**Summary**—The light originating from seven light-emitting diodes of different colours is guided, one at a time, into a measuring cell by means of a fibre optic coupler. Detection is carried out with photodiodes which are connected to a log-ratio amplifier yielding direct absorbance readings. Optical filters are used to narrow the emission band from blue light emitting diodes as these bands are relatively wide compared to those of the emitters of other colours. An inexpensive and compact multi-wavelength photometer covering the visible range is thus obtained, which in many cases can replace a conventional spectrophotometer for absorbance measurements. The performance for a range of commonly used photometric analytical procedures is described and compared to conventional measurements with a spectrophotometer.

Light-emitting diodes (LEDs) produce light with bandwidths of typically 25 nm which is comparable to the combination of wideband sources with interference type optical filters. It is, therefore, possible to carry out photometry with LEDs without the use of wavelength discriminating devices. the use of LEDs in photometric detectors has often been reported[1–21] and its application in flow-through methods has been reviewed.[22,23] The LEDs are commonly combined with photodiodes which measure the light intensity after passage through the sample. Geometric arrangements reported include dip-type probes and flow-through cells. The detectors have usually been connected to operational amplifiers in the current follower configuration which yield an output voltage directly proportional to the photo-current and hence light intensity. This signal represents transmittance measurements. A value corresponding to absorbance can be obtained by connection to a logarithmic amplifier. This is more appropriate because it is this value that is directly related to concentration according to Beer–Lambert's law. Such devices have been reported more recently.[17–21] LEDs with colours ranging from the blue to the infrared are available and, therefore, with the exception of the near-UV cover all the wavelength range that is commonly used for analytical spectrophotometry. Absorbance bands for molecular absorption spectroscopy are usually fairly wide, typically 100 nm, and it is therefore almost always possible to find a matching LED. A range of six LEDs of the colours blue, green, yellow, orange, red and near-infrared can thus in many cases replace a conventional visible-range spectrophotometer. However, most LED-photometers described to date have only employed a fixed wavelength for a predetermined purpose. A change of wavelength had to be effected by physically changing the light source. This limitation has been caused by the difficulty in coupling light from more than one source into a single detector cell. Bi-colour LEDs are available which contain two light emitting substrates in one body and have been used for a dual wavelength detector.[13] A tri-colour device has been constructed by using a green/yellow bi-colour LED and a number of red LEDs arranged concentrically around the bi-colour LED in order to pass red light into the cell as well.[14,15] The coupling of the light from two separate LEDs into a single cell with bifurcated optical fibres for the purpose of correction for turbidity has recently been described.[16] Here a multi-LED photometer is described that employs a fibre optic coupler to guide the light from up to seven LEDs into a single measuring cell.

## EXPERIMENTAL

### *Electronic and optical components*

The 2 × 7 fibre optic coupler star coupler (15 × 4.5 × 1 cm) was purchased from Luxmatic (PF-SC 2 × 7/1000, Baar, Switzerland) and has cladded plastic fibre pig tails with 1 mm core. LEDs were obtained from Farnell Electronic Components (Auckland, New Zealand) (blue, Part No. 233-511), Radiospares (Auckland, New Zealand) (orange, Part No. 578-200), Hewlett-Packard (Palo Alto, CA) (yellow, HLMA-DLOO) and from Siemens (Wellington, New Zealand) (green, SFH 751; red, SFH 750; infrared, SFH 452). The photodiodes were also obtained from Siemens (SFH 250). The components from Siemens are specifically designed for easy coupling with the 1 mm plastic optical fibres. Conventional LEDs were connected by removing the plastic body close to the active substrate and polishing the surface. Special adaptors made from perspex allowed butting of the fibre end onto the emitter. The log-convertor (LOG100JP) was obtained from Burr-Brown (Tucson, AZ, U.S.A.). The digital panel meter (OEM 33) was from Anders (London, U.K.) and the optical filters were obtained from Eastman Kodak (Wratten Gelatine Filters No 32, 58 and 87, Kodak, Rochester, NY, U.S.A.). Photocurrents were measured by temporarily connecting one of the photodiodes to an operational amplifier in the current follower configuration (OPA121, Burr-Brown).

### *Spectra and conventional absorbance measurements*

Absorbance spectra and conventional absorbance values were obtained with a Shimadzu UV-160A spectrophotometer using 1 cm cuvettes. The emission spectra of the LEDs were acquired on a Hitachi F-2000 spectrofluorometer by mounting them individually in the cell holder. The spectra were redrawn from the scaled numerical output of the instrument. The quoted relative sensitivity values were obtained by comparing the slope of the LED calibration curve (using a mean where this was not constant) with the one obtained on the spectrophotometer.

### *Estimated absorbance values*

The measured emission intensities for the LEDs (for 5 nm intervals from 400 to 600 nm) were corrected for the wavelength dependent sensitivity of the silicon photodiode detector. The sensitivity was taken as 0.327 at 400 nm and to be linearly increasing to 1 at 600 nm.[24] The resulting values were scaled to a peak intensity of unity. Absorbance spectra for the dye representing the different measured concentrations were obtained by scaling (again at intervals of 5 nm from 400 to 600 nm) against the spectrophotometer values for the wavelength of highest absorptivity. The individual values were then transformed into transmittance. A numerical estimate of the light intensities for the different wavelengths measured by the detector was obtained by multiplying the intensity with the transmittance values, since $T = I/I_0$ and $I = T \cdot I_0$, where $T$ is the transmittance, $I_0$ the original intensity (emission intensities of the LED) and $I$ the intensity after passage through the cell. Adding the result for all wavelength intervals gave an estimate for the total intensity over the entire wavelength range. By comparing the total for the different concentrations with the total initial intensity (sum of the values for the LED emission spectrum) an estimate for the integrated overall transmittances was obtained. These values was then transformed back into absorbance according to $A = -\log T$.

### *Solutions*

For the Al determination by the Chrome Azurol S method standards were prepared with an appropriate amount of a stock solution of $KAl(SO_4)_2$, 4 ml of 1% ascorbic acid, 10 ml of 0.1% Chrome Azurol S solution, 4 ml of 20% sodium citrate and this was diluted to 100 ml.[25] The standard solutions for the Cu determination by the Cuprizone method were made up with an appropriate amount of a stock solution of $CuSO_4$, 5 ml of buffer (pH 8–9, 10% citric acid, pH adjusted with ammonia), 12 ml of 0.1% Cuprizone solution and this was diluted to 100 ml.[25] For the $NH_3$ determination by the Indophenol method, standard solutions were prepared from an appropriate amount of a stock solution of $NH_4Cl$, 10 ml of sodium phenolate (70 g of phenol in 15 ml of ethanol plus 20 ml acetone this was diluted with ethanol to 100 ml, then 10 ml of this solution was mixed with 10 ml of 30% aqueous NaOH and diluted with water to 50 ml), 4 ml of 2% sodium hypochlorite and this was diluted to 100 ml.[25] The standard solutions for the Cu determination by complexation with ethylenediaminetetraacetic acid (EDTA) were made up with an appropriate amount of a stock solution of $CuSO_4$, 5 ml of ammonia, 2 ml of 0.05*M* EDTA

and diluted to 100 ml.[26] The standard solution for the Ca determination were made up from an appropriate amount of a stock solution prepared from $CaCO_3$, 10 ml of 0.03% Chlorophosphonazo III, 4 ml of buffer solution (pH 7.5, 50 ml of 0.1*M* $KH_2PO_4$ and 41 ml of 0.1*M* NaOH diluted to 100 ml) and dilution to 100 ml.[25] The standard solutions for the chromium calibration curves were prepared from an appropriate amount of a stock solution of potassium dichromate mixed with 20 ml of $H_2SO_4$ (1:3) and diluted to 100 ml.[25] For the nitrite determination by a modified Griess method, the standards were prepared from an appropriate amount of a stock solution of $NaNO_2$, 2 ml of 0.5% sulphanilamide in 20% (v/v) HCl, 2 ml of 0.3% *N*-(1-naphthyl)-ethylenediamine dihydrochloride in 1% (v/v) HCl and dilution to 100 ml.[27] The standards for phosphate determination were made up with an appropriate amount of a stock solution of $KH_2PO_4$, 10 ml of molybdate ascorbic reagent (10 ml of 1% ammonium molybdate in 0.5*M* nitric acid and 10 ml of 0.7% ascorbic acid diluted to 100 ml) and diluted to 100 ml.[28]

## RESULTS AND DISCUSSION

### *Construction*

The circuit diagram for the multi-LED photometer is shown in Fig. 1. One out of a range of up to seven LEDs is selected with a rotary switch. The LEDs are connected to 1 mm plastic optical fibres leading to the coupler. The 7 × 2-plastic fibre star coupler which is based on the same type of 1 mm plastic fibres is used to merge the light from the seven input channels into two output fibres. One of these is brought to the measuring cell. The cell consists of a black perspex body into which the fibre is inserted and has a 1 cm pathlength and a cell volume of 8 $\mu$l. Details have been given elsewhere.[20] It would of course also be possible to pass the light through a conventional cuvette rather than employing the cell used here. The other fibre leads to the reference photodiode. The amplifier is wired in a log-ratio configuration which emulates absorbance measurements according to $V_o = \log(i_{ref}/i)$, where $V_o$ is the output voltage and $i_{ref}$ and $i$ are the currents from the reference and signal photodiodes, respectively.[29] The arrangement corresponds therefore to a double beam configuration and corrects for drifts in emission intensity of single LEDs and differences in intensity for the individual LEDs. The photocurrents resulting were found to be between about 5 and 18 nA for the green to infrared LEDs. Blue LEDs are presently only available with low intensities and a value of 410 pA was determined for the blue LED used here. This difference in currents for the different LEDs is within the dynamic range of the log-ratio amplifier and does not pose a problem.[29] The output voltage is brought to a digital panel meter for direct display of the measured absorbance. A metal box with dimensions of 20 × 6 × 15 cm (width × height × depth) is used to house the complete circuitry. The measuring

cell is mounted on the outside of the case for separation of the wet chemistry from the electrical part.

*Spectral considerations*

The emission spectra of the LEDs used for the photometer are given in Fig. 2. Note, that the intensities have been scaled. Incidentally, the spectral window almost exactly covers the visible range of the electromagnetic spectrum (380–780 nm).

The centre range from about 560–660 nm is covered by the widely used LEDs with colours from green to red. A large variety of types with different peak wavelengths, intensities and bodies are available for this range. The particular devices chosen here were picked in order to give a good distribution of peak wavelengths at 563, 590, 620 and 660 nm. The bandwidths for these LEDs are in the order of 20–25 nm (full width at half maximum).

For the longer wavelength range between about 700 and 800 nm few LEDs are available which is the reason for the gap at around 730 nm. Note, that the near-infrared LED with a maximum at 770 nm was combined with an optical filter (Kodak Wratten 87) in order to eliminate low emission intensities which were found at shorter Wavelength for this device.

The wavelength range below 550 nm is covered by blue LEDs. These have only recently become readily available and show an emission band of typically 70 nm bandwidth. This is relatively wide compared to the LED spectra of other colours, as illustrated by the dashed line in Fig. 2. The peak wavelengths of the available types are all between 450 and 480 nm and, therefore, there is also a lack of flexibility in the visible region below 550 nm. To alleviate this situation it was chosen to combine blue LEDs with optical filters. By combination with a long wavelength cut-off filter with appropriate properties (Kodak Wratten 32) it was found possible to obtain a band with a peak at 461 nm (first spectrum from the left in Fig. 2) which is close to the peak of the unfiltered emission, but shows a bandwidth of only 38 nm as compared to the 70 nm of the unfiltered band. The combination with a short wavelength cut-off filter (Kodak Wratten 58) yielded a band at 513 nm with a bandwidth of 40 nm (second spectrum in Fig. 2). These bandwidths do not quite match the values obtained with the conventional LEDs but are a considerable improvement to the unfiltered emission band. The wavelength filters cause a reduction of the photocurrent on the detector from the 410 pA for the unfiltered blue LED to 180 and 80 pA for the shorter and the longer wavelength bands, respectively.

*Performance*

The system was tested with several photometric procedures. The calibration curves obtained with the LEDs in the centre range (560–660 nm) are given in Figs 3–7. Generally the LEDs that gave the highest sensitivity were employed and for comparison conventional measurements with a spectrophotometer using the wavelength of peak absorbance were also carried out. As the pathlength is 1 cm in both cases, it is possible to directly compare the results obtained with the two methods.

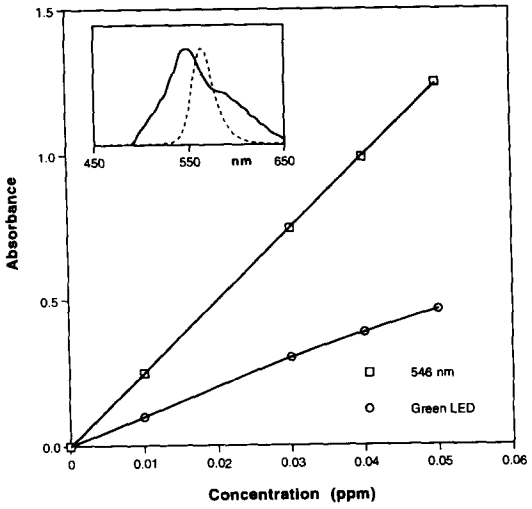

Fig. 3. Calibration curves for the determination of aluminium by the chrome azurol S method obtained for the wavelength of highest sensitivity on a spectrophotometer and for the LED-photometer. The inset shows the absorbance spectrum of the complex (solid line) and the emission band from the LED (dashed line).

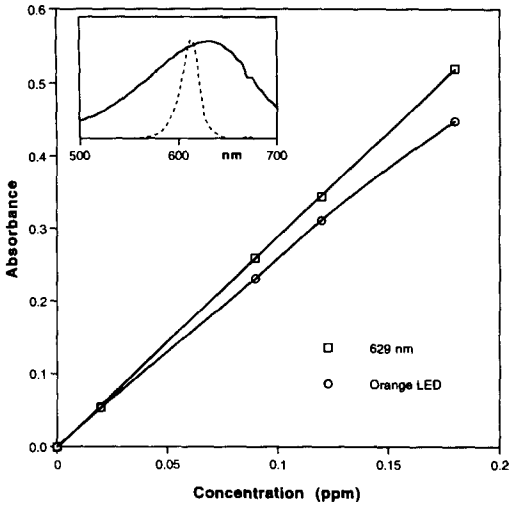

Fig. 5. Calibration curves for the determination of ammonia by the indophenol method.

The calibration curve obtained for the determination of aluminium by the chrome azurol S method is given in Fig. 3. A considerable loss of sensitivity (60%) is observed as it is not possible to match the absorbance peak at 546 nm (see inset of Fig. 3) with an LED having an emission band closer than the one of the green emitter (peak at 563 nm, dashed line inset of Fig. 3). A much closer match of the calibration curves was found for the determination of copper ions by the cuprizone method, see Fig. 4, where the sensitivity of the LED calibration curve is 90% of the spectrophotometer value. This is not surprising since the emission band of the yellow LED comes close to the peak of the wide absorbance band of the complex as illustrated in the inset of Fig. 4. The situation is very similar for the ammonia determination by the indophenol method using an orange LED as illustrated in Fig. 5. Not quite such a good match was possible for the copper determination by measuring the absorbance of its complex with ethylenediaminetetraacetic acid (EDTA), see Fig. 6, were the red LED shows a relative sensitivity of 75%. The match is poorer again for the calcium complex with chlorophosphonazo III using the same LED leading to a 40% loss of sensitivity as shown in Fig. 7.

The red wavelength region between 660 and 770 nm is perhaps not often used and the lack

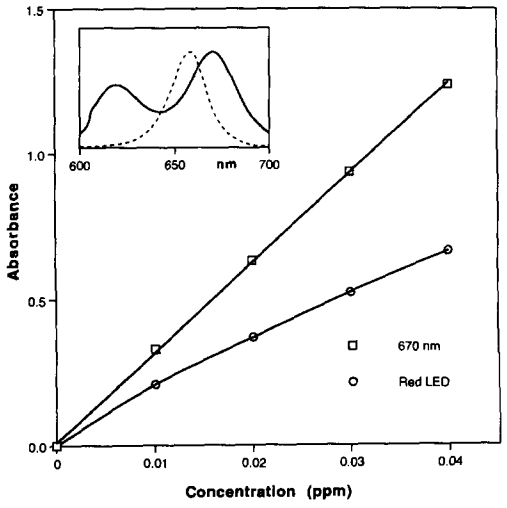

Fig. 7. Calibration curves for the determination of calcium by the chlorophosphonazo III method.

of LEDs with different colours for this range is not a major hindrance. A common analytical procedure employing this wavelength region, however, is the molybdate method for phosphate. As illustrated in Fig. 8, excellent results can be obtained by using the near-infrared LED with a peak-wavelength at 770 nm.

As was reported previously, the light from a blue LED may be used for the determination of absorbing species with peaks in the region of 450–510 nm.[20] It is demonstrated here that the sensitivity with this LED can be improved in certain cases by combination with inexpensive optical filters. The calibration curves for dichromate with a peak absorbance at the low edge of the emission from the blue LED (442 nm) are given in Fig. 9. An improvement of the relative

Calibration curves of the determination of chromium by the dichromate method obtained for the wavelength of highest sensitivity on a spectrophotometer and for the LED-photometer using the blue LED with and without long wavelength cut-off filter. The inset shows the absorbance spectrum for dichromate (solid line) and the emission bands for the blue LED with and without filter (dashed lines).

sensitivity compared to the spectrophotometer from 40 to 60% was found for this system on introducing the optical filter. More pronounced is the effect for the determination of nitrite by a modified Griess method as illustrated in Fig. 10. The dye has an absorbance peak at 535 nm which falls into the relatively wide gap in

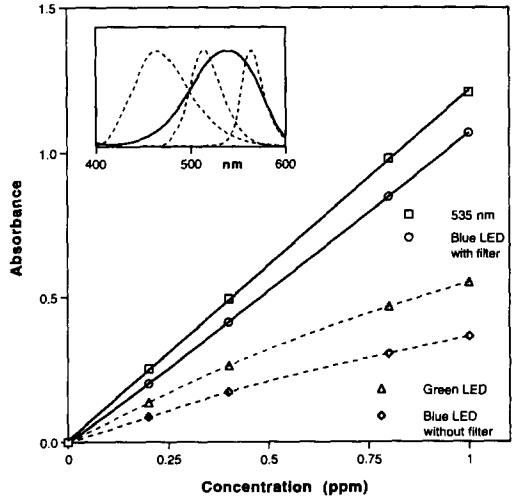

Fig. 10. Calibration curves for the determination of nitrite by the modified Griess method obtained for the wavelength of highest sensitivity on a spectrophotometer and for the LED-photometer using the blue LED with and without short wavelength cut-off filter and the green LED. The inset shows the absorbance spectrum for the dye (solid line) and the emission bands for the blue LED with and without filter and the green LED (dashed lines from left to right, respectively).

emission between the unfiltered blue and the green LEDs as seen in the inset of Fig. 10. Both the blue and the green LEDs led to a sensitivity of less than 50% of the result of the monochromatic wavelength of 535 nm. The use of the optical filter which eliminates low wavelengths from the blue LED emission led to a sensitivity of 90% of the spectrophotometer result for this important photometric procedure.

The relative sensitivity cannot be anticipated from the closeness of the peaks of absorbance and emission bands alone. This for example would predict a lower sensitivity for the copper determination by complexation with EDTA (Fig. 6, $\Delta\lambda = 75$ nm) than for the calcium determination with the chlorophosphonazo III method (Fig. 7, $\Delta\lambda = 10$ nm) when in fact the opposite is observed. Similarly, by considering the spectral match for the nitrite determination (Fig. 10) it is not apparent why the blue LED with filter should give a curve of higher sensitivity than the green LED. It is however possible to fairly closely predict the experimental calibration curves by numerically integrating Lambert–Beer's law over the entire spectra of LEDs and dyes as well as considering the variation of the detector sensitivity with wavelength. When applying this procedure (see Experimental Section) to the data for Fig. 10 a good prediction for the three different LED calibration curves was obtained as is illustrated in Fig. 11. The curvature obtained with some of the LED calibration graphs is also predicted and it can be shown that this is due to the fact that the absorptivities are not constant across the spectral emission bands for the LEDs. The loss of sensitivity of the silicon photodiode detector towards the short wavelength range has the effect of causing a slight apparent skewing of the LED emission spectra towards the high wavelength side of the bands.

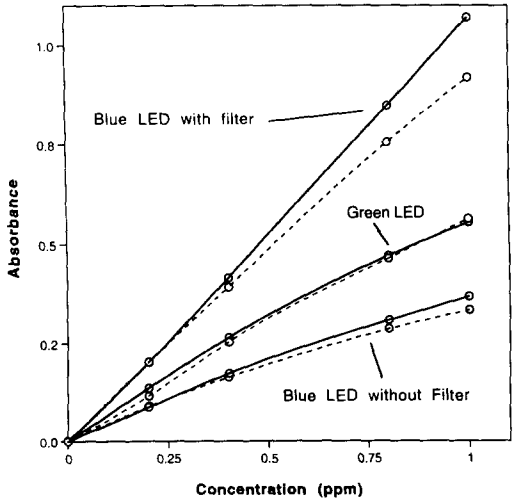

Fig. 11. Calibration curves for the nitrite determination as predicted theoretically from the spectra of the dye and the LEDs (dashed lines) in comparison with the experimental data (solid lines).

The precision obtained with the LEDs was generally 0.002 absorbance units or better (standard deviation, $n = 5$) which is close to the resolution of the instrument (0.001 absorbance units) and comparable with the spectrophotometer results. The relative error in terms of concentration depends on the slope of the calibration curve and varies between about 0.2% in the best case and about 5% for the worst case reported here. Whether the loss of sensitivity encountered with the LEDs is significant depends therefore on the desired relative precision in terms of concentration but should not be a concern in most cases.

## CONCLUSION

It was found that by combining different LEDs covering a wide wavelength range a versatile, inexpensive, compact and portable photometer for absorbance measurements in the visible wavelength range can be obtained. The instrument may also be used in the field as it can be powered by a battery. The lack of strict adherence to Lambert–Beer's law in terms of non-linearity of many of the calibration curves is not a limitation provided the user is aware of this fact and the calibration is carried out appropriately.

*Acknowledgements*—The authors thank Dean Clark from Siemens Wellington for providing samples of some of the optoelectronic components used. Grants from the University of Auckland Research Committee and New Zealand Lottery Science are gratefully acknowledged.

# COMPARISON OF CALIBRATION METHODS IN QUANTITATIVE DIFFUSE REFLECTANCE INFRARED SPECTROSCOPY

Z. KRIVÁCSY[1] and J. HLAVAY[2]*

[1]Hungarian Academy of Sciences, Research Group of Analytical Chemistry, University of Veszprém, H-8201 Veszprém P.O. Box 158., Hungary

(*Received* 1 *August* 1994. *Revised* 28 *October* 1994. *Accepted* 28 *October* 1994)

**Summary**—Four different calibration methods were used for quantitative analysis of quartz and calcite in atmospheric aerosols by diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS): (A) conventional calibration with one measurement on each standard (single calibration); (B) calibration with an internal standard; (C) calibration with parallel ($n = 4$) measurements on each standard (multiple calibration); (D) multiple calibration followed by reference reflectance correction. The accuracy and the precision of the methods were compared and it was found that by using method D the reliability of the conventional pellet preparation transmission technique can be achieved.

Recently, the number of the quantitative applications of diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS) has been increased. This is owing to the simplicity, speed and the unique potential of the method compared to the time-consuming conventional pellet preparation technique. In DRIFTS, the sample preparation is usually simple, the sample can be investigated in its original physical-chemical state providing the opportunity for *in situ* investigations. Nevertheless, the precision of DRIFTS is usually less that of the transmission IR spectroscopy.

The relationship between the reflectance ($R_\infty$) and the absorbing and scattering properties of the sample can be obtained by the solution of the radiation transfer equation.[1] One of the solutions used most often in DRIFTS is called the Kubelka–Munk (K-M) function ($f(R_\infty)$):

$$f(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{k}{s} = \frac{2.303a}{s} \cdot c, \quad (1)$$

where $k$ is the absorption, $s$ is the scattering coefficient of the sample, $a$ and $c$ are the absorptivity and the concentration of the analyte, respectively. The K-M function is linear with the concentration of the analyte if the scattering coefficient is kept constant.

Reinecke *et al.*[2] studied dioctyl phthalate quantitatively as follows. They filled the sample cup with KBr and deposited the analyte on the surface of the KBr from tetrahydrofuran solutions of different concentrations. The quantification of the measurements was based on the K-M function, however, the experimentally obtained K-M function was modified with the absolute reflectance of the reference material. This modification should be performed since the reflectance of the sample ($R_{\infty,s}$) can only be measured against the reflectance of the reference ($R_{\infty,r}$):

$$R_{\infty,\text{exp}} = \frac{R_{\infty,s}}{R_{\infty,r}}, \quad (2)$$

where $R_{\infty,\text{exp}}$ is the experimentally observed reflectance. Kortüm[1] has already pointed out that in the lack of an ideal reference material with $R_{\infty,r} = 1$, the exact value of $R_{\infty,r}$ has to be known to calculate the true value of the K-M function. Reinecke *et al.* developed a method to determine the value of $R_{\infty,r}$ from experimental data. It was found that by this modification the intercept of the calibration curve changed from the unreliable negative value to a positive one close to zero and the linear regression coefficient ($r$) increased from 0.9980 to 0.9992 indicating the improvement in accuracy and the precision of the method.

*Author to whom correspondence should be addressed.

Another possibility to improve the precision of an analytical method is to use an internal standard. Wiberley *et al.*[3] applied potassium thiocyanate (KSCN) in transmission IR technique for quantitative determination of copolymers and free fatty acids. In DRIFTS, the quantitative determination of (3-aminopropyl)triethoxysilane on silica gel surface was carried out using the 1870 $cm^{-1}$ Si-O combination band of the support as a reference absorption band, and $r = 0.9980$ was obtained with linear calibration.[4] Similarly, a normalization against glass absorption bands was made by McKenzie and Koenig[5] for surface analysis of coatings on standard E-glass.

Nevertheless, to obtain reliable quantitative results in DRIFTS is not an easy task. In this work (i) different calibration methods were applied for the quantitative analysis of inorganic crystalline compounds, and (ii) the accuracy and the precision, *i.e.* the reliability of the methods were compared by study of standard samples and environmental aerosols.

## EXPERIMENTAL

### *Materials and sample preparation*

Standard quartz and calcite (Department of Mineralogy, University of Veszprém) and spectroscopic grade KBr (Merck) were used to prepare the calibration mixtures. The concentration of the mixtures ranged between 0.023 and 1 w/w%. The mixtures in the 0.023–0.2 w/w% range and in the 0.2–1 w/w% range were prepared from 1 w/w% and 5 w/w% stock mixtures, respectively. The particle size for quartz and calcite was $<3$ $\mu$m and $<6$ $\mu$m, respectively. The particle size distribution of KBr was determined by Jeol JSM-50A (Japan) scanning electron microscope and was found as $d < 10$ $\mu$m. The aerosol samples were collected in a one-month period at different places in Veszprém county. First, the samples were mechanically removed from the filter, then alcoholic treatment was performed to separate the aggregates and to reduce the particle size. After evaporation of the alcohol the samples were mixed with KBr. For DRIFTS measurements 1 w/w% mixtures of the original samples were prepared. The sample cups in DRIFTS were filled by applying 1 MPa pressure for 1 min using home-made sample filling accessories.[6] The mass of the sample and the depth of the cup were $70 \pm 1.5$ mg and 2 mm, respectively. For the IR transmission measurements, pellets containing 2–3 mg sample and 797–798 mg KBr were prepared.

### *Infrared measurements*

The spectra were recorded by a Digilab FTS 45 and a Digilab FT 60A Fourier transform spectrometer (U.S.A.) with a DTGS detector. A resolution of 4 $cm^{-1}$ was used and 64 scans averaged. The diffuse reflectance spectra were transformed to K-M units. Intensities of the 799 $cm^{-1}$ and 780 $cm^{-1}$ ($\nu_s$ Si-O—Si) and 695 $cm^{-1}$ (deformation) bands of quartz and the 876 $cm^{-1}$ ($\gamma$ $CO_3^{2-}$) as well as 713 $cm^{-1}$ ($\beta$ $CO_3^{2-}$) bands of calcite were determined after a two-point baseline correction. The concentrations of quartz and calcite in the aerosols were calculated from the concentrations of those in the measured 1 w/w% mixtures.

### *Calibration methods*

The calibration curves were prepared by four different methods as follows.

*Method A, single calibration.* One measurement was carried out on each standard sample and the values of the K-M function of the absorption bands were determined.

*Method B, application of an internal standard.* One measurement was done on each standard sample containing 0.2 w/w% $K_2SO_4$ as an internal standard. The K-M values of the absorption bands were normalized against the K-M value of the 621 $cm^{-1}$ $\delta SO_4^{2-}$ absorption band.

*Method C, multiple calibration.* Parallel measurements ($n = 4$) were carried out on each standard sample. The sample cups were reloaded between the parallel measurements. The average value of the K-M functions of the absorption bands was calculated and used as the calibration point at each standard concentration.

*Method D, multiple calibration and reference reflectance correction.* The first step of this calibration was the multiple calibration (method C), then the real value of $R_{\infty,r}$ was determined from the experimental results according to the method of Reinecke *et al.*,[2] and the experimentally measured K-M functions were modified by the calculated value of $R_{\infty,r}$.

## RESULTS AND DISCUSSION

### *Reliability of the methods*

For the investigation of the reliability of the methods, first calibration curves for the different absorption bands of quartz and calcite were

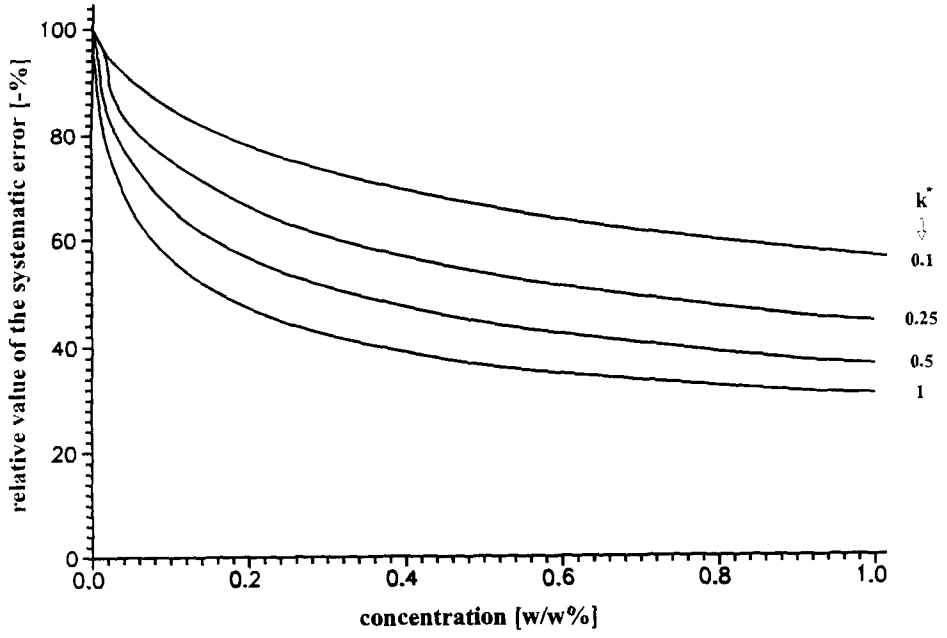

Fig. 1. Theoretical curves for the relative value of the systematic error as a function of the sample concentration for different values of $k^*$ ($R_{\infty,r} = 0.8$).

prepared. It was observed that using the methods A, B, and C for calibration the intercepts of the calibration curves were relatively large negative values in all cases. This is in accordance with the observation of Reinecke *et al.*[2] The negative values for the intercept cannot be explained by the K-M theory. The deviation has been found so large in some cases that the calibration curves have crossed the $x$-axis at the $c = 0.06$–$0.08$ w/w% range. In this case, by the calibration curve, the value of the calibration points at the lowest concentrations should have a negative number. For example, in case of the 799 $cm^{-1}$ band of quartz at $c = 0.023$ w/w% the measured value of the K-M function with method A was 0.0023, however, calculated from the calibration curve it should have been $-0.0112$. This considerable and always negative

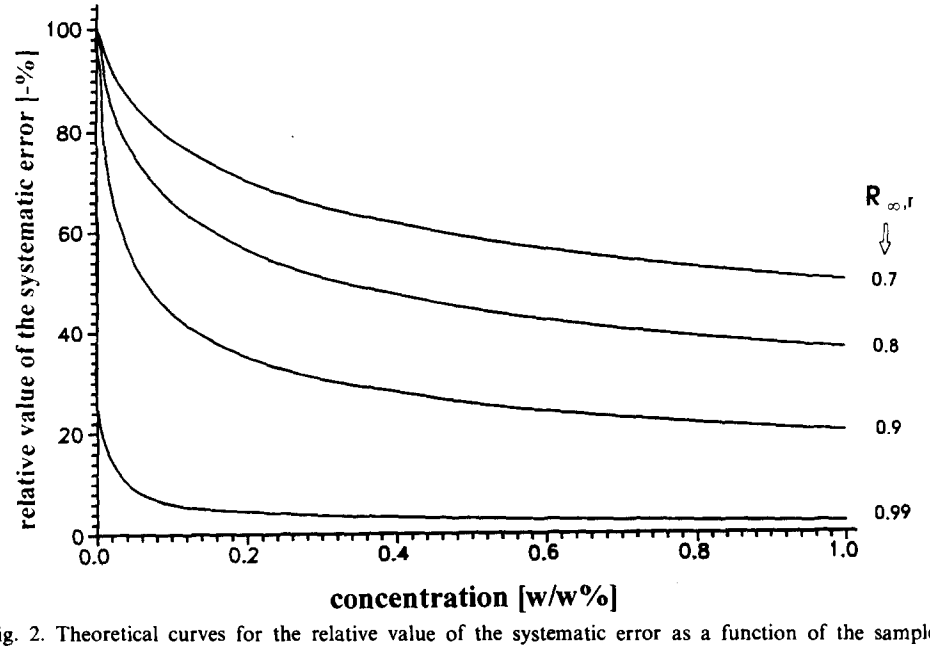

Fig. 2. Theoretical curves for the relative value of the systematic error as a function of the sample concentration for different values of $R_{\infty,r}$ ($k^* = 0.5$).

Table 1. Values of $k^*$ and $R_{\infty,r}$ for the different absorption bands of quartz and calcite

| | Absorption bands of quartz | | | Absorption bands of calcite | |
|---|---|---|---|---|---|
| | 799 $cm^{-1}$ | 780 $cm^{-1}$ | 695 $cm^{-1}$ | 876 $cm^{-1}$ | 713 $cm^{-1}$ |
| $k^*$ | 0.472 | 0.353 | 0.148 | 0.444 | 0.218 |
| $R_{\infty,r}$ | 0.825 | 0.818 | 0.752 | 0.878 | 0.853 |

bias presumably means that the analytical method is distorted by a systematic error.

The systematic error is presumed to exist owing to the incorrect determination of the K-M function assuming $R_{\infty,r} = 1$. In order to study the effect of this type of error on the quantitative analysis theoretical calculations were performed.

The relative value of the systematic error of the K-M function ($\Delta_r$) caused by the absence of the exact value of $R_{\infty,r}$, can be written as

$$\Delta_r = \frac{f(R_\infty)_{exp} - f(R_\infty)_{mod}}{f(R_\infty)_{mod}}, \quad (3)$$

where $f(R_\infty)_{mod}$ is the modified K-M function with $R_\infty = R_{\infty,r}{}^* R_{\infty,exp}$ and $f(R_\infty)_{exp}$ is the experimentally measured K-M function with $R_\infty = R_{\infty,exp}$. If the K-M functions in equation (3) are replaced according to equation (1), the following expression is obtained:

$$\Delta_r = -(1 - R_{\infty,r}) \frac{1 - R_{\infty,r} R^2_{\infty,exp}}{(1 - R_{\infty,r} R_{\infty,exp})^2}. \quad (4)$$

It can be seen from equation (4) that $\Delta_r$ is determined both by $R_{\infty,r}$ and $R_{\infty,exp}$. The sign of $\Delta_r$ is always negative, but if $R_{\infty,r} = 1$, the systematic error is zero. Furthermore, if $R_{\infty,exp} \to 0$ (total absorption) then $\Delta_r \to 1 - R_{\infty,r}$ and if $R_{\infty,exp} \to 1 (c \to 0)$ then $\Delta_r \to -1$ or $-100\%$.

Based on equation (4) theoretical functions between $\Delta_r$ and the sample concentration were also determined for the condition of $c \leqslant 1$ m/m%, where the K-M function is linear with the concentration and $f(R_\infty)_{exp} = k^* . c$. In this case, along with the sample concentration, the value of the systematic error is determined by $R_{\infty,r}$ and $k^*$ (the sensitivity of the analytical method). Theoretical curves for the concentration dependence of $\Delta_r$ at different values of $k^*$ ($R_{\infty,r} = 0.8$) and at different values of $R_{\infty,r}$ ($k^* = 0.5$) are plotted in Figs 1 and 2, respectively. It can be seen that in the 1 w/w% $\geqslant c \geqslant$ 0.2 w/w% range the value of the relative systematic error is only slightly increasing, but in the 0.2 w/w% $> c >$ 0 w/w% range the increase of the error is rather sharp.

After the theoretical calculations, experimental values of $\Delta_r$ as a function of the sample concentration for the different absorption bands of quartz and calcite were determined. The curves for quartz and calcite obtained from the results of method C ($f(R_\infty)_{exp}$) and method D ($f(R_\infty)_{mod}$) are plotted in Fig. 3A, B, respectively. Based upon the shape of the curves it can be concluded that the experimental curves are similar to that of the theoretical ones. The magnitude of $\Delta_r$ was also changed by the theoretical calculations and was increased both by decreasing $R_{\infty,r}$ and $k^*$. The values of $R_{\infty,r}$ and $k^*$ determined from the experimental results of method C are summarized in Table 1. Since $R_{\infty,r}$ is considerably $< 1$ ($R_{\infty,r} = 0.752$–$0.878$) the $-100\%$ limit for the values of $\Delta_r$ is approached if $c = 0.023$ w/w%.

The presence of the systematic error using method A, B, or C was also proved both by the investigation of standard samples and environmental aerosols. The standard samples containing quartz and calcite in known concentration were used to validate the analytical methods. The results for aerosols were compared to those of obtained by the pellet preparation transmission IR technique used as a reference method.

Based on the results of the validation, the relative error of the quantitative determination ($\Delta_c$) was calculated as

Table 2. Relative error and its mean value for the determination of quartz and calcite in standard samples in the different DRIFTS methods

| | Concentration of the analyte [w/w%] | | | Absolute value of the mean error |
|---|---|---|---|---|
| | 1–0.2 | 0.2–0.075 | <0.075 | |
| Method A | −5%–+5% | −10%–+10% | +20%–+222% | 31% |
| Method B | −5%–+5% | −5%–+5% | −20%–+25% | 9% |
| Method C | −4%–+3% | −14%–+9% | +23%–+143% | 21% |
| Method D | −3%–+3% | −5%–+3% | −10%–+3% | 3% |

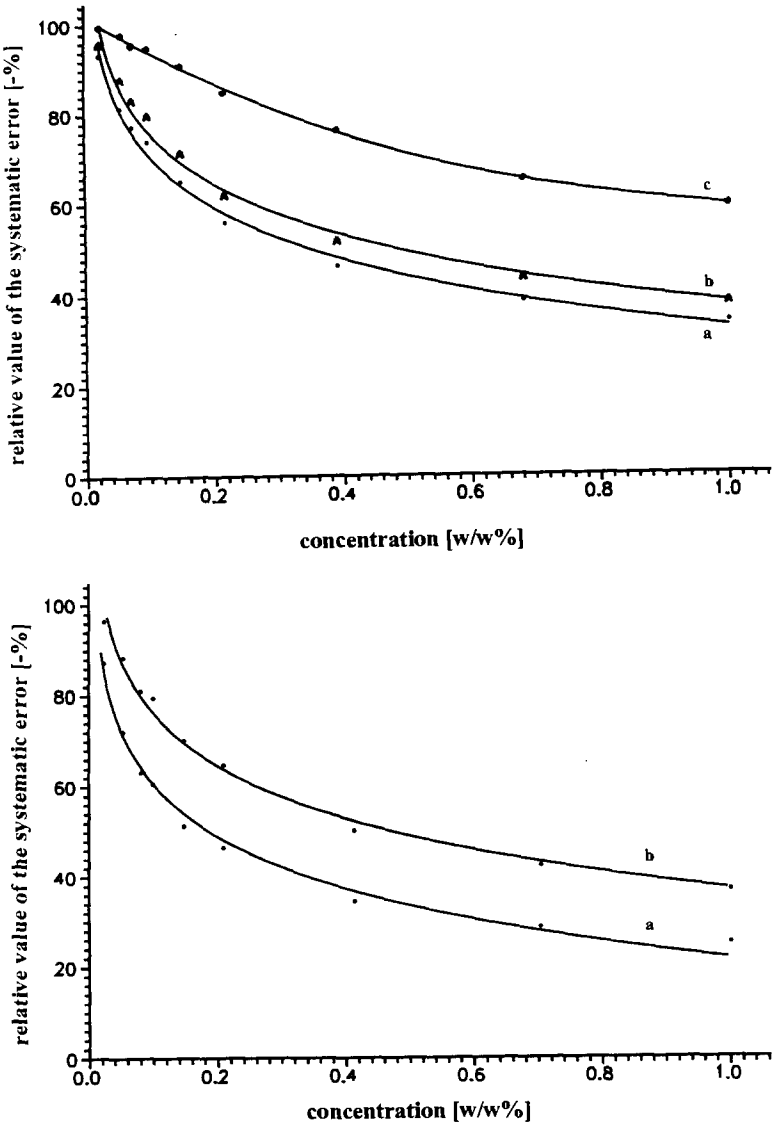

Fig. 3. (A) Experimental curves for the relative vaues of the systematic error ($\Delta_r$) as a function of the sample concentration for the bands of quartz obtained from the results of methods C and D. Absorption bands: (a) 799 $cm^{-1}$, (b) 780 $cm^{-1}$, (c) 695 $cm^{-1}$. (B) Experimental curves for the relative values of the systematic error ($\Delta_r$) as a function of the sample concentration for the bands of calcite obtained from the results of methods C and D. Absorption bands: (a) 876 $cm^{-1}$, (b) 713 $cm^{-1}$.

$$\Delta_c = \frac{c_{meas} - c_{true}}{c_{true}}, \qquad (5)$$

where $c_{meas}$ and $c_{true}$ are the measured and the true concentrations, respectively.

The data for $\Delta_c$ are listed in Table 2. It can be seen that the magnitude of the error is strongly influenced by the sample concentration and the results can be separated into three groups. In the 1 w/w% $\geq c \geq$ 0.2 w/w% range $\Delta_c$ is small independently of the analytical method used which means that in this region the systematic error is still negligible. If 0.2 w/w% $> c \geq$ 0.075 w/w% the errors for method A or C are two to five times higher than those for method B or D. If $c <$ 0.075 w/w% the systematic error can be extremely high resulting even in 150–200% deviation from $c_{true}$. The deviation in this concentration range is positive in all cases in accordance with the negative bias in the calculation of the K-M function. However, in case of the method B, $\Delta_c$ is relatively small having both positive and negative values even if $c <$ 0.075 w/w%. This means that the application of an internal standard partially compensates the effect of the systematic error. The best results were obtained by method D where $-5\% < \Delta_c < 5\%$ was obtained in most cases in the entire concentration range and the average

Table 3A. Concentration of quartz in aerosol samples determined by the different methods of DRIFTS and pellet preparation technique for the 799 $cm^{-1}$ absorption band (w/w%)

| Sample | Method A | Method B | Method C | Method D | Pellet technique |
|---|---|---|---|---|---|
| 1 | 15.0 ± 3.0 | 14.6 ± 1.5 | 15.2 ± 2.0 | 14.6 ± 1.0 | 14.0 ± 1.1 |
| 2 | 12.6 ± 3.0 | 12.4 ± 1.5 | 13.4 ± 2.0 | 11.8 ± 1.0 | 9.5 ± 0.5 |
| 3 | 12.4 ± 2.6 | 12.9 ± 1.3 | 12.1 ± 1.8 | 10.7 ± 0.9 | 10.9 ± 0.6 |
| 4 | 10.1 ± 3.1 | 7.3 ± 1.5 | 10.6 ± 2.0 | 7.3 ± 0.9 | 7.0 ± 0.7 |
| 5 | 9.2 ± 2.7 | 6.3 ± 1.4 | 9.5 ± 1.8 | 6.5 ± 0.9 | 5.0 ± 0.7 |

absolute value of the relative error was found to be 3%.

Based on the results it can be concluded that in cases of the method A, B and C the analysis is influenced by a nonlinear systematic error that is mainly caused by the inadequate calculation of the K-M function assuming $R_{\infty,r} = 1$. However, if the exact value of $R_{\infty,r}$ is determined and the modified value of the K-M function is calculated (method D), the systematic error of the determination can be omitted and the average relative error of the analytical method is ±3%.

The four DRIFTS methods and as a reference, the transmission IR technique were used for the determination of quartz and calcite of aerosol samples and the results are summarized in Table 3A and B, respectively. The effect of the systematic error on the results can most evidently be seen when the quartz concentration has been determined by method A or C and the concentration of quartz has been relatively low (Table 3A, samples 4 and 5). In these cases the measured mean values for quartz concentrations are significantly higher because of the significant systematic error compared to that of either method D or the pellet technique. However, the values obtained for calcite are in a good agreement independently of the method used. This is owing to the relatively high calcite concentration of the samples, when the effect of the systematic error on the analytical result using method A or C is within the magnitude of the random error.

The confidence interval was also calculated as an additional parameter to describe the reliability of the whole analytical procedure. For method D, the magnitude of the confidence limits were found to be three to six times smaller than those for the other DRIFTS methods and about the same compared to the conventional IR transmission technique. This indicates that the reliability of the two different techniques is comparable.

After these general observations the particular features of the modified calibration procedures are discussed in more detail.

*Application of an internal standard*

Potassium sulphate was selected as an internal standard because of its similar refractive index to KBr and relatively simple IR spectrum. The deformation band of $SO_4^{2-}$ at 621 $cm^{-1}$ has been chosen as the reference one because this band is of a well-defined shape and relatively intense absorbance and it does not interfere with the absorption bands of the investigated compounds (Fig. 4). The utility of the internal standard was tested first by carrying out parallel measurements ($n = 5$) on the samples containing 0.5 w/w% analyte and 0.2 w/w% $K_2SO_4$. The RSD of the intensity of the selected absorption bands was decreased from ±4.2% to ±1.5% and from ±3.7% to ±1.3% for quartz and calcite, respectively, proving the effect of the internal standard on the increase of measurement repeatability. However, the application of the internal standard has some disadvantages. One of these is the increase of the detection limit of the method, since the total concentration of the sample for the absorbing substances should not exceed 1 w/w%. Furthermore, the sample must be free of sulphate or other compounds absorbing at the wavelength domain of the reference band. The presence of sulphate or spectral interferences should usually

be checked by preliminary investigation of the sample.

*Multiple calibration*

The performance of parallel measurements on the same sample and averaging the spectra in order to obtain more reliable results is a well-known procedure in DRIFTS. However, the aim of this procedure has been primarily to compensate for the failure of inadequate sample preparation, *e.g.* the irreproducibility of the sample packing. Furthermore, it should be realized that the requirements for a multiple calibration to improve the precision of quantitative DRIFTS also comes from the mathematical behaviour of the relative error of the K-M function. A mathematical model was developed for the concentration dependence of the relative error of DRIFTS measurements and the following equation was obtained:[7]

$$\frac{df(R_\infty)}{f(R_\infty)} = \sqrt{1 + \frac{2}{k^* c}} \cdot \frac{dR_{\infty,s}}{R_{\infty,s}}. \qquad (6)$$

From equation (6) one can see that if both the sample concentration and the sensitivity of the method are small (*e.g.* $c \leqslant 0.1$ w/w% and $k^* < 0.2$), the relative error for a single measurement can be $> \pm 10\%$ even if the sample preparation is appropriately reproducible ($dR_{\infty,s}/R_{\infty,s} = \pm 1\%$). This is a theoretical explanation for the high relative error of a single measurement and the necessity of spectral averaging to determine the reliable position of the calibration points. On the other hand, the disadvantage of the multiple calibration is the time consuming procedure compared to the single calibration methods.

## CONCLUSION

DRIFTS can appropriately be used for quantitative determination of quartz and calcite in aerosol samples diluted in a nonabsorbing matrix. However, keeping the experimental parameters (*e.g.* particle size, packing density, 1 w/w% sample concentration, KBr matrix) constant, accurate and precise quantitative analysis, especially in low analyte concentration range, can only be performed if multiple calibration and subsequently reference reflectance correction is carried out. In this case the reliability of the pellet preparation technique can be achieved.

# APPLICATION OF POTENTIOMETRIC STRIPPING ANALYSIS FOR SPECIATION OF COPPER COMPLEXES WITH A NON-ADSORBABLE LIGAND ON A MERCURY ELECTRODE

HELENA M. V. M. SOARES* and M. TERESA S. D. VASCONCELOS†
LAQUIPAI, Chemistry Department, Faculty of Science, P4000 Porto, Portugal

(*Received* 1 *August* 1994. *Revised* 28 *October* 1994. *Accepted* 28 *October* 1994)

**Summary**—Potentiometric stripping analysis (PSA) was used for determination of conditional stability constants ($\beta'$) of copper(II) complexes. Glycine was used as a model of a non-adsorbable ligand on the mercury electrode that forms well defined 1:1 and 1:2 copper(II)–glycine complexes, which are labile within the time scale of the analytical technique. The calculations were performed by the DeFord–Hume method, which was applied to the shifts in peak potential ($dt/dE$ *vs.* $E$) provoked by the presence of different concentration of the ligand in the metal solution. For comparison purposes, the study was also carried out by differential pulse anodic stripping voltammetry (DPASV). The results obtained by PSA both at pH 6.0, $\log \beta'_1 = 5.0 \pm 0.2$ and $\log \beta'_2 = 7.6 \pm 0.2$, and at pH 6.5, $\log \beta'_1 = 5.7 \pm 0.6$ and $\log \beta'_2 = 8.5 \pm 0.4$ (standard deviations are given), were in agreement with those obtained by DPASV and from the literature, which indicates that PSA is suitable for this type of study.

The main application of potentiometric stripping analysis (PSA) technique has been for determination of the total concentration of heavy metals in diverse types of samples.[1–4] Anodic stripping voltammetry (ASV) techniques have been frequently used for speciation studies, owing to their selectivity and high sensitivity.[5,6] However, the similarity between PSA and ASV suggests PSA may also be used for speciation purposes. The initial step of the analytical techniques is the same: the metal(s) as hydrated form or/and as labile complexes is (are) deposited on the working electrode at a controlled potential. However, instead of applying an anodic potential scan to strip the metal(s) as is used in ASV, in PSA a chemical oxidant from the solution is allowed to diffuse to the working electrode and to oxidize the amalgamated metal(s). In this case, the potential of the working electrode is followed as a function of the stripping time ($t$). The identity of the metal and/or the extension of its complexation (in the case of labile complexes) are given by the peak potential obtained from the curves: current = f[potential ($E$)], in ASV, and $dt/dE = f(E)$, in PSA. In standard solutions, each metal generates a peak whose height is proportional to the metal concentration. Therefore, it can be expected that both techniques give the same type of information. In addition, since redox couples[7] and surface-active substances[8] from the solution do not interfere to the same extent in PSA as they do in ASV methods, PSA may have advantages for studies involving metal speciation. On the other hand, in PSA, an oxidizing agent [mercury(II) in many cases] must be present in the solution, in large excess relatively to the analyte, during the stripping step. Therefore, if the solution also contains ligands and the characteristics of the signal depend on the stripping step, the oxidizing agent might interfere in the metal speciation. Thus, comparative studies of PSA and ASV suitabilities for heavy metal speciation,[9] particularly for determination of conditional stability constants of complexes in natural waters, deserve interest, but are hard to find in the literature.

These facts prompted us to investigate the suitability of PSA for determination of conditional stability constants of copper complexes with organic ligands. Copper was chosen because we are involved in projects whose purpose is the study of the influence of copper speciation on its toxicity for microalgae[10] and bacteria[11] in

synthetic culture media. Glycine, an amino acid that is not adsorbed at the mercury electrode, and humic acid, which is marked adsorbed, were selected as model ligands, because both can be considered decomposition products of living organisms in aqueous medium.

For copper(II)–humic acid, the results of the study in progress[12] suggest that, for humic acid concentrations lower than 0.1 m$M$, the adsorption phenomena do not interfere in the determination of the conditional stability constants by PSA, but interfere markedly if DPASV is used.

In this paper, the results obtained for the copper(II)–glycine system are discussed.

## THEORY

In the case of monomeric ligands, L, if there are no adsorption phenomena on the electrode, DeFord–Hume's[13] method has been used for determination of stability constants of metal complexes by voltammetric techniques.[14,15]

For the reaction (the electric charges were omitted for the sake of simplicity, except for the metal ion whose charge is important for equation 3):

$$M^{n+} + jL \leftrightarrow ML_j, \quad (1)$$

whose overall conditional stability constant is:

$$\beta'_j = [ML_j]/([M^{n+}][L]^j). \quad (2)$$

The values of $\beta'_j$ can be obtained by the following equation:[16,17]

$$\Delta E_p = E_p^a - E_p^p = (2.303RT/nF) \times \left[ \log\left( 1 + \sum_{j=0}^{j} \beta'_j [L]^j \right) + \log(i_p^p/i_p^a) \right], \quad (3)$$

where $\Delta E_p$ denotes the difference between the peak potentials measured in metal solutions without and with the ligand. $E_p^p$ and $i_p^p$, and $E_p^a$ and $i_p^a$ are the peak potentials and current for the metal in the presence (p) and in the absence (a) of the ligand, respectively; $n$, $R$, $T$ and $F$ have their usual meaning.

Equation (3) presupposes that: (i) $ML_j$ are labile; (ii) the system is electrochemically reversible; and (iii) the ligand concentration at the electrode surface is equal to the bulk concentration. In addition, if the diffusion coefficient(s) of the complex(es) ($D_{ML_j}$) is (are) similar to those for the free metal ion ($D_M$), $\log(i_p^p/i_p^a) = 0$ (because $i_p^p/i_p^a \cong 1$ since $D_M \cong D_{ML_j}$). The last condition is only valid for small simple ligands such as $Cl^-$, $OH^-$ and amino acids,[18] like glycine. In this case, equation (3) takes the form:

$$\Delta E_p = E_p^a - E_p^p = (2.303RT/nF) \log\left( 1 + \sum_{j=0}^{j} \beta'_j [L]^j \right). \quad (4)$$

Theoretical studies of Chau *et al.*[19] showed that equation (4) is also valid for PSA, but as far as we know, this technique has not been applied for determination of stability constants before.

From equations (3) or (4), it follows that a polynomial fits the experimental data (titrations of metal solutions with a ligand solution). Its degree gives the number of complexes and the coefficients correspond to the overall formation constants.

Buffle *et al.*[20,21] concluded that DeFord–Hume's method can only be applied when the ratio between the total ligand and the total metal concentrations in the analytical solution ($[L]_t/[M]_t$) is higher than 1000 and the deposition time ($t_d$) is low enough to avoid surface effects during the anodic step. In fact, during the stripping step, the metal concentration at the mercury electrode surface ($[M]^0$) is much higher than in the bulk solution, the exact value depending on the $t_d$ and the [M] present in the bulk solution. If the ligand concentration in the solution is not large enough to guarantee excess even at the mercury electrode surface, ligand saturation by the metal at the mercury electrode surface will occur.[22] As a result, the chemical conditions at the electrode surface may change drastically by complex formation at the electrode surface, which are different from those in the bulk solution.[22] This phenomenon gives rise to a non-linear $i_p$ *vs.* $t_d$ function (S-shaped curve) and a decrease of $\Delta E_p$ with $t_d$ ($\Delta E_p$ should be independent of $t_d$).[22]

When $[L]_t/[M]_t$ is lower than 1000, the determination of stability constants by equation (3) requires a previous extrapolation of $\Delta E_p$ *vs.* $t_d$ curve for $t_d = 0$.[20,21]

## EXPERIMENTAL

### *Reagents and material*

For the preparation of solutions, reagent of analytical grade or equivalent without further purification were used, together with deionized water with resistivity $>14$ M$\Omega$ cm. Glycine, from Sigma, ref. G-7126 was used. Copper solutions were prepared from a stock standard solution 0.787 m$M$ $CuCl_2$.

All glass and plastic ware was cleaned by soaking in 20% nitric acid for 24 hr and then rinsing several times with water.

*Apparatus*

PSA and DPASV measurements were performed by using an Eco Chemie Autolab multimode polarograph with an IME module connected to a Metrohm 663 VA device and a MTEK computer. The Metrohm multimode was used in the static mercury drop mode (SMDE).

Alternating current polarography (ACP) measurements were carried out with a dropping mercury electrode (DME) on a Metrohm E506 polarograph combined with a Metrohm 663 VA device.

In all experiments, a conventional three-electrode arrangement, consisting of a glassy carbon electrode, as a counter electrode, an Ag/AgCl(s) 3*M* KCl electrode, as reference, and a multi-mode electrode were used.

*Procedures*

The measurements were performed at 20°C in 0.01*M* potassium nitrate, at pH 6.0 and 6.5, buffered with 0.01*M* piperazine-*N*,*N*-bis[2-ethane-sulfonic acid] (PIPES). Previously, it was verified that PIPES forms no complexes with copper(II). Twenty milliliters of the working solution was used for each experiment. The dissolved oxygen was purged from the solution by using a nitrogen gas stream for 10 min.

Metal losses owing to adsorption on the cell walls[23] were quantified by calibrating the voltammetric system at the same pH and during the same time as the samples but without ligand.

DPASV measurements were carried out using the following instrumental settings: deposition potential, $E_d = -0.3$ V *vs.* Ag/AgCl(s) 3*M* KCl, 50 mV pulse height, 60 msec pulse duration, 1 sec pulse repetition time and 5 mV/sec scan rate. In PSA, the same $t_d$ and $E_d$ were used. In all experiments performed by PSA, 47.2 $\mu$l of 2 m*M* of mercury(II) chloride as the oxidizing agent, which corresponded 4.72 $\mu M$ mercury(II) concentration, were added to the cell solution only just at the end of the deposition period, in order not to disturb the chemical equilibrium in the bulk solution.

PSA and DPASV complexation measurements were carried out by the batch mode on solutions with a concentration of copper(II) of 0.787 $\mu M$ copper(II), which was about four times higher than the limit of detection of both techniques in the experimental conditions ($t_d = 120$ sec and $E_d = -0.3$ V) used.[9] The concentration of glycine was varied between 1.12 and 31.6 m*M*. From the values of $E_p$ obtained in the absence (a) and in the presence (b) of the ligand, $\Delta E_p = E_p^a - E_p^p$ were calculated and used for deriving the conditional complex constants $\beta_1'$ and $\beta_2'$ by equation (4). For this purpose it was assumed that $[L] = [L]_t$, since the ligand concentrations were in very large excess relatively to the metal.

To test the non-occurrence of adsorption phenomena at the mercury electrode, experiments by ACP were performed. For this purpose, an amplitude of the alternating potential of 10 mV, 75 Hz of frequency, a dropping time of 0.8 sec and a scan rate of 5 mV/sec were used. The alternating component of the current ($i_{ac}$) was recorded at a phase angle ($\varphi$) of 90° for solutions with 1.12 or 17.8 m*M* glycine. The total potential range scanned in an experiment was from 0 to −1.2 V.

The occurrence of surface effects at the mercury electrode was tested by DPSAV for $t_d$ between 30 and 1400 sec. Solutions with 0.787 $\mu M$ copper(II) and two different glycine concentrations, 0.55 and 1.12 m*M*, were used.

## RESULTS AND DISCUSSION

*Adsorption and surface effects*

Erroneous stability constants are obtained by the DeFord–Hume method applied to voltammetric data[24-26] when adsorption phenomena take place on the working electrode. Therefore, in a first stage of this work, the absence of glycine adsorption at the Hg electrode was

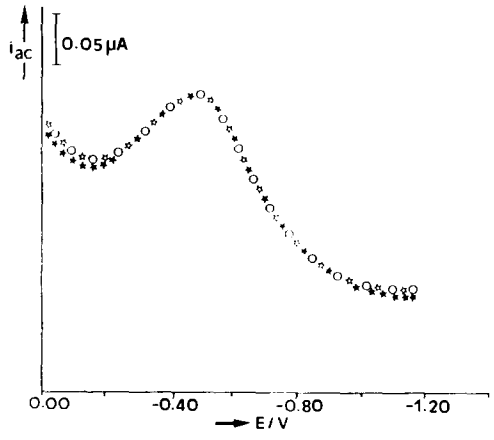

Fig. 1. AC polarograms for glycine solutions: amplitude = 10 mV; frequency = 75 Hz; scan rate = 5 mV/sec; $\varphi = 90°$. [Glycine] = (★) 0.00; (☆) 1.12 m*M*; (○) 17.8 m*M*.

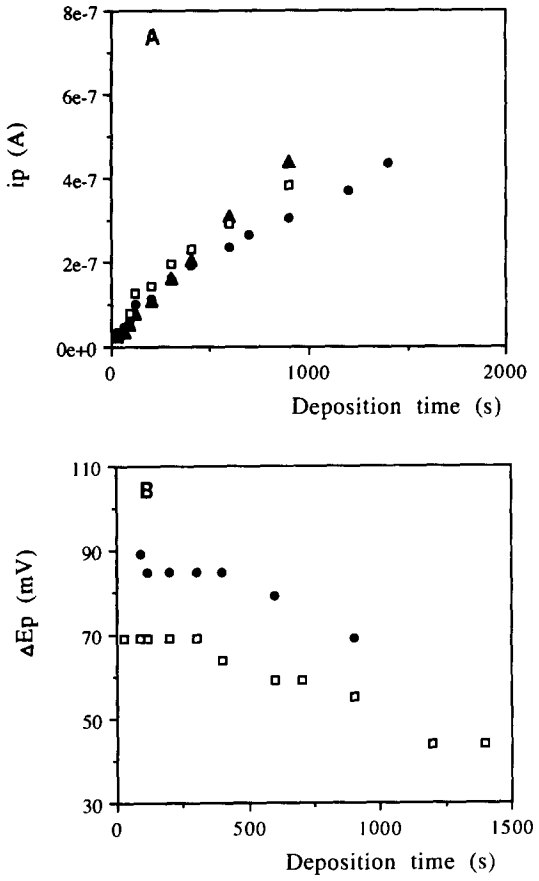

Fig. 2. Influence of glycine (▲ without ligand, □ 0.55 m$M$, and ● 1.12 m$M$) on the DPASV response for a 0.787 $\mu M$ copper(II) solution. $E_d = -0.3$ V *vs.* Ag/AgCl(s), 3$M$ KCl. This is a typical example of an experiment performed twice. (A) $i_p = f(t_d)$; (B) $\Delta E_p = f(t_d)$.

experimentally confirmed. For this purpose, curves of $i_{ac} = f(E)$ by ACP with a phase angle of 90° were recorded. At this phase angle, $i_{ac}$ is capacitive in nature and proportional to the double-layer capacity. Figure 1 shows that $i_{ac} = f(E)$ curves for the two different ligand concentrations are superposed with the curve without ligand, which indicates that no adsorption of glycine occurs.[18]

To evaluate the surface concentration of the oxidized metal during the stripping step, recordings of $i_p = f(t_d)$ and $\Delta E_p = f(t_d)$[18] were performed by DPASV, for two different $[\text{glycine}]_t/[\text{copper}]_t$ ratios. For $[\text{glycine}]_t/[\text{copper}]_t = 699$, an S-shaped curve for $i_p$ *vs.* $t_d$ was obtained (Fig. 2A) as well as a decreasing $\Delta E_p$ with $t_d$ (Fig. 2B). For the higher ratio, 1423, the $i_p$ *vs.* $t_d$ recording was linear and superposed with the curve recorded without glycine until $t_d = 400$ sec (Fig. 2A). This result indicated that no important surface effects occurred when $[\text{glycine}]_t/[\text{copper}]_t = 1423$, and therefore, this or higher values were used in the complexation studies. Furthermore, that result (Fig. 2A) showed that the diffusion coefficient of the metal ion was not significantly influenced by complexation, as expected, because the ligand is a relatively small amino acid.[18]

*Complexation*

Potentiograms and voltamograms carried out for solutions with 0.787 $\mu M$ copper(II) without and with 1.41, 7.94 or 31.6 m$M$ glycine are presented respectively in Fig. 3A and B. This shows that the values of $i_p^p$ obtained for the different glycine concentrations were close and similar to that obtained in the absence of glycine ($i_p^a$), which shows that the copper(II)–glycine complexes were labile within the time scale of these techniques. This figure also shows that the

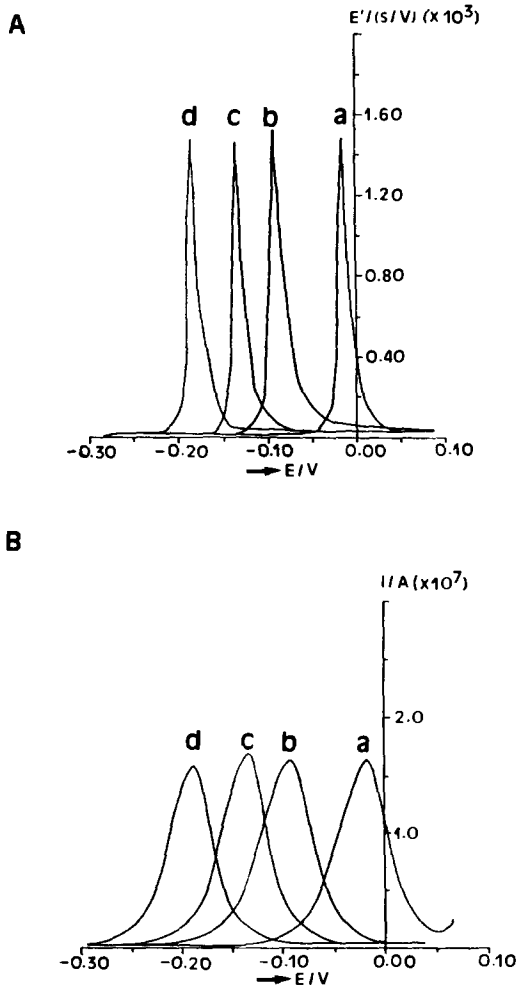

Fig. 3. Potentiograms (dPSA mode) (A) and DPASV voltammograms (B) for 0.787 $\mu M$ copper(II) and different glycine concentrations: (a) 0.0; (b) 1.41; (c) 7.94; and (d) 31.6 m$M$.

Table 1. Values of peak width ($W_{1/2}$) and potential ($E_p$) obtained for solutions with 0.787 $\mu M$ of copper and various glycine concentrations by PSA and DPASV at pH 6.5

| Curves in Fig. 3 | Glycine ($mM$) | DPASV ($mV$) | | PSA ($mV$) |
|---|---|---|---|---|
| | | $W_{1/2}$ | $E_p$ | $E_p$ |
| a | — | 60 | −16 | −15 |
| b | 1.41 | 55 | −94 | −98 |
| c | 7.94 | 54 | −134 | −136 |
| d | 31.6 | 54 | −189 | −185 |

$E_p$ became more cathodic when the glycine concentration increased. Comparable results ($dt/dE$ values) were obtained by PSA (Fig. 3A). The $\Delta E_p = E_p^a - E_p^p$ values were also similar for both techniques (see Table 1). These cathodic shifts resulted from the fast complexation of copper(II) by glycine during the stripping step.[18] Therefore, the cathodic shift depends on the $[L]_t/[M]_t$, but not on $E_d$, which should be only negative enough to allow the reduction of the free metal ion. Figure 3A and B and Table 1 show that, in the absence of ligand, an $E_p \cong -0.015$ V was obtained by both techniques. Therefore, the overpotential selected, *ca.* −0.3 V, can be considered sufficient for the present study purposes.[6]

In addition, results obtained by DPASV (Table 1) indicate that in the absence of glycine, a peak width ($W_{1/2}$) in agreement with theoretical predictions[27] was attained under our experimental conditions. In the presence of glycine, $W_{1/2}$ may still be considered according to theory,[27] although slightly smaller values were obtained (Table 1). Therefore, as no broadening of the peaks was found, the chemical system can be considered reversible.[16] As PSA and DPASV have similar response times ($\log t$(sec) between −0.5 and −1.2[28]), one can also assume that the system has similar electrochemical behaviour in both techniques. Therefore, under the experimental conditions used, the copper(II)–glycine system seems to fulfill the conditions for application of the DeFord–Hume method.[13]

Table 2. Conditional stability constants determined* by PSA and DPASV and calculated from the literature

| $\log \beta'_n$ | PSA | DPASV | Literature† |
|---|---|---|---|
| pH 6.0 | | | |
| $\beta'_1$ | 5.0 ± 0.2 | 4.9 ± 0.6 | 4.58 |
| $\beta'_2$ | 7.6 ± 0.2 | 7.7 ± 0.3 | 7.89 |
| pH 6.5 | | | |
| $\beta'_1$ | 5.7 ± 0.6 | 5.5 ± 0.5 | 5.08 |
| $\beta'_2$ | 8.5 ± 0.4 | 8.6 ± 0.4 | 8.89 |

*Standard deviation ($n \geq 3$) are given.
†Calculated from ref. [29] (see text).

$\Delta E_p = f(\log [\text{glycine}])$ plots, obtained from both PSA and DPASV experimental data at pH 6.0, are present in Fig. 4, which show that curves rather than straight lines were obtained, because of the presence of more than one copper(II)–glycine complex. The data obtained by both techniques fitted a second degree polynomial well, the overall conditional stability constants being obtained from the coefficients of the polynomial (see Table 2):

$$\Delta E_p = (2.303RT/nF) \times \log(1 + \beta'_1[\text{glycine}] + \beta'_2[\text{glycine}]^2). \quad (5)$$

Table 2 shows that PSA and DPASV originate practically identical stability constants. From these results, it can be concluded, that the presence in the solution of mercury(II) during the stripping step, had no significant interference in the analytical signal, probably because the glycine was in large excess.

From stoichiometric stability constants in the literature[29] $\log \beta_1 = 8.5$ and $\log \beta_2 = 15.4$ ($T = 20°C$, $I = 0.01M$), the $\beta'_s$ at values at pH 6.0 and 6.5 were calculated (see Table 2), and were similar to those obtained in this study. In

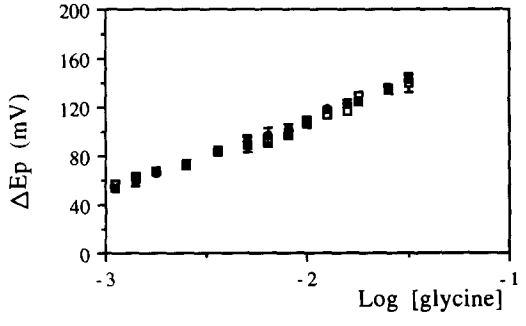

Fig. 4. Mean values and standard deviations ($n = 3$) of $\Delta E_p$ *vs.* [glycine] for 0.787 $\mu M$ copper(II) obtained by PSA (□) and DPASV (●) at pH 6.0.

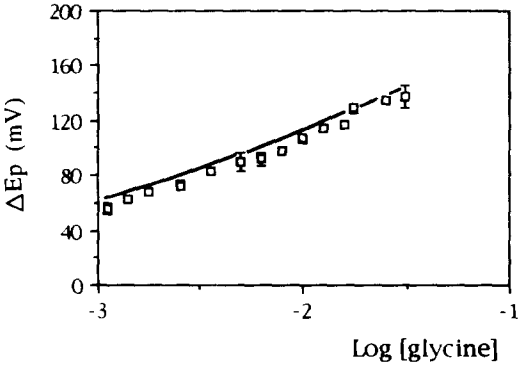

Fig. 5. Mean values and standard deviation ($n = 3$) of $\Delta E_p$ *vs.* [glycine] for 0.787 $\mu M$ copper(II) obtained by PSA (□) and calculated (full line) from known $\beta'$ values from the literature at pH 6.0 (see Table 2).

addition, Fig. 5 shows that the $\Delta E_p$ values estimated from known $\beta'_s$ values (pH 6.0) were similar to the analytical $\Delta E_p$ values obtained by PSA.

The agreement between the experimental results and literature data indicates that copper(II), instead of copper(I) (which is frequently involved in the mechanism of oxidation of copper(0) to copper(II) on stripping of amalgamated copper), is formed directly (*i.e.* by a two-electron process) in the stripping step. This fact corroborates literature information about the electrochemical behaviour of the copper(II)–glycine system,[30] and makes the stripping techniques suitable for determination of the respective stability constants.

Table 2 also shows that, in the pH range studied, the $\beta'_s$ values of the copper(II)–glycine complexes depend markedly on the pH value, as expected since carboxylic groups are involved in the complexation.

## CONCLUSION

The present work showed that PSA is suitable for estimating quantitatively the stability of metal–organic complexes, since the ligand is non-adsorbable at the mercury electrode surface and the conditions for application of the DeFord–Hume method are fulfilled.

# FLOW ANALYSIS-SPECTROPHOTOMETRIC DETERMINATION OF L-DOPA IN PHARMACEUTICAL FORMULATIONS BY REACTION WITH *p*-AMINOPHENOL

BERWEEN A. HASAN,* KARIM D. KHALAF* and MIGUEL DE LA GUARDIA†

Department of Analytical Chemistry, Faculty of Chemistry, University of Valencia, 50 Dr. Moliner, Burjassot 46100, Valencia, Spain

(*Received* 1 *August* 1994. *Revised* 1 *November* 1994. *Accepted* 1 *November* 1994)

**Summary**—A new method has been developed for the spectrophotometric determination of L-dopa in pharmaceutical formulations. The method is based on the reaction between the open-chain quinone of L-dopa, obtained in NaOH, and the benzoqinoneimine form of *p*-aminophenol, in the presence of $KIO_4$. The reaction product is determined at 574 nm by using both alternately procedures, one based on the stopped-flow and another on a flow injection approach. Under the best experimental conditions L-dopa can be determined with a limit of detection of 52 ng/ml and a relative standard deviation of 0.2% for three replicate measurements of a solution containing 4 μg/ml.

L-Dopa or levodopa (3-hydroxy-L-tyrosine) is a catecholamine with the amine group attached to a benzene ring bearing two hydroxyl groups. L-Dopa is a forerunner of dopamine, which is depleted from the brain in Parkinson disease and is commonly employed in the treatment of this disease. L-Dopa is effective in relieving hypokinesia and may also decrease rigidity, oculogyric crises and tremor.[1] The compound is rapidly absorbed through the bowel at the level of the small intestine after oral adminstration and widely distributed in the tissue and metabolized to dopamine by a decarboxylation process. Dopamine is further metabolized to other metabolites and for this reason, carbidopa and benserazide are used as inhibitors for the decarboxylase activity.[2]

Many methods have been developed for the determination of L-dopa and its metabolites in biological and pharmaceutical formulations, such as chromatography techniques and thin-layer chromatography (TLC) has been used for the separation and determination of L-dopa.[3,4] Gas chromatography (GC) has also been employed to study the effect of L-dopa and dopamine in rat brain.[5] High-performance liquid chromatography (HPLC) has been widely used for the determination of L-dopa in brain, plasma, urine, liver, serum, tissues and biological fluids using electrochemical detection,[6–19] or fluorescence detection at 325 nm[20] and 322 nm.[21]

Spectrophotometric methods have also been used for the determination of catecholamines in pharmaceutical formulations and hence, direct measurement of L-dopa in tablets was carried out at 280 and 290 nm,[22] or by derivative spectrophotometry at 276 nm,[23] and in the presence of boric acid,[24] $Na_2B_4O_7$,[25] $Na_2HPO_4$,[26] and germanium dioxide[27] which provide maximum absorbance at 239.5, 287, 292.5 and 292 nm, respectively.

L-Dopa has been determined in the visible region based on the use of several derivative reagents such as $PdCl_2$,[28] metaperiodate,[29] *o*-phenathroline,[30] molybdophosphoric acid,[31] ninhydrine,[32] $NH_4VO_3$[33] and enzymatic incubation with tyrosinase[34] to yield coloured species which show absorption maxima at 392, 520, 510, 825, 582, 430 and 540 nm, respectively. A photokinetic method, based on the photochemical reaction of Rose Bengal with EDTA in the presence of catecholamines has also been proposed[35] for the analysis of pharmaceuticals.

Flow-injection analysis (FIA) was originally designed to carry out several on-line analytical processes, and in spite of the great improvement in the analytical figures of merit provided by the FIA methodology, there are only few

*Permanent address, University of Baghdad, Iraq.
†Author to whom correspondence should be addressed.

papers dealing with the automatization of the L-dopa or other catecholamines. L-Dopa was determined based on FIA-chemiluminometric oxidation with $KMnO_4$,[36] and also by flow injection stopped-flow kinetic spectrophotometry using a micellar-catalyzed reaction with 1-fluoro-2,4-dinitrobenzene to produce a complex which is measured at 340 nm.[37]

L-Dopa has also been determined fluorometrically in pharmaceutical preparations by means of the photochemical inhibition of the reaction between phloxin and EDTA,[38] and a flow system has been developed for the study of the catecholamine secretion from bovine adrenal medulle cells which permits the electrochemical determination of catecholamines.[39]

The purpose of the present investigation is to develop a simple and sensitive method for the determination of L-dopa in pharmaceutical formulations by FIA-spectrophotometry. The proposed method is based on using *p*-aminophenol (PAP) as a derivative reagent which has been successfully employed for the determination of phenolic compounds with a free *para*-position, obtained from the alkaline hydrolysis of carbamate pesticides,[40–43] and also for the direct determination of cresols,[44] and other phenols[45] in natural waters.

## EXPERIMENTAL

### *Apparatus*

A Hewlett-Packard 8452A diode array spectrophotometer, equipped with an HP 89530A MS-DOS software (with a response time of 0.1 sec) was used for the spectrophotometric determination. A flow cell with 50 $\mu$l. internal volume and 1 cm pathlength was used for the absorbance measurements.

Two manifolds of three channels (Fig. 1) were employed to carry out the spectrophotometric determination of L-dopa in the stopped-flow (Fig. 1A) and in the FIA mode (Fig. 1B).

A Gilson $P_2$ minipulse peristaltic pump was used in all cases to transport the carrier solutions. Standard solutions and samples were injected, in the FIA mode, using a Rheodyne type 50 rotary injection valve. As can be seen in Fig. 1A, channel 1 was used to transport *p*-aminophenol and channel 2 to introduce L-dopa in the stopped-flow mode or to inject samples and standards in the FIA mode in a water carrier stream. Channel 3 was employed to transport a sodium hydroxide solution.

The connections between any two channels of both manifolds employed were made by Y-shaped merging zones in order to ensure good mixing between reagents.

Flexible poly(vinyl chloride) tubes of 1.52 mm internal diameter, suitable for peristaltic pump, were used to provide a flow-rate up to 4.2 ml/min in each channel.

A reaction coil of 45 cm ($R_1$) was used to ensure a good mixing between *p*-aminophenol (PAP) and L-dopa. Another reaction coil of 8 m ($R_2$) was employed to provide a good reaction yield between L-dopa and PAP in the presence of sodium hydroxide. The coloured species obtained were measured at 574 nm.

All the reaction coils used in the manifolds were made of Teflon with an internal diameter of 0.8 mm.

### *Reagents*

All reagents were of analytical grade and demineralized distilled water was used throughout.

The L-dopa stock solution (24 $\mu$g/ml) was prepared by dissolving 0.00625 g L-dopa (Fluka) in 250 ml boiled and cooled distilled water. This solution was stored in a refrigerator, being stable for many days.

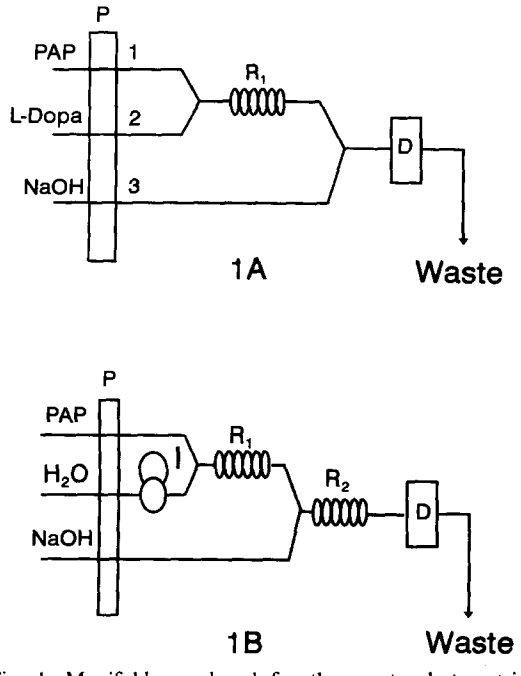

Fig. 1. Manifolds employed for the spectrophotometric determination of L-dopa, (1A) stopped-flow mode and (1B) FIA mode, (P) peristalitic pump, (D) detector, ($R_1$ and $R_2$) reaction coils, (I) injection valve.

The *p*-aminophenol (PAP) standard solution (100 $\mu$g/ml) was prepared daily by dissolving 0.025 g PAP (Fluka) in 250 ml of boiled and cooled distilled water, being stable for more than 8 hr. Stock solution (1*M*) of sodium hydroxide (Probus) was prepared in distilled water and working solutions were prepared by diluting the stock one.

*General procedure*

For the solid formulation of Madopar®, the tablets were ground and, from the final fine powder, 0.0172 g was accurately weighed and dissolved in 250 ml of boiled and cooled distilled water using an ultrasonic water bath for 10 min to ensure complete dissolving of L-dopa in water. The solution was filtered using a Whatmann filter paper No 42 to avoid any suspended excipient. Low concentrated solutions were prepared by diluting the aforementioned filtered solution with boiled and cooled distilled water in order to avoid any oxidation of L-dopa by the dissolved molecular oxygen of water. The spectrophotometric measurements were carried out in stopped-flow mode by introducing sample solutions in channel 2, as indicated in Fig. 1A, using 0.2*M* of sodium hydroxide solution and 100 $\mu$g/ml of PAP, and after mixing all these solutions stopping the flow and carrying out the measurements after 1 min, while in the FIA mode, samples and standards were injected in the manifold indicated in Fig. 1B using 600 $\mu$l. injection volume and distilled water as carrier stream with a flow rate of 3.2 ml/min. In both cases, the spectrophotometric measurements were carried out at 574 nm against a standard calibration graph obtained from standard solutions of L-dopa treated in the same way.

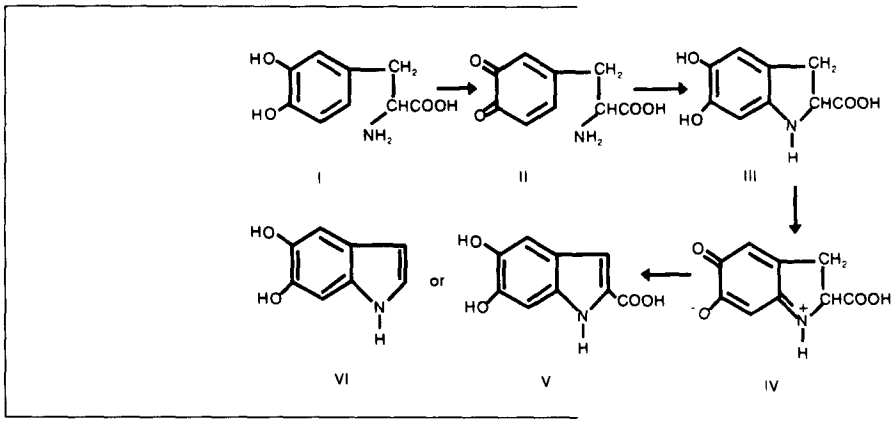
## RESULTS AND DISCUSSION

*Preliminary study of* L-*dopa stability in aqueous solutions*

L-Dopa(levodopa) is slowly soluble in water (66 mg/40 ml $H_2O$)[46] but it undergoes oxidation processes even by the dissolved molecular oxygen, and for these reasons, special attention was taken for the preparation of standard solutions.

In this work, the standard solution of L-dopa was prepared in boiled and cooled distilled water and the UV/Vis spectrum of the prepared solution was daily monitored by using the diode array spectrophotometer for more than 15 days; and results obtained showed that the aqueous solution of L-dopa is highly stable.

On the other hand, it is well known that, L-dopa (**I**) is first oxidized to the open-chain quinone (**II**) which gives a yellow coloured solution[47] which has a very transitory existence[48] and evolves to leucodopachrome (**III**); this substance is in turn oxidized to dopachrome (**IV**) which can be then undergo further transformation by an internal oxidation-reduction mechanism to 5,6-dihydroxyindole-2-carboxylic acid (**V**), or to 5,6-dihydroxyindole (**VI**)[49] according to the following scheme.



The behaviour of L-dopa in sodium hydroxide 0.2*M* was studied, using the manifold indicated in Fig. 1A, in which distilled water was introduced in channel 1 and 10 $\mu$g/ml of a L-dopa solution was introduced continuously by channel 2 and 0.2*M* NaOH solution by channel 3. Figure 2 shows that the interaction between L-dopa and sodium hydroxide produces a yellow solution which presents two absorption bands at 302 and 440 nm. However, the band at 440 nm decreased gradually and, after 3 min, a new absorption band appeared at 326 nm. This behaviour can be explained by the oxidation of

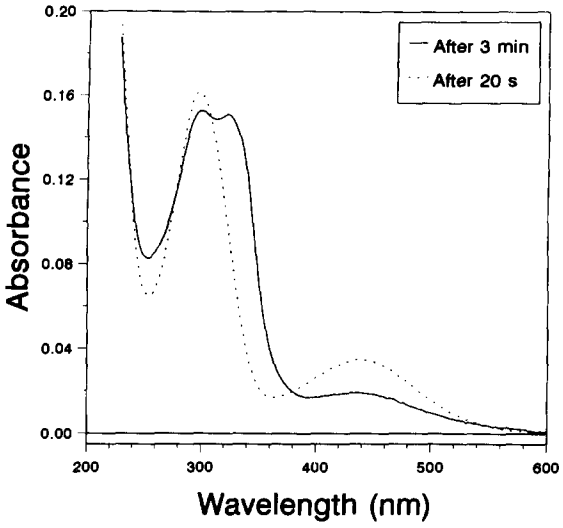


Fig. 2. UV-Vis spectra of 10 mg/ml of L-dopa in 0.2*M* NaOH after 20 sec (· · ·) and after 3 min (——).

L-dopa to the open-chain quinone (**II**) which showed an absorption at 440 nm, and after that evolves to leucodopachrome (**III**).[48]

*Reaction between* L-*dopa and* p-*aminophenol*

It has been mentioned that when PAP (**1**) is oxidized, by the dissolved molecular oxygen or by other oxidizing agents such as $KIO_4$, the benzoquinoneimine form of PAP (**2**) produced readily reacts with the free *para*-position of phenolic compounds by an electrophilic attack which produces complex species which absorb in the visible region.[50] Thus, the aim was to couple benzoquinoneimine (**2**) with the open-chain quinone (**II**) in order to produce a complex compound (**3**). The spectrum in Fig. 3 indicates that the reaction between 100 $\mu$g/ml of PAP and 10 $\mu$g/ml of L-dopa in an alkaline medium of 0.2*M* NaOH carried out in the stopped-flow mode, using the manifold indicated in Fig. 1A, shows a high absorption intensity at 574 nm. The full colour development was achieved after 60 sec, and it remained stable for more than 20 min. On the other hand, when $KIO_4$ was previously mixed with PAP, the colour was formed and decomposed very rapidly.

A possible reaction mechanism is shown in the scheme of the reaction between PAP and L-dopa.

Some evidence about the aforementioned reaction was obtained by additional experiments. When L-dopa is mixed with a NaOH solution and coupled with PAP after 2, 3, 4, and 5 min, results obtained show that there was no reaction between L-dopa and PAP, owing to the formation of leucodopachrome (**III**), in which the *para*-position is blocked.

The reaction between L-dopa and PAP carried out in an alkaline medium of 0.2*M* NaOH provides a higher sensitivity and selectivity than that obtained for the direct spectrophotometric determination of L-dopa prepared in distilled water and measured in the UV-region (see Fig. 3).

*Stopped-flow spectrophotometric determination of* L-*dopa*

The effect of NaOH concentration (from 0.1 to 1*M*) and PAP (from 25 to 300 $\mu$g/ml) on the reaction between L-dopa and PAP was studied using the manifold shown in Fig. 1A.

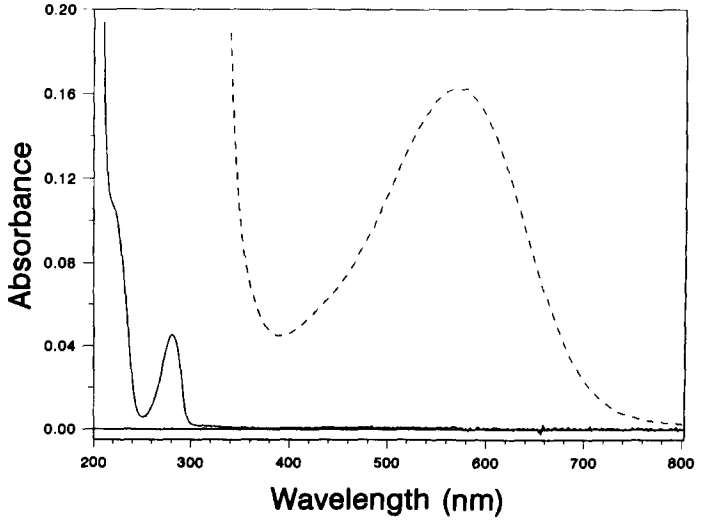

Fig. 3. UV/Vis spectrum of a solution of 10 mg/ml of L-dopa in distilled water (——) and the spectrum of the reaction product between 10 $\mu$g/ml of L-dopa and 100 $\mu$g/ml of PAP in 0.2*M* NaOH (· · ·).

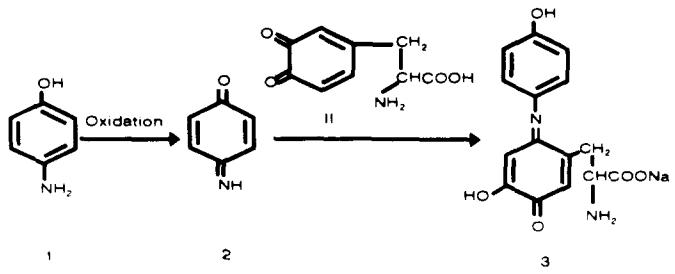

Reaction between PAP and L-dopa.

Results obtained showed that the use of 100 $\mu$g/ml of PAP and 0.2$M$ NaOH provide the highest absorption intensity after a reaction time of 60 sec and hence, a calibration graph was carried out for a series of standard solutions (from 2 to 8 $\mu$g/ml L-dopa) which provided a typical calibration line with the following regression characteristic features:

$$A_{574} = 0.0020 + 0.01495C \ (C \text{ in } \mu\text{g/ml of L-dopa})$$

with the regression coefficient $r$ of 0.9999. The limit of detection obtained was 60 ng/ml and the relative standard deviation of three replicate measurements of a solution containing 4 $\mu$g/ml of L-dopa was 1%.

The stopped-flow method was applied to the determination of L-dopa in real pharmaceutical formulations and hence, Madopar® tablets, which contain 250 mg L-dopa and 50 mg benserazide, was used as a test sample, using the recommended general procedure.

Table 1 shows that the recovery percentages obtained were from 98 to 102% of L-dopa in Madopar® which provided high accurate results and evidence that there is not any effect of benserazide on the final recovery because benserazide does not react with PAP.

In order to verify the validity of the methodology developed, some synthetic samples were prepared by adding known amounts of L-dopa to commonly used excipients, such as starch and lactose, or to pharmaceutical preparations containing other products, such as paracetamol.

Table 1. Determination of L-dopa by stopped-flow spectrophotometry in Madopar® tablets

| Nominal value ($\mu g/ml$) | Found by proposed method ($\mu g/ml$) | Recovery (%) |
|---|---|---|
| 2 | 1.95 ± 0.09* | 98 |
| 4 | 4.05 ± 0.10 | 100.4 |
| 5 | 5.1 ± 0.2 | 101.3 |
| 6 | 6.12 ± 0.06 | 102 |

*Average values found ± SD corresponding to five independent analyses.

Table 2 summarizes the results shown and as can be seen very good recovery values were found, thus indicating that excipients should not provide real problems in the determination of L-dopa by means of its reaction with PAP.

*Study of some possible interferences*

As indicated before all free *para* position phenols can react with PAP to form coloured species, and from our own experience it can concluded that PAP is a general derivative reagent for all these compounds. However, each phenol requires different reaction conditions and reacts with PAP at different rates. Table 3 summarizes the experimental conditions found for the reaction between PAP and *o*-cresol, *m*-cresol, phenol, resorcinol and *m*-aminophenol in the stopped flow mode. As can be seen each compound requires different conditions, and they also provide different absorption maxima, thus indicating the tremendous possibilities offered by this reaction for the simultaneous determination of a series of phenols.

On the other hand, and compared with the reaction between L-dopa and PAP it is shown that simple phenolic compounds need the use of $KIO_4$ and that in the absence of this oxidizing reagent reactions take place very slowly which also contributes to providing a selective method for the determination of L-dopa in pharmaceuticals.

*FIA-spectrophotometric determination of L-dopa*

The effect of flow injection analysis (FIA) parameters were evaluated under the best conditions found for the determination of L-dopa by stopped-flow; such as the reaction coil length $R_2$ (from 1 to 8 m), flow rate (from 1 to 4 ml/min) and the injection volume (from 100 to 800 $\mu$l.). The reaction between L-dopa and PAP was studied using the manifold indicated in Fig. 1B. Results obtained show that a reaction coil of 600 cm, with a flow rate of 3.2 ml/min and an injection volume of 600 $\mu$l. provide the

Table 2. Analysis of L-dopa in synthetic samples in the presence of some commonly used excipients

| Excipients | Concentration added ($\mu g/ml$) | Concentration found ($\mu g/ml$) | Recovery (%) |
|---|---|---|---|
| Starch | 3.94 | $4.00 \pm 0.003$ | 101.5 |
| Lactose | 2.99 | $2.92 \pm 0.02$ | 97.7 |
| Paracetamol | 1.44 | $1.46 \pm 0.04$ | 101.4 |

Table 3. Experimental conditions found for the stopped-flow determination of a series of phenols with PAP

| Experimental conditions | *o*-Cresol | *m*-Cresol | Phenol | Resorcinol | *m*-Aminophenol |
|---|---|---|---|---|---|
| PAP ($\mu g/ml$) | 100 | 300 | 500 | 50 | 115 |
| $IO_4^-$ ($M$) | 0.004 | 0.004 | 0.004 | 0.0002 | 0.004 |
| NaOH ($M$) | 0.06 | 0.06 | 0.005 | 0.006 | 0.05 |
| Reaction time | 35 min | 12 min | 45 min | 45 sec | 10 min |
| $\lambda$ ($nm$) | 614 | 632 | 626 | 540 | 576 |

best absorption intensity. An $R_2$ coil of 45 cm was used only to provide a radial homogenization between PAP and L-dopa. A calibration graph obtained for a series of standard solutions of L-dopa (from 2 to 8 $\mu$g/ml) using the above parameters provided a typical calibration line with the following analytical regression features:

$$A_{574} = -0.0097 + 0.01323C$$

(C in $\mu$g/ml of L-dopa)

with a regression coefficient $r$ of 0.9999. The limit of detection obtained in these conditions was 52 ng/ml and the relative standard deviation for three replicate measurements of 4 $\mu$g/ml of L-dopa was 0.2%. The proposed FIA-method provides high reproducible results and permits the measurement of low concentration levels of L-dopa with a sample throughput of 120 injections/hr. The above FIA-methodology has been applied to the determination of L-dopa in Madopar® tablets using the recommended method and the recovery percentages obtained were from 99.4 to 102.7% (Table 4) which means that there is no significant difference between the results obtained by the proposed method and those reported.

## CONCLUSION

The proposed two procedures (stopped-flow and FIA-methods) offer clear advantages for the fast determination of L-dopa in the presence of related compounds, such as benserazide in pharmaceutical formulations. The method is very simple, does not require any chemical sample pretreatment, is highly economic and very fast and provides highly accurate results with low detection limits.

Table 4. FIA-spectrophotometric determination of L-dopa in Madopar® tablets

| Nominal values ($\mu g/ml$) | Found values ($\mu g/ml$) | Recovery |
|---|---|---|
| 2 | $2.01 \pm 0.06$ | 100.7 |
| 4 | $4.11 \pm 0.06$ | 102.7 |
| 5 | $5.11 \pm 0.01$ | 102.2 |
| 6 | $5.97 \pm 0.04$ | 99.4 |

# EXTRACTIVE SEPARATION OF GROUP IVB ELEMENTS: ANALYSIS OF ALLOY SAMPLES

S. M. KAKADE and V. M. SHINDE*

Analytical Laboratory, Department of Chemistry, The Institute of Science, 15, Madam Cama Road, Bombay 400 032, India

(*Received* 15 *July* 1994. *Revised* 31 *October* 1994. *Accepted* 1 *November* 1994)

**Summary**—A method is proposed for the extraction and mutual separation of quadrivalent titanium, zirconium and hafnium from hydrochloric acid using triphenylphosphine oxide dissolved in toluene as an extractant. The optimum conditions for the extraction and separation have been evaluated from critical study of acid concentration, extractant concentration, period of equilibration and effect of diluent. The effect of foreign ions on the extraction and determination is also discussed. The probable composition of the extracted species has been deduced from log$D$–log$C$ plots. The method affords mutual separation of titanium, zirconium and hafnium and is applicable to the analysis of alloy samples.

Titanium, zirconium and hafnium have increased rapidly in commercial importance. Titanium and its alloys are useful in defence applications, particularly in aircraft, missiles and in rocketry. Zirconium is used in nuclear reactors as a structural and container material. It also finds use in a variety of alloy steels and when added to niobium, forms a superconducting alloy. Hafnium is used as a control material in water cooled nuclear reactors and rectifiers and hence a method is desired for separation and determination of these metal ions.

Several oxygen containing solvents such as dibutyl hydrogen phosphate,[1] bis-(2-ethylhexyl)phosphate,[2,3] tri-*n*-butyl phosphate[4–7] tributylphosphine oxide,[8] tri-isoamylphosphate,[9,10] trioctylphosphine oxide,[11] mesityl oxide,[12] 2,mercaptopyridine-1-oxide,[13] dioctyl methylene diphosphate,[14] 2-ethylhexyl dihydrogen phosphate,[15] petroleum sulphoxide,[16] *N*,*N*-diethyl carbamoylphosphate and *N*,*N*-diethyl carbamoyl methylene phosphate,[17] 4-benzoyl-3-methyl-1-phenyl pyrazolin-5-one[18] and tetraphenyl imidodiphosphate,[19] have been used for extraction studies of quadrivalent titanium, zirconium and hafnium. The methods using high molecular weight amines are also critically discussed in earlier communication.[20] The existing methods have limitations such as longer extraction period,[1,5,7,10,11,14,16,17,19] use of salting out agents,[3,12,18] incomplete extraction,[6,8,9] critical controlling of temperature[10,16,19] and coextractions.[13,15] In our laboratory we have explored the utility of triphenylphosphine oxide for separation of group elements such as gallium, indium and thallium[21] and vanadium, niobium and tantalum.[22] An extension of this study showed that triphenylphosphine oxide dissolved in toluene can also be used for extraction and separation of group IVB elements, namely titanium(IV), zirconium(IV) and hafnium(IV). The proposed method has the following advantages:

1. Extraction time is in seconds.
2. Extraction is possible both at trace and macrolevel.
3. Extraction occurs in single step and recoveries of elements are >99.0%.
4. Provides mutual separation of titanium, zirconium and hafnium.
5. Method is applicable to the analysis of alloy samples.
6. Method is reproducible and accurate.

## EXPERIMENTAL

### *Apparatus*

The absorbance and pH measurements were taken on spectronic 20-D (Milton Roy and Co.) and Control Dynamics digital pH meter with combined glass electrode. ICP-AES was carried out using a Plasmalab 8440 Labtam instrument.

### *Reagents and chemicals*

The stock solutions of titanium(IV), zirconium(IV) and hafnium(IV) were prepared by dis-

*Author to whom correspondence should be addressed.

Table 1. Optimum extraction conditions for titanium(IV), zirconium(IV) and hafnium(IV)

| Metal ion | Acid concentration/ total volume | Organic phase | Extraction period (*sec*) | Stripping solution | Determination procedure |
|---|---|---|---|---|---|
| Titanium(IV) (5–15 μg) | 9.0*M* HCl/10 ml | 2 × 5 ml of 6.5% TPPO in toluene | 60 | 2 × 5 ml water | Spectrophotometry using $H_2O_2$[26] |
| Zirconium(IV) (1–10 μg) | 7.0*M* HCl/10 ml | 5 ml of 6.0% TPPO in toluene | 50 | 2 × 5 ml water | Spectrophotometry using Alizarin Red S as reagent[26] |
| Hafnium(IV) (1–10 μg) | 3.5–5.0*M* HCl/10 ml | 5 ml of 3.5% TPPO in toluene | 35 | 2 × 5 ml water | Spectrophotometry using Xylenol Orange[26] |

solving 1 g potassium titanyl oxalate (together with 2 g of ammonium sulphate in 25 ml concentrated sulphuric acid), 0.1 g zirconium nitrate (in 25 ml concentrated nitric acid) and 0.45 g hafnium dioxide (Koch-light) (in 9 ml of 48% hydrofluoric acid and 1 ml concentrated sulphuric acid), respectively, and diluting to 250 ml with distilled water. The solutions were standardized by known methods[23-25] and diluted as required.

Triphenylphosphine oxide (TPPO) (Fluka grade) dissolved in toluene was used for extraction and separation of titanium(IV), zirconium(IV) and hafnium(IV).

All other chemicals used were of analytical reagent grade.

*General extraction procedure for titanium(IV), zirconium(IV) and hafnium(IV)*

To an aliquot of a solution containing microgram amounts of metal ions, hydrochloric acid was added to give the desired molarity in a total volume of 10 ml (the optimum extraction conditions are reported in Table 1). The solution was transferred into a separating funnel and extracted with TPPO dissolved in toluene for the required shaking time. After removing the aqueous layer, the metal ions were stripped from the organic layer with two 5 ml portions of water and subsequently determined spectrophotometrically.

For titanium(IV), 2 ml of 3% hydrogen peroxide[26] solution were added; made up to the mark with water and the absorbance measured at 410 nm using water as blank. For zirconium(IV), 1 ml of 1% gum arabic solution, 5 ml of 0.05% aqueous solution of Alizarin Red S[26] were added and diluted up to the mark with 0.1*M* hydrochloric acid and the absorbance measured at 520 nm using reagent blank as reference. For hafnium(IV), 2 ml of 1% ascorbic acid and 2 ml of 0.05% aqueous solution of Xylenol Orange[26] were added and diluted up to the mark with water and the absorbance measured at 530 nm using reagent blank prepared analogously.

## RESULTS AND DISCUSSION

Variation in the concentration of acid (HCl/HBr) and TPPO (using toluene as the diluent) show that the quantitative extraction of titanium(IV) occurs from 9.0*M* HCl solution with 6.5% TPPO, whereas extraction of zirconium(IV) is quantitative with 6.0% TPPO from 7.0*M* HCl solution (Figs 1 and 2). Hafnium(IV), extraction is quantitative from 3.5 to 5.0*M* HCl with 3.5% TPPO. Titanium(IV), zirconium(IV) and hafnium(IV) showed no extraction from hydrobromic acid solution.

The suitability of several solvents such as benzene, toluene, xylene, carbon tetrachloride and chloroform for the extraction of titanium(IV), zirconium(IV) and hafnium(IV) using the proposed method was investigated. It was found that TPPO dissolved in toluene or benzene gives quantitative extraction of titanium(IV), zirconium(IV) and hafnium(IV). In all other diluents extraction was incomplete.

Variation of the shaking period showed that the minimum extraction periods for titanium(IV), zirconium(IV) and hafnium(IV) are 60, 50 and 35 sec, respectively. Prolonged shaking leads to emulsion and hinders phase separation.

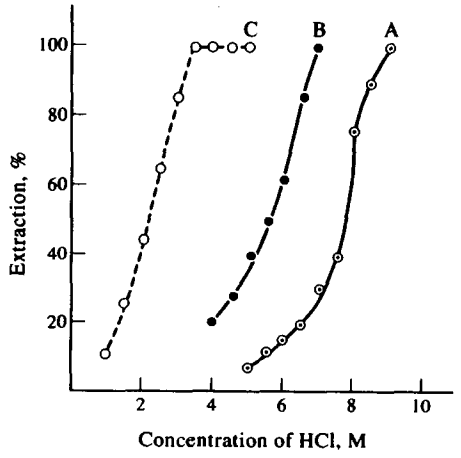

Fig. 1. Extraction behaviour of: Ti(IV), curve A; Zr(IV), curve B; and Hf(IV), curve C all as a function of HCl concentration with 6.5, 6.0 and 3.5% TPPO in toluene, respectively.

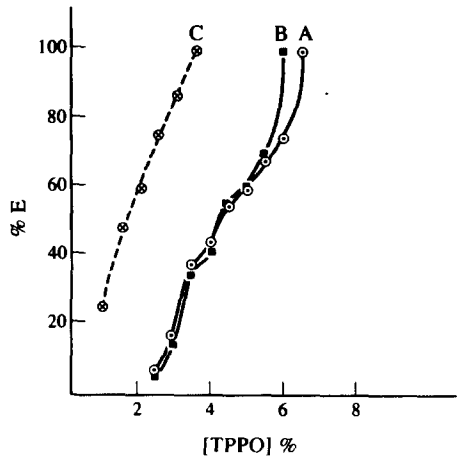

Fig. 2. Extraction behaviour of Ti(IV), curve A; Zr(IV), curve B; and Hf(IV), curve C all as a function of TPPO concentration of 9.0, 7.0 and 3.5*M* HCl concentrations, respectively.

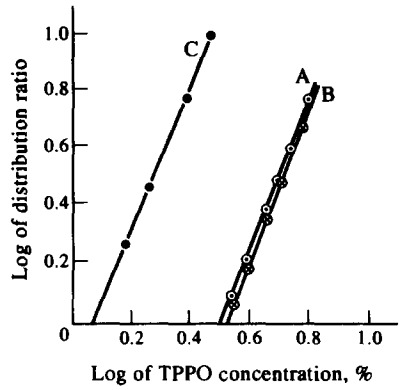

Fig. 3. Plot of the log of the distribution ratio vs log of the TPPO concentration at 9.0, 7.0 and 3.5*M* HCl concentrations for Ti(IV) (A), Zr(IV) (B) and Hf(IV) (C), respectively.

*Nature of extracted species*

The nature of the extracted species was established using log*D*–log*C* plots. A plot of log of distribution ratio *vs.* log of TPPO concentration for titanium(IV), zirconium(IV) and hafnium (IV) at 9.0, 7.0 and 3.5*M* HCl concentration, respectively, gave slopes of 2.3, 2.2 and 2.4, respectively (Fig. 3) indicating a metal to TPPO ratio of 1:2. Since the extraction of titanium(IV), zirconium(IV) and hafnium(IV) are done at reasonably high HCl concentrations, we expect formation of tetrachloro species such as $MCl_4$ [M is titanium(IV), zirconium(IV) or hafnium(IV)] which are further solvated by TPPO. The probable mechanism of solvation is

$$MCl_4 \cdot 2H_2O + 2TPPO \rightleftharpoons MCl_4 \cdot 2TPPO + 2H_2O.$$

TPPO, being more basic, supplants the water molecules and renders the species hydrophobic. A $MCl_4$ type of species was proposed by earlier workers also, for instance $Hf(NO_3)_4 \cdot 2TBP$[27] and $ZrCl_4 \cdot 2TOPO$[28]. At low HCl concentration, however, there is a possibility of species such as $ZrOCl_2 \cdot 2TPPO$ or $HfOCl_2 \cdot 2TPPO$.

*Effect of foreign ions*

Various cations and anions were investigated in an interference study on the extraction and

†Iron(III) is masked with 500 μg of EDTA.

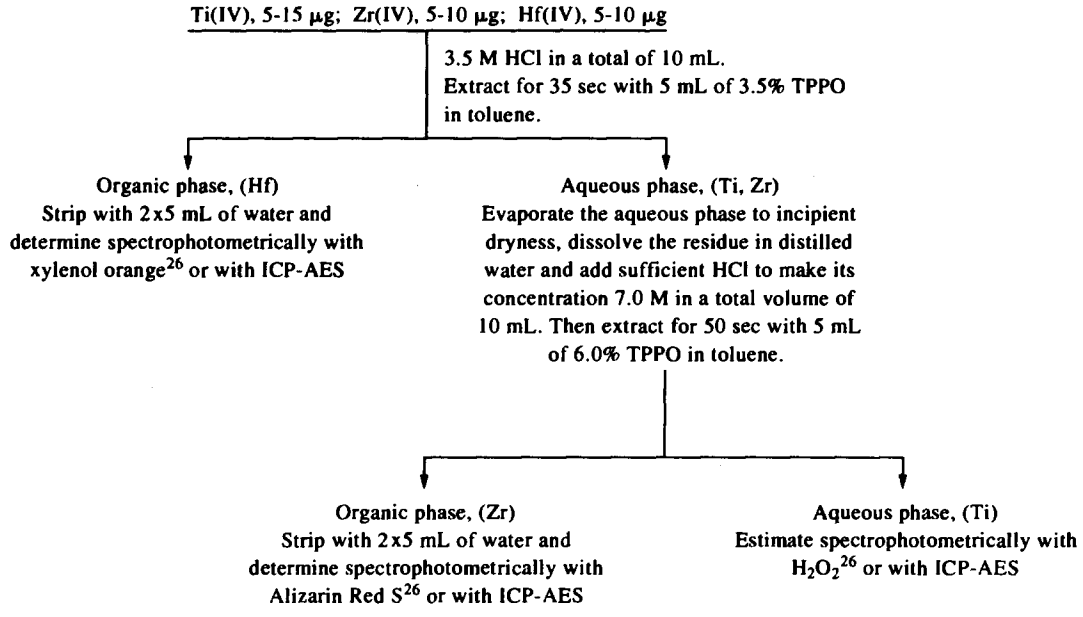

Fig. 4. Flow chart for the mutual separation of Ti(IV), Zr(IV) and Hf(IV) in synthetic mixtures.

determination of titanium(IV), zirconium(IV) and hafnium(IV) by the recommended procedure. The tolerance limit was set at the amount required to cause $\pm 1\%$ error in metal recovery. The results are reported in Table 2.

*Mutual separation of titanium(IV), zirconium(IV) and hafnium(IV)*

Titanium(IV), zirconium(IV) and hafnium(IV) were separated from a ternary mixture by the scheme shown in Fig. 4. The recoveries of titanium, zirconium and hafnium were >99.0% (Table 3).

*Application to the analysis of alloys*

The proposed method was applied to the separation and determination of titanium(IV), zirconium(IV) and hafnium(IV) in alloys such as Ce–Zn–Zr (BCS 307) (0.125 g alloy dissolved in 2 ml concentrated hydrochloric acid and diluted to 25 ml with distilled water), sillimanite (BCS 309) (0.025 g alloy dissolved in 4 ml of aqua regia, evaporated, filtered and diluted to 25 ml with distilled water) and 6% Zn–Al (BCS 300/1) (0.1 g alloy dissolved in 2 ml concentrated hydrochloric acid and diluted to 25 ml with distilled water). We could not procure samples containing hafnium, hence a known amount of hafnium was added to alloy solutions and the procedure was followed for its recovery. The analysis show that the procedure is applicable to alloys which contain all three metals. The recoveries of zirconium and hafnium in Ce–Zn–Zr (Zr, 0.56%; Fe, 0.0021%; Mn, 0.006%; Zn, 2.08%; Cu, 0.005%; Ni, 0.001%; total rare earth 2.84% + 1 mg Hf); that of titanium and hafnium in sillimanite ($SiO_2$, 34.1%; $Fe_2O_3$, 1.51%; CaO, 0.22%; $Na_2O$, 0.34%; $Al_2O_3$, 61.1%; $TiO_2$, 1.92%; MgO, 0.17%; $K_2O$, 0.46% + 1 mg Hf) alloy and recoveries of titanium, zirconium and hafnium in Zn–Al alloy (Ti, 0.09%; Fe, 0.24%; Mg, 2.74%; Zr, 0.18%; Cu, 1.27%; Cr, 0.13%; Si, 0.014%; Mn, 0.33%; Zn, 5.83% + 1 mg Hf) are better than 99%. The recoveries of titanium, zirconium and hafnium were confirmed by ICP-AES before and after extraction.

Table 3. Determination of titanium, zirconium and hafnium in ternary mixtures

(*Received* 6 *July* 1994. *Revised* 28 *October* 1994. *Accepted* 1 *November* 1994)

**Summary**—A porous cellulose tape impregnated with a processing solution that includes 4-*p*-nitrobenzylpyridine, *N*-benzylaniline and methanol is a highly sensitive means of detecting phosgene and maintains stable sensitivity for at least three months in air in a desiccator. When the sample including phosgene was passed through the tape, the color of tape changed to red. The degree of color change was proportional to the concentration of phosgene at a constant sampling time and flow rate. The degree of color change could be recorded by measuring the intensity of reflecting light (555 nm). The detection limit was 6 ppb for phosgene with a sampling time of 60 sec and a flow rate of 400 ml/min. Reproducibility tests showed that the relative standard deviation of response ($n = 10$) was 2.6% for 0.2 ppm phosgene. No interference was observed from ethanol (1 vol.%), trichloroethylene (1 vol.%), acetone (1 vol.%), carbon dioxide (4.9 vol.%), carbon monoxide (100 ppm), nitrogen dioxide (100 ppm), sulfur dioxide (50 ppm), hydrogen chloride gas (5 ppm), chlorine (3 ppm), acetic acid gas (24 ppm), ammonia (40 ppm), or benzyl chloride (20 ppm).

Phosgene is a highly toxic, colorless, irritating gas. It is important in dye manufacture and in the production of polycarbonate and polyurethane resins, carbamates, organic carbonates, chloroformates, and pesticides. Its occurrence in air is often unpredictable, since many organochlorine compounds thermally and photochemically decompose into phosgenes. Phosgene may also be important in air pollution study, since phosgene is synthesized in the lower troposphere by photochemical smog reactions of halocarbons. The establishment of a threshold limit value of 0.1 ppm of phosgene in air[1] emphasized the need for a sensitive, reliable, and specific method for the determination of phosgene in industrial environments. Several methods have been reported for the detection of phosgene, including colorimetric procedures[2–5] and chromatographic techniques,[6,7] but to achieve widespread routine use, the method should be simple, specific, capable of unattended operation, and also inexpensive. However, few methods exhibit all these desirable performances. Consequently, we chose a tape monitor because of its high sensitivity and selectivity, easy maintenance, continuous monitoring function, small size, low running cost and greater ease of operation in the automatic mode.[8] We investigated a suitable reagent that reacts with phosgene to produce a color stain. Of the investigated colorimetric procedures, the most specific and sensitive reagent used for phosgene was a mixture of 4-*p*-nitrobenzylpyridine (NBP) and *N*-benzylaniline (BA).[4] We studied tape impregnated with these reagents in order to determine phosgene concentrations less than 0.1 ppm in air. In this paper, we described a study to develop a monitoring tape for the determination of phosgene in air in the range 6 ppb to 0.2 ppm. The concentration of NBP and BA in processing solution, gas flow-rate, sampling time, reproducibility, effect of temperature and humidity of sample gas, and stability of the tape and response to other gases were investigated to evaluate the characteristics of the tape for the determination of phosgene in air.

## EXPERIMENTAL

### *Reagents and samples*

A processing solution was prepared as follows. To *ca* 100 ml of methanol, 1.5 g of

4-*p*-nitrobenzylpyridine (NBP) and 3 g of *N*-benzylaniline (BA) were added.

Standard phosgene mixtures (0.2–0.03 ppm) were prepared continuously by purging a FEP Teflon permeation tube with various constant flows of purified air (99.9%; Taiyo Sanso).

Humidified phosgene mixtures were prepared by mixing dry air passing through a Gore-Tex (porous Teflon; 4 mm i.d, 6 mm o.d. and 50 mm length) tube immersed in water (25 ± 2°C) with 0.2 ppm phosgene.[9] The relative humidity of the gas mixture was determined by a humidity sensor (Model HMI32; Vaisala) in the gas flow.

*Monitoring tape*

The porous cellulose tape (Whatman 1Chr papers, 20 mm wide, 0.18 mm thick and 25 m length) was immersed in the processing solution for 1 min, oven-dried at 40°C and stored in a desiccator.

*Apparatus*

The experimental apparatus was similar to that previously used.[8] The end (*ca.* 1 cm in diameter) of tube from the suction unit is attached tightly to a tape. The sample gas was sucked through the tape at a constant flow rate (400 ml/min) and a constant sampling time (60 sec). A tape is continuously fed past and exposed to air from a sample draw line. When exposed to phosgene, the NBP-BA reagent on the tape reacted with phosgene to change its homogeneous color. The degree of color change was recorded by measuring the reflected light of 555 nm. Then the pathway of the tape was renewed by moving the tape every 60 sec. The response (reflection absorbance, $A$) is defined by $A = -\log V_1/V_0$, where $V_0$ and $V_1$ are outputs of blank (an atmospheric air) and of the sample, respectively. The 30 min time was required to measure the responses after the tape was set in the tape monitor. All the measurements were carried out at 25 ± 2°C.

## RESULTS AND DISCUSSION

A review of the methods employed to detect trace amounts of phosgene in air disclosed that a few major approaches to the problem had been investigated: (1) determination of chloride ion after hydrolysis, (2) colorimetric analysis. In the first category attention was turned to procedures that depend on the hydrolysis of phosgene to $CO_2$ and HCl: $COCl_2 + H_2O \rightarrow CO_2 + 2HCl$. We studied tape using pH indicator reagents,[10] such as Methyl Yellow, for monitoring tape of acidic gases, which is a highly sensitive means of detecting HCl.[11] In this experiment, we studied tape impregnated with Methyl Yellow for phosgene gas. However, this tape was not successful in detecting 1 ppm phosgene.

In the following sections, we investigate colorimetric analysis; in this experiment, we examined tape using NBP–BA reagents that had obtained good results for phosgene in previous reports.[4] It was concluded that tape impregnated with NBP–BA reagent could serve as a sensitive monitoring tape for phosgene, but the tape impregnated with only NBP was not sensitive for phosgene (1 ppm).

*Reflectance spectra*

After this tape had been exposed to 0.2 ppm phosgene for a sampling time of 60 sec at a flow rate of 400 ml/min, the visible reflectance spectrum of the exposed tapes was recorded with a UV-2200 spectrophotometer (Shimadzu), using a freshly prepared barium sulfate disk as a reference standard (Fig. 1). The solid and broken spectra show the reflectance spectra of the tape exposed to 0.2 ppm phosgene and air (without phosgene), respectively.

*Concentration of NBP-BA reagent*

To obtain the optimum conditions for the detection of phosgene, the response for phosgene was measured with various concentrations

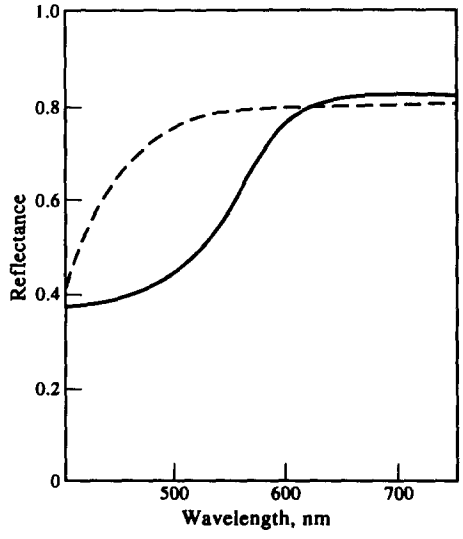

Fig. 1. Reflectance spectra of tapes exposed to $COCl_2$ and air (reference: $BaSO_4$ disk). The solid and broken lines show the reflectance spectrum of the tape exposed to $COCl_2$ in air and air, respectively.

Table 1. Effect of concentration of 4-*p*-nitrobenzylpridine (NBP) and N-benzylaniline (BA) in processing solution on response

| Concentration in processing solution (%) | | |
|---|---|---|
| NBP | BA | Response |
| 0.025 | 0.5 | 0.069 |
| 0.50 | 1.0 | 0.094 |
| 1.5 | 3.0 | 0.105 |
| 2.5 | 5.0 | 0.106 |
| 3.5 | 7.0 | 0.108 |

Concentration of $COCl_2$: 0.2 ppm.
Sampling time: 60 sec.

of NBP–BA reagent (mixture of NBP and BA in the ratio of 1:2, we confirmed it by an analysis of NBP and BA in the mother liquor after the reaction was complete) in the processing solution and various flow-rates of the sample gas. The response for phosgene increased with an increase in concentration of NBP–BA reagent and increased slightly at levels about 1.5 wt% NBP in the processing solution (Table 1). The processing solution used was prepared with 1.5 wt%:NBP–3.0 wt%:BA.

*Gas flow-rate*

Table 2 shows the effect of the sample gas flow-rate on response. The response increased with increase the sample gas flow-rate and slightly above 350 ml/min. The optimum sample gas flow-rate was estimated to be 400 ml/min.

*Sampling time*

The response for fixed concentration of phosgene was plotted against various sampling times. Nonlinear graphs between response and sampling time were obtained in the range 0.05–0.2 ppm and *vs.* sampling time in the range 10–90 sec (Fig. 2).

*Calibration graph*

Typical calibration graphs for phosgene using the optimum experimental condition are shown in Fig. 3. A linear relation was obtained in the region of 0.03–0.2 ppm of phosgene. The response for 0.8 ppm of phosgene was 0.32 which corresponded to 80% for 0.8 ppm. By using optimum conditions, the detection limit (signal-to-noise ratio = 3) was 6 ppb for phosgene with a sampling time of 60 sec. Reproducibility tests ($n = 10$) showed that the relative standard deviation of response was 2.6% for 0.2 ppm phosgene, and the relative standard deviation of the calibration graph was 3.5%.

Table 2. Effect of sample gas flow-rate on response

| Gas flow rate (*ml/min*) | Response |
|---|---|
| 100 | 0.037 |
| 200 | 0.058 |
| 300 | 0.084 |
| 350 | 0.100 |
| 400 | 0.106 |
| 500 | 0.107 |

Concentration of $COCl_2$: 0.2 ppm.
Sampling time: 60 sec.

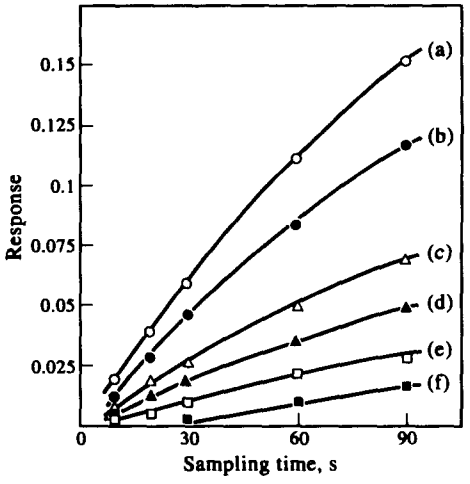

Fig. 2. Relation between sampling time and response at various concentrations of $COCl_2$. Flow rate: 400 ml/min [$COCl_2$]: (a) 0.2 ppm, (b) 0.15 ppm, (c) 0.1 ppm, (d) 0.075 ppm, (e) 0.05 ppm, (f) 0.03 ppm.

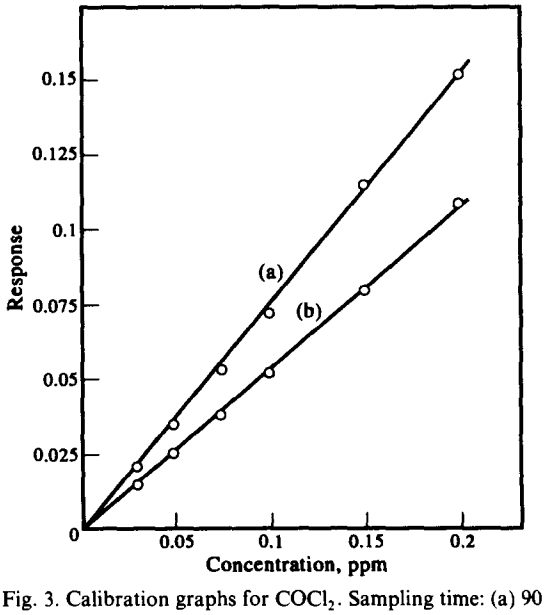

Fig. 3. Calibration graphs for $COCl_2$. Sampling time: (a) 90 sec, (b) 60 sec.

Table 3. Effect of humidity of sample gas on response

| Humidity (%) | Response |
|---|---|
| 10 | 0.084 |
| 30 | 0.097 |
| 40 | 0.105 |
| 50 | 0.105 |
| 60 | 0.110 |
| 80 | 0.110 |

Concentration of $COCl_2$: 0.2 ppm.
Sampling time: 60 sec.

*Humidity of sample gas*

Table 3 shows the effect of humidity of sample gas on the response of the tape. The tape was hardly affected by humidity in the region 30–80%RH used in this experiment, but response decreased gradually at levels below 30%RH. It can be concluded that there is very little effect of humidity on the response of the tape under normal conditions (40–60%RH).

*Temperature of sample gas*

Table 4 shows the effect of the temperature of sample gas variation within the range of 0–40°C on the response of the tape. The tape is hardly affected by temperature in the region 0–30°C used in this experiment, but decreased gradually at levels above 30°C. It can be concluded that there is very little effect of temperature on the response of the tape under normal conditions (10–30°C).

*Selectivity*

The response of the tape for various gases are given in Table 5. The tape is hardly affected by other gases in the concentration ranges used in this experiment, except for acetyl chloride.

*Long-term stability*

As it is very important in the preparation of a reliable tape to use high stable reagents on exposure to air, its stability in a desiccator was studied. The relationship between storage time and response of the tape impregnated with NBP–BA reagent was investigated (Table 6). After storage for about 3 months in a desiccator the response for phosgene was 90% of the original level.

In conclusion, the monitor tape impregnated with NBP–BA reagent is very suitable for the determination of phosgene concentrations in the range 0.006–0.2 ppm. This tape monitor method is simple, specific, capable of unattended operation and is recommended for field operation.

Table 4. Effect of temperature of sample gas on response

| Temperature (°C) | Response |
|---|---|
| 0 | 0.108 |
| 10 | 0.108 |
| 20 | 0.105 |
| 30 | 0.094 |
| 40 | 0.084 |

Concentration of $COCl_2$: 0.2 ppm.
Sampling time: 60 sec.

Table 5. Response for various gases

| Gas examined | Concentration of gas | Response |

# APPLICATION OF A CHOLINESTERASE BIOSENSOR TO SCREEN FOR ORGANOPHOSPHORUS PESTICIDES EXTRACTED FROM SOIL

SATISH KUMARAN and MASATOSHI MORITA*

National Institute for Environmental Studies, 16-2 Onogawa, Yatabe, Tsukuba, Ibaraki 305, Japan

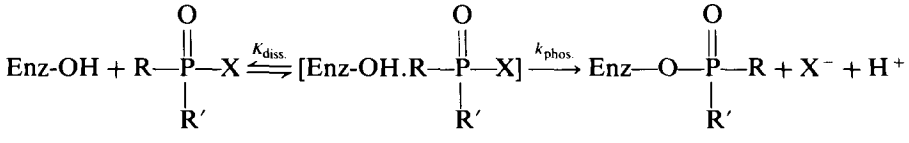
(*Received* 20 *January* 1994. *Accepted* 4 *August* 1994)

**Summary**—Based on the principle of enzyme inactivation, a butyrylcholinesterase (EC 3.1.1.8.) biosensor, to determine some organophosphorus (ORP) pesticides (Fenitrothion, Diazinon, Parathion ethyl, Mevinphos and Heptenophos) in soil extracts, is presented. The enzyme was immobilized on pre-activated Pall Biodyne™ transfer membranes, which were physically attached to the sensitive ends of glass pH electrodes. Contact of the enzyme with pesticide samples results in specific inhibition of enzyme activity. Sensor calibration was possible by correlating the inhibition of enzyme activity (monitored by observing reduction in electrode potential changes with substrate additions) with varying concentrations of pesticide compounds in a buffer solution. A simple procedure was designed to extract ORP pesticides from spiked soil samples using a mixture of dichloromethane and acetone as the extraction solvent mixture. The sensor was successfully used to determine pesticide concentrations ranging from a low of 35 ppb (Diazinon) to 21 ppm (Fenitrothion) in soil, with resultant relative standard deviations of percentage enzyme inactivation less than 12%. The complete extraction and analytical procedure is simple, inexpensive and rapid. Mass production of the enzyme membranes and their easy attachment to the electrodes, render them disposable after a single use. The biosensor is seen as a potential analytical instrument for early warning against pesticide contaminations in soil.

Organophosphorus (ORP) pesticides represent a very large part of agricultural chemicals in widespread use. Owing to their potential mammalian toxicity, the monitoring of pesticide residues in agricultural and food products and in environmental matrices has become a priority field in pesticide research and analysis. The agricultural usage of such chemicals leave residues in soil from fall-out from aerial spraying, in rain or dust or from plant or animal which become incorporated with the soil. Thus, the soil is an environmental reservoir for these residues from which they move into the atmosphere, water or living organisms.

The most common method to analyse organophosphate residues is gas chromatography (GC) with nitrogen–phosphorus or flame-photometric detection, although liquid chromatography is also receiving attention for high detection sensitivity and selectivity.[1] Several extraction procedures and clean-up approaches have been reported for numerous pesticides from soil.[2–5] In most cases, these techniques for extraction and analysis are laborious, time-consuming and expensive.

The toxicity of several ORP pesticides to mammals has been studied quite extensively and is well documented.[6] The inhibition of cholinesterases by these compounds is the result of the formation of stable covalent intermediates such as phosphoryl–enzyme complexes, which hydrolyze very slowly. The reaction scheme below represents the inhibition of the enzyme by an organophosphorus ester.



Since the inhibition mechanism is very specific, several analytical techniques have been

*Author to whom correspondence should be addressed.

developed for the determination of such pesticides on the basis of cholinesterase inhibition.[7-10] Recently, a bienzyme sensor[11] has been reported for the determination of organophosphorus pesticides. The biosensor is based on the immobilization of choline oxidase and butyrylcholinesterase on a preactivated nylon membrane attached to a hydrogen peroxide electrode. In yet another study,[12] only butyrylcholinesterase was immobilized onto such preactivated polyamide membranes and used in conjunction with pH glass electrodes to determine organophosphorus and carbamate pesticides. The present work deals with this simple, rapid and inexpensive method to determine ORP pesticides in soil extracts, beginning from sample extraction to the use such butyrylcholinesterase-based biosensors for analysis.

## EXPERIMENTAL

### *Reagents*

Butyrylcholinesterase (EC 3.1.1.8) from horse serum, with a reported specific activity of 18 units/mg protein, was purchased from Sigma Chemical (St. Louis, MO, U.S.A.), and was used as such without any treatment. Butyrylcholine chloride (Sigma Chemical) was used as substrate.

Polyamide pre-activated Pall Biodyne™ general purpose transfer membranes (Type A, porosity 3 $\mu$m), said to present 50% carboxylic and 50% amine groups for protein attachment, were obtained from Nippon Genetics Co., Japan.

The ORP pesticides, Fenitrothion, Diazinon, Parathion Ethyl, Mevinphos and Heptenophos were Pestanal® chemicals, all purchased from Riedel de-Haen AG (D-3016, Seelze, Germany). Stock solutions of the ORP compounds were made in HPLC grade acetonitrile (Cica Merck).

Bromine water (2–3% w/v) from Wako Chemicals, Japan, was used to oxidize the ORP compounds containing P=S moieties to the corresponding P=O esters, thereby making them more reactive as inhibitors.

The composition of the working buffer, used for the preparation of the substrate solution and to conduct the potential measurements, was $2.5 \times 10^{-3}M$ HEPES [4-(2-hydroxyethyl)-piperazine-1-ethane sulfonic acid] from Sigma Chemical, containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatine (Sigma Chemical) from porcine skin. The pH of the buffer was adjusted to 7.55 before use.

Dichloromethane and acetone (both min. 99.5% purity) were purchased from Wako Chemicals, Japan, and used to prepare the extraction solvent mixture.

Toyo Roshi filter paper No. 2 was used to filter the soil samples in the extraction procedure.

Milli-Q® water was used wherever necessary. All other reagents used were of analytical grade.

### *Enzyme immobilization and biosensor preparation*

Butyrylcholinesterase (3.8 mg) was dissolved in 1 ml sodium phosphate buffer ($2.5 \times 10^{-3}M$, pH 6.5). Six pieces of the transfer membrane measuring $15 \times 21$ mm$^2$ were cut and dipped into the enzyme solution one by one, each left immersed in the solution for only 2 min. The membranes were then dried in a stream of nitrogen. A casein blocking solution using phosphate buffered saline (PBS) pH 7.4 ($4 \times 10^{-2}M$ dihydrogen sodium phosphate, $8 \times 10^{-3}M$ in the sodium hydrogen phosphate, $0.15M$ sodium chloride) was freshly prepared. The 0.5% (m/v) solution of casein in PBS was heated to 60°C while stirring. The solution was left to cool to room temperature, before filtering through a 0.45 $\mu$m membrane filter to remove aggregates. The membranes were dipped in the blocking solution one by one, each being left immersed for 2 min. The membranes were completely dried in a stream of nitrogen before being cut into $3 \times 3$ mm$^2$ pieces and stored at 4°C.

The biosensor was prepared by attaching a $3 \times 3$ mm$^2$ piece of enzyme membrane to the bulb of the pH glass electrode (TOA pH combination electrode, Type GST-5425C). The attachment was done using a piece of nylon stocking material and a silicone 'O' ring (Fig. 1a).

### *Soil spiking and extraction*

Soil was collected from the Institute grounds by removing a trowel full down to about 10 cm. The matrix was placed in a tray and left to dry at about 35°C on top of an oven. The dried soil had a particle size distribution of $<0.125$ mm 11.9%, 0.5–0.125 mm 46.2% and $>0.5$ mm 41.9%. Total organic and clay content of the soil were found to be 16.1 and 6%, respectively. The fresh soil had a pH of 6.7 and a moisture content of 14.4%.

Spiking of the soil sample was done by injecting a known amount of the pesticide stock solution to a portion of 1 g ($\pm 0.005$ g) of soil

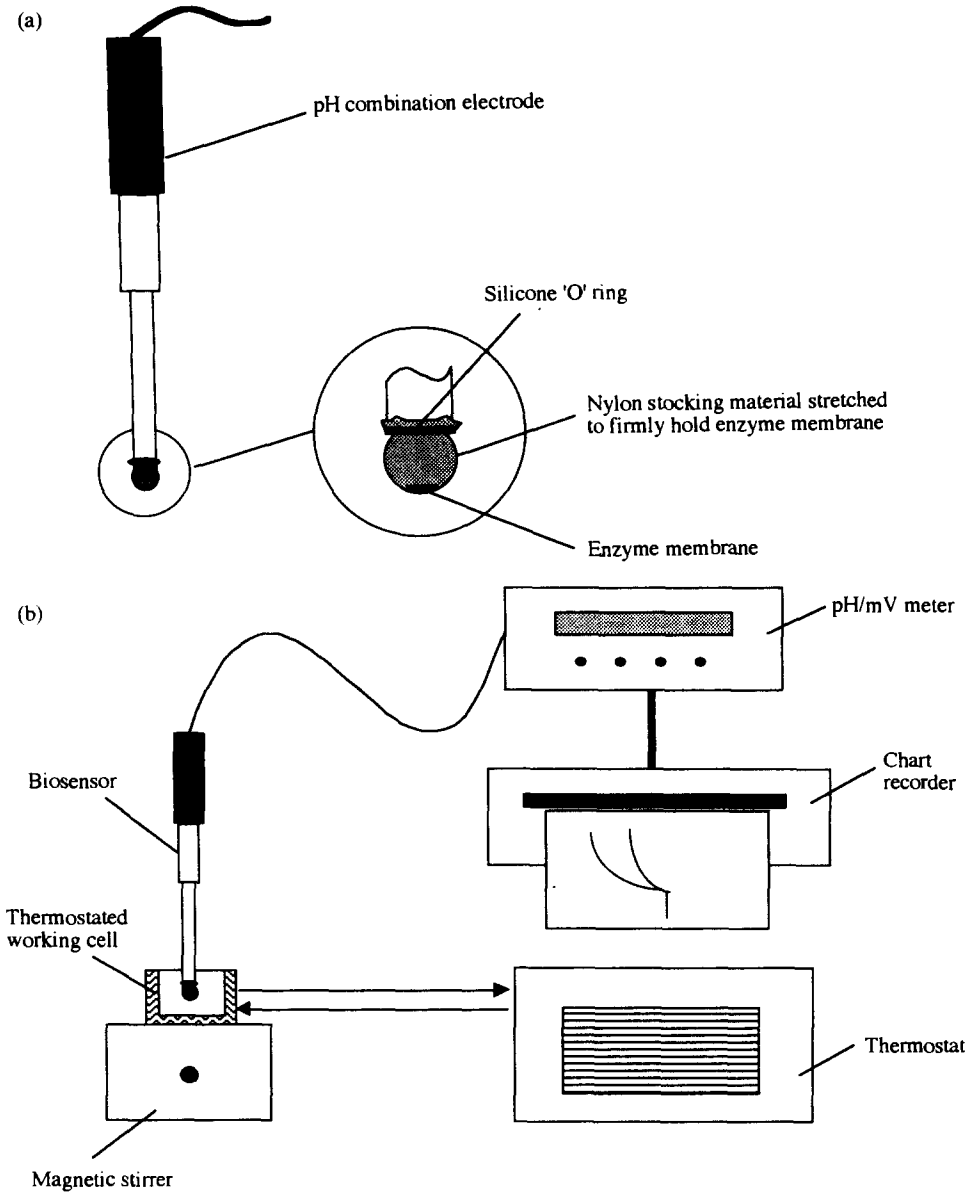


Fig. 1. (a) The biosensor. (b) The experimental set-up.

in a clean 10 ml graduated test tube. The tube was capped and the contents were mixed and left undisturbed overnight at room temperature.

Anhydrous sodium sulfate (100 mg) and 5 ml of a dichloromethane/acetone mixture (2/1 v/v) were added to the spiked soil sample before leaving the tube in a sonicating bath for 2 min. The mixture in the tube was then shaken vigorously by hand for 15 min. The sample was filtered and the cake was washed with an additional 10 ml of solvent mixture. The test tube containing the filterate and washings was placed in a water bath at 35°C with nitrogen bubbling into it till all solvent was completely evaporated.

To the dry residue in the test tube, 100 $\mu$l of acetonitrile was added and mixed, before topping the volume to 10 ml with HEPES working buffer. The tube was left in the sonicator for 2 min to ensure that no residue remained attached to the walls of the test tube. The contents of the tube were then poured into the working cell for analysis.

*Apparatus and analytical procedure*

Figure 1b represents the experimental set-up. The potential measurements were conducted in 25 ml magnetically stirred cells, maintained at 25°C with a thermostat (Endocal RTE 210). The biosensor was linked to a pH meter (TOA

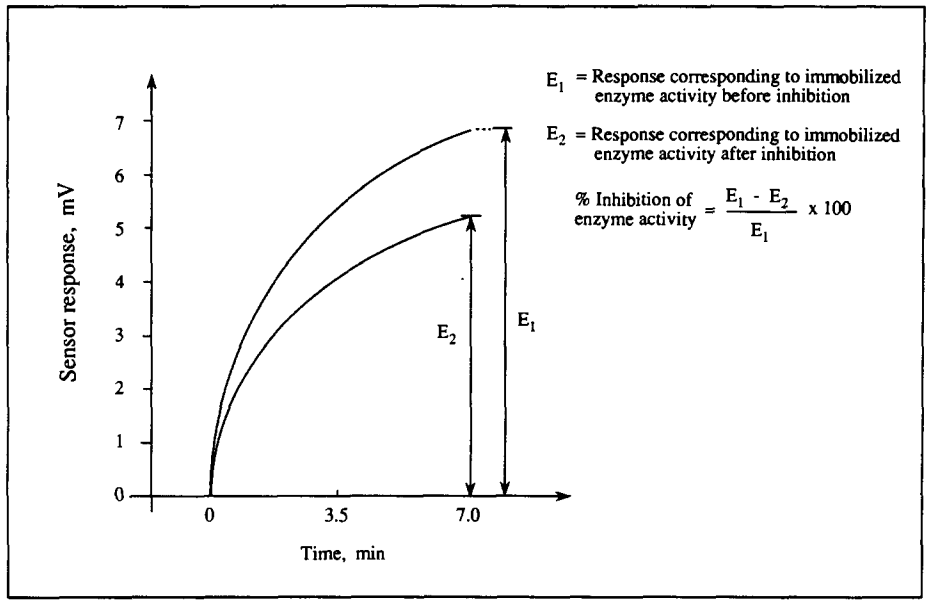

Fig. 2. Typical sensor response and calculation of enzyme inhibition.

Digital pH meter, Type HM-50V), connected to a chart recorder (Rikadenki R50).

The analysis was done by first conducting the blank tests: 20 ml of the HEPES working buffer was pipetted into the working cell and the biosensor placed into it. When a steady baseline was registered, 24 $\mu$l of 1$M$ butyrylcholine chloride was added to the cell. This resulted in a working substrate concentration of $1.2 \times 10^{-3}M$ in the cell.

Butyrylcholinesterase on the membrane catalyzes the hydrolysis of its substrate, butyrycholine, to choline and butyric acid according to the reaction below.

$$\text{Butyrylcholine} + H_2O \xrightarrow{\text{BuChE}} \text{choline} + \text{butyric acid.}$$

The acid dissociates further to release $H^+$ ions, resulting in a local variation of pH. This local variation of pH at the membrane is sensed by the electrode and the response is recorded.

The recording was stopped exactly after 7 min after addition of the substrate. This was done to avoid long waiting times before any steady-state in the electrode response was reached. The working cell was rinsed clean and refilled with the 10 ml HEPES buffer containing the dissolved pesticide residue along with another 10 ml of buffer. Where the pesticide being analysed was the sulfur analog, 4 $\mu$l of bromine water was added to the cell at this stage to transform it to the corresponding oxygen analog. The biosensor was then placed into the cell and the contact time between the enzyme membrane and the pesticide solution was noted. After a contact time of exactly 10 min, the substrate was once again added to the contents of the cell and the above procedure was repeated to note the electrode response. Figure 2 shows typical sensor responses and illustrates the procedure to calculate the percentage inhibition of enzyme activity, based on a diminished sensor response.

Calibration plots were initially made in plain buffer for the biosensor by adding different concentrations of pesticides directly to the working cell. Such plots were later used to determine the efficiency of pesticide extraction from spiked soil.

## RESULTS AND DISCUSSION

### *Choice of working conditions*

The composition of the working buffer, given above, was similar to that used in previous studies.[13] Figure 3 presents a calibration plot of the sensor to butyrylcholine. It was noticed that the response potential change remained below 15 mV, indicating that the number of active sites of the enzyme present in the membrane was suitable for inhibitor determination.[12] A working substrate concentration of $1.2 \times 10^{-3}M$ was chosen, as it was within the linear portion of the curve. The response potential change corresponding to the immobilized enzyme activity for this substrate concentration was about 6.5 mV.

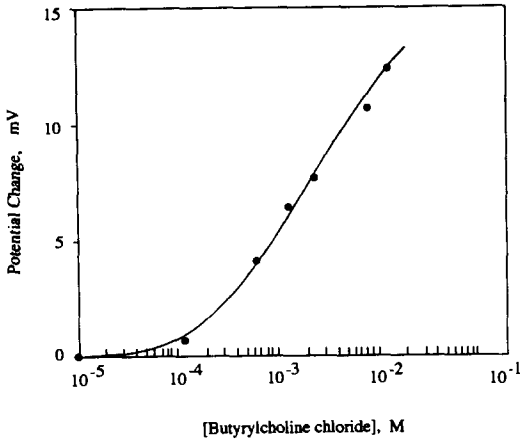

Fig. 3. Calibration plot for butyrylcholine. Working buffer: $2.5 \times 10^{-3}M$ HEPES, containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatin, temperature 25°C.

Earlier studies have demonstrated the high repeatability of measurements using enzyme membranes prepared in lots.[13] However, these membranes were also tested for repeatability in their response to consecutive substrate concentrations of $1.2 \times 10^{-3}M$. For three different membranes the RSD values were less than 5% ($n = 7$).

Figure 4 illustrates the influence of enzyme–pesticide contact time and temperature on the percentage inhibition of enzyme activity. The percentage inhibition was higher with longer contact time periods, indicating that better detection limits could be achieved with extended contact times. However, the experiments were conducted with a contact period of 10 min, in order to maintain a short analysis time. Furthermore, with a 10 min contact, satisfactory detection limits could be achieved with most of the pesticides tested. As expected, the temperature plot indicated a mixed influence on enzyme activity. With higher temperatures, the kinetics of inhibition and thermal deactivation of the enzyme were accelerated. This was seen as a rising curve without any optimum. A temperature of 25°C was chosen to conduct the experiments.

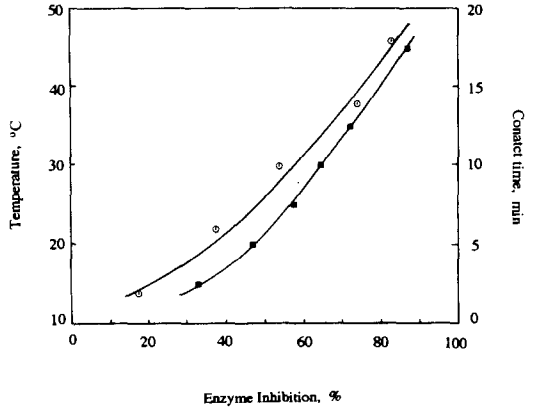

Fig. 4. Influence of enzyme–pesticide contact time (⊙ Heptenophos $3 \times 10^{-7}M$, temperature 25°C) and temperature (■ Mevinphos $8 \times 10^{-7}M$, contact time 10 min) on percentage inhibition of enzyme activity. Working buffer: $2.5 \times 10^{-3}M$ HEPES, containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatin.

Before the experiments were conducted, tests were done to ensure that blank soil extracts or acetonitrile (used to dissolve the pesticides) or bromine water (used for oxidation), did not inhibit the enzyme, individually or combined, at concentrations encountered in the analysis. No effect was observed with 100 $\mu$l acetonitrile in 20 ml buffer in contact with the enzyme up to 25 min. Bromine water, however, inhibited the enzyme and had to be maintained at additions of 4 $\mu$l in 20 ml buffer.

The tests showed that the blank extracts from soil used in this study contained no pH-modifying or other anticholinesterase substances. If pH-modifying substances are co-extracted, the working buffer concentration will have to be correspondingly changed to counter their effect. Other possible interferences in such an analytical method can arise mainly owing to the presence of anticholinesterase compounds such as carbamates, nicotine, $Pb^{2+}$ and $F^-$ ions.[13]

*ORP pesticide analysis*

Calibration plots of the biosensor were made showing extent of enzyme inactivation with varying concentrations of the different pesticides in the working cell, when they were added directly into it. Figure 5a and b are plots for Fenitrothion and Diazinon, respectively. Depending on the inhibitory power of the compound, different limits of detection were observed. Here, the enzyme was more sensitive to Diazinon, (detection limit: $10^{-8}M$) than Fenitrothion (detection limit: $3 \times 10^{-6}M$), both corresponding to a reduction in the response potential change of 1.1–1.7 mV.

Calibration plots showing enzyme inhibition from spiked soil extracts for Fenitrothion and Diazinon are presented in Figure 6a and b. Determination of Fenitrothion was possible in the range from 10 to 320 ppm in soil, while for Diazinon the range was from 10 to 500 ppb.

Since the RSD for the plain substrate injections as reported above was up to 5%, a reduction of about 1.2–1.5 mV in response potential change or 20% in sensor response

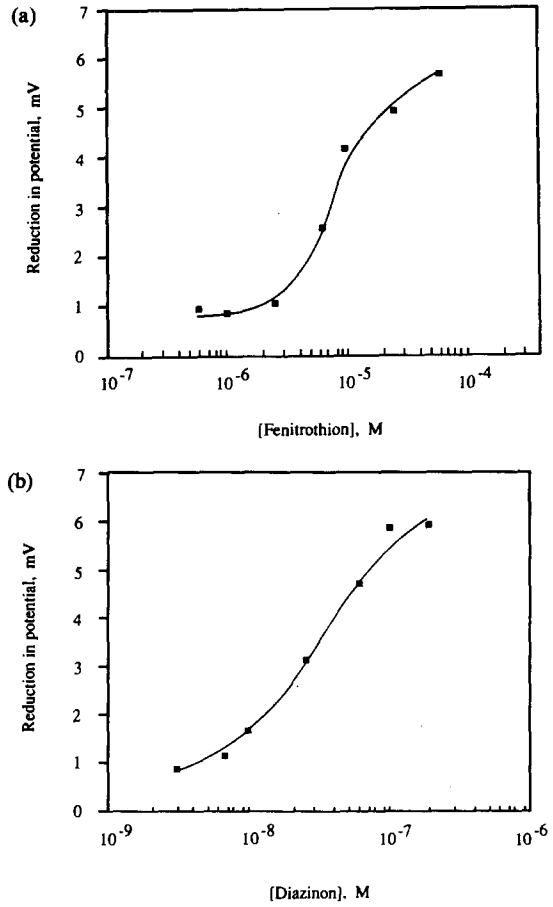

Fig. 5. (a) Calibration plot for Fenitrothion in $2.5 \times 10^{-3}M$ HEPES buffer containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatin, temperature 25°C, contact time 10 min. (b) Calibration plot for Diazinon in $2.5 \times 10^{-3}M$ HEPES buffer containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatin, temperature 25°C, contact time 10 min.

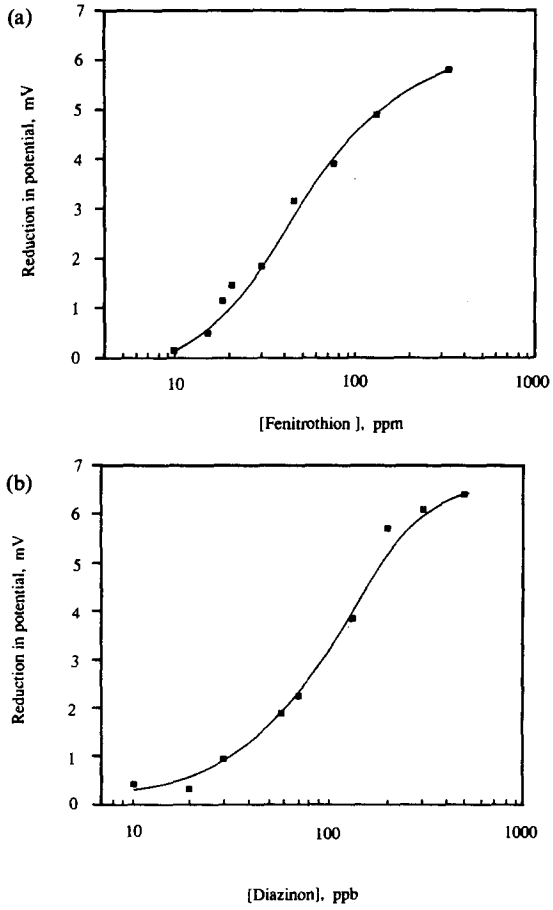

Fig. 6. (a) Calibration plot for Fenitrothion in soil. Working buffer: $2.5 \times 10^{-3}M$ HEPES, containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatin, temperature 25°C, contact time 10 min. (b) Calibration plot for Diazinon in soil. Working buffer: $2.5 \times 10^{-3}M$ HEPES, containing $2 \times 10^{-2}M$ $MgCl_2$, $0.1M$ NaCl and 0.01% (m/v) gelatin, temperature 25°C, contact time 10 min.

(which translates to about 3 times the standard deviation encountered for plain injections) was considered safe to indicate enzyme inactivation owing to the presence of the pesticides. The pesticide concentration leading to a 20% inactivation was, therefore, chosen to represent the detection limit measured by the biosensor.

The detection limits obtained by the sensor (spiked pesticide concentrations) for which the average enzyme inhibitions ranged from 18.6 to 21.1% are presented in Table 1. The corresponding RSD values of the percentage enzyme inhibitions and range of reductions in response potentials are also reported. It was observed that the RSD values remained less than 12%. Data on efficiency of the extraction method as measured from the sensor response is also presented. At concentrations corresponding to the

Table 1. Detection limits of the ORP pesticides tested

| ORP pesticide | Detection limit* | Reduction in potential ($mV$) | Average % inhibition | RSD (%) ($n = 3$) | Average extraction efficiency (%)† | RSD (%) ($n = 3$) |
|---|---|---|---|---|---|---|
| Fenitrothion | 21 ppm | 1.4–1.7 | 20.8 | 7.8 | 75.4 | 9.6 |
| Diazinon | 35 ppb | 1.1–1.4 | 20.3 | 8.8 | 136.2 | 9.4 |
| Parathion ethyl | 3.9 ppm | 1.0–1.4 | 20.5 | 10.7 | 100.0 | 13.6 |
| Mevinphos | 1.4 ppm | 1.2–1.6 | 21.1 | 11.6 | 83.3 | 13.1 |
| Heptonophos | 650 ppb | 1.1–1.4 | 18.6 | 5.4 | 44.8 | 6.2 |

*Corresponds to pesticide concentration spiked in soil (1 ppm = 1 $\mu$g/g, 1 ppb = 1 ng/g).
†As determined from biosensor calibration plots made with pesticide addition into working buffer.

detection limits of the ORP pesticide compounds, the average extraction efficiencies varied from 44.8% (Heptenophos) to 136.2% (Diazinon), with RSD values less than 14%. Such wide variations can only be a result of the low concentrations and possible interactions of the pesticide compounds with organic matter and clay present in soil.

As determined in other studies,[12] the activity of the immobilized enzyme is rapidly lost with continuous use, although when stored dry at 4°C, they have been found to retain their original activities even after a period of 3 years. The membranes prepared in this work showed similar trends. On average, they lost about 65 and 85% of their original activity after 3 and 7 days, respectively. No significant enzyme activity was noticed after 10 days. This rapid loss in activity with continuous use, however, need not be viewed as a disadvantage because the same membrane is not used continuously. Since the enzyme membranes can be mass produced and possess excellent storage stability, they can be discarded after a single use.

## CONCLUSIONS

Determination of ORP pesticides in soil extracts with the butyrylcholinesterase biosensor presents an approach which is cheap, simple and fast. No sophisticated instrumentation nor highly skilled personnel are required to conduct the tests. The pre-activated transfer membranes used for enzyme immobilization are inexpensive and easily available. The enzyme membranes can be mass produced and stored for several years before use. Since the construction of the biosensor involves easy attachment of the membranes to the pH electrode, the need to reactivate or reuse these membranes after enzyme inhibition is precluded, thereby making them disposable after a single use. Beginning from extraction of the pesticide compound by the described procedure, only about an hour is required to obtain the analytical result.

The biosensor demonstrates the possibility of achieving satisfactory detection limits, although these can be improved at the cost of analysis time. Once calibrated, the biosensor can be used as an analytical instrument to screen for ORP pesticides on a routine basis, especially in situations which demand an early warning of soil contamination.

# PREPARATION OF POLYPYRROLE-COATED PLATINUM MODIFIED ELECTRODE IN CHLOROFORM IN THE PRESENCE OF VARIOUS SUPPORTING ELECTROLYTES AND ITS USE FOR THE CATALYTIC OXIDATION OF HYDROQUINONE IN AQUEOUS AND CHLOROFORM SOLUTIONS

M. H. POURNAGHI-AZAR* and R. OJANI
Electroanalytical Chemistry Laboratory, University of Tabriz, Tabriz, Iran

(*Received* 16 *June* 1994. *Accepted* 12 *September* 1994)

**Summary**—Polypyrrole (PPy)-coated platinum modified electrode was prepared electrochemically in chloroform in the presence of tetrabutylammonium perchlorate, tosylate, tetrafluoroborate, periodate, and hydrogen sulphate. Evidence in favour of the occurrence of a redox reaction at the film/solution interface was given by ferrocene oxidation. The electrocatalytic effect of the PPy-coated electrode was revealed by oxidation of hydroquinone on it in water and chloroform. The influence of dopant anion, method of electrosynthesis and operation temperature were demonstrated. The calculated heterogeneous electron transfer rate constant ($k^o$) at the PPy-modified Pt electrode at 25°C was $1.4 \times 10^{-3}$ cm/sec which is 1000-fold greater than the value ($< 10^{-6}$ cm/sec) reported for bare electrode.

One of the important applications of chemically modified electrodes is the electrocatalysis of electrochemical reactions. Among electronically conducting polymers for making modified electrodes, polypyrrole (PPy) has received much attention since 1979 when it was synthesized by Diaz *et al.*[1] The ability of PPy to electrocatalysis some electrochemical reactions has been reported.[2–4] Many investigations have shown the influence of solvent, supporting electrolyte, operation temperature, monomer concentration and method of electropolymerization on the properties of PPy.[5–7] According to previous studies, the polymerization of pyrrole is performed in aprotic solvent[7] and acetonitrile has been the most commonly used solvent. Recently, PPy was prepared on a platinum electrode in acetonitrile and its electrocatalytic effects demonstrated.[8]

The high dissolving power and extracting property of chloroform against organic, organometallic and pharmaceutical compounds, make it as an excellent solvent and the study of electrochemical behaviour of these compounds at bare and chemically modified electrodes is interesting in order to develop new electroanalytical methods.[9–12]

It is the aim of this work to electrosynthesize PPy on a Pt electrode in chloroform as an aprotic solvent, convenient for the electropolymerization which proceeds via a radical mechanism, and used the PPy-coated platinum modified electrode to catalyse some slow oxidation processes in aqueous and particularly in chloroform media for analytical purposes. In this context we report the ability of PPy film prepared in chloroform to oxidize hydroquinone in both media and demonstrate the influence of the type and concentration of dopant anion, electropolymerization method and operation temperature on the electrocatalytic effects.

## EXPERIMENTAL

### *Chemicals*

The solvent was chloroform GR from E. Merck. The supporting electrolytes were tetrabutylammonium perchlorate (TBAP), tetrafluoroborate (TBATFB), periodate (TBAPI) from Janssen; benzoate (TBABz) and tosylate (TBATS) prepared in our laboratory according to the following procedures.

*Author to whom correspondence should be addressed.

*Preparation of TBATS.* A given amount of *p*-toluenesulphonic acid was dissolved in distilled water and the solution neutralized by gradual addition of a required volume of 40% aqueous solution of tetrabutylammonium hydroxide (TBAOH) using a pHmeter. The salt (TBATS) was extracted into chloroform and the white crystalline salt obtained by evaporation of the solvent.

*Preparation of TBABz.* A stoichiometric amount of benzoic acid (insoluble in water) and NaOH (1:1 mol/mol) were introduced in a given volume of water, the soluble sodium benzoate was formed, a required volume of 40% aqueous solution of TBAOH was added and TBABz was extracted into chloroform, the solvent was evaporated and the TBABz was obtained.

The other reagents were of analytical grade, the water was deionized and distilled. The solutions were bubbled with $N_2$ gas (99.99) for 30 min and kept under nitrogen atmosphere during the electrochemical experiments.

*Apparatus*

All voltammograms were recorded with a three electrode system using an EG&G model 273 potentiostat/galvanostat, electrochemical analysis software 3,00 model 270 with an IBM personal computer connected to an Epson model FX-850 printer. Working electrodes were bare and PPy-coated Pt electrodes (area 0.126 $cm^2$ from EG&G). The reference electrodes were SCE in aqueous media and Ag/AgI in chloroform as previously described.[9] A UTU.ZN-68/CZSP-D-98 thermostat from Poland was used for thermostatting the polymerization media.

*Electropolymerization*

The working electrode surface was polished using a thin layer of alumina powder (0.05 $\mu$m), then washed with water and acetone, respectively and used after drying. The PPy films were prepared in 0.5*M* solutions of dopant anion and 0.1*M* pyrrole in chloroform. In the potentiostatic method the applied potential was 1.2 V *vs.* the reference electrode. In the galvanostatic method the current density was 15 $\mu A/cm^2$ (E = 1.1 V) and in the potentiodynamic method the potential was scanned between −0.4 and 1.2 V with a scan rate of 50 mV/sec. Grafting the films onto electrode was stopped when an amount of charge equal to 3 mC had been passed. During the polymerization, the solution were thermostatted.

## RESULTS AND DISCUSSION

*Electrochemical behaviour and properties of the PPy films*

Cyclic voltammograms (CVs) of PPy–$ClO_4^-$ films prepared by different electrochemical methods were recorded in 0.5*M* TBAP–chloroform solution in the absence of the monomer (Fig. 1). The peaks related to doping–undoping cycle were observed at about 0.24 and 0.04 *V*. The corresponding process may be shown as follows:

$$PPy_f^\circ + A_s^- \rightleftharpoons PPy^+A_f^- + e_m$$

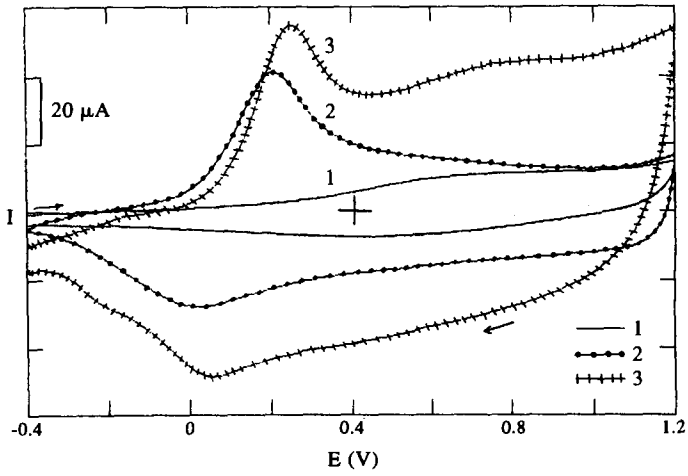

Fig. 1. The CVs of PPy–$ClO_4^-$-coated Pt electrode in 0.5*M* TBAP–$CHCl_3$. PPy films were synthesized (1) potentiodynamically (scanned between −0.4 and 1.2 V), (2) galvanostatically (current density, 15 $\mu A/cm^2$; electrode potential, 1.1 V) and (3) potentiostatically (potential was controlled at 1.2 V). The deposition charges in all cases were approximately 2 mC. The scan rate was 50 mV/sec.

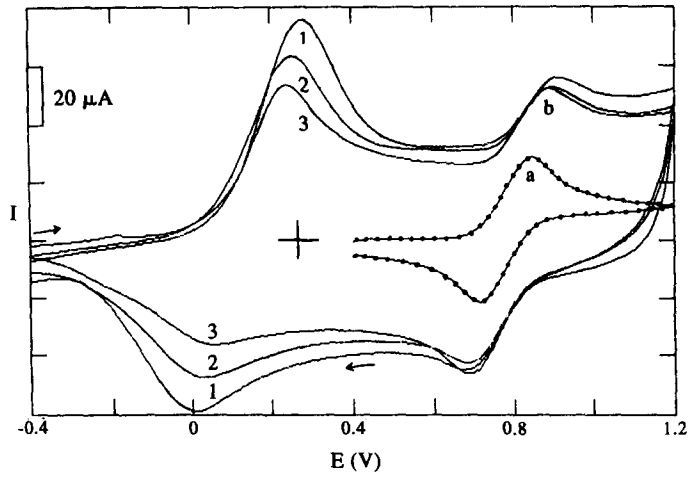

Fig. 2. The CVs of 1 m*M* ferrocene (a) on bare Pt electrode and (b) PPy–$ClO_4^-$-coated Pt electrode with various thickness of the PPy film in 0.5*M* TBAP chloroform solution. The deposition charges were (1) 3 mC, (2) 2.5 mC, (3) 2 mC. The ferrocene peak fell at higher potentials, scan rate was 50 mV/sec.

or

$$PPy\ A^-B_f^+ \rightleftharpoons PPy^+A_f^- + B_s^+ + e_m.$$

Where subscripts s, f and m refer to solution, polymer and metal, respectively. $A^-$ and $B^+$ show the anion or cation intervening in the doping–undoping cycle.

The PPy film prepared by the galvanostatic method was oxidized at a lower potential value than the others and gave redox peaks with a low charging current (Fig. 1). Therefore, we have used this method for the electrochemical experiments in this work.

The PPy films prepared by each method were very stable and quasi-metallic yellowish which changed to brown and dark-green with increasing film thickness. The oxidation of ferrocene at the PPy-coated Pt electrode with various thickness reveals that the redox process was localized at the film/solution interface, because the height of the anodic peaks does not depend on the thickness (Fig. 2), which is typical of the diffusion controlled conditions.

*Oxidation of hydroquinone on the PPy-modified electrode*

The CVs of $H_2Q$ on bare and PPy-coated Pt electrodes in 0.1*M* $LiClO_4$ aqueous solution at pH 2 are shown in Fig. 3. The peak separation potentials $\Delta E_p$ is equal to 550 mV on bare electrode which decreased to 140 and 90 mV at scan rates of 50 and 20 mV/sec, respectively on the

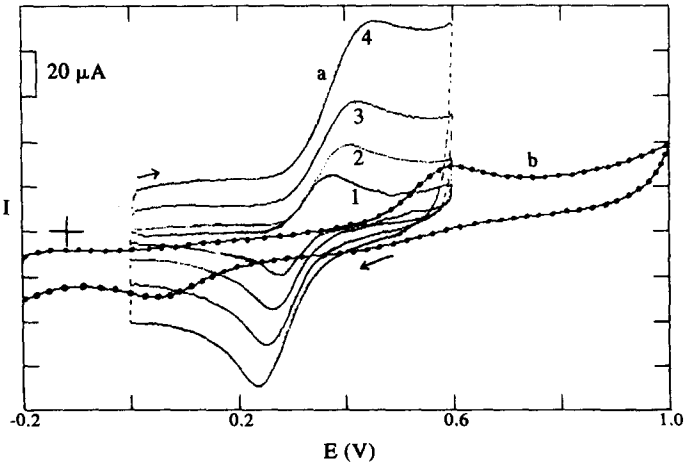

Fig. 3. The CVs of 1 m*M* hydroquinone (a) on PPy–$ClO_4^-$-coated Pt electrode in 0.1*M* $LiClO_4$ aqueous solution, pH 2, at various scan rates: (1) 20, (2) 50, (3) 100, (4) 200 mV/sec and (b) bare Pt electrode with a scan rate of 50 mV/sec. The polymer was prepared by the galvanostatic method and deposition charge was about 3 mC.

$V = 50$ mV/sec.
*Electrocatalytic effect.

PPy-coated electrodes (Fig. 3). Using the method proposed by Nicholson[13] the heterogeneous electron transfer rate constant ($k^\circ$) value on the PPy-coated Pt was obtained at $1.4 \times 10^{-3}$ cm/sec which is about 1000-fold greater than the value at the bare electrode ($10^{-6}$ cm/sec).[14]

The decrease of $\Delta E_p$ for $H_2Q$ CVs from 813 mV at the bare electrode to 550 mV at the PPy-coated electrode at a scan rate of 50 mV/sec in 0.5$M$ TBAP–chloroform solution also illustrates the electrocatalytic effect of the polymer on the oxidation of hydroquinone in chloroform. The characteristic data for the oxidation of $H_2Q$ on the bare and PPy-modified Pt electrodes in aqueous and chloroform media are given in Table 1.

