | 30 × 26 × 12 cm ca. 5 kg | Chemical laboratory required |

fat content of a large cheese can vary by several percent depending on where the sample is extracted from the cheese. The only way to form an appropriate average here is to take samples from different parts of the cheese and combine the results, perhaps using appropriate weighting factors. Since wet chemistry analysis typically makes use of samples weighing of the order of grams only, the large scale inhomogeneity of cheeses has roughly the same effect on wet chemistry results as it does on the spectroscopy results.

Since the optothermal technique is easy to handle and provides results so quickly it could be used to study the fat, protein and moisture contents of cheeses before and during their ripening in cheese factories, making it possible to steer the ripening process toward desired results. Alternatively, the optothermal method can be appropriately applied when reasonably fast screening of large numbers of samples is necessary before possible detailed analysis of suspect samples by wet chemistry, for instance. In either case it is desirable that the repeatability of the measurement results be improved. Instrumental improvements have been made subsequent to the measurements reported here and improved repeatability is expected (although it has not yet been demonstrated).

One could consider homogenizing cheese samples prior to analysis in FTIR–ATR instruments in order to get around the problem of the large fat globules, but this is not easily done for cheese and it would complicate the analysis procedure. In contrast, milk, cream and related products can be homogenized relatively easily and can thus be prepared for analysis by FTIR–ATR instruments. This is not necessary when using the optothermal method. It is expected that the optothermal method could be used to determine fat, protein and moisture contents for a large variety of milk products without pretreatment. Examples include milk, cream, sour cream, butter, mayonnaise, yoghurt and quark.

Finally, we should like to point out that wet chemistry analysis automatically means that the used chemicals must be disposed of in an environmentally acceptable manner, not always a simple matter. Spectroscopic methods

do not produce environmentally unacceptable waste.

Received 15 May 1995; accepted 10 July 1995

**Abstract**

Several papers have appeared in the literature describing the determination of antimony, where antimony(V) is extracted into the organic phase and the organic solutions directly analyzed by atomic absorption spectrometry (AAS). This paper describes a procedure where antimony from the organic solution is reductively stripped into an aqueous phase and analyzed for antimony by AAS. The advantage of the method for a routine process control laboratory is highlighted.

*Keywords:* Antimony; Lead–zinc concentrates; Smelter products; Atomic absorption spectrometry

## 1. Introduction

Determination of antimony by atomic absorption spectrometry (AAS) has been fairly comprehensively covered in the literature [1–6]. Donaldson [1] developed several methods for the determination of small amounts of antimony in copper, nickel, lead, zinc and molybdenum concentrates and related materials. These methods involve preliminary separation of antimony(III) from the matrix element by co-precipitation with hydrous ferric and lanthanum oxides. The precipitate is dissolved in dilute hydrochloric acid and the antimony determined either by AAS or, if the sample contains $<100\ \mu g\ g^{-1}$ of antimony, by the spectrophotometric iodide method after further separation from iron, lead and other coextracted elements by chloroform extraction as antimony xanthate. Although these methods yield accurate results for antimony, they are time-consuming, particularly the spectrophotometric method, and the AAS method is not applicable to samples with high lead and iron contents.

Methods have also been employed by several workers in which antimony is extracted by organic solvents from hydrochloric acid solutions and the antimony content determined by aspirating the organic phase into the flame [3–6].

Although analyzing the organic solutions helps to achieve increased sensitivity leading to determination of smaller quantities [2], a few problems ae faced in using this technique. The liquid trap should be drained of the water, and filled with organic solvent. While feeding the organic solution, the fuel content has to be kept low to avoid a sooty flame and the flame tends to flare violently unless the fuel and air are tightly controlled. This leads to unstable conditions and fluctuating results. Especially in

a process control laboratory, the analyst would feel more comfortable feeding aqueous solutions for quick analysis. Recently a paper [7] was published from our laboratories wherein thallium was determined in our process solutions and in zinc and cadmium metals by first extracting thallium into isopropyl ether and then stripping back to the aqueous phase using a sodium sulphite solution.

We have now also worked out a procedure for the determination of antimony on similar lines and applied it to lead and zinc smelter products. The procedure involves suitable decomposition of the sample and taking up the salts in 7.5 M hydrochloric acid. Sodium nitrite is added to oxidise antimony(III). The chloro-complex of antimony(V) is extracted with isopropyl ether, antimony is stripped from the organic phase to the aqueous phase with sodium sulphite solution and the stripped solution is analyzed for antimony.

## 2. Experimental

### 2.1. Apparatus

An Electronic Corporation of India model 4103-B atomic absorption spectrometer is used under the following conditions: wavelength, 217.6 nm; spectral band width, 0.2 nm; current, 10 μA; flame, air–acetylene.

### 2.2. Reagents

All chemicals used were of analytical grade.

#### 2.2.1. Standard antimony solution

Pure antimony metal (1 g) is heated with 10 ml of concentrated sulphuric acid in a 250 ml beaker until dense white fumes are evolved. Hydrazine sulphate (1 g) is added after cooling and the solution heated again until dense white fumes are evolved. The beaker is then cooled in ice water. 100 ml of 2 M hydrochloric acid is added and the mixture allowed to attain room temperature. The contents of the beaker are transferred to a 1 l standard flask and made up to the mark with 2 M hydrochloric acid. The solution contains 1 mg $ml^{-1}$ of antimony and is suitably diluted with 7.5 M hydrochloric acid to obtain a 100 μg $ml^{-1}$ solution.

#### 2.2.2. Sodium sulphite solution (0.5% w/v)

Anhydrous sodium sulphite (0.5 g) is dissolved in 100 ml of water.

#### 2.2.3. Sodium nitrite solution (25% w/v)

Sodium nitrite (25 g) is dissolved in 100 ml of water.

### 2.3. Procedures

#### 2.3.1. Calibration

To 30 ml of 7.5 M hydrochloric acid in each of six 125 ml separating funnels 0.0, 1.0, 2.0, 3.0, 4.0 and 5.0 ml of antimony working standard (0–500 μg) solutions are added from a semimicroburette. Sodium nitrite (1 ml) followed immediately by 20 ml of isopropyl ether are added to each separating funnel. The separating funnels are shaken gently for 1 min and the layers are allowed to separate. The lower aqueous layers are transferred to another set of separating funnels containing 10 ml of isopropyl ether and once again shaken for 1 min. The lower aqueous layers are discarded and the organic layers added to the first set of separating funnels.

Sodium sulphite (20 ml) is added to each separating funnel containing isopropyl ether and shaken for 3 min. The layers are allowed to separate.

The aqueous layers are collected in 50 ml volumetric flasks. The organic layers are further shaken with a small portion (10 ml) of sodium sulphite solution and the aqueous portions collected in the same volumetric flasks. The solutions are made up by the addition of the required quantity of water. The aqueous solutions are then analyzed by AAS for antimony. The absorbance of the blank (zero added antimony), if any, is deducted from the absorbance values of the standards.

### 2.4. Sample treatment

Depending upon the antimony content, 0.5–1.0 g of sample is placed in a 250 ml beaker. Potassium bisulphate (1 g) and concentrated sulphuric acid (10 ml) are added and the beaker is heated until dense fumes are evolved (1 h). The beaker is cooled and the walls are washed down with a small quantity of water (10 ml). Hydrazine sulphate (1 g) is added and the beaker is heated again until dense white fumes are evolved. The beaker is cooled in the water, 20 ml of 7.5 M hydrochloric acid is

Table 1
Analytical results obtained for lead–zinc concentrates and other related products

| Sample | Antimony [a] found % (present method) | Standard deviation | Certified antimony value and range, % | Antimony found by AAS method [1] % |
|---|---|---|---|---|
| Zinc concentrate CZN-1 | 0.052 | 0.0005 | 0.052 (0.052–0.054) | 0.053 |
| Zinc concentrate (Zawar mines) | 0.0084 | 0.0010 | – | – |
| Zinc concentrate (Agucha mines) | 0.0100 | 0.0004 | – | 0.0105 |
| Lead concentrate (Agnigundala Mines) | 0.0058 | 0.0005 | – | – |
| Lead concentrate (Sargepalli mines) | 0.1150 | 0.002 | – | 0.1156 |
| Sludge (Zinc Oxide Plant) | 0.0430 | 0.002 | – | – |
| Moore Cake | 0.0380 | 0.0007 | – | – |

[a] Average of five results.

added and the beaker warmed just enough for the salts to dissolve and then cooled. The contents of the beaker are transferred directly to a 125 ml separating funnel. The sides of the beaker are washed with small portions (5 ml at a time) of 7.5 M hydrochloric acid and the washings transferred to a separating funnel. The solution is processed as described under *Calibration* starting from the addition of sodium nitrite. Antimony in the sample is determined in the aqueous phase by comparing with processed standards.

Note: For samples containing more than 600 $\mu g\ g^{-1}$ of antimony, 1.0 g of the sample is processed and the contents are transferred to a 100 ml standard flask and made up to the mark with 7.5 M hydrochloric acid. A suitable aliquot is taken and processed as described above.

## 3. Results and discussion

Table 1 gives the results obtained for antimony in lead–zinc concentrates and other related products. The values for CANMET CZN-1 (zinc concentrate) are comparable with certified values. The values were checked by Donaldson's iron–lanthanum collection/AAS method for zinc concentrate (Agucha mines) and lead concentrate (Sargepalli mines).

The results show that the recommended method can be conveniently applied for the determination of antimony in lead and zinc concentrates and its related products. The values were found to be stable over a period of one week. An analyst can comfortably complete the analysis of 6–8 samples by this method in less than 8 h (one shift).

### 3.1. Selection of organic solvent

Methyl isobutyl ketone (MIBK), *n*-butyl acetate and isopropyl ether are the most common solvents employed in the estimation of antimony. While the extraction of antimony from hydrochloric acid solution into these solvents is quantitative, it was observed that stripping of antimony with sodium sulphite from these solvents did not yield quantitative recoveries. From MIBK, antimony could not be stripped at all, while with *n*-butyl acetate small losses were suspected. Recoveries obtained were about 95% only. With isopropyl ether, the stripping was quantitative and moreover the phase separation was much better than with *n*-butyl acetate. Hence isopropyl ether was preferred in the present work.

# Correction of iron interface in the spectrophotometric flow injection catalytic determination of molybdenum in plants

Elma Neide Vasconcelos Martins Carrilho, Francisco José Krug *, Elias Ayres Guidetti Zagatto

*Centro de Energia Nuclear na Agricultura, Universidade de São Paulo, P.O. Box 96, 13400-970 Piracicaba, São Paulo, Brazil*

Received 12 April 1995; revised 5 July 1995; accepted 7 July 1995

**Abstract**

Iron interference in the spectrophotometric catalytic determination of molybdenum based on the iodide–hydrogen peroxide reaction can be corrected by using sulphosalicylic acid as masking and color-forming reagent. The catalytic influence of iron ions is circumvented to the extent of about 90% and correction of any remaining iron ions is possible by monitoring the colored iron(III)–salicylate complex at 490 nm. In this way, iron is also determined. With the proposed system, molybdenum can be determined in plant and food digests within the 0–100 μg Mo $l^{-1}$ range in the presence of up to 25 mg Fe $l^{-1}$, at a sampling rate of about 50 determinations $h^{-1}$. The relative standard deviation of 10 consecutive measurements was estimated as < 2%. Results for samples were comparable with those obtained by graphite furnace atomic absorption spectrometry. In addition, recoveries within the range 94–100% were calculated.

*Keywords:* Iron interference; Molybdenum determination; Sulphosalicylic acid; Flow injection; Plants

## 1. Introduction

Molybdenum is an essential nutrient for animals and plants and its determination in plant, soil and food materials is of utmost importance. Nevertheless, only a few well-equipped laboratories accomplish molybdenum determination on a routine basis. In general, molybdenum occurs in low concentrations in plant [1,2] (0.5–3.0 mg $kg^{-1}$) and food materials, which makes the direct determination in the sample digest by simple techniques such as classical spectrophotometry and flame atomic absorption spectrometry difficult. Although an automated spectrophotometric flow injection procedure based on the thiocyanate method with solvent extraction was developed in this laboratory [3], alternative methods exploiting kinetic catalysis have also been investigated [4–6].

The spectrophotometric method based on the catalytic effect of Mo(VI) ions in the oxidation of iodide by hydrogen peroxide [4] has been suggested to be very promising for the determination of molybdenum in biological materials [5–7]. The produced triiodide ion is spectrophotometrically monitored under the same conditions for the catalytic (presence of molybdenum) and non-catalytic (blank) reactions, and the difference between the absorbance signals is proportional to the molybdenum content in the sample. However, selectivity appears to be the main limitation, as other ions have similar catalytic properties. Svehla and Erdey [8] pointed out that interferences of several chemical species in the iodide–

*SSDI* 0039-9140(95)01688-0

hydrogen peroxide reaction were mainly due to the different reaction rates for triiodide formation in the presence and absence of molybdenum.

This indicator reaction has been used in continuous flow systems for molybdenum determination in plant digest by different procedures, but prior iron separation by precipitation as hydroxide [5], on-line iron separation with ion exchange resin [6], or solvent extraction [9] have been needed. Masking agents for iron, such as fluoride in air-segmented flow systems [10], and sulphosalicylic acid in flow injection amperometry [11], have also been recommended.

The aim of the present paper is to describe an alternative procedure for the spectrophotometric catalytic determination of molybdenum by using a flow injection system that does not require previous iron separation or on-line molybdenum concentration. Amongst the several reagents evaluated in the present work, sulphosalicylic acid proved to be suitable for the determination of molybdenum in the presence of iron.

## 2. Experimental

### 2.1. Apparatus

The equipment consisted of a model 432 Femto spectrophotometer (São Paulo, Brazil) furnished with a tubular flow cell (12 mm optical path, 70 µl inner volume) from the same manufacturer and coupled to a REC 61 Radiometer recorder, an Ismatec mp13R peristaltic pump with Tygon tubes, and other accessories.

A manual sliding bar injector with two commutation sections [12], 0.5 mm i.d. Tygon microbore tubing (Norton Performance Plastics), and y-connections made from perspex were used to build the manifold.

### 2.2. Reagents, standards and samples

All chemicals were of analytical-grade quality and freshly distilled–deionized water was used throughout.

A 1000 mg $l^{-1}$ molybdenum stock solution was prepared by dissolving 0.9201 g of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ in 500 ml of 1% v/v HCl.

Working standard solutions (0.0–100.0 ng Mo $ml^{-1}$) were prepared in 0.1% v/v nitric acid by appropriate dilutions of the stock solution. For selectivity evaluation, solutions with 5.0–50.0 mg Fe $l^{-1}$ ($Fe_2O_3$), 1.0 mg V $l^{-1}$ ($NH_4VO_3$), 10.0 mg Cr $l^{-1}$ ($K_2CrO_4$), 500 mg Mg $l^{-1}$ ($MgSO_4 \cdot 7H_2O$), 500 mg Al $l^{-1}$ ($AlCl_3 \cdot 6H_2O$), 500 mg P $l^{-1}$ ($Na_2HPO_4$) or 1000 mg Ca $l^{-1}$ ($CaCO_3$) were also prepared in 0.1% v/v nitric acid.

Potassium iodide solution 2.0% w/v ($R_1$, Fig. 1) was prepared by dissolving 2.5 g KI in 100 ml of water and hydrogen peroxide solution 0.025% v/v ($R_2$, Fig. 1) was prepared daily from a 30% $H_2O_2$ solution. The sample carrier stream (C, Fig. 1) was a 0.1% v/v nitric acid solution.

A 0.1 M sulphosalicyclic acid solution (M, Fig. 1) was prepared by dissolving 2.54 g $C_7H_6O_6S \cdot 2H_2O$ in 100 ml of water.

Biological samples were dry ashed according to the following procedure. 2.000 g of ground (60 mesh) and oven-dried (60°C to constant weight) samples was ashed in a porcelain crucible for 4 h at 550°C. The ash was moistened with a few drops of water and 10 ml of 4 M nitric acid was added; the mixture was then dried at 60°C. The residue was taken up with successive portions of 10–15 ml of 0.1 M nitric acid solution, filtered through Whatman filter paper into a 100 ml volumetric flask, and made up to volume with the same acid. Before using, the solution was left to stand for about 12 h.

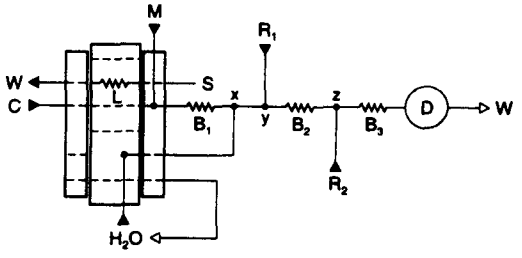

Fig. 1. Diagram of the flow set-up for molybdenum (and iron) determination. $B_1$, $B_2$ and $B_3$ = 10, 20 and 250 cm reaction coils; D = spectrophotometer at 350 nm for molybdenum and/or 490 nm for iron; S = sample, aspirated at 2.6 ml $min^{-1}$; L = sampling loop (200 µl); $R_1$ = 0.025% v/v hydrogen peroxide solution at 0.4 ml $min^{-1}$; $R_2$ = 2.5% w/v potassium iodide solution at 0.8 ml $min^{-1}$; M = 0.1 M sulphosalicylic acid flowing at 0.3 ml $min^{-1}$; W = waste; x, y and z = confluence points; C = sample carrier stream (0.1% v/v $HNO_3$) at 1.6 ml $min^{-1}$; $H_2O$ = water at 2.6 ml $min^{-1}$.

### 2.3. The flow injection system

With the system in the situation depicted in Fig. 1, the sample is continuously aspirated to fill the sampling loop, and the sample carrier stream and reagents are continuously flowing towards detection. Water flows to improve system washing by dissolving any triiodide adsorbed in the inner walls of the analytical path. After introducing the selected sample volume into the sample carrier stream, the water stream recycles in its reservoir. The masking agent is added via a confluence point located in the commutator at a suitable flow rate to avoid excessive dispersion-dilution of the sample zone in the $B_1$ reactor where the masking reaction takes place. The same criterion was used for predefining $R_1$ and $R_2$ flow rates and to provide suitable mixing conditions inside the $B_2$ and $B_3$ helical coils. Thereafter, the sample zone passes through the detector where the absorbance at 350 nm is measured for molybdenum (plus unmasked iron) and at 490 nm for the iron–salicylate complex. The system was dimensioned to provide the best figures of merit for molybdenum. For iron determination at 490 nm, further system optimization was not carried out because the sensitivity was already suitable.

### 2.4. Figures of merit

The detection limits for molybdenum and iron were determined after 20 consecutive measurements of the blank solution (0.1% v/v nitric acid) according to IUPAC [13]. The accuracy for molybdenum determination was assessed by analyzing the same digestes by graphite furnace atomic absorption spectrometry in a Varian SpectrAA40 coupled with a GTA-96 furnace with pyrolytically coated graphite tubes and controlled by a DS-15 Date Station from the same manufacturer. The heating programme was adjusted accordingly. Accuracy assessment for iron determination was made with flame atomic absorption spectrometry with an air–acetylene flame.

## 3. Results and discussion

Concentrations of hydrogen peroxide (0.025% v/v) and potassium iodide (2.5% w/v) and the final pH of the reaction medium were selected by taking into account the ratio between catalytic and non-catalytic signlas and the detection limit. Although the catalytic reaction rate increased with the concentrations of either hydrogen peroxide or potassium iodide, the non-catalytic signal (baseline) also increased. Similar behavior was observed earlier [5].

The pH of the reaction mainly affects the non-catalyzed reaction, i.e. it does not limit sensitivity for reaction pH values lower than two, and the lower the pH value the lower the baseline signal. Therefore, during sample pretreatment it was decided that the final acidity of the digest should be 0.1% v/v nitric acid. To avoid pH gradients along the sample zone, the same acid solution was used as carrier stream. In doing this, the pH of the solution leaving the flow cell was about 1.6.

Preliminary experiments were carried out with several masking agents for iron. Tartrate, citrate, triethanolamine, pyrophosphate and oxalic acid minimized or even suppressed the interference of up to 15 mg $Fe\,l^{-1}$ in the determination of 100 μg $Mo\,l^{-1}$, but they also affected the catalytic reaction. Similar behaviour was observed with a 0.05% w/v sodium fluoride solution which caused a 90% decrease in iron interference and also affected the catalytic reaction rate leading to a 40% lowering in sensitivity. Higher fluoride concentrations did not improve the masking efficiency significantly, but decreased the reaction rate more than proportionally.

Sulphosalicylic acid provided 85% masking efficiency, but with two advantages when compoared with fluoride and other iron-forming complexes. It did not change the catalytic reaction rate due to molybdenum, and iron could be determined as the iron(III)–sulphosalicylate complex [14] at 490 nm by using the same flow injection manifold. The system could also be used for the simultaneous determination of iron and molybdenum with a diode array detector, or sequentially with two spectrophotometers.

The slope and linearity of the analytical calibration curves were not affected by the presence of up to 25 mg $l^{-1}$ iron when sulphosalicylic acid was used (Fig. 2). As a consequence, it was possible to infer that molybdenum could be determined in the presence of iron, because absorbances were additive. By knowing the iron content in the original sample, the absorbance due to molybdenum measured at 350 nm was corrected according to the following equations:

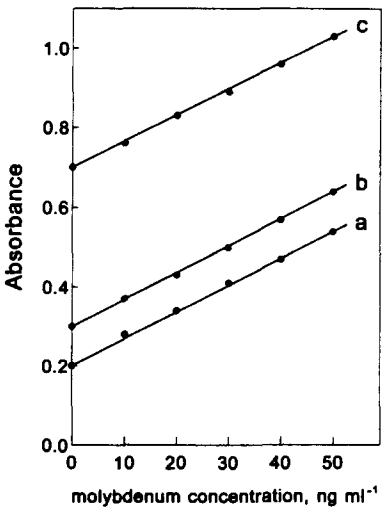

Fig. 2. Molybdenum calibration curves with and without iron in the presence of 0.1 M sulphosalicylic acid (total absorbance values recorded at 350 nm): (a) molybdenum alone ($r = 0.9998$); (b) molybdenum + 5 mg Fe $l^{-1}$ ($r = 0.9997$); (c) molybdenum + 25 mg Fe $l^{-1}$ ($r = 0.9998$).

$$A_{Mo} = A_{Mo+Fe} - a_{Fe}C_{Fe}$$

$$CA_{Mo} = A_{Mo}/a_{Mo}$$

where $A_{Mo}$ = absorbance at 350 nm due to molybdenum, $A_{Mo+Fe}$ = absorbance at 350 nm due to molybdenum plus iron, $a_{Fe}$ and $a_{Mo}$ = iron and molybdenum absorptivities at 350 nm, $C_{Fe}$ = iron concentration determined at 490 nm, and $C_{Mo}$ = corrected molybdenum concentration.

The influence of other elements on molybdenum determination (based on a mass/volume ratio of 1 g per 50 ml of the biological digest) at the 50 μg Mo $l^{-1}$ level was also investigated in the presence of sulphosalicylic acid at 350 and 490 nm. as much as 1000 mg Ca $l^{-1}$, 500 mg Mg $l^{-1}$, 500 mg Al $l^{-1}$ and 500 mg P $l^{-1}$ did not interfere with iron determination at 490 nm. As expected, interferences were observed for high concentrations of chromium (5 mg $l^{-1}$) and vanadium (0.5 mg $l^{-1}$) only at 350 nm with signal enhancements not exceeding 20%. The influences of chromium(VI) and vanadium(V) are well-known since both elements catalyze the iodide oxidation by hydrogen peroxide [15]. Hopefully, chromium and vanadium do not occur at these levels in the digests, taking into account their maximum reported concentrations in dry plant tissues and food materials: i.e. 5 μg Cr $g^{-1}$ and 10 μg V $g^{-1}$ [16–18]. The expected interference of phosphorus due to molybdophosphoric acid formation, also observed in earlier work [6], was only noticed for concentrations of phosphorus 10 times higher than its normal level in the digests, a 15% suppression in the molybdenum absorbance signal being observed in the presence of 250 mg P $l^{-1}$.

Regarding tungsten(VI) and titanium(VI), which also catalyze the indicator reaction, parallel experiments revealed that the system could tolerate their presence up to the maximum repored levels in biological materials [16]. Tungsten and titanium did not interfere at concentrations lower than 0.2 mg $l^{-1}$ and 1 mg $l^{-1}$ respectively. These interferences are also discussed elsewhere [9,19].

There is good agreement between molybdenum concentration values obtained with the proposed flow injection catalytic method and graphite furnace atomic absorption spectrometry (Table 1). In addition, Table 2 shows recoveries of about 100% for the same sample digests referred to in Table 1, which is also a good indication of the accuracy of the proposed method. The relative standard deviation of measurements ($n = 5$) for digests containing molybdenum within the range 10–50 ng $ml^{-1}$ did not exceed 2%. The detection limit was 0.6 ng Mo $ml^{-1}$ for a 200 μl sample volume, and a throughput of 100 determinations per hour (50 per hour for molybdenum and 50 per hour for iron) was typically obtained. The flow system proved to be quite stable, simple and

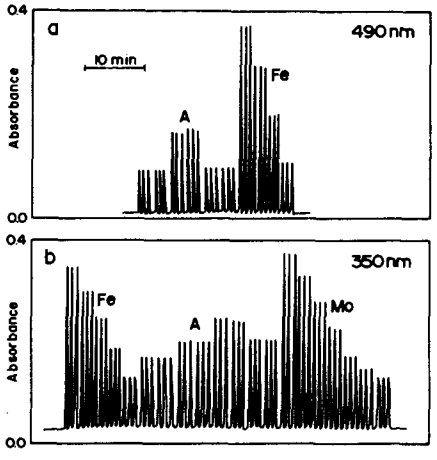

Fig. 3. Recorder tracing of a routine run. All measurements in triplicate. (a) Recording at 490 nm. From right to left, four iron standard solutions (5.0, 10.0, 15.0 and 20.0 mg $l^{-1}$), and eight samples (the last two with iron contents lower than the detection limit). (b) Recording at 350 nm. From right to left, seven molybdenum standard solutions (0.0, 10.0, 20.0, 40.0, 60.0, 80.0 and 100.0 μg $l^{-1}$) eight samples, and five iron standard solutions (0.0, 5.0, 10.0, 15.0 and 20.0 mg $l^{-1}$).

reasonably robust, and can be used for most plant tissues, food and other biological products, where iron content in the digest does not exceed 25 mg $l^{-1}$ (1200 mg Fe $g^{-1}$ dry matter). The calculated detection limit for iron was 0.2 mg $l^{-1}$ at 490 nm. Samples with higher iron contents are not common and were not found for validation but limitations due to the linearity of the analytical calibration curves are expected. In this situation, the injected volume could be reduced accordingly for iron on-line dilution, with a proportional lack of molybdenum sensitivity. A typical recorder tracing relating to molybdenum and iron determination in plant digests is shown in Fig. 3.

# New aspects of the reaction of silver(I) cations with the ethylenediaminetetraacetate ion

Luciana Saran, Eder Cavalheiro, Eduardo Almeida Neves *

*Departamento de Quimica, Universidade Federal de São Carlos, Cx. Post. 676, CEP 13.565-905, São Carlos, Brazil*

Received 3 April 1995; revised 17 July 1995; accepted 17 July 1995

**Abstract**

The highly neutralized ethylenediaminetetraacetate (EDTA) titrant (95–99% as $Y^{4-}$ anion) precipitates with $Ag^+$ cations to form the $Ag_4Y$ species, in aqueous medium, which is well characterized from conductometric titration, thermal analysis and potentiometric titration of the silver content of the solid. The precipitate dissolves in excess $Y^{4-}$ to form a complex, $AgY^{3-}$. Equilibrium studies at 25°C and ionic strength 0.50 M ($NaNO_3$) have shown from solubility and potentiometric measurements that the formation constant (95% confidence level) $\beta_1 = (1.93 \pm 0.07) \times 10^5\ M^{-1}$ and the solubility products are $K_{S0} = [Ag+]^4[Y^{4-}] = (9.0 \pm 0.4) \times 10^{-18}\ M^5$ and $K_{S1} = [Ag+]^3[AgY^{3-}] = (1.74 \pm 0.08) \times 10^{-12}\ M^4$. The presence of $Na^+$, rather than ionic strength, markedly affects the equilibrium; the data at ionic strength 0.10 M are: $\beta_1 = (1.19 \pm 0.03) \times 10^6\ M^{-1}$, $K_{S0} = (1.6 \pm 0.4) \times 10^{-19}\ M^5$ and $K_{S1} = (1.9 \pm 0.5) \times 10^{-13}\ M^4$; at ionic strength tending to zero; $\beta_1 = (1.82 \pm 0.05) \times 10^7\ M^{-1}$, $K_{S0} = (2.6 \pm 0.8) \times 10^{-22}\ M^5$ and $K_{S1} = (5 \pm 1) \times 10^{-15}\ M^4$. The intrinsic solubility is 2.03 mM silver (I) in 0.50 M $NaNO_3$. Well-defined potentiometric titration curves can be taken in the range 1–2 mM with the Ag indicator electrode. Thermal analysis revealed from differential scanning calorimetry a sharp exothermic peak at 142°C; thermal gravimetry/differential thermal gravimetry has shown mass loss due to silver formation and a brown residue, a water-soluble polymeric acid (decomposition range 135–157°C), tending to pure silver at 600°C, consistent with the original $Ag_4Y$ salt.

## 1. Introduction

Ethylenediaminetetraacetate (EDTA) ($H_4Y$ and $Y^{4-}$ ion), ethylenediaminetetraacetic acid and related compounds (complexones) constitute a class of polycoordinate ligands which have important analytical uses [1–3] due to their formation of strong complexes with a 1:1 ratio of ligand:metal cation in complexometric titrations.

Direct titration of $Ag^+$ with EDTA using a conventional buffer and a colorimetric indicator has never been considered due to a relatively low $\beta_1$ formation constant, as determined by Schwarzenbach [4] to be of the order of $10^7\ M^{-1}$ [1–5], a value that decreases to a smaller conditional constant $\beta'_1$ in a buffered medium. One indirect titration has been proposed through reaction of $Ag^+$ or AgCl with the $[Ni(CN)_4]^{2-}$ anion to form $[Ag(CN)_2]^-$ and release of an equivalent $Ni^{2+}$, able to be titrated with EDTA [6,7].

In a recent article [8] new possibilities for complexometric titrations were proposed on the basis of using complexones at high $\alpha_0$ conditions, i.e. at a highly neutralized species with the active form $Y^{4-}$ which guarantees a full complexing power for the complexone. The titration of $Mg^{2+}$ and other divalent cations with EDTA can be followed potentiometrically

* Corresponding author. Fax: (55) 74-8350.

*SSDI* 0039-9140(95)01692-9

with the glass electrode or the end point found by phenolphthalein, due to a pH jump caused by the hydrolysis of the $Y^{4-}$ anion [8].

Because of the full complexing power of EDTA under this high $\alpha_0$ condition [8] the EDTA/$Ag^+$ reaction deserves to be better studied. As part of this subject equilibrium aspects of this reaction and thermoanalytical data are herein described.

## 2. Experimental

### 2.1. Chemicals and solutions

All chemicals (mostly Merck) were of A.R. specification.

A standard 0.05 M EDTA solution expressed in active [$Y^{4-}$] titre (99% neutralized) was prepared from reaction of NaOH solution with the $Na_2H_2Y \cdot 2H_2O$ salt, as formerly described [8]. This EDTA salt was properly neutralized with standard NaOH to prepare buffers with the desired [$HY^{3-}$]/[$Y^{4-}$] ratio.

Standard NaCl solution was used to standardize 0.1 M $AgNO_3$ potentiometrically. Other solutions containing $NaNO_3$ for ionic strength adjustments and KI for $Ag^+$ titration at the millimeter level were prepared by weighing the dry solid directly without further standardization.

The $Ag_4Y$ solid phase was prepared by reaction of at least 50 ml of the 0.05 M EDTA, $Y^{4-}$, with a volume of 0.1 M $AgNO_3$ in slight excess with regard to the sroichiometric amount (4.01:1) added rapidly at room temperature and in diffuse light. After 10 min the suspension was filtered, washed with small volumes of cold water and finally with ethanol. The solid was then vacuum dried and kept in darkness.

### 2.2. Thermal analysis

Thermogravimetry (TG) analysis and differential thermogravimetry (DTG) analysis were performed with a DuPont TA-951 module joined to a DuPont 9900 thermoanalyzer system. The calorimetric analysis (differential scanning calorimetry, DSC) was performed with a DuPont DSC-910 module. All techniques were computer controlled.

Weighed samples (5–7 mg) were placed in a platinum crucible (for TG) or in an aluminum crucible with a cover (for DSC) under pure dinitrogen at 100 ml $min^{-1}$.

### 2.3. Equilibria and electrochemical measurements

All equilibrium data were obtained at $25 \pm 0.1$°C.

Potentiometric measurements with scale resolution $\pm 0.1$ mV were performed with a Micronal B 375 pH meter. A borax buffer (pH 9.18) was used to calibrate the glass electrode for measurements in alkaline EDTA buffers for p$K'$ determination.

A 1 cm silver wire was used in the potentiometric titrations and other potentiometric measurements in a cell with silver chloride reference electrode (see Results and discussion section). The 0.50 M $NaNO_3$ salt bridge was a gel with 3% agar–agar. All working solutions were previously bubbled with dinitrogen.

The conductometric titration was performed with a Micronal B330 instrument in the region of 2000 μS, with about 0.2% resolution. The cell with two platinized electrodes contained 10.30 ml of 0.1004 M silver nitrate solution which was titrated with 0.04894 M EDTA ($Y^{4-}$) at 25°C. Volume corrections were applied to the measured conductometric data.

In order to characterize the composition of the silver editate at least three dried samples of about 0.3 g were titrated potentiometrically with standard 0.1 M NaCl in the presence of 2–3 ml of 10% nitric acid in order to avoid interference of the ligand.

Saturated solutions of $Ag_4Y$ were obtained by treating about 0.1 g of the solid with volumes of the electrolyte (40 ml) with efficient magnetic stirring for at least 12 min. Saturation occurs in 5–10 min but long contact with aqueous medium causes slow hydrolysis of the precipitate within hours. The excess of solid of the recently saturated solution was separated by filtration and an aliquot of 20.00 ml was treated with 1 ml 10% nitric acid and titrated with 2.00 mM KI, potentiometrically, in order to determine the total silver(I) from the intrinsic solubility. The measured pH of the recently saturated solutions was close to seven.

Data treatment was computer assisted through QuickBASIC programs and the ORGIN graphic system (Microsoft™). All deviations attributed to experimental data were taken at 95% confidence level (Student $t$ test).

## 3. Results and discussion

### 3.1. Formation of $Ag_4Y$

Fig. 1 shows the titration of $Ag^+$ with EDTA (99% as $Y^{4-}$) followed potentiometrically with a silver wire as indicator electrode. The potentiometric curve is assymetrical and distorted due to formation of a white precipitate which dissolves during the course of the titration towards a not well-defined end point but close to a 1:1 ratio of $[Y^{4-}]/[Ag^+]$.

A reverse titration of 2.0 mM EDTA with a 0.1 M $Ag^+$ showed in the initial part a sharp potential jump consistent with a 1:1 ratio of the reactants (Fig. 2), followed by a discontinuity in the upper region of the curve, exactly at the point where precipitation takes place. After this point the $AgY^{3-}$ species is being converted to the $Ag_4Y$ precipitate and a second less well-defined potentiometric jump is attained. This second inflection point is close to a 4:1 ratio of $[Ag^+]/[Y^{4-}]$, as inferred from a derivative curve taken in this second region.

The conductometric titration of $Ag^+$ with EDTA ($Y^{4-}$) has shown a well-defined first step consistent with the precipitation of $Ag_4Y$ (Fig. 3). Conductance increases with the dissolution of the precipitate in the titrant EDTA to form only $AgY^{3-}$, as inferred from a second stoichiometric point, although less well-defined.

Preparation of the solid phase was performed only in cold solutions (see Experimental section). Attempts to use hot solutions or homogeneous precipitation always lead to hydrolysis of $Ag^+$ and parallel reduction to produce a metal mirror. Potentiometric titrations of a dry sample with standard chloride solution to precipitate AgCl, in acidic medium to protonate the ligand, confirmed the composition of the precipitate to be $Ag_4Y$, within 99.9%.

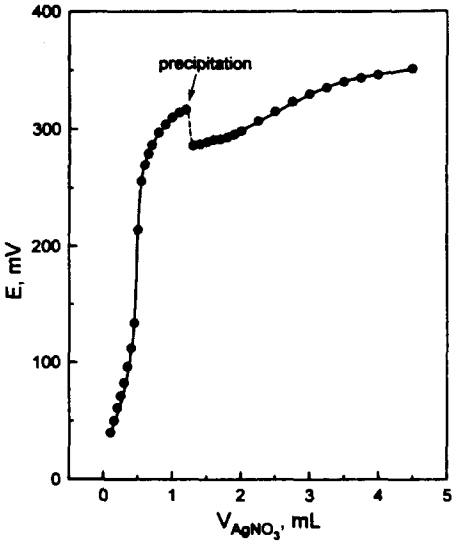

Fig. 2. Potentiometric titration curve of 25.00 ml of 2.000 mM free EDTA (99% neutralized) with 0.1000 M $AgNO_3$ with a silver indicator electrode. First stoichiometric point consistent with $AgY^{3-}$ formation.

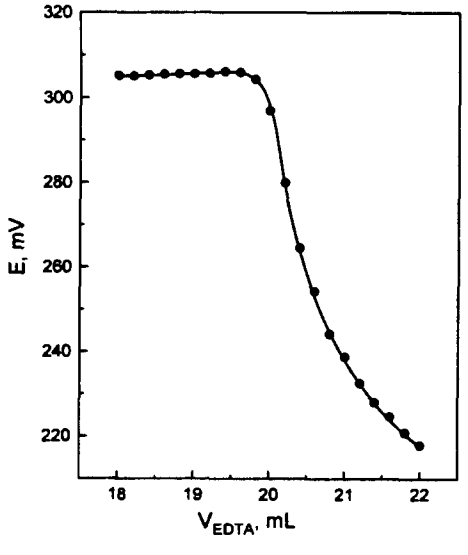

Fig. 1. Potentiometric titration curve of 10.03 ml of 0.1010 M $AgNO_3$ with 0.05010 M free EDTA (99% neutralized) with a silver indicator electrode.

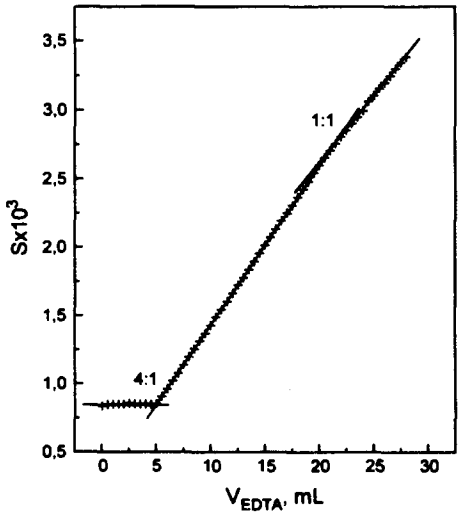

Fig. 3. Conductometric titration of 10.03 ml of 0.1004 M $AgNO_3$ with 0.05010 M free EDTA (99% neutralized) indicating the formation of a $Ag_4Y$ precipitate (first stoichiometric point) and $AgY^{3-}$ complex (second stoichiometric point).

Table 1
Data from homogeneous and heterogeneous equilibrium studies at 25°C

| $I$ (M) | $C_{Ag}$ (M) | $\beta_{AgY^{3-}}$ ($M^{-1}$) | $K_{S0}$ ($M^5$) | $K_{S1}$ ($M^4$) |
|---|---|---|---|---|
| $5.0 \times 10^{-4}$ | $(4.60 \pm 0.14) \times 10^{-4}$ | $(1.82 \pm 0.05) \times 10^{7}$ | $(2.6 \pm 0.8) \times 10^{-22}$ | $(5 \pm 1) \times 10^{-15}$ |

| $5.0 \times 10^{-1}$ | $(2.03 \pm 0.02) \times 10^{-3}$ | $(1.93 \pm 0.07) \times 10^{5}$ | $(9.0 \pm 0.4) \times 10^{-18}$ | $(1.74 \pm 0.08) \times 10^{-12}$ |

$C_{Ag}$ is the silver(I) concentration in the saturated solution of $Ag_4Y$.

### 3.2. Equilibrium studies in homogeneous solutions

Potentiometric titration of the 2 mM $Ag^+$ cations with EDTA was initially performed in 0.50 M $NaNO_3$ medium, defining the following cell, virtually free from junction potentials:

Ag|AgCl, 0.10 M NaCl, 0.40 M $NaNO_3$:0.50 M $NaNO_3$: $[Ag^+] = 2.00$ mM, 0.50 M $NaNO_3$|Ag
(Reference electrode) (Salt bridge) (Working solution, 20.00 ml)

This cell presents the following Nernst equation at $25.0 \pm 0.1$°C in non-complexing medium, for a conditional potential $E_S^{0\prime} = 0.4721$ V:

$$E_S = 0.4721 + 0.05916 \log[Ag^+] \quad (1)$$

The EDTA solution used to titrate the working solution had the following composition: $[Y^{4-}] = 0.1250$ M, $[HY^{3-}] = 1.25 \times 10^{-3}$ M and $[Na^+] = 0.50$ M. This solution has an ionic strength greater than 0.5 M, due to the presence of a quadruply-charged anion. However, this parameter was revealed to be not so important as the sodium concentration, which remains constant in the titration.

By addition of the titrant solution to the $[Ag+]/Ag$ compartment the initial potential changes from $E_S$ in non-complexing medium to a lower $E_x$ value in complexing medium, defining a potentiometric curve. Volume corrections were considered and variable $E_x^{0\prime}$ data were calculated from the corresponding $E_x$ value and total silver(I) concentration value, $C_{Ag}$, beyond the stoichiometric point in order to calculate the $[Ag^+]$ value at equilibrium from the Nernst equation (1) above. The free ligand concentration $[Y^{4-}]$ was calculated by discounting the silver(I) concentration used to form $AgY^{3-}$ and also correcting the small decrease caused by ligand hydrolysis. The ratio of $[AgY^{3-}]/[Ag^+][Y^{4-}]$ gives the $\beta_1$ formation constant. Seven values were obtained, and the average $\beta_1$ was $(1.93 \pm 0.07) \times 10^5$ $M^{-1}$. Table 1 shows the results obtained at three ionic strengths together with data obtained for the heterogeneous equilibrium (see next topic). A marked increase in $\beta_1$ is observed at lower ionic strength (about 0.0005 M), tending to the old value referred to in the literature [1–5]. The sodium cation has a marked effect on the equilibria, rather than the ionic strength, due to a non-negligible interaction of $Na^+$ with the highly charged $Y^{4-}$ anion. The titration performed at lower ionic strength could not be performed at constant $[Na^+]$ and the formation constant changes with the volume of the titrant, 0.125 M in $[Y^{4-}]$, requiring extrapolation procedures to the initial condition.

The ligand hydrolysis

$$Y^{4-} + H_2O \rightarrow HY^{3-} + OH^-$$

was used to make small corrections to $Y^{4-}$ concentrations during the titration of the working solutions, by using a conditional $pK'$ (mixed ionization constant of concentrations ratio and $a_{H+}$) value calculated from the buffer equation

$$pK'_4 = pH + \log([HY^{3-}]/[Y^{4-}]) \quad (2)$$

The concentration of both forms was 5.00 mM at two electrolyte concentrations: $NaNO_3$ 0.50 M and $NaNO_3$ 0.10 M; EDTA buffer only at 0.005 M and 0.00050 M. The $pK'_4$ values are respectively 9.04, 9.58, 10.11 and 10.84; the $pK'_b$ values referred to the conjugated basis, used to calculate the hydrolysis, are respectively 4.96, 4.42, 3.89 and 3.16.

### 3.3. Heterogeneous equilibria

More information was obtained for the intrinsic solubility of the solid phase $Ag_4Y$ from 0.50 M $NaNO_3$ in distilled water. The low solubility of silver iodide (solubility product $10^{-17}$ $M^2$) was adequate for the precise deter-

mination of the total silver(I) molar concentration, $C_{Ag}$, in the saturated solutions, as very sharp potentiometric titration curves with iodide solution were obtained at the millimolar concentration level. Some dilute nitric acid is added to protonate the ligand and avoid any interference during the titration.

On the basis of the composition of the solid phase and the high tendency to form the 1:1 complex the following mass balances can be applied for the saturated solution, analyzed for the total silver content $C_{Ag}$, and its relation with the total EDTA, $C_Y$ and ionic species:

$$C_{Ag} = 4C_Y \therefore C_Y = C_{Ag}/4 \quad (3)$$

$$C_Y = [Y^{4-}] + [AgY^{3-}] \cong [AgY^{3-}]$$
$$\text{as } [Y^{4-}] \ll [AgY^{3-}] \quad (4)$$

$$C_{Ag} = [Ag+] + [AgY^{3-}]$$
$$\therefore [Ag+] = [C_{Ag} - [AgY^{3-}] = C_{Ag} - C_Y \quad (5)$$

The $[Ag^+]$ and $[AgY^{3-}]$ values can be calculated from the mass balance and the smaller $[Y^{4-}]$ concentration can be obtained as follows:

$$[Y^{4-}] = [AgY^{3-}]/[\beta_1[Ag^+] \quad (6)$$

This $[Y^{4-}]$ data completes the concentration values necessary to calculate the two solubility products:

$$Ag_4Y \Rightarrow 4Ag^+ + Y^{4-} \qquad K_{S0} = [Ag^+]^4[Y^{4-}] \quad (7)$$

$$Ag_4Y \Rightarrow 3Ag^+ + AgY^{3-} \qquad K_{S1} = [Ag^+]^3[AgY^{3-}] \quad (8)$$

Table 1 also shows the results of these two heterogeneous equilibrium at three experimental conditions. The intrinsic solubility of the solid phase as well as the solubility products suffer marked change with the presence of the electrolyte.

All data in Table 1 show deviations at a 95% confidence level, from application of the Student $t$ test.

The reaction of EDTA anions with $Ag^+$ followed a different behaviour with regard to a large number of studied cations, as precipitation takes place. This became evident during the particular condition of using the tetra-neutralized ligand with predominance of the $Y^{4-}$ anion.

The stability constant ($\beta_1$, at very low ionic strength) for the normal 1:1 complex was found to be higher than that of the $Ag^+$ cation with ethylenediamine [9] which is of the order of $10^6\ M^{-1}$. The affinity with the carboxylic group, as shown in acetate complex [10], is very small in comparison with the amine one. However, some increase in affinity of EDTA with $Ag^+$, in aqueous medium, with regard to the ethylenediamine complex, can be attributed to another five-membered ring formation of one of the three acetate groups with the $Ag^+$ bound to the bicoordinative amine site, neutralizing one positive charge. On this basis only one $Ag^+$ is effectively coordinated to three ligands of EDTA in solution. In the solid phase the three other cations should probably neutralize the negative charge of the $AgY^{3-}$ anion in the crystal lattice.

The $Na^+$ cation is known to interact to some extent with EDTA to form a complex or ion pair for which $\beta_1$ is $4.6 \times 10^1\ M^{-1}$ [11]. This can explain the marked effect on the magnitude of the conditional stability constants of the silver(I)/EDTA system (homogeneous and heterogeneous equilibrium) in the presence of the background electrolyte, $NaNO_3$, rather than being attributed to the increase in ionic strength. This means that the presence of $Na^+$ cations decreases the complexing power of EDTA.

The analytical possibilities of the reaction are limited by the formation of the $Ag_4Y$ precipitate. However, concentrations below the intrinsic solubility provide well-defined potentiometric curves for silver(I) concentrations in the range 1–2 mM by titrating with the highly neutralized EDTA.

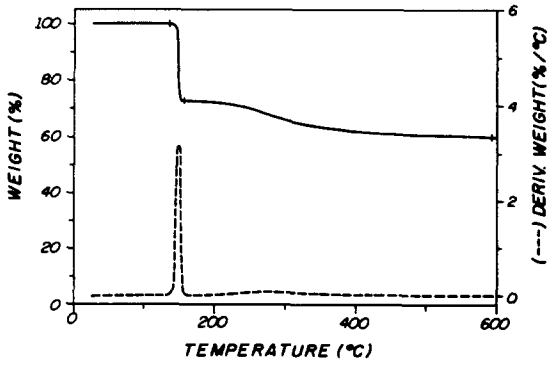

Fig. 4. TG and DTG thermodiagrams with 7.00 mg of $Ag_4Y$, indicating a decomposition range of 135–157°C. Final mass loss of 40.15% at 600°C is consistent with a pure silver residue.

### 3.4. Thermoanalytical data

Fig. 4 shows a thermogravimetric diagram taken with a 6.921 mg sample. It shows a sudden mass loss of 27.2% at 157°C. After 185°C the mass loss continues slowly towards 600°C. The final residue of 4.143 mg is 59.86% of the initial mass and is consistent with the pure silver residue from the thermal decomposition of $Ag_4Y$ (the theoretical value is 59.95%).

A thermal decomposition of about 1 g of the $Ag_4Y$ solid was performed at 162°C under nitrogen in order to obtain some data about the nature of the calcinated residue at this intermediate temperature. The aqueous extract revealed partial solubility of the residue giving a brown acidic solution. This solution does not precipitate with chloride ions, which excludes the presence of $Ag^+$ cations. The extract with diluted nitric acid (0.1 M) presented the same brown color and no precipitation with chloride ions; this excludes the presence of basic species of silver such as $Ag_2O$ or $Ag_2CO_3$ in the calcinated solid. The residue from the aqueous extract dissolves in concentrated nitric acid with nitrous oxide evolution; its diluted solution gave extensive precipitation with chloride ions showing that the calcinated residue contains metallic silver.

Another sample of the calcinated residue (0.0593 g) was suspended in 25 ml of distilled water and gave a pH of 3.74. The potentiometric titration of the suspension with 0.01 M NaOH showed a well-defined potentiometric curve with only one equivalent point of pH 7.49. Calculations from the titration data showed that the soluble brown fraction (possibly a polymeric product) contains an acid group with $pK = 3.9$ and $1.9 \times 10^{-4}$ equivalents of $H^+$ per gram of the solid residue from calcination at 162°C.

Fig. 5 shows an interesting result obtained from the DSC diagram, as a very sharp exothermic peak was found at 141.9°C either in nitrogen or air atmosphere. No endothermic peak characteristic of dehydration or fusion was evident. The peak integration leads to a value of $-115.5\ J\ g^{-1}$, a result that shows a sudden decomposition of $Ag_4Y$, without fusion. A DSC diagram for the acid form $H_4Y$ also gave a sharp but endothermic peak, at 255.9°C, corresponding to $+594.7\ J\ g^{-1}$. It should be mentioned that some differential thermal analysis diagrams for the EDTA chelates of lanthanides [12] and some divalent metal cations [13] show less sharp decomposition peaks, some of them exothermic.

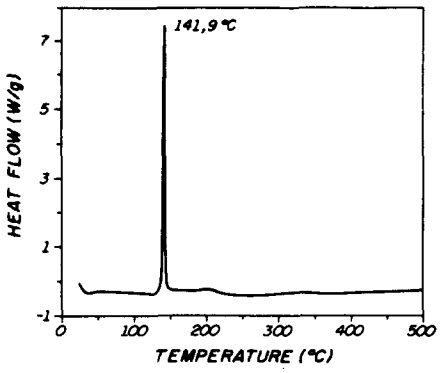

Fig. 5. DSC thermodiagram with 4.80 mg of $Ag_4Y$, showing a sharp exothermic peak at 142°C. Integration leads to $-\Delta H = -115.5\ J\ g^{-1}$.

# Two trends of sample dispersion variation with carrier flow rate in a single flow-injection manifold

Yonghung Li, Huichang Ma *

*Research Center for Eco-Environmental Sciences, Academia Sinica, P.O. Box 2871, Beijing 100085, China*

Received 3 January 1995; revised 7 July 1995; accepted 17 July 1995

**Abstract**

Two trends of sample dispersion variation with carrier flow rate in a single flow-injection manifold are completely revealed for the first time and an inflection point in the dispersion coefficient ($D$) vs. flow rate ($q$) curve is discovered. With the increase of the flow rate, the value of $D$ increases before the inflection point but decreases after the inflection point. The value of the carrier flow rate at the inflection point ($q_m$) is independent of the sample injection volume, the tube length, the tube coil radius and the tube inner diameter. It is only affected by the substance diffusion coefficient ($D_m$) of the analysis. The value of $q_m$ decreases as $D_m$ increases. Therefore, the value of $D_m$ for a sample can be estimated according to the $D_m$ vs. $q_m$ curve.

*Keywords:* Sample dispersion variation; Carrier flow rate; Flow-injection manifold

## 1. Introduction

In the flow injection analysis (FIA), the dispersion coefficient ($D$) is defined as $D = C^0/C$, i.e. as the ratio of the concentrations before and after the dispersion process has taken place in the individual elements of fluid. If a readout is taken of $C = C^{max}$, i.e. the element corresponding to the maximum on the output curves, then $D = C^0/C^{max}$. Since the dispersion coefficient represents the degree of dilution of the sample, the value of $D$ directly affects the sensitivity of any flow injection assay. Therefore, the study of the sample dispersion coefficient is very important in basic FIA research.

It is well known in FIA that the factors predominantly affecting the sample dispersion are the sample injection volume ($V_{inj}$), the tube length ($L$) and inner diameter ($d$), the tube coil radius ($R_c$), the carrier flow rate ($q$), the diffusion coefficient of the analyte ($D_m$) and temperature. The originators of FIA, Ruzicka and Hansen [1], determined that the value of $D$ decreases with decreasing flow rate in a single flow injection manifold. However, Li and Narusawa [2] demonstrated in their experiments that the value of $D$ gradually increases with a decrease in flow rate. Gomez-Nieto et al. [3] gave an empirical formula, $D = 2.342L^{0.167}q^{-0.206}d^{0.495}$, which indicates that $D$ is inversely proportional to the flow rate. Thus, there are two completely different opinions. Up until now, no satisfactory explanation has been given for this.

Since flow rate is an important factor which affects the dispersion coefficient, this paper will investigate and experimentally test these two opinions and try to offer a reasonable explanation, which it is hoped will be instructive to experimentalists who wish to design flow injection systems.

## 2. Experimental

### 2.1. Reagents

Aqueous solutions of $1.59 \times 10^{-2}$ M $Cu(NH_3)_4^{2+}$ in 1.0 M ammonia and 1.0 M ammonia were mainly used as sample and carrier respectively. The sample solution was prepared by dissolving 0.400 g $CuSO_4 \cdot 5H_2O$ in 100 ml of 1.0 M ammonia. Other colored inorganic chemicals such as $K_3Fe(CN)_6$ and $K_2Cr_2O_7$ were also used as samples.

All reagents used were of analytical reagent grade and were obtained from Peking Chemical Works, Peking, China. All solutions were prepared with distilled water.

### 2.2. Apparatus

An FIA-91 flow injection analyzer (made in Shanghai No. 3 Analytical Instrument Factory) was used. This is an integrated instrument which consists of two four-channel peristaltic pumps, a 16-port valve, a grating spectrophotometric detector, a Laser PP40 X–Y printer plotter and a microcomputer system. Program control and data processing are conducted automatically by the microcomputer system.

### 2.3. Procedure

The manifold of the single channel FIA system used is shown in Fig. 1. As can be seen from Fig. 1, after the sample is injected it is forwarded by the carrier to pass through a certain length of coiled tube and eventually to the spectrophotometric detector. For different values of $V_{inj}$, $L$, $R_c$, $d$ and $D_m$, the effect of flow rate on sample dispersion is observed.

## 3. Results and discussion

### 3.1. Effect of flow rate on dispersion coefficient with different injection volumes

In these experiments, an aqueous solution of $1.59 \times 10^{-2}$ M $Cu(NH_3)_4^{2+}$ in 1.0 M ammonia as spiked sample and an aqueous solution of 1.0 M ammonia as carrier were used. Selected results are listed in Table 1 and a group of $D$ vs. $q$ curves are shown in Fig. 2. The correlations between residence time ($T_r$) and flow rate are listed in Table 2. From Table 1 it can be seen that the residence time increases with increasing injection volume ($V_{inj}$) while the dispersion coefficient decreases. For identical values of $V_{inj}$, $T_r$ decreases with increasing flow rate.

From Fig. 2 it is obvious that there is an inflection point (where $dD/dq = 0$) in the $D$ vs. $q$ curve. With increasing flow rate the value of $D$ increases before this point but decreases after this point. The value of $q$ at the inflection point ($q_m$) is independent of the injection volume.

In a single FIA system, $T_r$ decreases as $q$ increases. Ruzicka and Hansen [4] have given a theoretical formula, $D = 2qT_r^{1/2}t_i^{1/2}/W_0\pi(d/2)^2$, where $t_i$ is the mean residence time and $W_0$ is

| $V_{inj}$ (μl) | Before inflection point | | After inflection point | |
|---|---|---|---|---|
| | $a$ | $r$ | $a$ | $r$ |
| 40 | −0.886 | −0.9996 | −1.052 | −0.9978 |
| 80 | −0.884 | −0.9995 | −1.042 | −0.9940 |
| 120 | −0.896 | −0.9998 | −1.021 | −0.9993 |
| 160 | −0.891 | −0.9993 | −1.047 | −0.9989 |
| 200 | −0.879 | −0.9985 | −1.091 | −0.9941 |

independent of $q$ and $t$. It is known that $t_i = kL/q$ ($k$ = constant). Thus, $D + f(qT_r)^{1/2}$ ($f$ = constant). If $T_r = fq^{-1}$ ($f$ = constant), the two effects, with the inverse changes of $T_r$ and $q$ on the dispersion coefficient, can offset each other. However, Table 2 shows that $T_r = fq^{-0.886}$ ($f$ = constant, $a_{mean} = -0.886$) before the inflection point. This means that $T_r$ decreases more slowly with increasing flow rate than is to be expected. The relative longer $T_r$ time makes $D$ increase with the increase in flow rate. However, after the inflection point, $T_r = fq^{-1.051}$ ($f$ = constant, $a_{mean} = -1.051$) which means that $T_r$ decreases more quickly with increasing flow rate than expected. The relative shorter $T_r$ time makes $D$ decrease with the increase in flow rate. Treating the data in the paper of Li and Narusawa [2] statistically, we obtained $T_r = fq^{-1.018}$ ($f$ = constant, $r = -0.9991$). From Gomez-Nieto et al. [3] we can show that the relationship between $T_r$ and $q$ is $T_r = fq^{-1.022}$ ($f$ = constant, $r = -0.9993$) when $d = 0.35$ mm and $L = 104$ cm or when $d = 0.5$ mm and $L = 154$ cm. The indices of $q$ are both smaller than $-1.0$ while these two papers have the same conclusion, i.e. that $D$ gradually decreases as $q$ increases.