*Influence of the electropolymerization conditions*

The parameters affecting the electrocatalytic properties of PPy films were the type and concentration of dopant anion, method of electro-

polymerization and operation temperature. The CVs of 1 m$M$ $H_2Q$ in 0.1$M$ $LiClO_4$ aqueous solution at pH 2, at PPy-coated Pt electrode prepared in chloroform solutions of some dopant anions such as $ClO_4^-$, $BF_4^-$, $IO_4^-$ and tosylate are shown in Fig. 4. The characteristic data are given in Table 2. The greatest electrocatalytic effect was from $ClO_4^-$ and the value of $\Delta E_p$ was minimum for a concentration of 0.5$M$ TBAP (Fig. 4). This may be attributed to (a) high oxidation level as well as high conductivity of PPy–$ClO_4^-$ films,[7] (b) relatively effective doping of PPy–$ClO_4^-$ film compared with the others during the electrochemical oxidation of $H_2Q$ in the presence of 0.1$M$ $ClO_4^-$ solution and (c) preventing release of $ClO_4^-$ ion in PPy–$ClO_4^-$ film placed in $ClO_4^-$ solutions. For $IO_4^-$ the background currents were most pronounced and the stability of PPy–$IO_4^-$ films was considerably lower, probably owing to its high oxidizing power. On the other hand, the chronopotentiogram recorded during the galvanostatic polymerization of pyrrole in $CHCl_3$–benzoate solution, showed that the potential of the working electrode did not remain at 1.1 V (electropolymerization potential of pyrrole) and immediately changed to a very positive value (> 1.8 V), therefore, electropolymerization did not occur. At the same time, the surface of the working electrode was contaminated by forming insoluble oligomers and the conductivity of the electrode fell dramatically. This behaviour is attributed to the basicity of the $Bz^-$ ion preventing the growth of the polymer chain.[15] This was confirmed by the addition of a stoichiometric amount of anhydrous sulphuric acid in order to convert $Bz^-$ to BzH which led to the polymerization of pyrrole in the presence of the $HSO_4^-$ formed.

Similar results were obtained in chloroform solution with 0.5$M$ TBAP + $10^{-3}M$ $H_2Q$. The characteristic data are shown in Table 2.

The influence of temperature on the electrocatalytic effect of PPy was demonstrated using the PPy-coated Pt electrode prepared at various temperatures in chloroform solution of 0.5$M$ TBAP. The CVs of $H_2Q$ at room temperature in water reveal that the electrocatalytic effect of the polymer is increased as the polymerization temperature varies from 0 to 35°C and then decreased when the temperature increased up to 45°C. The same results were obtained in chloroform. This behaviour was explained by the low conductivity of polymer at high temperature[16]

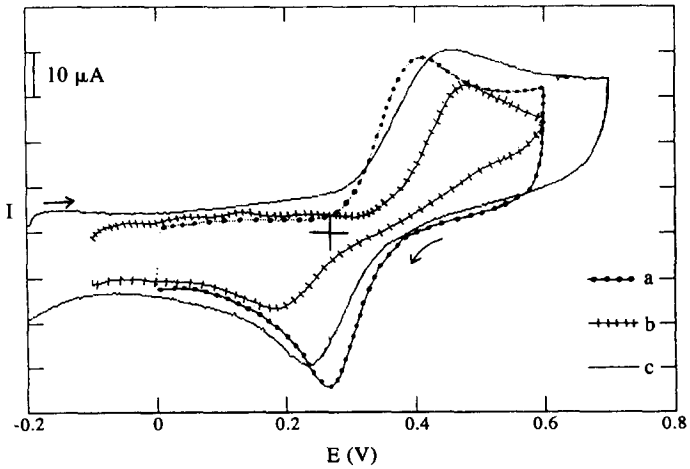

Fig. 5. The CVs of 1 m$M$ $H_2Q$ + 0.1$M$ $LiClO_4$ aqueous solution on PPy-coated Pt electrode prepared by various methods. (a) Galvanostatic, (b) potentiodynamic and (c) potentiostatic. The deposition charges in all three cases were approximately equal, scan rate: 50 mV/sec.

and the poor quality of films at low temperature.[17]

Another affecting parameter was the electrosynthesis method used for the preparation of PPy films. The experimental data obtained from the cyclic voltammetry of $H_2Q$ at PPy-coated Pt electrodes prepared by various methods confirm that the galvanostatic method was the most effective one as well as its electrochemical behaviour (Fig. 5).

## CONCLUSIONS

The results obtained from this study show that the electropolymerization of pyrrole can be performed in chloroform. The PPy film formed on the Pt disk electrode was very stable, quasi-metallic, smooth and coloured from yellowish to dark green depending on its thickness. The electrochemical activity of PPy film is affected by the method of electropolymerization and the best activity is observed for the galvanostatic method. The charge transfer reaction occurs at the film–solution interface. An obvious electrocatalytic effects of PPy film on the oxidation of $H_2Q$ at PPy-coated Pt electrode is observed in aqueous and chloroform solutions. The influence of polymerization conditions such as dopant anion, temperature and method of electrosynthesis on its electrocatalytic effect are evident. These findings suggest the possibility of using PPy-coated platinum electrodes as a chemically modified electrode for the catalysis of some slow oxidation processes in chloroform which are presently under investigation in our laboratory.

# FIBER-OPTIC CHLORINE PROBE BASED ON FLUORESCENCE DECAY OF *N*-(6-METHOXYQUINOLYL)-ACETOETHYL ESTER

SATYAJIT KAR*† and MARK A. ARNOLD

Department of Chemistry, University of Iowa, Iowa City, IA 52242, U.S.A.

(*Received* 6 *September* 1994. *Revised* 14 *October* 1994. *Accepted* 14 *October* 1994)

**Summary**—A fiber-optic probe for measuring chlorine in aqueous solution is evaluated. The probe uses a microporous gas-permeable membrane to trap a small volume of aqueous internal solution made of *N*-(6-methoxyquinolyl)acetoethyl ester (MQAE) in front of a fiber-optic assembly. The working principle of this probe is based on a combination of fluorescence quenching and redox reaction of MQAE by chloride ion and chlorine, respectively. While the magnitude of total fluorescence decay is independent of the sample concentration, the initial rate of decrease in fluorescence intensity is linearly proportional to the chlorine concentration over the range from 8.4 to 418 $\mu M$. Once the probe is exposed to a chlorine sample, the probe tip must be refilled with a fresh aliquot of the internal solution before the next measurement. In this mode, the probe displays excellent reproducibility; the relative standard deviation of the initial rate of fluorescence decay ($n = 3$) is only 1 percent. This probe can also be used for the measurement of hypochlorous acid (HOCl) in aqueous solution. The response properties are identical to those of the chlorine probe.

Chlorine sensing is particularly important because chlorine is used extensively in the chemical industry and in the sterilization of drinking water. The toxicity of chlorine[1] causes problems of overexposure during both manufacturing and use. The danger of pollution demands a sensitive and reliable method for the accurate measurement of chlorine.

The measurement of chlorine in water is complicated by interferences from the combined forms of chlorine (i.e. chloramines) and other potential disinfectants, such as chlorine dioxide and ozone[2]. The currently available methods for the determination of free chlorine are photometric[3], amperometric[4], and chemiluminescence[5]. Narayanaswamy and co-workers[6], have recently reported a number of potential polynuclear aromatic hydrocarbon molecules, which experience fluorescence quenching by chlorine in methanol. However, data are not available regarding the quenching of these compounds in aqueous solution.

This paper describes a fiber-optic probe for measuring free chlorine ($Cl_2$/HOCl) in aqueous solution. The working principle of this probe is based on a combination of fluorescence quenching by chloride and a direct reaction by chlorine with the indicator dye *N*-(6-methoxyquinolyl)-acetoethyl ester (MQAE) in an isolated aqueous-based internal solution. This probe uses a microporous gas-permeable membrane to trap a small volume of internal solution in front of a fiber-optic assembly (FOA). Chlorine from the sample diffuses across the gas-permeable membrane and enters the internal solution. A fraction of this chlorine is converted to chloride ions and the combination of chloride and chlorine diminishes the fluorescence of MQAE. The resulting change in fluorescence intensity is measured as a function of time through the FOA. The rate of change of the fluorescence intensity is related to the concentration of chlorine in the sample.

## EXPERIMENTAL

### *Apparatus and reagents*

Fluorescence quenching measurements from the internal solution were performed with an FOA by using an instrumental arrangement similar to that reported earlier[7] with some modifications. Light from a 100 W tungsten–

halogen lamp passed through an IR-blocking filter and then a KV-470 cut-off filter before being focused into a bundle of quartz optical fibers. The exiting radiation was collimated before passing through a mechanical chopper, which was operated at 224 Hz. One of the fused-silica optical fibers carried the chopped light and directed this excitation radiation towards the internal solution at the tip of the FOA. A second set of fused-silica fibers collected a portion of the luminescence from the internal solution and directed this light to a 490 nm bandpass filter. After passing through the filter, the light was focused onto the face of a photomultiplier tube (PMT) which was operated at 650 V.

MQAE was purchased from Molecular Probes (Eugene, OR), and used as received. Chlorine standards were prepared from stock sodium hypochlorite (NaOCl) solutions, whose chlorine concentration was established by iodometric titration. All other reagents were analytical grade quality and were purchased from common suppliers. All solutions were made with distilled-deionized water that was prepared immediately before use by passing the house distilled water through a Milli-Q three house water purification unit.

*Procedures*

*Probe fabrication.* Chlorine probes were constructed by trapping a small volume of internal solution between a gas-permeable membrane and an FOA (Fig. 1). The FOA was fabricated by packing one 600 $\mu$m (FP-600-UHT) and seven 400 $\mu$m (FP-400-UHT) fibers into a 7.0 cm long (2.5 mm i.d. and 3.0 mm o.d.) plastic tubing. Both types of fibers were high-hydroxy fibers designed for UV transmission and were obtained from 3M Specialty Optical Fibers, West Haven, CT. The FP-600-UHT fiber had a numerical aperture of 0.30, core diameter of $600 \pm 10$ $\mu$m, cladding diameter of $830 \pm 30$ $\mu$m, and buffer diameter of $1050 \pm 30$ $\mu$m. The FP-400-UHT fibers had a numerical aperture of 0.30, core diameter of $400 \pm 8$ $\mu$m, cladding diameter of $600 \pm 30$ $\mu$m, and buffer diameter of $750 \pm 30$ $\mu$m. The 600 $\mu$m fiber was positioned in the center of seven 400 $\mu$m fibers. Epoxy was applied to hold the fibers and fill the void volume inside the fiber–tubing assembly. The other end of the

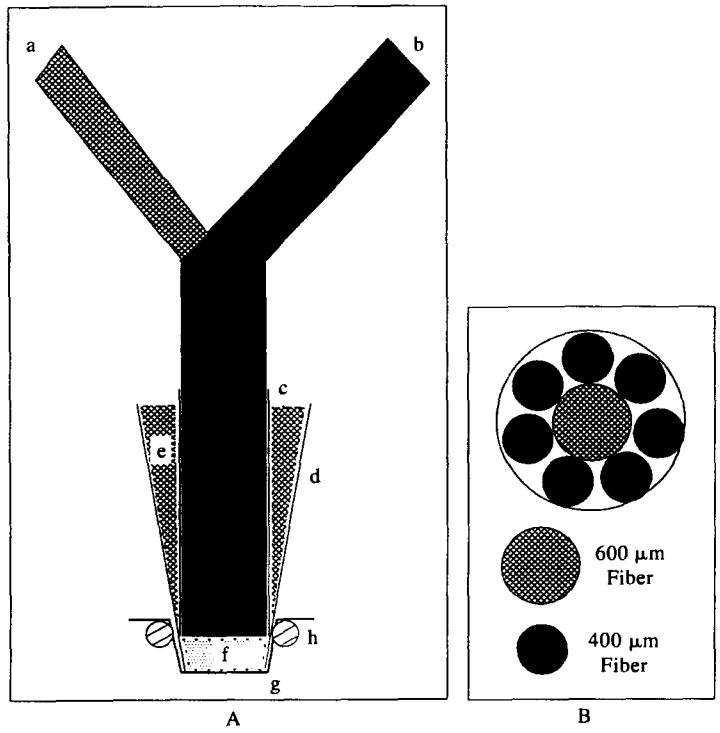

Fig. 1. Schematic diagram of the fiber-optic chlorine probe. Part A: a, 600 $\mu$m excitation fiber; b, seven 400 $\mu$m emission fibers, c, plastic tubing; d, conical plastic pipette tip; e, epoxy, f, internal solution; g, microporous Teflon membrane; and h, plastic spacer ring. Part B: arrangement of fibers at the probe tip (cross-sectional view).

600 $\mu$m and seven 400 $\mu$m fibers were inserted through two plexiglass connectors separately and held in position with epoxy. The fiber ends were polished with 400-grit abrasive paper. The FOA was then inserted into a conical shaped small plastic tube and held in place by an adhesive sealant. A small reservoir was created at the tip by slightly recessing the FOA relative to the outer edge of the tube. The outer diameter of the resulting probe tip was about 5.0 mm and the volume of the reservoir was less than 10 $\mu$l. The internal solution and gas-permeable membrane were added by inverting the probe body, applying approximately 20 $\mu$l of solution into the reservoir, stretching a small square of membrane over the solution and holding the membrane in place with a plastic spacer ring. Unless otherwise mentioned, the internal solution was composed of 0.1 m*M* MQAE in water. Gas-permeable membranes were microporous Teflon from Gore and Associates (Elkton, MD) and had an average pore size of 0.02 $\mu$m.

*Spectral measurements.* Absorbance spectra of aqueous standard MQAE solutions were obtained on an OLIS-modified Cary-14 spectrophotometer (On-Line Instrument Systems, Inc.). Fluorescence measurements were obtained with an SLM AMINCO SPF-500 C spectrofluorimeter. The excitation spectra of 0.10 m*M* MQAE were obtained by measuring the luminescence intensity at 456 nm while varying the excitation wavelength from 250 to 600 nm. Fluorescence spectra, on the other hand, were collected by using a fixed excitation wavelength of 346 nm and recording the emission intensity as a function of wavelength from 350 to 600 nm. Fluorescence intensities of a series of 1 to 100 $\mu M$ aqueous MQAE solutions were measured at 456 nm by using 346 nm as the excitation wavelength. The effect of pH on the fluorescence intensity was examined by measuring the fluorescence spectra (excitation at 346 nm) of 0.17 m*M* MQAE solutions in different buffer solutions over the pH range from 3.58 to 10.27.

*Fluorescence quenching measurements.* The effect of $Cl^-$, $OCl^-$, HOCl, and $Cl_2$ on the fluorescence intensity of MQAE were tested. Microliter aliquots of 1.0*M* stock solution of NaCl were added to 0.1 m*M* aqueous solution of MQAE to study the quenching caused by the $Cl^-$ ion. In order to correct for the dilution due to the addition of the $Cl^-$ standard, an equal volume of 0.2 m*M* MQAE was added. Fluorescence intensities were measured before and after the addition of quencher. Quenching by $OCl^-$ was tested by adding a standard NaOCl solution to a freshly prepared 0.17 m*M* aqueous solution of MQAE in a pH 10.66 buffer. The effect of HOCl on fluorescence intensity was investigated by adding a standard NaOCl solution to a 19 $\mu M$ solution of MQAE in 0.1*M* $H_2SO_4$. Finally, the effect of $Cl_2$ on the fluorescence intensity of MQAE was measured by mixing microliter aliquots of 1.0*M* NaCl and standard NaOCl followed by the addition of 2.0 ml of a 17 $\mu M$ MQAE (in 0.1*M* $H_2SO_4$) solution. The Stern–Volmer quenching constant was calculated from a linear fit to the equation

$$F_0/F = 1 + K_q[Q] \quad (1)$$

where $F_0$ and $F$ are the fluorescence intensities in the absence and presence of quencher, respectively, $[Q]$ is the concentration of quencher, and $K_q$ is the Stern–Volmer constant.

*Probe characterization and chlorine calibration curves.* Unless stated otherwise, measurements were made in thermostatted glass jacketed cells and the temperature was maintained at 25°C with a Fisher model 90 water bath. The probe tip was immersed in a 20.0 ml aliquot of a 0.10*M* hydrochloric acid (blank) solution. A particular chlorine concentration was obtained by making a microliter addition of a sodium hypochlorite (NaOCl) standard to the blank solution. The probe response was recorded for about 30 min. The probe tip was refilled with fresh internal solution and response to a different concentration of chlorine was measured. The rate of decrease in fluorescence intensity was computed as the slope from the linear regression analysis of the linear portion of the intensity–time plot. Finally, a calibration curve was constructed by plotting the slope with respect to the chlorine concentration.

## RESULTS AND DISCUSSIONS

### *Spectroscopic properties of MQAE*

MQAE was considered as a $Cl^-$ sensitive fluorescent compound for the detection of $Cl_2$ with the fiber-optic probe in aqueous solution in an indirect approach. Verkman *et al.*[8] synthesized and characterized MQAE as water soluble (270 g/l. at 23°C) and highly $Cl^-$ sensitive (Stern–Volmer constant $200M^{-1}$) compound with peak excitation and emission wavelengths of 355 and 460 nm, respectively, and molar absortivity of $4850M^{-1}$ $cm^{-1}$.

Fluorescence intensity of this compound was quenched by $Cl^-$, $Br^-$, $I^-$, $SCN^-$, and by organic anions such as citrate. However, MQAE fluorescence was not affected by $NO_3^-$, $SO_4^{-2}$, $HCO_3^-$, $Na^+$, $K^+$, and $Ca^{2+}$, and pH in the range of 4–8.

According to our studies, a plot of fluorescence intensity *vs.* concentration is linear over the concentration range from 1 to 25 $\mu M$ MQAE. The effect of chloride on the absorption spectrum of MQAE was evaluated in order to determine the mode of quenching. The presence of chloride did not significantly perturb the absorption spectrum of MQAE, which indicates the absence of static quenching. From a regression analysis of a plot of $F_0/F$ *vs.* $[Cl^-]$, $199.1 \pm 0.7 M^{-1}$ was obtained as the Stern–Volmer constant for fluorescence quenching of MQAE by $Cl^-$. Interestingly, we have discovered that the fluorescence of MQAE is also quenched by the $OCl^-$ ion. Under the experimental conditions described above, $Cl_2$ and HOCl slowly decreased the fluorescence intensity until the fluorescence diminished completely, indicating a decomposition of MQAE possibly due to oxidation of MQAE by $Cl_2$ and HOCl. MQAE also decomposed in a $0.01 M$ NaOH solution by hydrolysis.

*Principle of probe operation*

To carry out the measurement of gaseous chlorine in aqueous solution by the fiber-optic chlorine probe, the spectroscopic properties of MQAE (as described above) and the following reactions are considered[5]:

$$Cl_2 + H_2O \rightleftharpoons HOCl + H^+ + Cl^- (K_d = 4.0 \times 10^{-4}) \quad (2)$$

$$HOCl + H_2O \rightleftharpoons H_3O^+ + OCl^- (K_a = 3.16 \times 10^{-8}). \quad (3)$$

According to the above equations, the addition of NaOCl in a $Cl^-$-containing acidic solution (such as dilute HCl) provides most of the chlorine species in the form of $Cl_2$. A portion of the chlorine then diffuses through the gas-permeable membrane and reaches the internal MQAE solution. It is evident from the above reactions that a high pH in the internal MQAE solution is desirable. High pH facilitates an immediate dissociation of $Cl_2$ into equimolar quantities of chloride and hypochlorite ions. Thus, no appreciable partial pressure of chlorine gas will build up in the internal solution. As a result, gaseous chlorine will continue to cross the membrane due to the difference in partial pressure between the sample and internal MQAE solutions. The rate of $Cl_2$ influx will depend on its partial pressure in the outside sample solution and will be limited by the concentration of MQAE, volume of internal solution, membrane porosity, and membrane thickness.

*Background and internal solution composition*

A $0.1 M$ HCl solution was chosen as the background solution into which the fiber-optic probe was placed. This solution ensured the formation of $Cl_2$ when standard NaOCl was added. Equations (2) and (3) suggest that the formation of HOCl is thermodynamically unfavorable. Therefore, gaseous $Cl_2$ is the only species that can diffuse through the membrane and enter the internal solution.

Selection of the internal solution composition is a critical issue. Although chloride ion formation is favorable under basic conditions, MQAE hydrolysis limits the pH to values below 12.0. The background fluorescence intensity of MQAE in $0.1 M$ NaOH decreased with time, which resulted in poor reproducibility of the probe response in repeated measurements. An acidic internal solution, on the other hand, restricts the dissociation of $Cl_2$ to form chloride. However, measurements with acidic internal solutions are possible because $Cl_2$ itself diminishes the fluorescence of MQAE. In the current system, the internal MQAE solution was made in water. In this solution, some quantities of all forms of chlorine species are present. In slightly basic solution (pH 9.0), background fluorescence intensity was stable. This pH also ensures almost a complete conversion of $Cl_2$ into $Cl^-$ ion. However, the magnitude and rate of change of probe response due to a $Cl_2$ sample were identical to those obtained when the internal solution was made with plain water.

*Calibration curve*

Figure 2 illustrates six intensity–time curves representing the exposure of the probe to 8.4–835 $\mu M$ $Cl_2$ solutions. The internal solution was composed of 0.1 m$M$ MQAE in water. For each measurement, the probe tip was refilled with a fresh aliquot of internal solution. It is evident from these curves that initially the intensity of fluorescence decreased linearly with time. The initial rate of decrease in fluorescence inten-

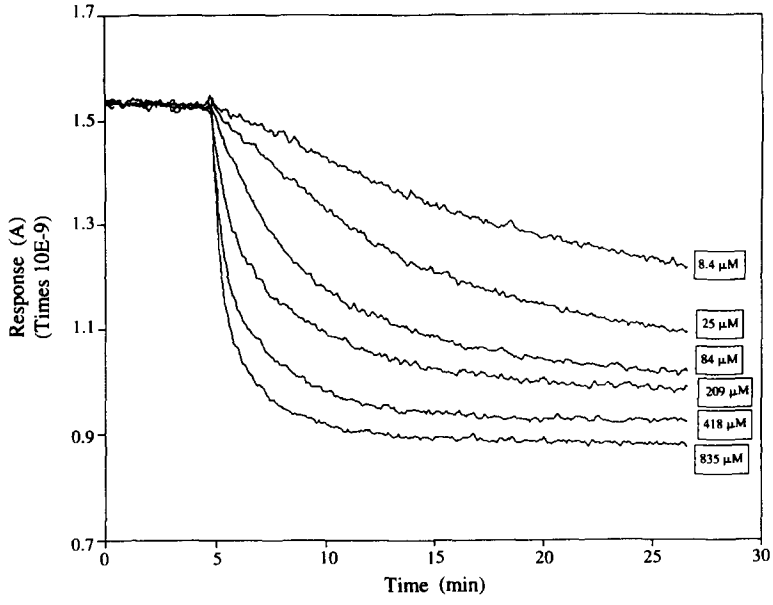

Fig. 2. Intensity–time curves for the chlorine probe obtained from different concentrations of standard chlorine solutions.

sity was proportional to the concentration of $Cl_2$ in the sample. This rate of change in response represents the flux of $Cl_2$ transported through the gas-permeable membrane. If the probe is kept in the sample solution for sufficient time, the final intensity for all sample concentrations is identical. Once the signal became steady, it remained essentially unchanged when the concentration of $Cl_2$ in the sample was increased. The magnitude of the total signal change was not dependent on the concentration of $Cl_2$ in the sample. Therefore, a Stern–Volmer plot could not be used as the calibration method for this probe. The initial rate of decrease in fluorescence intensity was calculated from linear regression analysis of the linear portion of the intensity–time curves. Calibration curves were constructed by plotting these slopes as a function of $Cl_2$ concentration. A typical calibration curve is presented in Fig. 3. The slopes increased linearly as a function of chlorine concentration over the range from 8.4 to 418 $\mu M$. This linearity was not maintained at high $Cl_2$ concentrations because the rate of $Cl_2$ influx became

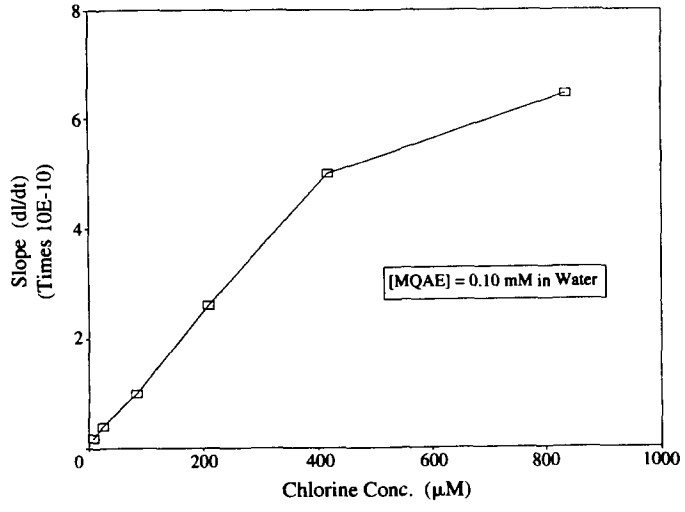

Fig. 3. Calibration curve for the chlorine probe made by plotting the rate of decrease in response as a function of concentration of standard chlorine solutions.

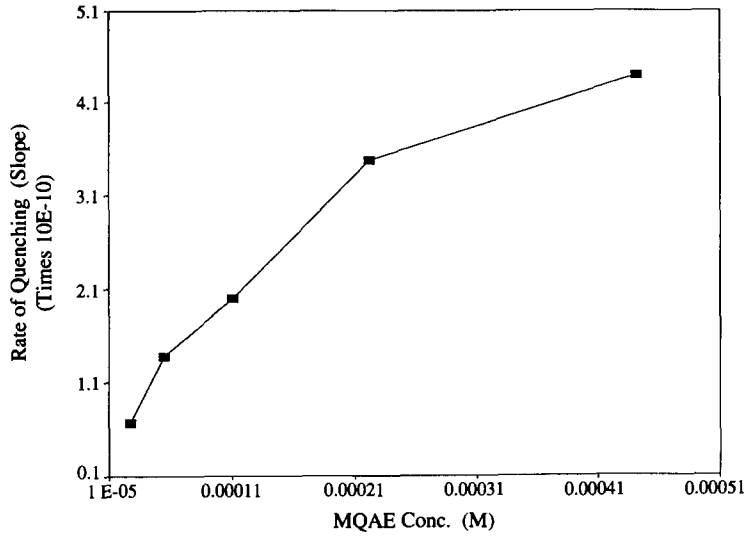

Fig. 4. Effect of the concentration of MQAE on the rate of decrease in the fluorescence signal. The concentration of chlorine in the sample was 168 $\mu M$.

limited by the porosity and thickness of the gas-permeable membrane.

*Reversibility*

The probe response was not reversible. After the probe reached a steady signal in a $Cl_2$ solution, the probe was immersed in 20.0 ml of either 0.1$M$ HCl (background) solution or in 0.1$M$ NaOH solution to extract gaseous chlorine species ($Cl_2$ and HOCl, respectively) from the internal solution. The fluorescence signal remained unchanged even after 30 min indicating that the interaction between MQAE and chlorine species is irreversible. The inability to remove chlorine from the internal solution may be caused by either a high stability constant for the quencher–fluorophore complex or extremely high concentrations of the chlorine species in the internal solution, which causes the decomposition of MQAE due to oxidation by HOCl and $Cl_2$. In either case, once the probe is exposed to a $Cl_2$ sample, the probe cannot be reused and must be refilled with a fresh aliquot of the internal solution before the next measurement.

In an attempt to make the probe reversible, the internal MQAE solution was made with 1.0 m$M$ NaCl in order to drive equation (2) toward the formation of $Cl_2$. The response property of the resulting probe was the same as before with no reversibility. These observations suggest that typical steady-state gas-sensing measurements cannot be obtained with this type of probe.

*MQAE concentration in internal solution*

Probe responses were recorded for a 0–168 $\mu M$ chlorine concentration step while varying the concentration of MQAE in the internal solution from 0.028 to 0.442 m$M$. The rate of change of signal, which represents the sensitivity of the probe, increases with higher MQAE concentrations as shown in Fig. 4. At MQAE concentrations approaching 0.442 m$M$, the response rate began to level off at a maximum value. This leveling off was probably caused by the effectiveness of complex formation between the quenchers and the excited state of MQAE being limited by the bimolecular collision rate responsible for dynamic quenching. Self absorption at high concentration of MQAE could also be a factor.

*Reproducibility*

The probe displayed good reproducibility when a fresh aliquot of internal solution was used for repeated measurements. Figure 5 demonstrates the reproducibility of the probe for consecutive responses for a 0–168 $\mu M$ chlorine concentration step. Each measurement was performed after refilling the probe tip with fresh internal solution. The magnitude of overall signal change is identical in three measurements; the relative standard deviation of the initial rate

of change of fluorescence intensity is about 1 percent.

*Probe calibration*

Once constructed, the probe requires calibration so that it can be used for determination of $Cl_2$ in unknown samples. The baseline response could not be re-established after the first exposure of the probe to a sample solution. Therefore, for analysis of unknown samples, it is necessary to make a calibration curve by following the procedure described earlier where the probe tip is refilled before each measurement. If all the experimental parameters are kept constant, then the concentration of an unknown sample can be measured by comparing the slope of the initial intensity–time curve with the calibration curve. Since the response of the refilled probe is reproducible, multiple analyses can be performed with a single probe unit. The probe tip must be refilled with fresh internal MQAE solution for each determination, which is a relatively simple procedure.

*HOCl gas measurements*

A system was designed where HOCl was the only species present in the sample solution by making microliter additions of a standard solution of NaOCl to the sample cell containing 0.01*M* $H_2SO_4$. The internal MQAE (0.1 m*M* in water) solution was trapped at the probe tip with a gas-permeable membrane. When sufficient partial pressure of HOCl was established in the sample solution, HOCl diffused through the membrane and entered the internal MQAE solution.According to equations (2) and (3), the predominant chlorine species in the internal solution would be HOCl. As was expected, the fluorescence intensity decreased when HOCl entered the internal solution. Unfortunately, the probe did not respond to a second addition of HOCl. Overall, the response properties of the HOCl probe are similar to those of the $Cl_2$ probe.

## CONCLUSION

The aspects of developing a fiber-optic probe based on MQAE-quenching for the measurement of free chlorine in aqueous solution are presented. Compositions of the internal and blank solution were identified as aqueous MQAE and dilute HCl, respectively. Although the total fluorescence decay cannot be used for the calibration purpose, the initial rate of fluorescence decay is proportional to the sample concentration. The probe possesses excellent reproducibility when the probe tip is refilled with fresh internal solution before each measurement.

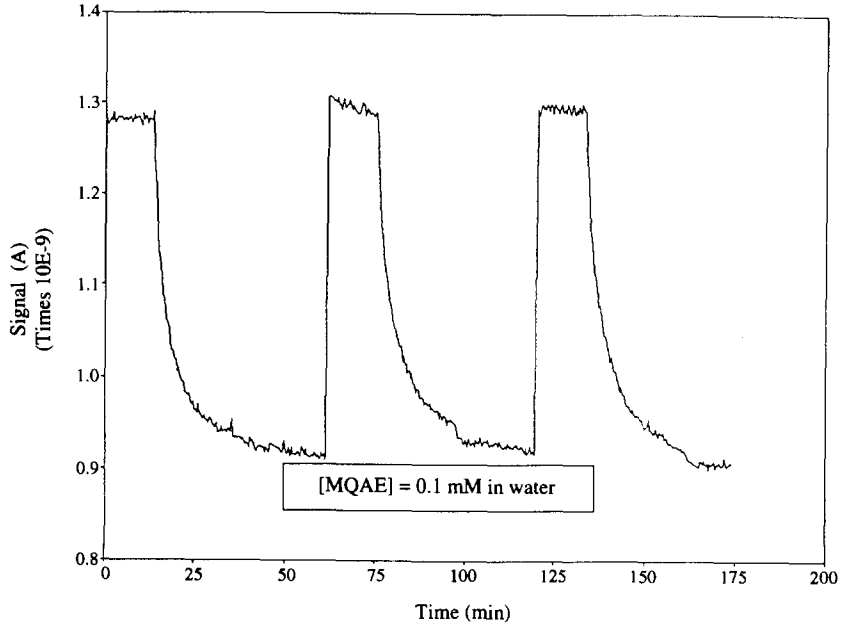

Fig. 5. Reproducibility of the chlorine probe obtained by measuring repeated responses to 168 $\mu M$ $Cl_2$ solutions. The probe tip was refilled with fresh internal MQAE (0.1 m*M* in water) solution before each measurement.

*Acknowledgements*—Financial support by the National Science Foundation (#BNS-8716768) is acknowledged. Very helpful discussions with Dr Purnendu K. Dasgupta are appreciated.

# BOOK REVIEWS

**Chemometrics for Analytical Chemistry, Volume 1—PC-aided statistical data analysis:** M. MELLOUN, J. MILITKY and M. FORINA, Ellis Horwood, 1992. Pages 330. £65.00. ISBN 0-13-126376-5.

This book is the first of a set (it is not clear whether another one or two volumes are intended) designed to provide a fairly comprehensive treatment of chemometrics for analytical scientists at the advanced undergraduate or postgraduate level. There is a matching and extensive suite of software (on 4 high density floppy discs), variously called Adstat or Chemstat, which provides both elementary and advanced statistical calculations and utilises the extensive example data sets described in the book. This software is PC-based (minimum configuration is a 286 processor, 1 Mb RAM, 8.5 Mb hard disk space, maths co-processor recommended), and I have not heard of a Mac version, or of the price of the PC version.

This first volume covers exploratory data analysis, univariate statistics, one- and two-way ANOVA, and exploratory and factor analysis of multivariate data. It does not include (despite the claims on the back cover) regression methods: these must await later volume(s). Adstat/Chemstat has eight modules, five of which deal with regression and calibration. The book's coverage of many topics is exceptionally detailed to the point of intimidation: several variants of box-and-whisker plots are given extended treatment, while Laplace, 1- and 2-parameter exponential, rectangular, and 2- and 3-parameter log-normal distributions are covered in addition to the familiar normal and Poisson ones. Elsewhere the comprehensive coverage is welcome, for example in the good treatment of robust methods, absent from many other texts. The book claims to require little mathematical background, and matrix algebra is summarised in a separate and very condensed appendix, but the reality is that from the very first page integration, partial differentiation, *etc.* are assumed to be absolutely familiar, whereas alas they are not for many students these days. A knowledge of basic statistics would also be useful before starting the book.

The software is probably of value most obviously in its provision and treatment of a number of useful and interesting data sets. The calculation facilities offered are equalled or exceeded by many other established suites of statistics software, and extensive testing would be needed to verify that Adstat/Chemstat is stable and bug-free. It provides good printout options, with presentation standard graphics on Epson- and Hp-compatible printers, but the manual is written in very poor English, in contrast to the book where the translation editing is generally excellent, and which has the rare attribute of a good index.

When the remaining volumes of text are published and when the software has an improved manual this combined book and software will provide a formidable resource for teachers of chemometrics. But it will be hard going for many students, and it is certainly not suitable for beginners.

J. N. MILLER

**Asphaltene Particles in Fossil Fuel Exploration, Recovery, Refining, and Production Processes:** M. K. SHARMA and T. F. YEN (editors), Plenum, New York, 1994. Pages xiii + 244. US$75.00. ISBN 0-306-44709-6.

This well produced book documents the proceedings of the International Symposium on Asphaltene Particles in Fossil Fuel Exploration, Recovery, Refining and Production Processes held in Las Vegas, Nevada, 13–17 July 1992. Eighteen selected papers are presented and these can be divided into four main categories: (1) Bitumen and Coal-Derived Asphaltenes, (2) Asphalt and Asphaltene Conversion, (3) Surface and Colloidal Aspects of Asphaltenes, and (4) Thermodynamic and Molecular Aspects of Asphaltenes. The intended objective of the book is to reflect the current understanding of formulation and process problems related to asphaltenes. Almost all of the contributing authors are from Canada or the USA and several different disciplines are represented, *e.g.* chemical and petroleum engineering, geological engineering, and civil and environmental engineering. Some authors contribute to more than one paper, *e.g.* the editor T. F. Yen is co-author of six of the 18 papers. Both an author index and a subject index are included.

The various papers attempt to define asphaltenes as the heavy ended fraction of petroleum or the bitumen fraction which is insoluble in hot *n*-pentane. Investigations of the molecular properties of the asphaltenes—high molecular weight polyaromatic or polycyclic molecules which may be joined together by links containing heteroatoms such as N, O and S—are presented. One interesting paper discusses the concept of a "single molecule representation" or "average molecule" to interpret the NMR spectra. Physical properties discussed include rheological behaviour, surface activity and thermodynamics.

Asphalt is a very complex mixture that consists of saturates, aromatics, resins and asphaltenes. These four fractions can be separated by column chromatography and the final paper of this book entitled 'Fractionation of asphalt by thin-layer chromatography interfaced with flame ionization detector and subsequent characterization by FTIR' is perhaps the most analytical report presented. Another paper by J. Lian and T. F. Yen classifies asphalts into sol, sol-gel and gel types depending on their physical and chemical properties. The sol and sol-gel types are used for paving while the gel type asphalts are used in roofing.

# BOOK REVIEWS

**Chemometrics for Analytical Chemistry, Volume 1—PC-aided statistical data analysis:** M. MELLOUN, J. MILITKY and M. FORINA, Ellis Horwood, 1992. Pages 330. £65.00. ISBN 0-13-126376-5.

This book is the first of a set (it is not clear whether another one or two volumes are intended) designed to provide a fairly comprehensive treatment of chemometrics for analytical scientists at the advanced undergraduate or postgraduate level. There is a matching and extensive suite of software (on 4 high density floppy discs), variously called Adstat or Chemstat, which provides both elementary and advanced statistical calculations and utilises the extensive example data sets described in the book. This software is PC-based (minimum configuration is a 286 processor, 1 Mb RAM, 8.5 Mb hard disk space, maths co-processor recommended), and I have not heard of a Mac version, or of the price of the PC version.

This first volume covers exploratory data analysis, univariate statistics, one- and two-way ANOVA, and exploratory and factor analysis of multivariate data. It does not include (despite the claims on the back cover) regression methods: these must await later volume(s). Adstat/Chemstat has eight modules, five of which deal with regression and calibration. The book's coverage of many topics is exceptionally detailed to the point of intimidation: several variants of box-and-whisker plots are given extended treatment, while Laplace, 1- and 2-parameter exponential, rectangular, and 2- and 3-parameter log-normal distributions are covered in addition to the familiar normal and Poisson ones. Elsewhere the comprehensive coverage is welcome, for example in the good treatment of robust methods, absent from many other texts. The book claims to require little mathematical background, and matrix algebra is summarised in a separate and very condensed appendix, but the reality is that from the very first page integration, partial differentiation, *etc.* are assumed to be absolutely familiar, whereas alas they are not for many students these days. A knowledge of basic statistics would also be useful before starting the book.

The software is probably of value most obviously in its provision and treatment of a number of useful and interesting data sets. The calculation facilities offered are equalled or exceeded by many other established suites of statistics software, and extensive testing would be needed to verify that Adstat/Chemstat is stable and bug-free. It provides good printout options, with presentation standard graphics on Epson- and Hp-compatible printers, but the manual is written in very poor English, in contrast to the book where the translation editing is generally excellent, and which has the rare attribute of a good index.

When the remaining volumes of text are published and when the software has an improved manual this combined book and software will provide a formidable resource for teachers of chemometrics. But it will be hard going for many students, and it is certainly not suitable for beginners.

**Asphaltene Particles in Fossil Fuel Exploration, Recovery, Refining, and Production Processes:** M. K. SHARMA and T. F. YEN (editors), Plenum, New York, 1994. Pages xiii + 244. US$75.00. ISBN 0-306-44709-6.

This well produced book documents the proceedings of the International Symposium on Asphaltene Particles in Fossil Fuel Exploration, Recovery, Refining and Production Processes held in Las Vegas, Nevada, 13–17 July 1992. Eighteen selected papers are presented and these can be divided into four main categories: (1) Bitumen and Coal-Derived Asphaltenes, (2) Asphalt and Asphaltene Conversion, (3) Surface and Colloidal Aspects of Asphaltenes, and (4) Thermodynamic and Molecular Aspects of Asphaltenes. The intended objective of the book is to reflect the current understanding of formulation and process problems related to asphaltenes. Almost all of the contributing authors are from Canada or the USA and several different disciplines are represented, *e.g.* chemical and petroleum engineering, geological engineering, and civil and environmental engineering. Some authors contribute to more than one paper, *e.g.* the editor T. F. Yen is co-author of six of the 18 papers. Both an author index and a subject index are included.

The various papers attempt to define asphaltenes as the heavy ended fraction of petroleum or the bitumen fraction which is insoluble in hot *n*-pentane. Investigations of the molecular properties of the asphaltenes—high molecular weight polyaromatic or polycyclic molecules which may be joined together by links containing heteroatoms such as N, O and S—are presented. One interesting paper discusses the concept of a "single molecule representation" or "average molecule" to interpret the NMR spectra. Physical properties discussed include rheological behaviour, surface activity and thermodynamics.

Asphalt is a very complex mixture that consists of saturates, aromatics, resins and asphaltenes. These four fractions can be separated by column chromatography and the final paper of this book entitled 'Fractionation of asphalt by thin-layer chromatography interfaced with flame ionization detector and subsequent characterization by FTIR' is perhaps the most analytical report presented. Another paper by J. Lian and T. F. Yen classifies asphalts into sol, sol-gel and gel types depending on their physical and chemical properties. The sol and sol-gel types are used for paving while the gel type asphalts are used in roofing.

Overall some interesting research is presented in this collection of papers. The diagrams and tables are very clear (although one conversion sequence lacks arrows and occasionally the English is abrupt) and the print font and size are consistent throughout. A useful publication, especially for those working in the oil or chemical industries.

**Flow-Through (Bio)Chemical Sensors:** M. VALCÁRCEL and M. D. LUQUE DE CASTRO, Elsevier, Amsterdam, 1994. Pages 331. Dfl 355.00 US$202.75. ISBN 0-444-89866-2.

As a result of intense commercial and academic interests, an impressive amount of manpower has been spent at numerous laboratories worldwide on the development of chemi- and biosensors. Yet, considering these vast research efforts, the practical applications of sensor technology have been rather limited. The reasons for this lack of visible success are many, but one of the major factors is undoubtedly owing to the harsh requirements that these devices must fulfil in order to meet the desires of their originators as well as the expectations of the end-users in real-life applications. To be useful, a biosensor must inevitably meet a variety of demands which must be honoured simultaneously. However, considering the diversity of chemical and physical events that can be involved in its function, in addition to satisfying individually dictated reaction parameters, it is not surprising that operational compromises necessarily have to be made for practical synchronization of all the processes required. Therefore, and in order to implement functions such as periodic calibration, conditioning and regeneration, it is, as this reviewer has repeatedly advocated, advantageous to use these devices in a flow-through mode. Or more specifically in the flow injection mode. Only in such a *sensor system*, comprising fluid drives, injectors and flow-through cells, can all experimental conditions be strictly affixed and reproducibly maintained under computer control.

Although principally and conceptually implied by the authors, this is exactly, in my opinion, what this monograph should have been about, as such a broad concept would have been its *raison d'etre*. Yet, Valcárcel and Luque de Castro surprisingly appear to have gone only half the way, by emphasizing the advantages of flow-through sensor construction rather than pointing out that a full transition is necessary from a dip type probe to a sensor system. This is indeed surprising considering that their experience includes authorship of two monographs and numerous papers on flow injection. One can only wonder why they have selected this approach, especially considering that volume 7 in this series from Elsevier is, in fact, focused on, and entitled, 'Biosensors' (by F. Scheller and F. Schubert), while at the same time the text contains a good deal of recycled material from these prolific authors' previous works. This is by no means meant to be a negative comment, but rather a question mark as to whether such a narrow subject area actually can bear an entire monograph *per se*.

The book is divided into five main chapters, where the introductory Chapter 1 provides an overview of (bio)chemical sensors and their place within analytical chemistry as this field has emerged over the last couple of decades. With its emphasis on the practical and mechanistic aspects of these devices (as their operation "requires that the sensor [can] be reliably used by unskilled personnel, who often work under stressing conditions") and its rendition of commercially available sensors (one wonders if they indeed fulfil these requirements), and the accompanying philosophical remarks, this chapter is interesting reading. The second chapter is devoted to essential and fundamental concepts of (bio) sensors, their construction and classification, and their modes of operation (batch and continuous flow mode), while the following three chapters arrange the most relevant types of flow-through (bio)chemical sensors according to the processes taking place at the sensing/recognition microzone, as well as their position in space and time. In this context, the three operational key parameters are *separation*, *reaction* and *detection*, the applicable combinations of which resolve the ensuring structural arrangement of the monograph. Thus, Chapter 3, with well over 100 pages and the largest in the book, is devoted to flow-through sensors based on integrated reaction and detection in the absence of a separation process, *i.e.* describing sensors based on either immobilized species (catalyst, antibody or reagent) or *in situ* produced reagents. Chapter 4 deals with sensors based on integrated separation and detection (separation being accomplished for instance via gas diffusion or liquid–liquid extraction), special emphasis being placed on multi-determination sensors (*e.g.* ISE and ISFETs), while Chapter 5 reviews flow-through sensors relying on the sequential or simultaneous integration of all the three intricate processes involved for their function.

As the reading progresses, it very quickly becomes apparent that the conditions *sine qua non* for successful application of biosensors are the timing of sample introduction into the sensor and data collection. These events must be reproduced from cycle to cycle since the dynamic response of a sensor must be captured in a reproducible fashion. For that reason alone a flow injection-based sensor system is the only viable choice. Unfortunately, this information is not emphasized or systematically organized, but rather scattered throughout the monograph (indeed flow injection is not even mentioned in the otherwise detailed index). What the book offers is essentially an account on the construction and operation of biosensors, a feature which is at the same time its strength as well as its weakness, leaving no room for a critical evaluation or a theoretical treatment (interestingly, the entire book does not contain a single mathematical equation). Yet, the overview of types and configurations of biosensors is comprehensive. The only significant omission is the absence of a discussion of the BIAcor system, which, marketed by Pharmacia, probably is the most successfully applied automated biosensor system known today. However, the book has a pedagogical value (as one would expect from two experienced university professors), the descriptions are painstakingly detailed with many examples, and the text is supplemented with an abundance of figures, from the authors' own works as well as generously selected from the current literature.

It is my belief that the authors have spent a commendable effort compiling this book, which is well documented and gives a wealth of information, to seasoned researchers and novices alike. It is only to be hoped that this publication will advance the field toward real life applications—a development badly needed in this fashionable field of research.

E. H. HANSEN

Overall some interesting research is presented in this collection of papers. E. H. HANSEN

**Instrumental Methods for Determining Elements:** L. TAYLOR, R. B. PAPP and B. D. POLLARD, VCH, Weinheim, 1994. Pages ix + 322. DM128.00 £51.50. ISBN 1-56081-038-6.

Analysts are often faced with the need to qualitatively and/or quantitatively determine elements—single or multi, stand-alone or as the detection component of a bigger system. If you have already chosen a technique and are happy with it, then this book may not be for you. It does not give in-depth treatment of any particular technique although you may find general and useful information and up-to-date references for in-depth treatment. If you do not know which technique to use or you are considering alternatives, then this book is extremely helpful.

The book begins with two 'introductory' chapters giving brief examination of the factors which govern the choice of a technique. It then follows with seven chapters dedicated to atomic absorption, atomic emission, voltametry, potentiometry, chromatography, X-ray fluorescence and combustion techniques. It ends with a chapter on miscellaneous techniques which describes briefly capillary electrophoresis, flow-injection analysis, mass spectrometry, neutron activation analysis and UV/Vis spectrometry. In fact most of the available techniques for elemental analysis have been covered.

Each of the dedicated chapters gives a minimal account of the necessary theory, a simple but adequate description of the instrumentation (with helpful illustrations), a succinct examination of choice factors such as sensitivity, detection limit, automation and operating costs, and also a substantial list of applications. What is particularly useful are the references to applications, lists of suppliers with addresses and the price range (given in American currency).

This book is obviously written by pesons who are in the trade as the information given is usually comprehensive, practical and up-to-date. There are few mistakes, most of them editorial and appear in Chapter 6. As the title suggests, the techniques described will be limited to total determination of elements but some mention has been made on speciation. A slight misgiving is the very brief (half a page) treatment on ICPMS which is a powerful and increasingly popular technique for elemental analysis.

This book is very readable and provides much useful and practical information. I think it deserves a place on the shelves of many analytical laboratories.

**Pharmacodynamics and Drug Development—Perspectives in Clinical Pharmacology**: N. R. CUTLER, J. J. SRAMEK and P. K. NARANG (editors), Wiley, Chichester, 1994. Pages: xv + 491. £65.00. ISBN 0-471-950-521.

This textbook may be of particular interest to researchers in the pharmaceutical industry and those in academia who have close links with industry. Users will require a sound knowledge of pharmacokinetics and at least some knowledge of pharmacodynamics. It does not, however, claim to be a basic textbook but rather one which addresses the increasing interest in the use of pharmacodynamic modelling in the design of clinical trials.

The first seven chapters provide an overview of pharmacodynamics and the causes of variation in both pharmacokinetics and pharmacodynamics. Unfortunately there is a certain amount of duplication in the material covered by the authors of different chapters but this permits each chapter to be read in isolation.

The second section of the book addresses the application of pharmacodynamic modelling to areas of the cardiovascular system, central nervous system and the use of antibiotics, antineoplastics and antiviral agents. This section provides ample demonstration of both the utility of pharmacodynamic models and the difficulty of selecting appropriate models and suitable measures of effect.

The final three chapters of this textbook consider molecular approaches to clarifying the mechanisms of drug action. They provide an interesting counterpoint to the rest of the text with consideration of methods for classification and elucidation of $\alpha$-adreno receptors, muscarinic receptors and serotonin receptors.

This textbook is unlikely to appeal to a large readership but provides a valuable overview of recent work in pharmacodynamics.

M. HAWTHORN

**Polymeric Site-Specific Pharmacotherapy**: A. J. DOMB (editor), Wiley, Chichester, 1994. Pages xi + 464. £75.00. ISBN 0-471-93824-6.

This book comprises a review of a most relevant and expanding area of research into efficient drug delivery systems in which drugs may be delivered specifically to their sites of action thereby increasing therapeutic effectiveness and reducing harmful systemic effects. Bio-absorbable polymers, of which there is an ever-increasing array, may be used as ideal drug carrier systems to the target tissue for the treatment of several diseased states. Each chapter, dealing with a specific site of target tissue, has been written by specialist authors active in their respective areas of research. The presentations are extensively detailed and referenced and therefore the book would be aimed largely at postgraduate level rather than the undergraduate student.

The initial chapters review extensively several biocompatable polymers in current use for implantation. These chapters concentrate on the types of polymers, their structure, degradation rates, blending possibilities, and some major concerns such as biocompatability and toxicity (especially tests for cytotoxicity, mutagenicity and teratogenicity). The kinetics of drug release from polymer implants are also thoroughly reviewed. A further chapter deals specifically with the concepts necessary to understand modelling of drug delivery to brain tissue from interstitial sources. There is a chapter with an in-depth account of tumour-specific drug targeting constituting a description of the work done over a period of time on polymer-conjugated

M. HAWTHORN

**Polymeric Site-Specific Pharmacotherapy**: A. J. DOMB (editor), Wiley, Chichester, 1994. Pages xi + 464. £75.00. ISBN 0-471-93824-6.

This book comprises a review of a most relevant and expanding area of research into efficient drug delivery systems in which drugs may be delivered specifically to their sites of action thereby increasing therapeutic effectiveness and reducing harmful systemic effects. Bio-absorbable polymers, of which there is an ever-increasing array, may be used as ideal drug carrier systems to the target tissue for the treatment of several diseased states. Each chapter, dealing with a specific site of target tissue, has been written by specialist authors active in their respective areas of research. The presentations are extensively detailed and referenced and therefore the book would be aimed largely at postgraduate level rather than the undergraduate student.

The initial chapters review extensively several biocompatable polymers in current use for implantation. These chapters concentrate on the types of polymers, their structure, degradation rates, blending possibilities, and some major concerns such as biocompatability and toxicity (especially tests for cytotoxicity, mutagenicity and teratogenicity). The kinetics of drug release from polymer implants are also thoroughly reviewed. A further chapter deals specifically with the concepts necessary to understand modelling of drug delivery to brain tissue from interstitial sources. There is a chapter with an in-depth account of tumour-specific drug targeting constituting a description of the work done over a period of time on polymer-conjugated

anticancer agents (SMANCS). A chapter is concerned with interstitial drug delivery to the brain using controlled-release polymers, overcoming the problem of the blood–brain barrier. There is also a discussion of the treatment of neurologic diseases by using biodegradable polymers as matrices for controlled delivery of neurotransmitters. There is an interesting review of developments related to the site-specific targeting of drugs to the bone marrow. As the authors point out, the ability to target colloidal drug carriers to bone marrow may hold promise for the improvement of cancer chemotherapy and radiotherapy. The subject of polymeric perivascular delivery systems is also addressed. Studies are described confirming the feasibility of using drug-eluting polymeric matrices placed around the adventitial surface of injured carotid arteries to evaluate the effects of specific drugs. Attention is also paid to techniques of localised cardiac administration of therapeutic agents, *e.g.* antiarrhythmic agents, and their potential for improving cardiovascular pharmacotherapies. Acute osteomyelitis, a serious bone infection, is very difficult to treat, and a chapter deals with drug delivery systems, such as carrier systems, that will ensure high local effects of effective antibiotics. The gastrointestinal tract also comes under scrutiny when physiological parameters crucial for the rational design of specific drug delivery are discussed. Some traditional and novel methods that target and localise drugs in the alimentary tract are reviewed. The description of drug delivery systems used in ophthalmology concentrates on solid erodible or non-erodible polymeric systems including a discussion of solid nano- and micro-particles and capsules. The interesting survey of methods of site-specific drug delivery to the lung discusses the use of carriers as aerosols, liposomes, microspheres, erythrocytes and antibodies. There is a discussion of the use of polymers for the prevention of surgical adhesions, and a chapter containing general information on the regulatory process for a polymer implant from a point of view of a research scientist involved with the approved process of a drug delivery system. However, Quality Assurance and clinical trial processes are not discussed. The final chapter describes methods used to delivery drugs to the peripheral nerves, such as sustained site-specific systems of local anaesthetics constituted of either liquid or solid matrices.

There are not many books covering these topics in such an up-to-date manner by authors with first hand knowledge of their topics. In an age when cost effective medical and pharmaceutical practice is under the spotlight, there would be few health professionals not interested in site-specific pharmacotherapy.

D. L. MUNDAY

**Environmental Analysis**: R. N. REEVE, Wiley, Chichester, 1994. Pages: xx + 263, £19.50. ISBN 0-471-95134-X (hardback); 0-471-93833-5 (softback).

This new volume in the successful *Analytical Chemistry by Open Learning* series departs from the approach of the previous volumes in that it deals with a field of application of analytical techniques, rather than with a particular technique. It is, of course, a most important field these days, and this volume will certainly be of interest to many people who are not primarily chemists, but who nevertheless require to do some analyses in the course of their investigations.

Roger Neeve discusses transport of pollutants in the environment, then goes on to deal with water analysis, first for major, then for trace constituents. This enables him to survey the applicability of both chromatographic and spectroscopic techniques, but the reader is referred to other relevant volumes in the ACOL series for further details of the theory of these techniques. Analysis of solids—in particular of soils and sediments—is covered next, which permits some account of sample handling and pretreatment, both for inorganic and for organic compounds. Indeed, sampling crops up at various points as appropriate to each type of environmental material. The review of methods in air analysis is rather brief, but does cover the question of sampling as it relates to measurements of exposure of people at work. Particulates are dealt with separately, giving an excuse to mention a few more exotic techniques, such as X-ray spectroscopy and neutron activation, but there is a serious omission in that X-ray diffraction is absent. Finally, under ultra-trace analysis, GC-MS gets a balanced and informative discussion—it seems here, as in the other mentions of trace organics generally, that this is where the author is at home.

The ACOL house style necessarily leads to a certain amount of repetition of material to hammer the main points home, but in this case the space so used could have been much better employed giving a few real details: that the scallops for which analyses are reported in Fig. 2.4b (surely a Table, not a Figure) were exposed to spiked or contaminated seawater (p. 30), that the quick permanganate test for oxygen demand takes 10 min boiling (p. 62), that special glass electrodes should be used for low-conductivity river waters (p. 66), that temperature affects electrical conductivity of salt solutions markedly (p. 69), that EDTA, or CDTA, must be added to samples for the potentiometric determination of fluoride, so as to mask the trace metals (p. 83), and that $CS_2$ is the most appropriate solvent for trace organics by GLC when the FID is used (p. 103), to give some examples. So often the reader's appetite is whetted by what looks like becoming interesting but then the reader is left to hunger as the author has to go on to another topic.

There are a number of errors, especially in Chapter 2 such as the formula for DDT (p. 26). The axis in Fig. 3.1a has a wrong concentration scale for ions in seawater, and the method of oxidation of the organics in water does not affect the sensitivity of the TOC determination (p. 63) but the method of detection of the evolved $CO_2$ does. However, the book gets steadily better as it goes on, and I have to say that I enjoyed reading it, and will recommend it for students at a beginner's level who need to be introduced to the fascinating problems of applying analytical chemistry to real samples. This is, however, not a book for someone wanting to *do* some environmental analysis, but rather one for the arm-chair scientist who wants to think about it.

I. L. MARR

anticancer agents (SMANCS). A chapter is concerned with interstitial drug delivery to the brain using controlled-release polymers, overcoming the problem of the blood–brain barrier. There is also a discussion of the treatment of neurologic diseases by using biodegradable polymers as matrices for controlled delivery of neurotransmitters. There is an interesting review of developments related to the site-specific targeting of drugs to the bone marrow. As the authors point out, the ability to target colloidal drug carriers to bone marrow may hold promise for the improvement of cancer chemotherapy and radiotherapy. The subject of polymeric perivascular delivery systems is also addressed. Studies are described confirming the feasibility of using drug-eluting polymeric matrices placed around the adventitial surface of injured carotid arteries to evaluate the effects of specific drugs. Attention is also paid to techniques of localised cardiac administration of therapeutic agents, *e.g.* antiarrhythmic agents, and their potential for improving cardiovascular pharmacotherapies. Acute osteomyelitis, a serious bone infection, is very difficult to treat, and a chapter deals with drug delivery systems, such as carrier systems, that will ensure high local effects of effective antibiotics. The gastrointestinal tract also comes under scrutiny when physiological parameters crucial for the rational design of specific drug delivery are discussed. Some traditional and novel methods that target and localise drugs in the alimentary tract are reviewed. The description of drug delivery systems used in ophthalmology concentrates on solid erodible or non-erodible polymeric systems including a discussion of solid nano- and micro-particles and capsules. The interesting survey of methods of site-specific drug delivery to the lung discusses the use of carriers as aerosols, liposomes, microspheres, erythrocytes and antibodies. There is a discussion of the use of polymers for the prevention of surgical adhesions, and a chapter containing general information on the regulatory process for a polymer implant from a point of view of a research scientist involved with the approved process of a drug delivery system. However, Quality Assurance and clinical trial processes are not discussed. The final chapter describes methods used to delivery drugs to the peripheral nerves, such as sustained site-specific systems of local anaesthetics constituted of either liquid or solid matrices.

There are not many books covering these topics in such an up-to-date manner by authors with first hand knowledge of their topics. In an age when cost effective medical and pharmaceutical practice is under the spotlight, there would be few health professionals not interested in site-specific pharmacotherapy.

**Environmental Analysis**: R. N. REEVE, Wiley, Chichester, 1994. Pages: xx + 263, £19.50. ISBN 0-471-95134-X (hardback); 0-471-93833-5 (softback).

This new volume in the successful *Analytical Chemistry by Open Learning* series departs from the approach of the previous volumes in that it deals with a field of application of analytical techniques, rather than with a particular technique. It is, of course, a most important field these days, and this volume will certainly be of interest to many people who are not primarily chemists, but who nevertheless require to do some analyses in the course of their investigations.

Roger Neeve discusses transport of pollutants in the environment, then goes on to deal with water analysis, first for major, then for trace constituents. This enables him to survey the applicability of both chromatographic and spectroscopic techniques, but the reader is referred to other relevant volumes in the ACOL series for further details of the theory of these techniques. Analysis of solids—in particular of soils and sediments—is covered next, which permits some account of sample handling and pretreatment, both for inorganic and for organic compounds. Indeed, sampling crops up at various points as appropriate to each type of environmental material. The review of methods in air analysis is rather brief, but does cover the question of sampling as it relates to measurements of exposure of people at work. Particulates are dealt with separately, giving an excuse to mention a few more exotic techniques, such as X-ray spectroscopy and neutron activation, but there is a serious omission in that X-ray diffraction is absent. Finally, under ultra-trace analysis, GC-MS gets a balanced and informative discussion—it seems here, as in the other mentions of trace organics generally, that this is where the author is at home.

The ACOL house style necessarily leads to a certain amount of repetition of material to hammer the main points home, but in this case the space so used could have been much better employed giving a few real details: that the scallops for which analyses are reported in Fig. 2.4b (surely a Table, not a Figure) were exposed to spiked or contaminated seawater (p. 30), that the quick permanganate test for oxygen demand takes 10 min boiling (p. 62), that special glass electrodes should be used for low-conductivity river waters (p. 66), that temperature affects electrical conductivity of salt solutions markedly (p. 69), that EDTA, or CDTA, must be added to samples for the potentiometric determination of fluoride, so as to mask the trace metals (p. 83), and that $CS_2$ is the most appropriate solvent for trace organics by GLC when the FID is used (p. 103), to give some examples. So often the reader's appetite is whetted by what looks like becoming interesting but then the reader is left to hunger as the author has to go on to another topic.

There are a number of errors, especially in Chapter 2 such as the formula for DDT (p. 26). The axis in Fig. 3.1a has a wrong concentration scale for ions in seawater, and the method of oxidation of the organics in water does not affect the sensitivity of the TOC determination (p. 63) but the method of detection of the evolved $CO_2$ does. However, the book gets steadily better as it goes on, and I have to say that I enjoyed reading it, and will recommend it for students at a beginner's level who need to be introduced to the fascinating problems of applying analytical chemistry to real samples. This is, however, not a book for someone wanting to *do* some environmental analysis, but rather one for the arm-chair scientist who wants to think about it.

**The Kirk-Othmer Encyclopedia of Chemical Technology: Volume 11, Fourth Edition, Flavor characterization to Fuel cells**: J. I. KROSCHWITZ and M. HOWE-GRANT (editors), Wiley, New York. 1994. Pages: xxviii + 1121. £185.00. ISBN 0-471-52680-0. (v. 11).

Volume 11 covers 26 topics—all beginning with the letter 'F'. It is dominated by almost 500 pages dealing with fluorine (the most electronegative and reactive element) and its inorganic and organic compounds. Details of the production, economic aspects and uses of fluorine are presented but most detail is reserved for the numerous compounds of this element. Indeed, bibliographies are given after each compound type, *e.g.* 84 references follow the section 'Fluorine compounds, inorganic (boron)' and similarly 124 references are given for the (calcium) section. Physical properties, chemical properties, manufacture, economic aspects, toxicity, uses, *etc.*, are all given. Fluorine polymers are well covered—PTFE, FEP, ETFE, PFA, PVF, PVDF, and PCTFE all have separate entries.

Those working in the food and consumer industries will also find this volume interesting as numerous topics relate to these areas. Chapters on food additives, food packing, food processing, nonconventional foods, and naturally occurring food toxicants are included. There are also related entries on flavor characterization, flavors and spices, and fruit juices. Although all entries are by necessity very factual I enjoyed discovering the names of the chemicals responsible for the flavor characteristics of substances such as caramel, chocolate, coffee, cognac, onion, popcorn, strawberry, *etc.* Details of individual spices were also of interest, *e.g.* the aroma of *Pimenta* berries resembles that of cloves, cinnamon, black pepper, and nutmeg, hence the name allspice or *quatre épices.*

Entries in this volume which are clearly of interest to chemical engineers include flotation, flow measurement, fluidization, fluid mechanics and fracture mechanics. Mathematical expressions, graphs, flow sheets and other diagrams are much in evidence for these entries.

The remaining contents include flocculating agents, fluorescent whitening agents, foamed plastics, foams, forensic chemistry, formaldehyde, fractionation (blood), Friedel-Crafts reactions and fuel cells. The section on forensic science is short, for example, the table of commonly encountered drugs of abuse could be extended, but the reader is directed to other parts of the encyclopedia for additional information and the entry is followed by a comprehensive bibliography.

As with all volumes so far published in this series the editors have produced an excellent collection of topics which is presented in a clear and logical manner. There is something here for chemists of all persuasions.

# ELECTROCHEMICAL BEHAVIOUR OF SOME NATURALLY OCCURRING HYDROXY DERIVATIVES OF 9,10-ANTHRAQUINONE IN CHLOROFORM AT MERCURY AND GLASSY CARBON ELECTRODES: APPLICATION OF AC POLAROGRAPHY TO THE ANALYSIS OF RHUBARB ROOTS

M. H. POURNAGHI-AZAR,* F. SHEMIRANI and S. POURTORK

Electroanalytical Chemistry Laboratory, Faculty of Chemistry, University of Tabriz, Tabriz, Iran

(*Received* 25 *May* 1994. *Revised* 14 *October* 1994. *Accepted* 14 *October* 1994)

**Summary**—Electrochemical behaviour of some naturally occurring hydroxy derivatives of 9,10-anthraquinone such as chrysophanic acid (Ch), rhein (Rh) and emodin (Em) at mercury and glassy carbon electrodes using two different supporting electrolytes in chloroform is described. In the presence of piperidinium perchlorate (0.75*M*) + piperidine (0.25*M*) as a suitable acid supporting electrolyte, the reduction of Ch and Rh was a reversible two-electron process without complicating chemical reactions or adsorption phenomena, but the reduction process of these compounds in the presence of tetrabutylammonium perchlorate (TBAP) 0.5*M* + 5% acetic acid (AcOH) in chloroform was quasi-reversible. In both supporting electrolytes the overall reduction process of Em was irreversible. In the AC polarography and DP voltammetry at a GC electrode, the detection limit for Ch, Rh and Em was acceptably low and the relative standard deviation for the determination of $5 \times 10^{-6}M$ level, never exceeded 2%. AC polarography has been used for the determination of Ch and Em in a local rhubarb sample after extraction into chloroform and separation by column chromatography.

The hydroxy derivatives of 9,10-anthraquinone are of great importance in phytochemistry and pharmacy. Dock-flower, senna and rhubarb have all been used as oriental laxative medicaments owing to the presence of anthraquinones. Simultaneous determination of hydroxy derivatives of anthraquinone in some medicinal plants and pharmaceutical preparations has remained a problem in analytical chemistry for years. The earlier methods involved analytical methods, combined with separation procedures as TLC–spectrophotometry,[1] TLC–fluorimetry,[2] TLC–densitometry,[3] extraction–spectrophotometry,[4] and column chromatography–spectrophotometry.[5]

Because of the pronounced oxidation–reduction properties of anthraquinones, electrochemical methods are convenient for their determination. A few polarographic methods have been reported.[6,7] Most of these methods, suffer from a lack of sensitivity or specifity and are time-consuming and complex. Some methods based on HPLC reported recently[8,9] are relatively fast and selective.

On the basis of the results obtained from our previous studies on the electrochemical behaviour of quinones and anthraquinones in chloroform,[10–12] extraction AC and DP polarography in chloroform has been used for the determination of K group vitamins and anthracycline group anticancer drugs in pharmaceutical preparations.[13,14] In this manner, the AC method was used for the determination of 9,10-anthraquinone in paper samples and black liquors after their extraction into chloroform.[12] Extraction polarography for the determination of naturally occurring hydroxy derivatives of 9,10-anthraquinone seems to be fast and simple. On the other hand, in our analytical chemistry department, 1,8-dihydroxy 6,methylanthraquinone or chrysophanic acid (Ch), 1,8-dihydroxy 3,carboxyanthraquinone or rhein (Rh) and 1,3,8-trihydroxy 6,methylanthraquinone or emodin (Em), three principal anthraquinone derivatives in medicinal plants (Scheme 1) were recently separated by HPLC

Scheme 1

using chloroform–acetic acid (95:5) as mobile phase.[15] Therefore, the electrochemical detection of these compounds in HPLC seems to be possible. In this respect, the study of electrochemical behaviour of Ch, Rh and Em in chloroform at mercury and solid electrodes is desirable.

This paper presents the results obtained from polarography of Ch, Rh, and Em in chloroform in the presence of 0.75*M* piperidinium perchlorate (PP) + 0.25*M* piperidine (P) as a suitable supporting electrolyte[12] and voltammetry on a glassy carbon electrode in chloroform–acetic acid (95:5) + 0.5*M* tetrabutylammonium perchlorate (TBAP). An attempt is made to use AC polarography for the determination of Ch, Rh and Em in rhubarb roots.

## EXPERIMENTAL

### *Chemicals and reagents*

The solvent used was chloroform G.R from E. Merck or Fluka. Piperidinium perchlorate (PP) 0.75*M* + piperidine (P) 0.25*M* or tetrabutylammonium perchlorate (TBAP) 0.5*M* were used as supporting electrolytes. PP was prepared by gradual addition of the required amount of perchloric acid to a given volume of piperidine at room temperature. TBAP was purified by recrystallization from a mixture of water–acetone and drying at 60°C *in vacuo* for 24 hr.

Chrysophanic acid (Ch), rhein (Rh) and emodin (Em) were from Aldrich, other chemicals were P.A grade from E. Merck or Fluka.

### *Electrodes*

The reference electrode, Ag/AgI (satd), TBAI 0.05*M* and TBAP 0.50*M* in chloroform in separated compartments, was directly immersed in the reaction cell. It gave stable and reproducible potentials when evaporation was prevented and the solution was protected from light. The working electrode was mercury (DME and HMDE) or glassy carbon (GC) disk (0.062 $cm^2$ area obtained from Metrohm or 0.126 $cm^2$ from EG & G). The auxiliary electrode was a platinum wire.

### *Apparatus*

All voltammograms were recorded with a three electrode system. A multipurpose instrument from EG & G including; potentiostate/galvanostat model 273, Electrochemical Analysis Software 3.00 model 270 coupled with an IBM Personal computer and an Epson FX 850 printer were used. A rotating electrode system model 616 from EG & G was used for the voltammetric measurements at a rotating GC disk electrode A polarecord E 506 with E 663 stand, a function generator V.A. Scanner 610 from Metrohm and a X-Y Hewlett-Packard 3310-A recorder were used for AC polarography at DME and cyclic voltammetry at HMDE.

In all electrochemical experiments the test solution was deaerated by a stream of $N_2$ passing through chloroform.

### *Extraction of free anthraquinones from a local rhubarb sample (procedure I)*

Some free hydroxy derivatives of anthraquinone such as Ch, Rh and Em are soluble in chloroform and, therefore, can be extracted from medicinal plants as follows: about 0.05 g of powdered rhubarb root sample was weighted and placed in a 15 ml test tube. It was extracted with chloroform, shaken three times with 10,10 and 5 ml portions of chloroform (15 min each on a shaker), centrifuged in order to separate and the chloroform layers combined.

### *Extraction of anthraquinonic glycosides (procedure II)*

After extraction of the free anthraquinones (oxidized forms) from the sample, the residue was shaken three times with 10,10 and 5 ml portions of water–methanol (50:50) mixture (15 min each on a mechanical shaker) and the

residue separated by centrifugation. In order to hydrolyse the glycosides, the water–methanol phase was placed in a funnel equipped with a water cooler, 2.5 ml of conc HCl added, boiled for 20 min, cooled and transferred into a 100 ml separatory funnel. The released anthraquinones were extracted three times with 10,10 and 5 ml portions of chloroform, and the extracts combined.

*Extraction of total anthraquinones (procedure III)*

In order to hydrolyse and oxidize the glycosides and the reduced forms of anthraquinones, about 0.05 g of powdered sample was placed in a 15 ml test tube, and the procedure for anthraquinone glycosides followed, replacing 2.5 ml HCl with 2.5 ml HCl–40 ml $FeCl_3$ 10% (as an oxidizing agent). In this process the total anthraquinones were extracted into chloroform as their free oxidized forms.

*Identification of hydroxy derivatives of anthraquinone occurring in the rhubarb root sample (procedure IV)*

Using the chloroform layers obtained from the extraction procedures above for TLC, the sample spot was accompanied by spots of standard solutions of Ch, Rh and Em with a 2 cm interval, using TLC plastic sheets, silica gel 60 F 254 layer thickness 0.2 mm. The plate was developed for 10 cm in a mixture of cyclohexane and ethylacetate (60:40), dried at 100°C and the spots detected under UV light.

*Separation of the extracted hydroxy derivatives of anthraquinone by column chromatography (procedure V)*

Fifteen grammes of silica gel was placed in a beaker containing a mixture of hexane and ethylacetate (60:40) as mobile phase and this suspended silica gel entered in a column 20 cm long and 2 cm diameter with a stopcock and allowed to settle into a wet bed with a little liquid remaining above the surface. The stopcock was opened and the liquid level allowed to fall just to the top of the bed. The chloroform layers obtained from the extraction processes were evaporated on a water bath, and the residues dissolved in 2 ml of mobile phase, this solution was carefully pipetted onto the top of the bed. The mobile solvent reservoir containing about 60 ml of mobile phase was positioned and the flow of this phase started with a flow rate of 0.3 ml/min. The effluent solution was collected in a series of 20 fractions of 3 ml each, using a fraction collector they were grouped into two groups of 10 fractions by TLC. Combining the fractions of each group, the solvent was evaporated and the residues dissolved in 10 ml chloroform and transferred into the polarographic cell. The quantities of Ch and Em were determined by AC polarography using PP ($0.75M$) + P ($0.25M$) as supporting electrolyte.

## RESULTS AND DISCUSSION

*Electrochemical behaviours*

*On the mercury electrode.* In chloroform in the absence of an acid and with a convenient supporting electrolyte such as TBAP, the reduction of Ch, Rh, and Em at the DME gives one cathodic wave related to the semiquinone formation.[10] The wave nearly coalesces with the cathodic limit of the electroactivity range, therefore an accurate and quantitative measurement of this wave could not be made. The results obtained from DC and AC polarography, controlled potential coulometry and cyclic voltammetry showed that the reduction of Ch and Rh in the presence of $0.75M$ PP + $0.25M$ P as a suitable acid electrolyte[12] in chloroform was a two-electron, nearly reversible process. The overall reduction reaction of Em under the same conditions was irreversible, because the cyclic voltammetry of Em at the Hg electrode gave only one cathodic peak and the corresponding anodic peak was not discernable. These may be attributed to the formation of reduction product, dihydroemodin, containing five hydroxyl groups per molecule and insoluble in chloroform (see Introduction). The formulation of insoluble dihydroemodin in this medium has been confirmed during the controlled potential coulometry of Em. Typical example of cyclic voltammograms obtained at a scan rate of 100–800 mV/sec are shown in Fig. 1 and characteristic data of DC and AC polarograms are summarized in Table 1.

*On solid electrodes.* Current–potential curves for the reduction of $5 \times 10^{-4}M$ chrysophanic acid, rhein and emodin in chloroform–acetic acid (95:5) in the presence of TBAP $0.5M$, were recorded at GC, Pt and Au electrodes. Under these conditions, the studied anthraquinones were not reducible at Pt and Au electrodes. At the GC electrode with different rotation speeds, a single two-electron cathodic wave with a well defined limiting current was obtained (Fig. 2a). The height of the waves was linearly dependent

§$E_p$ of pulse voltammograms at GC electrode.

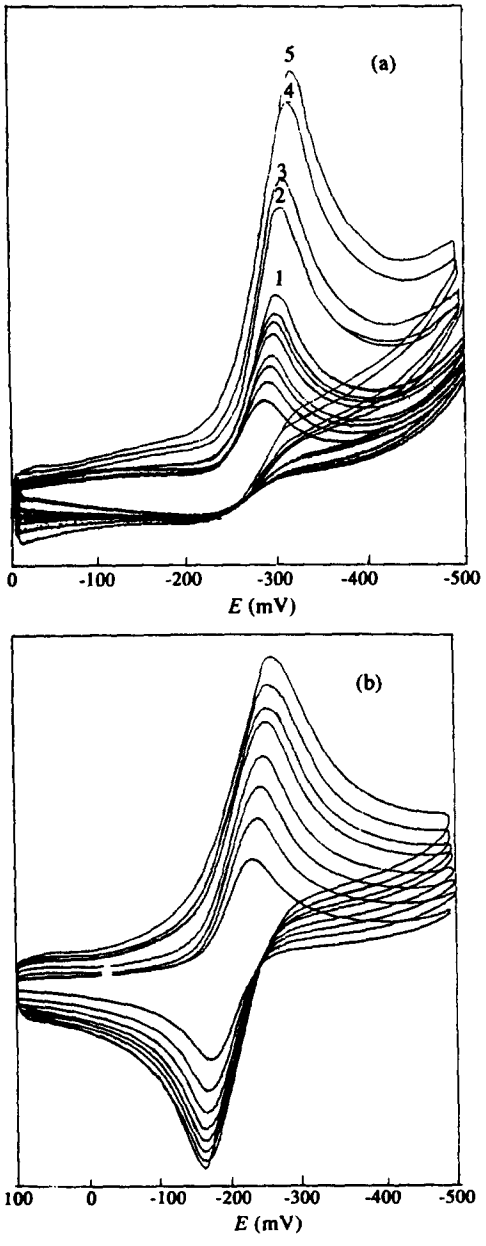

Fig. 1. Cyclic voltammograms of (a) 0.2 m*M* emodin and (b) 0.5 m*M* rhein at HMDE in chloroform solution of 0.75*M* PP + 0.25*M* P. Scan rates: 100–800 mV/sec, for rhein in 100 mV increments, for emodin (1) 100 (2) 400, (3) 500, (4) 700 and (5) 800 mV/sec.

on the concentration of the anthraquinones. This linearity confirms that the electrode process was mass transfer dependent. Plotting of $\log[(i_d - i)/i]$ against $E$, gave a straight line with a slope of 0.048, 0.048 and 0.068 V, respectively. The slopes obtained indicate that the reduction of Ch and Rh in this medium was a two-electron quasi-reversible process, but the reduction process of emodin tended to be irreversible.

Cyclic voltammetry of Ch and Rh at GC electrode produced one cathodic and anodic peak for each, but for emodin the corresponding anodic peak was not discernable. The values of $\Delta E = E_p^a - E_p^c$ for Ch and Rh at a low scan rate (<20 mV/sec) and with IR compensation were 55 and 56 mV, respectively. The $i_p^a/i_p^c$ ratio at a scan rate of 20 mV/sec was 0.75 which increased to unity at a scan rate of 2000 mV/sec. These confirm that an irreversible chemical reaction follows a quasi-reversible electron transfer reaction, note that the following chemical reaction is very fast in the case of emodin.

*Analytical application*

The results obtained from the studies on the electrochemical behaviour of Ch, Rh and Em at mercury and glassy carbon electrodes indicate that the electrochemical reduction of these compounds is quasi-reversible. These findings suggest the possibility of using polarography and voltammetry at a GC electrode for the determination of these compounds in chloroform in the presence of two different supporting electrolytes.

*AC and DP polarography.* AC polarography in the presence of PP (0.75*M*) + P (0.25*M*) gave a well defined two-electron reduction peak for each anthraquinone. The calibration graphs were linear over the range $10^{-6}$–$5 \times 10^{-5}$*M* Ch, Rh and Em. The detection limits with this method were 0.2, 0.1 and 0.8 μg/ml, respectively. The characteristic data of the AC polarograms are summarized in Table 1. From the data in the table it can be concluded that $\Delta E_p$ between Ch and Em, Ch and Rh are not large

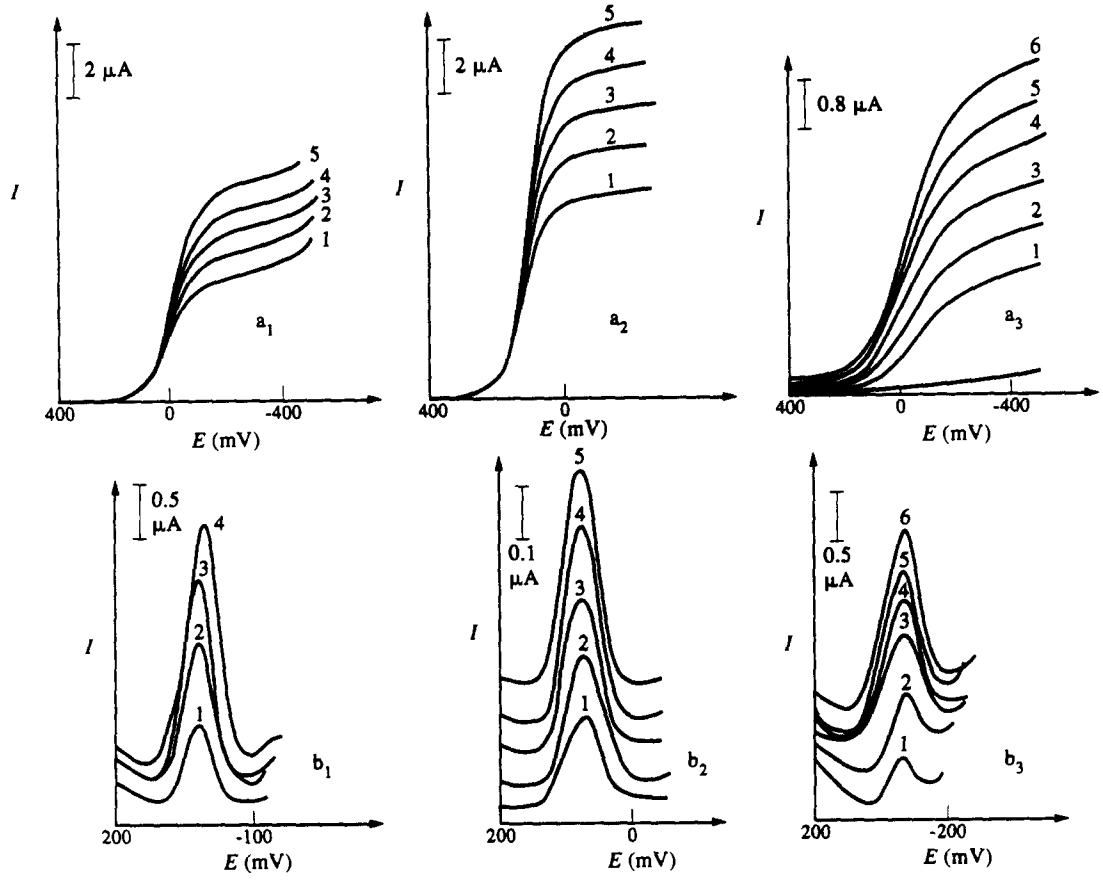

Fig. 2. Voltammetry of the anthraquinones in chloroform–acetic acid (95:5) + 0.5*M* TBAP at GC electrode ($A = 0.026$ cm$^2$). (a) Rotating disk voltammograms with rotation speed of 1000 rp/min. ($a_1$) Ch: 8, 9.1, 10.5, 11.9 and 13.3 × $10^{-5}$*M*, ($a_2$) Rh: 7.9, 9.1, 10.5, 11.9 and 13.3 × $10^{-5}$*M*, ($a_3$) Em: 5.4, 7, 8.6, 10.2, 11.7 and 13.1 × $10^{-5}$*M*. (b) Differential pulse voltammograms with pulse amplitude of 50 mV, pulse width of 60 msec, duration between pulses 1 sec, and scan rate 4 mV/sec: ($b_1$) Ch: 2.37, 4.72, 7.04 and 9.35 μ*M*, ($b_2$) Rh: 2.25, 2.68, 3.09, 3.5 and 3.91 μ*M*, ($b_3$) Em: 1.85, 3.64, 5.36, 7.01, 8.62 and 10.17 μ*M*.

enough to allow simultaneous determination of these compounds in a mixture. The assays in this connection remained unsuccessful.

The pulse polarograms recorded under the same conditions coalesced with the cathodic limit of electroactivity range and quantitative measurement of these peaks could not be made.

*DC and DP voltammetry at a GC electrode.* DC voltammetry at a rotating disk GC electrode revealed that the height of the waves was linear dependent on the concentration of the anthraquinones (Fig. 2a). The correlation coefficient of the calibration graph over the range 5 × $10^{-5}$–$10^{-3}$*M* was 0.999. The relative standard deviation for three determinations of 5 × $10^{-5}$*M* of the anthraquinones was about 1.5%. The detection limit for Ch, Rh and Em was 1.5, 1 and 5.7 × $10^{-5}$*M*, respectively. On the other hand, a well defined DP voltammogram was obtained for different concentrations of Ch, Rh and Em at a GC electrode in chloroform–acetic acid (95:5) + 0.5*M* TBAP (Fig. 2b). The calibration graphs were linear over the range $10^{-6}$–5 × $10^{-5}$*M* and the detection limit obtained at about 5 × $10^{-7}$*M* is acceptably low. The method may thus be used for the determination of anthraquinones in μg/ml concentration level. The relative standard deviation for the determination of $10^{-6}$*M* Ch and Rh was about 3%. The characteristic data of the DC and DP voltammograms are summarized in Table 1. From the data in Table 1 the $E_{\frac{1}{2}}$ and $E_p$ of Ch, Rh and Em are very close to each other and simultaneous determination of these compounds by DP voltammetry was not possible.

*Analysis of a local rhubarb*

*Determination of free anthraquinones.* AC polarography of 10 ml portion of chloroform layer obtained from the extraction of 0.027 g of the rhubarb root into 25 ml chloroform (procedure I) in the presence of PP (0.75*M*) + P (0.25*M*) as

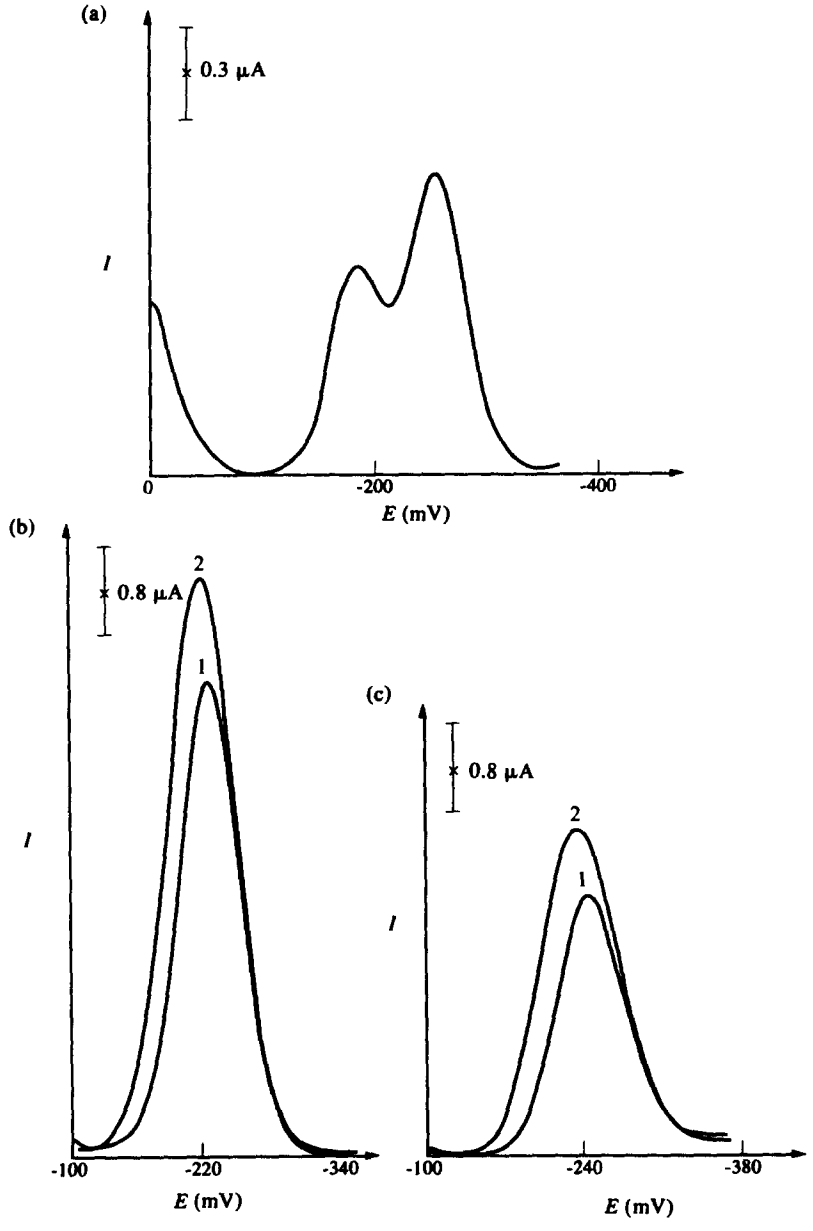

Fig. 3. Alternating current polarograms of (a) chloroform layer containing free anthraquinones obtained according to extraction procedure I for 0.027 g of a local rhubarb root sample into 25 ml chloroform, (b, c) combined fractions obtained from column chromatography (procedure V) for 0.067 g of sample, ($b_1$) Ch, ($c_1$) Em, ($b_2$) $b_1$ + 0.2 ml $5 \times 10^{-4}M$ Ch, ($c_2$) $C_1$ + 0.2 ml $5 \times 10^{-4}M$ Em. Supporting electrolyte was 0.75$M$ PP + 0.25$M$ P. $\underset{\sim}{V}$ = 10 m $V$, $f$ = 1 sec and $f$ = 75 Hz.

supporting electrolyte, presents two peaks with peak potentials very close to $E_p$ of Ch and Em under the same conditions (Fig. 3a). Addition of a standard solution of Ch or Em to the test solution augmented the height of the first or second peak, respectively. TLC of this chloroform layer confirmed that chrysophanic acid and emodin were the unique free anthraquinone

Table 2. Amounts* (percent in dried sample) of different forms of hydroxy derivatives of 9,10-anthraquinone in a local rhubarb root sample

components of the sample. A precise and simultaneous determination of Ch and Em was unsuccessful. Therefore, the components of the solution were separated by column chromatography according to procedure (V) and then determined by AC polarography using the standard addition method. Typical example of AC polarograms related to Ch and Em, extracted from 0.067 g of the rhubarb sample and separated by column chromatography are shown in Fig. 3b, c and the quantity obtained for each are summarized in Table 2.

*Determination of glycosides and total anthraquinones.* TLC of the chloroform layer obtained from extraction procedures II and III showed that the anthraquinones released during the acid hydrolysis of glycosides and oxidation of reduced forms were again Ch and Em. The chromatographic separation and AC polarographic measurement of the released anthraquinones were carried out in a similar manner as described for the free anthraquinones. The results are shown in Table 2.

*Recovery studies*

The extraction efficiency of the free anthraquinones into chloroform (procedure I) was investigated as follows: solid residue left from the extraction step was added to a polarographic cell containing a chloroform solution of PP (0.75$M$) + P (0.25$M$), in which the solubility of free anthraquinones is high. The mixture was stirred for about 20 min and allowed to settle. AC polarography of the solution showed that free anthraquinone was absent from the residue. This confirms the exhaustion of the sample during the extraction by chloroform.

In addition, the recovery of spiked powdered rhubarb samples with a known amount of pure Ch + Em was very close to 100%. Nearly 100% recovery of spiked extracting solvent of glycosides (water + methanol) with a known quantity of pure Ch + Em and anthrone (reduced form of anthraquinone) has been confirmed during the extraction by procedures II and III, respectively. We have also shown that the reduced forms of anthraquinones in the samples were not oxidized by dissolved oxygen in the solutions during the extraction steps according to procedures I and II. This study was carried out using anthrone as an available reduced form of anthraquinone. The results obtained from recovery studies are summarized in Table 3.

## CONCLUSION

On the basis of results obtained from DC and AC polarography, controlled potential coulometry and cyclic voltammetry, the reduction of Ch and Rh in the presence of PP (0.75$M$) + P (0.25$M$) in chloroform is a two-electron nearly reversible process, but the overall reduction reaction of Em was irreversible in this medium. The results obtained from rotating disk electrode and cyclic voltammetry at a GC electrode confirm that the reduction of Ch, Rh and Em in 5% AcOH + 0.5$M$ TBAP solution is a two-electron quasi-reversible process following an irreversible chemical reaction.

DC and AC polarography are directly applicable for the determination of Ch, Rh and Em in chloroform. From data in Table 1 it can be concluded that $\Delta E_{\frac{1}{2}}$ or $\Delta E_p$ between Ch and Rh, and Ch and Em are not large enough to allow determination of these compounds in a mixture. Therefore, the analysis of the mixture necessitates a preliminary separation by column chromatography. The AC polarographic method proposed in this work is suitable for the analysis of rhubarb roots.

The results obtained from differential pulse voltammetry reveal that this method may be used for the determination of Ch, Rh and Em at the $\mu$M/l level in chloroform. On the other hand, these findings suggest the possibility of using the amperometric measurement at the GC electrode for the electrochemical detection of the naturally occurring hydroxy derivatives of

9,10-anthraquinone during their analysis by HPLC using chloroform–acetic acid (95:5) as mobile phase (flow rate of 0.6–1 ml/min) and Spherisorb–CN as stationary phase. These are presently under investigation in our laboratory.

# ON-LINE PRECONCENTRATION AND SEPARATION OF PALLADIUM, PLATINUM AND IRIDIUM USING α-AMINO PYRIDINE RESIN WITH FLAME ATOMIC ABSORPTION SPECTROMETRY

P. Di and D. E. Davey*

School of Chemical Technology, University of South Australia, The Levels, S.A. 5095, Australia

(*Received* 18 *March* 1994. *Revised* 17 *October* 1994. *Accepted* 21 *October* 1994)

**Summary**—A flow injection on-line microcolumn method has been studied for the separation and preconcentration of noble metals, Pd, Pt and Ir, followed by flame AAS determination. An α-amino pyridine resin was used as preconcentration reagent. Non-noble metals studied could be eliminated by 2*M* HCl solution in the rinsing stage. A group-eluent for all Pd, Pt and Ir was studied. Separation of individual noble metals could also be accomplished using selective eluents. This approach can be used both for the separation and determination of Pd, Pt and Ir in samples. The sensitivities and the sample frequency have been improved. The method has been applied to certified samples.

The separation and determination of trace amounts of noble metals in mineral, metallurgical and environmental samples has been made difficult by the limited concentration of these metals in nature, and various interferences in both separation and determination methods. A preconcentration procedure is, therefore, often needed to increase concentration levels in analysed solutions and remove matrix interference. A number of organic extractants for the concentration and separation of noble metals have been studied by solvent extraction and paper and column chromatography.[1–6] Some chelating resins have been found more effective,[7,8] whilst cationic surfactants have also been investigated.[9] Efforts have also been made to improve determination methods of noble metals. For example, Lu *et al.* modified a tungsten wire with trioctylphosphine oxide (TOPO) to preconcentrate gold in waste water, then placed the wire in a graphite cup for direct atomic absorption spectrometry determination.[10] However, it is true to say that traditional preconcentration methods have been unwieldy, with large sample consumption (50–500 ml) and long preconcentration times (10–100 min per sample).[11,12]

On-line preconcentration techniques offer a way around these hurdles, and atomic absorption spectrometry (AAS) or inductively coupled plasma-optical emission spectrometry (ICP-OES) promise improved sensitive and rapid methods for trace element analysis by such means.[13–16] Recently, Taylor[17] and Qi[18] presented methods for gold analysis with on-line preconcentration AAS, the first by forming supported-liquid membranes, the second linking a functional group of a neutral phosphine oxide extractant to an inert fibre and then packing the fibre into a column. They reported that the sensitivity and analysis frequency were greatly improved using these techniques.

Compared with off-line preconcentration methods, an on-line method requires a fast concentration and elution reaction, which implies that highly selective reagents are needed in a continuous-flow system. In our previous work,[19] an organophosphorus compound, di(methylheptyl)methyl phosphonate (DMHMP), was studied as an on-line preconcentration reagent for gold with AAS analysis, the basis for the selection being the work of Li and coworkers.[20] These authors determined the selectivities of DMHMP for more than 50 metals with paper chromatography, and it was found that only Au and Tl could be fully retained by DMHMP. Following the lead given by Pohlandt and

Table 1. AAS parameters used for the determinations of Pd, Pt and Ir

| Element | Wavelength (*nm*) | Slit (*nm*) | Lamp current (*mA*) | Flame type and flow rate (*l./min*) | Burner height (*mm*) | Aspiration rate (*ml/min*) |
|---|---|---|---|---|---|---|
| Pd | 246.7 | 0.2 | 5.0 | air (8.0)–acetylene (2.5) | 5.0 | 4.5 |
| Pt | 266.0 | 0.2 | 10.0 | air (8.0)–acetylene (2.0) | 5.0 | 4.5 |
| Ir | 208.9 | 0.2 | 20.0 | air (8.0)–acetylene (3.0) | 5.0 | 4.5 |

Steele,[21] we then designed a reverse-phase extraction column for an on-line preconcentration system with the DMHMP coated on macroporous resin beads. Both a single column and dual column system were found to give increased sensitivity. A computer program was also developed to control both the FIA preconcentration procedure and simplex optimisation of the system parameters, such as the column dimensions, the flow rates and the aspiration rate of flame AAS.[19]

In fact, as pointed out by Qi,[18] a number of preconcentration reagents are available for noble metals. Some neutral phosphine oxide and nitrogenous extractants have been found so effective for noble metals that their extraction constants are several orders of magnitude higher than those of competing elements.[22,23] However, if the affinity of noble metal with reagent is too strong, elution would become more difficult, a particular problem in an on-line operation. In such cases, to determine the noble metals, the resin containing the analytes has to be decomposed to prepare the analyte solution,[23] or alternatively, some strong acids have to be used in the elution.[8,21] Some reverse-phase extraction columns are not suited to this circumstance as a relatively weak physical adsorption exists between extractants and adsorbent resin beads, and the lifetime of the column would be affected by strong acid.

In the present study, an α-amino pyridine (AP) resin, formed by bonding a functional group of α-amino pyridine to a cross-linked polyphenylethene support, has been selected as the immobilized phase of the column. A similar on-line manifold to that previously designed by us for a Au study[19] has been employed to preconcentrate and separate the other noble metals, namely Pd, Pt and Ir. Eluents, both for the group of elements, and also for the individual metals were studied. The resin has performed well in both the preconcentration and elution stages for the noble metals analysed, flame atomic absorption spectrometry being used as the analysis method.

## EXPERIMENTAL

### *AAS determination*

The atomic absorption spectrometer used for all determinations throughout this work was a GBC 905 flame model instrument (GBC Scientific Equipment Pty Ltd, Australia). GBC hollow cathode lamps for Pd, Pt and Ir were used in the experiments. Peak areas computed by the software in the AA instrument were chosen for the measurements of Pd and Pt and peak height was chosen for the Ir determination. The graphs and data were printed with an Epson RX 80 printer (Epson Corporation, Japan). All backgrounds were corrected by the deuterium lamp. All instrumental parameters are summarized in Table 1.

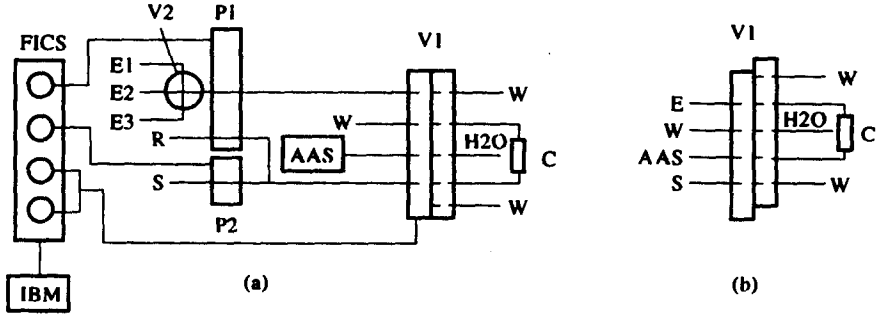

Fig. 1. The manifold used with on-line separation and preconcentration of Pd, Pt and Ir with AAS determination. (a) Preconcentration stage; (b) separation and elution stage. S: Sample; E, E1, E2, E3: eluent; R: rinsing solution; and W: waste.

*On-line preconcentration system*

The manifold of the on-line preconcentration flow injection system is shown in Fig. 1. It consists of two peristaltic pumps (an 8-channel multi-speed pump P1, Gilson, France, and a single speed pump P2, Mini-S 860, Ismatec, Switzerland), a pneumatic valve (V1, home-made) with a glass microcolumn (C), and a flow injection control system (FICS, home made) linked to an IBM computer. A four-way rotary valve (V2, Rheodyne Incorporated, U.S.A.) was also used to change eluent. Tygon pump tubes (2.06 mm i.d.) were used for all solutions and connected by Teflon connectors (Gradko, U.K.) to PTFE fine-bore tubing (0.8 mm i.d.).

A program allowing the time parameters to be entered into the computer prior to the run was developed to control the on-line preconcentration operations. Sixty seconds was chosen for the preconcentrations, and 20–30 sec was selected for the elutions.

*Reagents*

Stock solutions of Pd, Pt and Ir (each 1 mg/ml) were prepared using spectro-grade $(NH_4)_2PdCl_4$, $(NH_4)_2PtCl_6$ and $(NH_4)_3IrCl_6$ (Chemicals Co. Pty. Ltd, Tianjin, China). An α-amino pyridine (AP) resin (60–80 mesh, Institute of Polymer Chemistry, Nankai University, China) was employed as an immobilized phase. Buffer solutions were prepared from $KH_2PO_4$(AR) by NaOH addition. The other chemicals used in this work are all analytical grade.

*Column preparation and regeneration*

The AP resin contained in a beaker was washed repeatedly following the sequence, 6*M* HCl solution, deionized water, 6*M* NaOH solution, and then deionized water. The deionized water wash was continued until the effluent solution became neutral. One end of the glass column was first blocked with a small piece of plastic foam. The column was then filled with the AP resin. The other end of the column was again finally blocked with foam. The column dimensions were 3.5 mm (i.d.) × 10 mm (l); 10 ml 0.5*M* $Mg(ClO_4)_2$–0.5*M* $HClO_4$–0.5*M* HCl solution was used to regenerate the column.

## RESULTS AND DISCUSSION

*Preconcentration reaction*

Separation and concentration reagents most used for platinum metals and gold include organophosphorus,[1-3,18] sulfoxide[24] and thiourea derivatives,[8,25,26] and some nitrogen-containing compounds.[11,12,27] Most of them contain either a lone pair-bearing atom or a group readily protonated in an acidic solution, or both of these. Two mechanisms were proposed by Mojski[1] for the extraction of noble metal chloride complexes:

(a) solvation

$$MeCl_p^{(p-n)-} + m(R)_{(o)} = MeCl_n(R)_{m(o)} + (p-n)Cl^- \quad (1)$$

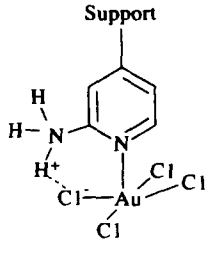
(b) ion-exchange

$$MeCl_p^{(p-n)-} + (p-n)(RH^+ \cdot Cl^-)_{(o)} = (RH^+)_{p-n}MeCl_{p(o)}^{(p-n)-} + (p-n)Cl^-, \quad (2)$$

where Me is a noble metal, R is an extractant or a resin, and o represents an organic phase or a resin phase.

In the first case, the reagent must have one or more co-ordinate atoms available to replace the chloride ligands from the central ion. In the second, the system requires an acid environment to protonate the organic reagent.

The α-amino pyridine (AP) resin selected in this study, contains a coordinating pyridine N and an amino group which easily associates with $H^+$ in acid solution. The structure of the AP resin with $AuCl_4^-$ has been discussed[28] and is given as follows:



A similar mechanism may apply in the present study for $PdCl_4^{2-}$, $PtCl_6^{2-}$ and $IrCl_6^{3-}$. $[PdCl_4]^{2-}$ is either a planar,[29,30] or a bridged structure. Such bridged species are generally subject to cleavage by donors to give mononuclear species.[31] $PtCl_6^{2-}$ and $IrCl_6^{3-}$ are known to be octahedral complex anions.[31] During the preconcentration stage, the AP resin may form coordinate complexes with these anions by replacing the chloride ions with pyridine N linkages or form ion pair compounds by association through the chloride ions in the complex with the $—NH_3^+$, or both processes may happen at once, as with $AuCl_4^-$.

pH tests show that the recoveries of Pt and Ir are not effected significantly within the pH range 0–5, while the recovery of Pd strongly decreases

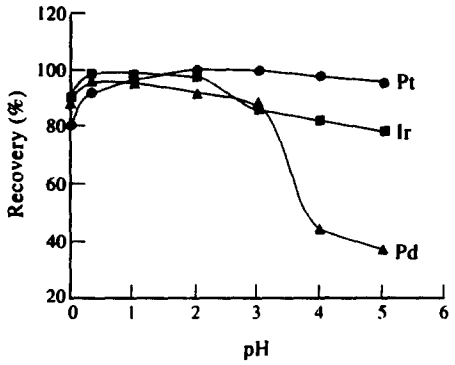


Fig. 2. Effect of pH on the preconcentration of Pd, Pt and Ir. The concentrations of solutions are 0.5 μg/ml for Pd, 1 μg/ml for Pt, and 10 μg/ml for Ir.

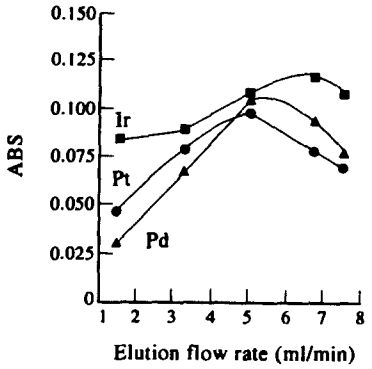

Fig. 4. Effect of elution rate on the determination of Pd, Pt and Ir. The flow rates were changed by altering the pump speed during the elutions. The same eluent, 0.5*M* $Mg(ClO_4)_2$–0.5*M* $HClO_4$–0.5*M* HCl, was used for three elements. Noble metal concentrations as in Fig. 2.

when pH > 2 (Fig. 2). Therefore, the reactions of platinum and iridium with AP resin appear to mainly conform to the solvation mechanism, while ion exchange may be involved in the preconcentration of palladium.

Figure 2 shows that recoveries greater than 90% were achieved for Pd and Ir when the pH was between 0.3 and 2. Pt showed similar recoveries in the pH range 0.3–5. In the experiment, the solutions to be analysed could be prepared in pH 0.3–2 solution for the preconcentration of Pd, Pt and Ir. Of course, the other interesting feature of this experiment is that pH 4–5 can now be chosen to partially eliminate Pd in the Pt and Ir preconcentration steps.

*Flow rates during sample introduction and elution*

Since a time-based sampling mode was used in the preconcentration stage, a faster sample flow rate may provide improved sample throughput through the column. However, analytes may not be efficiently preconcentrated on the column, and partly lost when the flow rate is too high. A sample flow rate of 6.4 ml/min using 2.06 mm (i.d.) pump tube was found optimal for the preconcentrations of all three elements (Fig. 3).

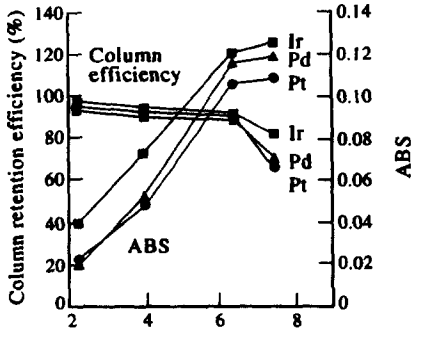

Fig. 3. Effect of sample flow rate on the column retention efficiency and absorbance for Pd, Pt and Ir. The column retention efficiency were obtained by measuring the concentrations of the solutions before and after their passing the column. See Fig. 2 caption for the concentrations of the metals.

The optimal elution rates of Pd, Pt and Ir were then determined, with a constant aspiration rate of 4.0 ml/min into the AAS. As shown in Fig. 4, Ir was relatively easy to elute and gave a higher absorbance at the elution rate of 6.8 ml/min, while the elution of both Pt and Pd was best carried out at the flow rate of 5.0 ml/min.

The fast sample and elution flow rates prove that the AP resin has performed satisfactorily during both the preconcentrations and the elutions. Firstly, a fast sample flow rate implies improved sensitivity, with good sample throughput; secondly, a fast preconcentration reaction provides the column with good retention efficiency for the selected analytes; and thirdly, a good tolerance of the resin for strong acid elution ensures a long lifetime for the column.

*The selection of eluents*

*Group elution.* Perchloric acid and solutions of perchlorate salts have been used to elute noble metals in off-line column preconcentration systems with similar reagents to that studied here.[28,32] In this study, $NaClO_4$ and $Mg(ClO_4)_2$ in HCl solution were investigated for Pd, Pt and Ir elutions. An unsatisfactory elution for Pt and high backgrounds in the three element determinations were, however, observed with $NaClO_4$ solution (Fig. 5a). $Mg(ClO_4)_2$ with 0.5*M* HCl solution was found effective in the elutions and gave a low background in the flame AAS determinations for the chosen noble metals

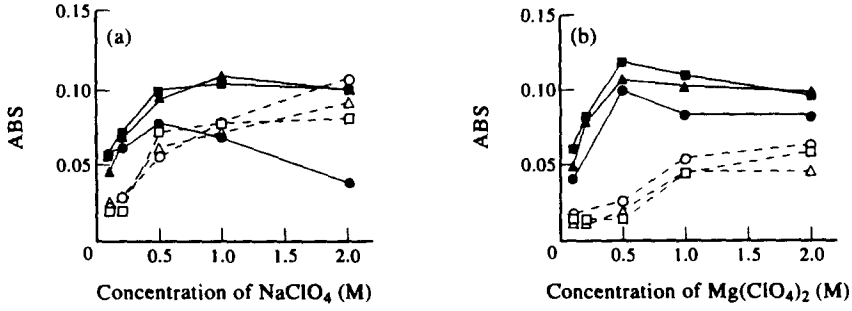

Fig. 5. Selection of the eluent for the Pd, Pt and Ir group. (a) 0.1–2.0*M* $NaClO_4$–0.5*M* HCl solution; (b) 0.1–2.0*M* $Mg(Cl_4)_2$–0.5*M* HCl solution. The dashed lines show the background absorption recorded during the determinations. [—▲— Pd; —●— Pt; —■— Ir; Background values - - - △ - - - Pd; - - - ○ - - - Pt; - - - □ - - - Ir].

(Fig. 5a, b). The better performance of the $Mg(ClO_4)_2$ solution can be attributed to its relatively low background in the flame, and in its ability to provide more $ClO_4^-$ (compared to a solution of $NaClO_4$), improving the overall metal elution. At a $Mg(ClO_4)_2$ concentration of 0.5*M*, even higher absorbances could be obtained but salt deposits occurred on the burner when the concentration of $Mg(ClO_4)_2$ was further increased. Thus, we chose to add 0.5*M* $HClO_4$ to the eluent to increase the $ClO_4^-$ concentration in the solution. A final solution of 0.5*M* HCl–0.5*M* $HClO_4$–0.5*M* $Mg(ClO_4)_2$ performed satisfactorily as the eluent for Pd, Pt and Ir. Figure 6 shows the elution curves of those elements determined individually using the flame AAS method. The procedure described should enable the simultaneous determination of the three noble metals listed using ICP-OES or multi-element AAS detection.

*Selective elutions.* Interferences between noble metals in their determinations by flame AAS may be of crucial importance, and thus efforts have been made to reduce such potential influences in determinations.[33,34] In this section of our work, selective elution for the metals has been studied to avoid any interference in determinations with the group eluent for samples with high concentrations of one or more noble metal.

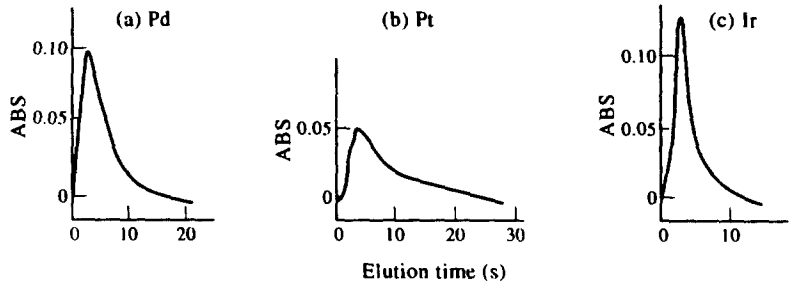

Fig. 6. Elution curves of Pd (a), Pt (b) and Ir (c) determined by FAAS. The eluent used was 0.5*M* HCl–0.5*M* $HClO_4$–0.5*M* $Mg(ClO_4)_2$ solution.

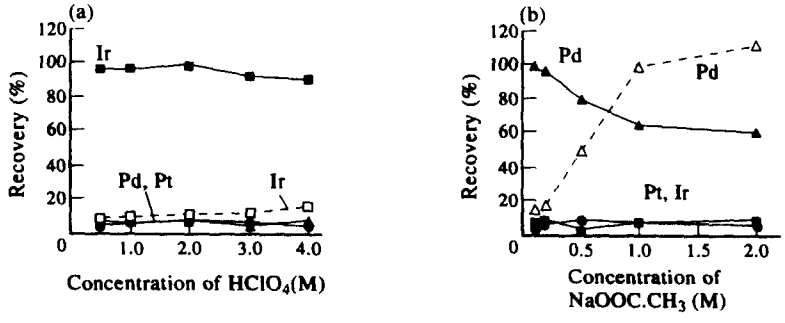

Fig. 7. Selection of the eluent for individual elements. (a) 0.5–4.0*M* $HClO_4$–4*M* HCl solution; and (b) 0.1–2.0*M* $NaOOC.CH_3$–0.5*M* HCl solution. The dashed lines show the relative absorption of the background against the analyte signal.

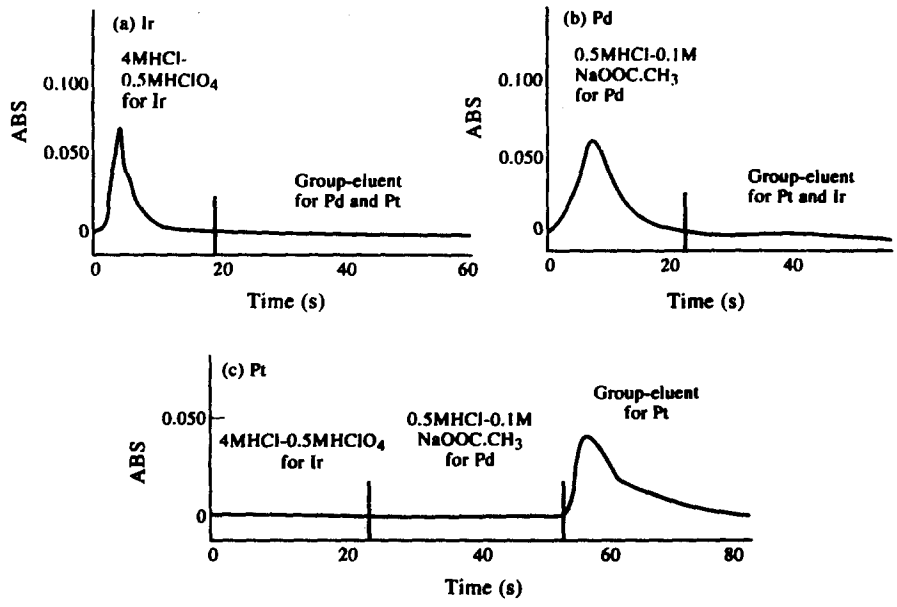

Fig. 8. Separation of Ir (a), Pd (b) and Pt (c) using selective eluents. The group eluent was 0.5*M* HCl–0.5*M* $HClO_4$–0.5*M* $Mg(ClO_4)_2$ solution.

0.5*M* $HClO_4$–4*M* HCl and 0.1*M* $NaOOC.CH_3$–0.5*M* HCl were found efficient for the Ir and Pd elutions, respectively. The performance of these eluents is shown in Fig. 7(a, b). The background absorption of eluents did not influence the determinations at the selected concentration of the eluents. The separation procedures for Pd, Pt and Ir, determined individually by flame AAS, are shown in Fig. 8(a–c).

In the cases of Fig. 8(a, b), Ir and Pd were the specific elements to be determined. They were eluted by their own selective eluents and determined at their characteristic wavelengths. Other metals of interest could be then eluted by the group eluent described earlier. Since no particular eluent had been found to be suitable for the Pt elution, the group eluent was used to elute that element (Fig. 8c). In this case, Ir and Pd had to be removed using the selective eluents prior to the Pt elution. No signal for Pt was detected during the Ir and Pd elutions.

*Separation of Pd, Pt and Ir with non-noble metals*

The influences of co-existing alkali, earth alkali and heavy metal salts in this system were investigated and the results are presented in Table 2. The non-noble elements studied could be washed off the column by 2*M* HCl solution prior to the elution of the noble metals. This separation step could be carried out for 20 sec or more in the rinsing stage of the system operation (Fig. 1a).

The recoveries of the noble metals were strongly influenced by iron in the solution at levels higher than 200 mg Fe/ml. This chemical

Table 2. Effect of the presence of salts on Pt, Pd and Ir recoveries

| Salt added | Concentration of added salt (*mg/l.*) | Recovery of the noble metals (%) Pt (5 *mg/l.*) | Pd (1 *mg/l.*) | Ir (5 *mg/l.*) |

interference can be eliminated by adding 0.2*M* EDTA solution to complex most of iron in samples prior to the sample preconcentration stage.

*Comparison with conventional methods*

Direct flame AAS possesses low sensitivity for the determination of noble metals. The sensitivity can be improved by combining a preconcentration procedure with the determination.[8] Conventional preconcentration methods are, however, time-consuming since many manual operations are involved in an off-line sample introduction and eluate collection. The on-line preconcentration technique with computer control provides a much quicker and more precise method for noble metal analysis. Table 3 compares the detection limits, relative standard deviations and sample frequencies of the on-line technique and conventional methods.

*Sample analysis*

Pd, Pt and Ir were separately determined using group eluent in mixed composition samples and certified standard samples, containing $K^+$, $Na^+$, $Ca^{2+}$, $Mg^{2+}$, $Al^{3+}$, $Fe^{3+}$, $Cr^{3+}$, $Ni^{2+}$, $Pb^{2+}$ and $Cu^{2+}$, with metal to analyte ratios of 200–60,000. Pd and Pt in a certified ore sample were also determined using the group eluent. Solutions containing different levels of Pd, Pt and Ir were prepared using the certified standard materials and determined separately both with the selective eluents. The results are shown in Table 4. Non-determined noble metals (50 mg/l.)

Table 4. Determination of Pt, Pd and Ir from mixed composition samples and certified samples

Samples 1–4 were prepared with the compounds mentioned in the experimental section and for matrices described in the text. Samples 5, 7–9 were prepared with certified standard materials, provided by Johnson Matthey, Materials Technology, U.K., with the same matrices as prepared for samples 1–4. Sample 6 is a certified ore sample, SARM 7, provided by South African Bureau of Standards (SABS), South Africa.
The results listed are the average values of six tests. Error estimates are appropriate standard deviation values.
*The concentration units of this sample were originally given in g/t, rather than mg/l. as given in the table.
UD: Under detection limit.
ND: Not determined.

were added to samples for the selective elution to test the efficiency of the elution process.

## CONCLUSIONS

On-line microcolumn preconcentration techniques have provided simpler, more sensitive and more rapid methods for the analyses of trace elements, being especially successful in heavy metal analysis. The reports concerning rare metal and noble metal analysis by this approach are, however, scarce because of the lack of appropriate preconcentration reagents.

In this study, an α-amino pyridine resin-packed microcolumn has performed satisfactorily for noble metal preconcentration and separation. Pd, Pt and Ir can be simultaneously retained on the column by adjusting the sample solution at pH 0.3–2 in the sampling stage, and then be eluted from the column using the group-eluent. Most non-noble metals studied do not influence the noble metal analysis and could be eliminated by 2*M* HCl during the rinsing stage. Separation of the noble metals could then be done by first adjusting the sample solution to pH 4–5, followed by elution for the individual element.

The use of an on-line flow technique and computer control meant that the analysis frequency was also increased compared to the conventional preconcentration method. The sensitivities and recoveries were satisfactory.

# SPECIATION OF Cr(III) AND Cr(VI) AND SEPARATION OF COMMON ANIONS BY ION PAIR CHROMATOGRAPHY WITH *TRANS*-1,2-DIAMINECYCLOHEXANE-*N*,*N*,*N*′,*N*′-TETRAACETIC ACID

A. PADARAUSKAS* and G. SCHWEDT†

Institut für Anorganische und Analytische Chemie, Technische Universität Clausthal, Paul-Ernst Strasse 4, 38670 Clausthal-Zellerfeld, F.R.G.

(*Received* 11 *August* 1994. *Revised* 25 *October* 1994. *Accepted* 25 *October* 1994)

**Summary**—A reversed phase ion pair chromatographic method for the simultaneous determination of Cr species and common anions on a $C_{18}$-bonded stationary phase was developed by using acetonitrile-water (2:98 v/v) containing 1.0 m*M* tetrabutylammonium hydroxide and 0.5 m*M* *trans*-1,2-diaminecyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid (DCTA) at pH 6.5 as mobile phase and UV-detection at 210 nm. Chromatographic parameters were optimized for separation of Cr(III)–DCTA complex, chromate and other anions. The detection limits were found as 8 ng/ml for Cr(III) and 35 ng/ml for Cr(VI). Under the optimum conditions, most other ions did not interfere. The method can be applied to separate a number of common anions simultaneously with the separation of Cr(III) and Cr(VI).

Chromium exists in the environment predominantly in two oxidation states, Cr(III) and Cr(VI). The toxicity of their compounds differs widely: the hexavalent state of chromium is more toxic than the trivalent state. Also, the trivalent state is necessary for the maintenance of normal glucose tolerance factor.[1,2] Therefore, it is important to establish an accurate, rapid and simple method for the determination of both chromium species.

Several methods for the speciation of chromium have been proposed, as shown in review articles.[3,4] In most of them only one Cr species is directly determined and the concentration of the other is calculated by substraction from the total Cr content, which is determined separately.

Some possibilities for separation of Cr species are co-precipitation,[5,6] ion-exchange,[7,8] or solvent extraction[9,10] followed by a spectrometric or electrochemical detection of Cr in the separated fractions. Both procedures are complicated and time consuming.

High-performance liquid chromatography (HPLC) is extensively applied to the determination and speciation of a number of metal ions. It provides several advantages over many other methods, as the separation, the identification and the quantitation of the different species down to trace concentration levels can be performed in one procedure. Schwedt[11] described a reversed-phase HPLC system with UV-detection for the separation and determination of Cr(III) and Cr(VI) by using different reaction products of Cr species with ammonium pyrrolidindithiocarbamate. The procedure is applied to the determination of both Cr species in waste water. Andrle and Broekaert[12] optimized this procedure by a modified simplex method.

Several papers have been published on the determination of Cr species using HPLC combined with atomic absorption spectrometric detection[13–15] and ion chromatography (IC) with direct current plasma emission[16] or chemiluminescence[17] detecton. However, when using hyphenated techniques, the interface usually complicates the operation procedure and the eluting condition is restricted by the detection mode.

An alternative to the traditional IC method is reversed-phase ion pair chromatography (IPC).

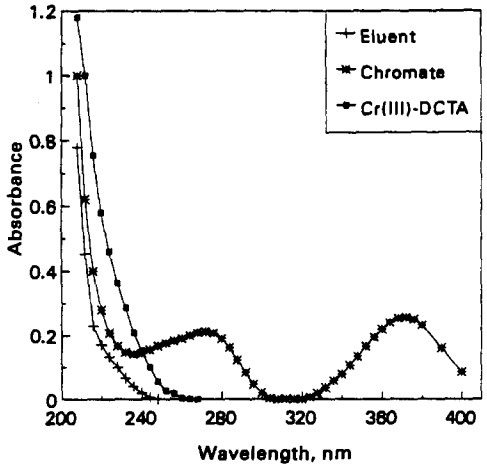

Fig. 1. UV-absorption spectra of Cr(III)–DCTA chelate, chromate and eluent. Chromium(III) and chromate concentrations, 0.1 m*M*.

In this method, a dynamic ion-exchange bed is created by the sorption of a hydrophobic counter ion (from a ion-pairing reagent) in the eluent on the stationary phase of a reversed-phase column.[18] In IPC many different parameters modify the retention of the solute and the selectivity of the separation. So it is more efficient and selective than IC and able to separate and determine inorganic, organic and complex ions.[19]

Usually, Cr(III) exists in a positively charged state and Cr(VI) in a negatively charged state. This can be simplified by converting Cr(III) to a negatively charged complex ion and then separating from Cr(VI). Aminepolycarboxilic acids are known for their ability to form highly stable metal complexes in a negatively charged state.[20] Jen *et al.*[21] used a reversed-phase IPC system with a $C_{18}$ column to determine Cr species based on the formation of a stable Cr(III) complex with ethylendiaminetetraacetic acid (EDTA). The interesting results obtained with this ligand suggest a possibility of using other aminopolycarboxilic acids. It is true that many metal complexes of 1,2-diaminecyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid (DCTA) have larger stability than the complexes formed by EDTA.[22]

In this study, a reversed-phase IPC procedure based on the off-line DCTA chelation was developed for the simultaneous separation and determination of Cr(III), Cr(VI) and common anions.

## EXPERIMENTAL

### *Apparatus*

The HPLC instrumentation consisted of a high-performance liquid chromatographic pump L-6000 with a 100-$\mu$l injection loop, an UV/Vis detector L-4200 and a Chromato-Integrator D-2000 (Merck/Hitachi, Darmstadt, F.R.G.). The separation column used was Nucleosil $5C_{18}$ (250 × 4 mm I.D.) (Macherey-Nagel, Düren, F.R.G.). Absorption spectra were obtained by a model Lambda 2 UV/Vis spectrophotometer (Perkin-Elmer).

### *Reagents and solutions*

All chemicals used were of analytical reagent grade. Deionized water was obtained by passing distilled water through a Waters Milli-Q water-purification system. Stock solutions for Cr(III), Cr(VI) and other anions were prepared from inorganic salts in concentrations of 1 mg/ml. Analyte solutions [except Cr(III)] were prepared

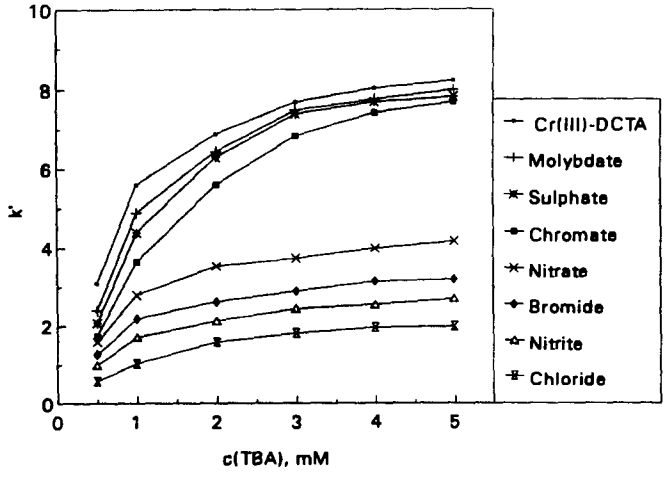

Fig. 2. Effect of TBA concentration on the capacity factor ($k'$). Eluent: acetonitrile–water (2:98 v/v) containing TBA and 0.5 m*M* DCTA, pH 6.5; flow-rate 1.0 ml/min.

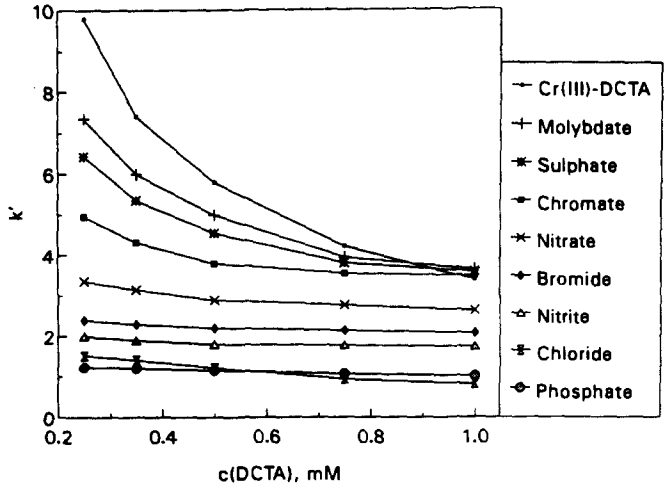

Fig. 3. Effect of DCTA concentration on the capacity factor ($k'$). Eluent: DCTA and 1 m$M$ TBA, other conditions as in Fig. 2.

daily by dilution of appropriate volumes of the stock solutions.

DCTA was obtained from Fluka (Neu-Ulm, F.R.G.), tetrabutylammonium hydroxide (TBA) from Merck (Darmstadt, F.R.G.). The acetonitrile used for mobile phase preparation was of HPLC quality (Merck, Darmstadt, F.R.G.). The mobile phase was prepared from acetonitrile, TBA and DCTA followed by pH adjustment with 0.1$M$ NaOH. All mobile phases were filtered through a 0.45 $\mu$m membrane filter and degased by stirring for 1 h under vacuum before use.

*General procedure*

The analyte solutions of Cr(III)-DCTA chelate were prepared in the following manner. To an aliquot of the solution containing $\leqslant 500$ $\mu$g of Cr(III) in a 25 ml calibrated flask were added appropriate [Cr(III)/DCTA molar ratio 1:5] volume of 5.0 m$M$ DCTA solution (pH 6.5). After heating in a water-bath at 60°C for 10 min, the solution was cooled to room temperature and diluted to the mark with water.

The formation of Cr(III)–DCTA complex was investigated by absorption measurements at 540 nm.[23] In all experiments the flow-rate of the mobile phase was 1.0 ml/min and samples of 100-$\mu$l volumes were analysed.

At least triplicate injections were made for each experiment. The relative standard deviations of capacity factors all of ions were less than 0.5%. The calibration graphs for Cr species were obtained by plotting the peak area against the concentration of the injected ion. The detection limits were obtained based on a signal-to-noise ratio of 3.

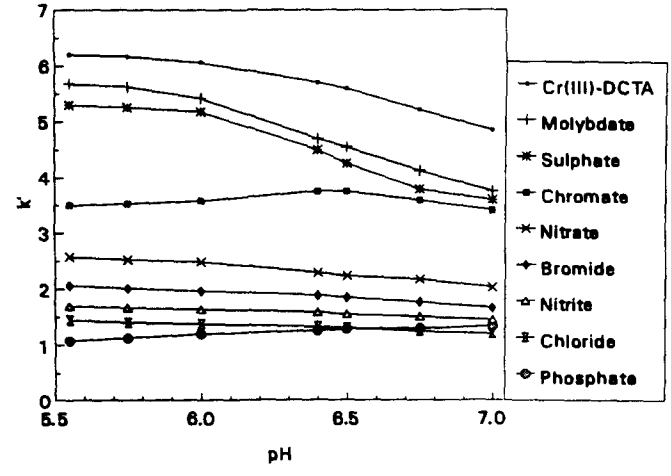

Fig. 4. Effect of eluent pH on the capacity factor ($k'$). Eluent: 1 m$M$ TBA, other conditions as in Fig. 2.

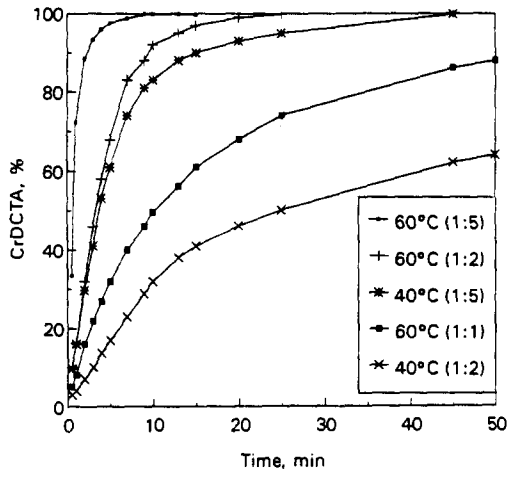

Fig. 5. Effect of temperature and Cr(III)/DCTA molar ratio on the rate of complex formation. All solutions at pH 6.5.

The building materials and leather extracts were prepared by shaking 0.200–0.500 g of the sample crushed with 20 ml of mobile phase or water for 6 hr. After addition of DCTA, heating and dilution as described above, the solutions were filtered through a 0.45 $\mu$m membrane filter and samples of 100-$\mu$l volumes were analyzed.

## RESULTS AND DISCUSSION

### *Absorption spectra of* Cr *species*

The UV absorption spectra of mobile phase containing 1 m*M* TBA, 0.5 m*M* DCTA and 2% acetonitrile (v/v) and both Cr(III) chelate with DCTA and chromate in the mobile phase against water as the blank are shown in Fig. 1. All solutions were at pH 6.8. Three absorption maxima of chromate were observed at wavelengths of 370, 272 and below 220 nm. The Cr(III)–DCTA complex does not absorb UV-light above 250 nm. Both Cr species are detectable at a wavelength range of 200–250 nm and the maximum of detection sensitivity is below 220 nm. In the present studies, a detection wavelength of 210 nm was used. This wavelength is suitable also for the direct detection of a number of anions (e.g. bromide, nitrite and nitrate) and indirect detection of anions, which have no absorption, such as chloride, phosphate and sulphate.

### *Effect of mobile phase composition*

It is important to choose mobile phase in optimizing separation of Cr species and other anions. Selection of the mobile phase concentration was based on not only resolution but also signal response and separation time: Mobile phases containing TBA concentrations ranged from 0.5 to 5.0 m*M* (Fig. 2). The results obtained show that all anions are more strongly retained with increasing amount of TBA in the mobile phase. But the change of the TBA concentrations has greater influence on the retention time in the lower range than in the higher range of the concentrations. The explanation of this fact can be the limited adsorption capacity of the stationary phase and/or the increasing concentration of phosphate with increasing TBA concentration. While the TBA concentration increases (up to 5 mM), the signal responses of all anions decrease.

Figure 3 shows the dependences of the retention on the concentration of DCTA in the mobile phase. For elution of inorganic anions and Cr(III) chelate with DCTA all capacity factors decreased regularly with increasing DCTA concentration. Thus with increasing DCTA concentration selectivity of separations and the signal response of directly detected anions [$NO_2^-$, $Br^-$, $NO_3^-$, $CrO_4^{2-}$, $MoO_4^{2-}$ and Cr(III)–DCTA] decreases. The elution sequence of some anions can be reversed by changing the DCTA concentration. With high concentrations the Cr(III)–DCTA complex was eluted before $MoO_4^{2-}$, $SO_4^{2-}$, $CrO_4^{2-}$ and $Cl^-$ before $HPO_4^{2-}$.

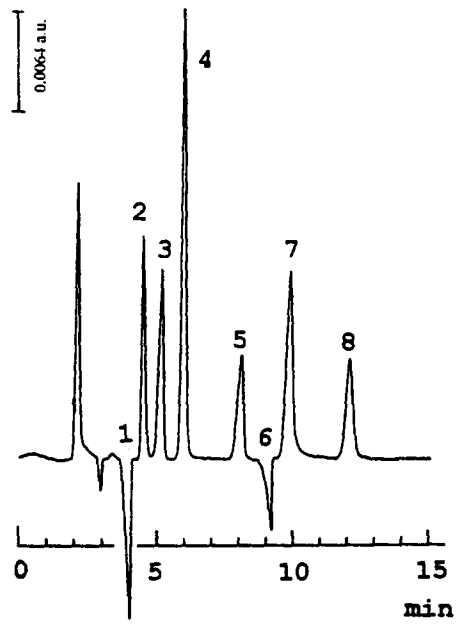

Fig. 6. Chromatogram of Cr species and common anions under the optimum conditions. Eluent: acetonitrile–water (2:98 v/v) containing 1 m*M* TBA, 0.5 m*M* DCTA, pH 6.5; flow-rate 1.0 ml/min. (1) $Cl^-$ (10 ppm); (2) $NO_2^-$ (0.25 ppm); (3) $Br^-$ (5 ppm); (4) $NO_3^-$ (0.5 ppm); (5) $CrO_4^{2-}$ (2 ppm); (6) $SO_4^{2-}$ (10 ppm); (7) $MoO_4^{2-}$ (2 ppm); (8) Cr(III) (0.5 ppm).

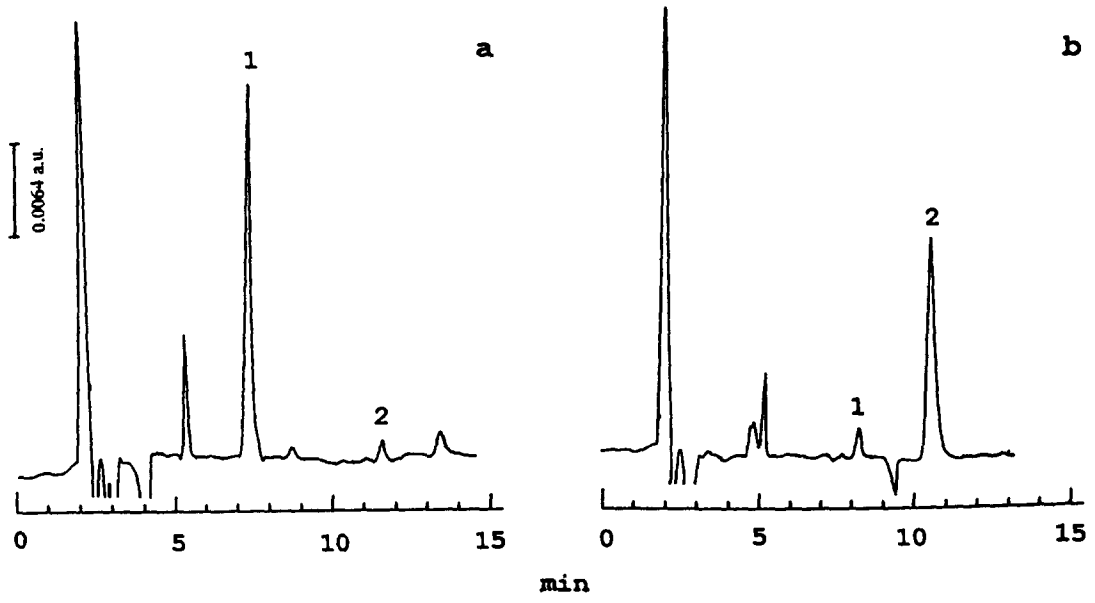

Fig. 7. Chromatograms of mortar (a) and leather (b) extracts with eluent. Condtions as in Fig. 6. (1) $CrO_4^{2-}$; (2) Cr(III).

*Effect of pH*

The active species of aminepolycarbonic acids as eluents are their anions, which depend directly on the pH of the mobile phase. The influence of pH on selectivity and retention of the Cr species and some inorganic anions were therefore systematically investigated. Results are shown in Fig. 4. In consideration of the stability of the silica-based stationary phase and the solubility of DCTA, pH of the mobile phase was adjusted to a certain value between 5.5 and 7. It can be observed that the capacity factors of some anions except $CrO_4^{2-}$ and $HPO_4^{2-}$ increase with decreasing the pH of the mobile phase. This fact can be explained by the decrease elution strength of mobile phase because of the protonation of the DCTA anion with increasing acidity [$pK_1$(DCTA) = 2.4; $pK_2 = 3.5$; $pK_3 = 6.1$ and $pK_4 = 12.4$). There are two species of Cr(VI) in neutral medium: $CrO_4^{2-}$ and $HCrO_4^-$ ($pK_2(H_2CrO_4) = 6.5$). With increasing acidity of mobile phase the equilibrium $CrO_4^{2-} + H^+ = HCrO_4^-$ moves to the right, *i.e.* the quantity of monocharged $HCrO_4^-$ ions increases. Competition of two contrary processes takes place in the system. Protonation of the DCTA anion increases the retention of Cr(VI). On the other hand with protonation of $CrO_4^{2-}$ ions their charge and retention at the same time decreases. In addition, with decrease of mobile phase pH dimerization of $HCrO_4^-$ ions to dichromate takes place because the signal response of Cr(VI) ions begins to decrease at pH < 6.5. The influence of pH has the same effect on the capacity factor $HPO_4^{2-}$.

*Formation of* Cr(III)*–DCTA complex*

Chromium(III) forms kinetically inert complexes and its chelation reactions are very slow.[22] Therefore, for speciation of Cr with DCTA, off-line derivatizing of Cr(III) is required. In addition, it is important for the analytical technique that all procedures last only a short time.

The ratio of complex formation depends on temperature, ligand concentration, pH and other parameters. Figure 5 shows the time necessary for complete formation of Cr(III)–DCTA complex at various temperatures and Cr(III)/DCTA molar ratio. All solutions were at pH 6.5. At room temperature this reaction happened very slowly. If the solution was warmed up to 60°C and Cr(III)/DCTA molar ratio was 1:5, it required only 10 min to complete the chelation.

Under these conditions the following experiments were carried out.

*Characteristics of* Cr *determination*

In order to test the applicability of the method for analysis of Cr species calibration graphs were constructed. Calibration graphs of peak area *vs.* Cr concentration were linear in the concentration ranges 0.1–20 μg/ml for Cr(III) and 0.2–20 μg/ml for Cr(VI) with correlation coefficients both above 0.998 ($n = 3$).

Table 1. Results of building materials and leather extracts analysis ($n = 3$)

| Sample | Element | IPC ($mg/g$) | R.S.D. (%) | Spectophotometry* ($mg/g$) |
|---|---|---|---|---|
| Brick (White) | Cr(VI) | 8.51 | 1.2 | 8.75 |
| | Cr(III) | 0.22 | 2.4 | 0.16 |
| Brick (red) | Cr(VI) | 11.2 | 0.9 | 11.6 |
| | Cr(III) | 0.28 | 2.5 | 0.23 |
| Mortar | Cr(VI) | 52.4 | 0.7 | 50.8 |
| | Cr(III) | 1.16 | 1.8 | 1.25 |
| Leather | Cr(VI) | 0.09 | 2.8 | 3.58† |
| | Cr(III) | 3.61 | 1.2 | |

*Spectrophotometry with diphenylcarbazide.[24]
†Total Cr with atomic-absorption spectrometry.[25]

The repeatability was examined with five injections of 2 $\mu$g/ml of each Cr species. The relative standard deviation for Cr(III) was 1.34 and for Cr(VI) −1.17%.

The detection limits were 8 ng/ml for Cr(III) and 35 ng/ml for Cr(VI), respectively. Because the method developed is to be applied for the speciation of Cr in water and other samples, possible interferences of concomitants were investigated. Moreover, the influence of Cr(III) species present on the determination of Cr(VI) was studied. Solutions containing Cr(III)–DCTA complex and chromate were analysed using the calibration function mentioned previously. It was found that excess of the other Cr species up to 20-fold caused no interferences to each other. The metals Ca, Mg, Ni, Cu, Co, Zn and Fe, which are often present in real samples, were added separately in concentrations of 10 $\mu$g/ml and no influences from them were found in the analysis results. A standard chromatogram of Cr species and other anions is shown in Fig. 6.

*Application examples*

The proposed method was applied to the simultaneous determination of Cr species in real samples. In the leather industry Cr(III) compounds are used as tanning agents. Building materials with a chromate additive have persisted at high temperature and are used for heat storage. Human skin often comes into contact with these materials and, therefore, determination of mobile Cr species in these samples is an important task. Figure 7 shows the chromatograms of mortar (a) and leather (b) extracts. The column used for the leather analysis (Fig. 7b) longer than that used for mortar analysis (Fig. 7a) and for the chromatogram in Fig. 6. Generally, with a longer column the retention times of the analyte ions are shorter. The influence of the column quality appears in the retention time of Cr(III) earlier than in that of other ions, therefore the retention time of Cr(III) in Fig. 7b is different from that in Fig. 7a or Fig. 6. The retention time of Cr(VI) ions differs only a little because of the same reason. The results of the determination of Cr species in building materials and leather extracts are shown in Table 1.

In conclusion, this IPC method is a simple and practical technique for the simultaneous determination of Cr(III), Cr(VI) and other anions in real samples.

# FACTORIAL DESIGN FOR THE RESPONSE EXPLORATION OF A FLOW INJECTION SYSTEM

A. MATOUSEK DE ABEL DE LA CRUZ, J. L. BURGUERA, M. BURGUERA and C. RIVAS

IVAIQUIM (Andean Institute for Chemical Research), Faculty of Sciences, University of Los Andes, P.O. Box 542, Mérida 5101-A, Edo. Mérida, Venezuela

(*Received* 3 *August* 1994. *Revised* 1 *November* 1994. *Accepted* 1 *November* 1994)

**Summary**—A factorial composite design was employed for the exploration of the response as a function of the flow rate and length of the dispersion coil of a flow injection system employed for on-line dilution and determination of copper by flame-AAS. For this purpose, an empirical response function (RF), which takes into account the peak height and the response time, was employed to evaluate the response. This RF was modified using the coefficient of variation in order to discriminate not only for high absorbance and adequate response time, but also for the best precision.

Flow injection (FI) has proved to be a convenient way of sample introduction for spectrometric techniques, owing to the possibility of handling small sample volumes under controlled conditions of dilution. However, often the difficult in controling the variability among the transient signals is one of the principal weaknesses of the technique in this case.[1-3] FI systems are generally characterized by complex interrelations between several factors, for example, the dilution of a plug of sample inserted in a continuous carrier stream is influenced by physical variables such as the injected volume, the flow rate, the geometry (size and orientation) of the mixing coils or dilution chambers employed, and if the analytical method involves other phenomena such as chemical reactions. Other important factors such as reagent concentration, pH, kinetics, etc., make the optimization a very complicated and time-consuming process.[1,3] Furthermore, if the FI system is coupled to the nebulizer of the flame burner, the competing fast aspiration flow introduces an additional source of variation.[4,5]

The optimization of analytical systems is carried out in order to find the combination of factors levels which maximizes the response. The traditional empirical univariate method of optimization involves varying each parameter in turn while keeping the others constant. This method has been applied to improve the behavior of analytical systems with varying degrees of success. However, in complex systems, such as the FI systems, in which the variables involved may not be independent of each other, this method may not be suitable owing to the convergence problems which may appear in some particular situations. In recent years, several methods for response surface modeling and prediction have been applied successfully to the optimization of flow injection systems such as the simplex and the Powell.[6-8] These methods are very useful for the optimization of flow and chemical conditions of flow injection systems, however, they offer little information about the nature of the response surface, and the experimental generation of this surface is needed as an aid to characterize the system.[6] Factorial optimization is a very fast method to find the conditions that maximize the response of system as long as the area of response surface studied presents only one maximum and the same is not located at the border of the surface.[9-13] There are several reasons for employing a factorial design instead of an univariate (one-at-a-time) design for system optimization, particularly when the experiment is carried out to test whether the response depends on a factor level. First, with the factorial design it is possible to detect and estimate any interaction among the factors involved which is not possible with an univariate design. Second, when the effects of the factors are additive, the factorial design requires fewer measurements, in order to obtain the same precision. Third, when the optimization involves more than one variable or factor, and the factors affect the response in an interactive fashion (the variables are not independent of each

other), the univariate method is unsatisfactory for achieving the optimum conditions.[10-13] Box and Wilson[14] added star designs (additional axial and center points) to $2^k$ factorials to form central composite designs which are useful for modeling response surfaces with a reduced number of experimental runs.

In this work we study the usefulness of a totally randomized factorial central composite design (a second factorial design augmented with a star)[10,13] as a tool for the rapid exploration of the response as a function of the flow rate and the length of the dispersion coil of a flow injection system for on-line dilution.

## EXPERIMENTAL

### *Apparatus*

A Varian atomic absorption apparatus model AA-1475 with deuterium lamp background corrector was employed as a detector. A Varian copper hollow cathode lamp was operated at 4 mA at a wavelength set to 324.6 nm and a spectral slit-width of 0.5 nm. Two peristaltic pumps, a Gilson (model Miniplus 2) and a Sage Instruments (model 375 A) were employed. A graduated 50 $\mu$l micro-syringe and a homemade septum injector were used for initial sample introduction. The suction air-pressurized device consists of a bottle with a pressure regulator up to 40 cm Hg and an Iwaki AP-115 air pump which produces the suction pressure. A Gralab 900 digital temporizer was used to control the operation time of a solenoid injector described elsewhere by Burguera *et al.*[15,16] PTFE tubing of 0.8 mm i.d. was employed in all the system, except for the injector valves where resistant and flexible Viton® tubing was employed. The loops of the dispersion coil had an i.d. of 1 cm. All the connections were made as indicated in Fig. 1.

### *Reagents*

A stock solution of Cu (10,000 mg/l.) prepared by dissolving 1 g of copper (Merck, 99.99%), in 15 ml of $HNO_3$ (1:1) (Merck, 65% Pro-Analysis), to a final volume of 100 ml, was employed for the dilutions. Deionized water was used throughout.

### *Manifold*

The flow injection manifold employed is represented in Fig. 1. The graduated dilution chamber with agitation has a maximal volume of 50 ml. The agitation is produced with a small motor at the top of the chamber. Valves (V1–V5) are controlled by the temporized solenoid injector.

### *Operation*

For the present work the flow system has two sets of tubing (set 1: $V_1$, $V_3$ and $V_5$; set 2: $V_2$ and $V_4$), which are used for regulating the flow of sample and carrier through the system. The doubly stopping shutter of the solenoid injector[15] either closed or opened any of these sets of tubing at a fixed time, thus allowing the sequential introduction of sample as described below. The sample volume was assessed by a procedure similar to that used earlier,[15] by the differences in weight over cycles of 50 injections.

The operation of the manifold is as follows: (1) 25 $\mu$l of concentrated copper solution (500–4000 mg/l.) are injected using the sample injection septum (I of Fig. 1); (2) the pump number 1 is operated for 3 min until the 25 ml mark is reached in the dilution chamber (flow rate of 8.3 ml/min), where the solution is constantly agitated; (3) the loading operation is performed by operating the solenoid injector for 2 to open and close the first and second sets of valves, respectively. In this way the sample fills the coil 1 by suction, while the carrier is pumped

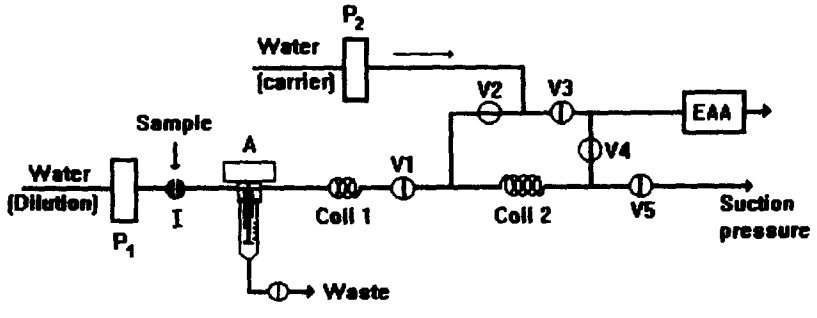

Fig. 1. Representation of the flow-injection manifold employed (A, dilution chamber with agitation; $P_1$ and $P_2$, peristaltic pumps; V1–V5 valves 1–5.

by $P_2$ to the spectrometer's nebulizer; (4) The sample introduction procedure is performed by activating the solenoid to the alternate position for 10 sec in order to pump the solution contained in coil 2 to the spectrometer's nebulizer; (5) The injection cycle is performed by the sequential alternation of both solenoid positions for periods of 0.8 and 10 sec. This allows the repetitive and reproducible intercalation of 120 $\mu$l in coil 2 and its transportation to the nebulizer by the carrier solution. By injecting 120 $\mu$l of sample volumes good precision and sensitivity were obtained. Besides, no overheating of the solenoid valve was observed when the solenoid activation time was of 0.8 sec, which was used to dispense this sample volume.

*Software*

The three-dimensional graph of the experimental surface was plotted with the aid of the Excel program (version 4.0; for Windows 3.1 of Microsoft). The statistical analysis of the factorial model for surface fitting and the plot of the estimated response function was realized with the aid of the Statgraph program (version 5.1, Statistical Graphics).

*Procedures*

*Response surface.* A three dimensional response surface (RS) was constructed from the data obtained by systematically varying the factors levels.[11] In order to elaborate the RS, a fixed volume (120 $\mu$l) of a 20 mg/l. copper solution was injected in the FI system at least 10 times in each set of conditions of carrier flow rate and dispersion coil length. The carrier flow rate was varied from 3.5 to 10 ml/min for each dispersion coils employed of 34, 50, 70, and 140 cm. An aspiration rate of 6.0 ml/min for the spectrometer nebulizer was kept constant throughout the experiment.

Firstly, the RS was constructed taking the average peak height absorbance. Secondly, the response was evaluated as a modified experimental target function similar to the one successfully employed earlier for this purpose. This response function (RF) is a linear combination of the peak height and residence time aimed to achieve the maximum sensitivity and sample throughput.[6,7]

$$\mathrm{RF} = k_1 H_n + k_2(1 - t_n), \qquad (1)$$

were $H_n$ and $t_n$ are the normalized values of the peak height and residence time, and the constants $k_1 = k_2 = 0.5$ give the same signification to both terms.[6]

The modified response function (MRF) employed in this work also takes into account the variability of the peak height absorbance measured in each set of experimental conditions. This is accomplished by dividing the RF calculated by the coefficient of variation (CV) of at least 10 consecutive measurements.

$$\mathrm{MRF} = RF/CV. \qquad (2)$$

This modification favors not only the conditions in which the maximum sensitivity and sample throughput are reached, but also the ones in which the precision is best. This function was employed in the construction of the experimental response surface and in the factorial design for surface fitting to the mathematical model from which the optimum values of the variables were derived.

*Univariate evaluation of the response.* The response was evaluated employing the univariate method. For this purpose, the response was evaluated for varying the coil length at a fixed flow rate. The coil length of maximal response was chosen from the curve obtained. Then the response was evaluated varying the flow rate from 3.5 to 10 ml/min.

*Factorial exploration of the response of the FI system.* The exploration of the response of a flow injection system (carrier flow and dispersion coil length) of the manifold represented in Fig. 1 was carried out using a second factorial design ($2^k$, $k = 2$ factors) augmented with a star design to form a second order composite design.[14] Composites or complete factorial require at least $2^k + 2k + 1$ experimental runs ($k$ = number of factors).[17,18] For the response surface fitting, an orthogonal two-factor central composite design with five center points was employed. The additional center points are used for the evaluation of the internal variation of the method.[10,13] The central composite design employed had four cube points, four axial points and five center points and an axial spacing of $\pm 1.2671$, for a matrix of 13 experimental runs which were carried out in a randomized way. The minimum ($-1$), maximum ($+1$), medium (0) and axial ($\pm 1.2671$) values of the factors codified in this matrix are presented in Table 1. The design expanded the run ranges from 3.5 to 8.5 ml/min for the carrier flow rate and from 34 to 224 cm for the dispersion coil length.

Table 1. Values of the factors codified in the factorial matrix

| | −1 | +1 | 0 | −1.2671 | +1.2671 |
|---|---|---|---|---|---|
| Carrier flow rate (*A*) (*ml/min*) | 4 | 8 | 6 | 3.5 | 8.5 |
| Dispersion coil length (*B*) (*cm*) | 55 | 205 | 130 | 34 | 224 |

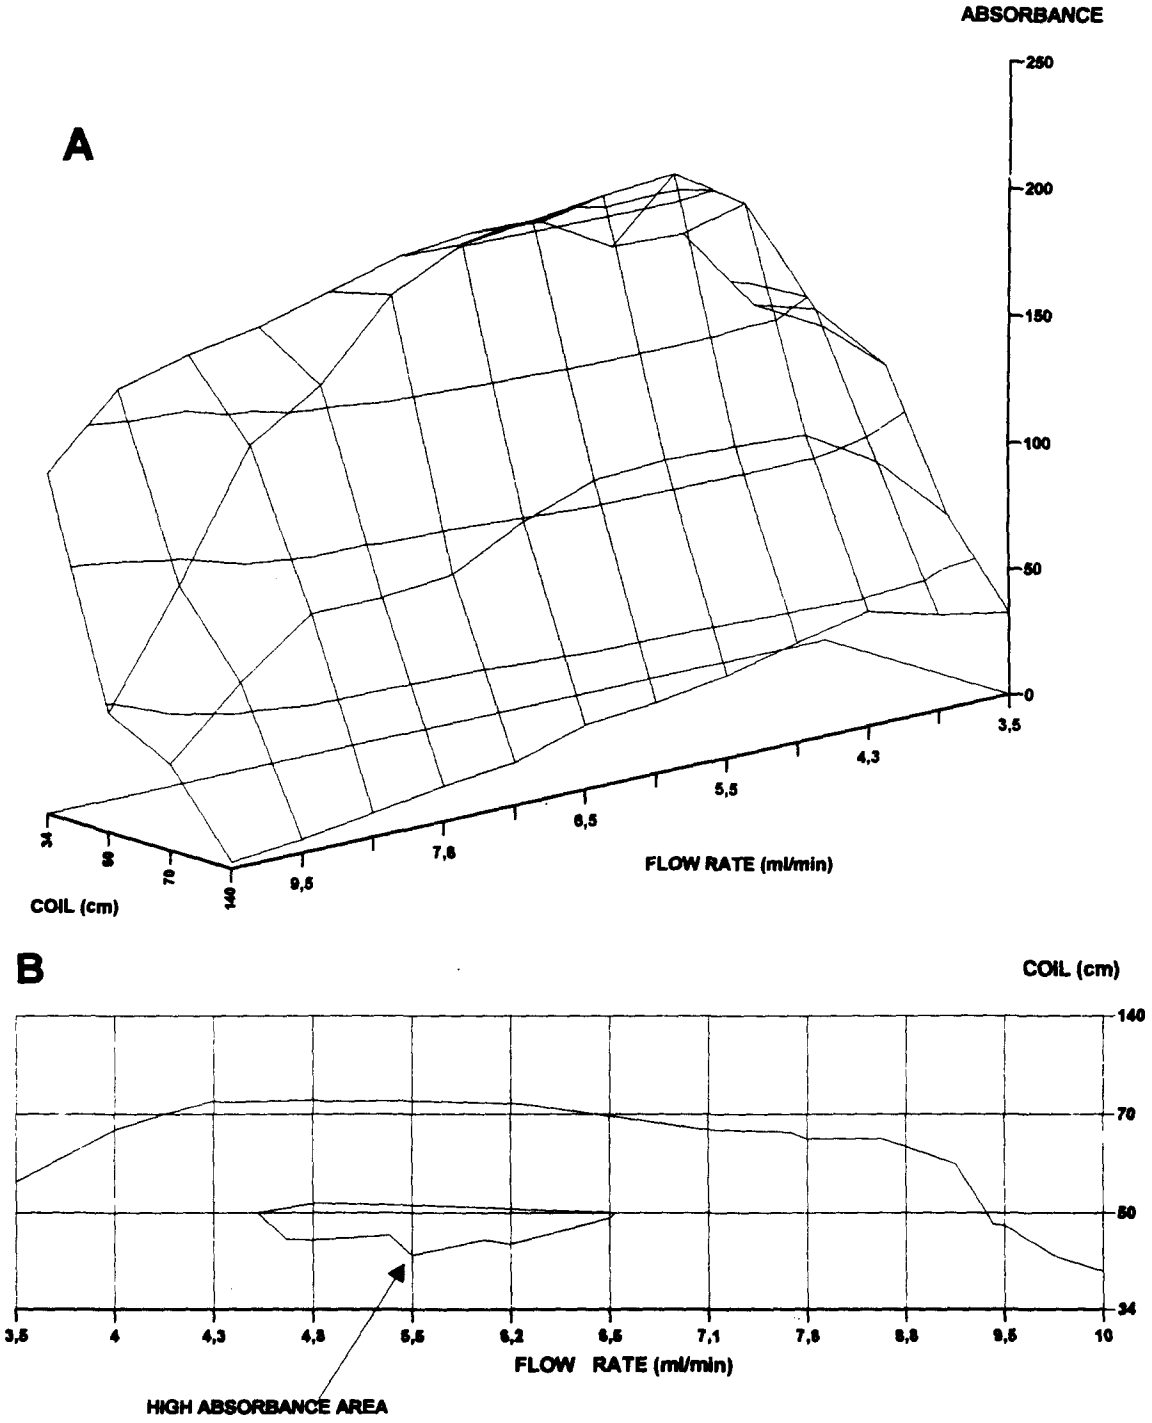

Fig. 2. (A) Three-dimensional plot of the peak height absorbance experimental response produce by the variation of the dispersion coil length *vs.* the flow rate. (B) Peak height absorbance contour surface plot showing the area of maximal response for the dispersion coil of 50 cm and flow rates between 4.5 and 6.5 ml/min.

## RESULTS AND DISCUSSION

### *Description of the experimental response*

The RS for the peak height absorbance surface and its contour surface are projection is presented in Fig. 2. The RS derived from the application of the RF to the absorbance and response time data is shown in Fig. 3, and the plot of the %CV vs. flow rate for the different coil lengths is presented in Fig. 4. The RS obtained from the MRF and its contour surface are shown in Fig. 5.

The RS for the peak absorbance (Fig. 2A) shows a flat maximal absorbance for the 50 cm coil over a wide range (Fig. 2B) of carrier flow rates (~4–6 ml/min) which apparently could indicate the possibility to chose among any of this flow rates without any adverse effects over the quality of the signal. Though the application of the RF (Fig. 3) discriminates the too-long and too-short response times, it did not changed the appearance of the surface in the area of maximal response. However, a study of the distribution of the %CV for the different flow rates and coil lengths (Fig. 4) suggests that the variation gradually increases with the flow rate and that it is very high for all the coil lengths at flow rates over 7.1 ml/min. The lowest variation appears to be related to the shorter coils (34 and 50 cm) and to moderate low flow rates of 4–6 ml/min. In fact, from the MRF surface (RF discriminated by the CV) shown in Fig. 5A, it is evident that the shape of the surface changes drastically, and from the MRF contour surface shown in Fig. 5B, the maximal response appears to be lying at the surface area which corresponds to a flow rate of around 5 ml/min and a dispersion coil of near 50 cm. However, in spite that the MRF yields an RS which gives an apparently better picture of the location of the maximal response (maximal absorbance, minimal variation and adequate response time), a more detailed description of the area of maximal response would be required in order to chose the optimum values of the parameters. This would require a considerable amount of experimentation with no guarantee of the successful location of the real maximal response.

### *Factorial optimization*

The factorial optimization of the FIA system performed gave the estimated regression

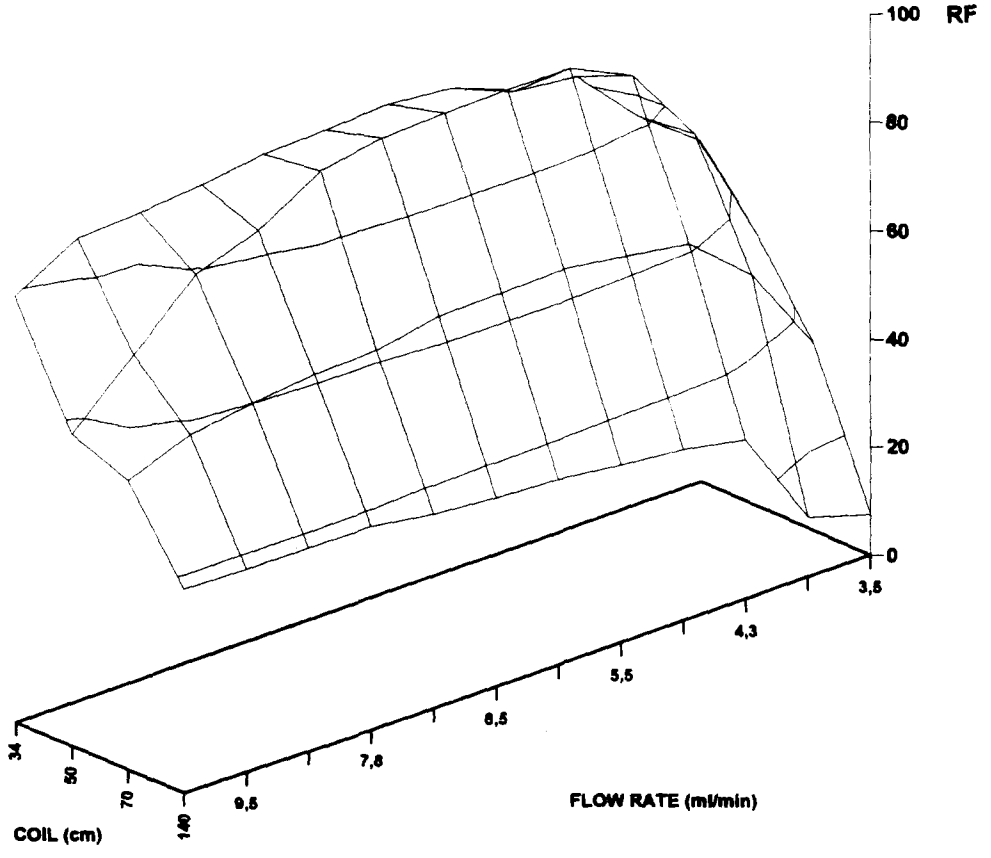

Fig. 3 Experimental response surface obtained from the empirical target function RF.