Thus, it is clear that the view of Ruzicka and Hansen [4] coincides with the part before the inflection point while of view of Li and Narusawa [2] coincides with the part after the inflection point in this experiment. Therefore, this experiment has clearly revealed the two trends of sample dispersion variation with flow rate.

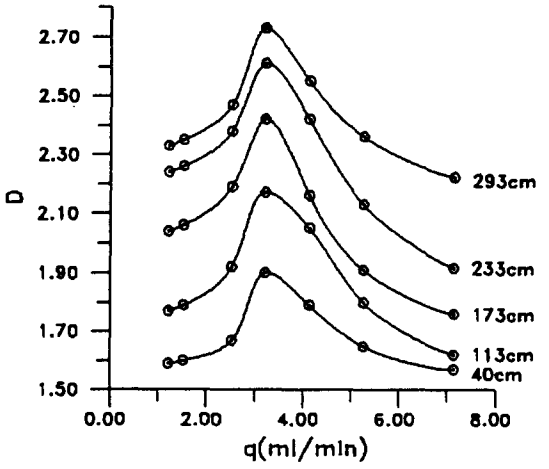

Fig. 3. The $D$ vs. $q$ curves with various tube lengths ($V_{inj} = 80$ μl; tube: $d = 0.5$ mm; $R_c = 1.0$ cm).

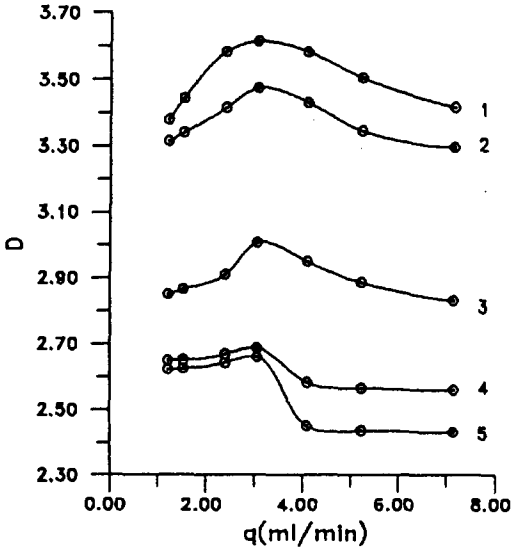

Fig. 4. The $D$ vs. $q$ curves with various tube coil radii ($V_{inj} = 80$ μl, tube: $L = 233$ cm; $d = 0.5$ mm). $R_c$ (cm): (1), 0.5; (2), 1.0; (3), 1.5; (4), 2.0; (5), 2.5.

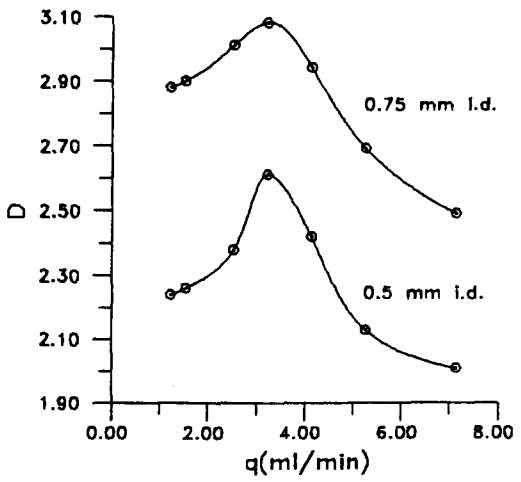

Fig. 5. The $D$ vs. $q$ curves with various tube inner diameters ($V_{inj} = 80$ µl, tube: $L = 233$ cm; $R_c = 1.0$ cm).

### 3.2. *Effect of tube length ($L$) on the D vs. q curve*

The effect of tube length on the correlation between $D$ and $q$ was examined in the range 40–293 cm. Using the same sample and carrier as before, the injection volume was fixed at $V_{inj} = 80$ µl. The results obtained are shown in Fig. 3 which indicates that the value of $D$ increases as $L$ increases at the same flow rate. This is because of longer dispersion times caused by longer tube lengths. According to Fig. 3, it is evident that there is an inflection point in the $D$ vs. $q$ curve at different tube lengths and the value of $q_m$ is constant even as the tube length changes.

### 3.3. *Effect of tube coil radius on the D vs. q curve*

To test the effect of tube coil radius ($R_c$), tube coils of various radii were used. Using the same sample and carrier as before, the FIA system was fixed at $V_{inj} = 80$ µl, tube length $L = 233$ cm. From the results shown in Fig. 4, it is obvious that the value of $D$ increases as the tube coil radius decreases. The results also indicated that there is a inflection point and that the value of $q_m$ remains the same as the tube coil radius varies.

### 3.4. *Effect of tube inner diameter on the D vs. q curve*

The effect of tube inner diameter was investigated by using different inner diameter tubes. The same sample and carrier as before were used and the injection volume was fixed at $V_{inj} = 80$ µl while the tube length was $L = 233$ cm. From the results shown in Fig. 5 it can be seen that $D$ increases as $d$ increases which is identical to former conclusions. The value of $q_m$ remains the same as $d$ varies.

### 3.5. *Effect of the analyte coefficient on the D vs. q curve*

To test the effect of $D_m$, various samples and their corresponding carriers as listed in Table 3 were used. The flow injection manifold was fixed at $V_{inj} = 80$ µl, $L = 233$ cm and $d = 0.5$ mm. The experimental temperature was about 25 °C. The results are shown in Fig. 6.

From Fig. 6 it is obvious that the value of $q_m$ decreases while $D_m$ increases and that $D$ increases with increasing $D_m$ while the flow rate is constant.

It is well known that in a single channel FIA system, the sample dispersion during the flow towards the detector is composed of two parts: one is the convection dispersion which is caused by the flow of the carrier and is directly proportional to the value of the flow rate; the other is the diffusion dispersion which is caused by the diffusion of the analyte and is directly proportional to the diffusion coefficient of the analyte. When $V_{inj}$, $L$, $R_c$, $d$ and $q$ are kept constant, the convection dispersion part remains constant. Therefore, higher dispersion can be obtained because of increased diffusion dispersion of the analyte, i.e. the value of $D$ increases.

It has been shown that before the inflection point, the dispersion increases because of the increase in $q$ and the relatively slower decrease of $T_r$. However, the diffusion dispersion part decreases more quickly for the larger $D_m$ value of the analyte as $T_r$ decreases. Therefore, the value of $q_m$ is smaller when the $D_m$ value of the analyte is larger (Fig. 7).

## 4. Conclusions

The experiments in this paper revealed the law of the variation of sample dispersion coefficient with carrier flow rate in single coiled

Table 3
Samples and carriers used to test the effect of analyte diffusion coefficient on the $D$ vs. $q$ curve (temperature = 25 °C)

| Sample | Carrier | Diffusion coefficient ($\times 10^{-5}$ cm$^2$ s$^{-1}$) |
|---|---|---|
| $4.56 \times 10^{-3}$ M $K_3Fe(CN)_6$ in 1.0 M NaOH[a] | 1.0 M NaOH | 0.45 |

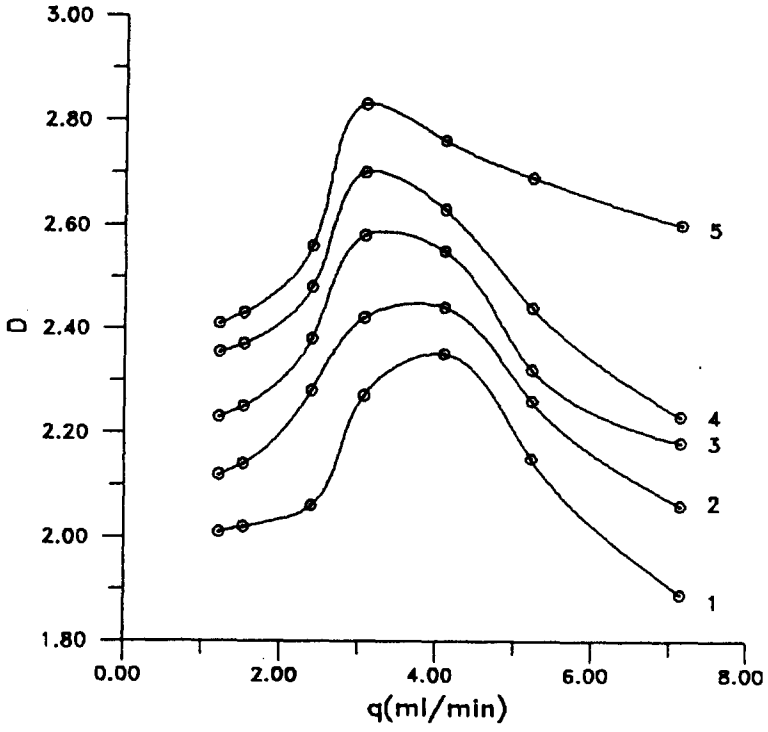

Fig. 6. The $D$ vs. $q$ curves with various analyte diffusion coefficients ($V_{inj} = 80$ μl, tube: $L \approx 233$ cm; $d = 0.5$ mm; $R_c = 1.0$ cm). $D_m$ ($\times 10^{-5}$ cm$^2$ s$^{-1}$: (1), 0.45; (2), 0.57; (3), 0.76; (4), 0.96; (5), 1.24.

tube channel FIA systems and yield the following guidelines which should be useful to experimentalists who wish to design FIA systems.

(1) There is an inflection point (where $dD/dq = 0$) in the $D$ vs. $q$ curve.

(2) With the increase in the flow rate, the value of $D$ increases before the inflection point and decreases after this point.

(3) The value of $q$ at the inflection point is independent of the sample injection volume, the tube length, the tube coil radius and the inner diameter of the tube. It is only affected by the diffusion coefficient of the analyte.

(4) The value of $q_m$ decreases while $D_m$ increases. According to the $q_m$ vs. $D_m$ curve, the $D_m$ value of an unknown analyte can be roughly estimated. Further work on the determination of $D_m$ is now in progress.

# Selective and efficient uphill transport of Cu(II) through liquid membrane

Afsaneh Safavi *, Saadat Rastegarzadeh

*Department of Chemistry, Shiraz University, Shiraz, Iran*

Received 3 January 1995; revised 29 June 1995; accepted 18 July 1995

**Abstract**

1,2-Bis methyl (2-aminocyclopentene carbodithioate) ethane is an excellent synthetic carrier for efficient and specific transport of Cu(II) ions through a liquid membrane and has the ability to transport Cu(II) ions uphill.

*Keywords:* Liquid membranes; Copper ion transport; Carbodithioate derivatives

## 1. Introduction

The specific transport of metal ions through a membrane is widely known to play an essential role in biological processes [1]. Selective transport of transition metal ions through liquid membranes has become increasingly noteworthy. So far, a number of carriers for heavy metal ions have been reported [2–5], but there are a few which can transport then not only selectively but also efficiently. Different methods for the specific transport of Cu(II) ions across a liquid membrane have the drawbacks of a slow rate of transport or a lack of high selectivity. For example, it has been reported [2] that the urea-containing octameric oligomer $[-CH_2CH_2N(CONHPh)-]_8$ provided the selective passive transport of copper ion through a liquid membrane. However, the flux of transport was small; after 24 h only 37% of total copper ion was transported.

The use of 6-amino-6'-dodecylamino-2,2'-bipyridine [3] as a suitable carrier for the transport of Cu(II) through a liquid membrane showed that after 20 h 50% of the total Cu(II) was transported to the receiving phase.

The transport of Cu(II) ion across a liquid dichloromethane membrane containing a lipophilic dioxycyclam derivative has also been reported [5]. The percentage of Cu(II) transported after 53.5 h was $65 \pm 5\%$.

It was also reported that *N,N'*-bis(8-quinolyl)glutaramide [6] can selectively and effectively transport copper ion (63%) through a chloroform membrane after 2 days. A liquid membrane system with simultaneous proton counter-transport was developed for selective solvent extraction of Cu(II) over Ni(II) and Co(II), using benzoylacetone as a mobile carrier [7], but its selectivity has been questioned [8].

Therefore, the development of effective and specific systems for studying the transport of metal ions, and in particular Cu(II), is still a challenging task from both the practical and theoretical viewpoints.

1,2-Bis methyl (2-aminocyclopentene carbodithioate)ethane (BMACD) (Fig. 1) has been shown to react with Cu(II), and the complex mimics the properties of "blue copper(II)" proteins and oxidases [10,11]. Here, we report that BMACD is an excellent carrier for the specific, rapid and uphill transport of Cu(II) ions through a liquid membrane, which may mimic the characteristics of biological transport.

## 2. Experimental

### 2.1. Synthesis of the ligand

The ligand BMACD was synthesized according to the procedure described previously [12].

### 2.2. Transport experiments

All the transport experiments were carried out at ambient temperature (25°C). The cell used for the transport experiments was a cylindrical glass cell (4.0 cm i.d.) holding a glass tube (2.0 cm i.d.) which separated two aqueous phases. The liquid membrane (30 ml of $CH_2Cl_2$ solution of BMACD, $2.7 \times 10^{-3}$ M) was located at the botton of the glass beaker lying below two aqueous phases, and bridging them. The aqueous source phase (2.5 ml) contained one or several kinds of metal ions out of Cu(II), Ni(II), Co(II) and Zn(II) ($10^{-4}$ M) buffered at pH 6.5 with ammonium buffer. The receiving phase (10 ml) contained threonine (0.038 M) at pH 1.8 which acts as a "scavenger" for the transported metal. The cell was covered with aluminum foil to minimize evaporation and light exposure. The organic layer was magnetically stirred by a Teflon-coated bar (27 mm × 5 mm diameter). In the course of the transport experiment, samples of both aqueous phases were analyzed for metal content by atomic absorption spectroscopy (AAS). A similar experiment was carried out in the absence of carrier ligand for reference.

### 2.3. Physical measurements

pH measurements on the aqueous layers were performed by using a combined glass electrode with a Corning pH meter 125. AAS analyses were performed on a Pye Unicam SPQ atomic absorption spectrophotometer.

## 3. Results and discussion

BMACD (Fig. 1) has the desired Cu(II) transport ability which can transport Cu(II) against its concentration gradient. In particular, it is a multidentate ligand which allows the formation of a fairly stable 1:1 complex and also the process of formation of the metal–carrier complex at the aqueous source phase/organic layer membrane interface (as well as the demetalation process at the membrane/receiving phase interface) is sufficiently fast.

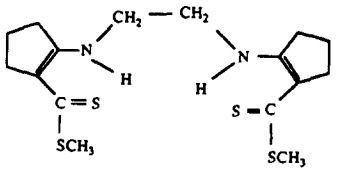

Fig. 1. Molecular structure of BMACD.

It has been reported before [12] that complexation between BMACD and Cu(II) occurs through deprotonation of the ligand. In preliminary experiments, the acidity of the receiving phase was adjusted with different buffers such as citrate, phthalate or sulfuric acid. The results are shown in Table 1. However, later, it was decided to study the effect of the presence of different amino acids in the receiving phase as scavenger for the metal ion (Table 2). The results revealed that although with citrate buffer (pH 3.5) in the receiving phase the transport of Cu(II) ion is possible, the use of amino acids can induce an uphill transport of the cation with a much higher flux and among the different amino acids tried threonine was found to be the most effective metal scavenger.

As expected a minor leaching effect of the ligand into the aqueous phase(s) was observed in the pH range of 1–4. This could be due to the ligand protonation and subsequent stabilization in the aqueous phase(s). Since the leaching only involved charged species, the problem was overcome by introduction of a lipophilic counter ion (such as a fatty acid) in the organic phase which can impart a greater degree of lipophilicity to the charged species.

Table 1
Effect of acidity of the receiving phase adjusted by different compounds on the transport of Cu(II) ion. Experimental conditions: source phase, 2 ml of $1.1 \times 10^{-4}$ M $Cu^{2+}$ ion, pH 7.5; liquid membrane phase, 35 ml of $1.0 \times 10^{-3}$ M BMACD and $1.0 \times 10^{-3}$ M palmitic acid in dichloromethane; receiving phase, 10 ml 0.1 M solution of each compound; rate of stirring = 250 rev $min^{-1}$

| Receiving phase | pH | Time (h) | % Transport to receiving phase |
|---|---|---|---|
| Citrate | 3.5 | 10.15′ | 66.43 |

Table 2
Effect of receiving phase composition on the transport of Cu(II) ion. Experimental conditions: source phase, 2 ml of $1.1 \times 10^{-4}$ M $Cu^{2+}$ ion, pH 7.5; liquid membrane phase, 35 ml of $10^{-3}$ M BMACD and palmitic acid in dichloromethane; receiving phase, 10 ml 0.1 M solution of each species; pH 1.75; time of transport: 6 h 15′; rate of stirring = 250 rev $min^{-1}$

| Receiving phase | % Transport to receiving phase |
|---|---|
| L-Threonine | 80.2 |
| Arginine | 68.6 |
| Cysteine | 47.4 |
| Glycine | 24.75 |
| Histidine | 17.24 |
| Asparagine | 5.71 |
| Citrate | 2.49 |
| Tryptophan | 0 |

The fatty acid used in this study was palmitic acid, whose concentration was optimized together with other variables in the system via a simplex program. Simplex optimization gave the following conditions as the best for the transport of Cu(II): pH of the source, 6.5; concentration of BMACD, $2.7 \times 10^{-3}$ M; pH of receiving phase, 1.8 adjusted by HCl; volume of source, 2.5 ml; concentration of palmitic acid, $1.9 \times 10^{-3}$ M; volume of receiving phase, 10 ml; concentration of threonine, $3.8 \times 10^{-2}$ M. Using the above optimum conditions, almost all the copper (≈94%) can be transported in less than 3.5 h.

### 3.1. Transport of metal ions

The membrane system operated here is illustrated schematically in Fig. 2. After complexation of a carrier with a metal ion on the left side of the membrane, the complex formed diffuses down its concentration gradient. On the right side of the membrane, the metal ion is released into the receiving phase, probably via a combination of two mechanisms, namely proton exchange [12] and ternary complex formation [13] (ligand–metal–threonine). The released carrier in the neutral form diffuses back

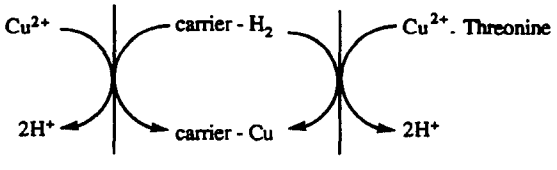

Fig. 2. Liquid membrane system for transport of Cu(II).

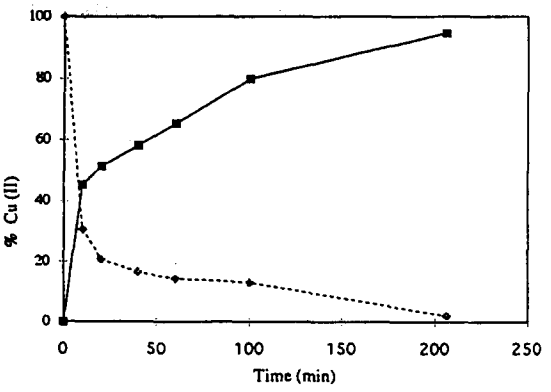

Fig. 3. A plot of Cu(II) ion transport by BMACD vs. time under optimum conditions. (– – –) shows amount of Cu(II) ions in source phase and (—) in receiving phase.

across the membrane. The net result is the transport of metal ion from the source phase, on the left, to the receiving phase, on the right, across the liquid membrane.

Permeability of the membrane system for $Cu^{2+}$ ion also depends largely on the nature of the amino acid in the receiving phase. The presence of a suitable amino acid in the receiving phase is believed to play an essential role in the metal ion releasing process via formation of a ternary complex, carrier–$Cu^{2+}$–amino acid. Such ternary complexes have been recognized as being an important transient species in biological processes [13,14]. Thus, the presence of threonine in the receiving phase and formation of the above-mentioned copper complex reduces the concentration of free Cu(II) ion in the receiving phase and consequently increases the concentration gradient between the two aqueous phases, which in turn results in a higher transport flux. Furthermore, amino acids are hardly soluble in the membrane phase and hence they are found to scarcely move into the aqueous source phase.

It is noteworthy that log $K$ for cation-receiving phase ligand interaction is a very important parameter for determining cation transport selectivity [15], because the larger log $K$, the smaller the concentration of free cation in the receiving phase and the larger the concentration gradient between the aqueous phases. However, towards this end, the importance of the kinetics of liberation of the cation into the receiving phase and its effect on the selectivity of transport should not be ruled out [16].

Additionally the concentration–time profile of Cu(II) transport was studied. Fig. 3 shows a rapid rise in metal concentration in the receiving phase as well as a sharp decrease in Cu(II)

Table 3
Transport of Cu(II) under optimum conditions after 3.5 h in a competitive experiment for an equimolar mixture of Cu(II), Ni(II), Co(II) and Zn(II) in the source phase

| Cation | % Transport to receiving phase | % Remaining in source phase |
|---|---|---|
| $Cu^{2+}$ | 85 | 10 |
| $Ni^{2+}$ | 0 | 100 |
| $Co^{2+}$ | 0 | 100 |
| $Zn^{2+}$ | 0 | 100 |

Table 5
Transport of Cu(II) under optimum conditions after 3.5 h in the presence of equimolar concentrations of Pb(II) and Cd(II)

| Cation | % Transport to receiving phase | % Remaining in source phase |
|---|---|---|
| $Cu^{2+}$ | 94 | 5 |
| $Cd^{2+}$ | – | 100 |
| $Pb^{2+}$ | – | 51 |

concentration of the source phase during the first 20 min of transport.

The selectivity of the above system was studied under the optimum conditions by undertaking competitive transport experiments (starting from an equimolar solution of Cu(II), Ni(II), Co(II) and Zn(II) mixture; the same mixture but with ten times greater concentrations of the interfering ions; and also an equimolar solution of Cu(II), Cd(II) and Pb(II) mixture). The results (Tables 3–5) demonstrate the excellent selectivity of BMACD for transporting Cu(II).

The reproducibility of the transport process was studied by performing the transport experiment several times. The percent relative standard deviation was found to be 2.2%.

## 4. Conclusion

The present study demonstrates that the ligand BMACD is an excellent carrier for selective and efficient transport of Cu(II). The presence of threonine as a "scavenger" in the receiving phase increases the efficiency of transport as well as the speed to a great extent without affecting the selectivity. Uphill transport of Cu(II) against its concentration gradient is easily performed with the above system.

Table 4
Transport of Cu(II) under optimum conditions after 3.5 h in a competitive experiment for a mixture containing Ni(II), Co(II) Zn(II) with concentrations ten times that of Cu(II) in the source phase

| Cation | % Transport to receiving phase | % Remaining in source phase |
|---|---|---|
| $Cu^{2+}$ | 60 | 36.9 |
| $Ni^{2+}$ | – | 85.5 |
| $Co^{2+}$ | – | 89.3 |
| $Zn^{2+}$ | – | 87.5 |

In conclusion, besides the biological importance of the membrane system studies in this work, our experiments demonstrate the potential application for highly selective removal or purification of Cu(II) ion from mixtures with high efficiency, precision and speed.

# Simultaneous spectrophotometric determination of three food dyes by using the first derivative of ratio spectra

J.J. Berzas Nevado, C. Guiberteau Cabanillas, A.M. Contento Salcedo

*Department of Analytical Chemistry and Foods Technology, University of Castilla-La Mancha 13071, Ciudad Real, Spain*

Received 15 February 1995; revised 13 July 1995; accepted 14 July 1995

**Abstract**

Ternary mixtures of colorants E-123 (Amaranth), E-124 (Ponceau 4R) and E-120 (Carminic acid) are resolved by using the first derivative ratio spectrum–zero crossing method without the need for any separation step. Calibration graphs were linear up to 64 mg $l^{-1}$ of carminic acid, 32 mg $l^{-1}$ of Amaranth and 32 mg $l^{-1}$ of Ponceau 4R. The method was applied to different commercial food products and results concordant with high performance liquid chromatography were obtained.

*Keywords:* Food dyes; First derivative spectrophotometry

## 1. Introduction

Color is the first sensory quality by which foods are judged, and food quality and flavor are closely associated with color. Amaranth and Ponceau 4R are two synthetic azo dyes available as red powders that can be present in common foods, drinks, yoghurts, gelatines, etc. These colorants must be named in the list of ingredients after an extensive study of the genotoxicity of food, drugs, cosmetic color and other azo, tryphenylmethane and xanthrene dyes completed by Combes and Haveland-Smith [1]. If these colorants come into contact with some kinds of drugs (e.g. aspirin, benzoic acid) within the human body they can induce allergic and asthmatic reactions in sensitive people. Carminic acid is another natural colorant which is also present in the same kind of foods as Amaranth and Ponceau 4R. The presence and amounts of these three dyes must be controlled as none of them are totally inoccuous. Taking into account the chromophoric characteristics of the three compounds, visible spectrophotometric methods can be used for their quantitative analysis. However, the absorption spectra of Amaranth, Ponceau 4R and carminic acid are very overlapped and direct measurements of the absorbance are not suitable for resolving mixtures of these colorants without a separation step.

Chromatographic methods have been used for colorant analysis in food [2–4]. These techniques are very suitable when the sample contains several colorants. However taking into account other factors such as economy and rapidity, multicomponent analysis by spectrophotometric methods can be a good choice for resolving the colorants contents in food.

Sasaki and co-workers [5,6], Zhang and Huang [7], Momosaki and Fujimoyo [8] and Zeng and co-workers [9,10], proposed quantitative analysis of food colors and similar dyes by multiwavelength measurements. Sasaki [11,12] determined food colorants by derivative spectrophotometry.

We have developed the "derivative of ratio spectra method" which allows the resolution of

*SSDI* 0039-9140(95)01695-3

binary mixtures [13] of chromophores with overlapped spectra. The method is based on the measurements of signal greatest sensitivity, usually a maximum or a minimum in the derivative ratio spectra. The method was extended to resolving ternary mixtures by the simultaneous use of the zero crossing method and derivative of ratio spectra method [14]. In this case the measurements are made at zero crossing wavelengths.

In previous papers we have used this method for resolving different binary and ternary mixtures of colorants [15–18].

Previously, we have proposed methods to determine Amaranth and Ponceau 4R in a binary mixture [15] using the first derivative of ratio spectra as well as the first derivative of absorption spectra. The method was applied to different commercial products containing these colorants. In this paper we include a third colorant, carminic acid, with the aim of demonstrating the ease with which the derivative methods (ratio spectra) circumvent the problem of overlapping spectral bands, so allowing the simultaneous determination of these three dyes (Amaranth, Ponceau 4R and carminic acid) without prior separation.

The proposed method was applied to different commercial products and the results compared with those obtained with high performance liquid chromatography (HPLC) technique used as reference.

## 2. Experimental

### 2.1. Apparatus

A Beckman Instruments DU-70 Spectrophotometer connected to an EMC fitted with Beckman Data Leader Software [19] and an HP DeskJet 510 Printer were used for all the measurements and treatment of data.

### 2.2. Solutions

All solvents and reagents were of analytical reagent grade. Amaranth and Ponceau 4R aqueous solutions were prepared from Aldrich products and carminic acid aqueous solution from Sigma products. Amaranth, Ponceau 4R and carminic acid stock solutions have a concentration of 200 mg $l^{-1}$. Acetic acid/sodium acetate buffer (0.1 M and pH 4.8) was made from analytical reagent grade materials.

### 2.3. Procedure

Samples were prepared in 25 ml calibrated flasks containing 2–32 mg $l^{-1}$ of Amaranth or 2–32 mg $l^{-1}$ of Ponceau 4R or 8–64 mg $l^{-1}$ of carminic acid or their ternary mixtures and 5 ml of pH 4.8 buffer solution and were diluted with water to the mark. The concentration ratio range of the colorants used in the ternary mixtures was 1:0.7 to 1:4 (determined colorant: total interferent colorants). The absorption spectra of the samples thus prepared were recorded against water at 600 nm $min^{-1}$ and stored in the EMC 486.

The stored spectra of Ponceau 4R, carminic acid and ternary mixtures were divided by a 16 mg $l^{-1}$ standard Amaranth spectrum. The first derivatives of the ratio spectra were obtained with $\Delta\lambda_k$ 8 nm and smoothed with the use of 13 experimental points. By measuring the first derivative ratio spectra at the zero crossing points, we can determine Ponceau 4R at 561 nm ($^1DD_{561}$) (zero crossing point of carminic acid) and carminic acid at 373 nm ($^1DD_{373}$) (zero crossing point of Ponceau 4R).

The concentration of Ponceau 4R is proportional to the amplitude at 561 nm and the concentration of carminic acid is proportional to the amplitude at 373 nm. These wavelengths were used to construct the respective calibration graphs.

In contrast, stored spectra of Amaranth and the ternary mixtures were divided by a standard of carminic acid of 16 mg $l^{-1}$. A $\Delta\lambda$ value of 8 nm was used to obtain the first derivative of ratio spectra which were smoothed with the use of 13 experimental points.

Amaranth is determined by measuring at 549.7 nm in the first derivative of ratio spectra ($^1DD_{549.7}$) (zero crossing point of Ponceau 4R). The signal at this wavelength is proportional to the concentration of Amaranth.