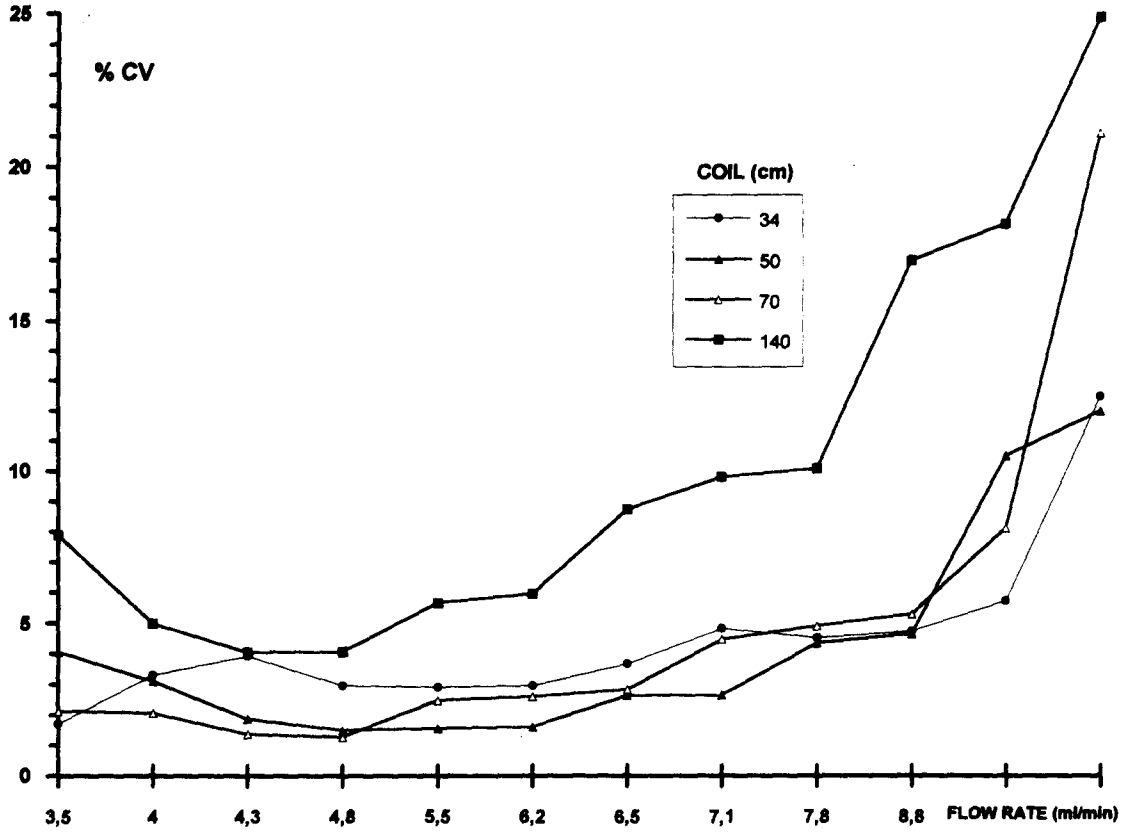

Fig. 4. Plot of % CV *vs.* flow rate. The minimal variation is observed for flow rates between 4.3 and 5.5 ml/min and dispersion coil length of 36 and 50 cm.

coefficients the second-order equation (equation 3) which describes the response as a function of the coded factor levels

$$Y = 53.01 - 11.16A - 15.82B - 22.05A^2 - 9.13B^2 + 8.69AB. \quad (3)$$

The analysis of variance (ANOVA) of the two-factor composite design is presented in Table 2. The sums of squares owing to the regression as a percentage of the total sum of squares was 99.9%, indicating that most of the variance is explained by the regression equation. The ratio of the sum of squares due to lack-of-fit and the sum of squares due to pure error is 0.35 (Table 2), a low value which indicates that the second order model is an adequate approximation to the data. The total error mean square of 0.3897 can be used as an estimate of the error variance. The square root of this value (0.6243) gives the standard deviation about the regression. Three times this value (1.87) indicates that there is a 99.7% probability that any single additional measurement within the region of interest would fall within plus minus 1.87 units of the predicted response. The adequacy of the fit was further evaluated analyzing the coefficients of the regression. First, the estimated variances of the individual coefficients were obtained by multiplying corresponding value of the principal diagonal of the $X'X^{-1}$ matrix by the residual mean square.[17,18] The square root of these variances provide the standard error of the estimates. The regression coefficients were then individually tested in order to determine if they were significantly different from zero. This was achieved by forming ratios of the coefficients to their standard errors to give $t$-values. The probability that the coefficient is not zero is equal to one minus twice the probability that a sample from a $t$-distribution should be at least as large as the observed $t$-value. The probability values observed of $>99.5\%$ in all indicate that all the coefficients would seem to be non-zero. This confirms that an adequate fit has been made.

The plot of the mathematically estimated response surface and its contour, using MRF as the target function, are shown in Figs 6 and 7, respectively. The predicted maximal response according to this model is 64.11, and its correspondent stationary or critical point are of

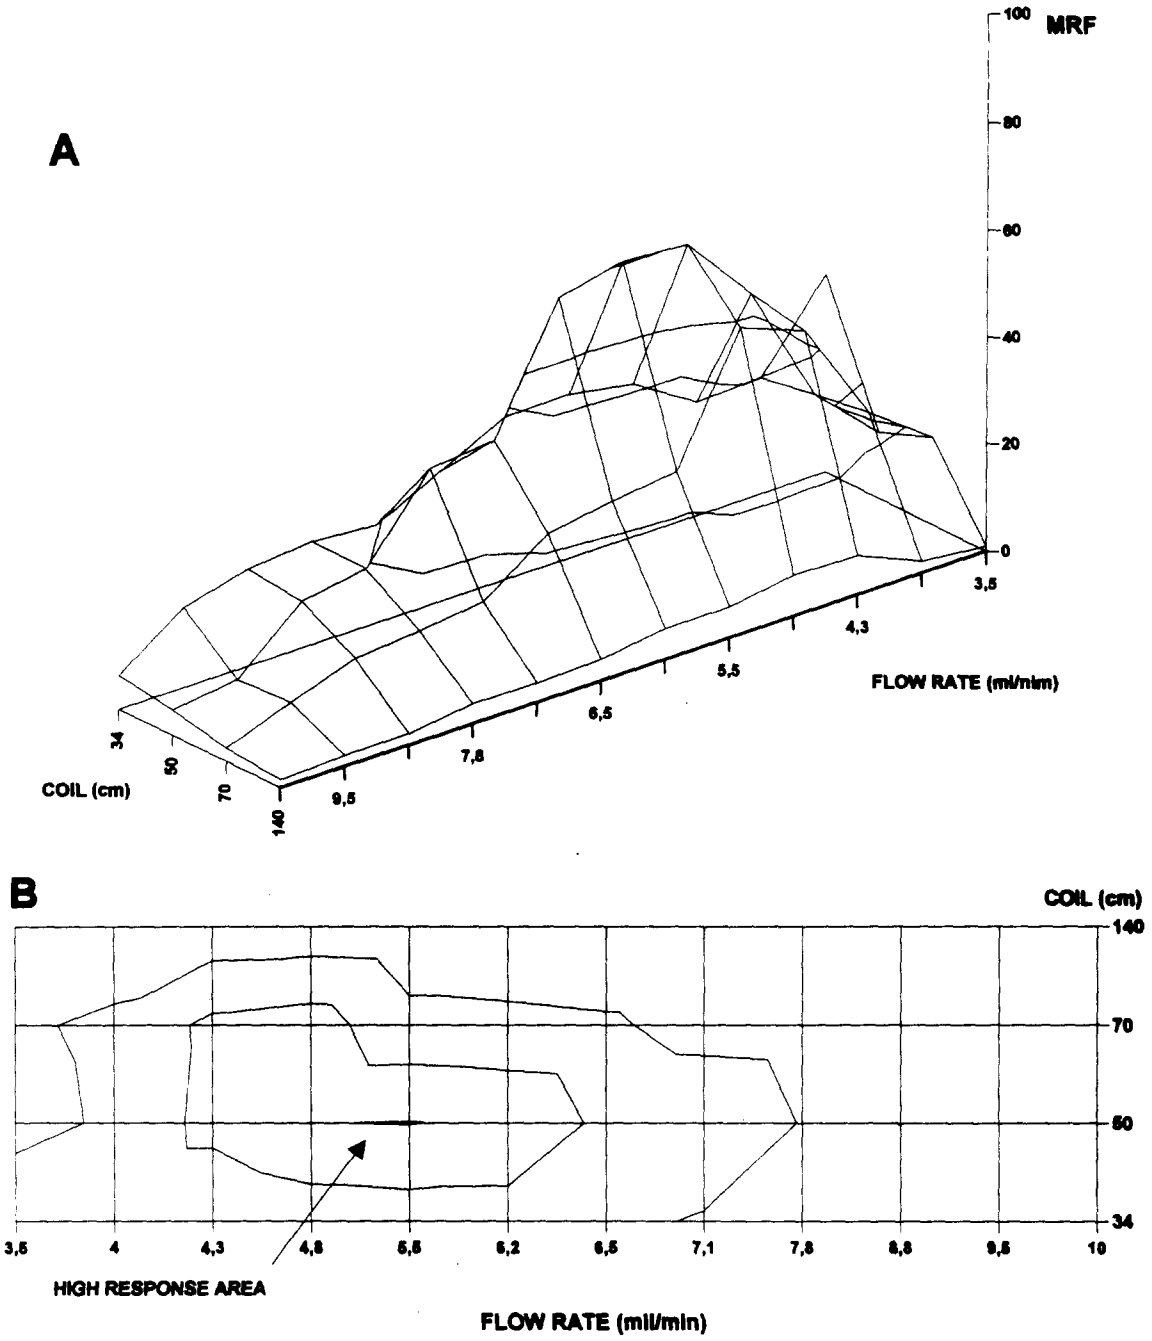

Fig. 5. (A) Response surface calculated with the modified target function MRF; (B) Contour map of the MRF response surface showing a narrower area of maximal response at flow rates between 4.8 and 5.5 ml/min.

$-0.4669$ for $A$ and $-1.0875$ for $B$. This maximal response was found by taking partial derivatives of the prediction equation with respect to each factor. These derivatives were equated to zero and solved for the factor levels. The optimal values of the factors predicted by this model are of 5.07 ml/min for the carrier flow rate and of 48.5 cm for the dispersion coil length. These values agree with the area of maximal response observed in the experimental response surfaces derived from the MRF (Fig. 5A and B). A comparison of the results obtained for the values of the dispersion coil and the flow rate with the factorial and the univariate methods is presented in Table 3.

Fixing the optimal conditions found for the FI system, an experimental response of 63.0 was observed for an injection of 120 $\mu$l of a solution

Table 2. ANOVA for the MRF–carrier flow rate–dispersion coil

| Effect | SS | d.f. | MS | *F*-ratio |
|---|---|---|---|---|
| Flow rate (*A*) | 898.90115 | 1 | 898.9011 | 2306.84 |

*R*-squared = 0.9995.
*R*-squared (adj. for d.f.) = 0.9992.

of 20 mg/l. of copper (2.4 $\mu$g/injection), which is a 98.3% of the expected response. The low carrier flow of 5.07 ml/min (lower than the aspiration rate of 6.0 ml/min) agrees with the results reported by Fang and Welz.[8] They studied the effects of carrier flow rate and of the. aspiration rate over the peak height absorbance and found that (for injection volumes $\geqslant 100$ $\mu$l) lower-than-aspiration carrier flow rates improve the precision and the sensitivity in flow injection systems possibly due to an increase in the nebulization efficiency.

The characteristics of the calibration graph equation obtained after setting the conditions found (5 ml/min flow rate of carrier and 48.5 cm dispersion coil length) are described by the equation: $Y = 0.23 + 10.49X$ for an *r*-squared of 0.9999, where $Y$ represents absorbance and $X$ (5–60 mg/l.) represents the copper concentration. A coefficient of variation (CV) of 2.0% (from 1.5 to 2.4%) was obtained for 20 consecutive measurements of 20 mg/l. copper.

## CONCLUSION

The optimization of the carrier flow rate and the dispersion coil length of the FI system studied by the modification of the response surface, employing the MRF as the target function, yields the practical possibility to discriminate not only for the conditions of best sensitivity and residence times but also for the ones that minimize variation an therefore improve the precision. The factorial optimization of the system using this MRF is a tool which allows to find, in a rapid and efficient way, the optimum conditions for the maximal response. However, it must be kept in mind that the factorial method has several important limitations for its application, for example, when the maximal response is located at the border of the surface. In the particular situation studied, the maximum is located near the center of the experimental surface, and the modification of the RS by the MRF gives a roughly parabolic surface.

Table 3. Univariate *vs.* Factorial—Comparison of results

| | Method | |
|---|---|---|
| | Univariate | Factorial |
| No. of experiments | 20 | 13 |
| No. of measurements | 200 | 130 |
| Coil length of maximal response (*cm*) | 50 | 48.5 |
| Flow rate of maximal response (*ml/min*) | 5.5 | 5.07 |
| Maximal response | 60.0 | 64.14 |

# DETERMINATION OF IRON AT ng/ml LEVEL BY SOLID PHASE SPECTROPHOTOMETRY AFTER PRECONCENTRATION ON CATION EXCHANGE FILTERS

F. CAPITÁN GARCÍA, RAMÓN CHECA, RAMIRO AVIDAD and L. F. CAPITÁN-VALLVEY*

Department of Analytical Chemistry, University of Granada, 18071 Granada, Spain.

(*Received* 11 *July* 1994. *Revised* 28 *September* 1994. *Accepted* 9 *November* 1994)

**Summary**—A cationic exchanger paper is used to retain analytes in solution and, after drying, to analyze directly by measuring the UV-Vis absorbance of the paper. The method was applied to determination of iron using its known 1,10-phenanthroline complex. Using 100 ml of sample the applicable concentration range was between 1.0 and 10.0 ng/ml with a detection limit of 0.2 ng/ml and a RSD around 2%. The method was applied to determination of iron total in snow, human serum and wine.

Preconcentration is not only an alternative to the use of sophisticated instrumentation in trace level analysis, but is also a previous step in the treatment of the sample before the measurement when the analyte to be determined is present in the sample at levels below the detection limits of the method.

The use of filters (cellulose, ion exchange resin loaded paper or PTFE, chelating paper, glass fiber, *etc.*) is a very elegant way to retain analytes and is often used as a preconcentration procedure. When the sample is concentrated by fixation on the filter it is usually desorbed with the aid of a reagent[1] or dissolved together with the filter, before making the measurements.[2] Another way is to make the measurement directly on the filter in order to combine preconcentration and measurement. The use of ion-collecting filters as a preconcentration step for analysis of water by X-ray spectrometric techniques has also been described in the literature.[3]

The direct measurement of luminescence properties allows the direct assay of substances in the solid-phase.[4]

UV-Vis absorption techniques used in connection with filtration systems are related to solid phase spectrophotometry (SPS).[5] Four main groups of applications are described in the literature:

(i) Use of finely divided ion-exchanger resin particles ($d \leqslant 30$ $\mu$m) to collect rapidly coloured analytes or reaction products and back coagulation by addition of suspensions of oppositely charged resin particles. The filtration of the coagulated resin through a filter paper and the measurement of the absorbance allows one to do the analysis.[6–9]

(ii) In some cases the desired coloured complex in the presence of ionic surfactants is collected onto a membrane filter and then determined directly on it.[10–11]

(iii) Separation by a membrane filter of the coloured complex sorbed with a finely dispersed ion exchanger and direct spectrophotometric measurement.[12]

(iv) The direct retention of a complex on a solid support. For instance, the strong retention of the Be(II)–Chromazurol B complex in a cellulose nitrate membrane filter in the presence of hexadecyltrimethylammonium bromide combined with SPS allows the Be analysis.[13]

The aim of this work was to use an ion-exchanger paper to retain a coloured complex by filtration and, after its preconcentration, to analyze it directly on the same filter by SPS. To the best of our knowledge the retention of analytes or reaction products on ion-exchanger paper through filtration and direct determination has not been reported.

As a model system we have selected the well known Fe(II)–1,10-phenanthroline system,

*Author to whom correspondence should be addressed.

applying it to the analysis of both Fe(III) and Fe(II) in samples from several provenances.

## EXPERIMENTAL

### *Apparatus and software*

All spectrophotometric measurements were performed with a UV-Vis Beckman DU-8B spectrophotometer. A pellet holder (ref. MD-OZ) from an IR spectrophotometer Beckman IR 4240 was used as a support for the filter paper disk. A Crison 501 digital pH-meter with a combined glass-saturated calomel electrode and a vacuum pump (Edwards model ED 100) were used.

We used a 47 mm glass filter holder Millipore (ref. XX1004700) taking advantage of a ring-shaped metachrylate plug with an internal diameter of 14 mm to decrease the filtration area contacting a like rubber ring of 1 mm thickness to allow for good adjustment and avoiding lateral diffusion of the solution.

Startgraphics software package[14] was used for regression analysis (linear model).

### *Reagent*

All reagents used were of analytical reagent grade. Reverse osmosis type quality water was used for the dilution of samples and preparation of reagents.

Fe(III) stock solution (1 g/l.) was prepared by dissolution of 1 g of Fe metal (Merck) in 50 ml of $HNO_3$ (1:1) (v/v) and later dilution with high purity water to 1 l. Working solutions were prepared by appropriate dilution maintaining the pH at 2.2 in all instances by addition of $1M$ $HNO_3$.

Buffer solutions of the required pH were prepared from $0.01M$ sodium acetate (Merck) and $0.01M$ acetic acid (Merck).

A stock solution of hydroquinone ($9.0 \times 10^{-4}M$) was prepared by dissolving appropriate amounts of hydroquinone (Merck) in water.

A stock solution of 1,10-phenanthroline ($2.78 \times 10^{-3}M$) was prepared by dissolving 0.1250 g of 1,10-phenanthroline (Merck) in hot water and levelling off to 250 ml.

Cation exchanger paper was Whatman P-81 cellulose phosphate paper, thickness 0.23 mm, linear flow rate (water) 125 mm/30 min and an exchange capacity of 20.34 $\mu$eq/cm$^2$ calculated by us. This paper was cut in a circular shape of 16 mm diameter. In order to compact the filter paper and obtain repeatability in the measured absorbance, immediately before utilization 100 ml of deionized water was filtered through the paper disks.

### *Absorbance measurements*

The paper disk with the retained coloured complex was placed on a 13 mm KBr pellet holder from an IR spectrophotometer and subsequently attached into the sample compartment of a UV-VIS spectrophotometer. The absorbance was measured at 510 nm with a slit width of 5 nm.

The net absorbance of the complex fixed on the paper disk was obtained at 510 nm subtracting from the observed absorbance the absorbance of a paper disk equilibrated with blank solution.

### *General procedure*

To an aliquot of sample containing between 100 and 1000 ng of iron, 10 ml of pH 3.5 acetate buffer solution, 5 ml of $9.0 \times 10^{-4}M$ hydroquinone solution and 2 ml of $2.78 \times 10^{-3}M$ 1,10-phenanthroline solution were added levelling to 100 ml with water. After 10 min the mixture was filtered under suction at 10 ml/min through a 16 mm diameter circular cation exchanger paper, which was dried by blowing hot air for 10 min at 60°C.

The other paper filter disk was prepared using a blank solution containing all the reagents except the analyte and treated in the same way. The absorbance of both paper filters (sample and blank) were measured at 510 nm. The calibration curve was drawn in the same way using Fe(III) solutions of known concentration.

### *Procedure for real samples*

For determination of iron in 2 ml samples wine were previously diluted to 200 ml with water and appropriate volumes were taken for analysis applying the General Procedure. The standard addition method was used for calibration purposes.

For determination of Fe in snow, 10 ml samples were taken and the standard addition method was also used.

In the case of human serum a blood sample was previously centrifuged and 1 ml of serum was taken and diluted to 25 ml with water. Appropriate volumes were taken for analysis applying the General Procedure. For calibration, the standard addition method was used.

*Treatment of the samples*

Wine, serum and melted snow were filtered through filter paper of pore size 0.45 μm (Millipore HAWP04700) and collected into a polyethylene container which had been carefully precleaned with nitric acid and water. The snow samples were preserved at pH 2.2 with nitric acid and stored at 4°C till analysis. Analysis were performed with the least possible delay and the usual general precautions were taken to avoid contamination.

## RESULTS AND DISCUSSION

The simplest system for retention of an analyte on an ion-exchanger filter is its filtration through it. Owing to hindrances caused by the glass filter holder located below the ion-exchanger paper, the use of a vacuum pump was required.

As a small diameter filtration zone increases the sensitivity of the method and a large diameter decreases filtration time, we selected a 16 mm diameter filter as a compromise and a glass filter holder as described under Apparatus.

*Physical variables*

In order to test the influence of the vacuum pressure on the absorbance measurements different values of vacuum pressure, *i.e.* different flow rates, were checked for solutions containing 15.0 ng/ml of iron. The absorbance remained stable at vacuum pressure values higher than 70 mbar (Fig. 1). As a compromise, 75 mbar vacuum pressure (rate of filtration 10 ml/min) and filtration times of around 10 min were used.

On the other hand, as adequate reproducibility requires measurements to be carried out over dry paper, several drying tests indicated the suitability of blowing hot air at 60°C for 10 min.

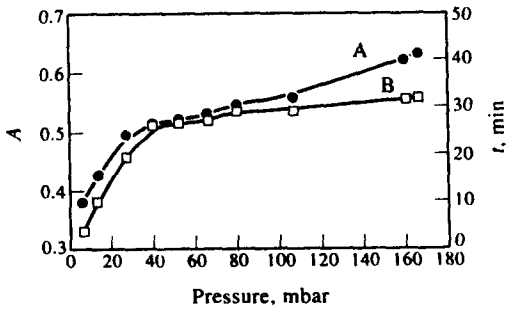

Fig. 1. Absorbance of the Fe(II)–1,10-phenanthroline complex as a function of the pressure and filtration time at $\lambda = 518$ nm. [Fe(III)] = $2.7 \times 10^{-7} M$; [hydroquinone] = $4.5 \times 10^{-5} M$; [1,10-phenanthroline] = $5.56 \times 10^{-5} M$. (A) Absorbance *vs.* pressure; (B) filtration time *vs.* pressure.

(A) Absorbance *vs.* pH adjusted by $H_2SO_4$ (0.1 *M*); (B) absorbance *vs.* pH adjusted by acetate buffers (0.01 *M*).

*Chemical variables*

The cationic Fe–1,10-phenanthroline complex is strongly retained on cellulose cation exchanger paper (Whatman P-81) containing phosphate as functional groups, showing the well known red colour of the complex and an absorption spectrum similar to that of solution ($\lambda_{max} \doteq 510$ nm).

The effect of pH was studied using sodium hydroxide and hydrochloric acid for adjustment.

The optimum pH value for the fixation of the Fe(II)–1,10-phenanthroline complex was within the range 3–5.5 (Fig. 2). At pH values below 3 absorbance of the complex decreases significantly because the fixation process does not take place owing to the protonation of the functional groups. At pH values above 5.5, the $Na^+$ cations compete with the complex in the fixation. This behaviour is different to that showed in solution where the absorbance does not change for pH range between 2 and 9.

Citrate, monochloroacetate, hydrogen phthalate, oxalate and acetate buffer solutions of various concentrations ($1 \times 10^{-1}$, $1 \times 10^{-2}$ and $1 \times 10^{-3} M$) were tested. It was found that acetic acid–sodium acetate ($1 \times 10^{-2} M$) buffer affected the absorbance reading the least.

An acetic/acetate buffer solution pH 3.5 (0.01 *M*) was used to adjust the pH according to the major buffer capacity and the minor decrease in the analytical signal (Fig. 2).

An increase in the concentration of the cationic components of the solution brings about a

competition in the complex retention which reduces the absorbance. From a study carried out with several common electrolytes (NaCl, $KNO_3$ and $NaNO_3$) it was shown that for concentration levels of electrolyte up to $10^{-3}M$ there were no absorbance decreases, while for values such as $10^{-2}M$ decreases of 60% were detected.

It was observed that the proportion of 1,10-phenanthroline necessary for the formation and retention of the complex is higher than in solution, in which proportions near stoichiometric are needed. Here a plateau was observed between $10^{-4}$ and $10^{-5}M$, $5.65 \times 10^{-5}M$ was selected as working concentration.

The most useful reducer for Fe(III) was hydroquinone, ascorbic acid and hydroxylamine also having been assayed. Independence from hydroquinone concentration was observed between $3.0 \times 10^{-4}$ and $1.0 \times 10^{-6}M$. In this work $4.5 \times 10^{-5}M$ hydroquinone solutions were used in all instances.

The stability of the complex fixed on the filter paper is very high. Thus, measurements repeated on samples formerly evaluated up to three years ago showed only a decrease in absorbance of around 5%.

*Analytical parameters*

*Effect of sample volume on sensitivity.* One of the main advantages of the solid-phase spectrophotometry method is the potential increase in sensitivity with an increase in the volume of the sample taken for analysis. This effect can be assessed by measuring the absorbance of ion exchange paper equilibrated with different volumes of solution containing the same concentration of Fe(III) and proportional amounts of the other reagents.

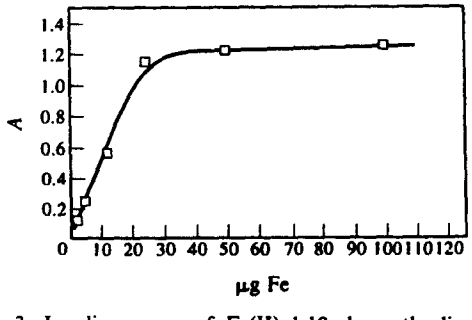

Fig. 3. Loading curve of Fe(II)–1,10-phenanthroline on ion-exchange filters. [Fe(III)] = $4.6 \times 10^{-7}M$; [hydroquinone] = $4.5 \times 10^{-5}M$; pH 3.7 [$CH_3COOH$/$CH_3COONa$] = $0.01M$; [1,10-phenanthroline] = $5.56 \times 10^{-5}M$. Filtration rate = 10 ml/min.

Table 1. Analytical parameters and statistical calculus

| Parameter | Sample volume 100 *ml* |
|---|---|
| Intercept | 0.012 |
| Standard error (intercept) | $2.91 \times 10^{-3}$ |
| Slope | 0.034 |
| Standard error (slope) | $5.51 \times 10^{-4}$ |
| Standard error of estimation | $3.93 \times 10^{-3}$ |
| Linear dynamic range (*ng/ml*) | 1.0–10.0 |
| Correlation coefficient | 0.9998 |
| Detection limit (*ng/ml*) | 0.2 |
| Quantification limit (*ng/ml*) | 1.0 |

Figure 3 show the dependence of absorbance *vs.* increasing amounts of Fe(II)–1,10-phenanthroline. Amounts of Fe greater than 13 μg cannot be retained by the ion exchange papers because they exceed the loading capacity of the filters.

*Analytical features*

A calibration graph for the determination of Fe(III) was prepared as described under Procedure. The regression line equation for the iron concentration was $A = 3.37 \times 10^{-2}C$ (ng/ml) + 0.012 ($r = 0.9998$) in the range 1.0–10.0 ng/ml. In all instances 100 ml of sample volume were used. The analytical parameters are summarized in Table 1.

At iron concentrations higher than 10 ng/ml the calibration graph bends, thus in order to adjust correctly the values a 2nd-order equation is required. The relative standard deviations were 5.3 and 4.9% for 10 replicate determinations of 5.0 and 10.0 ng/ml of Fe(III).

If we define the sensitivity of a method as the analyte concentration giving an absorbance of 0.100 then we have no doubt that the method reported in this paper is quite sensitive when compared to other spectrophotometric methods described in the literature. Using the proposed method, the sensitivity is some $4.6 \times 10^{-8}M$ which is indeed much higher than the $10^{-5}M$ for the common 1,10-phenanthroline spectrophotometric method in solution and nearly one order of magnitude higher than the resin phase method ($5.8 \times 10^{-7}M$).[15]

The detection limit ($k = 3$) according to IUPAC[16] and the quantification limit ($k = 10$)[17] were calculated for 100 ml sample volumes, the results obtained are summarized in Table 1.

*Effect of foreign ions*

A systematic study of the effect of common foreign ions on the determination of iron at the 5.0 ng/ml level was undertaken. The tolerance level was defined as the amount of foreign ions

Table 2. Effect of foreign ions on the determination of 5.0 ng/ml of Fe(III)

| Foreign ions | Tolerance level (*ng/ml*) |
|---|---|
| K (I) | 20,000 |
| Na (I) | 15,000 |
| Mg (II) | 10,000 |
| $SiO_3^{2-}$ | 4000 |
| Ca (II) | 1000 |
| Ni (II) | 400 |
| $SO_4^{2-}$ | 400 |
| $PO_4^{3-}$ | 200 |
| Co (II) | 80 |
| Al (III) | 40 |
| Cu (II) | 30 |
| Cr (III) | 30 |
| $F^-$ | 30 |
| Zn (II) | 10 |
| EDTA | 5 |

producing an error not exceeding $\pm 5.0\%$ in the determination of the analyte (Table 2).

*Applications*

The proposed method was applied to determination of iron in samples of wine (C. B. Alvear and Espinosa brands), snow from Sierra Nevada, Granada (Spain) and human serum from patients of the Ruiz de Alda Hospital (Granada). In all instances the standard addition method was used in order to avoid the matrix effect. As a reference method we used graphite furnace AAS and the 1,10-phenanthroline spectrophotometric method.

Table 3 shows that results are comparable when using the proposed method and the reference methods whenever the detection limits of each of the methods can be compared.

Table 3. Determination of iron in different samples

| Sample | Proposed method | Reference methods |
|---|---|---|
| Wines | | |
| Espinosa | 7.3 *μg/ml* | 6.8* *μg/ml* |
| Alvear | 2.1 *μg/ml* | 2.1* *μg/ml* |
| Human serum | 787 *μg/ml* | 800* *μg/ml* |
| Snow | 17.5 *ng/ml* | 18.3† *ng/ml* |
| Sierra Nevada (Granada) | | |

Data are based on the average obtained from four determinations.

*1,10-Phenanthroline spectrophotometric method in solution.

†Graphite furnace atomic absorption spectrometry.

## CONCLUSIONS

A new application of ion-exchanger paper as a system to collect coloured species that contain the analyte by filtration, followed by drying of the retaining paper and solid phase spectrophotometry is described. It has been used for iron determination using 1,10-phenanthroline as a reagent, revealing several advantages over the solution and resin phase methods.

The increase in sensitivity obtained with the proposed method ($4.6 \times 10^{-8} M$) with respect to the solution method ($8.96 \times 10^{-6} M$) and the resin phase method ($5.8 \times 10^{-7} M$) is substantial. The method is faster and simpler than the resin phase method because no isolation of the ion-exchanger from samples is required. Furthermore, there are no equilibration steps, only the passage of the solution through a filter. Moreover, only measurement at one wavelength is needed and not two as is usual in the SPS methods.

Other advantages are the higher stability of the complex fixed on the filter and the fact that it is possible to retain the iron as a complex and then to be able to measure it at a much later time without apparent loss in detection levels.

(*Received* 5 *August* 1994, *Revised* 1 *November* 1994, *Accepted* 8 *November* 1994)

**Summary**—In order to determine the fate of the herbicides atrazine (as well as some of its degradation products) and metolachlor in water and sediments, a method was developed to extract and analyse these compounds. The two matrices were separated completely by centrifugation followed by filtration using nylon filters (0.45 $\mu$m). Sediments were extracted with a mixture of methanol–0.1*N* hydrochloric acid (50:50, v/v) using a wrist-action shaker. Filtered water and extracts of sediments were adjusted to pH 4, then concentrated and purified onto two solid-phase extraction cartridges using in tandem $C_{18}$ bonded phase column atop sulfonic acid bonded column (SCX). Atrazine, deethylatrazine, deisopropylatrazine and metolachlor retained by the $C_{18}$ column were eluted with ethyl acetate. Chlorodiaminotriazine and hydroxyatrazine retained by the SCX column were eluted with a 50:50 (v/v) acetonitrile–0.1*M* $Na_2HPO_4$ aqueous solution (pH 8.5). The extracts were quantified by high performance liquid chromatography with diode array detector (HPLC-DAD) and by gas chromatography with nitrogen–phosphorus detector (GC-NPD). Overall percent recoveries were about 75% and detection limits were between 0.05 and 0.15 $\mu$g/l., and 0.5 and 1.5 $\mu$g/kg for water and sediments, respectively.

Atrazine [6-chloro-*N*-ethyl-*N*′-(1-methylethyl)-1,3,5-triazine-2,4-diamine] and metolachlor [2-chloro-*N*-(2-ethyl-6-methylphenyl)-*N*-(2-methoxy-1-methylethyl acetamide] are pre- and post-emergent herbicides, used in combination to control weeds in a variety of food crops. Their widespread utilization and their remanence in soil are responsible for their presence in environment.[1–6].

In soil, atrazine is slowly degraded over a period of weeks to months through hydrolytic reactions and microbiological transformations.[7] Its degradation products which have significant toxicity[5] should also be considered for their environmental impact.

In order to reduce the loss of herbicides when used as treatment, and to prevent soil and water contamination, it is essential to assess their residue level, after treatment, in runoff water and sediments which constitute drainage sources towards surface and groundwater.

The aim of the present work was to develop a rapid, inexpensive, quantitative and reproducible method for the determination of atrazine, four of its principal degradation products and metolachlor in water and sediments.

Despite the fact that several studies on the subject have been published[8–11] none of them, with the exception of Schiavon's method,[12] describes extraction of these combined products from water or sediments. However, in some of these works,[13,14] extraction and purification of two or three of these products were exhibited in a chromatogram with other degradation products. The main difficulty consists essentially in extracting and purifying all these products together in different matrices.

Schiavon[12] developed a method to extract all these products from the soil, to concentrate the aqueous extract by lyophilization and to analyse it by high performance liquid chromatography (HPLC). Although this method has yielded good results, it is time consuming and, therefore, cannot be used for routine work.

*Author to whom correspondence should be addressed.

Solid-phase extraction (SPE) is by far the best method for isolating pesticides from water.[8,9,14–21] However, the specificity of adsorbents used for this method makes it impossible to extract all these products together which have different polarities. By using a large volume of water on a $C_{18}$ column, Nash *et al.*[19] recovered 95% of atrazine but only 26% of deethylatrazine, which is relatively more polar than the former compound. To avoid such a low recovery of degradation products, Karlaganis *et al.*[10] divided the water sample into two fractions; $C_{18}$ (non-polar) was used for atrazine and alumina oxide (polar) for deisopropylatrazine and deethylatrazine.

In the majority of articles on this subject, authors only report the efficiency for the recovery of parent products, which are mostly non-polar products, using non-polar adsorbents.[9,15,18,22,23]

On one hand, metolachlor, atrazine and its degradation products can be analyzed without difficulty by HPLC and gas chromatographic (GC) methods.[13,14,24–28] On the other hand, extraction and purification processes represent a real problem for analysts. In order to solve this problem a unique method has been developed to concentrate and purify simultaneously atrazine (AT), deethylatrazine (DEA), deisopropylatrazine (DIA), chlorodiaminotriazine (CDAT), hydroxyatrazine (HA) and metolachlor (M) in water and sediments samples, by using two cartridges in series: $C_{18}$ (non-polar) and SCX (polar and ion exchange).

To our knowledge, this is the first report, which describes the use of two SPE cartridges ($C_{18}$ and SCX) installed vertically in series, for efficient extraction and separation of AT, its four principal degradation products and M from runoff water and extracts of sediments.

## EXPERIMENTAL

### *Chemicals*

All the organic solvents (HPLC grade) were used as received from Caledon Labs (Georgetown, Ont., Canada). *O*-Phosphoric acid, hydrochloric acid, anhydrous sodium phosphate monobasic and acetic acid were purchased from Fisher Scientific (Fairlawn, NJ, U.S.A.). Propylamine hydrochloride sodium salt and sodium carbonate were obtained from Aldrich Chemical Company (Milwaukee, WI, U.S.A.). Water was distilled, deionized and filtered by Milli-Q-4-bowl reagent-grade water system (Continental Water Systems, Oakville, Ontario, Canada).

### *Standards*

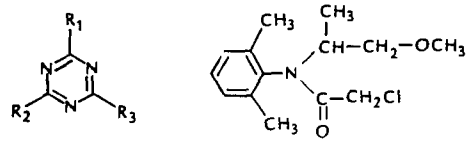
The analytical standards of AT, DEA, DIA, CDAT and HA were obtained from Chem Service (West Chester, PA, U.S.A.). M was obtained from Polyscience (Niles, IL, U.S.A.) and the internal standard (IS) diphenylamine from Aldrich Chemical Company. Figure 1 illustrates the chemical structure of the compounds.

### *Preparation of standards*

Stock standard solutions of AT, DEA, DIA, CDAT, and M and diphenylamine used as an internal standard (0.5 mg/25 ml) were prepared either in ethyl acetate (for GC analysis) or in acetonitrile (for HPLC analysis). A standard solution of HA was made by dissolving 0.5 mg of this compound in 10 ml of 0.1*M* HCl solution and adjusting its volume to 50.0 ml with acetonitrile. From these solutions, working standards were prepared at the concentration range of 0.1–5 mg/l.

### *Sampling and fortification of water and sediment samples*

Runoff water and entrained sediments were collected near an agricultural field following rainfall. The plot had a slope of 5% and was located on a Neuboir silty loam having a moderate organic matter content (4%). Samples



S-Triazine Metolachlor

| Atrazine and its degradation products | $R_1$ | $R_2$ | $R_3$ |
|---|---|---|---|
| AT | Cl | $NHCHC_2H_6$ | $NHC_2H_5$ |
| DIA | Cl | $NH_2$ | $NHC_2H_5$ |
| DEA | Cl | $NHCHC_2H_6$ | $NH_2$ |
| CDAT | Cl | $NH_2$ | $NH_2$ |
| HA | OH | $NHCHC_2H_6$ | $NHC_2H_5$ |

Fig. 1. Chemical structures of atrazine, its degradation products and metolachlor.

were preserved at 4°C until extraction procedure. Being taken in the spring and outside treated fields, the samples did not contain herbicides residue.

Water (100 ml) and sediment (10 g) samples, free of herbicides, were fortified under homogenization with 100–500 ng of each compound. Spiked samples were kept 2 h at room temperature before extraction. Unfortified samples were also analyzed for background comparison.

*Water samples. Liquid–liquid extraction.* Five hundred nanogrammes of each compound was added to 50 ml of a water sample. The extraction was carried out with three successive portions of 20 ml of organic solvent. The following solvents were tested: ethyl acetate, dichloromethane, ethyl acetate–isopropanol (50:50, v/v) and ethyl acetate–hexane (80:20 and 90:10, v/v).

*Solid-phase extraction.* In the preliminary experiments, different cartridges ($C_{18}$, $C_8$, $C_2$, CH, CN, 2OH, SCX) containing 100 mg of the adsorbents were used for the percent recovery of all the compounds. These pilot studies helped:

(i) to study the effect of each type of cartridge on percent recovery of each compound,
(ii) to select $C_{18}$ and SCX cartridges, which yielded the maximum per cent recovery.

In order to increase the concentration factor of the compounds by using higher sample volume (100 ml) compared to lower sample volume (25 ml), cartridges containing higher amount of adsorbent (1000 mg) were used. In addition, the degree of separation and purification is related to the quantity of adsorbent used.

A $C_{18}$ solid-phase cartridge of 6-ml volume size containing 1000 mg of $C_{18}$ octadecyl adsorbent (Lida, Kenosha, WI, U.S.A.) was mounted on top to an aromatic sulfonic acid cartridge filled with 1000 mg of propylbenzenesulfonyl adsorbent (Lida). A 75 ml reservoir was fixed on $C_{18}$ cartridge (Fig. 2). These cartridges were washed in series with 6 ml of methanol, then with 6 ml of distilled water followed by 2 ml of 0.1% acetic acid at a flow-rate of 3 ml/min. A 100 ml aliquot of the sample was centrifuged and filtered through 0.45 μm nylon filter, to which 0.1 ml of concentrated acetic acid was added (final pH 4). The sample was later aspirated through the two cartridges at a flow-rate of 3 ml/min. At no time during this operation were the cartridges allowed to aspirate to dryness. After the sample had been applied, the two

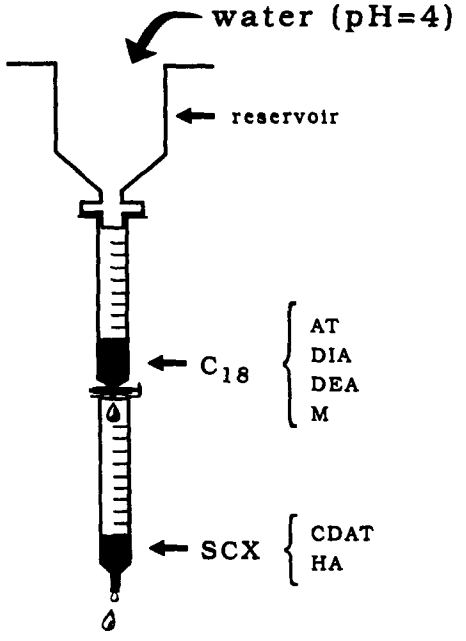


Fig. 2. Scheme for extraction of water samples.

solid-phase cartridges were rinsed in series with 6 ml of distilled water and then separated.

The $C_{18}$ cartridge was aspirated further for 30 min using vacuum to remove any residual water. AT, DEA, DIA and M were then eluted by passing 2 ml of ethyl acetate through the cartridge at a flow-rate of 1 ml/min.

The SCX column was rinsed again with 2 ml of acetonitrile to remove interfering products. The CDAT and HA were eluted from the column by passing a mixture of 2 ml of acetonitrile–aqueous 0.1*M* $Na_2HPO_4$ solution (50:50, v/v) (pH 8.5) through the column at a flow-rate of 1 ml/min. Twenty-five microliters of internal standard equivalent to 500 ng was added to each eluent emerging either from $C_{18}$ or SCX cartridge. These eluents were concentrated separately to 100 μl with nitrogen at 40°C for analysis.

*Sediment samples.* A sample of about 10 g was accurately weighed into a 50 ml centrifuge bottle. Prior to extraction, sediments were saturated with distilled water and a mixture containing 25 ml of methanol–0.1*N* hydrochloric acid (50:50 v/v) was added to it. The heterogeneous mixture was vigorously shaken using a wrist-action shaker for 30 min at 300 rpm. The extracts were centrifuged at 2300 rpm for 10 min, and the supernatant was decanted into a 250 ml bottle. The extraction was repeated twice. The centrifuge bottle was rinsed with 5 ml of organic-free water, which was

combined with the extract. The methanol was evaporated under vacuum and the pH was adjusted to 4 with a few milligrams of sodium carbonate powder. SPEs and elutions were carried out on each sediment extract (total volume of eluate was about 25 ml) using the two cartridges described in the procedure for water samples. Twenty-five microliters of internal standard equivalent to 500 ng was added to each eluent emerging either from $C_{18}$ or SCX cartridge. These eluents were concentrated separately to 100 $\mu$l with nitrogen at 40°C for analysis.

*High pressure liquid chromatography*

The sample extracts emerging from the SCX cartridge were analyzed using a Hewlett Packard 1090 Liquid Chromatograph equipped with a diode array detector. An ODS Hypersil $C_{18}$ guard column (5 $\mu$m, 20 mm × 4.0 mm) and an ODS Hypersil $C_{18}$ column (5 $\mu$m, 20 cm × 4.6 mm) were used with 60:40 (v/v) acetonitrile–water containing 0.017*M* of propylamine hydrochloride and 0.05*M* of sodium phosphate monobasic (pH 4.5) as the mobile phase at a flow-rate of 1.0 ml/min. The sample volume injected for analysis was 20 $\mu$l. CDAT was determined at a wavelength of 223 nm, and HA at 240 nm. Retention times were 2.679, 2.963 and 10.338 min for CDAT, HA and diphenylamine (IS), respectively. Since no traces of CDAT and HA were found in the field extracts, only the chromatogram of authentic standards of these compounds analyzed at 223 nm is presented in Fig. 3.

*Gas chromatography*

The sample extracts emerging from the $C_{18}$ cartridge were analyzed using a Hewlett Packard 5730A gas chromatograph equipped with a nitrogen–phosphorus detector. A DB-5 (5% phenyl–95% methyl) capillary column (30 m × 0.25 mm i.d., 0.25 $\mu$m coating thickness) was used with helium as the carrier gas at a flow-rate of 2 ml/min. The detector was supplied with hydrogen at a flow-rate of 3.4 ml/min and with air at a pressure of 35 psi. The nitrogen make-up flow-rate was 34.4 ml/min. The injector and detector port temperatures were 250 and 300°C, respectively. The temperature of the column was initially programmed at 50°C. It was increased to 160°C at a rate of 20°C/min, then to 185°C at a rate of 5°C/min and finally to 240°C/min at a rate of 20°C/min. The latter temperature was held for 3 min. The split/splitless capillary injector was operated in the splitless mode and the injection volume was 1 $\mu$l. Retention times were 9.225, 9.525, 9.702, 10.967 and 13.100 min for diphenylamine (IS), DIA, DEA, AT and M, respectively. Chromatograms of field extracts are shown in Figs 4 and 5.

## RESULTS AND DISCUSSION

Being aware that extraction and purification are the most critical steps in developing a

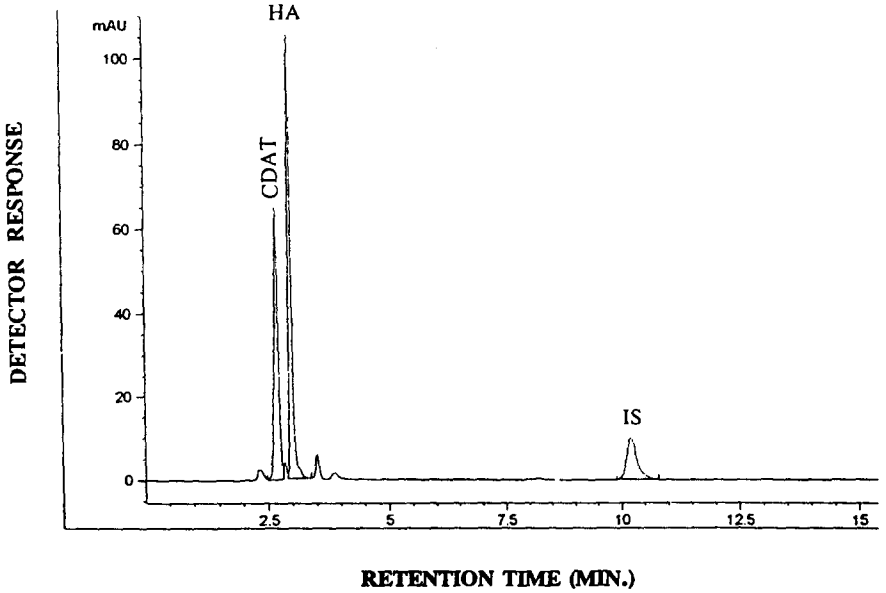

Fig. 3. Chromatogram of CDAT and HA standards by HPLC. CDAT, 1 $\mu$g/ml; HA, 5 $\mu$g/ml; IS, 5 $\mu$g/ml.

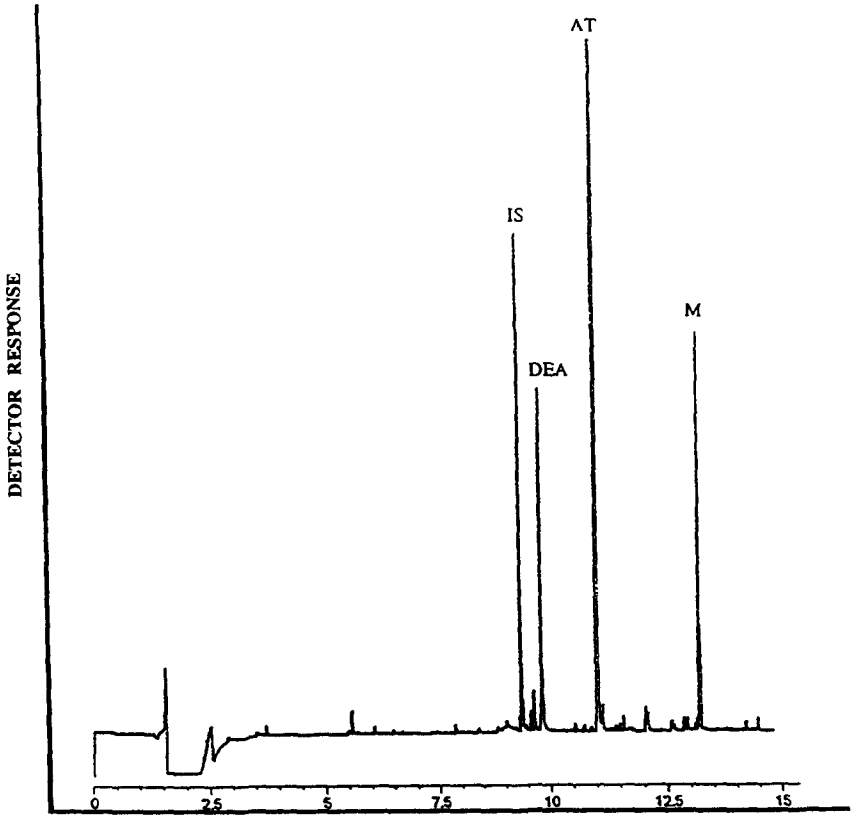

Fig. 4. Chromatogram of an extract of a water sample by GC. IS, 50 μg/l.; DIA, 1.9 μg/l.; DEA, 3.9 μg/l.; AT, 12.2 μg/l.; M, 13.3 μg/l.

method, this investigation was thus oriented towards that objective. The first attempt was made using liquid–liquid extraction methods and later more trials were given to the SPE techniques.

For liquid–liquid extraction methods, various organic solvents were tested by keeping water samples at neutral pH. None of them gave satisfactory results either for CDAT or HA (per cent recovery $<30\%$). For all others products, overall per cent recoveries were more than 80%. As for SPE techniques, three factors which determined the percent recoveries were studied namely the type of adsorbent (Table 1), the sample volume (Table 2) and the type of eluent.

The choice of SPE adsorbent and extraction conditions were driven by the physicochemical properties of the herbicide products. The work of Wenheng *et al.*[13] describing the separation of AT and HA by SCX cartridge was applied first in this study. The results obtained by this method are shown in Table 1. All the compounds studied possess at least one amine function and in addition HA contains an hydroxyl group. This fact leads one to think, that the sulfonic acid group of SCX cartridge will retain the compounds, whose functional groups are protonated by the acidic medium of the samples. The results show, that by using SCX cartridge, all compounds were retained except M (Table 1). This could be due to the presence of tertiary amine in the chemical structure of M. The presence of bulky substituents linked to the nitrogen atom in M (Fig. 1) may hinder the ion-exchange capacity of SCX cartridge. Since SCX cartridge could not separate all the compounds, other cartidges described in Table 1 were tried. The $C_{18}$ cartridge gave better per cent recovery for AT, DEA, DIA and M compared to all other cartridges. This fact was the turning point for the installation of $C_{18}$ and SCX cartridges vertically in series (Fig. 2). The ion-exchange process using SCX cartridge requires acidic pH. This pH did not affect the per cent recovery of the compounds, which were retained by $C_{18}$ cartridge. Therefore, all the field samples were acidified to pH 4 before applying to the two cartridges in series.

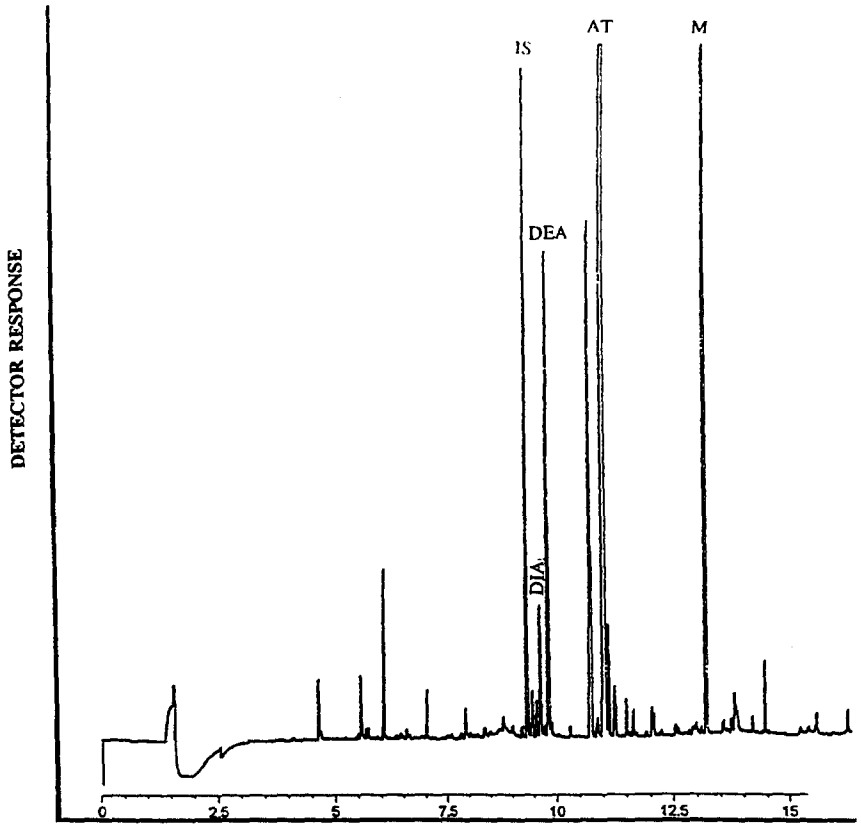

Fig. 5. Chromatogram of an extract of a sediment sample by GC. IS, 5 μg/kg; DIA, 27.2 μg/kg; DEA, 47.2 μg/kg; AT, 629.5 μg/kg; M, 824.3 μg/kg.

The volume of water has no effect on the recovery rate of parent compounds namely AT and M. Contrary, once the volume passes beyond 100 ml, the per cent recovery of DEA and DIA decreases significantly. The optimum sample volume was found to be 100 ml during the per cent recovery experiments of each component using $C_{18}$ cartridge (Table 2). The same volume was used for SCX cartridges as two columns were installed in series. Therefore, the effect of sample volume on SCX cartridge was not studied.

| M | 97 | 96 | 95 | 94 | ND | ND | ND |
| CDAT | ND | ND | ND | ND | ND | ND | 101 |
| HA | 41 | 6 | ND | 4 | ND | ND | 80 |

Twenty-five milliliters of water and 100 *mg* of adsorbent were used. Ethyl acetate (2 *ml*) was employed for elution of AT, DEA, DIA and M using $C_{18}$, $C_8$, $C_2$, CH, CN and 2OH cartridges whereas acetonitrile–aqueous 0.1*M* $Na_2HPO_4$ solution (50:50, v/v) (2 *ml*) was employed for elution of CDAT and HA using SCX cartridge.

The elution of HA and CDAT on $C_{18}$, $C_8$, $C_2$, CH, CN and 2OH cartridges was carried out using 2 *ml* of ethyl acetate followed by 2 *ml* of methanol.

Table 2. Effects of sample volume on per cent recoveries on a $C_{18}$ cartridge containing 100 mg of the adsorbent

| | Volume (*ml*) | | | | |
|---|---|---|---|---|---|
| Compound | 25 | 50 | 100 | 150 | 250 |
| AT | 99 | 96 | 97 | 95 | 92 |

| M | 97 | 95 | 98 | 96 | 95 |
| CDAT | ND | ND | ND | ND | ND |
| HA | 41 | ND | ND | ND | ND |

ND: Non detected.

A fixed quantity (500 *ng*) of each compound was spiked to different volumes of herbicide free-water. The elution of HA and CDAT was carried out using 2 *ml* of ethyl acetate following by 2 *ml* of methanol.

Table 3. Recovery of different products from fortified samples

| Compound | Adsorbent | Water samples | | Sediment samples | |
|---|---|---|---|---|---|
| | | Recovery (%) | C.V. (%) | Recovery (%) | C.V. (%) |
| AT | $C_{18}$ | 99 | 5 | 92 | 5 |
| DEA | $C_{18}$ | 98 | 6 | 89 | 7 |
| DIA | $C_{18}$ | 96 | 6 | 86 | 8 |
| M | $C_{18}$ | 97 | 5 | 91 | 5 |
| CDAT | SCX | 103 | 10 | 82 | 12 |
| HA | SCX | 78 | 10 | 75 | 12 |

The volume of water samples was 100 *ml*; the weights of sediment samples and adsorbents were 10 and 1 *g*, respectively. Values represent the mean of three tests.

Table 4. Detection limits (in ppb) of different compounds in water and sediment samples

| Sample | Compound (values in ppb)/method | | | | | |
|---|---|---|---|---|---|---|
| | AT/GC | DEA/GC | DIA/GC | M/GC | CDAT/HPLC | HA/HPLC |
| Water | 0.05 | 0.05 | 0.05 | 0.15 | 0.15 | 0.15 |
| Sediment | 0.5 | 0.5 | 0.5 | 1.5 | 1.5 | 1.5 |

Generally the use of solid phase cartridges would only be applicable to samples or extracts entirely free of sediments. On one hand, the sediments present in water can adsorb the herbicides. On the other hand, these sediments can affect the per cent recovery and can block the content of the cartridge rendering extraction impossible.

In order to determine the effect of eluents of per cent recoveries using $C_{18}$ cartridges, 1 ml aqueous solutions containing 100–500 ng of AT, its degradation products and M were directly deposited on these columns containing 100 mg of adsorbent and three tests were performed using three different solvents namely methanol, ethyl acetate and acetonitrile. The experiments on per cent recovery using SCX cartridges were performed according to the method already described in the literature.[13] With 2 ml of each solvent the total amount of the products was recovered with the exception of HA. HA could be totally recovered only with methanol. Ethyl acetate and acetonitrile yielded a recovery of about 30% of the latter compound.

The per cent recoveries of all the products are presented in Table 3. The overall coefficient of variation (C.V.) of the compounds extracted with $C_{18}$ is below 10%. The C.V. of those products extracted by SCX cartridge is below 12%.

The concentration factors obtained for water and sediment samples are 1000 and 100, respectively.

The detection limit of each compound was fixed to the minimum response of each detector to the respective compounds with a signal-to-noise ratio of 5. The lowest detection limits of each compound in water and sediment samples are given in Table 4.

## CONCLUSION

The per cent recoveries and detection limits obtained with the present method are satisfactory and, moreover, they correspond to those mentioned in the literature.[12,14,19] Using SPE the water volume is of primary importance for the recovery rate. It is obvious that the use of a large sample volume increases chances of detecting low concentrations. But unfortunately, it also has a negative double-action: the sample passage time in the cartridge is increased and the per cent recovery, for some products, is directly affected.[19]

The type of adsorbents and eluents also play major roles. The utilization of columns in series provides a good solution when one needs to simultaneously extract, purify and concentrate parent products and their degradation products, which otherwise would be highly time consuming. This method could very well be used with a great variety of products which have different polarities.

# EVALUATION OF A β-DIKETONE-IMBEDDED POLYURETHANE FOAM

S. KATRAGADDA, H. D. GESSER and A. CHOW*

Department of Chemistry, University of Manitoba, Winnipeg, MB, R3T 2N2, Canada

(*Received* 16 *August* 1994. *Revised* 3 *November* 1994. *Accepted* 8 *November* 1994)

**Summary**—A β-diketone-imbedded polyurethane foam was made for the sorption of uranium from aqueous solutions. The incorporation of the β-diketone functional group into the polyurethane foam was simple, and relatively inexpensive. The β-diketone foam was ground to facilitate the evaluation of its ability to extract uranium from aqueous solutions with a wide range of temperature and pH values. The β-diketone material showed superior extractability of uranium from solutions with pH 7 ± 3. In general, the β-diketone material showed greater extractability of uranium at all temperatures and pH values tested when compared to a blank polyurethane foam without the β-diketone functional group.

The use of polyurethane foams for the extraction, recovery and preconcentration of various inorganic and organic species from aqueous, non-aqueous and gaseous mixtures has received considerable attention during the past two decades. Reviews of literature devoted to polyurethane-based polymeric sorbents in separation chemistry have been documented by Moody and Thomas[1] and Braun *et al.*[2,3] Polyurethane foams are stable in most acids, bases and organic solvents. The foams will degrade in concentrated nitric or sulphuric acids or when heated above 180–200°C.

The field of reagent-treated polyurethane foam materials is very extensive and has been comprehensively reviewed by Braun *et al.*[2,3] He first published investigations[4,5] in 1972 using tributylphosphate-loaded polymer to sorb several metal complexes from solution and since then many other loaded or coated polyurethane materials have been examined for concentrating various inorganic and organic species and for separations as detailed in the reviews.[2,3] Several chelating agents have been immobilized on polyurethane foam using a plasticizer such as tributylphosphate[6,7] and this material used to selectively sorb metal ions from solution. Liquid ion exchangers can also be used conveniently when they are held on polyurethane foam[8,9] or in a plasticizer on the foam.[10] Polyurethane foams have also been used as supports for various extractants; for example, foams treated with dithiazone or diethyldithiocarbamate or sulphide-treated foams have been used for the sorption of mercury,[11–13] ethanediol-treated foams for antimony,[14] and pyridylazonaphthol-treated foams for the sorption of zinc, copper and mercury.[15] Copper and cadmium were extracted using polyurethane treated with benzoyl-acetone.[16] Braun *et al.*[17] found that foam could be coated with various colour-forming reagents either with or without plasticizer; these 'chromofoams' can be used qualitatively and semi-quantitatively to determine several metal ions. Huang *et al.*[18] and Korkisch *et al.*[19] have extracted uranium from nitrate solutions with polyurethane foam. Korkisch and Steffan[20] and Pearson and Bowen[21] have used polyurethane foam impregnated with trioctylphosphine oxide to sorb uranium from hydrochloric acid solution. Polyurethane foam, when coated with a long chain tertiary amine, was also effective in extracting uranium[22] from acidic solutions with pH values between 1 and 3.

Hypol™ prepolymers, which are derived from toluene diisocyanate, react with active hydrogen-containing compounds (*i.e.* $H_2O$, ROH, *etc.*) to form polyurethane foams that are both elastomeric and hydrophillic in nature. These foams can be prepared by mixing equal weights of Hypol™ prepolymers and water or other active hydrogen-containing compounds. Additives may be suspended or dissolved in either or both of the organic and aqueous layers.[23] Additives that contain a functional group for the

*Author to whom correspondence should be addressed.

sorption of uranium can be dissolved in the organic layer or the aqueous layer to produce a modified polyurethane foam with a functional group imbedded into the foam.

Selective extraction of uranium using sorbents with amidoxime functional groups has been reported extensively by workers in Japan and Europe,[24-32] mainly for the extraction of uranium from seawater. $\beta$-diketone has been shown to be particularly effective in extracting uranium from seawater with good selectivity[24] Other materials for extracting uranium include polystyrene with 1,3-diketone as the anchor group[25], a macrocyclic hexaketone and a cyclic tetraketone[33], and a poly-$\beta$-diketone resin.[34]

The preparation of a $\beta$-diketone-imbedded polyurethane foam using the Hypol™ prepolymer and the evaluation of this material for extracting uranium from aqueous solutions with a wide range of temperature and pH values is described in this paper.

## EXPERIMENTAL

### *Reagents*

1-Benzoylacetone, *N*-(2-thiazolyl)acetoacetamide, 4,4,4-trifluoro-1-phenyl-1,3-butanedione and Arsenazo III were obtained from Aldrich Co. (WI, U.S.A.). Acetylacetone and uranyl acetate were obtained from Fisher Scientific Co. (NJ, U.S.A.) and BDH (U.K.), respectively. The above chemicals were of reagent grade and were used without further purification.

Hypol™ FMP 2002 prepolymer, used in the production of the foam, was a sample provided by W. R. Grace and Co., (MA, U.S.A.). Uranium solutions ranging from 1 to 10 ppm were prepared by successive dilution of a 2000 ppm uranium stock solution which was prepared from uranyl acetate $[UO_2(CH_3COO)_2 . 2H_2O]$. Water was purified by reverse osmosis followed by a Barnstead Nanopure II™ system.

### *Apparatus*

A Fisher Accumet™ (Model 825 MP) pH meter was used to measure pH. Polyurethane foams, with and without $\beta$-diketone functional groups, were first cut into small pieces and were then frozen in liquid nitrogen. The frozen foams were ground to a powder in a stainless steel container on a Waring™ blender (Dynamics Corporation of American CT, U.S.A.).

Sample solutions were shaken either with a Burrell Wrist-Action Shaker (Burrell Corp., PA, U.S.A.) for solutions at 4°C and 22°C or a Dubnoff Metabolic Shaking Incubator (Precision Scientific, IL, U.S.A.) for solutions at 40°C and 70°C. Absorbance measurements were obtained with a Hewlett-Packard (Model 8452A) Diode Array spectrophotometer (Hewlett-Packard Company, CA, U.S.A.).

A quartz flow cell with 0.5 cm path length (Markson Science Inc., CA, U.S.A.) was used for the specrophotometric analysis. Sample solutions were pumped through the flow cell using a Piper Pump™ (Model P10T) peristaltic pump (Dungey Inc., Ontario, Canada).

### *Method*

Solutions containing uranium were analyzed using a continuous flow spectrophotometric method (CFSM).[35] This method consists of simultaneously pumping 0.006% Arsenazo III in 0.12*M* HCl (photometric reagent) and the uranium solution into a flow mixer to form the Arsenazo III–uranium complex. This complex then enters a flow cell where the absorbance is measured with a diode array spectrophotometer. A flow cell requires less time per sample because the tedious process of cleaning and rinsing is avoided and the time for complex formation is always constant.

Arsenazo III, [2,2′-(1,8-dihydroxy-3,6-disulphonaphthylene-2,7-bisazo)-bisbenzenearsonic acid, FW 776.37], reacts with a wide variety of metal ions in weakly acidic to alkaline aqueous solutions, but reacts with only a few metals in strong mineral acid, forming highly coloured complexes (molar absorptivity approximately $10^5$). Arsenazo III has been recommended as a highly sensitive and selective photometric reagent for Mg, Zr, U, Th and rare earths.[36] Arsenazo III is available as either a free acid or the disodium salt and is stable both as a solid and in the dissolved form. The free acid form of Arsenazo III was used for our analysis.

More than 150 papers have been published in the last three decades,[37,38] wherein Arsenazo III is the preferred choice of chromogenic reagent for the spectrophotometric determination of uranium. Uranyl ions form a 1:1 complex[39,40] in moderately acidic media and the stability constant for the complex[40] is $\log \beta_1 = 5.42$. For these analyses the concentration of Arsenazo III was always higher than that of uranium. The flow rates of the Arsenazo III solution and uranium sample solution were each 8 ml/min

with a combined flow rate of 16 ml/min when reaching the flow cell. At this flow rate the air bubbles that often adhered inside the flow cell were forced out.

An internal referencing method was used where the absorbance at a reference wavelength (768 nm) was subtracted from the absorbance at the analytical wavelength (650 nm). This absorbance difference was used to obtain the calibration curve and for sample analysis. Internal referencing was done to improve the precision of the results by minimizing the impact of any changes that cause a baseline shift due to dust or other particles, air bubbles or a drift in lamp intensity. Quantitative analysis was performed by using the 'Quantitation' program which was part of the software menu for the Hewlett-Packard system. Uranium standards ranging from 1 to 10 ppm uranium were used to obtain the calibration curve in Fig. 1 using a second order curve fit. The absorbance obtained was the average reading obtained for a 10 sec scan period.

The 0.006% Arsenazo III (wt/vol.) reagent solution in 0.12*M* HCl was prepared as it was found that acid concentrations higher than 0.12*M* HCl produced larger errors with lower pH uranium solutions and concentrations lower than 0.12*M* HCl resulted in larger errors with higher pH uranium solutions. The choice of 0.12*M* HCl permitted the analysis of uranium solutions whose pH ranged between 1 and 11.

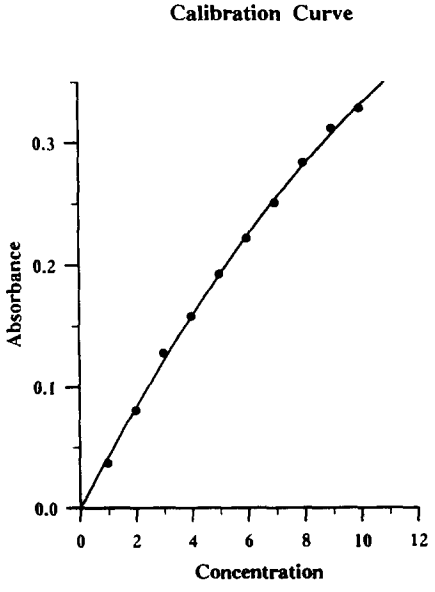

Fig. 1. Calibration graph for uranium standards between 1 and 10 ppm. A 5 mm Markson™ flow cell and 0.006%. Arsenazo III in 0.12*M* HCl was used.

*Procedure*

Hypol™ foams are usually produced by thoroughly mixing approximately equal weights, of Hypol™ prepolymer and water. Additives that contain β-diketones may be suspended or dissolved in either or both of the organic and aqueous layer. In a preliminary study, different β-diketones [acetylacetone, *N*-(2-thiazolyl)acetoacetamide, 1-benzoylacetone and 4,4,4-trifluoro-1-phenyl-1,1-butanedione] were used with varying amounts (1, 5 and 10% by weight) in the prepolymer matrix in an attempt to incorporate them into the Hypol™ foam matrix. Among various β-diketones studied only the foam prepared with 5% (wt/wt) 1-benzoylacetone, 'β-diketone foam', showed good foam formation and also exhibited the ability to extract uranium from aqueous solutions. The incorporation of acetylacetone and 4,4,4-trifluoro-1-phenyl-1,3-butanedione resulted in the formation of a solid plastic instead of a foam. *N*-(2-thiazolyl)Acetoacetamide formed a foam, but it did not extract uranium.

β-Diketone foam was prepared by mixing Hypol™ prepolymer with 1-benzoylacetone solid to form a clear viscous solution. An equal weight of water was then added to the viscous polymer solution followed by rapidly stirring of the mixture for 15 sec by using a glass rod. The mixture initially became cloudy and then rose to 10 times the original volume by releasing small bubbles of carbon dioxide. The resulting β-diketone foam became tack-free within 5 min and was air-dried in a fumehood for at least 8 h. The β-diketone foam was cut into small pieces which were frozen in liquid nitrogen and then the brittle foam was ground to a powder in a stainless steel container on a Waring™ blender. The size of this material was not determined but consisted of various small sizes of foam particles. These do not have the overall physical structure normally associated with the flexible polymer but naturally possess the same chemical composition. The physical form of the polymer should have no significant effect on the sorption since the mechanism is a chemical process. Because this is an evaluation investigation, it is more important that comparative studies be done in a reproducible manner and if possible, that an equilibrium be obtained. Powdered foam reaches equilibrium more quickly with the uranium solutions and also ensures more reproducible results. If the foam was used unground, it would take more time for the

uranium solution to equilibrate but qualitatively, the results would be the same as with the ground material.

The powdered foams were initially soaked in water for 4 h and the resulting slurry was then filtered under vacuum through a Whatman™ No. 541 filter paper using a Buchner funnel. The foam was recovered from the filter paper and the soaking and filtering was repeated twice more. The foam was washed in a similar manner with acetone and then left to dry under vacuum for 4 h to remove traces of acetone vapour. The above cleaning procedure was undertaken to remove any water or acetone soluble impurities. A blank foam was prepared in a similar manner without the addition of 1-benzoylacetone. The colour of the clean, dry $\beta$-diketone foam was cream yellow compared to the blank foam which was white.

The extraction capability was evaluated using 25 ml of 10 ppm uranium solution with $0.200 \pm 0.003$ g of foam in a 60 ml Nalgene™ bottle. The capped bottles were shaken for 5 h in an automatic shaker and the solutions filtered and then analyzed for uranium content using the spectrophotometric method.

*Characterization of the foam*

The extraction characteristics of the $\beta$-diketone foam were studied by equilibrating the foam with uranium solutions at different temperatures and pH values. Uranium solutions were adjusted with 2*M* HCl or 2*M* NaOH solution to pH values between 1.4 and 11.0 and studied at temperatures between 4°C and 70°C with $\beta$-diketone foam.

All solutions were equilibrated to the required temperatures before adding them to the plastic bottles containing the foam. Shaking of solutions at room temperature (22°C) and at cold room temperature (4°C) was done using a Burrell Wrist Action Shaker. Similar experiments at 40°C and 70°C were performed with a Dubnoff Metabolic Shaking Incubator equipped with a variable temperature-controlled water bath. Temperature measurements were within ±2°C.

Per cent extraction was calculated as

$$\%E = 100(I - F)I^{-1},$$

where % *E* is per cent extraction, *F* is the concentration of uranium left in solution after extraction and *I* is the concentration of uranium originally available for extraction. *I* is the concentration of uranium in solution after it was subjected to the identical filtration, pH and temperature conditions as the foam sample solution, but without the presence of any foam.

The concentration of available uranium, rather than the initial concentration (*i.e.* 10.0 ppm), was used to take into account any precipitation of uranium species which is known to occur at pH > 2. This precipitate is not visible to the naked eye, however, Feldman[41] *et al.* observed the precipitation of uranyl nitrate at pH > 4.5 by centrifuging the solution. The values for *I* and *F*, used in the calculation of % *E*, were the averages obtained from experiments that were performed in triplicate at the same pH and temperature.

## RESULTS AND DISCUSSION

The $\beta$-diketone foam exhibits high extraction between pH 3 and 8 with a decrease at either end of the pH ranges as shown in Figs 2–5.. The change in extraction can be explained by the fact that the formation of the various uranium species depends on the pH of the aqueous solutions.

For uranium solutions acidified with 2*M* HCl, the species formed in aqueous medium are $UO_2Cl_2$ and $UO_2Cl^+$ at pH values below 3, and above pH 10 species such as $UO_2(OH)_3^-$ are formed owing to the hydrolysis of the uranyl ion.[42] These species may not be as extractable by this foam.

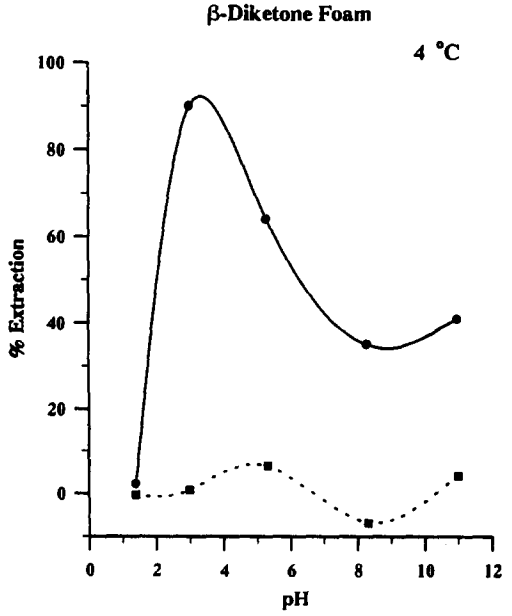

Fig. 2. Comparison for the extraction capability of uranium from solution by the $\beta$-diketone foam and blank foam at 4°C. —●— $\beta$-Diketone foam; - -■- - blank foam.

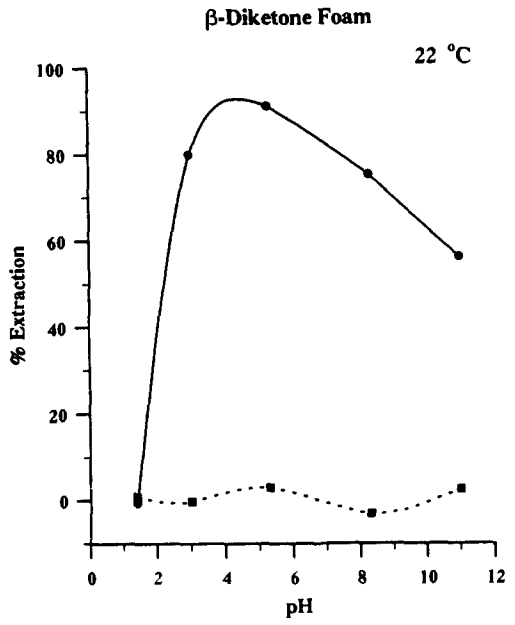

Fig. 3. Comparison of the extraction capability of uranium from aqueous solutions by the β-diketone foam and blank foam at 22°C. —●— β-Diketone foam; --■-- blank foam.

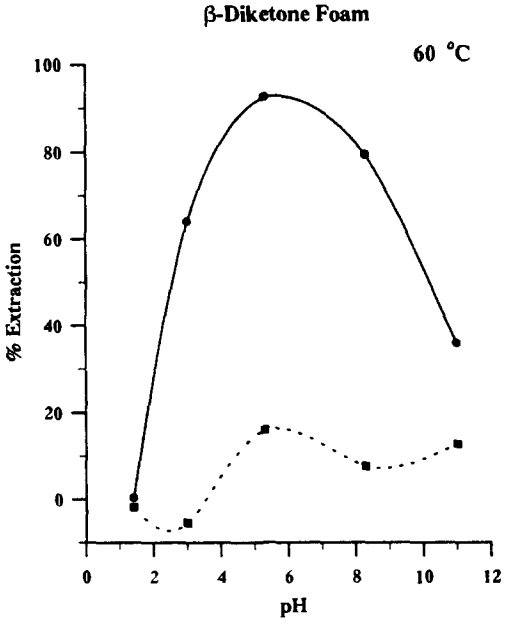

Fig. 5. Comparison of the extraction capability of uranium from aqueous solutions by the β-diketone and the blank foam at 60°C. —●— β-Diketone foam; --■-- blank foam.

Stary and Hladky[43] undertook a systematic investigation of the solvent extraction of 30 metals using various solvents such as acetylacetone, benzoylacetone and dibenzoylmethane in benzene. Included in their study was the extraction of uranium by benzoylacetone and the extraction profile reported by Stary and Hladky[43] is similar to the β-diketone foam profile at 22°C (Fig. 3). This suggests that the β-diketone foam's ability in sorbing uranium involves a solvent extraction type of mechanism.

It can be seen in Table 1 that between pH 3 and 8 the extraction generally increases with an increase in temperature from 4°C to 40°C,

followed by a drop at 60°C which may be attributed to the instability of the β-diketone foam at high temperatures. The decrease in extraction efficiency at the lower end of the pH range is due to a change in the uranium species and suggests using a solution with pH < 1 as a possible eluting solution to desorb uranium from the foam.

Blank foams (*i.e.* without the inclusion of 1-benzoylacetone) showed little capability in extracting uranium from aqueous solutions in comparison to the β-diketone foam. Overall, the β-diketone foams showed superior extractability of uranium over blank foam at all values of pH and temperatures tested as shown in Figs 2–5.

In general it was found that the variation in per cent extraction was higher for the blank foam when compared with the β-diketone foam. The ideal temperature was 40°C for maximum extraction of uranium by β-diketone foam for uranium solutions with pH $7 \pm 3$.

Gesser and Ahmed[22] have reported that Adogen-impregnated polyurethane foam is capable of extracting uranium from acidic solutions whose pH values range from pH 1 to 3. The β-diketone foam synthesized in this work extracts uranium from aqueous solutions whose pH values range from pH 3 to 10. Both foams (*i.e.* Adogen-impregnated and β-diketone foams) complement each other by extending the ability of modified foams to extract uranium from aqueous solutions with a wide range of pH values.

## CONCLUSIONS

1-Benzoylacetone was imbedded into the matrix of the polyurethane foam during the fabrication of the foam. The resulting β-diketone foam is capable of extracting uranium from aqueous solution between pH 3 and 10. The β-diketone foam would be useful for the sorption of uranium from natural waters as the pH of most natural waters is usually in the range of pH $7 \pm 3$. The β-diketone foam is simple to make, relatively inexpensive, has high porosity and has good chemical and mechanical stability. The above qualities make the β-diketone foam a promising sorbent for the separation and preconcentration of uranium for both analytical and large scale industrial applications, including the nuclear industry and in clean-up procedures for spills involving uranium.

# POTENTIOMETRIC AND COULOMETRIC TITRATION OF 2-THIOBARBITURIC ACID

WITOLD CIESIELSKI, JOANNA KOWALSKA and ROBERT ZAKRZEWSKI

Department of Instrumental Analysis, University of Łódź, Lindleya 3, 90-131 Łódź, Poland

(*Received* 22 *April* 1994. *Revised* 11 *November* 1994. *Accepted* 11 *November* 1994)

**Summary**—A new method for the determination of 2-thiobarbituric acid, using its reaction with iodine in an alkaline medium is presented. In the volumetric titration with potentiometric end-point detection, the determinability range is 10–400 μmol (1.4–58 mg). In coulometric titration using the biamperometric end-point detection, 0.1–20 μmol ($1.4 \times 10^{-2}$–2.9 mg) of 2-thiobarbituric acid was successfully determined.

2-Thiobarbituric acid (4,6-dihydroxy-2-mercapto-pyrimidin) is used in chemical analysis for spectrophotometric determination of copper,[1,2] iron,[2,3] bismuth,[4,5] and ruthenium[6] as well as many organic compounds including aldehydes and carbohydrates.

The tested compound has been determined previously by titration methods, using silver(I)[7] and mercury(II)[8] ions, iodine,[9,10] bromine chloride,[11] dichromate ions[12,13] and sodium methylate.[14] Spectrophotometric[15–22] and polarographic[23–26] methods, cathodic inversion voltamperometry[27] and chromatographic[28,29] methods have also been proposed. The determination has also been carried out using the induced iodine–azide reaction.[30–32] Hitherto developed iodometric back-titration methods for the determination of 2-thiobarbituric acid, consisted of introducing excess iodine to the tested sample and titration of the unreacted residue[9] after 10–20 min, or determination of the resultant iodide ions.[10]

In the present paper, the determination of 2-thiobarbituric acid by direct titration with iodine in an alkaline medium based on the apparent stoichiometry:

$$RS^- + 3I_2 + 6OH^- \rightarrow RSO_3^- + 6I^- + 3H_2O$$

is presented. Iodine disproportionates quickly in alkaline medium to give iodide and hypoiodite ions, so hypoiodite is the actual oxidizing agent. Since hypoiodite is a stronger oxidant than iodine in neutral medium the above reaction may be rapid and the proposed determination can be carried out.

In determinations of larger quantities of 2-thiobarbituric acid, volumetric titration with a potentiometric detection of the end-point was used. Lower amounts were determined by coulometric titration using biamperometric detection of the end-point.

## EXPERIMENTAL

### *Reagents*

Twice distilled water in glass apparatus, potassium iodide, sodium hydroxide. 2-Thiobarbituric acid purum (Fluka): a standard solution $2 \times 10^{-3}M$ was taken by dissolving a weighed amount of the reagent in $3M$ sodium hydroxide. Sodium salt of 5-ethyl-5′-(1-methylbutyl)-2-thiobarbituric acid (thiopental) (United Pharmaceutical Works, Praha). Iodine: standard solution $1 \times 10^{-1}M$ and $1 \times 10^{-2}M$.

### *Apparatus*

Universal coulometric analyser 'Radelkis' (Hungary), type OH-404. Electrolysis cell with two platinum electrodes with an area of 5 $cm^2$ each, working in generating circuit and with a OH-9381 double electrode in an amperometric indicator-circuit with two polarized electrodes. Mechanical stirrer. pH-meter type OP-206 'Radelkis' (Hungary) with platinum electrode and saturated calomel electrode.

### *Procedure*

*Volumetric determination.* A sample of 2-thiobarbituric acid (10–400 μmol) was dissolved in 50 ml of 3M NaOH solution and titrated with

iodine, using potentiometric detection of the end-point with a platinum indicator electrode and a saturated calomel electrode.

*Coulometric determination.* The coulometric titration was carried out in the reaction solution containing 1*M* KI and 3*M* NaOH. A sample solution containing 0.1–20 μmol of 2-thiobarbituric acid was introduced into 20 ml of the reaction solution placed in the anode part of the electrolysis cell. The polarization voltage applied to the indicator system electrodes was 200 mV. After starting the mechanical stirrer, stabilized current was passed through the solution. The current applied to the generating circuit (Table 1) depended on the quantity of the compound being determined and was adjusted so as to maintain the titration time from several to a dozen or so minutes. The charge ($Q$) was noted after completing the titration of 2-thiobarbituric acid up to an indicator current of 0.02 μA and a delay time of 5 sec.

The rate of the reaction between 2-thiobarbituric acid and hypoiodite close to the end of the coulometric titration is lower than the rate of hypoiodite generation. Therefore, the appearance of the excess of hypoiodite in the solution and the increase of the indication current cannot be considered to be the equivalence point of titration. Thus adtitration is necessary, which resolves into a renewed connection of current in the generation circuit if during the fixed period of time the indicator current decreases. This time is called the 'delay time'. The coulometric analyser, which was used made it possible to estimate the length of the delay time. The delay time was determined as the shortest time in which the correct results of the coulometric titration were obtained.

The 2-thiobarbituric acid content (μmol) in the tested sample was calculated according to Faraday's law:

Table 1. Results of coulometric determination of 2-thiobarbituric acid ($n = 6$)

| Taken (*μmol*) | Found $\bar{x} \pm t_{0.95} \cdot \bar{s}$ (*μmol*) | Relative standard deviation (%) | Current (*mA*) |
|---|---|---|---|
| 0.1000 | 0.1004 ± 0.0006 | 0.53 | 1 |
| 0.2000 | 0.1998 ± 0.0006 | 0.29 | 1 |
| 0.5000 | 0.5003 ± 0.0017 | 0.33 | 2 |
| 4.000 | 4.004 ± 0.016 | 0.38 | 10 |
| 10.00 | 9.987 ± 0.013 | 0.12 | 20 |
| 20.00 | 19.99 ± 0.023 | 0.11 | 20 |

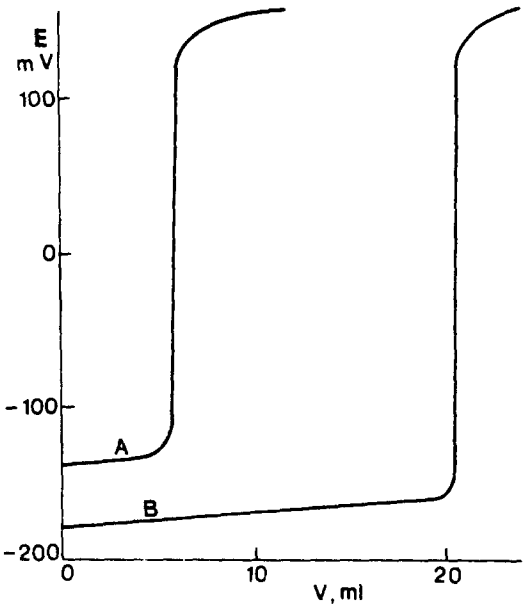

Fig. 1. Curves of potentiometric titration of (A) 10 *μmol* 2-thiobarbituric acid with $10^{-2}M$ iodine solution; (B) 400 *μmol* 2-thiobarbituric acid with $10^{-1}M$ iodine solution.

$$n = \frac{\Delta Q}{z \cdot F} 10^3,$$

where: $\Delta Q = Q - Q_0$ (mC), $Q_0$ is charge corresponding to blank titration, $z$ is number of electrons transferred in the reaction of 1 mol, $F$ is the Faraday constant ($F = 96485$ C/mol).

In order to compute the electric charge $Q_0$, a suitable amount of water instead of 2-thiobarbituric acid was introduced into the reaction solution placed in the anode part of the electrolysis cell.

## RESULTS AND DISCUSSION

It was found experimentally that the reaction rate of 2-thiobarbituric acid with iodine increases with an increase in concentration of sodium hydroxide. A concentration of sodium hydroxide greater than 2*M* provides a sufficiently high reaction rate enabling direct titration with iodine. In neutral and acidic medium, the reaction rate of iodine with 2-thiobarbituric acid was very low and iodometric titration was impossible.

### *Potentiometric titration*

In the volumetric titration of 10–400 μmol of 2-thiobarbituric acid, good results were obtained using the potentiometric detection of the end-point. Potentiometric titration curves are shown in Fig. 1 and the results of determinations are given in Table 2.

Table 2. Results of potentiometric determination of 2-thiobarbituric acid ($n = 6$)

| Taken ($\mu mol$) | Found $\bar{x} \pm t_{0.95} \cdot \bar{s}$ ($\mu mol$) | Relative standard deviation (%) |
|---|---|---|
| 350.0 | $349.7 \pm 0.9$ | 0.25 |
| 35.0 | $35.01 \pm 0.14$ | 0.37 |
| 10.0 | $10.03 \pm 0.11$ | 1.02 |

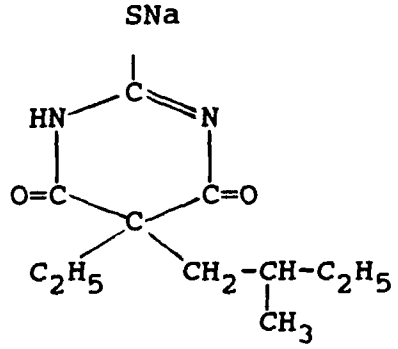
Direct titration considerably reduced the duration of analysis, and the use of potentiometric end-point detection improved the accuracy of determination in comparison with the methods using visual detection.[9,11,14] The proposed determination provided a higher rise in potential near the end-point (about 200 mV/0.05 ml of the titrant) than the potentiometric titration with mercury(II) ions.[8]

*Coulometric determination*

The use of potentiometric end-point detection in coulometric titration of lower amounts of 2-thiobarbituric acid has turned out to be impossible, owing to the slow settling of the platinum indicator electrode potential at low concentrations of the tested compound. The use of the biamperometric indicator system made it possible to obtain correct results in the coulometric determination of 2-thiobarbituric acid within the range of 0.1–20 $\mu$mol. The results of coulometric determination are given in Table 1. The coulometric method presented is characterized by a high accuracy and short analysis time. The reaction solution containing potassium iodide and sodium hydroxide is stable with time; unlike the acidic solutions, the alkaline one shows no oxidation of iodide ions with oxygen.

*Titration of a derivative of 2-thiobarbituric acid*

It was also examined whether potentiometric titration with iodine in the alkaline medium could be used for the determination of sodium salt of 5-ethyl-5′-(1-methylbutyl)-2-thiobarbituric acid (thiopental).



thiopental

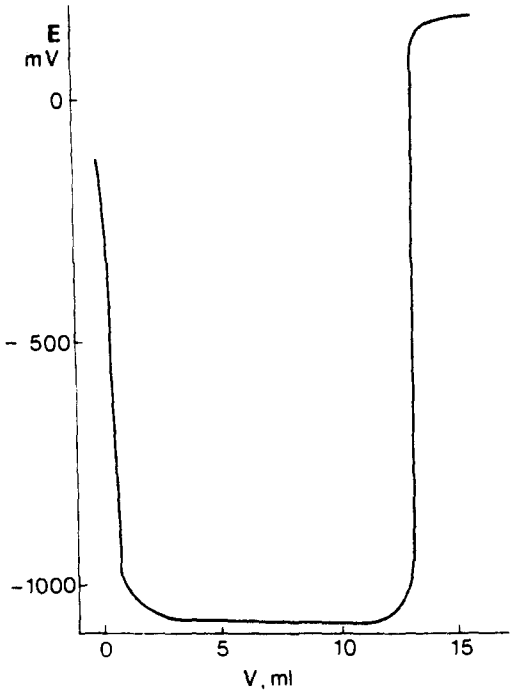


Fig. 2. Curve of potentiometric titration of 0.05 g of thiopental with $10^{-1}M$ iodine solution.

Again, in this case, the reaction rate increased with an increase in concentration of sodium hydroxide. To provide sufficient reaction rate employing the potentiometric titration, the concentration of sodium hydroxide had to be at least $5M$. Titrations of this compound were carried out at 5 and $10M$ NaOH and the identical titration curves obtained are shown in Fig. 2.

The shape of the potentiometric titration curve is noteworthy. A small amount of iodine (oxidizer) added brings about a strong potential drop in the initial part of the curve. The end-point of titration corresponding to the maximum potential increase indicates that the number of electrons transferred in the reaction of 1 mol thiopental is equal to 7.43. The titration results are reproducible, but the titration runs more slowly than that of 2-thiobarbituric acid, owing to the lower reaction rate.

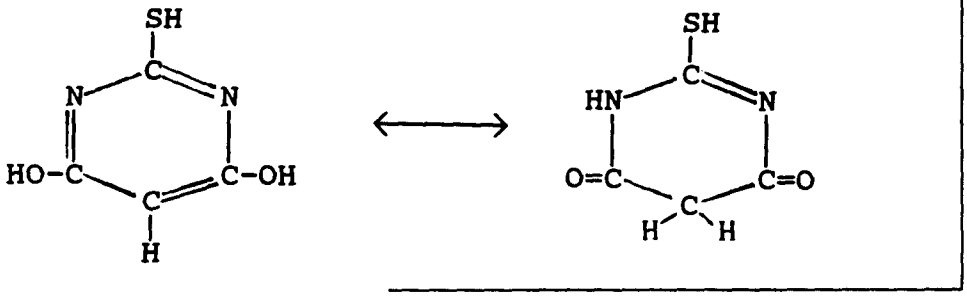
When excess iodine is added to the thiopental solution and the unreacted hypoiodite is back-titrated after 15 min,[9,33] the process proceeds according to the 8-electron apparent stoichiometry:

$$RS^- + 4I_2 + 10OH^- \rightarrow RO^- + SO_4^{2-} + 8I^- + 5H_2O.$$

The coulometric determination of thiopental failed owing to the iodine reaction being too slow. It is interesting to note that 2-thiobarbituric acid behaves differently from thiopental during the titration with iodine in a very strong alkaline medium.

In the potentiometric titration of 2-thiobarbituric acid in 5 and 10*M* NaOH the curve shape (Fig. 1) and the number of electrons transferred in the reaction of 1 mol of compound ($z = 6$) were unchanged.

The only difference in the structure of these compounds is the presence of two alkyl substituents at the fifth carbon atom in the thiopental molecule. This makes the formation of tautomeric forms impossible, unlike in the case of 2-thiobarbituric acid,



and hence the titration curves are completely different.

## CONCLUSIONS

Comparing the proposed determination of 2-thiobarbituric acid with the methods previously reported[7–32] one may conclude that it is characterized by a short analysis time, a simple procedure, commonly available reagents and determination over a wide order of magnitude (0.1–400 μmol in a sample). The accuracy of coulometric determinations is higher than reported previously.

(*Received* 15 *August* 1994. *Revised* 16 *November* 1994. *Accepted* 16 *November* 1994)

**Summary**—The spectrophotometric determination of pyridine and pyridine derivatives by means of the König reaction was studied in micellar media of sodium dodecyl sulphate (SDS), *N*-cetylpyridinium chloride and Triton X-100. The sensitivity was largely increased in SDS micellar medium. The attack of the pyridine ring with cyanogen bromide to produce a glutaconic aldehyde was not affected by the presence of SDS, but the yield of the coupling reaction with an arylamine to produce a polymethine dye was largely increased. In the SDS micellar medium, aniline was superior to other coupling reagents. The limits of detection (LODs) were $6 \times 10^{-7}$, $1 \times 10^{-6}$ and $5 \times 10^{-7}M$ for pyridine, pyrrol-ylmethylpyridine and nicotinic acid, respectively, and the reproducibility for $2 \times 10^{-5}M$ solutions was *ca.* 2%. In the absence of SDS, the LODs were $3 \times 10^{-6}$, $3 \times 10^{-6}$ and $9 \times 10^{-6}M$, respectively, and the reproducibility was *ca.* 3.5%. Application was made to the determination of nicotinic acid in pharmaceuticals.

The spectrophotometric determination of pyridine and pyridine derivatives can be performed previous derivatization with the König reaction[1,2] (Fig. 1). Pyridine derivatives with a hydrogen in at least one of the positions adjacent to the heterocyclic nitrogen react with cyanogen bromide to produce a derivative of glutaconic aldehyde. The stability of this compound is frequently poor, but a stable polymethine dye can be obtained by coupling with an arylamine or a compound containing an active methylene group. Polymethine dyes absorb in the 450–550 nm wavelength range. Coupling agents differ in their toxicity, and in the sensitivity and stability of the final product. Aniline,[3] benzidine,[4] *o*-toluidine,[5] barbituric acid, sulphanilic acid,[6] *p*-phenylenediamine,[7] anthranilic acid,[8] 4,4′-diaminostilbene-2,2′-disulphonic acid,[9] 2,2-dimethyl-1,3-dioxane-4,6-dione,[10] 4-aminosalicylic acid,[11] and 6-amino-1-naphthol-3-sulphonic acid[12] have been recommended.

In the last five years, an extensive investigation has been carried out in our laboratory on the improvement of analytical procedures through the use of micellar media. In the presence of surfactants, equilibrium, kinetic and spectral properties can be modified. Some favourable effects are the inhibition of undesirable reactions, such as hydrolysis and photolysis, stabilization of reaction intermediates, co-solubilization of non-polar and polar derivatization reagents, products and samples, and increase in reaction rates by means of micellar catalysis.[13] In some cases, use is made of the modification of a single parameter to improve an analytical procedure, but most frequently, the simultaneous alteration of various physico-chemical properties of the reagents, intermediates and products, is involved. Spectrophotometric procedures for the determination of organic compounds that have been improved by the use of micellar media are the coupling of the diazotized arylamines with *N*-(1-naphthyl)ethylenediamine,[14] the coupling of phenols with diazotized 2,4,6-trimethylaniline,[15] 4-aminoantipyrine, 2,6-dihalochinone chlorimides and 1-nitroso-2-naphthol,[16] the coupling of pyrroles with 4-(dimethylamino)benzaldehyde,[17] the nitrosation of *N*,*N*-diethylaniline,[18] the oxidation of pyridoxal in the presence of cyanide,[19]

and the reduction of 5,5′-dithiobis-(2-nitrobenzoic acid) with sulphur dioxide.[20]

Nicotinic acid is one of the many bioactive substances that can be determined by means of the König reaction. Nicotinic acid or niacin is a vitamin found in minute amounts in liver, yeast, milk, adrenal glands, white meat, legumes, whole cereals and corn. Poor dietary habits produce pellagra and may be corrected by administration of multivitamin preparations containing nicotinic acid. Increased requirements of this vitamin may be associated with hyperthyroidism, diabetes mellitus, cirrhosis, pregnancy, and lactation.

In this work, the effects of the presence of surfactants on the spectrophotometric analytical procedure for the determination of pyridine derivatives, by using the König reaction are studied. Aniline is demonstrated to be superior to other coupling reagents when used in sodium dodecyl sulphate (SDS) micellar solutions. Application is made to the determination of nicotinic acid in pharmaceuticals.

## EXPERIMENTAL

### *Reagents and apparatus*

The substrates were pyridine, nicotinic acid and pyrrol-ylmethylpyridine (Janssen Chimica, New Brunswick, NJ, U.S.A.). Cyanogen bromide (Fluka, Buchs, Switzerland) was used as the hydrolysis reagent. The coupling reagents were: *p*-aminophenol, aniline, *p*-phenylenediamine, *p*-toluidine (Panreac, Barcelona, Spain), sulphanilamide (Sigma, St Louis, MO, U.S.A.), *p*-aminobenzoic acid, sulphanilic acid (Fluka), and *p*-aminoacetophenone (Janssen Chimica). The surfactants were: sodium dodecyl sulphate (Merck, Darmstadt, Germany), *N*-cetylpyridinium chloride (Scharlau, Barcelona) and Triton X-100 (Panreac). Distilled deionized water (Barnstead, Sybron, Boston, MA, U.S.A.) was used throughout. A spectrophotometer UV-Vis-nir Lambda 19 (Perkin Elmer, Norwalk, CT, U.S.A.), and a Crison model micropH 2001 potentiometer (Barcelona, Spain), provided with a combined Ag/AgCl/glass electrode, were used.

### *Procedure*

The derivatives were prepared by mixing in a 25-ml volumetric flask, 5 ml of 0.2*M* acetic acid–sodium acetate buffer (pH 4.5), 5 ml of 0.5*M* SDS or 5 ml of water, 0–5 ml of pyridine, pyrrol-ylmethylpyridine or nicotinic acid, and 5 ml of 0.25*M* BrCN. After 10 min (time required to complete the hydrolysis of the substrate), 2 ml of 0.6*M* aniline was added for pyridine and pyrrol-ylmethylpyridine, and 0.4 ml for nicotinic acid. The mixture was allowed to react for 15 min, and the volume was completed up to the mark to measure the absorbance.

## RESULTS AND DISCUSSION

### *Optimization of the analytical procedure*

The optimization studies were performed using three model compounds: pyridine, pyrrol-ylmethylpyridine and nicotinic acid. Hydrolysis of these compounds to the corresponding glutaconic aldehyde derivatives, and the coupling of the derivatives with aniline to yield the polymethine dyes was studied spectrophotometrically in the presence and absence of SDS at room temperature. The absorbance of a blank solution prepared in the absence of the model compounds was also measured, and was checked to be always negligible. The wavelength of maximum absorption of the dyes changed in the different media studied (Table 1).

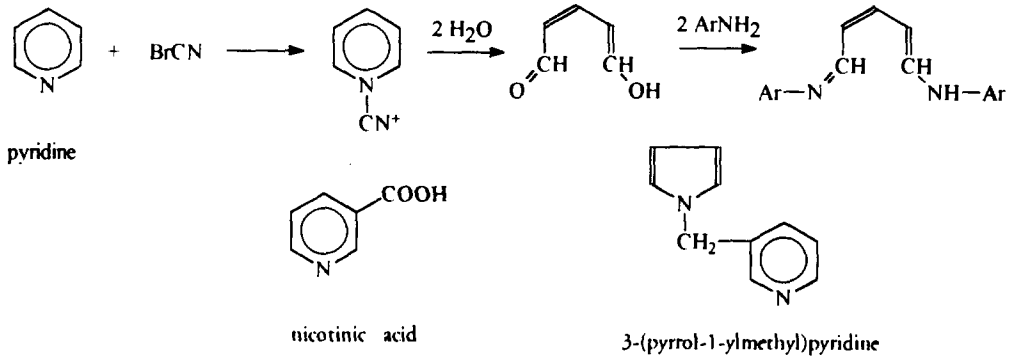

Fig. 1. Scheme of reaction for the hydrolysis of pyridine derivatives with cyanogen bromide, and coupling with an arylamine.

Table 1. Wavelengths of maximum absorption (nm) for the aniline polymethine dyes in the presence of surfactants*

| Compound | Non-micellar | Sodium dodecyl sulphate | *N*-Cetylpyridinium chloride | Triton X-100 |
|---|---|---|---|---|
| Pyridine | 480 | 485 | 480 | 490 |
| Pyrrol-ylmethylpyridine | 440 | 485 | 465 | 480 |
| Nicotinic acid | 430 | 440 | 460 | 470 |

*Wavelengths measured at pH 4.5 and for 0.1*M* surfactant solutions.

The influence of the time of hydrolysis and time of coupling on the final absorbance of the polymethine dyes was studied. First, the reaction time between the addition of BrCN and the addition of aniline was varied. Figure 2a shows the results obtained for nicotinic acid. The hydrolysis reaction was completed after 5 min, the absorbance being constant at least in the 5–45 min range in both SDS micellar and non-micellar media. The reaction rate was similar for both media, however, an important enhancement in the sensitivity of the reaction was observed in the micellar medium. Similar results were obtained for pyridine and pyrrol-ylmethylpyridine in the micellar medium.

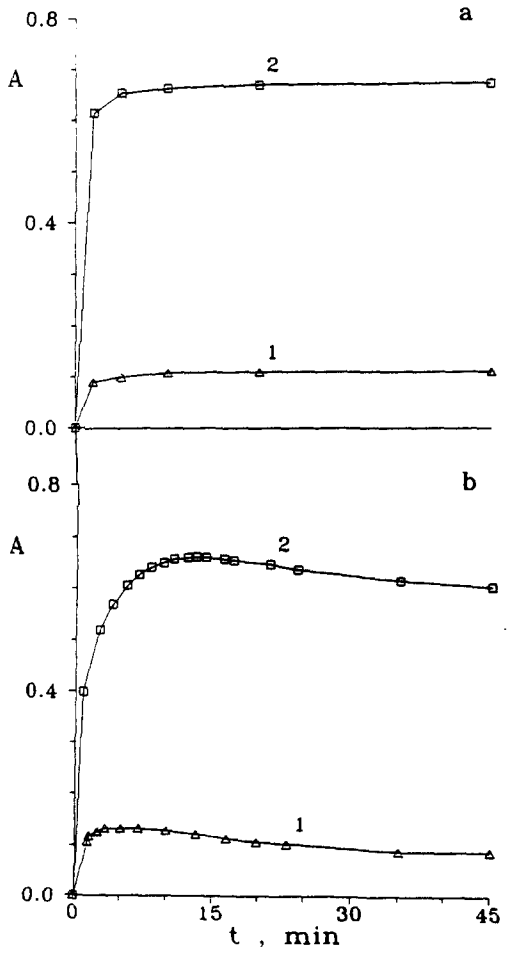

Fig. 2. Influence of the time of hydrolysis (a) and time of coupling (b) for $2 \times 10^{-5}M$ nicotinic acid in: (1) a non-micellar solution, and (2) a 0.05*M* SDS micellar solution.

Secondly, the absorbance was monitored for some time after the addition of aniline. For the three model compounds in an SDS micellar medium, a coupling time of 15 min was required, however, the derivative was not stable, and a slow decomposition began after a flat maximum (Fig. 2b). In the non-micellar solution, the derivatives were formed in less than 3 min, but they also showed a slow decomposition. The derivatives of pyrrol-ylmethylpyridine and nicotinic acid decomposed more rapidly in the absence of surfactant than in the micellar medium.

The concentration of BrCN was optimized by adding different volumes of 1*M* BrCN, to cover the 0–0.25*M* concentration range. In both SDS micellar and non-micellar media, and for the three model compounds, maximum absorbance was observed for concentrations of BrCN close to 0.05*M*. This concentration was used in the next series of experiments.

The aniline concentration was optimized within the 0–0.3*M* range. In the micellar medium, an increase in the absorbance of the pyridine dye was observed at increasing concentrations of aniline up to a concentration of 0.05*M*, the signal being almost constant within the 0.05–0.3*M* aniline concentration range. In the non-micellar medium, the absorbance of the pyridine dye increased up to 0.1*M* aniline, and was constant in the 0.1–0.3*M* range. For nicotinic acid, the absorbance was constant in the 0.005–0.02 and 0.01–0.03*M* aniline concentration ranges in the micellar and non-micellar media, respectively, and decreased slowly at higher aniline concentrations. A 0.05*M* aniline concentration was selected as adequate for the determination of pyridine and the pyridine derivatives, and was used in the recommended procedure.

*Influence of pH*

Both the hydrolysis and coupling reactions can be influenced by the pH of the solutions.

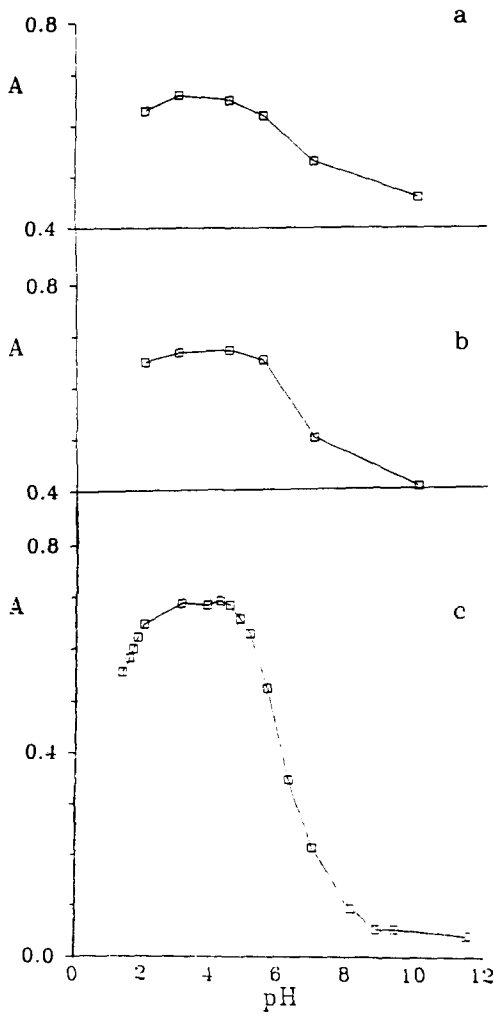

Fig. 3. Dependence of the absorbance of the polymethine dye of nicotinic acid on (a) the pH of the hydrolysis reaction, and (b) the pH of the coupling reaction (for a and b, the pH of measurement was 4.5). (c) Titration of the polymethine dye of nicotinic acid formed at pH 4.5, with NaOH (the absorbance was corrected for dilution). The concentrations of nicotinic acid and SDS were always $2 \times 10^{-5}M$ and $0.05M$ SDS, respectively.

First, the optimum pH for hydrolysis with BrCN was studied in a $0.1M$ SDS medium, by adding to the nicotinic acid solution 5 ml of a universal buffer ($0.1M$ acetic acid–$0.1M$ $NaHCO_3$–$0.1M$ $Na_2B_4O_7$), and HCl or NaOH to achieve a constant pH during hydrolysis in the 2–10 pH range. After 15 min from the addition of BrCN, the pH was adjusted to 4.5, aniline was added, and 10 min later the absorbance was measured. Figure 3a shows that the optimum pH range for hydrolysis was 3–5.

A similar study was performed for the coupling reaction. Nicotinic acid was hydrolyzed at pH 4.5, 5 ml of universal buffer was added, and the pH was adjusted to several values within the 2–10 pH range with HCl or NaOH. Aniline was added, after 15 min the pH of the solution was fixed to 4.5 and the absorbance was measured. The dependence of the absorbance with pH was similar to that observed for the hydrolysis reaction (Fig. 3b).

The polymethine dyes formed by coupling with aniline exhibited a decrease of the molar absorptivity in the pH 4.5–9 range, which was attributed to the deprotonation of the secondary arylamino group, For the nicotinic acid dye this equilibrium coincided with the deprotonation of the carboxylic group. The protonation equilibria were observed by titration with NaOH, by using simultaneous potentiometric and spectrophotometric monitoring. First, after 15 min of addition of aniline to the glutaconic aldehyde formed at pH 4.5, a small volume of HCl was added to lower the pH of the polymethine dye solution to 1. Then, the solution of the dye was titrated in the presence of the universal buffer with $0.25M$ NaOH, and the absorbance was measured at the wavelength of maximum absorbance (see Table 1). Figure 3c shows the absorbance–pH titration curve for the nicotinic acid dye, obtained in the SDS micellar medium. It may be observed that the absorbance was constant in the pH 3–4.5 range, and decreased abruptly outside this range. In the recommended procedure, an acetic acid/acetate buffer was used to regulate the final pH to 4–4.5.

In an acidic SDS micellar medium, the spectrum of the polymethine dye of nicotinic acid showed a maximum at 440 nm, which shifted to longer wavelengths at increasing pH values. Also, in a basic solution a new maximum appeared at 350 nm. The pyridine dye showed a wavelength of maximum absorption at 485 nm in acidic and weakly basic solutions, and a new maximum at 405 nm in a more basic medium. The pyrrol-ylmethylpyridine dye showed a maximum at 485 nm, which shifted to shorter wavelengths at increasing pH values.

For the polymethine dye of pyridine, the protonation constant of the arylamino group was evaluated according to García *et al.*,[21] being $\log K = 9.7 \pm 0.3$ and $7.6 \pm 0.2$ in a $0.1M$ SDS micellar and non-micellar media, respectively. The earlier protonation of the dye in the micellar solution indicated that the protonated cationic species was more strongly associated to the anionic SDS micelles than the basic non-ionic species. In the micellar medium, the protonation constants of the arylamino group of the polymethine dyes of nicotinic acid and pyrrol-

ylmethylpyridine were $\log K = 5.8 \pm 0.2$, and $7.8 \pm 0.1$, respectively. The protonation constant of the nicotinic acid dye should be slightly biased due to the almost simultaneous protonation of the carboxylate group. These constants could not be obtained in the absence of surfactant due to precipitation.

Usually, protonation of alkyl-arylamino groups takes place around pH 5–6. The larger values obtained both in the micellar and non-micellar media can be explained as owing to the large conjugated system of the polymethine dye molecule, where the positive charge of the acidic proton can be easily accepted and stabilized.

*Effect of the surfactant character*

A comparative study of the hydrolysis and coupling reactions, and the enhancement of the absorbance signal of the polymethine dyes was performed in micellar solutions of an anionic (SDS), cationic (*N*-cetylpyridinium chloride, NCPC) and non-ionic surfactant (Triton X-100). The experimental conditions (pH, BrCN and aniline concentrations) were those optimized above, and the concentration of the surfactants was always above the critical micellar concentration (cmc).

The influence of the concentration of the surfactant on the absorbance of the final product was first studied. The results for nicotinic acid can be observed in Fig. 4. The larger enhancement of the signal corresponded to SDS solutions. For this surfactant, a large and constant absorbance was achieved just above the cmc ($8 \times 10^{-3} M$). At the pH of the reaction, both the aniline and the polymethine dyes were protonated, and thus they were strongly bound to the anionic SDS micelles. On the other hand, at pH 4.5 the glutaconic aldehyde derivatives produced by pyridine and pyrrol-ylmethylpyridine are non-ionic, and should be associated to the SDS micelles by hydrophobic interactions. At this pH, the glutaconic aldehyde of nicotinic acid could be anionic, however, protonation of the carboxylate group of this derivative should take place at a higher pH in the SDS micellar medium than in non-micellar medium. The sensitivity enhancement produced by the SDS micelles could be explained in terms of an increase of both the reaction yield and the molar absorptivity of the polymethine dye. The experiments below were addressed to identify the main cause of the enhancement in sensitivity.

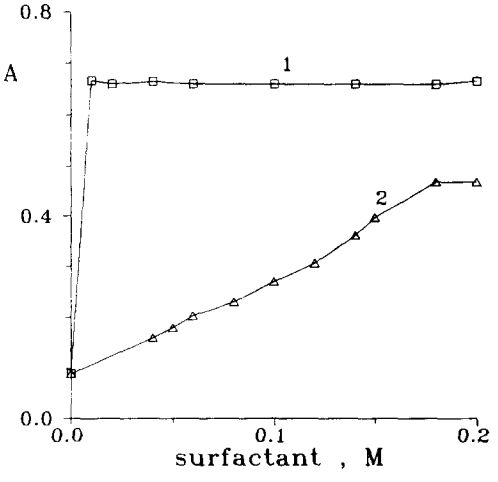

Fig. 4. Influence of the surfactant concentration on the absorbance of the polymethine dye of nicotinic acid for (1) SDS, and (2) NCPC.

For NCPC, the absorbance increased slowly with the concentration of surfactant. At the pH of the reaction, both the aniline and the polymethine dyes should be rejected by the cationic NCPC micelles. Thus, the increase of either the reaction yield or the molar absorptivity of the dye when the NCPC concentration increased was an unexpected result. This suggested that the sensitivity increase was mainly due to the association of the non-ionic glutaconic aldehyde to the surfactant assemblies, which is consistent with the hypothesis of the modification of the reaction pathway. Owing to the hydrophobic interactions, and independently from the charge of the surfactant, the association of the non-ionic form of the glutaconic aldehyde should increase when the concentration of the surfactant increases. It was checked that the polymethine dye of nicotinic acid was formed rapidly in the NCPC micellar solution, and the stability during the first 30 min was similar to that observed with SDS. Finally, a precipitate appeared in Triton X-100 solutions for a concentration of the surfactant larger than $0.02 M$, and no enhancement in the absorbance was observed for lower concentrations.

A series of experiments were performed to investigate the effect of the presence of SDS and NCPC on the hydrolysis and coupling reactions. The study was performed with nicotinic acid, by adding the surfactant at several points of the procedure: (1) before the addition of BrCN, to perform the hydrolysis and coupling reactions in the presence of the surfactant; (2) before the addition of aniline, thus only the coupling reaction occurred in the presence of the surfactant; (3) 10 min after the addition of aniline, to

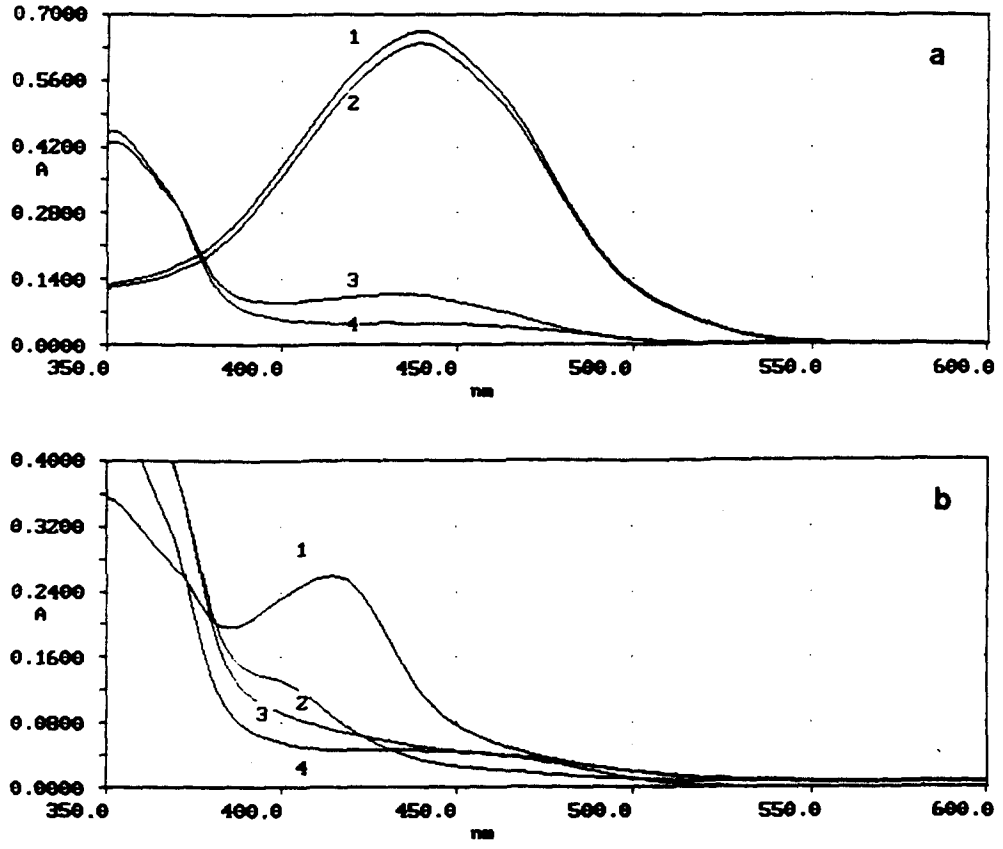

Fig. 5. Modification of the spectrum of the polymethine dye of $2 \times 10^{-5}M$ nicotinic acid in a micellar medium of (a) $0.1M$ SDS, and (b) $0.1M$ NCPC, when the surfactant was added (1) before hydrolysis, (2) before coupling, (3) before the measurement of the absorbance, and (4) no surfactant added.

observe the effect of the surfactant on the absorbance of the polymethine dye formed in a non-micellar medium; (4) the whole experiment was performed in the absence of surfactant.

The effect of the presence of the surfactant can be found out by observing the spectra of the dyes (Fig. 5). The similarity of the spectra obtained with procedures 1 and 2, when SDS was used, indicated that the hydrolysis reaction was not affected by the presence of the anionic surfactant (Fig. 5a). On the other hand, the comparison, in the same figure, of the spectra obtained with procedures 3 and 4 indicated that the absorbance of the polymethine dye formed in a non-micellar medium was only slightly enhanced in the presence of SDS. Therefore, most of the enhancement in the absorbance was produced by an increase in the reaction yield. This enhancement occurred when the surfactant was added before the hydrolysis of the pyridine derivative and also when it was added before the coupling reaction. Once finished the coupling reaction, the addition of the surfactant scarcely affected the absorbance of the solutions. Since no increase in the absorbance was produced by addition of SDS after the addition of aniline, a modification of the reaction pathway rather than an equilibrium shift should take place. Thus, the coupling reaction is in fact a competitive process in which the glutaconic aldehyde forms the polymethine dye and other less coloured or even colourless products.

The behaviour was completely different for NCPC, where the enhancement of the absorbance was mainly achieved when the surfactant was added before the hydrolysis (Fig. 5b). This adds a new evidence about the association of the glutaconic aldehyde derivative to the NCPC micelles.

*Use of other coupling reagents*

A study was performed on the influence of the nature of the coupling reagent on the formation of the polymethine dye in the SDS micellar medium. First, only two arylamines were taken, *i.e.* sulphanilamide and *p*-toluidine, more and less polar than aniline, respectively, to study the

time required for coupling. The results obtained in an SDS micellar and in non-micellar medium with these reagents were compared with those obtained with aniline. The model compound was pyridine.

The *p*-toluidine dye was sparingly soluble in a non-micellar medium, thus for this reagent, the analytical procedure required the presence of SDS. In the micellar medium, the coupling reaction with *p*-toluidine was very slow, being only completed after 40 min. When sulphanilamide was used in a non-micellar solution, 30 min was required to stabilize the absorbance, whereas in the presence of SDS the signal was constant after 20 min. Finally, when aniline was the coupling reagent, 5 and 20 min was required to achieve a constant absorbance, in the absence and presence of SDS, respectively. For the three arylamines, the final product was more stable in the micellar medium.

Secondly, the evaluation of the absorbance enhancement obtained with other arylamines was performed by measuring the signal 45 min after the addition of the coupling agent. The reagents studied were: *p*-aminoacetophenone, *p*-aminobenzoic acid, *p*-aminophenol, aniline, *p*-phenylenediamine, sulphanilamide, sulphanilic acid, and *p*-toluidine. Increasing volumes of the coupling agents were added to the glutaconic aldehyde solution to make a final concentration in the 0–0.3$M$ range.

The results are shown in Table 2. All the reagents gave the coupling reaction in the micellar medium. The micellar medium allowed the use of coupling reagents that formed sparingly soluble dyes in the absence of surfactant (*p*-toluidine and *p*-aminophenol). Most of the reagents studied gave maximum absorbance in the 0.05–0.1$M$ reagent concentration range. It should be remarked that only the use of aniline allowed a wide concentration range of the coupling reagent, giving the same absorbance signal (0.05–0.3$M$). In other cases, the sensitivity depended largely on the concentration of the coupling reagent. For some reagents, a constant absorbance was achieved above a given concentration of the reagent, but for other reagents, the absorbance increased continuously with their concentration (*p*-aminoacetophenone, *p*-aminophenol and sulphanilamide). Also, for some reagents, the polymethine dye or the reagent itself precipitated (sulphanilic acid and sulphanilamide). The sensitivity enhancement was large in all cases (usually 1.7- to 3.7-fold), but it was especially high for the *p*-phenylenediamine dye (13-fold), which could be a result of the very strong association of this reagent to the SDS micelles by both electrostatic and hydrophobic interactions. However, the molar absorptivity of the *p*-phenylenediamine dye in the SDS solution was similar to the aniline dye, and the reagent concentration range was more critical.

In the past, several reagents were proposed to substitute the use of aniline in the König reaction due to its low sensitivity. The results given

Table 2. Influence of different coupling reagents on the formation of polymethine dyes of pyridine (the concentration of pyridine was $2 \times 10^{-5}M$)

| Coupling reagent | Medium | Optimum concentration range ($M$) | Molar absorptivity ($M^{-1}\,cm^{-1}$) (reagent concentration, $M$) |

*Recovery with respect to the contents declared by the manufacturer.

in this work indicated, however, that in an SDS micellar medium aniline was perhaps the best coupling reagent of those studied, because of the large absorbance enhancements produced, which gave high molar absorptivities. Also, the coupling time (15–20 min) with aniline was not excessive, the optimum reagent concentration range was wide, and the reaction was possible for different substrates.

*Analytical figures*

The recommended procedure with aniline was used to obtain the calibration plots for pyridine, pyrrol-ylmethylpyridine and nicotinic acid. The calibration straight lines fitted by least-squares gave an intercept at 0.002–0.003. The molar absorptivities were $3.7 \times 10^4$, $2.35 \times 10^4$ and $4.25 \times 10^4 M^{-1}$ cm$^{-1}$, in a 0.1$M$ SDS medium, and $1.0 \times 10^4$, $1.0 \times 10^4$ and $3.0 \times 10^3 M^{-1}$ cm$^{-1}$, in the non-micellar solution, for pyridine, pyrrol-ylmethylpyridine and nicotinic acid, respectively.

The limits of detection (LODs) in the SDS micellar medium were obtained by measuring the absorbance of the blank solution in the absence of the analyte (16 replicates, 3s criterion), being $6 \times 10^{-7} M$, $1 \times 10^{-6} M$ and $5 \times 10^{-7} M$ for pyridine, pyrrol-ylmethylpyridine and nicotinic acid, respectively. The reproducibility was obtained from the measurement of the absorbance of 16 aliquots of the analytes, which were hydrolyzed and coupled separately. The coefficients of variation were 2.1% for $2 \times 10^{-5} M$ pyridine, 2.0% for $2 \times 10^{-5} M$ pyrrol-ylmethylpyridine, and 1.7% for $1.5 \times 10^{-5} M$ nicotinic acid. In the absence of SDS, the LODs were $3 \times 10^{-6} M$, $3 \times 10^{-6} M$ and $9 \times 10^{-6} M$, respectively, and the reproducibility *ca.* 3.5%.

*Evaluation of nicotinic acid in formulations*

The optimized procedure was applied to the determination of nicotinic acid in several pharmaceutical preparations. For the analyses, 10 tablets or pills were weighted and pulverized, a portion was taken, weighted, dissolved in 5 ml of ethanol, and diluted with 0.5$M$ SDS. In addition, the contents of 10 capsules were homogenized before a portion was taken, following the same procedure. The results are given in Table 3. The recoveries were always close to 100%, with coefficients of variation of 2.0–4.0%.

(*Received* 28 *June* 1994. *Revised* 13 *October* 1994. *Accepted* 16 *November* 1994)

**Summary**—S9788 is a novel triazinodiaminopiperidine derivative which reverses the multidrug resistance of tumour cells to anticancer drugs. In this study, a new HPLC method was developed to determine this compound in P388 leukaemia cells. The influence of various parameters (composition and pH of the mobile phase, nature of the column) on the separation of S9788 and derivatives was investigated. Using a microsphere C18 column and the optimal mobile phase (acetonitrile–0.4*M* phosphate buffer containing 0.2% triethylamine, 40:60 v/v, pH 6.5) it was possible to separate S9788 and seven hypothetical metabolites and derivatives in 15 min. The limits of detection and quantification of S9788 are 75 and 250 pg, respectively. This MDR modulator was extracted from biological media by a rapid two-step procedure which removed proteins before direct injection of the sample. Absolute recoveries ranged from 90 to 100% with a mean RSD (%) lower than 5.

The resistance of tumours to anticancer drugs, whether innate or acquired, is a crucial problem in the treatment of cancer diseases. Multidrug resistance (MDR) is a pleiotropic type of resistance which mainly affects anthracyclines, vinca-alkaloids and epipodophyllotoxines[1–4] and may be particularly important. The most important type of MDR is known to be associated with the overexpression of a membrane glycoprotein, Pgp 170. In tumours, Pgp encoded by the mdr-1 gene,[5] has been identified as an energy-transducing transport pump which appears to confer resistance by inducing the efflux of cytotoxic drugs, thereby diminishing their intracellular concentrations.[6] A wide variety of compounds have now been shown to reverse MDR *in vitro*.[7] Among these molecules only verapamil has been extensively tested in clinical studies; however, serious side effects such as hypotension and arrhythmia were observed.[8] S9788, a novel triazinodiaminopiperidine derivative which does not belong to any of the classes of agents known to reverse MDR, was able to increase the accumulation and retention of cytotoxic drugs in rodent and human tumour cell lines displaying the MDR phenotype.[9–13] This drug is currently under clinical investigation as an MDR modulator in cancer diseases.[9–13] However, numerous problems of disposition remain to be solved to understand its mechanism of action.[14] Therefore, the aim of this paper is to develop a selective high performance-liquid chromatography (HPLC)[15] assay suitable to study the intracellular drug accumulation *in vitro* of S9788 and five hypothetical metabolites. The optimisation of the isocratic elution conditions permitted the separation, within 15 min, of compounds which had very different partition coefficients. The protocol was conducted according to the stability and characteristics of the C18 or C8 reversed phase columns. We describe here a rapid method to extract S9788 from cancer cells and discuss for the first time the simultaneous HPLC separation of this drug in the presence of five potential metabolites and two structurally related derivatives.

## EXPERIMENTAL

Chemicals: S9788 (Fig. 1) was kindly provided by the Institute of International Research Servier (Courbevoie, France). Its hypothetical metabolites: S16636, S16637, S16638, S16639 and S16640 (Fig. 1) and a derivative S15061 tested as an internal standard (Fig. 2a) were kindly offered by Servier Research and Development Ltd (Fulmer, U.K.). Hexamethylmelamine (HMM) was a generous gift from the National Cancer Institute (Bethesda, MD, U.S.A.) (Fig. 2b).

### *Reagents and instrumentation*

All reagents were of analytical grade (Merck; Overijse, Belgium), except acetonitrile (Lab-Scan Analytical Sciences, Ireland, far UV grade). The HPLC system consisted of: a Rheodyne 71125 injector (Analysis, Belgium) equipped with a 100 $\mu$l injector loop, a Gilson 307 solvent delivery system (Analysis, Belgium) operated at a flow rate of 1.00 ml/min, a precolumn (10 × 4.6 mm) packed with reverse-phase ($R_2$) C18 (Chrompack, Belgium) and a column (100 × 4.6 mm) packed either with 3 $\mu$m reverse phase microsphere C18 or 5 $\mu$m chromspher C8 (Chrompack, Belgium).

Two detectors were used: a HP 1050 variable wavelength detector operated at 220 nm (Hewlett-Packard), linked to a Kipp and Zonen BD40 potentiometer recorder (Ankersmit, Belgium) and a photodiode array detector (Beckman Instruments: module 168 system gold and system gold chromatography software (ASW 2). After optimization of the method, the following mobile phase was chosen: 0.4*M* phosphate buffer containing 0.2% triethylamine and acetonitrile (60:40, v/v) on a C18 column. The pH of a 0.4*M* $KH_2PO_4$ solution was adjusted to 6 with 0.4*M* $K_2HPO_4$; the apparent pH of the mobile phase was 6.5. The flow rate was fixed at 1.00 ml/min, analyses were performed at ambient temperature and the injected volume was 50 $\mu$l.

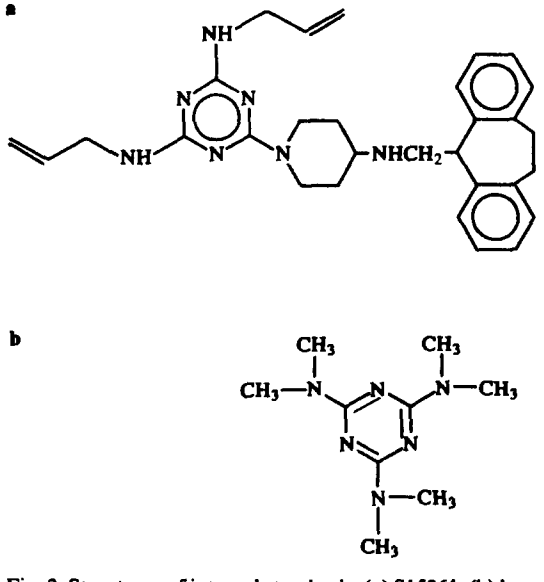

Fig. 2. Structures of internal standards. (a) S15061; (b) hexamethylmelamine (HMM).

### *Cell line and culture medium*

The P388 murine leukaemia cell line[16] was used to study the extraction procedure. These cells, obtained from the institute of Research Servier (Suresnes, France), were maintained in RPMI medium 1640 supplemented with 10% foetal calf serum, 2 m*M* L-glutamine (100 U/ml) 10 m*M* Hepes buffer (pH 7.4) (Gibco, Belgium), 20 $\mu$M $\beta$ mercapto-ethanol (Sigma, Belgium), penicillin (100 U/ml) and streptomycin (100 $\mu$g/ml).

### *Extraction of S9788, S15061 and HMM from P388 cells*

Before extraction, the cells were plated in 96 well microtiter plates (Nunc, Gibco, U.K.) (25,000 cells/well). The cells were then further incubated in a drug free medium (250 $\mu$l) for 24 hr at 37°C in humidified air containing 5% $CO_2$. The supernatant was then carefully drawn up and replaced by 100 $\mu$l of culture medium containing the investigated drug. After stirring for 30 sec, the cell suspension was transferred in a glass tube and the cells were disrupted and the proteins precipitated by adding of 0.4 ml acetonitrile. The tube was then stirred for 10 sec, left at 4°C for 10 min and centrifuged 10 min at 600 *g*. An aliquot (50 $\mu$l) of the supernatant was directly injected into the chromatograph. Low intracellular concentrations were determined by pooling cells from several wells.

## RESULTS AND DISCUSSION

The main goal of this work was to develop an HPLC method allowing the analysis of the new reversant drug S9788 in biological media and particularly in cancer cells. In order to identify the optimal separation conditions, the chromatographic behaviour of the analytes was studied as a function of pH and organic modifier concentration. The former was regulated with 0.025*M* phosphoric acid, 0.025*M* potassium dihydrogen and 0.025*M* monohydrogen phosphate. Four pH values (3.0, 4.0, 5.0, 6.0) were studied for each acetonitrile concentration (40, 50 and 60%) and column packing (C18, C8).

### *Influence of* $CH_3CN$ *concentration and pH*

*C18 column.* Table 1 shows that capacity factors were higher and that resolution and selectivity were better when the pH of the mobile phase was increased from 3 to 6. Investigations of buffers with pH above 6 were not conducted to insure an optimum stability of the column. On the other hand the trend showed that pH below 3 would decrease the resolution factor and increase the risk of hydrolysis of the bonded moiety. Furthermore, our data showed that at pH 6 the phosphate buffer system was mostly effective and the solutes were highly stable. Decreasing the acetonitrile concentration to 40% gave better selectivity and resolution at pH 5, the peak width was sharper at pH 6. The selectivity was

generally better when 50% acetonitrile were included into the mobile phase but 40% acetonitrile gave the highest capacity factor and the best resolution of analytes at all pHs. Our results showed that analysis with higher or lower concentrations of $CH_3CN$ would give either bad resolution, or unsatisfactory $k'$. For this reason we did not explore other $CH_3CN$ concentrations. To maintain easy and highly reproductible analysis conditions suitable for the determination of numerous samples, gradient elution was not investigated in this study.

*C8 column.* A complex behaviour was observed during the separation of these drugs on a C8 column. Generally, capacity factors increased as the pH increased but this feature was not systematically observed. No direct correlation, between selectivity and resolution on one hand and pH on the other was found. Capacity factors increased when the concentration of acetonitrile in the mobile phase was lower. Resolution and selectivity were generally poor when the concentration of the organic modifier decreased. These effects were particularly observed when the pH was raised from 3 to 6. Table 1, clearly indicates that an acceptable separation of S9788 and S15061 was reached with a C18 column and a mobile phase constituted of 40% of acetonitrile and 60% of 0.025*M* phosphate buffer containing 0.2% triethylamine. The C18 column was selected for further studies.

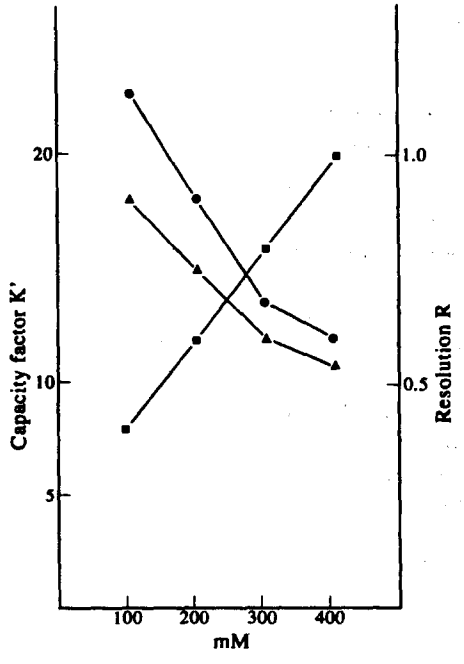

Fig. 3. Effect of phosphate buffer concentration on the resolution $R_s$ (■) and the capacity factors $k'$ of derivatives S9788 (▲) and S15061 (●).

*Tailing suppression*

Triethylamine significantly diminished the tailing of peaks whereas THF had no effect. In the range 0.05–0.2% in the mobile phase, triethylamine did not modify the retention

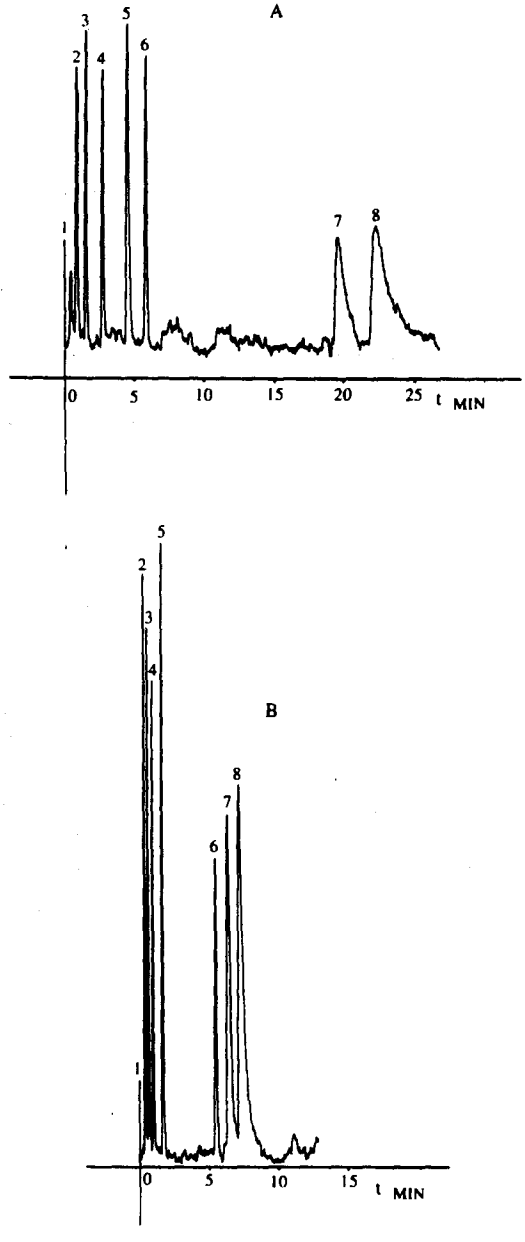

Fig. 4. Influence of buffer concentration on chromatographic separation. Peaks: 1 = injection; 2 = S16636 (2.0 μg); 3 = S16640 (0.5 μg); 4 = S16637 (0.5 μg); 5 = S16638 (0.5 μg); 6 = HMM (0.3 μg injected); 7 = S9788 (1.6 μg injected); 8 = S15061 (1.5 μg injected). Buffer contraction in mobile phase (A) 25 m*M* phosphate; (B) 400 m*M* phosphate.

times. Choice of optimal conditions required a compromise between maximum resolution for the two analytes and capacity to separate five additional hypothetical metabolites. In order to conduct the optimisation, we selected a mobile phase buffered at pH 6 and containing 0.2% triethylamine. These conditions permitted us to increase the capacity factor without an appreciable degradation of performances ($\alpha = 1.2$ and $R_s = 1.1$).

*Buffer concentration*

The buffer concentration (C18 column) was varied from 0.025 to 0.4$M$ phosphate at pH 6 in the presence of 40% of acetonitrile. Figure 3 shows that lower values of $k'$ were observed when phosphate concentration was increased. The $k'$ values were decreased while the resolution factors were better. Moreover, sensitivity was increased twice (Fig. 3, Fig. 4a, b). The optimum buffer concentration was found to be the highest tested (400 m$M$). At this concentration, no problem of salt precipitation was encountered. The optimum buffer concentration was found to be the highest tested (400 m$M$). This concentration was the maximum admissible limit to prevent salt precipitation which occurred when higher phosphate concentrations were used. The results showed that it was more adequate to increase the phosphate concentration than the percentage of $CH_3CN$ in the mobile phase in order to obtain the highest Rs with the lowest $k'$. At 0.025$M$, the $k'$ were very high and the trend clearly indicated that lower concentration of buffer could not offer acceptable analysis conditions. As a result the final composition of the mobile phase was acetonitrile–0.4$M$ phosphate buffer containing 0.2% triethylamine 40:60 (v/v). To obtain good operatory conditions for this type of column, the flow rate was fixed at 1 ml/min which produced a pressure of approximately 130 bars.

Table 3. Analytical parameters of the investigated compounds standard curves, linearity range 5–6.5 × $10^5$ ng/ml

| Compounds | $\lambda_{nm\ max}$ | $\epsilon_{max}$ $10^6$ |
|---|---|---|
| S9788 | 204 | 0.79 |
| S15061 | 199 | 0.70 |
| HMM | 225 | 0.56 |
| S16636 | 203 | 0.74 |
| S16637 | 203 | 1.13 |
| S16638 | 203 | 1.25 |
| S16640 | 204 | 1.64 |

$\lambda$: Wavelength; $\varepsilon$: molar absorbance coefficient.

*Calibration curve limit of detection and limit quantification*

Each data-item of the calibration curves was the mean of three injections (solvent:mobile phase). Linear regression equation and correlation coefficients are collected in Table 2. All drugs showed a linear relationship between peak height and concentration, over a range of 5 ng/ml–650 $\mu$g/ml. The absolute limits of detection and quantification, calculated as three and 10 times the standard deviation of the baseline signal, respectively were at the picogram level (Table 3).

*UV study*

The detection wavelength was chosen following a UV spectral study of all derivatives dissolved in the chromatographic mobile phase. Even though the optimal wavelength of the derivatives was around 205 nm (Table 3)

Table 4. Intra- and inter-assay validation of the S9788 determination after extraction

a working wavelength of 220 nm was chosen in order to minimize unspecified absorbance.

### *Extraction of S9788, HMM and S15061 from cancer cells*

The good linear relationship in the calibration curves calculated after extraction of these three drugs from cancer cells ($r > 0.996$), as well as the excellent recovery results (Table 4) are likely owing to the simplicity of sample treatment prior to analysis. The procedure used for the sample preparation is virtually a dilution in a acetonitrile/water mixture. This provides maximum of accuracy while introducing minimum of artefacts during the preparation. Intra-day variability was assessed with six extraction procedures and the inter-assay reproducibility was determined by pooling the data of three days. As indicated by the RSD (%) values (Table 4), the precision of this method is reasonably good and can be used in a very large range of concentrations. Similar results were found for drugs S16636, S16637, S16638, S166639 and S16640. Specificity of the method was controlled by diode array analysis. The chromatographic behaviour and recovery results showed that HMM and S15061 are possible internal standards (IS) to quantify S9788 in cells. HMM has the advantage of a shorter retention time.

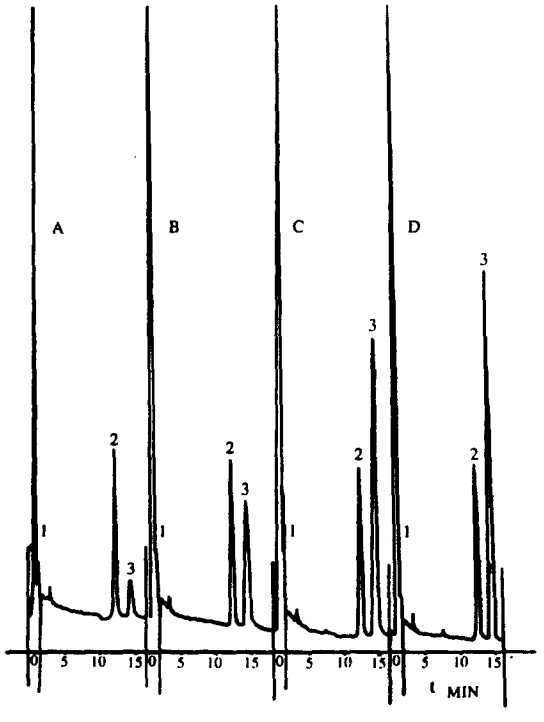

Fig. 5. Uptake of S9788 by P388 cells. Time (A) 1.00 min; (B) 10.00 min; (C) 60.00 min; (D) 120.00 min. Peaks: 1 = injection; 2 = HMM (IS); 3 = S9788. Incubated concentration of S9788:5 $\mu M$.

Preliminary *in vitro* transport studies of S9788, showed that the limit of quantification of the proposed method would allow us to determine the intracellular drug concentration vs. time curves from micro samples. This feature is essential in order to follow the transport kinetics in 96 well micro plates used for parallel cytotoxic tests. Figure 5 shows chromatograms obtained after incubation of S9788 with cells for 1, 10, 60 and 120 min. No metabolite was detected in P388 cells even after 120 min of incubation. Moreover, no interference peak was detected (HMM was used as IS). The results proved a (quick) penetration and accumulation of this new drug in the cells.

In conclusion, the HPLC system developed permitted the separation of S9788, five possible metabolites and two IS, which are molecules comprising a large range of lipophilicity and polarity, in less than 15 min. The selectivity and reproducibility of the method is good, allowing the successful determination of S9788 in P388 leukaemia cells.

*Acknowledgement*—Thanks are expressed to the KISANE foundation for its generous support which greatly contributed to the achievement of this study.

**Summary**—A flexible pervaporation module was developed and characterized. The spacers it uses allows the volume of the donor and/or acceptor to be altered as required. The performance of the module was tested as regards both dynamic behaviour and continuous pervaporation in terms of flow-rates, temperature, type of membrane, flow mode, *etc.* A method for the determination of ethanol in different types of wine was developed and applied to various samples in order to validate the proposed continuous separation approach.

Non-chromatographic continuous separation techniques make interesting choices for implementing various preliminary operations of the analytical process[1] in order to accommodate the raw sample to the measuring instrument.[2] Besides the well known advantages of separation techniques, they offer additional assets such as reduced human participation, easy on-line coupling with many instruments, diminished errors and hazards, markedly increased sample throughput and sparing used of sample and reagents. There are a variety of continuous sample treatment techniques that can be classified according to the type of interface involved in the mass transfer process, namely gas–liquid (*e.g.* gas-diffusion, continuous hydride generation, distillation, evaporation), liquid–liquid (*e.g.* dialysis, extraction) and solid–liquid (*e.g.* ion-exchange, precipitation, supercritical fluid extraction).

Indirectly improving the selectivity and sensitivity by interference removal and preconcentration, respectively, are no doubt the two primary targets of separation techniques in many analytical processes involving real samples. Occasionally, the complexity of such techniques entails using more than one separation approach in order to accomplish the desired sensitivity and/or selectivity levels. Coupling two identical or different continuous separation techniques can aid in dealing with complex samples via a synergistic effect. There are three general approaches to this type of coupling, namely (a) parallel; (b) serial; and (c) integrated.[3]

Separation membranes play a crucial role in continuous-flow systems, where they can be used for gas-diffusion or dialysis, as well as for separation of immiscible liquid phases, among others.[4] Continuous gas-diffusion techniques take advantage of the volatility of some analytes or their reaction products. They provide excellent means for enhancing selectivity and sensitivity.[2,5] A serial of parallel combination of gas-diffusion and another separation technique (*e.g.* dialysis,[6,7] ion-exchange[8,9]) in continuous flow systems clearly improves on the individual use of such techniques. On the other hand, continuous distillation and evaporation, both based on the differential volatility of the analyte and other sample components are scarcely used in continuous flow manifolds owing to the inherent difficulty to achieve reproducible results and the high complexity of the associated continuous separation methods.[2]

In this work we developed a relatively new approach to implementing non-chromatographic continuous separation techniques on the analytical scale based on the volatility of an analyte removed from a complex matrix. The proposed approach combines evaporation and

*Permanent address: Institute of Chemistry, State University of Campinas, SP, Brazil (C.P. 6154).

gas-diffusion through a gas-permeable membrane in the same unit. The phenomenon is called 'pervaporation' in order to emphasize the fact that the analyte or its reaction product (whichever the permeate is) undergoes a phase change from liquid to vapor before reaching the gas-diffusion membrane.[10] The new methodology integrates two different analytical separation principles in the same micromodule for simplicity, miniaturizability and minimal human participation in order to enhance analytical quality and productivity.[11]

Pervaporation is a developing membrane technology that is raising great expectations according to the DOE study 'Membrane Separation Systems. A Research Needs Assessment', sponsored by the US Department of Energy, which includes this integrated separation alternative on its top research priority list for organic/organic separations in the chemical industry.[12] Several pervaporation studies have been carried out on a small scale. Toshiro *et al.*[13] developed a new type of membrane based on the plasma-graft co-polymerization of 2-hydroxyethyl methacrylate with acrylic–methacrylic acids on polypropylene films that selectively permeate water from water–ethanol mixtures. Strathman *et al.*[14] used composite hollow-fibre membranes with poly(sulfone) as support, coated with a solvent-selective layer of poly (dimethyl siloxane) for continuous removal of ethanol from fermentation broths by pervaporation. Also, Hickey *et al.*[15] used hydrophobic silicone-based membranes for separation of alcohols such as n-butanol and isopropanol from a bioreactor.

There are few references to the use of pervaporation for analytical purposes. Schmidt *et al.*[16] used a pervaporation module coupled on-line with an enzymatic continuous manifold for the determination of ethanol and diacetyl in simulated brewing mixtures. Recently the same team have developed an improved pervaporation module integrated in a flow injection enzymatic manifold for the determination of ethanol in both beer and baker's yeast cultivation.[17] Determinations based the separation of aqueous–organic mixtures by pervaporation, followed by mass spectrometry or coupled gas-chromatography–mass spectrometry, were reported over 10 years ago.[18]

In this work we constructed a flexible miniature pervaporation module able to work in either a single or a double dynamic mode, that was coupled on-line to a continuous unsegmented flow manifold. After the module was characterized in hydrodynamic and separation terms, a non-enzymatic photometric method for the determination of ethanol in different types of wine was developed in order to test the potential of this integrated separation technique for analytical purposes.

## EXPERIMENTAL

### *Reagents*

All chemicals used were of analytical reagent grade, and solutions were prepared in distilled/deionized water. An aqueous potassium dichromate solution was prepared by dissolving 17.0 g of $K_2Cr_4O_7$ (Merck) in *ca.* 100 ml water, adding 162.5 ml $H_2SO_4$ (96%, Panreac) and making up to 500 ml with water. A $1 \times 10^{-2}M$ $Na_2B_4O_7$ aqueous solution was used as carrier for the Bromocresol Green (BCG) solution, which was also made in this borate medium (50 and 100 $\mu$g/ml). An absolute ethanol standard (Merck) was used at a suitable dilution. Wine samples provided by Official Start of the Montilla-Morilles region (Córdoba, Spain) were also used.

Cellulose, PTFE and PDVF pervaporation membranes (all of 5.0 $\mu$m pore size and 47 mm diameter and supplied by Millipore) were used.

### *Apparatus*

A Unicam 8625 spectrophotometer furnished with a Hellma QS flow-cell (10-mm light path) and connected to a Radiometer REC-80 recorder and a Selecta 382-S recirculating thermostat was used. A four-channel Gilson Minipuls-2 peristaltic pump fitted with a rate selector, a Rheodyne 5041 injection valve, and Teflon tubing of 0.5 mm i.d. was also used.

### *Pervaporation module*

The pervaporation unit was custom-built from machined parts and is shown schematically in Fig. 1. It consisted of the following elements:

(a) An upper chamber with an inlet and outlet through which the acceptor stream is circulated. The acceptor solution collected the gaseous analyte, whether by dissolution or by reaction with a suitable reagent contained in it.
(b) A thin membrane support (1 mm thickness) made of Teflon owing to the difficulty to machine it in methacrylate.

(c) Spacers of different thickness (from 2 to 10 mm) placed below and above the membrane support in order to enlarge the lower and upper chamber, respectively.
(d) A lower, donor stream/sample chamber through which the feed stream for evaporation/diffusion process was circulated.

The whole pervaporation module (membrane support excluded) was made of methacrylate in order to allow continuous checking of its operation during the experiments.
(e)–(g) Additional fastening devices intended to avoid leaking. Firm contact between parts was achieved by screwing the aluminium supports (e) with four cylinders (f). Previously, the different parts of the pervaporation module were aligned by passing (g) through the four cylinder bores.
(h) Connectors for the inlet and outlet stream in both chambers.

The cross-sectional views of Fig. 1(B) show the dimensions and shape of the two chambers.

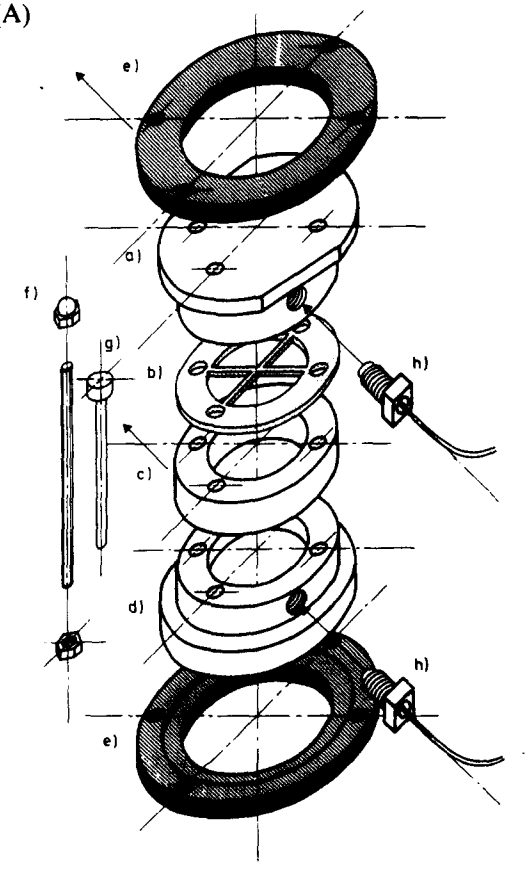

Fig. 1(A). (Caption on following page).

## RESULTS AND DISCUSSION

After the pervaporation module was designed and built, its performance was tested using the univariate experimental approach in order to determine which variables affected its operation. In this case the implementation of the optimization studies using a multivariate experimental design could be highly beneficial taking into account the large number of variables which influence the performance of the module, but these designs are usually 'blind' to the effect of each individual variable. For this reason the module was checked by the univariate method. First, it was checked for hydrodynamic performance, and for continuous pervaporation. Finally, a method for determining ethanol was developed and used to quantify the analyte in various types of wine.

### *Characterization of the pervaporation module*

*Dynamic behaviour.* In order to check the performance of the pervaporation unit (Fig. 1) in a continuous dynamic regime, it was coupled to a flow injection manifold as shown in Fig. 2. For this purpose a volume of 500 $\mu$l of 50 or 100 $\mu$g/ml Bromocresol Green (BCG) in borate buffer was injected into a borate carrier stream and the transient signal obtained on passage through the detector was monitored and used to determine the influence of the incoming and outgoing flow-rates ($q_{in}$ and $q_{out}$, respectively) of the donor and acceptor streams. Both the upper and the lower chamber were checked in turn by connecting the spectrophotometric detector to their outlets.

It should be noted that the detector waste in both the upper and lower chamber must be aspirated in order to aid circulation of the streams through the unit and avoid leakage of the solution through the membrane and the wall-module/membrane in the upper chamber, as well as to raise the donor stream level in the lower chamber.

The operation of the upper chamber was checked by keeping the flow-rate in the lower chamber constant ($q_{in} = q_{out} = 2$ ml/min) and changing at the upper chamber inlet between 0.7 and 3.0 ml/min while keeping both constant at 0.7 ml/min the $q_{out}$ and using the same value as in the inlet. Identical incoming and outgoing flow-rates resulted in no leakage, whatever their value. At $q_{in} > q_{out}$ the dye leaked both through the membrane and (particularly at the latter). Leakage was assessed by keeping $q_{out}$ constant at

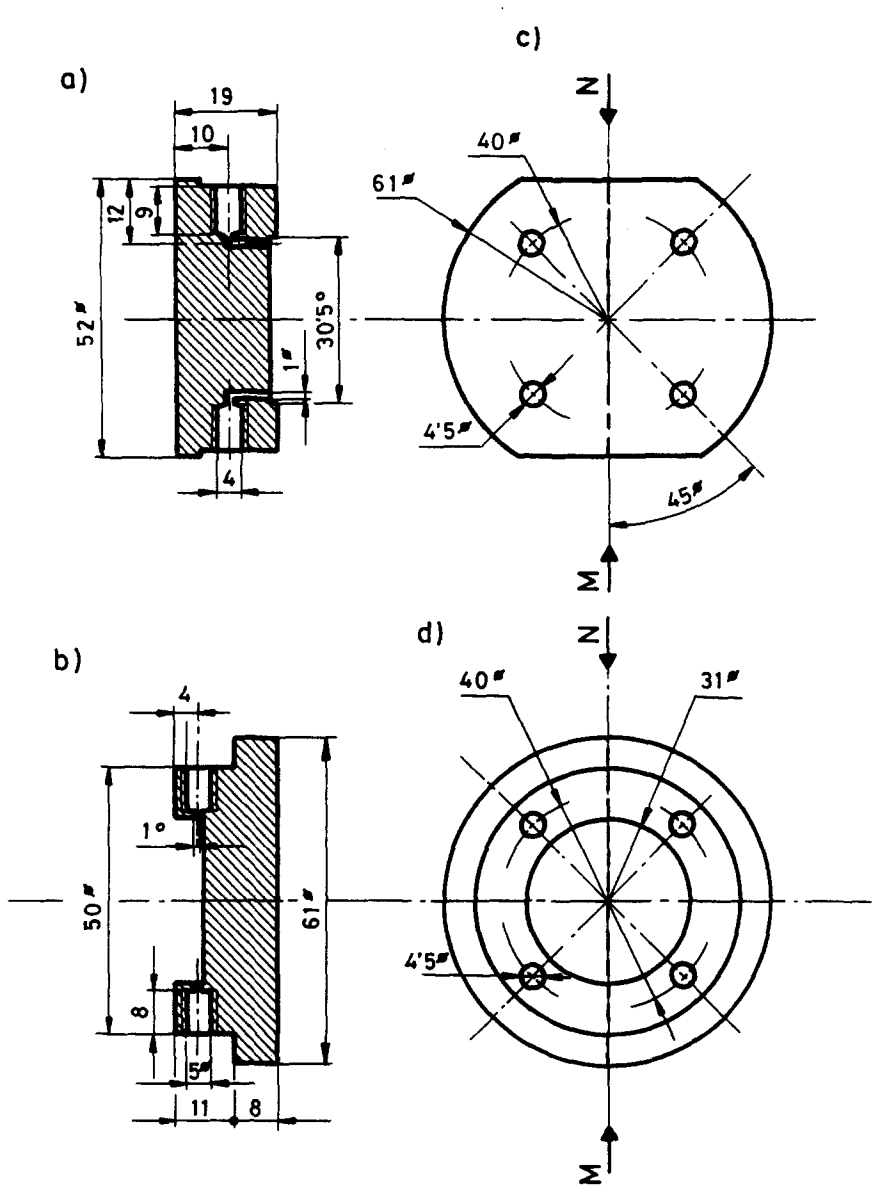

Fig. 1. (A) Parts of the pervaporation module. (a) Receptor chamber, (b) membrane support, (c) spacer, (d) donor/sample chamber, (e) aluminium supports, (f) and (g) rods for screwing and aligning the module, (h) connectors. (B) Cross-sectional (a and b) and plant views (c, d) of the acceptor and sample chambers, respectively.

0.7 ml/min while changing $q_{in}$. The analytical signal decreased by *ca.* 10% at $q_{in} = 1.0$ ml/min, and by as much as *ca.* 50% at $q_{in} = 3.0$ ml/min. The detector response was strongly distorted at $q_{out} > q_{in}$ as a result of air bubbles crossing the membrane and reaching the flow-cell. Thus, correct functioning of the upper chamber required using a flow-rate ratio $q_{in}/q_{out} = 1$.

The operation of the lower chamber was studied in respects: The influence of the $q_{in}/q_{out}$ ratio and the extent of homogenization of the injected dye in the carrier solution, on which reproducibility was found to depend. The different $q_{in}/q_{out}$ ratios were studied by injecting 1 ml of dye into the carrier solution and connecting the spectrophotometer to the chamber outlet. The solution level in the chamber remained virtually constant at $q_{out} > q_{in}$ at the in–out level and the maximum transient signal was obtained which was unstable as air bubbles were pulled to the flow-cell from the chamber liquid surface. Increasing the $q_{in}/q_{out}$ ratio decreased the solution level in the chamber being raised and as a result of dye augmented. A $q_{in}/q_{out}$ ratio of 1 was thus required for optimal functioning of the lower chamber.

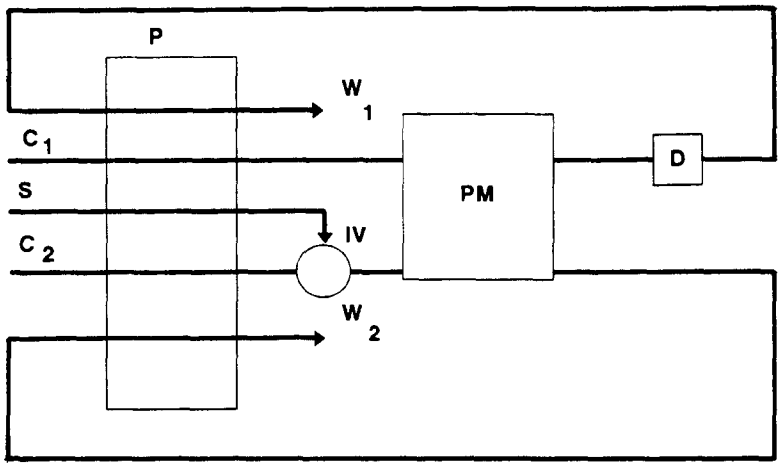

Fig. 2. Flow injection arrangement used to characterize the pervaporation module and develop a method for the determination of ethanol. ($C_1$ and $C_2$) Donor and acceptor stream, respectively; (S) sample; (IV) injection valve; (PM) pervaporation module; (D) detector; (W) waste.

Even if a unity flow-rate ratio was maintained, irreproducible signals were still obtained in successive injections. Dispersion of the dye in the carrier solution held in the chamber was visually observed to be non-uniform and irreproducible. This problem was addressed in two ways were: with magnetic stirring at 60 rpm and by packing the chamber with glass beads (0.3 mm diameter). As shown in Table 1, the reproducibility (as r.s.d.) was improved by using either magnetic stirring or a packed chamber, particularly in the latter case. Also, the signal obtained was higher as the chamber volume occupied by the sample/carrier mixture was smaller (even though the solution level was the same in all the experiments—$q_{in} = q_{out}$—the real volume was smaller as a part of it was occupied by the beads). In addition magnetic stirring would hinder thermostatting of the module, is usually required in pervaporation processes.

Based on the above results, no BCG was pervaporated (*i.e.* no dye passed from the lower chamber to the upper chamber).

*Continuous pervaporation.* The effect of the parameters potentially influencing continuous pervaporation in the proposed module was studied by using the flow system depicted in Fig. 2. Ethanol, the target analyte, was injected into a water-carrier stream that drove it to the lower chamber, where it evaporated and permeated across the membrane into a cold potassium dichromate acid stream where the following reaction took place:

$$2Cr_2O_7^{2-} + 3C_2H_5OH + 16H^+ \rightarrow 4Cr^{3+} 3CH_3COOH + 11H_2O.$$

The $Cr^{3+}$ formed was driven to the spectrophotometer and monitored at 600 nm.

The *flow-rates* of the donor and acceptor stream had a critical effect on the separation efficiency. Their optimal values were found to depend on the module design and the nature of the analyte.

First, the influence of the $q_{in} = q_{out}$ ratio for the acceptor stream was studied by keeping the donor stream conditions constant (2 ml/min and 40°C). A decrease in the analytical signal of *ca.* 50% was observed by changing the flow-rate from 0.5 to 1.0 ml/min (see Fig. 3). However, the decrease was not so marked above 1.0 ml/min. Higher acceptor stream/analyte interaction was achieved by decreasing the flow-rate as a result of the longer contact time.

According to van der Linden,[19] the amount of analyte that diffuses into the acceptor stream depends on the rate of diffusion of the analyte from the bulk solution to the membrane surface, partitioning between donor and separation element, diffusion inside the membrane pores, partitioning between membrane and acceptor, and diffusion from the membrane surface into the bulk acceptor.

Thus, the separation efficiency can be altered by changing the acceptor stream flow-rate.

Table 1. Ways of improving homogenization inside the sample compartiment

| Chamber type | Mean | SD | RSD (%)* |
|---|---|---|---|
| Open | 0.443 | 0.050 | 11.29 |
| Packed with glass beads | 0.548 | 0.004 | 0.79 |
| Magnetically stirred | 0.289 | 0.004 | 1.87 |

*Injection of 1 *ml* of 100 μg BCG/*ml*, $n = 10$.

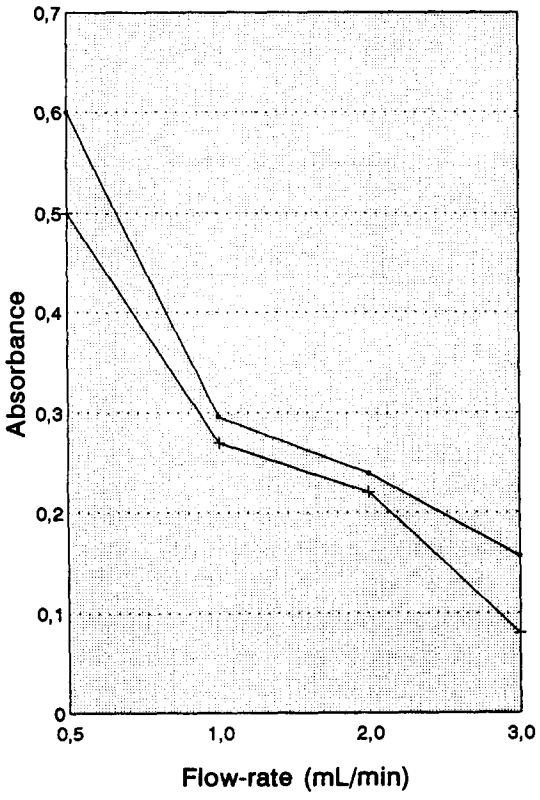

Fig. 3. Influence of the acceptor and donor flow-rate on the pervaporation process (injected volume 2.0 ml/min; 40°C; PTFE membrane, 5 $\mu$m pore size).

However, it should be noted that increasing the analytical signal in this way decreases the sampling frequency. Thus, a compromise must be made; a flow-rate of 2.0 ml/min selected for subsequent experiments as a compromise between sensitivity and throughput.

Second, the donor stream flow-rate was changed from 0.5 to 3.0 ml/min. Figure 3 also shows changes in the analytical signal with changes in this variable. The response was identical with that of the acceptor stream in all instances. Increasing the flow-rate shortened the residence time of the sample in the lower chamber, thereby reducing the time for analyte evaporation and decreasing the separation efficiency. An incoming and outgoing flow-rate of 2 ml/min as a compromise between adequate sensitivity and sampling frequency was also used for the donor stream.

The *separation unit variables* studied included the temperature (through which the pervaporation efficiency can be altered), the type of membrane used for permeating the analyte; and the volume of the sample and collecting chamber.

The effect of temperature was studied by immersing the donor carrier and sample reservoirs, the pervaporation module and the connecting tubes in a thermostatted bath at 30, 40, 50 and 60°C. Various membranes of the same pore diameter (5.0 $\mu$m) were assayed at each temperature. Figure 4 illustrates the influence of temperature and the type of membrane used on the absorbance of the transient signal obtained.

As expected, the separation efficiency increased with increasing temperature for any type of membrane, as the logical result of a higher analyte volatility. There was no a thermal gradient inside the pervaporation module, which would have boosted separation. The different types of membrane provided variable efficiency; PTFE yielded the best results (an analytical signal 30 and 60% higher than those provided by PDVF and cellulose membranes, respectively, at 30°C). An absorbance increase by *ca.* 80% was obtained with the PTFE membrane by raising the temperature from 30 to 60°C. Although the effect of tem-

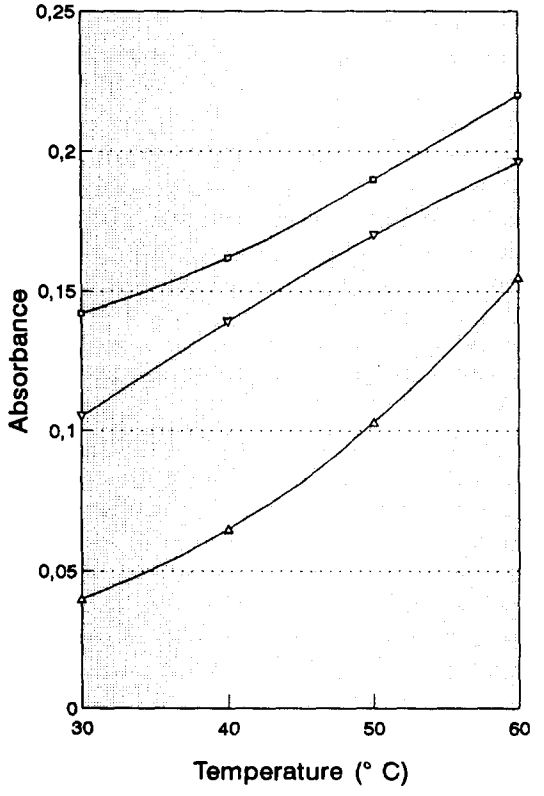

Fig. 4. Influence of temperature and the type of membrane used on the pervaporation process. Working conditions: membrane pore size 5.0 $\mu$m; inlet/outlet flow-rate 2.0 ml/min; sample volume, 2 ml of 10% (v/v) ethanol standard solution (□ PTFE, ▽ PDVF, △ cellulose membranes).