## 3. Results and discussion

### 3.1. Method development

The influence of pH on the absorption spectra of the three aqueous solutions of colorants was studied and it was observed that its influence was negligible between 2–9 (for Amaranth), 1–9 (for Ponceau 4R) and 1–5.5 (for carminic acid). A pH of 4.8 was considered suitable for use throughout. Under these condi-

tions diluted solutions of Amaranth, Ponceau 4R and carminic acid were stable for 15 days at least.

In Fig. 1 the absorption spectra of Amaranth, Ponceau 4R, carminic acid and their mixture recorded between 350 and 650 nm are shown. As can be seen, the absorption spectra of the colorants are very overlapped and because of this the determination of the three colorants is not possible by using direct absorbance measurements. The proposed method can resolve this problem.

The determination of two of the dyes in their ternary mixture can be done by using the spectrum of the third colorant of this mixture as divisor. The ratio spectrum is obtained by dividing the amplitudes of the absorption spectrum of the ternary mixture by a standard spectrum of one of the components. When the first derivative of the ratio spectrum is obtained, we have eliminated the contribution to the signal of the component used as divisor. The other two components can be determined by measurement at the zero crossing points as in derivative spectrophotometry.

Thus, it is possible to determine each colorant by using two divisors, e.g. carminic acid can be determined when Amaranth as well as Ponceau 4R is used as divisor.

In order to obtain good resolution it is necessary to study and to optimize the following parameters: concentration of the standard spectrum used as divisor; $\Delta\lambda$ to obtain the first derivative; smoothing function; and the zero crossing points.

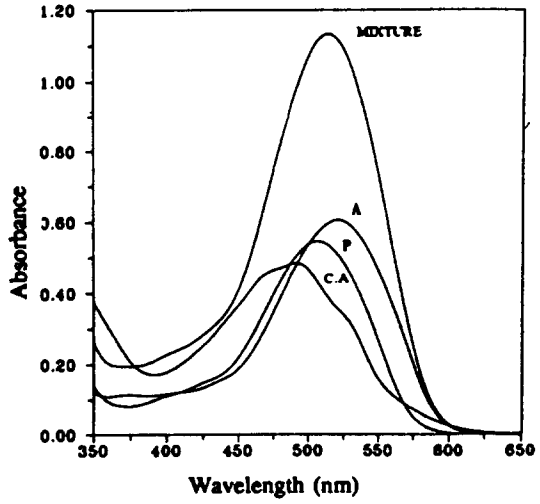

Fig. 1. Absorption spectra of (A) Amaranth (8 mg $l^{-1}$), (P) Ponceau 4R (8 mg $l^{-1}$), (C.A) carminic acid (24 mg $l^{-1}$), and their mixture.

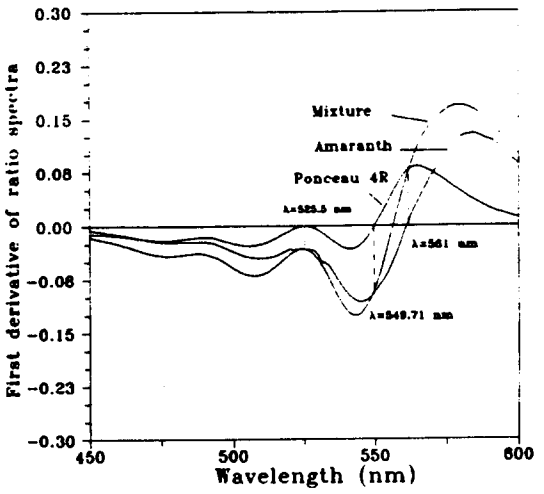

Fig. 2. First derivative of the ratio spectra of Amaranth (8 mg $l^{-1}$), Ponceau 4R (8 mg $l^{-1}$) and ternary mixtures (8 mg $l^{-1}$ of Amaranth, 8 mg $l^{-1}$ of Ponceau 4R and 20 mg $l^{-1}$ of carminic acid) using 32 mg $l^{-1}$ carminic acid spectrum as divisor.

*Determination of Amaranth and Ponceau 4R in the presence of carminic acid*

The influence of the variables mentioned above was studied and the values chosen as optimal were: a standard spectrum of 32 mg $l^{-1}$ of carminic acid to obtain the ratio spectra; a $\Delta\lambda$ value of 8 nm to obtain the first derivative ratio spectra; and 13 experimental points in the smoothing function.

Fig. 2 shows the first derivative ratio spectra of Amaranth, Ponceau 4R and a ternary mixture obtained by using the selected parameter values.

The wavelengths suitable for measuring the signal in the first derivative ratio spectra ($^1DD_\lambda$) were selected taking into account the zero crossing point method. These wavelengths were 561 nm (zero crossing point of the ratio spectrum of Amaranth) to determine Porceau 4R and 549.7 and 525.5 nm (zero crossing point of the ratio spectrum of Ponceau 4R) to determine Amaranth. At these wavelengths the first derivative of ratio spectra of the ternary mixture and standard spectra of Amaranth and Ponceau 4R are coincident, as can be seen in Fig. 2.

The calibration graph of Ponceau 4R was obtained by plotting the $^1DD_{561}$ signal against the concentration and gave a straight line up to 32 mg $l^{-1}$ of Ponceau 4R. For Amaranth, two calibration graphs were obtained at 525.5 nm ($^1DD_{525.5}$) and 549.7 nm ($^1DD_{549.7}$) and gave straight lines up to 32 mg $l^{-1}$ of Amaranth.

*Determination of carminic acid and Ponceau 4R in the presence of Amaranth*

In this case the optimal values established were: a standard spectrum of 16 mg $l^{-1}$ of Amaranth as divisor, a $\Delta\lambda$ value of 8 nm for the derivative ratio spectra, and a smoothing of 13 experimental points. Fig. 3 shows the first derivative ratio spectra of carminic acid and Ponceau 4R. The Ponceau 4R content can be determined by measurement at 561.5, 442.5 and 396.5 nm (zero crossing points for derivative ratio spectra of carminic acid) and carminic acid can be determined by measurement at 459 and 373 nm (zero crossing points for derivative ratio spectra of Ponceau 4R). Calibration graphs were established at wavelengths previously selected and gave straight lines up to 32 mg $l^{-1}$ for Ponceau 4R and 64 mg $l^{-1}$ for carminic acid.

*Determination of carminic acid and Amaranth in the presence of Ponceau 4R*

The values chosen as optimal were: a standard spectrum of 16 mg $l^{-1}$ of Ponceau 4R as divisor, a $\Delta\lambda$ value of 8 nm for first derivative ratio spectra, and a smoothing function of 15 experimental points. Fig. 4 shows the first derivative ratio spectra of carminic acid and Amaranth. As can be seen the carminic acid can be determined by measuring at 460 and 373.5 nm (zero crossing points for derivative ratio spectra of Amaranth) and Amaranth can be determined by measuring at 549.5 and 524 nm (zero crossing points for derivative ratio spectra of carminic acid). Calibration graphs were established at wavelengths selected and gave straight lines up to 32 mg $l^{-1}$ for Amaranth and 64 mg $l^{-1}$ for carminic acid.

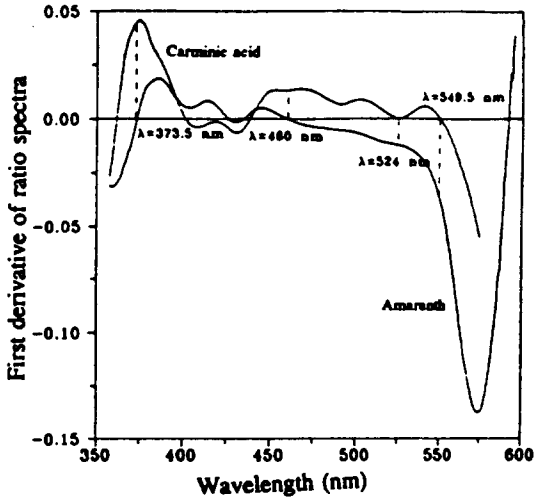

Fig. 4. First derivative of the ratio spectra of carminic acid (32 mg $l^{-1}$) and Amaranth (8 mg $l^{-1}$) using 16 mg $l^{-1}$ Ponceau 4R spectrum as divisor.

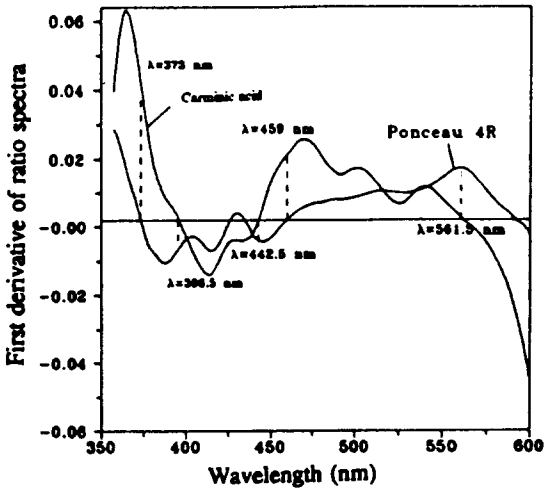

Fig. 3. First derivative of the ratio spectra of carminic acid (32 mg $l^{-1}$) and Ponceau 4R (8 mg $l^{-1}$) using 16 mg $l^{-1}$ Amaranth spectrum as divisor.

### 3.2. Statistical comparative study

Table 1 summarizes the calibration graphs obtained for each dye with each divisor. In all cases good regression coefficients are obtained.

In order to test the precision of the methods replicated samples were measured ($n = 9$) containing Amaranth (8 mg $l^{-1}$), carminic acid (20 mg $l^{-1}$) and Ponceau 4R (8 mg $l^{-1}$) individually (Table 2). The determination limits were calculated for each dye and are shown in the same Table [20,21].

Taking into account the calibration graphs, the reproducibility and the determination limit, we have selected as signals of measurement $^1DD_{549.7}$ and $^1DD_{561}$ to determine Amaranth and Ponceau 4R respectively when carminic acid is used as divisor.

In the case of Amaranth as the divisor, $^1DD_{561.5}$ to determine Ponceau 4R and $^1DD_{373}$ to determine carminic acid were selected. Finally, the determination of Amaranth and carminic acid (when Ponceau 4R is used as divisor) is proposed to be done at $^1DD_{549.5}$ and $^1DD_{524}$ and at $^1DD_{373.5}$ respectively.

Table 1
Calibration graphs ($n = 9$)[a]

## 4. Applications

### 4.1. Synthetic mixtures

The proposed method was applied for resolving the determination of Amaranth, Ponceau 4R and carminic acid in synthetic mixtures prepared in different proportions. The results corresponding to these determinations are summarized in Tables 3–5.

Taking into account the recoveries obtained, as well as the calibration graphs and the statis-

[a] Carminic acid. Measurement at 373 nm (divisor Amaranth).
[b] Amaranth. Measurement at 549.7 nm (divisor carminic acid).
[c] Ponceau 4R. Measurement at 561.5 nm (divisor Amaranth).

tical parameters, we can conclude that the best methods to determine Amaranth is by measurement at 549.7 nm in the first derivative ratio spectrum ($^1DD_{549.7}$) when the divisor used is carminic acid (32 mg $l^{-1}$). The recoveries obtained at the assayed ratios ranged between 92.2 and 102.3%.

In contrast the determination of Ponceau 4R is better when we use as the signal of measurement $^1DD_{561.5}$ (Amaranth as divisor). The recoveries found were between 95.7 and 103.3%.

Finally, the determination of carminic acid is proposed to be done by measurements at 373 nm in the first derivative ratio spectrum ($^1DD_{373}$), when Amaranth is used as divisor. The recoveries found were from 95 to 105%. In conclusion, this method is available for the simultaneous determination of Amaranth, Ponceau 4R and carminic acid.

### 4.2. Commercial products

In a previous paper, we have established methods that permit the determination of Amaranth and Ponceau 4R by using the first derivative absorption spectra and derivative ration spectra [15]. These methods were applied to determine these colorants in commercial food products such as gelatin desserts with strawberry flavor from Royal Brands S.A and beverages such as grenadine from Rives-Pitman S.A.

In order to apply the method proposed to determine Amaranth, Ponceau 4R and carminic acid in food samples, and because we have not found commercial products which contain all three colorants, we have spiked the commercial food products mentioned above with carminic acid: i.e. different amounts of carminic acid were added to 2 g strawberry gelatin and 4 ml grenadine.

The amount of colorant in each sample was calculated by using the established calibration graphs or by using the standard addition method. In both cases the methods described were applied.

The preparation of samples was as follows.

*Strawberry gelatins*

(1) Quantitative determination by direct preparation using the calibration graphs established: 2 g of product was diluted with 10 ml acetic acid/sodium acetate buffer solution (pH 4.8; ionic strength 0.1) and 25 ml distilled water in a beaker over a low heat with gentle swirling until dissolved. The solution was filtered and transferred to a 50 ml flask and diluted with distilled water to the mark. The absorption spectra were recorded with the instrumental conditions previously selected, and the methods described were applied.

(2) Quantitative determination by standard addition: to 2 g product was added different amounts (2, 4, 6, 8 mg $l^{-1}$) of dye to determine and the procedure (1) was followed.

*Grenadine*

(1) Quantitative determination by direct preparation using the calibration graphs established: 4 ml sample was diluted with 5 ml acetic acid/sodium acetate buffer solution (pH 4.8; ionic strength 0.1), transferred to a 25 ml flask and diluted with distilled water to the mark. The absorption spectra were recorded with the instrumental conditions previously selected and the methods described were applied.

(2) Quantitative determination by standard addition: to 4 ml sample were added different amounts (2, 4, 6, 8 mg $l^{-1}$) of dye to determine and the procedure (1) was followed.

We have used an HPLC method to analyze the samples based on the formation of an ion-pair, whose conditions we have previously established [15]. Table 6 shows the results obtained. As can be seen the results obtained by the HPLC method demonstrate that there is good agreement between the methods.

## 5. Conclusion

The methods proposed are suitable to determine synthetic mixtures of carminic acid, Ponceau 4R and Amaranth obtained in the laboratory. It is also possible to determine these colorants in real samples such as gelatin desserts with strawberry flavor and beverages.

# Indirect ultraviolet determination of silver with nickelocyanide ion by flow injection analysis

Amin T. Haj-Hussein

*Chemistry Department, Yarmouk University, Irbid, Jordan*

Received 5 June 1995; revised 20 July 1995; accepted 20 July 1995

**Abstract**

A flow-injection method for the ultraviolet spectrophotometric determination of silver, based on its reaction with nickelocyanide ion, $Ni(CN)_4^{2-}$, in ammoniacal buffer medium (pH 10) and subsequent measurement of the decrease in the absorption of the $Ni(CN)_4^{2-}$ complex at 275 nm is described. The calibration graph is linear in the range 10–400 μm silver. At a sampling rate of about 60 samples $h^{-1}$ with 35 μl sample injections, precision was about 1% relative standard deviation. The proposed method was successfully applied to the determination of silver in some common silver minerals.

*Keywords:* Silver; Nickelocyanide ion; Flow injection analysis

## 1. Introduction

Silver is widely distributed in nature and is a major component of a wide range of minerals. The large number of complex silver compounds which exist yield a correspondingly large number of spectrophotometric, volumetric and gravimetric analysis techniques for silver [1]. Nickelocyanide ion, $Ni(CN)_4^{2-}$, was used as analytical reagent for indirect determination of silver [2]. The analysis is based upon the ionic exchange reaction between $Ni(CN)_4^{2-}$ and $Ag^+$ which proceeds almost completely to the right, with the following stoichiometry in ammoniacal solution:

$$Ni(CN_4^{2-} + 2Ag^+ 2Ag(CN)_2^- + Ni^{2+}$$

The equivalent amount of $Ni^{2+}$ liberated may be titrated with standard EDTA using an appropriate indicator. This reagent, which absorbs in the ultraviolet region, has been used for the spectrophotometric determination of cyanide ion [3].

In an investigation of the reaction between $Ag^+$ and $Ni(CN)_4^{2-}$, in ammoniacal buffer solution, it was found that addition of silver ion decreased the ultraviolet absorbance of the $Ni(CN)_4^{2-}$ reagent. Moreover, the decrease in the ultraviolet absorption is linear with silver concentration up to 400 μM. This property is utilized as the basis for the development of a new ultraviolet–flow injection analysis (UV–FIA) method for the determination of silver.

This work describes improvements in simplicity and speed in the determination of $Ag^+$. A commonly used method is titration of $Ag^+$ with $Ni(CN)_4^{2-}$ followed by a back titration of $Ni^{2+}$ with EDTA and an appropriate indicator. This method can be simplified by eliminating the back titration step because the concentration of $Ni(CN)_4^{2-}$ can be monitored directly by UV absorption. By simplifying the method, the need to titrate to an endpoint is also eliminated. The one-step analysis is more rapid and well suited for the flow injection format which further enhances the speed of analysis.

FIA [4] is now a well-established technique for carrying out automatic wet chemical analy-

*SSDI* 0039-9140(95)01697-X

sis in a rapid and efficient way. It has been successfully applied for direct instrumental analytical methods with various detection techniques [4–9]. Therefore, it is of interest to adapt this silver determination method to a flow injection system for the continuous spectrophotometric determination of silver in silver minerals.

This paper describes a simple, rapid and specific method for the determination of silver, based on the reaction between $Ni(CN)_4^{2-}$ and $Ag^+$ by means of UV–FIA.

## 2. Experimental

### 2.1. Reagents

All chemicals used were analytical reagent grade, unless otherwise specified; all solutions were prepared with deionized water.

#### 2.1.1. Potassium nickelocyanide $K_2[Ni(CN)_4]$

Prepared as described elsewhere [2].

#### 2.1.2. Stock nickelocyanide ion solution, $1.0 \times 10^{-2}$ M

Prepared by dissolving the calculated amount of $K_2[Ni(CN)_4]$ in water.

#### 2.1.3. Stock ammoniacal buffer solutions

These are 1.20 M ammonia/ammonium nitrate buffers at pH 8.5, 9.3, 10.0 and 10.3. The pH values of these buffers were adjusted with ammonia or ammonium nitrate. All pH measurements were made using a Metrohm Herisau (Type E 520) pH meter.

#### 2.1.4. Carrier solutions

The carrier solutions were dilute ammoniacal buffer solutions (10%). Carrier solutions of pH 8.5, 9.3, 10.0 and 10.3 were prepared from the above stock solutions by accurate dilution with water.

#### 2.1.5. Reagent solutions

The reagent solutions, $Ni(CN)_4^{2-}$, were prepared by mixing the calculated amount of stock nickelocyanide ion solution with 10 ml of stock buffer solution of the required pH value, and diluting to 100 ml with water. The reagent solutions prepared are shown in Table 1.

#### 2.1.6. Standard silver solutions

Silver stock solution ($1.0 \times 10^{-2}$ M) was prepared by dissolving the calculated amount of dried $AgNO_3$ in water. The working silver solutions, $0.10–6.0 \times 10^{-4}$ M, were prepared by mixing the calculated amount of the stock silver solution with 10 ml of the stock buffer of the required pH value and diluting to 100 ml with water.

### 2.2. Dissolution of silver minerals

About 100 mg of sample (accurately weighed) was dissolved in 3 ml of 1:1 nitric acid. The solution was boiled until all the oxides of nitrogen were removed. The solution was diluted to about 50 ml and boiled again after addition of 5 ml concentrated ammonia solution. On cooling the insoluble matter was filtered off and made up to 100 ml with water.

Sample solutions of three silver minerals including native silver (Ag), proustite ($Ad_3AsS_3$) and pyrargyrite ($Ag_3SbS_3$) were prepared. Working solutions for the determination of silver were prepared by mixing aliquots of each sample solution (0.5 ml for native silver, 1.0 ml for proustite, and 1.0 ml for pyrargyrite) with 2.5 ml of the stock buffer (pH 10) and diluting to 25 ml with water.

### 2.3. Apparatus

A schematic dagram of the flow injection system is shown in Fig. 1. The system was assembled from 0.51 mm Microline tubing. The manifold consists of two lines, the top one carrying the carrier solution into which the sample is injected and the lower one carrying the reagent solution. Carrier and reagent solutions were delivered by an Ismatic peristaltic pump (Type MINI-S 860) operated with Tygon tubing. Sample solutions were injected manually into the carrier stream using a Reodyne four-way Teflon valve injector (Type 50). A home-made [4] confluence point with mixing point was used to obtain effective mixing without excessive dispersion of the sample solution. A DuPont ultraviolet spectrophotometer, equipped with a 10 mm flow cell, was used

Table 1
Reagent solutions prepared

| Concentration of $Ni(CN)_4^{2-}$ ($10^4$ M) | pH |
|---|---|
| 2.0 | 8.5 |
| 2.0 | 9.3 |
| 0.5, 1.0, 2.0, 3.0, 4.0, 6.0 | 10.0 |
| 2.0 | 10.3 |

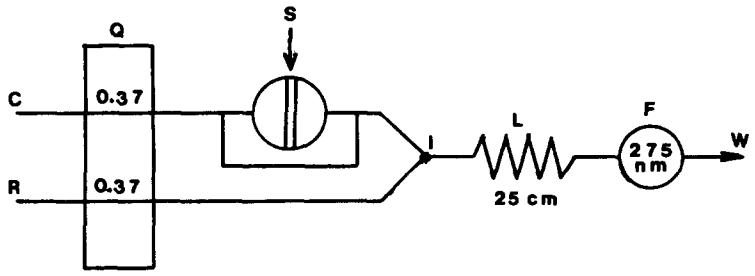

Fig. 1. Two-line manifold for indirect ultraviolet determination of silver. The internal diameter of the Microline tubing was 0.51 mm from the injection valve to the detector. C, carrier stream: R, reagent stream; Q, flow rate (ml $min^{-1}$); S, sample injection; I, confluence point; L, reaction coil; F, flow-through cell; W, waste.

as detector and was connected to a 1 mV Varian recorder (Model 9176).

### 2.4. FIA

The flow system illustrated in Fig. 1 is used. Different volumes in the range 25–200 µl of silver standard solutions were aspirated in the sample loop by means of a syringe. Samples were injected into the carrier stream by pumping at a rate of 0.37 ml $min^{-1}$. The reagent was added at a rate of 0.37 ml $min^{-1}$ in a confluence manner downstream to ensure the rapid and adequate mixing of the sample with the reagent. After an injection, the valve was returned to the load position when the baseline had been reached. The decrease in absorbance was monitored at the wavelength maximum (275 mM) for the $Ni(CN)_4^{2-}$ complex. The output (negative signals) of the ultraviolet spectrophotometer was registered on the chart recorder. When the baseline was reached, another slug of the sample could be injected. The area or the height of the negative absorbance peak can be used for the calibration.

## 3. Results and discussion

Determination of silver by this UV–FIA method is based on the decrease in absorption of nickelocyanide complex ion in ammoniacal buffer solution at 275 nm. The chemical variables and the FIA variables influencing the system were optimized to achieve reproducible results.

### 3.1. Optimization of chemical variables

Absorbance measurements were performed using the manifold shown in Fig. 1. Considering the baseline of the carrier solution (carrier of pH 10 was pumped in both lines of the manifold), the absorbance values at 275 nm of $NI(CN)_4^{2-}$ reagent solutions (pH 10) were measured in the concentration range $0.5 \times 10^{-4}$–$6.0 \times 10^{-4}$ M. Fig. 2 shows that the variation of absorbance with concentration of $Ni(CN)_4^{2-}$ solutions yields a linear relationship up to $2.0 \times 10^{-4}$ M and shows a considerable deviation at higher concentrations.

By injecting standard silver solutions into the carrier stream, using $2.0 \times 10^{-4}$ M $Ni(CN)_4^{2-}$ as reagent, a decrease in the absorbance values was obtained. Fig. 3 shows that the decrease in absorbance values at 275 nm is linear in the silver concentration range 0.10–4.0 $\times 10^{-4}$ M. This permits silver to be determined in quantities up to $4 \times 10^{-4}$ M. Moreover, it indicates that the reaction between $Ni(CN)_4^{2-}$ and $Ag^+$ with a mole ratio of 1:2 proceeds to completion using this FIA system.

The effect of pH on the reaction between silver and $Ni(CN)_4^{2-}$ was studied in ammoniacal ($NH_3/NH_4NO_3$) buffer medium at pH values in the range 8.5–10.3. Fig. 4 shows that no significant changes were observed.

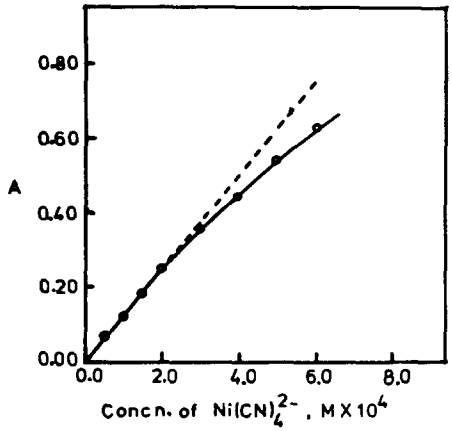

Fig. 2. Plot of absorbance versus concentration of $Ni(CN)_4^{2-}$ reagent solutions at 275 nm. Carrier stream was ammoniacal buffer (pH 10.0).

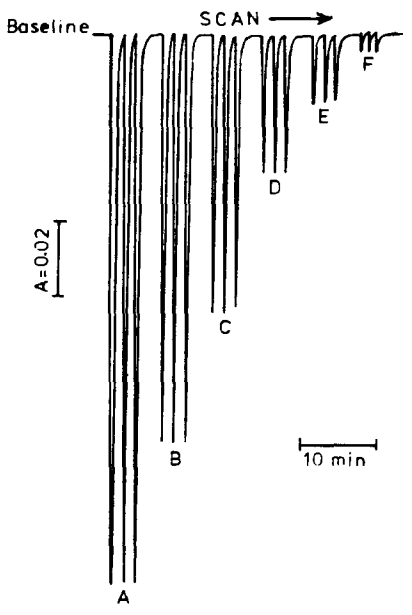

Fig. 3. Flow-injection signals for indirect ultraviolet determination of silver at a rate of approximately 60 samples $h^{-1}$ with the manifold shown in Fig. 1. Silver (μM): A, 400; B, 300; C, 200; D, 100; E, 50; F, 10. Concentration of $Ni(CN)_4^{2-}$ reagent was $2.0 \times 10^{-4}$ M; injection volume, 35 μl; carrier, ammoniacal buffer (pH 10); wavelength, 275 nm.

### 3.2. Optimization of FIA variables

#### 3.2.1. Wavelength selection

Fig. 5 depicts the absorption spectra of $Ni(CN)_4^{2-}$ complex ($2.0 \times 10^{-4}$ M) in ammoniacal buffer solution at pH 10.0. The curve exhibits a band with maximum absorbance at 275 nm which was chosen as the optimum wavelength for studying the factors influencing this FIA system.

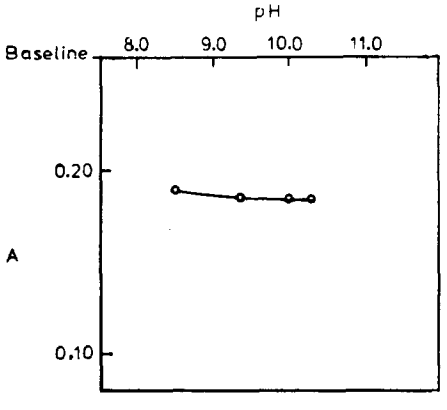

Fig. 4. Effect of pH on the determination of silver. Concentration of silver was $2.0 \times 10^{-4}$ M; other conditions were as given in Fig. 3.

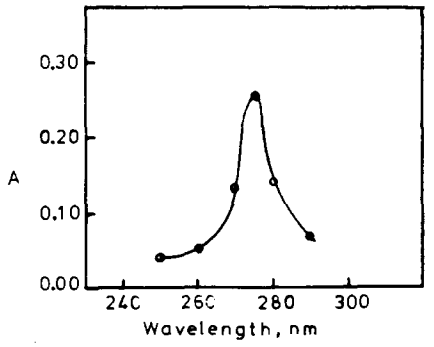

Fig. 5. Absorption spectrum of $Ni(CN)_4^{2-}$ at pH 10 with the manifold shown in Fig. 1. Concentration of $Ni(CN)_4^{2-}$ was $2.0 \times 10^{-4}$ M; carrier, ammoniacal buffer (pH 10.0).

#### 3.2.2. Sample injection volume

The optimum volume of injected sample was found to be 35 μl.

#### 3.2.3. Length of reaction coil

The signal (negative peak) increased linearly with length (15–100 cm) and internal diameter (up to 0.51 mm) of the reactor tube. A reactor length ($L$) of 25 cm and i.d. of 0.51 mm were chosen to give a compromise between maximum peak height and sampling frequency.

#### 3.2.4. Flow rate

The optimum flow rate was found to be 0.7 ml $min^{-1}$. At this flow rate with 35 μl sample injections in this work, the average sampling rate was around 60 samples $h^{-1}$.

### 3.3. System characterization

The flow system in Fig. 1 was used for preparing the calibration graph. The sample solution was injected from a sample loop of 35 μl. Typical signals are shown in Fig. 3. The calibration graph is linear up to $4.0 \times 10^{-4}$ M silver (400 μM). The limit of detection (2 × noise) for silver was 3 μM (0.32 ppm). The percent relative standard deviation for 10 replicate injections was $< 1\%$.