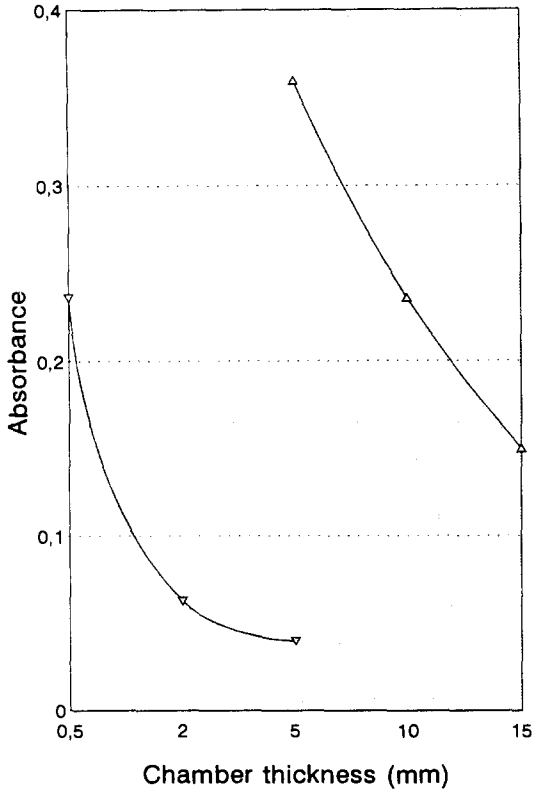

Fig. 5. Influence of the inner volume of the chambers on the pervaporation process. Working conditions: inlet/outlet flow rate = 2.0 ml/min (in both the acceptor and sample chamber); sample volume, 2.0 ml of 10% (v/v) ethanol standard solution and 40°C; PTFE membrane (▽ upper chamber, △ lower chamber).

perature on the performance of the other two membrane materials was more marked than that on PTFE, the absolute absorbance obtained was greater for the latter (see Fig. 4). In addition, the PTFE membrane proved more stable as it remained unaltered for at least one day's worth of work. On the other hand, the PDVF and cellulose membranes allowed leakage of the dichromate solution into the sample chamber after a few minutes. Taking into account the corrosive nature of the acceptor stream, which increased temperature, 40°C was selected in order to avoid rapid deterioration.

The inner volume of the acceptor and/or donor chamber was found to strongly affect the separation efficiency. The effect of this variable was readily studied by placing spacers of variable thickness (*c* in Fig. 1A) in the module as required. As can be seen in Fig. 5, both chambers performed optimally at the minimum volume tested; the spacers caused dilution of the analyte, both in the gas phase and in the acceptor liquid phase.

The effect of *halting the flow* during pervaporation was studied in three modes: by stopping the acceptor stream, the donor stream or both. The stop time was varied from 30 to 180 sec, and each time was tested in two sample introduction modes: continuous insertion and injection. In the latter mode, the flow was halted 10 sec after injection, *i.e.* when most of the injected plug was inside the lower chamber.

Figure 6 shows the effect of both variables. As can be seen, halting the acceptor stream strongly influenced the analytical signal in both sample introduction modes, which showed the membrane to have a restrictive effect.

A higher analytical signal was also obtained by increasing the stop-time. In fact an increase in the analytical signal by *ca.* 130% relative to the continuous working conditions was obtained for a 180 sec stop-time. The effect was even more marked (*ca.* 170%) if both streams were halted. The stopped-flow mode can be of special interest when a high sensitivity is required; however, these working conditions dramatically decrease sample throughput, which hinders application in routine work.

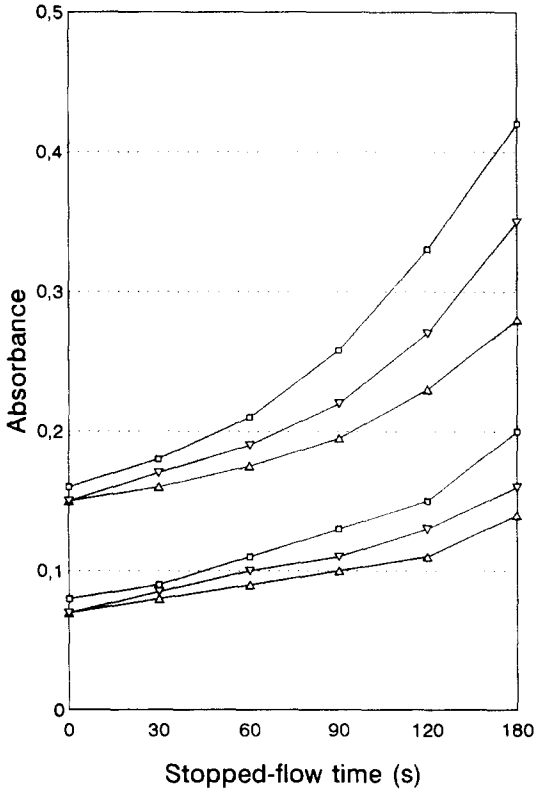

Fig. 6. Effect of stopping the acceptor stream, the donor stream or both on the pervaporation process. The flow was halted for 0 and 180 sec. (1) With continuous sample aspiration; (2) with sample injection, 1.0 ml of 10% (v/v) ethanol standard solution, 40°C (flow stopped in the upper chamber ▽; lower chamber △; both □).

*Determination of ethanol in wine*

The proposed manifold (Fig. 2) is remarkably stable; in fact, no significant change in the baseline absorbance was observed after 8 hr operation. Several calibration graphs were run at various temperature and stoptimes and fitted by least-squares polynomial regression. Their equations and statistical parameter are shown in Table 2. The working conditions can be matched to the linear range and sensitivity required. As noted earlier a flow stopping time of 180 sec provided the best slope for the calibration graph, to the detriment of the sample throughput. The slope was maximal at 60°C; under these conditions the relative standard deviation was increased as a result, however, and the membrane deteriorated more rapidly.

Wider linear ranges and better reproducibility were obtained by shortening or suppressing the flow stopping time. With no flow stopping, the sampling frequency obtained was 10 $hr^{-1}$, with a repeatability of 1.7%, expressed as RSD.

In order to test the performance of the reported approach on real samples, the ethanol content in various wines (white, rosé and red) was determined. Table 3 summarizes the results: the analyte contents found and the recoveries obtained from two standard additions (between 89.7 and 102.7%).

## FINAL REMARKS

Pervaporation enhances the performance of continuous flow systems, as shown in this work by using a pervaporation module to determine ethanol in real samples. The most salient advantage of continuous pervaporation over existing alternatives such as gas diffusion arises from the fact never contacts the separation membrane, thereby avoiding a number of problems (*e.g.* pore clogging) encountered in processing real samples (*e.g.* waste water, fermentation broth). By using appropriate working conditions, a variety of analytical problems can be addressed with the aid of the proposed module. Some potential applications include the direct determination of volatile species such as acetone, biacetil, alcohols, and the indirect determination of analytes forming volatile species such as fluoride and boron. In addition, pervaporation could be used for the determination of such analytes as ammonium, sulphite and carbonate by pH changes, and compared in terms of performance with conventional gas-diffusion methods for these ions.

# PHASE-INVERSION CELLULOSE ACETATE MEMBRANES FOR SUPPRESSION OF PROTEIN INTERFERENCES IN ANODIC STRIPPING VOLTAMMETRY

BOY HOYER* and NINA JENSEN

Department of Chemistry, Aarhus University, Langelandsgade 140, 8000 Aarhus C, Denmark

(*Received* 22 *July* 1994. *Accepted* 14 *November* 1994)

**Summary**—The phase-inversion (PI) method was used to cast permselective cellulose acetate membranes on glassy carbon electrodes with the aim of suppressing protein interferences in anodic stripping voltammetry (ASV). By using cadmium and lead as test analytes and differential pulse ASV as detection method, it was found that the modification of the electrode greatly reduces the interference from albumin. Cellulose acetate membranes prepared by the PI method give better protection against protein interference and have more reproducible permeability characteristics than membranes of comparable thickness prepared by the base hydrolysis method. An optimization study of the PI coating procedure was undertaken.

The direct determination of trace metals in polluted waters and biological samples by anodic stripping voltammetry (ASV) is often hampered by interference effects from organic constituents of the sample matrix. Adsorption of surface-active compounds onto the working electrode usually causes peak depression,[1] and the adsorption/desorption process as such may yield tensammetric peaks which can interfere with or be mistaken for the metal peaks.[2] Consequently, it is often necessary to mineralize the sample matrix prior to stripping analysis. However, sample decomposition complicates and lengthens the analytical procedure and introduces contamination risks.

Recently, coating of the working electrode with permselective membranes has been introduced as a means of circumventing the organic interferences in ASV. One of the most successful membrane materials for this purpose has proven to be cellulose acetate (CA). The coating of the electrode is done either by mounting a preformed bulk membrane directly in contact with the electrode, or by casting the membrane *in situ* on the electrode surface, usually followed by suitable conditioning. Stewart and Smart[3,4] covered a glassy carbon electrode with a bulk CA membrane (1000 MW cutoff) through which a thin mercury film was plated. For cadmium, excellent resistance toward organic interferences was obtained, although the membrane to some extent interfered with the mass transport of the analyte. Owing to their thickness, bulk membranes suffer from the general drawback that the time required for equilibration with the contacting solution is of the same order of magnitude as the duration of a typical ASV experiment, and the response time of the electrode can become a limiting factor. Moreover, bulk membranes strongly impede the mass transport of the analyte to and from the electrode surface, and cause a reduction of the sensitivity in ASV by a factor as high as 18,[5] which is unacceptable in most applications. In contrast, an *in situ* formed CA membrane can be made much thinner, partly owing to the fact that it is cast directly on a solid support (the electrode) and is not moved herefrom. Therefore, the membrane does not need to be mechanically self-supporting. Wang and coworkers have extensively demonstrated the utility of permselective, *in situ* formed CA coatings on electrodes for protection against surfactant interferences in stripping analysis[6,7] and for selective detection of low molecular weight species in amperometric detectors.[8,9] Electrode modification was carried out by casting a dense CA film which was subsequently subjected to base hydrolysis (BH). This treatment breaks the polymer backbone and increases the

*Author to whom correspondence should be addressed.

permeability of the CA membrane,[8] and the permselectivity can be controlled via the hydrolysis time. However, poor stability and reproducibility of CA coatings prepared in this manner have also been reported,[10] which probably is a result of the degradation of the membrane polymer in the BH step.[11]

An alternative way of controlling the permeability of CA membranes is achieved in the wet phase-inversion (PI) process, in which a pore former or swelling agent is added to the casting solution.[12] When the casting solvent has evaporated, leaving behind a viscous solution of CA and the pore former, the membrane is immersed in a non-solvent gelation bath where the polymer precipitates. The precipitation begins at the surface of the membrane and propagates as pore former is exchanged by non-solvent. The porosity of the resulting membrane depends in a complex manner on the composition of the casting solution, the pore former/swelling agent used, and the experimental conditions in the casting procedure.[12-14] Generally, anisotrophic membranes are produced with a dense skin layer, which accounts for the permselectivity, and a porous sub-layer.[12,14] Kuhn *et al.* concluded that this structure is also found in very thin membranes prepared by the PI process.[11] The PI method has two advantages in comparison with the BH method: firstly, the process does not involve any degradation of the CA polymer. Secondly, the main diffusional barrier in CA membranes prepared by the PI process is the thin skin layer, and the inevitable inhibition of the mass transport of analytes caused by the permselective coating is therefore minimal. In contrast, CA coatings prepared by the BH process are homogenous in depth, and the diffusional resistance of the membrane relative to its permselectivity is higher. In spite of these advantages, only Kuhn *et al.* have used the PI process for preparation of membrane coatings on electrodes.[11,15]

Nafion, a perfluorosulfonate cation-exchange resin, has also proven to be a useful material for preparation of protective electrode coatings in ASV. A Nafion-coated thin mercury film electrode (NCTMFE) is less susceptible to interference from surface-active compounds (including proteins) than the conventional TMFE,[16] and it has been used successfully for the direct determination of trace metals in body fluids.[17] Moreover, signal enhancement is achieved with the NCTMFE when used in conjunction with differential stripping techniques,[16,18] and it offers high signal stability.[18] However, the permselectivity of thin Nafion membranes is complex as it results from a combination of charge and size exclusion effects and hydrophobic interactions between the fluorocarbon polymer backbone and the penetrating species.[19-21] In contrast, the permselectivity of CA membranes is primarily based on size exclusion,[8] and this membrane material is, therefore, to be preferred when interfering species can be discriminated against on the basis of molecular size alone.

The purpose of the present work was to assess the usefulness of the PI process for preparation of CA-coated electrodes for protection against protein interferences in ASV, and to compare the virtues of CA coatings made by the PI and the BH methods. Most of the results and conclusions concerning the usefulness of the PI process for preparation of permselective membrane coatings on electrodes are not limited to ASV but also apply to many other electroanalytical methods where suppression of interferences from surface-active compounds is desirable.

## EXPERIMENTAL

### *Apparatus*

Voltammetric measurements were performed with a programmable electrochemical analyser.[22] The electrochemical cell comprised a Metrohm 628-50 rotating disk electrode unit with a 3-mm diameter glassy carbon electrode. The reference electrode was a Radiometer K401 saturated calomel electrode (SCE), while the counter electrode was a glass-fitted platinum wire (1 cm long, 0.5 mm thick).

### *Reagents*

Buffers and supporting electrolyte media were prepared from Merck Suprapur reagents and triply distilled water, while other reagents were of analytical grade. Cellulose acetate (39.8% acetyl content, 30,000 MW) was obtained from Aldrich. Bovine albumin (fraction V, essentially globulin free, lyophilized, 66,000 MW) was obtained from Sigma. A 0.1 (w/v)% albumin solution in distilled water was prepared daily. The composition of the casting solution for the PI membranes was: 20 ml acetone, 0.5 ml of 0.52*M* $Mg(ClO_4)_2$ in water and 0.05 g CA, while the casting solution for the BH membranes was composed of 10 ml acetone, 10 ml cyclohexanone and 0.05 g CA. The concentration of CA in both solutions was 0.25 (w/v)%. In the

following, the formulations of these casting solutions are referred to as the standard compositions.

*Procedure for preparation of modified electrodes*

Prior to coating, the glassy carbon electrode was polished with 0.25 $\mu$m diamond paste, rinsed with ethanol and dried with lens paper. Coating with CA was done by inverting the rotating disk electrode and applying 2.5 $\mu$l of the casting solution to the glassy carbon surface. Rotation was immediately switched on at 1500 rpm. In the preparation of the PI membranes, the duration of this evaporation step was 30 sec, after which the electrode was immersed in an ice-water gelation bath (0°) for 30 min. For the BH membranes, the evaporation step lasted 20 min, and the electrode was subsequently immersed in a 0.06$M$ KOH solution for 16 min. Mercury was deposited on the glassy carbon/CA substrate by electrolysis for 10 min. at $-1$ V *vs.* SCE in deaerated acetate buffer spiked with $2.5 \times 10^{-5}M$ mercury(II). A conventional thin mercury film electrode (TMFE) was prepared in the same manner apart from the polymer coating.

The procedure for the preparation of the BH membranes was adopted from Ref. 10, while the general guidelines for the preparation of the PI membranes were found in Ref. 11. In the following, a TMFE coated with CA by the BH or the PI process is abbreviated as BH-TMFE and PI-TMFE, respectively.

*Procedure for DPASV measurements*

All measurements were performed in 0.1$M$ acetate buffer spiked with $2.0 \times 10^{-7}M$ Cd(II) and $2.0 \times 10^{-7}M$ Pb(II). Solutions were deaerated with argon for 5 min prior to DPASV measurement. The working electrode was rotated at 750 rpm during deposition, while stripping was carried out in a quiescent solution following a 15 sec rest period. The stripping signals were recorded in differential pulse mode with the following instrumental settings: deposition potential, $-1000$ mV *vs.* SCE; deposition time, 2 min; scan range, $-1000$ to $-50$ mV *vs.* SCE; pulse height, 50 mV; pulse width, 22 msec; sampling time, 2 msec; pulse repetition time, 0.24 sec; effective scan rate, 12.3 mV/sec. Signals were smoothed with a seven-point Savitsky-Golay algorithm, and the background signal was corrected for by subtraction of an interpolated linear baseline. A freshly prepared electrode was preconditioned by performing two deposition/stripping cycles in the acetate buffer. In the stability studies, the repeated DPASV experiments were performed automatically under computer control.

In the protein interference experiments, the albumin concentration in the test solution was raised incrementally in the following sequence: 1, 2, 5, 10 and 20 ppm. Two stripping measurements were carried out after each addition. In this manner, the dependence of the DPASV peak current on the protein concentration could be studied, and the adsorption of protein onto the working electrode was closer to equilibrium.

## RESULTS AND DISCUSSION

The DPASV peak currents for cadmium and lead at the conventional TMFE are strongly depressed by albumin (Fig. 1 and Table 1). Moreover, the functional relationship between the peak current and the albumin concentration is such (*cf.* Fig. 1) that even low concentrations of albumin (1–2 ppm) cause a large peak depression, while further increases of the protein concentration only affect the peak current modestly. Both the BH- and the PI-cellulose acetate coatings suppressed the albumin interference, but the latter was clearly superior (Table 1). A $t$-test showed that the peak depression observed with the two electrode modification schemes is different at a 98% confidence level for cadmium as well as lead. Equally important, the variability of individual electrode preparations with respect to the suppression of the albumin interference is much smaller for the PI-TMFE than for the BH-TMFE. Most likely, this

The peak currents are given relative to the initial value prior to albumin addition. The measurements were performed with electrodes which were representative for each type of electrode preparation.

†No. of individual electrode preparations.

improvement is owing to the fact that no degradation of the cellulose acetate takes place in the PI process. Dam *et al.*[10] also attributed the poor reproducibility of BH-TMFEs to the breakdown of the polymer during the hydrolysis step.

The DPASV peak currents obtained with the PI-TMFE and the BH-TMFE are similar for cadmium as well as lead (Table 2). Thus, the superior resistance of the PI-TMFE over the BH-TMFE towards the albumin interference is not achieved at the expense of sensitivity. The peak currents at the membrane-coated electrodes are reduced by a factor of approximately 2.5 in comparison with the bare TMFE. This effect can be explained by increased diffusional resistance due to the membrane barrier, and possibly also a reduction of the effective electrode area. It was found that the signal suppression caused by albumin and the initial DPASV peak current for individual electrode preparations were weakly correlated. Thus, for the PI-TMFE the correlation coefficient was 0.42 for cadmium and 0.50 for lead, while the corresponding figures for the BH-TMFE were 0.72 and 0.67, respectively. The correlation can be explained by random variations in the distribution of pore sizes between individual membranes because a membrane with a more open pore structure will yield a higher signal but will withhold the interferent less effectively and vice versa.

The signal stabilities of the TMFE and the modified electrodes in the absence of albumin were similar (Table 3). For all electrode preparations, the decrease in the signal during the repeated stripping experiments was larger for lead than for cadmium. The PI-TMFE and the BH-TMFE have lower signal stability than the Nafion-coated TMFE.[18] As explained above, the addition of albumin in the protein interference study was done incrementally during a total of 12 deposition/stripping cycles, and the "natural" fall-off of the signal occurring in the absence of protein will, therefore, contribute to the peak depressions given in Table 1.

The detection limit for a PI-TMFE with typical sensitivity was found to be 9 n$M$ for cadmium and 5 n$M$ for lead ($3\sigma$ level, 2 min deposition time). The linear range for the DPASV peak current measured with a PI-TMFE was evaluated by varying the concentration of cadmium and lead between 40 n$M$ and 1.0 $\mu M$. Again, a 2 min deposition time was employed. For cadmium, the data for the resulting calibration line were: slope, 9.0 $\mu A/\mu M$; intercept, 0.15 $\mu$A; regression coefficient, 0.9990 ($n = 10$), while the corresponding figures for lead were: 19.1 $\mu A/\mu M$, 0.22 $\mu$A and 0.9989 ($n = 10$). Curvature of the calibration plot was observed at metal concentrations higher than 1 $\mu M$. In practice, however, this problem was easily remedied by lowering the deposition time.

The cellulose acetate coatings prepared by the BH as well as the PI method were transparent and somewhat more dull than the bare glassy carbon electrode. No pinholes in the polymer

§Data from Ref. 17.

layer could be seen in an optical microscope at 500× magnification. The cellulose acetate coating adhered strongly to the glassy carbon substrate, and withstood gentle wiping with filter paper.

As discussed by Kesting,[12] the properties of PI cellulose acetate membranes are strongly dependent on the formulation of the casting solution as well as the experimental conditions during drying and gelation of the membrane. Therefore, an optimization study was undertaken with the aim of preparing membrane coatings with high permselectivity and high reproducibility of the properties of the resulting electrodes. In order to avoid an excessive number of experiments, an experimental design was chosen in which one parameter at a time in the standard procedure described above was varied. Furthermore, some constraints on the formulation of the casting solution were chosen. Dam *et al.*[10] have previously obtained good protection against protein interference with a BH-TMFE by applying an amount of cellulose acetate corresponding to 0.8 $\mu$g/mm$^2$ on the electrode surface, and this value was initially chosen as reference for the PI membranes as well. The surface tension of the casting solution was such that a maximum of 2.5 $\mu$l could be applied to the glassy carbon surface without spillage during the spin-coating procedure. These considerations in combination dictate the polymer-to-solvent ratio in the casting solution. The composition of the swelling agent [0.52$M$ aqueous $Mg(ClO_4)_2$] was chosen on the basis of the recommendations in Ref. 11 and was not varied.

The influence of the concentrations of cellulose acetate and swelling agent in the casting solution on the properties of the PI-TMFE is given in Table 4. The DPASV peak current and the suppression of the albumin interference vary monotonically with the amount of cellulose acetate applied to the electrode, and the composition of the standard casting solution is an acceptable compromise between suppression of the albumin interference and sensitivity. Surprisingly, a reduction of the amount of swelling agent led to a poorer suppression of the albumin interference. This observation, which was verified in four separate experiments, implies that there is an optimal concentration of swelling agent in the casting solution at which the best rejection of albumin is obtained. For bulk PI membranes, the general rule is that permeability decreases monotonically with decreasing content of swelling agent.[12,14] However, it should be noted that the PI membranes employed in the present study were much thinner than those used in the previous model experiments,[14] and it is, therefore, likely that the explanation of the discrepancy is linked to this difference in the experimental conditions.

A number of variations of the coating procedure for the PI membranes were also attempted. At room temperature, the solvent

*The variations are relative to the standard composition of the casting solution given in Experimental. A minimum of three electrode modifications were carried out for each variation.

quickly evaporated when the casting solution was applied to the electrode surface, and the system was, therefore, far from equilibrium during the formation of the cellulose acetate/swelling agent phase. Thus, it was examined whether any advantages accrued from slowing down the evaporation of the solvent. This was accomplished in two different ways: by performing the electrode coating at 4° in a cold room (after equilibrating the equipment and the casting solution to this temperature), or by applying the casting solution in an atmosphere in equilibrium with mixtures of water and acetone in varying ratios. However, neither method led to any improvement in the properties of the resulting membranes and it was, therefore, concluded that the evaporation step in the electrode preparation procedure is not critical.

Spin-coating was found to improve the reproducibility of the characteristics of the PI-TMFE as well as the BH-TMFE in comparison with electrodes where no rotation was applied during the evaporation step. This improvement, which is quite general,[23] is probably a result of a more even spreading of the polymer over the electrode surface. Spin-coating changed the visual appearance of the coating: without rotation, chaotic refraction patterns could be seen, while the electrodes which had been rotated only had diffuse, concentric refraction rings. These observations can also be attributed to the more uniform polymer layer obtained by spin-coating.

The temperature of the gelation bath had a pronounced effect on the performance of the PI-TMFE. Increasing the gelation bath temperature to 22° was accompanied by a decrease in the discriminative power of the membrane towards albumin and an increase in the DPASV peak current for cadmium and lead, and gelation at 40° yielded electrodes which resembled the conventional TMFE. Thus, gelation in ice water is essential in order to obtain good permselectivity. These observations are in agreement with the work of Kesting *et al.*,[14] who explained the loss in permselectivity at higher gelation temperatures by rupture of the skin layer owing to mechanical stress during the rapid precipitation of the polymer.

Annealing of the PI membrane in warm or hot water after the gelation bath is known to decrease the permeability of the membrane,[14] and this procedure was also attempted. It was found that the effect of the treatment was strongly dependent on the temperature of the annealing bath. At 50°, little effect on the performance of the electrode was noted, but raising the annealing temperature to 60° or higher caused a substantial reduction in the DPASV currents without any accompanying improvement in the suppression of the albumin interference. Therefore, further use of the annealing procedure was given up.

In conclusion, the protein interferences in ASV are significantly suppressed at a PI-TMFE, and it offers better protection than a BH-TMFE coated with the same amount of CA. Moreover, the variation in permselectivity between individual coatings prepared by the PI process is smaller than is the case with the BH method. Even so, the reproducibility of the PI method with respect to the properties of the resulting membranes needs to be improved in order to make the PI-TMFE more useful for routine use. At present, the possibility of further optimizing the procedure for casting PI membranes onto electrodes is being investigated.

*Acknowledgements*—The authors are most grateful to Dr K. N. Thomsen, I/S Nordkraft, Aalborg, Denmark and Dr M. E. R. Dam, Aalborg University, Aalborg, Denmark, for valuable discussions and for providing a preprint of Ref. 10.

# NEW FLUORIGENIC REAGENTS AND THEIR FLUORESCENT REACTIONS FOR AMINO ACID MEASUREMENTS

M. AMINUDDIN* and J. N. MILLER

Department of Chemistry, Loughborough University of Technology, Loughborough, Leicestershire LE11 3TU, U.K.

(*Received* 10 *April* 1994. *Revised* 19 *September* 1994. *Accepted* 24 *September* 1994)

**Summary**—Naphthalene-2,3-dicarboxaldehyde, 1-phenylnaphthalene-2,3-dicarboxaldehyde and anthracene-2,3-dicarboxladehyde have been characterized for use as fluorigenic reagents for the determination of primary amines and amino acids at the microgram level. The reaction conditions, spectral properties and the stability of the derivatives (isoindoles) have been investigated with standard amino acids. The results have been compared with other fluorigenic reagents such as *ortho*-phthalaldehyde.

## INTRODUCTION

Fluorimetry is a sensitive method for detection of amino acids and there are a number of useful fluorigenic reagents such as *o*-phthalaldehyde (OPA),[1,2] dansyl chloride,[3] fluorescamine,[4] 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl)[5] and 3-benzoyl-2-quinoline carboxaldehyde (BQ CA).[6,7] Of these, OPA is widely used for amino functional groups. The reaction product is an isoindole with optimal wavelengths, $E_{ex} = 340$ nm and $E_{em} = 455$ nm. The emission, however, suffers spectral interferences, especially for biological samples in which background emission overlaps the emission of the isoindoles.

New reagents such as 1-phenylnaphthalene-2,3-dicarboxaldehyde ($\phi$NDA), anthracene-2,3-dicarboxaldehyde (ADA) including the published naphthalene-2,3-dicarboxaldehyde (NDA)[8,9] have been synthesized in the author's laboratory according to Cook *et al.*[8] and used for measuring amino acid groups. These reagents from fluorescent isoindoles (Fig. 1, I–III) with compounds containing a primary group. The emission wavelengths of the products obtained by using these reagents are much longer than those for OPA-adducts.

This paper reports reactions of these reagents and their utility for determination of amino acids in trace quantities. Important properties, *e.g.* reaction time, effect of solvent, pH of the medium and stability of the product, are reported.

## EXPERIMENTAL

### *Borate buffer* (pH 10.0)

Borax (4.8 g/l.) and sodium hydroxide (0.80 g/l.) were dissolved in distilled water and stirred well to obtain a clear solution.

### *Fluorigenic reagent solution*

Each fluorigenic reagent was dissolved in a minimum volume of ethanol and made up to the required volume with either distilled water or 0.025*M* sodium borate buffer (pH 10.0) to obtain solutions of known molarity.

*o*-Phthalaldehyde (OPA), ethanethiol (ET), 2-methyl-2-propanethiol (2MPT), 2-mercaptoethanol and 3-mercaptoropionic acid were purchased from Aldrich Chemical Co. Ltd. Amino acids and all other chemicals were of analytical grade.

### *Spectrofluorimetric procedure*

Dilute solutions, $10^{-4}$–$10^{-3}M$, of sample (0.2–0.3 ml) were treated with 1 ml of 10.9m*M* $\beta$-cyclodextrin ($\beta$-CD). A 0.5 ml portion of borax–sodium hydroxide buffer (pH 10.0) and 0.1 ml aqueous thiol solution (0.1% v/v) were then added, followed by the addition of the suitable fluorigenic reagent in slight excess over the sample. The final volume was made up to 5 ml with water. The fluorescence emission was

*Present address for correspondence: Department of Chemistry, Islamia University, Bahawalpur, Pakistan.

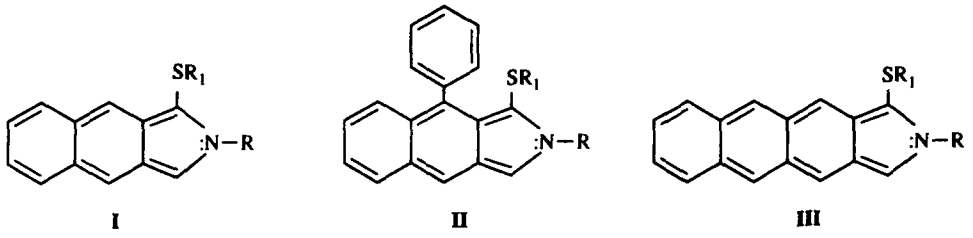

Fig. 1. Fluorescent isoindoles: I, NDA-derivative; II, $\phi$NDA-derivative; and III, ADA-derivative.

then measured at a suitable wavelength with excitation of the fluorescent derivative at an appropriate wavelength. Blanks without amino acid were used to evaluate blank interferences. For the OPA derivatives the labelling procedure was same as above but omitting $\beta$-CD from the reaction solution, unless stated otherwise.

## RESULTS AND DISCUSSION

### *Reaction and fluorescence spectra*

The fluorigenic reagents studied are dialdehydes similar to *o*-phthalaldehyde (OPA). With the use of a thiol as the nucleophilic substitution in derivative formation it may be assumed that the resultant fluorophores are 1-alkylthio-2-alkyl substituted isoindoles.[2,10,11] Decomposition occurs owing to spontaneous intramolecular sulphur-to-oxygen rearrangement leading to non-fluorescent 2,3-dihydro-1H-isoindole-1-one.[2,10] The fluorigenic reaction of the polyaromatic dialdehydes, e.g. NDA, $\phi$NDA and ADA, in the presence of thiol, with amines, amino acids and proteins is useful since it can be conducted in aqueous solution.

Figure 2 shows emission spectra of NDA and OPA-glycine derivatives using 2MPT and ET. The observed fluorescence spectra were obtained by excitation of the molecules at 462 and 350 nm, respectively. The fluorescence emission occurred at 550 and 510 nm for the NDA-adducts by using ET and 2MPT, respectively. A similar trend was observed for the OPA-adducts where the wavelengths of emission shifted from 450 to 410 nm for a corresponding change of thiols.

Similarly, $\phi$NDA and ADA derivatives of glycine were also found to give fluorescence emission at longer wavelengths, 520 and 640 nm, for excitation wavelengths of 462 and 470 nm, respectively.

The derivatization reaction, using all these new fluorigenic reagents, is fast. It takes only 3–5 min for full fluorescence intensities to develop.

### *Fluorescence intensity as a function of* pH

The yield of the derivative is sensitive to pH changes. The fluorescence intensity at 520 nm was measured as a function of pH. Glycine and NDA both at $2 \times 10^{-5}M$ concentration were derivatized in the presence of a thiol, varying the pH of the reaction medium from 5 to 12. Results showed that as the pH increased there was a gradual increase in fluorescence intensity, reaching a maximum around pH 10 followed by a continuous decrease in fluorescence intensity. The fluorescence increase with increasing pH may be ascribed to contributions owing to the unprotonated amino group at high pH. This point of view is supported by the fact that the reaction rates are faster[12] at high pH. The other fluorigenic reagents, $\phi$NDA and ADA, showed

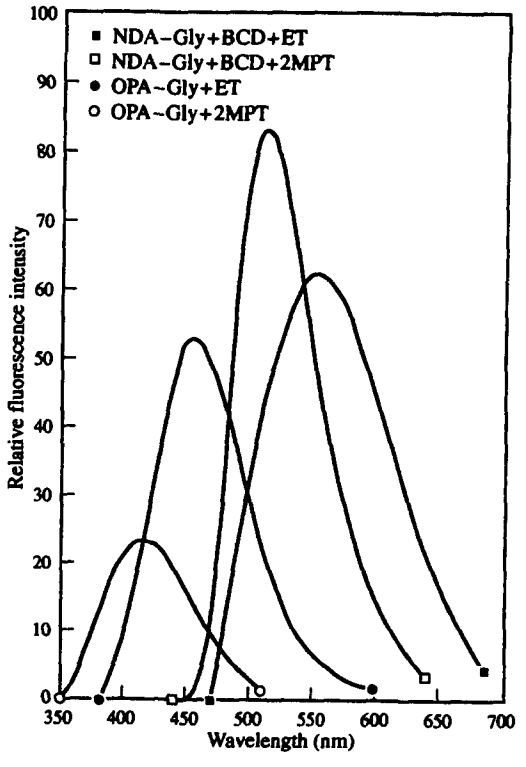

Fig. 2. Emission spectra of NDA- and OPA-glycine derivatives.

similar behaviour to that of the OPA fluorigenic reaction.

*Enhancement of fluorescence intensity by β-cyclodextrin and detergent*

In order to obtain enhanced fluorescence of the derivative, cyclodextrins were incorporated into the fluorigenic reaction of $10^{-4}M$ glycine with NDA of the same molarity as glycine. Cyclodextrin possesses cyclic sugar molecules which form a cavity rich in electron density because of glucosidic oxygens, and has the tendency to physically trap the guest molecules entering the cavity. Cyclodextrins, in fact, form complexes in aqueous solution with various substrates.[13] Experiments have indicated the effects of three cyclodextrins ($\alpha$, $\beta$ and $\gamma$). $\beta$-Cyclodextrin ($\beta$CD), enhances fluorescence intensity of the NDA derivatives by nearly eight times, compared with the NDA-derivative without $\beta$CD. Similar results were obtained using $\phi$NDA and ADA as fluorigenic reagents. However, the fluorescence enhancement was greater for an addition of a little over 2.5 mmol of $\beta$CD to the reaction mixture. The significant increase in fluorescence of the derivatives may be caused by side chain functional groups of the derivative entering the cavity while the rest of the molecule may remain outside.

The effect of the detergent, Brij-35, on fluorescence intensity is noticeable. In the presence of Brij-35, the NDA-glycine derivative formed with 2-methyl-2-propanethiol (2MPT) was found to give enhanced fluorescence. A very small improvement in the fluorescence intensity by the detergent may be a result of: (i) shielding of the NDA–glycine fluorophore from vibrational quenching by the hydrogen bond structure of water, (ii) alteration of the quantum efficiency[14–16] or (iii) increased local viscosity about the fluorophore micelle binding sites not being so effective as the deactivation modes.

*Influence of thiol structure on the stability of the derivatives*

The utility of thiol structure for amino acid analysis is demonstrated by the following observations. The wavelengths of emission are considerably affected by the thiol structure and this has been discussed in the preceding section. Furthermore, the thiol structure seems to alter the stability of the derivatives. The amino acid derivatives formed with the active, NDA, $\phi$NDA or ADA/thiol reagent exhibited not only varying fluorescent responses but also varying degrees of stability. The ADA–gly derivative using 2MPT was found to be very stable. On the other hand, NDA and $\phi$NDA derivatives of glycine with 2MPT were comparatively less stable and decomposed sharply. The stability was, however, found to be much more affected if the 2MPT is replaced by ethanethiol, 2-mercaptoethanol or 3-mercaptopropionic acid (not shown here). These results are in agreement with those for OPA-derivatives which showed similar instability[17,18] in the presence of 2-mercaptoethanol and ethanethiol. A branched thiol provides stability to the molecule through steric hinderance.

*Effect of solvents on the fluorescence properties of the derivatives*

A study of the effects of organic solvents on fluorescence intensity and wavelengths of emission has led to some interesting results. $\phi$NDA–glycine derivatives exhibited emission wavelength shifts from longer to shorter wavelengths as the reaction medium was changed from water to an organic solvent (Fig. 3). The results indicate that the lower the dielectric constants of the solvent, the shorter is the wavelength of emission, suggesting a much reduced dipole–dipole interaction between the fluorescent molecules and the solvent. The interaction is increased in water and the emission

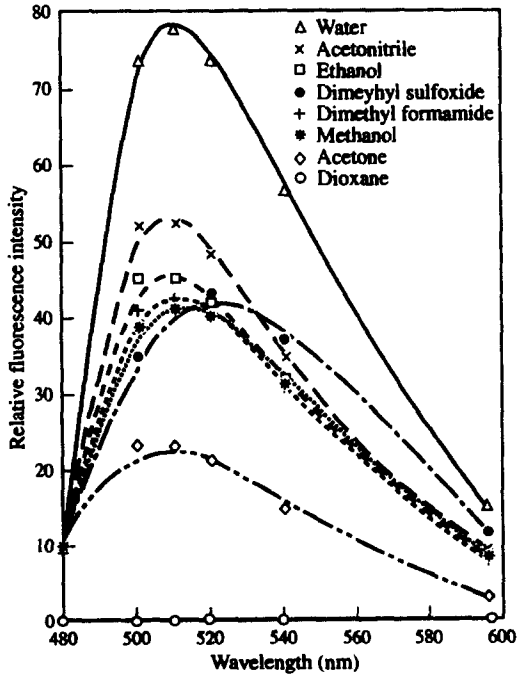

Fig. 3. Spectra of NDA–glycine derivative showing the effect of organic solvents on fluorescence properties.

moves further towards lower energy.[19] An investigation on NDA and OPA–glycine derivatives resulted in similar solvent effects on their spectral properties.

The effects of solvents on the fluorescence intensity of the NDA, $\phi$NDA and OPA-adducts seemed to be moderate. The fluorescence intensity seems to depend very much on the structure of the fluorigenic reagents. A more hydrophobic character associated with $\phi$NDA offers enhanced fluorescence in the solvents having lower dielectric constants. This result is supported by the observation that NDA-derivatives fluoresce more intensely in water as compared to organic solvents.

*Limits of detection*

One of the benefits of using fluorimetric methods of analysis is the ability to identify and determine much smaller quantities of analyte than would be possible using classical techniques.

Limits of detection for the technique are of particular interest. The limit of detection is defined as the quantity or concentration of analyte that produces a signal 2 standard deviations above the blank (i.e. $a + 2SY/X$), where $a$ is the background signal (the intercept) and $SY/X$ is the standard deviation of a single measurement. Such a concentration can be distinguished from the blank with 97.5% confidence.

The limit of detection for glycine using both NDA and $\phi$NDA was found to be $3.6 \times 10^{-7}$m$M$ ($3.2 \times 10^{-5}$ g/ml). This result compares with *o*-phthalaldehyde[20] which has limits of detection of $0.2 \times 10^{-9}$ mol/ml for $NH_4^+$ in sea-water[21] and picograms (55–100) for catechol-amines[22] in urine following prechromatographic derivatization reaction. The newly produced fluorigenic reagents offer a wavelength of emission which is at longer wavelengths (550–620 nm). Although the present study does not include work for real biological samples it is hoped that measurement of emission at the reported longer wavelengths will have little interferences, especially from the background signal[23] which has a direct bearing on the limit of detection in fluorescence spectrophotometry.

The detection limit capabilities[24] are greatly increased using high performance liquid chromatography (HPLC) coupled with laser-induced fluorescence (LIF) detection. The results in that study indicated that NDA is superior to OPA as a labelling reagent. The detections of amino acids using LIF were at the sub-fmol range with NDA-derivatization, lower by over an order of magnitude compared to the results for OPA-amino acids.

## CONCLUSIONS

The newly synthesized reagents have been useful for producing fluorescent derivatives of amino acids. The reaction is rapid and proceeds reproducibly in aqueous medium (pH 10, room temperature). The fluorescence emission of the derivatives at longer wavelengths makes the reagents suitable for use in the analysis of biological samples, minimizing interference.

(*Received* 17 *February* 1994. *Revised* 2 *November* 1994. *Accepted* 8 *November* 1994)

**Summary**—Two flow injection systems for the spectrophotometric determination of ascorbic actid at 245 nm have been described. On treatment with sodium hydroxide a fraction of the ascorbic acid was decomposed into substances, which do not absorb in UV region, and the decrease in signal measured. This was directly related to the amount of ascorbic acid present. The calibration graph was linear over the range 1–25 and 1–50 $\mu$g/ml in the two methods with a correlation coefficient of 0.9981 and 0.9994, respectively. The detection limit ($2\sigma$) was 0.5 and 0.2 $\mu$g/ml, respectively. The RSD for 1 $\mu$g/ml standard was 2.5 and 1.8% ($n = 6$) in the two methods, and the sampling throughput 30/hr. The methods permitted the use of 6 $\mu$g/ml of 2-mercaptoethanol as an anti-oxidant and stabilizer for ascorbic acid, which is difficult to handle at its $\mu$g/ml level. Upon matrix absorbance correction, spiked samples that are known to contain UV-absorbing substances produced an average recovery of 101% with a RSD of 1.2%. The methods were used for the rapid and simple determination of ascorbic acid in soft drinks, preserved fruit juices and pharmaceuticals and the results thus produced compared with those obtained by previously checked methods involving titration with iodine, chloranil 2,6-dichlorophenolindophenol, and HPLC. When there was a disagreement between the results, this was traced to the presence of substances which are known to interfere in comparison methods.

Its simplicity and relatively close correlation with the results of biological assays have led to the extensive use of titration with 2,6-dichlorophenolindophenol for the determination of ascorbic acid in fruit juices, pharmaceuticals and biological samples. However, difficulties are encountered with coloured samples, when the detection of the end point is cumbersome, or in the presence of reducing substances other than ascorbic acid, which can bleach the dye and make analysis non-specific.[1–3] Among these substances some are naturally present in fruit juices and biological fluids, *e.g.* cysteine, reduced glutathione and iron(II), whereas others are added to foodstuffs as preservatives, *e.g.* sulphite, dithionite and sulphide. Dithiothreithol,[4] homocysteine[5] and cysteine[6] are added to reduce concomitant dehydroascorbic acid to ascorbic acid in order to determine a total of two species. Excess thiol reagent can also react with the indophenol dye and vitiate the analysis. Besides achieving higher sensitivity and rapidity, most methods that are reported in literature attempt to circumvent some of these drawbacks.

Titration with *N*-bromosuccinimide in the presence of iodide/starch indicator, giving intense blue colour at the end point, has been reported to tolerate large quantities of iron(II),[7] and found applicable to coloured samples.[8] Interference from sulphur containing reducing substances was still a shortcoming. Many other redox titrants behave analogously.[9–11] Interference of thiol groups and sulphite has been avoided by their masking with acrylonitrile[12–14] and acrylamide,[15] and of sulphite with furan-2-aldehyde.[12]

Owing to the non-equilibrium state of the chemical system, interferences occur at a lower level in flow injection analysis. Manual titrimetric methods[12,16,17] based on redox properties of ascorbic acid have been adapted to flow injection analysis.[18–21] Methods based on reduction of

*Author to whom correspondence should be addressed

iron(III) and measurement of iron(II) by its complex formation with 1,10-phenanthroline,[22] or catalyzed light emission from luminol oxidation with hydrogen peroxide,[23] and photochemical reduction of methylene blue[24,25] have been of late reported. These methods work well for assay in drug formulations and fresh fruit juices, however, the interference of sulphur containing reducing substances is much the same.

A high sensitivity measurement of ascorbic acid has been carried out amperometrically.[26] The detector is not selective, however, when measurements are made without and with reaction with immobilized ascorbate oxidase that is incorporated in a flow injection system, and the difference in detector response is related with the ascorbic acid content, a good correlation with the actual values is obtained.[27] The enzyme activity has been reported to remain unimpaired in the presence of thiols.[28]

HPLC[5,6,29-31] is more selective and sensitive, nevertheless, in most methods ascorbic acid elutes very close to the void volume which may lead to errors.

Ascorbic acid absorbs strongly at 245 nm in acidic media and at 267 nm in neutral solutions, and is electroactive whereas dehydroascorbic acid has no such property. These characteristics form the basis for the determination of ascorbic acid. However, the detector response corresponds to any ascorbic acid present and to that of the sample matrix in case the concomitant substances either also absorb at the wavelength of determination in spectrophotometry, or are electroactive in amperometry. A correction can be made by measuring the matrix contribution on a second aliquot of sample solution in which ascorbic acid is predecomposed to produce materials that are unresponsive to the detector. The difference in detector response observed is related to ascorbic acid present. Since dilute solutions of ascorbic acid are only stable in the presence of reducing agents such as 2-mercaptoethanol, as used in this work, which does not absorb in the UV region of determination but has significant electroactivity, spectrophotometry was considered as a method of choice for matrix correction.

## EXPERIMENTAL

### *Apparatus*

A Shimadzu SPD-2A variable wavelength UV detector (8-$\mu$l flow-through cell), a Shimadzu C-R2AX integrator fitted with a printer-plotter, two Rheodyne 5020 4-way rotary valve sample injectors (Anachem), a Rheodyne 5031 double 3-way switching valve (Anachem) and an Ismatec Mini-S 820 peristaltic pump (Zurich) were used. The manifold and reaction coil tubing was 0.5 mm i.d. PTFE. Flangeless end fittings were made using plastic nuts and Tefzel couplers (Anachem). Home-made T-joints of 0.8 mm bore were employed.

### *Flow injection manifolds and experimental conditions*

*Manifold A.* The system consisted of a two-channel manifold with a carrier stream of 6 mg/l. of 2-mercaptoethanol with a flow rate of 0.36 ml/min and on to which a 4-way injection valve (V1) was placed, another similar valve (V2) was nested on the loop of the first valve (Fig. 1). Two 'a' and 'b' portions of loop on valve V1 were, respectively, 40 and 50-$\mu$l, whereas V2 had a 50-$\mu$l loop. The effluents were passed through a 80-cm reaction coil, merged with 0.2*M* sulphuric acid stream that had a flow rate of 0.13 ml/min, passed through another 30 cm coil and finally monitored at 245 nm. To determine the total absorbance of ascorbic acid and matrix, the sample solution was injected through valve V2 into the carrier stream whilst the valve V1 already in inject position. The matrix absorbance (plus that of any remaining ascorbic acid) was determined by simultaneously injecting 0.2*M* sodium hydroxide through valve V1, and sample solution through valve V2. The difference in peak heights was related to the amount of ascorbic acid present.

*Manifold B.* A single channel manifold was used that consisted of 6 mg/l. of 2-mercaptoethanol as a carrier solution with a flow rate of 0.82 ml/min and valves V1 and V2 were placed on it, valve V2 being nested on the loop of the valve V1 (Fig. 1). The loop sizes were the same as in manifold A. The simultaneously injected 0.02*M* sodium hydroxide and sample solution, through valves V1 and V2, respectively, were allowed to mix in a delay coil of 25 cm and then the plug stopped in the detector 6 sec after injection by diverting the flow of effluents to waste using a double 3-way switching valve (V3) placed between the delay coil and detector. The flow was resumed after 60 sec. The decrease in peak height during this period was owing to the decomposition of ascorbic acid, and related to its concentration.

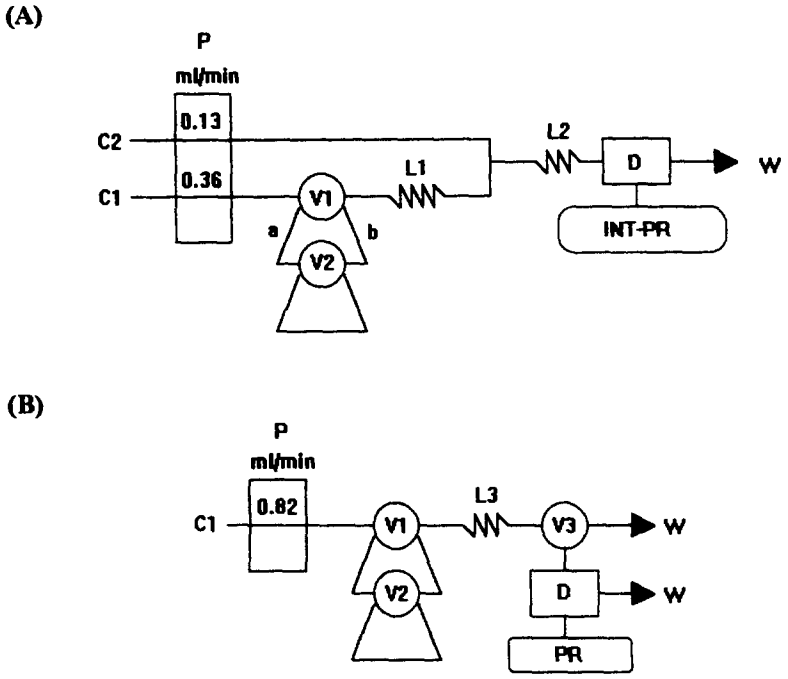

Fig. 1. Schematic diagrams of the flow injection systems used for the determination of ascorbic acid by matrix absorbance correction. Manifold (A) was used for continuous flow injection and (B) for stopped-flow experiments. C1 = water carrier; C2 = 0.2*M* sulphuric acid; V1 = 4-way loop injection valve ('a' = 40-$\mu l$; 'b' = 50-$\mu l$); V2 = 4-way loop injection valve (50-$\mu l$); V3 = double 3-way switching valve; L1 = delay coil of 80 cm; L2 = delay coil of 30 cm; L3 = delay coil of 25 cm; P = peristaltic pump; D = detector (8-$\mu l$) set to 245 nm; INT-PR = integrator and printer; PR = printer; and W = waste. All flow lines were made from 0.5 mm i.d. PTFE tubing.

*Reagents*

All reagents used were of analytical reagent grade. 2-Mercaptoethanol, 6 mg/l. was used as a carrier solution. Sodium hydroxide: 0.2 and 0.02*M*. Sulphuric acid: 0.2*M*. A guaranteed-reagent grade ascorbic acid from Sarabhai M. Chemicals (Baroda, India) was used that had a purity of 99.7% as determined by titration with 2,6-dichlorophenolinophenol,[32] 99.5% as determined by iodimetric titration[33] and 99.8% as determined by titration with chloranil.[15] A standard solution (1000 $\mu$g/ml) was prepared by dissolving 100.00 mg of ascorbic acid in 100 ml of de-ionized water in a calibrated flask. Calibration standards were prepared by sequential dilution of the stock solution with the carrier solution.

*Samples*

All pharmaceutical dosage forms and multivitamin preparations tested were fresh and purchased from the local pharmacy. A known number of capsules were weighed and ground into a fine powder. An accurately weighed aliquot containing about 100 mg of ascorbic acid was shaken with about 25 ml of de-ionized water and filtered through Whatman No. 41 filter-paper. The insoluble mass was washed with three successive 5 ml portions of water, and the filtrate plus washings were diluted to volume in a 100-ml calibrated flask. A known volume was further diluted with the carrier solution for analysis. The contents of a known number of vitamin C injections were mixed together and a suitable portion of the mixture was sampled. The stock solutions were used for analysis by the comparison methods.

Known volumes of thawed soft drinks and juice concentrates were mixed with 10 ml of the carrier solution and filtered through Whatman

| *Method using manifold B* | | | | | |
| $\Delta h$ *ml*/$\mu g$ | | $\Delta h$ | | | |
| 1–25 | 9.546 | −1.573 | 0.64 | 0.9981 | 12 |

$\Delta H$ and $\Delta h$ = Difference in peak heights in integrator arbitrary units and in *mm*, respectively.

No. 42 filter-paper. The residue was washed with 2 successive 2 ml portions of the carrier, and the filtrate plus washings were diluted with carrier to known volume in calibrated flasks to give solutions for analysis. Suitable portions of soft drinks and juice concentrates were diluted with water, filtered and analyzed by the comparison methods.

In cases when the sample contained a soluble salt of iron(II), which interfered in the proposed method, an aliquot of the above prepared stock solution was shaken with 5 ml of 25 mg/100 ml of sodium sulphide for 2 min and filtered. The filtrate was diluted with the carrier solution for analysis.

## RESULTS AND DISCUSSION

Ascorbic acid solutions deteriorate rapidly owing to oxidation by the dissolved oxygen. At 25°C, 1–20 $\mu$g/ml solutions have been found in this work to lose their total ascorbic acid content within 20 min. Thus, dilute solutions are very difficult to handle unless a stabilizing agent is used, and the sample pre-treatment, if any, and determination done under rapid flow injection conditions. Commonly used stabilizers are reducing agents, which interfere severely with methods based on the redox property of ascorbic acid, or metaphosphoric acid which has been reported to result in reduced retention of ascorbic acid on anion exchange columns.[29] 2-Mercaptoethanol was found to be transparent in the UV region, especially at 245 nm, and worked as an effective stabilizer. In this work, a 6 mg/l. solution of 2-mercaptoethanol has been used as a carrier and in preparing the working solutions of ascorbic acid.

A number of methods are described in the literature for producing a sample blank, such as enzymatic methods,[27,34,35] thermal decomposition,[36] catalytic decomposition with copper(II),[36–38] and UV irradiation, [36,39] Ascorbic acid is well known to be unstable in alkaline solutions,[36,40] the decomposition products being dehydroascorbic acid and threonic acid which do not appreciably absorb in UV region. Thus, adjustment of the sample pH to the alkaline range was studied as a potential blank correction method in this work. Although rapid, decomposition by alkali is not selective for ascorbic acid, many hydroxy compounds and certain dyestuffs are also unstable in alkaline media. Thus, the study of flow injection parameters aimed at decomposing only a good fraction of ascorbic acid before any side reaction becomes appreciable.

### *Study of flow injection parameters*

Out of several ways possible, nested loop injection was found as a simple means of effectively mixing ascorbic acid and sodium hydroxide. Initial flow injection experiments were carried out using manifold A (Fig. 1) in which the nested loop injectors placed on water carrier stream (C1, flow rate 0.82 ml/min) and the reaction quenching agent was 0.1*M* sulphuric acid (C2, flow rate 0.54 ml/min). The alkaline degradation reaction occurred in a coil (L1) of 100 cm and the neutralization reaction in another coil (L2) of 75 cm. Conditions were studied for the determination of 10 $\mu$g/ml

ascorbic acid using 0.1*M* sodium hydroxide as a reagent for producing blank absorbance.

Over a flow rate 0.1–1.2 ml/min of each channel studied, maximum peak height difference was observed when flow rate for C1 was 0.36 ml/min and for C2 0.13 ml/min. Other parameters studied were L1 = 80 cm (studied 30–135 cm); L2 = 30 cm (studied 10–135 cm); ascorbic acid loop size (valve V1) = 50 $\mu$l (studied 10–100 $\mu$l); sodium hydroxide loop size (valve V2), side 'a' = 40 $\mu$l (studied 10–100 $\mu$l), and side 'b' = 50 $\mu$l (studied 10–75 $\mu$l). Sodium hydroxide (studied 0.05–0.5*M*) and sulphuric acid (studied 0.025–0.4*M*) were each 0.2*M*.

†The results are the average of five determinations.

Under these conditions of sample blank determination 76% of ascorbic acid was decomposed.

In stopped-flow experiments using the manifold B (Fig. 1), the nested loops as used above were placed on water carrier stream (flow rate 0.82 ml/min), the mixing was allowed to occur in a reaction coil (L3) of 25 cm and the plug stopped in the detector for a pre-determined period. With this configuration, the peak maximum appeared 6 sec after injection. Sodium hydroxide concentration was found to play a critical role that determined the sensitivity of the method. A 0.02*M* sodium hydroxide solution was optimum over the studied range 0.01–1*M*. Most of the ascorbic acid was decomposed before reaching the detector when a more concentrated reagent was used, thus giving a small

peak height difference and poor sensitivity. During a stop flow period of 1 min, about 55% of ascorbic acid was decomposed. This period may be suitably altered if the sample matrix behaviour is known.

### *Calibration graph and statistical data*

Calibration graphs were constructed under optimum flow injection conditions using the manifolds A and B, and by using standard solutions of ascorbic acid. The regression data are given in Table 1. In the determination of 1, 5 and 10 $\mu$g/ml ascorbic acid in pure solution, the RSD ($n = 6$) as found by using manifold A (*manifold B*) was, respectively, 1.8% (2.5%), 1.1% (1.5%) and 0.6% (1%). The detection limit[40] was 0.2 $\mu$g/ml (0.5 $\mu g/ml$) with a RSD of 3%(5%).

### *Validation of matrix correction method*

The matrix correction method was validated by determination of ascorbic in soft drink cola that originally contained no ascorbic acid and had strong UV absorbance owing to the colouring matter caramel. Suitable aliquots of cola and of ascorbic acid standards were mixed, diluted to known volume and analyzed using manifold A. The values of actual responses are given in Table 2, and the calibration data are in

close agreement with those obtained using pure ascorbic acid (Table 1).

### *Sample matric interference*

Using manifold A, the determination of 10 μg/ml of ascorbic acid was carried out without any matrix absorbance correction in the presence of known amounts of a large variety of substances which are usually present in soft drinks, fruit juices and pharmaceutical preparations, and include sweeteners, acids, colouring agents, preservatives, mineral salts, amino acids, vitamins and active drugs. Many substances which have a chromophore either a C=C bond or a benzenoid structure interfere severely by absorbing at 245 nm (Table 3). Iron(II) fumarate did not interfere owing to its insolubility in the carrier in which the solutions were prepared. To assess the efficacy of the alkali treatment as a method of sample blank determination, recovery tests were carried out on laboratory made synthetic samples which are known to contain interfering substances (Table 4). The average recovery was 101% (range 98–104%) and average RSD of 1.2% (range 0.6–2.1%) over all spikes. The average RSD on % recovery was 1.7%.

### *Applications*

The flow injection technique was applied to determine ascorbic acid in soft drinks and preserved fruit juices by using manifold A (Table 5), and for recovery studies on a soft drink spiked with known amounts of ascorbic

acid using manifold B (Table 6). Method using manifold A was used to determine ascorbic acid in drug formulations prepared in the laboratory (Table 7) and commercially available pharmaceuticals (Table 8).

Titration with iodine,[33] chloranil[15] and with 2,6-dichlorophenolindophenol titration,[32] and HPLC[30] were used to produce comparison results. In many samples there was a difference between the results obtained by the different methods. This difference was not considered to invalidate the present method as the titration methods are prone to interferences and the end-point was difficult to determine in coloured solutions. Because of the presenece of stabilizers, which are reducing in nature, and colouring matter, preserved fruit juices are believed to be difficult samples to analyze for ascorbic acid by a redox method. HPLC appears to tolerate most interferences and produce similar results.

## CONCLUSION

The present flow injection methods are very simple and rapid (2 min per sample), and have high sensitivity. Using a background correction with sodium hydroxide, the method is made selective for ascorbic acid. This also allows the use of 2-mercaptoethanol as an anti-oxidant in the carrier solution and in preparing the sample solution otherwise ascorbic acid at $\mu$g/ml level concentration are very difficult to keep at ordinary temperatures. The accuracy of the method has been illustrated for various soft drinks, preserved fruit juices and pharmaceuticals but with the good sensitivity attained it would also be suitable for biological samples.

# EFFECTS OF SOLVATION ON PARTITION AND DIMERIZATION OF BENZOIC ACID IN MIXED SOLVENT SYSTEMS

HIROMICHI YAMADA,[1]* KYOKO YAJIMA,[1] HIROKO WADA[1] and the late GENKICHI NAKAGAWA[2]

(*Received* 1 *August* 1994. *Revised* 28 *October* 1994. *Accepted* 1 *December* 1994)

**Summary**—The partition of benzoic acid between 0.1*M* perchloric acid solution and two kinds of mixed solvents has been carried out at 25°C. The partition and dimerization constants of benzoic acid have been determined in the 1-octanol–benzene and 2-octanone–benzene systems. In both the mixed solvent systems, with increasing content of 1-octanol and 2-octanone in each mixed solvent, the partition constant of benzoic acid has been found to increase, and the dimerization constant of benzoic acid in each organic phase to decrease. These phenomena are attributable to solvation of monomeric benzoic acid by 1-octanol and 2-octanone molecules in each mixed solvent.

Halogenated solvents such as chloroform, carbon tetrachloride, 1,2-dichloroethane, *etc.*, have ben extensively used not only in the field of solvent extraction but also in other branches of chemistry. However, environmental concerns have led to voluntary control for the use of these halogenated solvents. The selection of the most appropriate solvent is an important factor in solvent extraction and a new useful solvent is expected to be developed in the place of these halogenated solvents. Such a mixed solvent is anticipated to be useful for solvent extraction, but has not been appreciably investigated for solvent extraction. A mixed solvent which consists of two kinds of solvents may be expected to retain the inherent property of each solvent and to induce a synergistic effect between the two solvents. In a series of investigations on the extraction of some metals with LIX 26 in heptane, 1-octanol was used to avoid third phase formation as phase modifier by Olazabal *et al.*[1-3] In the extraction of aluminum with LIX 26 in heptane containing 5–15% 1-octanol, it was found that the extraction curve of aluminum is independent of the 1-octanol concentration.[1]

In an investigation on solvent extraction of metal ions, it is necessary to have information about the partition equilibrium of the extracting agent itself. The partition constant of benzoic acid and its dimerization constant in the organic phase were presented in 2-heptanone–dodecane–water ($H^+$, $Na^+$, $SO_4^{2-}$) systems by Kalembkevich.[4] However, the values presented by him seem to be unreasonable, judging from the relationship between the partition and dimerization constants of benzoic acid which was not touched upon at all in his work and is referred to in detail in our present work.

The present work deals with the partition equilibrium of benzoic acid, which is known to be useful for metal ions such as copper(II), between aqueous solution and mixed solvents consisting of benzene and 1-octanol or 2-octanone. It has been found that with increasing concentrations of 1-octanol and 2-octanone in each mixed solvent, the partition constant of benzoic acid increases, and the dimerization constant of the acid in each mixed solvent phase decreases in both the mixed solvent systems. Detailed explanation for these phenomena was attempted by considering the solvation of monomeric benzoic acid by 1-octanol and 2-octanone molecules.

## EXPERIMENTAL

### *Reagents*

Reagent grade benzene was washed successively with concentrated sulfuric acid, dilute sodium hydroxide solution, dilute perchloric acid solution, and distilled, deionized water. 1-Octanol and 2-octanone of reagent grade solvents were purified in a similar manner as for benzene except for concentrated sulfuric acid. Benzoic acid and perchloric acid were of reagent grade and used without further purification. Aqueous solutions were prepared with distilled, deionized water. Mixed solvents were prepared to a given volume by diluting known amounts (by weight) of 1-octanol or 2-octanone with benzene. Before mixing, each solvent was saturated with water. A trace amount of water which is negligible was released by mixing the two solvents.

### *Procedures*

A volume of 10 ml each of 0.1$M$ perchloric acid aqueous solution and mixed solvent (Tables 1 and 2) containing 0.05–1.4$M$ benzoic acid were added to a 50 ml centrifuge tube. After shaking for 1 hr, which is sufficient for complete equilibration, the tube was centrifuged for 5 min at 3000 rpm. Subsequently the concentration of benzoic acid in the aqueous phase was determined by measuring the absorbance of the aqueous phase diluted 100 times with 0.1$M$ $HClO_4$ aqueous solution, at 229 nm, one of absorption maxima of benzoic acid ($\varepsilon = 1.11 \times 10^4 M^{-1}$ cm$^{-1}$). Trace amounts of benzene in the aqueous phase did not interfere with the measurement of the absorbance at 229 nm, because before measuring the absorbance each aqueous phase was diluted 100 times with 0.1$M$ perchloric acid solution.

Table 1. Partition and dimerization constants of benzoic acid (1-octanol–benzene system)

| No. | Concentration of 1-octanol ($M$) | | $\log K_{D,HA}'$ | $\log K_{2,HA}'$ | Sum |
|---|---|---|---|---|---|
| 0 | 0 | (0) | 0.14 | 2.42 | 2.70 |
| 1 | 0.10 | (1.5) | 0.81 | 1.05 | 2.67 |
| 2 | 0.25 | (3.7) | 1.07 | 0.52 | 2.66 |
| 3 | 0.30 | (4.5) | 1.21 | 0.16 | 2.58 |
| 4 | 0.40 | (6.0) | 1.31 | −0.09 | 2.53 |
| 5 | 0.50 | (7.5) | 1.39 | −0.43 | 2.35 |

| 23 | 6.00 | (94.3) | 1.85 | — | — |
| 24 | 6.40 | (100) | 1.91 | — | — |

The values in parentheses and sum are the same as in Table 1.

### *Apparatus*

The partition of benzoic acid was performed in a Cool Bath Shaker ML-10 (TAITEC Co., Koshigaya, Japan) thermostatted at 25.0°C. A Table Top Centrifuge Model 5100 (Kubota Seisakusho Ltd, Tokyo, Japan) was used for centrifugation. The solubility of water in each mixed solvent was coulometrically measured using a Karl-Fischer Moisture Titrator MKC-210 (Kyoto Electronics Manufacturing Co., Kyoto, Japan). Spectrophotometric determination was carried out on a UVIDEC-430A Double Beam Spectrophotometer (Jasco, Tokyo, Japan).

## RESULTS AND DISCUSSION

### *Determination of partition and dimerization constants of benzoic acid*

The partition ratio of benzoic acid between the aqueous and organic phases can be represented by the following expression with the use of three kinds of equilibrium constants, *i.e.* the partition constant between the aqueous and organic phases ($K_{D,HA} = [HA]_o/[HA]_w$), the dimerization constant in the organic phase ($K_{2,HA} = [(HA)_2]_o/[HA]_o^2$), and the dissociation constant in the aqueous phase ($K_a = [H^+][A^-]/[HA]_w$):

$$D = \frac{C_{HA,o}}{C_{HA,w}} = \frac{K_{D,HA}(1 + 2K_{D,HA}K_{2,HA}[HA]_w)}{1 + \dfrac{K_a}{[H^+]}}, \quad (1)$$

where the subscripts o and w refer to the organic and aqueous phases, respectively, and $[(HA)_2]_o$ denotes the concentration of the dimeric benzoic acid in the organic phase. As the dissociation of benzoic acid in the aqueous phase is negligible under the present partition conditions, the following equation can be obtained from equation (1):

$$\log D - \log K_{D,HA} = \log(1 + 2K_{D,HA}K_{2,HA}[HA]_w). \quad (2)$$

If $\log D - \log K_{D,HA} = Y$ and $2K_{D,HA}K_{2,HA}[HA]_w = X$, equation (2) is equivalent to $Y = \log(1 + X)$. Then, on the basis of equation (2), by fitting the plots of $\log D$ against $\log[HA]_w$ with the normalized curve, $\log(1 + X)$ *vs.* $\log X$, the partition and dimerization constants can be estimated from the respective deviations of the ordinate and abscissa between the plots and the normalized curve. The results for 0.5 and 6.0*M* 2-octanone–benzene mixtures are shown in Fig. 1. The plots for the former fit well with the normalized curve described above. Then, the monomeric and dimeric species of benzoic acid were found to coexist in the organic phase in such mixed solvent. On the other hand, the plots for the latter are parallel to the horizontal axis, irrespective of the concentration of benzoic acid (Fig. 1). In this system, it has been shown that the dimerization of benzoic acid in the organic phase does not occur to any appreciable extent. The similar results were obtained in the mixed solvent systems containing 1-octanol of more than 1*M* and 2-octanone of more than 5*M*,

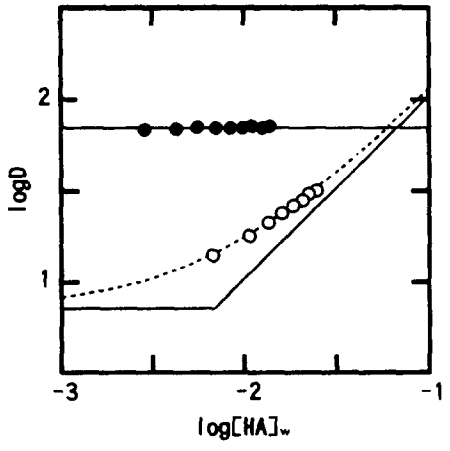

Fig. 1. Determination of the partition and dimerization constants of benzoic acid (2-octanone–benzene system). Open and closed symbols refer to the mixed solvents containing 0.5 and 6.0*M* 2-octanone, respectively. Dotted curve is the normalized curve, $\log(1 + X)$ *vs.* $\log X$. Solid lines are the asymptotes of the normalized curve.

respectively. In these cases the constant distribution ratio of benzoic acid is equal to its partition constant.

The values of the partition and dimerization constants of benzoic acid obtained for the 1-octanol–benzene and 2-octanone–benzene mixtures with various compositions are summarized in Tables 1 and 2, respectively. The values for pure benzene are also listed in the tables, and are in agreement with those presented by Fujii *et al.* within experimental error.[5]

As shown in the tables, with increasing the content of 1-octanol or 2-octanone in the mixed solvents, the partition constant of benzoic acid tends to increase, but the dimerization constant of the acid in each organic phase tends to decrease. These changes in the partition and dimerization constants of benzoic acid may be ascribed to solvation by 1-octanol and 2-octanone molecules.

*The effects of solvation on the partition constant of benzoic acid*

Benzoic acid is solvated with 1-octanol or 2-octanone molecules in the present mixed solvents in the following manner:

$$(HA)_o + n(S)_o \rightleftarrows (HA \cdot S_n)_o$$

with

$$\beta_{sv,n} = \frac{[HA \cdot S_n]_o}{[HA]_o[S]_o^n}, \quad (3)$$

where $S$ and $\beta_{sv,n}$ represent the solvent molecule, and the overall solvation constant of benzoic acid with 1-octanol or 2-octanone molecules, respectively. Then, in the region where the monomeric benzoic acid in the organic phase prevails, and the dissociation of benzoic acid in the aqueous phase is negligible, the distribution ratio of benzoic acid is equal to its conditional partition constant and can be represented as follows:

$$D = K_{D,HA}' = \frac{[HA]_o + \sum_n [HA \cdot S_n]_o}{[HA]_w}$$

$$= K_{D,HA}(1 + \sum_n \beta_{sv,n}[S]_o^n), \quad (4)$$

where $K_{D,HA}'$ and $K_{D,HA}$ denote the partition constants of benzoic acid for the mixed solvent and benzene, respectively. The partition constant of benzoic acid, which was determined in the present work, is this conditional constant, $K_{D,HA}'$ as shown below.

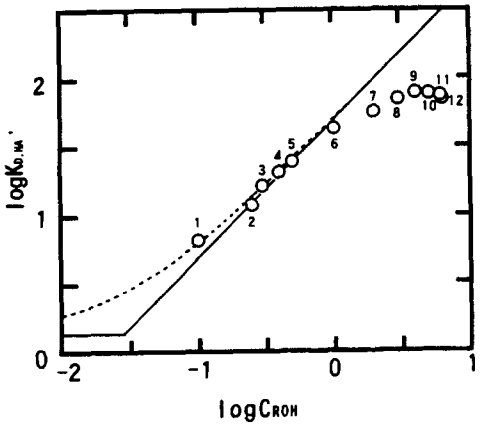

Fig. 2. Effect of solvation on the partition constant of benzoic acid (1-octanol–benzene system). Numbers are the same as in Table 1. Dotted curve and solid lines are the same as in Fig. 1.

If the main solvated species is only $HA \cdot S_n$, the following expression can be obtained from equation (4):

$$\log D = \log K_{D,HA}' = \log K_{D,HA} + \log(1 + \beta_{sv,n}[S]_o^n). \quad (5)$$

Substituting $\log K_{D,HA}' - \log K_{D,HA} = Y$ and $\beta_{sv,n}^{1/n}[S]_o = X$, the above expression is equivalent to $Y = \log(1 + X^n)$. According to equation (5), by fitting the plots of $\log K_{D,HA}'$ against $\log[S]_o$, with the normalized curve, $\log(1 + X^n)$ *vs.* $\log X$ with suitable $n$, the number of solvent molecules solvated to monomeric benzoic acid, and the solvation constant, $\beta_{sv,n}$ may be determined. Such plots are shown in Figs 2 and 3 for the 1-octanol–benzene and 2-octanone–benzene systems, respectively. In Figs 2 and 3, $\log K_{D,HA}'$ from Tables 1 and 2 is plotted against $\log C_S$

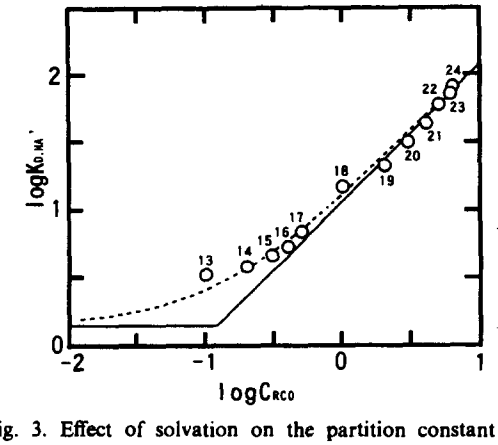

Fig. 3. Effect of solvation on the partition constant of benzoic acid (2-octanone–benzene system). Numbers are the same as in Table 2. Dotted curve and solid lines are the same as in Fig. 1.

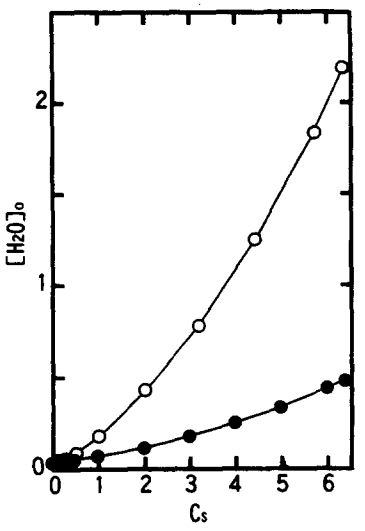

Fig. 4. Solubility of water in the mixed solvents. Open and closed symbols refer to the 1-octanol– and 2-octanone–benzene systems, respectively.

($C_S$: total concentration of 1-octanol or 2-octanone in each mixed solvent) instead of $\log[S]_o$. Under the present experimental conditions, $[S]_o$ can be approximated by the total concentration of 1-octanol or 2-octanone. The plots fit in the normalized curve with $n = 1$, *i.e.* $\log(1 + X)$ *vs.* $\log X$ in both the mixed solvent systems. It is suggested that the main monomeric species are HA and HA·S in each system. In addition, the solvation constant was obtained as follows: $\log \beta_{sv,1} = \log K_{sv,1} = 1.54$ for the 1-octanol–benzene system, and $\log \beta_{sv,1} = \log K_{sv,1} = 0.92$ for the 2-octanone–benzene system, respectively. As can be seen from Fig. 2, the plots deviate downward from the normalized curve, with increasing content of 1-octanol in the mixed solvent in the region where 1-octanol concentration is more than $1M$ in the 1-octanol–benzene mixture. In these regions the observed partition constant, $K_{D,HA}'$ is appreciably smaller than the value which is expected from solvation of benzoic acid by one 1-octanol molecule. The solubility of water in the mixed solvent increased with increasing concentration of 1-octanol in the mixed solvent (Fig. 4). Then, the decrease in the partition constant is attributable to the some effect of water on the mixed solvent and benzoic acid.

*Inhibition of dimerization of benzoic acid by solvation*

On increasing 1-octanol and 2-octanone contents in the respective mixed solvents, the dimerization constant of benzoic acid in the organic

phase decreased (Tables 1 and 2). Beyond 0.5*M* 1-octanol and 4.0*M* 2-octanone contents in each mixed solvent, respectively, the dimerization of benzoic acid did not occur to any appreciable extent in either mixed solvents. This decrease in the dimerization constant can be anticipated to result from the formation of solvated monomeric benzoic acid by 1-octanol or 2-octanone molecules. Taking into account solvation of monomeric benzoic acid by 1-octanol or 2-octanone molecules, the conditional dimerization constant of benzoic acid in each mixed solvent can be represented as follows:

$$K_{2,HA}' = \frac{[(HA)_2]_o}{([HA]_o + [HA \cdot S]_o)^2} = K_{2,HA}(1 + K_{sv,l}[S]_o)^{-2}, \quad (6)$$

taking logarithms of equation (6), the following expression is obtained:

$$0.5 \log K_{2,HA}' = 0.5 \log K_{2,HA} - \log(1 + K_{sv,l}[S]_o), \quad (7)$$

where $K_{2,HA}$ denotes the dimerization constant of benzoic acid in the benzene phase. The dimerization constant of benzoic acid estimated in this work is this conditional constant except for the pure benzene system. Substituting $0.5 \log K_{2,HA'} - 0.5 \log K_{2,HA} = Y$, and $K_{sv,l}[S]_o = X$, expression (7) is equivalent to $Y = -\log(1 + X)$. The plots of $0.5 \log K_{2,HA}'$ against $\log C_S$ on the basis of equation (7) are shown in Figs 5 and 6 for the 1-octanol–benzene and 2-octanone–benzene systems, respectively. As described above, $[S]_o$ can be approximated to the total concentration of 1-octanol or 2-octanone, $C_s$ under the present experimental conditions. The plots for 2-octanone–benzene system fit well with the normalized curve, $-\log(1 + X)$ *vs.* $\log X$ which is depicted on the basis of the values of $K_{2,HA}$ and $K_{sv,l}$ estimated in this work. Then, the decrease in the dimerization constant of benzoic acid is attributable to solvation of monomeric benzoic acid by one 2-octanone molecule as well as in the case of the increase in the partition constant of monomeric benzoic acid. On the other hand, the plots for the 1-octanol–benzene system deviate downward from the normalized curve in the region where the content of 1-octanol is more than 0.3*M*. Therefore, in this system the dimerization of benzoic acid has been suggested to be inhibited by not only solvation of monomeric benzoic acid by 1-octanol molecule but also some effects attributed to hydration by water molecules

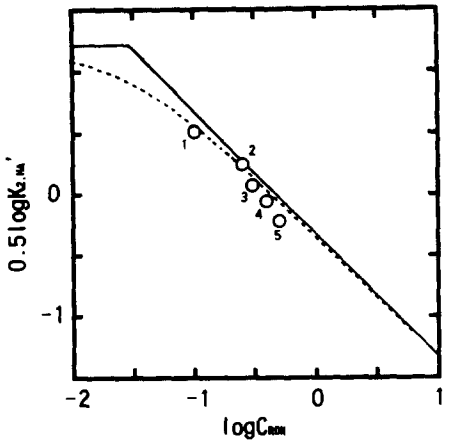

Fig. 5. Inhibition of dimerization of benzoic acid by solvation (1-octanol–benzene system). Numbers are the same as in Table 1. Dotted curve is the normalized curve, $-\log(1 + X)$ *vs.* $\log X$, which was located on the basis of $\log K_{2,HA} = 2.42$ in benzene and $\log K_{sv,l} = 1.54$. Solid lines are the asymptotes of the normalized curve.

whose concentration increases with increasing the 1-octanol content in this mixed solvent, or to the physical property of mixed solvent as a whole such as polarity, solubility parameter *etc.*

*Correlation of dimerization and partition constants of benzoic acid*

The relationship between the dimerization and partition constants of benzoic acid obtained in this work is shown in Fig. 7. The plots of $\log K_{2,HA}'$ *vs.* $\log K_{D,HA}'$ fit a straight line well with a slope of $-2$, which passes through the point for benzene, up to 0.25*M* of 1-octanol

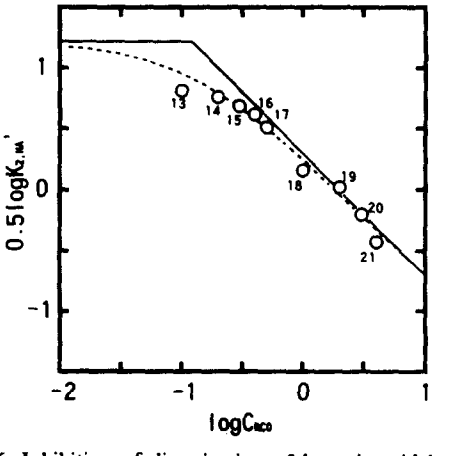

Fig. 6. Inhibition of dimerization of benzoic acid by solvation (2-octanone–benzene system). Dotted curve is the normalized curve, $-\log(1 + X)$ *vs.* $\log X$, which was located on the basis of $\log K_{2,HA} = 2.42$ in benzene and $\log K_{sv,l} = 0.92$. Numbers and solid lines are the same as in Table 2 and in Fig. 5, respectively.

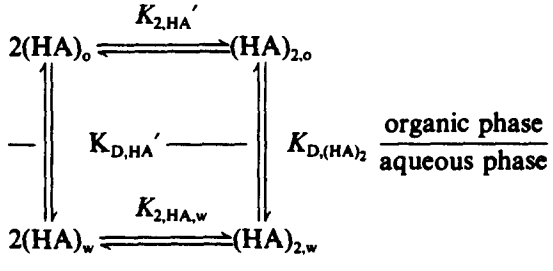
content in the 1-octanol–benzene system and 2.0$M$ of 2-octanone content in the 2-octanone–benzene system, respectively. In other words, the sum of $\log K_{2,HA}'$ and $2\log K_{D,HA}'$ is kept constant up to these contents of 1-octanol and 2-octanone in the respective mixed solvents (*cf.* Tables 1 and 2). In the 2-octanone–benzene system, the sum of $\log K_{2,HA}'$ and $2\log K_{D,HA}'$ is kept constant over the wide concentration region of 2-octanone, in contrast to the 1-octanol–benzene system, in which the sum remains constant only over the very limited concentration region of 1-octanol.

Similar relationships of the partition and dimerization constants of di-n-butyl phosphate[6] and some aliphatic carboxylic acids[7] for some organic solvents have previously been reported. However, the sum of $\log K_{2,HA}'$ and $2\log K_{D,HA}'$ reported by them varies widely from solvent to solvent, especially in the former case.

As the dissociation of benzoic acid in the aqueous phase can be neglected under the present experimental conditions, the partition behaviour of benzoic acid can be represented by the following scheme,



where $K_{2,HA,w}$ and $K_{D,(HA)2}$ denote the dimerization constant of benzoic acid in the aqueous phase, and the partition constant of dimeric benzoic acid, respectively. Then, the following relationship among the four kinds of equilibrium constants may hold:

$$\log K_{2,HA}' + 2\log K_{D,HA}' = \log K_{2,HA,w} + \log K_{D,(HA)2}. \quad (8)$$

From Fig. 7, and Tables 1 and 2, it is found that the value of the left-hand side of equation (8) tends to decrease rapidly from the constant value ($2.69 \pm 0.03$), when the 1-octanol and 2-octanone contents in each mixed solvent rise above 0.25 and 2.0$M$, respectively. As the dimerization constant of benzoic acid in the aqueous phase can be regarded as being constant, irrespective of the composition of the organic phase, the partition constant of dimeric

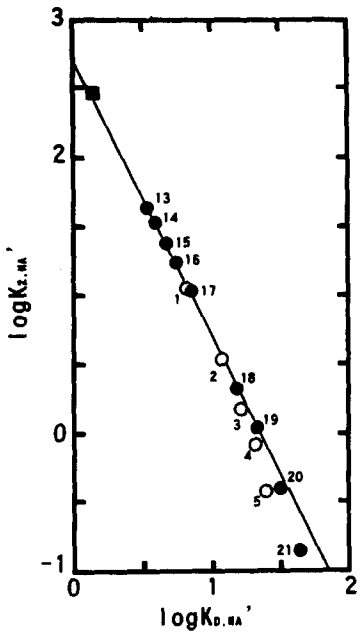


Fig. 7. Relationship between the partition and dimerization constants of benzoic acid. Open and closed symbols refer to the 1-octanol–benzene and 2-octanone–benzene systems, respectively. Closed square refers to benzene. Numbers are the same as in Tables 1 and 2. The solid line is a straight line with a slope of −2.

benzoic acid is also anticipated to remain constant under the region where the sum of $\log K_{2,HA}'$ and $2\log K_{D,HA}'$ remains constant, regardless of the composition of the mixed solvents. Therefore, it has been found that the partition behaviour of dimeric benzoic acid is difficult to be influenced by the solvent, contrary to that of monomeric benzoic acid which is subject to solvent effect. It is suggested that the main dimeric benzoic acid is the cyclic dimer in which two molecules are linked by a hydrogen bond, and because of the cyclic structure, dimeric benzoic acid is hard to be influenced by the solvent.

## CONCLUSIONS

As can be seen from Figs 2, 3, 5 and 6, significant differences in the solvent effect on the partition equilibrium of benzoic acid between 1-octanol–benzene and 2-octanone–benzene systems have been observed. This discrepancy may be attributed to whether the hydroxyl substituent is involved or not in the 1-octanol and 2-octanone which were mixed with benzene. In the 1-octanol–benzene system, the hydroxyl substituent in 1-octanol molecule is anticipated to enhance the solvation ability of the 1-octanol molecule and also to increase the solubility of water in 1-octanol–benzene mixed solvent by

hydrogen bonding. Enhancement of solvation ability is enhanced by the value of the solvation constant of monomeric benzoic acid, which is larger in the 1-octanol–benzene system than in the 2-octanone–benzene system. An increase in solubility of water in 1-octanol–benzene mixtures with increasing content of 1-octanol in the mixed solvents results in an increase in polarity as a whole and of the hydration ability of the mixed solvents. In a higher 1-octanol region of the mixed solvent, consequently, the partition and dimerization constants are anticipated to become smaller than those predicted by solvation of monomeric benzoic acid by the 1-octanol molecule.

In the 2-octanone–benzene systems, on the other hand, as shown in Figs 3 and 6, not only the increase in the conditional partition constant but also the decrease in the conditional dimerization constant may be reasonably explained on the basis of solvation of monomeric benzoic acid by 2-octanone. This suggests that the partition equilibrium of benzoic acid is not influenced to any appreciable extent by water, because of the lower concentration of water in the 2-octanone–benzene systems which can be attributed to the absence of the hydroxyl substituent in the 2-octanone molecule in contrast to the 1-octanol one.

In the 1-octanol–benzene systems, if it were not for the effects of water, the conditional partition constant of monomeric benzoic acid should be estimated to be log $K_{D,HA}' = 2.48$ by extrapolation to pure 1-octanol in Fig. 2.

It has been found that even such a simple equilibrium as the partition of benzoic acid is significantly dependent on kinds and contents of solvating solvents which are mixed with inert solvents. Then, the solvent extraction of a metal ion with an extracting reagent may be complicatedly influenced by kinds and contents of mixed solvents. Therefore, a useful mixed solvent for the solvent extraction of a metal complex can be expected to be developed by an additional investigation on mixed solvent for solvent extraction.

# THE IONIZATION CONSTANTS OF α-ALANINE IN NaCl AT 25°. EFFECT OF THE IONIC STRENGTH BASED ON THREE MODELS

S. FIOL, I. BRANDARIZ and M. SASTRE DE VICENTE*

Departamento de Química Fundamental e Industrial Facultad de Ciencias, Universidad de La Coruña, Campus da Zapateira, s/n 15071 La Coruña, Spain

**Summary**—In the present work we obtained the experimental p*K*s of the amino acid α-alanine in NaCl at 25° and different ionic strengths. The equilibrium constants have been potentiometrically determined with a commerical glass electrode and the results analysed through three models: two directly based on the Pitzer and Scatchard approaches to the ion specific interaction theory and the other based on a simpler modification of the Debye–Hückel equation. The three models fit the data reasonably well and the extrapolated p*K* values obtained show a good agreement. The goodness of the ridge regression method cannot be probed in this case.

The problem of the dependence of the protonation constants on ionic strength is of considerable importance both from theoretical and practical points of view.[1] However, systematic studies are scarce: a clear exception is the work by Sammartano *et al.*,[2–5] who have been using a semiempirical equation obtained by modifying the Debye–Hückel equation in order to find similarities in the behavior of some classes of ligands and for some background salts for several years. More recently, our group has started to study the dependence of the salt composition and ionic strength on the acid–base equilibrium constants of organic molecules both in single electrolytes and mixtures. The dependence mentioned above was assessed by using different models (Pitzer, Scatchard, Guggenheim[6–8]) which account for the specific interaction of any ion in solution. These treatments, mainly Pitzer's equations, have been widely used to determine the dependence of the osmotic and activity coefficients as a function of the ionic strength, particularly in aqueous solution of strong electrolytes. Weak electrolytes have been, however, scarcely dealt with, except for the work by Millero *et al.* on relevant inorganic equilibria in seawater.[9] In this work we report the ionization of α-alanine ($CH_3CHNH_2COOH$) at different ionic strength values in NaCl at 25°.[10] Data were treated in terms of Pitzer and Scatchard's models and the equations used by Sammartano *et al.*[4] Also the results were compared when the ridge regression (RR)[11] is applied instead of the ordinary least squares regression method, in order to overcome the presence of multicolinearity.[12]

## EXPERIMENTAL

The amino acids and NaCl were Merck (reagent and p.a. grade, respectively). Experimental details have been previously described.[13–16] Potentiometric titrations were carried out on a glass cell furnished with a thermostatting jacket and inlets for the electrode, burette and a nitrogen stream intended to remove $O_2$ and $CO_2$ and at the same time, homogenize the solution. Merck p.a. NaOH was added from a Crison microBU 2031 autoburette to the amino-acid solution containing Merck p.a. HCl, both 0.01*M*. The EMF was measured by means of a Crison micropH 2002 pH-meter furnished with Radiometer GK2401C combined glass membrane electrode, using Ag/AgCl as reference.

Stoichiometric equilibrium constants were calculated from data obtained in the potentiometric titrations of α-alanine by using the program MINIQUAD. The electrode was previously calibrated for the proton concentration in order to obtain the reference potential for each experiment. Calibrations were carried out for the pH-range between 2.3 and 2.9,[12] following the procedure described in Ref. 13 in order to minimize the influence of systematic errors. However, the response (nernstian or not)

*Author to whom correspondence should be addressed.

was checked in the whole interval. Known volumes of a 0.1*M* HCl solution of the desired ionic strength were added over a solution of the background electrolyte at the same ionic strength and the solution potential was measured on each addition.

The amino acid solutions were automatically titrated with the aid of the program ALIA,[17] (F. Penedo and F. Arce, unpublished work) which controls titrant additions from the burette, commands potential readings and creates the entry file for the program MINIQUAD. All regression analyses were performed by using the Statgraphics *Standard Statistical Package*.[17] The MINIQUAD provides p$K$ values in the molar scale while Pitzer and Scatchard models apply for molal scale. Conversion can be easily made from molar to molal scale: $pK_m = pK_c + \log(c/m)$, where $pK_m$ is in molal scale, $pK_c$ is in molar scale, $m$ is the concentration in mol/kg water and $c$ in $M$. The molality can be determined through the density. The expressions based on Sammartano *et al.*'s equations can be also used in molal scale since the difference owing to the p$K$ scale lies below the maximum experiment error conventionally admitted (*ca.* 0.06 p$K$ units).[18]

## RESULTS AND DISCUSSION

The protonation equilibria of neutral amino acids can be expressed as follows:

$$AH_2^+ \rightleftarrows AH + H^+, \quad K_1^T = K_1^* \frac{\gamma_{AH}\gamma_{H+}}{\gamma_{AH_2^+}} \quad (1)$$

$$AH \rightleftarrows A^- + H^+, \quad K_2^T = K_2^* \frac{\gamma_{A^-}\gamma_{H^+}}{\gamma_{AH}}. \quad (2)$$

The stoichiometric equilibrium constants of the aminoacid α-alanine are listed in Table 1. The final relationships obtained to show the $pK_i^*$ (in molal scale) dependence on ionic strength are as follows.

*Based on Pitzer's formalism*[19,20]

$$pK_1^* = pK_1^T + A_1 f^{(1)} + B_1 f^{(2)} + C_1 f^{(3)} \quad (3)$$

$$pK_2^* - D_2 f^{(4)} - E_2 f^{(5)} = pK_2^T + A_2 f^{(1)} + B_2 f^{(2)} + C_2 f^{(3)}, \quad (4)$$

where

$$A_1 = -\frac{1}{\ln 10}(\beta^0_{AH_2Cl} - \lambda - \beta^0_{HCl} + \theta_{AH_2Na} - \theta_{HNa}) \quad (5)$$

$$B_1 = \frac{-1}{\ln 10}(\beta^1_{AH_2Cl} - \beta^1_{HCl}) \quad (6)$$

$$C_1 = \frac{-1}{\ln 10}(\psi^\phi_{AH_2Cl} - C^\phi_{HCl} - \psi^\phi_{AH_2NaCl} - \psi_{HNaCl}) \quad (7)$$

$$A_2 = \frac{1}{\ln 10}(\beta^0_{ANa} + \theta_{ACl} + \beta^0_{HCl} + \theta_{HNa} - \lambda) \quad (8)$$

$$B_2 = \frac{1}{\ln 10}(\beta^1_{ANa} + \beta^1_{HCl}) \quad (9)$$

$$C_2 = \frac{1}{\ln 10}(C^\phi_{ANa} + C^\phi_{NaCl} + C^\phi_{HCl} + \psi_{ANaCl} + \psi_{HCaCl}) \quad (10)$$

$$D_2 = \frac{2\beta^1_{NaCl}}{\ln 10} \quad (11)$$

$$E_2 = \frac{2}{\ln 10}. \quad (12)$$

The ionic strength functions in equations (3) and (4) are as follows:

$$f^{(1)} = 2I$$

$$f^{(2)} = 1 - (2\sqrt{I})\exp(-2\sqrt{I})$$

$$f^{(3)} = I^2$$

$$f^{(4)} = -1 + (1 + 2\sqrt{I} + 2I)\exp(-2\sqrt{I})$$

$$f^{(5)} = -0.392\left(\frac{\sqrt{I}}{1 + 1.2\sqrt{I}} + \frac{2}{1.2}\ln(1 + 1.2\sqrt{I})\right). \quad (13)$$

*Based on Scatchard's formalism*[19]

$$pK_1^* = pK_1^T + P_1 I + Q_1 I^2 + R_1 I^3 \quad (14)$$

$$pK_2^* + \left\{\frac{2\sqrt{I}1.17202}{(1 + 1.5\sqrt{I})\ln 10}\right\} = pK_2^T + P_2 I + Q_2 I^2 + R_2 I^3, \quad (15)$$

*values in parenthesis correspond to the error in the parameters.
†$k$ is the ridge parameter: $k = 0$ applies for Ordinary Least Squares Regression and $k \neq 0$ for Ridge Regression.

where

$$P_1 = \frac{1}{\ln 10}\left(a^{(1)}_{HX} + b^{(0,1)}_{MX,HX} - a^{(1)}_{AH_2X} - b^{(0,1)}_{AH_2X,MX} + h_0\right) \quad (16)$$

$$Q_1 = \frac{1}{2\ln 10}\left(a^{(2)}_{HX} + b^{(0,2)}_{MX,HX} - a^{(2)}_{AH_2X} - b^{(0,2)}_{AH_2X,MX} + h_1\right) \quad (17)$$

$$R_1 = \frac{1}{3\ln 10}\left(a^{(3)}_{HX} + b^{(0,3)}_{MX,HX} - a^{(3)}_{AH_2X} - b^{(0,3)}_{AH_2X,MX}\right) \quad (18)$$

$$P_2 = \frac{1}{\ln 10}\left(a^{(1)}_{AH} + b^{(0,1)}_{MX,AH} + a^{(1)}_{MX} - h_0\right) \quad (19)$$

$$Q_2 = \frac{1}{2\ln 10}\left(a^{(2)}_{AH} + b^{(0,2)}_{MX,AH} + 2a^{(2)}_{MX} - h_1\right) \quad (20)$$

$$R_1 = \frac{1}{3\ln 10}\left(a^{(3)}_{AH} + b^{(0,3)}_{MX,AH} + 3a^{(3)}_{MX}\right). \quad (21)$$

Coefficients $A_i$, $B_i$, $C_i$ and $D_i$ in the Pitzer equations and $P_i$, $Q_i$ and $R_i$ in the Scatchard equations are parameters that result independently from the ionic strength and are related to the ionic interaction between the species involved in the equilibria and the medium.

*Based on a simpler modification of the Debye–Hückel equation*[2–5]

Among the very few systematic studies on ionization constants of organic compounds found in the literature we would like to mention the work carried out by Sammartano *et al.*[2–5] (and references therein). This group has systematically analysed the behaviour of such constants as a function of the ionic strength and the complex formation for a great number of

species: carboxylic acids, amines, amino acids, *etc.*

The general equation used by this group to express the stoichiometric equilibrium constants of amino acids is:

$$\log K_i^* = \log K_i^T - z_i^* \frac{\sqrt{I}}{2+3\sqrt{I}} + C_i I + D_i I^{3/2}, \quad (22)$$

where

$$C_i = p_i^* c_0 + z_i^* c_1 \quad (23)$$

$$D_i = p_i^* d_0 + z_i^* d_1 \quad (24)$$

$$p_i^* = \sum (\text{moles}_{\text{reactants}}) - \sum (\text{moles}_{\text{products}}) \quad (25)$$

$$z_i^* = \sum (pz^2)_{\text{reactants}} - \sum (pz^2)_{\text{products}}, \quad (26)$$

$z$ being the charge of the species. For the first equilibrium (1): $z^* = 0$ and $p^* = -1$ and for the second one (2): $z^* = 2$ and $p^* = -1$.

Taking these expressions into account, we can write the stoichiometric p$K^*$s as a function of the ionic strength by means of the following equations:

$$pK_1^* = pK_1^T - C_1 I - D_1 I^{3/2)} \quad (27)$$

$$pK_2^* + z^* \frac{\sqrt{I}}{2+3\sqrt{I}} = pK_2^T - C_2 I - D_2 I^{3/2}. \quad (28)$$

Table 2 shows for the three models the effect of multicolinearity between the explanatory variables in the calculation of highly correlated regression coefficients (close to unity) in the fitting interval used. This phenomenon is also revealed[12] by a value of the VIF (variation inflation factor) greater than 10, which is also shown in Table 3. From the data in Table 2 it follows that any of the assayed models reproduce experimental p$K^*$ *vs* I quite accurately and all the models yield similar curves (Fig. 1) and show an error of the fit within the conventionally admitted range for potentiometry wtih commercial $H^+$ glass electrodes (*ca.* 0.06 p$K$ units).[18]

The ridge parameters that appear in Tables 2 and 3 were obtained by applying the ridge trace method to equations (3), (4); (14), (15) and (27), (28). An analysis of the results also reveals that only for the p$K_2$ value does the application of ridge regression lead to smaller errors in the calculated parameters when using the Pitzer treatment. For the other parameters no improvement is observed.

The only parameter we can compare for the three models is the extrapolated p$K$. From Table 2 it can be concluded that good agreement can be achieved. For p$K_1^T$ the maximum difference between the values obtained is 0.03, which is under the 0.06 accepted as experimental error[18,21] and for p$K_2^T$ the difference become slightly greater that 0.06 p$K$ units, at 0.07. p$K_1^T$ values of $\alpha$-alanine in the literature[22] are very scarce and range from a minimum of 2.34 up to 2.63 while the averaged extrapolated value that we obtained is 2.55. The values found for p$K_2^T$ are 9.87, 9.89 and we obtained 10.08.

It can be concluded that although Scatchard and mainly Pitzer approaches are very useful for fitting data in wide ranges of $I$ and in mixtures of electrolytes, advantages that are not offered by other approaches, in the present case of a single electrolyte and a relatively reduced interval of ionic strength these models do not show remarkable superiority compared to a simpler model.

(*Received* 12 *October* 1994. *Revised* 5 *December* 1994. *Accepted* 5 *December* 1994)

**Summary**—A chemical separation method has been developed for the determination of $^{99}$Tc in various types of radioactive wastes. Such a method includes (i) fusion with NaOH, (ii) extraction in a column containing methyltrioctylammonium chloride, (iii) extraction by solvent with *N*-benzoyl-*N*-phenylhydroxylamine and, (iv) measurement by inductively-coupled plasma mass spectrometry (ICP-MS). From the performance standpoint, the recovery of $^{99}$Tc, using $^{99m}$Tc as a yield tracer, is higher than 70%. This analytical method, as developed, ensures effective decontamination with respect to the radionuclides, insofar the decontamination factors are greater than $10^{+5}$, whenever the residual activity may be measured. Taking into account a $3\sigma$ counting error, the detection limit obtained with the ICP-MS technique is 1.9 mBq/ml; the method enabling hence to detect activities as low as 0.3 Bq/g, with analysed samples of 0.2 g and a radiochemical yield of 70%. Studies have been dedicated to the $^{99}$Tc measurement, using the electrothermal vaporization ICP-MS technique, which lowers the detection limit by a factor 10, with the standard solution (0.3 pg/ml), compared with the previous ICP-MS technique.

Consideration has to be given to a number of long-lived radionuclides derived from the disposal of radwastes—and especially spent nuclear fuels, while assessing the environmental impact over the long term, of the nuclear power generation. It is thus essential to know the concentrations of long-lived nuclides (such as $^{79}$Se, $^{99}$Tc, $^{126}$Sn, $^{129}$I, $^{135}$Cs, $^{226}$Ra, $^{229}$Th, $^{237}$Np and $^{242}$Pu) as much in the spent nuclear fuels and other radwastes, as in the environment.[1] It is also mandatory to known the chemical behaviour of the radionuclides, to assess their transfer pathway in the environment over the long term, in the vicinity of the disposal sites. It stands to reason that the theoretical estimates to be validated by actual analytical determinations.

Among the whole spectrum of long-lived nuclides derived from nuclear reactors, special concern is given to $^{99}$Tc, on grounds of its long half-life (i.e. $2.2 \times 10^5$ *y*), decay mode ($\beta^-$), and the storage and disposal related problems, insofar $^{99}$Tc is very mobile in surface waters. Various analytical methods for determination of $^{99}$Tc in the environmental samples have been reported.[1] The techniques developed for $^{99}$Tc pre-concentration and/or pretreatment involve evaporation, [2,3] ion-exchange,[4,5] co-precipitation,[3,6,8] fusion,[8,9] and leaching with acidic solutions,[5,7,10,11]. The purification methods consist in co-precipitation with $(Ph)_4AsClO_4$,[12] ion-exchange[2,4,8–11,13,14] and extraction with organic solvents.[5,6,8,9,14,15] Such work does not concern radwaste samples containing radionuclides, which requires small-sized samples.

With respect to the determination of $^{99}$Tc in radwastes, the literature is scarce.[2,3] Compared with the environmental samples, determination of $^{99}$Tc in the radwaste samples differs basically insofar the latter contain several radioactive contaminants. Therefore, it is of the utmost importance to remove the associated ions from the radwaste samples used for the $^{99}$Tc separation.

The conventional method for $^{99}$Tc determination is $\beta$-counting either a low-background

proportional gas-flow counter, or a liquid-scintillation counter. This method has its drawbacks, as it requires a rather long counting time and a high degree of radiochemical $^{99}$Tc purification, to eliminate the $\beta$-emitting nuclides in the samples.

The inductively-coupled plasma mass spectrometry (ICP-MS) used until recent years,[18] has resulted in a very convenient method featuring low detection limits, which seems to be appropriate to radionuclides with a half-life exceeding 1000 years.[19] Halverson[20] and Rosenberg[1] have reviewed the application of mass spectrometry to the measurement of various low-concentration nuclides such as $^{99}$Tc, $^{129}$I, $^{135}$Cs and Pu isotopes.

This paper presents a method for measuring $^{99}$Tc derived from radwastes, using the ICP-MS technique. The separation method, as developed, enables to separate technetium from a 0.2-g radwaste sample, while using $^{99m}$Tc as a yield tracer (half-life: 6 hr). It also features the elimination from the $^{99}$Tc solution, of Ru—entailing isobaric interferences, and of many other radionuclides. Another advantage of this chemical separation method is that the ICP-MS may be used without a glove-box.

## EXPERIMENTAL

### *Apparatus*

The ICP-MS spectrometer used, was of the VG PlasmaQuad 2$^+$ type (VG Elemental, Winsford, Cheshire, U.K.). The operating parameters are shown in Table 1 The background at $m/z$ 101 was used for background correction at $m/z$ 99, in the absence of Ru. The scintillation spectrometer used, was a 1.K.B., Wallac 1410, with Instagel Packard. The activity of interfering radionuclides was measured with a high-purity germanium type detector (EGPC 18), connected to an appropriate data acquisition system.

### *Reagents*

A calibrated reference source of $^{99}$Tc has been purchased from L.M.R.I.,[21] and diluted in a 0.1*M* ammonia solution, having the appropriate specific activities. The $^{99}$Tc tracer has been derived from a medical $^{99m}$Tc generator (Elumatic III, 1.85 GBq, 50 mCi). Methyltrioctylammonium chloride and *N*-benzoyl-*N*-phenylhydroxylamine (BPHA) have been purchased from Aldrich Chemical Company Inc. All the chemicals were of the analytical-reagent grade.

*Glass filter (0.2 $g$), $^{99}Tc = 8$ $Bq/g$.

*Preparation of the extraction column*

Methyltrioctylammonium chloride (1 g) was dissolved in 10 ml of acetone/pentan (1:1) mixture. Voltalef 300 LDPL Micro (4 g) (Atochem) was added, with stirring, the mixture being further spread out and dried. The column (Wright DC 7/6 Amicon, dia. 8 mm) was filled with 1 g of the mixture. Before use, the column was washed with 50 ml of 0.1$M$ $HNO_3$.

*Chemical separation*

*Pretreatment.* The solid sample (0.2 g) taken from radwastes in a shielded box, was transferred to a nickel crucible, with 0.2 ml of the 12$M$ ammonia solution. An aliquot of $^{99m}Tc$ (5000 Bq)—as a tracer—was added to measure the radiochemical recovery. As regards the liquid waste sample, $^{99m}Tc$ was added to the solution which is adjusted to pH 7, with the 12$M$ ammonia solution. After volume reduction, the concentrated solution was transferred to the crucible. In any case, the resulting solution was dried at 150°C for 10 min prior to adding 4 g of NaOH. Fusion took place on heating to 600°C. After cooling down, 50 ml of 6$M$ $HNO_3$ were placed in the crucible and heated to 80°C. Twenty millilitres of 12$M$ ammonia solution were added and the solution was heated to reflux, and filtered after cooling. The dark blue solution was adjusted to pH 1.5, with 6$M$ $HNO_3$, prior to passing through the extraction column. The column was then washed with 50 ml of 0.1$M$ $HNO_3$ and the technetium was eluted with 20 ml of 6$M$ $HClO_4$.

*Purification.* The eluate was transferred to a separating funnel and was washed with 5 ml of $CHCl_3$; technetium was extracted twice with 10 ml of $CHCl_3$ 1%-BPHA w/v. The organic-phase was sent to another clean separating funnel, and washed with 10 ml of 6$M$ $HClO_4$. After adding 10 ml of 0.01$M$ $HNO_3$, the solution was stirred for 3 min to facilitate the technetium back-extraction to aqueous phase. This was performed twice to recover technetium more efficiently. The volume was then adjusted to 25 ml with 0.01$M$ $HNO_3$, and the $^{99m}Tc$ tracer activity measured by $\gamma$-counting. The final solution may be concentrated up to 2 ml, without dry evaporation.

## RESULTS AND DISCUSSION

The chemical separation method, described herein, has been developed with various kinds of radwaste, the sampling solutions being prepared using glass filters, ion-exchange resins, cellulose paper, textiles, distillation residues and waste-embedding bitumen. The technique developed for $^{99}Tc$ pretreatment involves fusion with NaOH prior to passing through an extraction column containing methyltrioctylammonium chloride, which is an ion-exchange reagent. The purification process used consists in extraction with BPHA (*N*-benzoyl-*N*-phenylhydroxylamine) ligand, dissolved in an organic solvent. BPHA is used extensively for the extraction of metal ions from aqueous solutions. Being an acidic extractant, this reagent generally extracts metal cations into organic solvents as chelates. This chemical separation method has been selected as it features a high percent of $^{99}Tc$

chemical recovery and an acceptable level of decontamination with respect to the radionuclides, as described below.

It is difficult to determine the chemical recovery of $^{99}$Tc, because technetium has no stable isotope. The $^{95m}$Tc[22], $^{97}$Tc[23] and $^{99m}$Tc[16] radionuclides have been used as yield tracer. As regards the chemical separation method described herein, the radwaste samples have been mixed with a $^{99m}$Tc tracer (half-life: 6 hr) obtained from a medical $^{99m}$Tc generator, the radiochemical recovery being performed by $\gamma$-counting, once the whole chemical separation is over.

*Pretreatment*

The pretreatment method has been developed, first with non-radioactive simulated samples, the solutions being prepared, using clean silica filters, cellulose filters, and ion-exchange resins. $^{99}$Tc is added to determine a specific radiochemical yield, with both $\beta$-counting and ICP-MS techniques. During the fusion process, the sample was completely dissolved whatever might by the matrix used. The loss of $^{99}$Tc observed at 600°C was less than 20%, as shown in Table 2. Technetium results to be more volatile from acidic solutions evaporated to dryness.[24] Most of the constituent elements prevailing in the initial solution were eliminated on passing through the extraction column, and the $^{99}$Tc recovery was then greater than 75%.

*Purification*

The purification method has been developed with radioactive-sample solutions. Table 3 shows the activities of the radionuclides present in the solution prepared from one of the radwastes used. As an instance, $^{99}$Tc activity was 8 Bq/g. Table 4 shows the decontamination factors of the main radionuclides ($^{54}$Mn, $^{60}$Co, $^{110m}$Ag and $^{137}$Cs). One may observe that the developed analytical procedure provides an effective extraction capability with respect to the nuclides. Using the extraction column, more than 99% of the original radioactive elements are separated from the technetium. The purification method complemented the radionuclide decontamination carried out with the chemical separation method. The decontamination fac-

*Average of three replicate determinations (ICP-MS) on 0.2 *g* waste samples.

tors were all over $10^{+5}$, when the residual activities can be measured: $^{99m+99}$Tc is extracted selectively in the organic phase (BPHA/$CHCl_3$), and no other radionuclides are found in the final chemical extract. Fouché,[25] in an extensive investigation of the extraction of pertechnetate ions by BPHA from perchloric acid solutions, found that Tc(VII) is extracted and that the extracted compound contains pertechnetate in a 1:1 ratio to BPHA.

### *$^{99}$Tc measurement by ICP-MS*

Determination of $^{99}$Tc by ICP-MS requires that $^{99}$Tc be free of Ru ($^{99}$Ru mass abundance: 12.7%) and free of Mo ($^{98}MoH^{+}$ having the same mass number as $^{99}$Tc). $^{99m}$Tc, as a tracer, was added to a solution prepared with Ru (4 mg/l.), Mo (4 mg/l.) and a silica-filter (0.2 g), to determine the extraction factors of Ru and Mo. After chemical processing, the $^{99m}$Tc chemical recovery was 70%, and a mass spectrum of the final solution was obtained (Fig. 1). As shown in Fig. 1, Ru is eliminated from the $^{99m}$Tc solution. Although the $^{98}$Mo peak is developed, no interferences from $^{98}MoH^{+}$ is reported. Table 5 shows Ru and Mo concentrations and the extraction factors, all greater than $10^{+5}$.

Furthermore, $^{99}$Tc, $^{106}$Ru and $^{99}$Mo were added to a solution prepared with a silica filter (0.2 g), as radiochemical tracers. On completion of the chemical process, the $^{106}$Ru was trapped with $^{99}$Tc, in the extraction column, but not extracted with BPHA ligand. As regards $^{99}$Mo, it was not trapped in the column, hence eliminated. In this case, the decontamination factors were also over $10^{+5}$.

### *Precision and minimum detectable activity*

The data presented in Table 6 serve to illustrate the precision of the technique as well as the levels of $^{99}$Tc present in 0.2 g waste and the overall yield typically obtained. The precision of determination depends on the concentration of $^{99}$Tc in final solutions but not of the initial radwaste used. The overall yield of $^{99m}$Tc recovery is, as a rule, greater than 70%, independently of the original material. The results secured by the ICP-MS technique have been compared with those obtained by the liquid scintillation counting method. The results were in good agreement (Table 7).

The detection limit, 1.9 mBq/ml (3 pg/ml) was lower than that for the liquid scintillation counting method (38 mBq/ml), as shown in Table 8. The detection limit ($3\sigma$ counting error) with respect to the ICP-MS technique was calculated

Table 7. Agreement between the ICP-MS and $\beta$-counting method measurements of $^{99}$Tc

| | $^{99}$Tc (*Bq/g*) | |
|---|---|---|
| Radioactive waste | ICP-MS | $\beta$ counter |
| Textile | $(9.1 \pm 0.1) \times 10^{+3}$ | $(9.3 \pm 0.4) \times 10^{+3}$ |
| Water | $43.0 \pm 1$ | $49 \pm 5$ |
| Water | $19.8 \pm 0.8$ | $20 \pm 10$ |

†High resolution ICP-MS.[27]

from the measurements carried out with 10 blank solutions obtained on completion of the chemical process—without using any radioactive sample—and from 10 measurements carried out with a standard $^{99}$Tc solution. The minimum detectable activity of the developed analytical procedure with a radiochemical yield of 70% and an analysed sample of 0.2 g, was found to be 0.3 Bq/g using ICP/MS, and 18 Bq/g with $\beta$-counter.

The chemical separation procedure took approximately one day, providing high chemical recoveries of technetium from limited amounts of radwastes containing many interfering elements. Using the autosampler in conjunction with the ICP-MS technique, up to four samples per hour could be analysed, which was much faster compared with the conventional counting techniques.

### *$^{99}$Tc measurement with ETV technique*

Lower detection limits can be obtained with more radioactive waste sampling. It is also possible to reduce the final solution from 25 to 2 ml and/or use electrothermal vaporization inductively coupled plasma spectrometry (ETV-ICP-MS), ETV as a means of sample introduction into an ICP-MS instrument.[26] Using this method, 50 $\mu$l of solution are placed in a graphite furnace, and by controlling the heating cycle, the samples can typically be dried, ashed, and then vaporized at temperatures up to 2800°C, using argon as the carrier gas. ETV-ICP-MS has been applied, chiefly, to improve the detection limits by a factor of 10 to 100, compared with the pneumatic nebulization methods (ICP-MS). The determination of technetium by ETV-ICP-MS has not been reported in the literature.

Our preliminary analytical results obtained with $^{99}$Tc standard solutions indicate detection limits of 0.3 pg/ml ($^{99}$Tc: 0.015 pg introduced). Unfortunately, it was not possible to obtain good results with solutions containing 0.01*M* $HNO_3$ because of the volatility of technetium from acidic solutions. Standard ammonia solutions of $^{99}$Tc could only be used. We are presently modifying the purification method to be able to use the ETV-ICP-MS technique. Likewise, we are investigating the possibility for using a chemical modifier to be inserted with the sample in the graphite furnace, which would prevent untimely $^{99}$Tc evaporation.

# UPTAKE OF CESIUM, STRONTIUM AND EUROPIUM BY A POLY(SODIUM ACRYLATE–ACRYLIC ACID) HYDROGEL

E. H. RIFI, F. RASTEGAR and J. P. BRUNETTE*

Laboratoire de Chimie Minerale et Analytique, E.H.I.C.S., C.N.R.S. URA 405, 1, Rue Blaise Pascal, 67008 Strasbourg Cedex, France

(*Received* 14 *October* 1994. *Revised* 2 *December* 1994. *Accepted* 2 *December* 1994)

**Summary**—The uptake of cesium, strontium and europium from dilute nitric acid solutions by a poly(sodium acrylate–acrylic acid) PAA hydrogel has been investigated. pH variations are consistent with cation exchange processes: $—COO^-$, $Na^+/H^+$, $—COO^-$, $Na^+/M^{m+}$ ($M^{m+} = Cs^+$ and $Sr^{2+}$) and $—COOH/Eu^{3+}$. Saturation of the gel is achieved for metal/carboxylate ratios $R = 0.5$. The swelling ratios of gels loaded with metal cations are those of uncharged, shrunk gels (Sr, Eu) or of charged, swollen gels (Cs) in agreement with the formation of uncharged $(—COO)_2Sr$, $(—COO)_2EuX$ (X = $NO_3$ or OH) type complexes and $(—COO^-, Cs^+)$ ion pairs. The metal cations are extracted in the gels following the order of their affinities with carboxylic groups $Eu^{3+} > Sr^{2+} > Cs^+$. An increase of the ionic strength of the metal aqueous solution up to 0.5*M* $NaNO_3$ leads to slightly decrease the europium uptake by the PAA hydrogel, but 0.1*M* $NaNO_3$ is sufficient to prevent the Sr and Cs extractions.

Swelling polymer (or copolymer) networks (polyethylene, polybutadiene, polystyrene, polyvinylchloride, polyurethane . . .) with solubility-consistent metal extracting solvents leads to lipophilic gels or impregnated resins which can be applied to recovery of precious metals, to removal of toxic or radioactive elements from various effluents and to metal preconcentration for environmental sample analysis.[1–9] Metal coordinating resins have also been extensively studied with the aim of preventing loss of expensive (but selective) ligands in the aqueous phase.[10] Because of the lipophilic character of neutral coordinating resins, the water–resin contact is often weak, thus limiting the ligand accessibility and the extraction rate.[11] Moreover, a number of these materials are expensive and their applications remain very specific. On the contrary, the water 'superabsorbent' property of cheap hydrophilic polymer or copolymer networks (e.g. hydrolysed polyacrylamide, ionized polymethacrylic and polyacrylic acids) has led to important applications in hygiene and agriculture, and also in concentrating macromolecular solutions by selective water absorption.[12] Since only a few of fundamental investigations on the complexation of metal cations with polyelectrolyte hydrogels were available,[13–22] application to metal recovery from dilute effluents have been patented only recently.[23] Water absorption in the hydrophilic polymer network warrants an excellent accessibility of the metal coordinating moieties, but the volume variations of the hydrogel, with pH and metal cation binding, must be considered in liquid–hydrogel extraction processes. Thus, further informations on the hydrogel behaviour immersed in metal cation solutions are needed with particular attention paid to the interdependence of physical and chemical parameters involved: *i.e.* metal valence, pH and ionic strength of the metal feed solution, gel swelling and shrinking, nature of the metal–carboxylate interactions, *etc.* The present paper deals with the uptake of metal cations of different valencies, cesium, strontium and europium, three metal ions which are relevant in radio-

active waste management, by a poly(sodium acrylate–acrylic acid) polymer network.

## EXPERIMENTAL

### *Reagents*

10SHP Super Absorbent Polymer (SAP), which is a poly(sodium acrylate–acrylic acid) polymer network, was supplied from Norsolor-Atochem Co. This material consists of 'cauliflower' type beads of about 0.5 mm average diameter. It is 1% cross-linked with diethylene glycol diacrylate, 80% ionized and contains 10 mmol —COO(H, Na)/g (residual water contents: 9%). All other chemicals, from Prolabo, Merck or Fluka, were of analytical grade.

### *Gel preparation*

Super absorbent polymer gels (SAPGel) were prepared by immersing 0.1 g of SAP network into 200 ml of bidistilled water. The excess of water was removed by filtration giving (46.8 ± 0.1) g of SAPGel.

### *Metal extraction and analytical procedure*

The following general procedure was used: SAPGel (0.94 g = $2.0 \times 10^{-5}$ mol —COO(H, Na) or 2 mg SAP network) was introduced into a thermostatted vessel (25.0 ± 0.2°C) containing 100 ml of $1 \times 10^{-4}M$ metal ion aqueous solution prepared with nitrate salts (Cs, Sr) or oxide (Eu). The gel samples were suspended in a small cotton gauze bag to avoid breakage during stirring using magnetic bars rotated at about 200 rpm. In order to avoid the erratic presence of $CO_2$, the experiments were run in stoppered vessels. Aliquots of metal ion solution were withdrawn and analysed, after suitable dilution by atomic emission (Cs, Sr) using a 2380 Perkin Elmer or a JY24 Jobin-Yvon ICP spectrophotometer, or by energy dispersive X-ray fluorescence (Eu) using an EDXRF Siemens prototype. Metal inside the gel was determined by mass-balance calculation or analysed after back extraction in $0.1M$ $HNO_3$. pH, measured with a digital pHmeter and a combination glass-reference electrode, was adjusted with concentrated $HNO_3$.

### *Gel swelling*

The gel swelling was measured by weighing the gel before and after contact (4–6 hr) with the aqueous solution.

## RESULTS AND DISCUSSION

### *SAPGel behaviour in aqueous solutions free of metal cations*

*Swelling.* If a SAPGel network is soaked in dilute $HNO_3$ solutions of various concentrations and free of metal cations, an internal acid–base rearrangement of the polymer is observed which is clearly indicated by a slow decrease of the hydrogen ion concentration in the outer solution. The higher the pH, the higher is the SAPGel ionization and, consequently, its swelling. Swelling ratios ($Q$) at various pH measured at equilibrium are given in Table 1.

It is interesting to note that, at pH 2.5, the swelling ratio decreases from 70 to 40 when the quantity of immersed SAP network increases from 2.0 to $7.6 \times 10^{-5}$ mol —COO(H, Na): in both cases, the resulting gel is neutral, *i.e.* entirely protonated and uncharged, and the more the $Na^+$ release in the outer solution, the less is the swelling ratio. An opposite behaviour is observed at pH 7, which probably means that the effective gel ionization, responsible for the swelling, is a little higher in the latter case. The swelling ratio is strongly dependent on the ionic strength of the outer solution: *e.g.* $Q$ = 370, 95, 55 and 45 when 9.4 mg of SAP network is

Table 1. Swelling of the SAP network in dilute $HNO_3$ (100 *ml*)

| | Free of metal cations | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| pH | 2.5 | 3.4 | 3.85 | 4.7 | 5.46 | 6.0 | 7.0 | —COO(H, Na) |

| $R$ | 0.20 | >0.8 | 0 | 0.42 | 0 | 0.50 |
| $Q$ | 190 | 210 | 38 | 36 | 70 | 70 |

soaked in 100 ml of water at $pH_i$ 5.4 and containing 0, 5, 25 and 100 g/l. $NaNO_3$, respectively.

*Dissociation.* It is not easy to determine the dissociation constant of carboxylic groups bound to the SAPGel because of the difficulties to measure the hydrogen ion concentration within the gel. One can consider the total gel in equilibrium with the outer solution but its titration leads to important changes of volume (1–500) and, moreover, several hours are needed to reach equilibrium in every step of titration. Nevertheless, it is interesting to note that the ionization ratio of the SAPGel is $\alpha = 0.5$ at pH 6.0 (pH of the outer solution after equilibration of 2 mg of SAP network soaked in 100 ml $HNO_3$ $10^{-4.2}M$). This value is close to the intrinsic $pK_a$ of the linear polyacrylic acid (6.17) at low ionic strength.[13]

*Cesium uptake*

When a SAPGel (*species in SAPGel) is soaked in a cesium nitrate solution, the cesium concentration in the outer solution decreases rapidly to reach a minimum after 20 min, then it slightly increases and reaches a stable value about 30 min later (Fig. 1). During this time, the pH increases and then stabilizes after 50 min. It is likely that during the first 20 min both *—$COO^-$, $Na^+/H^+$ and *—$COO^-$, $Na^+/Cs^+$ exchanges occur (reactions 1 and 2). After 20 min, excess of cesium in the gel is released in the outer solution (*—$COO^-$, $Cs^+/H^+$ exchange) because of the final acid–base rearrangement of the gel.

$$*\text{—}COO^-, Na^+ + H^+ \underset{-1}{\overset{1}{\rightleftarrows}} *\text{—}COOH + Na^+ \quad (1)$$

$$*\text{—}COO^-, Na^+ + Cs^+ \underset{-2}{\overset{2}{\rightleftarrows}} *\text{—}COO^-, Cs^+ + Na^+. \quad (2)$$

The cesium uptake, noticeable above pH 4.5, increases with pH and becomes constant above pH 6.5 with $R = 0.13$ [$R$ = mol metal in gel/total mol —COO(H, Na)] (Fig. 2). It is drastically lowered if $NaNO_3$ is added to the outer solution: no cesium extraction is observed from 0.1 to 0.5$M$ $NaNO_3$ at pH 7. These results agree with a cesium uptake via equilibrium 2.

Increasing the cesium concentration of the outer solution leads to increase the cesium uptake. A maximum occurs at $R = 0.5$ ($[Cs^+]_i > 6 \times 10^{-4}M$, pH 7) (i = initial parameters before liquid–gel contact). This value, far from 1, can be explained by the difficulty encountered by two cesium cations in approaching two neighbouring carboxylate anions because of the large $Cs^+$ size, and electrostatic repulsions. Thus, at saturation, each *—$COO^-$,

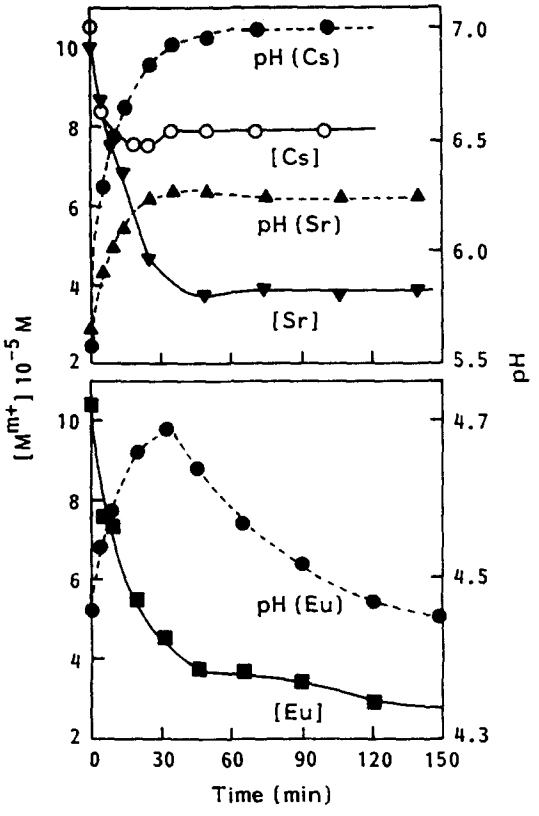

Fig. 1. Variations of the pH and metal ion concentration of an aqueous solution (100 ml) in contact with a SAPGel [—COO(H, Na) $2.05 \times 10^{-5}$ mol; $pH_i = 5.57$ (Cs), 5.66 (Sr), 4.46 (Eu); $[M^{m+}]_i = 1 \times 10^{-4}M$].

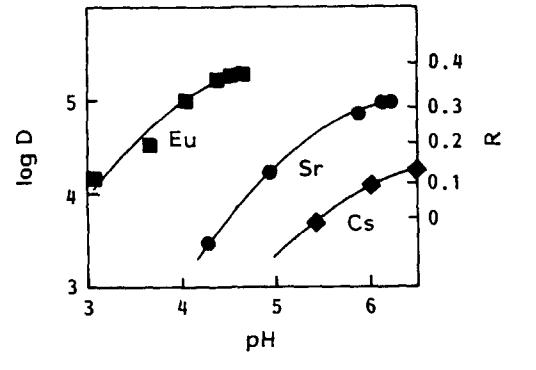

Fig. 2. pH effect on the uptake of cesium, strontium and europium from an aqueous solution (100 ml, $[M^{m+}]_i = 1 \times 10^{-4}M$) by a SAPGel [—COO(H, Na) $2.05 \times 10^{-5}$ mol]. pH measured at equilibrium (only $[HNO_3]_i$ was varied), shaking time > 3 hr. $R$ = mol metal in the gel/total mol —COO(H, Na). $D$ = [(metal amount/g of dry polymer)]/[(metal amount/ml of liquid phase)].

$Cs^+$ is probably surrounded by *—$COO^-$, $Na^+$ moieties.

Attempts to describe quantitatively the uptake of cesium and other cations ($Sr^{2+}$, $Eu^{3+}$) using elementary adsorption functions have failed: indeed, variations of ion concentrations in the outer solution lead to change the gel volume and the ion activities within the gel which are difficult to determine.

It is interesting to note that the swelling ratio of SAPGel loaded with cesium is that of a charged (ionic) gel since $Q = 190$ ($m/m_1$, swelling ratio) at pH 7.15 and $R = 0.2$ ($7.6 \times 10^{-5}$ mol —COO(H, Na) in 100 ml $[Cs^+]_i = 3.15 \times 10^{-3} M$), close to $Q = 210$ measured under the same experimental conditions in the absence of cesium (replace by $[Na^+]_i = 3.15 \times 10^{-3} M$) (Table 1). Thus, the uptake of cesium by the gel as *(—$COO^-$, $Cs^+$) ion pairs can explain the gel behaviour in cesium nitrate solutions.

*Strontium uptake*

The kinetics of strontium removal from a dilute aqueous solution by extraction into a SAPGel are shown in Fig. 1: pH of the outer solution increases whereas the strontium concentration decreases, both stabilizing about 1 hr after immersing the SAPGel into the solution. Both equilibria 3 and 4 could explain the strontium uptake:

$$n\text{*—COOH} + Sr^{2+} \underset{-3}{\overset{3}{\rightleftarrows}} \text{*(—COO)}_n Sr^{(2-n)+} + nH^+ \quad (3)$$

$$n\text{*—COO}^-, Na^+ + Sr^{2+} \underset{-4}{\overset{4}{\rightleftarrows}} \text{*(—COO)}_n Sr^{(2-n)+} + nNa^+, \quad (4)$$

where $n = 1$ or 2 and water molecules are omitted.

Strontium uptake via reaction 3 would have induced a significant pH decrease down to 4–4.5, which is not observed. On the contrary, a pH increase occurs in agreement with a *—$COO^-$, $Na^+/H^+$ exchange (reaction 1). It can be concluded that the strontium uptake mainly proceeds via reaction 4. The kinetics of the metal ion uptake process is relatively slow, but one must remember that fully swollen gels have been used in the present experiments: it follows that the diffusion of ions inside the hydrogel is likely the rate limiting factor. This is supported by a previous work[24] which has shown that increasing the cross-linking ratio of an hydrogel leads to a faster metal uptake because of a weaker polymer swelling and consequently a shorter diffusion distance inside the gel. Of course, the metal uptake becomes faster if the dry and unswollen polymer SAP network is directly soaked in the metal ion solution: in this case, the polymer network first swells but, because of the neutralization of electric charges by metal ion binding to the carboxylate anions, it quickly deswells.[25]

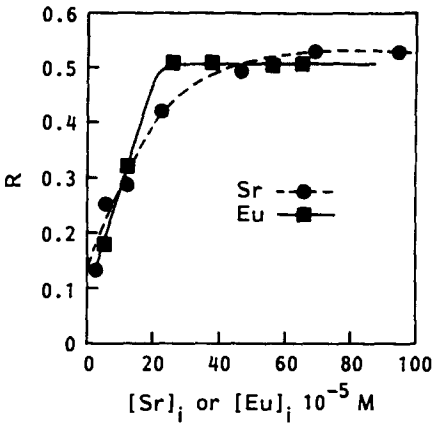

Fig. 3. Effect of the metal ion concentration on its uptake by a SAPGel [—COO(H, Na) 2.05 mol] immersed in 100 ml of aqueous solution. Strontium: $pH_i = 5.5$, europium: $pH_i = 3.9$. $R$ = mol metal in the gel/total mol —COO(H, Na).

The pH dependence of the liquid–gel strontium extraction is shown in Fig. 2: the extraction increases up to pH 6 and remains constant with $R = 0.32$. Increasing $[Sr^{2+}]_i$ (Fig. 3) leads to a saturation effect at $R = 0.53$ which is close to the stoichiometry of *$(—COO)_2Sr$ complexes. Swelling ratio measurements (Table 1) support the formation of such neutral complexes into the gel: indeed, when 7.5 mg SAP network are soaked in 100 ml of a strontium nitrate solution ($[Sr^{2+}]_i = 3.15 \times 10^{-3} M$), the swelling ratios are $Q = 36$ at pH 5.46 with $R = 0.42$, and $Q = 38$ at pH 2.50 with $R = 0$. In the absence of strontium, the swelling ratios are 250 and 40, respectively. At pH 2.50, the gels are uncharged and shrunk. At pH 5.46, it is likely that the formation of neutral (*—$COO)_2Sr$ type complexes explains the gel shrinking from 250 (charged gel) to 36 (uncharged and complexed gel). Similar results were previously found with other divalent cations, notably for $Cu^{2+}$ and $Cd^{2+}$.[25]

As previously observed with cesium, no strontium uptake by SAPGels was observed from 0.1 to $0.5M$ $NaNO_3$ solutions at pH 6.25, an obser-

vation which supports the strontium uptake via equilibrium 4.

Strontium removal from 100 ml of an aqueous solution (4.2 mg/l. Sr, $pH_i$ 5.6) can be achieved by soaking consecutively five SAPGels each containing $2 \times 10^{-5}$ mol —COO(H, Na): 80% Sr are removed by the first gel, whereas the Sr concentration after treatment with the fifth gel drops to less than 0.05 mg/l.

*Europium uptake*

The europium removal from an europium nitrate aqueous solution by a SAPGel is shown in Fig. 1. The pH *vs.* $t$ (current time) and $[Eu^{3+}]$ *vs.* $t$ diagrams deserve some comments: the pH increases from 4.46 to 4.70 where a maximum is reached after 30 min, then it decreases slowly to stabilize at 4.40 several hours later. $[Eu^{3+}]$ decreases rapidly during the first 30–50 min and remains almost constant after about 2 hr. Gel protonation (reaction 1) may explain the pH increase during the first 30 min. In the same time *—$COO^-$, $Na^+/Eu^{3+}$ cationic exchange can occur but after 30 min, the *—COOH form becomes predominant over *—$COO^-$, $Na^+$ and a release of protons is observed because of *—$COOH/Eu^{3+}$ cationic exchange. The very different trends of pH *vs.* time curves in Fig. 1 result from the different pH ranges of the metal liquid–gel extraction: Sr and Cs are extracted in the pH range 5.5–7 where the *—$COO^-$, $Na^+$ form predominates over *—COOH, whereas Eu is extracted in the pH range 4.4–4.7 where the *—COOH form predominates. Accordingly, the Cs and Sr uptakes proceed via *—$COO^-$, $Na^+/M^{m+}$ exchange, whereas Eu extraction proceeds via *—$COOH/Eu^{3+}$ exchange which induces a release of hydrogen ions in the outer solution. Unlike Cs and Sr extractions which are strongly decreased by increasing ionic strength of the outer solution, Eu extraction is only slightly decreased: $-20\%$ from $[NaNO_3] = 0$ to $[NaNO_3] = 0.5M$. This is in agreement with the suggested metal extraction process.

At pH 3.85, the gel saturation with europium occurs at $R = 0.50$ (Fig. 3). The swelling ratio drops from $Q = 120$ (in the absence of $Eu^{3+}$) down to $Q = 70$ because of the europium gel binding: indeed, 70 is the swelling ratio of the uncharged SAPGel measured at pH 2.5 in the absence of $Eu^{3+}$ under the same experimental conditions (Table 1). Thus, the formation of neutral *$(—COO)_2EuX$ complexes (X = $NO_3$ or OH) in the gel could explain the experimental data.

*Selectivity*

In order to check the selectivity of the SAPGel, $\approx 1.9$ g SAPGel ($4.0 \times 10^{-5}$ mol —COO(H, Na)) have been immersed into 100 ml of an equimolar solution ($[M^{m+}] = 8.5 \times 10^{-5}M$) of Eu, Sr and Cs at $pH_i$ 4.5: the extraction yield follows the expected order Eu (87.2%) > Sr (19.5%) > Cs (0) which allows an easy separation (this order is that of the affinities of metal cations with carboxylic sites).

*Metal stripping from the loaded SAPGel*

The is readily achieved in $0.1M$ $HNO_3$ after a few minutes.

## CONCLUSIONS

The uptake of cesium, strontium and europium by poly(acrylic acid–sodium acrylate) hydrogels from dilute aqueous solutions has been investigated. The uptake follows the order of the metal cation affinities towards the carboxylate group: $Eu^{3+} > Sr^{2+} > Cs^+$. The maximum SAPGel loading, $R$ = mol metal in the gel/total mol —COO(H, Na) = 0.5, observed with europium and strontium agrees with the formation of *$(—COO)_2Sr$ and $(—COO)_2Eu^+$ moieties. In both cases, the swelling factors are close to that of an uncharged SAPGel, and thus the formation of neutral *$(—COO)_2EuX$ (X = $NO_3$ or OH) type complexes is likely. The behaviour of the SAPGel in cesium solutions is very different since the swelling ratios are those of charged gels containing (*—$COO^-$, $Cs^+$) ion pairs. The maximum experimental uptake ratio of cesium is only 0.5, and sodium cations counterbalance the rest of carboxylate charges within the gel. Cesium and strontium uptakes decrease strongly with increasing sodium concentration ($NaNO_3$) in the outer solution according to a *—$COO^-$, $Na^+/M^{m+}$ cation exchange process. The europium uptake proceeds via a *—$COOH/Eu^{3+}$ exchange reaction which is characterized by a proton release into the outer solution and only a slight dependence on the $NaNO_3$ concentration. Europium, strontium and cesium stripping from loaded SAPGels is readily achieved by washing with $0.1M$ $HNO_3$. It is possible to remove metal cations from dilute solutions by immersing consecutively several SAPGels, which leads to very low concentrations, *e.g.* less than 0.05 mg/l. of strontium.

The complexation of metal cations by crosslinked sodium polyacrylate type hydrogels fol-

lowed by the gel shrinking gives the possibility of a 'pseudo-precipitation' of metal cations at low concentrations. Thus, they are promised agents for detoxication, or preconcentration of metal cations before analysis, but further experiments are needed which take in account the specific conditions of an application. Indeed, it has been shown here that high ionic strength can greatly limit the strontium and cesium extractions. Of course, synergistic effects or antagonisms may occur because of the presence of other ions in the metal solution: *e.g.* the high concentration of carboxylate groups in PAA hydrogels can favour the formation of mixed-metal carboxylates (previously found in related liquid–liquid extraction systems[26]), which can overthrow the expected selectivities.

# DETERMINATION OF SELENIUM IN FRESHWATERS BY CATHODIC STRIPPING VOLTAMMETRY AFTER UV IRRADIATION

GUNNAR MATTSSON, LEIF NYHOLM,* ÅKE OLIN and ULF ÖRNEMARK

Department of Analytical Chemistry, Institute of Chemistry, Uppsala University, P.O. Box 531, S-751 21 Uppsala, Sweden

(*Received* 23 *September* 1994. *Revised* 2 *December* 1994. *Accepted* 2 *December* 1994)

**Summary**—An analytical method was developed for the determination of total dissolved selenium in fresh waters, using linear sweep cathodic stripping voltammetry (CSV) in combination with UV photolytic digestion. Both the CSV method, based on the electrodeposition and stripping of $Cu_2Se$, and the UV irradiation procedure were investigated in detail. In the presence of dissolved organic substances, as in freshwaters, Se(VI) is reduced to Se(IV) by UV irradiation in 0.1*M* hydrochloric acid. Glucose can be used as the carbon source in samples low in natural dissolved organic carbon (DOC). The photolytic yields of Se(IV) were about 90% in both cases. Five freshwater samples were analysed for total selenium by CSV after UV photolysis, and by hydride generation atomic absorption spectrometry (HG-AAS) after oxidative digestion followed by reduction with hydrochloric acid. The results agreed well and the concentrations were in the range 70–190 ng/l., well above the detection limit of the CSV method at 2 ng/l.

Total selenium concentrations in natural waters are often in the ng/l. or low μg/l. range. A number of analytical methods has been applied to the quantitation of total selenium or Se(IV) in such waters.[1,2] Hydride generation-atomic absorption spectrometry (HG-AAS),[3,4] gas chromatography[5,6] and molecular fluorescence spectrometry,[7] each usually combined with a preconcentration technique, are most frequently employed. These methods are specific to Se(IV).

Electrochemical methods, which also respond to Se(IV) only, are not often resorted to, but differential pulse (DPV) and square-wave cathodic stripping voltammetry (CSV) have been used for the determination of total selenium and/or Se(IV) in fresh-,[8] sea-[9–11] and rainwater.[12–14] Attractive features of the CSV method are its efficient combination of the preconcentration and quantitation steps and the small sample volume needed. However, an accurate direct determination of Se(IV) in natural waters does not seem possible owing to interferences from surface active dissolved organic substances, as observed by Zelic and Branica,[14] and van den Berg and Khan.[10,11] Poor sensitivity and an interfering voltammetric peak were encountered in sea-, estuarine- and rainwater. The CSV technique is better suited for the determination of total selenium, as the interfering organic material is removed when the sample is digested in order to transform selenium bound in organic compounds to inorganic selenium.[3,10] After most wet digestion procedures, the selenium is present predominantly in its hexavalent oxidation state. A succeeding reduction step, usually employing a high concentration of hydrochloric acid,[1] is required. Since high concentrations of chloride at low pH interfere with the CSV method[15] and the margin available for dilution is limited in trace analysis, the common reduction procedures cannot be combined with a subsequent CSV determination. Development of an alternative digestion and reduction method is, therefore, essential for the application of CSV to lake- and riverwater samples.

Measures and Burton[5,16] reported that a reproducible distribution of total selenium between Se(IV) and Se(VI) resulted upon UV irradiation of standard solutions, sea-, estuarine- and riverwater. The samples were buffered with borate at pH 9 and hydrogen peroxide was added before irradiation for 5 hr. On the average, 86% of added Se(VI) or Se(IV) was recovered as Se(IV) with a 1250 W mercury lamp. The recovery was found to increase gradually with pH between 7 and 10 but it was not affected by

*Author to whom correspondence should be addressed.

the water salinity. Batley[17] found 89–98% yields of Se(IV) from Se(VI) added to 0.5*M* NaCl, distilled water or sea-water, buffered at pH 10.5 and deaerated during photolysis. A pH dependence of the fractional conversion to Se(IV) similar to that observed by Measures and Burton was reported. Dissolved oxygen, or addition of hydrogen peroxide or alcohols reduced the yields. Van den Berg *et al.*[10,11] were able to determine total selenium in sea- and estuarine-water by CSV after photolysis for 4 hr with a 1000 W high pressure mercury lamp. Complete recovery of Se(IV) was obtained from 4 n*M* Se(VI) added to sea-water at its natural pH 8, whereas the yield decreased rapidly at pH < 7.5. UV irradiation of the sample at pH ≥ 8 thus eliminates the organic interferents and transforms selenium predominantly to the tetravalent state. A pH ≥ 8 is, however, not suitable for natural freshwaters in general, since precipitation might occur of hydroxides or oxides of iron, manganese and other metal ions released from destructed humic and fulvic acid complexes. These precipitates are very efficient scavengers of Se(IV).[1] Modification of the UV irradiation procedure to make it applicable to acid solutions and compatible with the CSV method is reported here.

Co-electrodeposition in acidic solution of Se(IV) and added $Cu^{2+}$ at a mercury electrode, subsequently giving rise to a copper selenide stripping peak, appears to be the most convenient and reliable way to perform CSV determinations of selenium.[8,10,14,15] The deposition of selenium in the presence of $Cu^{2+}$ can be represented by

$$H_2SeO_3 + 2Cu^{2+} + 4H^+ + 8e^- \rightarrow Cu_2Se + 3H_2O. \quad (1)$$

The accumulated copper selenide is reduced in the stripping reaction

$$Cu_2Se + 2H^+ + 2e^- \rightarrow H_2Se + 2Cu(Hg). \quad (2)$$

Se(IV) can also be accumulated as HgSe,[18] but the $Cu_2Se$ stripping peak yields a lower detection limit, a longer linear calibration curve and is less subject to interference from peak splitting and from metal ions present in the sample.[8,10,14,15]

The influence of organic substances dissolved in freshwater on the CSV voltammograms is described. A methodology is presented for the accurate evaluation of the selenium concentration from linear sweep (LSV) voltammograms recorded in UV irradiated samples. The photolytic digestion method and the voltammetric finish were combined to a procedure which is described together with an application to five freshwater samples.

## EXPERIMENTAL

### *Chemicals*

Standard solutions of Se(IV) and Se(VI) were obtained by dilution of 1 g/l. stock solutions, which had been prepared from an ampoule of selenium dioxide in dilute nitric acid (Merck), and from solid sodium selenate (BDH), respectively. The Se(VI) solutions were standardized against Se(IV) standards by HG-AAS after reduction by hydrochloric acid. Dilute standard solutions contained 0.01–0.02*M* HCl. The water used had been deionized, distilled and further purified in a Milli-Q system (Millipore) to 18MΩcm quality. The mercury and the hydrogen peroxide (30%) were of Suprapur® quality (Merck). The other chemicals were of analytical grade. Deaeration of stripping solutions was performed with nitrogen which had passed through an acidic vanadium(II) scrubber solution in contact with zinc amalgam. Argon (99.998%) was employed for deaeration of solutions prior to some of the photolytic experiments.

### *Equipment*

The home-built UV irradiation apparatus was a modified version of that described by Gustavsson and Hansson.[19] It consisted of a TQ 718 high pressure mercury lamp (Heraeus) inserted into a quartz tube, which was mounted in the centre of a circular rack surrounded by an aluminium cage. The lamp was operated at 600 W. Twelve 60 ml stoppered quartz sample tubes surrounded the lamp symmetrically. Sample solutions were placed at the level of the lamp. To increase the radiative flux into the solutions, the aluminium surfaces facing the quartz tubes had been polished to mirror finish. The apparatus was cooled by a small fan and placed in a fume cupboard to dispose of generated ozone. Less than 1% of the sample volume was generally lost by evaporation during irradiation.

The hanging mercury drop electrode and the purging and stirring facilities employed in the CSV experiments all belonged to a Metrohm 647 VA Stand. To improve the performance of the electrode glass capillary, the tip was occasionally silanized *in situ*, *i.e.* without removing

the mercury from the capillary. After rinsing in dilute nitric acid and water, respectively, the capillary tip was soaked in dry methanol for 10–20 min, followed by rinsing with toluene and silanization with 5% dimethyldichlorosilane in toluene for about 30 min. Finally, the tip was rinsed with toluene, methanol and water, respectively. This treatment is important in order to secure reproducible and smooth backgrounds in the voltammograms. All potentials are given with respect to the Ag|AgCl|(3*M* KCl) reference electrode which was placed in a bridge containing 0.1*M* $HNO_3$. A glassy carbon rod served as the auxiliary electrode.

Linear sweep stripping voltammograms were recorded with a PAR 174A Polarographic Analyzer. Current and potential data were sampled by an IBM personal computer equipped with a data acquisition board (Keithley). The voltammograms were evaluated using a computer program written in the ASYST™ environment. This program allowed background subtraction, noise filtering, integration of peak areas and estimation of peak potentials and currents by fitting a third order polynomial to the data in the vicinity of the peak maximum. Baseline subtraction was carried out by fitting a third order polynomial to the data on each side of the peak. A Metrohm 646 VA Processor in combination with the 647 VA Stand was used to register differential pulse stripping voltammograms.

Selenium determinations by HG-AAS after liquid nitrogen cold trap preconcentration were carried out using the system previously described.[3] Digestions and reductions of Se(VI) to Se(IV) were performed in 250 ml beakers on a hot plate.

Determinations of dissolved organic carbon (DOC) were made with a Shimadzu 5000 TOC analyser at Pharmacia Biotech (Uppsala, Sweden). UV spectra were recorded with a Perkin-Elmer Lambda 17 UV/VIS spectrophotometer.

Quartz tubes, glass vessels and polyethylene bottles were soaked in 7*M* nitric acid and repeatedly rinsed with water before use.

*Water samples*

Water samples were collected in June 1994 as surface water from lakes and streams in the vicinity of Uppsala. The samples were filtered through a 0.45 $\mu$m membrane filter (Millipore), acidified to pH 2 with hydrochloric acid and then stored refrigerated in 2 l. polyethylene bottles. Analyses were completed within 3 weeks of collection.

*Analytical procedure for total selenium*

Approximately 40 ml of sample were weighed into each quartz tube. The solution was made 0.1*M* with respect to hydrochloric acid and 40 $\mu$l of 30% hydrogen peroxide were added. Some of the samples were spiked with 0.2 $\mu$g/l. of Se(VI) and used to determine the recovery of Se(VI) as Se(IV) after photolysis. The solutions were exposed to UV light for 60 min, then glucose (dissolved in 0.01*M* HCl) was added to a concentration of 30 mg/l. in order to establish more reducing conditions. Finally, the samples were irradiated for another 45 min. Note that these times will highly depend on the intensity of the UV lamp and other properties of the photolytic equipment such as the reflectance of the aluminium casing and the positions of the tubes relative to the lamp.

About 20 ml of the digested sample, accurately weighed into the electrode vessel, were deaerated with nitrogen for 6–7 min. Five mercury drops (0.13 $mm^2$ area) were extruded and electrodeposition was performed at −300 mV for 180 sec in stirred solution. After a rest period of 20 sec, a voltammogram was recorded from −300 to −850 mV with a scan rate of 200 mV/sec. A second voltammogram on the same sample was registered in a similar way after the addition of 1 mg/l. of $Cu^{2+}$, and a third after a standard addition of 0.4 $\mu$g/l. of Se(IV). The first voltammogram was used as a background and subtracted from the other two, as discussed in more detail below. The concentration of Se(IV) was evaluated using the LSV peak area and the sensitivity obtained from the increase in peak area between the second and third voltammograms brought about by the standard addition. The total concentration of dissolved selenium in the sample was obtained after correction for dilution and photolytic recovery and subtraction of the blank value. Blank solutions were subjected to the same treatment as sample solutions, except that additional 60 mg/l. of glucose were added prior to the first irradiation period.

*The HG-AAS procedure*

The water samples were digested by the addition of 30–50 mg of potassium permanganate per 100 ml of sample at pH 2.[3] The solution was boiled for 30 min, made 4*M* in hydrochloric acid and kept at boiling temperature for another 60 min in order to reduce Se(VI) to Se(IV). After dilution to 250 ml, Se(IV) was determined by

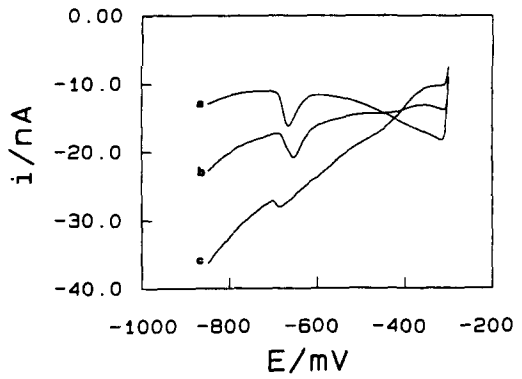

Fig. 1. The effect of dissolved organic substances on the cathodic stripping voltammogram. Dissolved organic matter from a lake water (Lafssjön) was added to a 0.4 μg/l. standard solution of Se(IV), also containing 0.1*M* hydrochloric acid and 1 mg/l. of $Cu^{2+}$. Concentrations of DOC in mg/l.: (a) 0; (b) 0.2; (c) 0.7.

HG-AAS as previously described.[3,4] The selenium concentration was evaluated from a calibration curve using peak heights.

## RESULTS AND DISCUSSION

### *The CSV method*

At the DOC levels of 1–100 mg C/l. normally found in freshwaters,[20] severe interference can be expected in stripping voltammetry.[21,22] The influence of dissolved organic matter on the CSV method was studied by addition of water from a lake (Lafssjön) and a stream (Sävjaån) to standard solutions of Se(IV). The results for the two waters were similar, and some characteristic LSV voltammograms are displayed in Fig. 1. Even DOC concentrations below 0.1 mg C/l. affected the shape of the background. The background current increased with the DOC concentration and the deposition time at potentials more negative than −400 mV. At about 0.5 mg C/l., the shape of the stripping peak also started to change, which caused a decrease in the peak height. At somewhat higher DOC concentrations, the peak became more asymmetric, split or disappeared. Only a very small, scarcely discernible stripping peak situated on a high and sloping background current was obtained from a drinking water sample containing 5–6 mg C/l. and spiked with 0.5 μg/l. of Se(IV). Similar observations were made when the experiments were repeated with DPV as the stripping technique. The change in the background was smaller, whereas the effect of high DOC concentrations on the shape and size of the stripping peak was more pronounced. The DPV peak disappeared almost completely at about 1 mg C/l.

It was found previously that the selenium concentration is best evaluated from the LSV peak area.[15,18] The fact that the LSV peak area was less influenced than the LSV and DPV peak currents by the presence of dissolved organic matter is another reason to use peak area measurements for analytical purposes. However, attempts to determine Se(IV) in freshwaters containing more than about 0.5 mg/l. of DOC are likely to fail. Since the freshwater samples studied contained 3–20 mg C/l. (see Table 1), a direct determination of Se(IV) was precluded. Only total selenium concentrations could thus be determined after destruction of organic material by UV irradiation.

A reliable background subtraction procedure is essential in LSV for accurate evaluation of peak areas and achievement of low detection limits. Most often, background voltammograms are recorded either in pure electrolyte solution or in the sample without a preceding deposition step.[21] Such background curves were, however, found to poorly match stripping voltam-

Table 1. Total dissolved selenium concentrations in fresh water samples determined by CSV and HG-AAS

| | | Total concentration of dissolved Se (*ng/l.*) | | | |
|---|---|---|---|---|---|
| Sample | DOC (*mg/l.*) | Uncorrected | CSV Recovery (%) | Corrected | HG-AAS |
| Blank solution | — | 3 ± 1 | 91 ± 2 | 3 ± 1 | 13 ± 4 |
| Institute drinking water | 3 | 172 ± 2 | 90 ± 4 | 190 ± 10 | 179 ± 9 |
| Ekoln, Skarholmen (lake) | 9 | 115 ± 1 | 86 ± 2 | 133 ± 4 | 118 ± 6 |
| Sävjaån, Falebro (stream) | 12 | 109 ± 1 | 94 ± 6 | 116 ± 8 | 121 ± 5 |
| Trehörningen (lake) | 12 | 70 ± 2 | 91 ± 6 | 77 ± 7 | 74 ± 7 |
| Lafssjön (lake) | 19 | 101 ± 1 | 96 ± 2 | 105 ± 3 | 96 ± 8<br>101 ± 6* |

Each DOC concentration is the mean of two measurements, differing by less than 0.6 mg C/l. Selenium concentrations and recoveries are presented as mean ± SD from three complete analyses.
*Digested with peroxodisulphate.

mograms recorded in incompletely digested water samples or other solutions containing dissolved organic matter. A change in the background current brought about by surface active or reducible substances can, on the other hand, be accounted for by recording stripping voltammograms before and after the addition of $Cu^{2+}$ to the sample. The former voltammogram, containing a fairly low and broad HgSe wave around $-500$ mV, is then subtracted from the latter, which exhibits a $Cu_2Se$ peak at $-660$ mV. By this procedure, demonstrated in Fig. 2, it is possible to check that there are no interfering peaks at the position of the $Cu_2Se$ peak and a blank voltammogram is obtained which will match the background of the $Cu_2Se$ stripping voltammogram well, except in the region of the small HgSe wave. The vertical shift between the two voltammograms seen in Fig. 2(a, b) is caused by the additional current from diffusion limited reduction of $Cu^{2+}$. The procedure was found to work well for the five freshwater samples analysed and no interfering peaks were detected. In fact, the backgrounds in these samples were generally low and smooth, revealing no sign of interference from residual organic substances after digestion.

The Se(IV) concentrations were evaluated by the method of standard additions. One subsample from each water received three consecutive standard additions of Se(IV) to check the linearity of the analytical curve. The plots of peak area *vs.* added Se(IV) concentration all showed good linearity with correlation coefficients $r \geqslant 0.9998$ ($n = 4$). Only one addition was made to the other subsamples, as the precision was satisfactory. The reproducibility of the CSV method was very good considering the concentration level. The within-day relative standard deviation of the sensitivity was 3–4% ($n = 12$), which is only slightly larger than the 2–3% usually encountered from consecutive measurements of the stripping peak area on a standard solution at the 0.1–0.5 $\mu$g/l. level. The sensitivities were not significantly different between the five water samples and between the samples and standard solutions. Therefore, the more convenient evaluation from a calibration curve can be used. This is true only for the peak area, since the peak shape and, hence, the peak current sensitivity varied between samples. Usually, the $Cu_2Se$ stripping peak was somewhat sharper in standard solutions than in digested samples. This indicates that the stripping process was slightly affected by the sample matrix while the efficiency of the deposition process, which is associated with the stripping peak area, was virtually unperturbed.

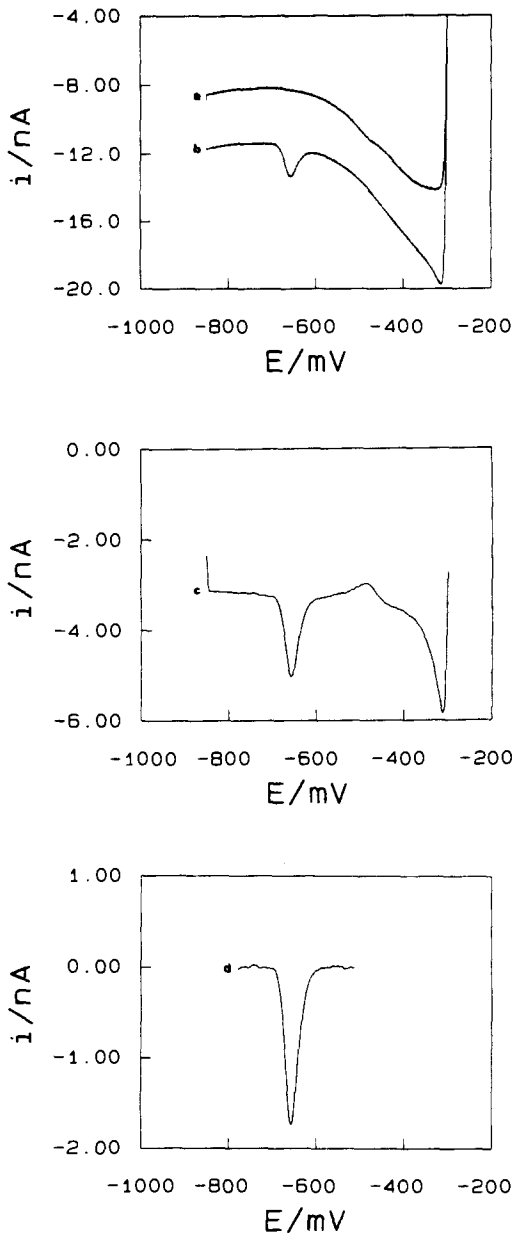

Fig. 2. The evaluation of a representative cathodic stripping voltammogram from a photolysed lake water sample (Lafssjön) containing 0.10 $\mu$g/l. of Se and 0.1*M* hydrochloric acid. (a) Voltammogram recorded in the absence of copper; (b) voltammogram acquired after the addition of 1 mg/l. of $Cu^{2+}$; (c) the resulting background subtracted (b – a) and filtered voltammogram; (d) the $Cu_2Se$ stripping peak at $-660$ mV after subtraction of the fitted baseline. The small negative HgSe wave appearing at $-500$ mV in (a) is reproduced as a positive wave in (c).

The detection limit of the CSV method, using a deposition time of 3 min, has previously been estimated to 2 ng/l. from three times the stan-

dard deviation of the $Cu_2Se$ stripping peak area recorded at 20 ng/l. of Se(IV).[15] In the present work, this low detection limit was further verified by the measurement of the blank level in Table 1.

*UV photolytic experiments*

Irradiation of alkaline standard solutions yielded fractional conversions that agreed with the observations made by Measures and Burton,[5] and by Batley.[17] After irradiation of two freshwater samples (Lafssjön and Sävjaån) for 3 hr at pH 9.8 (0.05*M* $NH_3$ added), the Se(IV) concentrations determined by CSV were, however, not reproducible and ranged from 75 to 100% of the total concentrations of selenium found by HG-AAS after permanganate digestion. These results initiated a study of the photolysis of acidic solutions containing selenium, despite the report of a recovery of only 5% of Se(IV) from sea-water at pH 3.7.[10]

In the presence of 0.1*M* HCl, irradiation of the two freshwater samples yielded fractional conversions to Se(IV) around 90%. The yield was found to be fairly independent of the hydrochloric acid concentration between 0.1 and 0.4*M*. In the presence of 0.3 g/l. of hydrogen peroxide, the recovery decreased to about 70%. The dissolved organic material (about 20 mg C/l.) was sufficiently digested after 1.5 hr also in the absence of hydrogen peroxide. The yellow colour still present after irradiation for 1.5 hr in samples previously deaerated with argon indicated that dissolved oxygen was essential for the photo-oxidation process.

In contrast to the freshwaters, standard solutions of Se(VI) in 0.01–0.4*M* hydrochloric acid yielded low and highly irreproducible recoveries of Se(IV) when irradiated, both in the presence and in the absence of hydrogen peroxide. The recovery was not improved if the solutions were deaerated with argon prior to photolysis. Obviously, some constituent of the freshwater samples facilitated the reduction of Se(VI) to Se(IV). The fairly high content of dissolved organic material suggests that the presence of certain organic substances, or organic material in general, supports the reduction. This hypothesis was tested by addition of various organic compounds to Se(VI) standard solutions prior to photolysis. Among the substances tested, glucose (0.17–0.36 m*M*) and maleic acid (0.25 m*M*) produced the highest yields of Se(IV), in both cases around 90%. With 2 m*M* methanol added alone or together with 0.03 m*M* benzoic acid, 2,5-dihydroxybenzoic acid, gallic acid, hydroquinone, maleic acid, nicotinic acid, phenylalanine, phthalic acid, salicylic acid or tryptophan, yields of 50–80% were obtained. Even though the concentration of the organic additives was rather low, interference in the CSV voltammograms from incompletely digested matter was encountered from most of the aromatic compounds. A few inorganic ions ($Fe^{2+}$, $Br^-$) that might occur in natural waters were also tested, but only negligible concentrations of Se(IV) could be detected after irradiation. No effort was made to optimize the conditions in the screening tests. Thus, higher yields of Se(IV) might have been obtained at other concentrations of the added compound or for other irradiation times.

Glucose was selected for further study as it gave rise to acceptable Se(IV) yields and interference-free solutions after photolysis. Selenium(VI) standard solutions containing glucose at three concentrations were irradiated and the yield of Se(IV) is plotted as a function of irradiation time in Fig. 3. Three time regions can be distinguished in the plots. Initially, the production of Se(IV) is quite fast and the time dependencies for the two lowest concentrations of glucose are similar. The second region is a plateau where the Se(IV) yield is about 90%. The length of this plateau depends on the glucose concentration. Finally, the concentration of Se(IV) drops almost to zero over a short period of time. Solutions from the end of the third region were reduced with 4*M* hydrochloric acid for 1 hr. As virtually all selenium was recovered as Se(IV) after this treatment, it can be concluded that the Se(IV) formed initially must have been re-oxidized to Se(VI). The

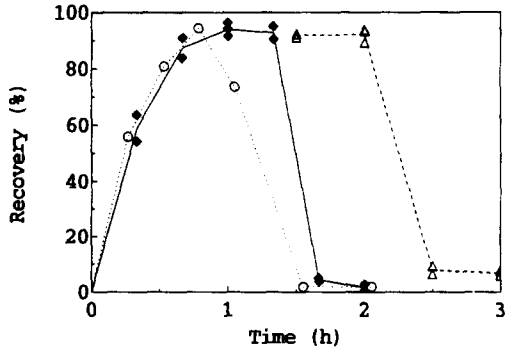

Fig. 3. Recovery of Se(IV) from UV irradiated Se(VI) standard solutions *vs.* irradiation time. The solutions contained 0.4 μg/l. of Se(VI), 0.1*M* hydrochloric acid and glucose/m*M*: (a) 0.056, ○; (b) 0.17, ◆; (c) 0.33, △.

conditions in the solutions apparently change from reducing to oxidizing during the course of the photolysis. Evaluation of the Se(IV) concentrations was not possible at the highest glucose concentration after irradiation times shorter than 1.5 hr owing to serious interferences in the stripping voltammograms. Some change in the shape of the LSV backgrounds was also noted for the lower glucose concentrations at short irradiation times. Since glucose itself does not cause such problems, the interferences must have been brought about by photo-oxidation products of glucose. This conclusion is supported by UV spectra of the irradiated solutions, which showed the generation and disappearance of a broad absorbance band between 210 and 300 nm.

With standard solutions of Se(IV) or Se(VI) containing 0.17 m$M$ glucose, the intermediate concentration in Fig. 3, the following observations were made. The recovery of Se(IV) after 1 hr of irradiation was $92 \pm 1\%$ (mean $\pm$ SD, $n = 4$) for solutions initially containing 0.4 $\mu$g/l. of Se(IV), and $93 \pm 3\%$ ($n = 5$) for solutions of Se(VI). Approximately the same yield was obtained with a 100 times higher concentration of Se(VI), which indicates that the fractional conversion is independent of concentration. Moreover, the yield of Se(IV) did not change for hydrochloric concentrations between 0.1 and 0.4$M$, but decreased somewhat for concentrations below 0.1$M$. In solutions of perchloric and sulphuric acid, on the other hand, the yield of Se(IV) was low. Deaeration with argon before irradiation did not seem to change the recovery, which may imply that dissolved oxygen is not the cause of incomplete conversion.

Hydrogen peroxide may have to be added to samples containing concentrations of DOC higher than about 25 mg C/l. to assist in the photo-oxidation. The effect of hydrogen peroxide on the recoveries is puzzling. A reduction in yield was observed when freshwater samples were irradiated in the presence of hydrogen peroxide, whereas the normal yield of about 90% Se(IV) was obtained from standard solutions containing 0.17 m$M$ glucose. All added hydrogen peroxide is decomposed, as judged from the CSV voltammograms.

A procedure leading to high and equal recoveries irrespective of the initial DOC content of the sample is, of course, desirable. The irradiation scheme finally adopted consists of two steps. In the first step, oxidation of dissolved organic matter is assisted by addition of hydrogen peroxide. With the addition of 0.3 g/l. of hydrogen peroxide, all the freshwater samples in Table 1 were sufficiently digested after 1 hr. DOC was determined in two of the digested water samples (Lafssjön and Sävjaån) and the carbon content was found to be reduced to 10 and 22%, respectively, of the initial concentration. No interference from surface active substances could be detected in the stripping voltammograms and the UV absorbance at 254 nm had decreased to about 3% of its initial value. Hence, an efficient photolytic degradation of the dissolved organic substances, preceding their complete photo-oxidation to carbon dioxide and water, occurs in the first step. Omission of this step or the addition of 60 mg/l. of glucose is recommended for solutions having a very low DOC content, such as blank and standard solutions. Otherwise, $Cl_2$ is likely to form and the conditions during the second step may become too oxidizing. The second irradiation is performed after the addition of 30 mg/l. glucose, which ensures a fractional conversion to Se(IV) of about 90% during a limited period of time. It must be observed that the appropriate lengths of the two steps in the procedure have to be found experimentally for each irradiation apparatus, as the radiative flux experienced by the sample solutions is highly dependent on the lamp and the configuration of the apparatus. Similar yields of Se(IV) were observed with a brand new lamp as with a lamp of the same type that had been operated for several hundred hours, but the irradiation times differed by 30–40%.