### 3.4. Interference study

A systematic study of potential interferences in the proposed method was made. Copper, nickel, zinc, lead, iron, bismuth and arsenic which may be found in the common silver minerals [10] were studied for their interfering effects. Each metal ion was studied in the range

Table 2
Determination of silver in some silver minerals determined by the proposed FIA method and by AAS

| Sample | Ag content (%) | |
|---|---|---|
| | FIA method | AAS method [a] |
| NS [b] | 96.6 | 97.5 |
| Pr [c] | 25.5 | 25.4 |
| Py [c] | 32.9 | 31.7 |

[a] A Pye Unicam SP9 atomic absorption spectrophotometer equipped with a silver hollow-cathode lamp was used. The wavelength was set at 328.1 nm and the operating conditions were adjusted following standard recommendations.

[b] Provided by the Geology Department, Yarmouk University. NS, native silver (Beaverdall, British Columbia, Canada).

[c] Provided by the Geology Department, University of Jordan. Pr, Prousite; Py, pyrargyrite (Frieberg, Sachsen, Germany).

$4.0 \times 10^{-4}$–$2 \times 10^{-4}$ M silver at pH 10 (ammoniacal buffer solution). No effects were apparent for $Zn^{+}$, $Ni^{2+}$ and $AsO_4^{2-}$ ions over the complete range of concentrations investigated. $Cu^{2+}$ caused decreased peaks when concentration exceeded $4.0 \times 10^{-4}$ M. In contrast, $Pb^{2+}$, $Fe^{2+}$ and $Bi^{3+}$ ions precipitated in the ammoniacal buffer solution. In the determination of silver in silver minerals, however, dissolving these minerals in nitric acid, followed by addition of excess ammonia and filtration would remove all these ions and so prevent interference.

### *3.5. Determination of silver in silver minerals*

The proposed method was applied to the determination of silver in native silver, proustite and pyrargyrite minerals. The results (silver content, %) of the analyses are summarized in Table 2.

A measure of the reliability of the proposed method is given by Table 2 in which the results are compared with those obtained using AAS by complete decomposition with nitric acid [11]. There is general agreement between the results of the methods. It is also apparent that the results for silver were not affected by various elements present in the mineralized samples.

Short communication

# Procedure for dissolving wolframite in order to determine trace elements by atomic absorption spectrometry

Silvano Mignardi, Umberto Masi *

*Dipartimento di Scienze della Terra, Università "La Sapienza", P. le A. Moro 5, 00185 Roma, Italy*

Received 25 January 1995; revised 22 June 1995; accepted 30 June 1995

**Abstract**

An analytical procedure for dissolving wolframite in order to determine trace elements by atomic absorption is reported. After decomposition of the mineral by alkaline fusion, the cooled flux is dissolved by heating with aqua regia. The finely crystalline precipitate of tungstite, which forms on standing, is filtered and dissolved by heating with aqua regia. Tungstite forms again in the latter solution and the filtration and solubilization are repeated until the solution contains negligible amounts of trace elements. Following this procedure, trace elements in 35 samples of natural wolframite have been dissolved and the solutions obtained have been analyzed by atomic absorption spectrometry for Fe, Mn, Cu, Zn, Pb, Co, Ni and Cd.

*Keywords:* Wolframite; Trace elements; Atomic absorption spectrometry

## 1. Introduction

Trace element analyses of natural wolframites are very rare. Wolframites are routinely analyzed using an electron microprobe (EM) [1,2], and therefore the results are reliable only for major elements. Trace element concentrations are generally near, or in the range of the analytical error [1,2]. Lack of information about trace element contents of wolframite therefore represents a major handicap in the interpretation of the results of geochemical studies of the origins of ore deposits. For other mineral phases, such as sulfides and oxides for instance, trace element composition is often useful in elucidation of the composition of the parent solutions [3–6].

To fill this gap, this paper describes a procedure for wolframite trace element solubilization, which allows determination of trace element concentrations by atomic absorption spectrometry (AAS). Thirty-five wolframite samples from two major hydrothermal deposits in Portugal have been analyzed. In addition to trace elements, Fe and Mn were also determined in the same solutions by AAS. For these two elements the results were compared with the corresponding concentrations determined by EM analysis with a Jeol JXA 50A with EDS Link system (counting time 100 s, 15 keV and 2 mA) [7].

## 2. Experimental

The procedure presented was derived from the industrial technique of $WO_3$ preparation, namely alkaline fusion of wolframite and subsequent purification of $WO_3$ by repeated acid leaching.

Subsamples of about 200 mg of powdered ($\phi \approx 0.25$ mm) wolframite were mixed with 1 g of $Na_2CO_3$ and 200 mg of $Na_2NO_3$ and the

Table 1
Average element concentrations (ppm) determined in the four solutions

| Element | Solution | | | |
|---|---|---|---|---|
| | A | B | C | D |
| Fe | 151536 | 2327 | 231 | 15 |
| Mn | 23201 | 65 | 9 | 5 |
| Cu | 200 | 15 | 10 | – |
| Zn | 210 | 20 | 5 | – |
| Pb | 85 | 10 | – | – |
| Co | 50 | 10 | – | – |
| Ni | 160 | 15 | – | – |
| Cd | 30 | 5 | – | – |

mixture was fused in a platinum crucible at approximately 700°C for 10 min. The fused mass was cooled and dissolved by heating with 10 ml of aqua regia; the solution (solution A) soon became turbid, with a very fine, crystalline (as proved by XRD analyses) precipitate of tungstite ($WO_3 \cdot H_2O$). The precipitate, which still contained some trace elements of wolframite, was filtered off and dissolved by heating with 15 ml of aqua regia in a Teflon crucible. This latter solution (solution B) also soon became turbid because of tungstite precipitation, and it too was filtered. The precipitate was again dissolved in 15 ml of aqua regia in a Teflon crucible and the third solution (solution C) was again filtered.

The three solutions obtained were then analyzed for Fe, Mn, Cu, Zn, Pb, Co, Ni and Cd by AAS using a double-beam Perkin-Elmer Model 460 spectrophotometer and matrix-matched standards.

As expected, solution C for all samples had lower element contents than solution B, which, in turn, was less rich than solution A. However, as solution C did not have negligible trace element concentrations, the tungstite precipitate from this solution was dissolved again in 15 ml of aqua regia, thus giving rise to solution D. After filtration, the latter solution was analyzed by AAS to give, finally, trace element concentrations lower than the analytical error, which thus were negligible.

## 3. Results and discussion

Table 1 shows the results obtained. It is apparent that over 99% of Fe and Mn of wolframite are contained in the two early solutions (solution A and solution B) and trace elements are detectable in all the solutions except solution D. However, the recovery of Pb, Co, Ni and Cd was analytically complete in solutions A and B, whereas that of Cu and Zn was complete only with solution C. This is probably because Cu and Zn are more (2–10 times) abundant than the other trace elements in the samples studied [7].

Table 2 shows major and trace element contents in selected wolframite samples from the Panasqueira mine (Portugal) determined by AAS compared with the data for the same samples analyzed by EM. For Fe and Mn the results obtained by the two techniques show no significant difference as the AAS values fall in the range of EM values at $\pm 1\sigma$; on the contrary, for trace elements the contents determined by EM are indefinite, being all below the analytical error ($\sigma$) and thus no comparison with the AAS data can be drawn.

Table 2
Concentrations of major (mass %) and trace (ppm) elements in selected samples from 35 analyzed wolframites from the Panasqueira deposit (Portugal) determined by AAS and EM. $\sigma$: microprobe analytical error (mass %)

| Element | Sample | | | | | | | | $\sigma$ |
|---|---|---|---|---|---|---|---|---|---|
| | P-501 | | P-511 | | P-512 | | P-525 | | |
| | AAS | EM | AAS | EM | AAS | EM | AAS | EM | |
| Fe | 15.08 | 15.20 | 15.63 | 15.07 | 15.73 | 15.38 | 14.94 | 15.22 | ±0.44 |
| Mn | 2.61 | 3.01 | 2.56 | 2.47 | 2.34 | 2.88 | 2.29 | 2.56 | ±0.52 |
| Cu | 704 | $<\sigma$ | 688 | $<\sigma$ | 70 | $<\sigma$ | 70 | $<\sigma$ | ±0.28 |
| Zn | 457 | $<\sigma$ | 213 | $<\sigma$ | 209 | $<\sigma$ | 219 | $<\sigma$ | ±0.48 |
| Pb | 65 | $<\sigma$ | 35 | $<\sigma$ | 50 | $<\sigma$ | 70 | $<\sigma$ | ±0.18 |
| Co | 70 | $<\sigma$ | 67 | $<\sigma$ | 65 | $<\sigma$ | 50 | $<\sigma$ | ±0.20 |
| Ni | 119 | $<\sigma$ | 148 | $<\sigma$ | 160 | $<\sigma$ | 119 | $<\sigma$ | ±0.23 |
| Cd | 25 | $<\sigma$ | 25 | $<\sigma$ | 30 | $<\sigma$ | 20 | $<\sigma$ | ±0.14 |

## 4. Conclusions

The following procedure is suggested to determine trace element abundance in wolframite. Fuse wolframite with $Na_2CO_3 + Na_2NO_3$ and dissolve the cooled fused mass by heating with aqua regia. Filter the tungstite which precipitates and dissolve the precipitate in aqua regia. Tungstite forms again in the new solution, so filtration and dissolution of the precipitate must be repeated until AAS analyses carried out on the solution give negligible trace element concentrations.

Although the procedure given here is more time-consuming than EM analyses, it is worthwhile as it allows the geochemist to measure trace elements at amounts significantly lower than 1000 ppm, whereas the analytical error of EM is generally larger.

## Acknowledgements

The authors thank Mr. G. Aurisicchio for assistance provided during atomic absorption analyses and Dr. C. Aurisicchio and Dr. M. Rettighieri for help during the microprobe work.

Received 4 April 1995; accepted 5 July 1995

**Abstract**

A multicomponent detection system using optical biosensors and flow injection analysis is described. The analysis of mixtures containing penicillin and ampicillin was realised by evaluating dynamic measurements of Phenol Red spectra in penicillinase optodes in combination with a diode array spectrometer. A variety of optodes has been produced by changing the composition of the receptor gel and the working pH. A set of characteristic quantities (describing dynamic and static features) could be obtained for each optode. These were used to compare the predictivity of classical multivariate calibration methods as well as of an artificial neural network. In addition, different algorithms were applied for the evaluation of the spectral data in order to select the most appropriate method for feature extraction. In consequence, the information obtained from the multivariate calibration models was used to set up an optimal sensor array consisting of four optodes with different types of penicillinase at different working pH.

*Keywords:* Penicillin; Ampicillin; Optical biosensors; Flow injection analysis; Multivariate data analysis

## 1. Introduction

Enzyme optodes have become well established as modern tools in certain areas of analytical chemistry during the last 15 years. This type of sensor based on fibre optic techniques has already been described in monographs [1,2]. In spite of this considerably long development time and the efficiency attained in laboratory set-ups the practical application is not established yet. The reasons are: (i) the relatively short lifetime of many optodes and (ii) their lack of signal stability due to interferences in typical analytical matrices. These problems can be overcome by combining optodes with flow injection analysis (FIA) and multivariate data analysis applied to an array of optodes rather than to a single one. Within the multivariate methods, partial least-squares (PLS) [3–7] is applied more and more in optical analysis of chemical systems [8–10].

However, in the area of optical sensing, and especially in the combination of spectral detection methods with an FIA system [11], just a few examples are given in the literature. For example, the determination of pesticides by differential degradation using PLS and spectral data produced in an FIA system is described in

*SSDI* 0039-9140(95)01684-8

Ref. [12]. Using a stopped-flow injection system [13], metal ions can be determined by kinetic analysis of spectra. Finally, mixtures of hydroxybenzaldehydes were analysed by photodiode array detection applying reproducible pH gradients produced by an FIA technique [14].

In this paper, the evaluation of transient signals from penicillinase optodes in an FIA system using multivariate methods is described. Lactam antibiotics, for example penicillin G or V, ampicillin and cephalosporin C, are effective drugs against infectious diseases. Although these drugs have been well studied in the past, new methods are still of interest to determine quickly and safely penicillin derivatives [15,16]. In principle, penicillin compounds can be individually detected by penicillinase optodes [17–19]. However, mixtures of penicillin components have not yet been analysed by enzyme optodes. In the present study, we report results obtained by simultaneous analysis of mixtures of penicillin G and ampicillin by an optode array. We compare several methods for feature extraction and multivariate calibration to select the optimum composition of the optode array.

## 2. Theory

### 2.1. Data evaluation and feature extraction

The data available from the optodes consist of the transient diffuse reflectance spectra in the visible wavelength region obtained at equidistant time intervals after the injection of an analyte into the FIA system. When the analyte reaches the sensor at time $t_0$, the flow is stopped. The change in the reflectance with time may then be described on an empirical basis by the exponential function given in Eq. (1) for each optode $i$:

$$R_i(\lambda, t) = R_i^{\text{stat}}(\lambda)[1 - e^{-k_i(t - t_0)}] \quad (1)$$

Here, $t_0$ corresponds to the time when the optode/analyte interaction starts. $R_i^{\text{stat}}$ comprises the wavelength-dependent maximum change in reflectance for the specific optode $i$ (static information). $k_i$ includes the dynamic behaviour of the optode $i$.

For the sensor evaluation, the dynamic features (i.e. the time dependence of the signal described by $k_i$) and the static features (i.e. the steady state signals described by $R_i^{\text{stat}}$) may be considered. The steady state signals should give information on the total concentration of analytes whereas the dynamic signals should contain analyte-specific information. In this section, we discuss algorithms for the extraction of both dynamic and static information from the spectral data.

The parameters in Eq. (1) may be obtained by non-linear least-squares regression. For online data evaluation, simultaneous application of Eq. (1) to the whole set of wavelengths would be time-consuming and is not necessary. A lot of data reduction techniques exist for removing the wavelength dependency from this equation. Three algorithms are described in the following. Their performance is compared in the results and discussion section.

The simplest algorithm disregards the spectral information measured and concentrates on the most prominent wavelength (i.e. the wavelength of maximum spectral change of the immobilized pH indicator). This algorithm is subsequently called the "monochromatic" algorithm.

More information is retained by using the integral reflectance over the monitored wavelength range. Then $R_i^{\text{stat}}(\lambda)$ is replaced by the integral maximum change in reflectance $R_i^{\text{stat}}$ whereas $k_i$ and $t_0$ should not be affected. This procedure is called the "integrative" algorithm.

The full spectral information is used in the feature extraction step by calculating the first principal component $\boldsymbol{R}_i^{\text{PC}}$ [5] using all reflectance spectra from the current experiment or the previous investigations and by solving the following linear matrix Eq. (2) with respect to the scalar $b_i(t)$ (principal component scores) for each sampling time $t$ (subsequently called the "spectral" algorithm):

$$\begin{aligned} \boldsymbol{R}_i(t) &= \boldsymbol{R}_i^{\text{PC}} \cdot b_i(t) + \boldsymbol{e}(t) \\ b_i(t) &= \frac{(\boldsymbol{R}_i^{\text{PC}})^T}{(\boldsymbol{R}_i^{\text{PC}})^T \cdot \boldsymbol{R}_i^{\text{PC}}} \boldsymbol{R}_i(t) \end{aligned} \quad (2)$$

Here $\boldsymbol{R}_i(t)$ denotes the vector of the spectral reflectance of optode $i$ at time $t$ with the elements $R_i(\lambda, t)$, and $\boldsymbol{R}_i^{\text{PC}}$ denotes the first principal component (PC) of optode $i$ with the elements $R_i^{\text{PC}}(\lambda)$. The stochastical nature of model Eq. (2) is indicated by the residual error term $\boldsymbol{e}(t)$. Eq. (1) is then transformed to

$$b_i(t) = b_i^{\text{stat}}[1 - e^{-k_i(t - t_0)}] \quad (3)$$

As confirmed by our measurements, this spectral algorithm is the most powerful method for several reasons. First, it makes use of the full amount of information obtained by calculation

of the first PC. Second, it offers possibilities to detect time-dependent changes in optode performance by monitoring the change in the first PC with time.

## 3. Experimental

### 3.1. Instrumentation and measurements

The flow injection manifold used is shown in Fig. 1. The following modules were integrated: two peristaltic pumps (MC-MS/CA4/8 and MS-4 Reglo-100) from Ismatec, Wertheim-Mondfeld (Germany); a six-way valve (TMV) from Latek, Eppelheim (Germany); two six-way valves (M-5011) and an injection valve (M-5020) from ERC, Alteglofsheim (Germany). Pumps and valves were interfaced to a PC 486DX by means of a multi input-output card (DCI 385) from Kosiol, Frankfurt am Main (Germany). The reflection/absorption spectra were recorded by a diode array spectrometer (MCS 230) from Carl Zeiss Co., Oberkochen (Germany) employing a bifurcated quartz fibre optic (Y-shape) and a xenon light source (CLX 111) from Zeiss. The biosensors were sequentially placed in an acrylic flow cell made in house [18,19]. All components were connected by Teflon tubes (0.8 mm i.d.) using commercially available connectors.

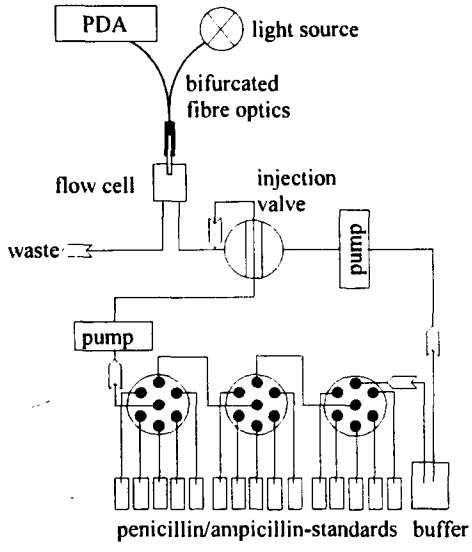

Fig. 1. FIA manifold for enzyme-based detection of time-dependent changes in absorption of a Phenol Red membrane. The spectra are recorded by means of a diode array spectrometer. The different mixtures of penicillin and ampicillin used as calibration and test data sets were stored in an ice-cooled bath during measurements.

During measurements an ice-cooled bath containing all samples retarded premature and non-catalysed hydrolysis of penicillin and ampicillin. The phosphate buffer passed the flow cell for 5 min with a flow rate of about 225 $cm^3 h^{-1}$ removing the previous sample from the sensor layer (thus the time for the regeneration process can be decreased down to 3 min). Simultaneously, the flow system sampling port consisting of three six-way valves was washed for 20 s. Next, the six-way valves were switched to one of the 15 standard solutions to fill the sample loop (250 µl) of the injection valve. When the injected sample volume had passed the sensor layer for 4 s the carrier stream was stopped and the data acquisition started. While penicillin and ampicillin are diffusing into the polyacrylamide gel they are hydrolysed by immobilised preparations of penicillinase causing a local pH shift in the receptor layer. Accordingly, a pH indicator (Phenol Red) changes its colour which is spectrally recorded using time intervals of 10 s for a period of 3 min.

### 3.2. Reagents and samples

Penicillinase ($\beta$-lactamase, EC 3.5.2.6) from *Escherichia coli* and ampicillin (sodium salt, prep. 1) were purchased from Boehringer Mannheim, GmbH (Germany). Penicillinase from *Bacillus cereus*, ampicillin (sodium salt, prep. 2), penicillin G (potassium salt) and Phenol Red (sodium salt) were obtained from Sigma. Phosphate buffer (5 mM) containing 100 mM KCl was prepared from reagents of analytical grade, used without any further purification and dissolved in distilled water. Standard solutions were prepared in phosphate buffer. Their pH was additionally controlled by a pH meter before measuring. The enzymes and the pH indicator Phenol Red were immobilised during the polymerisation of a polyacrylamide layer on a silanized glass substrate (10 mm diameter). The general immobilisation procedure is described in detail in Ref. [18]. The composition of membranes, working pH of the ambient medium, and codes for the investigated optodes are given in Table 1.

### 3.3. Calibration and test data set

Independent data sets were measured for calibration (model building) and testing (validation) of the different methods. The calibra-

Table 1
Sensor composition, pH of ambient medium, and codes for the enzyme optodes utilized in this study (t.i. = time interval for measurements)

| Code | Ambient and optode composition |
|---|---|
| EC7-1 | *E. coli penicillinase* (60 U/optode), Phenol Red, pH 7.0, t.i. 10 s for 180 s |
| BC7-1 | *B. cereus penicillinase* (460 U/optode), Phenol Red, pH 7.0, t.i. 10 s for 180 s |
| EC7.8-1 | *E. coli penicillinase* (60 U/optode), Phenol Red, pH 7.8, t.i. 10 s for 180 s |
| EC7.8-2 | *E. coli penicillinase* (60 U/optode), Phenol Red, pH 7.8, t.i. 5 s for 30 s |
| BC7.8-1 | *B. cereus penicillinase* (930 U/optode), Phenol Red, pH 7.8, t.i. 10 s for 180 s |

tion data set consisted of 11 objects; the test data set consisted of 4 objects. The composition of the binary mixtures is given in Table 2. For each object, the spectral reflectivity in the wavelength range 400–600 nm (100 data points per spectrum) for the five optodes in Table 1 was measured. The mixtures were presented in random sequence. The raw data are available from the authors upon request by electronic mail (gerolf.kraus@ipc.uni-tuebingen.de).

### 3.4. Data pre-processing

The spectral signals were transformed to wavelength-independent variables according to the algorithms described in the theoretical section. The first PC in Eq. (2) was calculated from mean-centered data of the calibration data set and accounted for 99.9% of the total signal variance. The injection time $t_0$ is not considered further. Two variables are thus obtained for each optode $i$ ($k_i$ comprising the dynamic features and $R_i^{stat}$ resp. $b_i^{stat}$ comprising the static features) with different scales. The variables were calculated by nonlinear least-squares regression. The mean relative standard deviation obtained for $b_i^{stat}$ and $k_i$ was 2.0% and 4.5% respectively. In order to weight the two types of variables equally, both scales were confined within the range 0–1 by division by the largest value of all $k_i$ and $R_i^{stat}$, $b_i^{stat}$ respectively. The models established from the calibration data set were used for the validation with the test data set without further alteration.

### 3.5. Characterisation of multivariate methods

For characterisation of the multivariate errors of calibration and prediction, the numbers that are defined by Eqs. (4)–(7) were introduced ($n_C$ and $n_P$ are the number of samples in the calibration and prediction data sets respectively). MSEC and MSEP denote the mean square errors of calibration and prediction, RAEC and RAEP denote the relative absolute errors of calibration and prediction (given in %):

$$\mathrm{MSEC} = \frac{\sum_{\text{calibration data set}} (c_{\text{predicted}} - c_{\text{true}})^2}{n_C} \quad (4)$$

$$\mathrm{MSEP} = \frac{\sum_{\text{prediction data set}} (c_{\text{predicted}} - c_{\text{true}})^2}{n_P} \quad (5)$$

$$\mathrm{RAEC} = \frac{\sum_{\text{calibration data set}} |c_{\text{predicted}} - c_{\text{true}}|/c_{\text{true}}}{n_C} \quad (6)$$

$$\mathrm{RAEP} = \frac{\sum_{\text{prediction data set}} |c_{\text{predicted}} - c_{\text{true}}|/c_{\text{true}}}{n_P} \quad (7)$$

### 3.6. Software

Data acquisition and system control were conducted with FIACRE [20], and MEASURE [21] software running under Windows™. Data evaluation was performed on a PC 80486/33 MHz. Data pre-processing was computed with Microsoft Excel™. Principal component analysis and PLS regression were calculated with Unscrambler 5.0 (CAMO/AS, Trondheim, Norway). The neural network was simulated with our own software running under Windows 3.1. Non-linear least-squares regression was calculated according to the Gauss–Newton–Marquardt algorithm [22] with our own software.

## 4. Results and discussion

An example of the change in spectral reflectivity during one measurement cycle is given in Fig. 2. The diagram demonstrates the reflectivity of a Phenol Red-doped membrane (EC7.8-1; see Table 1) at equidistant time intervals

Table 2
Design of calibration and test data sets

| | Object | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 |
| Calibration data set | | | | | | | | | | | |
| $c_{Penicillin}$ (mM) | 2 | 5 | 10 | 0 | 0 | 0 | 2 | 4 | 6 | 10 | 7 |
| $c_{Ampicillin}$ (mM) | 0 | 0 | 0 | 2 | 5 | 10 | 4 | 7 | 10 | 5 | 3 |
| | 1 | 2 | 3 | 4 | | | | | | | |
| Test data set | | | | | | | | | | | |
| $c_{Penicillin}$ (mM) | 8 | 3 | 4 | 5 | | | | | | | |
| $c_{Ampicillin}$ (mM) | 2 | 9 | 4 | 8 | | | | | | | |

between 10 s and 170 s after the analyte peak reaches the sensor and the flow was stopped. The curves show the membrane reflectivity relative to the reflectivity of the optode in a continuous flow of buffer.

### 4.1. Feature extraction

The monochromatic, integrative, and spectral methods described above were applied to the evaluation of the data set and compared with respect to their feature extraction properties. The wavelength at the peak maximum (570 nm) which was used for the monochromatic evaluation is marked by the vertical arrow in Fig. 2. The integrative evaluation was based on the integral absorbance in the range 400–600 nm marked by the horizontal arrows in Fig. 2. In addition, the loadings for the first PC are included in the window in the upper left part of Fig. 2. For the selection of the most appropriate feature extraction method, the whole set of optodes (cf. Table 1) was considered. After pre-processing as described above, the data sets from the different algorithms, each consisting of 10 variables (5 with dynamic features $k_i$, 5 with static features $R_i^{stat}$, $b_i^{stat}$), were subject to PLS2 calibration [7]. The number of primary factors was selected by leave-one-out cross-validation. The resulting models were used to predict the concentrations for the test data. The statistical data and the number of primary factors are summarised in Table 3. The results clearly indicate by the values of MSEP and RAEP that spectral evaluation is the most appropriate method for the extraction of the dynamic and static features. The integrative method which is also based on the spectral data yields slightly worse predictions but behaves better than the monochromatic approach. This demonstrates that spectral detection together with multivariate feature extraction enhances the predictivity and ruggedness of the optode array. The integrative method, although based on the full spectral information, does not make use of the whole information contained in the data set. The characteristic features are optimally extracted by the spectral (multivariate) method which therefore is used throughout the following discussion.

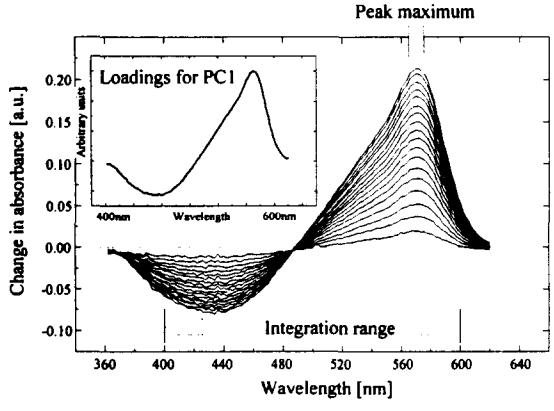

Fig. 2. Change in the spectral reflectivity during a measurement cycle. The peak maximum which was selected for single wavelength (monochromatic) evaluation is marked as well as the range that was selected for integration of the spectrum. The multivariate evaluation procedure was based on the loadings for the first PC (PC1) which are displayed schematically in the upper left part of the diagram. See text for detailed description of the algorithms.

### 4.2. Importance of dynamic and static features

To demonstrate the importance of both the dynamic and static features for solving the problem of multicomponent analysis, we repeated PLS2 calibration with two subsets of the full data set. For each subset 5 variables were selected. The first subset comprised only the static information. The other subset was

Table 3
Statistical data for comparison of different algorithms (monochromatic, integrative, spectral) for feature extraction. The Table includes the MSEC, the RAEC, the MSEP and the RAEP

| Feature extraction | | Calibration | | Prediction | |
|---|---|---|---|---|---|
| Algorithm | Number of primary factors | MSEC ($mM^2$) | RAEC | MSEP ($mM^2$) | RAEP |
| Penicillin | | | | | |
| Monochromatic | 5 | 0.084 | 8.0% | 0.515 | 15.7% |
| Integrative | 5 | 0.125 | 9.8% | 0.326 | 9.5% |
| Spectral | 5 | 0.094 | 5.8% | 0.275 | 7.0% |
| Ampicillin | | | | | |
| Monochromatic | 5 | 0.154 | 7.1% | 1.686 | 26.5% |
| Integrative | 5 | 0.170 | 7.2% | 0.275 | 10.0% |
| Spectral | 5 | 0.156 | 6.1% | 0.093 | 7.1% |

composed of the pure dynamic variables. In both cases, the values for the MSEP increased by a factor of six with respect to the values given in Table 3 for the spectral feature selection algorithm and the full data set. The values for RAEP obtained were greater than 13% (compared to 7% for the full data set). This shows, that neither the dynamic nor the static behaviour alone contains enough information for an optimum prediction.

### 4.3. Comparison of algorithms

Five standard methods for multivariate calibration were compared with respect to their performance for predicting the concentrations of the test samples. Aside from the PLS2 method already discussed, we applied PLS regression for a single compound (PLS1; e.g. Ref. [7]), principal components regression (PCR; e.g. Ref. [6]), multivariate least-squares regression (MLR; e.g. Ref. [5]), and a backpropagation neural network (BPN; e.g. Ref. [23]). The statistical data obtained from these methods are summarised in Table 4. For PCR, the same number of PCs (5) was selected as for PLS2. The backpropagation network was simulated with a partially connected $10{:}2 \cdot (4{:}1)$ architecture (one hidden layer with bipolar transfer functions [24] and sigmoidal transfer functions [23] for the output layer) which was trained with adaptive learning parameters (learning rate 0.01, momentum 0.2) in 1000 epochs. For the training of the artificial neural network, the concentration values of penicillin and ampicillin were scaled to the interval [0..1]. PLS2 results in the best calibration models (cf. MSEC, RAEC in Table 4) for both analytes and predictions (cf. MSEP, RAEP) for ampicillin. The concentration of penicillin is insignificantly better predicted by the PCR method (6.8% RAEC instead of 7.0% RAEC for PLS2). Nevertheless, the PLS2 method is the method of choice for the data considered here. The difficulty with training backpropagation neural networks with a small number of data can be seen from the predictions obtained with BPN. The latter predictions are in fact worse than those obtained by most of the other soft-modelling methods.