The irradiation procedure proposed is empirical and its physico-chemical rationale is unknown. Such knowledge might facilitate further optimization of the method with the objective to achieve 100% yields of Se(IV). An investigation of the wavelength dependence of the fractional conversion and a more extensive screening of photolytic additives beside glucose may be particularly fruitful approaches. The distribution of total selenium between 90% of Se(IV) and 10% of Se(VI) suggests that either a redox equilibrium is set up between the two oxidation states by the redox potential of the solution during irradiation, or a steady state is created by opposing reduction and oxidation reactions. The redox pair Se(VI)/Se(IV) is known to be very sluggish but equilibrium can be mediated by the $Cl_2/Cl^-$ couple. Both selenite and selenate ions absorb light below 230 nm,[23] and directly induced photo-reactions are, thus, poss-

ible and have been studied.[24] On the other hand, various molecules, including reactive radicals, are generated by the photochemical degradation of glucose and natural dissolved organic substances, and some of these might react with Se(IV) or Se(VI). Most of the carbon containing radicals are likely to have reducing properties. The absence of a significant reduction of Se(VI) in deaerated solutions free from organic compounds supports the view that organic radicals are involved. Highly oxidizing chlorine and hydroxyl radicals, which are formed by the action of UV light with wavelengths $<200$ nm,[25] may also be important, especially in the observed reoxidation of Se(IV) after long irradiation times. Perhaps these oxidizing radicals react with the degradation products of glucose and dissolved organic matter until the latter have been totally consumed. Thereafter they start to oxidize Se(IV).

*Determination of total selenium in freshwaters*

Five freshwaters of varying origin were analysed for total dissolved selenium by combining the UV photolysis and CSV procedures outlined above. The waters were also analysed by HG-AAS after permanganate digestion.[3,4] One of the samples (lake Lafssjön) was also digested with peroxodisulphate at pH 2[3] for comparison. The results, including recoveries of added Se(VI) as Se(IV) from the UV irradiation step and the concentrations of DOC, are presented in Table 1. They show reasonably good agreement between the two methods considering the low concentrations involved. The significantly different results for Lake Ekoln may be connected to the somewhat low recovery of added Se(VI) for this sample. The recovery of added Se(VI) as Se(IV) varied between 86 and 96% in the samples. The yields are, thus, similar to the yields of Se(IV) from Se(VI) and Se(IV) standard solutions containing glucose. By analysis of variance, no significant difference at the 95% level was found between the recoveries from the different water samples. Since the chemical constitution of the five water samples, most likely, varied quite a lot, it seems plausible that yields around 90% would be obtained also for other freshwater samples.

A low reagent blank, a low detection limit, fairly good precision and rather simple equipment are the main merits of the UV photolysis-CSV method. Recoveries less than 100% constitute a drawback of the method. Determination of the recovery adds to the analysis time and to the standard deviation of the final result. There is also a risk for an erroneous compensation for incomplete transformation to Se(IV), if added Se(VI) behaves differently than the various selenium species making up the total selenium concentration.

## CONCLUSIONS

Reduction of Se(VI) to Se(IV) by UV irradiation has been demonstrated in acidic solutions containing natural dissolved organic matter or added glucose. The developed irradiation procedure was found to be a digestion method well suited for the CSV determination of total dissolved selenium in fresh waters. Selenium concentrations can be evaluated from a calibration curve if LSV peak areas are measured. Most likely, the irradiation procedure can be adapted to other analytical methods for selenium as an attractive alternative to the more common wet digestion-hydrochloric acid reduction procedures. More detailed investigations are needed to clarify the mechanisms of the photolytic reduction of Se(VI) and to further optimize the irradiation method.

A desirable improvement of the method would be to perform UV irradiation on-line, incorporated in an automated flow system together with the voltammetric cell. Such flow systems, employing quartz coils as photolytic cells, have been constructed and successfully applied to the photo-reduction of nitrate[26] and to the photo-oxidation of dissolved organic matter and Cr(III).[27] Complete destruction of dissolved organic matter was reported to occur within a few minutes, which is a significant reduction in the irradiation time compared to the 1–4 hr normally required for batch-wise digestions.[27]

*Acknowledgements*—The authors greatly appreciate the assistance with computers and ASYST programming given by Alf Eriksson and Rolf Danielsson, and the help on practical matters provided by Lena Hansson and Roland Pettersson. Thanks are also due to Bo-Lennart Johansson for performing the DOC determinations.

# SIMULTANEOUS DETERMINATION OF EQUIVALENCE VOLUMES AND ACID DISSOCIATION CONSTANTS FROM POTENTIOMETRIC TITRATION DATA

G. PAPANASTASIOU* and I. ZIOGAS

Laboratory of Physical Chemistry, Department of Chemistry, Faculty of Sciences, Aristotle University of Thessaloniki, 540 06 Thessaloniki, Greece

(*Received* 7 *September* 1994. *Revised* 22 *November* 1994. *Accepted* 2 *December* 1994)

**Summary**—New iterative methods for analysis of potentiometric titration data of (a) mixtures of weak monoprotic acids with their conjugate bases, (b) solutions of polyprotic (di- and triprotic) acids, and (c) mixtures of two diprotic acids are presented. These methods, using data exclusively resulting from the acidic region of the titration curve permits the accurate determination of the analytical concentration of one or more acids even if the titration is stopped well before the end point of the titration. For the titration of a solution containing a conjugate acid/base pair, the proposed procedure enables the extraction of the initial composition of the mixture, as well as the dissociation constant of the concerned acid. Thus, it is possible by this type of analysis to distinguish whether a weak acid has been contaminated by a strong base and define the extent of the contamination. On the other hand, for the titration of polyprotic acids, the proposed approach enables the extraction of the accurate values of the equivalence volume and the dissociation constants $K_i$ even when the ionization stages overlap. Finally, for the titration of a mixture of two diprotic acids the proposed procedure enables the determination of the composition of the mixture even if the sum of the concentrations of the acids is not known. This method can be used in the analysis of solutions containing two diastereoisomeric forms of a weak diprotic acid. The test of the proposed procedures by means of ideal and Monte Carlo simulated data revealed that these methods are fairly applicable even when the titration data are considerably obscured by 'noise' or contain an important systematic error. The proposed procedures were also successfully applied to experimental titration data.

In a recent paper,[1] we developed new iterative methods for the analysis of potentiometric titrations data of weak monoprotic acids or of mixtures of monoprotic acids. By using these methods it is possible to extract the accurate values of the equivalence volume and simultaneously the acid dissociation constants. These methods are valid even when the titrations are carried out under conditions of varying ionic strength, but there is no reason why the analysis could not be done under conditions of constant ionic strength. Hence the addition of a neutral salt to the titrated solution to keep the ionic strength constant is not necessary. Therefore, the p$K$ values obtained in media of low ionic strength ($I < 0.1M$) are free of any possible 'salt effect'. On the other hand, it has been argued in literature that in media of high ionic strength, even in the absence of a 'salt effect', the theoretical prediction of the activities of the various ionic species become inaccurate; the higher the ionic strength at which measurements are made the more serious the difficulties in obtaining the dissociation constant become.[2]

In this paper, the logic of the above mentioned approaches has been extended to other more complicated titrations. Thus, we have obtained theory and methods for analysis of potentiometric titration data of (a) mixtures of weak acids with their conjugate bases (buffer solutions), (b) solutions of polyprotic (di- and triprotic) acids with overlapping ionization steps, and (c) mixtures of two diprotic acids. In the first case our analysis permits to define the 'prehistory' of the neutralization of the concerned acid and simultaneously to extract its dissociation constant. Therefore, this method is suitable to distinguish if a certain weak acid has been contaminated by a strong base and determine the extent of this contamination.

Over the years, a variety of solutions has been suggested for the analysis of potentiometric

*Author to whom correspondence should be addressed.

titration curves of polyprotic (mainly diprotic) acids or of mixtures of acids with weak bases.[3-9] However, most of these methods are valid under conditions of constant ionic strength or require prior knowledge of accurate values of the dissociation constants of the acids, these constants being determined by a separate titration. To our knowledge, methods for analysing titrations of triprotic acids with overlapping successive ionization steps (without prior knowledge of the $pK_i$ values) are not yet reported in the literature.

With our methods and accurate data it is possible to determine precise concentrations from the buffer region of the titration curve. Therefore, the accurate determination of the analytical concentration of one or more acids is possible even if the titration is stopped well before the complete neutralization of the solution. In addition the suggested methodology enables the determination of the corresponding $pK$ from the same experimental data and only in the case of the titration of a mixture of two diprotic acids the proposed method requires prior knowledge of the values of the corresponding dissociation constants.

It should be noted that the determination of the accurate $pK$'s values, apart from its theoretical significance, is of major analytical interest. Indeed, $pK$ being independent of the concentration could be considered as the 'fingerprint' of the titrated acid. So, from the comparison of the determined $pK$ values with tabulated ones it is possible to identify the titrated acid. It is evident that, the determination of the dissociation constants, especially of the polyprotic acids, require laborious calculations. However, with the opportunities offered today by high-speed personal computers, all the proposed methods can be easily carried out in a time interval from a few seconds to a few minutes.

## EXPERIMENTAL

The potentiometric titrations were carried out as described previously.[1] Conductivity water (conductance = $1.0 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$) was used throughout. Analytical reagent grade acids (Fluka, puriss p.a. >99.5%) were used without further purification; their purity was checked by potentiometric titrations. All sodium hydroxide solutions were prepared from stock solutions of known concentration (Merck, Titrisol).

## POTENTIOMETRIC TITRATION OF A SOLUTION CONTAINING A CONJUGATE ACID–BASE PAIR

### *Theoretical*

Consider a volume $V_0$ of a solution containing a conjugate acid–base pair, where the initial analytical concentrations (*i.e.* the total concentrations irrespective of form) of the weak acid HA and its conjugate base are respectively equal to $C_0$ and $C_b^0$. This mixture can be considered as being prepared by partial neutralization of a solution of the acid HA, of concentration $C_0'$ and volume $V_0 - Z$, with $Z$ ml of a solution of a strong base MOH of concentration $C_B$. At any point of the titration curve the mass and charge balance is expressed by the equations:

$$[A^-] + [OH^-] = [M^+] + [H^+] \quad (1)$$

$$T_L = [HA] + [A^-], \quad (2)$$

where

$$[M^+] = \frac{C_B \cdot V}{V_0 + V} + \frac{C_b^0 V_0}{V_0 + V} = b_N C_B (Z + V) \quad (3)$$

$$T_L = \frac{T_L^0 V_0}{V_0 + V} = \frac{(Z + V_e) C_B}{V_0 + V} = b_N C_B (Z + V_e) \quad (4)$$

$$C_b = \frac{C_b^0 V_0}{V_0 + V} = \frac{Z C_B}{V_0 + V} = b_N Z C_B, \quad (5)$$

where $V$ is the volume of the added titrant and $b_N = 1/(V_0 + V)$.

Assuming that all singly charged ions ($z_i = 1$) have the same activity coefficient $y_i$ and that the activity coefficients of uncharged species are unity, the acid constant of HA is given by

$$K_a = \frac{\alpha_H \cdot [A^-] \cdot y_i}{[HA]}, \quad (6)$$

$\alpha_H$ being the hydrogen ion activity.

Combining the above equations and rearranging gives

$$y = V_e - \frac{1}{K_a} x, \quad (7)$$

where

$$y = V + \frac{1}{y_i C_B b_N} \left\{ \alpha_H - \frac{K_w}{\alpha_H} \right\} \quad (8)$$

and

$$x = \alpha_H \left( y_i (V + Z) + \frac{\alpha_H}{C_B b_N} - \frac{K_w}{\alpha_H C_B b_N} \right), \quad (9)$$

where $K_w$ is the autoprotolysis constant of the solvent used. For dilute solutions ($I < 0.1M$) the

activity coefficient $y_i$ can be calculated from the Debye–Hückel equation:

$$\log y_i = -\frac{Az_i^2\sqrt{I}}{1 + B\mathring{a}\sqrt{I}}, \quad (10)$$

where $A$ and $B$ are constants, the values of which depend on the physical properties of the medium, [10] $I$ is the ionic strength of the solution, $z_i$ the charge number and $\mathring{a}$ the distance of closest approach of the ions. In principle $\mathring{a}$ is a function of the solvent and electrolyte, but in practice it is traditionally taken to be equal to 5 Å.[11–13] The ionic strength, at any point of the titration curve, is given by:[14,15]

$$I = [M^+] + [H^+] = b_N C_B(Z + V) + [H^+]. \quad (11)$$

To determine $y_i$, it is obviously necessary to know the value of $[H^+] = \alpha_H/y_i$ and vice versa. It is noted that when the electrode system is standardized against the aqueous buffer solutions recommended by the National Bureau of Standards, the measured pH value of a solution is identified very closely with the conventional value of $-\log \alpha_H$ (where $\alpha_H$ is the corresponding hydrogen ion activity). The values of $[H^+]$ and $y_i$ may be obtained from the measured value of $\alpha_H$ by successive approximations.[1,14] Assuming first $y_i = 1$, so that $\alpha_H = [H^+]$, it is possible to calculate $I$ from eqn (11), and hence $y_i$ from eqn (10). This new value of $y_i$ can be used to refine the values of $[H^+]$, $I$ and $y_i$. All these operations are repeated until $y_i$ converges (the criterion here being less than 0.00001 difference in $I$, between two subsequent cycles).

Equation (7) predicts a linear relationship between $y$ and $x$ with a slope equal to $1/K_a$. Alternatively, the experimental confirmation of such a correlation, using $V$ and pH data, supports the assumption that the titrated solution is a mixture of a monoprotic acid with its conjugate base. Then, $V_e$ and the acidity constant $K_a$ can be deduced, by linear regression, from the coefficients of eqn (7). This procedure can be realized by the presently proposed iterative method, which is analogous with previously proposed techniques for the determination of rate constants of various chemical and electrochemical reactions.[16–20]

*Iterative method for the determination of $Z$, $V_e$ and $K_a$*

It is assumed first that the value of $Z$ lies on an interval (a, b). Choosing arbitrarily from this interval a value for $Z$, it is possible to trace, by means of the experimental $V$ and pH data, the curve $y = f(x)$. This curve will approach a straight line to the extent where the chosen value of $Z$ also approaches the exact value of this parameter. Hence, the best linearity that could be obtained, by means of the available experimental data, evidently corresponds to the best approximation to the exact value of $Z$. Therefore, by seeking the $Z$ value within the interval (a, b), it is possible to trace $N$ curves $y = f(x)$, $N$ being the number of $Z$ values taken for these calculations. For each of these curves, the calculation of $R^2$ (square of the correlation coefficient) and $S_{y/x}$ (standard error of the estimate)[1,21] permits a comparison of the linearity of various $y = f(x)$ plots and trace the curves $R^2 = f(Z)$ or $S_{y/x} = f(Z)$. These curves must present respectively a maximum and minimum at a value of $Z$ equal to $Z_m$, which can be considered as the best approximation to the exact value of $Z$. The exact values of $V_e$ and $K_a$ can be deduced respectively from the $y$-intercept and the slope of the corresponding to $Z_m$ straight line.

*Application of the iterative method for the determination of $Z$, $V_e$ and $K_a$ using simulated and experimental data*

*Simulated data.* To establish the reliability of the proposed procedure, first it must be shown that it actually works by comparison to a system where the answer is already known. Experimentally, this implies that the proposed approach, applied to a previously reported system, gives a reasonable (or even better) precision on the extraction of the sought parameters. In this respect, it was considered necessary to test the proposed methods, first with simulated data corresponding to various values of $pK_a$, $Z$ and $V_e$ and second to experimental data resulting from titrations of mixtures of weak acids (of known $pK_a$) with their conjugate bases.

Simulated $V$ and pH ($pH = -\log \alpha_H$) data have been derived by solving eqn (7) using the so-called secant methods.[22] In all these calculations we assumed that $V_0 = 50$, $C_B = 0.1$ M, $V_e = 4.00$ ml ($C_0 = 0.008M$), $Z = 1.00$ ml ($C_b^0 = 0.002M$), $T = 298.15$ K and $pK_w = 14.0$. First, the titration of an acid with $pK_a = 4.80$ was considered. This value represents the mean $pK_a$ value of the lower members of the aliphatic series of monocarboxylic acids.[10,11] The results obtained are reported in Table 1. Taking into account that the NBS buffer solutions used for the standardization of the pH-meters are given at most to three decimal figures, the simulated

$V_0 = 50$, $C_B = 0.1M$, $V_e = 4.00$ ml ($C_0 = 0.008M$), $Z = 1.00$ ml ($C_b^0 = 0.002M$), $T = 298.15$ K, $pK_a = 4.80$ and $pK_w = 14.0$.

*Values that exactly fit equation (7).

†Mean values of six normally distributed deviates generated from the ideal data with standard deviation equal to 0.01 pH unit.

pH values were rounded to three decimal places. It is now examined whether it is possible, using these data and by means of the proposed method, to extract the values $pK_a = 4.80$, $V_e = 4.00$ ml ($C_0 = 0.008M$) and $Z = 1.00$ ml ($C_b^0 = 0.002M$).

The variations of $R^2$ and $S_{yx}$ with $Z$ are presented graphically in Fig. 1. It can be seen that these curves pass through a maximum and minimum, respectively, corresponding to $Z = 1.00$ ml. Furthermore, in the vicinity of the maximum ($4.9 \leqslant Z \leqslant 5.1$), it was found that the curve $R^2 = f(Z)$ can be perfectly fitted, by a least squares analysis, to the following polynomial (the squared correlation coefficient was very close to unity):

$$R^2 = \sum_{n=0}^{4} A_n Z^n = 0.1082 + 2.9761Z - 3.7216Z^2 + 2.0820Z^3 - 0.4447Z^4. \quad (12)$$

Consequently, the exact value of $Z$ at which $R^2$ reaches a maximum value can be determined from the solution of the following equation:

$$\frac{dR^2}{dZ} = \sum_{n=0}^{4} nA_n Z^{n-1} = A_1 + 2A_2 Z + 3A_3 Z^2 + 4A_4 Z^3 = 0. \quad (13)$$

From eqn (13) one obtains $Z_m = 1.00$ ml. Using this value, the following relationship was found:

$$y = 4.000 - 63091.16x. \quad (14)$$

Comparison of this equation with eqn (7) leads to the values: $V_e = 4.00$ and $pK_a = 4.80$.

In an attempt to generalize the conclusions concerning the applicability of the proposed method, this procedure was also applied to various simulated titration curves corresponding to different $pK_a$ ($3.0 \leqslant pK_a \leqslant 6.5$) and $Z$ values ($0.5 \leqslant Z \leqslant 2.5$). The obtained results showed that the proposed method reaches the desired values of $Z$, $V_e$ and $pK_a$ with a fair accuracy.

The examples studied previously showed that the proposed procedures are able to extract $V_e$ and $pK_a$ values in the particular case where the $V$ and pH data used, resulting from the buffer region of a titration curve, are free of experimental errors.

However, of more experimental interest is the question of how well the new techniques are able to cope with data containing random extraneous contributions, such as annoying

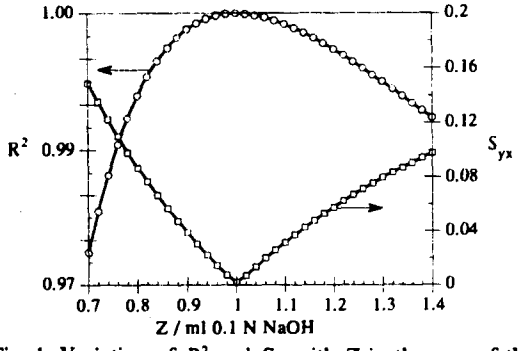

Fig. 1. Variation of $R^2$ and $S_{yx}$ with $Z$ in the case of the simulated titration of 50 ml of a conjugate acid–base pair [$C_0 = 0.008M$ ($V_e = 4.0$ ml), $C_b^0 = 0.002M$ ($Z = 1.00$ ml), $pK_a = 4.80$] with $0.1M$ NaOH at 25°C.

experimental 'noise'. To investigate this, a Monte Carlo technique was used, which has been detailed in a previous paper[18] and need not be repeated here. The main idea of this procedure is based on the observation that, often, random experimental errors closely follow a Gaussian (or normal) distribution. Thus, at each point ($V_i$ and $pH_i$) of the theoretical titration curve $pH = f(V)$, we produced a number $N$ of normally distributed random variables $pH_{i,j}$ with mean $pH_i$ and standard deviation $S_i$. In the experimental level, this implies the realization of N titrations with a precision equal to $S_i$. Using this technique, we treated again, as an example, the titration of an acid with $pK_a = 4.80$. In this treatment we assumed that $S_i$ is equal to 0.01 pH unit. At each volume $V_i$, we created six values of $pH_{i,j}$ and the results were averaged. The mean values $\overline{pH}_{i,j}$ are summarized in Table 1. Evidently, these values would coincide with the corresponding $pH_i$ ones only in the case where the number $N$ of the produced random variables $pH_{i,j}$ tends to infinity. Using these Monte Carlo data $\overline{pH}_{i,j}$, the proposed method gives the values $Z = 1.006$ ml, $V_e = 4.005$ ml and $pK_a = 4.799$. These results are respectively within 0.6, 0.12 and 0.03% ($\delta pK_a = 0.001$) of their true magnitudes. Evidently the proposed techniques are able to extract $Z$, $V_e$ and $pK_a$ values, even when the pH data are obscured by noise.

Finally, the proposed methods were applied to various simulated titration curves, corresponding to different $pK_a$ values, where the pH data contained a systematic error equal to 0.01 pH unit (about 5–10 times greater than the accuracy of a precision instrument). Experimentally such errors are usually introduced by an erroneous standardization of the pH-meter assembly. A systematic error in the pH values gives rise to systematic titration errors $\delta Z$, $\delta V_e$ and $\delta pK_a$ in the values of $Z$, $V_e$ and $pK_a$.

In all instances examined here ($Z = 1$ and $3.5 < pK_a < 6.5$), it was found that the titration errors $\delta Z$, $\delta V_e$ and $\delta pK_a$, at constant $\delta pH$, are dependent upon the strength of the acid that is being titrated. These errors decrease as $pK_a$ increases. For moderately strong acids (with $pK_a < 3.8$) $\delta V_e$ is less than 0.2%, $\delta pK_a < 0.008$ and only $\delta Z$ takes values greater than 1.0%. On the contrary, for acids with $pK_a \approx 4.8$ (such as the lower members of the aliphatic series of monocarboxylic acids) $\delta Z$ takes values less than 0.2%. For such acids the proposed techniques are able to extract the values $Z$, $V_e$ and $pK_a$ with only a modest error ($\delta Z \approx 0.14\%$, $\delta V_e \approx 0.00\%$ and $\delta pK_a \approx 0.01$), even when the pH data contain a systematic error $\delta pH = 0.01$.

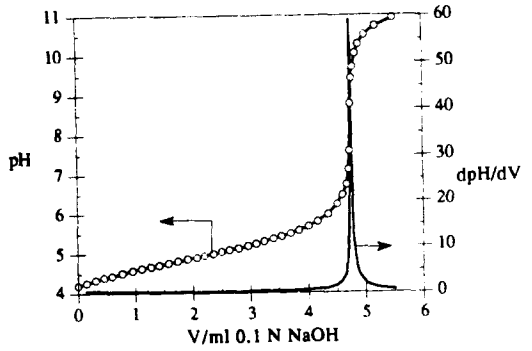

Fig. 2. Titration and differential titration of 50 ml of a mixture of propionic acid ($C_0 = 0.0095M$) with sodium propionate ($C_b^0 = 0.002M$, $Z = 1.00$ ml) with $0.1M$ NaOH at 25°C.

It is noted that in all calculations an unweighted least squares method has been used. However, in some selected examples, the data have been also analysed by means of a weighted least squares method reported in literature.[23] No significant differences have been found.

*Experimental data.* In the attempt to test this methodology on experimental data, a solution was prepared by mixing 5 ml of $0.1151M$ propionic acid with 1 ml of $0.1M$ NaOH and diluting with water until the final volume of 50 ml ($V_0 = 50$ ml, $C_0 = 0.0095M$, $Z = 1$, $C_b^0 = 0.002M$). This solution was titrated with $0.1M$ NaOH. The titration curve presents a pronounced inflection at $V \approx 4.75$ ml. (Fig. 2) The obtained measurements, lying in the 0 to 75% neutralization range of the corresponding titration curve, are given in Table 2. The plots of $R^2 = f(Z)$ and $S_{yx} = f(Z)$ present a maximum and a minimum, respectively, at a value of $Z$, equal to $Z_m$, lying in the vicinity of $Z = 1$ (Fig. 3). The exact value of $Z_m$ has been found

Table 2. Experimental titration of a mixture of propionic acid ($C_0 = 0.0095M$) with sodium propionate ($C_b^0 = 0.002M$, $Z = 1.00$ ml) with $0.1M$ NaOH at 25°C

| $V$ | pH | $V$ | pH |
|---|---|---|---|
| 0.00 | 4.200 | 1.58 | 4.760 |
| 0.15 | 4.266 | 1.74 | 4.807 |
| 0.31 | 4.335 | 1.91 | 4.856 |
| 0.46 | 4.395 | 2.07 | 4.904 |
| 0.60 | 4.445 | 2.20 | 4.943 |
| 0.78 | 4.510 | 2.36 | 4.991 |
| 0.96 | 4.569 | 2.50 | 5.035 |

| 1.28 | 4.671 | 2.80 | 5.132 |
| 1.42 | 4.713 | 2.96 | 5.188 |

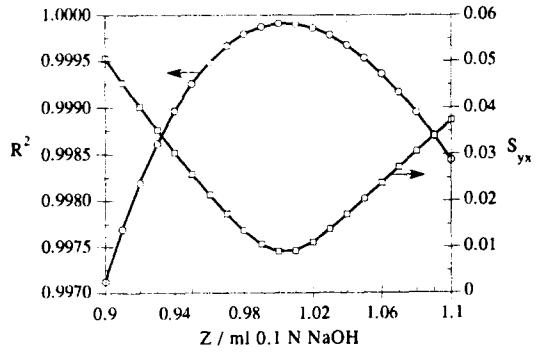

Fig. 3. Variation of $R^2$ and $S_{y.x}$ with $Z$ in the case of the titration of 50 ml of a mixture of propionic acid ($C_0 = 0.0095M$) with sodium propionate ($C_b^0 = 0.002M$, $Z = 1.00$ ml) with $0.1M$ NaOH at 25°C.

equal to 1.004 ml by seeking within the intervals (0.90, 1.10) and (1.000, 1.010) the $Z$ value successively. Furthermore, for $0.90 \leqslant Z \leqslant 1.10$ it was found that the curve $R^2 = f(Z)$ can be perfectly fitted, by least squares, to the following polynomial (where the squared correlation coefficients were very close to unity):

$$R^2 = \sum_{n=0}^{5} A_n Z^n = 0.2778 + 1.9511Z - 1.7374Z^2 - 0.5084Z^3. \quad (15)$$

By combining this equation with eqn (13), one again obtains the root $Z_m = 1.0035 \approx 1.004$ ml ($C_b^0 = 0.00201M$). From the coefficients of the linear regression equation $y = f(x)$ corresponding to this value of $Z$ we obtain $V_e = 4.751$ ml ($C_0 = 0.00950M$) and $pK_a = 4.878$. These values are in excellent agreement with the expected values of the above parameters. It is noted that the p$K$ value of propionic acid, reported in literature, is equal to 4.874 at 25°C.[10,11]

## POTENTIOMETRIC TITRATION OF WEAK POLYPROTIC ACIDS WITH STRONG BASES

Consider a solution of a molecular polyprotic acid $H_nA$ with overlapping ionization steps. A volume $V_0$ of this solution of initial analytical concentration $C_0$ is titrated with a solution of a strong base MOH of concentration $C_B$. The titration is assumed to be carried out in the acidic range. In this range, the analysis of the titration curve leads to the following equation:[24]

$$\hat{h} = \frac{\dfrac{K_1}{\alpha_H y_1} + \dfrac{2K_1K_2}{\alpha_H^2 y_2} + \cdots + \dfrac{nK_1K_2 \ldots K_n}{\alpha_H^n y_n}}{1 + \dfrac{K_1}{\alpha_H y_1} + \dfrac{K_1K_2}{\alpha_H^2 y_2} + \cdots + \dfrac{K_1K_2 \ldots K_n}{\alpha_H^n y_n}}, \quad (16)$$

with

$$\hat{h} = \frac{[M^+] + [H^+] - [OH^-]}{C} \quad (17)$$

and

$$C = \frac{C_0 V_0}{V_0 + V} = b_N C_0 V_0 = \frac{1}{n} b_N C_B V_e, \quad (18)$$

where $y_i$ denotes the activity coefficient of the species $H_{n-i}A^{i-}$ ($i = 0,1,2 \ldots n$) and $K_i$ the dissociation constant of the corresponding ionization step:

$$H_{n-(i-1)}A^{(i-1)-} \rightleftarrows H_{n-i}A^{i-} + H^+. \quad (19)$$

For diprotic acids, assuming that $y_0 = 1$, a combination of eqns (16)–(18) gives:

$$y = -K_1 + K_1K_2x, \quad (20)$$

with

$$y = \frac{Z}{X} \quad \text{and} \quad x = \frac{Y}{X} \quad (21)$$

and

$$X = \frac{y_2\left\{b_N C_b\left(V - \dfrac{V_e}{2}\right)y_1 + \alpha_H - \dfrac{K_w}{\alpha_H}\right\}\alpha_H}{y_1} \quad (22)$$

and

$$Y = b_N C_b (V_e - V) y_1 + \frac{K_w}{\alpha_H} - \alpha_H \quad (23)$$

$$Z = \left(b_N C_b V y_1 + \alpha_H - \frac{K_w}{\alpha_H}\right)\alpha_H^2 y_2. \quad (24)$$

For dilute solutions ($I < 0.1M$), the activity coefficient $y_1$ and $y_2$ can be determined from eqn (10), with the ionic strength $I$ of the solution from the appropriate formula.[15]

The determination of $V_e$, $K_1$ and $K_2$ from eqn (20), using $V$ and pH data, is possible with the iterative method proposed here. It is assumed first that the value of $V_e$ lies on an interval (a, b). Choosing arbitrarily from this interval a value for $V_e$, calculation of $y_1$ and $y_2$, at any point of the titration curve, requires knowledge of the corresponding value of $I$. On the other hand, $I$ is a function of $K_1$, $K_2$, $y_1$ and $y_2$. So, determination of $y_1$ and $y_2$ requires prior knowledge of $y_1$ and $y_2$. It appears that these calculations constitute a typical case of a vicious circle. However, calculation of $y_1$ and $y_2$ may be obtained by successive approximations. Assuming first that $y_1$, $y_2 = 1$, it is possible to determine from the coefficients of eqn (20), by means of the experimental $V$ and pH data, approximate values (apparent constants) of $K_1$, $K_2$.

Starting from these values and assuming

again that $y_1$, $y_2 = 1$, so that $\alpha_H = [H^+]$, it is possible to calculate $I$ at any chosen point of the titration curve, and hence $y_1$ and $y_2$ from eqn (10). These new values of $y_1$ and $y_2$ can be used to refine values of $I$ and repeat until it converges (the criterion being less than 0.00001 difference in $I$, between two subsequent cycles). By repeating these approximations at each point of the titration curve, it is possible to trace the curve $y = f(x)$ and determine by least squares the values of $K_1$ and $K_2$. These new values can be used to refine the values of $K_1$ and $K_2$ and repeat until they converge (the criterion being less than 0.0001 difference in $pK_1$ and $pK_2$ values, between two subsequent cycles). The final curve $y = f(x)$ obtained, by means of these approximation, will approach a straight line to the extent the chosen value of $V_e$ also approaches the exact value of this parameter. Hence, the best linearity that could be obtained, by means of the available experimental data, evidently corresponds to the best approximation to the exact value of the equivalence volume. Therefore, by seeking within the interval (a, b) the $V_e$ value, it is possible to trace $N$ curves $y = f(x)$, $N$ being the number of $V_e$ values taken for these calculations. For each of these curves, the calculation of $R^2$ and $S_{yx}$ permits the comparison of the adequacy of the fit of eqn (20) to the experimental $V$ and pH data. At the true value of $V_e$, these statistics may reach a maximum and minimum value respectively. Then, the exact values of $K_1$ and $K_2$ can be deduced respectively from the coefficients of the corresponding straight line.

An analogous procedure can be used in order to analyse the titration curves of triprotic acids. Assuming again that $y_0 = 1$, a combination of eqns (16)–(18) gives:

$$Y = K_1 + K_1K_2X_1 + K_1K_2K_3X_2, \qquad (25)$$

with

$$Y = \left(\frac{\hat{h}}{1-\hat{h}}\right)\alpha_H y_1,$$

$$X_1 = \left(\frac{2-\hat{h}}{1-\hat{h}}\right)\frac{y_1}{\alpha_H y_2}$$

and

$$X_2 = \left(\frac{3-\hat{h}}{1-\hat{h}}\right)\frac{y_1}{\alpha_H^2 y_3}. \qquad (26)$$

As in the case of diprotic acids, the activity coefficients $y_1$, $y_2$ and $y_3$ introduced in the above relationships can be determined from eqn (10), with the ionic strength $I$ of the solution from the appropriate formula.[26,27] The coefficients $y_1$, $y_2$ and $y_3$ can be calculated by successive approximations as in the case of diprotic acids.

Equation (25) predicts that the relationship $Y = f(X_1, X_2)$ is linear. The determination of $V_e$, $K_1$, $K_2$ and $K_3$ from this equation, using $V$ and pH data, is possible with the iterative method proposed here. As previously, we assume that $V_e$ lies in an interval (a, b). By seeking within this interval the $V_e$ value, it is possible to obtain $N$ relationships $Y = f(X_1, X_2)$, $N$ being the number of $V_e$ values taken for these calculations. For each of these relationships, the calculation of $R^2$ and $S_{yx}$ permits the comparison of the adequacy of the fit of eqn (25) to the experimental $V$ and pH data. At the true value of $V_e$, these statistics may reach a maximum and minimum value, respectively. Then, the exact values of $K_1$, $K_2$ and $K_3$ can be deduced, respectively, from the coefficients of the corresponding multiple linear regression equation.

The proposed procedures were applied to various simulated titration curves corresponding to different $pK_i$ and $V_e$ values of diprotic or triprotic acids. The obtained results showed that the proposed methods reach the desired values of the above parameters with a fair accuracy even when the data are considerably obscured by extraneous 'noise' or contain an important systematic error. For polyprotic acids and $pK_1 > 2.9$, the proposed techniques lead to the exact value of $V_e$ even when the pH data contain an important systematic error $\delta pH = 0.02$. For these acids a rough calibration of the electrode system is sufficient in order to extract the accurate value of the acid concentration.

The proposed methods were also applied on experimental data. Thus, in the titration of a diprotic acid, a solution of 0.00988$M$ succinic acid ($pK_1 = 4.209$, $pK_2 = 5.638$ at 25°C[11,25]) was prepared. A volume of 50 ml of this solution was titrated with 0.2$M$ NaOH. It was found that the graph $S_{yx}$ *vs.* $V_e$ presents a pronounced minimum (Fig. 4). In the vicinity of the minimum ($4.92 \leqslant V_e \leqslant 4.94$), the following polynomial was found:

$$(R^2 = 0.9997) \qquad 10^7 S_{yx} =$$

$$14889.0 - 6049.38V_e + 614.678V_e^2. \qquad (27)$$

From this equation one obtains $V_e^{min} = 4.9208$ ml ($C_0 = 0.00984M$) which is in excellent agreement with the expected value of the equivalence volume ($V_e = 4.94$ ml). Using this value, one

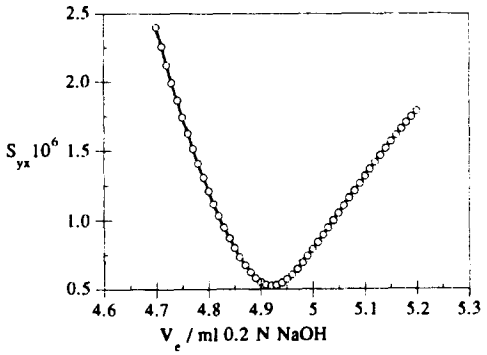

Fig. 4. Variation of $S_{yx}$ with $V_e$ in the case of the titration of 50 ml of 0.00988$M$ succinic acid with 0.2$M$ NaOH at 25°C.

obtains $pK_1 = 4.205$ and $pK_2 = 5.635$ from the coefficients of the corresponding linear regression equation $y = f(x)$. These values virtually coincide with those reported in the literature.

Finally, in the attempt to test this methodology on experimental data of the titration of a triprotic acid, a solution of 0.00968$M$ citric acid was prepared. A volume of 50 ml of this solution was titrated with 0.3$M$ NaOH. As previously, it was found that the plot $S_{yx} = f(V_e)$ presents a very pronounced minimum (Fig. 5). In the vicinity of the minimum ($4.82 \leqslant V_e \leqslant 4.84$), the following polynomial was found:

$$(R^2 = 0.9989)$$

$$10^2 S_{yx} = 109.06 - 45.130 V_e + 4.6689 V_e^2. \quad (28)$$

From this equation one obtains $V_e^{min} = 4.833$ ml ($C_0 = 0.0967M$) which is in excellent agreement with the expected values of the equivalence volume ($V_e = 4.84$ ml). Using this value, one obtains $pK_1 = 3.127$, $pK_2 = 4.776$ and $pK_3 = 6.385$ by fitting equation (25) to the titration data. These values virtually coincide with those suggested by N.B.S. ($pK_1 = 3.128$, $pK_2 = 4.761$ and $pK_3 = 6.396$ at 25°C).[28]

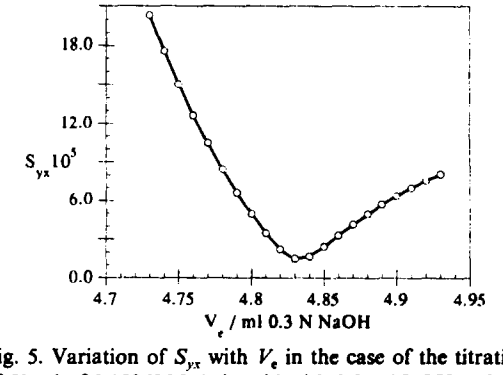

Fig. 5. Variation of $S_{yx}$ with $V_e$ in the case of the titration of 50 ml of 0.00968$M$ citric acid with 0.3$M$ NaOH at 25°C

## POTENTIOMETRIC TITRATION OF MIXTURES OF TWO WEAK DIPROTIC ACIDS WITH STRONG BASES

The titration of mixtures of two weak monoprotic acids has been treated previously.[1] Here, we present a method for analysis of potentiometric titrations of mixtures of two diprotic acids. It is noted that this problem has also been treated by Purdie *et al.* previously.[29] However, Purdie's method requires the knowledge of the sum of the concentrations of the acids; the $pK$'s values being known. On the contrary, in the present method the sum of the concentrations need not be known.

Consider a solution of a mixture of two weak diprotic acids $H_2A_1$ and $H_2A_2$ of initial analytical concentrations $C_1^0$ and $C_2^0$. A volume of $V_0$ of this solution is titrated with a solution of a strong base MOH of concentration $C_B$. Assuming that all equally charged ions have the same activity coefficients, the dissociation constants $K_{i1}$, $K_{i2}$ of the acid $H_2A_i$ (with $i = 1, 2$) are given by:

$$K_{i1} = \frac{\alpha_H \cdot [HA_i^-] \cdot y_1}{[H_2A_i]}$$

and

$$K_{i2} = \frac{\alpha_H \cdot [A_i^{2-}] \cdot y_2}{[HA_i^-] \cdot y_1}, \quad (29)$$

where $y_1$ and $y_2$ are the activity coefficients of the species $HA_i^-$ and $A_i^{2-}$, respectively.

At any point of the buffer region a relatively simple calculation gives:

$$Y = \left(\frac{K_{11}}{K_{21}}\right) C_1^0 + C_2^0 X, \quad (30)$$

where

$$Y = \frac{F \alpha_H^2 y_1 y_2 D_1}{b_N V_0 (\alpha_H y_2 + 2K_{12} y_1) K_{21}}$$

$$X = \frac{D_1 (\alpha_H y_2 + 2K_{22} y_1)}{D_2 (\alpha_H y_2 + 2K_{12} y_1)} \quad (31)$$

$$D_i = 1 + \frac{K_{i1}}{\alpha_H y_1} + \frac{K_{i1} K_{i2}}{\alpha_H^2 y_2}$$

$$F = b_N C_B V + \frac{\alpha_H}{y_1} - \frac{K_w}{\alpha_H y_1}. \quad (32)$$

For dilute solutions ($I < 0.1M$) the activity coefficients $y_1$ and $y_2$ can be determined from

eqn (10). Concerning the ionic strength $I$, a simple calculation gives:

$$I = [M^+] + [H^+] + [A_1^{2-}] + [A_2^{2-}] = b_N C_B V + \frac{\alpha_H}{y_1} + \frac{b_N V_0}{\alpha_H^2 y_2}\left(\frac{K_{11}K_{12}C_1^0}{D_1} + \frac{K_{21}K_{22}C_2^0}{D_2}\right). \quad (33)$$

Equation (30) predicts a linear relationship between $Y$ and $X$ with a $y$-intercept and slope equal to $K_{11}C_1^0/K_{21}$ and $C_2^0$, respectively. So, the composition of the mixture can be deduced, by linear regression, from the coefficients of eqn (30); the acidity constants $K_{i1}$, $K_{i2}$ (with $i = 1, 2$) being known. This procedure can be realized by the presently proposed iterative method.

Assuming first that $I = b_N C_B V + \alpha_H$, so that $\alpha_H \approx [H^+]$ and $[A_1^{2-}], [A_2^{2-}] \approx 0$, it is possible to determine from the coefficients of eqn (30), by means of the experimental $V$ and pH data, approximate values of $C_1^0$ and $C_2^0$. Starting from these values and assuming again that $\alpha_H \approx [H^+]$, it is possible to calculate $I$ from eqn (33) at any chosen point of the titration curve, and hence $y_1$ and $y_2$ from eqn (10). These new values of $y_1$ and $y_2$ can be used to refine values of $I$ and repeat until it converges (the criterion being less than 0.00001 difference in $I$, between two subsequent cycles). By repeating these approximations at each point of the titration curve, it is possible to trace the curve $Y = f(X)$ and determine by least squares the values of $C_1^0$ and $C_2^0$. These new values can be used to refine the values of $C_1^0$ and $C_2^0$ and repeat until they converge (the criterion being less than $10^{-12}$ difference in $C_1^0$ and $C_2^0$ values, between two subsequent cycles).

This procedure was applied to various simulated (ideal and Monte Carlo) titration data corresponding to different $C_1^0$ and $C_2^0$, $pK_{i1}$ and $pK_{i2}$ values. The obtained results showed that the proposed method reaches the desired values of $C_1^0$ and $C_2^0$ with a fair accuracy even when the data are considerably obscured by extraneous 'noise' (about 5–10 times greater than the accuracy of a precision instrument). Finally, in the attempt to test the proposed methodology on experimental data, a mixture was prepared by mixing 20 ml of 0.00988$M$ succinic acid with 30 ml of 0.00982$M$ tartaric acid. This mixture was titrated with 0.20$M$ NaOH. In all the calculations, we used experimental $pK_{i1}$ and $pK_{i2}$ values obtained, as described previously, from separate titrations. Thus, we used the values $pK_{11} = 4.205$, $pK_{12} = 5.635$, $pK_{21} = 3.033$ and $pK_{22} = 4.366$ which are in excellent agreement with the corresponding values suggested by N.B.S. ($pK_{11} = 4.209$, $pK_{12} = 5.638$, $pK_{21} = 3.033$ and $pK_{22} = 4.366$).[11,25,30] Assuming first that $I = b_N C_B V + \alpha_H$, so that $\alpha_H \approx [H^+]$ and $[A_1^{2-}], [A_2^{2-}] \approx 0$, the following approximate values of $C_1^0$ and $C_2^0$ were obtained: $C_1^0 \approx 4.043 \times 10^{-3}M$ and $C_2^0 \approx 5.878 \times 10^{-3}M$. Starting from these values one finally obtains, after four iterations, the following values: $C_1^0 = 3.928 \times 10^{-3}M$ and $C_2^0 = 5.883 \times 10^{-3}M$. These values are in excellent agreement with the expected values of $C_1^0$ ($= 20 \times 0.00988/50 = 3.952 \times 10^{-3}$) and $C_2^0$ ($= 30 \times 0.00982/50 = 5.892 \times 10^{-3}$). Finally, it should be noted that at these values of $C_1^0$ and $C_2^0$, the anticipated by equation (30) linear relationship between $Y$ and $X$ has been perfectly confirmed ($R = 0.99995$).

## CONCLUSIONS

The methods proposed in this investigation, based on equations without approximations, are valid throughout the acidic strength range. These methods, using data resulting from the acidic region of the titration curves, enable the prediction of the accurate value of the equivalence volume and determine simultaneously the acid dissociation constants, even if the titration is stopped well before the complete neutralization of the solution. The proposed procedures are valid even when the titrations are performed under conditions of varying ionic strength, but there is no reason why the analysis would not be carried out in conditions of constant ionic strength. Hence the addition of a neutral salt to the titrated solution to keep the ionic strength constant is not necessary. Therefore, the $pK$ values obtained in media of low ionic strength are free of any possible 'salt effect'.

The main advantage of the proposed techniques, in comparison to other approaches appearing in the literature, is the simultaneous determination of the equivalence volume and the accurate values of the corresponding $pK$. Indeed, $pK$ being independent of the concentration could be considered as the 'fingerprint' of the titrated acid. So, from the comparison of the determined $pK$ values with tabulated ones it is possible to identify the titrated acid.

In the titration of a solution containing initially a monoprotic acid in admixture with its conjugate base, the proposed procedure determines the initial composition of the mixture as well as the accurate values of the dissociation

constant of the concerned acid. Thus, it is possible by this type of analysis to distinguish if an weak acid has been contaminated by a strong base and define the extent of the contamination. This method is fairly applicable even when the titration data are considerably obscured by experimental 'noise' or contain an important systematic error.

In the titration of polyprotic (di- and triprotic) acids, the proposed procedures enable the extraction of the accurate values of the equivalence volume and the dissociation constants $K_i$ even when the ionization stages overlap. This investigation revealed that these methods are fairly applicable even when the titration data are considerably obscured by experimental 'noise' or contain an important systematic error.

Finally, in the titration of a solution containing a mixture of two diprotic acids, the proposed method enables the determination of the composition of the mixture without prior knowledge of the sum of the concentrations of the acids. This method could be applied to the determination of the composition of two-component mixtures of closely related acids such as mixtures containing two diastereoisomeric forms of weak diprotic acids.

(*Received* 7 *June* 1994. *Revised* 2 *December* 1994. *Accepted* 2 *December* 1994)

**Summary**—A method has been developed for the spectrophotometric determination of siderophores using flow-injection analysis (FIA) based on the reaction of siderophores with the ternary complex Eriochrome Cyanine R–Fe(III)–cetyltrimethylammonium bromide. 2,3-Dihydroxybenzoic acid, 2,3-dihydroxynaphthalene, and tolypocine were used as the model iron-binding ligands. The calibration curve for one of the siderophores (tolypocine) is linear in the concentration range $2.6 \times 10^{-6}$–$1.5 \times 10^{-4}M$. The determination limit ($10\sigma$) for tolypocine was $2.6 \times 10^{-6}M$. The applicability of the method was demonstrated on the determination of the complexation ability of siderophores produced by some entomopathogenic fungi. Samples can be analysed at a rate of 30 samples per hour.

Siderophores are natural low molecular weight iron-binding ligands containing catechol, hydroxamic, α-hydroxy-carboxylic or oxazoline groups. The extracellular production of siderophores and selective transmembrane withdraw of iron complexes help various microorganisms to obtain iron, an essential element for their growth and multiplication.[1,2] In living organisms siderophores produced by some pathogens are able to compete with iron-binding proteins of their hosts. In some cases, a correlation was found between the production of siderophores and the ability of these pathogens to cause systemic disease.[3] Thus in principle, the development of a suitable method for the determination of siderophores might contribute to the evaluation of the virulence of causative pathogens of immunocompromized, e.g. HIV-positive persons. Since manipulation with the infected material represents a serious health hazard, FIA was chosen as a method permitting fully automated sample handling.[4–6] To avoid such a health hazard in the course of the method development, fungi which are not pathogenic to humans were used as a model in this study.

Tolypocine ($C_{15}H_{21}NO_3$, $M_r$ 263,34) is a siderophore isolated from the fungus *Tolypocladium geodes* and has the structure of hydroxamic acid (1′*S*,2′*R*,4′*S*,6′*R*)-5-(2′-vinyl-4′,6′-dimethyl-cyclohexyl)-1,4-dihydroxy-2(1*H*)-pyridone. The isolation and characterization of tolypocine were described by Jegorov *et al.*, who also described the crystal structure of tolypocine and its Fe(III) complex.[3] Some related fungal genera used in this study also produce hydroxamic acids of similar structure.[7]

Catecholic siderophores can be determined by the Arnow spectrophotometric method based on the nitration of the aromatic ring by sodium nitrite in the presence of sodium molybdenate.[8] This method is selective for aromatic vicinal diols that are not substituted in the 3- or 4-positions.[9] In the presence of triethylamine in ethanol solutions, aromatic vicinal diols also form blue-green chelates with Fe(III) ions.[10] Rioux *et al.*[9] described a method for the spectrophotometric determination of catechol compounds based on the ability of the vicinal aromatic hydroxyl group to reduce Fe(III) to Fe(II) in acidic medium. Our work follows from the work of Schwyn and Neilands,[11] who described a method for the determination of various types of siderophores based on the replacement of a weakly bonded triphenylmethane dye from the Fe(III)–dye–surfactant complex by the siderophore.

## EXPERIMENTAL

### *Apparatus and manifold*

A Pye-Unicam PU 8800 spectrophotometer with 1.0-cm quartz curvettes was used for recording the spectra. A Radiometer PHM 64 pH-meter was used. A scheme of the apparatus for flow-injection analysis constructed in our laboratory is depicted in Fig. 1. The length of reaction coil was $L = 6$ m, the reagent was pumped at a flow rate of $v_2 = 0.4$ ml/min and the carrier stream of deionized water had a flow rate of $v_1 = 1.0$ ml/min.

The equipment for flow-injection analysis was constructed using a peristaltic pump (Cole-Parmer Instrument Co., U.S.A.) with tygon pumping tubing, rotation injection valve (Valco, U.S.A.), Spekol 11 spectrophotometer with accessory EK 5 (K. Zeiss, Germany) and flow-through cell (Hellma, German, internal volume 80 $\mu$l), TZ 4620 x -t recorder (Laboratorní přistroje, Czech Republic), PE tubing 0.5 mm i.d.), polypropylene connectors (Cole-Parmer Instrument Co., U.S.A.).

The HPLC measurements were carried out with a reverse phase C-18, Pico-fag (Waters), particle size 4 $\mu$m. Dimensions of the column were 150 x 3.9 mm. The mobile phase for tolypocine consisted of 60% methanol, 0.2% trichloroacetic acid and water, flow rate 1.5 ml/min. UV photometric detection at 290 nm was used; measurement was carried out at 20°C. Retention time for tolypocine was 5.50 min.

### *Chemicals*

All chemicals were of analytical grade and were used as received. The following aqueous stock solutions were used: Chrome Azurol S (CAS, $2 \times 10^{-3}M$, Merck, Germany), Pyrocatechol Violet (PV, $2 \times 10^{-3}M$, Lachema, Czech Republic), Eriochrome Cyanine R (ECR, $2 \times 10^{-3}M$, Lachema, Czech Republic), cetyltrimethylammonium bromide (CTAB, $5 \times 10^{-2}M$, Lachema, Czech Republic), 1-ethoxycarbonylpentadecyltrimethylammonium bromide (Septonex, $5 \times 10^{-2}M$, Slovakofarma, Slovak Republic), 2,3-dihydroxynaphthalene (2,3-DHN, $5 \times 10^{-3}M$, Fluka, Switzerland), pyrocatechol, pyrogallol and hydroquinone ($5 \times 10^{-3}M$, Lachema, Czech Republik). The purity of ECR was checked using thin-layer chromatography.[12] $1 \times 10^{-3}M$ Fe(III) ion solutions were prepared by dissolving $FeCl_3 . 6H_2O$ (Lachema, Czech Republic) in $1 \times 10^{-3}M$ hydrochloric acid. The iron content was checked by the AAS method. The $5 \times 10^{-4}M$ standard solution of tolypocine was prepared by dissolving tolypocine, $C_{15}H_{21}NO_3$[3] in a 40% (v/v) aqueous methanol solution. The $1.67M$ stock solution of piperazine buffer was prepared by dissolving anhydrous piperazine (Merck, Germany) in deionized water; the pH value was adjusted with hydrochloric acid to pH 7.0. The solution was quantitatively transferred to a 1000 ml volumetric flask and filled with deionized water. All the chemical glass used was prior rinsed with $6M$ hydrochloric acid.

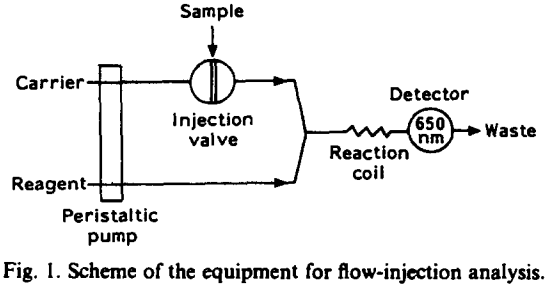

Fig. 1. Scheme of the equipment for flow-injection analysis.

### *Reagent preparation*

A solution of Eriochrome Cyanine R (12.5 ml) with a concentration of $2 \times 10^{-3}M$ and 2.5 ml of a solution of $FeCl_3$ with a concentration of $1 \times 10^{-3}M$ were pipetted into a 250 ml volumetric flask and left to react for 3 min. Then 12.5 ml of $5 \times 10^{-2}M$ CTAB solution was added to 75 ml of the stock solution of piperazine buffer, transferred quantitatively to the volumetric flask with ECR and Fe(III), and filled with deionized water. The reagent can be used for measurement 15 min after mixing the ECR and Fe(III) solutions.

### *Fungal material*

The following entomopathogenic fungal strains were used for the study: *Scopulariopsis bravicaulis* (CB-SR), *Olpitrichum* sp. (CCEB 2061, *Dendrolimus pini*), *Tolypocladium geodes* (CCF 257, *Tolypocladium inflatum* (CCF 1897), *Tolypocladium terricola* (CB-TTR1), *Beauveria bassiana* (CB-BBA5, *Hylobius abietis*), *Trichoderma konigii* (CCEB 2063, Cuba), *Paecilomyces farinosus* (CB-STR, *Hylobius abietis*), *Paecilomyces fumosoroseus* (CCEB 2012), *Beauveria brongniartii* (cceb 2176, *Ibs typographus*, Bulgaria). Strains were cultivated and provided by Dr Z. Kadlec (Galena, České Budějovice). Fungi were cultured either stationary (21 days at 25°C in conical flasks on 100 ml of Sabouraud medium) or in submerged culture

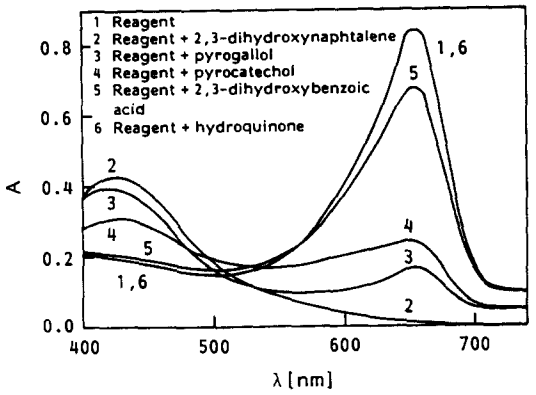

Fig. 2. The absorption spectrum of the reagent in the absence and presence of hydroxy compounds. $c_{ECR} = 3.75 \times 10^{-5}M$; $c_{Fe(III)} = 3.75 \times 10^{-6}M$; $c_{CTAB} = 1.5 \times 10^{-4}M$; $c_{hydroxy\ compound} = 3 \times 10^{-5}M$; pH 7.5; $t = 2$ min.

(10 days at 25°C in conical flasks in 200 ml of Sabourad medium). A 72-hr submerged preculture on Sabouraud medium (18 g glucose (Lachema, Czech Republic), 18 g maltose (Lachema, Czech Republic), 8 g pepton (Fluka, Switzerland), 0.3 g yeast extract (Difco) per 1000 ml) was used as inoculum (1:10, v/v). Samples of the non-sterile media were obtained by filtration of the fermentation broths and were used without stabilizers.

## RESULTS AND DISCUSSION

The described method is based on the fact that the Fe(III) has a high affinity for the siderophores.[3,11] Thus, the following reaction occurs:

$$[Fe^{3+} - B - T] + S \rightarrow [Fe^{3+} - S] + B - T, \quad (1)$$

where B is the triphenylmethane dye, T is the tenside and S is the siderophore.

The reagent is the complex of the triphenylmethane dye with Fe(III) in the presence of the cationogenic tenside (the tensides shift the absorption maximum of complexes to the longer wavelength, increasing the $\lambda_{max}$ difference of complex and dye[13]).

### *Spectrophotometric determination of* 2,3-*dihydroxynaphthalene*

Preliminary experiments were carried out using 2,3-dihydroxybenzoic acid (2,3-DHBA), which has been used in some other methods as a model substance for determining siderophores.[1,9] Its reaction with the following triphenylmethane dyes was studied: Chrome Azurol S, Pyrocatechol Violet and Eriochrome Cyanine R. The most sensitive was found to be Eriochrome Cyanine R[14-16] ($\varepsilon_{650} = 3.2 \times 10^6 M^{-1}$). In the course of reaction of the Fe(III)–dye–tenside complex with a siderophore, the color changes from blue, corresponding to the ternary complex, to an orange, corresponding to the liberated dye–tenside. The decrease of absorbance is monitored at the wavelength of the absorption maximum of the original ternary complex (reagent).

As the reaction of 2,3-DHBA with the reagent was not sufficiently sensitive, a different substance was sought, that would have greater affinity for the Fe(III) ions and retaining complexing properties similar to the siderophores. Comparison was carried out (see the absorption spectra in Fig. 2) using hydroxy compounds with hydroxyl groups in the *ortho* position on the aromatic nucleus. Hydroquinone, with hydroxyl groups in mutually *para* positions, which does not form a complex with Fe(III), was also used for comparison. As follows from Fig. 2, a redox reaction with Fe(III) did not occur even with this substance. On the basis of these reactions, 2,3-dihydroxynaphthalene (2,3-DHN) was chosen for further work; the affinity of this substance for Fe(III) makes it useful for the determination of this element.[15-17] Of the cationogenic tensides CTAB and Septonex were selected for study of the reaction. The effect of the pH (Fig. 3), reagent composition and concentrations of the individual components of the reagent [ECR, Fe(III), CTAB, Septonex] on the sensitivity of the reaction was studied. The sensitivity achieved using CTAB tenside is approximately twice the greatest sensitivity of the reaction using Septonex. The following optimum reagent composition was found: $c_{Fe(III)} = 1 \times 10^{-5}M$, $c_{ECR} = 1 \times 10^{-4}M$, $c_{CTAB} =$

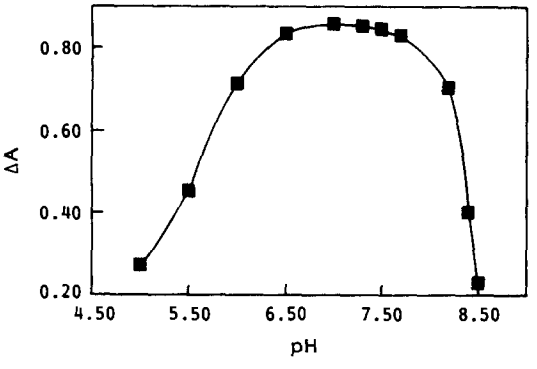

Fig. 3. Dependence of the absorbance change ($A$) at the wavelength of maximum reagent absorbance on the pH. $c_{ECR} = 7.5 \times 10^{-5}M$; $c_{Fe(III)} = 7.5 \times 10^{-6}M$; $c_{CTAB} = 3 \times 10^{-4}M$; $c_{2,3\text{-}DHN} = 3 \times 10^{-5}M$, $t = 60$ s.

$2.5 \times 10^{-3}M$, *i.e.* where the ratio of the concentrations of the components of the reagent is Fe(III):ECR:CTAB = 1:10:250. The maximum decrease in the absorbance was obtained 90 sec after mixing the reagent with the 2,3-DHN solution; the absorbance values were constant for at least 300 sec. In addition, it was found that the reaction rate is practically temperature-independent at all the temperatures tested; the equilibrium state of the reaction was attained 90 sec after mixing the reagent with the test substance.

The reagent with pH 7.0 exhibits maximum absorbance at 650 nm. If stored in a glass volumetric flask, it is stable for 4.5 hr; new reagent must be prepared for a longer series of measurements. In the measurement of a number of series of samples during a single day, it was found useful to store the reagent in a polyethylene bottle, where the absorbance at 650 nm attains maximum value after 2 hr and is constant for at least 10 hr. The lower stability of reagent in a glass volumetric flask than in a polyethylene bottle is probably caused by higher sorption of reagent on the glass wall.

Under the optimum conditions found ($\lambda = 650$ nm, pH 7.0, $c_{Fe(III)} = 1 \times 10^{-5}M$, concentration ratio Fe(III):ECR:CTAB = 1:10:250, $t = 90$ sec), the dependence of the absorbance change ($\Delta A$) on the concentration of 2,3-dihydroxynaphthalene was measured; the calibration curve is linear for the 2,3-DHN concentration range from $5 \times 10^{-7}$ to $8 \times 10^{-6}M$, *i.e.* 0.08–1.28 $\mu$g of 2,3-dihydroxynaphthalene per mil. The reproducibility of the measurement was tested in repeated determinations. The relative standard deviation of the measurement (determined from 5 measurements) varied from 0.7 ($8 \times 10^{-6}M$) to 1.3% ($5 \times 10^{-7}M$). The parameters of the calibration straight line $A = a + b \,.\, c_{2,3\text{-DHN}}$ were $b = 8.83 \times 10^{-4}M$, $a = -0.0178$, and the correlation coefficient $r = 0.9998$. The detection limit ($3\sigma$) was $5 \times 10^{-7}M$ and the determination limit ($10\sigma$) was $1.2 \times 10^{-6}M$. A study was also made of the effect of the presence of methanol on the reaction of reagent with 2,3-dihydroxynaphthalene. It was found that methanol disturbs the reaction above a concentration ratio of 2,3-DHN:methanol = $1:10^5$.

*Spectrophotometric determination of tolypocine*

Using parameters optimized with 2,3-dihydroxynaphthalene, tolypocine was used as an alternative ligand. An appropriate amount of $5 \times 10^{-4}M$ methanol solution of tolypocine was added to the Fe(III):ECR:CTAB (1:10:250) reagent in a volumetric flask and diluted with deionized water. Reagent with deionized water was used as blank. After 90 sec the absorbance was measured at a wavelength of 650 nm, giving the calibration curve. The dependence of the absorbance change ($\Delta A$) on the tolypocine concentration (measured at the same conditions as in the case of 2,3-DHN) was linear from $8 \times 10^{-7}$ to $2 \times 10^{-5}M$, *i.e.* from 0.2 to 5.3 $\mu$g tolypocine per ml. The relative standard deviations (from 5 measurements) varied in the range 0.9% ($2 \times 10^{-5}M$) to 1.9% ($8 \times 10^{-7}M$). The parameters of the calibration straight line were $b = 4.96 \times 10^{4}M^{-1}$, $a = -0.017$, and the correlation coefficient $r = 0.9994$. The detection limit ($3\sigma$) is $7.6 \times 10^{-7}M$ and the determination limit ($10\sigma$) was $1.7 \times 10^{-6}M$.

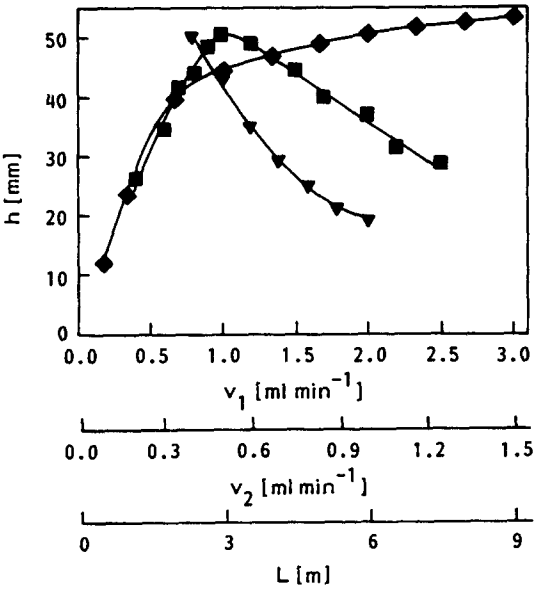

Fig. 4. Dependence of the recorded peak height (h) on the flow rate of the carrier stream $v_1$ (▼, at $v_2 = 0.4$ ml/min, $L = 6$ m) on the flow rate of the reagent $v_2$ (■, at $v_1 = 1.0$ ml/min, $L = 6$ m) and on the length of the reaction coil L (◆, at $v_1 = 1.0$ ml/min, $v_2 = 0.4$ ml/min). pH 7.0, $c_{Fe(III)} = 1 \times 10^{-5}M$, concentration ratio Fe(III):ECR:CTAB = 1:10:250, $c_{2,3\text{-DHN}} = 3.5 \times 10^{-5}M$, volume injected = 100 $\mu$l.

*Optimization of flow-injection analysis*

The parameters of the flow-through apparatus were optimized on the basis of the reaction with 2,3-dihydroxynaphthalene in order to achieve the maximum sensitivity and reproducibility of the determination. Figure 4 depicts the effect of the length of the reaction coil, and the flow rate of the carrier stream and of the reagent

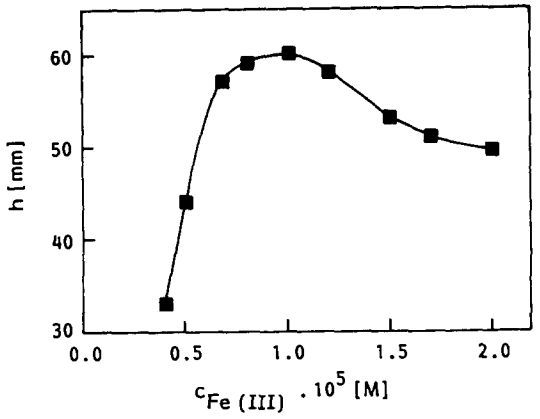

Fig. 5. Dependence of the recorded peak height (h) on the reagent concentration related to the Fe(III) concentration [the concentration ratio Fe(III):ECR:CTAB = 1:10:250]. $L = 6$ m, $v_1 = 1.0$ ml/min, $v_2 = 0.4$ ml/min, pH 7.0, $c_{2,3\text{-}DHN} = 3.5 \times 10^{-5} M$, volume injected = 100 $\mu$l.

on the height of the peaks obtained. It follows from this figure that the optimal FIA parameters were: reaction coil length, $L = 6$ m (chosen as a compromise between the maximum sensitivity of the determination and maximum number of analyses per hour), carrier stream flow rate, $v_1 = 0.10$ ml/min, reagent flow rate, $v_2 = 0.4$ ml/min. The optimal ratio of the reagent components was determined by varying the concentrations of the individual components and was found to be Fe(III):ECR:CTAB = 1:10:250. The optimum reagent concentration (Fig. 5) was related to a Fe(III) concentration of $1 \times 10^{-5} M$.

The effect of the injected volume of sample on the sensitivity of the determination was evaluated in the range 35–1000 $\mu$l, under the selected optimum conditions. The optimum injection volume was selected as 100 $\mu$l. The effect of the injected volume on the linear calibration dependence was also tested (Table 1). It was found that (compared to an injected amount of 35 $\mu$l), the injection of 100 $\mu$l increased the sensitivity of the determination, found from the slope of the calibration curve, by about 2.5-fold. Using an injected amount of 35 $\mu$l, a total of 40 samples per hour could be analysed; the use of an injected amount of 100 $\mu$l decreased this to 30 analyses per hour.

It follows from these results that the constructed apparatus for flow-injection analysis exhibits parameters comparable with equipment used by other authors.[18–21]

*FIA determination of tolypocine*

The dependence of the peak height ($h$) on the tolypocine concentration was linear in the concentration range from $2.6 \times 10^{-6}$ to $1.5 \times 10^{-4} M$, *i.e.* from 0.7 to 39.5 Mg tolypocine per ml. The relative standard deviation (from 5 measurements) varied in the range 1.2% ($1.5 \times 10^{-4} M$) to 3.5% ($2.6 \times 10^{-6} M$). The parameters of the calibration straight line $h = a + b \,.\, c$ were $b = 7.7 \times 10^5$ mm $.\, M^{-1}$, $a = 5.48$ mm and the correlation coefficient $r = 0.9994$. The determination limit ($10\sigma$) was $2.6 \times 10^{-6} M$.

*Determination of siderophores in real samples*

The parameters of simple spectrophotometric and FIA analysis optimized for the model compounds were used to determine the production of siderophores by some entomopathogenic fungi. Conditions and results of this study are summarized in Table 2. In the case of analysed siderophores the duration of reaction was a few minutes; the measurement was carried out in 90 sec after injection of sample. As follows from the table, all fungal strains belonging to genera *Beauveria* and *Paecilomyces* produce relatively large amount of siderophores. Assuming that the fungus *Tolypocladium geodes* produce only tolypocine its concentration was evaluated by the method of standard additio. The value obtained, *i.e.* 17.5 $\mu$g/ml ($6.6 \times 10^{-5} M$) is in good agreement with that found by HPLC (data not shown). In contrast, the production of siderophores was very small with the isolates of *Scopulariopsis* and *Olpitrichum*. The correlations between the results of spectrophotometric and FIA analysis of samples obtained by stationary and submerged cultivation are given

Table 1. Parameters of the calibration straight lines for various injected volumes of the test substances

| Injection volume, $V$ ($\mu l$) | 35 | 100 | 500 |
|---|---|---|---|
| Intercept, $a$ ($mm$) | 2.02 | 5.36 | 5.41 |

*$c_{ECR} = 1 \times 10^{-4} M$, $c_{Fe(III)} = 1 \times 10^{-5} M$, $c_{CTAB} = 2.5 \times 10^{-3} M$, pH 7.0, protocol: reagent 5 *ml*, medium 1 *ml*, water to the total volume 10 *ml*, $t = 90$ *sec*.

†$L = 6$ *m*, $v = 1.0$ *ml/min*, $v_2 = 0.4$ *ml/min*, pH 7.0, $c_{Fe(III)}$ $1 \times 10^{-5} M$, Fe(III):ECR:CTAB = 1:10:250, volume injected = 100 *µl*.

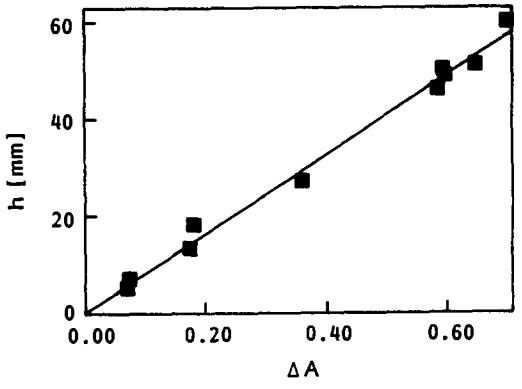

Fig. 6. Correlation graph between the spectrophotometric and FIA results for siderophores produced by various fungal isolates cultivated by stationary cultivation.

in Figs 6 and 7. The parameters of the correlation straight lines $h = a + b \,.\, \Delta A$ were $b = 81.79$ (76.77), $a = 0.0657$ (0.0400) and the correlation coefficient $r = 0.9954$ (0.9955)) for stationary (submerged) cultivation.

Owing to the fact that the different fungal isolates produce various types of siderophores, which also differ in their stability constants with Fe(III), values obtained represent only the relative complexation ability, *e.g.* the sum of contributions of all ligands present in the particular medium. Only in the case, the sole siderophore is produced, the method can be used for the quantification of its production. Whereas the methods like GC or HPLC are usually much better for the determination of the absolute concentration of the particular compound, FIA is the favoured method for the screening of siderophores of unknown structure. Owing to the extremely short time necessary for one analysis, FIA is also a method of choice for the fast comparison of fungal or bacterial isolates even in the case where the structure of the produced siderophores is well known.

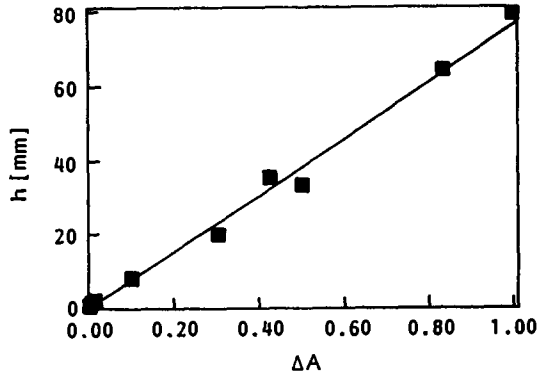

Fig. 7. Correlation graph between the spectrophotometric and FIA results for siderophores produced by various fungal isolates cultivated by submerged cultivation.

# DETERMINATION OF THE INTRINSIC SITE p$K_a$ VALUE AND COOPERATIVITY OF THE SYMMETRICAL HEXADENTATE CHELATOR *N,N′,N″*-TRIS[2-(3-HYDROXY-2-OXO-1,2-DIHYDROPYRIDIN-1-YL)ACETAMIDO]ETHYLAMINE

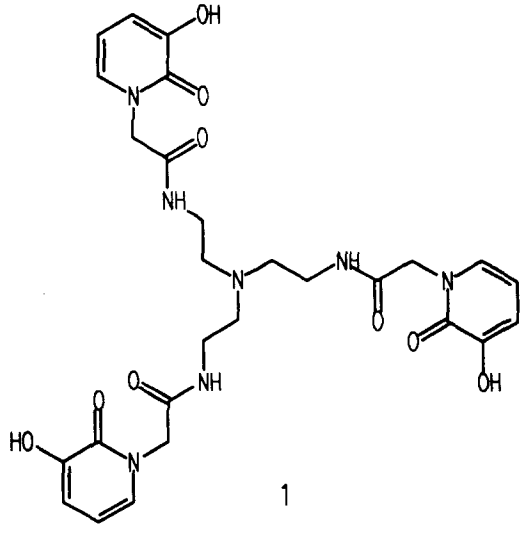
PAUL D. TAYLOR

Department of Chemistry and Biological Chemistry, University of Essex, Wivenhoe Park, Colchester, CO4 3SQ, U.K.

(*Received* 7 *June* 1994; *Revised* 29 *November* 1994; *Accepted* 2 *December* 1994)

**Summary**—The three overlapping p$K_a$ values of *N,N′,N″*-tris[2-(3-hydroxy-2-oxo-1,2-dihydropyridin-1-yl)acetamido]ethylamine, a tripodal hexadentate chelator formed from three 3-hydroxy-2(1*H*)-pyridinone moieties amide linked to tris-(2-aminoethyl)amine, were determined by simultaneous spectrophotometric and potentiometric titration. The data was analysed by non-linear regression with constraints to deal with (a) the highly correlated absorptivities and (b) the highly correlated p$K_a$ values. The three p$K_a$ values were optimized first from the spectrophotometric data (absorbance *vs.* pH) by non-linear regression to a model in which the molar absorptivity of the *i*th species ($\epsilon_i$) was constrained by the correlation equation $\epsilon_i = \epsilon_0 + (\epsilon_3 - \epsilon_0)i/3$ with $i = 0, 1, 2, 3$, where $\epsilon_3$ and $\epsilon_0$ represent the molar absorptivities of the most protonated and least protonated species, respectively. The molar absorbitivity of the four species defined by three p$K_a$ values is, therefore, linearly related to proton stoichiometry. The p$K_a$ values were then optimized from the potentiometric data (pH *vs.* titrant volume) by non-linear regression to a model in which the three p$K_a$ values were constrained by the correlation equation $pK_{a_i} = pK_{a_{int}} + b(i-1) + (i-2)\log(3)$ where $i = 1$, 2 or 3. This expresses the three p$K_a$ values in terms of only two optimizable parameters, the intrinsic site p$K_a$ (p$K_{a_{int}}$) and the interaction energy between sites (b). The fixed term $(i-2)\log(3)$ accounts for the statistical effect on the p$K_a$ values of three equivalent ionizable sites. The modified analytical derivatives required for optimization of these parameters by the Gauss–Newton–Marquardt algorithm and the merits of optimizing p$K_a$ values with these two correlation equations are discussed. The optimized p$K_a$ values were $9.31 \pm 0.01$, $8.75 \pm 0.01$ and $8.19 \pm 0.01$. The separation between p$K_a$ values is 0.58 comprising 0.477 for the statistical effect and 0.081 for the interaction energy while the intrinsic site p$K_a$ is $8.672 \pm 0.005$. The tertiary amine at the centre of the tripodal backbone has a p$K_a$ of $5.88 \pm 0.03$.

Braibanti *et al.*[1] have emphasized the inadvisability of optimizing several stepwise p$K_a$ values in molecules with several identical ionizable sites, as independent variables. The hexadentate metal-ion chelator *N,N′,N″*-tris[2-(3-hydroxy-2-oxo-1,2-dihydropyridin-1-yl)acetimido]ethyl-amine (**1**), is of medicinal interest in the treatment of iron-overload.[2] The molecule coordinates iron(III) strongly with its three identical 3-hydroxy-2(1*H*)-pyridinone units, each of which has an ionizable hydroxyl group. The p$K_a$ values of these identical groups are, therefore, highly correlated. This work considers two methods for optimising the three p$K_a$ values by non-linear regression to models which account for this correlation.



1

The analysis of spectrophotometric data (absorbance vs. pH) was carried out using a correlation equation which linearly relates molar absorptivity to proton stoichiometry. Thus, if the molar absorptivities of the most protonated and the least protonated species are represented by $\epsilon_3$ and $\epsilon_0$, respectively, then the molar absorptivity of the $i$th protonated species is given by eqn (1).

$$\epsilon_i = \epsilon_0 + (\epsilon_3 - \epsilon_0)i/3. \quad i = 0,1,2,3 \qquad (1)$$

The work demonstrates that this simple equation is valid for the particular case examined and suggests the criteria to test its validity in other cases.

The analysis of potentiometric data (pH *vs.* titrant volume) was carried out using a correlation equation which expresses the stepwise $pK_a$ values of identical sites, in terms of an intrinsic site $pK_a$, a statistical term, and a site interaction term (eqn 2). In the case of $n$ identical subunits, purely statistical factors would lead to $n$ $pK_a$ values, with the $i$th $pK_a$ given by $pK_{a_{int}} - \log\{(n - i + 1)/i\}$ where $pK_{a_{int}}$ is the intrinsic $pK_a$ of the site. In this case, $n = 3$ and the three $pK_a$ values of the hexadentate would then be $pK_{a_1} = pK_{a_{int}} - \log(3)$, $pK_{a_2} = pK_{a_{int}} - \log(1)$ and $pK_{a_3} = pK_{a_{int}} - \log(1/3)$ or $pK_{a_i} = pK_{a_{int}} + (i - 2)\log(3)$. Interaction between sites introduces an additional term, largely coulombic, for each $pK_a$ which is assumed in eqn (2) to increase linearly with the charge on the species from which a proton is dissociating.

$$pK_{a_i} = pK_{a_{int}} + b(i - 1) + (i - 2)\log(3). \quad i = 1,2 \text{ or } 3 \qquad (2)$$

The determination of an intrinsic site $pK_a$ and an electrostatic correction, proportional to the net charge, has previously been performed for polymers, using the linear transformation of Tanford[3] eqn (3), which is itself obtained from the Linderstrøm–Lang equation.[4]

$$pH - \log\frac{\alpha}{(1-\alpha)} = pK_{a_{int}} - Cz. \qquad (3)$$

Here, $\alpha$ is the proportion of protonated sites, $z$ is the average net charge and $C$ is electrostatic proportionality factor. The value of $\alpha$ can be determined from the spectrophotometric data [if eqn (1) is valid], or from the potentiometric titration data. The net charge may be calculated from $z = J(\alpha - \alpha_u)$, where $\alpha_u$ is the value of $\alpha$ at which the net charge is zero and $J$ is the maximum number of protons that can be bound.

The author is grateful to one of the referees for suggesting that the interaction term in eqn (2) might not be linear. J. R. Miller, at this Department, has suggested that a coulombic interaction term should be expressed as the sum of pairs of interactions between ions. The number of ways of choosing such pairs increases with the number of ionized sites according to $i!/2!(i-2!)$ or $i(i-1)/2$. The first few terms of this quadratic expression are, therefore, 0, 1, 3 for $i = 1, 2, 3$. The interaction term in eqn (2) would then be $b\{i(i-1)/2.\}$ instead of $b(i-1)$. However, the experimental results are more consistent with a linear effect of charge on $pK_a$. In either case, only two parameters, $pK_{a_{int}}$ and $b$ need to be optimized to determine all three $pK_a$ values.

The reliability of the spectrophotometric and potentiometric methods are compared.

## SPECTROPHOTOMETRIC ANALYSIS

The computer program NONLIN15[5] was used for non-linear, least squares regression analysis of the titration data. The program uses the Gauss–Newton–Marquardt algorithm to optimize the $pK_a$ values from spectrophotometric and potentiometric data.[5,6] New analytical partial derivatives for $\partial A/\partial\epsilon_i$ were calculated to introduce correlation eqn (1). Since the analytical derivatives for absorptivities are simply the species concentrations, the required derivatives are easily calculated from eqn (4).

$$\partial A/\partial\epsilon_i = [L^{-3}] + ([LH_3] - [L^{-3}])i/3. \quad i = 0,1,2,3 \qquad (4)$$

The partial derivatives of the two underlying molar absorptivities, $\epsilon_0$ and $\epsilon_3$, are then given by eqn (5) and (6).

$$\partial A/\partial\epsilon_0 = \Sigma[(\partial A/\partial\epsilon_i)(\partial\epsilon_i/\partial\epsilon_0)] \qquad (5)$$

$$\partial A/\partial\epsilon_3 = \Sigma[(\partial A/\partial\epsilon_i)(\partial\epsilon_i/\partial\epsilon_3)] \qquad (6)$$

The derivatives $\partial\epsilon_i/\partial\epsilon_0$ and $\partial\epsilon_i/\partial\epsilon_3$ required in eqns (5) and (6) are easily calculated from eqn (1) (*e.g.* $\partial\epsilon_i/\partial\epsilon_0 = 2/3$).

## POTENTIOMETRIC ANALYSIS

Equation (2) indicates that only two parameters, $pK_{a_{int}}$ and $b$, define all three $pK_a$ values. Optimization of $pK_{a_{int}}$ and $b$ was again accomplished using NONLIN15. Analytical

partial derivatives for $\partial pH/\partial pK_{a_{int}}$ and $\partial pH/\partial b$ are required. These were obtained from eqns (7) and (8).

$$\frac{\partial pH}{\partial pK_{a_{int}}} = \sum_{i=1}^{3} \frac{\partial pH}{\partial pK_{a_i}} \frac{\partial pK_{a_i}}{\partial pK_{a_{int}}} \quad (7)$$

$$\frac{\partial pH}{\partial b} = \sum_{i=1}^{3} \frac{\partial pH}{\partial pK_{a_i}} \frac{\partial pK_{a_i}}{\partial b} \quad (8)$$

$$\frac{\partial pH}{\partial pK_{a_{int}}} = \sum_{i=1}^{3} \frac{\partial pH}{\partial pK_{a_i}} \quad (9)$$

$$\frac{\partial pH}{\partial b} = \sum_{i=1}^{3} \frac{\partial pH}{\partial pK_{a_i}} (i-1). \quad (10)$$

The evaluation of analytical partial derivatives $\partial pH/\partial pK_{a_i}$ in eqns (7) and (8) has been discussed previously.[5,6] Equations (9) and (10) follow, since, in the case of a linear interaction term, we find from eqn (2) that $\partial pK_{a_i}/\partial pK_{a_{int}}$ is unity while $\partial pK_{a_i}/\delta b$ is simply $i-1$ [or $i(i-1)/2$ for the quadratic interation term]. The statistical terms in eqn (2) were provided and fixed during optimization. Other optimized parameters were the electrode zero, initial acidity and ligand concentration.

## EXPERIMENTAL

Titrations were performed using an automated titrator which has been described previously.[5] This acquires data for the pH, titrant volume, absorbance at a monitor wavelength and full spectra at regular intervals of absorbance change. Hydrochloric acid solution ($0.2M$) and potassium hydroxide ($0.2M$) were prepared from nominally $1M$ Aldrich Volumetric Standards. Ionic strength was maintained at $0.1M$ with potassium chloride (BDH Analar). All solutions were made up with 18MΩ/cm water. Temperature was maintained at $25.0 \pm 0.1$°C with a Grant-Barrington thermocirculator. The hexadentate chelator *N,N′,N″*-tris[2-(3-hydroxy-2-oxo-1,2-dihydropyridin-1-yl) acetamido]ethylamine was synthesized and purified in our laboratory. The calibration titration and all subsequent titrations were performed without removal of the glass electrode. Factor analysis was carried out using a QuickBasic 4.5 program which implements Hotelling's original procedure with Horst's scaling factor and an initial trial vector given by a zero-one vector with one in the position of the largest diagonal entry in the symmetrical matrix being factored, and zero for all other elements.[7]

## RESULTS

### *Spectrophotometric titrations*

Spectra (350–200 nm) taken at intervals during the titration are shown in Fig. 1. Two isosbestic points at 300 and 275 nm and three temporary isosbestic points at 243, 227 and 207 nm are apparent. Factor analysis of the data matrix from 350–250 nm, where only the heterocycle changes in absorbance, gives only two components. This indicates that over this wavelength range the spectra of the four species defined by three $pK_a$ values, are all linear combinations of two spectra but does not necessarily mean that the linear combination coefficients are *linearly* related to proton stoichiometry. However, the additional observation of the isosbestic points at 300 and 275 nm in this conserved titration system *does* require that linear combination coefficients are *linearly* related to proton stoichiometry. The assumption of eqn (1) is, therefore, fully justified.

Factor analysis of the data matrix using the data from 250–200 nm gives the three components shown in Fig. 2. The extra component is required to account for the spectrum of the fifth species resulting from ionisation of the tertiary amine group. The spectra of the four remaining species $LH_3$, $LH_2^-$, $LH^{-2}$ and $L^{-3}$ are, therefore, still constructed from just two principal components. Non-linear regression analysis of these three principal components according to correlation eqn (1), is shown in Fig. 2. The optimized parameters are given in

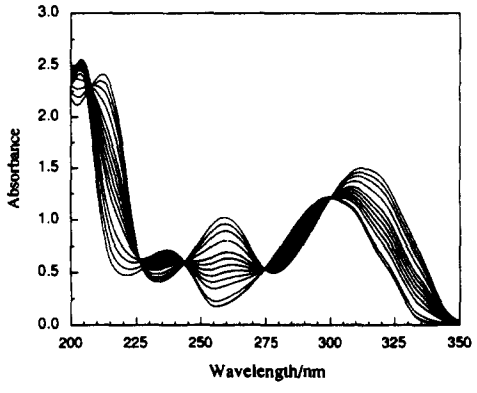


Fig. 1. Spectra of compound 1 from 350 to 200 nm at pH values of 3.310, 5.768, 6.656, 7.520, 8.079, 8.272, 8.439, 8.587, 8.726, 8.862, 9.134, 9.405, 9.678, 10.217. Absorbance increases with increasing pH at 220, 258 and 325 nm.

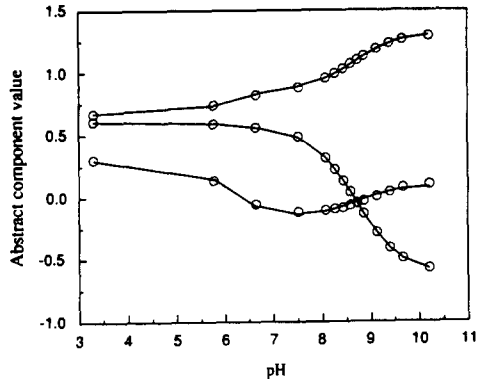

Fig. 2. Factor analysis of the absorbance data from 250 to 220 nm (○). The solid lines are simulated from the parameters in Table 1, optimized by non-linear regression.

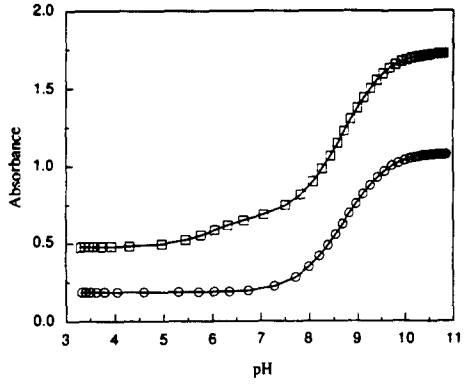

Fig. 3. Single wavelength titration of 1 at 258 nm, (○); and 220 nm (□). The ionization of the tertiary amine group ($pK_a$ 5.88) is only apparent at 220 nm.

Table 1, column 1. The single wavelength titrations at 220 and 250 nm are shown in Fig. 3. At 258 nm only the heterocycle changes in absorbance, while at 220 nm an additional sigmoid for the ionization of the central tertiary amine is apparent. Non-linear regression analysis of the single wavelength spectrophotometric titration data at 220 nm was performed according to correlation eqn (1). The molar absorptivities of $LH_3$ ($\epsilon_3$) and $L^{-3}$ ($\epsilon_0$) were, therefore, optimized as independent variables, while $\epsilon_1$ and $\epsilon_2$ were calculated from eqn (1). The molar absorptivity of the species $LH_4^+$ ($\epsilon_4$) which has the tertiary amine protonated, was also optimized as an independent variable. Optimized parameters are shown in Table 1, column 2.

*Potentiometric titration*

Potentiometric titrations at two ligand concentrations are shown in Fig. 4. The buffer region around pH 6 is the result of ionization of the central tertiary amine of the tripodal backbone. The ionization of the hydroxyl groups of the three heterocycles, produces a buffer region (pH 8–10) which extends for three times the width of the tertiary amine group buffer region. Analysis was performed using the correlation in eqn (2), initially without reference to the spectrophotometric data. Global non-linear regression optimization of the intrinsic site $pK_a$ ($pK_{a_{int}}$) and the interaction term ($b$) from the two potentiometric titrations, gave values of $pK_{a_{int}} = 8.660 \pm 0.008$ and $b = 0.099 \pm 0.006$. The first heterocyclic proton dissociation ($LH_3 = LH_2^- + H^+$) leads to the formation of a mono-anion from a neutral ligand. The coulombic interaction term is therefore zero and only the statistical term $(i-2)\log(3) = -0.0477$ contributes in eqn (2) to give $pK_{a_1} = 8.183 \pm 0.008$. The second and third dissociation constants can similarly be calculated from eqn (2). The fourth $pK_a$ for the

Table 1. The four $pK_a$ values of *N,N′,N″*-tris[2-(3-hydroxy-2-oxo-1,2-dihydropyridin-1-yl)acetamido]ethylamine (1), optimized from spectrophotometric data using correlation eqn (1) and from potentiometric data using correlation eqn (2)

tertiary amino group was optimized simultaneously as an independent variable to give $5.87 \pm 0.03$.

## DISCUSSION

Correlation eqn (1), which linearly relates absorptivities to proton stoichiometry, has been shown here to be valid on the basis of an isosbestic point *and* the presence of only two principal components for the four species defined by the three heterocycle $pK_a$ values. Application of correlation eqn (1) to the analysis of spectrophotometric data at 220 nm (Table 1, column 2) gives $pK_a$ values with a spacing of $0.563 \pm 0.008$ ($pK_{a_3}$–$pK_{a_2}$) and $0.554 \pm 0.005$ ($pK_{a_2}$–$pK_{a_1}$). The regular spacing of the $pK_a$ values, within experimental error, is independent evidence of the validity of the linear interaction term used in the potentiometric correlation eqn (2), rather than the quadratic interaction term. From eqn (2) the spacing between successive stepwise ionizations $pK_{a_{i+1}}$ and $pK_{a_i}$ is given by eqn (11), from which eqn (12) gives the interaction term $b$.

$$pK_{a_{i+1}} - pK_{a_i} = b + \log(3) \qquad (11)$$

$$b = pK_{a_{i+1}} - pK_{a_i} - \log(3). \qquad (12)$$

The mean spacing between successive $pK_a$ values ($\{pK_{a_3}$–$pK_{a_2}\}/2 + \{pK_{a_2}$–$pK_{a_1}\}/2$) is 0.558. Using this value for $pK_{a_{i+1}} - pK_{a_i}$ in eqn (12), gives the spectrophotometrically determined interaction term $b$ as 0.081.

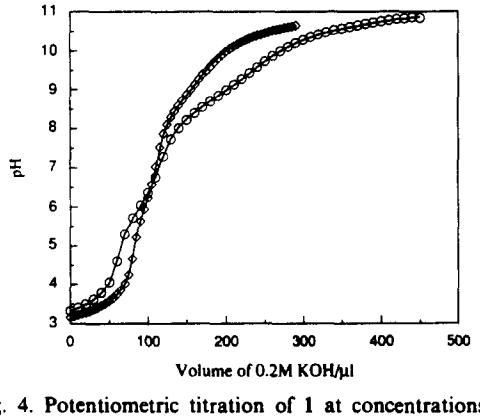

Fig. 4. Potentiometric titration of 1 at concentrations of 0.214 nm, ⟨◇⟩; 0.428 mM, (○), with 0.2*M* KOH. The solid lines are simulated with the optimized parameters. The interaction term $b$ in this plot was fixed at the value determined from the spectrophotometric titration (0.081), and the remaining parameters optimized. When $b$ was optimized simultaneously a value of $0.099 \pm 0.006$ was obtained with no significant improvement in fit.

Optimization of the potentiometric data using eqn (2) gives the results shown in Table 1, column 3. Here the value of $b$ is 0.099 rather than 0.081 determined spectrophotometrically. However, if the value of $b$ is fixed at 0.081 during optimization of the potentiometric data (Table 1, column 4), the goodness of fit is not significantly impaired (solid line in Fig. 4). A satisfactory fit was also obtained using the quadratic interaction term $i(i-1)/2$, however, the separation of the $pK_a$ values obtained in this way ($pK_{a_3}$–$pK_{a_2} = 0.621$ and $pK_{a_2}$–$pK_{a_1} = 0.549$) were not consistent with the values obtained spectrophotometrically.

The best procedure, therefore, is to optimize the spacing between the $pK_a$ values from the spectrophotometric data according to the correlation of eqn (1). This eliminates the effect of several potential sources of systematic error such as errors in the concentration of ligand, initial acidity, contamination by carbonate and $pK_w$. The value of $b$ then calculated from eqn (12), may then be fixed during optimization of the potentiometric data according to eqn (2). The rigorous internal calibration of the glass electrode, which is possible with potentiometric titrations, can then be applied. The values obtained in this way were $pK_{a_1} = 8.19$ ($\pm 0.01$), $pK_{a_2} = 8.75$ ($\pm 0.01$), $pK_{a_3} = 9.31$ ($\pm 0.01$) while the tertiary amine has a $pK_a$ of 5.88 ($\pm 0.03$). This low tertiary amine $pK_a$ is presumably due to the partial positive charge on the three amide functions. It would, of course, be simple to include both correlation eqn (1) and (2) in the analysis of the spectrophotometric titration. In conclusion, correlation eqn (1) is valid if the interaction energy between adjacent ionisable sites is linear with respect to proton stoichiometry and this interaction leads to linear alteration of molar absorptivities. This is true, within experimental error, for molecule 1 although the interaction between sites has been shown to be a minor contribution to the spacing between successive $pK_a$ values compared to the statistical term. Larger interaction energies may lead to shifts in the $\lambda_{max}$ of absorption peaks. The assumption of linear alteration of molar absorptivities will then be only approximately valid for wavelengths over which the first derivative of the spectrum is approximately constant. The presence of an isosbestic point *and* the presence of only two principal components for the $n + 1$ absorbing species in factor analysis of the absorbance data should be used to confirm the validity of eqn (1).

*Acknowledgement*—I wish to acknowledge J. R. Miller at this Department for helpful discussion of the manuscript.

**Summary**—The on-line solid phase extraction of trace amount of lead in flow-injection system with flame AAS detection was investigated using cellulose sorbents with phosphonic acid and carboxymethyl groups, $C_{18}$ sorbent non-modified and modified with Pyrocatechol Violet or 8-quinolinol, commercial chelating sorbents Chelex 100 and Spheron Oxin 1000, non-polar sorbent Amberlite XAD-2 modified with Pyrocatechol Violet and several cation-exchange resins. The best dynamic characteristics of retention were observed for functionalized cellulose sorbents. For Cellex P assumed as optimum sorbent, elution with a separate fractions of nitric acid and ethanol allows the differentiation between tetraalkyllead and sum of inorganic lead and organolead species of smaller number of alkyl groups. The detection limit for the determination of inorganic Pb(II) was estimated as 0.17 $\mu$g/l. at preconcentration from 50 ml sample at a flow rate of 7 ml/min.

Solid-phase extraction (SPE) is a preconcentration technique of rapidly growing importance in trace metal determination with atomic absorption spectrometry. The main advantage of this is the possibility of the use of a relatively simple detection system with flame atomization instead of flameless techniques, which require more expensive equipment and are usually much more sensitive to interferences from macrocomponents of various natural matrices. Especially efficient preconcentration can be carried out in flow-injection (FI) systems and this methodology has been discussed in several reviews.[1-3]

Lead is a trace heavy metals of great importance in environmental protection, and the development of a fast and efficient method for its determination has been the subject of numerous studies. In recent years growing attention has been paid not only to the determination of total lead content, but also to its speciation, with particular emphasis to very toxic organolead species, mostly using chromatographic methods interfaced with atomic absorption spectrometry.[4-6]

In SPE of lead species in FI systems, interactions based on chelate formation are generally utilized. The appropriate ligand is immobilized on a stationary support or is dissolved in the carrier solution and sorption of chelates formed on non-polar sorbents is utilized for the preconcentration.

The commercially available chelating resins Chelex 100 with imminodiacetic groups was among the earliest used for that purpose,[7,8] as well as its Japanese analogue Muromac A-1,[9] although their use is troublesome because of swelling of the resin and changes of the microcolumn packing during elution of retained metal ions with solutions of mineral acids.

The most commonly used sorbents for the on-line preconcentration of lead are those containing immobilized 8-quinolinol. They include commercially available Spheron Oxin 1000[10] or the resin synthesized by cross-linking with appropriate aldehyde.[11] Sorbents with oxine immobilized on controlled-pore glass[12,13] or silica gel[14,15] were more frequently used. Sorption of oxine chelates formed in the solution on non-polar resin Amberlite XAD-2 was also reported.[16] In the latter case similar results were obtained for oxine and pyrrolidine dithiocarbamate. A strong influence of the presence of other cations including Ca and Mg was observed for oxine immobilized on silica gel.[14] The selectivity

*Author to whom correspondence should be addressed.

of lead preconcentration can be improved by the use of appropriate masking agent.[15]

The preconcentration of Pb(II) chelates with dithiocarbamate was also carried out with the use of a column with bonded silica reversed-phase sorbent with octadecyl functional groups.[17-19] The sorption on silica and $C_{18}$ bonded silica columns was employed for the speciation of Pb(II) complexes,[20] whereas Amberlite XAD-4 modified with thioglycolate complexing group was applied for efficient Pb(II) preconcentration.[21] Preconcentration of Pb(II) based on ion-exchange in FI-AAS systems was reported only with the use of activated alumina.[22]

The aim of this study was to investigate the possibility of the use of commercial cellulose sorbents for on-line Pb(II) preconcentration in FI-AAS systems. They should be suitable for such an application owing to very fast sorption and desorption properties. A study on the possibility of differentiation between inorganic and organic lead species using different eluents were also carried out. The use of Cellex P for off-line preconcentration of lead and other metals was reported earlier.[23,24]

## EXPERIMENTAL

### *Apparatus*

A Beckman atomic absorption spectrometer model 1272 equipped with an Unilam air/acetylene burner was used for AAS measurements. The measurements were performed at 283.3 nm, using a HCl lamp at 10 mA current and at slit width 0.41 nm. In conventional measurements with an aspiration nebulizer the uptake was 3.5 ml/min. The output absorbance signal was recorded with a potentiometric strip-chart recorder Knauer 1000 (Berlin, Germany).

The flow injection manifold consisted of a peristaltic pump model MS/4 Reglo from Ismatec (Zurich, Switzerland), low pressure rotary injection valve model 5020 from Reodyne (Cotati, CA, U.S.A.) and a home-made rotary injection valve. The manifolds were assembled using teflon tubing of 0.8 mm i.d. The same tubing of 8 cm length was used for the coupling between the flow injection manifold and the flame AAS. The FI carrier flow rate was lower than the nebulizer uptake and the nebulizer was working on starvation mode without any compensation. For elution of tetraethyl lead loaded columns with different solvents a teflon tubing loop was used, without need of the use of solvent resistant pump tubes.

A digital pH meter model OP-211/1 from Radelkis (Budapest, Hungary) was used for pH measurements and plate shaker model 357 from Elpan (Warsaw, Poland) was used for static mode experiments.

### *Reagents*

A 1000 ml/l. Pb(II) standard solution was obtained from the Research and Development Centre for Standard and Reference Materials (Warsaw, Poland) and diluted as required. For preparation of all solutions deionized water from the Waters Milli-Q system was used.

Pyrocatechol Violet (PV) was from BDH chemicals and 8-quinolinol from POCh (Gliwice, Poland). Alkyllead compounds used were a kind gift from Wilhelm University, Munster, Germany and they are abbreviated in the text as follows: DMLCl, dimethyllead chloride; TriMLCl, trimethyllead chloride; DELCl, diethyllead chloride; TriELCl, triethyllead chloride; TEL, tetraethyllead.

The following cationic sorbents were used: Cellex P (CP) and Cellex-CM (CCM) from Bio-Rad (USA) which is highly purified cellulose powder with phosphonic acid or carboxymethyl exchange groups of ion-exchange capacity 0.8 and 0.65 meq/g, respectively; chelating resin Chelex-100 from Bio-Rad; chelating resin Spheron-Oxine 1000 containing 8-quinolinol immobilized on glycol methacrylate from Lachema (Brno, Czechoslovakia); Amberlite XAD-2 from BDH; reversed phase bonded silica gel with octadecyl functional groups, 40–60 $\mu$m diameter, from POCh (Gliwice, Poland); Dowex 50 W × 4 cation exchanger, 50–100 mesh from Serva (Germany); Varion KS cation exchanger from Nitrokemia (Hungary).

### *Preparation of Amberlite XAD-2 loaded with PV*

The dry XAD-2 resin (1 g) was washed with 2*M* HCl, distilled water, 1*M* NaOH and distilled water again to remove traces of soluble species. The resin was put in a stoppered bottle, 50 ml PV solution containing 0.045 g of the reagent was added and the bottle put in a mechanical shaker for 1 hr. The resin was filtered out and washed with distilled water, ethanol and left to be air-dried.

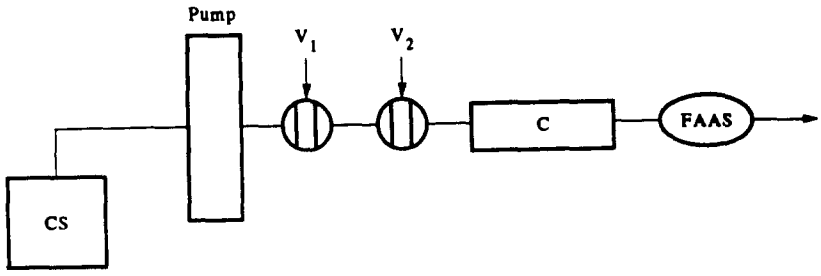

Fig. 1. Schematic diagram of flow-injection system used for the optimization of preconcentration and elution conditions. CS, container with carrier solution; $V_1$, $V_2$, injection valves; C, column with sorbent; FAAS, flame atomic absorption spectrometer.

*Retention of* Pb(II) *on different sorbents in static conditions*

To 0.2 g of the sorbent, 20 ml solution containing 1 mg Pb(II) was added, the pH of the solution was adjusted with nitric acid or sodium hydroxide to the required value, and the mixture shaken for 1 hr on a plate shaker. The mixture was left to settle and the Pb concentration determined by FAAS in conventional mode with aspiration of analyte solution.

*On-line preconcentration of* Pb(II)

The manifold used for the optimization of the conditions for the on-line preconcentration is shown in Fig. 1. Valve $V_1$ is used for the injection of the Pb(II) solution, and $V_2$ for the injection of the eluent. C is a microcolumn made of 1 ml plastic pipette tip, packed with the sorbent. The solid sorbent is held in place inside the column by placing a piece of plastic foam in the outlet of the column. For large volume samples $V_1$ is removed from the manifold and the sample is continuously aspirated.

*Determination of the ion exchange breakthrough capacity*

The breakthrough capacity of the sorbents was determined by pumping 5 mg/l. Pb(II) solution through a column with a packed bed of 20 mm height (400 $\mu$l volume) at flow rate of 6 ml/min until the concentration of the effluent was the same as the feed ($C/C_0 = 1$), 50 ml effluent portions were collected, in which the Pb(II) content was measured by conventional aspiration and flame AAS detection.

*Retention and recovery of* Pb(II) *on Cellex-P*

A column of bed height 20 mm (400 $\mu$l volume) was used. Two hundred milliliters of 0.1 mg/l. Pb(II) solution was pumped at 5 ml/min. The preconcentrated Pb(II) was eluted by two successive portions of 1 ml of 1*M* nitric acid in a 4 ml volumetric flask and then the Pb concentration was determined by conventional FAAS.

*Effect of the presence of common cations on the retention of* Pb(II) *on different sorbents*

The effect of the presence of Na, K, Mg, Ca, Cu, and Fe(III) cations on the retention of Pb(II) on different sorbents was examined.

The microcolumn used was 20 mm bed height (400 $\mu$l volume). Using 25 ml of 0.1 mg/l. Pb(II) solution containing the interfering cation Na, K, Mg, Ca at concentrations up to 200 mg/l., and for Cu, and Fe(III) up to 20 mg/l. were examined. The elution signal obtained was compared to the signal of solution without interferents.

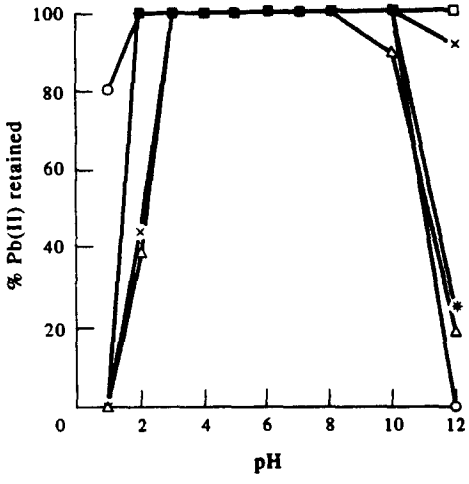

Fig. 2. Effect of pH on retention of Pb(II) in static conditions for Cellex P (*), Cellex-CM (△) Spheron Oxin 1000 (○) Chelex-100 (=) and Varion KS (×).

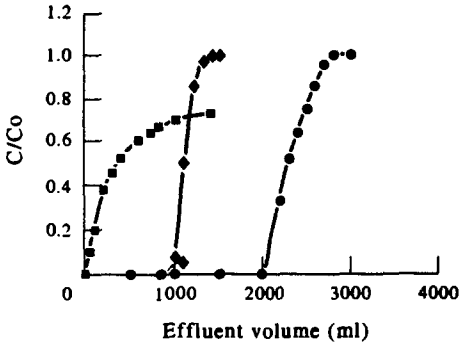

Fig. 3. Breakthrough curves for Cellex P (●), Cellex-CM (◆) and Spheron Oxin 1000 (■) columns for the continuous delivery of 5.0 μg/l. Pb(II) at flow rate 6.0 ml/min.

### *Speciation of lead in natural samples with Cellex P sorbent*

The collected water samples, were filtered, using a 0.45 μm filter, and acidified to pH 2.5 with nitric acid.

Samples (50 ml) were used for preconcentration at flow rate of 5 ml/min, two portions were taken from each sample, one spiked with Pb(II) and TEL, while the other was analyzed as collected for inorganic lead and TEL. The inorganic lead with the organolead compounds except TEL were eluted with 1*M* nitric acid while TEL was eluted with ethanol.

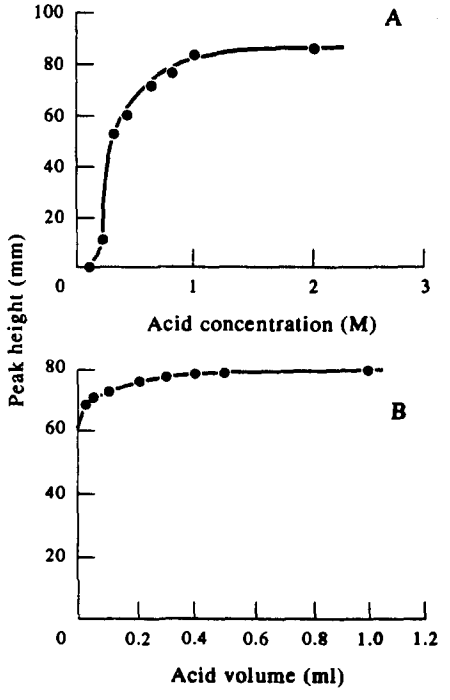

Fig. 4. Effect of nitric acid concentration at injection volume 1 ml (A) and of the injection volume of 1*M* nitric acid (B) on peak height corresponding to the elution of Pb(II) retained on Cellex P sorbent from 1.0 ml of 5.0 mg/l. Pb(II) solution at a flow rate of 3.3 ml/min.

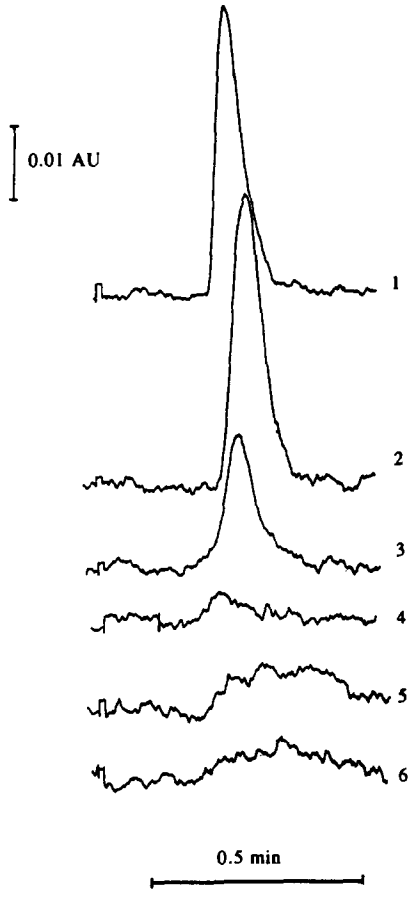

Fig. 5. Elution peaks recorded for Pb(II) with expanded time preconcentrated from 1.0 ml of 5.0 mg/l. Pb(II) solution at (pH 4.5), flow rate 3.3 ml/min and 0.4 ml bed volume for columns with Cellex P (1), Cellex-CM (2), Spheron Oxin 1000 (3), Pyrocatechol Violet loaded XAD-2 (4), Chelex 100 (5), Dowex 50 w × 4 (G) and Varion KS (6). Preconcentration without pH adjustment. Elution with 1.0 ml of 1*M* nitric acid.

## RESULTS AND DISCUSSION

### *Comparison of sorbents for* Pb(II) *preconcentration*

In the preliminary study for the selection of the appropriate sorbent for further study, a number of sorbents was tested for the retention of Pb(II) in batch mode at various pH values (Fig. 2). Pb(II) was completely retained on all sorbents examined in a broad range of pH. For some of the examined sorbents a breakthrough capacity determination was also carried out (Fig. 3). It can be seen that both Cellex P and Cellex CM gave the ideal breakthrough curves, and the capacity was calculated as 0.66 meq/g for CP, and 0.52 meq/g for CCM. In the case of Spheron Oxin 1000 some of Pb(II) was detected in the second portion (50 ml) of effluent and the concentration of Pb(II) in the effluent did not

reach that of the feed Pb solution of 5 mg/l. even after pumping 1400 ml. For Chelex-100 there was no Pb(II) detected even after pumping of more than 7 l. of Pb(II) solution indicating height capacity (2.9 meq/g as stated by the manufacturer).

*Elution of* Pb(II) *retained on Cellex P*

Because of the good properties of cellulose sorbents exhibited in the batch mode, and since CP was successfully used earlier for off-line preconcentration of Pb(II),[23,24] this sorbent was selected for the study of the elution of retained Pb(II). Two acids, hydrochloric and nitric were tested for the elution of Pb(II) retained on CP. Both gave satisfactory results and for further study nitric acid was chosen as it does not precipitate Pb(II). The effect of acid concentration and acid volume is shown in Fig. 4. It was found that 1.0*M* acid completely eluted Pb(II) retained on CP, since when 1 ml of 2*M* nitric acid was injected for the second time, no second peak was observed indicating that the elution was complete and 0.5 ml of 1*M* nitric acid was sufficient for the elution. For further study either 0.5 or 1.0 ml of 1*M* nitric was used for the elution of Pb(II).

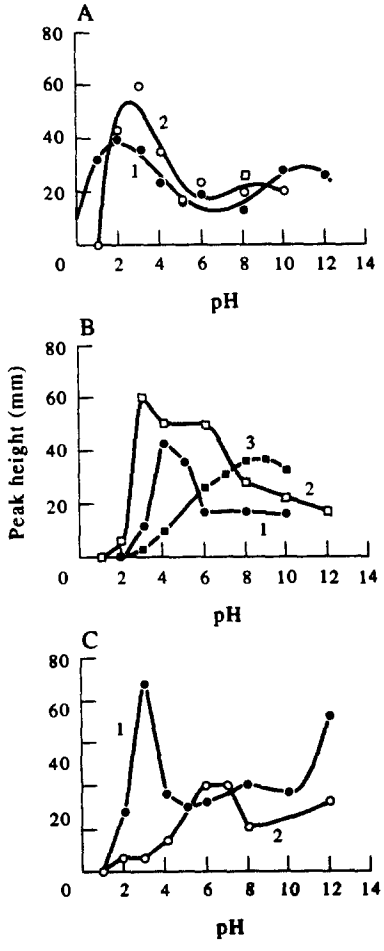

Fig. 6. Effect of pH on flow-injection signal magnitude obtained for preconcentration of Pb(II) from 25 ml 100 μg/l. (Pb(II) solution on 25 mm column with (A) Cellex P (1) and Cellex CM (2); (B) $C_{18}$ silica gel (1), $C_{18}$ loaded with Pyrocatechol Violet (2), $C_{18}$ loaded with oxine (3); (C) Spheron Oxin (1), Pyrocatechol Violet loaded XAD-2 (2). Elution with 1.0 ml of 1*M* nitric acid.

In order to compare different sorbents in dynamic condition the elution signal corresponding to preconcentration of 1 ml 5.0 mg/l. Pb(II) solution of pH 4.5 (without adjustment) on each sorbent of the same bed volume using 1.0 ml 1*M* nitric acid for elution was recorded on an expanded time scale (Fig. 5). The highest peaks were obtained using CP, CCM, and Spheron Oxin 1000, indicating that the elution process of the retained Pb(II) from these sorbents was fast. The elution peaks for two cation exchangers Varion KS and Dowex 50 W × 4 were small and broad indicating that the elution process using this eluent was much slower, while for others, the process was moderate.

*Effect of* pH *and flow rate on the retention of* Pb(II) *on different sorbents*

The effect of pH on the retention of Pb(II) on different sorbents was also studied in dynamic conditions. The column used was 25 mm bed height (500 μl) and 25 ml of 0.1 mg/l. Pb(II) solution was preconcentrated on the sorbent at a flow rate of 6 ml/min. The retained analyte was eluted with 1 ml of 1*M* nitric acid at a flow rate of 3.3 ml/min. It was found that for the sorbents studied the optimum pH was on the acidic side (2–4) except for $C_{18}$ loaded with 8-quinolinol and XAD-2 loaded with PV, in which the optimum pH was in the alkaline range (7–10) (Fig. 6).

The effect of preconcentration flow rate was also studied for the investigated sorbents. It was found that the variation of the flow rate from 3.0 to 10 ml/min had no effect on the signal when CP or CCM were used, while for Spheron Oxin 1000 the signal magnitude was reduced with increasing sampling flow rate.

*Effect of potential interferences*

The obtained results for two Cellex sorbents and oxine sorbent are shown in Table 1. The best selectivity was obtained for Cellex P, where only some positive interference was observed at high Ca concentration. The same effect, however, was found in conventional aspiration of

Pb(II) solution containing calcium. At 100 mg/l. Ca and 10 mg/l. Pb(II) 12% enhancement of signal was observed in comparison to Pb(II) measurement without calcium. This suggests the spectral nature of this interference. A similar effect was also observed for Pb(II) preconcentration on immobilized 8-quinolinol,[14] however, on the contrary preconcentration using Cellex P in the presence of magnesium exhibited a much smaller effect.

For the other tested sorbents much larger interferences were observed. Using $C_{18}$, even in the presence of 50 mg/l. sodium, the Pb signal was reduced by 82% and in the presence of 5 mg/l. Fe(III) no signal was obtained. In the presence of 50 mg/l. Ca or Mg the signal was reduced by 100 and 95%, respectively.

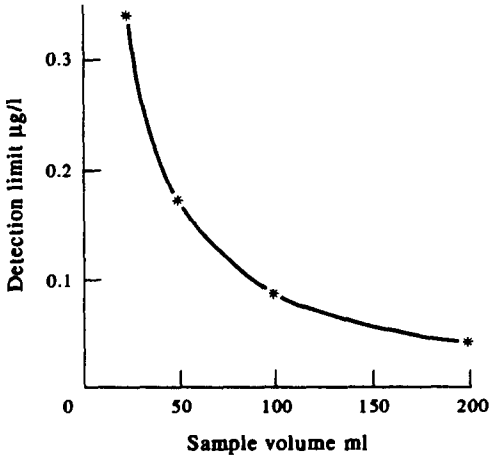

Fig. 7. Effect of the volume of preconcentrated Pb(II) solution on detection limit in flow-injection system with 25 mm column with Cellex P. Preconcentration at flow rate 7.0 ml/min. Elution with 1 ml of 1*M* nitric acid at flow rate 3.0 ml/min.

Using $C_{18}$ loaded with PV (PV was added to the sample), in the presence of 50 mg/l. Na, Ca or Mg the signal was reduced by 55, 82 or 77%, respectively, while in the presence of 5 mg/l. Cu(II) or Fe(III) it was reduced 68 or 81%, respectively.

Using $C_{18}$ loaded with 8-quinolinol, in the presence of 10 mg/l. Mg the Pb signal was reduced by 12%, while in the presence of 5 mg/l. Fe(III) the signal was reduced 11%.

Using XAD-2 loaded with PV, the presence of Na or K at 10 mg/l. the signal was enhanced by 10 or 23%, respectively, and in the presence of Cu(II) or Fe(III) at 5 mg/l. the signal was suppressed by 14 or 75%, respectively.

### *Calibration and detection limit*

For the FIAAS system with C-P column, the linearity of response as a function of preconcentrated sample volume was examined. The sample pH was adjusted to 2.5 with nitric acid. Preconcentration was done at a flow rate of 6 ml/min. In the volume range from 5 to 100 ml, for preconcentrated 10 µg/l. solution the obtained relation was described by the equation: $H = 2.00V + 0.0$, and the correlation coefficient was 1.0 ($n = 10$), where $H$ is the peak height (mm) and $V$ is the sample volume (ml).

For the calibration in the Pb(II) concen-

Table 2. Comparison of the efficiency of Pb(II) preconcentration on solid sorbents in flow injection systems with flame AAS detection

| Sorbent used | Sampling volume (*ml*) | Sampling rate ($hr^{-1}$) | CE value | Reference |
|---|---|---|---|---|
| Activated alumina | 25 | 12 | 50 | 22 |
| Chelex 100 | 10 | 60 | 50–100 | 8 |
| | 10 | 10 | 10–13 | 28 |
| 8-quinolinol on CPG | 100 | 2 | 20 | 12 |
| | 12 | 20 | 13 | 14 |
| Muromac A-1 | 20 | 13 | 20–39 | 9 |
| Cellex P | 50 | 6 | 10–15 | This work |

tration range 10–100 $\mu$g/l. for the sample volume 50 ml, the relation was linear in the range studied. The equation for the plot obtained is: $H = 0.705C + 0.545$, where $H$ is as above and $C$ is the sample concentration in $\mu$g/l., with a correlation coefficient of 0.9989 ($n = 10$).

The detection limit based on the triple value of the standard deviation of the blank for lead (II) determination using a 50 ml sample was estimated as 0.17 $\mu$g/l. The precision at the 10 $\mu$g/l. level was 5.9% RSD ($n = 10$).

The effect of the preconcentrated sample volume on the detection limit was also examined and it was found that the detection limit could be decreased down to 0.04 $\mu$g/l. for sample volume of 200 ml (Fig. 7). The efficiency of the on-line preconcentration is usually given by enrichment factor and concentration efficiency (CE) values. In the system developed for the analyte preconcentration from 50 ml sample containing 10–50 $\mu$g/l. Pb(II), the enrichment factor ranges between 100 to 150. For flow rate 5 ml/min. this corresponds to concentration efficiency value in the range 10–15. As can be seen from the comparison shown in Table 2. This is rather a low value referring to other works reported in the literature, but the developed method, in contrary to previous reports, provides some possibility of speciation.

Some improvement of concentration efficiency can be expected by lowering the sorbent bed dimensions and also the diameter of

the tubing connecting the FI system with AAS. For a concentration of Pb(II) in the sample larger than 3 $\mu$g/l. a sample volume of 25 ml is sufficient. This will increase the sampling rate up to 10–12 $hr^{-1}$. For the preparation of calibration plot, five different standard solutions are required and it takes about 40 min to perform the calibration procedure. The Cellex P column can be used for months without any significant change of its ion-exchange properties. This corresponds to hundreds of cycles of sorption and elution.

*Sorption of alkyllead compounds on different sorbents*

Using 5 mg/l. tetraethyllead (TEL) solution several sorbents were also tested for the retention of this compound in on-line mode. It was found that using RP $C_{18}$, and Amberlite XAD-2 loaded with PV, most of the analyte passed through the column without retention. Using CP, TEL was completely retained on the column and then it could be completely eluted with ethanol. For the elution of TEL from CP

Table 4. Effectiveness of elution of alkyllead compounds and inorganic lead retained on Cellex P 25 mm, column of bed volume 0.4 ml with consecutive 1 ml portions of 0.1 and 1.0*M* nitric acid (preconcentration from 1 ml of 5 mg/l Pb solutions)

*$H$ = Peak height in *mm*, $C$ = concentration in *mg/l.*

a number of other solvents were also tested, including methanol, acetone and acetonitrile. However, ethanol was found the best, nitric acid showing no elution of the TEL species.

In the study of TEL retention on CP it was observed that the elution signal was reduced in time without peak broadening (Fig. 8). It can be attributed to several reasons. One of them is the decomposition of TEL by light, which was observed by other authors, too.[25] It can be also caused by the adsorption of the compound on the walls of the container.[26] This may also result from the effect of ethanol on the sorbent since when the column is used the flow rate is reduced owing to the back pressure of the packed resin that became more compact. After about 30 min stabilization, the microcolumn can be used for quantitative determinations.

Several other alkyllead compounds examined (DELCl, DMLCl and TriMLCl) were also completely retained on CP. The ionic alkyllead compounds were found to behave similarly to inorganic Pb(II) in that they were completely eluted by 1*M* nitric acid, while the neutral TEL species was not eluted by the acid as mentioned above. The effectiveness of elution of the different alkyllead compounds is shown in Table 3.

Additionally, it was found that trimethylleadchloride (TriMLCl) was completely eluted by 0.1*M* nitric acid, and since this dilute acid solution did not elute Pb(II), the possibility of

Table 6. Parameters of linear dependence of flow-injection peak height on the volume of preconcentrated 0.1 mg/l. alkyllead solutions for the system with Cellex P column in the volume range from 5 to 50 ml (elution with 1 ml of 1*M* nitric acid)

| Alkyllead species | Curve equation* | Correlation coefficient |
|---|---|---|

$H$ = Peak height in *mm*, $V$ = volume in *ml.*

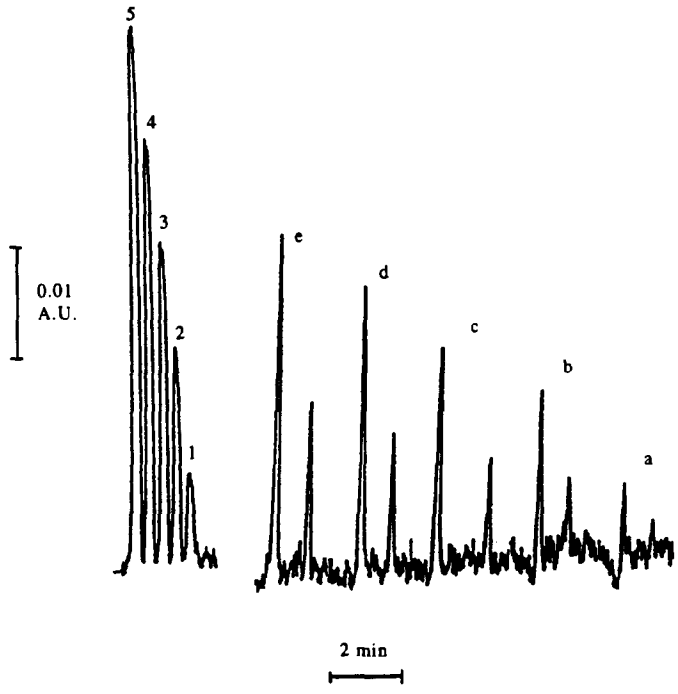

Fig. 9. Examples of recording for flame AAS determination with conventional aspiration (A) obtained for 2 (1), 4 (2), 6 (3), 8 (4) and 10 (5) mg/l. Pb(II) and for flow-injection determination with preconcentration on 20 mm column (B) of solutions containing: (a) 10 $\mu$g/l. Pb(II) and 10 $\mu$g/l. TEL; (b) 20 $\mu$g/l. Pb(II) and 20 $\mu$g/l. TEL; (c) 30 $\mu$g/l. Pb (II) and 30 $\mu$g/l. TEL; (d) 40$\mu$g/l. Pb(II) and 40 $\mu$g/l. TEL and (e) 50 $\mu$g/l. Pb(II) and 50 $\mu$g/l. TEL. Sample volume for preconcentration 50 ml. Elution with 1.0 ml of 1*M* nitric acid for Pb(II) (smaller peak) and 0.5 ml ethanol for TEL (larger peak).

the differentiation of the ionic alkyllead compounds and inorganic lead was tested. It was found, however, that the other ionic alkyllead compounds, dimethylleadchloride, diethylleadchloride and triethylleadchloride (DMLCl, DELCl, and TriELCl) were only partially eluted using the diluted acid (Table 4). So, it can be concluded that the only speciation that can be done is the elution of ionic alkyllead compounds together with inorganic lead by 1*M* nitric acid, then the elution of TEL by ethanol.

The parameters of linear calibration curves obtained in FI-AAS measurements of alkyllead compounds retained on CP from 1 ml solution of concentration range 1–5 and elution with 1 ml of 1*M* nitric acid are shown in Table 5. The parameters of linear dependence on the volume is shown in Table 6.

Table 7. Analysis of natural water samples for lead preconcentrated on Cellex P column of 0.4 ml bed volume for 50 ml sample [Eluent (1) 1.0 ml of 1.0*M* nitric acid for Pb(II); (2) 0.5 ml ethanol for TEL]

| | Lead concentration ($\mu g/l.$) | | | |
|---|---|---|---|---|
| Sample | Pb(II) added | Pb(II) found | TEL added | TEL found |
| Tap water | 0.0 | 8.5 | 0.0 | — |
| | 20.0 | 25.7 | 20.0 | 20.7 |
| G. water I | 0.0 | 4.3 | 0.0 | — |
| | 20.0 | 25.7 | 20.0 | 19.23 |
| G. water II | 0.0 | 8.4 | 0.0 | — |
| | 20.0 | 23.2 | 20.0 | 21.3 |
| G. water III | 0.0 | 2.4 | 0.0 | — |
| | 20.0 | 23.5 | 20.0 | 20.6 |
| River water | 0.0 | 5.9 | 0.0 | — |
| | 20.0 | 27.1 | 20.0 | 19.4 |

The recording of the signal obtained for standard samples containing different Pb(II) and TEL concentrations is shown in Fig. 9.

*Analysis of natural water samples*

The results obtained (Table 7) indicate that the lead level in the water samples analyzed was below the permissible level for drinking water (50 $\mu$g/l.)[27] and the TEL in these samples was below the detection limit of the method which for 50 ml sample was estimated as 1.8 $\mu$g/l. The spiked samples show that the recovery was 81–105% for a spike of 20 $\mu$g/l. of lead from different water samples.

*Acknowledgements*—A.M.N. expresses his gratitude to the Secretary of the Scientific Research of Libya for the scholarship. The authors thank Dr Norbert Buschmann of the Westfalian Wilhelms University, Munster, Germany, for gift of samples of alkyllead compounds. This research was supported by grant No. 2 055 91 01 from the Polish State Committee for Research.

# DETERMINATION OF ANTHRAQUINONES IN RHUBARB ROOTS, DOCK FLOWERS AND SENNA LEAVES BY NORMAL-PHASE HIGH PERFORMANCE LIQUID CHROMATOGRAPHY

DJ. DJOZAN* and Y. ASSADI

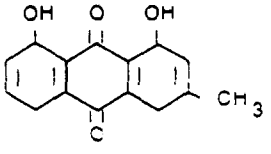
Department of Analytical Chemistry, Faculty of Chemistry, University of Tabriz; Tabriz, Iran

(*Received* 17 *January* 1994. *Revised* 22 *November* 1994. *Accepted* 1 *December* 1994)

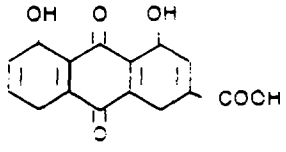
**Summary**—A normal-phase high performance liquid chromatography using a 5-$\mu$m Spherisorb-CN column (250 × 4.6 mm i.d.) has been used for determination of the monomeric anthraquinones and their glycosides present in rhubarb roots, senna leaves and dock flower. The effects of various parameters were studied and the conditions for the extraction of the anthraquinones from herbal samples and their chromatographic separation were optimized. The nature and the quantity of anthraquinones and their conjugates were determined with a good precision and accuracy.

## INTRODUCTION

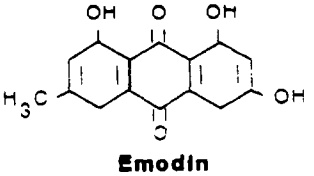
Senna leaves, rhubarb roots and dock flowers are used as oriental laxative medicines. These plants contain a wide variety of compounds including monomeric anthraquinones (as shown below), together with their glycosides and dimeric anthrones glycosides. Sennosides are the purgative principles of these plants[1] and like other glycosides are metabolized by animals and humans into monomeric rhein or other anthraquinones which are the active metabolites.[2,3]



**Chrysophanol**



**Rhein**



**Emodin**

The natural free anthraquinones are not effective and it has been confirmed that they are reduced into anthrones and anthranoles in the human intestine, and act as laxative compounds.[4] The stimulant laxatives composed of the anthraquinones (*e.g.* senna, rhubarb, *etc.*) are the cause of the greatest side-effects and are often abused by the public,[5–7] therefore the identification and analysis of anthraquinones in herbal samples, pharmaceutical preparations and biological fluids are of great importance.

A few spectrophotometric and electrochemical methods have been reported for the determination of these compounds and their conjugates. An earlier fluorimetric method suffered from a lack of sensitivity and specifity;[7,8] another fluorimetric method involving thin layer chromatographic separation with two solvent systems was somewhat time-consuming and complex.[9] Simultaneous determination of chrysophanol (Ch), rhein (Rh), emodin (Em) and their glycosides in some medicinal plants and pharmaceutical preparations has remained a problem in analytical chemistry for years.[10] Recently, an electrochemical method has been developed for direct analysis of these compounds in chloroform.[11,12] It is still non-selective, but it may be a valuable and new detection system for such compounds in normal-phase liquid chromatography.

The aim of this work was to develop a normal-phase chromatographic method using

*Author to whom all correspondence should be addressed.

chloroform as mobile phase for effective separation and determination of anthraquinones.

## EXPERIMENTAL

### *Chemicals and reagents*

Rhein (Rh), emodin (Em) and chrysophanol (Ch) were from Aldrich-chemie (U.K.). Solvents, acetic acid and all other reagents were purchased from E. Merck (Germany). Chloroform was distilled, poured through the silica column and redistilled.

### *Apparatus*

The HPLC apparatus consisted of Bruker LC-21, equipped with a Bruker UV-Vis detector model LC 313 I, Rheodyne loop injector and Qx–16 Epson personal computer with Epson FX–800 printer. A normal-phase column of Spherisorb-CN (250 × 4.6 mm i.d., particle size 5 $\mu$m) was from Bischoff (Germany).

### *Solutions*

Stock solutions (100 ppm) of Ch, Em and Rh were prepared in chloroform. The standard solutions of 0.01–100 ppm were prepared by dilution of the stock solution with mobile phase, from which a 20 $\mu$l aliquot was injected.

### *Chromatographic procedure*

The column temperature was ambient (25 ± 4°C). For separation of anthraquinones, the isocratic elution with an organic phase of chloroform–concentrated (96%) acetic acid (95:5 v/v) was carried out at a constant flow-rate of 0.7 ml/min. The absorption of the column eluate was monitored at 254 nm.

### *Extraction of anthraquinones from herbal samples*

Rhubarb roots, senna leaves and dock flowers were examined in this work. Dried and powdered herbal samples (0.100 g) were mixed twice with 40 ml water and methanol (50:50). The mixtures were stirred for 15 min, filtered collected and diluted to 100 ml with water (solution A). A 10 ml portion of solution A were extracted three times with 5 ml portions of chloroform. The organic phases were collected into 25 ml conical flasks, 1.25 ml of concentrated acetic acid was added to each flask and then diluted to 25 ml with chloroform (solution B). These solutions were used for determination of monomeric anthraquinones. The impurities were eliminated by a one step pre-extraction of solution A into 5 ml chloroform in alkaline media.

For the determination of glycosides, five 10 ml portions of solutions A, each acidified with 1 ml concentrated HCl and separately refluxed. The refluxing times ranged from 5 to 60 min. The solutions were cooled rapidly and the extraction carried out as in the previous step. The extracts (solution C) were used for the determination of total anthraquinones (free anthraquinones and acid hydrolysed glycosides).

## RESULTS AND DISCUSSION

### *Detection wavelength*

The absorption spectra of Ch, Rh and Em dissolved in mobile phase were studied at 200–700 nm using both batch and stop flow mode. Owing to the remarkable absorption of

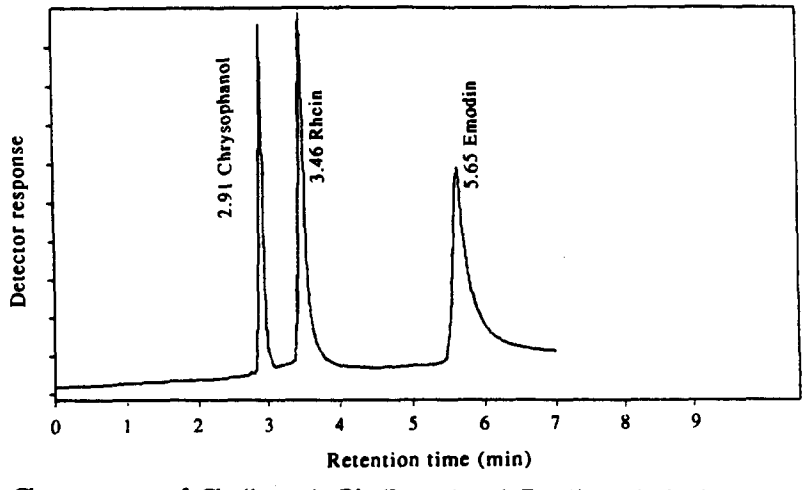


Fig. 1. Chromatogram of Ch (1 ppm), Rh (2 ppm) and Em (4 ppm). Stationary phase: 5-$\mu$m Spherisorb-CN. Mobile phase: chloroform–pure (99.9%) acetic acid (95:5). Flow rate: 1 ml/min.

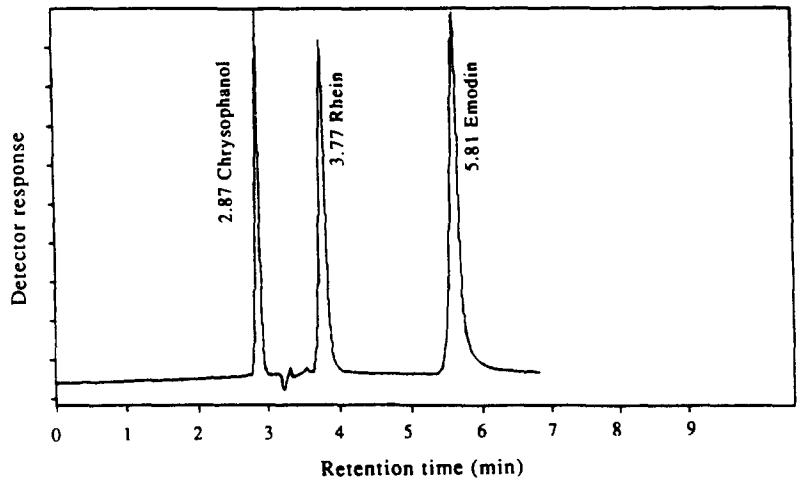

Fig. 2. Chromatogram of Ch (1 ppm), Rh (2 pmm) and Em (4 ppm). Stationary phase: 5-μm Spherisorb-CN. Mobile phase: chloroform–concentrated (96%) acetic acid (95:5). Flow rate: 1 ml/min.

chloroform at $\lambda < 245$ nm, the strong background attenuation increase the noise. Two maxima at about 254 and 430 nm were observed for these compounds. For the sensitive quantitative analysis, the column eluate was monitored at 254 nm.

*Optimization of HPLC parameters*

*Choice of packing material.* One of the best commercially available stationary phases for normal-phase HPLC is the bonded phase with cyano group, therefore we selected 5-μm Spherisorb-CN column (250 × 4.6 mm i.d.).

*Choice of mobile phase.* The pure chloroform was used as mobile phase and the effect of ethanol, methanol and concentrated acetic acid were examined as modifiers. From the obtained chromatograms (Fig. 1), the chromatographic performance characteristic such as plate numbers, $N_1 = 8731$, $N_2 = 5555$ and $N_3 = 3649$ (where 1, 2 and 3 are chromatographic peaks of chrysophanol, rhein and emodin, respectively) and column resolution ($R_s > 1.5$) reveal a good efficiency when 5% v/v pure acetic acid (containing 0.1% water), was added as modifier. It should be noted that the

*$Y$ = Peak area, $X$ = concentration (*mg/l*).
†$S/N = 3$.

water content in the mobile phase was only 0.005%. The peak tailing ($T_1 = 1.00$, $T_2 = 1.25$ and $T_3 = 3.15$ for Ch, Rh and Em, respectively) was probably caused by the packing, because it has been shown that the residual silanol group on partially reacted bonded phase can interact with solutes in a mode different from the bonded stationary phase, which often leads to tailing peaks.[13,14]

*Effects of traces of water.* The chromatograms obtained with a mixture of chloroform–acetic acid–water (95:4.8:0.2), prepared by means of pure chloroform and acetic acid (96%), is illustrated in Fig. 2. The comparison of the chromatograms in Figs 1 and 2 reveals that increasing the water amount in the mobile phase (from 0.005 to 0.2%) effectively improves the peaks symmetry ($T_1 = 1.00$, $T_2 = 1.00$, $T_3 = 1.05$) and plate numbers ($N_1 = 9577$, $N_2 = 9090$ and $N_3 = 11904$) without retention times distortion. These phenomena probably are due to the presence of small amounts of water molecules in the mobile phase that cause a decrease in the tendency of the residual silanol group to interact with susceptible solutes.

*Flow rate.* For the investigation of the optimum flow rate the variation of plate height ($H$) *vs.* mobile phase velocity for different monomeric anthraquinones were studied. From the results obtained the optimum flow-rates were in the range 0.3–0.7 ml/min.

The chromatograms obtained for the standard solutions with 0.7 ml/min flow rate of mobile phase are shown in Fig. 3. The plate numbers, peaks resolution and retention times ($N_1 = 13370$, $N_2 = 12315$, $N_3 = 15340$, $R_s > 1.5$) represent a useful resolution and reasonable analysis time.

### *Qualitative analysis*

The standard solutions of analytes (20 μl) were analysed using optimized chromatographic conditions. Owing to the reproducibility of the retention time (RSD% < 1.4) and height resol-

ution ($R_s \gg 1.5$) in any arbitrary concentration of analytes in two successive peaks, the qualification of each compound can be affected precisely. The signal to analyte concentration proportional in the extract of herbal samples was studied by comparing the absorption of two wavelengths (254 and 430 nm).

*Quantitative analysis*

The standard solutions of Ch, Rh and Em were injected into chromatograph with different concentrations. The amount of each compound were plotted *vs.* peak area. Characteristic data of the calibration curves and the obtained detection limit (L.O.D.) are presented in Table 1. From these results, the quantitative analysis of the anthraquinones can be carried out with a good sensitivity and accuracy.

*Herbal samples*

Rhubarb roots, senna leaves and dock flowers were examined in this work.

*Determination of free anthraquinones.* Solution B (20 $\mu$l) (see Experimental) was injected for the separation and determination of monomeric anthraquinones. The results obtained are presented in Table 2.

*Determination of glycosides.* Solution C (20 $\mu$l) (see Experimental) was injected for the separation and determination of total anthraquinones (free anthraquinones and acid hydrolyzed glycosides). The weight percentage of anthraquinones *vs.* hydrolysing time is plotted in Fig. 4. Since the curve of each sample reaches a plateau in more than 10 min, the total anthraquinone in the herbal samples may be analysed following acid hydrolysis in a convenient time with a good precision. The quantity obtained for glycosides are shown in Table 2.

*Recovery study of extraction procedures.* The original and spiked samples with 100 ppb of each Ch, Em and Rh were treated as mentioned previously and injected. The absence of a chromatographic peak (smaller than L.O.D. or detector threshold) in the third extract proves the complete extraction of accessible anthraquinones in the first and second steps.

## CONCLUSION

From the obtained results the efficiency of the proposed method for the qualitative and quantitative analysis of the free anthraquinones and their conjugates in the cited medicinal plants has been proved. This method can also be utilized for the analysis of these compounds in biological media.

## Short Communication

# INVESTIGATION OF THE EXTRACTION EQUILIBRIA IN THE SYSTEM HEXACHLORIDORHENATE(IV)–NEOTETRAZOLIUM CHLORIDE–DICHLOROETHANE–WATER

ZH. SIMEONOVA, A. ALEXANDROV* and S. DICHEVA

Department of General and Inorganic Chemistry, Plovdiv University, BG-4000 Plovdiv, Bulgaria

(*Received* 3 *August* 1994. *Revised* 22 *November*. *Accepted* 5 *December* 1994)

**Summary**—The neotetrazolium hexachloridorhenate(IV) ($NTReCl_6$) has been synthesized and its composition checked. The optimum conditions for the extraction of $NTReCl_6$ with dichloroethane have been established. The recovery factor for one-fold extraction is $R = 74\%$. The distribution constant, $K_D$, extraction constant, $K_{ex}$, and ion-association constant, $\beta$, have been determined. Neotetrazolium chloride was found to be suitable reagent for extraction–spectrophotometric determination of rhenium(IV) ($\epsilon_{NTReCl_6} = 3.42 \pm 0.20 \times 10^4 M^{-1}\ cm^{-1}$).

In contrast to rhenium(VII) very little work has been reported on the liquid–liquid extraction of rhenium(IV).[1–5] In a previous article[6] we reported on the formation and extraction of iodo-nitro-tetrazolium hexachloridorhenate. The present paper reports on the extraction of $ReCl_6^{2-}$ with neotetrazolium chloride (NTC). NTC differs from the previously studied iodo-nitro-tetrazolium chloride (INT) by the number of substituents in tetrazolium rings.

## EXPERIMENTAL

### *Reagents and apparatus*

2,2′;5,5′-Tetraphenyl-3,3′-(*p*-biphenyl)-ditetrazolium chloride, neotetrazolium chloride (NTC) from Fluka, $2 \times 10^{-3} M$ aqueous solution. Potassium hexachloridorhenate(IV) was synthesized and recrystallized as described elsewhere.[7] $2 \times 10^{-4} M$ aqueous solution. 1,2-Dichloroethane, Puriss, from Fluka was used without additional purification.

A Carl Zeiss Jena VSU-2P spectrophotometer was used for all absorbance measurements. The samples were shaken on a Thys 2 shaking machine (Germany).

### *Procedures*

*Establishment of optimum extraction conditions.* Dichloroethane (10 ml), an aliquot of the NTC solution to cover the concentration from $4 \times 10^{-5}$ to $8 \times 10^{-5} M$ NTC and an aliquot of the potassium hexachloridorhenate(IV) solution to cover the concentration range from 0.5 to 5.2 $\mu$g/ml $ReCl_6^{2-}$ were introduced into 100-ml separatory funnels. The aqueous phases were brought to 10 ml with water and the funnels shaken on a shaking machine for 60 min. The oganic layer was filtered through a filter paper impregnated with dichloroethane into a 1-cm quartz cell and the absorbance measured at 281 nm against dichloroethane. The absorbance of the blank was also measured.

## RESULTS AND DISCUSSION

On mixing aqueous solution of NTC and $K_2ReCl_6$ an ion-association complex was formed. The absorbance of this aqueous solution of the complex corresponds to the sum of absorbances of the individual components $K_2ReCl_6$ and NTC which is an indication that the resulting compound is an ion-association complex. No frequency shift was observed. In 1,2-dichloroethane, $NTReCl_6$ is soluble, NTC-slightly soluble and $K_2ReCl_6$ not soluble at all. The composition of the complex was

*Author to whom correspondence should be addressed.

determined by the continuous variation method[8] to be 1:1, which corresponds to the formula $NTReCl_6$. The same NTC to $ReCl_6^{2-}$ molar ratio was obtained according to the Likussar and Boltz method[10] (see below). In both methods the absorbance of the complex $NTReCl_6$ was measured in the organic phase.

Hydrochloric acid appeared to be the best medium for the formation of the ion-association complex and its subsequent extraction. The experiments were carried out with a constant concentration of $ReCl_6^{2-}$ in the aqueous phase of $0.5 \times 10^{-5}M$ and $4.0 \times 10^{-4}M$ NTC and varying pH values of the aqueous phase adjusted by means of suitable buffer solutions. The optimum pH range for the formation and extraction of $NTReCl_6$ was established to be within pH 3–7. Maximum extraction of $ReCl_6^{2-}$ was achieved with a 30-fold excess of NTC. The absorbance of $NTReCl_6$ (organic layer) *vs.* original concentration of $ReCl_6^{2-}$ (aqueous phase) plot showed good linearity in the range of $0.13 \times 10^{-5}$ to $1.17 \times 10^{-5}M$ $ReCl_6^{2-}$. The molar absorptivity of $NTReCl_6$ in dichloroethane was found to be $\epsilon = 3.42 \pm 0.20 \times 10^4 M^{-1}\,cm^{-1}$. The molar absorptivity of $(INT)_2ReCl_6$ was $3.9 \times 10^4 M^{-1}\,cm^{-1}$,[6] while the molar absorptivity of $NT(ReO_4)_2$ was $\epsilon = 7.0 \times 10^3 M^{-1}\,cm^{-1}$.[11] Hence, the molar absorptivity of $NTReCl_6$ is higher by a factor of 10 than that of $NTReO_4$.

The effect of diverse ions that usually accompany rhenium in environmental and industrial samples was studied under the optimum extraction conditions. The following amounts are tolerated with the extraction of $2.5 \times 10^{-6}M$ $ReCl_6^{2-}$ with NTC: Ni(II), $1.7 \times 10^{-2}M$; Mo(VI), $8.3 \times 10^{-3}M$, Cd(II), $7.1 \times 10^{-3}M$, Zn(II), $7.6 \times 10^{-3}M$; Cu(II), $4.7 \times 10^{-3}M$; Fe(III), $8.9 \times 10^{-3}M$. $BrO_3^-$, $IO_4^-$ and $ClO_4^-$ interfere.

*Determination of the equilibrium constants $K_{ex}$, $K_D$, $\beta$*

The extraction equilibrium was studied according to the chemical model applied in Ref. 9. The following equilibria were considered:

(i) formation of an ion-associate in the aqueous phase according to the reaction:

$$NT^{2+} + ReCl_6^{2-} \rightleftharpoons NTReCl_6, \qquad (1)$$

with an equilibrium constant (ion-association constant)

$$\beta = [NTReCl_6]/[NT^{2+}][ReCl_6^{2-}].$$

(ii) Distribution of the ion-association complex between the aqueous and the organic phase

$$[NTReCl_6] \rightleftharpoons NTReCl_6]_{org}, \qquad (2)$$

with a distribution constant

$$K_D = [NTReCl_6]_{org}/[NTReCl_6].$$

The overall extraction process is described by the equation:

$$NT^{2+} + ReCl_6^{2-} \rightleftharpoons [NTReCl_6]_{org} \qquad (3)$$

with a corresponding equilibrium constant

$$K_{ex} = [NTReCl_6]_{org}/[NT^{2+}][ReCl_6^{2-}].$$

According to Ref. 9 the constants $K_{ex}$ and $K_D$ can be graphically determined from the experimental $\lg D_{ReCl_6^{2-}}$ *vs.* lg[NTC] plot (Fig. 1). The distribution coefficient $D_{ReCl_6^{2-}}$ was determined with a constant $ReCl_6^{2-}$ concentration in the aqueous phase according to the formula:

$$D_{ReCl_6^{2-}} = [NTReCl_6]_{org}/[NTReCl_6] + [ReCl_6^{2-}].$$

$K_{ex}$ and $K_D$ are read from the plot and $\beta$ calculated from $\beta = K_{ex}/K_D$. The slope of the plot shows the composition of the extracted species. Figure 1 presents an experimental $\lg D_{ReCl_6^{2-}}$ *vs.* lg[NTC]. The slope of the plot confirms the composition of the extracted complex to be $NT^{2+}:ReCl_6^{2-} = 1:1$.

The value of $K_{ex}$ was determined independently by the Likussar and Boltz method[10]

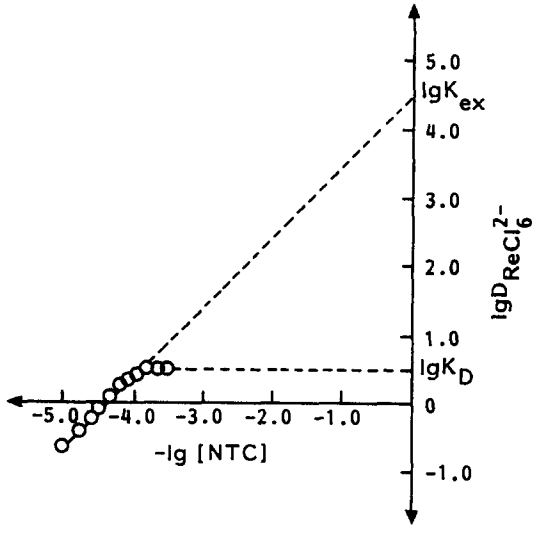

Fig. 1. $\lg D_{ReCl_6^{2-}}$ *vs.* $\lg C_{NTC}$ plot ($C_{ReCl_6^{2-}} = 1.6 \times 10^{-5}M$).

Table 1. Values of $K_{ex}$, $K_D$ and $\beta$ for the extraction system $ReCl_6^{2-}$–neotetrazolium chloride (NTC)–water–dichloroethane

| | | | |
|---|---|---|---|
| 1 | $\lg K_{ex}^* = 4.46 \pm 0.10$ | $K_{ex}^* = (2.99 \pm 0.74) \times 10^4$ | $n = 7$ |
| 2 | $\lg K_{ex}\dagger = 4.41 \pm 0.02$ | $K_{ex}\dagger = (2.70 \pm 0.70) \times 10^4$ | $n = 4$ |
| 3 | $\lg K_D = 0.46 \pm 0.03$ | $K_D = 2.40 \pm 0.22$ | $n = 6$ |
| 4 | $\lg \beta = 3.99 \pm 0.05$ | $\beta = (1.02 \pm 0.12) \times 10^4$ | $n = 10$ |

*Value obtained from the $\lg D_{ReCl_6^{2-}}$ *vs.* $\lg C_{NTC}$ plot.[9]
†Value calculated by the Likussar and Boltz method.[10]

with $C_{NT^{2+}} + C_{ReCl_6^{2-}} = 1.0 \times 10^{-4} M$. Table 1 lists the values of equilibrium constants of the system $ReCl_6^{2-}$–neotetrazolium chloride (NTC)–water–dichloroethane.

## CONCLUSIONS

The extraction constant $K_{ex} = (2.99 \pm 0.74) \times 10^4$ and the recovery factor achieved with one-fold extraction is $R = 74\%$. The extracted species $NTReCl_6$ is an ion-association complex of moderate stability $\beta = (1.02 \pm 0.12) \times 10^4$. The molar absorptivity of the ion-associate $\epsilon = (3.42 \pm 0.20) \times 10^4 M^{-1}$ $cm^{-1}$ competes favourably with the molar absorptivity of neotetrazolium perrhenate NT $(ReO_4)_2$ ion-associate ($\epsilon = 7.0 \times 10^3 M^{-1}$ $cm^{-1}$). The results obtained show that NTC can be successfully applied to the selective extraction of Re(IV).

*Acknowledgement*—The authors would like to thank the National Research Fund for financial support.

# THE DEVELOPMENT OF A SAMPLER–SENSOR USING A VANADIUM–OXINATE–POLYMER FILM FOR THE SELECTIVE AND DIRECT DETERMINATION OF ATMOSPHERIC ETHANOL

E. T. HAYES, A. GALAL and H. B. MARK, JR.

Department of Chemistry, University of Cincinnati, Cincinnati, OH 45221-0172, U.S.A.

(*Received* 12 *July* 1994. *Revised* 27 *July* 1994. *Accepted* 10 *August* 1994)

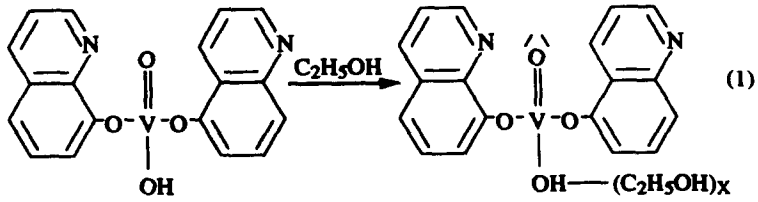
**Summary**—The development of a sensor for the direct and selective determination of atmospheric ethanol is in the initial stages. The sensor takes advantage of the selective chemical reaction between ethanol and vanadium oxinate. This reaction occurs in an organic medium where a red colored complex is the product. This reaction is determined spectrophotometrically where the absorbance maxima is 475 nm. The focus of this paper is to discuss the parameters necessary to develop a solid sorbent sampling–sensor which can be used to determine atmospheric ethanol.

Over the course of the past 10 years, this research group has been developing sampler-sensoring devices for trace gas analysis.[1–3] The research involves the use of chemical reagents immobilized on solid sorbents for selective surface reaction with the analyte of interest. In most cases, the reaction between the reagent and analyte on the surface results in the formation of an irreversible complex. The product yields a colored or fluorescent surface where either visual and/or an appropriate spectrochemical technique can be utilized to determine the analyte concentration. The advantages of using solid sorbents for trace gas analysis are low cost, selectivity, simplicity, high sample collection efficiency, suitable storage time, and detection limits in low ppm–ppb range.[4]

In addition to these advantages, the use of an archimedean sampler-sensor adds the dimension of direct *in situ* analysis of air pollutant. An archimedean sampler–sensor has been developed in this laboratory for the direct determination of air pollutants and has been previously described.[2] The novelty of this device is the elimination of instrumentation for analyte determination. The species of interest is quantified by measuring the spiral length of color established by the pollutant reaction.

The use of sorbent material for the determination of atmospheric ethanol is not widely accepted, but there exist detector tubes available for this analysis. Sorption tubes containing activated charcoal are common for ethanol detection.[5] Although suitable for atmospheric ethanol determination, activated charcoal tends to be nonspecific and adsorbs other organic volatiles present. In addition, humidity greater than 60% can reduce the adsorptive capacity of activated charcoal.[6] In general, chemical sorbent chosen for atmospheric ethanol need not be very sensitive since the Federal Permissible Exposure Limits (PEL) is 1000 ppm. However, the surface reagent must be selective to ethanol due to the presence of other organics and high humidity available in environmental and industrial atmospheres.[5]

In this research, the reagent chosen for ethanol selectivity is a compound referred to as vanadium oxinate. 7 Vanadium oxinate, a phenol ester of orthovanadic acid, reacts with ethanol to form a red colored complex (equation 1).



(1)

Vanadium oxinate grey green — Alcoholate complex red

This reaction is characteristic of alcohols over all organic functionalities. As a matter of fact, this reagent, which is sparingly soluble in many organic solvents, has been used to remove low levels of ethanol in mixtures containing other organics.[7] In addition this compound is completely insoluble and non-reactive with water. Because of the selectivity, the vanadium oxinate has been used to determine levels of ethanol in beers, wine, blood samples, and other solvent mixtures.[8-10] The detection occurs with minimum sample preparation and the ethanol levels are quantified with basic UV-Vis spectrophotometry. Thus, because of its selectivity, vanadium oxinate appears to be a prime sorbent reagent for the selective determination of atmospheric ethanol using a sampler–sensor device.

## EXPERIMENTAL

### *Reagent*

The vanadium oxinate was prepared to adding solutions of 0.02*M* ammonium vandate (Fischer) to 2.5% 8-hydroxyquinoline (MCSB) in 5% acetic acid (Fischer). The resulting precipitate was soaked in an acetic acid–sodium acetate (Fischer) solution, pH 4, for 1 hr. All solutions were prepared in analytical grade deionized water. The precipitate was filtered in a sinitered glass filter and allowed to dry overnight in the oven at temperatures ranging from 100 to 120°C. Reagent solutions ranging from $2.0 \times 10^{-4}$ to $4.5 \times 10^{-4}M$ were tested for solubility and ethanol sensitivity in the following solvents: (1) toluene, (2) 2,4-dichlorotoluene, (3) cyclohexane, (4) acetonitrile, (5) benzene, and (6) chloroform. The chloroform had to be washed with analytical grade deionized water to remove residual ethanol. The effectiveness of these reagent solutions were tested in contact with solutions of ethanol at concentrations (V/V) ranging from 0.001 to 10%. The ratio of organic to aqueous phase was 1 to 2, and analyses were carried out in 25 ml test tubes. Reaction times were varied from 20 min to 3 hr depending on concentration and temperature. The colored product in the organic phase was analyzed spectrophotometrically at 475 nm.

In addition to various solvents, several polymers were also investigated as a matrix for vanadium oxinate immobilization. The following polymers were explored: (1) polyvinyl acetate, (2) polymethacrylate, (3) cellulose acetate, (4) polyethylene oxide, and (5) polyvinyl alcohol. The polymer films were formed by dissolving 10 mg of vanadium oxinate and 2 g of polymer in 60 ml of solvent. An aliquot of 2 ml was placed on a polypropylene disk (7.5 cm diameter) where the solvent would evaporate, leaving a caste film. These polymer films were tested for the mechanical stability, capacity to immobilize the reagent, and interaction with atmospheric ethanol.

### *Instrumentation*

UV-Vis spectra of the various solutions were obtained on either a Perkin-Elmer Lambda 5 UV/Vis Spectrophotomer or Hewlett Packard 8452A Diode Array Spectrophotometer. The sample was placed in a 1 cm quartz curvette. These spectrophotometers were also used to analyze atmospheric ethanol collected on the various polymer surfaces. The complex was recovered in an appropriate solvent for analysis. Calibration gas standards were prepared from a VICI Dynacalibrator Model 230-50-2. A 5 mm diffusion vial (VICI metronics) with 100% ethanol was inserted into the instrument chamber and concentration was controlled by adjusting the gas flow rates. The atmospheric ethanol entered a reaction chamber where reaction with the vanadium–oxinate polymer film occurred.

## RESULTS AND DISCUSSION

### *Solvent test*

Initial research was devoted to determining the best solvent for the dissolution of the vanadium compound. Ideally the solvent should meet several criteria. The ideal requirements are as follows: (1) totally immiscible with water, (2) possess a low dielectric constant, (3) be able to dissolve sufficient amounts of the vanadium–oxinate, (4) non-hazardous to users, (5) ability to dissolve a polymer–reagent mixture for the film formation, and (6) have a high volatility. Furthermore, the reaction with ethanol in the aqueous or gas phase has to be rapid, have a large formation constant to yield sensitivity, and must be selective. It is to be noted that none of the solvents tested fulfilled all the criteria. The advantages and limitations of each of the solvents in contact with ethanol solutions is listed below.

*Toluene.* Toluene meets many of the ideal specifications for choosing a solvent. It has a low dielectric constant, immiscible with water, and non-hazardous to potential users. Never-

theless, vanadium–oxinate is sparingly soluble in toluene limiting the effectiveness to determine low levels of ethanol. Reagent solutions ranging from $2.0 \times 10^{-4}$ to $5.0 \times 10^{-3} M$ were tested. Levels of 0.5% (5000 ppm) and 1% (10,000 ppm) were detected at the saturated reagent concentration. This is insufficient for the required PEL (1000 ppm) needed for atmospheric ethanol.

*2,4-Dichlorotoluene.* 2,4-Dichlorotoluene was chosen to investigate possible substituent effects of the chlorine on improved solubility. Results for this solvent, however, had identical detection levels as toluene offering no advantages.

*Cyclohexane.* In terms of the criteria, cyclohexane has similar properties to toluene. However, the vanadium oxinate is completely insoluble in cyclohexane; therefore, no color formation occurred in the organic phase with ethanol solution.

*Acetonitrile.* This was the only water miscible solvent investigated; thus it is in essence undesirable. In addition, acetonitrile is more hazardous than the previous solvents mentioned. Nevertheless, the acetonitrile can dissolve a sufficient amount of vanadium oxinate to determine ethanol levels of 0.1% (1000 ppm).

*Benzene.* Benzene is the solvent most widely used to dissolve the vanadium compound, but it is the most toxic, thus, least preferred. The desirable aspect of using benzene is that ethanol levels as low as 0.05% (500 ppm) can be determined.

*Chloroform.* Chloroform is a compromise solvent, therefore, being the choice solvent for sensor development. It dissolves a sufficient amount of vanadium to determine ethanol at levels of 0.01% (100 ppm) and it is immiscible. The apparent disadvantage is the toxicity of this solvent; although, its toxicity is less severe than benzene and acetonitrile. Figure 1 shows the UV-Vis spectra of the vanadium solution in contact with 1 and 3% ethanol solutions. The absorbance maxima occurs at 475 nm. This maxima agrees closely to reported literature values for this complex.[9] In addition, this solvent is capable of dissolving most of the polymers investigated. Its volatility is suitable for casting polymer films containing the immobilized reagent.

Regardless of the solvent, there was a major problem associated with dissolution of the vanadium compound. Vanadium–oxinate, as mentioned earlier, is sparingly soluble in most solvents. When this compound dissolves in an organic medium, it forms a dark black solution which tends to precipitate in the organic layer on standing. Thus, the reagent solution has a variation in color intensity and absorbance for a particular ethanol concentration which is time dependent. In order to circumvent this particular problem, sieving of particles and filtering of solutions were employed before analysis. However, time dependent changes persisted. This problem is carried into the second stage of polymer film development for atmospheric determination of ethanol. In conclusion, none of the above solvents fulfil all requirements of ideality. Chloroform is the choice solvent due to its ability to determine ethanol at levels of 0.01% (100 ppm).

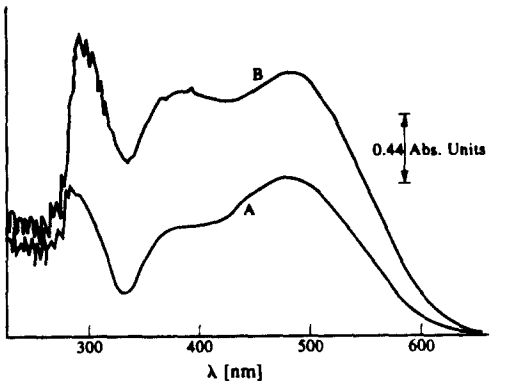


Fig. 1. Absorbance spectra of vanadium–oxinate solution in contact with (A) 1% aqueous ethanol, (B) 3% aqueous ethanol.

*Polymers*

The next stage of sensor development was to find a polymer which can incorporate the vanadium compound in a film. In essence, the ideal polymer should have compatibility with the ethanol promoting adsorption and/or permeability, it should be soluble in organic solvents that dissolve the vanadium oxinate, it needs to be mechanically stable when cast, and the reagents should be homogeneously distributed in the film. Thus, these criteria were explored for identifying the choice polymer.

*Polyethylene oxide.* Polyethylene oxide had many desirable properties for immobilizing the reagent. It exhibited mechanical stability, dissolved well in chloroform, and formed homogeneous films of the immobilized reagent. It also exhibited surface reaction with ethanol solutions of 10% (v/v) and greater. However, no reaction occurred with atmospheric ethanol.

*Polyvinyl alcohol.* Polyvinyl alcohol had many undesirable attributes as a substrate matrix.

This polymer did not have any permeability for the ethanol. In addition, the oxine reagent was formed in non-homogeneous and irreproducible zones on the polymer surfaces. Although the surface vanadium reagent reacted with ethanol solutions, it was impossible to obtain reproducible color changes with ethanol concentration.

*Polymethacrylate.* The polymethacrylate be haved similar to polyethylene oxide in all regards. Surface color change reactions with ethanol solutions greater than 10% (v/v) occurred, but it was non-active to atmospheric ethanol.

*Cellulose acetate.* Cellulose acetate was very ineffective. As a matter of fact, this polymer film was mechanically unstable on incorporating the vanadium reagent. Thus, no further testing were performed.

*Polyvinyl acetate.* Polyvinyl acetate fulfilled all the necessary requirements for formation of a sensor film. It readily permeated with the ethanol and exhibited a rapid color change for both ethanol solutions and gases. Solutions of 1% (V/V) and 1200 ppm of ethanol gases were easily detected. In addition, the films were mechanically stable and uniform in terms of reagent distribution. Figure 2 shows the UV-Vis spectra of films exposed to 8300 ppm and 10,000 ppm of ethanol where the film was dissolved in chloroform. Notice the characteristic absorbance maxima of 475 nm.

In summary, polyvinyl alcohol and cellulose acetate which are hydrophillic in nature tend to precipitate the vanadium compound out as the solvent evaporates on casting the film. Polyethylene oxide and polymethacrylate films distribute the vanadium compound uniformly on film formation. However, the ethanol does not readily permeate these films, thus, forming color changes only with ethanol solutions greater than 10% (v/v). Moreover, this inability to adsorb ethanol produces no color change for atmospheric samples. Polyvinylacetate shows both hydrophobic and hydrophillic characteristics. Thus this polymer promotes the uniform distribution of the vanadium oxinate on casting and has sufficient hydrophillicity to interact with the atmospheric ethanol. This allows the ethanol to react both at the surface and within the matrix with reagent. Response time for color formation varied from 3 to 6 hr for atmospheric samples depending on concentrations.

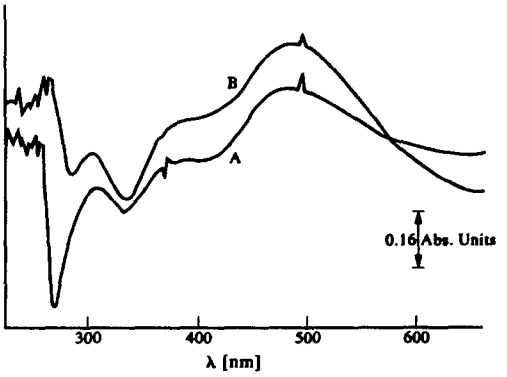

Fig. 2. Absorbance spectra of vanadium–oxinate film in contact with (A) 8300 ppm ethanol–air sample, (B) 10,000 ppm ethanol–air sample.

## CONCLUSIONS

The combination of a reagent, solvent, and polymer for an immobilized surface sensor film for atmospheric ethanol determination was successfully completed. The selectivity of the vanadium–oxinate towards ethanol is excellent in both the solution and gas phase. Ethanol solutions as low as 0.01% (v/v) were determined in chloroform solvent–reagent system, and the immobilized vanadium oxinate–polyvinyl acetate substrate film can detect as little as 1200 ppm of atmospheric ethanol. However, the problem of solvent–vanadium stability gave non-reproducible color formation for each concentration of ethanol tested. This has not yet been solved. Thus, continued work must be performed on establishing stable and homogeneous reagent solutions for improved sensor data reproducibility. Once this problem is solved, the applicability of these films for use in the archimedean sampling–sensor unit can be evaluated.

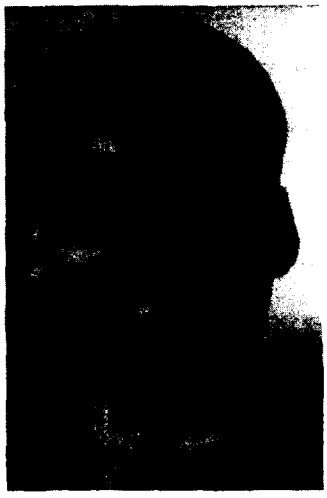
# The Benedetti–Pichler Award



**Leslie Colin Ebdon**

Leslie (Les) Colin Ebdon, Deputy Vice-Chancellor (Academic), at the University of Plymouth in Plymouth, UK, will be presented with the prestigious Benedetti–Pichler Memorial Award by the American Microchemical Society, during a symposium in his honor at the annual meeting of the Eastern Analytical Symposium in Somerset, NJ, USA, November 12–17, 1995. This award is given annually and was established in 1966 to recognize outstanding achievements in microanalytical chemistry.

Les obtained a B.Sc. in chemistry in 1968 and a Ph.D. in 1971 at Imperial College, University of London, UK. His Ph.D. was supervised by Professor Tom West and (the late) Professor Gordon Kirkbright. He was a lecturer in chemistry at Makerere University, Kampala, Uganda for two years before accepting a position as lecturer in analytical chemistry at Sheffield Polytechnic, Sheffield, UK, being promoted to senior lecturer in 1976. In 1981, Les took the newly promoted position of Reader in Analytical Chemistry in the Department of Environmental Sciences at Plymouth Polytechnic, which later became the University of Plymouth. In 1989 he became Deputy Vice-Chancellor (Academic) at the University of Plymouth.

Les's interests are in trace analysis particularly applied to environmental problems. At present he has nearly 200 publications, 4 books, and 5 patents. He has given plenary lectures in over 20 countries and over 200 invited conference contributions. He is the 1986 SAC Silver Medal recipient. He currently serves on the editorial board of 8 journals. In a recent survey (Chemistry & Industry, August 1993, p. 571,) Les was reported as the most cited analytical chemist in the UK and the 14th most cited of all UK chemists.

The following is a list of presentations at the Benedetti–Pichler Award Symposium at Eastern Analytical Symposium:

**Ramon M. Barnes**, Department of Chemistry, University of Massachusetts, Amherst, MA, USA
*Electrophoresis and ICP-MS*

**Kenneth W. Jackson**, Department of Environmental Health and Toxicology, State University of New York at Albany, Albany, NY, USA
*Electrothermal Atomic Absorption Spectrometry: Fundamental Research Leads to Accurate Applied Methods*

**Richard F. Browner**, Department of Chemistry, Georgia Institute of Technology, Atlanta, GA, USA
*Coupling Microflow Chromatography to LC-ICP-MS, LC-MS, and LC-MS-MS*

**Robert G. Michel**, Department of Chemistry, University of Connecticut, Storrs, CT, USA
*New Laser Technologies for Atomic Spectroscopy*

**Les Ebdon**, Department of Environmental Sciences, University of Plymouth, Plymouth, Devon, UK
*New Plasmas for Old Speciation Problems*

## NOMINATIONS FOR THE 1996 BENEDETTI-PICHLER AWARD

The American Microchemical Society is soliciting nominations for the prestigious 1996 Benedetti-Pichler Award. The award, established in 1966, is given annually to recognize outstanding achievements in microanalytical chemistry. The award consists of a plaque and expenses to attend the Eastern Analytical Symposium in Somerset, NJ, USA, in November 1996 to receive the award at a session in honor of the awardee.

Nominations, including at least two supporting letters, should be sent no later than October 30, 1995 to:

Len Klein
Secretary
American Microchemical Society
FMC Corporation
Agricultural Chemical Group
P.O. Box 8
Princeton, NJ 08543, USA

# Adsorptive stripping measurements of germanium(IV) in the presence of pyrogallol

ChangQing Sun *, Qian Gao, LiLing Liu

*Department of Chemistry, Jilin University, Changchun, 130023, People's Republic of China*

Received 16 June 1994; revised 15 November 1994; accepted 16 December 1994

**Abstract**

The adsorptive stripping voltammetric determination of germanium(IV) based on the adsorptive accumulation of the germanium(IV)–pyrogallol complex on a hanging mercury drop electrode is reported. The reduction current of the adsorbed germanium complex is measured by differential-pulse cathodic stripping voltammetry. The peak potential is at −0.42 V vs. Ag/AgCl (saturated KCL). The effects of various parameters (ligand concentration, supporting electrolytic composition and concentration, accumulation potential and collection time) on the response are discussed. With controlled accumulation for 3 min, the detection limit is $1.2 \times 10^{-9}$ M germanium. The relative standard deviation (at $1.2 \times 10^{-8}$ M germanium) is 3.6%. Possible interferences are evaluated. The applicability of the method to the determination of germanium(IV) in ore samples was also successfully carried out.

## 1. Introduction

Germanium is a rare element in the earth's crust and because of its industrial and biological significance, a highly sensitive method is required for reliable measurement. Germanium(IV) complex with organic ligands such as polyhydroxy compounds [1–4] have been applied in the polarographic determination of germanium, but these methods are not sufficiently sensitive to detect trace germanium. Recently, the adsorptive characteristics of complexes have been used in the determination of traces of inorganic elements [5–7]. The adsorptive stripping measurements of germanium(IV) in the presence of catechol and pyrogallol have been reported [8] and the method has been applied to determination of trace germanium in ginseng and garlic.

In this paper, a sensitive adsorptive stripping voltammetric method is described for the determination of trace amounts of germanium based on differential-pulse cathodic stripping voltammetry (DPCSV) of the accumulated germanium(IV) complex with pyrogallol at a hanging mercury drop electrode. The optimum analytical conditions for germanium(IV) determination are discussed in detail.

## 2. Experimental

### 2.1. Apparatus and reagents

The voltammograms were recorded on a PAR model 384A polarographic analyzer. The working electrode was a PAR model 303 static mercury drop electrode and a medium-sized hanging mercury drop electrode (HMDE) was employed. Ag/AgCl(saturated KCl) and platinum wire served as reference and auxiliary electrode, respectively, A model 79-1 voltammetric analyzer (Jinan Fourth Radio Factory, China) coupled with a model Series 60000 XYt recorder (Gould Electronics, China) was used for cyclic voltammetry.

* Corresponding author. Fax: (86) 431-823-907

Unless specified otherwise, all reagents were of analytical-reagent grade. All solutions were prepared from doubly distilled water. A stock solution of $1.2 \times 10^{-2}$ M germanium(IV) (atomic absorption standard) was used and diluted with water as required. A stock solution of 0.1 M pyrogallol was prepared weekly and was stored at 4 °C in a refrigerator.

### 2.2. Procedure

Voltammetric stripping experiments were performed in the following manner. The supporting electrolyte (10 ml) containing 0.5 M HCl, 0.1 M KCl and $4 \times 10^{-4}$ M was pyrogallol transferred into the voltammetric cell and purged with pure nitrogen for 4 min. The preconcentration potential (usually 0.0 V vs. Ag/AgCl (saturated KCl)) was applied to a fresh mercury drop while the solution was stirred. Stirring was stopped and after 30 s the voltammogram recorded by applying a negative scan (at 4 mV $s^{-1}$) from 0.0 to −0.60 V using the differential-pulse stripping mode. After the ground voltammogram has been obtained, the adsorptive stripping experiment was repeated with a new drop for the addition of the germanium sample. After additions of each sample, nitrogen was passed through the solution for about 1 min.

## 3. Results and discussion

### 3.1. Response characteristics

Fig. 1 shows cyclic voltamperograms for $6 \times 10^{-7}$ M germanium(IV) in a medium containing $4 \times 10^{-4}$ M pyrogallol, 0.1 M KCl and 0.5 M HCl. In the absence of accumulation, only a small peak from the reduction of the germanium–pyrogallol complex was observed at −0.42 V (a). When the above experiment was repeated for a 30 s stirring period at −0.20 V vs. Ag/AgCl (saturated KCl), a significantly larger cathodic peak was observed (b), indicating an interfacial accumulation of the complex. The fact that a well-defined cyclic voltammetric response was observed shows the remarkable sensitivity associated with the interfacial accumulation process.

To check the applicability of the adsorption preconcentration behaviour of the germanium(IV)–pyrogallol complex at the HMDE for the determination of germanium(IV) by

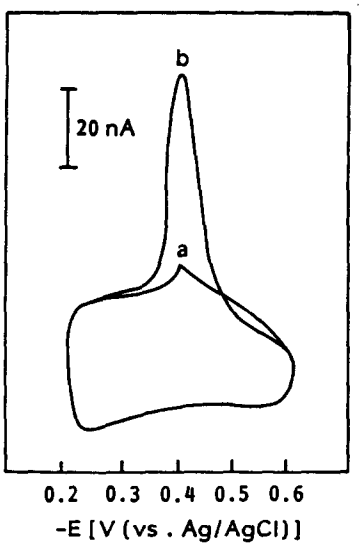

Fig. 1. Cyclic voltamperograms of germanium(IV) after 0 (a) and 30 (b) sec stirring at −0.20 V vs. Ag/AgCl (saturated KCl). Scan rate, 100 mV $s^{-1}$. The solution contained 0.5 M HCl, 0.1 M KCl, $4 \times 10^{-4}$ M pyrogallol and $6.0 \times 10^{-7}$ M Ge(IV).

DPCSV, different parameters (supporting electrolytic composition and concentration, accumulation potential, collection time, ligand concentration and germanium(IV) concentration) were investigated.

By comparing $HClO_4$, HAc–NaAc, $H_2SO_4$, and KCl–HCl solution, we found that the germ-anium(IV)–pyrogallol complex peak was highest and constant in KCl–HCl solution and the optimum concentration was 0.1 M KCl and 0.5 M HCl.

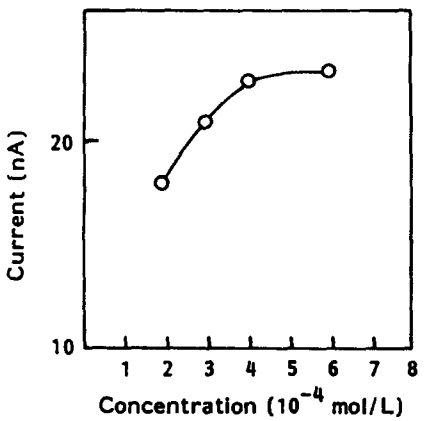

Fig. 2. Dependence of the reduction peak current of the adsorbed Ge(IV) complex with pyrogallol on the concentration of pyrogallol. The solution contained 0.1 M KCl, 0.5 M HCl and $1.2 \times 10^{-7}$ M Ge(IV). Scan rate, 4 mV $s^{-1}$. Preconcentration time, 30 s. Preconcentration potential, 0.0 V vs. Ag/AgCl (saturated KCl).

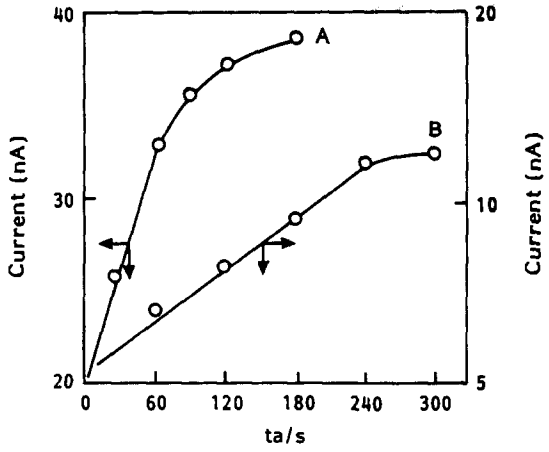

Fig. 3. Dependence of the reduction current of the adsorbed Ge(IV) complex with pyrogallol on the preconcentrated time. The conditions are 0.1 M KCl, 0.5 M HCl, $4 \times 10^{-4}$ M pyrogallol and $1.2 \times 10^{-7}$ M Ge(IV) (A) and $3.6 \times 10^{-8}$ M Ge(IV) (B). Other conditions are the same as those in Fig. 2.

Fig. 2 shows the dependence of the germanium(IV)–pyrogallol complex peak on the ligand concentration. The peak height increases linearly with the pyrogallol concentration at a concentration of less than $4 \times 10^{-4}$ M. The peak height tended to remain constant at a concentration of more than $4 \times 10^{-4}$ M. Therefore, $4 \times 10^{-4}$ M was selected as the optimum concentration of the pyrogallol.

The dependence of the maximum stripping peak current on the collection time was examined for samples containing $1.2 \times 10^{-7}$ M (Fig. 3A) and $3.6 \times 10^{-8}$ M (Fig. 3B) germanium(IV) in the range of 0–300 s. The maximum peak height was observed at 120 and 240 s for $1.2 \times 10^{-7}$ M and $2.6 \times 10^{-8}$ M germanium (IV), respectively, and was constant during the longer time.

The effect of the accumulation potential on the stripping peak current of the germanium(IV)–pyrogallol complex was examined over the potential range from 0.0 to −0.30 V in 0.1 M KCl, 0.5 M HCl, $4 \times 10^{-4}$ M pyrogallol and $1.2 \times 10^{-7}$ M germanium(IV) solution at the optimum collection time. The largest peak current was obtained at a deposition potential of 0.0 V and the current decreased slowly at more negative potentials. Electrostatic exclusion may be responsible for the observed effect. Because the germanium (IV)–pyrogallol complex appears negatively charged, a more positive potential is favorable for its adsorption at HMDE. Therefore, 0.0 V was selected as the accumulation potential in the recommended procedure.

From the results above, we chose the following as the optimum experimental condition: 0.1 M KCl, 0.5 M HCl, $4 \times 10^{-4}$ M pyrogallol. The accumulation potential was 0.0 V vs. Ag/AgCl (saturated KCl).

### 3.2. Analytical application

The greatest advantage of the determination of germanium(IV) by proposed adsorptive stripping voltammetric method is the inherent sensitivity. Under the optimum conditions, a linear relationship between the peak current and the germanium(IV) concentration was obtained in the range of $0–6 \times 10^{-7}$ (Fig. 4A), $0–6 \times 10^{-8}$ (Fig. 4B) and $0–10 \times 10^{-9}$ (Fig. 4C) M when collection time was 60, 90 and 180 s, respectively. When the collection time was 180 s, the detection limit of the method was $1.2 \times 10^{-9}$ M. Reproducibility tests on eight results at $1.2 \times 10^{-8}$ M germanium(IV) showed a relative standard deviation of 3.6%.

The selectivity of the method was tested by studying the effects of foreign ions on the determination of $1.2 \times 10^{-8}$ M germanium(IV). The results showed that 100-fold excess of Cu(II), Cd(II), Fe(III), Fe(II), Co(II), Pb(II), Mg(II), Al(III), Ni(II), Mn(II), Zn(II), Ca(II) and 20-fold exess of As(III) did not interfere with the determination of germanium(IV) under the experimental conditions. In addition, because Tin(IV) can complex with pyrogallol

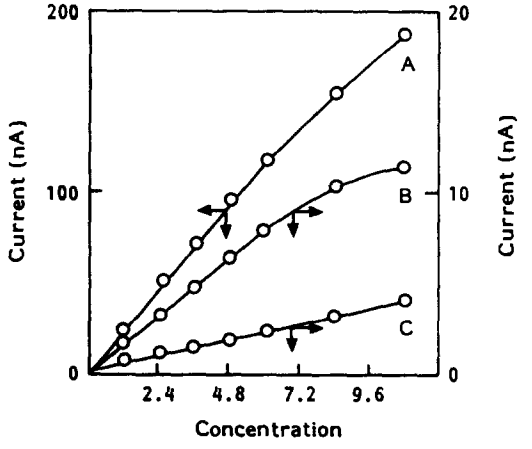

Fig. 4. Dependence of the reduction peak current of the adsorbed Ge(IV) complex with pyrogallol on the concentration of germanium(IV). The conditions are as follows. (A) $0–10.8 \times 10^{-7}$ M Ge(IV), preconcentration time was 60 s. (B) $0–10.8 \times 10^{-8}$ M Ge(IV), preconcentration time was 90 s. (C) 0–10, $8 \times 10^{-9}$ M Ge(IV), preconcentration time was 180 s. Other conditions are the same as those in Fig. 3.

Table 1
Results of the determination of germanium in standard ore samples

| Sample | Stated content ($\mu g\ g^{-1}$) | Content determined ($\mu g\ g^{-1}$) | Average value found ($\mu g\ g^{-1}$) |
|---|---|---|---|
| GSD-2 | 1.70 | 1.65, 1.71, 1.68 | 1.68 |
| GSD-4 | 1.40 | 1.35, 1.40, 1.39 | 1.38 |
| GSD-5 | 1.40 | 1.32, 1.39, 1.41 | 1.37 |

and adsorb at HMDE, a cathodic stripping peak was produced. In experiments it was found that the sensitivity of tin(IV) was low. When the concentration of tin(IV) was 20-fold excess of Ge(IV), the relative response was 5.6%.

The adsorptive stripping voltammetric method can be applied to the determination of germanium(IV) in ore samples. A 0.2 g ore sample was dissolved in 5 ml of nitric acid (1 + 1) and the solution diluted to 25 ml. An appropriate volume of this sample solution was transferred into a 50 ml volumetric flask containing supporting electrolyte and diluted to the required volume with water. After these steps, a certain amount of this solution was added to the cell and tested to the procedure above.

Typical results obtained for standard samples are summarized in Table 1. The results for the determination of germanium(IV) are in agreement with the stated contents.

## 4. Conclusions

The results above demonstrate the feasibility of the method for the determination of trace germanium by cathodic stripping voltammetry. The detection limit is $1.2 \times 10^{-9}$ M. The method is sensitive, simple and relatively rapid.

# Electrocatalytic oxidation and flow detection of cysteine at an aquocobalamin adsorbed glassy carbon electrode

Huimei Li, Tao Li, Erkang Wang *

*Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, People's Republic of China*

Received 12 July 1994; revised 15 December 1994; accepted 16 December 1994

**Abstract**

A chemically modified electrode (CME) constructed by adsorption of aquocobalamin (VB12a) onto a glassy carbon electrode surface was demonstrated to catalyze the electro-oxidation of cysteine, a sulfhydryl-containing compound. The sulfhydryl oxidation occured at 0.54–0.88 V vs. Ag/AgCl depending on pH value (3.0–10.0). The electrocatalytic behavior of cysteine is elucidated with respect to solution pH, operating potential and other variables as well as the CME preparation conditions. When used as the sensing electrode in flow injection amperometric detection, the CME permitted detection of the compound at 0.8 V. The detection limit was 1.7 pmol. The linear response range went up to 1.16 nmol. The stability of the CME was shown by RSD (4.2%) over 10 repeated injections.

## 1. Introduction

Numerous methods for the amperometric determination of physiologically important thiols following liquid chromatographic separation have been reported. Unfortunately, those thiols exhibit irreversible oxidation requiring extreme positive overpotential at most conventional electrode surfaces and, consequently, are not ideally suitable for quantification via conventional electrochemical approaches following liquid chromatography [1–3]. Electrochemical detection of those species is usually performed at mercury [4–7] or mercury amalgam [8,9] electrodes at which the formed mercury sulfide species can be oxidized at comparatively modest values of applied potential. Much effort has been made towards decreasing the overpotential and increasing the oxidation current [10–22]. Zagal et al. [10] reported the phthalocyanine tetrasulphonate adsorbed graphite electrode used for the electrocatalytic oxidation of cysteine. Baldwin [11,12] has developed carbon paste electrode containing cobalt phthalocyanine (CoPC) to decrease the overpotential for the oxidation of sulfhydryl compounds. Later, a polymeric CoPC chemically modified electrode was constructed to improve the stability of the electrode in organic solvents [13]. Some other medically important sulfhydryl containing substances such as thiopurines [14] and 2-thiothiazolidine-4-carboxylic acid [15] were also detected ideally on CoPC carbon paste electrode and electropolymerized CoPC glassy carbon electrode, respectively. Hart et al. [16–18] devised a carbon–epoxy resin composite electrode chemically modified with CoPC for catalytic oxidation and determination of glutathione following liquid chromatography. Kulys et al. [19] constructed graphite electrodes modified with tetracyano-*p*-quinodimethene, tetrathiafulvalene and 1,1′-dimethylferrocene for the electrocatalytic

oxidation and determination of sulfhydryl compounds. He et al. [20] prepared a Nafion-$Os(bpy)_3^{2+/3+}$ film coated glassy carbon electrode for the determination of trace amounts of thiols via LCEC. Wang [21] and Cox [22] devised mixed-valent inorganic film modified electrodes for electrocatalysis and determination of those thiols.

Aquocobalamin (VB12a) is a Co(III) corrin complex with the structure shown in Fig. 1. It is related to the biologically active adenosylcobalamin, in which adenosine replaces water as an axial ligand. In conjunction with the proper enzyme system, the latter compound catalyzes a variety of group-transfer and other unique reactions in living systems [23]. There is an extensive body of literature on the chemistry of VB12 [24,25], and there has been recent interest in its catalytic properties for organic reduction [26–29], mostly about the alkylhalides [27–29], and also about oxygen [30]. The catalytic utility of VB12a in reduction is due to its facile chemical or electrochemical reduction to B12s [Co(I)alamine], a powerful nucleophile that is readily alkylated to yield alkyl Co(III) alamins. Compared to the wide research on catalytic reduction by VB12a, there has been little study on the catalytic oxidation by vitamin B12 and its analogues [31,32], not least the catalytic mechanism. In view of the well known catalytic activity of VB12a toward a wide variety of redox systems, we have constructed an aquocobalamin modified electrode (VB12a–CME) which not only greatly enhanced the oxidation peak but also decreased the oxidation overpotential of cysteine. We further investigate the use of the VB12a–CME as analytical sensors in voltammetry and flow injection analysis (FIA).

## 2. Experimental

### 2.1. Reagents and apparatus

Vitamin B12 and DL-cysteine (Cys) were of biochemical grade obtained from Shanghai Chemical Corp. (Shanghai, China). A stock solution (0.1 M) of cysteine was prepared with 0.1 M KOH and stored at 4 °C in the dark. Doubly distilled water was used for the preparation of all solutions. Vitamin B12a was obtained by photolysis [33,34]. A $1 \times 10^{-3}$ M solution of vitamin B12 in acetate buffer pH 4.75 was subjected to photolysis for 30 min.

Voltammetric experiments were performed with a laboratory-built voltameter. All experiments were done by using a three-electrode cell configuration with a modified or unmodified glassy carbon working electrode, a saturated Ag/AgCl reference electrode and a platinum wire auxiliary electrode.

Flow injection analysis was performed with a Gilson 306 pump (Gilson Medical Electronics, France), a model 7125 Rheodyne injector (Berkeley, CA, U.S.A.) with a 20 µl sample loop and a model 400 electrochemical detector with MP 1303 GCE for detection. The mobile phase was 0.1 M potassium phosphate buffer (pH 7.0), containing 50 µM EDTA, and was delivered at a constant flow rate of 1.0 ml/min. The mobile phase was filtered through 0.45 µm Type HA filter paper (Millipore Corp., U.S.A.) and was briefly degassed in an ultrasonic bath and a vacuum system about 15 min before use. The experiments were carried out at room temperature. A 125 W mercury lamp was used for photolysis.

### 2.2. Electrodes

Prior to surface modification, the glassy carbon electrode was polished successively using 1, 0.3 and 0.05 µm alumina powder suspension on

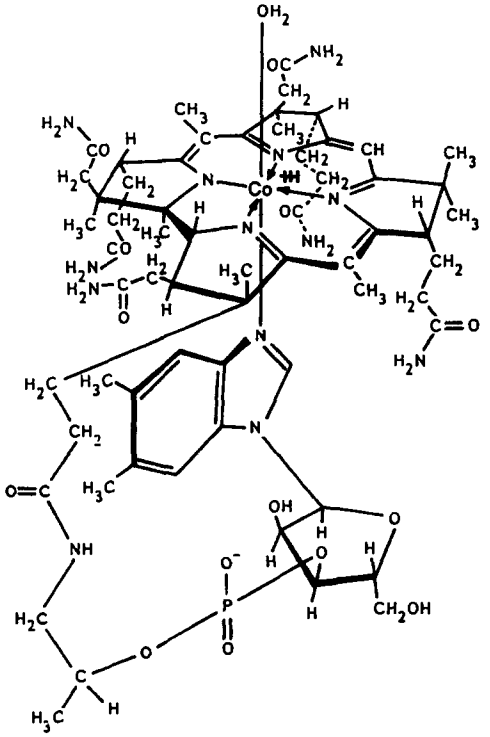

Fig. 1. The structure of aquocobalamin.

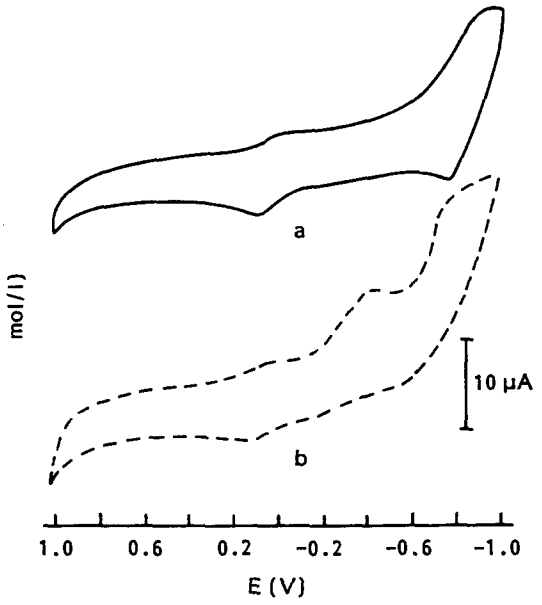

Fig. 2. Cyclic voltammograms of 1 mM vitamin B12a on bare glassy carbon electrode in 0.1 M phosphate buffer (pH 7.0) before (b) and after (a) degassing with nitrogen for 10 min. Scan rate, 100 mV/s.

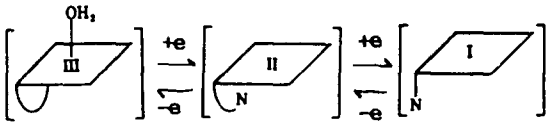
a smooth cloth and then thoroughly ultrasonicated in a water bath several times, and finally rinsed with water. This electrode is referred to as fresh glassy carbon electrode (GCE). The CME was prepared by applying 10 μl of 1 mM aquocobolamin solution onto the dried GCE surface. The electrode was then left to dry in the air, until a uniform brown reddish film was observed to cover the entire disk. The electrode was rinsed with water and was then ready to use.

## 3. Result and discussion

### 3.1. Cyclic voltammetry of vitamin B12a

Fig. 2 shows cyclic voltammograms of vitamin B12a on the freshly cleaned glassy carbon in a neutral phosphate buffer solution. Fig. 2a was obtained after degassing with oxygen, while Fig. 2b was not degrassed with oxygen. Two cathodic waves, $P_c$ and $P_{c'}$ were observed at cathodic scan, with peak potential of $E_{pc} = 0.01$ V and $E_{pc'} = -0.94$ V which were with two corresponding anodic peaks ($E_{pa} = -0.1$ V and $E_{pa'} = -0.75$ V).

A detailed picture of the redox behavior of vitamin B12a has emerged from the work of Saveant [35–37]. As shown in those reports, VB12a is electroactive and followed two steps of a one-electron transfer redox process at the pH values involved in our experiment. The base-on aquo-B12a and the base-on B12r are the electrochemically reacting species as shown below:



base-on base-on base-off

The first redox couple $P_c$ and $P_a$ features the reversible reduction and oxidation of B12a and B12r through its aquous form, and the second redox pair ($P_{c'}$ and $P_{a'}$) represents the redox process of B12r and B12s couple, the peaks at −0.54 and −1.0 V in Fig. 2b belong to the catalytic reduction of oxygen by VB12a. [37].

### 3.2. Electrocatalysis

Among the compounds whose redox reactions have been shown to be catalyzed by B12a are homocysteine and several other sulfhydryl-containing species [31]. In view of the importance of these compounds in a number of biological, pharmaceutical and environmental areas, we investigated the electrocatalytic oxidation of cysteine on VB12a and applied the VB12a–CME for the determination of cysteine. The CVs obtained for a GCE (a), VB12–CME (b) and VB12a–CME (c) immersed both in 0.1 M phosphate buffer (pH 7.0) blank solution and in the same solution doped with 0.5 and 1 mM cysteine are shown in Fig. 3. The VB12a–CME containing higher modifier concentration were found to yield a slightly higher current level and thus was not investigated further. By itself, the VB12a–CME exhibited anodic and cathodic peaks which matched the adsorption wave observed for a VB12a solution in Fig. 2b (without degassing oxygen by $N_2$). The introduction of a cysteine to this CME/solution system resulted in a marked increase in current and a decrease in overpotential compared with the GCE/solution system. As before, the catalytic currents observed were proportional to the cysteine concentration and no cathodic currents were seen on the reverse scan. Furthermore, the currents due to the cysteine oxidation were diffusion controlled exhibiting a linear dependence on the square root of the scan rate range from 10 to 250 mV/s. Compared to the significantly catalytic oxida-

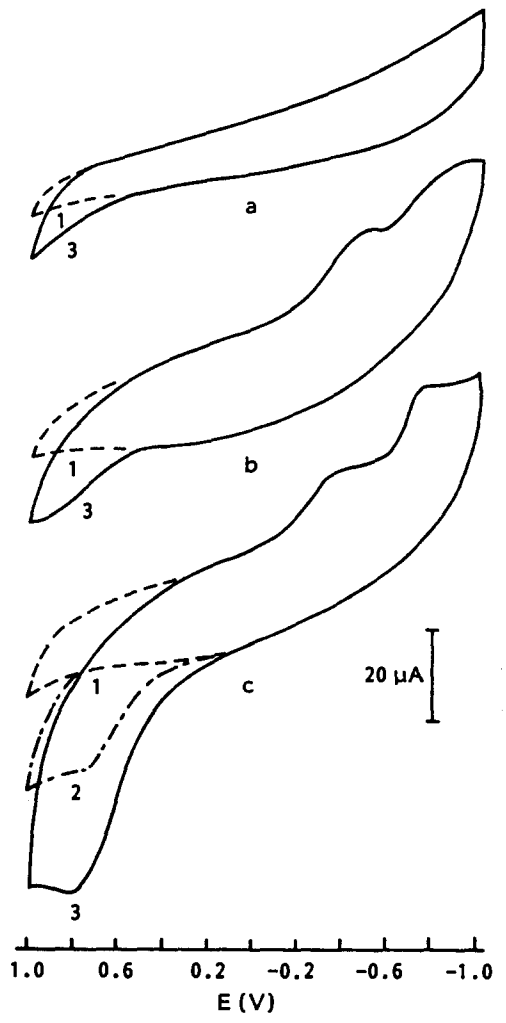


Fig. 3. Cyclic voltammograms of GCE (a), VB12–CME (b) and VB12a–CME (c) in 0.1 M phosphate buffer solution (1) and doped with 0.5 mM (2) and 1 mM (3) cysteine. Scan rate, 100 mV/s.

tion of cysteine on VB12a, there was almost no catalytic effect towards cysteine on VB12 (Fig. 3b), where the current was almost the same as at GCE with the addition of an adequately high concentration of cysteine. The catalytic mechanism was not clear. It is the same phenomenon in the chemically catalytic oxidation homocysteine by VB12a derivatives [31].

The effects of different pH values on catalytic peak current and oxidation wave are illustrated in Fig. 4. In general, increasing the solution pH caused a shift of the catalytic waves to lower potentials, and an identical increasing anodic current. The peak currents in neutral and alkali media were generally larger than those in low pH values.

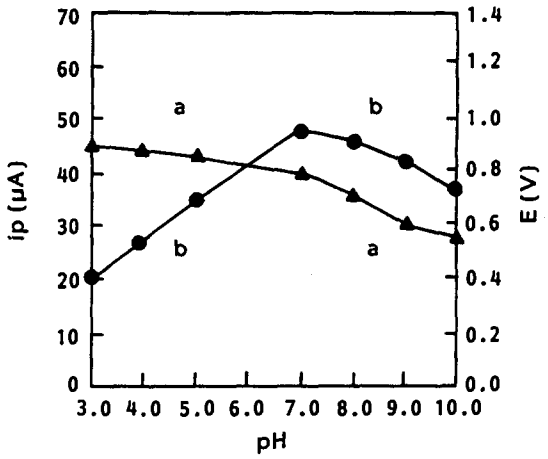

Fig. 4. Media pH effect on the peak potential (a) and peak current (b) on CVs obtained at VB12a–CME for 1 mM cysteine in 0.1 M phosphate buffer. Scan rate, 100 mV/s.

### 3.3. Flow injection amperometry

Despite some uncertainty concerning the catalysis mechanism, it was apparent that the response enhancement produced by the use of VB12a–CME should make its usage attractive in a number of analytical applications. One area where its use could be of particular advantage is as the sensing electrode for the detection of thiols in flow injection analysis and liquid chromatography.

Hydrodynamic voltammograms (HDVs) obtained for cysteine via flow injection on both GCE and VB12a–CME are shown in Fig. 5. A

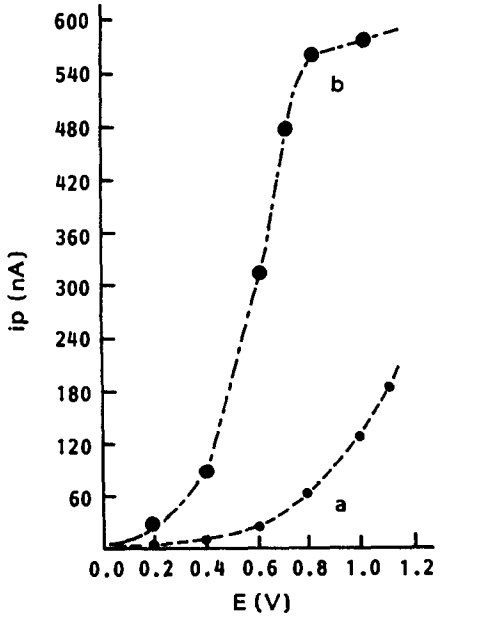

Fig. 5. Hydrodynamic voltammograms of $5.0 \times 10^{-5}$ M cysteine of GCE(a) and VB12a–CME(b). Mobile phase, 0.1 M phosphate buffer (pH 7.0) Flow-rate, 1.0 ml/min. Injection volume, 20 μl.

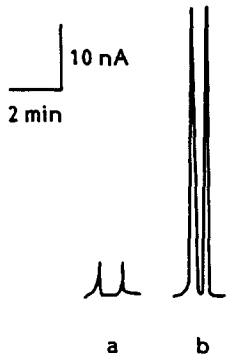

Fig. 6. Flow injection amperometric responses at GCE(a) and VB12a–CME(b) of $4 \times 10^{-6}$ M cysteine. Potential applied at 0.8 V vs. Ag/AgCl. Flow conditions as in Fig. 5.

substantial decrease in the half-wave potentials was observed at the CME and the response to cysteine was greatly enhanced. The optimum response in items of sensitivity, i.e. operation on the plateau region, occurred at 0.8 V. Also provided for comparison is the HDV obtained at an unmodified carbon electrode, which, as in CV, showed little response at potentials lower than 1.0 V. The mobile phase employed in these flow injection experiments consisted of 0.1 M phosphate buffer (pH 7.0) containing 50 μM EDTA.

On the basis of the HDVs, it appeared that the optimum potential for FIA detection of cysteine at VB12a–CME should be larger than 0.8 V vs. Ag/AgCl. As a high detection potential results in a more serious deactivation and high noise, 0.8 V was chosen as the detecting potential. Anodic peaks were obtained at this potential only when the VB12a–CME was employed (Fig. 6). Under those conditions, the calibration curve for cysteine was linear with injected amounts of analyte from 1.16 nmol to 1.7 pmol (Table 1). The regress equation was

RSD = 4.2%.
Experimental conditions as Table 1.

$ip = -0.521 + 1.124C$ (ppm) (the correlation coefficient was 0.996). The detection limit was 1.7 pmol ($S/N = 2$). Typical peak currents obtained in this manner for the injection of $5.0 \times 10^{-6}$ M cysteine solution yielded a relative standard deviation of 4.2% for 10 successive trails (Table 2).

## 4. Conclusion

A VB12a–CME was constructed and showed effective catalysis of the oxidation of cysteine. In general, the performance of the VB12a–CME for cysteine determination seems to be at least comparable to that of other carbon- and mercury-based electrode systems. The detection limit of 1.7 pmol found for VB12a–CME is not less than those of previous reported assays [1–15]. The VB12a–CME was used in the flow injection analysis of cysteine with satisfactory results for high sensitivity and stability.

# Dual-wavelength $\beta$-correction spectrophotometric determination of arsenic in wastewater with ethyl violet

Hong-Wen Gao

*Huaibei Environmetal Monitoring Centre, Anhui Province 235000, People's Republic of China*

Received 4 April 1994; revised 3 October 1994; accepted 7 December 1994

**Abstract**

Arsenic has been determined by $\beta$-correction spectrophotometry with ethyl violet (EV) in the presence of sodium nitrite which is an oxidant and effective for removing absorption spectra and increasing analytical sensitivity. Extraction with benzene can separate most other metals ions and concentrate arsenic in wastewater. The $\beta$-correction method can eliminate completely the effect of excess EV in its As colored solution to give the real absorbance of the chelate produced. Sensitivity, precision and accuracy are all increased. Beer's law is obeyed over the range 0–2.0 mg $l^{-1}$ at 630 nm and the detection limit of arsenic is 0.02 mg $l^{-1}$. The results show that the relative standard deviation was less than 12% with the recovery between 91.0 and 114%.

## 1. Introduction

Arsenic is a poisonous element and often exists in waters, polluted by, for example, the pesticide chemical, paper and other industries. Although spectrophotometry with Ag-DDC [1] is now a usual method for the determination of trace arsenic, the reaction between arsenic(III) and ethyl violet (EV) in the presence of sodium nitrite was developed first. Sodium nitrite is an oxidant for changing trivalent As(III) in a colored solution into As(V), it was also found to be effective in removing the absorption spectra and increasing sensitivity. Both the extraction with benzene and the back-extraction with water may separate other metal ions [2] to increase the selectivity. Because of the serious effect of excess EV in As solution, it is difficult to accurately determine trace As by single wavelength spectrophotometry. The $\beta$-correction method described in this paper is a new dual-wavelength method for the determination of trace metal, which is different from other dual-wavelength spectrophotometries [3–6]. It may completely eliminate the interference of excess complex to give the real absorbance of chelate produced. The sensitivity, precision and accuracy by the dual wavelength $\beta$-correction method are all higher than those for the ordinary one. Recently, such a method has been applied to the analysis of $Be^{2+}$ [7] $Sb^{3+}$ [8] etc. Here, this method is utilized for the determination of trace amounts of arsenic(III) in wastewater using the above reaction. Beer's law is obeyed over the range 0–2.0 mg $l^{-1}$ As at 630 nm and the relative standard deviation is less than 12% and the recovery between 91.0 and 114%. The detection limit of arsenic is 0.02 mg $l^{-1}$. It is suitable for the determination of As(III) in wastewater from the chemical industry.

## 2. Principle

The following reaction of the colorant R and the metal is given to illustrate the $\beta$-correction

*SSDI* 0039-9140(95)01503-5

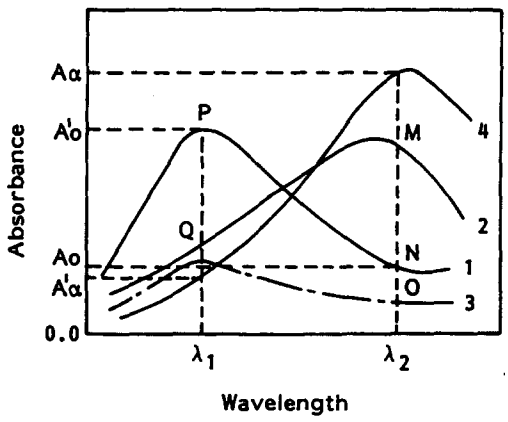

Fig. 1. Absorption spectra of R and its Me colored solution: (1) R ($a$ amount); (2) R($a$) + Me($b$) colored solution; (3) excess R ($c$ amount); (4) MeR$\gamma$ chelate. All against water reference.

principle and its spectrophotometry. The reaction is expressed by

$$a\mathrm{R} + b\mathrm{Me} \rightarrow b\mathrm{MeR}\gamma + c\mathrm{R}$$

where $a$ and $b$ are the starting amounts of R and Me, respectively, and $c$ is the excess R in its colored solution. $\gamma$ is the complex-ratio of R to Me. The absorption spectra sketch is shown in Fig. 1. At the wavelength $\lambda_2$ the real absorbance ($A_c$) of the MeR$\gamma$ chelate should be equal to the interval MO but not MN. The $A_c$ value is expressed by

$$A_c = (\Delta A - \beta\, \Delta A')/(1 - \alpha\beta) \quad (1)$$

where $\alpha$ and $\beta$ are both correction coefficients. They are calculated by, respectively,

$$\alpha = A'\alpha/A\alpha \quad (2)$$

and

$$\beta = A\mathrm{o}/A'\mathrm{o} \quad (3)$$

$\Delta A$, $\Delta A'$ are the absorbances of the colored solution of R ($a$ amount) with Me ($b$ amount) at $\lambda_2$ and $\lambda_1$, respectively, against its reagent blank ($a$R) reference. From Fig. 1 $\Delta A = \mathrm{MN}$ and $-\Delta A' = \mathrm{PQ}$. $A\alpha$, $A'\alpha$ are the absorbance of the chelate MeR$\gamma$ at $\lambda_2$ and $\lambda_1$, respectively, against water. $A$o, $A'$o are that of a reagent blank at $\lambda_2$ and $\lambda_1$ against water, $A\alpha$, $A'\alpha$; $A$o, $A'$o are shown in Fig. 1.

## 3. Experimental

### 3.1. Apparatus and reagents

Visible spectra were recorded with a Model 7230 spectrophotometer (Shanghai Third Analytical Instruments) in a 3 cm cell.

Standard arsenic(III) solution, 1.00 g $l^{-1}$: 0.1320 g $l^{-1}$ of arsenic trioxide (C.P., Beijing Chemical, China) was dissolved in 5 ml of 10% sodium hydroxide then the solution neutralized to pH 6–7 with 10% hydrogen chloride and diluted to 100 ml with distilled water. A 10.0 mg $l^{-1}$ arsenic solution was prepared by dilution. EV (Shanghai Chemical Reagents, China) solution, 0.010%; sodium nitrite (A.R., Beijing Hongxing Chemical, China) solution, 1%; hydrochloric acid solution, 0.125 mol; Benzene (Shanghai Organic Chemical, China).

### 3.2. Recommended procedures

To 50 ml of a wastewater containing less than 50 μg of arsenic(III), sulfuric and hydrochloric acid were added to give the desired 10 mol hydrogen ion molarity in a total volume of 100 ml. The solution was transferred into a separating funnel and extracted with 10 ml benzene. After separating the aqueous layer, As(III) was stripped with two 5 ml portions of water. The water-phase solution was taken in a 25 ml standard flask. Then, 2 ml of hydrochloric acid solution, 0.5 ml of sodium nitrite solution and 1.5 ml of EV solution were added. It was diluted to volume with distilled water and mixed well. After 1–5 min, the absorbances were measured at 560 and 630 nm, respectively, against a reagent blank reference.

## 4. Results and discussion

### 4.1. Absorption spectra

The absorption spectra of EV against water in the presence of sodium nitrite, that of As(III)–EV colored solution against its reagent blank and that of As–EV chelate which was measured from the colored solution as the mole ratio of EV to As(III) nears zero against the water reference, are shown in Fig. 2. From curve 3, two wavelengths may be selected such that the difference in absorbance is maximal: 560 and 630 nm. From curves 3 and 4, we see that sodium nitrite is effective in increasing the sensitivity and removing the absorption spectra. From curve 1,$\beta$ was calculated as 0.657 and from curve 2,$\alpha$ as 0.623.

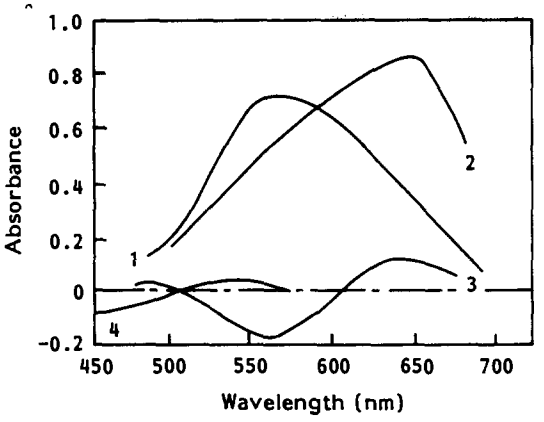

Fig. 2. Absorption spectra of EV and its As(II) colored solution in the presence of sodium nitrite: (1) EV (6.0 mg) with 0.02% sodium nitrite against water reference in 0.01 M HCl; (2) the colored solution of As(III) (500 mg) and EV(6.0 mg) with 0.02% sodium nitrite, regarded as only As–EV chelate not excess EV in the colored solution, against water reference; (3) the colored solution of As(III) (2.0 mg) and EV (6.0 mg) with 0.02% sodium nitrite, against its reagent bland reference; (4) same as (3) with sodium nitrite.

### 4.2. *Effect of EV concentration*

The effect of EV in the presence of sodium nitrite is shown in Fig. 3. Curve 1 is drawn from curves 2 and 3 and formula (1). From curves 1 and 2, $A_c$ is much higher than $\Delta A$, which shows the high sensitivity of the dual-wavelength $\beta$-correction method. From curve 1, $A_c$ reaches a maximal valve remains constant for the addition of more than 1.5 ml of 0.010% EV solution.

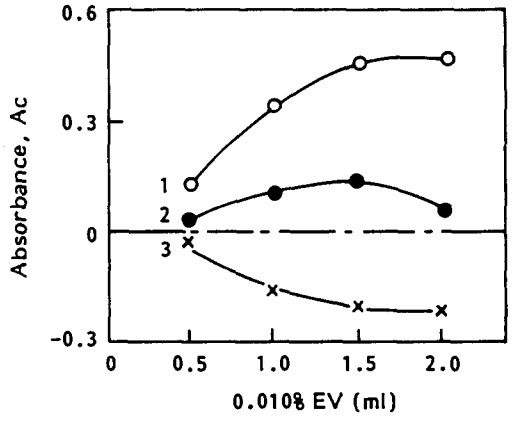

Fig. 3. Effect of EV in the presence of sodium nitrite at 630 nm: (1) the real absorbance ($A_c$) of the As–EV chelate in its colored solution containing 2.00 mg As(III); (2) the absorbance of the colored solution of As(III) (2.00 mg) and EV against its reagent blank reference; (3) same as (2) at 560 nm.

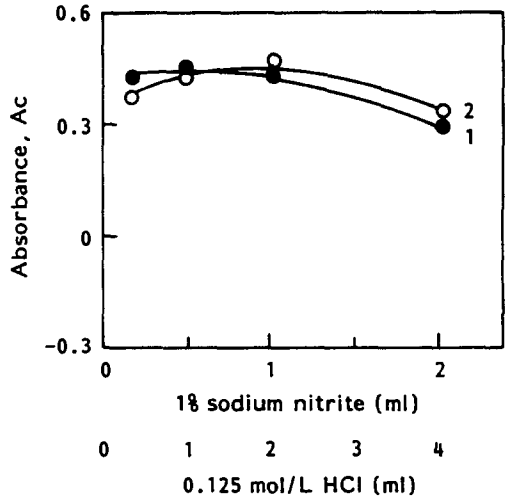

Fig. 4. Effect of HCl and sodium nitrite concentration on $A_c$ of As(III) (2.0 mg) colored solution at 630 nm: (1) 0.125 M HCl; (2) 1% sodium nitrite.

### 4.3. *Effect of acid and sodium nitrite concentration*

Varying molar concentration of HCl in a colored solution was investigated and the effect on the $A_c$ value of the colored solution containing 0.800 mg As has been drawn as Curve 1 in Fig. 4. The use of between 0.3 and 2.0 ml of 0.125 M HCl was found to give maximal colour intensity. Curve 2 in Fig. 4 shows the effect of sodium nitrite concentration. We see $A_c$ reach a maximum and was mostly stable for the addition of 1% sodium nitrite between 0.2 and 1.5 ml.

### 4.4. *Stoichiometry of complex*

A trial to determine As(V)–EV composition in the presence of sodium nitrite for the aqueous binary complex using the continuous variations method showed the As to ligand ratio to be 1:1. On the other hand, attempts to determine the composition of ternary complex were not made, because about 100-fold molar excess of nitrite ($NO_2^-$) was required for complete complex formation.

### 4.5. *Effect of development time*

The effect of reaction time on the real absorbance of 2.0 mg As(III) solution at 630 nm is shown in Fig. 5. We see that the formation of the complex of As(V) with EV in the presence of sodium nitrite is complete in 1 min but the fading of the colors becomes rapid after

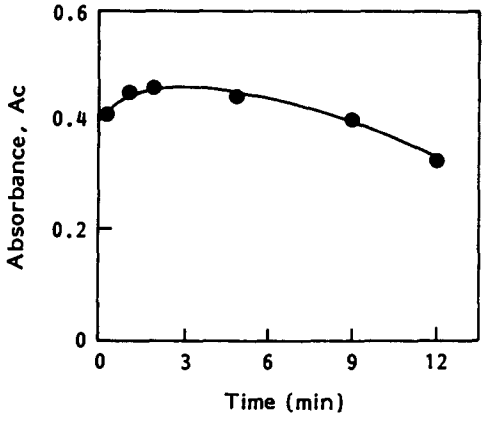

Fig. 5. Effect of development time on $A_c$ of As(III) (2.00 mg) colored solution at 630 nm.

10 min. Therefore, the measurement of absorbance should be completed in 1–5 min.

### 4.6. Calibration graph

A series of standard arsenic solutions were prepared and the absorbance of each was measured and plotted. Curves of $A_c$ and $\Delta A$ with As concentration ($x$) at 630 nm have been drawn in Fig. 6. Curve 1 is more linear than curve 2. It shows that the accuracy of the $\beta$-correction method is higher than that of the single wavelength method. The sensitivity of the recommended procedure is increased as shown by the higher gradient.

### 4.7. Effect of foreign ions

Once both the recommended extraction and back-extraction are carried out, none of the following metal ions affect the determination of 50 μg of As: 10 mg of $Na^+$, $K^+$, $Ca^{2+}$, $Mg^{2+}$, $Ti^{4+}$, $Al^{3+}$, $V^{5+}$, $W^{3+}$; 2 mg of $Zn^{2+}$, $Pb^{2+}$, $Mn^{2+}$, $Sn^{2+}$, $Fe^{2+}$, $Be^{2+}$; 1 mg of $Ni^{2+}$, $Cu^{2+}$, $Hg^{2+}$, $Cd^{2+}$; and 0.1 mg of $Sb^{3+}$, $Ag^+$, $Te^{3+}$.

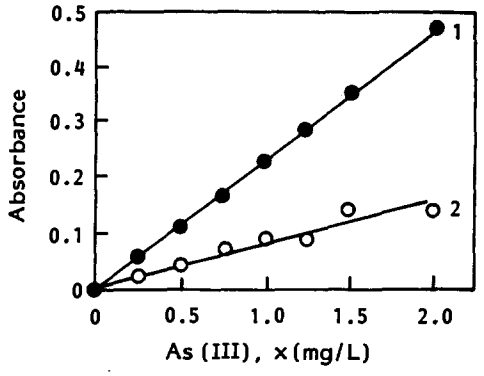

Fig. 6. Standard curves for the determination of As(III) at 630 nm: (1) $A_c$–$x$; (2) $\Delta A$–$x$.

### 4.8. Precision and detection limit

Direct replicate (10) determinations of standard As(III) solutions containing 2.00 mg As(III) were made, the relative standard deviation (RSD) being 2.3%. However, the RSD for the single wavelength method was 7.8%. Therefore, the precision by the dual-wavelength $\beta$-correction spectrophotometry is higher than that of the single wavelength method.

We used a real absorbance of 0.010 to calculate the detection limit of arsenic as 0.02 mg for 50 ml of wastewater.

### 4.9. Samples analysed

As a test of the method, arsenic(III) was determined in wastewater, from sulfuric acid [1] chemical [2], river [3] and Environmental Certified Reference Material: No. 3620106 [4]. The

Table 1
Analytical results of arsenic in wastewater

| Sample | Arsenic (mg $l^{-1}$) | | | RSD (%) | Recovery (%) |
|---|---|---|---|---|---|
| | By Ag–DDC | Added | Found [a] | | |
| 1 [b] | 81.4 | 0 | 76.3 | 2.6 | |
| | | 100 | 169 | | 92.7 |
| 2 | 0.391 | 0 | 0.419 | 7.6 | |

# Trace adsorptive voltammetric determination of antimony in hair

Xiaoli Zhang *, Chengsong Ma, Lizeng Wang, Jianguo Zhang

*Department of Chemistry, Shandong University, Jinan, Shandong 250100, People's Republic of China*

Received 12 July 1994; revised 14 November 1994; accepted 9 December 1994

**Abstract**

A very sensitive electrochemical procedure for trace determination of antimony is described. The complex of antimony with *p*-dimethyl-aminophenyl-fluorone (p-DMPF) is adsorbed on a hanging mercury drop electrode (HMDE), and the reduction current of the accumulated complex is measured by voltammetry. In linear sweep voltammetry, the reduction potential of the complex is more positive than that of the free dye. The peak height of the complex is proportional to the concentration of antimony in the range of $4.0 \times 10^{-9}$ to $4.0 \times 10^{-7}$ M, the detection limit is $1.0 \times 10^{-9}$ M Sb(III) for a 5 min preconcentration time. The relative standard error for the determination of $8.0 \times 10^{-8}$ M Sb(III) is 2.9%.

## 1. Introduction

Antimony exists widely in alloy, rock, soil, mineral, air, water and biological samples, China having the largest natural deposits of antimony in the world. Lately, the study of the distribution, excretion and accumulation of antimony in the human body has been widely studied in biological science. Human hair is the excretory organ and storehouse of trace elements in the human body. Thus, sensitive analytical methods to determine trace Sb in human hair are needed.

Many methods for determining trace Sb are available, including spectrometry, fluorometry, etc [1–3]. The polarographic behaviour of antimony has been reported previously. In the early 1960s, Gao [4] observed the Sb–hydrogen catalytic wave in an aqueous $Na_2SO_4$–$CoSO_4$–$(C_4H_9)_4NBr$ medium. This method may be used to determine Sb in semiconductor materials at a level of $2.0 \times 10^{-7}$ M. In succinic acid buffer solution (pH 4), a complex polarographic wave which is formed by $Sb^{3+}$ and cupferron was observed by Donoso. The detection limit of this AC polarographic method is $2 \times 10^{-6}$ M Sb(III) [5]. In recent years, some other methods for Sb analysis have also been reported [6–9], the lower detection limit of Sb with these methods is ca. $10^{-8}$ M.

While studying the Ga–salicyl fluorone complex adsorption wave [10], we found that after Sb had combined with fluorone type reagents, a clear adsorptive complex wave appeared on a Hg electrode. In this paper, the polarographic behaviour of Sb(III)–*p*-dimethylaminophenyl-fluorone (p-DMPF) is reported. The experimental results showed that Sb could give a sensitive complex adsorptive wave in 0.01 M $H_2C_2O_4$ (pH 1.8) which contained a small amount of DMPF. The linear relationship holds between the peak height of the complex and the concentration of Sb in the range from $4.0 \times 10^{-9}$ to $4.0 \times 10^{-7}$ M, the detection limit is $1.0 \times 10^{-9}$ M. This method has been applied to the analysis of trace Sb in human hair and satisfactory results were obtained.

## 2. Experimental

### 2.1. Apparatus

A Model (79-1) voltammetric analyser (Jinan Fourth Electronic Factory, China) coupled with an X-Y recorder (Model 3086) (Shanghai Dahua Instrument Factory, China) were used. The three-electrode system consisted of a HMDE as the working electrode, a Pt plate as the counter electrode and a SCE as the reference electrode. A Model pHs-2 pH meter (Shanghai Second Analytical Instrument Factory, China) was used.

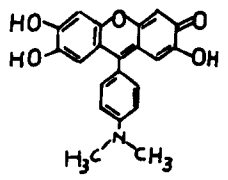
### 2.2. Reagents

A $1 \times 10^{-2}$ M stock solution of $Sb^{3+}$ was prepared by dissolving the appropriate amount of antimony metal in concentrated $H_2SO_4$ (GR) with heating. After being cooled, this solution was transferred to a 100 ml volumetric flask and diluted to the mark with 40% $H_2SO_4$. Standard solutions were obtained by diluting this stock solution with water. A $1 \times 10^{-3}$ M stock solution of p-DMF was prepared by dissolving the p-DMPF in ethanol (GR) containing 10 ml of 6 M HCl. A 0.5 M $H_2C_2O_4$ solution was prepared by dissolving reagent grade $H_2C_2O_4$ in water. All of the solutions were prepared from triply distilled water.

## Results and discussion

### 3.1. Voltammetric behaviour of p-dimethylaminophenyl fluorone

The fluorone dye, *p*-dimethylaminophenyl fluorone (p-DMPF) is commonly used as a developer in spectrophotometry. DMPF gives a reduction wave in various acidic or weak acidic electrolytes, such as HAc/NaAc, HCl, $HClO_4$, $H_2SO_4$, $H_2C_2O_4$, $NH_4Cl$ and $(CH_2)_6N_4$. In a solution of pH 2.0, DMPF gives a well-defined wave in DC, normal-pulse polarography (NPP), and differential pulse polarography (DPP). A logarithmic analysis of DMPF DC polarograms indicated that two electrons are involved in the reduction step as is the case for fluorescein. A series of solutions containing 0.01 M $H_2C_2O_4$ and $3.2 \times 10^{-7}$ M DMPF were prepared with different pH values by adding HCl or NaOH. The peak potentials and peak currents of these mixtures were measured by voltammetric analysis. The results are shown in Table 1.



*p*-Dimethylaminophenyl fluorone

From Table 1, one can see that in the range of pH 1–6, a relationship of $E_p$ −0.59–0.06 pH holds. According to the relationship $s = (m/n)59$ mV (25 °C) [11], where $n = 2$ [12] and $m = 2$, every DMPF molecule must consume two $H^+$ during reduction.

### 3.2. Voltammograms of the Sb(III)–DMPF system

Voltammograms for DMPF containing $H_2C_2O_4$ solutions in the absence (a) and presence (b) of Sb(III) are shown in Fig. 1. When the DMPF containing solution was stirred for 1 min while the electrode was held at −0.25 V prior to the scan, a large cathodic peak associated with the reduction of the adsorbed DMPF was observed at −0.68 V. When the same experiment was repeated after the addition of $1.0 \times 10^{-7}$ M Sb(III), two additional peaks associated with the reduction of the Sb–DMPF complex were observed at −0.38 and −0.56 V, a very small peak $P_2$ and a large peak $P_3$, appeared at a position more positive than the reduction peak of DMPF $P_1$. It is reasonable to propose that the two new peaks result from the Sb(III) complex with DMPF.

Table 1
DMPF reduction waves at different pH values

| pH | 1.0 | 2.0 | 2.4 | 2.8 | 3.8 | 4.5 | 5.3 | 5.7 | 6.0 |
|---|---|---|---|---|---|---|---|---|---|
| $-E_p$ (V) | 0.65 | 0.70 | 0.73 | 0.75 | 0.80 | 0.84 | 0.90 | 0.91 | 0.94 |
| $i_p$ (μA) | 0.29 | 0.44 | 0.52 | 0.66 | 0.58 | 0.52 | 0.48 | 0.29 | 0.10 |

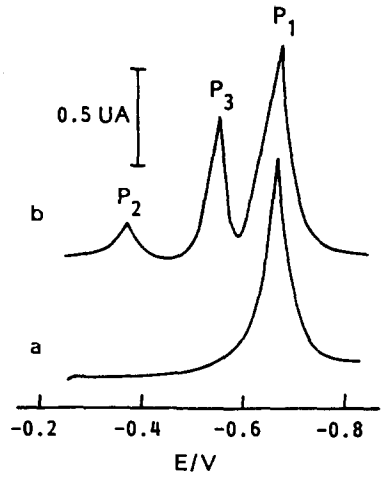


Fig. 1. Typical adsorption reduction voltammograms for DMPF containg solutions in the absence (a) and presence (b) of $1.0 \times 10^{-7}$ M Sb(III). Preconcentration for 60 s at −0.25 V; DMPF concentration $1.0 \times 10^{-6}$ M; scan rate, 100 mV/s; electrolyte, 0.01 M $H_2C_2O_4$ (pH 1.8).

### 3.3. Composition of the Sb-DMPF complex

Voltammograms for the Sb–DMPF complex are shown in Fig. 2. A peak $P_2$ appeared at a more positive potential when the concentration of Sb(III) was lowered. The peak potential of the $P_2$ was −0.38 V (Fig. 2a). When the concentration of Sb(III) was higher, another new peak, $P_3$, appeared at a potential slightly positive compared with that of DMPF. The peak potential of $P_3$, $E_{P_3}$, was −0.56 V (Fig. 2b). With an increase of the concentration of Sb(III), $P_2$ decreased, and $P_3$ gradually increased. These results suggest that Sb(III) reacted with DMPF to form two complexes, i.e. $SbL_3$ and SbL. This conclusion also has been

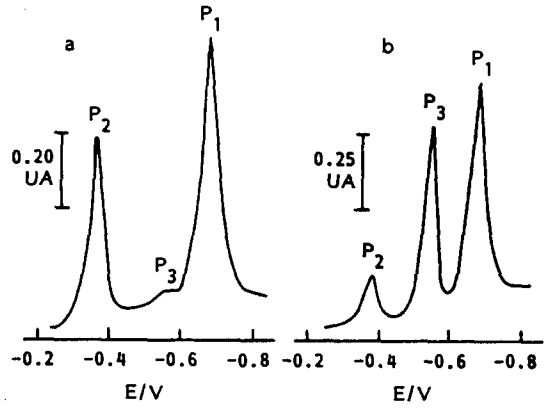

Fig. 2. Adsorption reduction voltammograms of Sb(III)–DMPF complexes at different Sb(III) concentrations. (a) $2.0 \times 10^{-8}$ M; (b) $8.0 \times 10^{-8}$ M. Experimental conditions as in Fig. 1.

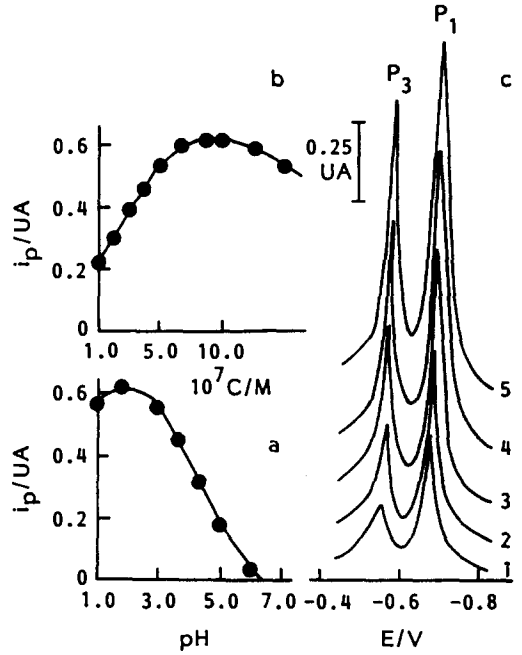

Fig. 3. Effect of pH (a), DMPF concentration (b) and scan rates (c) on the Sb(III)–DMPF adsorptive stripping response. Other conditions as in Fig. 2(b), except for $E_a$ = −0.45 V; pH (a); $C_{DMPF}$ (b); and scan rates (c): scan rate $V$ (mV/s): (1) 40, (2) 60, (3) 80, (4) 100, (5) 120.

proposed by Xia [13] using spectrophotometry. This means that at lower concentrations of Sb(III), the prevailing form of the complex is $SbL_3$ and with increasing concentrations of Sb(III), the concentration of SbL gets larger.

We use the following equation [14]:

$$1/i_p = 1/i_{p_{max}} + 1/\beta i_{p_{max}} C_L^m$$

to obtain the coordination number of the complex adsorbed on the surface of the electrode, where $i_p$ is the measured peak current, $i_{p_{max}}$ is the peak current when all the metal ions form the complex and $C_L$ is the concentration of the ligand. When $m = 3$, a straight line is obtained from a plot of $1/i_p$ vs. $1/C_L^3$. This indicates that the composition of the electroactive complex on the surface of the mercury electrode, which results in peak $P_2$ is Sb:DMPF = 1:3. When the same method is repeated for peak $P_3$, we get Sb:DMPF = 1:1.

### 3.4. Response characteristics and optimization

The effect of various operational parameters on the Sb–DMPF adsorptive stripping response is shown in Fig. 3. The pH dependence of the complex peak was studied in the range from pH 1 to 6 (Fig. 3a). No peaks were observed at pH values higher than 6. The

relationship between the peak current of the reduction of the Sb–DMPF complex, $i_{p_3}$ and pH is shown in Fig. 3a. Maximum peak current was reached at pH 1.8. Therefore, this value was used throughout this study. The DMPF concentration had a pronounced effect on the adsorptive stripping response (Fig. 3b). As the DMPF concentration increased, the peak current rapidly increased at first and then less rapidly. The effect of the scan rate on the peak current was evaluated over the 40 to 120 mV/s range (Fig. 3c), the current of $P_3$ varied linearly with the potential scan rate. The peak current, $i_{p_3}$ increased upon extending the preconcentration time, $t_a$. These phenomena suggest that the reactant is adsorbed on the electrode surface.

### 3.5. Linear range and reproducibility

There are two linear relationships between the Sb(III) concentration and the reduction peak current of the Sb(III)–DMPF complex. Using linear sweep voltammetry, a linear relationship between Sb(III) concentration and peak current of peak $P_2$ in the concentration range of $4.0 \times 10^{-9}$ to $5.0 \times 10^{-8}$ M Sb(III) can be obtained in 0.01 M $H_2C_2O_4$(pH 1.8) and $1.0 \times 10^{-7}$ to $1.0 \times 10^{-6}$ M DMPF. Another linear relationship between the Sb(III) concentration and the peak current of $P_3$ is $2.0 \times 10^{-8}$ to $4.0 \times 10^{-7}$ M Sb(III). The relative standard error for the determination of $8 \times 10^{-8}$ M Sb(III) is 2.9%.

### 3.6. Analytical utility

The experimental results show that a 1000-fold excess of $Cu^{2+}$, $Zn^{2+}$, $Al^{3+}$, $Fe^{3+}$, $Ca^{2+}$, $Mg^{2+}$; a 200-fold excess of $Pb^{2+}$, $Ni^{2+}$, $Nb^{5+}$; a 10-fold excess of $V^{5+}$; 50-fold excess of $Ga^{3+}$; and a two-fold excess of $Mo^{6+}$ and $Sn^{4+}$ did not interfere with the determination of $8.0 \times 10^{-8}$ M Sb(III).

A human hair sample was prepared by placing an exact amount of sample in a 50ml beaker. Approximately 15 ml of a mixed acid ($HNO_3$: HCl:$H_2O$, 1:3:3) was added to the beaker, and it was heated on a hotplate at 80 °C for about 5 h. Then, 1 ml of $HClO_4$ was added to the sample and it was heated until the evolution of white smoke. After cooling, the resulting white deposit was dissolved in water, and transferred to a 50 ml volumetric flask and diluted to volume with water.

Table 2
Results of the determination of Sb(III) in samples of human hair

| Sample | Content determined [a] (ppm) | Added (ppm) | Found [a] (ppm) | Recovery (%) |
|---|---|---|---|---|
| A | 2.40 | 2.50 | 4.88 | 99 |
| B | 2.25 | 2.00 | 4.13 | 94 |
| C | 3.30 | 3.00 | 6.33 | 101 |
| D | 2.65 | 3.00 | 5.74 | 103 |
| E | 3.00 | 3.00 | 5.88 | 96 |

[a] The values are the mean of five determinations.

Typical results determined by linear sweep adsorption voltammetry with two successive standard additions for treated samples, and the analysis of samples spiked with known quantities of Sb(III) are summarized in Table 2.

# Separation mechanism exploration on metal–MBTAE–salicylic acid mixed ligand complexes by reversed-phase high performance liquid chromatography

Liu Qiping, Wang Yuanchao, Liu Jinchun *, Cheng Jieke

*Department of Chemistry, Wuhan University, Wuhan 430072, People's Republic of China*

Received 15 July 1994; revised 15 November 1994; accepted 28 November 1994

**Abstract**

The separation and determination of platinum metal and co-existing metal complexes by reversed-phase high performance liquid chromatography (HPLC) with 2-(6-methyl-2-benzothiazolylazo)-5-diethylamino phenol (MBTAE) as a precolumn derivatizing reagent is presented. The separation mechanism of these complexes was investigated by combining spectrophotometry with HPLC while salicylic acid was contained in the mobile phase. The results show that most platinum metal ions, Co(II) and Cu(II) can form ternary mixed ligand complexes with MBTAE and salicylic acid. The relationship of the retention behavior of complexes and the surface tension of the mobile phase ($\gamma$), the column temperature ($T$), and the composition and space configuration of complexes was also investigated. Some possible configurations of complexes are also proposed. These may all be illustrated well from the viewpoint of solvophobic theory. These method allowed the prediction of the composition and structure of metal complexes by utilizing HPLC.

## 1. Introduction

Platinum metals are rare and highly dispersed in the earth. They co-exist with large amounts of non-noble metals. Though platinum metals analysis had been a concern of analysts from early times, it is still difficult to preconcentrate, separate and quantitatively determine them owing to their similar physicochemical properties, various valences and existing species in solution. The development of HPLC provided a powerful and practical technique for platinum metals analysis, and the micro and trace analysis of platinum metals by HPLC had been a challenging research topic in inorganic analysis.

In order to avoid possible changes in species or valence during the chromatographic process, platinum metal ions are often detected in the form of stable complexes. The application of inorganic [1,2] or organic [3–5] reagents to platinum metals analysis had been frequently reported. Much attention had been paid to the organic reagents utilized because of their useful properties and wide selection. Therefore, it was our first premise to synthesize and select a group reagent with good stability and high sensitivity for separation and determination of platinum metals by HPLC. Among the organic reagents, pyridylazo compounds owing to high detection sensitivities with platinum metal ions, have been mostly applied, e.g. PAN [6] and various new reagents [7,8]. These reagents remarkably enhance the detection sensitivities of platinum metals. The use of thiazolylazo reagents in platinum metals analysis by HPLC has increased gradually in recent years [9,10]. These reagents contain a sulfur coordination

* Corresponding author.

*SSDI* 0039-9140(95)01510-8

atom and can form stable complexes with platinum metal ions. They can not only enhance the detection sensitivities, but also increase the number of platinum metals separated and detected. They have been applied to complicated real sample analysis [11–13].

Among the reported literature, an overwhelming majority is concerned with the selection and optimization of separation conditions, a few are on mechanism research. Furthermore, there was also a limit to the detection sensitivities and the number of separated platinum and co-existing metals.

2-(6-Methyl-2-benzothiazolylazo)-5-diethylamino phenol (MBTAE) is a new reagent which was synthesized by us [14]. It has been used for the separation and determination of some platinum and co-existing metal ions in the presence of ethylenediaminediacetic acid diethyl acetate (EDDD) [11] and malic acid [13]. Novel use of MBTAE in the presence of salicylic acid (SA) as well as a separation mechanism study of metal mixed ligand complexes is emphasized in this paper. The results showed that Pd(II) and Ni(II) can form binary complexes with MBTAE, while other platinum metal ions, Co(II) and Cu(II) can form ternary mixed ligand complexes with MBTAE and SA. All of the complexes except Rh(III) and Ir(IV) can be separated well at the mobile phase of the methanol–water system. Good correlations were found among the retention values of complexes and the surface tension of the mobile phase ($\gamma$), the column temperature ($T$), and the composition and space configuration of the complexes. All of these can be interpreted by solvophobic theory. It allowed the prediction of the composition and configuration of the metal complexes and had also some reference value for metal complexes analysis.

## 2. Experimental

### 2.1. Apparatus and reagents

A Shimadzu LC-6A high performance liquid chromatograph equipped with a Shimadzu C-R3A recorder was used. A Shimadzu UV-3000 spectrophotometer. Model DF-801 acidimeter from Zhongshan University and a supersonic degasser from Shanghai Int. Corp. were also used. The chromatographic column was Spherisorb C18 (5 μm, 150 × 4.6 mm i.d.) from Dalian Research Institute of Chemistry and Physics of China.

Stock solutions of Os(IV), Ir(IV), Ru(III), Rh(III), Pd(II) and Co(II) were prepared from analytical grade $(NH_4)_2OsCl_6$, $(NH_4)_2IrCl_6$, $RuCl_3$, $RhCl_3$, $PdCl_2$ and $CoSO_4$ dissolved in 1 M HCl, respectively. Ni(II) and Cu(II) standard solutions were obtained by dissolving 99.99% nickel and copper metals in dilute nitric acid, respectively. Pt(II) standard solution was obtained by reducing analytical grade $K_2PtCl_6$ standard solution with $SO_2$. The work solutions were 10.0 or 1.0 μg/ml.

Sodium salicylate from Shanghai Reagent Corp. was prepared as 0.2 M. Buffer solutions were mixed with 1 M acetic acid and 1 M sodium actate by adjusting to the proper pH values with an acidimeter. The synthesis and identification of MBTAE was given previously [14]. It was prepared in 0.02% absolute alcohol solution. Tetrabutylammonium bromide (TBA. Br) solution was prepared as 0.5 M. Methanol and alcohol were of analytical grade and double distilled water was used.

### 2.2. Analytical procedure

A known volume of Ru(III), Rh(III), Pd(II), Os(IV), Ir(IV), Pt(II), Co(II), Ni(II) and Cu(II) standard solutions were added to a 25 ml volumetric flask. Then 4.0 ml of pH 5.0 acetic acid–sodium acetate buffer solution, 2.0 ml of 0.02% MBTAE solution and 5 ml of 95% alcohol were added in order. The mixture was heated in an 80°C water-bath for 40 min, cooled to room temperature and diluted to the mark with 95% alcohol. This solution (20 μl) was injected onto the chromatographic column for analysis.

The composition of the mobile phase was of (v/v) methanol–water (82:18) containing 10.0 mM SA. 10.0 mM of pH 5.0 acetate buffer solution and 5.0 mM TBA. Br. The mixture was filtered through a 0.45 μm Millipore filter and degassed for 10 min before use.

The ODS column was pre-equilibrated with the mobile phase for 30 min. The column temperature was kept at 35°C. The flow rate was 1.0 ml/min. All of the complexes were detected at 575 nm with peak area for quantitative analysis.

## 3. Results and discussion

In reversed-phase HPLC, the interactions among the solute, solvent and stationary phase

are very complicated. Many models and theories have been proposed to interpret it including the solvophobic theory proposed first by Horvath and co-workers [15] which is well regarded. This theory emphasizes the important action of the mobile phase during the chromatographic process. It holds that during the chromatographic process, the polar mobile phase excludes non-polar or weak-polar solutes, and the combination of solute and stationary phase reduces the exclusion action from the solvent. According to Horvath's hypothesis and their mathematical calculations, an equation closely related to the experimental parameters is obtained:

$$\ln k' = \ln \Phi + \frac{[N\,\Delta A + 4.836N^{1/3}(K^e - 1)V^{2/3}]}{RT}\gamma \quad (1)$$

where $\Phi$ is the volume ratio of the stationary and mobile phase, $N$ is the Avogadro constant, $\Delta A$ is the reduction of the surface area as a consequence of the association of the solute with the stationary phase, $K^e$ is a factor for converting the bulk surface to molecular dimensions, $R$ is the universal gas constant, $V$ is the molar volume of the solvent, $T$ is the absolute temperature and $\gamma$ is the surface tension of the bulk solvent.

The importance of Eq. (1) is that it connects the microscopic chromatographic process with the macroscopic parameters of the mobile phase, the column temperature, etc. Therefore, the retention behavior of solutes can be predicted by adjusting and controlling the chromatographic parameters.

It was well known that platinum metal ions can form stable complexes with many ligands containing an oxygen atom. In this paper, salicyclic acid was chosen to investigate the complexes' retention behavior. The results are shown in Fig. 1. An interesting aspect is that the Cu–R complex (where R is MBTAE) was

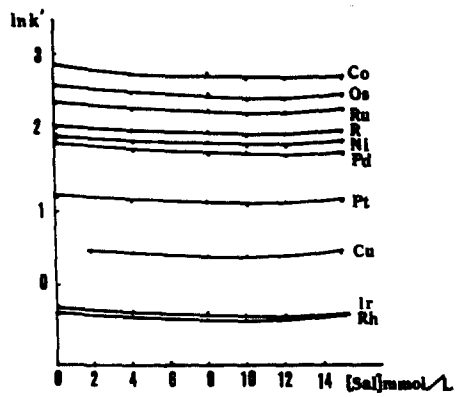

Fig. 1. The effect of SA concentration on ln $k'$. Chromatographic conditions: column, Spherisorb C18 (5 μm, 150 × 4.6 mm i.d.); mobile phase, methanol–water (82:18, v/v), 0 ~ 15 mM SA, 3 mM TBA. Br, 20 mM, pH 5.0 HOAc–NaOAc; flow rate, 1.0 ml/min; column temperature, 35°C; detection wavelength, 575 nm.

retained strongly on the C18 column when SA was absent from the mobile phase, and no peak could be observed for the Cu–R complex even after a long elution time. In contrast a remarkably sharp and symmetric Cu–R peak appeared after SA was added to the mobile phase. Not only the retention time, but also the detection limit, was reduced for platinum metals in the presence of SA (Table 1). The detection limits of platinum metals were raised by three to 33 times. Under optimum conditions, a typical separation chromatogram is shown in Fig. 2.

Now the problem was that the separation mechanism of platinum and their co-existing metals on a C18 column still cannot be explained clearly if only based on the results of Figs. 1, 2, and Table 1. Therefore, it was necessary to explore further the effect of the mobile phase composition, the oven temperature, the composition and the configuration of complexes on retention behavior of platinum and co-existing metals.

Eq. (1) indicated that ln $k'$ is directly proportional to the surface tension of the mobile phase ($\gamma$) and the reciprocal of column temper-

ature ($1/T$). Strictly speaking, with the mixed solvents as mobile phase, the dependence of $\ln k'$ on surface tension values is strongly non-linear as a consequence primarily of non-linearity between $\gamma$ and the composition in mixed solvents. Moreover, the molar volume of the eluent is a function of its composition, and $K^c$ is also likely to change. At a certain column temperature, if the change of mobile phase composition is comparatively small, $K^c$ and $V$ would be regarded as constants. So $\ln k'$ will be linear with $\gamma$ as shown in $\ln k' = A + B\gamma$ (Table 2). For the same reason, when the mobile phase composition was kept as a constant for a given temperature, $\gamma$ was a fixed value, $\ln k'$

Chromatographic conditions were the same as Fig. 2.

can also be regarded as linear with $1/T$ as shown by $\ln k' = A' + B'/T$ (Table 3). Good linear relationships between $\ln k'$ and $\gamma$, and $\ln k'$ and $1/T$ were established in the tested range (Tables 2 and 3).

Yet, there was still a question. What was the function of SA in the metal ion–MBTAE–SA system? Can it be regarded as the secondary complexing component to react with metal ions to form ternary mixed ligand complexes? How did it affect the retention behavior of metal complexes? It is generally believed that ternary mixed ligand complexes have three main characteristics as compared with binary complexes. The first is the sensitization action, the second is the solubilization action. Lowering the detection limits and shortening the retention time are the direct results of the above two actions on chromatography. These results are supported by data in Table 1. The third characteristic is the change of maximum absorption wavelength ($\lambda_{max}$) of metal complexes. The change of $\lambda_{max}$ of complexes in the presence of SA is shown in Table 4. It showed that most complexes had different changes in $\lambda_{max}$. The Ru–R complex showed two peaks when SA was absent. However, after SA was added in the mobile phase, the second peak, Ru–R (644 nm), disappeared and the $\lambda_{max}$ of the first

R: MBTAE.

peak changed and its absorption increased. All of these are beneficial for the separation and quantitative analysis of Ru(III).

It is reasonable to deduce from the above discussion that SA may take part in coordination with metal ions and MBTAE to form ternary mixed ligand complexes under the given conditions. To verify this deduction, we determined the metal complexes composition by the Asmus [17] and Shi Huiming [18] methods, respectively (Table 5).

In Table 5, the complexes can be divided into four types: (i) Ni(II) and Pd(II) only reacted with R to form 1:2 complexes, and they did not complex with SA; (ii) Cu(II), Pt(II), Ir(IV) can react with R and SA to form ternary mixed ligand complexes of 1:1:1; (iii) Rh(III) formed 1:1:2 complex with R and SA; (iv) Ru(III), Os(IV), Co(II) reacted with R and SA to form ternary mixed ligand complexes of 1:2:1.

Why was the ternary mixed ligand complex more stable than the binary complex? An important factor was the electrostatic effect. It included the charge-neutrality principle and an entropy effect. The net charge of each complex after forming binary complexes is listed in Table 6. According to the charge-neutrality principle, if a complex is neutral, it is more stable than that with charge, and will not try to react with another charged ligand. In contrast, if a binary complex is charged, it is not sufficiently stable and will try to react with other ligands with the opposite charge to form a ternary mixed ligand complex. In Table 6, Pd–R and Ni–R complexes are neutral and thus it would be difficult for them to react with SA to form a ternary mixed ligand complex. The other binary complexes in Table 6 have +1, +2, or +3 charges and had a greater tendency to react with SA. The Co–R complex in Table 6 had an unusual behavior, differing from the others. This may be a result of the oxidation of Co(II), producing Co(III) under the experimental conditions, which would make a Co(III)–R complex with a +1 charge. It would then react with SA to form a ternary mixed ligand complex. Once the ternary mixed ligand complex is formed, both the system disorder tendency and its entropy increase, and this would increase the stability of complexes.

Eq. (1) also indicated that the slope of the $\ln k'$ vs. $\gamma/T$ curve is related to the $\Delta A$ value if the mobile phase composition change relatively slowly at the given temperature. Under these circumstances, $\ln K'$ can be regarded as being proportional to $\Delta A$. The larger the contact area of complexes with the hydrophobic stationary phase, the bigger the $\Delta A$ value and the curve slope. Otherwise, the $\Delta A$ value and the curve slope should be smaller. In our experiment, the volume of the MBTAE molecule was much bigger than that of the SA. Therefore, it would contribute much more to the $\Delta A$ value than the SA molecule does. The results in Tables 2 (B value), 3 (B′ value) and 5 demonstrate this. The sequence of curve slopes was (M:R:SA) 1:2:1 > 1:1:2 > 1:1:1.

An interesting question here was why the binary complex slopes of Ni–R and Pd–R(1:2) were larger than those of Ru–R–SA, Os–R–SA, and Co–R–SA complexes whose composition was 1:2:1? It cannot be explained only by the complex composition.

On the basis of reaction principles, metal complexes may have 12 kinds of configurations. They belong to the plane quadrilateral and regular octahedral structure, respectively. The configuration of the Pd–R and Ni–R complexes was plane quadrilateral and the others were regular octahedral. The typical configurations are shown in Fig. 3. We believe a plane quadrilateral complex would occupy a larger surface area on the stationary phase when adsorbed by the stationary phase, because its molecule is situated in the same plane, it has a larger cross-sectional area. This means that the $\Delta A$ value would increase and the slope of curve would be larger. On the other hand, a regular octahedral structure had eight planes, and its effective cross-sectional area is smaller than that of the plane quadrilateral when ad-

Table 6
Charge of the binary complexes

| | Ru–R | Rh–R | Pd–R | Os–R | Ir–R | Pt–R | Co–R | Ni–R | Cu–R |
|---|---|---|---|---|---|---|---|---|---|
| Charge | +1 | +2 | 0 | +2 | +3 | +1 | 0 | 0 | +1 |

sorbed by the stationary phase. So its contribution for $\Delta A$ and slope of curve would be smaller compared with the plane quadrilateral structure. For these reasons, the slope of the Ni–R and Pd–R complexes (1:2) was larger than that of the (Ru, Os, Co)–R–SA complexes (1:2:1).

## 4. Conclusion

Based on the above discussion we obtain the following conclusions.

(i) SA can react with some binary metal complexes to form ternary mixed ligand complexes under certain chromatographic conditions.

(ii) This method remarkably improved the detection limit of platinum metals, shortened the analytical time and increased the number of separable and determinable elements in the presence of SA in the mobile phase.

(iii) The retention behavior of metal complexes in reversed-phase HPLC was related to the stationary phase, the composition and properties of the mobile phase, the column temperature, and the composition and configuration of complexes.

In this paper, solvophobic theory gives a satisfactory interpretation to the retention mechanism of platinum metals and their coexisting metal complexes on a C18 column with salisylic acid in the mobile phase. This work should be of value in predicting the composition, configuration and retention behavior of metal complexes by the HPLC technique.

Received 20 June 1994; revised 3 January 1995; accepted 5 January 1995

**Abstract**

The determination of several *N*-substituted phenothiazine derivatives was carried out by the reaction of the drug with manganese dioxide entrapped in a polymeric material in a packed-bed reactor; the oxidized drug was monitored at $\lambda_{max}$. The calibration graph is linear over the range 5–50 μg/ml of phenothiazine derivatives with a relative standard deviation of 0.5–1% (at 10 μg/ml) and sample throughput of 40–48 $h^{-1}$. The influence of foreign compounds was studied and the method was applied to the determination of six different phenothiazine derivatives in pharmaceutical formulations.

## 1. Introduction

The phenothiazines are one of the most important groups of pharmaceuticals, used as antihistamines, tranquillizers, antiemetics and anti-Parkinson drugs and, therefore, their determination in pharmaceutical formulations is of considerable importance [1]. On the other hand, phenothiazines exhibit certain interesting analytical properties owing to their characteristic structure, the presence of chemically active sulfur and nitrogen atoms and substituents. It is important to point out the liability to oxidation by means of many oxidants with formation of coloured or fluorescent oxidation products. The oxidation involves a series of one-electron steps providing free radicals and cations [2–4]. As a result, there are many published procedures dealing with the determination of different phenothiazines with the aid of strong oxidative reagents. Some FIA procedures which have been published deal with formation of ion-association compounds with liquid–liquid separation [5] or turbidimetric monitorization [6], fluorimetric or spectrophotometric procedures based on the reaction with oxidants in solution [7–11] or immobilized [12–15] or fluorimetric procedures based on photoreactions [16–21]. Other FIA procedures using amperometric [22,23] and voltametric [24,25] detection have also been reported.

On the other hand, the use of solid-phase reactors has become one of the most interesting developments in continuous-flow analytical methodologies, including FIA. The interest is ascribed to their different advantages over reagents in solution; the advantages have been reported earlier [26,27]. This paper deals with the immobilization of reagents based on polymerization of linear unsaturated polyester chains as a type of the broad category of physical entrapment of the reagent. The proposed procedure allows the use in flow-injection manifold of reagents commercially

available as fine powder without high-pressure FIA manifolds. The analytical procedure is based on the reaction of the drug with manganese dioxide and spectrophotometric monitorization of the oxidized drug which results in a simpler FIA manifold and lower consumption of reagents.

## 2. Experimental

### 2.1. Reagents and apparatus

Promazine (PMZ · HCl), promethazine (PMT · HCl), thioridazine (TRZ · HCl) and chloropromazine (CPM · HCl) hydrochlorides, diethazine maleate (DTZ · ML) and trifluoroperazine (TFP) were obtained from Polfa, Jelenia Góra, Poland and the aqueous solutions were prepared in bidistilled water. Hydrochloride, sulfuric, citric and ascorbic acids, formaldehyde, glucose, lactose calcium and sodium chlorides, sodium sulfite and disodium-EDTA were obtained from POCh, Gliwice, Poland. All reagents used were of analytical-grade unless otherwise stated. The bed-reactor was prepared with $MnO_2$ (A.R., Panreac, Barcelona, Spain), Al-100-A polyester resin solution (Reposa, Valencia, Spain) containing low-molecular weight polyester chains, with a cobalt compound as an activating agent and metyl ethyl ketone as a catalyst (Akco, Valencia, Spain) in the reaction.

*FIA manifold*

Fig. 1 shows the continuous-flow manifold used. A sample injector from Rheodyne, model 5041; and a Gilson Minipuls 2 pump were used. The determination of phenothiazine derivatives was carried out by means of a model 8452A diode array spectrophotometer (Hewlett-Packard, Waldbronn, Germany) at different wavelengths, with a flow-cell of 18-μl and 1 cm path length (Tecator, Hoganas, Sweden). The PTFE tubing was of 1.0 mm i.d. for the solid-phase bed reactor and the rest of the manifold.

*Preparation of the solid-phase reactor*

The bed-reactor was prepared as described previously [28]. A 11.81-g mass of manganese dioxide was added to 15.74 g of the resin solution; after its homogenization by manual stirring the catalyst was added and stirred before it became solid. The obtained solid was reduced to small particles, out of which those measuring 300–400 μm were selected, washed and introduced into the PTFE tubing by suction.

### 2.2. Determination of phenothiazine derivatives

*Tablets*

Five tablets were powdered and a weighed portion, equivalent to one tablet was dissolved in methanol and any remaining residue was

filtered. The clear solution was made up to 100 ml with methanol. Aliquots of 10 ml of the methanolic solution were taken and evaporated to dryness. Solid residue was dissolved and diluted to 100 ml with bidistilled water. Calibration graphs were constructed from the results obtained with standard solutions of the phenothiazine derivatives.

*Injections*

The content of the drug in vial injections was diluted and levelled with bidistilled water up to 50 ml before introduction into the stream for analysis.

## 3. Results and discussion

Preliminary batch studies were designed to examine the reaction between the immobilized reagent with different N-substituted phenothiazines in aqueous solutions. Different acidic media were tested. Spectra of aqueous solutions were obtained before and after the oxidative treatment; absorption spectra after oxidation are shown in Fig. 1. In further experiments oxidized forms of the drugs were measured spectrophotometrically at the corresponding wavelengths of maximum absorbance. Non-oxidized forms of the drugs were not absorbed at these wavelengths.

Further preliminary tests were carried out with the aid of different flow assemblies to select the best manifold-configuration. The assembly in Fig. 2 was selected as the one producing the best compromise between the peak height and reproducibility of the transient signals. In this assembly the aqueous drug solution is injected into a pure distilled water stream which merges with the acidic solution stream.

The influence of the acidic media was tested with the aid of the selected flow assembly and hydrochloride and sulfuric acids were selected for further studies.

Different concentrations of HCl and $H_2SO_4$ were tested (flow-rate of carrier and acidic solution 3.2 ml/min, column length 170 cm, injector-detector length 270 cm and sample volume 612 μl). Hydrochloride acid was selected for further work in 1.0 M concentration, except the determination of thioridazine hydrochloride in which the selected concentration was 0.5 M.

The influence of the temperature was studied by the introduction the bed-reactor into a water-bath; the influence of this parameter resulted in decreased outputs owing to the increase of the reaction rate; the complete reaction leads to the final oxidation products which are colorless. Room temperature was the suitable choice.

The optimization of FIA parameters was carried out by the univariate method for 10 μg/ml of each phenothiazine derivatives in the order: column length (612 μl sample volume, 3.2 ml/min flow-rate and 1.0 M HCl), sample volume (170 cm column length, 3.2 ml/min flow-rate and 1.0 M HCl) and flow-rate (170 cm column length, 612 μl sample volume and 1.0 M HCl). The optimized response of the measuring system was the flow-injection peak height. The FIA parameter corresponding to the assembly selected as the best ones are given in Table 1.

## 4. Analytical applications

The calibration graphs were obtained by plotting peak-height (in mm) vs. phenothiazines concentration (μg/ml). The corresponding regression coefficients, detection limits (considered as three times the background noise) and the linearity ranges for each tested drug are depicted in Table 2. The reproducibility (15 replicates) calculated for chlorpromazine as %RSD, was (drug amount in μg/ml and RSD as %): 10, 1.3; 20, 1.0; and 30, 0.5. Sample throughput (tested for 25 μg/ml), 40 $h^{-1}$, except for thioridazine hydrochloride which was 48 $h^{-1}$.

The influence of foreign compounds that are commonly found in pharmaceutical formulations containing phenothiazines was investigated for chlorpromazine hydrochloride. Various concentrations of the possible interfer-

Table 2
Analytical parameters on the determination of N-substituted phenothiazines

| Thioridazine hydrochloride | $0.591c + 0.660$ | 0.9994 | 1.1 |
| Chlorpromazine hydrochloride | $1.170c + 0.081$ | 0.9995 | 0.6 |

[a] Linearity range for all drugs was 5–50 μg/ml.
[b] The correlation coefficients were calculated using 10 different concentrations of each amalyte.

Table 3
Influence of foreign compounds on the chloropromazine determination

| Compound | Concentration (μg/ml) | Relative error (%) |
|---|---|---|
| Ascorbic acid | 0.1 | 5.0 |
| Citric acid | 10.5 | 4.0 |
| Phenol | 2230 | 2.3 |
| Formaldehyde | 214 | 3.7 |
| Glucose | 100 | 2.6 |
| Lactose | 252 | 4.0 |
| NaCl | 451 | 1.8 |
| $CaCl_2$ | 56 | 4.0 |
| $Na_2SO_3$ | 19 | 4.0 |
| $Na_2$-EDTA | 37 | 3.8 |

ing substances were added to the solution containing 10 μg/ml, up to the amounts when the relative error (by comparison with pure chlorpromazine hydrochloride solutions, 10 μg/ml) was about 5%. The results in terms of concentration (μg/ml) and relative error (%) are depicted in Table 3. Phenol, formaldehyde, lactose and NaCl were tolerated in large amounts. Ascorbic acid and sodium sulfite interferred owing to their redox properties.

Promazine, chlorpromazine and thioridazine were determined in Promazine injection, Fenactil injection (Polfa, Jelenia Góra, Poland) and Melleril tablets (Sandoz, Rueil-Malmaison, France), respectively. The relative error was calculated by comparing the results with the content obtained with the aid of the proposed FIA assembly with the official gravimetric method [29] based on reaction with silicotungstic acid or by the Blażek's method [30] based on absorption measurements of phenothiazine derivatives at 254 nm in methanolic solution. Obtained results and calculated relative errors are depicted in Table 4.

## 5. Conclusions

The results show that the procedure based on physical entrapment of the solid reagent ($MnO_2$) by a polymeric resin is quite simple, fast, inexpensive, and can be alternative to procedures utilizing other strong oxidizing reagents. The proposed FIA system is suitable for the control analysis of the phenothiazine derivatives in pharmaceutical preparations.

# Determination of aniline by adsorptive stripping voltammetry using an improved diazotization and coupling procedure
## Application to the evaluation of the light degradation of D&C Red No. 33 in the presence of ascorbic acid

J.A. Rodrigues *, A.A. Barros

*Department of Chemistry, Faculty of Sciences, University of Porto, 4000 Porto, Portugal*

Received 25 October 1994; revised 3 January 1995; accepted 4 January 1995

**Abstract**

A method for the determination of aniline was developed, based on the diazotization and coupling of the aromatic amine to form an azo compound capable of being determined by adsorptive stripping voltammetry. A fast derivatization procedure was developed using 1-naftol as the coupling agent. A detection limit of 0.8 μg/l was obtained for aniline, using an accumulation time of 2 min. The method was applied in the determination of the amount of aniline in the colouring matter D&C Red No. 33, after a liquid–liquid extraction with chloroform, before and after submitting the colouring matter to a process of degradation, using accelerated light conditions in the presence of ascorbic acid.

## 1. Introduction

Adsorptive stripping voltammetry (AdSV) has been demonstrated to be a highly sensitive electroanalytical method for the determination of a wide range of electroactive compounds [1]. The use of derivatization reactions in analytical chemistry to improve the characteristics of analytes is widely reported. In the case of AdSV using derivatization reactions prior to making determinations has extended the advantages of the technique to a range of electroinactive or poorly adsorbed compounds and permits the differentiation of the analyte from interferents by providing signals at different potentials from those of unmodified molecules [2].

Aromatic amines are compounds that can be easily absorbed by the skin causing a systematic poisoning [3] and some of them are recognized carcinogenic agents [4]. A method frequently employed for the determination of aromatic amines involves diazotization and coupling, with formation of an intensely coloured azo compound, that can be detected spectrophotometrically [5]. In this work the same method of derivatization was applied in the determination of aniline, but an adsorptive stripping voltammetric method of detection was used instead, that enables a much lower detection limit to be achieved. In fact, the compound formed by diazotization and coupling of aniline, being structurally similar to azo colouring matters, is expected to be electroactive and to adsorb at the surface of a mercury electrode [6]. Using 1-naftol as a convenient coupling agent, conditions were optimized for the adsorptive stripping voltammetric determination of the azo compound

* Corresponding author.

*SSDI* 0039-9140(95)01512-4

formed, with a limit of detection of 0.8 μg/l being obtained for the determination of aniline.

The method was applied in the determination of aniline in the colouring matter D&C Red No. 33, before and after submitting the colouring matter to a process of accelerated light degradation. The method includes a liquid–liquid extraction of the aromatic amine from the azo dye, using chloroform, before the diazotization and coupling process.

## 2. Experimental

### 2.1. Instrumentation and conditions

The adsorptive stripping voltammetric determination was performed by differential-pulse voltammetry using a Metrohm system including a VA stand (E663), a VA scanner (E612), a VA detector (E611) and a VA controller (E608). This equipment was connected with a X-Y recorder (Houston 2000).

A three electrode system was employed, with the multimode electrode of the VA stand in its HMDE configuration, a glassy carbon counter electrode and a silver/silver chloride (3 M KCl) reference electrode.

In the voltammetric analysis, after bubbling $N_2$ for 15 min to deoxygenate the solution, accumulation was performed with stirring (2000 Hz) using a mercury drop area of 0.52 $mm^2$. After a rest period of 10 s, a cathodic potential scan of 10 mV $s^{-1}$ was applied, with cathodic pulses of 50 mV every second.

Measurements of pH were made using a pH 537 microprocessor pH meter, with a combined pH-reference electrode, both from WTW (Germany).

Light degradation studies were carried out in a specially constructed light box containing a 500 W tungsten filament lamp (Philips E40). To dissipate heat produced by the lamp, a fan was placed under the sample container.

### 2.2. Reagents and solutions

All chemicals were of analytical grade. Deionized and distilled water was used for the preparation of solutions.

D&C Red No. 33 (Colour Index No. 17200) is the disodium salt of 8-amino-2-phenylazo-1-naftol-3,6-disulfonic acid; the colouring matter was obtained from HKohnstamm, New York and has a pure dye content of 85% (about 15% of sodium chloride and sodium sulfate are present to match the required colour strength).

The diazotization solution was prepared daily by dissolution of 50 mg of sodium nitrite in 50 ml water. The coupling solution was prepared daily by dissolution of 50 mg of 1-naftol in 50 ml of 1 M sodium hydroxide. Stock standard solutions of aniline (about 200 mg/l) were prepared weekly by weighing about 50 mg of aniline accurately, dissolving it in water and diluting to 250 ml. More dilute standards were prepared daily by convenient dilution with water. Solid ascorbic acid was directly added in the preparation of the solutions for the degradation studies.

### 2.3. Diazotization and coupling of aniline

Solutions containing up to 100 μg of aniline were diluted to 10 ml and acidified with sulfuric acid to a pH of 2.5. Then, 1 ml of 0.1% sodium nitrite was added and the mixture was allowed to react during 5 min with stirring. Finally, 1 ml of 1-naftol 0.1% in 1 M NaOH was added and the solution diluted with 0.2 M ammonium nitrate to 25 ml, obtaining a pH of about 9 ready for the subsequent voltammetric analysis.

### 2.4. Extraction of aniline from D&C Red No. 33

About 50 mg of colouring matter was weighed accurately and dissolved in 100 ml of a solution 0.01 M in NaOH and 1% in NaCl. The solution was transferred to a separation funnel and extracted three times with 20 ml of chloroform. The organic extracts were drained through a washed (25 ml of chloroform) glass wool pledget in the constriction of a funnel into the flask of a rotary evaporator. Sulfuric acid 0.002 M (10 ml) was added to the chloroform extract, and the organic layer was completely removed in the rotary evaporator, using reduced pressure and a temperature of 45 °C. The aqueous solution remaining in the evaporator was diluted to 50 ml with 0.002 M sulfuric acid and 10 ml aliquots were used in the diazotization and coupling procedures previously described, preceding the voltammetric analysis.

### 2.5. Light degradation studies of D&C Red No. 33

In the light degradation box, 100 ml of 0.1% solutions of D&C Red No. 33, containing different amounts of ascorbic acid, were submitted to intense light. The solutions were contained in small, screw capped, glass vials, held at a uniform close distance from the 500 W lamp. After the established degradation time, aniline was extracted, diazotized and coupled with 1-naftol, and the azo compound formed was determined by adsorptive stripping voltammetry, as previously described.

## 3. Results and discussion

### 3.1. Determination of aniline

The spectrophotometric determination of aniline, after diazotization and coupling, is commonly used in the analysis of primary aromatic amines and has been extensively studied, with a large number of methods being proposed and recommended. In spite of the similarity of the methods, with slight differences concerning the nature of the coupling agent or some conditions of analysis, only occasionally efforts have been made to establish standard procedures, as is the case of Norwitz's work [5]. Taking into consideration this situation and the fact that we intend to use a voltammetric method of determination, instead of a spectrophotometric one, it was decided to make a complete investigation of the method of determination of aniline, including all the steps connected with the derivatization procedure. As the voltammetric response of the azo compound formed was used to measure the completeness of the derivatization reaction of aniline, voltammetric variables had to be studied before optimization of the reactions of diazotization and coupling was undertaken.

### 3.2. Selection of the coupling agent

Besides some general conditions that must be fulfilled irrespective of the method of detection (stability of the coupling agent, fastness of the coupling reaction, stability of the azoic product), two more conditions are needed for a coupling agent used with adsorptive voltammetric detection: not to interfere with the determination and to produce an azoic compound that adsorbs on the mercury electrode. The investigation started with H-acid (8-amino-1-hydroxy-3,6-naphthalenedisulfonic acid), the coupling agent selected by Norwitz [5], but the compound was found to interfere slightly in the voltammetric determination, with a marked effect on the detection limit of the method. Two other coupling agents were tried, resorcinol and 1-naftol, both phenols, a group of compounds that is known to react quickly with diazotized aniline. Resorcinol could not be used because it formed an unstable azo compound and resorcinol itself was oxidized, probably by atmospheric oxygen [7], giving a product that interfered in the voltammetric determination. On the contrary, 1-naftol proved to be a suitable coupling agent, being stable in alkaline solution and forming a stable azo derivative that was adsorbed on mercury. The only drawback of 1-natftol is its low solubility in water that forced the preparation of its solutions in 1 M sodium hydroxide.

### 3.3. Selection of pH and accumulation potential for the voltammetric determination

It was decided to use a pH value of 9 because both voltammetric sensitivity and adsorption of derivatized aniline were higher at this pH. The effect of varying the potential of accumulation, necessarily more positive than the reduction potential of the compound, was negligible. So it was fixed at the more negative value allowed, 200 mV more positive than the reduction potential. It was decided to use an accumulation potential about 400 mV more positive than the reduction potential of the compound.

### 3.4. Amount of coupling agent and sodium nitrite

It was found that 1 mg of 1-naftol and 1 mg of sodium nitrite were sufficient for the quantitative diazotization and coupling of up to 100 μg of aniline. This excess of diazotization and coupling agents ensures that the reaction is sufficiently quantitative and fast.

### 3.5. Selection of the coupling conditions

The coupling reaction is considered before the diazotization reaction because it does not impose many restrictions. In fact the only potential problem is the decomposition of the

diazotized aniline before coupling, and this does not happen as the coupling reaction is very fast if the pH of the solution is between 9 and 13. For simplicity, a pH of 9 (ammoniacal buffer) was used for coupling, the same that is used in the subsequent voltammetric analysis. The elimination of excess nitrite prior to the coupling reaction can be obtained, for example, by addition of sulfamic acid, but the need for this elimination is still controversial [5]. In our work it was not undertaken because it was found that the presence of nitrite had no influence on the results.

### 3.6. Selection of the diazotization conditions

In the preparative chemistry of azo compounds it is recommended that diazotization takes place in an ice bath. This low temperature is used to minimize the decomposition of the diazonium ion before the coupling reaction. In our case there was no need of such a precaution, which made the method simpler. In fact, as can be seen in Fig. 1, the same amount of derivatized aniline was formed in an ice bath and at room temperature, probably because the diazotized aniline is quite stable and the coupling reaction is fast. The use of room temperature is even better as it is possible to use a shorter diazotization time.

Another important variable in diazotization is pH. Acid conditions are required, but there is not a simple dependence of diazotization rate on pH [8,9]. Results obtained using solutions with different concentrations of sulfuric acid show that diazotization rate increases with decreasing acidity (Table 1). A sulfuric acid concentration between $10^{-3}$ and $10^{-2}$ M proved to be a good choice.

Using the method of determination of aniline just optimized, and described in the Experimental section, a calibration curve for aniline was obtained. A detection limit less than 1 ppb can be obtained if adsorptive accumulation is used (Fig. 2). Of course, for higher concentrations of aniline the saturation of the mercury electrode must be taken into consideration. For instance, with an accumulation time of 2 min the calibration curve is linear only if the concentration of aniline does not exceed 20 ppb. The proposed method has a detection limit about 50 times lower than the spectrophotometric method, if an accumulation time of 2 min is used.

Table 1
Diazotization of aniline (%)

| Diazotization time | $H_2SO_4$ concentration | | | | |
|---|---|---|---|---|---|
| | 1 M | 0.2 M | 0.1 M | 0.02 M | 0.002 M |
| 1 min | 11 | 20 | 25 | 79 | 100 |
| 5 min | — | — | 69 | 100 | 100 |

### 3.7. Determination of aniline in D&C Red No. 33

One of the applications of some primary aromatic amines is in the production of synthetic colouring matters, using the diazotization/coupling procedure just mentioned. As azoic colouring matters are used in the colouration of foods, drugs and cosmetics, it is important to have methods to verify if the amine used in the production of a colouring matter was completely removed after synthesis. Aniline is the primary aromatic amine used in the synthesis of the colouring matter D&C Red No. 33 (Fig. 3).

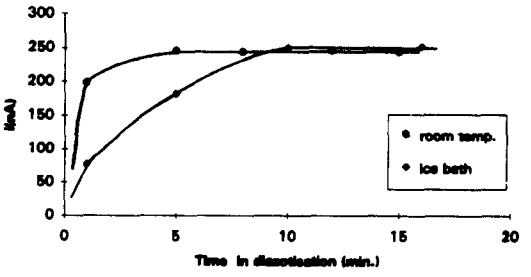

Fig. 1. Effect of temperature on the rate of diazotization of 100 μg of derivatised aniline. Analysis by AdSV: 1 min of accumulation; aniline concentration = 80 ppb; supporting electrolyte, 0.1 M ammonia buffer; pH 10. Diazotization in 0.02 M sulphuric acid.

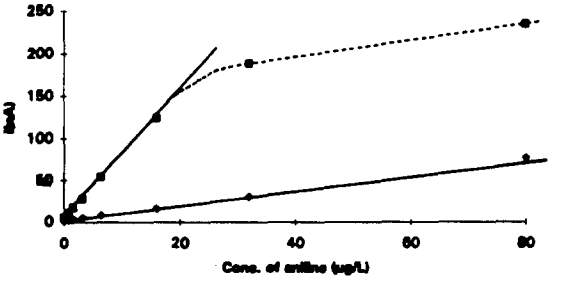

Fig. 2. AdSV calibration curves for derivatized aniline, using different accumulation times. Acc. potential = −240 mV (vs. AgCl/Ag, KCl 3 M); supporting electrolyte, 0.1 M ammonia buffer; pH 10. Acc. time (min): ◆ 0; ■ 2.

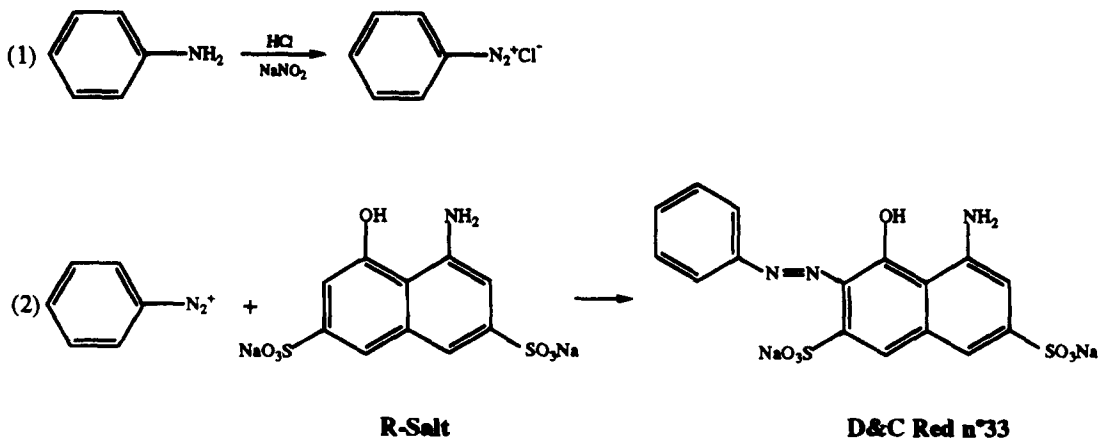

Fig. 3. Synthesis of the colouring matter D&C Red No. 33: (1) diazotization, (2) coupling.

Of course, if the usual method of analysis of amines is employed, involving their conversion into azo compounds, the colouring matter itself, structurally similar to the derivatized amine, will interfere in the determination. Thus, an intermediate step is needed for the separation of the amine from the colouring matter. The spectrophotometric determination of aniline (and other primary aromatic amines) in D&C Red No. 33 was reported by Bailey [10], based on the extraction of the amines from an aqueous solution of the colouring matter into chloroform. In our laboratory we have made a similar determination of aniline, using the adsorptive stripping voltammetric method in the detection step and the results are in good agreement with those reported in Bailey's work. The method of standard additions was used, with standards of aniline being added to the samples before the diazotization and coupling reactions (Fig. 4). Using standards alone, the same result was obtained with and without extraction, proving that extraction was complete. For a set of three replicates, the amount of aniline found in the colouring matter D&C Red No. 33 was $17 \pm 1$ ppm. The amount of aniline found in a commercial sample of D&C Red No. 33 is low considering the fact that this compound is used as an intermediate in the preparation of this colouring matter. As referred to by Bailey [10], this result suggests that the D&C Red No. 33 is thoroughly purified by the manufacturer before its commercialization, which is expected owing to the applications of this colouring matter and the potential health hazards associated with the aniline.

### *3.8. Determination of aniline formed in the degradation of D&C Red No. 33 solutions*

The method was also applied in the determination of aniline formed in studies of degradation of 0.1% solutions of D&C Red No. 33. In fact, besides being intermediates in the synthesis, the presence of amines in colouring matters

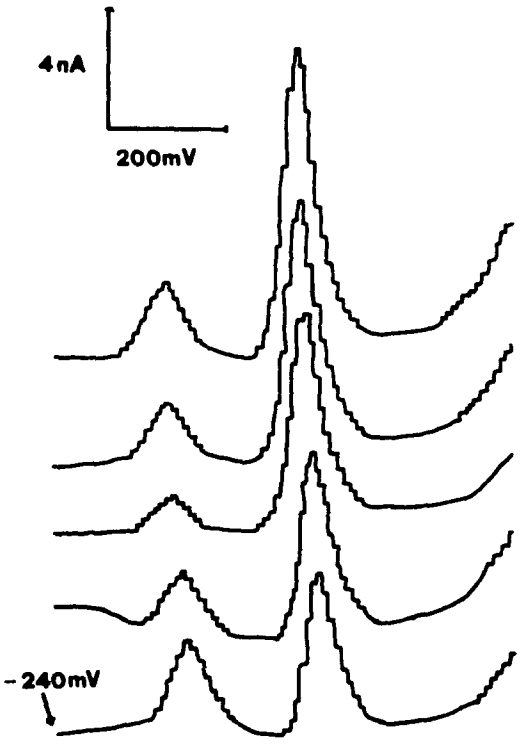

Fig. 4. AdSV determination of aniline in the colouring matter D&C Red No. 33. using the method of standard additions. Accumulation = 2 min. Aniline added (ppb) from bottom to top: 0, 0.8, 1.6, 3.2, 4.8.

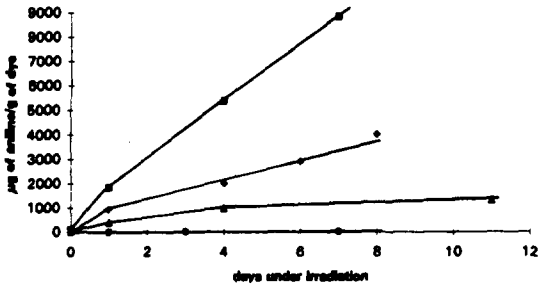

Fig. 5. Effect of the amount of ascorbic acid and of degradation time on the formation of aniline from D&C Red No. 33. Supporting electrolyte 0.1 M phosphate buffer, pH 7. Amount of ascorbic acid (%): ● 0; ▲ 0.02; ◆ 0.2; ■ 2.

can have a different origin, if degradation of the colouring matters occurs by reductive splitting of the azo group [11]. Although solutions of D&C Red No. 33 submitted to intense light conditions to accelerate degradation were found to be quite stable, in the presence of the antioxidant ascorbic acid the colouring matter was degraded to produce aniline, to an extent increasing with the amount of ascorbic acid and with the degradation time (Fig. 5). It was found that the main reason for degradation is the presence of ascorbic acid, as the results obtained with the use of light irradiation are not very different from those obtained in the dark (Table 2). Some preliminary studies indicate that the influence of pH on degradation is not very important, as similar values for degradation were obtained with pH 2 and 7.

Table 2
Degradation of D&C Red No. 33 in the presence of 0.2% ascorbic acid, at pH 2 (μg of aniline found/g of colouring matter).

| | Degradation times (days) | | | | |
|---|---|---|---|---|---|
| | 0[a] | 0.2 | 1 | 2 | 10 |
| In the dark | 17 | 198 | 645 | — | 5159 |
| Light irradiation | 17 | 101 | 888 | 1332 | — |

# Determination of palladium by flame atomic absorption spectrometry combined on-line with flow injection preconcentration using a micro-column packed with activated carbon fibre

Soulin Lin *, Chunsong Zheng, Guizhen Yun

*Department of Applied Chemistry, China University of Geosciences, Wuhan 430074, People's Republic of China*

Received 17 August 1994; revised 27 December 1994; accepted 5 January 1995

**Abstract**

The versatility of flow injection as a procedure for enhancing the performance of atomic spectrometry is demonstrated by the on-line separation and preconcentration of analyte ions of interest for methods employing atomic spectrometric measurements. In this paper, a sensitive method for the determination of palladium by flame atomic absorption spectrometry associated on-line with the flow injection technique has been developed. A flow system comprising a micro-column packed with activated carbon fibre was used for the concentration of palladium. In order to further enhance the performance of the analysis a new manifold with an additional column has been designed to increase the sensitivity by doubling the analytical signals. The method is sensitive and easily operating with a sampling rate of 15–20/h. The detection limit of this method is 0.3 ng/ml in standard solution and the precision is 3.9% relative standard deviation at 50 ng/ml. Recoveries of palladium in spiked solutions are 103–107%.

## 1. Introduction

Palladium is an element of medium sensitivity for atomic absorption spectrometry (AAS) and inductively coupled plasma-atomic emission spectrometry (ICP-AES). Enrichment of the element is often needed prior to determination. Palladium is often determined together with Ru, Rh, Pt, Os and Ir in samples for platinum-group element analysis. AAS determinations have been applied to the analysis of platinum group elements (PGEs) by the fire assay method [1–3] in early works. The detection limits reported were 0.06 ppm (20 g sample) [1] and 0.08 ppm [3]. Hoashi et al. [4] described a method for the determination of Pd, Pt and Rh in iron meteorites by procedures involving extraction into organic solvents and subsequent analysis of the extracts by graphite furnace AAS. The reported detection limit was 0.01 μg/g (0.1–0.5 g sample). Since its appearence in 1980 [5], inductively coupled plasma-mass spectrometry(ICP-MS) has become one of the most sensitive techniques for the determination of the PGEs. Methods demonstrating the application of ICP-MS to the determination of these precious metals with and without fire assay preconcentration have been published [6–8]. However, all these procedures require complex chemical manipulation of the samples and the analysis of sample solutions. Totland et al. [9] reported a method for direct determination of the PGEs in solid samples where the PGEs are directly determined by slurry nebulization ICP-MS. Excellent data of limits of quantitative analysis

(0.04–0.2 μg/g) for the method were reported and the analytical reproducibility was in the range 2–30% RSD. The detection limit for palladium was 0.17 ng/ml in HCl blank. However, these procedures require expensive instruments not common in conventional laboratories.

The objective of this work is to develop a method utilizing the combination of the flow injection preconcentration technique and atomic absorption spectrometry for the determination of Pd at a low concentration level. We used a flow system similar to that described by Olsen et al. [10]. The preconcentration column was packed with activated carbon fibre (ACF) to retain Pd and eluted by thiourea. Chemical conditions and manifold parameters were investigated in detail and the potential of ACF as a preconcentrator was demonstrated. In order to increase the concentration factor, we have designed a so-called double column manifold, which will be discussed in detail in the manifold section, to double the concentration of Pd, and thus double the analytical signal. With this manifold scheme, up to 145 times preconcentration of Pd with a sample throughput of 15–20/h can be achieved. It is apparent that the present FIA–FAAS system with online preconcentration might thus challenge the detection limits for graphite furnace AAS [11] and ICP-MS [12].

## 2. Experimental

### 2.1. Apparatus and manifold

The flow injection units used were an IFIS-A intelligent flow injection sampler comprising an eight-channel rotary injection valve and two three-channel peristaltic pumps (Xian Spring Institute, China) for the majority of experiments and a FIA-2400 flow injection analyser (Xintong Scientific Instrument Corp., China) for manual operation. All experiments were conducted with a WFX-1A atomic absorption spectrometer (Beijing Second Optical Instrument Factory, China) and a single pen recorder (PM 8521, Philips, Holland) for measuring and registering the absorption signals. A palladium hollow cathode lamp with an operating current of 6 mA was used. The sensitive Pd 247.64 nm line and a narrow spectral bandpass of 0.2 nm were adopted. A fuel-lean stoichiometric air–acetylene flame was employed for the atomization of palladium.

The manifold comprising a single column for the preconcentration of palladium is shown in Fig. 1. The two positions of the valve rotor (the channels are arranged in a circular pattern) refer to sampling S and elution E. The preconcentration process proceeds when the valve is in position 'a' and the elution process starts by back flushing with eluent stream E when the valve is switched to position 'b'. The preconcentration column with an inner volume of 180 μl (3 mm i.d. × 25 mm) was made of Perspex and was demountable for packing the activated carbon fibre.

The manifold scheme for the double column system is shown in Fig. 2. Note that the double column system differs in principle from the existing dual column system described in the literature [13,14] in that : (i) the two columns are in parallel in the preconcentration mode and the columns are connected in series in the elution mode; (ii) the double column system

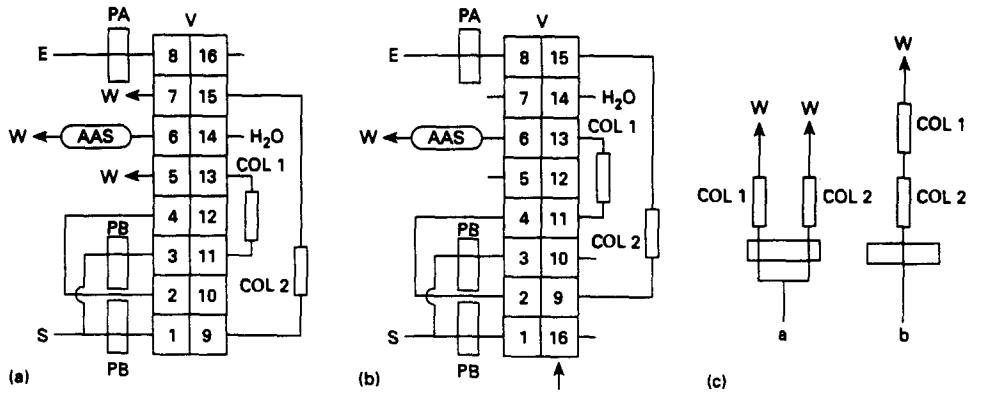

Fig. 2. Manifold scheme of double column system for FI preconcentration-atomic absorption preconcentration. V, rotary injection valve; PA, PB, peristaltic pump; COLI, COL2, preconcentration column packed with ACF; AAS, atomic absorption spectrometer; E, elution solution; S, sample solution; W, waste; a, preconcentration position; b, elution position; c, diagram of the principle of double column system.

doubles the analytical signal without doubling the preconcentration time, and thus the concentration efficiency (CE) can be increased; and (iii) the double column system can easily be reduced to a single column system simply by sampling water instead of sample solutions in the COL 1 channels.

### 2.2. Reagents and procedures

All reagents were of analytical reagent grade. Water from subboiling distillation was used throughout.

A Pd standard solution of 1000 μg/ml was prepared from palladium chloride and was made 2% in hydrochoric acid. This solution may be further diluted to give a series of calibration standards. The elution solution was prepared by dissolving 1 g thiourea in 100 ml water and the solution was made 1 M in hydrochloric acid. the buffer solution (pH 3.0) was prepared according to Clark and Lubs [15]: 50 ml 0.2 M KHphthalate + 20.40 ml 0.2 M HCl, diluted to 200 ml. The activated carbon fibre (High Polymer Institute, Zhongshan University, China) was treated with dilute nitric acid and thouroughly washed with water prior to use.

Most experiments were carried out with the IFIS-A intelligent flow injection sampler. The program and time cycle of operation are shown in Tables 1 and 2.

## 3. Results and discussion

### 3.1. Chemical conditions

*Acidity of the sample solution*

Palladium can be retained onto ACF in slightly acidic solution and the acidity of the solution considerably affected the retention of the metal. Experimental results indicated that the best pH value for the retention of the metal was 3.0. Sample solutions should approximately be adjusted to slightly acidic with dilute hydrochloric acid or sodium hydroxide solution and the solution finally made exactly pH 3 with KHphthalate buffer solution prior to sampling. Nitric acid was not preferred owing to the suppression effect on the absorption of palladium onto the activated carbon fibre.

*Concentration and acidity of thiourea solution*

The absorption signal increased with increasing thiourea concentration and remained unchanged when the concentration of thiourea exceeded 1.5%. In order to shorten the time to wash thiourea out of the column and manifold tubing for the next sample, a compromise thiourea concentration of 1% was used. Although a 10% loss of absorption signal resulted from this concentration, the wash time could be greatly reduced. The thiourea solution was

Table 1

made 1 M in hydrochloric acid to achieve maximum sensitivity. Again, nitric acid was not preferred.

*Interferences*

Elements other than palladium of the platinum group, as well as cadmium, copper, and lanthanum were tested for interference effects. The platinum group elements at concentration levels listed in Table 3 did not interfere in the determination of 50 ng/ml of Pd. The three other elements showed no interference effects. Alkali and alkaline earth elements showed no affinity with ACF and did not interfere with the determination of palladium.

### 3.2. Manifold parameters

Manifold parameters were optimized with respect to flow rates and sampling time. The effects of these parameters on the absorption sensitivity are shown in Figs. 3–5. The selected flow rates can be summarized as 5.2 ml/min for sampling and 4.1 ml/min for elution. It can be seen from Fig. 5 that the required concentration factor depends on the sampling time. Since

Table 3
Effects of coexisting ions (me)

| Ion | Added (μg/ml) | Concentration ratio (me/Pd) | Recovery (%) |
|---|---|---|---|
| 0 | 0 | 0 | 100 |
| Ag | 2.5 | 50 | 100 |
| Au | 5 | 100 | 100 |
| Pt | 3.2 | 64 | 103 |
| Cd | 2.5 | 50 | 97 |
| Cu | 5 | 100 | 100 |
| La | 2.5 | 50 | 100 |

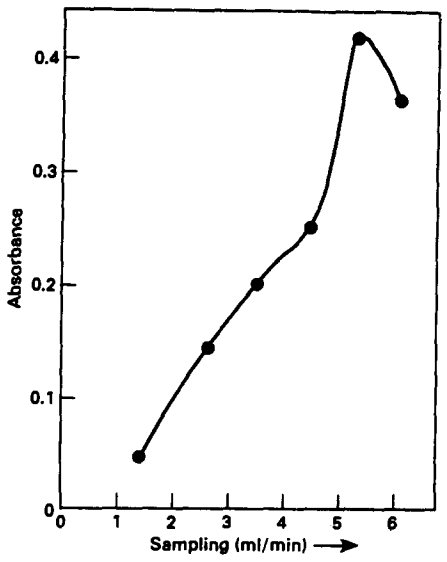

Fig. 3. Effect of the flow rate for sampling on the absorption sensitivity. Pd = 50 ng/ml (pH 3), sampling time = 2 min.

high concentration efficiency (a CE value up to 38 can be achieved) can be obtained by this method, longer sampling time is allowable and a sampling time of 3 min was used for investigation of analytical performance and for real sample analysis throughout unless otherwise stated.

### 3.3. Calibration graphs and analytical performance

Good linearity of the calibration graph of palladium was obtained in the range 0–30 ng/

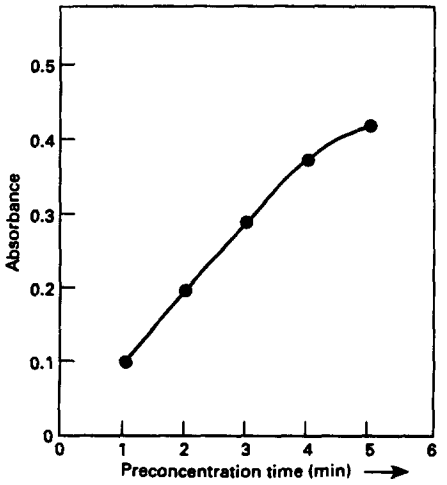

Fig. 4. Effect of sampling time on the absorption sensitivity. Pd 50 ng/ml, sampling flow rate = 5.2 ml/min.

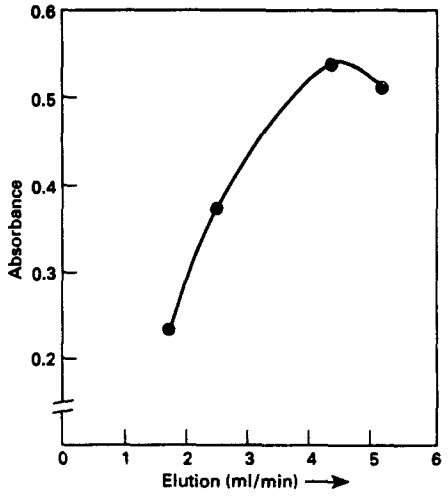

Fig. 5. Effect of the flow rate for elution on the absorption sensitivity. Pd = 200 ng/ml, sampling flow rate = 5.2 ml/min, sampling time = 3 min.

ml. The regression equation for calibration is $y = 0.014x + 0.0043$ with a correlation coefficient of 0.998. Sensitivities, detection limits and precision for direct nebulization and for sampling with preconcentration using single and double systems are listed in Table 4 for comparison. The sensitivities listed are referred to slopes of the calibration curves and the detection limits are calculated based on $3\sigma$.

## 4. Real sample analysis

Three geological samples were analysed for palladium with the suggested procedure to investigate the accuracy of the proposed method. Sample I (standard reference rock sample GSO-Au-2 containing 52.5 ng/g of Au) and sample II(Yangxin copper ore containing 200 ng/g of Au and 6500 ng/g of silver) were used as blank ores and Pd was spiked. Sample III and the analytical result of palladium was provided by the Hubei Geological Bureau.

### 4.1. Procedure

*Calibration series*

Palladium (0, 0.5, 1.0, 1.5, 2.0, 2.5 μg) was pipetted into six 25 ml colorimetric tubes, respectively, and made up to about 10 ml with water, adjusted to approximately pH 3 with pH test paper. KHphthalate buffer solution (2 ml) was added and diluted to the mark with water.

*Sample preparation*

Rock sample (0.1000 g) was weighed into a PTFE crucible, wetted with water, 10 ml of hydrofluoric acid added, heated and evaporated to dryness. Aqua regia (15 ml) was added and it was heated gently to dissolve the residues and evaporate to near dryness. Hydrochloric acid (2 ml) was added to eliminate nitric acid. Then, a few drops of (1 + 1) hydrochloric acid added and the wall of the crucible rinsed with hot water and transferred to a 100 ml volumetric flask and made up to the mark with water. The resulting solution (1 ml) was pipetted to a 25 ml colorimetric tube and subsequently treated the same as the standard series. The analytical data obtained using double column system are listed in Table 5. It can be seen that the analytical results of sample III was in good agreement with the reference value and the recoveries of Pd in all samples were satisfactory.

Table 4
Comparison of analytical performance

| Mode of sampling | Sensitivity (A $ng^{-1}$ $ml^{-1}$) | Detection limit (ng/ml) | Precision (RSD%) | Concentration factor (CF) |
|---|---|---|---|---|
| Direct nebulization | $9.6 \times 10^{-5}$ | 46 | 2.3 (1000 ng/ml) $n = 11$ | |
| With preconcentration (single column) | $6.6 \times 10^{-3}$ | 0.8 | 3.5 (100 ng/ml) $n = 8$ | 69 |
| With preconcentration (double column) | $1.4 \times 10^{-2}$ | 0.3 | 3.9 (50 ng/ml) $n = 8$ | 145 |

Table 5
Analytical results

| Sample | Found (μg/g) | Reference (μg/g) | Spiked (μg) | Recovery (%) |
|---|---|---|---|---|
| I | 0 | — | 1 | 107 |
| II | 0 | — | 1 | 107 |
| III | 580 | 530 | 2 | 103 |

## 5. Conclusion

Flow injection solid phase extraction is a potentially important technique in trace and/or ultra-trace analysis. Through optimizing the wash stage, sample loading rate and manifold design, high CE values are achievable. Data demonstrated in this paper are very encouraging. The main features of the suggested flow system are (i) that it can easily double the analytical signal and (ii) the system is semi-automated with only one manual step of feeding samples.

# Investigations for the determination of lead by in situ hydride trapping within a graphite electrothermal atomizer for routine analysis

D. Erber *, L. Quick, F. Winter, K. Cammann

*Institut für Chemo- und Biosensorik e.V., Mendelstraße 7, D-48149 Münster, Germany*

Received 11 July 1994; revised 23 December; accepted 3 January 1995

**Abstract**

A new commercial system consisting of a flow injection analysis system for hydride generation coupled with a transversely heated graphite atomizer–atomic absorption spectrometer for the determination of lead is investigated in detail. The hydride generation is optimized by using an ammonium peroxodisulphate–hydrochloric acid system as oxidant and sodium borohydride as reducing reagent. The addition of sodium cumol sulphonate as surface active substance shows advantages considering efficient plumbane production. The hydride trapping and atomization in a graphite electrothermal atomizer is also optimized. The characteristic concentration was 0.74 μg/l, the detection limit was 0.70 μg/l for 500 μl sample volumes. The relative operation standard deviation of this method was smaller than 2%. Further examinations demonstrate the influence of several heavy metals on the determination of lead. Finally, the measurement of standard reference materials shows the efficiency of the method in combination with decomposition with aqua regia solutions.

## 1. Introduction

Since 1975 the determination of lead using hydride techniques has been of great interest and research in trace metal analysis. Plumbane production and following detection investigated for analytical purposes was first described by Thompson and Thomerson [1]. Further applications of this analytical problem have been published with a full range of generation and detection methods [2–13]. Difficulties arose from two facts: the oxidation of lead (II) to lead (IV) followed by plumbane generation and its stability [14,15].

Oxidants like potassium dichromate [3,16], ammonium cerium nitrate [9], potassium permanganate/manganese sulphate [5] or hydrogen peroxide [2,6] made the production possible, but the use of dichromate seemed to be problematic owing to the health hazard and environmental relevance. However, hydrogen peroxide as a substitute showed less sensitivity. Similar results were only obtained with ammonium peroxidisulphate [4,8,12].

Another relevant problem is the efficient atomization of lead. Obviously, the almost exclusively used quartz tube is not well suited to obtain satisfactory sensitivity, e.g. detection limits of 30 μg/l for lead [13]. However, the enrichment and atomization of gaseous products from hydride-forming elements in a graphite furnace has been well known for some time [16–22]. The first use of this technique was reported by Lee [23]. The in situ trapping technique needs the graphite furnace both for hydride trapping and for the atomization. The hydrides purged from the gas–liquid separator decompose in the preheated graphite furnace (ca. 300–600 °C) and are then trapped on the graphite surface. The trapped products are

* Corresponding author.

*SSDI* 0039-9140(95)01517-5

then atomized normally at 1600–2000 °C. This technique is superior to quartz tube atomization. It should be preferred because of its greater sensitivity and its effective elimination of possible influences of hydride generation kinetics. The lastest developments of Perkin-Elmer make it possible to accomplish this process for the first time in a routine way [24].

With the use of a continuous flow or flow injection system, the sensitivity for the determination of lead could be increased and interferences be minimized. The combination of flow injection hydride generation and graphite furnace seems to be advantageous for the detection limits owing to continuous hydride enrichment in the furnace without any loss of reproducibility. However, inconsistent data are given in the literature with regard to interferences on the determination, e.g. the influence of nickel [7,10,11]. Certainly, different observations are dependent on the parameters used. Generally, tolerable concentrations of interfering metallic ions in flow injection procedures are often reported to be one or two orders of magnitude higher than in batch systems [25].

The use of surface active substances such as sodium cumol sulphonate or Triton X-100 [26] increases the sensitivity with great effect. Such micellaric systems influence different analytical systems and have been used in diverse applications [26,27]. The maintenance of more effective hydride formation described for lead and arsenic using several substrates [12,28] was confirmed for lead by the application of several surface active substances in this study.

The technique is applied for the determination of lead in several real samples decomposed with aqua regia extraction. It demonstrates the suitability and the efficiency of the technique by analysing standard reference materials with different organic and inorganic matrices. The results are compared with results obtained by another graphite furnace routine analysis system (ZL 4100 from Perkin-Elmer) and a special new arrangement with a graphite furnace (frequency modulated simultaneous AAS) developed by Cammann et al. [29].

This paper reports the optimization procedure for the hydride generation of lead as a simple and fast method for its determination using the continuous flow system hydride generation atomic absorption spectrometry with enrichment and atomization in a graphite furnace.

## 2. Experimental

### 2.1. Instrumentation

A Perkin-Elmer Model 4100 ZL atomic absorption spectrometer was used in combination with the FIAS 200. The available background correction with longitudinal Zeeman effect was not required for this application. For the hydride trapping and atomization in the graphite furnace a special application software from Perkin-Elmer was used (software version 7.21). The hydride generator was coupled via a Teflon tube to the graphite furnace. A quartz tip was fixed to a pipet arm inside the graphite furnace during the enrichment time. Before atomizing, the pipet arm was moved outside this oven.

The flow injection system scheme is described in Fig. 1. Three tubes with reagents for the hydride generation are connected to the chemifold in which plumbane is formed. An inert gas stream transports the hydride products to the graphite furnace. The parameter for the hydride generation, trapping and atomization are summarized in Table 1. The program for the enrichment step is presented in Table 2. Because of large amounts of reagents, two pump tubes instead of the normal one are used as waste tubes to prevent an overflow of the gas–liquid separator.

For the assessment of the results obtained, a new method in atomic absorption spectrometry was used and it is described in the following. In frequency modulated simultaneous AAS (FremsAAS) [29] the light is provided with additional information by modulation of the light sources with different frequencies (300–700 Hz). By using interference filters the resonance lines are separated from other emission. Lock-in amplifiers selectively amplify the modulated signal of light source in a DC signal.

### 2.2. Gases and substances

Argon (99.996%); (Sauerstoffwerk Westfalen AG, Münster). As(III)-, Bi(III)-, Mn(II)-standard: 0.100 g (all Fixanal; Riedel de Haën AG, Seelze). Sb(III)-, Cr(VI)-standard: 1.000 g (Fixanal). Se(IV)-, Ti(IV)-, Cr(III)-, V(V)-, As(V)-, Sn(IV)-, Pb(II)-, Hg(II)-, Cd(II)-, Cu(II)-, Ni(II)- standard: 1.000 g (all Titrisol; E. Merck, Darmstadt). Fe(III)-, Zn(II)-, Co(II)-standard solution: 1g/l (all E. Merck). Sodium borohydride p.a., sodium hydroxide p.a., sodium per-

Estuarine sediment CRM 277, aquatic moss (*Platihypnidium ripariodes*) BCR 61, rye grass CRM 281 [all Commission of the European Communities, Community Bureau of Reference (BCR), Brussels]; pine needles SRM 1575 (U.S. Department of Commerce, National Institute of Standards and Technology Gaithersburg, MD, U.S.A.).

### 2.4. Optimization of the hydride generation and atomization technique

Several parameters were optimized to reach highest sensitivity for the lead determination. Erber et al. [30] optimized some parameters by using this technique for the sensitive detection of ionic organolead compounds. Because of a large difference between the hydride generation of organolead compounds and lead itself, which is a result of the enormous difference in stabilities of the hydride products, optimization of the parameters, especially for inorganic lead, was necessary to achieve good results. The parameters having influence on the sensitivity of the formation of lead hydride are sodium borohydride as reducing reagent, the oxidization agent ammonium peroxodisulphate, the type and concentration of the acid and the sodium cumol sulphonate (chemical), as well as the flow of the inertia gas and the enrichment temperature and the atomization temperature (apparational). The optimization procedures were carried out by measuring a solution of 50 µg/l lead. Because apparational parameters and chemical parameters are mostly independent from each other, the first mentioned are optimized first.

*Inert gas flow*

Argon as an inert gas transports the hydride products from the gas–liquid separator to the graphite furnace and so the influence of its flow rate on the signal intensity was investigated. The results are presented in Fig. 2. The optimum argon flow rate was 125 ml/min as opposed to the optimum flow rate by the generation of organolead hydride products [30].

*Enrichment and atomization temperature*

The enrichment temperature, as well as the atomization temperature, is, in combination with the type of graphite furnace, a major parameter for the sensitivity of a method. Several investigations into the enrichment temperature and the theoretical foundations about the sorption and atomization are described [19,28].

The optimum high enrichment temperature of 600 °C we found in concordance with Aroza

et al. [8] seems to favour a normal thermic decomposition to the element and rules out simple physisorption of the hydride or its decomposition product [19]. The determination of the enrichment temperature, i.e. the decomposition of the lead hydride, was carried out using an atomization temperature of 1600 °C. A steady increase of sensitivity was found (Fig. 3). Temperatures of more than 600 °C seem inappropriate in order to avoid unnecessary strain on the pipetting quartz tip. It will gradually be damaged. For routine analysis, an enrichment temperature of 450 °C was sufficient.

Other authors point out that a zirconium- or palladium-coated graphite tube show a more effective adsorption for hydrides in general and especially for lead hydride [11,20,25,28]. This allowed lower enrichment temperatures to be used. The reason for this seems to be a catalytic dissociation on zirconium carbide or palladium rather than a thermal decomposition [11,19].

Since we could not detect significant differences at the temperatures we used, we did not modify graphite tubes with zirconium or palladium solutions. The graphite tubes for the Perkin-Elmer 4100 ZL obviously have a surface that is well suited for the decomposition of lead hydrides. But the decisive reason for not modifying the graphite tube was the instability of plumbane. At higher temperatures it decomposes spontaneously, in contrast to the relatively stable hydrides, e.g. of arsenic or antimony. No catalytic process is needed for the decomposition of plumbane. By using a modifier for signals with decreased peaks heights, large peak areas were obtained.

The surface of the graphite tube is also a significant parameter for the atomization temperature [28]. Modifying the graphite tube after enriching the hydrides with palladium or zirconium also influences the atomization of lead [31]. The modification seems impractical in this case for routine applications because the enrichment technique has no programmable step and no device for automatic pipetting of a modifier. We settled for a tube treatment after hydride enrichment, and we experienced no loss of reproducibility or sensitivity. We determined an atomization temperature of 1800 °C and an enrichment temperature of 450 °C to be satisfactory (Table 3).

Table 2
FIAS-program for the enrichment step

| 5 | 5 | 120 | 0 | fill |

*Tube life-time*

The total measurements here were carried out with two graphite tubes. Consequently, the life-time of one graphite tube was greater than 4000 firings. It showed no dependence on the sample matrix in contrast to the conventional graphite furnace technique, where the life-time of the tube directly depends on the matrix. The tube gets broken because of the normal wearing process.

The chemical parameters were optimized with the physical parameters listed in Table 1.

*Acid*

For the determination of lead it is very important, besides finding the optimum concentration, to choose the right type of acid. This has already been described in the literature for other hydride-forming elements [32,33]. Hydrochloric acid again proved to be the most appropriate acid. Nitric acid or weak acids such as acetic acid did not produce as good a sensitivity as hydrochloric acid (Fig. 4). Even tartaric acid, which has been used until now [13], did not reproduce the sensitivity of hydrochloric acid in combination with the oxidation agents used here.

We found a direct correlation between the maximum sensitivity and the pH of the acid. This can be explained by the fact, that the oxidation power of ammonium peroxodisulphate depends directly on the concentration of $H^+$. We found a pH of ca. 1.7 to be the optimum with the three acids we used. Even small variations of the optimum pH showed a drastic decrease in sensitivity. Therefore, it is important to adjust the pH to the optimum value by treating the samples with ammonia or sodium hydroxide when preparing the samples.

*Sodium borohydride reductant*

Sodium borohydride is still considered to be the best reductant for AAS. The signal intensity steadily increased with an increasing concentration of $NaBH_4$ (Fig. 5). The limiting factor though is the fact, that concentrations of more than 1% (w/v) $NaBH_4$ lead to so much foaming that parts of the liquid in the gas–liquid separator will be transferred into the Teflon tube and the graphite oven. On addition of an anti-foaming agent the plumbane generation efficiency is increased very little with higher concentrations of $NaBH_4$. However, this effect influences the signal intensity less than the effect caused by the use of surface active substances, which tend to foam in the reactor (see

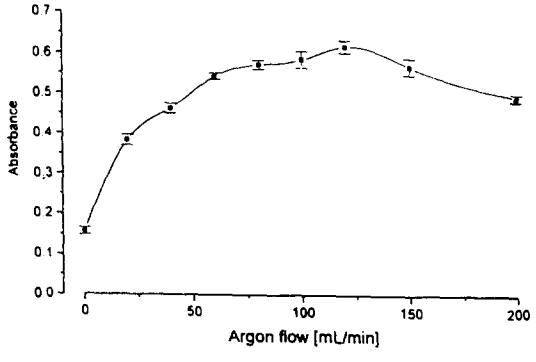

Fig. 2. Influence of the argon flow rate on the signal intensity.

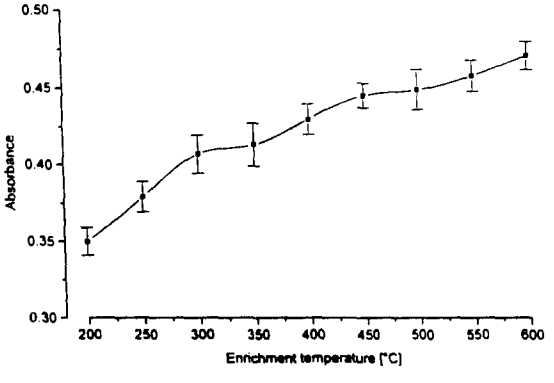

Fig. 3. Signal intensity by increasing enrichment temperature.

Table 3
Temperature program for the graphite furnace routine

| Step | Temperature (°C) | Ramp (s) | Hold (s) | Gasflow (ml/min) |
|---|---|---|---|---|
| Enrichment | 450 | | | |
| Pre-treatment | 450 | 1 | 20 | 250 |
| Atomization | 1800 | 0 | 5 | 0 read |
| Glow out | 2300 | 1 | 2 | 250 |

Effect of surface active substances). To achieve good results, a concentration of 0.5% (w/v) was quite sufficient for the hydride generation. The lead content in the $NaBH_4$ is no problem, as expected, the plot show a linear increase (Fig. 5).

*Ammonium peroxodisulphate oxidant*

A successful determination of lead requires that, prior to reduction, all lead must be oxidized to Pb(IV) by some oxidant, because only Pb(IV) forms sufficiently stable hydrides [15,34]. Several oxidants, such as potassium permanganate, potassium dichromate and hydrogen peroxide, have been more or less successfully tried out. As other authors found, ammonium peroxodisulphate proved to be the optimum oxidant for oxidizing lead(II) ions [4,8,12]. When using a FIA system, it is necessary to follow the proper sequence when adding the various substances (see Fig. 1). An increase of ammonium peroxodisulphate show a similar linear increase in sensitivity in Fig. 6, as well as $NaBH_4$.

In order to save material, all the following determinations have been carried out with a concentration of 5% (w/v) and not with the concentration for maximum sensitivity. This also leads to much less foaming owing to higher concentrations in some samples.

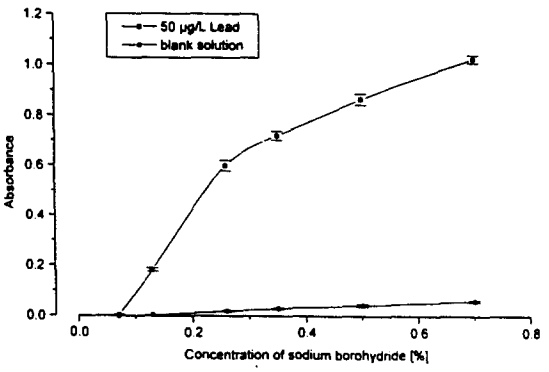

Fig. 5. Dependence between signal intensity and reducing reagent.

*Effect of surface active substances*

Surfactant organized substances or organized molecular assemblies have an enormous influence on the chemical equilibrium, reaction rates and other important chemical features owing to their capacity to create a special microenvironment for reactions at a molecular level [26]. It was shown, that surfactant organized substances greatly support the formation of hydrides [12,28]. In this work the addition of three types of this organized media were investigated to study the effect on plumbane generation. Sodium cumol sulphonate (SCS), Triton 100 and tetrabutylammonium hydrogensulphate (TBHS) were tested. The effect of those substances on plumbane formation is shown in Fig. 7. It can be seen that the absorption signal increased with increasing surfactant substances concentration until a plateau was reached. Those substances have been added to the carrier. Though higher signals can be achieved by adding the substances directly to the sample solution, the sample preparation will be much easier when the required substances are combined in the FIA system. Especially as the signal gain is only 20–30%.

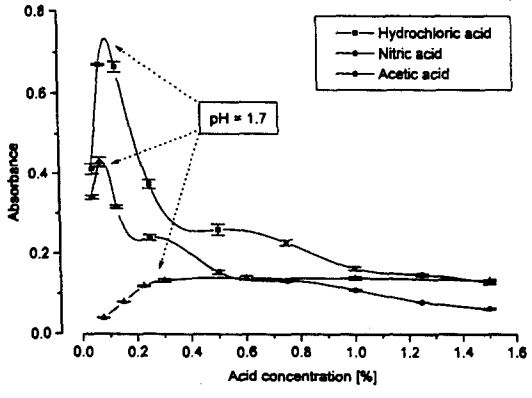

Fig. 4. Influence of different acids on the signal intensity.

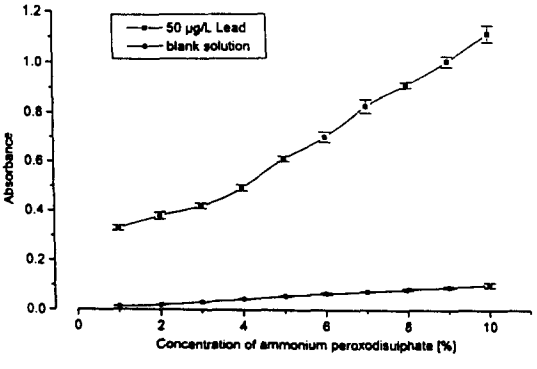

Fig. 6. Signal intensity by increasing the oxidant.

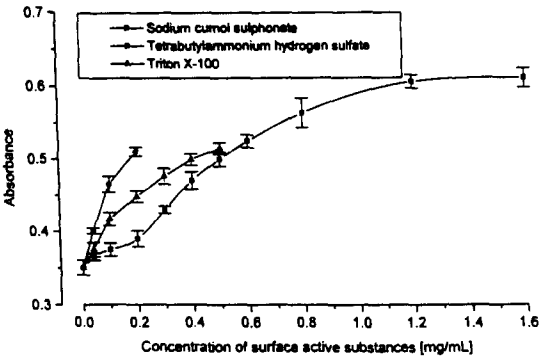

Fig. 7. Effect of surface active substances on the lead determination.

The maximum concentration was also limited by foaming in the gas–liquid separator, which drives some of the liquid into the Teflon tube or the graphite furnace. The additional membrane for this separator, manufactured by Perkin-Elmer somewhat reduces this effect, and can increase the signal by a factor of 1.3 to two as other authors also found [12]. The signal mainly depends on the degree of foaming in the sample solution. Sodium cumol sulphonate showed the best results, because it barely foamed even in large concentrations. Real samples could be determined best when using SCS, because SCS could buffer varying pH values in the sample solutions.

*Sample preparation*

The standard reference materials were first dried as described in the BCR information reports about the certification details. After drying the reference materials were digested with aqua regia according to DIN 38414-S7 [35]. For the sample aquatic moss CRM 061, an aqua regia disintegration with reverse acid ratio (invers aqua regia) was accomplished because of its better decomposition [36]. These solutions are not filtered but after filling into graduated flasks were decanted into polyethylene bottles. These solutions were diluted to demand with suprapure water and neutralized with ammonia to pH ca. 2, (pH paper accuracy is sufficient).

*Interferences from other heavy metals*

The interfering effect of some metals for the determination of lead were investigated (Table 4). The listed elements are normally the main metal components in real samples after aqua regia extraction.

Every determination using hydride techniques have so far shown interferences that influence the determination to various degrees [32,37,38]. Two mechanisms of interference are generally possible. First the formation of the hydride is inhibited in the presence of transition metals and second, other hydride-forming substances as well as other gaseous substances interfere with the determination itself [26]. The interference through transition metals are influenced by the parameters concentration and type of acid, type of reductant and the contact time between the sample solution and the reductant during the hydride formation. The interferences in flow injection analysis tend to be one or two orders of magnitude lower than in batch systems because the normally slow interfering reactions are often suppressed by using short reaction coil lengths. Another aspect is the high flow rate of the sample and reagent through the reaction coil and the gas–liquid separator. Because of the high flow rate the possibility of accumulating reduced metals or metal borides therein is very small. Such deposits are often considered to be important sources of interferences in hydride generation [25]. Also, the small sample volumes introduces smaller absolute amount of interferent into the hydride generation system. This is important because the absolute amount of interferent has often been shown to be more important than its relative concentration.

Table 4
Interferences of some heavy metals on the determination of lead

| Interferent | Relation | Recovery (%) |
|---|---|---|
| Mn(II) | 1:100 | no influence |
| Mn(VII) | 1:50 | positive interference (+20%) |

| Number of measurement ($N$) | 14 | 20 |

Those hydrides produced as a by-product mainly interfere in the atomization phase (when using a quartz cell) but, since there is no direct atomization in the graphite tube, there should be no further interference [26]. Because Table 4 shows a strong signal depression for selenium it is possible that hydride forming substances may already interfere during the reduction in the reactor. Transition metals, as oxidants, and mercury induce/introduce a positive interference because, in the case of dichromate and permanganate, they increase the mobility of lead through their oxidation power in the reaction.

Therefore, interferences for the determination of lead with this method should be expected, but they can be minimized with the parameters mentioned above. Only selenium causes significant interference. But selenium seems to interfere with every hydride technique [3,26,32].

## 3. Results and discussion

The calibration shows a linear range in the concentration range up to ca. 50 µg/l lead and then changes into a typical second order function. The absolute sensitivity, the characteristic mass, defined as the amount of lead required to give 1% absorption (peak height A = 0.0044) is 368 pg. The characteristic mass of lead reported in the literature was 10 pg for GF-AAS [39]. The large difference between the characteristic masses can be explained with the inefficient generation of plumbane by the hydride generation technique. For comparing with the graphite furnace technique the characteristic concentration is decisive and not the characteristic mass, because the concentration criterion is dependent on the available volume. Because the large sample volumes in the enrichment technique the poor yield of hydride products can be compensated for. The resulting characteristic concentration was 0.74 µg/l for a 500 µl sample volume. The characteristic concentration reported for GF-AAS was 0.2 µg/l for a 50 µl sample volume [39]. By using a greater sample volume or the continuous mode, lower characteristic concentrations in the same range or less like GF-AAS are obtainable by the hydride generation technique. The detection limit, defined as the amount of lead required to give an absorbance equal to three-fold standard deviation of the blank absorbance [40], was 0.70 µg/l for a 500 µL sample volume. For GF-AAS the detection limit is 0.1 µg/l for a 50 µl sample volume. The characteristic data of the method computed by formulas taken from Funk et al. [41] are presented in Table 5.

In order to compare GF-AAS hydride generation with other AAS methods, we determined the lead contents of some standard reference material samples. The reliability of the method was tested by measuring the content of lead in several real samples. Organic and inorganic materials with different matrices were decomposed with aqua regia and measured with the described method. The parameter for weight-in-quantities, dry processes of the samples, the decomposition method (aqua regia or invers aqua regia) and the results found with the described technique are presented in Table 6. The results obtained by this method were compared with those obtained by graphite furnace absorption spectrometry and the new multi

element-GFAAS. Satisfactory results with very good agreement by all three methods were observed. The accuracy of the results are also in accordance with the certification (Table 7).

## 4. Conclusion

This vapor generation and enrichment method offers many advantages with respect to simplicity and speed and substantially improved sensitivity. Additionally, it was observed that this technique is mostly free from interferences. The detection limit in the flow injection system was 0.70 μl for a 500 μl-sample loop. By enrichment of greater sample volumes with a continuous flow step, the sensitivity increases by more than a factor of 10. Naturally, because of the different stabilities of the hydride products of organolead compounds and lead itself, the method is more sensitive for organolead compounds. The method works well for organolead compounds, and also works satisfactorily for the inorganic compound.

Because the detection limit reached by this method is higher than that provided by the conventional graphite furnace, application in a continuous mode is paramount. In biological materials, where the content of lead is very small, the enrichment step in continuous mode allowed the detection of lead in the pg/g range. In this study a continuous mode was unnecessary to obtain good results because of the great weight-in-quantities.

This method in flow injection mode is simple to carry out and can be conveniently used for the analysis of large numbers of samples on a routine basis. Accurate results can be obtained if the concentration levels of the interfering metals are less than the lead concentration. This is safely possible for materials like fly ashes or sediments. Significant interference effects have been encountered when analysing biological materials. By using the standard addition method, most problems can be eliminated, only the sensitivity of the lead signal decreased.

The measurements of standard reference materials have shown accurate results according to the certification of these materials. No problems were found using the standard addition method if the evaluation of the signals are carried out by measuring peak area instead of peak height.

Using surfactant substances the sensitivity of lead determination increases and positive influences by the suppression of some interferences have been observed.

Received 25 October 1994; revised 21 December 1994; accepted 13 January 1995

**Abstract**

A method for the simultaneous determination of sulphide and sulphite is described, which involves continuous $H_2S$ and $SO_2$ generation, preconcentration in a liquid nitrogen trap and measurement of the molecular absorption spectra of volatiles in the gas phase in 190–220 nm range. Under the recommended conditions (sample flow: 50 ml/min and concentrated sulphuric acid flow: 12 ml/min; generation time: 4 min) linear response ranges from 0.05 μg/ml for $S^{2-}$ and 0.20 μg/ml for $SO_3^{2-}$ are obtained with detection limits of 0.05 and 0.20 μg/ml respectively. Synthetic mixtures of the two components have been solved and a comparative study of different calculation methods has been made. In conclusion, multiwavelength methods offer better precision and accuracy.

## 1. Introduction

Classical approaches to the simultaneous determination of sulphur anions, i.e. titration [1], spectrophotometry [2,3] or polarography, typically involve differential assays, reaction of the sample with iodine, bromine compounds of many others [4,5] under different conditions. In many cases, the need for extensive manipulation of samples, subtraction of large numbers from each other, and substantial time investment per sample limit their applications. Automatized or semi-automatized methods offer opportunities to approach the problem. Burguera and Burguera [6] have attempted the simultaneous determination of several sulphur anions using a relatively uncommon technique, molecular emission cavity analysis (MECA); Hauge [7] and Sonne [8] have described a complicated simultaneous photometric flow injection determination of sulphide, polysulphide, thiosulphate, sulphite and sulphate based on different chemical reactivities, differing p$K_a$s and volatilities of the various sulphur-containing acids, and kinetic differences.

Many papers about several sulphur-containing anions determination are based on chromatographic separation and later determination. So Story [9] has indeed demonstrated the successful determination of a large number of sulphur anions with postcolumn reaction detection. Other authors that use chromatographic separation are Shpigun et al. [10] for determining sulphide, sulphite, sulphate and thiosulphate, or Steudel et al. [11] for sulphide, sulphite, thiosulphae and polysulphide.

Although previous methods offer good results, they all show different problems; for example, instrumental complexity (as MECA), sensitivity (as Sonne's method) or the excessive manipulation of samples (as methods with post-column deviation). Furthermore, the methods described are in fact sequential, not simultaneous, which leads to more complex

procedures. The introduction of diode-array detection systems in UV-visible spectrophotometers allows new developments in GPMAS (Gas Phase Molecular Absorption Spectrometry) by Sanz et al. for single [12–15] and multicomponent simultaneous determinations [16–18]. The first papers on this technique were published by Cresser and Syty, independently. Both of them used a mono-channel detection system (an atomic absorption spectrometer with hollow cathode or deuterium lamps as radiation sources) so they were not able to perform simultaneous determination; Syty reported only single sulphide (by $H_2S$ generation) [19] or sulphite (by $SO_2$ generation) [20] determination.

From this period on, few works have been published on sulphite or sulphide [21] single determination of GPMAS. Simultaneous determination has only recently been proposed by Jin et al [22]. Using a similar approach to Syty, they perform simultaneous determination by measuring sequentially from two different radiation sources (magnesium and tellurium hollow cathode lamps) emitting at 202.6 and 214.3 nm; these wavelengths are far from the maximum molecular absorption of $SO_2$ and $H_2S$ (198 and 196 nm, respectively) and two problems could arise: low sensitivity (which can be avoided by using a more expensive long path cell) and low precision (reproducibility values are not indicated by the authors). In addition, owing to the high overlap of the molecular absorption spectra of both volatiles, the use of the two-wavelength method for simultaneous determination is prone to inaccuracy.

In this paper generation of sulphur volatiles in a continuous mode, coupled to a retention in liquid nitrogen, permits the use of GPMAS with diode-array detection for the simultaneous determination of sulphide and sulphite at low concentration levels. Different mathematical data treatments for binary determinations of these compounds have been compared; the multiwavelength method give more accuracy and precision than the two wavelength methods.

## 2. Experimental

### 2.1. Apparatus

All measurements were performed using a Hewlett-Packard model HP 8451A diode-array spectrophotometer furnished with a quartz flow cell of 1 cm path length (Hellma 174 QS) and equipped with a Keyboard HP98155A (Hewlett-Packard), a floppy disk drive for bulk data storage (Hewlett-Packard HP9121) and a graphics plotter (HP7475A). For mathematical treatment a Hewlett-Packard Vectra microprocessor with Eureka® software was used. Masterflex models 7518-10 and 7016-20 peristaltic pumps (Cole Parmer Instrument Co. Chicago, Illinois 60648), were employed throughout.

### 2.2. Reagents

All reagents used were of analytical-grade quality. Doubly distilled water was used.

Standard sulphide solution was prepared by dissolving $Na_2S \cdot 9H_2O$ (0.75 g) in 100 ml water, and then titration with ferricyanide. This and working standard solutions (perpared by serial dilution of the stock solution), were prepared daily.

Standard sulphite solution was prepared by dissolving $Na_2SO_3 \cdot 7H_2O$ in a 5% glycerin water solution as stabilizer. Working standards were prepared by serial dilution of the stock solution, immediately before use.

Concentrated perchloric (70%, 1.67 g/ml) and sulphuric (96%, 1.84 g/ml) acids were also used.

### 2.3. System description. Procedure

Volatiles generation and cold trap systems are shown in Fig. 1. Two peristaltic pumps were used for mixing analytes solution (50 ml/min) and concentrated sulphuric acid (12 ml/min). $H_2S$ and $SO_2$ generated into the mixing coil (in which an additional 600 ml/min nitrogen gas-auxiliary carrier flow, AF, was flowing) were separated in a first gas–liquid separator where there was a nitrogen flow (transport flow, TF, 100 ml/min) and the remaining liquid phase reached a second gas–liquid separator. The volatiles were swept through a water trap (a flask full of Raschig rings and immersed in an ice and salt bath at $-10\,^{\circ}C$) and were finally condensed in the U-tube immersed in liquid nitrogen which contained a small quantity of glass spheres (2 mm diameter). The Raschig rings and the small glass spheres were both silanized.

After generation and trapping of volatile compounds for 4 min, the U-tube was closed, removed from the liquid nitrogen and left at

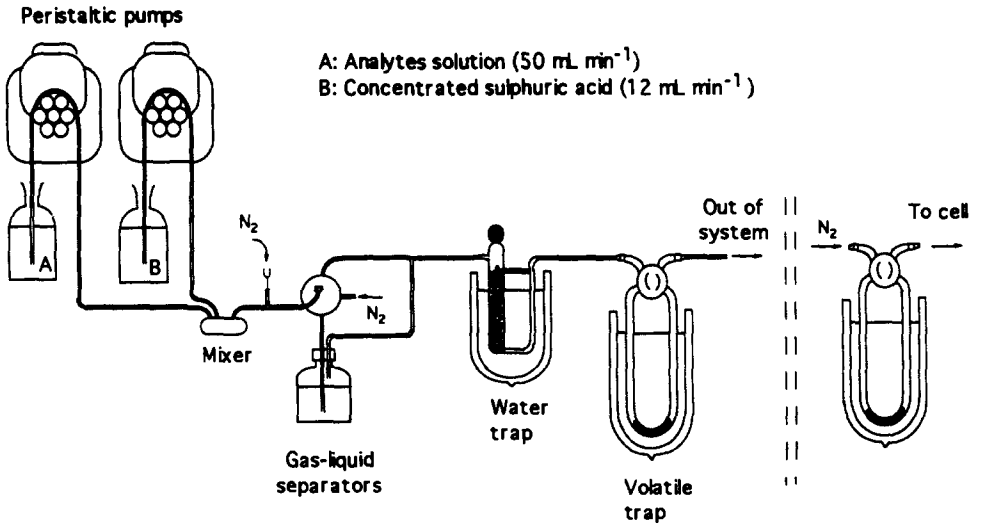

Fig. 1. Schematic diagram of the system (see explanation in the text).

room temperature. After 10 min the volatiles were transported to the continuous flow cell, placed in the spectrophotometer, with a nitrogen flow (measuring flow, MF) of 2000 ml/min.

To measure the transient signal, the spectrophotometer was programmed with a BASIC program that permitted us to obtain and store molecular absorption spectra in the 190–250 nm range, with a time interval of 0.2 s. All determinations of mixtures and standards were made at least in triplicate.

To determine $S^{2-}$ and $SO_3^{2-}$ contents in a mixture, the maximum absorbance values for every wavelength between 190 and 220 nm were obtained (the spectral bandwidth of the spectrophotometer was 2 nm, so 16 absorbance values were used).

## 3. Results and discussion

### 3.1. Optimization of parameters

Generation and preconcentration of volatiles were performed using a system which is based on another described in a previous paper [18]. This system had been used for hydride generation so many parameters had to be reoptimized because the nature of the compounds to be generated is quite different.

Although other mixers have been employed, the results obtained using that shown in Fig. 1 were the best. With respect to the glass reaction coil, different lengths were studied (3, 10 and 40 cm), and almost no influence on the absorbance or signal shape was observed, so a reaction coil length of 3 cm (the minimum possible) was chosen. Using 40 cm instead of 3 cm gives a slight decrease in absorbance (about 10%) observed.

In most manifolds used in continuous flow determinations involving a gas–liquid separation process, a single gas–liquid separation step is used. In this work we observed that two serial gas–liquid separators produce signal increases of 35% compared to the use of only one separator. This increase is explained if one considers that the temperature of the solution to be separated is higher than ambient (owing to the heat liberated during the mix of aqueous analyte solution and concentrated sulphuric acid) so the separation process continues in the second gas–liquid separator; in addition, the shape of this second gas–liquid separator favours the process further.

Nitrogen TF is one of the parameters which most affects the analytical signal. As has been described for hydride generation [18], the TF must be the lowest possible to obtain the maximum retention yield in the liquid nitrogen trap. This is logical considering that the larger the flow, the less the residence time of the volatiles in the trap. However, when we employed low flows (as hydride) for sulphur volatiles, a retention of the nitrogen in the cryogenic trap was observed; when the trap was later brought to room temperature, the nitrogen suddenly escaped from the valve and allowed the volatiles to escape. In order to avoid this problem, three alternatives were tested.

Table 1
Variation of $SO_2$ signal with AF/TF ratio (total flow = 1200 ml/min)

| AF (ml/min) | TF (ml/min) | AF/TF (ml/min) | Signal |
|---|---|---|---|
| 1100 | 100 | 11 | 0.036 |
| 1030 | 170 | 6 | 0.040 |
| 600 | 600 | 1 | 0.030 |
| 100 | 1100 | 0.1 | 0.025 |

AF = Auxiliary flow, TF = transport flow.

(a) Changing the cryogenic trap to another at a higher temperature, so that nitrogen gas could not be held. A liquid nitrogen–ethanol bath (ca. −117 °C) was used, but a large decrease in absorbance values was observed which indicated a low retention yield for sulphur volatiles.