### 4.4. Variable selection

All calculations described in the previous sections were based on the full set of 10 variables calculated from the spectral signals of all five optodes (cf. Table 1). As demonstrated above, both dynamic and static features comprise valuable information for the quantification of penicillin and ampicillin. Now, the question arises whether all optodes or variables are necessary to obtain the described performance. The results will be even better if variables with little or no contribution to the calibration problem can be identified and discarded. Selection of the least important variables can be achieved by (i) inspecting the correlation matrix of the sensor signals (pair correlations) or (ii) by inspecting the loadings [7] of the variables for the primary factors. Fig. 3 shows the corresponding loading plot. The correlation matrix reveals two values close to unity for the pair correlations of the dynamic features of EC7.8-2 and BC7.8-1 and the static features of EC7.8-2 and BC7-1. This high correlation with other signals implies that the in-

Table 4
Comparison of the performance of different multivariate methods for correlation of sensor signals with analyte concentrations. The Table includes the statistical data for PLS regression (PLS2 and PLS1 [7]), PCR [6], MLR [5], and BPN [23]. The MSEC and RAEC value for MLR are close to zero because the system of linear equations is only slightly overdetermined (10 variables for 11 objects)

| | Method | | | | |
|---|---|---|---|---|---|
| | PLS2 | PLS1 | PCR | MLR | BPN |
| Penicillin | | | | | |
| MSEC | 0.094 | 0.305 | 0.155 | 0 | 0.326 |
| RAEC | 5.8% | 12.5% | 9.0% | 0% | 11.1% |
| MSEP | 0.275 | 0.456 | 0.273 | 6.242 | 0.598 |
| RAEP | 7.0% | 9.2% | 6.8% | 56% | 11.0% |
| Ampicillin | | | | | |
| MSEC | 0.156 | 0.229 | 0.209 | 0 | 0.214 |
| RAEC | 6.1% | 8.5% | 7.6% | 0% | 7.5% |
| MSEP | 0.093 | 0.115 | 0.294 | 1.226 | 0.273 |
| RAEP | 7.1% | 9.1% | 15.4% | 22.5% | 10.8% |

formation gathered by optode EC7.8-2 is redundant. The loading plot (Fig. 3) shows a weighted picture of the same fact. The loadings of the described pairs of variables look very similar in both cases with the virtual exception of the loadings for the fifth factor with respect to the static features of EC7.8-2 and BC7-1. Since this factor accounts for only 0.1% of the total variance, this difference has in fact no effect on the correlation. This has to be taken into account for the interpretation of the loading plot.

In addition, further information can be obtained from this loading plot. The small loadings of the static features of EC7.8-1 for all five factors show that this variable does not help to solve the calibration problem. In fact, this variable models only the error (as seen by high loadings for the secondary factors which are not presented here). Thus, deleting this variable from the data sets should result in better predictivity of the calibration model. Therefore a new PLS2 model was calculated without this variable and without the redundant optode EC7.8-2. The predictivity of the model increased significantly (MSEP = 0.039, RAEP = 3.9% for penicillin and MSEP = 0.074, RAEP = 5.1% for ampicillin, see Table 4 for comparison). This discussion shows a way to utilise the information from multivariate calibration models to optimise the selection of variables and optodes from an optode array.

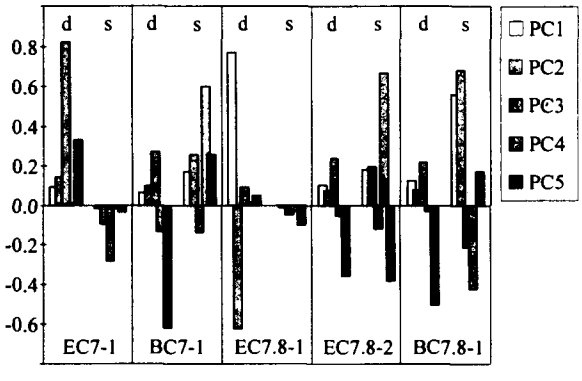

Fig. 3. Diagram of the loadings of the 10 variables for the first five PCs. The corresponding optodes are indicated at the bottom of the picture. The assignment of the variables to dynamic (d) and static (s) features is indicated at the top. See text for a detailed interpretation.

## 5. Conclusion

In the presented study we have shown that simultaneous analysis of penicillin and ampicillin concentrations is feasible with an array of four optodes incorporated in an FIA system. The optodes were based on immobilised penicillinase in the presence of a pH indicator. The concentrations of unknown samples are predictable with a relative absolute error <6%. Detailed analysis of the multivariate data reveals (1) that dynamic together with static features comprise valuable information, (2) feature extraction is best performed by multivariate analysis of the full spectral data, (3) selection of variables and optodes is easily performed on the basis of the loading plots and correlation matrix, and (4) the standard PLS2 method is appropriate for the data analysis. Taking these results into account for future

investigations it should be possible to reduce the calibration set optimising the choice of influencing parameters as the pH, the amounts and types of enzymes or pH indicators. The results clearly demonstrate that multivariate evaluation should be involved in the analysis of optode arrays especially as the presented algorithms are well established and the calculations can be carried out by a personal computer in a matter of seconds.

Received 13 June 1994; revised 11 July 1995; accepted 12 July 1995

**Abstract**

Within the past several years significant advances have been made towards the development and incorporation of chemically modified electrodes as selective detectors for high performance liquid chromatography and flow injection analysis. In many cases the chemically modified electrode systems closely approach the "ideal" detector specifications of chemical and mechanical stability along with a significant linear response region. This paper will discuss the characterization and incorporation of ionomeric poly(ester-sulfonic acid) coated electrodes as nonaqueous electrochemical detectors. The orientation of the electrodes in the detector system as well as the increased sensitivity levels to $10^{-10}$ g ml$^{-1}$ for cationic species and $10^{-9}$ g ml$^{-1}$ for neutral species will be presented. Also the applicability of the ionomer coated electrodes as nonelectrolyte detectors achieved a reproducible response with detection limits to $10^{-6}$ g ml$^{-1}$. Overall this system performed as well as, or better than, more specialized and expensive thin layer electrochemical detectors.

*Keywords:* Chemically modified electrodes; Amperometric detectors; Poly(ester-sulfonic acid); Flow injection analysis

## 1. Introduction

The use of ionomer-coated electrodes to enhance electrochemical amperometric signals has been the subject of significant research efforts for the past ten years [1–12]. The incorporation of these modified electrodes into flow analysis systems as ultra-sensitive electrochemical detectors is for use under low and non-electrolyte conditions [12–16].

This paper reports the incorporation of a poly(ester sulfonic acid)-coated dual platinum disc electrode flow cell system as a reduced and non-electrolyte detector for flow injection analysis (FIA). As previously reported, the poly(ester sulfonic acid)-coated electrode systems are stable and exhibit fast partitioning of analyte materials under various nonaqueous conditions [12]. Several different electrochemical flow cell types with modified electrodes have been reported in the literature, however their relatively high cost and degree of specialization have limited their widespread acceptance and use as viable alternatives to spectroscopic detectors [13–16]. The detector system described herein incorporates a chemically modified commercially available thin layer dual electrode cell as the basis for the detector system. The electrode surfaces are coated with a thin film of an ionomeric material via a solution casting process. To accomplish universal flow across the flow cell, the electrode block is oriented such that electrodes

* Corresponding author. Fax: 716-475-5766; e-mail: TXGSCH@RIT.EDU

*SSDI* 0039-9140(95)01689-9

are in series, reference downstream, and the entire cell volume is over the thin film membrane. The resultant thin layer amperometric detector system is stable under flow; has exhibited a reproducible, low detection limit response for both reduced and non-electrolyte experimental conditions; and has shown increased sensitivity for both cationic and neutral analytes as compared to uncoated systems. This electrode/coating system also lowered the capacitive current levels from microamps for uncoated systems to less than 50 ηamps for the coated electrodes. Therefore, while analyte signals did decrease slightly because of diffusion limitations, the S/N ratios were significantly enhanced by approximately two orders of magnitude.

## 2. Experimental

### 2.1. Apparatus

A Bioanalytical System (BAS) Model LC-44 thin layer flow cell was used as the primary detector system. This system consists of a stainless steel mounting block with a removable electrode assembly and Teflon flow spacer. The electrode to be modified was a BAS Model MF-1012 dual 2 mm platinum disk electrode encased in a PEEK block. The Teflon spacers used to define the channel volume of the cell were either 2 or 3 μl. A three electrode configuration was employed with the anionomer coated platinum disk as the working electrode, the stainless steel block as the auxiliary electrode, and the second coated platinum disk as the reference electrode. The poly(ester sulfonic acid)-coated platinum electrode behaved similar to a coated wire electrode with a stable reference potential $225 \pm 5$ mV negative of a Ag/AgCl reference electrode. Therefore all potentials are reported versus the ionomer/platinum reference electrode.

Samples were injected through a Rheodyne Model 7125 injection valve equipped with either a 10 or 20 μl injection loop. The flow of the mobile phase across the FIA cell was maintained with a Hewlett Packard Model 1050 dual piston pump equipped with a pulse damper.

The amperometric signals were measured with an EG&G PAR Model 273 potentiostat/galvanostat. The output was displayed on either a Hewlett Packard Model 7015B time base recorder or a Hewlett Packard Model 3394a integrator. The entire electrochemical flow cell system was encased within a Faraday cage. Voltage regulators were used on all instrumentation to minimize any fluctuations of the 120 V a.c. line.

### 2.2. Reagents

All experiments were performed with Burdick and Jackson HPLC grade acetonitrile which was kept under a continuous helium purge. The electrolyte, tetrabutyl ammonium hexafluorophosphate, was purchased from Aldrich recrystallized thrice from ethanol and dried in vacuo at 100 °C prior to use. The poly(ester sulfonic acid) ionomer, AQ55D, was purchased from Eastman Kodak Co. and filtered through a 0.45 μm Whatman Acrodisk prior to use. $Ru(bpy)_3Cl_2$ and *p*-hydroquinone were purchased from Aldrich and used as received. Ferrocence and $Ru(NH_3)_6Cl_3$ were purchased from Strem Chemical Co. and used as received. Purity of all analytes was confirmed with voltammetric analyses prior to injection into the flowing system.

### 2.3. Procedure

The electrodes were first cleaned and polished with 1.00, 0.30 and 0.05 μm alumina on a Buehler Ecomet II Polisher. The electrodes were than immersed in water and sonicated for 30 min, removed and dried in a 110 °C oven for 1 h, and placed in a vacuum dessicator to cool. AQ-55 films between 4 and 5 μm were solution cast over the entire surface of the flow channel by applying 25 μl of a 2% w/w AQ55 aqueous dispersion. After application of the ionomer solution, the electrodes were placed in an 85 °C oven for 1 h. A detailed description of the AQ55 casting procedures has been summarized in the literature [12,13].

## 3. Results and discussion

This investigation was concerned with the amperometric response of AQ55-coated electrodes to neutral and cationic analytes in FIA. The AQ55 ionomer undergoes minimal swelling, is insoluble, and maintains its structural integrity in acetonitrile under flow conditions of 0.5–2.0 ml $min^{-1}$. Attempts to incorporate AQ55-modified electrodes in non-

buffered aqueous solutions or methanol flowing streams, as has been reported in the literature [13], was unsuccessful because of the unpredictable behavior of the membrane. In most aqueous/methanol experiments the membranes would quickly deteriorate and be completely removed from the electrode surface within seconds. In other experiments, membranes would last for longer periods of time; however, the amperometric signal exhibited a time dependence. With a mobile phase of either acetonitrile, methylene chloride, or tetrahydrofuran the membranes were stable for extended time periods, 24 h or more, and showed no variation in amperometric response. Within this investigation, acetonitrile was the solvent of choice for the low electrolyte and nonelectrolyte FIA investigations because of the known values for membrane diffusion and partitioning rates [12].

Experimental results for the analysis of $Ru(bpy)_3^{2+/3+}$ at a typical coated electrode are summarized in Figs. 1–3. $Ru(bpy)_3^{2+/3+}$ was chosen as the analyte because the $E°$ for the redox couple is at the oxidative extreme of the acetonitrile/platinum potential window; therefore, the amperometric response is in the region where the signal-to-noise ratio would be at a minimum. Experiments were also conducted with hydroquinone to evaluate the response of the coated electrode to an organic molecule with an irreversible oxidation.

Fig. 1 shows representative data for the response of the AQ55-coated detector system under reduced, 0.05 to 0.001 M, electrolyte conditions and an analyte concentration of

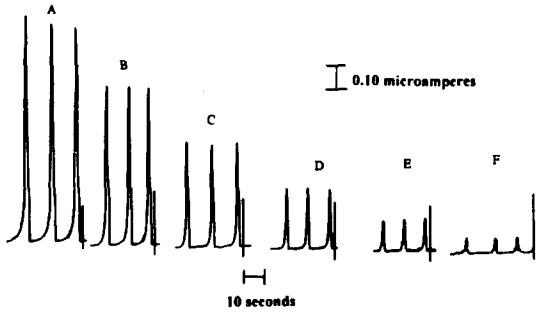

Fig. 1. Repetitive flow injection amperometric response at a dual platinum electrode coated with a 5 Nm AQ55 ionomeric membrane. Experimental conditions: working electrode was a 2 mm platinum disk; a channel volume of 2.9 µl; mobile phase of acetonitrile/0.01 M TBAHP at a flow of 1.0 ml $min^{-1}$; 10 µl injections of $5 \times 10^{-7}$ g $ml^{-1}$ of $Ru(bpy)_3^{2+}$ dissolved in mobile phase. Curves: (A) 0.975 V; (B) 0.950 V; (C) 0.925 V; (D) 0.900 V; (E) 0.875 V; (F) 0.850 V vs. AQ55/platinum reference electrode.

$5.00 \times 10^{-8}$ g $ml^{-1}$. As illustrated, the FIA amperometric signals are extremely reproducible with baseline response times of less than 3 s, an excellent membrane re-equilibrium time. Repetitive injections of the analyte solutions over 8 h showed less than a 1% loss in amperometric response. The hydrodynamic voltammogram generated in Fig. 2 illustrates the exceptional experimental behavior at the membrane-coated detector. The plot of $E$ vs. $\log[(i_{lim} - i)/i]$ was linear with a slope of 64 mV which is in good agreement with the theoretical value of 59 mV. Therefore, it appears that the increased resistance across the ionomeric membrane does not cause an activation overpotential to occur for the described experimental conditions.

In order to determine the detection limits of this membrane-coated, amperometric detector system a series of analyte solutions of various concentrations were evaluated. Fig. 3a illustrates the response of the AQ55-coated detectors down to $10^{-10}$ g $ml^{-1}$. It is apparent that the response of the detector was linear to approximately $10^{-9}$ g $ml^{-1}$ with a lower limit of detection at $10^{-10}$ g $ml^{-1}$. (The log vs. log plot is necessary for clarity, the linear region is similar for the non-logarithm plots.) This detection limit is over 2 orders of magnitude better sensitivity than the response reported at similar uncoated electrodes. Concentrations less than $10^{-10}$ g $ml^{-1}$ were beyond the sensitivity of the potentiostat and therefore not evaluated. Fig. 3b is an example of the response of the detector to the $10^{-10}$ g $ml^{-1}$ solutions. In between each injection of analyte, electrolyte solution was injected to insure that there was no response caused by the injection valve. The piston strokes of the pumping system are the small regular peaks which appear at these current sensitivity settings.

The oxidation of the hydroquinone molecule, under the same electrolyte experimental conditions as $Ru(bpy)_3^{2+/3+}$, was irreversible (as expected) with an $E_{pa} = 0.79$ V vs. coated reference. The hydrodynamic voltammogram and resultant plot of $E$ vs. $\log[(i_{lim} - i)/i]$ showed a linear response with a slope of 180 mV (an irreversible wave) and a detection limit of $10^{-8}$ g $ml^{-1}$.

As mentioned, the 2 mm platinum electrode in a 3 µl flow channel achieved an amperometric current response down to $10^{-10}$ g $ml^{-1}$ for inorganic cationic species. Unexpectedly, the observed detection limits for the oxidation of

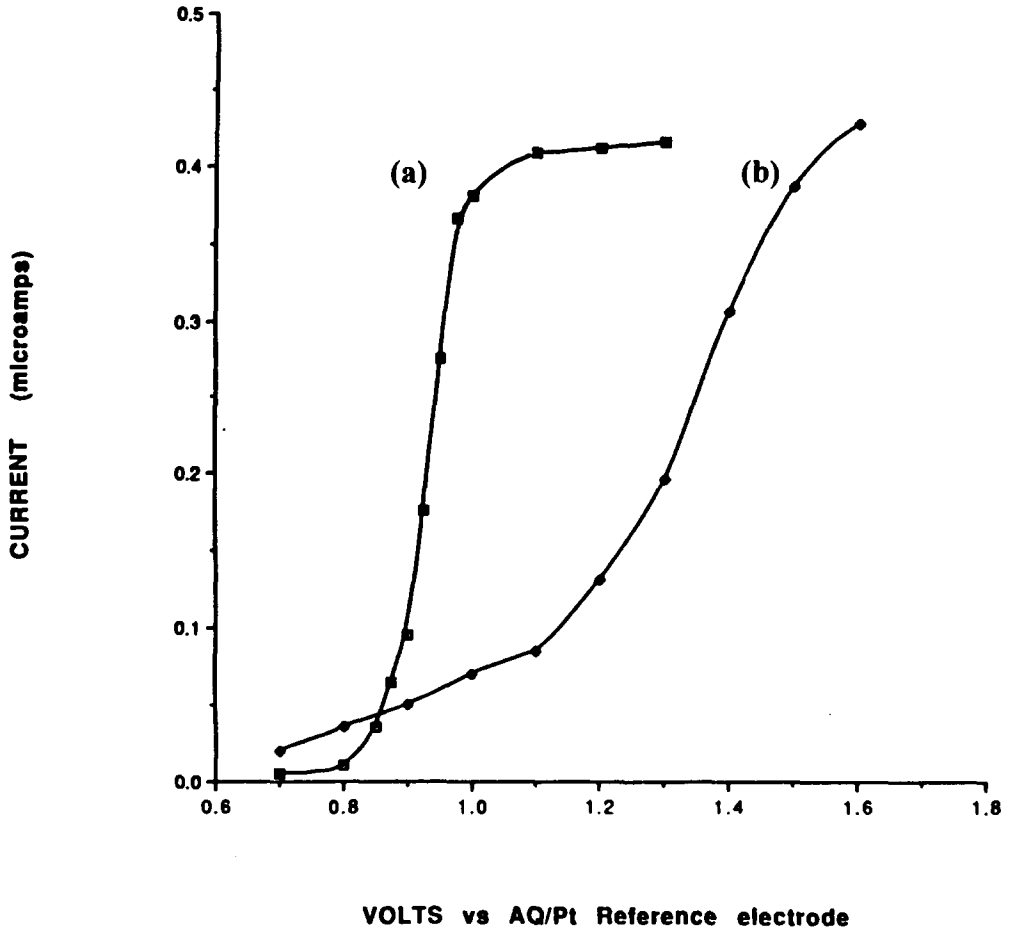

Fig. 2. Hydrodynamic voltammograms for the FIA of $Ru(bpy)_3^{2+}$ in acetonitrile at an AQ55-coated platinum disk electrode: (a) 10 µl injections of $10^{-7}$ g ml$^{-1}$ of $Ru(bpy)_3^{2+}$ in 0.01 M TBAHP; (b) 10 µl injections of $10^{-5}$ g ml$^{-1}$ $Ru(bpy)_3^{2+}$ in acetonitrile with no added electrolyte.

neutral species, $10^{-9}$ g ml$^{-1}$ for ferrocene and $10^{-8}$ g ml$^{-1}$ for hydroquinone, were about 2 orders of magnitude greater than for uncoated electrodes. Fan and Harrison [17] have shown that neutral species can partition into Nafion membranes and have proposed the concept of an effective diffusion coefficient, $D_{eff}$. $D_{eff}$ is equal to the product of the membrane partition coefficient, $K_p$, and the membrane diffusion coefficient, $D_{mem}$, ($D_{eff} = K_p \times D_{mem}$). Partition coefficients of approximately $10^5$ and $10^1$ were observed respectively, for the incorporation of cationic and neutral species from acetonitrile into the AQ55 membranes. However, since the $D_{mem}$ values are $10^{-10}$ and $10^{-5}$ cm s$^{-1}$ for the cationic and neutral species the $D_{eff}$ values for both the cationic and neutral species are of approximately the same magnitude. This equality of $D_{eff}$ contributes to the similar detection limits for the cationic and neutral species.

The evaluation of this detector system under nonelectrolyte conditions is illustrated in the hydrodynamic curve b of Fig. 2. Limited success with the use of the coated design as a nonelectrolyte detector was achieved. Using an acetonitrile mobile phase, ionomer-coated working electrode, and $Ru(bpy)_3^{2+}$ as an analyte, a linear amperometric response to $10^{-6}$ g ml$^{-1}$ was observed. As expected the absence of electrolyte within the mobile phase increased the resistance within the cell, creating a significant activation overpotential. This overpotential is evidenced by the approximately 400 mV positive shift of the $E_{1/2}$ value. Also the increase of the slope to 120 mV is further evidence of the increased resistance across the membrane–electrode interface. Finally, unlike the ionomer-coated electrodes exposed to a mobile phase which maintained a constant electrolyte concentration, the membranes exposed to nonelectrolyte conditions

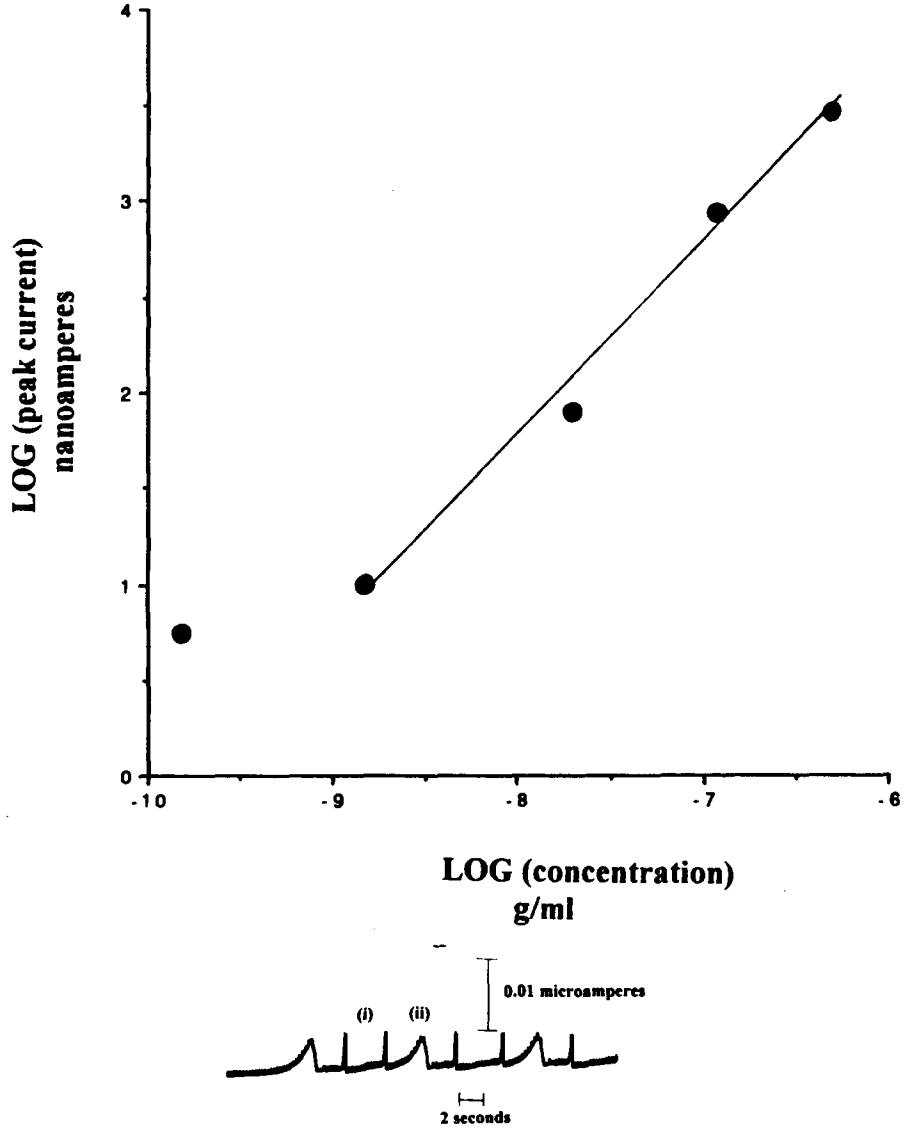

Fig. 3. (a) Detection limits for the amperometric response of $Ru(bpy)_3^{2+}$ at an AQ55-coated platinum electrode in 0.01 M TBAHP/acetonitrile solution at a flow of 1.0 ml $min^{-1}$. (b) Alternate injections of 20 µl of 0.01 M TBAHP solutions, curve (i); and $1.5 \times 10^{-10}$ g $ml^{-1}$ of $Ru(bpy)_3^{2+}$, curve (ii).

were extremely sensitive to the experimental history of the electrode. One explanation for the carryover effects is that $Ru(bpy)_3^{2+/3+}$ incorporates into the membrane and remains as a charge carrier. After repeated experiments the concentration of $Ru(bpy)_3^{3+}$ increases within the membrane causing the decreased signal and lack of reproducibility for the amperometric response. Since under low electrolyte conditions no carryover effects were observed, it is assumed that the electrolyte cations rapidly exchanged with the analyte cations in between injections thereby replenishing the membrane with inert electrolyte ions. Therefore, to eliminate the carryover effects under nonelectrolyte conditions, injections of 0.10 M electrolyte solution were made after every $Ru(bpy)_3^{2+}$ injection. After the injections of 0.10 M electrolyte it is assumed that the membranes absorb a small amount of the electrolyte solution and in essence create an in-situ electrolyte source which maintains a low electrolyte concentration. Under these conditions the amperometric response was not as sensitive as under electrolyte conditions, but did become highly reproducible.

## 4. Conclusion

The high speed and sensitivity of this AQ55 thin layer electrochemical flow cell coupled with its excellent reproducibility, low cost and ease of use make it an attractive alternative to other electrochemical and spectroscopic detector systems. Also, the sensitivity to neutral as well as cationic species, $10^{-9}$ and $10^{-10}$ g ml$^{-1}$ respectively, enhances the applicability well below the detection limits for most flow analysis detectors.

With respect to the nonelectrolyte applications of the AQ55-coated electrode system, while the results with the ionomer coating are promising, much work is still needed to reduce the resistance effects and lower the detection limits. Presently, from preliminary results in our laboratory, the use of cationomeric/anionomeric blends has lowered the resistive effects but the sensitivity levels have not improved. We are continuing our efforts on the incorporation of coated arrays and platinized membranes and hope to construct a viable electrochemical detector for "normal-phase" chromatography.

# Chemically amplified kojic acid responses of tyrosinase-based biosensor, based on inhibitory effect to substrate recycling driven by tyrosinase and L-ascorbic acid

Yasushi Hasebe *, Katsuhiro Oshima, Osamu Takise, Shunichi Uchiyama

*Department of Environmental Engineering, Saitama Institute of Technology, 1690 Fusaiji, Okabe, Saitama 369-02, Japan*

Received 27 April 1995; accepted 24 July 1995

**Abstract**

A tyrosinase-based chemically amplified biosensor, based on the substrate recycling of polyphenols driven by tyrosinase-catalyzed oxidation and chemical reduction by L-ascorbic acid (AsA), has been utilized for the highly sensitive detection of inhibitors of tyrosinase such as kojic acid, benzoic and $SCN^-$ ion. The amplified current response of immobilized tyrosinase-coupling oxygen electrode due to the recycling was suppressed by the addition of inhibitors, and a highly amplified response to kojic acid over other inhibitors was observed in the presence of 5 mM AsA. The amplification factor (AF) of kojic acid is substantially proportional to the AF of substrates, and the AF for $1 \times 10^{-7}$ M kojic acid was increased by up to a factor of 143 when $1 \times 10^{-5}$ M dopamine was used as a competitive substrate in the presence of 5 mM AsA. The amplified calibration curve of kojic acid obtained with 5 mM AsA was shifted towards more than a two decades lower concentration range compared with that of the non-amplified response, and the detection limit of kojic acid was lowered to $7 \times 10^{-8}$ M.