(b) Addition to the analyte solution of a substance capable of forming a gas in an acidic environment; this gas could act as an internal carrier gas [21]. $NaBH_4$ can not be used because it is a reducing agent and would transform sulphite into sulphide. Low carbonate concentrations were employed, but $CO_2$ causes the same problem as nitrogen.

(c) Increasing the nitrogen flow. To do this an AF was bubbled through the reaction coil (between mixer and first gas–liquid separator). This alternative gives successful results.

Nitrogen TF and AF were studied in a wide range of possible flow-rate combinations. $H_2S$ and $SO_2$ were optimized separately. Table 1 shows $SO_2$ absorbance for different AF/TF ratios (maintaining a total flow of 1200 ml/min). The optimum value was for a ratio equal to 6. Table 2 shows the $SO_2$ absorbance variation with total flow (maintaining an AF/TF of 6). The best results were obtained using 700 ml/min total flow. A total flow of nitrogen of less than 400 ml/min produced the retention of $N_2$ in the cryogenic trap. Contrary to what happened with $SO_2$ absorbance, the $H_2S$ optimization showed the best results using a total flow of 2000 ml/min. Finally, 700 ml/min total flow (AF = 600 ml/min and TF = 100 ml/min) was used because sulphite sensitivity was poorer than sulphide. With respect to the nitrogen MS, 2000 ml/min was found to be the optimum for different reasons, as discussed previously [18].

Table 2
Variation of $SO_2$ signal with total flow (AF/TF ratio = 6)

| AF (ml/min) | TF (ml/min) | Total flow (ml/min) | Signal |
|---|---|---|---|
| 1800 | 300 | 2100 | 0.027 |
| 1030 | 170 | 1200 | 0.040 |
| 600 | 100 | 700 | 0.063 |
| 430 | 70 | 500 | 0.044 |

AF = Auxiliary flow, TF = transport flow.

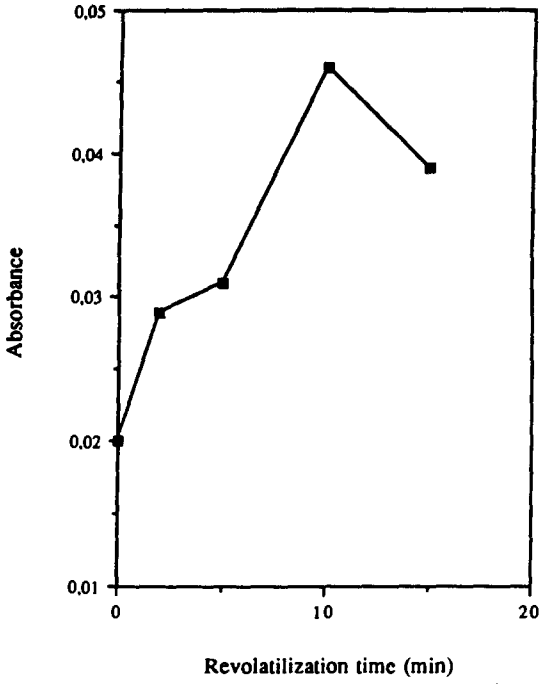

Fig. 2. Variation of absorbance with revolatilization time.

An exhaustive study was also performed of the time necessary for volatiles revolatilization at room temperature from the nitrogen trap; Fig. 2 shows peak height variation with this time (from 0 to 15 min). Other assays were performed by heating the U-tube after this time, but no improvements in the analytical signal were observed.

Sulphuric and perchloric acids at various concentrations were used both to achieve optimum acidity of the medium and to obtain quantitative generation of $H_2S$ and $SO_2$. These acids were selected because they are used for batch generation of $H_2S$ and $SO_2$, respectively. A first comparison for both acids in a 50% (v/v) solution, indicated better results by using 50% $H_2SO_4$; the reason was, perhaps, the high temperature of the acid solution that favours the volatilization of $H_2S$ and $SO_2$. In a second series of assays, the absorbance values obtained using different concentrations of sulphuric acid indicated that concentrated acid gives much higher results than any other acid concentra-

Table 3
Optimization of analyte flow/acid flow ratio

| Analyte flow (ml/min) | Acid flow (ml/min) | $H_2S$ signal | $SO_2$ signal | Analyte/acid |
|---|---|---|---|---|
| 50 | 2 | 0.022 | 0.027 | 24:1 |
| 50 | 6 | 0.021 | 0.035 | 8:1 |
| 50 | 12 | 0.023 | 0.048 | 4:1 |

tion, which confirms the positive heating effect obtained with this acid.

Another optimized chemical parameter was the acid flow/analytes flow ratio. Ratios ranging from 24:1 and 4:1 did not produce variations in absorbance for $H_2S$, whereas the best results for $SO_2$ appeared when a 4:1 ratio or lower is used (Table 3). On the other hand, maintaining the 4:1 ratio and decreasing flow (acid flow = 3 ml/min and analyte flow = 12 ml/min, for example) gave a slight enhancement in signal (about 15%) but the analysis time increased.

The best conditions for the simultaneous determination of sulphide and sulphite by GP-MAS are given in Table 4.

### 3.2. Analytical characteristics

Under the compromise conditions found for $S^{2-}$ and $SO_3^{2-}$, individual calibration studies were performed by measuring the absorbance at the corresponding wavelengths of maximum absorbance (196 and 198 nm for $S^{2-}$ and $SO_3^{2-}$, respectively). The equations of the calibration graphs obtained by the method of least squares were:

$$Y = 1.46 \times 10^{-3} + 5.03 \times 10^{-2}[S^{2-}] \qquad r = 0.998$$

$$Y = 1.65 \times 10^{-3} + 1.57 \times 10^{-2}[SO_3^{2-}] \qquad r = 0.998$$

A linear response from 0.05 μg/ml to at least 5 μg/ml for sulphide and from 0.2 μg/ml to at least 20 μg/ml for sulphite was obtained; reproducibility values (expressed as RSD) were 2.9% (for 0.2 μg/ml $S^{2-}$) and 3.1% (for 0.8 μg/ml $SO_3^{2-}$). Detection limits calculated from a signal three times the height of the background of the blank measurement were 0.05 μg/ml for sulphide and 0.2 μg/ml for sulphite.

In conclusion, the sensitivity of this method (expressed as specific absorptivity, in ml $\mu g^{-1}$ $cm^{-1}$) is 10 times higher than we obtained by batch model [21]. With regards to the results obtained by other authors, it is very difficult to make comparisons; as we have used a 1 cm optical path length cell while other authors have used larger cells (normally, 15 cm optical path length). Using specific absorptivity as the comparison parameter, the values obtained by this method are about 15 times higher than obtained by other authors [22].

### 3.3. Simultaneous determination

In this work several mathematical procedures for the resolution of three synthetic samples of sulphite and sulphide have been tested, involving different versions of the two-wavelength method and multiwavelength methods.

### 3.4. Two-wavelength methods

In these methods, absorbance is measured at two appropriate wavelengths; the concentrations of both components were determined by resolving the following equations system:

$$\mathrm{Abs}_{(\lambda 1)} = a_{(\lambda 1)^{\bullet}}^{\mathrm{Sulphide}}[S^{2-}] + a_{(\lambda 1)^{\bullet}}^{\mathrm{Sulphite}}[SO_3^{2-}] - \mathrm{Abs}_{(\lambda 1)}^{\mathrm{blak}}$$

$$\mathrm{Abs}_{(\lambda 2)} = a_{(\lambda 2)^{\bullet}}^{\mathrm{Sulphide}}[S^{2-}] + a_{(\lambda 2)^{\bullet}}^{\mathrm{Sulphite}}[SO_3^{2-}] - \mathrm{Abs}_{(\lambda 2)}^{\mathrm{blak}} \qquad (1)$$

where $\mathrm{Abs}_{(\lambda 1)}$ and $\mathrm{Abs}_{(\lambda 2)}$ are the absorbance

Table 6

| 210–220 | 0.51 | 1.6 | 0.93 | 17.3 | 2.1 | 1.7 |
| 212–220 | 0.53 | 1.6 | 0.80 | 16.8 | 1.9 | 2.5 |

of the mixture at each of the two wavelengths; $a_{(\lambda 1)}^{\text{Sulphite}}$, $a_{(\lambda 1)}^{\text{Sulphide}}$, $a_{(\lambda 2)}^{\text{Sulphite}}$, $a_{(\lambda 2)}^{\text{Sulphite}}$, $a_{(\lambda 2)}^{\text{Sulphide}}$ are the specific absorptivity (slope of calibration graph) of the individual compounds at the wavelength specified. The selection of $\lambda_1$ and $\lambda_2$ were performed on the basis of two analytical parameters as follows.

(i) Optimum sensitivity. This is the more used criteria for wavelength selection and corresponds to the maximum absorbance value of each of the two volatiles, i.e. 196 and 198 nm.

(ii) Optimum precision. The two wavelengths were calculated by applying a procedure described by DiTusa et al. [23], resulting in 196 and 212 nm for this case.

By using both methods, the results were very unsatisfactory (negative concentration values were obtained in some cases), so new alternatives were tested.

(i) Wavelength average. In this method each of the absorbance values is obtained as the average of the absorbance at three close wavelengths; firstly, the average at 192, 196 and 200 nm and secondly the average at 194, 198 and 202 nm. By this method the wavelength inaccuracy of the spectrophotometer is partially avoided.

(ii) Time average. As has been indicated above, we obtained a sequence of 50 spectra in each measurement and we used the maximum absorbance spectrum for obtaining the absorbance values at the selected wavelength. In many cases the maximum absorbance values spectrum appears close to other spectra of a similar area. This method, therefore, uses the average absorbance values at similar times (taking the two spectra before the maximum and the two after the maximum), in order to correct the time inaccuracy.

(iii) Wavelength and time averages. This method is a combination of the previous two.

The results obtained using these alternatives were unsatisfactory too, so multiwavelength methods were applied.

### 3.5. *Multiwavelength methods*

In this method absorbance values obtained in a wavelength range is employed. Blanco et al. [24] demonstrated that the best results in the resolution of mixtures of species with overlapped spectra are obtained when the widest possible wavelength range is used. Such a range was 190–220 nm throughout this work. Two different methods has been tested:

(i) Multiwavelength Linear Regression Analysis (MLRA), proposed by Blanco et al. [25]. Table 5 shows the results obtained. Concentrations found agreed reasonably with known values. This method was also applied after performing a time average of absorbance values, but no better results were observed.

(ii) Complete Multiwavelength Method (CMM). This method basically consists of solving a set of equations similar to Eq. (1); the number of the equations is selected empirically but normally corresponds [24] to the wavelength range in which a higher overlapping of the spectra is observed. In order to solve the equations, mathematical program (Eureka®)

using an iterative procedure was employed. Different wavelength intervals were assessed and the best results were obtained using all wavelengths between 190 and 220 nm (which means a set of 16 equations, because the spectral bandwidth of the spectrophotometer is 2 nm). The results obtained for several ranges are shown in Table 6. All results are the average of three determinations and the RSD values were, in all cases, lower than 4%. The time average of the absorbance values did not give better results either.

It can be concluded that two-wavelength methods produce imprecise and inaccurate results; using either MLRA or CMM the results are satisfactory.

## 4. Conclusions

This procedure shows some advantages against previous GPMAS determination, such as higher sensitivity and the possibility of using the whole molecular absorption spectrum, allowing better reproducibility and accuracy in the results. Also it is possible to forecast the spectral interferences present. As opposed to other methods, sensitivity values are similar, neither complex nor specific instrumental is required and it is easy to apply.

**Abstract**

A simple, rapid and economic method has been developed for the reduction of potassium permanganate in alkaline carbonate uranium leach liquors to a colourless solution. The pink colour of permanganate, if not reduced, seriously impedes the determination of carbonate, bicarbonate and phosphate by titrimetry and spectrophotometry. Out of 17 reductants investigated, commercial sugar has been found to be the most effective, rapid, simple and interference free for further estimations. To the best of the authors' knowledge, this is the first time that sugar as a reductant has been made use of in analytical investigations.

## 1. Introduction

Tetravalent uranium present in primary and secondary uranium ores does not dissolve in sulphuric acid or carbonate solution at discernible rates, and requires the addition of an oxidant for its oxidation to the hexavalent state. Potassium permanganate is an effective oxidant and hence accepted as an additive in alkaline carbonate leaching for uranium [1]. Because hydroxyl ions are formed during carbonate leaching, it is imperative also to add bicarbonate to prevent the precipitation of leached uranium by providing the required amount of hydrogen ions. The potassium permanganate added imparts a pink colour to the uranium leach liquors, thus vitiating the methods of estimation of carbonate and bicarbonate by titration and phosphate by spectrophotometry. The determination of these three anions in alkaline uranium leach liquors is of immense use for the economic exploitation of leaching procedures, and hence investigations were carried out to overcome the interference of the pink colour of the permanganate in the estimation procedures. These experiments were carried out on uranium leach liquors of phosphatic siliceous calcite-dolostone samples from Cuddapah Basin, Andhra Pradesh, India. The results are presented in this paper.

## 2. Experimental

### 2.1. Reagents

20% sugar solution is prepared by dissolving 20 g of commercial sugar in water and making up to 100 ml. The solution is filtered through Whatman No. 40 filter paper. Fresh solution is prepared every day as the sugar solution develops bacterial growth due to fermentation on standing, making it unsuitable for pipetting. All other chemicals used are of Analar quality.

### 2.2. Instrumentation

A Shimadzu UV-240 model double beam spectrophotometer was used for the absorption measurements.

### 2.3. Procedure

A 50.0 ml aliquot of the carbonate leach liquor of uranium containing potassium permanganate as an oxidant is taken in a 100 ml beaker. Freshly prepared 20% sugar solution (10.0 ml) is added and stirred with a glass rod. The permanganate in the liquor is reduced to $MnO_2xH_2O$ and the precipitate settles to the bottom within 30 min, leaving a clear, colourless supernatant liquid. Three aliquots, 10.0 ml each of the supernatant solution, are taken into three separate breakers for analysis. From the first two beakers, carbonate and bicarbonate are determined by titration with standard HCl solution [2], using phenolphthalein and bromocresol green as indicators. In the third aliquot, phosphate is determined spectrophotometrically using a vanadomolybdo reagent [3]. A 10.0 ml aliquot of the 20% sugar solution is taken as a blank for each determination.

## 3. Results and discussion

Because of the presence of dolomitic limestone in Cuddapah basin samples only carbonate leaching for uranium extraction is to be adopted, as the acid consumption in acid leaching is very high. Under alkaline carbonate leaching parameters, uranium present in association with phosphates and Fe–Ti mineral complexes is not solubilised [4]. Potassium permanganate is one of the oxidants studied for oxidising tetravalent uranium to the hexavalent state. As little as 0.01 ml of 0.02 M permanganate imparts a pale pink colour to 100 ml of water [2], so it has to be decolourised to avoid interferences in the determination of carbonate, bicarbonate and phosphate. 17 reductants were tried to reduce the pink coloured permanganate ion either to the colourless manganous ion or to the precipitation of manganese dioxide. All reductants studied are able to decolourise the alkaline leach liquor, but each reductant except sugar has its own advantages and disadvantages for uniform applicability.

Sodium chloride or hydrochloric acid decolourises the leach liquors only on heating, whereas hydroxylamine hydrochloride and stannous chloride reduce even in cold conditions. The resulting solution can be used for phosphate estimation only, but carbonate and bicarbonate cannot be estimated quantitatively. Sodium thiosulphate and hydrogen sulphide decolourise, but the resulting solution is very turbid and hence not useful for further estimations. Sodium sulphate and sulphurous acid also reduce permanganate. Although there is no interference for the phosphate estimation, the same cannot be assumed for other estimations. In the presence of potassium iodide the liberated iodine imparts an unwanted brown colour to the solution rendering it useless for further estimations. When ferrous iron is used for reduction, the iron precipitates and interferes in all the estimations.

Ethyl alchohol or ascorbic acid also give colourless solutions; they not only give turbidity to the leach liquors, but also reduce the molybdovanadate reagent used for phosphate estimation. If hydrogen peroxide is used, the excess should be boiled off. Oxalic acid reduces only on heating, disturbing the carbonate/bicarbonate system. The reducing effect of activated charcoal on permanganate is very slow and also leads to inaccurate values for carbonate and bicarbonate.

The fact that permanganate is inherently unstable in the presence of manganese(II) ions, particularly in an alkaline medium [2], has been made use of for decolourisation. In the result-

ing solution, phosphate can be determined; however, the carbonate and bicarbonate values are not accurate.

Although sucrose, the commercial sugar is a non-reducing sugar [5], as far as the reduction of Fehling solution is concerned, because of the linkage of the aldehyde group of the glucose part with the ketonic group of the fructose part, its addition to the pink coloured alkaline leach liquors causes the reduction of $Mn^{7+}$ to $MnO_2xH_2O$. This may be due either to the presence of monosaccharide (glucose/fructose) which is a reducing sugar or to the high redox potential of the permanganate [5]. In the supernatant solution of leach liquors after decolourisation by the addition of sugar solution, phosphate is determined by the molybdovenadate method [3], and carbonate and bicarbonate are determined by titration with standard HCl [2] using phenolphthalein and bromocresol green as indicators without any interference. Glucose also reduces the pink colour of permanganate. However, in the case of pure glucose, the only advantage is that the reduction takes place within 10–15 min as opposed to the 30 min necessary for commercial sugar. However, this time factor is outweighed by the cost of glucose with respect to commercial sugar, to provide an economic method.

Percentage recovery values calculated by adding known amounts of phosphate, carbonate and bicarbonate and determined by the present procedure are given in Table 1. The recovery values obtained vary from 93 to 101%. The values of phosphate, carbonate and bicarbonate in some alkaline permanganate leach liquors of uranium after decolourisation with sugar solution are presented in Table 2. The values of carbonate and bicarbonate obtained by pH titration with a pH meter [2] and phosphate values obtained by a plasma emission technique [6] are also presented in this table. The values are in fairly good agreement, reflecting the accuracy of the method.

## 4. Conclusion

The pros and cons of various reagents for the reduction of permanganate show that sucrose is the best reductant to obtain a clear and colourless solution for the estimation of carbonate and bicarbonate by titrimetric, and phosphate by absorptiometric methods without any interference. The advantages of this procedure are simplicity, rapidity, economy, and freedom from interference to give uniform applicability.

## Acknowledgements

The authors are thankful to Sri.KK. Dwivedy, Director, AMD and to Sri.M. Vasudeva Rao for permission to publish the paper, and for encouragement. The inspiration in the form of continuous guidance from Sri.K.P. Cheria is gratefully acknowledged. The authors are also thankful to R. Anupama for her technical assistance.

# Determination of total selenium content in sediments and natural water by graphite furnace-atomic absorption spectroscopy after collection as a selenium(IV) complex on activated carbon

Toshio Kubota *, Kazuhiro Suzuki, Tadao Okutani

*College of Science and Technology, Nihon University, 1-8-14, Kanda-Surugadai, Chiyoda-ku, Tokyo, 101 Japan*

Received 31 May 1994; revised 23 January 1995; accepted 24 January 1995

**Abstract**

A trace level of Se was collected on activated carbon (AC) as the Se(IV)-3-phenyl-5-mercapto-1,3,4-thiadiazole-2(3*H*)-thione (Bismuthiol II) complex. The AC was directly introduced as an AC-suspension into the graphite tube atomizer and the Se concentration was determined by atomic absorption spectroscopy (T. Okutani, T. Kubota, N. Sugiyama and Y. Turuta, Nippon Kagaku Kaishi, (1991) 375). The amount of Se in heavily contaminated samples including sediment, lake water and seawater was determined using this method. The sediments were digested with $HNO_3$–$HClO_4$–HF and the interference from $AlF_3$ was removed using $H_3BO_3$–$HClO_4$. Lake water and seawater were acidified with $H_2SO_4$ and digested with $KMnO_4$. The Se concentrations of these samples were determined by this method with satisfactory results.

The above method is simple, rapid and applicable to heavily contaminated samples.

## 1. Introduction

Se is an essential trace nutrient, and Se deficiency diseases are known in veterinary medicine, but the ingestion of greater than trace levels of Se is toxic to animals and humans.

Se and Se compounds are listed as the Basel convention on the control of transboundary movements of hazardous waste and their disposal [1].

Therefore, the determination of Se in the environment has become important. Se has been determined by atomic absorption spectroscopy (AAS), ICP atomic emission, fluorometry, etc. Hydride generation/electrothermal AAS [2] and fluorometry with 2,3-diamino naphthalene [3,4] are the most sensitive techniques, and currently applicable to environmental samples. However, the former is subject to interferences from coexisting ions, while the latter has a large blank absorption which makes it necessary to remove coexisting materials, so HPLC has to be used.

The authors reported a method [5] in which the activated carbon (AC) collected Se(IV)-3-phenyl-5-mercapto-1,3,4-thiadiazole-2(3*H*)-thione (Bismuthiol II) complex was directly introduced as an AC-suspension into the graphite furnace (GF) for AAS. This method is simple, rapid and relatively free from interferences caused by coexisting ions. Therefore, it was applied to heavily contaminated samples such as sediments, seawater and lake water.

Sediments contain large amounts of Al, Fe, Si and organic matter. The digestion of the sediment to determine the concentration of volatile elements such as Se is very difficult. Se

values in the sediment (NIST, SRM-1645) reported so far are in the 0.85–24 μg $g^{-1}$ [6]. This is mainly caused by differences in the digestion methods. Therefore, the authors renewed their investigation into the digestion methods. From the results, the sediments were digested with $HNO_3$–$HClO_4$–HF, and the interferences from $AlF_3$ were removed using $H_3BO_3$–$HClO_4$. The sediments could be digested in a shorter time without Se volatilization using this method.

In natural water, Se exists as organic and inorganic forms. It has been pointed out that when Se is determined as the Se(IV) organic derivative and the organic compounds do not completely digest, the interference from the organic compounds will remain [7]. Therefore, preparation of natural water was investigated. From the results, natural water was acidified with $H_2SO_4$ and prepared by heat treatment after adding $KMnO_4$. Seawater and lake water could be completely prepared using this method.

These preparations were applied to the environmental samples, and Se content was then determined by the reported method with satisfactory results.

## 2. Experimental

### 2.1. Apparatus

A Seiko Model SAS 727 atomic absorption spectrometer equipped with a Model SAS 705V GF atomizer, a Se hollow-cathode lamp and a deuterium background corrector (BGC – $d_2$) was used. The optimum operating conditions are listed in Table 1. Ultrasonic cleaner Model B2200 (Bransonic) and aluminum dry block bath Model AL1000 (Scinics) were used.

### 2.2. Reagents

The standard Se(IV) solution was prepared by dilution of a 1000 μg $ml^{-1}$ atomic absorption standard (Wako Pure Chemicals Co., Ltd.) with 0.1 M HCl. The standard Se(VI) solution was prepared by dissolution of $Na_2SeO_4$ (Soekawa Rika Co., Ltd.), and diluted with water. Pd solution (2000 μg-Pd $ml^{-1}$) was prepared by dissolution of 1 g $PdCl_2$ in 300 ml 1 M HCl. 2-Amino-4-(methylseleno) butanoic acid (Se-methionine) (Sigma) and 3-phenyl-5-mercapto-1,3,4-thiadiazole-2(3*H*)-thione (Bismuthiol II) (Dojindo Laboratories) were used without further purification. AC (Merck No. 2186, <300 Tyler mesh) was soaked in 3 M HCl for 1 day, and washed with deionized water until it was neutral, then dried at 120 °C for 2 h. All other reagents were of analytical grade.

### 2.3. Preconcentration and determination [5]

A sample solution (100–1000 ml) containing less than 0.5 μg of Se(IV) was put in a beaker. The solution was adjusted to 1.5 M HCl by the addition of conc. HCl followed 5 ml of 0.1% Bismuthiol II solution, and the solution was then stirred for 5 min to form the complex. 50 mg of AC was added and stirred for 5 min for collection of the complex. The AC was separated from the aqueous phase through a membrane filter (8 μm pore size) (Filtration B), and the AC phase on the filter was then dispersed in 5 ml of water (containing 0.5 ml of 2000 μg-Pd $ml^{-1}$ solution) using an ultrasonic cleaner for 30 s (AC-suspension). 10 μl of magnetically stirred AC-suspension was pipetted into the graphite furnace. The peak height was measured under the conditions shown in Table 1.

### 2.4. Digestion of sediment [8]

A dried sample (0.1–0.2 g, containing less than 0.5 μg-Se) was put in a 50 ml Teflon beaker, followed by addition of 4 ml of $HNO_3$, 3 ml of $HClO_4$ and 5 ml of HF. The solution was allowed to stand for 30 min to avoid any loss of the volatile Se compound. The beaker was capped with a Teflon lid and then heated on a dry block bath at 165 °C until 2–3 ml of the volume remained in the draft chamber equipped with a hand-made air filter to avoid contamination. If the digestion was incomplete and the final solution was not clear yellow, the acid mixture was added and heated again. After the solution was cooled, 4 ml of 4% $H_3BO_3$ solution and 0.5 ml of $HClO_4$ were added, and the solution was heated at 165 °C until approximately 2 ml of volume remained. The residual solution was diluted to 100 ml with water, and then filtered using a membrane filter.

### 2.5. Preparation of natural water

A sample of water (100–1000 ml) containing less than 0.5 μg of Se was put into a digestion vial. 100 ml of 4.5 M $H_2SO_4$ and 20 ml of 5% $KMnO_4$ solution were added per 100 ml of sample volume. The mixture was heated at 110 °C for 1 h in an oil bath. After cooling, the vial was opened. A few drops of 10% $NH_2OH$–HCl solution was added until residual $MnO_2$ was dissolved. In order to reduce Se(VI) to Se(IV), the sample water was adjusted to 1.5 M HCl using conc. HCl, and 4.5 g of KBr was added per 100 ml of sample volume. The mixture was heated at 90 °C in a water bath for 30 min [5]. If the solution was colored, a small amount of $NaHSO_3$ was added until it was colorless. This solution was employed for the determination of Se concentration.

## 3. Results and discussion

### 3.1. Matrix modifier

In the reported method [5], 10 μl of Rh solution (500 μg-Rh $ml^{-1}$) was injected into the GF as a modifier. The GF was heated to dryness, and then 10 μl of the AC-suspension was injected and GF-AAS performed. Using the established procedure, Se sensitivity was varied in relation to heating times of exposed GF. The matrix modifiers, $Rh(NO_3)_3$, $Ni(NO_3)_2$ and $PdCl_2$ were investigated using the AAS standard solution (1000 μg $ml^{-1}$). The data are shown in Table 2. The use of these modifiers shows an almost equal increase in sensitivity. However, the Ni and Rh solutions contained much Se, but the Pd solution contained very little, so the Pd solution was used for the matrix modifier of the Se determination. The absorbance of Se became almost constant by adding more than 200 μg $ml^{-1}$ of the Pd solution. The two methods for the addition of Pd solution were compared, i.e. the Pd solution and AC-suspension were separately injected into the GF. In contrast, a mixture of the Pd solution and AC-suspension was injected into the GF. In addition to this method, both sample suspensions were previously exposed to ultrasonic cleaning for 30 s. The latter method resulted in either an increase in sensitivity or an improvement in reproducibility.

### 3.2. Effect of foreign ions

In a previous paper [5], the effects of foreign ions were investigated. The digest of sediment should have a higher concentration of foreign ions. Therefore, the solution containing 0.25 μg of Se and foreign ions of equal weight included in 0.2 g of pond sediment (NIES No. 2) was digested and diluted to 100 ml. The solution was concentrated to 5 ml of AC-suspension, and Se content was determined by the proposed method [5]. Because the recovery of Se was 100 ± 10%, the presence of foreign ions was regarded as having no effect. From the results, the following had no effect:

Table 2
Comparison of the effects of Pd, Rh and Ni on Se sensitivity

| Metal amount (μg) | Peak height (mm) | |
|---|---|---|
| | Reagent blank | Se [a] |
| – | 6 [b] | – |
| Pd 5 | 6 | 44 |
| Rh 5 | 8 | 40 |
| Ni 5 | 26 | 41 |

Metal solution is injected into GF as a modifier, GF is heated to dryness, and then 0.2 ng Se is injected and GF is operated.
Metal solution used Pd: $PdCl_2$, Rh: $Rh(NO_3)_3$, Ni: $Ni(NO_3)_2$.
[a] Reagent blank is substracted.
[b] Background signal.

500 μg ml$^{-1}$ of Al(III), K(I) and $SiO_3^{2-}$; 2 μg ml$^{-1}$ of Zn(II); 1 μg ml$^{-1}$ of Cr(III), Cr(VI) and V(V); 0.2 μg ml$^{-1}$ of Co(II), Ni(II), Cd(II), $AsO_3^{3-}$ and $AsO_4^{3-}$.

### 3.3. Reduction of Se(VI) to Se(IV)

Se(VI) in prepared natural water was reduced to Se(IV) using the previously reported method [5]. However, in the case of the sediment, the sample volume after digestion was less than 2 ml, so Se(VI) was reduced using only HCl. We then referred to the report of Yamada et al. [4]. 2 ml of 6 M HCl was added to the digest. Se(VI) was then reduced to Se(IV) by heating in boiling water for 15 min. The solution was diluted to 100 ml (about pH 1) with water and filtered with a membrane filter (5 μm pore size), and the precipitate was removed. The filtrate was employed for the determination of Se. Using this method, standard Se(VI) solution was reduced and determined, and the value was in agreement with the equal concentration of the standard Se(IV) solution.

### 3.4. Digestion of sediments

#### $HNO_3$–$HClO_4$–HF digestion

In a previous paper [8], the sediments were completely digested in a short time using the $HNO_3$–$HClO_4$–HF mixture. The method was applied to the determination of Se in the sediment. The sediments were digested in the same manner when reconstituted digest was evaporated to dryness. 2 ml of 6 M HCl was then added to the residue, and the Se(VI) was reduced by heating and then diluted to 100 ml with water. The precipitate was removed by filtration with a membrane filter (Filtration A). Se in the filtrate was preconcentrated using Bismuthiol II and AC, and its concentration determined. Se values of the pond sediment (NIES No. 2) varied widely from 0.5 to 1.0 μg g$^{-1}$. Further, when the residue after evaporation to dryness became white, Filtration A was easily used and the white precipitate was obtained. When the residue (after evaporation to dryness) became black–brown, the precipitate was not obtained after Filtration A. Filtration B in the preconcentration process was difficult, and atomic absorption could not be measured because of a large molecular absorption. The causes of these phenomena were then investigated.

### 3.5. Interference from coexisting ions with the digestion

The influences of various ions in the sediment on $HNO_3$–$HClO_4$–HF digestion and preconcentration were investigated. A 1% solution of each of $SiO_3^{2-}$, Al(III) and Fe(III) was prepared, and the same quantity of each ion contained in 0.2 g of the standard pond sediment (NIES No. 2) was put in separate Teflon beakers. Se(IV) solution (containing 0.1 μg of Se) and 3 ml of mixed acid ($HNO_3$:$HClO_4$:HF = 4:3:5) were added. The digestion, preconcentration and determination were then normally run. From the results, $SiO_3^{2-}$ and Fe(III) did not entirely interfere with these processes. However, Al(III) interfered with the filtration during the digestion process, and Filtration A became very difficult. Further, when the digestion was incomplete, the atomic absorption of Se could not be measured because of the large molecular absorption, even if BGC-$d_2$ was used. These phenomena were the same as during the digestion of sediment. A small amount of the white precipitate obtained from Filtration A was then injected into the GF, and GF-AAS was performed. A large degree of molecular absorption was observed, and atomic absorption due to Se could not be determined.

Therefore, the chemical binding energy and crystal structure of the white precipitates were investigated using X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD). The observed binding energy and the peak strength ratio of Al to F in the white precipitate nearly agreed with those of the reagent $AlF_3$. XRD spectra of the white precipitate agreed with $AlF_3$ spectra from the powder diffraction file No. 31-0011 [9], but unknown spectra still partly remained. The white precipitate was mainly made up of $AlF_3$.

$AlF_3$ formed by the reaction of Al(III) and HF does not dissolve in water, but forms a stable hydrate [10]. If $AlF_3$ is not formed, the interferences with preconcentration and determination processes should not occur. Therefore, the method to prevent formation of $AlF_3$ was investigated. Yamada et al. [4] reported that HF could be masked using $H_3BO_3$. If HF is masked, $AlF_3$ should not be formed.

In contrast, the Se values determined by this method varied widely. This is how Se was thought to volatilize through a process of evaporation to dryness.

Table 3
Analytical results of selenium in sediments

| Sample | Found value ($\mu g\ g^{-1}$) | | Reported value ($\mu g\ g^{-1}$) |
|---|---|---|---|
| | Standard addition method | Calibration curve method | |
| NIES No. 2 Pond sediment | 0.92 | $0.95 \pm 0.04$ [a] ($n = 11$) | $0.73 \pm 0.06$ [4] 0.50 [11]0.576 [11] |
| NIST SRM 1646 Estuarine sediment | 0.68 | $0.68 \pm 0.03$ [a] ($n = 7$) | 0.43 [6], 0.58 [6], 0.59 [6] $0.61 \pm 0.018$ [12] |

[a] Average and standard deviation.

Table 4
Preparation of artificial water samples

| Method | Reagents | Preparation procedure | Recovery (%) |
|---|---|---|---|
| A | $K_2S_2O_7$ (0.8 g) | 30 min at 120 °C in pressure cooker | 80 |
| B | $KMnO_4$ (0.08% 20 ml) $H_2SO_4$(6 M 20 ml) | In boiling water for 30 min | 83 |
| C | $H_2O_2$(30% 8 ml) NaOH (1 M 4 ml) | Boil until fine bubbles subside | 101 |
| D | $KMnO_4$ (5% 20 ml) $H_2SO_4$ (4.5 M 100 ml) | 60 min at 110 °C | 100 |

Sample water is spiked with Se-methionine (0.25 μg Se) in pure water (100 ml).

In order to improve these results, new procedures were investigated. During the digestion process, the digest did not evaporate to dryness, but evaporation stopped with 2–3 ml remaining. After the residue was cooled, 4 ml of 4% $H_3BO_3$ solution and 0.5 ml of $HClO_4$ were added, and the solution was heated (at 165 °C) until approximately 2 ml remained. 2 ml of 6 M HCl was then added to the residue, and heated for 15 min in boiling water, reducing Se(VI) to Se(IV). Using the Al(III) solution, Al(III), Fe(III) and $SiO_3^{2-}$ mixed solution containing 0.1 μg of Se, this procedure was investigated. From these experiments, Filtration A in the digestion process, and Filtration B in the preconcentration process were easily operated for a short time. Se in these solutions was quantitatively recovered.

### 3.6. Determination of total selenium in sediments

The proposed method was applied to the determination of total Se in the sediments. The results obtained are listed in Table 3. In both samples, the standard addition curves are parallel to the calibration curve. The values from both determinations agree well, and the relative standard deviation is 4–5%. However, Se values obtained from both samples are larger than the other values already reported [4,6,11,12]. It seems that the NIES and NIST sediments could be digested without Se volatilization by the proposed method.

### 3.7. Preparation of natural water

Preparation procedures were investigated using the sample water, which was prepared by the addition of Se-methionine to deionized water and natural water.

Deionized water spiked with Se-methionine was used to investigate various digestion methods. The results are shown in Table 4. Tested digestion methods are (A) persulfate digestion for total phosphorus determination [13], (B) permanganate digestion for chemical oxygen demand determination [13], (C) alkaline hydrogen peroxide digestion [14], (D) permanganate digestion [14]. Methods C and D completely decomposed Se-methionine into Se(IV).

The lake water spiked with Se-methionine was also examined using methods C and D. The results are shown in Table 5. Only method

Table 5
Preparation of natural water

| Method | Reagents | Preparation procedure | Recovery (%) |
|---|---|---|---|
| C | $H_2O_2$ (30% 8 ml)<br>NaOH (1 M 4 ml) | Boil until fine bubbles subside | 8 |
| D | $KMnO_4$ (5% 20 ml)<br>$H_2SO_4$ (4.5 M 100 ml) | 60 min at 110 °C | 100 |

Lake water is filtered through a 0.45 μm pore size membrane filter.
Sample water is spiked with Se-methionine (0.25 μg Se) in 100 ml of natural water.

Table 6
Analytical results of selenium in natural water

| Sample | Filterable ($\mu g\,l^{-1}$) | | Non-filterable ($\mu g\,l^{-1}$) [b] |
|---|---|---|---|
| | Standard addition method | Calibration curve method | Calibration curve method |
| Lake water (Lake-Inba in Chiba) [c] | 0.15 | $0.15 \pm 0.01$ [a] ($n = 6$) | 0.043 ($n = 2$) |
| Sea water (Ichikawa coast of Tokyo bay) [d] | 0.19 | $0.18 \pm 0.01$ [a] ($n = 6$) | 0.036 ($n = 2$) |

[a] Average and standard deviation.
[b] Se contents of non-filterable compound in 1 l of sample volume.
[c] Sample taken 26 August 1993.
[d] Sample taken 2 September 1993.

D completely decomposes Se-methionine. Therefore, in subsequent experiments, method D was adopted.

### *3.8. Determination of total selenium in natural water*

The method was applied to heavily contaminated natural water. The sample water was first filtered using a membrane filter (0.45 μm pore size), and then the filtrate was prepared by the proposed method and total Se was determined. The non-filterable compound was digested by the same method with the sediment.

The results are shown in Table 6. The standard addition curves of both samples are parallel to the calibration curve. Total Se values of the filtrate agree well with the standard addition method and the calibration curve method. Non-filterable Se values are indicated per sample volume, and are 20–30% of the filterable Se value.

# Transport of iron halides through polyurethane ether-type membranes

R.D. Oleschuk, A. Chow *

*Department of Chemistry, University of Manitoba, Winnipeg, Man. R3T 2N2, Canada*

Received 19 September 1994; revised 23 January 1995; accepted 25 January 1995

**Abstract**

The transport of iron(III) using polyether-based polyurethane membranes was studied. The rate at which iron passes through the membrane depends on the formation of the $HFeX_4$ species, which is related to the initial acid and salt concentration of the metal solution. Iron is quantitatively transported from a cell of high acid-halide concentration to one with low concentration.

## 1. Introduction

The isolation of selected metals from solution has been a problem in industry and for analysis. In sample preparation and in actual analysis, separation is an important aspect of analytical chemistry, and in most cases the separations are neither quick nor quantitative. When measurement techniques are used to determine a species or compound in a sample, interferences from extraneous substances in that sample can cause significant problems. Thus, the removal of interferences or the isolation of the analytical species is of considerable importance. In industry, separations are needed to produce purer materials and cleaner effluents. In many instances, quantitative separations are not needed or are not possible; in others, speed is not a major factor.

Membranes used for separations are barriers separating two phases that are permeable and often selective towards a particular species present in one of the phases. Several materials have been used as membranes, ranging from bi-layers that surround living cells to thin semi-permeable polymeric barriers. Ideally, analytical membranes would provide quantitative separation of a permeating species, but in most cases they provide partial enrichment of one of the phases. The term "membrane" in polyurethane chemistry has been applied to two separate solid physical forms: non-porous polymer film membranes, as used in this investigation, and those which are porous, made of polyurethane foam that allows solutions to percoalate through the membrane. The non-porous membranes, although providing a lower surface area, separate the two solutions and prevent them from mixing.

Polyurethane foams (PUFs) were first shown by Bowen [1] to act as selective absorbents for a number of substances from aqueous media. The mechanism by which the sorption occurs has been investigated by several authors. The first to emerge was the solvent extraction mechanism [1], which showed that compounds extracted by ether-based polyurethane foams were analogous to those extracted by diethyl ether. From this, it was proposed that polyurethane foams could be used as solid substitutes for diethyl ether [2,3]. An ion-exchange mechanism was later suggested, where sorption was explained by the interaction of ions and the weak or strong anion exchange sites of PUF.

* Corresponding author. Fax: (204)275-0905.

*SSDI* 0039-9140(95)01537-X

The third mechanism, the cation chelation [4] mechanism, explained that sorption was due to the helical structure of the polyether-type PUF that possesses a receptive site for extraction. Each site forms a cage with a metal complex possessing the appropriate cation to "fit" the cage. The order of extraction of complexes with differing cations was found to be ($Li^+ < Na^+ < Cs^+ < K^+$), which is similar to the cyclic polyether dicyclohexyl-18-crown-6. The mechanism and many uses of polyurethane sorption have been reviewed by several authors [5–8].

It has previously been shown that some iron and gallium chloride complexes [9] and cobalt thiocyanate [10] complexes can be extracted and transported through polyurethane membranes, demonstrating their possible use for metal separations. The extent of the metal halide complex formation depends on the stability constants of the individual complex and the concentration of the halide present. These properties control the proportion of metal halide complex present and therefore can probably be used to facilitate the selective transport and separation of metals. In this paper, iron is used as a probe into the nature and mechanism of the separation because of its well-known propensity to form $HMX_4$ complexes. The effects of varying concentrations of different acids and halides on the transport of the metal through the membrane were investigated. As well as the effects of different salts, temperatures and membrane thicknesses were studied. Previous publications [9,10] describing the use of polyurethane membranes have shown promising results for possible separation of metal mixtures. The present investigation of iron transport through the membrane was undertaken to obtain a better understanding of the transport process essential to establishing the potential of this process.

## 2. Experimental

### 2.1. Apparatus and reagents

All iron analyses were performed with a Varian SpectrAA-20 atomic absorption spectrometer equipped with a Cathodeon hollow cathode lamp and a Varian Mark VI burner head coupled with an air–acetylene flame. The wavelength observed was 248.3 mm with a slit width of 0.2 nm, and the lamp current was set at 6 mA. All chemicals used were of reagent grade. Stock iron solutions were prepared using ferric nitrate supplied by Fisher Scientific. Hydrochloric and hydriodic acids were supplied by Mallinckrodt, and hydrobromic acid by Fisher Scientific. All water used was purified by a Barnsted Nanopure™ II system using reverse osmosis-treated feeedstock. The membranes used were of the polyurethane ether type (XPR-625-FS) in two different thicknesses (0.025 mm and 0.050 mm) and were provided by Stevens Elastomerics/Urethane Products Northhampton, MA.

The apparatus used for membrane testing consisted of two separate cells (a starting and receiving cell). The starting cell was a Nalgene 125 ml PETG (polyethylene terephthalate copolyester) media bottle (cat # 2015–0125) with a 2 cm diameter hole drilled into the screw cap. A small notch was also cut at the side of the drilled hole to prevent air bubbles from being trapped along the membrane surface. The receiving cell consisted of a 100 ml beaker, cut to an appropriate height to allow a smaller volume of receiving solution to be used. Media bottles are very well suited for the starting cells because they enable a quick easy way of fastening the membrane to the bottle with an air and water tight seal. For units to be run at elevated temperatures, a small hole was drilled into the edge of this starting cell to prevent any pressure build-up. Membranes were cut into 5 cm × 5 cm squares and placed on top of the open media bottle holding a sample. The cap was placed on the bottle and carefully tightened, yielding a membrane with an active surface area of 5.3 $cm^2$. The media bottle was then inverted and immersed in the solution held by the receiving cell, and the air bubbles removed through the notch with the membrane separating the two solutions. Each unit was then wrapped in Parafilm™ to prevent evaporation of the solution. At elevated temperatures Parafilm softened and melted, and instead a plastic wrap, Resinite by Borden Chemical, was substituted. For each experiment a number of units were prepared and then stopped after various times during the experiment to obtain a separation profile and establish reproducibility. After the cells were stopped by removing the starting flask from the receiving cell, each cell was individually weighed to determine any solution losses due to either evaporation or leakage through the membrane. The volume of solution was calculated using the solution den-

Table 1
Percentage of Iron in the $FeCl_4^-$ complex at various HCl concentrations and time required for quantitative transport

| HCl concentration (M) | % Fe in the $FeCl_4^-$ complex | Time required for quantitative transport (h) |
|---|---|---|
| 9.0 | 53.4 | 4 |
| 7.0 | 25.8 | 7.5 |
| 5.0 | 7.7 | 48 |
| 3.0 | 1.0 | – |
| 1.0 | 0.02 | – |
| 0.1 | $1.15 \times 10^{-5}$ | – |

sity. The final volumes in the top and bottom cell were close to the initial values for trial where no iron movement was observed. Where iron was transported, the volume changed only slightly unless the membrane failed, and then significant leakage occurred.

All iron solutions were prepared from a 1000 mg $l^{-1}$ standard prepared by dissolving $Fe(NO_3)_3 \cdot 9H_2O$ in water in a 1000 ml volumetric flask.

## 3. Results and discussion

### 3.1. Effect of HCl concentration

The stability constants of iron(III) species with chloride ions in the aqueous phase can be represented as follows:

$$Fe^{3+} + nCl^- \rightleftharpoons FeCl_n^{3-n}$$

Using the iron chloride complex stability constants [11], the data in Table 1 were calculated. The chloride concentration was taken to be equal to the activity of the chloride ion. As the HCl concentration increases, the percentage of iron as the $HFeCl_4$ complex also increases. To study the effects of varying concentrations of HCl, and consequently varying proportions of the $HFeCl_4$ complex in solution on the separation, 15 mg $l^{-1}$ iron solutions were prepared with several HCl concentrations (0, 1.0, 3.0, 5.0, 7.0, 9.0 M).

A separation experiment was performed with each of the different acid solutions in the starting cell with all the receiving cells containing 0.1 M HCl. The 0.1 M HCl was needed to prevent hydrolysis of the iron once it had passed through the membrane. At concentrations of zero and 1.0 M HCl, no iron is transported from the starting to the receiving cell over the time that the experiment was run. With 3.0 M acid, only a small amount of iron was transported across the membrane. At HCl concentrations of 5.0 M and greater, it was found that the iron is quantitatively transported to the receiving cell, and a smooth separation profile is obtained where the transport rate increases with an increase in HCl concentration. This supports a previous suggestion [12] that the transport of iron through the polyurethane membrane is due to the $HFeCl_4$ complex. In Table 1 it is shown that for solutions containing less than 3.0 M HCl, less than 1% of the iron is in the $FeCl_4^-$ complex, and most of this is present as the extractable $HFeCl_4$ complex at these high acidities. At higher HCl concentrations, there are significant amounts of the $HFeCl_4$ present to facilitate transport across the membrane. With an increase in concentration of the species required for transport, we would expect to see an increase in the rate of transport as well. This should continue to occur if more of the $HFeCl_4$ complex is present, or until the membrane becomes saturated, at which point the rate of transport will have reached a maximum. This can be seen in the results; with each increase in HCl concentration there was a corresponding increase in the rate of transport as shown in Figs. (1a) and (1b), although no maximum was observed. The quantitative transport of iron to the receiving cell from 5.0 M HCl required 48 h, while only requiring 9 h when the HCl concentration was increased to 9.0 M. The acid concentrations of the starting and receiving cells were found to equalize when an equilibrium between them had eventually been established. This phenomenon was only apparent when concentrations of 5.0 M HCl or greater were used. The transparent membrane gradually became cloudy and translucent, and then white, opaque and "puckered". In the experiments run at room temperature over a period of 48 h, the physical changes did not appear to play a part in the separation.

(b) Receiving cell iron contents corresponding to each of the starting cell HCl concentrations in (a). Each receiving cell initially contained 30 ml of 0.1 M HCl.

### *3.2. Effect of other halo-acids*

Experiments using HBr and HI in place of HCl in both the starting (5.0 M) and receiving flasks (0.1 M) were performed. The use of HBr produced a five-fold increase in transport rate as compared to HCl. This phenomenon can be attributed to two possible factors: the $HFeBr_4$ complex may form more readily because of higher stability constants, and the complex is a weaker acid so it would be in higher concentration than the chloride analogue. The relative

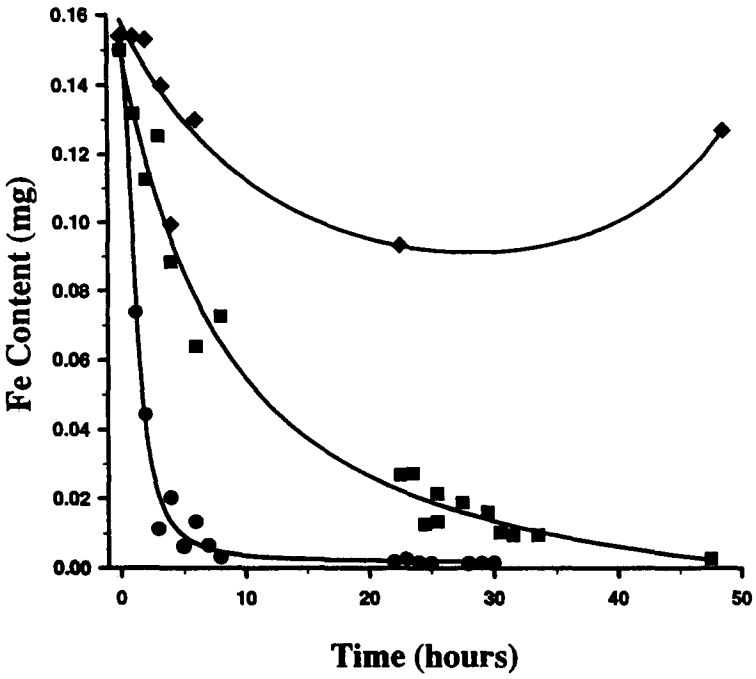

Fig. 2. Iron separation profile for starting cells containing 10 ml of 15 mg $l^{-1}$ iron with a concentration of 5.0 M HCl: ◆, hydriodic acid; ■, hydrochloric acid; ●, hydrobromic acid.

strength of the complexes is determined by respective ionic sizes and electronegativities. In the early stages of the separation using hydriodic acid, no iron is transported through the membrane. After 3 h the membrane becomes porous, so that iron and acid solution can pass through it. Because it does not form a tetrahedral complex in the presence of iodide ions, iron is not transported through the membrane. The results of the separations performed using the different halo-acids are presented in Fig. 2.

It is important to note that when HCl and HBr were used the iron was quantitatively (>98%) transported from the starting to the receiving cell, and then remained in the receiving cell. Also, the phenomena occurring in our case is not diffusion, as other authors [13] using polyurethane membranes have reported. Rather, an uphill transport process predominates. Our investigation has shown that a quantitative separation of iron is possible with our membrane, which would not occur if simple diffusion was the sole process acting on the system. Once the iron is transported from the starting to the receiving cell, it is then in an environment that contains less halide than the starting cell. The equilibrium is then shifted from the $HMX_4$ complex to other species that do not possess the ability to be extracted and transported through the membrane. The iron is therefore trapped in the receiving cell, and cannot proceed back through the membrane to the starting cell until sufficient halide is present to re-form the complex or the membrane becomes porous allowing diffusion back into the starting flask.

### 3.3. Membrane thickness

To determine the effects that the thickness of the membrane had on the rate of transport, a 0.025 mm membrane was used that was half as thick as that used previously. As expected, the iron was transported across the thinner membrane twice as fast as across the thicker membrane, as shown in Fig. 3. This indicates that the rate-determining step of the separation is the movement of the iron through the polymer rather than its sorption onto the polymer surface. Further, if the polymeric membrane could be made thinner then a faster separation might be possible, although this may cause some mechanical problems.

### 3.4. Effect of temperature

The effect of temperature on the rate of transport was studied using the following set of conditions. The starting flask contained 10 ml of 15 p.p.m. Fe in 5.0 M HCl and the receiving

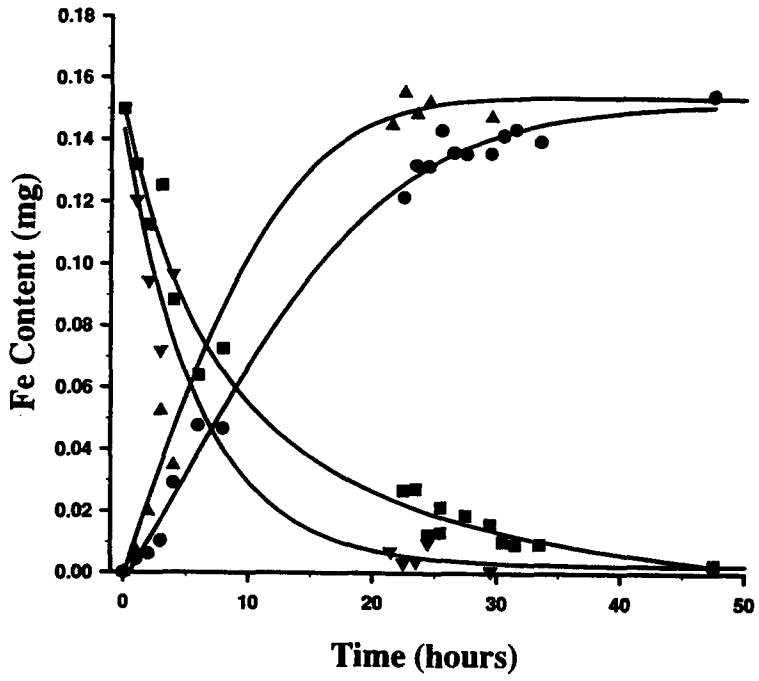

Fig. 3. Iron separation profile using two different membrane thicknesses. Starting cells contained 10 ml of 15 mg $l^{-1}$ iron in 5.0 M HCl, and receiving cells 0.1 M HCl: ■, starting cell using a 0.050 mm thick membrane; ●, receiving cell using a 0.050 mm thick membrane; ▲, receiving cell using a 0.025 mm thick membrane.

flask containing 30 ml of 0.1 M HCl. These conditions were chosen because the iron is quantitatively transported through the membrane in a reasonable amount of time (less than 2 days at room temperature). Under these conditions five experiments were run at different temperatures (5, 22, 37, 50, 65°C) to obtain thermodynamic data. As expected, the rate of transport increased markedly with an increase in temperature. The reason for the increase in transport rate may be due to two factors. The increase in temperature allows more molecules to overcome the activation barrier and may also cause a shift in the equilibrium of favour further $HFeCl_4$ formation. Separation data are presented in Table 2.

Table 2
Time required for quantitative transport of iron at vrious temperatures

| Temperature (°C) | Time required for quantitative transport (h) |
|---|---|
| 5 | 250 |
| 22 | 48 |
| 37 | 22 |
| 50 | 10 |
| 65 | 4 |

The energy of activation was calculated to be 50 kJ $mol^{-1}$ using an Arrhenius plot, as shown in Fig. 4. This value is consistent with values [14,15] found for the sorption and transport of aqueous salt and acetic acid solutions in polyurethane membrane material. It was assumed that during the experiment the same percentage of iron remained as the $FeCl_4^-$ complex. If the temperature affected the equilibrium of the iron chloride complex there would be a deviation from linearity. Considering the linearity of the plot in Fig. 4, the effects of the different temperatures on the equilibrium appear to be minimal.

As in the experiments at room temperature, the membrane became white, opaque and puckered, but at 65°C the membrane became porous as well. The porosity of the membrane led to the back flow of iron from the receiving cell into the starting cell. Extended experiments at lower temperatures also resulted in the same condition, but required more time to do so. This phenomenon was shown to be caused by the swelling and "puckering" of the membrane, subsequently causing the formation of microscopic holes which can be seen by optical or scanning electron microscope. These holes then allow the restricted, but non-selective, passage of acid from the starting to the receiving cell. The formation of holes was observed to be

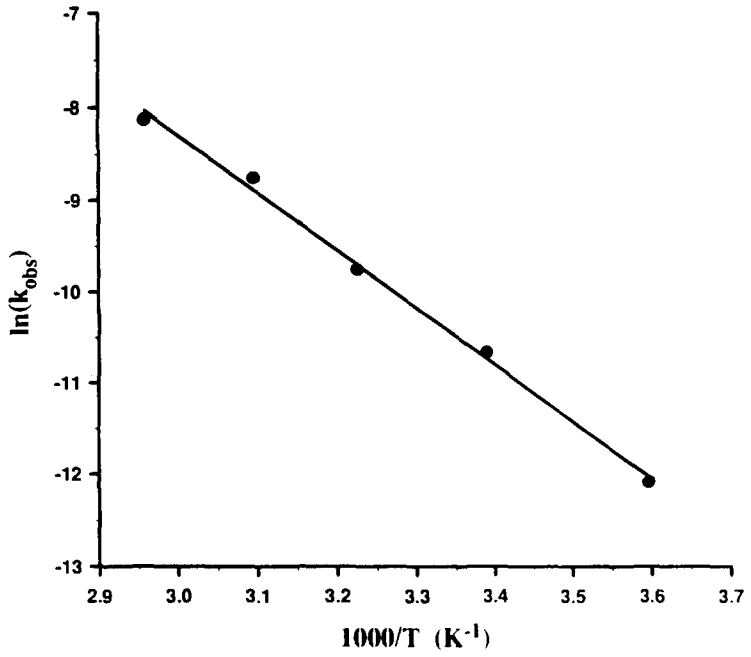

Fig. 4. Arrhenius plot of 0.050 mm membrane at 5, 22, 37, 50, and 65°C. Starting cells contained 15 mg $l^{-1}$ Fe in 5.0 M HCl, and receiving cells 0.1 M HCl.

separate from the transport of iron, and primarily due to the harsh conditions to which the membrane was subjected.

### 3.5. Salt effects

It is possible to form the $FeCl_4^-$ complex by the addition of chloride salts. Preliminary investigations performed using 5.0 M HCl with 0.5 M salts (NaCl, KCl, LiCl) yielded no difference in transport rate. A further experiment was undertaken where a high concentration of a salt was used in the place of a high concentration of HCl. LiCl was chosen for its high solubility in water. Some acid was needed to keep the iron in solution, so the experiment was performed with 60 p.p.m. iron in 4.8 M LiCl and 0.2 M HCl in the starting flask, and 0.1 M HCl in the receiving flask. The larger iron concentration was necessary because the salt solutions needed dilution by a factor of four before analysis by atomic absorption spectrophotometry. The results of the separation are presented in Fig. 5. The separation profile looks quite different when compared to that of the experiment performed with 5.0 M HCl in the starting flask, although the total chloride concentrations are identical. When LiCl was used, the separation proceeded much more slowly and was not quantitative within the time of the experiment. Using stability constants [6], the percentage of iron in the iron–tetrachloro complex in this LiCl solution was calculated to be 5.5%. Although this is less than the 7.7% with 5.0 M HCl is used, the lower concentration does not fully explain the dramatic change in transport behaviour. This indicates that the acid must play an integral part in the transport together with the chloride concentration. It is probable that ether groups present in the polymer, which we believe participate in the chelation of the iron complex, need to be protonated in order for the iron complex to be sorbed and transported through the membrane. In the LiCl experiment the transporting complex is $LiFeCl_4$, compared to $HFeCl_4$ in the previous HCl experiments, highlighting the role that the size of the cation plays in the transport of the metal across the membrane. Previous studies by Hamon et al. [4] indicate that the cation does indeed play a paramount role in the extraction of a metal complex by PUF. They found that the cation complexes were increasingly extracted in the following order ($Li^+ < Na^+ < Cs^+ < Rb^+ < K^+$), but this phenomenon was not observed in the current investigation. The difference may be due to the fact that this polyurethane is a different type produced by a different manufacturer. To a lesser degree, the differences may be due to the polymer being in a different physical form, the membrane being a film rather than an open cell

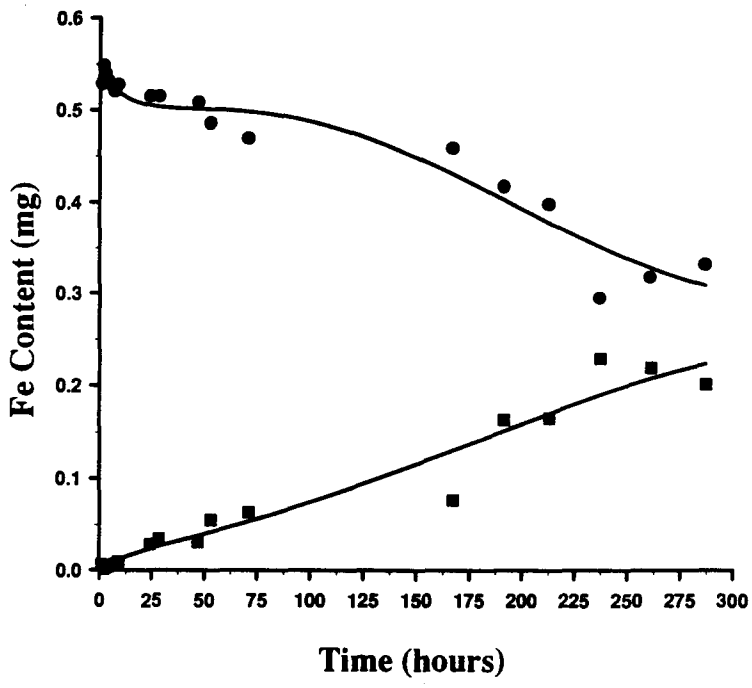

Fig. 5. Iron separation profile, with 10 ml of 60 ml $l^{-1}$ Fe in 4.8 M LiCl and 0.2 M HCl in the starting cell, and 30 mL of 0.1 M HCl in the receiving cell: ●, starting cell; ■, receiving cell.

PUF. Therefore, the "sites" available in the membrane may have a different size preference for accepting different-sized cations, and thus the complexes will be extracted and transported to differing degrees.

## 4. Conclusions

The transport of iron from hydrochloric acid solutions of concentrations less than 1.0 M does not occur through polyurethane membrane material. At 3.0 M HCl, transport of iron begins but is quite slow; at concentrations of 5.0 M and greater, the transport becomes quantitative (>99%). This effect is due to the increased formation of the $HFeCl_4$ complex, which is the species extracted into the polyurethane membrane. The higher the HCl concentration, the greater the percentage of iron in the ferric–tetrachloro complex, which results in faster transport rates. Substituting hydrobromic acid, the transport rates quintuple, primarily due to the $HFeBr_4$ being a weaker acid. Thus more of the iron–bromide complex is in the protonated form, which leads to a higher extraction rate and faster transport.

The transport of iron from hydrochloric acid is aided by an increase in temperature. At 5°C the quantitative transport of iron requires more than 10 days in comparison to 7 h at 65°C. Membrane thickness also plays an important role in the time needed for transport. Quantitative transport through a membrane 0.050 mm thick requires 48 h, as compared to 24 h with a thickness of 0.025 mm.

The use of salt rather than hydrochloric acid to form the ferric–tetrachloro complex leads to a slower process that does not allow quantitative separation. This is possibly due to two factors: the size of the complex and the need for the ether groups present in the polymer to be protonated in order for transport to occur.

The phenomenon of quantitative transport across an ether-type polyurethane membrane provides evidence that the polymer may be used to separate mixtures of metals based on their ability to form halide complexes. Although the active transport of iron presented in this paper is not presently practical for its separation, it demonstrates the ability of polyurethane membranes to quantitatively transport a metal from one phase to another. The method is inherently simple and inexpensive compared to other available techniques, and may prove an interesting alternative to other separation processes presently available for both analytical and industrial applications.

# Determination of polycyclic aromatic hydrocarbons in drinking and surface waters from Galicia (N.W. Spain) by constant-wavelength synchronous spectrofluorimetry

M.J. López de Alda Villaizán, J. Simal Lozano, M.A. Lage Yusty *

*Department of Analytical Chemistry, Nutrition and Bromatology, Area of Nutrition and Bromatology, Faculty of Pharmacy, University of Santiago de Compostela, E-15706 Santiago de Compostela, La Coruña, Spain*

Received 1 November 1994; revised 3 January 1995; revised 26 January 1995; accepted 27 January 1995

**Abstract**

We describe a fast, new method for determination of the joint concentration of the six polycyclic aromatic hydrocarbons (PAHs), designated by current legislation as indicators of the quality of drinking waters and surface waters intended for the abstraction of drinking waters. The limit of detection of the new method was 6 ng $l^{-1}$, its limit of quantification 20 ng $l^{-1}$, its precision (CV%) 2.48 and its recovery 94.05%. Its speed allowed rapid PAH screening of 404 samples of surface and drinking water from Galicia (N.W. Spain).

## 1. Introduction

Since 1930, when Kennaway and Hieger according to Fabre and Truhaut [1] found dibenz[*a*,*h*]anthracene to be carcinogenic, interest in the determination of polycyclic aromatic hydrocarbons (PAHs) in foodstuffs and the environment has been spurred by progressively increasing knowledge and awareness of their toxic and carcinogenic properties, and by the increase in PAH emissions by industry. As a result, their study has been given priority by various environmental and public health authorities [2–4]. In European Community legislation [5–7], PAH concentration in drinking water and waters destined for use as such is limited in terms of the joint concentration of six fluorescent indicator PAHs (fluoranthene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, benzo[*a*]pyrene, indeno[123-*cd*]pyrene and benzo[*ghi*]perylene), even though other fluorescent contaminants and also quenchers may be present. The maximum admissible joint concentration for drinking water and class $A_1$ and $A_2$ surface waters is 0.2 μg $l^{-1}$, while the maximum for class $A_3$ surface waters is 1 μg $l^{-1}$. The established minimum annual sampling frequency is 1 for surface waters, and ranges from 1 to 20 for drinking water (depending on the volume of water produced or distributed and the size of the population affected); special provisions are also made for occasional sampling in accidental or particular situations.

Methods proposed for the determination of PAHs in aqueous systems have been based on a wide variety of analytical techniques, the most frequently used being chromatography. Nevertheless, chromatographic methods often prove to be heavy consumers of both time and materials, and most of them do not conform to the reference methods which, according to European legislation, should be employed wherever possible for the determination of toxic substances in water. These reference methods require "measurements of UV fluorescence after extraction with hexane; gas chromatography or measurement of the UV fluorescence after thin layer chromatography; measurements in comparison with those of standard mixtures containing equal concentrations of the six indicator substances" [6,7].

* Corresponding author.

*SSDI* 0039-9140(95)01545-0

In view of the above observations, we previously developed a method [8] for determination of PAHs in water based on extraction with hexane and measurement of UV fluorescence, as recommended in the European legislation. The method precision (CV% = 3.8) and accuracy (recovery = 77%) and its detection limit (5 ng $l^{-1}$) meet those exacted in the legislation [6] in addition, this method is simple and does not consume large amounts of reagent.

In this work, we report the optimization of this method, which led to improved precision and very much improved accuracy without significant increases in limits of quantification or detection, and increased sample throughput. We also describe the application of the new, optimized method to screening of drinking and surface waters sampled in Galicia (N.W. Spain).

## 2. Experimental

### 2.1. Reagents

Fluoranthene and benzo[*a*]pyrene standards were purchased from Aldrich, and benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, indeno-[123-*cd*]pyrene and benzo[*ghi*]perylene standards from Sugelabor.

Residue analysis grade granulated anhydrous sodium sulphate and *n*-hexane, and analytical grade sulphuric acid, were all purchased from Merck. The sulphuric acid was extracted with *n*-hexane prior to use (we recommend that the purity of all reagents be verified under analysis conditions prior to measurement).

### 2.2. Water samples

Water sampling was carried out in 1991 by personnel of the Servicio Galego de Saude of the Xunta de Galicia. A total of 404 water samples were taken over two sampling periods (January 29–June 3, and June 24–December 16) from the network supplying the 60 most highly populated municipalities of Galicia, N.W. Spain. Sampling points were grouped into zones C, D and T, corresponding respectively to water catchment areas (the inlets of water treatment plants), the distribution network (points between the outlets of those plants and the distribution network), and consumers' taps, thus enabling water quality to be monitored along the length of the supply system.

### 2.3. Apparatus

All spectrofluorimetric measurements were performed with a Perkin-Elmer LS-50 luminescence spectrometer equipped with a xenon discharge lamp, Monk-Gillieson monochromators and 1 cm quartz cuvettes. For acquisition and processing of spectral data by Fluorescence Data Manager software, the LS-50 was serially interfaced (RS232C) to a Handok HNS-286 PC linked to a Nec Pinwriter P6+ colour printer for hard copy.

The spectra were obtained with the following instrumental parameters: both excitation and emission slits 5 mm, scan speed 1500 nm $min^{-1}$, constant wavelength interval between excitation and emission monochromators 120 nm. Synchronous spectra were recorded between 245 and 450 nm at 20 °C.

### 2.4. Procedure

100 μg $l^{-1}$ and 100 mg $l^{-1}$ stock standards of each PAH in *n*-hexane (which were prepared in the laboratory and were stable under refrigeration) were diluted with *n*-hexane as appropriate. Seven working standards containing equal concentrations (0.1, 0.2, 0.4, 0.6, 0.8, 1.0 and 2.0 μg $l^{-1}$) of each of the six PAHs were prepared by mixing suitable volumes of these individual stock solutions and diluting with *n*-hexane. The spectra of these standards were run and the spectral area between 275 and 395 nm was regressed on the known total concentration in order to obtain a calibration curve. The PAH content of water samples was determined by extracting 1 l of sample as described previously (Fig. 1) [8], running the extract with the spectrofluorimeter settings specified above, and using the calibration line to obtain PAH concentration from the spectral area between 275 and 395 nm.

## 3. Results and discussion

The new, optimized method employs wider excitation and narrower emission slit widths (now both 5 nm), a faster scan speed (1500 nm $min^{-1}$), and quantification of the PAHs by integration of peak area over a narrower wavelength interval (275–395 nm) than described previously [8]. Under these conditions, method precision and accuracy are much improved without significant increases in limits

of detection and quantification. Determination of the joint concentration of the six PAHs is also much faster, speed being a particularly important consideration in the analysis of drinking water, as screening for PAHs is generally carried out on a large number of samples and on a frequent basis [6,7].

Under the new conditions, instrumental response was highly linear (the correlation coefficient of the calibration line was 0.9955) and the limit of detection (calculated, following ACS guidelines [9] for reducing the risk of false positives, as the concentration corresponding to a spectral area equal to the average measured area for blanks plus six standard deviations) was 6 ng $l^{-1}$, well below the officially stipulated limit of 40 ng $l^{-1}$ [6]. It was verified experimentally that this quantity of PAH was indeed detected in water samples. The limit of quantification, calculated as the concentration corresponding to a spectral area equal to the average measured area for blanks plus 10 standard deviations, was 20 ng $l^{-1}$. Method precision, calculated as the coefficient of variation of the results obtained when the whole extraction/spectrometry procedure was applied to six replicate 1 l water samples spiked with 0.03 μg of each indicator PAH, was 2.48%, much better than the officially stipulated 50% [6]. Mean recovery from six water samples spiked at levels close to the official maximum allowable PAH concentration was 94.05%.

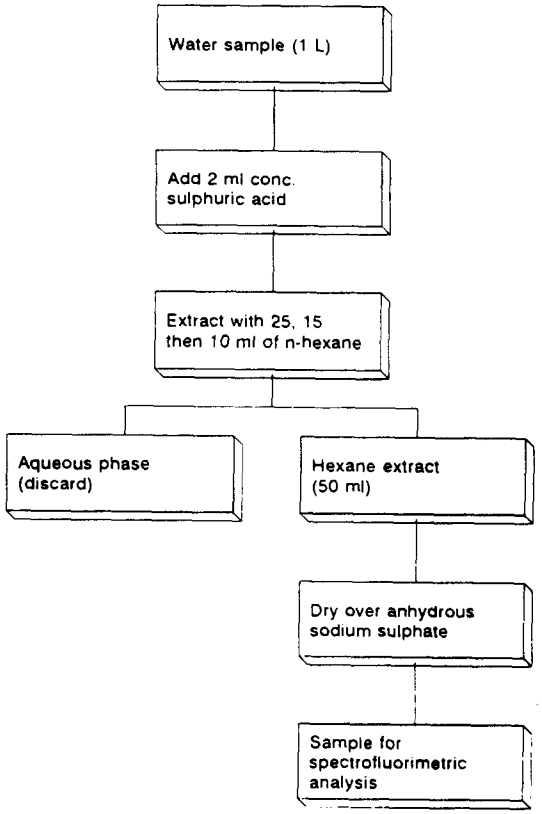

Fig. 1. Treatment of water samples prior to determination of polycyclic aromatic hydrocarbons by constant-wavelength synchronous spectrofluorimetry.

PAH screening of the 404 water samples by this optimized method indicated that: levels were below the maximum allowed concentration [5,7] of 200 ng $l^{-1}$ in all cases; quantifiable levels were present in only one in three samples; where quantifiable, PAH levels were generally well below the maximum. These results confirm the high quality of both the raw and the treated water.

In order to determine whether there were significant differences between the PAH levels in (a) samples taken during the first sampling period and those taken during the second, and (b) samples taken from the three sampling zones, we used one-way analysis of variance (ANOVA) to compare mean results. The means for the two sampling periods (15 ng $l^{-1}$ for Jan.–June; 9 ng $l^{-1}$ for June–Dec.) were found to be different at the 95% confidence level (signification level = 0.0085 for 402 degrees of freedom within sampling periods). These differences are attributable to variations in rainfall during the sampling periods: according to data from the Galician Meteorological Centre [10], for the first sampling period, most of the samples were taken during the driest months of 1991, while for the second period sampling coincided with the wettest months of 1991.

Significant differences (signification level = 0.0369) were observed between the mean PAH levels found in zones C (catchment), D (distribution) and T (consumers' taps). The least significant difference (LSD) intervals at the 95% confidence level indicated that PAH levels in samples from zone C (mean $\approx$16 ng $l^{-1}$) were significantly higher than in those from zones D and T (both means $\approx$10 ng $l^{-1}$). These results confirm that the water treatment system is effective, and that PAH levels are not significantly altered during water distribution.

In conclusion, we propose that the above-described method be adopted for determination of the joint concentration of the six PAHs designated by current European legislation as indicators of the quality of drinking waters and surface waters destined for use as such. Its

precision (coefficient of variation) is 2.48% in contrast with the officially stipulated 50%, its detection limit 10 ng $l^{-1}$ as opposed to the officially stipulated 40 ng $l^{-1}$, and its limit of quantification 28 ng $l^{-1}$. Recovery (94.05%) is likewise better than official requirements (50%). Additional advantages over the reference methods laid down in European legislation are greater speed, greater operational simplicity and lower maintenance costs. Application of this method to the PAH screening of water used to produce drinking water in Galicia (N.W. Spain) confirmed them to be of high quality.

# A new sample cell design for studying solid-matrix room-temperature phosphorescence moisture quenching

S.W. Tjioe, R.J. Hurtubise *

*Department of Chemistry, University of Wyoming, Laramie, WY 82071-3838, USA*

Received 15 December 1994; revised 26 January 1995; accepted 31 January 1995

**Abstract**

A new sample chamber was developed that can be used in the measurement of the effects of moisture on the room-temperature solid-matrix phosphorescence of phosphors adsorbed onto filter paper. The sample chamber consists of a sealed quartz cell that contains a special teflon sample holder. Sulfuric acid solutions in the quartz cell determine the percentage relative humidity in the cell and also determine the amount of moisture adsorbed onto the filter paper. The new sample chamber is much easier to use than a flowing nitrogen gas system. Results from both systems are compared with respect to ease of use and the amount of moisture adsorbed onto the filter paper.

## 1. Introduction

Solid-matrix room-temperature luminescence is a very useful analytical method for the trace analysis of organic compounds. The adsorption of organic molecules onto dry filter paper can reduce the non-radiative decay of a phosphor from the triplet state [1,2]. Solid-matrix room-temperature phosphorescence (SMRTP) and fluorescence (SMRTF) give greater quantum yields, in many cases, than the corresponding solution at low temperature [3]. In general, hydrogen-bonding interactions between the filter paper and the lumiphor is one of the main mechanisms responsible for the strong luminescence observed at room temperature [4]. The rigid environment provided by the filter paper reduces non-radiative transitions of the excited molecules and enhances luminescence.

Nissan [5] pointed out that the strength and number of hydrogen bonds in hydrogen-bond dominated solids, as measured by Young's modulus, decreases drastically upon the adsorption of moisture. The decrease in modulus is directly related to two regions of hydrogen-bond dissociation in paper [6]. The first region extends from zero moisture content to a point where a BET monomolecular layer of moisture has been established in the filter paper. The weight fraction of moisture at such monolayer coverage is designated as $W_M$. Within this region, only a single hydrogen bond is broken upon the adsorption of a water molecule. After the moisture content of the solid matrix exceeds $W_M$, cooperative hydrogen-bond dissociation dominates. In this region, groups of hydrogen bonds dissociate upon the adsorption of a single water molecule. Consequently, a more drastic decrease in the rigidity of the solid matrix is observed.

Schulman and Parker [7] presented evidence to indicate that the adsorption of moisture by filter paper permitted oxygen to penetrate the paper more efficiently. Citta and Hurtubise [8] reported that the SMRTP intensity of model aromatic compounds adsorbed onto filter paper decreased dramatically in the presence of humid nitrogen gas. In the presence of humid oxygen gas of 75% relative humidity (% RH), the SMRTP of the model compound they in-

* Corresponding author. Fax: (307)766-2807.

*SSDI* 0039-9140(95)01548-5

vestigated was completely quenched. Purdy and Hurtubise [9] observed that SMRTP lifetimes of model compounds were comparatively insensitive to moisture in nitrogen gas. The quenching of SMRTP was primarily a result of diminished filter paper matrix rigidity [9]. The moisture quenching of SMRTP for phosphors on filter paper was thus referred to as "matrix quenching" in contrast to the conventional static quenching in solution [9]. Chen et al. [10] introduced an equation that describes the changes in the SMRTP intensity as a function of SMRTP lifetime ratios and an exponential expression that included the weight percent of adsorbed moisture. Further, Chen and Hurtubise [11] introduced a model for the moisture quenching of SMRTP via the decrease in the Young's modulus of filter paper.

In previous studies of solid-matrix moisture quenching, moisture was introduced into the sample compartment of the luminescence spectrometer containing the filter paper sample via a flow of humid gas [8–11]. The amount of moisture in the flowing gas was determined by the flow rate of the gas through a series of sulfuric acid solutions [12]. In this work, a much simpler system was developed to obtain constant humidity in a sample chamber that contained the filter paper sample. This new sample chamber consists of a quartz cell and a teflon filter paper sample holder. Sulfuric acid solutions were added to the cell to create a humid environment surrounding the sample holder. It can be placed inside the sample compartment of a luminescence spectrometer, which eliminates the need to flow humidified nitrogen gas into the cell compartment.

## 2. Experimental

### 2.1. Apparatus

Intensity and lifetime measurements were obtained with a Fluorolog 2+2 spectrofluorometer (Spex Industries, Edison, NJ) interfaced with a Spex Datamate computer and the Spex 1934C phosphorimeter accessory. The excitation source was a 50 W programmable pulsed lamp. A cooled Hamamatsu R928 photomultiplier tube was employed. The % RH in the sample compartment of the spectrofluorometer and in the procedure used to obtain adsorption isotherms was measured with a Vaisala HMI 31 hygrometer (Vaisala, Helsinki, Finland).

### 2.2. Reagent and chemicals

Absolute methanol (Baker, HPLC grade) was mixed with water (Baker, HPLC grade) in a 1:1 ratio. Thallium acetate (Aldrich, 99.99%) and glacial acetic acid (ACS Reagent grade, Fisher Scientific) were added to the above solvent to give 0.5 M thallium acetate and 0.3 M acetic acid. Benzo[*a*]pyrene-*r*-7,*t*-8,9,*c*-10-tetrahydrotet-rol (tetrol I-1) was used as the model phosphor (Midwest Research Institute, Kansas City, MO), The tetrol solution was prepared by directly dissolving a weighed amount of tetrol in the thallium acetate solution as described previously [13]. The concentration of the tetrol solution was 40 ng $\mu l^{-1}$. Sulfuric acid (ACS reagent) was diluted in distilled water to various concentrations and stored in stopped bottles [12].

### 2.3. Materials

Whatman No. 1 filter paper (Whatman Co., Clifton, NJ) was developed three times in absolute methanol, dried at 110 °C for 30 min and stored in a desiccator. Small circular disks of filter paper that were 0.4 cm in diameter were obtained from the developed filter paper sheet using a commercial paper punch. A teflon sampler holder and a delrin sample holder were custom made to hold the filter paper samples (Fig. 1). A quartz cell (Wilmad Co., Buena, NJ) was used as the sample chamber to contain the teflon sample holder. Compressed nitrogen gas (US Welding, Golden, CO) was filtered through an oxygen trap (Oxyclear, Oakland, CA) and Drierite (W.A. Hammond Drierite Company, Xenia, OH). Chemical resistant Duraseal film (Diversified Biotech, Boston, MA) was used to seal the top of the 1 cm quartz cell. This film allows only 0.00807 $cm^3\ cm^{-2}\ h^{-1}$ of $O_2$ and 0.646 $\mu g\ cm^{-2}\ h^{-1}$ of $H_2O$ to penetrate when used as described. An analytical balance was placed inside an Atomsbag (Aldrich) for the measurement of the weight increase of filter paper samples upon moisture adsorption in obtaining adsorption isotherms [10].

## 3. Experimental designs and procedures

### 3.1. Adsorption isotherm

An adsorption isotherm for water was obtained for thallium acetate treated paper as

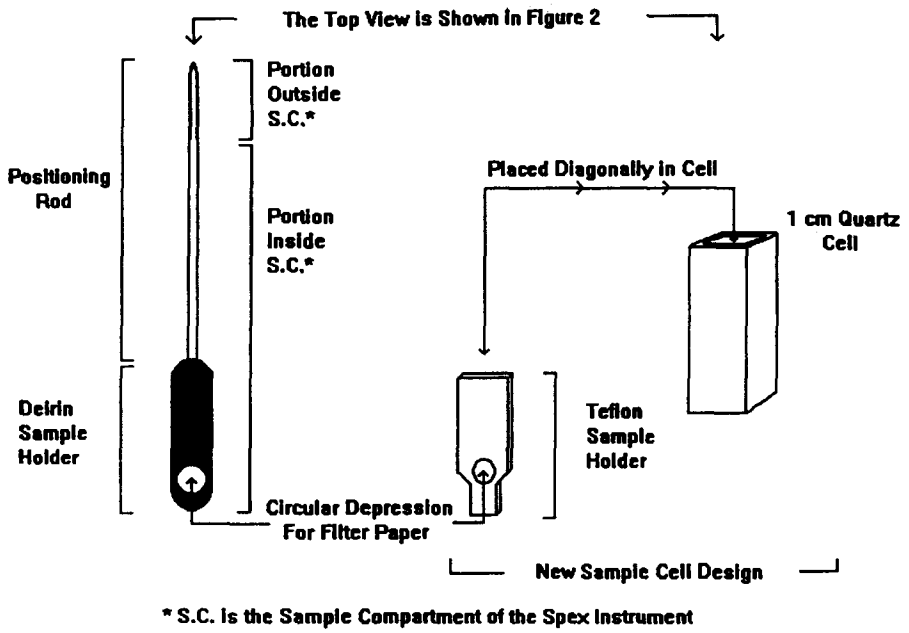

Fig. 1. Delrin and teflon sample holders.

described by Chen et al. [10]. Thallium acetate treated filter paper samples were suspended above sulfuric acid solutions of various concentrations for 45 min in stopped plastic bottles. The filter papers were weighed before and after this period of time. The adsorption isotherm was constructed by plotting the weight gained due to moisture adsorption against the % RH in the bottles. The % RH in the bottle was determined by the concentration of sulfuric acid, and the wt% of moisture at monolayer coverage ($W_M$) of thallium acetate treated filter paper was calculated using the BET method [14]. The data are given in Table 1.

The SMRTP quenching of I-1 was then determined in relation to the moisture content of the filter paper at various % RH. In general, the SMRTP intensities and phosphorescence decay curves were measured before and after the filter paper had acquired moisture. Moisture was introduced onto the filter paper via either a flow of humid nitrogen gas, or by suspending the filter paper sample above a solution of sulfuric acid in a sealed 1 cm quartz cell sample chamber. In both designs, filter paper samples were fitted into the sample holder. The sample holder was then placed in a sample chamber in which constant % RH was established. This is described in more detail below.

### 3.2. SMRTP quenching with flowing humid nitrogen gas

A delrin sample holder (see Fig. 1) was used to hold the filter paper samples. As indicated in the Figure, a positioning rod was attached to the upper part of the sample holder. The sample holder was placed on a stage inside the sample compartment of the spectrofluorometer.

Table 1
Adsorption isotherm data for thallium acetate treated whatman No. 1 filter paper

| % RH | Moisture (wt%) |
|---|---|
| 0 | 0.00 |
| 10 | 1.07 |
| 20 | 2.12 |
| 30 | 2.97 |
| 40 | 3.63 |
| 50 | 4.52 |
| 60 | 5.13 |
| 70 | 7.09 |
| 80 | 8.14 |
| 90 | 10.23 |
| 100 | 16.00 |

Each data point is the average of at least five trials. The standard deviation associated with each data point is less than 5%.
The linear region between 10 and 50% RH was used to calculate monolayer coverage, $W_M$. The calculated value of $W_M$ was 2.47 wt% moisture. The linear correlation coefficient was 0.999 for the region from 10 to 50% RH.

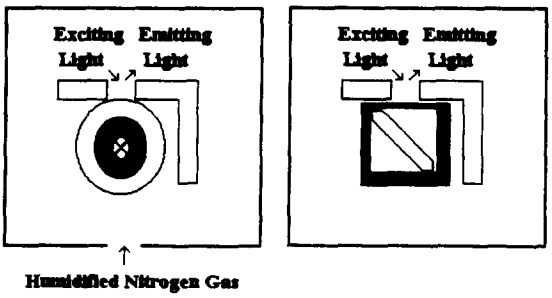

Fig. 2. Top view of sample holders in the cell compartment.

Fig. 2 illustrates the sample compartment of the instrument viewed from the top. The stage is indicated as a clear circle (left) and dark square (right) around the sample holders in Fig. 2. The upper 3 cm of the positioning rod was outside the sample compartment, so that the rotational orientation of the sample holder could be manipulated to obtain the maximum SMRTP intensity. The design on the left in Fig. 2 was used for flowing humid nitrogen gas. Compressed nitrogen gas was passed into the sample compartment via two paths. The nitrogen gas which came in via path (1) contained no moisture and provided 0% RH inside the sample chamber. The nitrogen gas which came in via path (2) was filtered through an oxygen trap and a set of three water bottles. Each water bottle contained approximately 500 ml of distilled water. The amount of moisture brought into the sample compartment via path (2) was determined by the flow rate of nitrogen gas. The %RH inside the sample chamber was constantly monitored by a digital hygrometer. It could be altered by adjusting the flow of gas through either path (1) or path (2).

One microliter of blank solvent was spotted on the surface of a filter paper sample which was on top of four other pieces of filter paper in the circular depression of the delrin sample holder (Fig. 1). The entire sample holder was dried in a oven at 110 °C for 30 min. It was then cooled at room temperature for 5 min under dry nitrogen gas inside the sample compartment. Both the blank and the sample were protected from the excitation light prior to the measurement step. The steady-state intensity of the blank filter paper was measured before the SMRTP decay curve of the blank filter paper was recorded. Dry nitrogen gas was continuously passed into the sample compartment throughout the measuring period. After obtaining SMRTP data under dry conditions, humid nitrogen gas from path (2) was directed into the sample compartment. Dry nitrogen gas inside the sample chamber was quickly displaced by the humid nitrogen gas. A fixed % RH was established inside the sample chamber within 20 min. The SMRTP intensity or phosphorescence decay curve of the humid blank filter paper sample was measured 45 min after a constant % RH inside the sample chamber was established. After blank measurement, the delrin sample holder was removed from the sample compartment and dried again at 110°C for 30 min. One-microliter aliquots of tetrol I-1 solution were transferred onto the top surface layer of the filter paper samples. After drying (30 min at 110 °C and then 5 min under dry nitrogen gas at room temperature), the steady-state SMRTP intensity and phosphorescence decay curve of I-1 on filter paper were measured. Mositure was then introduced again, and the SMRTP intensity and phosphorescence decay curve were obtained under humid conditions. The SMRTP intensity and phosphorescence decay curve from the blank filter paper samples were subtracted from the corresponding SMRTP intensity and phosphorescence decay curve of tetrol I-1 on dry and humid filter paper samples. The phosphorescence lifetimes of I-1 were calculated for dry and humid filter paper samples and are presented in Table 2 with respect to the moisture content of the filter paper.

### *3.3. SMRTP quenching within a Quartz cell sample chamber*

A teflon sample holder was custom made to hold the filter paper samples (Fig. 1). A 1 cm quartz cell was used to hold the teflon sample holder. It was sealed with a piece of Duraseal film and fitted snugly on a metal stage inside the sample compartment of the spectrofluorometer (Fig. 2). The teflon sample holder containing the blank filter paper samples was dried under identical conditions to the delrin sample holder. It was transferred to the sample compartment of the spectrofluorometer and placed diagonally into a quartz sample cell (Fig. 1). Dry nitrogen gas was directed into the quartz sample cell via a glass pipette for 5 min before it was sealed with a square piece of airtight Duraseal film. The SMRTP intensity and phosphorescence decay curves of the blank filter paper samples were recorded under the identical instrumental conditions as the flowing nitrogen gas system. After the RTP data on dry filter paper sample was recorded, the

| 7.50 | – | – | 1.90 | – |

[a] The $\tau_0/\tau$ and $P_0/P$ data were taken from Ref. [10].

Duraseal film was removed and 0.6 ml of a sulfuric acid solution was added to the quartz sample cell. A gentle stream of dry nitrogen gas was continuously passed into the quartz sample cell at 0.5 psi during the addition of sulfuric acid solution. The quartz sample cell was sealed again with a fresh piece of Duraseal film. The SMRTP intensity and decay curve of blank filter paper sample were recorded again after 45 min. After the measurements, the teflon sample holder was removed from the quartz cell and dried at 110 °C for 30 min. Sulfuric acid solution inside the quartz sample cell was discarded and the cell was rinsed with soap, nitric acid, tap water, distilled water and distilled ethanol, before being placed back onto the metal stage in the sample compartment. After drying, the teflon sample holder was cooled under dry nitrogen gas for 5 min at room temperature. One microliter of tetrol I-1 solution was spotted onto the top filter paper sample. The entire sample holder was dried again at 110 °C for 30 min. It was placed back into the quartz sample cell and cooled under dry nitrogen gas. The SMRTP intensity and phosphorescence decay curve of the tetrol on dry and humidified filter paper samples were recorded in the same fashion as the blank filter paper samples. The blank SMRTP intensity and phosphorescence decay curve data were subtracted from the corresponding sample data for I-1. The results are presented in Table 2.

### *3.4. Measuring the steady state SMRTP intensity and lifetime*

The steady state SMRTP intensity of the tetrol was measured by setting both the excitation and emission monochromators at appropriate wavelengths ($\lambda_{ex} = 345$ nm and $\lambda_{em} = 608$ nm). The initial delay was set at 0.1 ms, the gatetime (specified as "window" in Spex) was set at 5 ms, and the average intensity was obtained from 20 intensity values. The SMRTP decay curves of the filter paper and tetrol I-1 were also recorded at the excitation and emission wavelengths mentioned above. A phosphorescence lifetime program was loaded into the Datamate computer to obtain the phosphorescence decay curve. The phosphorescence decay curves obtained from filter paper samples with various moisture contents were all measured with 0.03 ms delay, 5 ms gatetime, and five flashes per data point. A time period of 0.07 ms was allowed between each flash, with 0.1 ms between consecutive data points. A total of 200 points was collected in constructing the phosphorescence decay curve. After subtracting the blank decay curve, the data for the phosphorescence decay curve from 0.03 to 12.75 ms were used in a linear regression program. The SMRTP lifetimes of the tetrol samples were calculated from the slope of the regression line.

## 4. Results and discussion

The weight percent (wt%) moisture values obtained on thallium acetate treated filter paper samples at a given %RH are presented in Table 1. The moisture content of filter paper increased linearly between 5 and 50% RH, and then more drastically above 70% RH. The linear correlation coefficient between 5 and 50%

RH was over 0.999. Using the linear portion between 5 and 50% RH, the monolayer coverage of water ($W_M$) was calcualted to be 2.47% using the BET method. This corresponds to approximately 24% RH. The point at which $W_M$ occurs is important because, as discussed in the Introduction, it separates two regions of hydrogen bond dissociation.

Table 2 lists the ratios of SMRTP intensities ($P_0/P$) and lifetimes ($\tau_0/\tau$) in relation to various percentages of moisture content in the filter paper. $P_0$ represents the SMRTP intensity on dry filter paper and $P$ represents the corresponding intensity with moisture. Similarly, the term $\tau_0$ is the SMRTP lifetime without moisture, and $\tau$ is the corresponding lifetime with moisture present. Each data point in Tables 1 and 2 represents the average of at least two trails.

As indicated in Table 2, the SMRTP intensity of I-1 was not affected much by moisture before $W_M$. The $\tau_0/\tau$ values also changed little for the flowing nitrogen gas system. After the wt% of water had reached about 2.0%, the $P_0/P$ values changed more rapidly with the flowing nitrogen gas system compared to the $\tau_0/\tau$ values with this system. The $\tau_0/\tau$ results from the quartz cell showed a similar trend compared to the flowing nitrogen gas system up to approximately 3.6 wt% water. After about 4.5 wt% water was adsorbed, the $\tau_0/\tau$ values became larger compared to the $\tau_0/\tau$ values obtained from the flowing nitrogen gas system. The $P_0/P$ ratios with the quartz cell system were considerably larger after about 4.5 wt% water, compared to the $P_0/P$ ratios from the flowing nitrogen gas system. Fig. 3 illustrates the data in Table 2 for both systems.

In general, the results from the two systems gave similar trends. The adsorption of moisture can be separated into two regions, as discussed by Chen et al. [10]. In the first region, which extends from 1 to about 2.5 wt% water, dynamic quenching dominates the entire quenching process. The intensity and lifetime ratios were about the same. In the second region, the $P_0/P$ ratio increased much faster than the $\tau_0/\tau$ ratios (Fig. 3). Fig. 3 clearly showed that identical quenching was not obtained for both systems over the entire wt% water range for the corresponding $\tau_0/\tau$ and $P_0/P$ ratios. This is most likely related to the fundamental differences between the two systems. With the flowing nitrogen gas system, the humidified nitrogen gas flows into and also exits the sample chamber. The nitrogen gas is constantly in motion, and thus moisture would not absorb as readily onto the filter paper as with a static system. The quartz cell sample chamber can be considered as a static system. As Fig. 3 shows, at greater than 3.5 wt% moisture, more water was adsorbed by the filter paper as indicated by the greater change in the $P_0/P$ ratios with the quartz cell compared to the flowing system. This is a result of the moisture being in more intimate contact with the filter paper in the quartz cell. In the flowing system, the cell compartment is very large and the humidified nitrogen is readily dispersed compared to the closed 1 cm quartz cell. The results in Fig. 3 showed that the type of system used to study moisture adsorption on filter paper is important, and the results are influenced by the design of the system. Thus, it would be important to use the same system for a given set of experiments to acquire consistent results.

Another important consideration related to the results in Fig. 3 is that the wt% water adsorbed onto the filter paper was obtained by

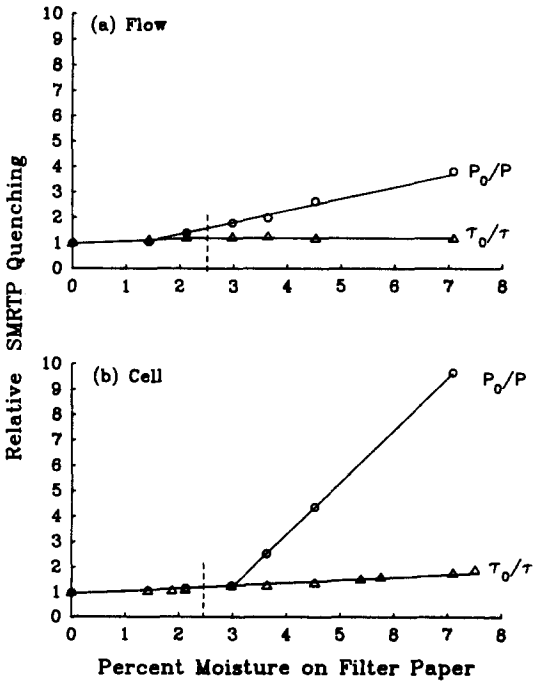

Fig. 3. SMRTP quenching of tetrol I-1(a) on Whatman No. 1 filter paper treated with thallium acetate-acetic acid solution under a flow of humid nitrogen gas (data from Ref. [10]), and (b) inside a sealed quartz sample cell. The ratio $P_0/P$ refers to the phosphorescence intensity ratio, and the ratio $\tau_0/\tau$ refers to the phosphorescence lifetime ratio. See text for additional details.

first suspending filter paper samples in bottles containing sulfuric acid solutions, and then weighing the samples in a humidity controlled environment. Most likely, the wt% moisture obtained under these conditions would be very similar to that in the quartz sample chamber. However, because all three systems (quartz cell, flowing system, and bottles with sulfuric acid) are not identical, the wt% moisture values in Table 1 would be proportional to the true wt% moisture adsorbed for the two systems investigated. This is indicated by the results in Fig. 3. The wt% moisture used in Figs. 3(a) and 3(b) is identical for both wt% moisture axes, but beyond 3.5 wt% moisture the $P_0/P$ values for the two systems become considerably different.

The trends in $\tau_0/\tau$ ratios obtained from the two systems are different. With the quartz cell, the $\tau_0/\tau$ ratio gave an approximate linear relationship with wt% moisture. The $\tau_0/\tau$ ratios for the flowing nitrogen gas system essentially reached a constant value above about 2.12 wt% water. Matrix quenching was more effective in the new sample chamber as indicated in Fig. 3 with the much greater slope of the $P_0/P$ plot in the region beyond 3.0 wt% water for the quartz cell. Matrix quenching involves the participation of moist filter paper in the quenching process. This type of quenching has been discussed by Chen et al. [10]. The separation between the two regions of SMRTP quenching discussed was also better clarified using the new design. It occurred slightly beyond $W_M$ at 3% moisture content (compare Figs. 3(a) and 3(b)). Using the new quartz cell design, the effects of a humid environment can be studied in the sample compartment of commercial luminescence instruments. In addition, the quartz sample cell can be transferred easily so that data can be obtained from instrument to instrument.

**Abstract**

Trimethylsilyl derivatives of 10 different hydroxy- and methoxyhydroxyflavonoid compounds were studied by the GC–FTIR technique. Optimal deviation parameters were determined for the flavonoids studied. The correlation found between retention and gas-phase IR data can successfully be used in structural identification of compounds having very similar chromatographic behaviour. The shift of the carbonyl frequency gives information on the presence of substituting agents

## 1. Introduction

Flavonoids are the most diverse and ubiquitous compounds of plants. Currently, the most common techniques used for the analysis of flavonoids are thin layer chromatography and reversed phase HPLC [1–4], in spite of the fact that it is difficult to handle problems originating from the similarity of retention behaviour and the use of classical detection methods. This is the reason why efforts are made to correlate retention and spectroscopic data or to use coupled techniques [5–7]. Coupling of thin layer and liquid chromatography with infrared spectroscopy as a detection technique encounters several practical difficulties and cannot be considered a routine method [8]. Therefore, the GC–FTIR technique has its advantage in the structural identification of compounds suitable for GC analysis either directly or indirectly (via derivatization). In the present work correlations between retention behaviour and the gas phase IR spectroscopic data are discussed.

## 2. Experimental

### 2.1. Materials

The flavonoid samples (min. 98% purity) used throughout the experiments are as follows: 3-hydroxyflavone (flavonol), 5,7-dihydroxyflavone, 4′,5,7-trihydroxyflavone (naringenin), 2′,3,4′,5,7-pentahydroxyflavone (morin), 3,3′,4′,5,7-pentahydroxyflavone (quercetin), 7-methoxyflavanone, 3-hydroxy-4′-methoxyflavone, 5,7-dihydroxy - 2′,3 - dimethoxyflavone,3′,5,7 - trihydroxy-4-methoxyflavone (hesperetin) and 3′,3,4′,5-tetrahydroxy-7-methoxyflavone (rhamnetin).

Compounds used as derivatization agents were 2,2,2-trifluoro-*N*,*O*-bis(trimethylsilyl)acetamide (BSTFA; Fluka and Merck), *N*-

* Corresponding author.

*SSDI* 0039-9140(95)01587-6

(trimethylsilyl)imidazole (Tri-Sil Z; Pierce), 1,1,1,3,3,3-hexamethyldisilazane (HMDS; Fluka) and trimethylchlorsilane (TMCS; Fluka). Hexane (Carlo Erba) and methanol (Reanal, Budapest) used as solvents were of chromatographic purity.

### 2.2. Derivatization

Two methanolic stock solutions (mixtures A and B) were prepared from both hydroxyflavonoids and methoxyhydroxyflavonoids. Mixture A contains flavonol, 5,7-dihydroxyflavone, naringenin, morin and quercetin in equal concentrations of 1 mg/ml. Mixture B contains 7-methoxyflavanone, 3-hydroxy-4'-methoxyflavone, 5,7-dihydroxy-2'3-dimethoxyflavone, hesperetin and rhamnetin of the same concentration (1 mg/ml). In order to evaporate the solvent, a given quantity (100–200 µl) was exposed to the air for some 12 h. In the case of mixture A 300 µl Tri-Sil Z and 200 µl hexane were added to the dry residue and silanization was maintained at 85 °C for 30 min. For mixture B, 300 µl BSTFA and 200 µl hexane were added, and the reaction was allowed to proceed at 70 °C for 60 min. Then the mixtures were made up to 1 ml with hexane.

### 2.3. Gas chromatographic separation

Separation of the components of mixtures A and B was made by means of a HP-588OA (Hewlett-Packard) type gas chromatograph. A HP-1 type fused silica capillary column (Hewlett-Packard; $l = 12$ m, 0.2 mm i.d., 0.33 µm film thickness) was used. Separations were made with programmed heating ($T = 180$ °C for 1 min, then 5 °C/min to 280 °C, and finally $T = 280$ °C for 5 min) using splitless injection (350 °C injector temperature) and a flame ionization detector (FID).

### 2.4. GC–FTIR analysis

GC–FTIR runs were performed by means of a HP-5880A gas chromatograph connected to a Bio-Rad FTS-45 type FTIR spectrometer via a Bio-Rad GC-32 interface equipped with a high sensitivity mercury cadmium tellurid (MCT) detector. Therefore, it was possible to carry out simultaneous FID and IR detection. The temperature of the transfer line and the light pipe (15 cm long, 1 mm i.d., gold-plated inside) was thermostated to 300 °C. The software-generated chromatogram was obtained by the Gram-Schmidt vector orthogonalization method. Spectra were recorded at a resolution of 8 $cm^{-1}$.

## 3. Results and discussion

### 3.1. Derivatization

The preparation of the trimethylsilylated derivatives of flavonoid compounds is widely discussed in the literature [9–11]. Although no difficulties associated with derivatization are reported, we found that complete derivatization (100% conversion) can only be achieved with flavonoids of low substitution owing to the strong intramolecular hydrogen bonds of polysubstituted flavonoids. The breaking of these bonds requires stronger derivatization agents, or an increase in the temperature of the silanization reaction which, on the other hand, may result in the decomposition of the molecule or the occurrence of side-reactions. Our observations are in good agreement with those of Brownbridge [12]. It was also recognized that the FID is rather insensitive to trimethylsilyl derivatives of flavonoids (e.g. the detection limit for derivatized quercetin was 0.04 mg/ml) which is probably a result of the high thermal stability of these compounds [9,10]. This is one of the reasons why relatively high concentrations were used.

Both mixtures (A and B) were reacted with BSTFA, Tri-Sil Z and HMDS:TMCS (2:1 v/v) reagetns for different times at various temperatures. It was found that mixture B was very sensitive to the strength of the derivatization agent and to the temperature of the reaction. This is supported by the linear FID response (in the 0.05–1.0 mg/ml concentration range) to reaction products obtained during the derivatization of quercetin with BSTFA in a microwave oven (Philips M610; stage 6; 2 × 5 minutes). Similar results were obtained with the Tri-Sil Z derivatization agents. The regression coefficients obtained in the above concentration range with derivatization agents BSTFA and Tri-Sil Z were $R = 0.9998$ and 0.9996, respectively, in spite of the fact that—unlike the literature results [9–11]—complete decolourization was not observed.

The optimal parameters for the reaction of hydroxyflavonoids were 30 min reaction time and 80 °C reaction temperature with Tri-Sil Z derivatization agent. For the reaction of

methoxyhydroxyflavonoids, the use of BSTFA reagent at 70 °C for 60 min was found to be optimal. The FID and reconstructed Gram–Schmidt chromatograms recorded under the above conditions are shown in Fig. 1.

### 3.2. GC–FTIR analysis

Gas spectra with a good signal-to-noise ratio were obtained only when the amount of the compound to be detected in the light pipe was a minimum of 80–100 ng. This is an additional reason to use relatively high sample concentrations.

The symmetrical deformation vibration of the siloxane methyl groups connecting to silicon appears at 1260 $cm^{-1}$ in the form of a characteristic band. The methyl rocking band occurs at $850 \pm 30$ $cm^{-1}$ including the Si–C stretching mode. The Si–O–C band appears at $1100 \pm 100$ $cm^{-1}$. This frequency, however, strongly depends on the chemical environment. In the spectra of flavonoid derivatives the Si–O–C stretching and the methyl rocking bands occur in the 1305–1166 $cm^{-1}$ and the 920–840 $cm^{-1}$ ranges, respectively.

In order to compensate for errors originating from the changing concentration of components in the light-pipe, the peak intensity ratios of the Si–O–C stretching ($\nu_{Si-O-C}$) and the methyl rocking ($\rho_{CH_3(Si-CH_3)}$) bands ($A\nu_{Si-O-C}/A\rho_{CH_3(Si-CH_3)}$) were related to the relative retention. Since the increase of the number of $-O-Si(CH_3)_3$ substituents on the flavone molecule results in the increase in intensity of both the Si–O–C stretching and the methyl rocking bands, and the retention time increases with the molecular weight on an apolar column, it seemed to be logical to correlate the relative intensity with the relative retention. For calculation of the relative retention $t_R/t_{R'}$, the flavonoid (flavonol) having the lowest retention time was selected as a reference. Data obtained from the spectra are summarized in Table 1. There was a close correlation between the relative retention and the peak intensity ratio of the $\nu_{Si-O-C}$ and $\rho_{CH_3(Si-CH_3)}$ bands (Fig. 2). In the $t_R/t_{R'} < 2$ range a significant difference can be observed in the curves ob-

Table 1
Correlation between relative retention $t_R/t_{R'}$ and some data of gas phase IR spectra

| Compound | $t_R/t_{R'}$ | $\nu_{C=O}$ ($cm^{-1}$) | $\nu_{Si-O-C}/\rho_{CH_3(Si-CH_3)}$ | $\Delta\nu_{C=O}$ ($cm^{-1}$) |
|---|---|---|---|---|
| Flavonol | 1 | 1661 | 1.78 | −45 |
| 5,7-Dihydroxyflavone | 1.8 | 1666 | 0.85 | −40 |
| Naringenin | 2.08 | 1696 | 0.61 | −10 |
| Morin | 2.27 | 1652 | 0.65 | −54 |

| Rhamnetin | 2.28 | 1650 | 0.69 | −56 |

Carbonyl reference frequency: 1706 $cm^{-1}$.

tained for methoxyhydroxy and hydroxyflavonoids. In the $t_R/t_{R'} > 2$ range, however, a constant intensity ratio of 0.6–0.7 is expected. In the "substituent sensitive" region of the relative peak intensities (between 2.1 and 0.7) the number of the $-O-Si(CH_3)_3$ substituents or the expected retention times of the derivatives can be estimated. A further study is necessary to investigate which spectral properties can be used to estimate the retention time of highly substituted derivatives.

The carbonyl stretching frequency of the substituted flavone molecule differs strongly from that of the nonperturbated one, depending on the position of the substituent. IR spectra available in the literature [1,2,13] were recorded in KBr, nujol, $CCl_4$ and dioxane matrices, only. Therefore, it seemed reasonable to select the vapour phase C=O stretching band of 7-methoxyflavanone as a 'nonperturbated' reference frequency (1706 $cm^{-1}$). The frequency shifts of the carbonyl bands relative to this frequency ($\Delta\nu_{C=O}$) are given in the last column of Table 1. It can be seen from the band shifts that the carbonyl frequencies of the derivatives of naringenin, hesperetin and 7-methoxyflavanone used as reference material are observed around 1700 $cm^{-1}$, while those of the flavonol, morin, quercetin, 3-hydroxy-4'-methoxyflavanone and rhamnetin derivatives show band shifts of 45–56 $cm^{-1}$. The shift of the $\nu_{C=O}$ stretching frequency relative to the reference position (1706 $cm^{-1}$) may be due to steric hindrances. It is interesting to note that with molecules substituted at the C-3 position (flavonol, 3-hydroxy-4'-methoxyflavone) a frequency shift of 45–47 $cm^{-1}$ was observed. On the other hand, the carbonyl vibration is less hindered in molecules substituted at the C-5 position (e.g. for naringenin $\Delta\nu = 10\ cm^{-1}$). For molecules substituted at both the C-3 and C-5 positions frequency shifts of 54–56 $cm^{-1}$ were observed. The influence is not additive and it seems that the effect of substituents at the C-5 position is stronger than at the C-5 one.

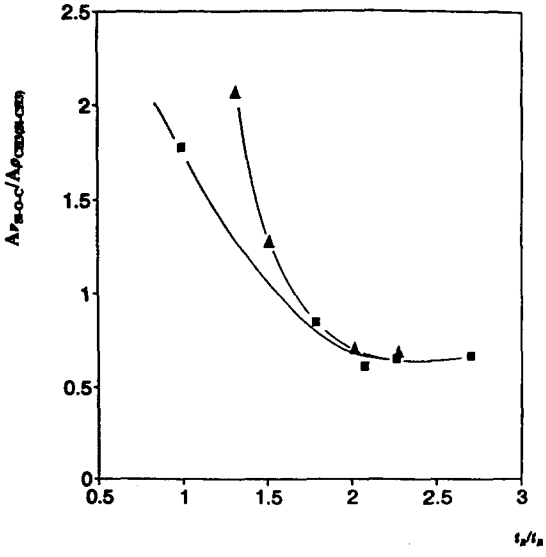

Fig. 2. Correlation between relative retention ($t_R/t_{R'}$) and the peak intensity ratio of the $\nu_{Si-O-C}$ and $\rho_{CH_3(Si-CH_3)}$ bands. ▲, Methoxyhydroxyflavonoids; ■, hydroxyflavonoids.

## 4. Conclusion

Based on the results obtained it can be stated that the GC–FTIR method has advantages over HPLC or TLC techniques when the identification of structure is difficult owing to similarities in retention behaviour and/or to limitations of classical detection methods. The shift of the carbonyl band frequency is particularly sensitive to C-3 and C-5 substitution. With the correlation between relative retention and the $\nu_{Si-O-C}/\rho_{CH_3(Si-CH_3)}$ band ratio, the number of substituents can be estimated.

# Letter to the Editors

Dear Sir,

An analytical method for speciation of mercury by GC/CVAFS after aqueous phase ethylation and room temperature precollection has been originally published by Bloom [1], and improved by Liang et al. [2]. The method has been extensively used in more and more laboratories for the determination of mercury species in a variety of environmental and biological materials.

Using the original method [1], the ethylation derivatives are precollected on Carbotrap® columns. As described in our paper [2], because of its catalytic activity as well as other unknown factors, the Carbontrap® may sometimes cause a decomposition of organo-Hg species during thermal desorption of these compounds from the Carbontrap® column to a GC column. To eliminate this problem, we have suggested the use of Tenax® traps in the improved method. We found that the Tenax® has an excellent trapping efficiency, which does not cause the decomposition of organo-Hg species, indicating that it is a good trapping material. We have also found, however, that when these traps were used, the sensitivity decreased with increasing measurement number, especially when new traps were used. The magnitude of decrease was found to depend on the measurement frequency. For instance, in a frequency of 10 measurements per day, no significant decrease was observed, but if 10 measurements were completed per hour, a gradual decrease in sensitivity appeared after about 10 measurements, and, sometimes even, no signals were observed after about 40 measurements. We found that letting the GC column stay at the measurement temperature or higher overnight, the sensitivity returned to normal. On the next day, however, the same pattern in the sensitivity was observed again. The reason for this is probably because the Tenax® is a polymer containing numerous volatile compounds such as aromatic hydrocarbons. The volatile compounds from the Tenax® may release to and deposit on the GC column while heating the Tenax® trap at a higher temperature for desorbing organo-Hg species resulting in interference in the GC process.

Based on the above explanation, in order to protect the GC column from the deposition of the volatile compounds released from the Tenax® trap, a precolumn was inserted between the Tenax® trap and GC column, and was kept at room temperature. The precolumn was constructed by packing a small amount of OV-3, the same material as used for packing the GC column, into the same quartz tubing as used for packing the Tenax® trap [1]. After inserting this precolumn, the gradual decrease in the sensitivity with increasing measurement number was no longer observed, thus, the interference was eliminated. It was indicated that here the precolumn played the role of a filter, and the compounds released from the Tenax® could not go through the precolumn at room temperature, while the organo-Hg compounds can go through with no retention. The only problem is that after inserting the precolumn, the peaks broadened and the retention time extended, thus the peak height sensitivity decreased and the throughput reduced. To avoid this problem, the amount of OV-3 used for packing the precolumn was minimized. The optimal amount was found to be about 20 mg. Further, to shorten the retention time the temperature of the GC column was slightly increased. Both the peak height sensitivity and the throughput were finally compensated. We cleaned the precolumn every day before starting the analysis by heating it with the wire used for heating the trapping column to desorb the organo-Hg species [1] at about 200°C for 5 min, while disconnected from the GC column. A precolumn can be used for at least 6 months with excellent protection efficiency.

# Investigation of the contact charge transfer absorption of organic solvents with oxygen for use in oxygen determination

Ming Fat Choi *, Peter Hawkins

*Faculty of Applied Sciences, University of the West of England, Coldharbour Lane, Frenchay, Bristol, BS16 1QY, UK*

Received 4 March 1994; accepted 13 April 1994

**Abstract**

The contact charge transfer (CCT) absorption spectra of dimethylsulphoxide (DMSO), *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), ethanol, methanol, water, benzene (Bz), *N,N'*-diethylaniline (DEA), *N,N'*-dimethyl-*p*-toluidine (DMT) and *N,N'*-diethyl-*p*-toluidine with molecular oxygen have been investigated. These solvents form strong ultraviolet/visible CCT absorption spectra with intensities that are related to the partial pressure of the applied oxygen. DMSO, DMF, DMA, Bz, DEA and DMT are shown to form 1:1 molecular contact complexes with molecular oxygen. A simple oxygen sensing system is described using CCT absorption spectroscopy of DMT at a wavelength of 400 nm, with a gas flow rate of 60 $cm^3$ $min^{-1}$ through the solvent in a cuvette with a pathlength of 1 cm. Inexpensive plastic fibres are used to relay the light from a xenon lamp source to the cuvette and back to a photo-detector. The response of the sensing system to changes in oxygen concentration is reversible, non-linear and in good agreement with the Beer–Lambert law. The most sensitive response region is from 0 to 20% $O_2$ with a change in signal level of about 35%. The solvent used shows no deterioration in performance over a long period and can be used to determine gaseous oxygen concentrations from 0 to 100%. It does not respond to carbon dioxide.

## 1. Introduction

The determination of oxygen concentrations in various gaseous and liquid samples, and biological fluids has important applications in environmental, clinical and analytical chemistry, and oxygen concentrations are often closely related to the progress of many chemical and biochemical reactions. Considerable effort has been devoted over many years to the development of new techniques for the measurement of the oxygen concentrations. A very common oxygen sensor is the Clark-type electrode, which is one form of a direct amperometric gas sensor, or its modifications [1,2]. It is easily calibrated and has a relatively rapid response. However, this electrode usually requires a steady supply of oxygen to the sensor surface for a reliable response as it consumes oxygen (irreversible), and so is not recommended for use in a very small static sample. It also has a limited working life and is easily poisoned by $H_2S$, proteins and various organic compounds. Other electrochemical oxygen sensors have been developed, including conductometric sensors [3] and potentiometric sensors [4–6]. One alternative to the electrochemical oxygen sensors uses the paramagnetic nature of molecular oxygen to alter the force of attraction between a diamagnetic material and a steady magnetic field [7]. This system has limited applications and cannot be used with liquid samples. Other alternative methods are the luminescence-based optical fibre sensors which have increased in importance in recent years. The sensor is usually made from a fluorescent

* Corresponding author.

compound attached to the tip of a fibre-optic cable. Excitation light, after passing along a light fibre, interacts with the fluorescent compound and the fluorescence, picked up by the same or another fibre, is transmitted to a detector. The principle of the measurement is based upon the fluorescence quenching or lifetime changes of the fluorescent compound exposed to different oxygen concentrations [8–12]. Unfortunately, the optical fibre fluorosensors are subject to several limitations such as: the time-consuming preparation of the sensing material; poor long-term stability of the sensing material; and a generally limited dynamic range. Another type of fibre-optic sensor is based on the absorption change of a metallic-organic compound; however, its response is also pH-dependent [13].

It has been found that some organic solvents exhibit new absorption bands when in contact with oxygen [14]. Tsubomura and Mulliken [15] concluded that this is caused by the formation of contact charge transfer (CCT) pairs between the organic solvents and molecular oxygen. A theoretical investigation of the absorption spectra caused by oxygen has also been given by them. Molecular oxygen acting as an electron acceptor via its triplet electronic state ($^3O_2$) can form a donor–acceptor (D–$^3O_2$) contact pair with some solvents acting as electron donors (D). Radiation absorbed by the ground state D–$^3O_2$ contact pair gives an excited state (D–$^3O_2$)* which subsequently dissipates the excess energy via several different possible mechanisms. If the difference in energy between the excited and ground states is relatively small, especially for those donors with low ionization potentials, then de-excitation to the ground state usually occurs without any photodecompostion of the donor and the acceptor [16]. The CCT absorption bands lie in longer wavelength regions if the solvents have lower ionization potentials, and usually appear as extensions to the long wavelength edge of the absorption spectra of the de-oxygenated solvents. The peaks of the CCT absorption bands are generally masked by the much stronger absorption bands of the solvent itself. The CCT absorption intensity of the organic solvents is also related to the partial pressure of oxygen in the gas mixtures above the solvents, and the reaction between the solvents and oxygen is reversible [17].

The purpose of the investigation was to study the CCT absorption spectra of a number of different solvents with oxygen and then to explore the possibility of building a simple detecting system for oxygen using one of the solvents. The solvents studied in the investigation were dimethylsulphoxide (DMSO), *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), ethanol (EtOH), methanol (MeOH), water ($H_2O$), benzene (Bz), *N,N'*-diethylaniline (DEA), *N,N'*-dimethyl-*p*-toluidine (DMT) and *N,N'*-diethyl-*p*-toluidine (DET). The results of this investigation show that DMT has strong CCT absorption bands extending into the visible region and it was chosen for use in the detecting system for oxygen. This detecting system has several advantages: inexpensive plastic optical fibre can be used; DMT is inexpensive and readily available (without the time-consuming preparation of oxygen-sensitive material); it can detect a wide range of concentrations of gaseous oxygen; it can possibly be further developed into a multi-analyte sensing system; the solvent used is stable for a long period without loss of sensitivity.

## 2. Experimental

### 2.1. Chemicals and reagents

DMSO (99.9%, HPLC grade), acetonitrile (MeCN, >99.9%, HPLC grade), DMA (>99.9%, HPLC grade), DMF (>99.9%, HPLC grade), DEA (>99%), DMT (>99%), MeOH (>99.9%, HPLC grade), EtOH (denatured with 5% isopropyl alcohol, HPLC grade), Bz (>99.9%, HPLC grade) and *n*-heptane (99%, spectrophotometric grade) were purchased from Aldrich. DET (99%) was obtained from Kodak Laboratory Research Products, UK. Water was deionized by the Purite R0200-Stillplus HP system. 'White spot' nitrogen gas (oxygen free), oxygen gas, carbon dioxide and hydrogen gas were obtained from BOC Limited, UK.

### 2.2. The gas mixing system

The gas mixing system is shown in Fig. 1. Different oxygen concentrations (in the range 0–100%) in the gas stream were produced by controlling the flow rates of the oxygen and the diluent nitrogen gas entering the mixing chamber. The gas mixture was passed through a portable oxygen meter (Oxywarn 100I from

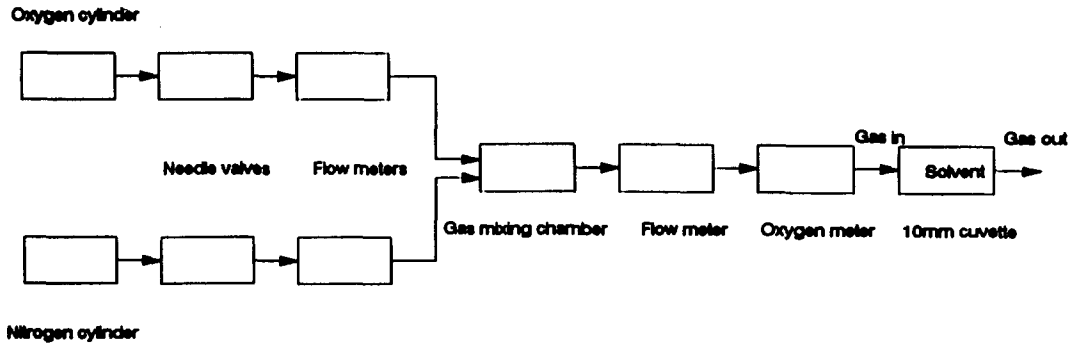

Fig. 1. Schematic diagram of the gas mixing system for generating oxygen standards.

Draeger Manufacturing, UK), where the oxygen concentration in the gas mixture was determined before passing through the solvent contained in a 1 cm pathlength spectrophotometer cuvette.

### 2.3. Instrumentation

CCT absorption spectra were measured on a Perkin-Elmer Lambda 15 Spectrophotometer. In the sensing system for oxygen, a laboratory-made optical system was set up (Fig. 2). An intense beam of ultraviolet/visible (UV/vis) radiation of a known wavelength was produced using the internal 150 W xenon lamp and monochromator (bandpass width 34 nm) of a Perkin-Elmer MPF-3 Fluorescence Spectrophotometer, and then modulated by passing it through a frequency-stabilized light chopper operating at a frequency of 211 Hz (Model 9000 from Monolight Instruments, UK) before being launched into a bundle of plastic optical fibres (1 m length and 2 mm diameter from RS Components, UK). The transmitted radiation from the fibres irradiated the front surface of a 1 cm quartz cuvette containing 3 ml of the solvent, with gaseous oxygen standards continuously passing through it at a flow rate of 60 $cm^3$ $min^{-1}$. A second bundle of plastic fibres (each of 0.5 m length, 2 mm diameter) was placed on the back surface of the cuvette to collect the transmitted light. The other end of this bundle led directly onto the front surface of a 100 $mm^2$ silicon photo-voltaic detector (RS Components, UK), and the output signal connected to a Bentham 277 current pre-amplifer and a Bentham 223 lock-in amplifer (Bentham Instruments Ltd, UK) which was synchronised to the modulated light beam by a reference signal provided by the light chopper. The signal from the amplifier was recorded on a Gould BS-271 recorder (Gould Bryans Instrument Ltd., UK) or displayed on a Bentham 217 digital unit.

## 3. Results and discussion

### 3.1. The CCT absorption spectra of the solvents using the spectrophotometer

Corrections for the UV/vis absorptions were done automatically by filling the reference beam cuvette in the spectrophotometer with the solvents saturated with air. Different oxygen concentrations of the gaseous standards at flow rates of about 30 $cm^3$ $min^{-1}$ were passed through the solvents to be investigated until they were totally gas saturated (about 3 min) and the UV/vis absorption spectra were recorded immediately.

In addition to all the solvents listed above, the CCT absorption spectra for different mole fraction mixtures of DMSO/MeCN, DMF/MeCN, DMA/MeCN, Bz/MeCN, DEA/*n*-heptane and DMT/*n*-heptane were also recorded.

The CCT absorption spectra of $H_2O$, MeCN, MeOH, EtOH, *n*-heptane, Bz, DMSO, DMF, DMA, DMT, DEA and DET with oxygen are shown in Fig. 3. The CCT absorption bands are broad and extend from the UV to the vis regions, depending on the solvent, and are related to the ionization potentials of the individual solvents as described by Jortner and Sokolov [18]. The lower the ionization potential of the solvent, the larger the red-shift of the CCT absorption spectrum. The ionization potentials of these solvents are given in Table 1. The results agree with the conclusions of Jortner and Sokolov; DMT, DEA and DET, with the lowest ionization potentials, have the most red-shifted CCT absorption bands lying in the

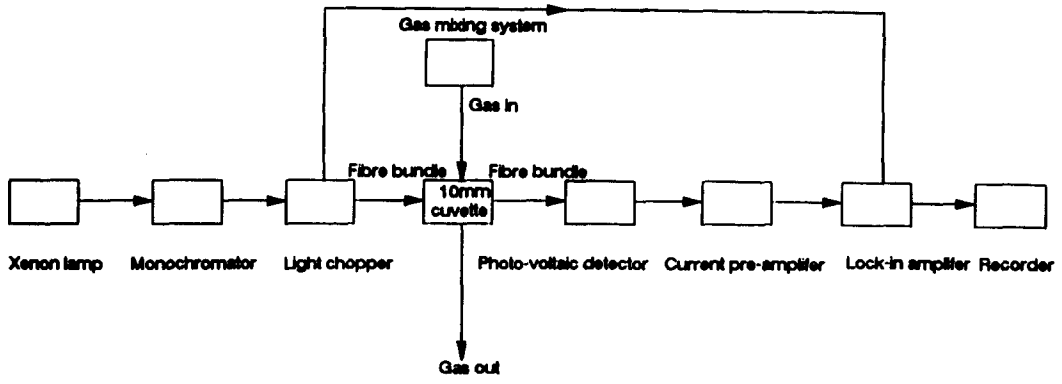

Fig. 2. Schematic diagram of the sensing system for the determination of oxygen.

visible region, whereas MeOH, EtOH, *n*-heptane, Bz, DMSO, DMF and DMA, with higher ionization potentials, have CCT absorption spectra in the UV region. $H_2O$ and MeCN, with the highest ionization potentials of the solvents investigated, have a CCT absorption band extending possibly into the vacuum UV region. The CCT absorption bands disappear when the dissolved oxygen is removed by purging the solvents with nitrogen, carbon dioxide or hydrogen. The CCT absorption band maxima could not be determined accurately in the region under investigation because of the overlap of the continuous bands with the much stronger absorption band of the solvent itself. The apparent CCT absorption band maxima of MeOH, EtOH, *n*-heptane, Bz, DMSO, DMF, DMA, DMT, DEA and DET with oxygen shown in Fig. 3 are almost certainly distorted, particularly at shorter wavelengths (stray effect occurs), by instrumental errors arising when the strong absorption of the solvent itself causes the intensity of the transmitted radiation through the sample and reference cuvettes to fall below the detection limit of the detector in the spectrophotometer. For $H_2O$ and MeCN, the CCT absorption bands appear to have maxima which occur at less than 190 nm and beyond the range of the spectrophotometer.

### *3.2. The effect of oxygen concentration on the CCT absorption spectra*

Suppose $x$ donor molecules, D, react with an oxygen molecule to form a CCT complex D$x$–$O_2$ which is responsible for the CCT absorption:

$$x\mathrm{D} + \mathrm{O_2} \rightleftharpoons \mathrm{D}x\text{–}\mathrm{O_2}$$

The concentration of the D$x$–$O_2$ CCT complex can be represented by

$$[\mathrm{D}x\text{–}\mathrm{O_2}] = K[\mathrm{D}]^x[\mathrm{O_2}] \quad (1)$$

where [D] and [$O_2$] are the mole fractions of donor (in this case, the solvent) and dissolved oxygen respectively, and $K$ is the equilibrium constant. According to the Beer–Lambert law, the absorbance of the D$x$–$O_2$ CCT complex, $A_{O_2}$, will follow the equation

$$A_{\mathrm{O_2}} = [\mathrm{D}x\text{–}\mathrm{O_2}]ba \quad (2)$$

where $b$ is the optical pathlength of the cuvette and $a$ is the molar absorptivity of the CCT complex. Substituting [D$x$–$O_2$] from Eq. (1) into Eq. (2):

$$A_{\mathrm{O_2}} = K[\mathrm{D}]^x[\mathrm{O_2}]ba \quad (3)$$

The mole fraction of the dissolved $O_2$ in a solvent is proportional to the partial pressure of $O_2$, $P_{O_2}$, applied to it. Eq. (3) can be modified to give

$$A_{\mathrm{O_2}} = K[\mathrm{D}]^x(P_{\mathrm{O_2}}/k')ba \quad (4)$$

where $k'$ is Henry's constant for the solvent and oxygen. $K$, $k'$, $b$ and $a$ can be replaced by another constant, $k_1$, and so Eq. (4) can be further reduced to

$$A_{\mathrm{O_2}} = k_1[\mathrm{D}]^x P_{\mathrm{O_2}} \quad (5)$$

As [D] is the concentration of the solvent which can be assumed to remain constant over the range of oxygen concentrations used, the absorbance of the CCT complex will be directly proportional to $P_{O_2}$. This theoretical result is supported by the CCT absorption spectra shown in Fig. 4(a) for DMT. The other solvents were tested and all produced similar results to DMT, but these are not shown in this paper. The graphs in Fig. 4(b), however, show

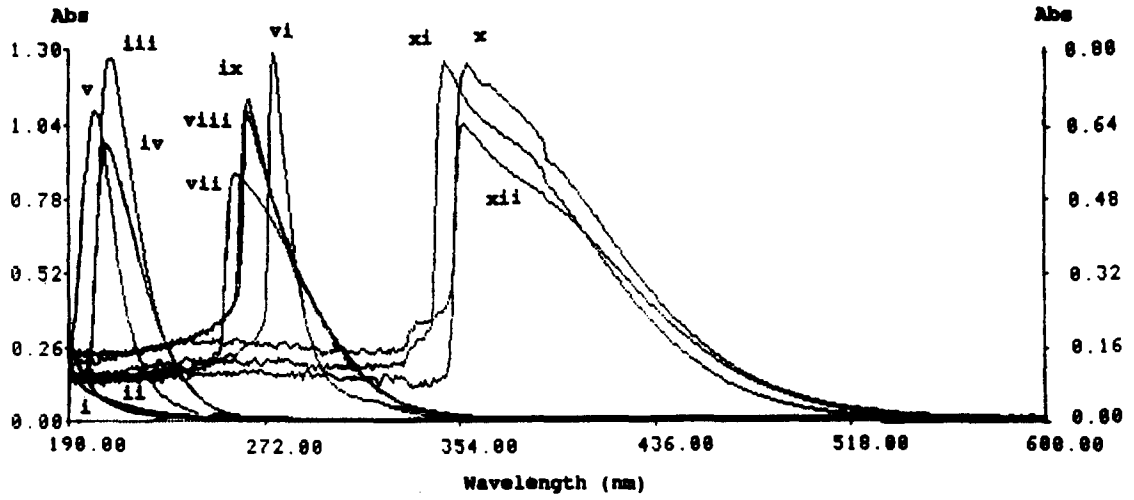

Fig. 3. Effect of oxygen on the CCT absorption spectra of the solvents. Absorbance ranges: (i) $H_2O$, 0.00–0.80; (ii) MeCN, 0.00–0.80; (iii) MeOH, 0.00–1.30; (iv) EtOH, 0.00–1.30; (v) *n*-heptane, 0.00–1.30; (vi) Bz, 0.00–0.80; (vii) DMSO, 0.00–0.80; (viii) DMF, 0.00–0.80; (ix) DMA, 0.00–1.30; (x) DMT, 0.00–1.30; (xi) DEA, 0.00–1.30; (xii) DET, 0.00–1.30. All solvents were saturated with 100% oxygen. The optical pathlength of cuvettes is 1 cm and the reference is the corresponding air-saturated solvent.

the results for all the solvents of $A_{O_2}$ plotted against $P_{O_2}$, where $A_{O_2}$ = absorbance of the solvent containing oxygen with a partial pressure of $P_{O2}$ – absorbance of the solvent saturated with nitrogen, i.e. $P_{O_2} = 0$. The slopes, *y*-intercepts and correlation coefficients of the graphs are tabulated in Table 1, and show that $A_{O_2}$ varies linearly with $P_{O_2}$. Similar straight line graphs are obtained for the solvent when other wavelengths in the CCT absorption bands are used and clearly plots of $A_{O_2}$ against $P_{O_2}$ will have the greatest slope for wavelengths at the maximum of the absorbance peak for the CCT spectrum. However, reliable results can only be obtained using wavelengths near the red end of the CCT absorption spectrum, because of problems caused by the strong absorption of the solvent at the peak of the CCT absorption as described earlier.

### 3.3. The effect of the concentration of the solvent on the CCT absorption

If $P_{O_2}$ is kept constant, Eq. (5) can be expressed as

$$A_{O_2} = k_2[\mathrm{D}]^x \quad (6)$$

where $k_2 = k_1 P_{O_2}$. Taking the logarithm on both sides of Eq. (6), the expression becomes

$$\log(A_{O_2}) = x \log[\mathrm{D}] + \log k_2 = x \log[\mathrm{D}] + k_3 \quad (7)$$

where $k_3$ is a constant. Plotting $\log(A_{O_2})$ against log[D] will produce a straight line graph with a slope equal to $x$. The values of

Table 1

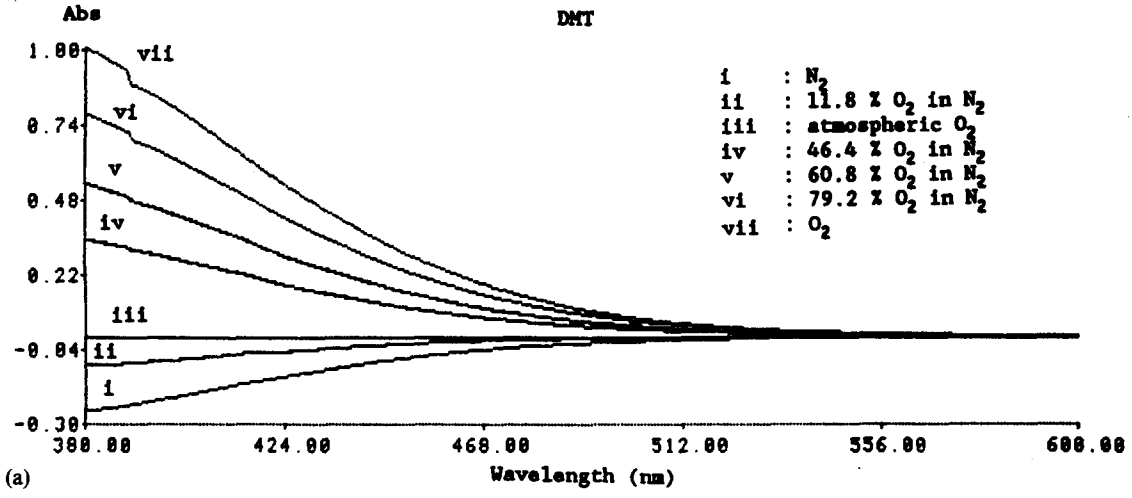
| DET | 6.93 | 8.18 | 7.80 | 0.9988 |

[a] Calculated using Ref. [20]

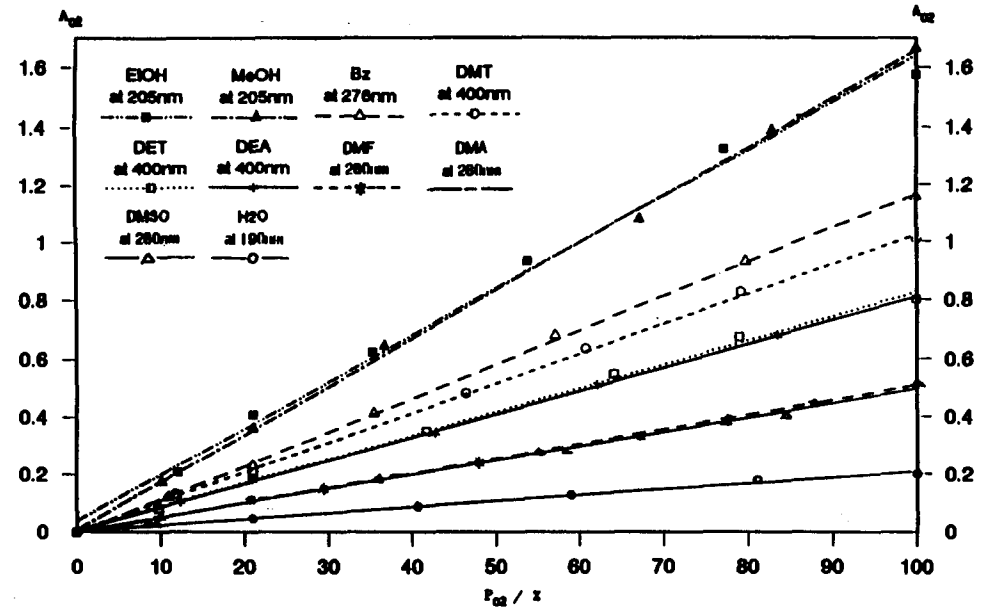
[D] were varied experimentally by diluting some of the solvents with MeCN or *n*-heptane which have no CCT absorption bands at the wavelengths used and the values of $x$ determined by plotting $\log(A_{O_2})$ against log[D] for a series of DEA/*n*-heptane, DMT/*n*-heptane, Bz/MeCN, DMSO/MeCN, DMF/MeCN and DMA/MeCN mixtures at a particular partial pressure of oxygen. The results for the CCT absorption spectra of DMT/*n*-heptane mixtures are shown in Fig. 5(a). The other solvent mixtures behave in a similar way to the DMT/*n*-heptane mixture, although these results are not reported in the paper. The plots of $\log(A_{O_2})$ against log[D] for all the solvent mixtures are shown in Fig. 5(b). The results in Table 2 show that the slope of each line is close to unity, which means that in each case the CCT complex is formed from one donor and one oxygen molecule. In the analysis of the results, it has been assumed that for a particular series of solvent mixtures, the concentration of dissolved oxygen (or Henry's constant) is the same in each case: this assumption is reasonable since, even for the most dilute mixture used, the solvent concentration is much greater than the concentration of dissolved oxygen.

### 3.4. The design of a sensing system for oxygen

The experimental results of the CCT absorption spectra of the solvents show that DMT is



(a)

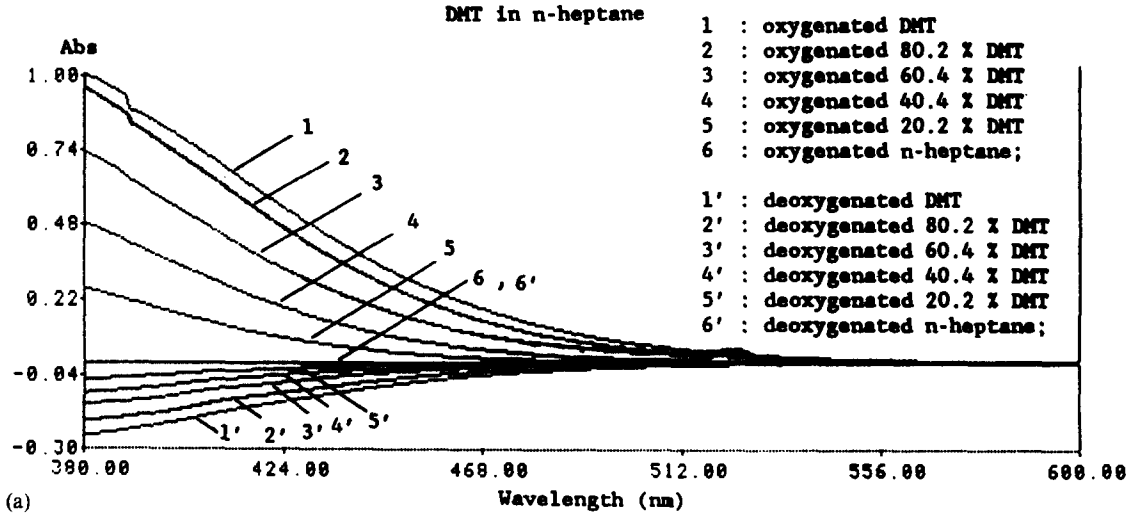


(b)

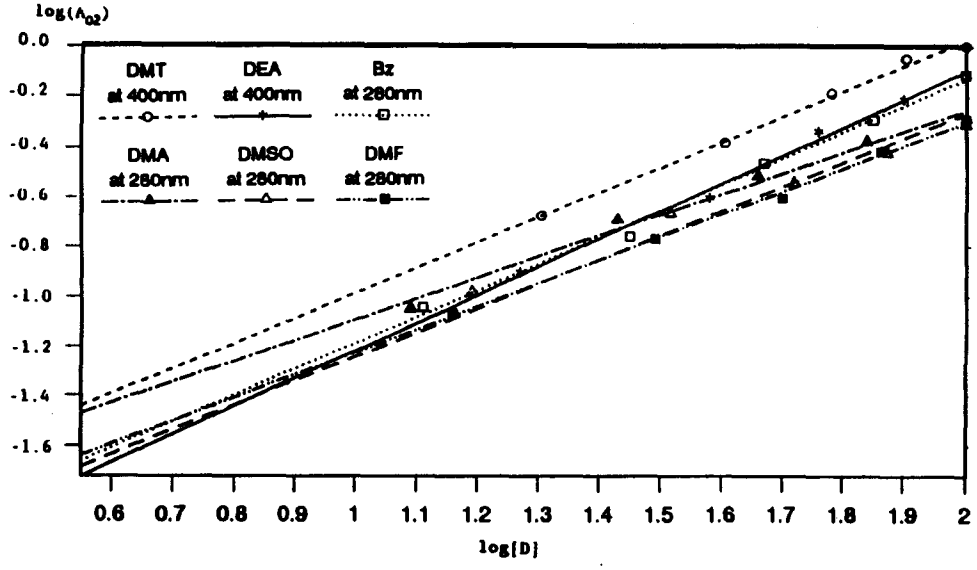
Fig. 4. (a) Effect of different oxygen concentrations on the CCT absorption spectra of DMT. The optical pathlength of the cuvettes is 1 cm and the reference is air-saturated DMT. (b) Effect of different oxygen concentrations on the CCT absorption of the solvents. The plots are the absorbance of the solvent, $A_{O_2}$, at the wavelengths shown for the different solvents against the partial pressure of applied oxygen, $P_{O_2}$ in the solvent.

a promising solvent to be used in the development of a sensing system for oxygen. It has a CCT absorption spectrum extending well into the visible region so it can be used with inexpensive plastic fibres; it is also more sensitive to oxygen than DEA or DET. In addition, many amino compounds like DMT, exhibiting CCT absorption, do not result in any products on irradiation and are recovered unchanged [16]; it is also an inexpensive and readily available solvent. Using the apparatus described earlier (Fig. 2), the response, reproducibility and total signal change of the sensing system were investigated with light at a wavelength of 400 nm and gas at a flow rate of 60 $cm^3$ $min^{-1}$ through the solvent in a 1 cm pathlength cuvette. Fig. 6 shows the response of the sensing system to step changes in gas concentrations from 100% $O_2$ to 100% $N_2$ (0%$O_2$) and back to 100% $O_2$, and then from 100% $O_2$ to 100% $CO_2$ (0% $O_2$) and back again to 100% $O_2$. The reversibility of the sensing system is good and there is no cross interference from $CO_2$. The response time is 1.3 min and 2.2 min for a 90% signal change from $N_2$ to $O_2$ and from $O_2$ to $N_2$, respectively.

The response of the sensing system when subjected to different levels of oxygen was investigated (Fig. 7). As expected, the decrease in signal level with increasing oxygen concentration is non-linear (Fig. 8(a)). The sensitivity (indicated by the slope of the graph) decreases as the concentration of oxygen increases and



(a)



(b)

Fig. 5. (a) CCT absorption spectra of DMT/*n*-heptane solvent mixtures. Solvent mixtures are in mole percentages. The measurement conditions are the same as Fig. 4(a). (b) Effect of the concentration of the different solvents [D] on CCT absorption. Plots of $\log(A_{O_2})$ against log [D].

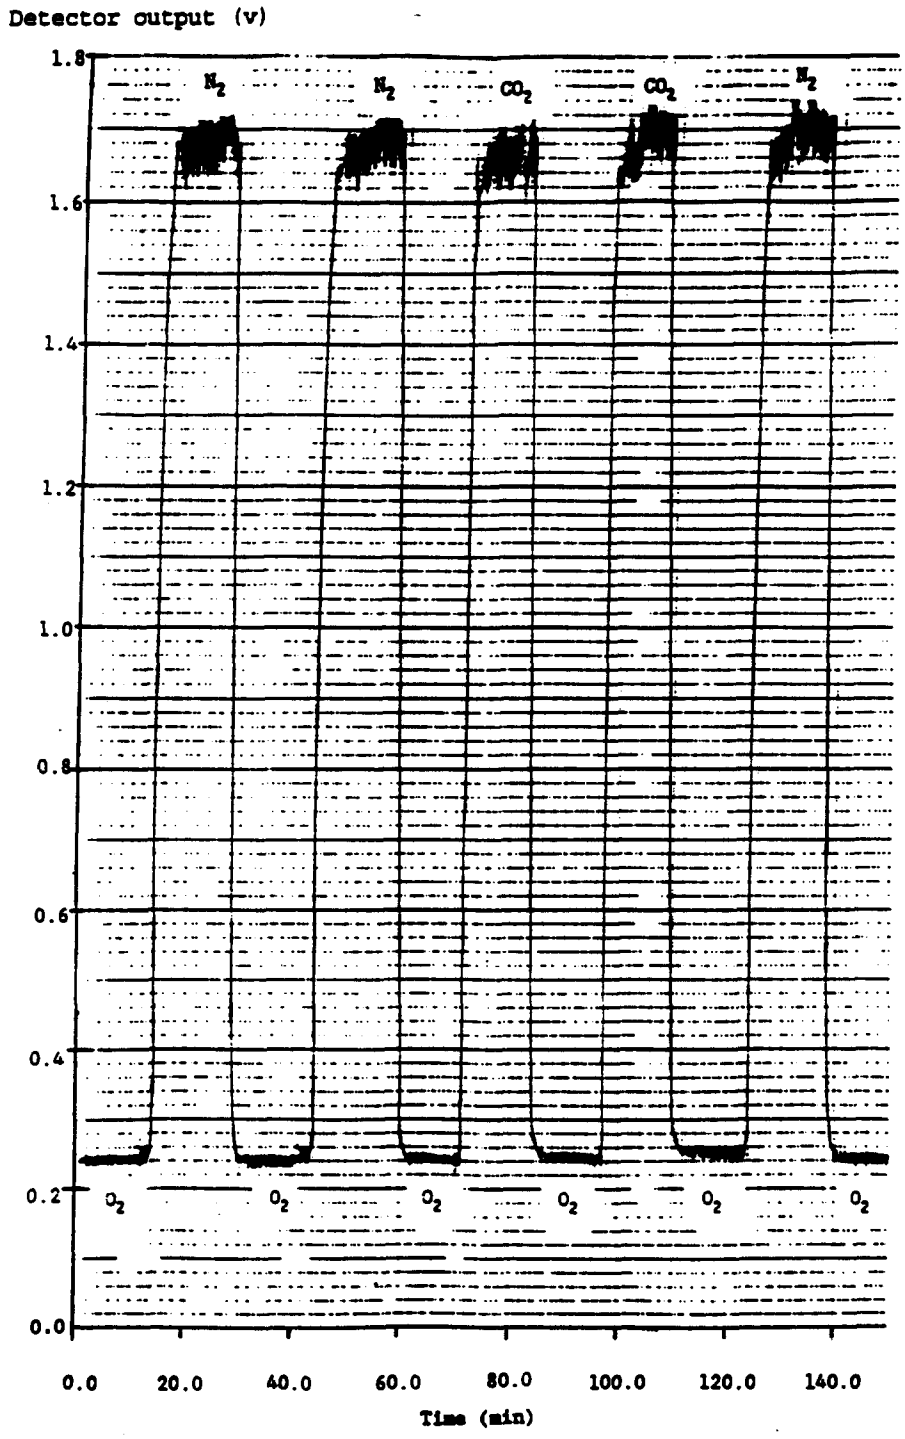


Fig. 6. Response time, reproducibility and total signal change of the sensing system for oxygen when subjected to rapid changes between oxygen → nitrogen → oxygen and oxygen → carbon dioxide → oxygen. 3.0 ml of DMT in a 1 cm cuvette was used with light of wavelength 400 nm and a gas flow rate through the DMT of 60 $cm^3$ $min^{-1}$.

the most sensitive region is between 0 and 20% $O_2$ with about a 35% change in signal level. The sensing system responds over the range 0–100% $O_2$ with a response which is in agreement with the Beer–Lambert law, so that a linear graph (slope = 0.008 21% and correlation coefficient = 0.9968) is obtained when $\log(I_{N_2}/I_{O_2})$ is plotted against $[O_2]$; $I_{N_2}$ is the signal level recorded in nitrogen only (i.e. $[O_2] = 0$) and $I_{O_2}$ is the level recorded in a gas mixture having an oxygen concentration of $[O_2]$ (Fig. 8(b)).

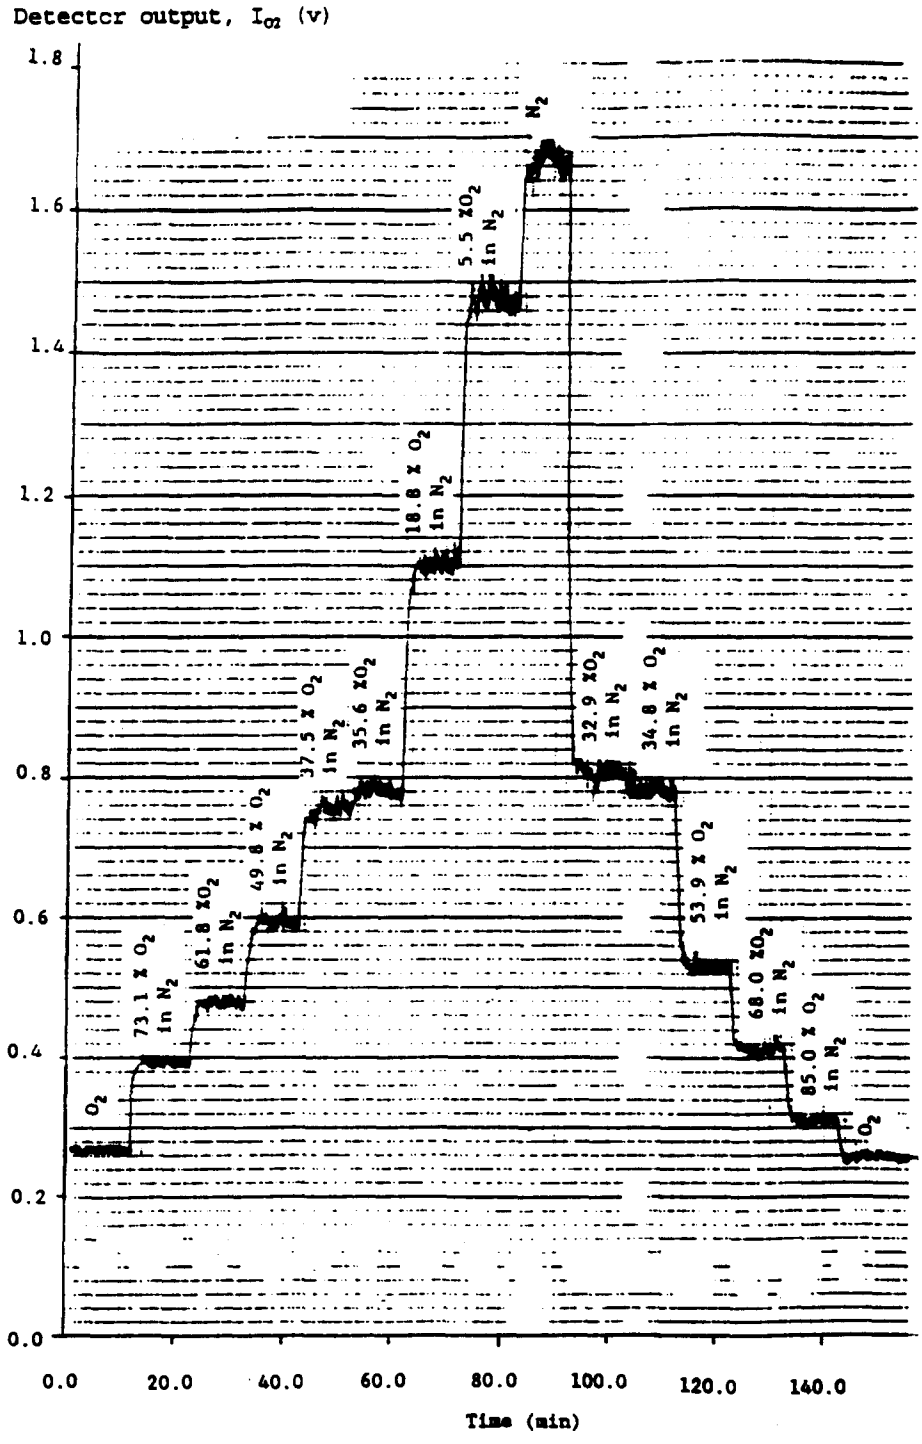

Fig. 7. Variation in output signal level $I_{O_2}$ of the sensing system for oxygen when subjected to different oxygen concentrations. Measurement conditions were the same as in Fig. 6.

The solvent used has very good stability with no noticeable change in the response to oxygen over a long period under the experimental conditions.

## 4. Conclusions

This study demonstrated the possibility of using some aniline derivatives or other solvents

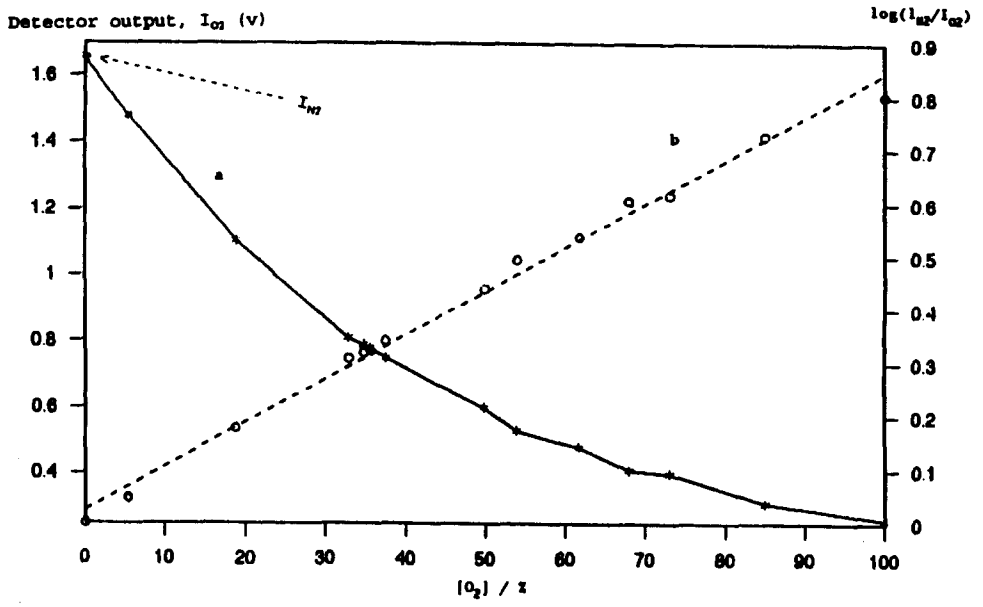

Fig. 8. Graphs plotted using data from Fig. 7. (a) Plot of the detector output ($I_{O_2}$) against $[O_2]$. (b) Plot of $\log(I_{N_2}/I_{O_2})$ against $[O_2]$, where $I_{N_2}$ is the signal level with nitrogen passing through DMT.

having low ionization potentials (e.g. DMT) as an oxygen-sensitive material for the determination of gaseous oxygen. The response time of the above sensing system is slow, but it can be reduced substantially by using a miniaturized, thin-wall cuvette which fits on the end of the fibre bundles. Although the present sensing system is a single wavelength monitoring system, the stability of the signal can be further improved by placing a light beam splitter in front of the cuvette and ratioing the output of the sample beam to the output of the reference beam. A further advantage of using DMT is that other analyte-sensitive materials can be incorporated to give a multi-analyte-sensitive material. An example is the dissolution of the pH-sensitive dye in the solvent for simultaneously sensing oxygen (based on the CCT absorption of solvent) and carbon dioxide (based on the change of absorbance of dye). Some of our preliminary experiments show that the principle is working, and further investigation is still being undertaken. One possible disadvantage of the sensing system is the cross interference from strong acidic gases such as hydrogen chloride [15] and other electron acceptors such as nitric oxide [18].

Table 2
The slopes, $y$-intercepts and correlation coefficients of Fig. 5(b)

| Solvent | Slope | $y$-Intercept | Correlation coefficient |
|---|---|---|---|
| DEA | 1.12 | −2.34 | 0.9973 |
| DMT | 1.01 | −2.00 | 0.9979 |
| Bz | 1.06 | −2.24 | 0.9965 |
| DMSO | 0.98 | −2.22 | 0.9938 |
| DMF | 0.92 | −2.15 | 0.9985 |
| DMA | 0.84 | −1.93 | 0.9943 |

Received 22 December 1994; revised 4 January 1995; accepted 13 January 1995

**Abstract**

Four new sulfur-containing compounds based on pyridine, benzene, 1,8-naphthyridine and 1,10-phenanthroline have been synthesized. These molecules have been incorporated into a polymeric matrix as neutral carriers and evaluated as silver sensors. Two of the compounds (pyridine and benzene) show high selectivity for $Ag^+$. The sensor with the pyridine-based compound, in particular, shows near-Nernstian response and good sensitivity towards $Ag^+$ with a short response time (<10 s), making it ideal for use in flow analysis.

## 1. Introduction

A significant number of macrocycles ranging from crown ethers to acyclic dithia benzene derivatives have been reported to possess good to excellent selectivity for silver when used in polymeric membrane electrodes [1–7]. The affinity exhibited by these molecuels for this $d^{10}$ metal is primarily due to the presence of sulfur atoms that serve as donor atoms for complexation.

We previously reported a work [8] describing a series of pyridine-based macrocycles containing sulfur and/or oxygen atoms in a two- to six-atom bridge unit. The reagents containing sulfur atoms showed high bonding affinities for class b acceptors, particularly silver and mercury. The ionophores in this series all contained an octyloxy group in the pyridine ring to convey lipophilicity to the molecule, making it more compatible with poly(vinyl chloride) which was used as the matrix in the sensor membrane.

We have carried out further work on sulfur-containing molecules for use in sensors for the silver ion, which are described in this paper. The four molecules studied are all open chain thiol esters based on pyridine, benzene, 1,8-naphthyridine and 1,10-phenanthroline. The molecules which have been synthesized and investigated are shown in Fig. 1. It is interest-

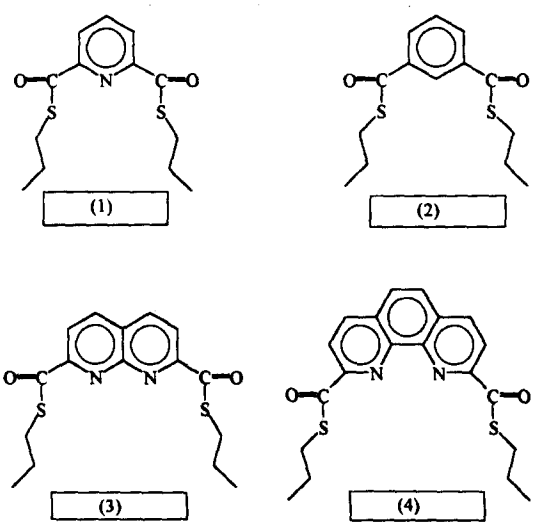

Fig. 1. Structures of pyridine thiol ester (1), benzene compound (2), naphthyridine compound (3) and phenanthroline compound (4).

ing to note that these compounds, dissolved in a suitable plasticizer, showed good compatibility with PVC without the necessity of having a long alkyl chain in their structure.

## 2. Experimental

### 2.1. Preparation of compounds

The synthesis of the four compounds was similar in that the appropriate dicarbonyl chloride was reacted with propanethiol. The reaction to form the benzene derivative took longer and produced a yellow oil, while the other three eventually produced solids.

*(a) S,S-Dipropyl-2,6-pyridinedicarbothiolate (1)*

A mixture of 2,6-pyridinedicarboxylic acid (5.0 g), thionyl chloride (20 ml) and a drop of dimethylformamide was refluxed for 3 h. The thionyl chloride was removed in vacuo and the dicarbonyl chloride was recrystallized from light petroleum (b.p. 60–90 °C) before being used immediately in the next step.

Propanethiol (6 ml) was added to the dicarbonyl chloride and dichloromethane (50 ml) in a flask protected by a calcium chloride drying tube. The mixture was refluxed for 1 h. The cooled solution was then washed with NaOH (10%) (3 × 50 ml) and water (3 × 50 ml). The organic layer was separated, dried ($MgSO_4$) and the solvent evaporated to leave white crystals, which were recrystallized from methanol/water (15:1) to give the thiol ester (1) (5.28 g, 71%), m.p. 40–42 °C. $^1$H NMR ($CDCl_3$, 90 MHz) $\delta$: 1.18, t, $J$ 9 Hz, $CH_3$; 1.85, h, $J$ 9 Hz, $CH_2\underline{CH_2}CH_3$; 3.18, t, $J$ 9 Hz, S-$CH_2$; 8.05–8.38, m, ArH. Analysis: Calcd. for $C_{13}H_{17}NO_2S_2$: C, 55.1; H, 6.0; N, 4.9. Found: C, 55.4; H, 6.3; N, 5.2.

*(b) S,S-Dipropyl-1,3-benzenedicarbothiolate (2)*

The thiol ester (2) was prepared as for 1 from isophthaloyl dichloride (2 g) and propanethiol (2 ml), and refluxed for 8 h, to give a yellow oil. $^1$H NMR $\delta$: 1.13, t, $J$ 9 Hz, $CH_3$; 1.80, h, $J$ 9 Hz, $CH_2\underline{CH_2}CH_3$; 3.20, t, $J$ 9 Hz, S-$CH_2$; 7.62, t, $J$ 8 Hz, H-5; 8.25, d, $J$ 8 Hz, H-4,6; 8.65, s, H-2.

*(c) S,S-Dipropyl-1,8-naphthyridine-2,7-dicarbothiolate (3)*

The thiol ester (3) was prepared as for 1 from 1,8-naphthyridine-2,7-dicarbonyl chloride [9] (0.7 g) and propanethiol (1 ml) to yield a red viscous oil, which was solidified in dry ice/acetone and then recrystallized repeatedly from hexane to yield a yellow solid (50 mg), m.p. 77–79 °C. $^1$H NMR $\delta$: 1.10, t, $J$ 9 Hz, $CH_3$; 1.80, h, $J$ 9 Hz, $CH_2\underline{CH_2}CH_3$; 3.12, t, $J$ 9 Hz, S-$CH_2$; 8.24 + 8.50, d + d, $J$ 9 Hz, ArH. Analysis: Calcd. for $C_{16}H_{18}N_2O_2S_2$: C, 57.5; H, 5.4; N, 8.4. Found: C, 57.4; H, 5.6; N, 8.3.

*(d) S,S-Dipropyl-1,10-phenanthroline-2,9-dicarbothiolate (4)*

The thiol ester (4) was prepared as for 1 from 1,10-phenanthroline-2,9-dicarbonyl chloride [9] (0.8 g) and propanethiol (1 ml) to yield a solid which was recrystallized from methanol (0.5 g; 50%), m.p. 133–135 °C. $^1$H NMR $\delta$: 1.17, t, $J$ 9 Hz, $CH_3$; 1.89, h, $J$ 9 Hz, $CH_2\underline{CH_2}CH_3$; 3.22, t, $J$ 9 Hz, S-$CH_2$; 8.08, s, H-5,6, 8.45 + 8.55, d + d, $J$ 9 Hz, H-3, 4, 7, 8. Analysis: Calcd. for $C_{20}H_{20}N_2O_2S_2$: C, 62.5; H, 5.2; N, 7.3. Found: C, 62.5; H, 5.3; N, 7.3.

### 2.2. Construction of electrodes

Mixtures of poly(vinyl chloride) (34 mg), *o*-nitrophenyl-*n*-octylether (NPOE) (63.5 mg), reagent (2 mg) and potassium tetrakis(*p*-chlorophenyl)borate (0.5 mg) were dissolved in 1 ml of freshly purified tetrahydrofuran (THF) [8]. Approximately eight drops of each membrane solution were added dropwise into a glass electrode barrel (length 100 mm; i.d. 3 mm; o.d. 10 mm) clamped vertically onto a glass microscope slide. The solvent was allowed to evaporate and a clear homogeneous membrane was obtained which adhered firmly to the end of the barrel.

An internal reference element (Ag/AgCl) was then fitted inside the electrode barrel which was filled with an appropriate internal solution ($10^{-1}$ M KCl or $KNO_3$ with 2 drops of 0.1 M $AgNO_3$). Electrodes were conditioned overnight in a 0.1 M solution of the primary ion.

An Orion Ag–AgCl double-junction reference electrode with an outer chamber filling solution of 10% $KNO_3$ solution was used in conjunction with the working electrodes. The electrochemical cell for this study was as follows:

Ag–AgCl/internal solution/sensor membrane/test solution//reference electrode.

Potential measurements were made, as previously described [8], with an Orion 901 Iona-

lyzer digital pH/mV meter interfaced to an Apple IIe microcomputer through a switching box to allow evaluation of several electrodes at one time.

### 2.3. Response characteristics

Initial response tests were done in KCl or $KNO_3$ solutions in the concentration range of $10^{-5}$ to $10^{-1}$ M to ensure the electrodes were functioning. Subsequent electrode response studies were done in $Ag^+$ solutions, since $Ag^+$ was found to be the preferred ion based on preliminary selectivity studies performed against $K^+$ as the primary ion. A criterion of stability [8] was employed in all e.m.f. measurements such that the steady-state potential was defined as the value which did not change by more than $\pm 0.1$ mV over a period of 2 min.

### 2.4. Selectivity study

As mentioned above, all the ligands reported here showed a high selectivity for the $Ag^+$ ion, and so further selectivity studies were carried out using $Ag^+$ as the primary ion. The two-point mixed-solution method [10] was used for this purpose. This was carried out by measuring the potential in a $10^{-3}$ M solution $Ag^+$ and then in a mixed solution containing $10^{-3}$ M of $Ag^+$ and $10^{-1}$ M of the interfering ion. Owing to the narrow linear range of compound **2**, a $10^{-4}$ M solution of $Ag^+$ and a mixed solution of $10^{-4}$ M $Ag^+$ and $10^{-2}$ M of the interfering ion were used for the pertinent selectivity study. Selectivity coefficients were then calculated using the Nicolsky equation. Ion activities were estimated using the Debye–Hückel equation.

All inorganic salts were of analytical reagent grade and all solutions were made up in NANO pure water (17 MΩ cm, Barnstead, Dubuque, IA, USA).

### 2.5. Flow system

The flow injection (FI) system used consisted of a Gilson Minipuls 2 peristaltic pump, an automatic injector system [11], a multi-channel potentiometric flowcell [11,12] and a PC-based data acquisition unit. Teflon tubing of 0.5 mm i.d. was used in the manifold.

Data collection and analysis were achieved using the flow control system (FCS) software [13] designed for flow injection work. The software utilizes an A/D card which collects and converts analytical signals from a maximum of eight detectors at a specified sampling rate. Data processing routines such as peak measurement (i.e. height, width, area), data smoothing, noise filtering, baseline correction and statistical analysis are done by the software.

The automatic injector system [11] was composed of two miniature two-way solenoid valves (Lee Co., CT, USA) which deliver the desired sample volume (50 μl for this work) and the carrier solution to the flow injected manifold. The software controls the sample volume injected using an electronically-controlled pulse to switch the solenoid valve on for sample delivery.