*Keywords:* Biosensors; Tyrosinase; Substrate recycling; L-Ascorbic acid

## 1. Introduction

Tyrosinase (polyphenol oxidase, EC 1.14.18.1) is a copper-containing metallo-enzyme and catalyzes hydroxylation of phenol to catechol and subsequent dehydrogenation to *o*-quinones accompanied by the conversion of molecular oxygen to water, and a number of biosensors using immobilized tyrosinase membrane have been reported [1–5]. However, in order to enhance the sensitivity and decrease the detection limits of enzyme-based biosensors, recycling of substrates and cofactors catalyzed by more than two kinds of enzyme have been utilized for the signal amplification of several biosensor systems [6–11]. In this connection, we have recently proposed the tyrosinase-based chemically amplified biosensing systems for catechol [12] and catecholamines [13,14], in which substrates are recycled between the reduced form (catechol compounds) and the oxidized form (*o*-quinone compounds) by combining tyrosinase-catalyzed oxidation and chemical reduction by L-ascorbic acid (AsA). In these systems, a remarkably amplified signal could be obtained by monitoring the amplified change in the concentration of dissolved oxygen [12,13] and pH [14] during the recycling, and highly sensitive determination of polyphenols (nanomolar to micromolar order) has been achieved.

TAL 42:12-5

Kojic acid (5-hydroxy-2-(hydroxymethyl)-4*H*-pyran-4-one) is an antibiotic substance produced in an aerobic process by a variety of micro-organisms from a wide range of carbon sources. The assay of kojic acid is therefore important for monitoring the fermentation process. A convenient and direct biosensor system for kojic acid, however, has not been reported so far to our knowledge. It is known that kojic acid competitively binds to the catalytic site of tyrosinase because of its structural similarity to polyphenols and then inhibits the tyrosinase activity. In practical applications, kojic acid has been used in some cosmetics to prevent serious sun-burning caused by an accumulation of melanin in subcutaneous tissue produced via a tyrosinase-catalyzed metabolic pathway. If the inhibition of kojic acid is reversible and tyrosinase is not inactivated, an effective and highly sensitive determination of kojic acid using chemically amplified polyphenol sensors would be expected because the amplified signal of the sensor is arising from the recycling of trace amounts of substrates that compete with inhibitors. On the bases of a similar analytical concept, the determination of enzymatic inhibitors based on substrate recycling systems using double-enzyme reactions [15] and electroenzyme reactions [16–18] have already been reported by other groups.

In this study, we demonstrate the effectiveness of the chemically amplified recycling biosensor using immobilized tyrosinase and AsA for highly sensitive determination of tyrosinase inhibitors, especially kojic acid, and the amplification characteristics of kojic acid obtained in the presence of AsA are described compared with those of a non-amplified response without AsA.

## 2. Experimental

### 2.1. Materials

Tyrosinase (EC 1.14.18.1, from mushroom, 2400 units $mg^{-1}$ of catechol oxidase activity) was purchased from Sigma, Sodium L-ascorbate (AsA), kojic acid, sodium benzoate, sodium thiocyanate, dopamine nonohydrochloride, catechol, phenol and noradrenaline hydrochloride were of analytical grade and were used without further purification. Acrylamide monomer, *N,N*-methylenebisacrylamide, *β*-dimethyl-aminopropyonitrile, potassium persulfate, potassium dihydrogenphosphate and disodium hydrogenphosphate were of extra pure reagent grade. Deionized water was used for preparing the buffer and sample standard solutions.

### 2.2. Preparation of immobilized-tyrosinase electrode

The enzyme electrode was fabricated by placing a tyrosinase-entrapped polyacrylamide gel ( $\approx 3$ mm diameter, 0.2 mm thickness) on the surface of the gas-permeable membrane of a Clark-type oxygen electrode (Denki Kagaku Keiki Ltd.). The tyrosinase-entrapping gel was prepared as follows: acrylamide monomer (375 mg) and *N,N*-methylenebisacrylamide (20 mg) were dissolved in 2 ml of 0.1 M phosphate buffer (pH 6.5) containing 1–10 mg of tyrosinase, and then poured onto a flat Petri dish (8.5 cm diameter). Next, 5% *β*-dimethylaminopropyonitrile (0.25 ml) and 1% potassium persulfate (0.25 ml) were added, and the solution was polymerized under a nitrogen atmosphere. The tyrosinase membrane thus prepared was cut off with a microtip ($\approx 3$ mm i.d.) for the sensor preparation, and stored in 0.1 M phosphate buffer (pH 6.5) at 4°C in a refrigerator when not in use.

### 2.3. Procedure

Amperometric measurements were conducted using a potentiostat (Nikko Keisoku NPOT-1), one pen recorder (Nippon Denki Kagaku Ltd.) and an immobilized tyrosinase electrode. The enzyme electrode was immersed in 25 ml of 0.1 M phosphate buffer (pH 6.5) containing AsA in a 50 ml beaker and stirred constantly on a thermostated water bath (Eyela, RC-12, Tokyo Rikakikai). A beaker was opened to the atmosphere and the oxygen was supplied continuously from the air. After the steady-state background current baseline had been obtained, 5–50 μl of a standard solution of polyphenols (dopamine, catechol, phenol) was added with a micropipette and the current response based on the consumption of dissolved oxygen was monitored. After the current response to polyphenols reached a steady-state value, standard solutions of tyrosinase inhibitors (kojic acid, benzoic acid, NaSCN) were added, and the decrease in the steady-state current was measured. All measurements were conducted at 35°C and pH 6.5 (optimum

pH for tyrosinase activity; data from Sigma). Standard solutions of substrates and inhibitors were prepared by dissolving the reagents in 0.1 M phosphate buffer (pH 6.5).

## 3. Results and discussion

A cyclic reaction scheme of catechol compounds driven by tyrosinase and L-ascorbate (AsA) for the determination of tyrosinase inhibitors is shown in Fig. 1. Enzymatically oxidised *o*-quinone compounds were chemically reconverted to catechol compounds by L-ascorbate and reoxidized repeatedly. As a result, the current response of immobilized tyrosinase electrode, based on the reduction current of dissolved oxygen, was amplified in the presence of AsA, and permits the highly sensitive determination of catechol compounds (less than micromolar level) [12,13]. It is known that tyrosinase is inhibited by several kinds of compounds (e.g. kojic acid and $SCN^-$ ion) which competitively bind at the recognition site and catalytic site of tyrosinase respectively [16,17]. Consequently these inhibitors hinder the recycling rate and lead to a decrease in the amplified current response of the tyrosinase-modified oxygen electrode.

Fig. 2 illustrates the typical stepwise current response curves of immobilized tyrosinase electrode obtained by successive addition of kojic acid with dopamine as a competitive substrate in the presence and absence of 5 mM AsA. In this system, the concentration of dissolved oxygen in the bulk solution would remain constant throughout the experimental period because the oxygen was constantly supplied from air by constant stirring. The steady-state current (≈400 nA) obtained by the addition of dopamine, where the rate of oxygen consumption in the enzyme layer is equal to the rate of

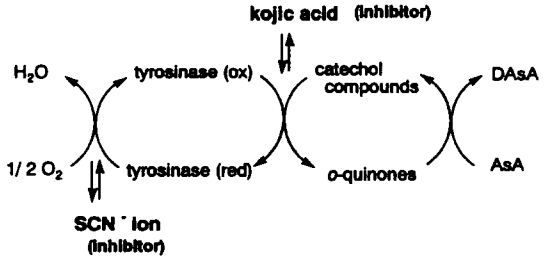

Fig. 1. A redox recycling scheme of polyphenols for the determination of tyrosinase inhibitors, using tyrosinase and L-ascorbic acid (AsA). DAsA: dehydroascorbic acid.

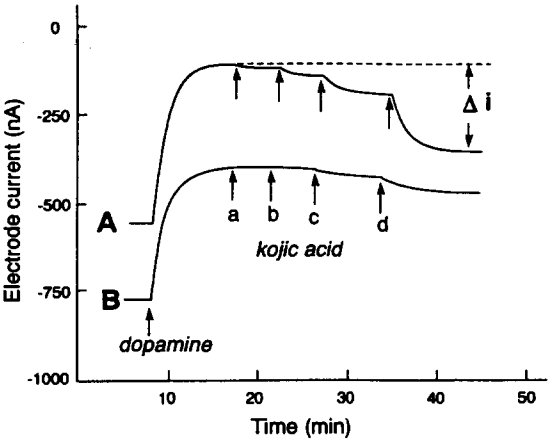

Fig. 2. Typical amplified and non-amplified current response curves of immobilized tyrosinase electrode obtained by successive addition of kojic acid in the presence (A) and absence (B) of 5 mM L-ascorbate in the sample solution with dopamine (A, $1 \times 10^{-5}$ M; B, $2 \times 10^{-4}$ M) as competitive substrate. Kojic acid concentration: a, $1 \times 10^{-6}$ M; b, $3 \times 10^{-6}$ M; c, $1 \times 10^{-5}$ M; d, $1 \times 10^{-4}$ M. 0.1 M phosphate buffer (pH 6.5) was used.

oxygen supply from the bulk solution, was apparently diminished by the addition of kojic acid, and the current reached another steady-state value within ≈4 min. The current difference between the steady-state current before and after kojic acid addition ($\Delta i$) was found to be dependent on the kojic acid added. Furthermore, in the presence of AsA, a lower concentration of kojic acid (micromolar order) induces a current response, whereas no response to kojic acid at less than $1 \times 10^{-5}$ M was observed without AsA. These results indicate that the addition of kojic acid reduces the extent of recycling of dopamine and results in an amplified change in the current response of the tyrosinase electrode. In general, inhibition of enzyme is often irreversible because of the tight binding of non-catalytic inhibitors. In this case, the rinsing of the enzyme membrane by immersing the electrode in phosphate buffer for about 5 min allows the subsequent measurement of dopamine and kojic acid but the current response to dopamine decreases to approximately 92% compared to that of the first response. These results suggest the possibility of highly sensitive detection of kojic acid using a tyrosinase-coupling electrode in the presence of AsA. However, from the practical point of view, the replacement of the enzyme membrane is required after the measurement of a relatively high concentration of kojic acid.

In order to obtain the higher sensitivity, optimal amounts of enzyme should be chosen, so we first investigate the effect of the amount of tyrosinase upon the inhibition current ($\Delta i$) for $1 \times 10^{-4}$ M kojic acid with 5 mM AsA (Fig. 3). The magnitude of $\Delta i$ decreased at higher and lower amounts of tyrosinase, and the largest response was obtained around 5 mg of enzyme. The decrease in the change in current at high enzyme loading may be caused by a shift from enzyme reaction kinetics being rate limiting to a situation where molecular diffusion is rate limiting. In other words, with a large amount of enzyme the kojic acid binds at active sites of the enzyme in the resting state (substrate free) which do not distribute the signal change. Consequently, the remainder of the experiments were carried out using a membrane containing 5 mg of tyrosinase. As reported previously, the sensitivity and amplification factor of the chemically amplified polyphenol sensor were remarkably dependent on AsA concentration, because the reduction rate of *o*-quinones by AsA is directly attributable to the rotation number of substrate per unit time which determines the sensitivity and the magnitude of the amplification factor [12,13]. Fig. 4 shows the effect of AsA concentration on the inhibition current for $1 \times 10^{-4}$ M kojic acid with dopamine as a competitive substrate. This AsA concentration dependency on the inhibition current is essentially similar to that for the amplified response of polyphenols, and maximum response was obtained at an AsA concentration around 5 mM. At a higher concentration of AsA ( > 10 mM), current response is rather decreased, probably because the background concentration of dissolved oxygen to be reacted with the reduced form of enzyme was decreased by the auto-oxidation of AsA by dissolved oxygen.

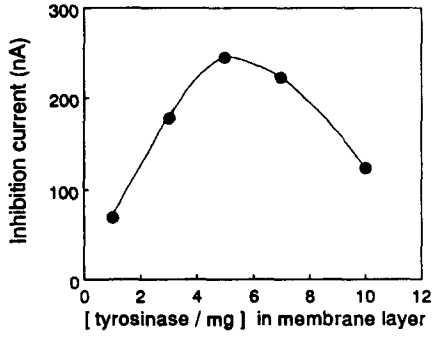

Fig. 3. Effect of the amount of tyrosinase in the membrane layer (in preparation) on the inhibition current to $1 \times 10^{-4}$ M kojic acid in the presence of 5 mM L-ascorbate with $1 \times 10^{-5}$ M dopamine in 0.1 M phosphate buffer (pH 6.5).

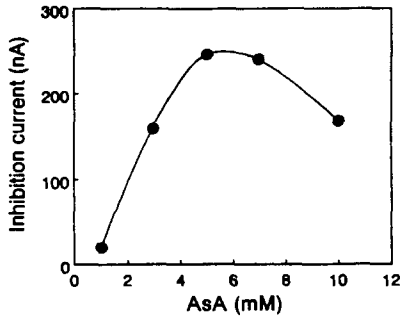

Fig. 4. Effect of AsA concentration on the inhibition current to $1 \times 10^{-4}$ M kojic acid. The amount of enzyme in the membrane layer (in preparation) is 5 mg. Other experimental conditions are the same as in Fig. 3.

Fig. 5 plots the relationship of the amplification factor (AF) between dopamine (substrate) and kojic acid (inhibitor) obtained at each concentration of AsA. AFs of dopamine and kojic acid were calculated by using the following equations and the non-amplified current responses to $2 \times 10^{-4}$ M dopamine (380 nA) and $1 \times 10^{-4}$ M kojic acid (28 nA) obtained without AsA respectively:

$$AF_{dopamine} = [\Delta I_d(nA)/380\ nA] \times [2 \times 10^{-4}\ M/C_d(M)]$$

$$AF_{kojic\ acid} = [\Delta I_k(nA)/28\ nA] \times [1 \times 10^{-4}\ M/C_k(M)]$$

where $\Delta I_d$ and $\Delta I_k$ represent amplified currents for dopamine and kojic acid respectively, and $C_d$ and $C_k$ represent the corresponding concentrations of dopamine and kojic acid respectively. The AF of kojic acid seems to be proportional to the AF of dopamine, suggest-

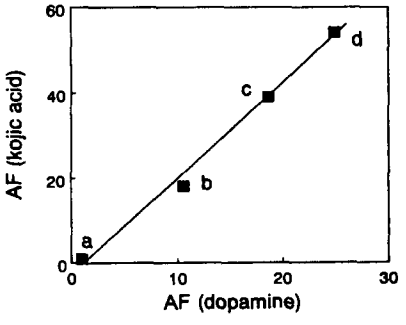

Fig. 5. The relationship of the AF between kojic acid and dopamine obtained at each concentration of L-ascorbate: a, 0 mM; b, 0.5 mM; c, 1 mM; d, 5 mM.

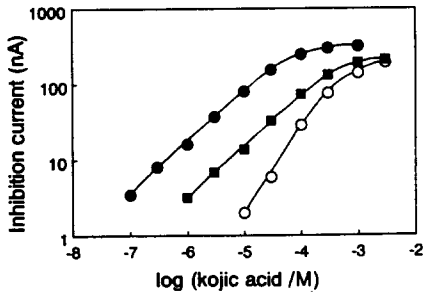

Fig. 6. Amplified and non-amplified calibration curves of kojic acid obtained at (○) 0 mM, (■) 0.5 mM and (●) 5 mM of AsA. The concentrations of dopamine used are $2 \times 10^{-4}$ M, $6 \times 10^{-5}$ M and $1 \times 10^{-5}$ M at 0 mM, 0.5 mM and 5 mM of AsA respectively.

ing that the recycling number of the substrate is substantially in accordance with the sensitivity of kojic acid, probably because the opportunity for the inhibitor to compete with the substrate is increased when the AF (turnover number of the enzyme) is large.

Fig. 6 depicts the amplified and non-amplified calibration graphs of kojic acid, plotting the inhibition current ($\Delta i$) against kojic acid concentration, obtained at each concentration of AsA. Without AsA in the sample solution, no response to kojic acid at less than $1 \times 10^{-5}$ M was observed, and the calibration curve showed a linear response over the concentration range between $1 \times 10^{-5}$ M and $1 \times 10^{-3}$ M. In contrast, the linear portion of the calibration curves apparently shifted towards the lower concentration range with an increase in AsA concentration, and the detection limit of kojic acid was found to be decreased to about $7 \times 10^{-8}$ M ($S/N = 3$, $\approx 3$ nA). In addition, the dynamic range obtained with 5 mM AsA was found to be extended ($1 \times 10^{-7}$–$1 \times 10^{-4}$ M) compared with that of the non-amplified response, indicating that the AF was increased with a decrease in kojic acid concentration. Since the amplified signal arises from the recycling of trace amounts of substrate, signal inhibition is also induced by a lower concentration of competitive inhibitor in the presence of AsA.

As shown in Fig. 1 tyrosinase activity is known to be inhibited not only by polyphenol analogs but also by some anions (i.e. $SCN^-$ ion) which have potential to bind with copper ion at the catalytic site of tyrosinase. Table 1 summarizes the analytical results of several tyrosinase inhibitors (kojic acid, benzoic acid and $SCN^-$ ion) obtained with and without AsA. Highly sensitive responses to kojic acid and benzoic acid over $SCN^-$ ion were observed in the presence of 5 mM AsA, and the AF for $1 \times 10^{-7}$ M kojic acid was increased by more than a factor of 140. These differences in amplified behavior are considered to be explicable in terms of the differences in inhibitory mechanism. Namely, kojic acid and benzoic acid have structural similarity to polyphenols and compete with trace amounts of substrates that are recycled by AsA, and the selectivity of kojic acid over benzoic acid may stem from the structural differences of these inhibitors. In contrast, $SCN^-$ binds with copper ion at the catalytic site of the enzyme and competes with dissolved oxygen. Therefore, the slight amplification of $SCN^-$ ion is due to the differences in background oxygen concentration level (see Fig. 2). The relative standard deviation for five measurements of $2 \times 10^{-6}$ M kojic acid with dopamine and 5 mM AsA was $\approx 5\%$.

In general, tyrosinase has a broad catalytic activity towards a wide variety of mono- and polyphenolic compounds, such as phenol, catechol and catecholamines. Analytical results for kojic acid with several competitive substrates in the presence of 5 mM AsA are summarized in Table 2. The relatively highly sensitive detection of kojic acid was possible when phenol and catechol were used as competitive substrates. Amplification factors of catechol and phenol are higher than those of catecholamines [13,14], so net concentrations of phenol and catechol that compete with kojic acid are lower than those of dopamine and noradrenaline. These results are further evidence that the AF of the substrate determines the sensitivity of kojic acid in this recycling system. The long-term storage stability of the enzyme membrane was also investigated. The tyrosinase membrane used in this study was found to keep its catalytic activity for a period of more than 2 weeks (giving more than 80% current for $1 \times 10^{-5}$ M dopamine; compared to that for the first day) but the current response was decreased to less than 2/3 after 20 days.

The considerable advantages of this method using immobilized tyrosinase and AsA over other recycling systems based on electrochemical enzymatic reactions [16–18] are as follows. (1) A highly amplified signal can be obtained with AsA because the chemical reduction rate of *o*-quinones by AsA occurring in a three-dimensional solution may be larger than the rate of electrochemical reduction occurring at a restricted two-dimensional electrode surface.

Table 1
Analytical results for several inhibitors using a tyrosinase-membrane electrode in the presence of dopamine

| [Inhibitors] (M) | [AsA] (mM) | Kojic acid | | | Benzoic acid | | | $SCN^-$ ion | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | | $\Delta i$ (nA) [a] | AF [b] | D.L. (M) [c] | $\Delta i$ (nA) [a] | AF [b] | D.L. (M) [c] | $\Delta i$ (nA) [a] | AF [b] | D.L. (M) [c] |
| $1 \times 10^{-3}$ | 0 | 152 | 1 | $1 \times 10^{-5}$ | 77 | 1 | $1 \times 10^{-5}$ | 56 | 1 | $8 \times 10^{-5}$ |

[a] Inhibition currents to each inhibitor in the presence of $2 \times 10^{-4}$ M (non-amplified) and $1 \times 10^{-5}$ M (amplified) of dopamine.
[b] Amplification factors were calculated using non-amplified $\Delta i$ values to $1 \times 10^{-3}$ M and $1 \times 10^{-4}$ M inhibitors.
[c] D.L. = detection limit.
[d] n.d. = none detected.

Table 2
Analytical results of kojic acid using a tyrosinase-membrane electrode in the presence of several competitive substrates and 5 mM AsA

| Substrate | [substrate] [a] (M) | Kojic acid | | |
|---|---|---|---|---|
| | | $\Delta i$ (nA) [b] | Dynamic range (M) | D.L. (M) |
| Dopamine | $1 \times 10^{-5}$ | 80 | $1 \times 10^{-7} \sim$ approx. $1 \times 10^{-4}$ | $7 \times 10^{-8}$ |
| Catechol | $1 \times 10^{-6}$ | 98 | $7 \times 10^{-8} \sim$ approx. $1 \times 10^{-4}$ | $5 \times 10^{-8}$ |
| Phenol | $1 \times 10^{-6}$ | 122 | $7 \times 10^{-8} \sim$ approx. $7 \times 10^{-5}$ | $3 \times 10^{-8}$ |
| Noradrenaline | $2 \times 10^{-5}$ | 55 | $3 \times 10^{-6} \sim$ approx. $1 \times 10^{-3}$ | $1 \times 10^{-6}$ |

[a] The concentration required for the amplified current ( $\approx 350 \sim 400$ nA) in the presence of 5 mM AsA.
[b] Inhibition current to $1 \times 10^{-5}$ M kojic acid.

(2) A relatively wide concentration range and a highly sensitive determination of kojic acid is possible in the presence of AsA. (3) Serious interference by electrochemically active substances is easily avoided by preaddition of AsA to the sample solution. However, at the present stage, the replacement of the enzyme membrane is required after the exposure of the membrane to the solution containing a high concentration of inhibitors (1 mM) because the conplexation of inhibitor with enzyme is not completely reversible. Further, from the point of view of practical applications for the kojic acid sensor, pre-treatments to remove other inhibitors may also be required in advance (i.e. $SCN^-$ ion forms a water-insoluble complex with methylene blue).

In conclusion, a chemically amplified polyphenol sensor using immobilized tyrosinase and AsA is useful for highly sensitive determination not only of substrates but also of enzymatic inhibitors, especially kojic acid, and this analytical concept is expected to be applicable to other enzymatic recycling systems.

# Book reviews

***The Kirk-Othmer Encyclopedia of Chemical Technology***, Vol. 7, 4th edn., Composite Materials to Detergency, edited by J.I. Kroschwitz and M. Howe-Grant, Wiley-Interscience, Chichester, 1993, xxviii + 1117 pp., £150.00. ISBN 0-471-52675-4 (v.7).

Reviews of the different volumes of this encyclopedia appear regularly in *Talanta*. Volume 7 covers 37 topics and ranges, alphabetically, from Composite Materials to Detergency. Almost 80 authors, mainly from American academia and industry, have contributed to this volume.

More pages (140) are devoted to technological aspects of copper (Copper, Copper Alloys, Copper Compounds) than any other topic in this current volume. Emphasis here is on copper recovery and processing, wrought and cast alloys are treated separately and the properties and uses of commercially important copper compounds are surveyed.

Composite Materials (108 pages) are presented under the headings: Survey, Polymer-Matrix (e.g. thermoplastics) and Ceramic-Matrix (especially high temperature materials). A combination of mechanical engineering and chemical principles is clearly evident in this treatment. A separate section on Dental Materials (77 pages) covers a wide range of relevant ceramics, cements, plasters, waxes, alloys, etc. and is followed by a small section on Dentifrices.

Other topics in volume 7 which are covered in some depth include Controlled Release Technology (Agricultural and Pharmaceutical—the latter overlapping with the section on Drug Delivery Systems in volume 8), Cosmetics (over 6000 different cosmetics ingredients have been identified) and, Crystallization (kinetics, size distribution, crystallizers). General treatment is given to some computer-related topics—Computer-Aided Design and Manufacturing, Computer-Aided Engineering, Computer Technology and, Databases. The latter contains helpful lists of numerous scientific databases. Some of the minor, but interesting, topics include: Contact Lenses (both rigid and flexible), Contraceptives (including a list of available oral contraceptives), Cryogenics (liquefaction), Cyanides, Desiccants and Design of Experiments.

In common with previous volumes extensive bibliographies are included, the editing is excellent, and every science library should subscribe to this encyclopedia.

Who is this book aimed at? As a researcher with a passing interest in hyphenated techniques I am aware, through literature searches and review articles, who the key players are in GC–MS, LC–MS and CE–MS. With the online data bases and CD/ROM facilities searching through the literature is by no means a tedious task (as the preface to this volume suggests). Indeed before the researcher would wish to contact an acknowledged expert in the

field I would have thought that a literature search would be an essential pre-requisite. The preface goes on to suggest that you can pick up the phone and 'swiftly obtain information one needs regarding experimental set ups, specific consumables, etc.' For those poor souls whose addresses are included in this volume I pass on my sympathy. A suitable quotation to leave on your answer phone comes from a memorable interview between Mohammed Ali and Michael Parkinson... 'read my book'.

There is one very good use for this book that has been considered by the editor. Those who organise international conferences on hyphenated techniques will find the book extremely useful in compiling a list of potential contributors and delegates. If you are in this position the book is a good buy; otherwise I'd be tempted to give this one a miss.

B.A. McGaw

***Inorganic Chemistry***, 2nd edn., by D.F. Schriver, P.W. Atkins and C.H. Langford, Oxford University Press, Oxford, 1994, xviii + 819 pp. + additional information, softback, £19.50. ISBN 0-19-855396-X.

This is the second edition of the textbook published initially in 1990 and which was very successful. The second edition shows considerable modification and reorganization. The book is divided into three parts: Part 1, *Foundations*; Part 2, *Systematic chemistry of the elements* and Part 3, *Advanced topics*. Part 1 (ca. 310 pp.) has chapters on atomic and molecule structure, molecular shape and symmetry, structure of solids, acids and bases, d-metal complexes and oxidation and reduction. After establishing the foundation of the subject the authors, in Part 2 (ca. 170 pp.), provide a systematic comprehensive account of the chemistry of the elements and their compounds. Metals, hydrogen and its compounds, main-group organometallic compounds, boron and carbon groups, nitrogen and oxygen groups and halogens and noble gases are dealt with in six chapters. Part 3 is a very subjective section as the authors had to be very selective in the choice of appropriate topics in order to give the reader a sense of the current frontier research. It contains chapters on electronic spectra of complexes, reaction mechanisms of d-block complexes, d- and f-block organometallic compounds, catalysis, structures and properties of solids and bioinorganic chemistry.

Within each chapter there are worked examples, exercises and problems and short answers are also provided. A set of *Key points* has been introduced at the end of each chapter.

In Part 1, the discussion of molecular shape and symmetry as a separate chapter in this edition is an example of a much improved reorganization of the material. It has also been extended to include topics such as infrared and Raman spectroscopy.

The introduction of the new chapter, *The metals*, is also a necessary improvement from the first edition.

According to the authors, much of the changes were the result of suggestions from readers. As a consequence Part 3 has been augmented, refined and extensively updated.

The shift of topics, for example NMR, to separate sections called *Further information* acknowledges the generality of this material, which in the first edition may have been lost by association with a specific chapter such as hydrogen and its compounds.

A very useful book—highly recommended.

S.M.S.V. Doidge-Harrison

***Chemical Speciation in the Environment***, edited by A.M. Ure and C.M. Davidson, Blackie, London, 1995, xiii + 408 pp., £79.00. ISBN 0-7514-0021-1.

Chemical speciation used to mean the qualitative and quantitative *determination* (expressed as % distribution) of the different chemical forms of a given element. Nowadays it has diverged to embrace the different physical/chemical forms present, not necessarily of a particular element. It can also be interpreted as the description for species composition, i.e. not of analysis. Indeed, these various interpretations have been adopted by contributors of this book.

Physical and/or chemical interactions between different components in an environment give rise to different forms (species) of each element. Thus description of possible interactions is necessary background for speciation. Readers may also expect descriptions on different speciation methods and equally important, the use of speciation results to understand/predict behaviour (e.g. availability and toxicity) in

field I would have thought that a literature search would be an essential pre-requisite. The preface goes on to suggest that you can pick up the phone and 'swiftly obtain information one needs regarding experimental set ups, specific consumables, etc.' For those poor souls whose addresses are included in this volume I pass on my sympathy. The introduction of the new chapter, *The metals*, is also a necessary improvement from the first edition.

According to the authors, much of the changes were the result of suggestions from readers. As a consequence Part 3 has been augmented, refined and extensively updated.

The shift of topics, for example NMR, to separate sections called *Further information* acknowledges the generality of this material, which in the first edition may have been lost by association with a specific chapter such as hydrogen and its compounds.

A very useful book—highly recommended.

S.M.S.V. Doidge-Harrison

***Chemical Speciation in the Environment***, edited by A.M. Ure and C.M. Davidson, Blackie, London, 1995, xiii + 408 pp., £79.00. ISBN 0-7514-0021-1.

Chemical speciation used to mean the qualitative and quantitative *determination* (expressed as % distribution) of the different chemical forms of a given element. Nowadays it has diverged to embrace the different physical/chemical forms present, not necessarily of a particular element. It can also be interpreted as the description for species composition, i.e. not of analysis. Indeed, these various interpretations have been adopted by contributors of this book.

Physical and/or chemical interactions between different components in an environment give rise to different forms (species) of each element. Thus description of possible interactions is necessary background for speciation. Readers may also expect descriptions on different speciation methods and equally important, the use of speciation results to understand/predict behaviour (e.g. availability and toxicity) in

the environment. Of the interactions/background, this book has adequate coverage. Of methods and techniques, there is sufficient coverage for some elements but not for others. Of the implications and applications of speciation, it is generally rather lacking.

The book has 12 chapters. The first is a good overview of the subject and an introduction/summary of the subsequent chapters. Chaper 2 is a comprehensive but brief account of the methodologies used in speciation. Chapter 3 is a useful chapter on techniques of metal speciation, with more details on spectroscopic techniques, particularly on NMR. Chapter 4 is a quite complete but brief account on coupled techniques (e.g. HPLC–MS). Chapter 5 gives a comprehensive background to phase diagrams and computer simulations. A discussion of computer programmes and some examples are given but it would have been helpful to expand this part. Chapter 6 describes the formation mechanisms and interaction mechanisms of metal-containing species in the atmosphere. with examples. This chapter is well-balanced and informative. Chapter 7 gives a brief overview of speciation methodology in fresh waters but the emphasis is on interactions (especially metal complexation) and behaviour of species which is a needed aspect of the book. Chapter 8 describes interactions at surfaces and in solution in the soil environment, with adequate examples. Metal complexation is discussed in greater (and useful) detail. However, the authors used p$K$ for formation of complexes. Formation constants are normally expressed by log $K$ and from their figures and tables, it seems that it is log $K$ that they meant, e.g. a larger p$K$ (log $K$), a stronger complex. Chapter 9 gives a well-balanced account, with adequate examples, of the methodology of metal speciation in sediments and combustion waste. Chapter 10 gives an informative account on the speciation of the important radionuclides. Chapter 11 is a general account on the species of some metals found in micro-organisms, plants and animals. In my opinion, it is very difficult to give a comprehensive account of this subject. Chapter 12 has the title of a concluding chapter (Trends and Development) but is limited to a rather general account on the methodology of speciation, mostly of the metalloids.

Overall the book is very readable, well-presented, up-to-date and reasonably priced for its volume of information. I recommend it to all researchers involved in environmental and analytical studies.

***Emerging Technologies in Hazardous Waste Management—IV***, edited by D.W. Tedder and F.G. Pohland, American Chemical Society, Washington, DC, 1994, ix + 317 pp., US$ 89.95. ISBN 0-8412-2857-4.

This volume is a continuation of the symposia on the theme of Emerging Technologies in Hazardous Waste Management organised by the American Chemical Society, and grew out of a selection of 18 papers from the 1992 meeting in Atlanta. The first group deals with aspects of soil remediation, starting with an excellent account of a chemical engineer's approach to modelling a real system from which organics were being removed by vapour extraction. Analysis of the data enabled performance to be measured and predicted, not just from an efficiency point of view but also from an economic one. This is typical of the successful multi-disciplinary approaches to these problems, illustrating how the chemist must broaden his horizons when tackling environmental remediation problems. Electrokinetic remediation—basically large-scale electrophoresis using soil as the bed—is discussed for the removal of anionic pollutants, then a study of the kinetics of the biodegradation of phenols in soils and finally, in this section, the use of bacteria to assist in the mobilisation of heavy metals in soils.

Nine papers deal with minimising the production of waste during the manufacturing stage. Application of artificial intelligence to a programme of waste minimisation presents the general scene for improved process management, and is followed by an account of the removal of mercury from a waste stream by emulsion extraction. The combination of physical adsorption and bacterial degradation is shown to be useful in minimising losses of petrol vapours from air streams, while loss of $SO_2$ from sulphur-rich fuels can be significantly reduced by mixing a scavenger such as lime with the fuel before combustion. Chemically-assisted bacterial degradation of pentachlorophenol (with hydrogen peroxide) and of triazine pesticides (with ozone) has been shown to work significantly faster than microbiological action alone.

***Emerging Technologies in Hazardous Waste Management—IV***, edited by D.W. Tedder and F.G. Pohland, American Chemical Society, Washington, DC, 1994, ix + 317 pp., US$ 89.95. ISBN 0-8412-2857-4.

This volume is a continuation of the symposia on the theme of Emerging Technologies in Hazardous Waste Management organised by the American Chemical Society, and grew out of a selection of 18 papers from the 1992 meeting in Atlanta. The first group deals with aspects of soil remediation, starting with an excellent account of a chemical engineer's approach to modelling a real system from which organics were being removed by vapour extraction. Analysis of the data enabled performance to be measured and predicted, not just from an efficiency point of view but also from an economic one. This is typical of the successful multi-disciplinary approaches to these problems, illustrating how the chemist must broaden his horizons when tackling environmental remediation problems. Electrokinetic remediation—basically large-scale electrophoresis using soil as the bed—is discussed for the removal of anionic pollutants, then a study of the kinetics of the biodegradation of phenols in soils and finally, in this section, the use of bacteria to assist in the mobilisation of heavy metals in soils.

Nine papers deal with minimising the production of waste during the manufacturing stage. Application of artificial intelligence to a programme of waste minimisation presents the general scene for improved process management, and is followed by an account of the removal of mercury from a waste stream by emulsion extraction. The combination of physical adsorption and bacterial degradation is shown to be useful in minimising losses of petrol vapours from air streams, while loss of $SO_2$ from sulphur-rich fuels can be significantly reduced by mixing a scavenger such as lime with the fuel before combustion. Chemically-assisted bacterial degradation of pentachlorophenol (with hydrogen peroxide) and of triazine pesticides (with ozone) has been shown to work significantly faster than microbiological action alone.

Finally, a group of papers describes problems of cyclic gas release events in very large tanks storing radio-active waste. Detailed chemical analysis and long-term monitoring have enabled the causes to be elucidated and remedial action to be taken to avoid risk of explosion. Once again, it is the combination of several approaches which is shown to be successful.

There is much fascinating information in this volume, often in considerable detail, which may serve to give pointers to others working in environmental remediation chemistry. This well produced book of carefully selected material is to be recommended.

I.L. Marr

***Determination of Trace Elements***, edited by Z.B. Alfassi, VCH, Weinheim, 1994, xiv + 607 pp., DM 280, £112. ISBN 3-527-28424-9.

What—another book on trace element analysis? This book is certainly large, comprehensive, authoritative and thorough. How does it score otherwise? As it is a multi-author text, the final quality must depend on the work of the editor in helping to structure the individual contributions and then to harmonise them, avoiding overlap of contributions as well as omission of useful material. There are many familar names among the authors. Tölg and Tschöpel give us an updated essay on the sources of systematic errors in trace analysis—always important and therefore essential reading. Kirchmer discusses the concept(s) of limits of detection at some length, and does, I am glad, point out the dangers in using the linear regression of the calibration to estimate the l.d. of a method, an approach which can often give dramatically wrong values, but which is nevertheless often used in commercial software. A chapter on sampling and sample preparation unfortunately repeats too much of Chapter 1 relating to sources of error, but the next, that on separation and preconcentration, gives a good systematic coverage outlining the equilibria involved and giving examples. I think that the chapter on atomic absorption could have been much shorter—there are plenty of texts on this subject, and what is needed here is a survey of the place of AAS in trace and ultra-trace analysis. The balance and the content are much better in the chapter on plasma spectroscopy, which deals with both optical and mass detection systems.

Instrumental neutron activation analysis and radiochemical neutron activation analysis get two separate chapters, in which the author is nearly successful in hiding the distinction between these related topics, but does nevertheless give a lot of detailed information. Polak presents a readable account of surface analytical techniques and shows how they can be used for determination of trace species in solution following adsorption. Wandruszka selects material very carefully for his contribution on electrochemical methods, concentrating on combined preconcentration and stripping methods such as ASV and demonstrating their relevance in speciation at ultra-trace levels.

The combinations of chromatography with atomic spectroscopy, gradually becoming established, especially for determinations of organometallics, strikes a good balance between the overview and the experimental detail, with many helpful examples. The chapter on speciation gives an unusual view in presenting the subject with reference to the use of radio-analytical methods. In the main, this deals with solid phase samples, with speciation in different phases and in depth profiling. The final contribution discusses trace elements in relation to environmental and health sciences, and has much to say on the special considerations which must be given to the history and state of the patient before conclusions can be drawn from the results of chemical analysis. In spite of the tiresome repeated referencing to other writings of the same authors, there is much useful material in this chapter, not so readily available to most analytical chemists.

So, how does it score? The weakness in this volume lies in the editing—several chapters would have benefitted from linguistic assistance, and others could have been shortened without loss to the book as a whole. But there are many well written and informative chapters, contributing to what will certainly prove to be a valuable reference source on the state of trace analysis in the mid 1990s. Many of these chapters could well be useful background reading for postgraduate taught courses. At DM 280 or £112 this is not cheap, but it is certainly worth recommending for the library.

***Laser Spectroscopy—Techniques and Applications***, by E.R. Menzel, Dekker, New York, 1995, xv + 298 pp., US$ 135.00. ISBN 0-8247-9265-3.

This is perhaps the best text that I have read on the techniques and applications of laser spectroscopy. The author makes it clear that the book is intended for the non-specialist and achieves a admirable mixture of the basic essentials (with as little mathematics as possible) and a concise, comprehensive review of applications. Many researchers, especially those in bioscience and medicine to whom a deeper treatment of theoretical aspects is often inappropriate and usually off-putting, will welcome this book as an 'entry level' text. Laser spectroscopy is now a maturing technique that is ripe for exploitation in diverse fields of scientific endeavour.

The book is divided into nine chapters and starts with an overview of the interactions between molecules and light and on the general principles of laser operation. Chapter 2 reviews spectroscopic instrumentation and includes sections on absorption spectrophotometers, spectrofluorometers and synchronous luminescence spectroscopy. Chapters 3–6 are devoted to specific spectroscopic techniques (absorption-based laser spectroscopy, photoluminescence intensity-based and lifetime-based laser spectroscopy, and laser Raman spectroscopy) and give a strong emphasis to recent developments and applications. The book concludes with three chapters on selected applications (including medicine, semiconductors and analytical chemistry), selected spectroscopic techniques (including multidimensional fluorescence, optically detected magnetic resonance, circular dichroism, etc.) and finally a very readable chapter on emerging spectroscopies. The latter covers such exciting techniques as tunable IR lasers, ring lasers and X-ray lasers.

This book will be of great interest to those wanting a 'bird's eye view of laser spectroscopy'. The up-to-date references and comprehensive coverage of applications will be of use to the specialist and non-specialist alike. For those of us teaching applied spectroscopy this book will be an invaluable resource.

## BIOSENSORS CIRCLES THE GLOBE

Following the tremendous success of the third Biosensors conference held in New Orleans in 1994 involving over 300 submitted abstracts and participants from 30 countries, **The Fourth World Congress on Biosensors** will take place on 29–31 May 1996 in Bangkok, Thailand.

The conference, organised by Elsevier Advanced Technology, returns to the Far East in '96 completing a six year cycle of biannual meetings in strategic sectors of the globe.

**Biosensors '96** is the principal conference in the field. The intense three day event covers every facet of the science, application and commercial exploitation of Biosensors and Bioelectronics and will be attended by all the prime movers in the field.

For the first time in 1996, a symposium on Bioelectronics will be dedicated to the more general exploitation of biochemicals in electronic devices. The plenary sessions in this year's event will emphasise new horizons, with critical appraisals of the opportunities offered by improved understanding of biophysical interactions at the molecular level.

The Biosensors Congress is ***the*** forum for highly original communications and provides a comprehensive picture of recent developments and catalyses interactions that mould the future directions of the area.

### Format of the Congress

The congress will be structured as three symposia:

- Catalytic Biosensors
- Affinity Biosensors
- Bioelectronics

Contributions describing the industrial development of analytical instruments, as well as more fundamental aspects of the technology, will also be encouraged and supplemented by a display of commercial equipment.

### Exhibition

Following the excellent response to the first exhibition held at ***Biosensors '96***, there will be increased space allocated at the '96 event for companies to display their commercial equipment.

### Biosensors and Bioelectronics Award

For the first time the supporting journal for the conference, ***Biosensors and Bioelectronics***, will sponsor an award for the most original oral and poster presentations, to be selected at the conference.

## INTERNATIONAL ION CHROMATOGRAPHY SYMPOSIUM

The International Ion Chromatography Symposium 1995 will be held October 1st–5th at The Grand Kempinski in Dallas, Texas. Program Chairman Donald Pietrzyk heads a scientific committee of internationally renowned ion chromatography experts and an organizing committee of local scientists.

This year's program features six plenary lectures and over 120 technical presentations.

This three-day international meeting provides a unique opportunity for scientists from a variety of disciplines to exchange ideas and results on current methods and procedures in ion chromatography and capillary electrophoresis for the separation and determination of small organic and inorganic ions. Topic areas include:

- Advances in Column Technology and Column Selectivity
- Advances in Detection
- Special Sample Treatment Procedures
- Anion Analysis
- Cation/Transuronic Analysis
- Capillary Wall Modifications
- Environmental Applications
- Pharmaceutical Applications
- Health Science Applications
- Industrial Problem Solving
- On-Line Analysis
- Data Handling

## INTERNATIONAL CONFERENCE ON ENVIRONMENTAL SCIENCE

January 10–13, 1996, Trivandrum, India

and workshop on

## PRESENT STATUS OF ANALYSIS OF TRACE METALS AND NUTRIENTS IN THE MARINE ENVIRONMENT

January 8–13, 1996, Trivandrum, India

The scientific program of the conference will cover the following topics:

- Multidimensional Techniques for Environmental Monitoring
- Pollutant Sensors
- Speciation
- Quality Assurance for Environmental Data
- Modelling of Environmental Data
- Waste Water and Drinking Water Treatment — Emerging Technologies

The workshop will be devoted to:

- An in-depth discussion on the status of sampling and analysis of sea water, sediments and biota for trace elements; of nutrients in sea water; their distribution in relation to biological, chemical and hydrographic processes
- A review of the data on trace elements in the different oceans
- Guidelines for future research and for interlaboratory collaboration

## FIRST ANNOUNCEMENT

### 5th International Congress on Trace Elements in Medicine and Biology

**Therapeutic Uses of Trace Elements**
*Satellite Workshop: Molecular Basis of Copper Metabolic Disorders*

4–7 February 1996, Méribel, France

**MAIN TOPICS:**

- Therapeutic forms of trace elements
- Large epidemiological and intervention studies related to trace elements
- Trace element supplementation of population groups at different periods of age
- Trace elements, bone physiology and bone diseases
- Trace element status and treatment in relation to inflammatory conditions and infections
- Trace elements in digestive diseases and in endocrinology
- Pharmacological applications of trace elements
- Genetic disorders of copper metabolism

**OFFICIAL LANGUAGES:**

French and English (simultaneous translation)

**ORGANIZED BY:**

## 10TH INTERNATIONAL CONFERENCE ON FOURIER TRANSFORM SPECTROSCOPY

Budapest, August 27–September 1, 1995

**OPENING SPEAKER: R. R. ERNST, NOBEL LAUREATE CHEMISTRY, 1991**

**PLENARY SPEAKERS:**

J. E. BERTIE
J. W. BRAULT
C. CASTIGLIONI
D. B. CHASE
HAI-LUNG DAI
J. P. DEVLIN
C. B. FARMER
J. A. DE HASETH
H. M. HEISE
K. ITOH
J. C. LAVALLEY
J. P. MAILLARD
C. MARCOTT
H. NEUGEBAUER
M. N. POPOVA
E. PRETSCH
F. SIEBERT
W. THEISS
M. WINNEWISSER

**ROUND-TABLE OR PANEL DISCUSSIONS WILL BE ORGANIZED IN THE FOLLOWING TOPICS:**

- Catalysis
- Environmental and life sciences
- Quantitative accuracy of FTIR spectrometry
- Contributed papers as posters: Send your 1-page abstract by March 30, 1995

Special pre-conference event:

**1st EURO-AMERICAN INTENSIVE SHORT COURSE ON ADVANCED INFRARED AND RAMAN SPECTROSCOPY**

Hungarian Academy of Sciences, Veszprém, Hungary, August 23–26, 1995

SPECIAL FOCUS: INDUSTRIAL AND ENVIRONMENTAL ASPECTS

**LECTURERS:**

Prof. D. B. Chase
Prof. J. G. Grasselli-Brown
Prof. P. R. Griffiths
Prof. J. A. de Haseth
Prof. R. Kellner
Prof. J. A. Lercher
Prof. J. Mink
Prof. E. Pretsch
Prof. H. W. Siesler

A special package price is available for both events on request.

For further information please contact:

Prof. János Mink
University of Veszprém, Dept. of Analytical Chemistry,
H-8201 Veszprém, P.O. Box 158, Hungary
Tel: +36-88-421-869; Fax: +36-88-426-016
E-mail: mink@iserv.iki.kfki.hu

## ICFIA '95
## JAFIA

August 13–17, 1995, Seattle, Washington

The seventh International Conference on Flow Injection Analysis **(ICFIA '95)** and the 24th Semi-Annual Meeting of the Japanese Association for Flow Injection Analysis **(JAFIA)** will be held jointly at Meany Tower Hotel in Seattle, Washington.

The meeting will focus on developments in the growing fields of FIA and SIA—methods, applications, software and hardware.

Publishers and producers of instruments, equipment, and software relevant to FIA are invited to exhibit.
Registration fees and deadlines: By May 1, 1995, $225; May 2–July 1, $250; after July 1, $275.
Students: By May 1, $100; after May 1, $125.
Deadline for abstracts: July 1, 1995.

For a registration form or more information, contact

Gary D. Christian
Dept. of Chemistry, BG-10
University of Washington
Seattle, WA 98195
FAX: 206-685-3478
e-mail: christia@chem.washington.edu

## 1995 FIRST MEDITERRANEAN BASIN CONFERENCE ON ANALYTICAL CHEMISTRY

Cordoba, Spain, 5–10 November, 1995

In order to promote collaboration among analytical scientists of the whole Mediterranean Basin, the *1995 First Mediterranean Basin Conference on Analytical Chemistry* will provide an adequate forum for reporting and thoroughly discussing the latest research results in basic and instrumental developments in Analytical Chemistry.

Other aims of this Conference are:

- To promote new opportunities for young scientists in the Mediterranean Sea area (particularly for those in the Southern Bank): to attend international meetings in countries of the region, to attend training workshops on new analytical techniques, to attend short courses on new techniques and trends in Analytical Chemistry and to establish new links for research in/or other countries of the region.
- To stimulate the progress of Analytical Chemistry as a whole by solving analytical problems affecting the Mediterranean Area.

The program has been designed to attract participants from industry, universities and research centers. The program will comprise invited plenary and key-note lecturers, contributed oral papers, and posters, distributed in several Symposia covering the following topics: Education of Analytical Chemistry, Environmental Analytical Chemistry, Agriculture and Food Analysis, Geoanalytical Chemistry and Benefitiation of Minerals, Biomedical Analysis, Archeometry and Art Objects Preservation, Quality Assurance and Harmonization of Procedures.

A few Short Courses, Special Sessions on "hot" topics, and an Exhibition of Instrumentation has also been arranged.

Invited lecturers who have already confirmed their contribution include M. Valcárcel, I. B. Brenner, D. Barceló, S. Caroli, A. Laachach, O. X. F. Donnard, M. M. Khater, H. Muntau, J. Albaigés, B. Y. Meklati and P. Quevauviller.

## CALL FOR PAPERS

Titles of submitted oral or poster presentations are solicited with the preliminary registration card by 30 May, 1995. Submission of final Conference Abstracts are requested not later than 30 June, 1995.

## SOCIAL ACTIVITIES

Varied social activities, including a visit to Granada, are being planned.

## FURTHER INFORMATION

For further information and pre-registration forms, please contact:

Prof. Alfredo Sanz-Medel (Chairman)
Department of Physical and Analytical Chemistry
Faculty of Chemistry
University of Oviedo
C/ Julian Claveria, s/n
33006 Oviedo, Spain
Tel: 34-8-5 10 34 80 or 34-8-5 10 34 74
Fax: 34-8-5 10 31 25

## Fundamentals of Chromatography Course
## June 12–16, 1995

Kent State University's Department of Chemistry and Varian Associates will co-sponsor a course, "Fundamentals of Chromatographic Analysis", during June 12–16, 1995. This course, which has been well received by the industrial community, has been presented ten previous years.

The course will provide a coherent overview of chemical separations via chromatographic methods. It is unique from most other short courses in that material will be included on gas, liquid and thin-layer methods. It will emphasize the three techniques as complementary rather than competing processes. The course will be a blend of fundamental information on theory and instrumentation with emphasis placed on the latest developments and trends. Additional periods will provide time to discuss practical problems related to HPLC, GC, GC–MS, TLC and CE instrumentation. Some laboratory sessions will be available for the students.

Dr. Roger K. Gilpin, Chairman of Chemistry at Kent State University, and Dr. Neil D. Danielson, Professor at Miami University, will be the principle lecturers. Ronald E. Lewis of Varian will discuss/demonstrate laboratory instrumentation.

Information on this course can be obtained by writing to the Department of Chemistry, Kent State University, Kent, OH 44242, or by calling 216/672-2032.

---

## XIIITH NATIONAL CONFERENCE ON ANALYTICAL CHEMISTRY
May 23–25, 1996, Craiova, Romania

Organized by the Romanian Society of Analytical Chemistry.

For further information, please contact:

Cristina Matachescu,
Romanian Society of Analytical Chemistry,
13 Blvd. Republicii,
Sector 3, 70346 Bucharest, Romania
Tel/Fax: 00 401 631 0060.

## PBA '95 SIXTH INTERNATIONAL SYMPOSIUM ON PHARMACEUTICAL AND BIOMEDICAL ANALYSIS

St Louis, Missouri, U.S.A.
23–26 April 1995

PBA '95 will be held 23–26 April 1995 in the historic Union Station Hyatt Regency Hotel in St Louis. The symposium is organized by the *International Association for Pharmaceutical and Biomedical Analysis*, chaired by Professor John F. Stobaugh, with sponsorship from a wide range of international organizations. It follows highly successful meetings held in Barcelona (1987), York (1990), Boston (1991), Baltimore (1992) and Stockholm (1994). The objectives of the Symposium are to provide a stimulating forum for delegates to meet in the pleasant and sociable surroundings of St Louis, where they can be updated on the latest developments in analytical science and instrumentation, applied across the range of pharmaceutical and clinical sciences. All those involved in the analysis of drugs, related materials, forensic samples and endogenous compounds are cordially invited to attend.

The programme for PBA '95 will start off on 23 April with a series of half-day Workshops on the following topics: Diode-array/Mass Spectrometric Detection in LC; Analysis of Solids and Excipients; Microdialysis Sampling; Laboratory Information Management Systems; Assay Validation; Capillary Electrophoresis; Sample Preparation.

The scientific programme will include invited Keynote Lectures on topical themes, Oral Presentations, Poster Presentations and the ever-popular Poster Discussion Sessions, where authors may summarize their poster in a short Oral Presentation for discussion in smaller groups.

Topics to be covered include:

- Analytical biotechnology
- Bioanalysis in clinical and preclinical drug development
- Sample preparation and derivatization
- Spectroscopic methods (NMR, MS, CD, FT-IT, UV-Vis, CL, FL)
- Advances in separation techniques (LC, CE, GC, SFC)
- Analysis of stereoisomers
- Analytical considerations in drug delivery
- Applications of monoclonal antibodies
- Assay validation and regulatory issues
- Automated methods of analysis
- Drugs of abuse
- Therapeutic drug monitoring, clinical and forensic toxicology
- Pharmaceutical Quality Control—analysis of bulk drugs and formulations

The City of St Louis is an excellent place for meeting colleagues and making new contacts in convivial circumstances designed to maximize the opportunity to obtain the latest information on advances in analysis relevant to pharmaceutical and biomedical analysis. This Symposium will overlap with and be followed by the 6th International Symposium on Chiral Discrimination (ISCD '95) in the same venue, 26–28 April, 1995, giving a unique opportunity to meet delegates and speakers from both fields.

For further information please contact:
Miss Shirley E. Schlessinger, Symposium Manager, PBA '95/ISCD '95
Suite 1015, 400 East Randolph Drive,
Chicago, IL 60601, U.S.A.
Tel: 1-312-527-2011

## ISCD '95: SIXTH INTERNATIONAL SYMPOSIUM ON CHIRAL DISCRIMINATION

St Louis, Missouri, U.S.A.
26–28 April, 1995

ISCD '95 will be held 26–28 April 1995 in the historic Union Station Hyatt Regency Hotel in St Louis. The symposium is chaired by Professor Daniel W. Armstrong, and is sponsored by a number of international organizations. It follows highly successful meetings held in this series in France (1988), Rome (1991), Tübingen (1992), Montreal (1993) and Stockholm (1994).

The objective of ISCD '95 is to provide a stimulating forum for the discussion of recent developments in chiral discrimination, a topic of profound importance in many different scientific fields. This interdisciplinary forum aims to unify and broaden the perspectives of participants through reports and discussions on cutting-edge developments in chiral discrimination and stereochemistry. ISCD '95 will focus on chiral research of specific concern to pharmaceutical and medicinal scientists. All those involved in any aspect of chiral discrimination are cordially invited to attend.

The scientific programme will include invited Keynote Lectures, Oral Presentations, Poster Presentations and Poster Discussion Sessions, where authors will be invited to make a short Oral Presentation for discussion in smaller groups. Topics to be covered include:

- Molecular Recognition
- Racemization
- Chiral Ligand Binding
- Advances in Enantiomeric Separations (LC, CE, GC and SFC)
- Stereochemical Aspects of Pharmacokinetics
- Stereoselective Catalysis
- Catalytic Antibodies
- Regulatory Issues
- Food and Beverage Issues
- Circular Dichroism and Polarimetry
- Chiral NMR Shift Reagents
- Enzymatic Methods
- Stereochemical Aspects of Synthesis
- Large-scale Separation of Enantiomers
- Stereochemical Aspects of Pharmacodynamics
- Stereochemical Theory
- Determination of Absolute Configuration
- Method Validation
- Environmental Issues
- Geochemical Aspects

Delegates will meet in the pleasant and convivial surroundings of St Louis, which is an excellent place for making new contacts and for networking among colleagues to find out the latest information on advances in the field. This Symposium will overlap with and be preceded by the 6th International Symposium on Pharmaceutical and Biomedical Analysis in the same venue, 23–26 April 1995, giving a unique opportunity to meet delegates and speakers from both fields.

For further information please contact:
Miss Shirley E. Schlessinger, Symposium Manager, PBA '95/ISCD '95
Suite 1015, 400 East Randolph Drive,
Chicago, IL 60601, U.S.A.
Tel: 1-312-527-2011

# HPLC '95: 19TH INTERNATIONAL SYMPOSIUM ON COLUMN LIQUID CHROMATOGRAPHY

Innsbruck, Austria
28 May–2 June 1995

HPLC '95 will be held in the Innsbruck Convention Center from 28 May to 2 June 1995. This symposium will be chaired by Professor Wolfgang Lindner and forms the 19th in a distinguished series of meetings, which have been the premier event for the presentation of the latest scientific and instrumental advances in separation science. There will be a strong focus on the most dynamically developing techniques and applications in liquid chromatography, capillary electrophoresis and related methods including hyphenated techniques. All those involved in any area of separation science and its applications are cordially invited to attend.

The format for HPLC '95 will be similar to that for successful meetings held earlier in Europe and the USA, with topical issues in *Oral Sessions*, a strong focus on *Poster Presentations* and special *Poster Discussion Sessions*. A comprehensive *International Technical Exhibition* will be presented as an integral part of the scientific programme. *Workshops* and *Discussion Fora*, also involving the international Exhibitors, will be held on selected topics.
This broad interdisciplinary forum will highlight the following scientific themes:

- Separation methods, including HPLC, SFC, HP-affinity chromatography and related methods
- Capillary electrophoresis and electrokinetic chromatography
- Hyphenated techniques and coupled techniques, including mass spectrometry
- Chiral recognition and separation of stereoisomers
- Separation techniques in biotechnology
- New developments in sorption materials
- Preparative techniques in chromatography
- Selective and sensitive detection systems
- Sample preparation and derivatisation strategies
- Applications in pharmaceutical, clinical, food, environmental and forensic analysis, etc
- Chemometrics in separation science
- Validation and regulatory issues

Delegates will meet in the convivial social surroundings of the Tyrolean city of Innsbruck, where there will be ample time for networking among colleagues and updating on the latest developments in the field.

In view of the rapid developments currently taking place in separation science, the Organizers will be happy to receive **LAST MINUTE CONTRIBUTIONS** as *Poster Presentations*, if an Abstract is submitted by **10 May, 1995**.

For further information please contact:

HPLC '95 Secretariat,
Tyrol Congress,
Marktgraben 2
A-6020 Innsbruck, Austria

## INTERNATIONAL MASS SPECTROMETRY SOCIETY

At its meeting in conjunction with the 13th International Mass Spectrometry Conference (IMSC) in Budapest on 31 August, the International Scientific Committee of the International Mass Spectrometry Conference voted to establish an International Mass Spectrometry Society (IMSS). The increasing internationalization of science and the many advantages of formal methods of co-operation across national boundaries prompted this move. To implement this motion, the Committee established a working group to draw up a constitution and policies. This group consists of R. G. Cooks (U.S., Chair), E. Gelpi (Spain), C. Lifshitz (Israel), M. Linscheid (Germany), J. MacLeod (Australia), Y. Nakagawa (Japan), and N. M. M. Nibbering (Netherlands). This group welcomes suggestions from all interested in the future of mass spectrometry. Please contact any of the above individuals with suggestions on objectives, governance, membership, finances and the like.

The committee is also considering the future role of the IMSS in improving communications between mass spectrometry groups and societies, in the organization of the IMSC and the publication of its proceedings, in the preservation of the history of mass spectrometry, in improving the teaching and practice of mass spectrometry in countries in which it is not well-developed, in facilitating acquisition of funding for mass spectrometry from super-governmental bodies and in improving the status of the subject through membership of the IMSS in appropriate international scientific organizations.