The multi-channel potentiometric flowcell [11,12] used in this study is an improved version of a miniature flowcell [14] previously reported in the literature. The flowcell consisted of four silver wires which served as contacts for the $Ag^+$ sensing membrane. The reference electrode was Ag/AgCl with its own reference stream consisting of 0.1 M $NH_4NO_3$ with $10^{-6}$ M $AgNO_3$. The same solution was used as carrier and all standard $AgNO_3$ solutions were made up in 0.1 M $NH_4NO_3$.

### 2.6. Steady-state measurements

Steady-state measurements were done by continuously pumping each silver standard solution into the flowcell until equilibrium was attained.

## 3. Results and discussion

### 3.1. Silver ion response

The potential responses in $AgNO_3$ solutions of the PVC electrodes based on the four neutral carriers synthesized are summarized in Table 1. The pyridine-based neutral carrier (**1**) exhibits Nernstian behavior in the activity range of $10^{-5}$–$10^{-1}$ M, with a slope of 58 mV/decade change in $Ag^+$ activity. The dithiabenzene compound (**2**) shows a near-Nernstian slope of 55 mV/p$Ag^+$ activity in the range of $10^{-4}$–$10^{-2}$ M. However, for the naphthyridine (**3**) and phenanthroline (**4**) based carriers, a non-Nernstian response is observed with slopes of 49 mV/p$Ag^+$ between $10^{-4}$ and $10^{-1}$ M, and 36 mV/p$Ag^+$ between $10^{-4}$ and $10^{-2}$ M,

Table 1
Potential responses of silver-selective membrane electrodes based on ionophores **1–4**

| Compound | % ionophore (m/m) | Slope (mV/pAg$^+$) | Concentration range (M) |
|---|---|---|---|
| **1** | 2% | 58.0 | $10^{-5}$–$10^{-1}$ |
| **2** | 2% | 55.0 | $10^{-4}$–$10^{-2}$ |
| **3** | 1% | 55.0 | $10^{-5}$–$10^{-1}$ |
| **3** | 2% | 49.0 | $10^{-4}$–$10^{-1}$ |
| **3** | 5% | 41.0 | $10^{-4}$–$10^{-1}$ |
| **4** | 2% | 36.0 | $10^{-4}$–$10^{-2}$ |
| **4** | 2% | −53.0 | $10^{-2}$–$10^{-1}$ |

respectively. Attempts were made to improve the response of the former by varying the amount of the reagent. Increasing the ionophore content to 5% (m/m) gave a slope of 41 mV/pAg$^+$ over $10^{-4}$–$10^{-1}$ M, while reducing it to 1% (m/m) improved the slope to 55 mV/pAg$^+$ in the activity range of $10^{-5}$–$10^{-1}$ M.

Very good response times were obtained for compounds **1** and **2**, the $t_{95\%}$ being no more than 10 s with good reproducibility. Significantly slower response times were found for compounds **3** and **4**.

Between $10^{-2}$ and $10^{-1}$ M, the phenanthroline compound (**4**) showed a negative slope of −53 mV/pAg$^+$, a response close to that expected for a monovalent anion. Such behavior has been observed in previous work [8] and is explained as being due to strong complexation of the silver ion by the ligand which inhibits metal ion exchange with the resulting positively charged complex. Such a complex can, however, extract a charge-satisfying anion such as nitrate, thus giving rise to an anion response.

### 3.2. Selectivities

Selectivity coefficients for Ag$^+$ with respect to other cations for the electrodes based on the three ionophores **1**, **2** and **3** are summarized in Fig. 2. It can be seen that the electrodes for the three ionophores are highly selective for the silver ion, particularly in the presence of other heavy metal ions. The one exception to this is Hg$^{2+}$, which irreversibly poisons the membrane in each case. In fact, there is evidence [15] for the pyridine-based ligand that reaction with mercury leads to disintegration of the ionophore structure. Work is continuing on an investigation of this phenomenon [15].

Attempts to carry out selectivity studies for the phenanthroline derivative (**4**) failed because most metal ions interfered strongly and irreversibly. This is not surprising as phenanthroline is known to be a very effective chelating agent for transition metals.

The high selectivity towards Ag$^+$ exhibited by compounds **1** and **2** is an indication that, although the binding between the metal and the ionophores is relatively strong, the complex formed is quite labile. The presence of the sulfur atoms in the propyl side chains, which serve as excellent receptors for the Ag$^+$, is the key factor in the high selectivity demonstrated by ionophores **1** and **2**. This is consistent with previous work describing a number of macrocycles [8], in which oxygen atoms in the rings were substituted by sulfur atoms resulting in much higher bonding affinities towards class b acceptors such as Ag$^+$ and Hg$^{2+}$. This work also demonstrates that it is not necessary to form a macrocyclic ring in order to obtain high selectivity for a particular ion.

The only structural difference between compounds **1** and **2** is the presence of the nitrogen atom in the former. The lower selectivity for Ag$^+$ is attributable to this nitrogen atom which can be involved in complexation, particularly with transition metals.

Compounds **1** and **2** share some similarities with a group of ionophores reported in the literature [7]. The benzene-based compound (**2**) is similar to a family of acyclic dithia benzene derivatives [7] which display a Nernstian response towards Ag$^+$. The main structural difference lies in the presence of the thiocarboxylate groups and two propyl pendant chains in **2**, whereas the reported dithia benzene derivatives either had shorter or longer side chains and no CO functional groups. The same work also reported a group of acyclic $NS_2$ ligands which resembled the parent molecule of compound **1** in a similar way. Although the structural differences between one of the reported molecules and compound **1** are only minor, it is interesting to note that no special selectivity has apparently been found for that particular ligand and the rest of the group.

We have, evidently, developed a highly sensitive and selective silver sensor based on a pyridine thiol ester (**1**), which displays a Nernstian response over a wide concentration range. It also has a very fast response of less than 10 s and exhibits excellent electrode reproducibility.

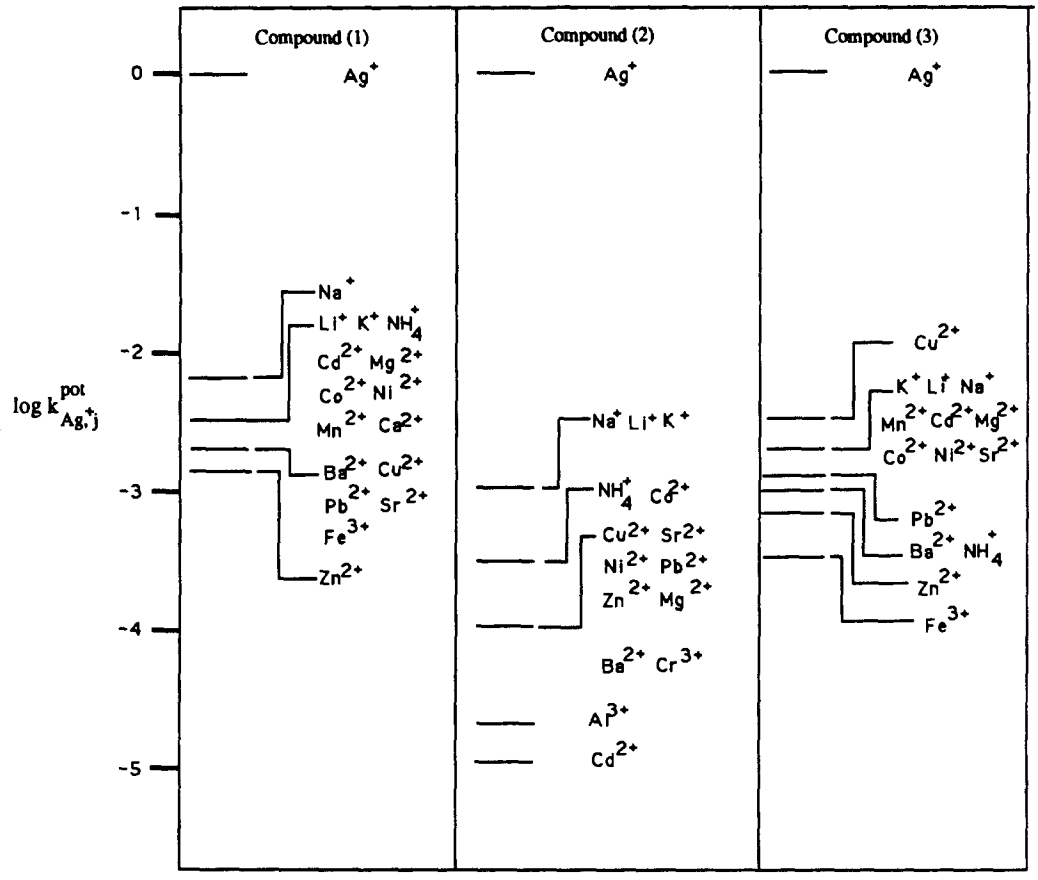

Fig. 2. Selectivities of ionophores 1, 2 and 3 for various metals against $Ag^+$ as the primary ion.

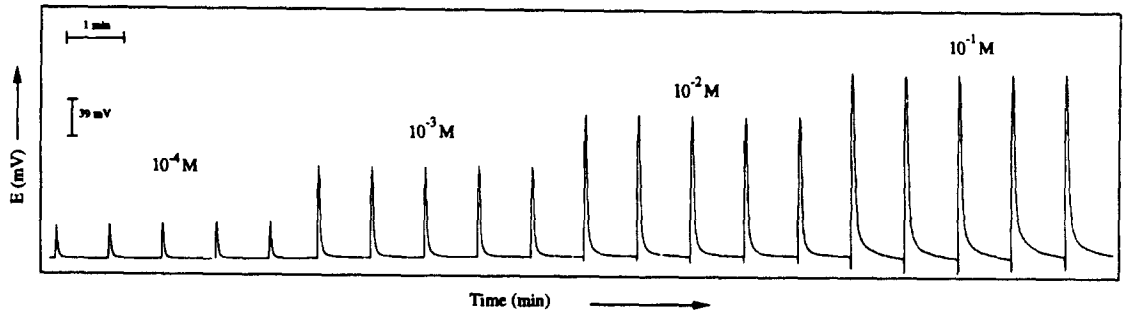

Fig. 3. Typical flow injection calibration plot for the silver-selective sensor based on ionophore 1.

Although the dithiabenzene compound (2) appears to possess good selectivity, its response characteristics are inferior compared to the pyridine thiol ester (1).

Because of its excellent reproducibility and fast response, the sensor has particular advantages in flow analysis. It has been applied to flow injection for the direct measurement of silver, and a typical output generated by the FCS software [13] is shown in Fig. 3. It can be seen that the peaks are very sharp with good precision (RSDs for the peak height measurements of 1% for $10^{-3}$–$10^{-1}$ M and <2% for $10^{-4}$ M).

A typical calibration graph for a range of silver standards with $10^{-4}$–$10^{-1}$ M $Ag^+$ is shown in Fig. 4, and is compared with that obtained from steady-state measurements. It can be seen that the FI calibration is almost identical to the steady-state case which demonstrates the very fast response of the sensor, making it ideal for use in flow injection.

Further work [12] is presently being done on the application of this pyridine-based silver sensor in the indirect determination of chloride in water samples.

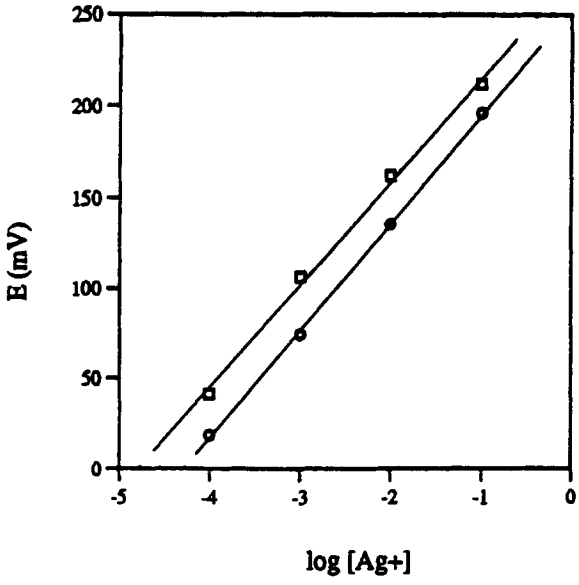

Fig. 4. A comparison of the silver sensor response in steady-state and flow injection modes: □, FI mode; ○, steady-state mode.

## Acknowledgments

We wish to thank the Australian Research Council (ARC) for financial support. One of the authors, C.G. Gregorio, is grateful for an Australian International Development Assistance Bureau award.

# Book reviews

***Physical Chemistry***, 5th edn., by P.W. Atkins, Oxford University Press, Oxford, 1994, xix + 1031 pp. + about 100 pp. of additional information, softback, £24.00. ISBN 0-19-855730-2.

The first edition of this book appeared in 1978 and there has been a new edition every 4 years. Its low price is a reflection of its popularity and it is claimed by Oxford University Press to be the world's best-selling textbook on physical chemistry. It is certainly purchased in great numbers by students studying chemistry at university.

So what is new for this edition? Well, the most obvious addition is the use of a colour — blue — to enhance many of the diagrams and headings. *Justifications* are also introduced where, for example, derivations of mathematical formulae are presented. This separates some of the in-depth treatment, which may seem daunting at first, from the text. Other details also considered to be somewhat intrusive are given as *Further information* at the end of the book.

The main layout of the text is still in three parts: Part 1—*Equilibrium*; Part 2—*Structure*; and Part 3—*Change*. The 29 chapters are prefixed with chapter 0 which gives an overview of the book's content. New to Part 1 is the introduction of *Molecular interpretations* which show the interpretation of a bulk result in terms of atomic and molecular properties. These interpretations supplement the rigour of thermodynamics and are an addition which will be welcomed by many students. At the end of each chapter a checklist of key ideas is now present, a feature which formerly appeared at the beginning of each chapter. However, each chapter now starts with an abstract of the contents so, overall, the important concepts are more than adequately emphasised.

Numerous problems (with answers) are also presented at the ends of chapters and a separate Solutions Manual may be purchased. In addition there are many worked examples in the text and each of these are clearly explained under the headings: *Method*, *Answer* and *Comment*.

This is a book which attempts to cover a very wide number of topics and hence some will only be dealt with at a cursory level.

A *Further reading* section addresses this criticism where references to articles of general interest and texts and sources of data and information for each chapter are grouped together. I found the treatment of tables in the text somewhat disjointed as some are contained in the relevant chapter, some are presented in a shortened form in the chapter and in a longer form in a *Data section* and others — some short, some long — are only given in the *Data section*.

Many academic staff from the UK and USA have made contributions to the preparation of this book and I am sure this edition will be welcomed by them as many up-to-date changes have been made since the fourth edition. The book must first find favour with academic staff who recommend books for students to purchase. It is to be hoped that the many innovations in the text will find favour amongst both staff and students.

***Photochemical Vapor Deposition*** by J.G. Eden, Wiley, Chichester, 1992, xi + 193 pp., £43.95. ISBN 0-471-55083-3.

Photochemical vapour deposition (photo-CVD) is a recent development of CVD, where the introduction of visible or UV light into the CVD reactor opens up new possibilities of reducing film-growth temperatures and for producing novel materials. These materials include abrasion-resistant coatings, epitaxial layers for semiconductor lasers and low scatter films for optical components such as mirrors and beam splitters. This is clearly a topic of enormous technological importance, where experimental techniques may change as a result of ongoing

developments. The appearance of this authoritative monograph by Professor Eden is therefore very welcome.

After a brief Introduction in Chapter 1, Chapter 2 covers the fundamental aspects of photo-CVD including a general classification of photo-assisted deposition processes, the optical characteristics of molecular ad-layers and surface kinetics. Chapter 3 deals with reactors, optical sources and all the associated equipment. Subsequent chapters present a systematic overview of the applications of these methods in the deposition of metal films, semiconductors (such as elemental C and Si and various compounds and Ga, for example), dielectrics (such as $SiO_2$ and $Al_2O_3$) and indeed of polymer films.

The presentation throughout is clear and straightforward with easy-to-follow diagrams and useful tables. This book can be commended to industrialists interested in these applications, to experienced researchers, and to new students approaching this topic for the first time.

***Kirk-Othmer Encyclopedia of Chemical Technology***, Vol. 12, 4th edn. (Fuel Resources to Heat Stabilizers, edited by J.I. Kroschwitz and M. Howe-Grant), Wiley, New York, 1994, xxviii + 1091 pp., £185.00. ISBN 0-471-52681-9 (v. 12).

Well over 12 000 pages of this encyclopedia, which contains a wide variety of topics related to chemical technology, have now been published. The entries are arranged in alphabetical order and volume 12 extends to the letter 'H'.

Four different elements and their compounds are covered in this current volume: gallium, germanium, gold and hafnium. In each case physical and chemical properties are given along with details of occurrence, manufacture, economic aspects, analytical procedures, health and safety, and uses.

Several entries deal with fuel. These include fuel resources, fuels from biomass, fuels from waste, fuels — synthetic, furnaces — fuel fired, gas — natural and gasoline, and other motor fuels. Many tables, flow-charts and graphs are included here and as with all entries a substantial number of references are given.

Other entries which clearly relate to chemical engineering include the topics: fusion energy, geothermal energy, geotextiles, groundwater monitoring, hardness, hazard risk analysis and heat-exchange technology.

The related entries — glass, glass-ceramics, glasses (organic–inorganic hybrids) and glassy metals cover over 120 pages with photographs supplementing the tables and figures.

Classes of chemical compounds in this volume include glycols and Grignards and there are separate entries for gelatin and glycerol. Several chemical structures and reactions are presented. Other diverse entries which I found to be of interest — and will no doubt refer to again — deal with fungicides-agricultural, gastrointestinal agents, gemstones, genetic engineering, growth regulators, gums, and hair preparations.

As with previous volumes a wealth of information is presented on a wide variety of diverse topics that should satisfy the intellectual curiosity of most, if not all, chemists.

P.J. Cox

developments. The appearance of this authoritative monograph by Professor Eden is therefore very welcome.

Review

# Metal speciation in solid matrices

Arabinda K. Das [1], Ruma Chakraborty [1], M. Luisa Cervera, Miguel de la Guardia *

*Department of Analytical Chemistry, University of Valencia, 50 Dr. Moliner St., 46100 Burjassot, Valencia, Spain*

Received 17 November 1994; revised 16 January 1995; accepted 7 February 1995

**Abstract**

The literature on metal ion speciation in solid matrices is reviewed, taking into account its applications in the analysis of soil, sediment, biological materials, foodstuff and other solid samples. The pretreatment methods of various solid materials required for carrying out speciation studies have been highlighted. The basis of the methods of separation of different species from matrices, such as sequential extraction, selective extraction, etc. is discussed. The instrumental techniques used for the characterization of different chemical species in solid matrices have been mentioned. The literature survey reveals the analytical details of the developed methodologies, and these have been examined in terms of the limit of detection, precision and accuracy.

## 1. Introduction

An increasing number of recent publications have dealt with the study of chemical speciation of trace elements. At present, the necessity to advance our knowledge of the mobility of chemicals in soils and the physiological activity of the inorganic elements makes necessary not only the determination of the total amount of these elements, but also the exact determination of the concentration of their different chemical forms [1].

Speciation analysis normally refers to the determination of species of metals and metalloids including organometallic compounds. As a matter of fact, speciation is very significant when applied to trace elements, because the analytical difficulties are related to the choice of relevant techniques for measurement of the individual species.

Speciation studies of trace elements in various phases in the environment are widely used in investigating the effects of a particular element in the ecosystem. Speciation analysis is also concerned with the characterization of poorly defined forms of metal ions.

Different aspects of speciation have been discussed in some recent review articles and books [2–6]. For example, the different general aspects of speciation analysis were reviewed by Lund [2]. Also, Van Loon and Barefoot [3] reviewed a selection of major developments in the field of analytical methodology for elemental speciation for the period from January 1986 to December 1990. Nevertheless, much of the published work on metal speciation has dealt with the determination of trace metal species in natural waters. It also transpires that papers on speciation in solid matrices are scattered in the literature.

Although it is now possible to determine various elements at the nanogram per gram level in different samples with the aid of currently available analytical instrumentation, the same measure of success has not yet been

* Corresponding author.

*SSDI* 0039-9140(95)01557-4

achieved for the determination of the same elements in solid matrices. This is currently due to changes in the species during the pretreatment of samples. Also, inaccurate results are sometimes obtained because of the differences in the analytical response of the various physical and chemical forms of the same element. A further problem that is encountered in chemical speciation of solids is that the analytical sensitivity for certain elements is inadequate, as we are dealing with only fractions of the total content. Thus it will be highly interesting to study different aspects of speciation studies in various types of solid samples, in order to evidence the present state of the art.

The references for which the present work has been carried out were collected from the Analytical Abstracts database (period 1980–March 1994) and from the Chemistry Citation Index (1991–March 1994).

The papers that have been found in the present literature review could be classified into three groups depending on a matrix criterion (for the convenience of the readers, the reference numbers of the respective groups are given in square brackets): (i) speciation of soil and sediment samples [2,7,9,10,13,17,20–27,31–41,45–72]; (ii) speciation of solid biological and food materials [5,16,23,65,75–77, 80–133]; and (iii) speciation of miscellaneous solid samples [16,32,42–44,134–143].

## 2. Speciation of soil and sediment samples

Soils and sediments constitute concentrated reservoirs of trace metals in which amounts are more magnified than those present in other adjacent phases of the environment, e.g. water, air. In the literature, speciation studies of soils and sediments are usually reported independently. This is because most natural soils are characterized by oxidized conditions, whereas non-polluted sediments are usually deposited under oxygen-deficient conditions [7]. In the environment, different situations as a consequence of the anthropogenic activity may also occur. Thus waste deposits with a high coal ash content may show a high diversity in surface layers, resulting in reducing conditions underneath; or dredged anoxic sediments may be deposited under aerobic conditions. Hence the composition of soils and sediments reflects the nature of the original base rock, the degree of degradation and leaching introduced by weathering cycles, and the influence of external inputs [8]. Metal cations in soils may be present in several different physicochemical forms, i.e. as simple or complex ions, as easily exchangeable ions, as organically bound, as occluded by or coprecipitated with metal oxides or carbonates or phosphates and secondary minerals, or as ions in crystal lattices of primary minerals [9]. From the chemical point of view, the chemical compounds of a sediment may be carbonates, hydroxides, silicates, sulfides, phosphates and organics in various stages of crystallization, stoichiometry, water content, and so on [10]. Again, the principal metal forms in sludge are soluble, being present as precipitated or coprecipitated in metal oxides, adsorbates and associated with biological residues [11].

### 2.1. Pretreatment

Storage and preparation of soil or sediment samples prior to leaching with selective reagents may affect the extractability of elements. For example, exchangeable potassium can be converted into a non-exchangeable form when samples are dried [12]. Manganese and iron solubilities decreased dramatically on air-drying, but after oven-drying, the solubility of manganese exceeded by several times that found in moist samples [13]. Nevertheless, soils and sediments all vary in their moisture content depending on the location and the time of sampling. Provided that the metal species are stable the matrix should be dried either by freeze-drying or by air-drying at 40 °C. Most trace organics associated with them are bound to the organic surfaces of the matrix. The metal species may be leached from such samples by soaking and stirring or sonicating the sediment with HCl, and extracted into the organic solvent i.e. ethyl acetate [14]. Other workers reported [15] a similar use of acid to leach the compounds from the sediment along with methanol as an additive. Alternately, the metal species may be exhaustively extracted in a Soxhlet apparatus, after acidification with HCl. A weakly bonded/adsorbed fraction may be removed by sonication with an electrolyte such as $NH_4Cl$, followed by extraction with solvents of increasing polarity. The strength of the extraction medium can be further increased with dilute and then with more concentrated HCl, followed by organic solvent and acetic acid mixtures. Additional solvent extraction, by boiling with 2-mercaptoethanol in Tris–buffer

will disrupt the S–S linkage and release the more strongly bound organometallic compounds. Nevertheless, the concentration of many metal species in soil and sediment is completely dependent on the method used for extraction [16].

The effects of pretreatments on the leaching of elements vary from element to element and seem to depend on the form of occurrence of the element in the sediment sample. The drying of organic stream sediment tends to decrease the concentration of readily extractable elements [17].

Various approaches to sampling and sample pretreatments for metal speciation in soils and sediments have recently been reviewed by Rubio and Ure [18]. They have discussed the avoidance of contamination and loss, field sampling and subsampling of air-dried soils and sediments. Location of sampling points, kinds of sample and sampling apparatus for suspended sediments, bottom sediments and interstitial water, measurement in situ, and pretreatment and storage of the sample have also been presented.

### 2.2. Extraction techniques

In order to assess the reactivity of the species or binding forms of heavy metals in solid soil, sediment and sludge samples, extraction procedures have been applied both as single leaching steps and combined in sequential extraction schemes [19] with a representative sample size and without the need of any sample preparation. Extraction media could be neutral electrolytes, like $CaCl_2$ or $MgCl_2$, buffers of weak acids, like acetic acid or oxalic acid, chelating agents, like EDTA or DTPA, redox agents, like $NH_2OH$, strong acids, like HCl, $HNO_3$, $HClO_4$ or HF, or bases, like NaOH or $Na_2CO_3$.

The ability of various extracting agents to release metal ions depends on their association with particular soil fractions. Extractants like electrolytes, weak acids and chelating agents release metals from coordination sites, while strong acids and other redox agents are capable of releasing additional quantities of metal as a result of the decomposition of the soild matrix.

Sequential extraction schemes have been described by several workers [20] for sediments and dredged material also. Consecutive leaching techniques allow us to obtain information about the mobilities of major and trace constituents under different environmental conditions such as acidic or alkaline, oxidizing or reducing behaviour, the action of chelating agents, and so on. From this study, the actual chemical form of the investigated species occurring in soil or sediment can be concluded, leading to predictions about both origin and bioavailability [21].

Subjecting soil and sediment samples to multiple extraction has not been proved as an attractive alternative to sequential extraction, possibly because the latter approach tends to more readily identify the sediment component(s) responsible for retaining the majority of the elements of interest. The most appropriate sequence can be determined by the type of soil or sediment being examined, the horizon involved, the elements of interest, and so on [22].

As a matter of fact, sequential extraction provides more information than single extraction and has several advantages [7].

(i) Extractive procedures applied are comparable to those occurring in nature. In natural environments, soil and sediments are subject to similar leaching procedures by natural and anthropogenic electrolyte solutions.

(ii) The total sum of all fractions should be more-or-less 100%, so the results are self-checking.

(iii) It is an essential tool in establishing element partitioning with natural samples.

(iv) Chemical extraction sequences can be used for the estimation of the potential remobilization of metals under changing environmental conditions.

Microwave-assisted extraction techniques have been very useful in the study of the speciation of metals not only in geological and environmental samples but also in biological samples [23–25]. This is because the use of microwave ovens in chemistry provides a very effective means for supplying high temperatures in a short time [26]. Extraction rate experiments using conventional and microwave-assisted heating showed that microwave-assisted heating produces results comparable to those of the conventional procedure. Sequential microwave extraction procedures were established from the results of extraction rate experiments [27].

Other operationally defined speciation schemes include the use of the combination of a chromatographic fractionation of the soil solution followed by the analysis of the fraction by a sensitive analytical procedure. Thus Gardiner et al. [28], used size-exclusion HPLC

with electrothermal-atomic absorption spectrometric analysis (ET-AAS) to identify aluminium species in soil solutions. Speciation schemes also make use of combinations of anion- and cation-exchange columns to fractionate various species of metals like cadmium and lead in soil solution [29]. Supercritical fluid extraction is fast becoming an alternative technique to the more conventional methods for soils and sediments [30].

### 2.3. General procedures

It has already been mentioned that for speciation studies in soils, sediments and similar materials, sequential extraction schemes are widely used. In an elaborate review article, Pickering [22] summarized the different extraction schemes as described in the pertinent literature. In Table 1 various frequently used sequential extraction procedures [31–39] are presented.

The groupings used in descriptions of distribution patterns are somewhat arbitrary, but the fractions more commonly considered appear to be the ion-exchangeable, the weakly absorbed, organic-bound, hydrous oxide component and lattice component material. The latter component has been termed as "residual", with the sum of the other fractions being "non-residual".

The behaviour of each fraction differs according to the type of reagent required for the release of a specific fraction [8] of the target elements in the target sample, thus providing the specific characteristics of each sample. Nevertheless, the extraction sequence proposed by Tessier et al. [32] had been most widely used [7,10,40,41] and applied not only to soils and sediments, but also to atmospheric particulate matter [42–44].

Although some workers water-wash the samples prior to sequential extraction without their analysis, Gatehouse et al. [31] considered water treatment as one of the extraction steps. The use of hydrazine for the extraction of non-silicate Fe phases is unique in comparison to other extraction schemes.

The extraction scheme presented by Sposito et al. [33] was effective for arid-zone field soils enabling an experimental precision at any extraction step of better than 5%. Miller and McFee [34] applied their technique for the speciation of Cd, Cu, Pb and Zn in soils, making use of a sequential extraction procedure for sewage sludges and a selective extraction procedure for manganese oxides.

The method of Psenner et al. [35] has been used for the evaluation of the speciation of inorganic constituents in sediments of the Danube [10] river. The grain size of the sediment is the most decisive parameter in such an analysis. However, dithionite must be avoided because it contains a lot of impurities of heavy metals and can cause problems in flame atomic absorption spectrometric determinations. On the other hand, the presence of $S^{-2}$ in dithionite must be avoided [45].

The special feature of the Shuman and Hargrove [36] method is the use of NaOCl as an oxidizing agent. The effect of $OH^-$ ions present makes the organic fraction more accessible and easily removable. This reagent is also considered to cause less damage to amorphous constituents and clay minerals, but it can oxidize some Mn to $MnO_4^-$. Another disadvantage is the associated precipitation of released metal ions in the alkaline solution. For extraction of exchangeables, e.g. by using $NH_4NO_3$, it may, however, lower the pH sufficiently for $H^+$ ion competition for sites to be discernible, and hydrolysis of clays will be promoted. Extraction with $NH_4Ac$, as proposed by Kersten and Förstner [37], avoids the aforementioned effect by acting as a buffer.

In the course of the elution sequence of the procedure of Zeien and Brümmer [38], the acidity of the extractants increases. The heavy metals are fractionated according to their mobility during the first two steps of the extraction sequence, whereas steps three to seven fractionate according to their binding characteristics. However, this method is only applicable to oxidized soils with below 5% $CaCO_3$.

Hirner et al. [39] proposed an extraction sequence based on the specific isolation of soluble (by solvent extraction) and insoluble (by demineralization) organic constituents. The last step of any sequential procedure is the quantitative dissolution of the final extraction residue.

The different extraction procedures cited above are not always selective. It seems that all the reagents used in the various schemes have advantages and disadvantages and there is not an ideal reagent. This is because chemical reagents may themselves alter the indigenous speciation of a trace element, and in the choice of extractants, less powerful leaching solutions will probably be more selective for specific

Table 1
Commonly used sequential extraction procedures for extracting various components of soils and sediments

| Authors | Extractant [a] | Fraction |
|---|---|---|
| Gatehouse et al. [31] | $H_2O$ | Water-solubles |
| | $NH_4Ac/HAc$ | Exchangeables |
| | $NH_2OH \cdot HCl/HAc$ | Oxides |
| | $H_2O_2/HNO_3$ | Sulfides and organics |
| | $N_2N_4 \cdot HCl$ | Non-silicate Fe phases |
| | $HClO_4$ | Residuals |
| Tessier et al. [32] | $MgCl_2$ | Exchangeables |
| | NaAc/HAc | Carbonates |
| | $NH_2OH \cdot HCl/HAc$ | Oxides |
| | $H_2O_2/HNO_3/NH_4Ac$ | Organics |
| | $HF/HClO_4$ | Residuals |
| Sposito et al. [33] | $KNO_3$ | Exchangeables |
| | NaOH | Sorbed components |
| | EDTA | Organics |
| | $HNO_3$ | Carbonates and sufildes |
| Miller and McFee [34] | $H_2O$ | Water–solubles |
| | $KNO_3$ | Exchangeables |
| | $Na_4P_2O_7$ | Organics |
| | EDTA | Carbonates, Fe occluded (amorphous) |
| | $NH_2OH \cdot HCl/HNO_3$ | Mn-oxide occluded |
| | Na-citrate/$NaHCO_3/Na_2S_2O_4$ | Crystalline Fe-oxide occluded |
| | $HNO_3$ | Sulfides |
| | $HNO_3/H_2O_2$ | Residuals |
| Psenner et al. [35] | $HCO_3^-/S_2O_4^{2-}$ | Organics and humics (partially) |
| | NaOH | Humics |
| | HCl | Carbonates, Fe hydroxides, sulfides (partially) |
| | Hot NaOH | Kaolinite (partially), sulfides |
| Shuman and Hargrove [36] | $Mg(NO_3)_2$ | Exchangeables |
| | NaOCl | Organics |
| | $NH_2OH \cdot HCl/NH_4Ac$ | Mn oxides |
| | $(NH_4)_2Ox$ | Fe oxides (amorphous) |
| | Ascorbic acid/oxalate buffer | Fe oxides (crystalline) |
| | $HCl/HF/HNO_3$ | Residuals |
| Kersten and Förstner [37] | $NH_4Ac$ | Exchangeables |
| | NaAc/HAc | Carbonates |
| | $NH_2OH \cdot HCl/HNO_3$ | Mn oxides |
| | Oxalate buffer | Fe oxides (amorphous) |
| | $H_2O_2/HNO_3/NH_4Ac$ | Sulfides and organics |
| | $HNO_3$ | Residuals |
| Zeien and Brümmer [38] | $NH_4NO_3$ | Exchangeables (non-specifically adsorbed) |
| | $NH_4Ac$ | Exchangeables (specifically adsorbed) |
| | $NH_2OH \cdot HCl/NH_4Ac$ | Mn oxides |
| | $(NH_4)_2EDTA$ | Organics |
| | $(NH_4)_2Ox$ | Fe oxides (amorphous) |
| | Ascorbic acid/oxalate buffer | Fe oxides (crystalline) |
| | $HF/HClO_4/HNO_3$ | Residual |
| Hirner et al. [39] | $H_2O$ | Water solubles |
| | $NH_4Ac$ | Exchangeables |
| | $C_6H_6/CH_3OH$ | Soluble organics (solvent extractables) |
| | $C_6H_6/CH_3OH/KOH$ | Soluble organics (humic and fulvic acids) |
| | HCl | Mineral matrix (easily soluble) |
| | HF | Mineral matrix (hardly soluble) |
| | $HCl/HClO_4/HNO_3$ | Insoluble organics |

[a] The different extractants are employed sequentially and each one provides leaching of the noted metal fractions, as indicated by the authors.

fractions than more severe reagents, which may attack in other forms, although the overall efficiency of extraction may be lower [9]. Also to be taken into consideration are factors such as readsorption processes, the time required to carry out the experiments, the effect of temperature and the ratio between the solid mass and the volume of the extractant solution.

One serious concern about the extraction schemes stated in Table 1 and other similar schemes is that the rate of extraction is slow and takes several days to complete the analysis. For example, the procedure of Tessier et al. [32] needs 5 overnights [10] for the extraction steps to be completed during the analysis of a sediment sample whereas the procedure after Miller and McFee [34] needs more than 77 h [46] for sequential extraction for soil speciation. Use of PTFE reactors and microwave-assisted digestion procedures at high pressures and temperatures has usually been effective to overcome this problem [22–26]. Another way by which the speciation studies have been made rapid is by using on-line treatment. In an experiment for studying speciation of heavy metals like Cd, Zn, Cu and Pb performed by Scokart et al. [47], a small column (0.5 cm in diameter) was packed with soil (1 g) and eluted successively with water, $BaCl_2$, acetate buffer/EDTA and $HNO_3$ furnished by a peristaltic pump. The leachates were directly injected into an inductively coupled plasma-optical emission spectrometer in order to analyze immediately the extracted solution. Actually, it gives a kind of chromatogram of the chemical species of the elements studied which may be considered as a picture of their availability.

### 2.4. *Modifications of the usual extraction sequence*

When the requirement is not the complete analysis of the soil or sediment but to study the speciation of specific component(s), modification of the usual extraction sequence has been proposed. An improvement in analytical measurements for single and sequential procedures applied to soil and sediment analysis has been reported by Quevauviller et al. [48]. The study indicated that broadly acceptable extraction schemes can be established, e.g. a single-extraction (EDTA/acetic acid/ammonium acetate) method for soil and a sequential extraction (with acetic acid, hydroxylammonium chloride, ammonium acetate and $H_2O_2$) method for sediment. Few specific examples may be cited here.

For Cd speciation, sequential extractions were performed with $H_2O$, $CaAc_2$, NaAc, NaOH and Na citrate [49]. Columns packed with Amberlite IR-120 cation-exchange resin were used together with Amberlite XAD-2 absorbent resin to investigate Cd speciation in solutions of sewage-sludge-amended soils [50].

Similarly, Cu species may be sequentially extracted by using $CaCl_2$, HAc, $K_4P_2O_7$, oxalate buffer and HF [51]. For marine sediments, extraction of the organic-bound fraction by hot (100 °C) sodium dodecylsulfate–sodium bicarbonate at pH 9.2 has been recommended [52].

The speciation studies of aluminium were performed by extracting soil samples with $CaCl_2$, then with KCl, and the separation of the aluminium species was carried out by the ion-chromatographic method [53].

For the evaluation of the speciation of tin in finely grained sediments of the Danube river, a leaching sequence was presented [20] which consisted of treatment with ethanol, $NH_2OH \cdot HCl$/HAc, oxalate buffer, $KMnO_4$/$HNO_3$, $NH_4I$ and tartaric acid. Owing to the very high toxicity for marine organisms of tributyltin, there is great interest in its speciation in environmental samples. The sediment samples collected from Porto Vecchio Bay (Corsica, France) were analyzed by three different speciation methods of which extraction of tin species in HAc followed by hydride generation, cold trapping, separation on a GC column and determination by graphite furnace-AAS furnished the best results [54]. The extraction of tributyltin from spiked sediment by a supercritical fluid ($CO_2$ containing 5.1 M methanol) has been reported by Dachs et al. [55]. Extracts were derivatized with 20% $C_2H_5MgCl$ in tetrahydrofuran and analyzed by GC with flame photometric detection. Recently, the speciation of some tributyltin compounds has been studied by using Mössbauer spectroscopy, in anoxic and oxic estuarine sediments [56]. The study indicated that tributyltin fluoride remains in its polymeric form after interaction with both types of sediments.

The extraction and speciation of inorganic arsenic ($As^{3+}$ and $As^{5+}$) in soil and sediment samples have been reported by various workers [57,58]. The method involves extraction with 60% $HNO_3$ followed by hydride generation-AAS. To determine the amount of arsenic com-

pounds such as arsenate, arsenite, monomethyl arsonate and dimethyl arsinate in Japanese soils, Takamatsu et al. [59] developed an analytical technique that consisted of sequential extraction with HCl, HCl/KI, benzene, and $H_2O/H_2O_2$ followed by anion-exchange chromatography and final determination of arsenic by flameless atomic absorption spectrometry.

A sequential extraction procedure [60] using the following reagents in the order $H_2O$, $NH_4Ac$, NaAc/HAc, $NH_2OH \cdot HCl$/HAc, $H_2O_2/NH_4Ac$, $HNO_3$ was applied to study the speciation of Chernobyl-derived radionuclides, i.e. $^{137}Cs$ and $^{90}Sr$ in soils. In general, both $^{137}Cs$ and $^{90}Sr$ had lower mobility factors in the Russian soils compared to the Norwegian soils. Speciation of $^{137}Cs$ and $^{90}Sr$ in soils and bottom sediments in the Chernobyl accident zone was also studied by Konoplev et al. [61] who found that the adsorption of $^{137}Cs$ and $^{90}Sr$ in the environment is controlled by the cation-exchange capacity and the selectivity of the solid phase and the cationic composition of the liquid phase.

Speciation of $Ca^{2+}$ ions and particulate calcium as $Ca_3(PO_4)_2$ needs neither sample preparation nor extraction step and the species were studied by flame AAS using slurries [62].

On the other hand, speciation between $Sb^{3+}$ and $Sb^{5+}$ is difficult in the solid samples because a quantitative recovery is only obtained in $HF + HNO_3 + H_2SO_4 + HClO_4$, which alters the oxidation state. To determine Sb in solid samples, the batch hydride generation method is recommended in preference to automated (flow injection analysis (FIA) or continuous) methods, because a clear solution is not obtained after any of the sample treatments used. In the FIA and continuous methods, previous filtration of the suspension is required before analysis to avoid clogging of Teflon tubing [63].

Organometallic compounds are often difficult to determine in soil and sediment samples [2]. There are few reports on the study of organomercury compounds in soils and sediments [64]. A search for new methods of mercury speciation based on liquid chromatography, as well as quality control and application to sediments, has been described by Cela et al. [65]. The speciation of mercury in soils and sediments has also been studied by a thermal evaporation technique [66]. The determinations of organomercury and total mercury were carried out by HPLC–AFS and cold vapour AAS respectively.

Selenium exists in soil in several oxidation states and as a variety of inorganic and organic compounds. Speciation studies on this element, particularly in soil samples, are scanty [67,68].

Recently, for studying the speciation of Fe(II) and Fe(III) in contaminated aquifer sediments, single-step extraction including 1 M $CaCl_2$, NaAc, oxalate, dithionite, Ti(III)-EDTA, 0.5 M HCl, 5 M HCl, hot 6 M HCl and a sequential extraction by HI and $Cr^{2+}$HCl were tested on saturated iron minerals and nine aquifer sediments [69].

### 2.5. Analytical details

Table 2 summarizes details of the analytical performance of some speciation methods for soil and sediment samples. It transpires that sequential extraction is the most common technique for the preferential separation of various components. The resultant extract solutions are usually then analyzed by instrumental techniques suitable for the chemical multielement analysis of liquids, i.e. atomic absorption spectrometry (flame and graphite furnace), and inductively coupled plasma spectrometry (ICP-OES and ICP-MS). However, the complementary approach, i.e. analysis of the solid extraction residues by X-ray fluorescence spectrometry is also possible [7]. Of these techniques, AAS has been used widely because of its simplicity and low cost. By introducing flow injection analysis (FIA), sensitivity is further increased. Thus a 5.5-fold to 60-fold increase in the sensitivity is obtained for flame AAS and a 15 fold to 50 fold increase for ET-AAS [73].

From Table 2 it is also evident that the information about the analytical performance of the developed methodologies is scarcely reported. The limits of detection obtained are in the parts-per-million to parts-per-billion range. The precision is usually adequate for these determinations (relative standard deviations between 0.4 and 8%).

The usual speed of analysis in conventional extraction methods is enhanced with a microwave-assisted treatment, as previously indicated, and is also further improved by use of an ICP-S method of determination. A typical sixfold to fifteenfold increase in speed has been reported [27,74].

Accuracy data have been reported in a few papers, and in general these data concern the determination of the total content of metals and not the accuracy of determination of each

Table 2
Analytical details of metal ion speciation studies of soil and sediment samples

| Element | Species | Matrix | Separation and measuring technique | LOD [a] | R.S.D. [b] (%) | Recovery (%) | Ref. |
|---|---|---|---|---|---|---|---|
| Al, As, Ca, Co, Cr, Cu, Fe, K, Mg, Mn, Ni, P, Pb, Zn | Animal and plant tissues partially humics; humics, rest of animal and plant tissues; carbonates, iron hydroxides, some sulfides; part of kaolinite, rest of sulfides | Lacustrine sediment (Danube river Austria) | Sequential, AAS, ICP and photometry | – | – | – | [10] |
| Al, Ca, Co, Cu, Fe, K, Mg, Mn, Na, Ni, Pb, Zn | Exchangeable cations, fulvic fraction, humic fraction, secondary manganese oxide fraction, secondary iron oxide fraction, residue | Sediment (Plynlimon, U.K.) | Sequential, flame AAS | Na, K, Mg:1 ppm; Ca, Fe:5 ppm; Al, Mn: 2 ppm; Pb:0.5 ppm; Co, Ni, Cu:0.2 ppm; Zn:0.1 ppm | – | – | [13] |
| Al, As, Cd, Co, Cu, Cr, Fe, Pb, Mn, Ni, Zn | Mobile (weak extraction) fraction, acid digestion fraction | Organic stream sediment (Finland) | Selective, AAS (Flame, GF-) | – | – | – | [17] |
| Sn | Organics, carbonates, Fe and Mn hydroxides, sulfides, cassiterite | Sediments and soils (Danube river, Austria) | Sequential, ET-AAS | – | – | – | [21] |
| Ca, Cr, Fe, Mn, Pb, Zn | Exchangeables, carbonate bound, bound to Fe and Mn oxides, organic material | Sediment (California Gulch Colorado) | Sequential, ICP-S | – | 11 | 76–120 (conventional) 62–120 (microwave) | [27] |
| Cd, Cr, Cu, Ni, Pb, Zn | Carbonate, Fe and Mn oxides, organic matter and silica | Sediment (Besos river, Spain) | Sequential, AAS (Flame, GF-), XRF | – | – | – | [40] |
| Ba, Ca, Cr, Cu, Fe, K, Mn, Rb, Sr, Ti, Zn | Exchangeables, bound to carbonates, Fe and Mn (hydr)oxides, organics, silicates | Soil (Sardinia, Italy) | Sequential, total reflection XRF | $<1$ mg $kg^{-1}$ for trace Elements; 20–100 mg $Kg^{-1}$ for major elements | – | – | [41] |

Table 2 (contd.)

| Element | Species | Matrix | Separation and measuring technique | LOD [a] | R.S.D. [b] (%) | Recovery (%) | Ref. |
|---|---|---|---|---|---|---|---|
| Cd, Cu, Pb, Zn | Water soluble ions; easily exchangeable ions; strongly adsorbed, chelated or complexed ions; secondary clay minerals and metal oxides; primary minerals or highly fixed ions | Soil | Selective, ICP-S | – | – | – | [47] |
| Al | $Al(H_2O)_6^{3+}$, $[Al(OH)_n(H_2O)_{6-n}]^{(3-n)+}$, $[AlF(H_2O)_5]^{2+}$, $[AlF_2(H_2O)_4]^{+}$, $[Al(oxal)(H_2O)_4]^{+}$, $[Al(Hcitrate)(H_2O)_4]^{+}$ | Soil | Selective ion chromatography | 0.455 ppb | – | – | [53] |

| Hg | Inorganic mercury, methylmercury | Sediment (Ria de Pontevedra, Galicia, Spain) | Selective, chromatography | – | | – | [65] |
| Se | Se(IV) | Soil | Selective, ion chromatography | 20 ppb | – | – | [67] |
| Se | Se(IV), Se(VI) | Soil | Selective, ion chromatography | 30 ppb | – | | [68] |
| Al, Cd, Cu, Pb and Zn | Bound to carbonates, bound to Fe and Mn oxides, organic matter bound, bound to silicates | Sediment (semi-rural area of Belgium | Sequential, AAS (Flame, GF-), ICP | | 5–8 | – | [70] |
| Al, As, Co, Cr, Cu, Fe, K, Mg, Ni, P, Pb, Zn | Animals and plant tissues, humics, carbonates, hydroxides, sulfides, kaolinite | River sediments and soils | Sequential, AAS, ICP and photometry | – | – | | [71] |
| Sn | Cassiterite | Rock | Selective, HG-AAS | – | – | – | [72] |

[a] LOD, limit of detection

[b] R.S.D., relative standard deviation.

one of the species or fractions analyzed. Thus recoveries of total metals in certified sediment samples ranged from 76 to 120% for the conventional procedure and 62 to 120% for the microwave procedure. Recoveries of total metals using microwave and conventional techniques were reasonably comparable except for iron (62% by microwave as against 75% by conventional). Substitution of an aqua regia/HF extraction for total/residual metals results in essentially complete recovery of metals [27].

The precision obtained from 31 replicate samples of the California Gulch (Colorado) sediment which yielded about an average of 11% R.S.D. excludes the exchangeable fraction which was more variable [27].

In the case of the speciation studies of Sb(III) and Sb(V), very low recoveries ($18.8 \pm 8.4$–$48.2 \pm 2.2\%$) have been reported. Again, when a quantitative recovery ($107.1 \pm 6.1\%$) is obtained, the oxidation state of antimony is altered yielding errors in speciation [63].

## 3. Speciation of solid biological and food materials

In contrast to inorganic materials where the number of element species is relatively small, trace elements can be present in living matter in a large variety of chemical forms. The purpose of most investigations into the chemical speciation of trace elements in biological systems has been to identify the physiologically active forms, the storage and transport of species, the metabolites of trace-element-containing drugs and to find sensitive indices of the status of trace elements [75]. With increasing knowledge of the metabolism and biological effects of trace elements, it has become increasingly apparent that there is a need not only to determine the total levels of an element in tissues and body fluids but also to measure its different chemical forms quantitatively.

The toxicity of chemical species of different elements is a function of both the target element and the chemical structure of the compounds considered, and it depends on the absorption pathways of the elements. Most of the species of interest in the toxicology of trace elements are small molecules. Many metals are capable of forming organometallic compounds and their toxic effects in some cases exceed by far those of the inorganic forms of the elements or the compounds formed with large molecules. In general, in the investigation of the toxic effects, the speciation of small molecules is of concern, whereas in the investigation of the biological functions the determination of large molecules has priority. Again most of the essential species of the trace elements, i.e. metalloenzymes, are produced in the organism after transformation of the different chemical forms of the elements present in the diet. The content of an essential compound decreases with insufficient dietary element supply and is thus related to the total element content [26].

Although the speciation of metals is widely recognized as a desirable goal in the analysis of biological materials (this has been particularly the case for clinical and environmental samples) interest is now being widened to include foods [77], because the bioavailability of metal species in food has been correlated with the extractability obtained by enzymolysis with gastric and intestinal fluids [78]. Quality control measures for toxic metals, neglected in many cases in food analysis, should be rigorously followed. No effort should be spared in determining the accuracy and precision for each separate food matrix, since each foodstuff is a different chemical matrix and requires special control of interferences [79].

### *3.1. Pretreatment of biological materials for carrying out speciation studies*

For speciation studies of biological materials, more stringent conditions have to be fulfilled during sample collection, pretreatment and storage [75]. It is necessary not only to collect a representative sample and to avoid chemical contamination, but also the integrity of the chemical species has to be maintained. During and after sampling, changes in parameters such as temperature, ionic strength, pH, redox potential, oxygen level, irradiation with UV light, etc. to which the sample is exposed, can influence the distribution of chemical species. As a matter of fact, the act of sampling itself may create conditions that could induce changes which may affect the types and prevalence of species found for a given element. In order to minimize the effect of the above changes, it is essential to choose those analytical conditions, in particular the pH and ionic strength of the working media, which do not differ markedly from those found in the original system.

The choice of sample storage containers is also a critical factor. In general, the most ap-

propriate action is to deep freeze samples immediately on collection to minimize any bacterial or enzyme degradation, loss through volatility or contamination of the sample. According to Uthe and Chou [80], biological tissue should be dissected at the sampling site and frozen in liquid nitrogen and then stored in a deep freeze to reduce enzyme release of heavy metals. Most studies on biological matrices are undertaken on wet tissue, rather than lyophilized materials, which is either extracted as fresh material or has previously been dissected and rapidly frozen.

Pretreatment techniques can only be chosen when the nature of the problem and the information required from the analysis of the sample have been understood clearly. Again the effect of storage on the distribution and the genuineness of the chemical species are both associated with such problems. For example, as stated above, biological tissue samples after collection are usually frozen until required, but such freezing of samples slows down on-going biochemical reactions which would otherwise disrupt the complexes or completely changes the distribution profile of a given element. The extent of damage to any constituent of interest would depend upon the conditions and time period of storage. Mechanical and physical effects of the ice crystals formed could denature proteins and may deactivate enzymes. Also, oxidation or reduction of side chains and light-catalyzed degradation of various proteins could continue to occur in the material during storage, particularly when transition metals are present [81].

Usually, sample preparation procedures for biological materials fall into two categories [77]. Firstly, those methods where the sample is analyzed after a minimal pretreatment by using slurry or solid sample introduction systems or alternately after dilution with an appropriate reagent for deproteinization, metal release or cell disruption. Secondly, there are methods where considerable sample pretreatment such as separation, extraction or destruction of the organic component by heat, solubilizing agents or oxidizing agents is necessary before determinations can be carried out.

### 3.2. Extraction techniques

The information required for speciation studies in the case of biological materials may be the oxidation state of the metal, the concentration of molecular species or the identity of the organometallic complex. The most common technique for obtaining such information involves separation procedures which isolate selectively the species of interest [82] or a separating column which generates a series of fractions containing organometallic complexes [83].

In principle, most of the separation modes available for liquid chromatography such as size-exclusion, normal-phase, reversed-phase, paired-ion reversed-phase and ion-exchange should be applicable to biological systems. Of these, fractionation according to size has been most frequently used. When chromatographic techniques are used to separate organometallic complexes, information on the concentration of organic molecules may also be obtained concomitantly from the elution pattern [84]. For efficient separation of sensitive non-stable species, gel permeation chromatography with aqueous eluents is used. Other techniques like ion-exchange chromatography may have the problem of loading the species, with separation of specific charges and/or substrates from either the column matrix or the buffer systems. This may result in changes in the original species. Thus leaching procedures are not much use in speciation analysis of biological samples [2]. For stable species only, electrophoretic separation can be applied in the form of a continuous flow-through or a capillary system [85].

Biological samples can also be extracted by blending as a paste or slurry with the selected solvent or solvent mixtures [86,87]. Sample tissue or plant material can be pulverized in liquid nitrogen to break up the matrix. Ionic lead species in grass and tree leaves may be solubilized with tetramethylammonium hydroxide from the crushed leaves in sodium diethyldithiocarbamate prior to extraction with pentane [88].

In general, organometals are more strongly bound to the protein, and for studying these systems, rupture of the protein–metal linkage is required. In such cases, enzymes can be used to destroy the substrate and release the organometal intact. For example, pepsin can be used to rupture the S–S bonds and bacterial protease K can be used to release organometals bound to proteins [16].

Recently, successful use has been made of pressure digestion in a microwave oven as an alternative procedure for solubilizing samples, because of the advantages it offers of reducing digestion time and reagents, thus decreasing

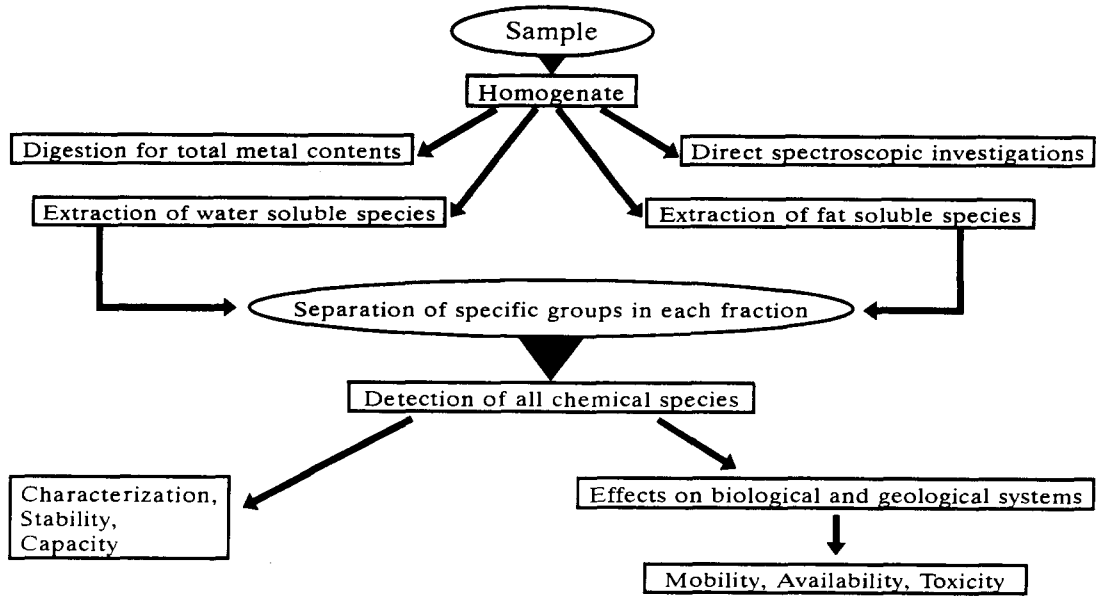

Fig. 1. General scheme that may be applied for metal ion speciation studies in biological materials.

contamination problems. Unfortunately, only a few studies on foods and biological matters have been published [23,89]. Supercritical fluid extraction is more suitable for isolating labile compounds and is an ideal technique for on-line automation. The method has been applied to speciation studies in biological tissues [90].

### 3.3. General procedure

For most speciation analyses, it is important to relieve the preferred species of other undesirable components of the sample matrix by selective extraction of either water- or fat-soluble forms. After selective separation, sensitive detection procedures followed by effects on biological systems, uptake and toxicological experiments which mimic real processes are carried out for complete speciation studies [91]. Various schemes like that shown in Fig. 1 are used to fulfil the requirements of speciation analysis.

For the elucidation of the structure, stability and capacity or the evaluation of the mobility, availability and toxicity of the metal species, different methods have to be used. Some of the instrumental techniques [75] that can be used to characterize chemical species in biological matters and the information that they may provide are summarized in Table 3.

Evidently, there is no unique procedure for speciation studies of all different types of biological materials. But depending on the nature of the material, some direct or combined method may be suggested. In some cases chemical species can be measured directly in the sample without interference from other components. For example, with several metal-containing enzymes, the enzymic activity can be taken as a measure of the concentration of the compound. Again enzyme systems specifically affected by the toxic form of the element may be monitored so that the inhibition of the enzymic activity can be taken as a measure of the toxic species. Immunoassay may be another direct way for the speciation of trace element compounds with antigenic properties [76].

On the other hand, various combined methods can be used in speciation studies. With some elemental species, relatively simple procedures may be used, i.e. volatilization of compounds or a single absorption or extraction step. For the speciation of small molecules like organometallic compounds, gas chromatography or high-performance liquid chromatography have been combined with analytical methods such as AAS and applied for routine analysis [5].

### 3.4. Various speciation methods

The procedures used for solubilization of the biological samples and subsequent determination of the analyte(s) by techniques like AAS, ICP-S, etc. are very wide. A critical examination of this subject reveals that major work has

Table 3
Major techniques for the characterization of chemical species in various matrices

| Instrumental techniques(s) | Information |
|---|---|
| AAS, ICP-AES, XRF, neutron activation, anodic stripping voltametry | Total metal content, detection of species, characterization of species is possible if the technique is coupled with a separation method |
| XRD | Determination of specific structures, principally crystalline compounds in tissues |
| IR and Raman spectroscopy | Structure and conformational changes |
| NMR | Structure, equilibrium and kinetic properties |
| Mass spectroscopy | Characterization of species |
| Mössbauer spectroscopy | Electronic structure, spatial arrangement, spin and oxidation states of the metal in the prosthetic group |
| Circular dichroism | Interaction between ligands and proteins, secondary structure of proteins and binding of metals at the active sites in enzymes |
| Molecular UV absorption and luminescence | Determination of specific species containing chromogenic or fluorogenic structures |

been done on the speciation of arsenic followed by that of mercury. The work on the speciation of other elements in biological materials are not many in number. This may be evident from the following discussions.

For the speciation of arsenic chemicals by atomic spectrometry, a series of procedures based on the use of a selective liquid–liquid extraction has been developed. The selective determination of inorganic arsenic and organic compounds in foods has been carried out by Münz and Lorenzen [92] by liquid–liquid extraction and hydride generation. Previously mineralized samples with $HNO_3$ were treated with ascorbic acid, to reduce As(V) to As(III), extracted from 7–9 M HCl into $CH_2Cl_2$. Inorganic arsenic was determined after a back extraction of the $CH_2Cl_2$ phase with water; the determination of organic arsenicals was achieved by evaporation of the remaining HCl phase, decomposition with $HNO_3$ and subsequent measurement by HG-AAS.

Inorganic arsenic species found in foods may also be selectively extracted with dilute $H_2SO_4$ from the lyophilized solid samples. Under these conditions organically bound arsenic remains stable [93].

For the determination of total inorganic arsenic in fish [94], solid samples were treated with NaOH and $Na_2SO_4$ on a boiling water bath for 20 min, after which HCl was added and arsenic was extracted with ammonium pyrrolidine dithiocarbamate (APDC) in MIBK. The arsenic was back-extracted with $HNO_3$ and then treated with a$H_2SO_4$ before measurements were carried out by the hydride generation technique.

Inorganic As(III) and As(V) were determined in biological materials [95] after solubilization with HCl, extraction into toluene and back-extraction with water. Organic arsenic was retained in the acidic solution. The total arsenic was determined after digestion with $HNO_3$, $H_2SO_4$ and $HClO_4$.

For selective determination of As(III) in foods, in the presence of As(V), the liquid–liquid extraction of $AsCl_3$ in $CHCl_3$ was proposed. The determination was carried out by hydride generation after back-extraction in water [96]. At pH 4–5 the hydride generation of arsenic with $NaBH_4$ permits the selective determination of As(III) in a mixture of As(III) and As(V). On the other hand, total arsenic can be determined by hydride generation from 5 M HCl. For the speciation of arsenic in solid biological samples and to avoid the oxidation of As(III), the use of concentrated $HNO_3$ and $H_2SO_4$ was substituted by the use of those acids diluted 1 + 2 with water [97].

A method for the separation of arsenic species from solid samples of orchard, tomato and oak leaves has been described by Sarx and Bächmann [98]. The volatilized arsenic species were separated into various fractions and determined by graphite furnace-atomic absorption spectrometry and microwave-induced plasma-optical emission spectrometry.

The major form of arsenic in fish and crustaceans is arsenobetaine. Although this compound has been shown to be non-toxic, for reasons of toxicological reassurance, its concentration and that of other arsenicals in foodstuffs of marine origin must be determined by some routine method [99]. Extraction of arsenobetaine from fish tissue homogenates may be performed by using $CHCl_3$–$CH_3OH$ mixtures. A recovery of 101 ± 4% was reported for the 1:2 solvent mixture extraction of freeze-dried fish muscle spiked with arsenobetaine [100]. For the routine analysis of arsenobetaine in marine samples, HPLC–ICP-AES would be a good choice in terms of sensitivity, selectivity and ease of operation [101], but even better sensitivity could be achieved with HPLC–ICP-MS [99].

In the determination of organoarsenic species by HPLC–ICP-MS, dried fish (1 g) was extracted with $CHCl_3$ or aqueous trypsin and the extracts were analyzed on an HPLC column containing anion-exchange resin with a mobile phase of alkaline potassium sulphate and with ICP-MS detection [102]. Recoveries ranged between 80 and 115% for arsenobetaine and arsenate. No monomethylarsonic acid was observed in any of the fish, though dimethylarsinic acid was detected.

The method proposed by Lunde [103] for the separation and analysis of organic-bound and inorganic arsenicals in marine organisms by neutron activation and X-ray fluorescence, based on the extraction of arsenic as $AsCl_3$ and subsequent removal by distillation at 100 °C, can be adapted for the analysis of inorganic arsenic in seafood products by HG-AAS after in-line microwave-assisted distillation of $AsCl_3$ [104].

Although the most popular way for the speciation of mercury is based on the selective reduction to $Hg^0$ following the procedure proposed by Magos [105], organic mercury can be determined by solvent extraction into toluene and electrothermal atomic absorption [106]. For this purpose, the solid residue of an extract in acetone from homogenized biological materials is treated with acid bromide and $CuSO_4$, and then the mercury is extracted into toluene. For the stabilization of methylmercury in the furnace, dithiozone was added to samples and standards and the mercury was atomized at 950°C. This method provides an average recovery of 97 ± 5% and supplies an alternative to the gas–liquid chromatographic method [107].

From the published papers on mercury speciation, it can be concluded that the reduction of mercurials can be selectively carried out by using different reduction steps with $SnCl_2$ and with $SnCl_2 + CdCl_2$. On the other hand, the pH strongly affects the reduction of mercurials by $NaBH_4$, specially in the presence of Fe(III), and finally it seems that a combination of $SnCl_2$ and $NaBH_4$ could be very convenient in order to carry out the speciation of mercury in biological samples [108]. Magos' method [105] was used for the speciation of mercury in brain tissue from monkeys [109] where the direct determination of mercury in 1 g of solubilizate was performed for total mercury by $CdCl_2 + SnCl_2$ reduction and for inorganic mercury by $SnCl_2$ reduction.

The extraction of $CH_3Hg^+$ as the bromide from fish samples by $CHCl_3$ and its direct determination in organic medium by cold vapour atomic absorption spectrometry was described by Rezende et al. [110]. Fresh fish muscle was cut into small pieces, prepared as a homogenate and mixed in a centrifuge tube with water, $H_2SO_4$ and KBr. Extraction with $CHCl_3$ was performed and methylmercury was determined by mixing the organic extract with 50% $HNO_3$ in DMF and 2% $NaBH_4$ in DMF (1:2:1).

A procedure for the determination of organic and inorganic mercury in biological materials like fish, oyster, meat, milk (dried), banana (dried), and wheat flour by GF-AAS has been reported [111]. To 0.5 g of the homogenate, 1% NaCl in 1 M HCl and benzene were added. Organic mercury extracted as chloride was re-extracted by 0.01 M thiosulphate solution. The organic mercury thiosulphate extract was next treated with 0.5 M $CuCl_2$, re-extracted in the benzene layer, and analyzed by GLC for speciation. Inorganic mercury was converted into a methyl chloride derivative by methanolic tetramethyltin (0.4 M) prior to extraction.

For rapid speciation studies on organomercury compounds in molluscs, a separation based on chromatography has been reported [65]. Frozen fish (0.5 g) was homogenized with water and 1 M $CuSO_4$. Acid potassium bromide and benzene were then added and the mixture was centrifuged. The organic layer (5 μl) was analyzed by capillary gas chromatography interfaced with AAS [86].

Trialkyltins are the class of organotins which have the greatest biocidal activity in mammals.

Arakawa et al. [112] reported the determination of tetraalkyltin and trialkyltin homologues in mammalian tissues. This technique involves the isolation of alkyltins from tissue homogenates as chlorides by simultaneous extraction with HCl and ethyl acetate, followed by extraction with *n*-hexane and stepwise elution with *n*-hexane + ethyl acetate on a silica gel column. The column eluate is injected directly into a gas chromatographic column. The method involves at least nine steps requiring six transfers of sample. This time-consuming process has been improved by Means and Hulebak [113]. In their method, methyltin compounds (monomethyl-, dimethyl-, trimethyl- and tetramethyl-) are purged from freshly homogenized mouse kidney and brain tissues using $NaBH_4$. The volatile organotin hydrides produced are cryogenically trapped on the head of a gas chromatographic column (at −40 °C) and eluted. The compounds are detected using selected ion monitoring in a mass spectrometer.

Determination of organometallic compounds in biological matrices is not very easy. Derivatization reactions including hydride generation and other sample treatments that lead to volatilization are employed, finally followed by GC separation [2]. Such procedures have been applied for the determination of Hg, As, Se, Sn and Pb species in biological samples [114,115]. AAS is used to quantify the elements in these cases. In a few cases, organometallic compounds of mercury, tin and arsenic have been determined in biological samples by HPLC with spectroscopic detectors [116]. Caroli et al. [117] used HPLC followed by ICP-AES to determine the iron proteins ferritin, transferrin, cytochrome C and iron protein succinate in a number of iron-based pharmaceuticals.

In order to investigate chemical speciation analysis in foodstuffs, protein-, pectin- and lipid-splitting enzymes like pepsin, pectinase, papain, bromelain and lipase have been used in stepwise extraction procedures [118]. The use of enzymes in the extraction procedures indicated clear differences in the solubility of the metal species, i.e. iron and manganese species, by pectinase from oat flakes and iron compounds by papain/lipase from wheat germ. The application of gradient gel electrophoresis provides a useful method for the separation of zinc, nickel and copper species in soybean fluor extracts [119]. The separated substances were electrophoretically eluted, followed by flame AAS determination of the metals. Thus is a sensitive separation method with a high resolving power that can provide various information concerning the metal species, e.g. molecular size, charge and stability.

Speciation of zinc and cadmium in different vegetable foodstuffs has been reported [120] where the cell breakdown was carried out by liquid shearing (ultraturrax treatment) of the crushed plants in a Tris–HCl buffer (pH 8). The homogenates were separated into cytosols (liquid fractions) and pellets (solid fractions) by centrifugation. The cytosols were again separated by gel permeation chromatography. The metal in each fraction was determined by GF-AAS after wet digestion in $HNO_3$.

Chau et al. [121] used tetramethylammonium hydroxide as tissue solubilizer to dissolve biological samples like fish without altering the chemical species of the alkyllead species. The various alkyllead species were isolated quantitatively by chelation extraction with sodium diethyldithiocarbamate, followed by *n*-butylation to their corresponding tetraalkyl forms, $R_nPbBu_{(4-n)}$ and $Bu_4Pb$ respectively (where R is Me, Et), all of which were determined by a GC–AAS method. The method could determine simultaneously the following species in one sample: tetraalkyllead ($Me_4Pb$, $Me_3EtPb$, $Me_2Et_2Pb$, $MeEt_3Pb$, $Et_4Pb$); ionic alkyllead ($Me_2Pb^{2+}$, $Et_2Pb^{2+}$, $Me_3Pb^{+}$, $Et_3Pb^{+}$); $Pb^{2+}$ ion.

Methyltin and butyltin and inorganic tin in oysters were extracted from frozen tissue with methanol and hydrochloric acid. The extracts were then treated by a hydride generation-AAS method [122].

### 3.5. Analytical details

As indicated in Table 4, it is clearly evident that there has been continuous interest in speciation studies of arsenic and mercury in biological materials. The decreasing order of toxicity of arsenic compounds has been found to be the following: metallic As, As(III), As(V), monomethylarsinic acid (MMA), dimethylarsinic acid (DMA). Again, compounds such as arsenobetaine, arsenocholine and arsenosugars are believed to be non-toxic. Consequently, a variety of procedures have been developed for determination of organic and organic species of arsenic, together with total arsenic in biological samples [92,93,96,98,100,102,104,

Table 4
Analytical details of metal ion speciation studies of biological and food materials in solid state

| Element | Species | Matrix | Separation and measuring technique | LOD | RSD (%) | Recovery (%) | Ref. |
|---|---|---|---|---|---|---|---|
| Hg | Organomercury | Molluscs, mussel tissue, tuna muscle | Extraction, GC | – | 10 | – | [65] |
| Hg | Organomercurials | Fish | Extraction, GC–AAS | 0.1 ng Hg | – | 95 | [86] |
| As | Inorganic As, DMA Phenylarsonic acid derivative | Food | Extraction, HG–AAS | – | – | – | [92] |
| As | Inorganic and organic arsenic | Dutch total diet | Extraction, spectrometry | – | – | 94–122 (inorganic As) 87–104 (organic bound As) | [93] |
| As | As(III), As(V) | Lobster, tuna, scallops, squid | Extraction, HG-AAS | – | – | 81–97 | [96] |
| As | DMA | Leaves of orchard, tomato, oak | Volatilization, AAS, MIP-OES | 10ppb(AAS) 0.1 ppb (MIP-OES) | – | – | [98] |
| As | Arsenobetaine, As(III), As(V), MMA, DMA, arsenocholine | Dogfish muscle | Extraction, HPLC–ICP-MS GF-AAS | 0.3 ng As (HPLC–ICP-MS), 0.02 ng As(GF-AAS) | – | $101 \pm 4$ | [100] |
| As | Organoarsenic species | Fish | HPLC, ICP-MS | – | – | 80–115 | [102] |
| As | Inorganic arsenic | Seafood | Microwave distillation, HG-AAS | 0.068 mg $kg^{-1}$ (dry mass) 0.023 mg $kg^{-1}$ (wet mass) | 9 | $97 \pm 3$ ($As^{III}$) $100 \pm 3$ ($As^{V}$) | [104] |
| Hg | Methylmercury | Homogenized tissue | Extraction, GF-AAS | 0.08 mg $kg^{-1}$ | – | $97.7 \pm 5.5$ | [106] |
| Hg | Organic and inorganic mercury | Hair, fish | Cold vapour AAS | 0.003–0.005 ppb | – | – | [108] |
| Hg | Total, inorganic and organic mercury | Brain tissue from monkeys | Cold vapour AAS | – | 31–41 (inorg Hg) 2–8 (methylHg) | – | [109] |

Table 4 (contd.)

| Element | Species | Matrix | Separation and measuring technique | LOD | RSD (%) | Recovery (%) | Ref. |
|---|---|---|---|---|---|---|---|
| Hg | $CH_3Hg^+$ | Fish | Extraction, cold vapour AAS | 25 ng Hg | – | 102 ± 2 | [110] |
| Hg | Methyl-, ethyl-, phenyl- and inorganic mercury | Meat, fish, oyster, dried banana, wheat flour | Extraction, GLC, GF-AAS | 0.003 ng $\mu l^{-1}$ methyl- and ethylHg 0.125 ng $\mu l^{-1}$ phenylHg | 2.1–8.1 | 96–105 | [111] |

127–129]. Many of these have evolved by coupling a gas- or liquid-chromatographic technique with an element-specific detector. Of the instrumental methods, atomic spectrometry is most widely used and most effectively developed, both in respect of methods using hydride generation coupled to atomic absorption or emission [92,96,104] and inductively coupled plasma-spectrometry [128] and electrothermal methods with graphite furnace [129]. Recently, ICP-MS has been used for the detection of arsenic [100,102]. In such cases, GC or HPLC was used as the method of separation. It can be shown from Table 4 that below-nanogram-level detection limits can be achieved in some methods [98,100,104]. Also the accuracy of some of the methods is very good [96,102,104]. However, only a few data are available concerning these aspects.

One question that arises when speciation of mercury is to be performed is the sample pretreatment used to bring the mercury species into solution. The treatment must be capable of solubilizing the species from the sample under investigation without breaking the C–Hg bond. In general, the chromatographic methods make use of solvent extraction for this purpose, using non-polar solvents, the organic mercury being extracted as chloride or bromide. Thus most of the speciation methods for mercury in solid biological materials depend on chromatographic separations with detection by means of cold vapour atomic absorption spectrometry [108–110]. Mercury has been detected by GF-AAS [106–111] and ICP-MS [123] by some workers in biological samples. It can be seen from data in Table 4 that the detection limits for various organomercury species are mostly in the parts per billion range or below [86,106,108,110,111,123]. Typical R.S.D. values lie within 10% [65,109,111] for organomercurials but for inorganic mercury they may be poor [109]. The recovery of the reported methods in cases in which this parameter has been reported is excellent [86,106,110,111].

Hydride generation has been satisfactory for the determination of alkyltin compounds containing carbon chains of four atoms or less; derivatization is required for more than four carbon atoms in the chain. Various workers have analyzed biological samples for organotins by extraction followed by GLC or GC–MS [112,113,124,125]. In such cases a better LOD value, i.e. 1 pg for trialkyltin [112], may be attained compared with HG-AAS (1–2.5 ng) [122].

Not many papers have been published on the speciation of Pb, Mn, Zn, Ni, Cu, Cd or Se in biological materials in the solid phase. Speciation studies of metalloproteins of these elements have been accomplished by extraction [117,118], separation by gel electrophoresis [119], on a Sephadex column [120] or by gas chromatography [126] followed by AAS determination of the analyte. Investigations of the different biochemical forms of selenium have been made by using GC–MS [132] or HPLC–AAS [133]. In most of these cases, the analytical parameters have not been stated. Nevertheless, in a typical study of inorganic and organic lead compounds in fish tissues by GC–AAS, an LOD of 7.5 ng $g^{-1}$, an R.S.D. of 6.5% for triethyllead and a recovery of 71–101% for diethyllead have been reported [121].

## 4. Speciation of miscellaneous solid samples

In this section we would like to discuss some papers concerning different solid matrices, in which speciation studies have been carried out on samples other than soil, sediment, biological or food samples. For example, details of metal speciation in atmospheric particulates and also speciation in wood, and coal, which have been developed in recent years, are presented below.

Several experimental procedures, varying in manipulative complexity, have been proposed for determining several chemical speices of particulate trace metals. Thus atmospheric particulates collected on a glass fibre filter can be acidified by soaking in HCl and extracted by shaking with toluene, ethyl acetate or methanol or by refluxing in a Soxhlet apparatus. Continuous Soxhlet extraction is sometimes preferred since the cycling time can be controlled and the exhaustive technique exposes fresh solvent, which can percolate into the pores of particles like fly ash which may have a hollow structure [16].

A sequential extraction procedure, originally applied in the study of soil sample [32], has been used for the analysis of urban dust particles [134]. In such a case, exchangeable metals were determined by extraction with $MgCl_2$, metals bounded to carbonate by leaching with an acetic acid buffer, metals bounded to Fe–Mn oxides by extraction with hydroxylamine at 96 °C, those bounded to organic matter by extraction with $H_2O_2$ at 85 °C, and residual metals by digestion with an $HF–HClO_4$ mixture.

Complex analytical methods were proposed for determining chemical species of selected trace metals in fly ash [135]. Morphological investigations and single particle analysis were performed by SEM/EDAX method. A survey of mineral-logical phases was made by X-ray powder diffraction and IR spectrometry. Sequential solvent-leaching experiments were carried out to obtain information on the mobility of metal species. Cu, Ni, Co, Cr, Pb and Cd were studied for determining exchangeable metals, carbonate, Mn oxides, organic matter, non-crystalline iron oxides, crystalline iron oxides and residual fractions.

Chemical species of iron, i.e. metal iron, soluble iron ($H_2O$, $H^+$), $Fe^{2+}$, $Fe^{2+}$ (ionic), $Fe^{3+}$ (ionic), $Fe_3O_4$ (magnetite), $Fe_2O_3$ (hematite) and FeO(OH) (goethite), have been determined in atmospheric particulate samples. Filtration, ultrafiltration, ion chromatography, extraction ($H_2O$, 0.02 M citric acid, 0.1 M HCl) and Mössbauer spectroscopy have been used for their characterization [136,137].

Speciation of Cu, Pb, Zn and Cr in dust of different origins and particle diameters has been reported by Gao et al. [138]. Major parts of these metals were bound to organic matter, Fe–Mn oxides and the rest as residuals. The exchangeable metals bound to carbonates and Fe–Mn oxides of these four heavy metals in small particles were superior to those in large particles. This illustrated that heavy metals in small particles are more active and toxic; the activity order being Zn > Pb > Cu > Cr.

Determination and speciation of ionic alkyllead compounds have presented a serious challenge for analytical chemist. In the environment these compounds have an anthropogenic origin but they may also be produced from biological transformations of $Pb^{2+}$ ions. Triethyllead, tetraethyllead and other alkyllead species in environmental samples have been studied by GC–AAS after extraction [139].

Possanzini et al. [140] developed a method for the speciation and separate determination of inorganic $NH_4^+$ salts in atmospheric aerosols. The speciation and quantification of organosilicon compounds at below parts-per-million levels in environmental and industrial samples require the separation of the compounds of interest coupled with sensitive, selective detection [141]. The combination of HPLC for separation and ICP-AES for detection is ideal for the determination of various organosilicon compounds. Separation of non-polar, high molecular mass poly(dimethylsiloxane) polymers was performed by size-exclusion chromatography with tetrahydrofuran or xylene as the mobile phase. Again, separation of polar, low molecular mass silanols was accomplished by reversed-phase HPLC with water–acetonitrile as mobile phase.

Methods for the determination of Cu, Cr and As and for the speciation of Cr(VI), As(III) and As(V) in wood and dust from impregnated timber (with those metal ions as preservatives) are given by Nygren and Nilsson [142]. Weak-acid-soluble Cr(VI) was determined by soaking a dust sample twice in NaAc buffer on a shaker for 5 min. the two extracts were filtered off using a membrane filter, combined and Cr(VI) was determined. For speciation studies of arsenic, a dust sample was leached twice in 45 ml of 6 M HCl for 1 h. The extracts were filtered through Millipore filter, combined and the volume adjusted to 100 ml. To 10 ml of the extract, 10 ml of 12 M HCl and 10 ml toluene were added. As(III) was re-extracted from the organic phase and determined by GF-AAS. After separation of As(III), As(V) was determined in the remaining solution after reduction with KI and following the same procedure.

Brown coal samples from different deposits have been analyzed [143] for the binding forms of their inorganic components. Besides the analysis of dried coals, ashing techniques and extraction procedures with different solvents (acids, bases, complexing agents, organic solvents with different polarity) have been investigated. ESCA, PIXE, INAA, ICP-AES, NMR and ion chromatography have been applied to the analysis of coals, ashes, wet ashes and extraction products. The bonding behaviour of more than 40 elements was characterized. Species identified in such cases were kaolinite, muscovite, calcite, apatite, iron pyrites, siderite, mica, rutile, quartz, bassanite, gypsum, anhydrite and hematite. On the other hand, major species in the coal ash were $SiO_2$, CaO, $Fe_2O_3$, $Al_2O_3$ and MgO.

Although the methodologies of the speciation studies included in this section are described in details, except in a few cases, the analytical characteristics are not stated, e.g. LOD [141]; 1–4 ng Si for methylsilanediols, 4–5 ng Si for polydi-methylsiloxane. Recoveries and coefficient of variation values are indicated only in some cases [142], and for Cr(VI), As(III) and As(V) they are, respectively, 94%, 1–8%; 82%, 4–5%; 89%, 4–12%.

## 5. Conclusion

In the investigation of the toxic and essential effects of trace constituents, a speciation study is often indispensable. It is clear that this is one of the important areas in speciation that has developed more rapidly. In the near future, an appreciable increase in applications can be expected because in recent years, the coupling of different separation and preconcentration techniques with various instrumentation has been established as an appropriate methodology for speciation.

It is evident that speciation studies have been carried out by two different approaches, one to identify unknown species by rigorous methods and other to identify compounds in experimental samples by comparison with standard compounds. The continued application and development of both approaches is necessary for complete speciation of various solid samples, and in this respect the availability of stable certified materials for different chemical species is an important challenge which will be a great help for the validation of new strategies.

On the other hand, in order to obtain accurate information on the chemical species in a sample, due consideration should be given to the sample collection, pretreatment and storage steps. More studies and applications of fast speciation analysis for solid samples in order to measure the very small concentrations of species are eagerly awaited.

## Acknowledgement

Funds to carry out this work were provided by the Universidad de Valencia (Spain) for which two of the authors (A.K.D., R.C.) are deeply indebted.

**Abstract**

2-Mercaptobenzothiazole loaded on previously treated clay was prepared, characterized and used for sorption and preconcentration of Hg(II), Pb(II), Zn(II), Cd(II), Cu(II) and Mn(II) from an aqueous solution. The support used was a natural clay previously treated with sulphuric acid solution. Adsorption isotherms of metal ions from aqueous solutions as function of pH were studied at 298 K. Conditions for quantitative retention and elution were established for each metal by batch and column methods. The chemically treated clay was very selective to Hg(II) in solution in which Zn(II), Cd(II), Pb(II), Cu(II) and Mn(II) were also present.

## 1. Introduction

The use of clays for adsorption and ion exchange studies [1–5], hydrolysis reactions [6], esterification of carboxylic acids [7] and whitening of oils [8] have been of interest to many researchers using natural aluminium silicates as rigid support.

Previously, Terada et al. [9,10] reported that 2-mercaptobenzothiazole (MBT) impregnated on silica gel surface can be used in preconcentration of metal ions present in water samples. MBT is insoluble in water but soluble in many organic solvents and can, therefore, be used in the preconcentration process of trace metals present in natural water [10].

Impregnation of organic molecules on a solid surface is a different process of organofunctionalization, e.g. grafting of organic molecules on silica gel surface. In the latter case, organic molecules are attached on the support by means of chemical bonding [11–15], while in the former case it is by means of physical interactions. Using the first process, sorbents are much easier prepared and under steric ground, the physically adsorbed reagents do not present any restrictions in coordinating with the metal ions on the surface. Quantitative retention of the metal ions complex species on the surface is achieved provided that they are insoluble in the solvent.

This work focuses on the preparation and utilization of treated natural clay as support for MBT looking at the following properties: (a) selective adsorption of heavy metal ions, (b) utilization as chromatographic columns packing material and (c) utilization in the preconcentration processes of heavy metal ions.

## 2. Experimental

All reagents were of analytical grade and used without further purification.

Sample (a) Natural clay; samples (b–g) chemically treated clay according to the procedures described.

### 2.1. Sample preparations

Natural clay from Jupia, city of São Paulo State, was used in this work. The clay was obtained by the dispersion and sedimentation method [16]. Various chemical treatments were applied to the material before use. A general procedure is as follows: the clay was treated with 0.5 M solution of potassium permanganate acidified with sulphuric acid solution (6.0 M). The mixture was gently shaken at different times (between 2 and 12 h) at 353 K and then filtered, washed with water and dried at temperatures between 353 and 873 K. The material was ground and sieved.

### 2.2. Chemical analysis and characterization

The samples were chemically analyzed and the results are summarized for various treatments in Table 1. The specific surface areas were determined by the BET technique using CG Scientific Instruments equipment.

### 2.3. Impregnation procedure

About 50 g of treated clay sieved between 70 and 200 mesh was immersed in 50 $cm^3$ of MBT acetone solution (8 w/v%) and shaken for few min and then the solvent was evaporated at room temperature under vacuum. The material was washed with deionized water and dried at 353 K under vacuum.

### 2.4. Isotherm of adsorption

The isotherms of adsorption of metal ions by MBT–clay were determined for Zn(II), Cd(II), Hg(II), Pb(II), Cu(II) and Mn(II) metal ions in aqueous solutions. About 0.5 g of the solids were shaken in 25 $cm^3$ of metal ion solutions (concentrations between $1.0 \times 10^{-3}$ and $1.0 \times 10^{-4}$ M) at $298.0 \pm 0.2$ K for 30 min. The quantity of metal ions in the supernatant solutions were determined by atomic absorption spectroscopy (AAS).

Adsorption isotherms of metal ions from solutions at different pH were also studied. In this case 0.5 g of the sorbent was immersed in 25 $cm^3$ solutions of metal ions of $9.0 \times 10^{-4}$ M and shaken for 30 min at $298 \pm 0.2$ K. The quantity of the metal ion in the supernatant in each flask was determined by AAS.

The quantity of adsorbed metal, $N_f$, was calculated by applying the equation

$$N_f = (N_a - N_s)/m$$

where $N_a$ is the initial mole number of the metal ion, $N_s$ is the metal mole number under equilibrium conditions and $m$ is the mass of the sorbent.

### 2.5. Preconcentration experiments

In the preconcentration experiments using the batch method, solutions of metal ions (25 $cm^3$) with a concentration of $2.0 \times 10^{-4}$ M at various pH were shaken with 1.0 g of MBT-clay at $298 \pm 0.2$ K for 30 min. The amount of metal ions in the supernatant solutions were measured by AAS.

For preconcentration experiments using the column method, a glass column of 20 cm height and 0.8 cm internal diameter was packed with about 8 g of the sorbent. About 10 $cm^3$ of metal ion solution at a suitable pH was passed through the column with a flow rate between 0.5 and 1.0 $cm^3\ min^{-1}$. The column was washed with 20 $cm^3$ of deionized water. The adsorbed metal ions were eluted passing 20 $cm^3$ of eluent (HCl solution) with a suitable composition and the effluent collected for analysis of the metal ions by AAS.

## 3. Results and discussion

X-ray diffraction patterns of the natural clay showed the presence of mixture including kaolinite, montmorillonite, illite and quartz. This is a common composition of the clay mineral found in the region [16]. The chemical treatments applied to the clay samples changed the composition and the specific surface areas as shown in Table 1. It is very clear that decreasing the $Al_2O_3$ content by acid treatment of the natural clay increases the specific surface area and the material becomes more porous [8]. The clay sample resulting from treatment f was used throughout this work.

### *3.1. Amount of reagent loaded on the supporting material*

The amount of MBT supported on the chemically treated surface was determined as follows: 0.5 g of the dried material was packed in a glass column tube and then 20 $cm^3$ of ethanol was passed to quantitatively elute MBT. The quantity of MBT was determined spectrophotometrically.

The amount of reagent loaded on the supporting material was 5.1 mg MBT clay. Under this treatment a reasonable surface coverage with MBT was possible achieving a loading values similar to those obtained using more porous materials such as silica gel [17–21].

### *3.2. Isotherms of adsorption*

Adsorption of metal ions from solution by a solid phase can occur with formation of surface complex between the adsorbed ligand and the metal. However, the sites responsible for the adsorption process are not exclusively due to the adsorbed organic molecule. Other sites on activated clay surface can also contribute to the adsorption process [1–8].

Initially the isotherms were carried out in aqueous solutions without prior adjusting of the pH. The curves resulting by plotting $N_f$ vs. $C$, where $C$ is the equilibrium concentration of the metal ion in solution in contact with the solid phase, are shown in Fig. 1. The adsorption capacities determined for each metal at saturation condition were (in $\mu mol\ g^{-1}$): Hg(II) = 13.5, Cd(II) = 10.0, Zn(II) = 6.9, Pb(II) = 3.5, Cu(II) = 11.0 and Mn(II) = 2.8. Fixing the initial concentration of metal ion and changing the pH solutions and plotting $N_f$ vs. pH, the set of curves shown in Fig. 2 were obtained. Fig. 2A shows that adsorption of Hg(II) by MBT–clay is independent of pH solution. Adsorption of the ion by untreated clay is negligible below pH 3 and at 6, the adsorption is about half of that of observed for treated clay (isotherm not shown). The high affinity of MBT–clay in all the pH solutions range by Hg(II) is explained well by the Pearson rule [22] because MBT and Hg(II) are soft base and acid, respectively. It can be observed that adsorption for the remaining metals is dependent of changes in pH solutions and increased when they vary from 1 to 6.

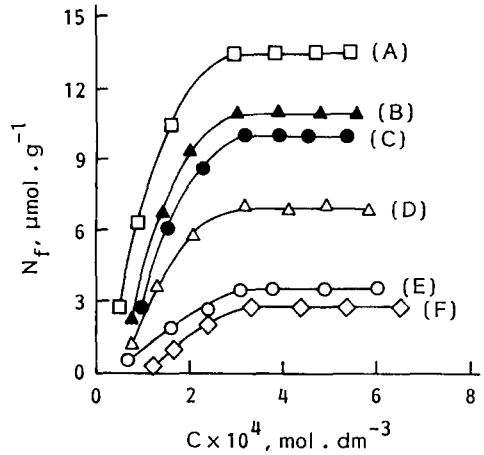

Fig. 1. Isotherms of adsorption of metal ions from solutions by MBT–clay. (A) Hg(II), (B) Cu(II), (C) Cd(II), (D) Zn(II), (E) Pb(II) and (F) Mn(II).

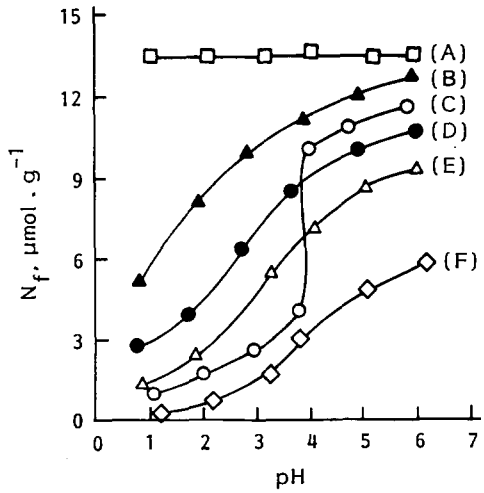

Fig. 2. Isotherms of adsorption of metal ions from solutions by MBT–clay as function of pH. (A) Hg(II), (B) Cu(II), (C) Pb(II), (D) Cd(II), (E) Zn(II) and (F) Mn(II).

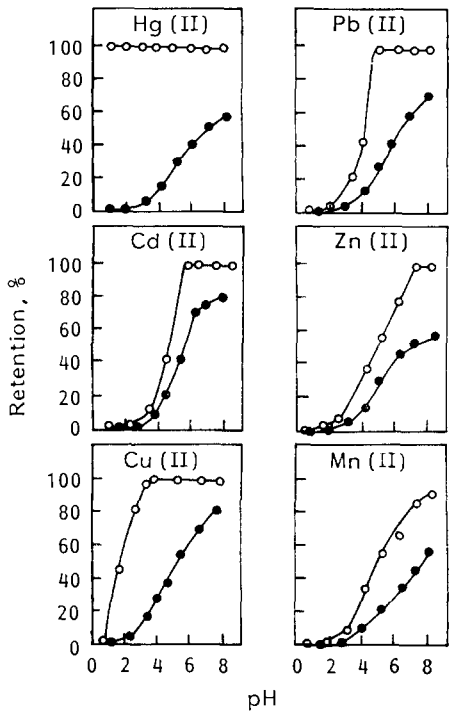

Fig. 3. Preconcentration of metal ions from aqueous solutions by MBT–clay as function of solution pH. Blank points of plots are MBT–clay and full points of plots are untreated clay.

### 3.3. Preconcentration of individual metal ions

*Batch method*

Preconcentration of each metal ion by MBT–clay from an aqueous solution at various pH solutions was examined by batch technique. In the experiments, the equilibrium pH solutions were measured for each experimental point. The results, expressed in per cent extraction, are presented in Fig. 3.

Hg(II) was quantitatively retained from pH 1 up to pH 8. Cu(II) was quantitatively retained on the chelating material from pH 3.5 up to pH 8, whereas untreated clay began to adsorb Cu(II) at pH 3. Pb(II) and Cd(II) showed nearly similar behaviors and were quantitatively retained at pH values of 5 and 5.5, respectively. Zn(II) was completely retained at pH 7.5 and Mn(II) was not quantitatively retained in the pH range of 1–8. In case of Zn(II), despite the high pH value, precipitation of metal hydroxide was not visually detected because the initial concentration of metal ions was very low ($10^{-4}$ M). In all these cases, a pronounced difference in adsorbability between MBT–clay and untreated material was observed.

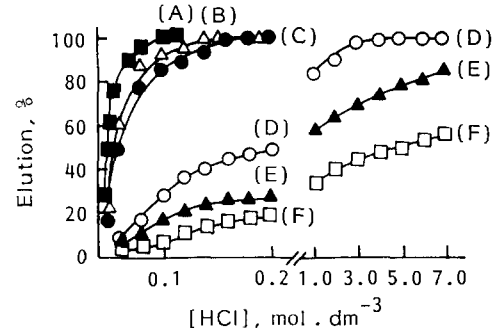

Fig. 4. Elution of metal ions adsorbed on MBT–clay by acid solutions. (A) Mn(II), (B) Zn(II), (C) Cd(II), (D) Pb(II), (E) Cu(II) and (F) Hg(II).

*Column method*

In the column experiment, each metal was quantitatively adsorbed adjusting the solutions pH according to the values found in the previous batch method. In every run, the effluent was collected and a quantity of metal ion analysed. Elution of the metals from the column were made passing 20 cm$^3$ of hydrochloric acid of different concentrations. The results are shown in Fig. 4.

It can be observed that, in the experimental conditions used, only Zn(II), Cd(II) and Mn(II) could be quantitatively eluted with 0.2 M HCl while 49% of Pb(II), 27% of Cu(II) and 19% of Hg(II) were eluted. Quantitative elution of Pb(II) was achieved passing 20 cm$^3$ of 4 M HCl solution while using this condition, 47% of Hg(II) and 73% of Cu(II) were eluted. Quantitative elution of Hg(II) and Cu(II) was possible by passing 20 cm$^3$ of 0.2 M thiourea solution acidified with 1 M HCl solution (Fig. 5).

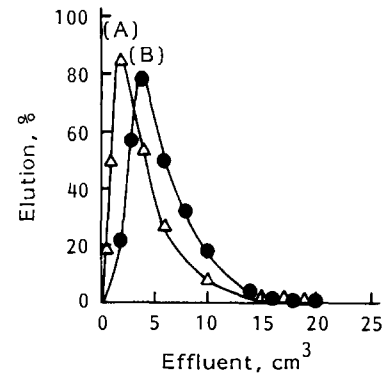

Fig. 5. Elution of (A) Cu(II) and (B) Hg(II) adsorbed on MBT–clay by 0.2 M thiourea solution in HCl (1.0 M).

Table 2
Recovery of metal ions from a mixture

| Ion | Concentration/$10^{-3}$ M | Recovery (%) [a] | | | | | |
|---|---|---|---|---|---|---|---|
| | | Zn(II) | Cd(II) | Hg(II) | Pb(II) | Cu(II) | Mn(II) |
| Zn(II) | 0.2 | — | 97 | 100 | 96 | 91 | 94 |
| | 2.0 | — | 67 | 100 | 54 | 66 | 47 |
| Cd(II) | 0.2 | 95 | — | 100 | 96 | 100 | 92 |
| | 2.0 | 24 | — | 100 | 59 | 96 | 43 |
| Hg(II) | 0.2 | 97 | 93 | — | 91 | 90 | 98 |
| | 2.0 | 92 | 61 | — | 62 | 43 | 43 |
| Pb(II) | 0.2 | 94 | 95 | 100 | — | 100 | 96 |
| | 2.0 | 44 | 66 | 97 | — | 78 | 68 |
| Cu(II) | 0.2 | 98 | 97 | 98 | 94 | — | 100 |
| | 2.0 | 94 | 65 | 92 | 63 | — | 100 |
| Mn(II) | 0.2 | 98 | 98 | 100 | 97 | 95 | — |
| | 2.0 | 70 | 82 | 100 | 78 | 82 | — |
| Co(II) | 0.2 | 100 | 100 | 100 | 95 | 100 | 100 |
| | 2.0 | 97 | 97 | 100 | 71 | 67 | 97 |
| Ni(II) | 0.2 | 98 | 100 | 100 | 93 | 89 | 100 |
| | 2.0 | 95 | 98 | 98 | 19 | 58 | 98 |

[a] Concentration of each ion was $0.1 \times 10^{-3}$ M.

### 3.4. Adsorption and recovery of a mixture of ions

Adsorption and elution studies of a mixture of metal ions as well as interference of Co(II) and Ni(II) were also carried out. In these studies, a series of solutions were prepared in which the metal ions concentrations were fixed at $0.1 \times 10^{-3}$ M except for one of them fixed at $2.0 \times 10^{-3}$ or $0.2 \times 10^{-3}$ M. The results are presented in Table 2.

Recovery of Hg(II) in the presence of other metal ions in concentrations twice or 20 times, was not significantly affected. However, Hg(II) at $2.0 \times 10^{-3}$ M significantly affected the recovery of Zn(II), Cd(II), Pb(II), Cu(II) and Mn(II) in a mixture containing these six ions. In the presence of transition metal ions at a concentration of $2.0 \times 10^{-3}$ M, only the recovery of Hg(II) was not affected.

## 4. Conclusions

MBT–clay has been shown to be an effective solid-phase selective sorbent for Hg(II). Formation of a stronger metal to sulphur donor atom bond accounts for the high affinity shown by MBT for Hg(II) on the basis of the Pearson hard–soft acid–base rule. The material can selectively adsorb Hg(II) from a solution and the presence of other heavy metals or some transition metals do not significantly interfere. An advantage in using this material as sorbent is the abundance of natural clay and the facility of preparation of the modified clay.

# Micellar medium for the analysis of complex mixtures of molybdenum and tungsten by derivative synchronous spectrofluorimetry in steels

C. Cruces Blanco *, A.M. García Campaña, F. Alés Barrero, M. Román Ceba

*Department of Analytical Chemistry, Faculty of Sciences, University of Granada, 18071 Granada, Spain*

Received 17 January 1994; revised 9 December 1994; accepted 12 December 1994

**Abstract**

The cationic surfactant hexadecyltrimethylammonium bromide enhances the fluorescence intensity of both molybdenum and tungsten complexes obtained with Alizarin Red S. This characteristic has been used for a sensitive simultaneous spectrofluorimetric determination of both ions over the range 32–4000 ng/ml and 49–2500 ng/ml for Mo and W, respectively. Good selectivity is achieved applying the well known synchronous derivative technique with a minucious pH selection. The proposed method has been applied to a certified steel sample with recoveries between 96 and 102%.

## 1. Introduction

Micellar media, primarly those formed by synthetic detergent molecules, have been used in luminescence analysis to enhance or otherwise modify the luminescence properties of molecules [1–3], especially improving the sensitivity of many spectrofluorimetric methods which already exist [4,5]. In the literature, several organic ligands for the individual spectrofluorimetric determination of molybdenum [6–8] and tungsten [6,9–13] have been proposed.

Alizarin Red S (ARS, the sodium salt of 1,2-dihydroxyanthraquinone-3-sulphonic acid) is a widely used reagent for the spectrophotometric and spectrofluorimetric determination of several inorganic species [14,15], including W and Mo [16,17]. Because of the similar spectral features of the inorganic complexes obtained with the same spectrofluorimetric reagent (Alizarin Red S), the determination of these ions in binary mixtures is not feasible. However, there are some simple and rapid instrumental approaches which allow the simultaneous determination of both complexes with overlapping spectral profiles without prior separation. Synchronous spectrofluorimetry offers improved selectivity over conventional spectrofluorimetry thanks to the narrower spectral bandwidth, which depends greatly on the wavelength increment chosen. Also, the application of derivatives to synchronous fluorescence spectrometry has proved a highly useful analytical technique for the direct resolution of mixtures, especially of two components of different compounds [18–22].

In this paper, the influence of several surfactants (anionic, cationic and non-ionic) on the fluorescence of the complexes of Mo(VI) and W(VI) with Alizarin Red S have been studied. The combination of these effects and the application of the synchronous derivative methodology have allowed the simple resolution of molybdenum and tungsten mixtures in real samples.

## 2. Experimental

### 2.1. Apparatus

Fluorescence was monitored with a Perkin-Elmer Model MPF-66 spectrofluorimeter, equipped with a 150 W xenon arc lamp and a R-928 photomultiplier. All measurements were performed in standard 10-mm path length quartz cells, thermostatically controlled at $25 \pm 0.5$ °C with a water-bath circulator (Frigiterm S-382). Excitation and emission monochromators were locked together and scanned simultaneously with a wavelength constant difference $\Delta\lambda = \lambda_{em} - \lambda_{ex}$. The scanning speed and response time of the spectrophotometer were set at 480 nm/min and 0.5 s respectively.

The spectrophotometer was connected to a Perkin-Elmer Model 7300 Professional computer provided with a PETLS application software (C 646-0280). A 101 Rhodamine quantum counter sample (Perkin-Elmer) was used for source intensity adjustment. Fluorescence data are given without spectral correction.

A Crison Digit-501 pHmeter was used for all pH measurements.

### 2.2. Reagents

All experiments were carried out with analytical reagent grade chemicals using doubly distilled and demineralized water.

Alizarin Red S solution ($1.0 \times 10^{-3}$ M) was prepared by weighing exactly 0.171 g of the reagent (Carlo Erba) and diluting to 500 ml with doubly distilled water.

Stock solutions of the following surfactant agents were prepared: sodium dodecylsulphate (SDS) (Merck, 0.18 M), polyoxyethylenedodecylether (Brij-35) (Merck, $4.2 \times 10^{-2}$ M), and hexadecyltrimethylammonium bromide (HTAB) (Merck, 0.14 M).

Molybdenum stock solution (0.1 mg/ml) was prepared from $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ (Merck) in doubly distilled water and standardized gravimetrically [23].

Tungsten stock solution (0.1 mg/ml) was prepared from $Na_2WO_4 \cdot 2H_2O$ (Merck) in doubly distilled water and standardized gravimetrically [24]. More dilute solutions were prepared by appropriate dilutions with doubly distilled water.

Buffer solutions of the required pH (4.3) were prepared from 1 M acetic acid and 1 M sodium acetate.

### 2.3. Procedure

*General*

An aliquot of sample containing 0.5–2.5 μg of molybdenum and 0.3–3.0 μg of tungsten with 0.3 ml of Alizarin Red S standard solution ($1 \times 10^{-3}$ M) or 4.7–40.0 μg Mo and 2.6–25.0 μg W with 0.5 ml Alizarin Red S standard solution ($1 \times 10^{-3}$ M) was added to 2 ml of 1 M acetic acid/acetate buffer solution (pH 4.3), 2 ml of 0.14 M HTAB solution and the mixture diluted to a final volume of 10 ml with demineralized water. A blank solution containing all the reagents, except both molybdenum and tungsten, was prepared and treated in the same way as described above. The synchronous fluorescence spectrum was recorded against the reagent blank, thermostatting the samples at $25 \pm 0.5$ °C with the following fixed instrumental parameters: $\Delta\lambda = \lambda_{em} - \lambda_{ex} =$ 110 nm; scan speed, 480 nm/min and a spectrometer response time of 0.5 s. The spectra were then archived on a disk file and the first-derivative was calculated by the Savitzky–Golay [25] method with 25 derivative points.

First-derivative measurements were taken as the vertical distance from the first-derivative synchronous spectrum at 486 nm to the base line for molybdenum and at 502 nm to the base line for tungsten.

The fluorescence intensities of these derivative signals are directly related to the concentration of each ion in their individual calibration graphs.

*Analysis of steel samples*

A BCS/SS Carbon Steel No. 451/1 with a certified content of C (0.054%), Si (0.116%), Mn (0.62%), P (0.009%), S (0.014%), Cr (0.104%), Mo (0.039%), Ni (0.016%), As (0.041%), Cu (0.47%), Sn (0.002%), Ti (0.105%) and W (0.099%), was analyzed. The sample (0.5 g) was dissolved in 25 ml of concentrated hydrochloric acid, 10 ml of nitric acid was added, the oxides of nitrogen boiled off and diluted to 50 ml. It was cooled, filtered and the filter washed with hot dilute hydrochloric acid and finally with hot water and diluted to 100 ml. The interference from Fe(III) was avoided by its precipitation as hydrated iron(III) oxide [26–28] by adding a 2 M NaOH solution to 10 ml sample solution. The resulting solution was filtered, neutralized and diluted to 100 ml. Aliquots (4 ml) of this solution

were used for the spectrofluorimetric determination of both ions.

## 3. Results and discussion

### 3.1. Effect of experimental variables

Alizarin Red S forms fluorescent complexes with Mo(VI) and W(VI) in aqueous media. The molybdenum complex has an excitation maximum of 488 nm and the tungsten complex at 478 nm. The emission spectra show maxima of 618 and 605 nm, respectively.

In order to choose an appropriate micellar medium to enhance the analytical signal of both complexes and to achieve the best separation between fluorescence maxima, cationic, anionic and non-ionic surfactants were tested.

Of the various surfactants tested, the greatest increase in the emission intensities of both complexes are obtained in the presence of the cationic surfactant (HTAB) and, for that reason, all further research has been carried out in this medium.

The fluorescence spectra of both complexes in the micellar medium selected are shown in Fig. 1. When these spectra were compared with those obtained without the micellar medium, a considerable increase in the fluorescence intensity of both complexes was obtained, but no appreciable changes in wavelength maxima were observed. For this reason, in this particular case an increase in sensitivity of the analytical determination of both ions using micellar medium is achieved, but they closely overlap and, consequently, the selectivity of the determination is not improved.

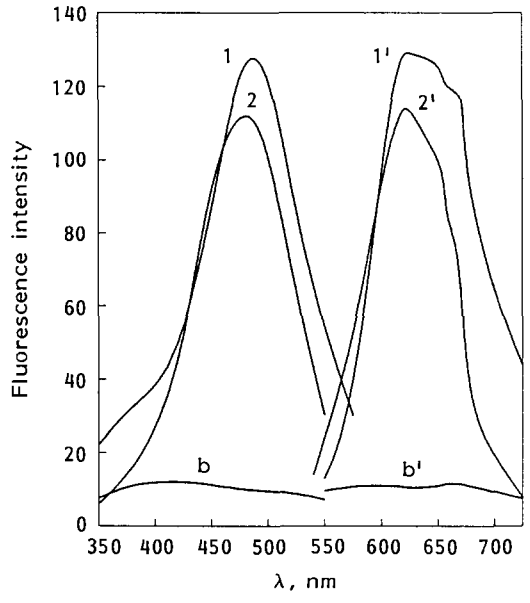

Fig. 1. Fluorescence spectra of molybdenum (1, 1') and tungsten (2, 2') complexes with Alizarin Red S in the presence of HTAB, with respect to the reagent blank. [Mo] = 250 ng/ml, [W] = 250 ng/ml, [ARS] = $3 \times 10^{-5}$ M, [HTAB] = $2.8 \times 10^{-2}$M, pH 4.3.

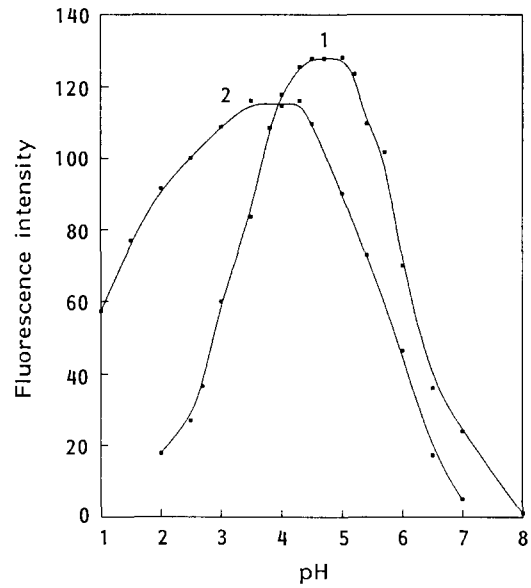

Fig. 2. Influence of pH on the fluorescence intensity of the Mo complex (1) and W complex (2). [Mo] = [W] = 250 ng/ml, [ARS] = $1 \times 10^{-5}$ M, [HTAB] = $1.4 \times 10^{-2}$ M.

Once the surfactant medium was selected, a minucious study of the appropriate pH to obtain the highest fluorescence intensity of each complex was carried out.

The reaction between molybdenum and tungsten with Alizarin Red S in the presence of the micellar medium selected (HTAB) in a concentration over its c.m.c. requires, in both cases, an acidic medium between 3.5 and 5.5 (Fig. 2). The greatest fluorescence intensity for both complexes simultaneously is obtained at a working pH of 4.3, which was selected for the rest of the experimental work. An acetic acid/acetate buffer solution of pH 4.3 gave the desired acid medium. The concentration of this buffer solution was studied and no effect on the fluorescence intensity of both complexes was observed, for which a final concentration of 0.2 M was therefore used.

Once the optimum pH for the formation of two complexes in the presence of the cationic surfactant HTAB was selected, the influence of its concentration on their fluorescence intensity

was studied. Different concentrations of HTAB around its c.m.c. were tested, showing that a concentration of $2.8 \times 10^{-2}$ M gave the best results.

The effect of the Alizarin Red S concentration was examined, over the concentration range $2 \times 10^{-6}$–$6 \times 10^{-5}$ M. A 2:1 (ARS:Mo) and 3:1 (ARS:W) molar ratio was needed to ensure maximum fluorescence intensity of both complexes and to avoid the decreased reproducibility of the measurements observed at higher concentrations.

The formation of both complexes is instantaneous and the fluorescence intensities remained constant almost 3 h after sample preparation, for which no precautions in fluorescence measurement have to be considered.

The dependence of the fluorescence intensity of both complexes on the temperature is critical. A temperature of $25 \pm 0.5$ °C gave the best results and it was chosen to carry out fluorescence measurements. The temperature control was carried out by thermostatting the sample compartment for the rest of the experimental work.

As was observed after different order of mixing of the different reagents for the complex formation, the addition of the surfactants before or after the complexes are formed did not play any significant role in the fluorescence intensity. Despite this absence of fluorescence modifications, an order of mixing of ions, Alizarin Red S, buffer solution and surfactant solution was chosen as the most convenient for the rest of the experimental work.

### *3.2. Synchronous derivative spectrofluorimetric conditions and instrumental variables*

As can be deduced from the excitation and emission maxima of these complexes in micellar medium, a preseparation should be carried out before their determination in a mixture.

Analytical advantages offered by synchronous derivative spectrofluorimetry have been made use of to analyze a mixture containing these two ions without any prior separation. For this purpose, a detailed study of the synchronous spectra for each complex alone in a range of wavelength intervals near the Stokes shift of each ion (130 and 127 nm for Mo and W, respectively), was performed. After careful observation of the spectral shapes of the different synchronous spectra, we selected a 110 nm wavelength scanning interval as the most appropriate to obtain the narrowest spectral shape and the best separation between fluorescence maxima (Fig. 3).

Despite a quite good separation of both synchronous spectra maxima being achieved, a considerable spectral overlap already existed. For this reason, the use of the additional resolution capability offered by derivative spectroscopy, is also needed. The synchronous first derivative spectra of two series of solutions containing increasing amounts of Mo and W complexes are shown in Fig. 4a. At the base line two isodifferential points at 486 and 502 nm can be observed for W and Mo complexes, respectively. Preliminary experiments showed that the fluorescence signals of the synchronous first derivative at 486 nm (working zero-crossing wavelength of W) are proportional to the Mo concentration and the fluorescence signals of the synchronous first derivative at 502 nm (working zero-crossing wavelength of Mo) are proportional to the W concentration.

Owing to the fact that at these wavelengths the changes in the fluorescence signal values with changing concentrations arise from each chelate while the other is zero, one compound can be determined without the interference of the other.

The zero-crossing method used in this paper to discriminate the overlapping bands needs

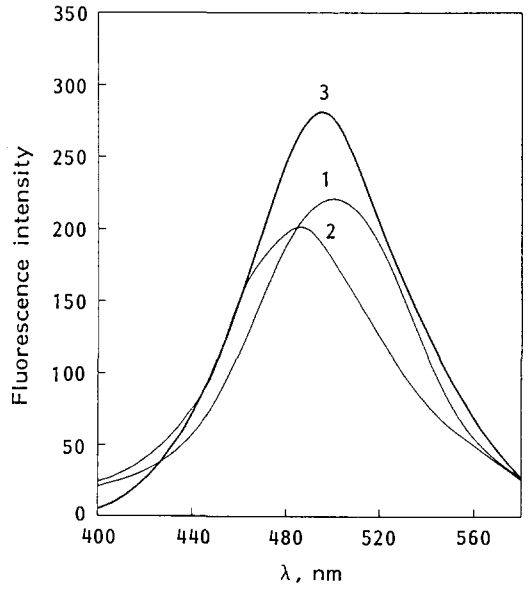

Fig. 3. Synchronous fluorescence spectra for the Mo complex (curve 1), W complex (curve 2) and a mixture of both complexes (curve 3) at $\Delta\lambda = 110$ nm. [Mo] = [W] = 1000 ng/ml. Wavelength scanning speed = 480 nm/min, response time = 0.5 s.

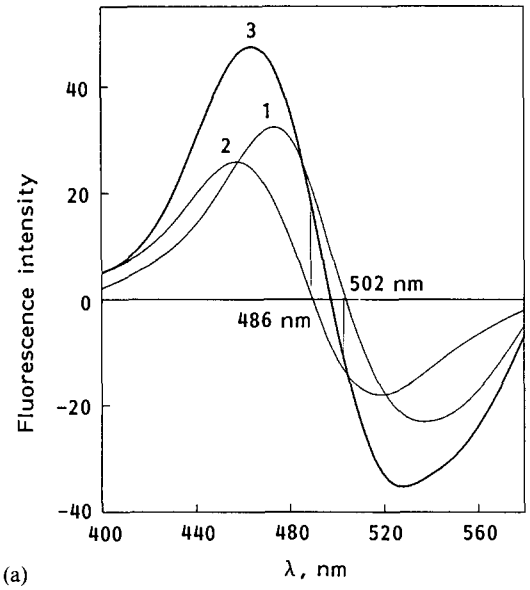

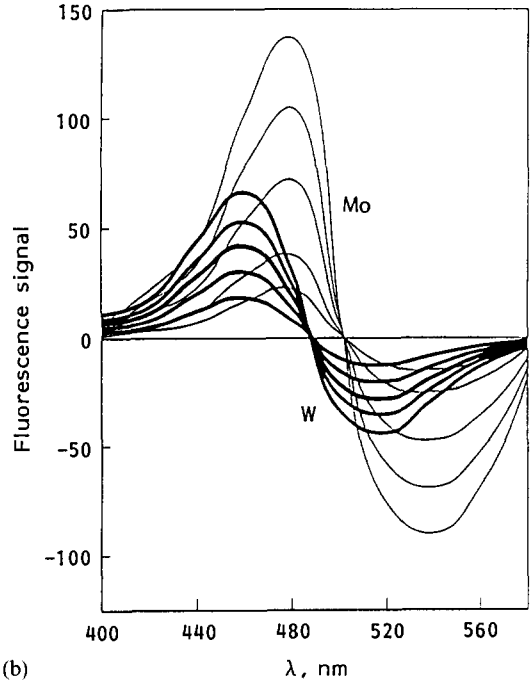

Fig. 4. (a) First-derivative synchronous spectra of the Mo complex (curve 1), W complex (curve 2) and a mixture of both complexes (curve 3) and (b) superimposed first-derivative synchronous spectra of two series of molybdenum and tungsten complexes covering the ranges for Mo (0.5, 1.0, 2.0, 3.0, 4.0 μg/ml) and W (0.5, 1.0, 1.5, 2.0, 2.5 μg/ml). Arrows indicate graphical measurements based on isodifferential points. Analytical parameters as in Fig. 3.

Beer's law to be obeyed in the full concentration range studied. This fact was proved with two solutions containing each analyte and a mixture of both. The resolution of the two equations satisfactorily resolves the mixture, indicating that the law is satisfied in the concentration range studied. The measurement wavelengths for both compounds using $\Delta\lambda = 110$ nm are indicated in Fig. 4b.

The use of the zero-crossing method in synchronous derivative spectrofluorimetry for resolving a mixture of chromophores with overlapped spectra produces a considerable loss of accuracy and sensitivity. This problem arises because the measurements are taken at a very critical wavelength, the localization of which is sometimes very difficult (see Fig. 4b).

The instrumental variables to be optimized when applying the derivative technique to the synchronous spectra are wavelength scanning speed, differentiation constant, spectrofluorimeter time constant and slit widths. All of them have a critical effect on the sensitivity and selectivity of the determination as they affect both the resolution and the fluorescence signal intensity because they modify the wavelength ranges and the relative intensity of derivative peaks.

Different values for these variables were tested, observing that the best resolution with the better signal-to-noise ratio was obtained when using a scan speed of 480 nm/min, a differentiation constant of 25 points (convoluting according to the Savitsky and Golay algorithm), a spectrofluorimeter time constant of 0.5 s and slit widths of 10 and 5 nm, depending on the calibration graph.

### 3.3. Analytical parameters

Having established the experimental and instrumental conditions, calibration graphs for the determination of Mo were prepared by measuring changes in the fluorescence signal at 486 nm, i.e. the isodifferential point of tungsten complex. Similarly for W, changes in the fluorescence signal at 502 nm, the isodifferential point of molybdenum, were measured.

These calibration graphs obtained by plotting fluorescence signal vs. molybdenum and tungsten concentrations are linear for 32–4000 ng/ml for Mo and for 49–2500 ng/ml for W. For concentrations of both ions higher than 500 ng/ml, a $5 \times 10^{-5}$ M reagent concentration should be used in order to retain the required ARS/ion molar ratio. Also, owing to the high fluorescence intensity of both complexes, a reduction of slit band width from 10 to 5 nm when applying higher concentrations is also needed.

Table 1
Analytical parameters of the proposed methods

| Element | Dynamic range (ng/ml) | Sensitivity, $S_A$ (ng/ml) | LOD (ng/ml) | LOQ (ng/ml) | RSD [a] (%) |
|---|---|---|---|---|---|
| Mo | 50–250 | 3.2 | 9.5 | 31.6 | 1.4 |
| | 500–4000 | 49.0 | 141.0 | 471.0 | 3.3 |
| W | 50–300 | 8.1 | 14.7 | 49.0 | 3.1 |
| | 500–2500 | 36.0 | 77.4 | 258.0 | 2.3 |

[a] Relative standard deviations for Mo and W at 150 ng/ml (lower ranges) and 1000 ng/ml (higher ranges), calculated from the calibration data set, $n = 3$.

Three replicates for each concentration value, with the blank signal included, were used in all cases to calculate the following equations of the corresponding equation lines [29,30].

Lower dynamic range

$$RFI = -2.43[Mo] + 8.67 \times 10^{-2} \qquad r^2 = 99.8\%$$

$$RFI = 4.95[W] + 4.63 \times 10^{-2} \qquad r^2 = 99.4\%$$

Higher dynamic range

$$RFI = 3.05[Mo] + 1.65 \qquad r^2 = 99.9\%$$

$$RFI = 2.13[W] + 7.78 \qquad r^2 = 99.8\%$$

As is evidenced by their determination coefficients ($r^2$), the linear regression analysis of the change in fluorescence signals at the isodifferential points selected shows good linear fit.

The main analytical parameters of the individual methods developed for Mo and W by using the derivative synchronous fluorescence spectrometry are summarized in Table 1. The analytical sensitivity, $S_A$, characteristic of the instrumental calibration method (calculated through the expression $S_{R,c}/b$, where $S_{R,c}$ indicates the regression standard deviation of instrumental response to concentration and $b$, the slope of the regression line) [30] and the precision expressed by the relative standard deviation calculated from the data set of calibration experiment for any concentration value [30], and detection (LOD) and quantitation limits (LOQ) [31], are indicated.

As can be observed from Table 1, very similar values of detection limits and other analytical parameters were obtained for both ions using first-derivative synchronous spectrofluorimetry. The relative standard deviation (RSD), also given in Table 1, shows good precision of both Mo and W determination.

Studies with mixtures of Mo and W at different concentration ratios (Table 2) revealed that the amplitude selected for the individual quanti-

|---|---|---|---|
| Mo | 390 (4.2) | 399.4 (1.8) | 102.4 |
| W | 990 (6.0) | 950.9 (3.4) | 96.1 |

[a] Certified values (mean of five determinations).
[b] Mean of three determinations.

tation of the ions is appropriate. It can be concluded that with the application of the synchronous derivative technique, good recoveries of Mo are obtained when W is in a 10-fold excess, and W with a 20-fold excess of Mo if present in the same solution. Although mixtures of these compounds in higher proportions could cause some interference, the application of synchronous derivative using the zero-crossing graphical model would permit the simultaneous determination of these ions in the usual proportions found in real samples.

### 3.4. Interference study

Quantitative recovery is only one aspect to be considered in evaluating the applicability of the method to these ions. The other aspect is selectivity. Selectivity is a function of the ability to eliminate components which would be detected with the determination procedure.

To test the efficiency and selectivity of the proposed analytical procedure to real samples, a systematic study was made of the effect of various species, in a wide range of concentrations, on the determination of $Mo^{VI}$ and $W^{VI}$ at the 200 ng/ml level by synchronous first derivative spectrofluorimetry.

If interference occurred, the ratio was progressively reduced until interference ceased. The tolerance criterion used was a deviation of twice the standard deviation, $S_s$, of the mean value of three measurements of 200 ng/ml of molybdenum and tungsten by the different methods proposed.

The results obtained are shown in Table 3. The analytical signal corresponding to each ion was converted into concentration using their corresponding equation lines. These results show that the great tolerance ratios of many ions frequently accompanying Mo and W in real samples are well tolerated without any prior separation technique.

## 4. Applications

### 4.1. Determination of molybdenum and tungsten in a certified steel

A British Chemical Standard (B.C.S) carbon steel $N_o$ 451/1 containing certified amounts of molybdenum and tungsten of 390 and 990 μg/g, respectively, was analyzed directly by measuring the fluorescence signal of the first derivative synchronous spectra. The average molybdenum and tungsten contents in the sample studied, based on three determinations, are shown in Table 4. In all cases there is very good agreement between officially certified values and those obtained by the method proposed.

In conclusion, the present paper shows a practical application of the synchronous derivative spectrofluorimetric technique in combination with the use of micellar media, which permitted an accurate and precise determination of two complexes with very similar fluorescence spectra, in only one simple scan, without any prior separation technique. The method could be easily applied to the analysis of both ions in different real samples.

# Flow injection analysis chemiluminescence detection of residual ozone

K.A. McGowan, G.E. Pacey *

*Department of Chemistry, Miami University, Oxford, OH 45056, USA*

Received 8 August 1994; revised 21 November 1994; accepted 28 November 1994

**Abstract**

Chemiluminescent reagents for the determination of residual ozone were compared. Each method was automated using gas diffusion flow injection analysis. The luminol method gave a four order of magnitude working range with an LOD of 0.008 mg $O_3$/l. The luminol method has better analytical characteristics than the standard colorimetric Indigo Blue methods

## 1. Introduction

In 1986 the United States Environmental Protection Agency (USEPA) enacted the safe drinking water act amendment. Some of the changes affecting water disinfection are: 99.9% inactivation of *Giardia lamblia* cysts; 99.99% inactivation of enteric viruses, legionella bacteria and heterotrophic plate count organisms; and trihalomethanes (THMs) must be kept below a yet to be determined range (possibly 0.10–0.01 mg/l). These specific changes apply to all surface water and surface water affected drinking water supplies [1]. These regulations mean that of the over 200 000 drinking water treatment plants in the United States, at least 30% will be affected. Many speculate that the drinking water treatment plants will change from chlorination, to one of the following disinfecting agents: ultraviolet radiation, ozone, chlorine dioxide, or chloramines [2].

For the past 90 years chlorine has been the predominant drinking and wastewater disinfectant and biocide used in the United States [3]. The use of chlorine as a disinfectant is primarily based on its strong germicidal properties, high oxidizing power, ease of application, measurement and control properties, and its relatively low cost. However, chlorination exhibits some significant shortcomings in satisfying the 1986 safe drinking water amendment, such as ineffective *Giardia lamblia* cyst inactivation and THMs production.

In many situations, ozone is the best choice as a replacement for chlorination since it has the potential to satisfy all criteria for potential alternative oxidants. These criteria were proposed by Symons for the USEPA [2].

1. The oxidant must be easily generated and in widespread use.
2. The oxidant must be an effective biocide.
3. The oxidant must provide an easily measured residual.
4. The oxidant must produce fewer undesirable by-products than choline.
5. The oxidant must be cost effective.

Current analytical methods for the determination of residual ozone are: standard iodometry [4], amperometry [4], arsenic(III) back titration [5], diethyl-*p*-phenylenediamine (DPD) [6] and Syringaldazine (FACTS) [7] all based on the oxidation of iodide ion to iodine, making them highly susceptible to interference from other oxidizing agents, such as atmospheric oxygen and hydrogen peroxide. These methods are not recommended [8]. The Acid

Chrome Violet K (ACVK) [9], the Leuco Crystal Violet [10] the arsenic(III) direct oxidation [11] the bis(terpyridine) iron(II) [12] and the Indigo Blue method [13,14] are colorimetric methods. In these methods, interferences from strong oxidizing agents other than ozone, such as chlorine and oxidized forms of manganese, are of some concern. For many of these methods, masking reagents like malonic acid and glycine, are used to minimize the interferences. The Indigo Blue method is currently the accepted method [15]. Two other methods are direct UV absorption at 260 nm [16,17], and an amperometric electrode method [18]. Under ultra-pure laboratory water conditions the direct UV measurement of ozone is recommended. However, dissolved organic and inorganic matter present in the ozone samples may interfere by absorbing in the 200–300 nm wavelength region [19]. Also, the detection limit for direct UV absorption in high [16,17].

The objective of this paper was to investigate chemiluminescent methods for the determination of residual ozone. Although there have been numerous publications about gas phase ozone chemiluminescent methods, the number of investigations for aqueous phase chemiluminescent measurements is limited. In particular the work of Takeuchi and Taskashi [20], which suggested that indigo disulphonate was an excellent choice for a chemiluminescent ozone method, did not investigate the obvious reagents. All methods are designed as gas diffusion flow injection analysis (GD-FIA) methods since FIA is inherently more precise especially for fast reactions like the chemiluminescence and volatile analytes like ozone. The reagent chemistries tested were indigo disulphonate (IDS), indigo trisulphonate (ITS) and luminol. Each system was optimized with respect to sensitivity, working range and LOD evaluated. Comparison to the previously reported colorimetric GD-FIA indigo method is made.

## 2. Experimental

All ozone methods examined were automated using GD-FIA. A diagram of the typical GD-FIA manifold used in these experiments is shown in Fig. 1. The gas diffusion manifold consisted of two PVC blocks with small channels bored as mirror images. A microporous teflon 0.45 micron gas diffusion membrane (W.L. Gore) is placed between the blocks. Teflon was chosen because of its excellent diffusion characteristics, resistance to the oxidizing capabilities of ozone and nonwetting characteristics which only allow a gas to be transferred through the membrane. Gas diffusion was incorporated into the FIA system to increase selectivity and matrix optimization for ozone measurements. Some of the decomposition products of ozone $O_3^-$, $HO_2^-$, $O_2^-$, OH, $HO_2$, and $H_2O_2$ will interfere by initiating chemiluminescence. However, the gas diffusion membrane allows only gaseous species to pass. Matrix modification allows a sample to be transferred from a matrix that may not be favorable for the chemistry being performed into a matrix that is more favorable toward that particular chemistry. In other words the solution in the donor stream side of the manifold inhibits the desired reaction, while the solution in the acceptor stream is optimized for the desired reaction.

A spiral-T-cell was positioned in a front of the PMT. One conduit carries the chemiluminescent reagent, while the other conduit (the accepter stream side of the gas diffusion manifold), carries the sample. The sample, ozone, and the reagent merge and the chemiluminescent reaction takes place in the spiral. The spiral-T-cell was designed using quartz tubing, which greatly enhanced the transmission of produced photons. Also, the back of the spiral was mirrored in order to increase, even further, the number of photons striking the PMT. The PMT signal was amplified through a Keithly electrometer.

The procedures for the experiments are as follows. Ozone was generated by an Ozone Research and Equipment model 03V9-9 ozonator. The generated ozone was then allowed to contact a 0.1 M phosphate buffer solution of

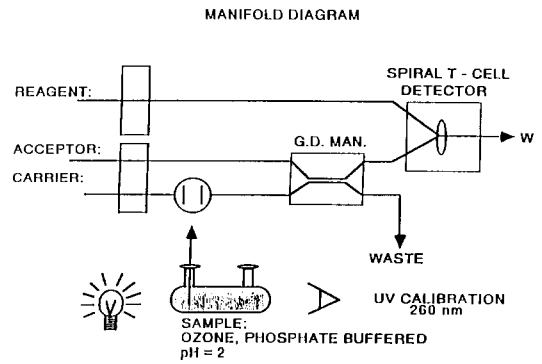

Fig. 1. Typical GD-FIA manifold for the residual ozone determinations.

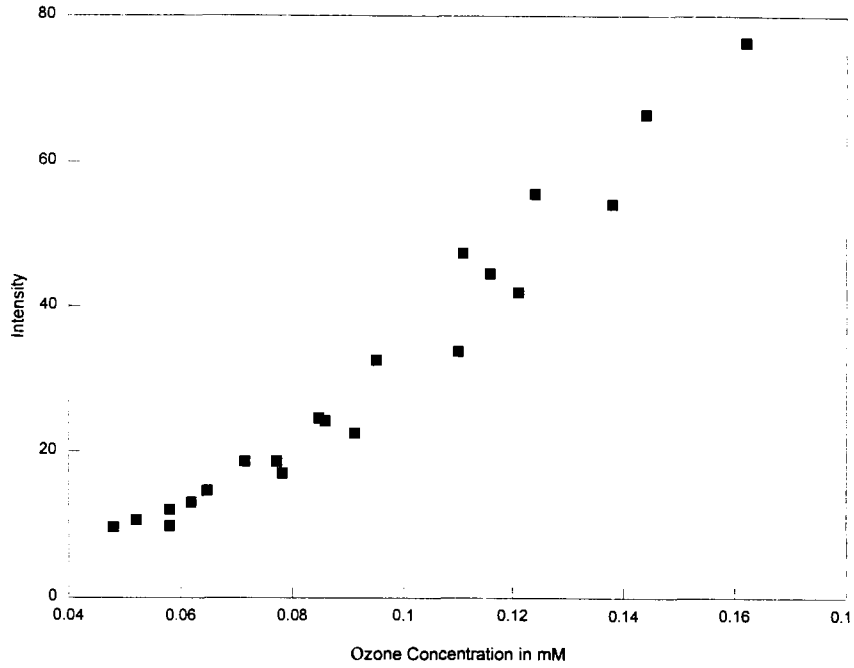

Fig. 2. Ozone chemiluminescent response to indigo disulphonate IDS. Electrometer setting at $10^{-8}$ A. ■, Ozone signal.

pH 2.12 by bubbling the ozone into a 3000 ml contractor vessel containing the solution. The solution in the vessel was used to make the standard ozone solutions. A 0.1 M phosphate buffer solution of pH 2 was chosen to minimize the instability of ozone. Ozone stability is greatest at this concentration and pH of buffer. Standard ozone solutions of varying concentrations were prepared by bubbling air, from a compressed air tank, into the contractor [21]. The bubbling of the air was then stopped and the solution was then standardized by direct UV absorption at 260 nm. The bubbling of air was then resumed in order to obtain a standard containing a lower concentration of ozone than the previous sample. This was continued until the method under investigation produced no signal above background. Depending on ozone concentrations, solutions were standardized in 2.5, 5.0, or 10.0 cm cuvettes. Ozone standards were then pumped directly out of the cuvettes into the FIA system. In this way, ozone standards were not allowed to come in contact with the laboratory environment. Lower concentrations of ozone standards ($< 10^{-6}$ M) were made by using a shrinking bottle device. The shrinking bottle is simply a large syringe into which previously standardized ozone of a higher concentration is placed. Known volumes of the standardized ozone from the shrinking bottle are then injected into sealed vessels of known volume. The injected standard is then diluted to a known volume with ozone demand free solution of the same buffer concentration and pH.

All carrier streams in these experiments were 0.1 M phosphate buffer of pH 2. The first reagent investigated, IDS, previously been optimized and these parameters were incorporated into the FIA system. The optimum IDS concentration is $2.14 \times 10^{-5}$ M (10 mg/l). This solution was prepared by dissolving 10 mg IDS in 1 l of 2 mM phosphate buffer, pH 7.2. The phosphate buffer was prepared by dissolving 0.174 g $K_2HPO_4$ and 0.136 g $KH_2PO_4$ in 1 l water. This buffer also comprised the acceptor stream.

The second reagent investigated, ITS, needed reaction conditions to be optimized. The ITS concentration was varied from 2 to 20 mg/l. A 1009 mg/l ITS stock solution was made by dissolving 100 mg ITS in 1 l 2 mM pH 7.2 phosphate buffer. Concentrations of 2–20 mg/l were made by diluting the appropriate amount of stock solution with the 2 mM, pH 7.2 buffer. The buffer solution pH was then varied in order to determine the optimum pH. The pH was varied from 5.2 to 10.28 in order to determine its optimum concentration. This was accomplished by dilution of a 50 mM stock solution. The acceptor stream was the buffer whose concentration and pH were determined to be optimum.

Luminol concentration, buffer pH, and buffer concentration for the reagent were previously optimized [21]. The optimum luminol concentration is $1 \times 10^{-4}$ M (17.70 mg/l). This solution was prepared by dissolving 17.70 mg in 1 l 0.1 M, pH 12.3 phosphate buffer. The buffer was prepared by dissolving 6.0 g $NaH_2PO_4$ and 3.4 ml $H_3PO_4$ in 1 l water. The acceptor stream in this experiment was deionized water.

Interference studies used diluted 30% hydrogen peroxide in the same sample matrix as the ozone and permanganate ion (from potassium permanganate) which is the reaction product between ozone and lower valence state manganese compounds.

All water in this experiment was distilled and deionized by a model D3600 Barnstead Nanopure double still system with a UV attachment. All chemicals were reagent grade.

## 3. Results and discussion

The data for the IDS experiment are shown graphically in Fig. 2. The results of three separate runs, five injection per data point, are fit. A nonlinear fit was observed but was not unexpected since a chemiluminescent event is not governed by Beer's Law. Unfortunately, a working range of only $5.20 \times 10^{-5}$ to $1.24 \times 10^{-4}$ M is observed. A working range at least three orders of magnitude wide is needed. The LOD of the method, as defined by three times signal-to-noise, was $5.20 \times 10^{-5}$ M.

For the ITS experiment, an optimization of the chemistry was required. The first optimization was that of the ITS concentration. Concentration of ITS were varied from 2 to 30 mg/l while the buffer solution pH and concentration were held constant at 7.2 and 2 mM respectively. The optimum concentration seems to be 14 mg/l. This ITS concentration was used throughout the investigation. The next variable to be optimized was the pH of the buffer solution. Solutions of varying pHs, 6.87–11.58, where made by the addition of dilute HCl. The ITS concentration was kept constant at 14 mg/l and the buffer concentration was also kept constant at 2 mM. The optimum pH seems to be between 7 and 9.5, therefore, it was decided to use a pH 7.2 buffer. For the optimized of the buffer concentration solutions were made with varying buffer concentrations, 0.28–10.28 mM. The concentration of ITS in the solutions was kept constant at 14 mg/l and the pH was kept constant at 7.2. The optimum buffer concentration seems to be in the range 1–5.28 mM. It was, therefore, decided to maintain the buffer concentration at 2 mM.

The data for the optimized ITS experiment are shown graphically in Fig. 3. The data represents three separate experiments with each data point representing five injections. This data did produce a linear fit, $R_2 = 0.993$; however, again the working range is limited. In this case the working range is $1.72 \times 10^{-5}$ to $1.03 \times 10^{-4}$ M with the lower concentration being the actual LOD.

The luminol method was investigated using the conditions previously used [21]. An acceptor stream of pH 3.0 phosphate buffer was reported as optimum. However, an acceptor stream of water was not examined. Upon examining the use of water it was discovered that the signal was increased 5.5 times that of the previously used acceptor stream. This is most likely due to the fact that luminol reacts best in highly alkaline conditions. However, when an acceptor stream having any buffer capacity of low pH is merged with the reagent stream the conditions for the luminol reaction become less than optimized, thereby resulting in a smaller signal.

The data for the luminol experiment are shown graphically in Fig. 4. It should be noted that both the IDS and ITS graphs have $y$-axis in the 10–100 intensity range while the luminol $y$-axis intensity is 100–500,000. The emission intensity of the luminol system is superior to IDS and ITS. The data represents three separate experiments and each data point is an average of five injections. The luminol method offers a much larger working range than either the ITS of IDS method. The working range is $4.84 \times 10^{-5}$ to $1.55 \times 10^{-4}$ M ozone. The lower concentration is the actual LOD. The working range encompasses approximately four orders of magnitude. The luminol system is measured at an electrometer setting of $10^{-5}$ A while the other two are at $10^{-8}$ A. Lower detection of ozone does appear to be possible.

A comparison of the manual standard method, the FIA automated standard method, the GD-FIA automation of the standard method and the GD-FIA luminol method is gives in Table 1. As can be seen the luminol method has lower detection, long working

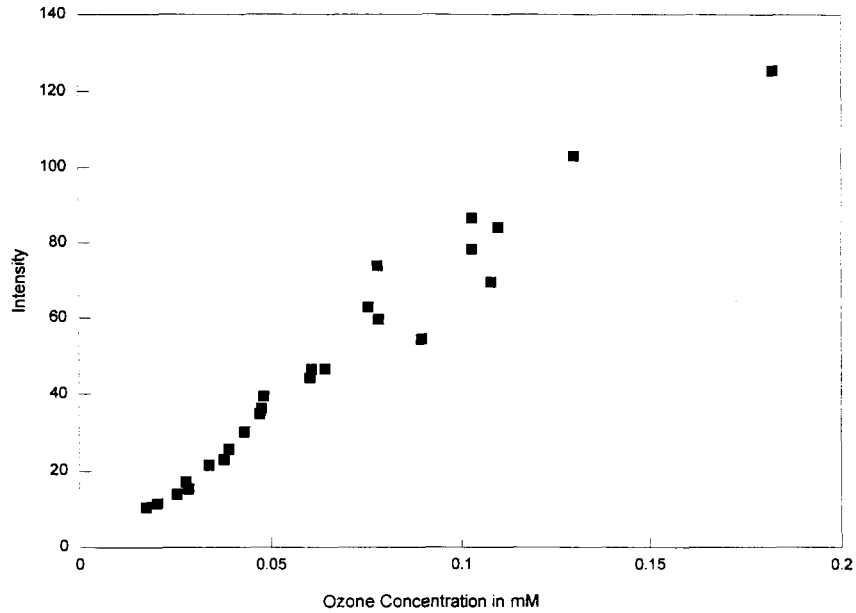

Fig. 3. Ozone chemiluminescent response to indigo trisulphonate ITS. Electrometer setting at $10^{-8}$ A. ■, Ozone signal.

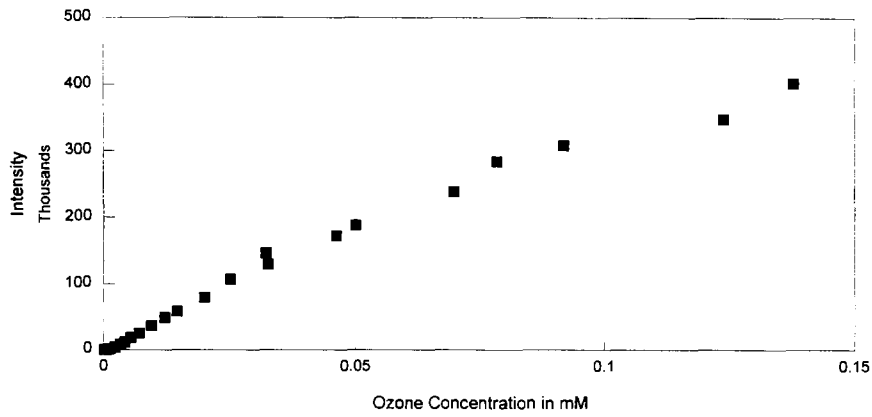

Fig. 4. Ozone chemiluminescent response to luminol. electrometer setting at $10^{-5}$ A. ■, Ozone signal.

range and less interferences than the other methods. Its sample throughput is the second largest. Given the simplicity of the hardware and the selectivity of the procedure, the luminol method should be given some consideration as a standard method for residual ozone.

Table 1
Comparison of FIA based ozone methods

| Method | Manual indigo | FIA indigo | GD-FIA indigo | GD-FIA luminol |
|---|---|---|---|---|
| Linear range (mg $O_3$/l) | 0.05–0.5 | 0.2–4 | 0.03–4 | 0.002–8 |
| Sample/hr | 20 | 120 | 65 | 100 |
| Interferences [a] | | | | |
| $H_2O_2$ | none | none | none | none |
| Mn 1 mg/l | 0.8 mg/l | 0.44 mg/l | none | none |

[a] The specified interference level produced a signal equal to the stated amount of ozone.

## 4. Conclusion

If one was to compare the three chemiluminescence methods the results would show that luminol is better than ITS and ITS is better than IDS. However, realistically neither ITS nor IDS compare in any manner to luminol. Two advantages of the luminol method over other reported methods are a direct result of automation with FIA. First, the response time is very fast when compared to the batch methods and second the sample volume required for the analysis is very small, allowing for conservation of a limited amount. Finally, there is the potential for gas phase detection incorporating reverse dual phase gas diffusion FIA.

Received 14 August 1994; revised 14 November 1994; accepted 28 November 1994

**Abstract**

A highly sensitive photometric flow-injection method is described for the determination of iron(II, III) based on the catalytic action on the oxidative coupling of *N*-phenyl-*p*-phenylenediamine with *m*-phenylenediamine in the presence of hydrogen peroxide. The sensitivity of the method was enhanced by the addition of Tween 80 as a surfactant. The dynamic range was 0.5–30 ng/ml of iron(II, III) with the relative standard deviations below 3% at a sampling rate of 30 $h^{-1}$. The proposed method was subject to few interferences from coexisting metal ions and was successfully applied to the determination of iron in natural water samples.

## 1. Introduction

The kinetic-catalytic method has proved to be an attractive means for trace analysis. Ultra-trace levels of chemical species which act as catalysts on an appropriate indicator reaction can be determined under the optimal conditions with simple instrumentation [1,2]. The addition of a ligand as an activator to the metal-catalyzed reaction improves the sensitivity and/or selectivity of these methods [1–3]. Another way for improving the sensitivity is the use of a surfactant which has the ability to form organized assemblies (micelles, microemulsions, monolayers, bilayers and vesicles) and can accelerate the rate of the catalyzed reaction [4,5].

Many batch procedures for the catalytic determination of iron have recently been reported, based on its catalytic action on the oxidation of organic substrates with hydrogen peroxide [6–9], perdisulfate [10] or periodate [11,12]. Though these methods allowed the determination of iron at sub-ppb and/or ppb levels, they include time as a variable to be strictly controlled and measured.

Flow-injection analysis (FIA) is well suited for kinetic-based methods, because it can easily control the reagent addition and the reaction time [1–3,13]. The catalytic flow-injection methods offer better accuracy, precision and speed, as well as higher sensitivity. Some iron(II, III)-catalyzed redox reactions have been applied to the flow-injection systems [3,14–18]. The oxidation of leuco Malachite Green with hydrogen peroxide was employed for the determination of 0.1–1.0 μg/ml of iron [14,15]. Cerda et al. [16] reported a flow-injection determination method for iron(III) based on the catalytic effect of iron(III)–EDTA complex on the oxidation of hydroxylamine by dissolved oxygen, by detecting nitrite produced

* Corresponding author.

*SSDI* 0039-9140(95)01509-4

by the Griess reaction. Iron(III) at 3.5–150 ng/ml was determined. An iron(II)-catalyzed chemiluminescent reaction of brilliant sulfoflavin with hydrogen peroxide was adopted to the flow-injection determination of iron(II) [17]; iron(II) and total iron in sea-water were determined using this reaction system after preconcentrating iron with a cation-exchange column in the sample loop [18]. The oxidative coupling of *p*-anisidine with *N*,*N*-dimethylaniline was adopted to a FIA system [3]; levels as low as 0.5 ng/ml of iron(III) can be determined. However, the calibration curve was not linear.

In an earlier paper [19], we reported a catalytic method with a batch mode for the determination of 0.6–6 ng/ml of iron(II, III) using an oxidative coupling of *N*-phenyl-*p*-phenylenediamine (PPDA) with *N*,*N*-dimethylaniline (DMA) in the presence of hydrogen peroxide. This method had a high sensitivity, but needed care in the mixing of sample and reagents at regular time intervals to obtain reproducible results. On the basis of this iron-catalyzed reaction, the highly sensitive and selective flow-injection photometric determination of iron has been developed. In the present system, *m*-phenylenediamine (PDA) was replaced with DMA owing to the higher solubility of PDA. Furthermore, the reaction was carried out in a micellar medium in order to accelerate the rate of the catalyzed reaction and to prevent the adsorption of the reaction product in the reaction coil. In the presence of Tween 80 as a surfactant, the sensitivity and sampling frequency of the method was increased. The concentration of hydrogen peroxide used was several orders of magnitude larger than the total iron concentration in the sample so that the iron was predominantly in the iron(III) form regardless of the initial amounts of iron(II) and iron(III). The proposed method could determine the total iron concentration in the range 0.5–30 ng/ml at a sampling rate of 30 $h^{-1}$.

## 2. Experimental

### 2.1. Reagents

All reagents used were of analytical-reagent grade. All solutions were prepared with deionized water purified with a Millipore Milli-Q system.

Standard iron(II) and iron(III) solutions (1.0 mg/ml) were prepared by dissolving weighted amounts of ammonium iron(II) sulfate and ammonium iron(III) sulfate in sulfuric (0.05 M) and hydrochloric (0.1 M) acids, respectively. These solutions were standardized by EDTA. The working standard solutions were prepared daily by diluting the stock solutions with the same acids.

*N*-Phenyl-*p*-phenylenediamine hydrochloride (PPDA) was obtained from Aldrich and used without further purification. A $2.0 \times 10^{-3}$ M PPDA solution containing polyoxyethylene(20) sorbitan monooleate (Tween 80, 0.2 wt%) was prepared. *m*-Phenylenediamine dihydrochloride (PDA) was purified by recrystallization from hydrochloric acid and a $1.0 \times 10^{-2}$ M PDA stock solution was prepared. A hydrogen peroxide solution (0.4 M) was prepared by dilution of a 30% solution (Mitsubishi Gasu Kagaku) with water. Ammonium acetate (2 M) and triethylenetetramine (trien, $1.0 \times 10^{-2}$ M) stock solutions were also prepared. Surfactants such as decyltrimethylammonium bromide (DETAB), dodecyltrimethylammonium bromide (DOTAB), tetradecyltrimethylammonium bromide (TTAB), tetradecyldimethylbenzylammonium chloride (zephiramine, TDBAC), hexadecyltrimethylammonium bromide (HTAB), hexadecylpyridinium chloride (HPC), sodium dodecylsulphate (SDS), polyoxyethylene(23) dodecanol (Brij-35), polyoxyethylene(9.5)p-1,1,3,3,-tetramethylbutylphenol (Triton X-100), polyoxyethylene(20) sorbitane monolaurate (Tween 20) and Tween 80 were used as received.

A working mixed solution of PDA ($4.0 \times 10^{-4}$ M), ammonium acetate (0.5 M) and trien ($1.2 \times 10^{-4}$ M) was prepared by mixing the stock solutions; the pH of the solution was adjusted to about 5.1 with 1.0 and 0.1 M hydrochloric acid.

### 2.2. Apparatus

A diagram of the flow-injection system for iron(II, III) determination is shown in Fig. 1, together with appropriate experimental parameters. The system was assembled from Teflon tubing (0.5 mm i.d.) and constructed using two double-plunger micropumps (Sanuki Kogyo, DMX-2400T), a sixway injection valve (Sanuki Kogyo SVM-6M2) with a loop, a circulating thermostatted bath (Toyo LH-1000C), a spectrophotometer (Soma Kougaku S-3250)

with a 10-mm micro flow-cell (8 μl) and a recorder (Nippon Denshi Kagaku V1250). A Hitachi 200-10 double-beam spectrophotometer with 10-mm cells and a Toa Model HM-5S pHmeter were also used.

### 2.3. Flow injection analysis

A carrier solution (R1, 0.1 M hydrochloric acid) was pumped into the analytical line at a flow rate of 0.8 ml/min (Fig. 1). At the same flow rate, the reagent solutions in the reservoirs R2 (hydrogen peroxide), R3 (PPDA and Tween 80) and R4 (PDA, trien and acetate) were pumped to the carrier stream at confluence points downstream. An aliquot of the sample solution (180 μl) was introduced into the carrier flow line by a loop-valve injector, and then merged in the reagent solutions. The color-forming reaction of PPDA with PDA proceeded in the reaction coil (RC, length 5 m) kept at 55.0 ± 0.1 °C. The absorbance of the colored product was monitored at 620 nm.

## 3. Results and discussion

In the presence of hydrogen peroxide, PPDA reacts with PDA to form a blue dye, which is thought to be *N*-phenyl-*N'*(2',4'-diaminobenzene-1,4-benzoquinone diiminonium ion. Iron(III) catalyzes this color-forming reaction in the slightly acidic medium. Iron(II) also catalyzes the reaction, being oxidized to iron(III) by hydrogen peroxide. Thus, the above two species of iron can act as the catalyst in the coloration and the total amounts of iron can be determined by measuring the absorbance of the dye produced at a constant time.

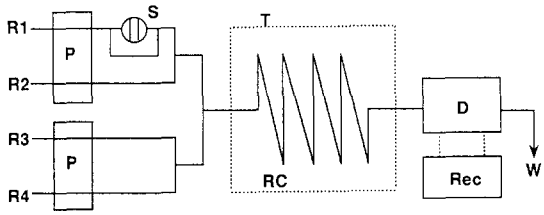

Fig. 1. Flow diagram for the determination of iron(II, III). R1, carrier (0.1 M HCl); R2, 0.4 M $H_2O_2$; R3, mixture of $2.0 \times 10^{-3}$ M PPDA and 0.2 wt% Tween 80; R4, mixture of $4.0 \times 10^{-4}$ M PDA, 0.5 M ammonium acetate and $1.2 \times 10^{-4}$ M trien; P, micropump (0.8 ml/min); S, sample injector (180 μl); RC, reaction coil (5 m); T, thermostatted bath (55 °C); D, spectrophotometer (620 nm); Rec, recorder; W, waste (pH 4.6).

[b] See text for names and abbreviations.
[c] From Refs. [20–22].

The absorption maximum of the dye was at 620 nm in the presence of Tween 80. The absorbance at this wavelength was, therefore, measured in the FIA system.

### 3.1. Choice of surfactant

As iron(III) standard solutions were injected to the FIA system in the absence of a surfactant, it appeared that the peaks were broader and the tailing of the peaks became appreciable. It seemed to be a result of the adsorption of the dye produced on the inner surface of the reaction coil and led to lower sampling frequency. To overcome the drawbacks, an attempt was made to add a surfactant to the reaction system. Furthermore, it was expected that micelles modified the rate of the iron-catalyzed reaction through the large electrostatic potential at the micellar surface or through hydrophobic forces [4,5]. Since the addition of SDS to the reaction system was observed the precipitate formed, cationic and non-ionic surfactants were tested. The relative peak heights in the absence and presence of surfactants are shown in Table 1. As can be seen in this table, the surfactants at the concentrations above critical micelle concentration (CMC) have an enhancing effect. In addition, the tailing of the peaks became smaller. The peak height for iron(III) increased as the concentration of Tween 80 increased and eventually became less dependent on the surfactant concentrations; on

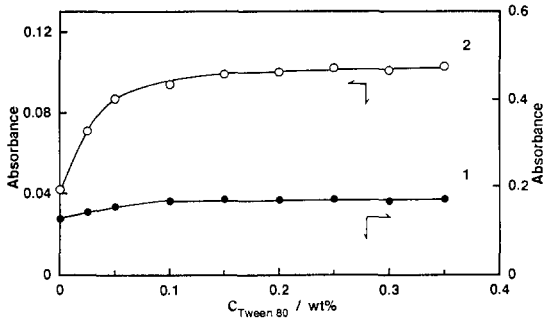

Fig. 2. Effect of Tween 80 concentration on the uncatalyzed (1) and catalyzed (2) reactions. Conditions as in Fig. 1, except for Tween 80 concentration. $C_{Fe(III)}$, 10 ng/ml.

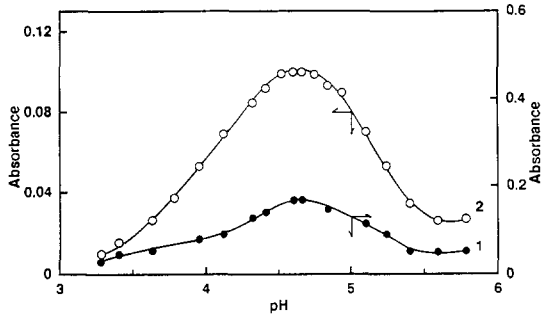

Fig. 4. Effect of pH on the uncatalyzed (1) and catalyzed (2) reactions. Conditions as in Fig. 1, except for pH. $C_{Fe(III)}$, 10 ng/ml.

the other hand, the height of baseline was almost constant (Fig. 2). The effects of concentration of other surfactants were similar to that of Tween 80. In this system, Tween 80 (0.2 wt%) was used as a surfactant. To check whether the micelle accelerated the catalyzed reaction or not, the absorbance–time curves were prepared in the absence and presence of Tween 80 (Fig. 3). The initial rate of the catalyzed reaction in the presence of the surfactant was slightly raised compared to that in the absence of surfactant, and the higher stability of the dye produced was obtained by adding surfactant. The above results suggest that the surfactant accelerates the iron-catalyzed reaction and stabilizes the dye produced. Furthermore, it suppressed the adsorption of the dye on the reaction coil.

### 3.2. *Effect of reaction variables*

To obtain the optimum conditions for the determination of iron(II, III), FIA variables were examined in the presence of Tween 80. Some preliminary experiments showed that

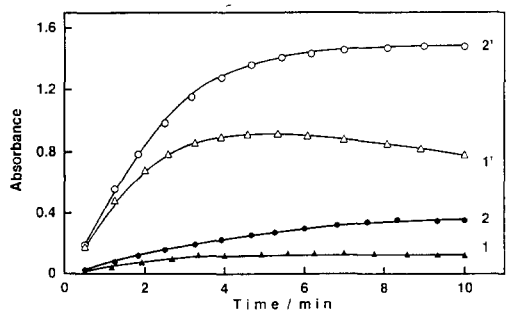

Fig. 3. Absorbance–time curves for the uncatalyzed (1, 2) and catalyzed (1′, 2′) reactions in an aqueous (1, 1′) and Tween 80 (2, 2′) medium. $C_{Fe(III)}$, 10 ng/ml; $C_{PPDA}$, $2.0 \times 10^{-4}$ M; $C_{PDA}$ $1.0 \times 10^{-4}$ M; $C_{H_2O_2}$ $2.0 \times 10^{-2}$ M; $C_{acetate}$, 0.13 M, $C_{Tween\ 80}$, 0.5 wt%. All at pH 4.6 at 55 °C.

heights of peak and baseline increased at the lower flow rate, owing to increase in the reaction time. By considering the stability of baseline and the sampling frequency, a 0.8 ml/min flow rate of carrier and reagent streams was selected for the procedure. By lengthening the reaction coil, the heights of peak and baseline were increased because of the longer reaction time. Since the lower height of baseline owing to the uncatalyzed reaction was favorable, a 5 m reaction coil was used. The peak height and peak width increased with increasing sample size; a 180-μl sample volume was adopted for the method. As the reaction temperature was elevated, there was an increase in the rates of the uncatalyzed and catalyzed reactions. For the sake of sensitivity, the temperature of the reaction coil was kept at 55 °C.

The effect of pH on the uncatalyzed and catalyzed reactions in the range 3.3–5.8 is shown in Fig. 4; a maximum peak height owing to the catalyzed reaction exists at about pH 4.6–4.7. The reaction was carried out in this pH range. Acetate was chosen as a buffer because it acted as an activator [19]. The peak height increased with increasing acetate concentration up to 0.4 M, above which it gradually increased; a 0.5 M acetate concentration was selected for the procedure.

An increase in the concentration of PPDA caused an increase in the rates of uncatalyzed and catalyzed reactions (Fig. 5). A concentration of $2.0 \times 10^{-3}$ M PPDA was chosen because of the desire to minimize the baseline readings owing to uncatalyzed reaction. With an increase in PDA concentration, the rate of the catalyzed reaction increased, reaching a maximum at a concentration above $2.0 \times 10^{-4}$ M; on the other hand, the rate of the uncatalyzed reaction gradually increased. A $4.0 \times 10^{-4}$ M PDA solution was used for the

procedure. As the hydrogen peroxide concentration increased, the rates of uncatalyzed and catalyzed reactions also increased. At concentrations above 0.3 M, the peak height for the catalyzed reaction was kept constant. A 0.4 M hydrogen peroxide concentration was selected as optimal.

### 3.3. Calibration graph

The calibration graphs for iron(II) and iron(III) were prepared by the recommended procedure using the flow system as shown in Fig. 1. The graphs were linear up to 30 ng/ml of both species of iron. The slopes of both graphs agree with each other within experimental error; the present method allows the determination of total iron. The detection limit for a signal-to-noise ratio of two was 0.2 ng/ml. The coefficients of variation for the determination of 5 and 10 ng/ml of iron(III) were 2.6 and 1.4%, respectively. The sample rate throughout was about 30 $h^{-1}$. In general, catalytic flow-injection methods have a lower sensitivity than batch methods as a result of shorter reaction time. The proposed flow-injection method, in which the reaction is carried out in a micellar medium, has a higher sensitivity, wider dynamic range and better reproducibility than the batch method reported previously [19].

### 3.4. Interference study

From preliminary experiments, copper(II) also catalyzed this indicator reaction. Some complexing agents for copper(II) were examined such as trien, *N*-(dithiocarboxy)sarcosine and triethanolamine. Among them, trien effectively suppressed the catalytic effect of copper(II) at concentrations below 100 ng/ml and did not affect the iron(III)-catalyzed reaction up to $2.4 \times 10^{-2}$ M; $1.2 \times 10^{-4}$ M trien was used.

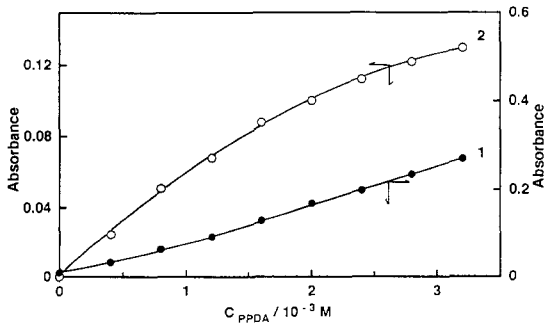

Fig. 5. Effect of PPDA concentration on the uncatalyzed (1) and catalyzed (2) reactions. Conditions as in Fig. 1 except for pH. $C_{Fe(III)}$, 10 ng/ml.

TAL 42-8-E

Table 2
Tolerance limits for foreign ions on the determination of 5 ng/ml of iron(III)

| Tolerance limit (ng/ml) | Ion added |
|---|---|
| 100 000 | As(V), Ba(II), Ca(II), K(I), Mg(II), Na(I), Sr(II), $BO_3^{3-}$, $Br^-$, $ClO_4^-$, $NO^{-3}$, $SO_4^{2-}$ |
| 10 000 | Ce(III), Hg(II), Se(IV), Te(IV), W(VI), $PO_4^{3-}$ |
| 1000 | Ag(I), As(III), Bi(III), Mo(VI), Zn(II), $F^-$, $I^-$, $NO_2^-$ |
| 500 | Al(III), Ce(IV), Cd(II), Mn(II), Ni(II), Pb(II), V(V), tartrate |
| 100 | Co(II), Cu(II), Cr(III), Cr(VI), Ti(IV) |
| 50 | Sn(II), Sn(IV), oxalate |
| 5 | $P_2O_7^{2-}$, citrate, EDTA |

The effect of other coexisting ions on the determination of 5.0 ng/ml iron(III) was examined in the presence of trien. The tolerance limits with an error of 5% are summarized in Table 2. Most of the ions listed in the table did not interfere in concentrations up to at least 100-fold excesses (by weight). Positive interferences were observed for Co(II), Cr(VI) and Ti(IV) at concentrations indicated in Table 2. Chromium(III) and tin(II, IV) caused negative error; however, these ions were allowed to coexist in up to 10-fold excesses. The selectivity of the proposed method is higher than that of the previous one [19]. The tolerance limits for these metal ions are greater than the levels normally present in natural water samples. Diphosphate, citrate, EDTA and oxalate interfered with the catalytic action of iron by the formation of complexes with iron(III).

### 3.5. Application

The proposed method was applied to the determination of iron in natural water to evaluate its usefulness. River, lake and sea-water samples were filtered through a Millipore filter (pore size 0.45 μm) and the filtrates were acidified with hydrochloric acid to about pH 1. Then iron was determined according to the recommended procedure by applying the calibration curve and standard addition methods. The results which were obtained from the calibration curve and the standard addition methods were in good agreement (Table 3).

Table 3
Determination of iron in river, lake and sea-water samples

## 4. Conclusions

A simple and rapid flow-injection method is proposed for the determination of iron in the range 0.5–30 ng/ml by using the iron-catalyzed reaction of PPDA with PDA in the presence of hydrogen peroxide and Tween 80. The addition of the surfactant to the reaction system has some advantages, viz. the catalyzed reaction can be accelerated, and the dye produced can be stabilized and its adsorption suppressed to the inner coil surface, leading to a higher sensitivity and sampling frequency. The proposed method can be applied to the analysis of natural water without preconcentration and separation. Compared with other catalytic flow-injection methods [3,14–18], the present method offers a higher sensitivity and a more extended dynamic range.

Received 5 December 1994; accepted 3 January 1995

**Abstract**

Solid-phase spectrophotometry has been applied to analysis for trace amounts of vanadium. Vanadium was sorbed in a styrene–divinylbenzene-type anion-exchanger Dowex 1-X8 as a vanadium-4-(2-pyridylazo)resorcinol complex. Resin phase absorbances at 562 and 800 nm were measured directly which allowed the determination of vanadium in the range of 0.1–2.4 ng/ml with a RSD of 1.5%. The method has been applied to the determination of vanadium in different samples, namely toadstool tissue, mussel tissue, petroleum crudes and swamp water.

## 1. Introduction

There are several biological systems which contain significant levels of vanadium-containing compounds. Plants have a baseline mean vanadium content of about 1–2 μg/g, and animals of less than 1 μg/g [1]. Comparisons between these levels and those in certain plants and animals indicate large accumulations of vanadium. So, the toadstool *Amanita muscaria* was found to contain unusually large concentrations of vanadium [2] and certain species of marine animals, *Ascidians*, concentrate vanadium in their blood to a level comparable to that of iron in the human blood [3]. The accumulation by tunicates and *Amanita* toadstools may have started at an earlier stage, with atmospheric oxygen still at a rather low level.

Vanadium's role in physiological systems includes participation in various enzyme systems as an inhibitor and a cofactor [4], catalysis of the oxidation of various amines [5] and normalization of sugar levels. Vanadium in trace amounts is an essential element for all cell growth, but is toxic in high concentrations [6]. The toxicity of vanadium to humans through industrial exposure increases with the oxidation state of the vanadium compound, with the +5 oxidation state being the most toxic [7]. The dumping of petroleum crudes is one of the most important marine pollution sources. Vanadium, together with nickel, is always present in petroleum crudes, especially those from Canada and Venezuela, in the form of vanadium porphyrins [7]. Since some marine animals, such as molluscs, grow in places where this effect is especially strong, the determination of vanadium in the tissue of these species can be used as a control parameter of the pollution levels.

Thus it is of importance to develop sensitive methods for determining vanadium. Spec-

trophotometry is the most common technique used for vanadium determination, owing to its high sensitivity and selectivity. The most useful method involving complex formation in aqueous solution appears to be that using the chromogenic agent 4-(2-pyridylazo)resorcinol (PAR) [8] in the presence of the masking agent CDTA. However, for the spectrophotometric determination of V(V) at sub-ng/ml levels in solution a previous preconcentration step is required. In this paper we have developed a very sensitive and selective method for the determination of vanadium with PAR by using solid-phase spectrophotometry (SPS). This technique introduced in 1976 [9] presents various important advantages: the sensitivity (expressed as molar absorptivity) is much higher (from $10^3$ to $10^4$ times) than the corresponding spectrophotometry in solution, it does not require an expensive instrumentation and the species interfering in spectrophotometry in solution can be excluded from the ion-exchanger in adequate conditions. Solid-phase spectrophotometry (SPS) combines the use of a solid support, usually an ion-exchanger, to preconcentrate the analyte with the aid of a chromogenic reagent and subsequent direct measurement of the absorbance of solid phase [10].

The proposed method has been satisfactorily applied to the determination of vanadium in diverse natural samples.

## 2. Experimental

### 2.1. Reagents

Analytical-reagent grade chemicals and doubly distilled water were used throughout. All experiments were carried out at room temperature.

Vanadium(V) stock solution was 1000 mg/l, as chloride (Aldrich). Solutions of lower concentration were prepared by dilution with doubly distilled water.

Ion exchanger: Dowex 1-X8 (200–400 mesh) anion-exchange resin (Aldrich) was used in the chloride form. The resin was washed several times with doubly distilled water, then treated with 2 M HCl for 4 h and finally with doubly distilled water until the washing was free from chloride. It was air-dried and stored in a polyethylene container.

Buffer solution HOAc/NaOAc of pH 3.8, was prepared by dissolving 2.7216 g of sodium acetate trihydrate, $NaOAc \cdot 3\,H_2O$ (Merck), and 8 ml of acetic acid in 1000 ml of water.

4-(2-pyridylazo)resorcinol solutions (PAR): solutions of various concentrations were prepared by dissolving 4-(2-pyridylazo)resorcinol monosodium salt (monohydrate) (Merck), in water. These solutions were stored under refrigeration and in absence of light. In these conditions they are stable for at least 4 days.

### 2.2. Apparatus

A single beam GBC 911A microprocessor-controlled UV-Vis spectrophotometer, from GBC Scientific Equipment Ply Ltd, with 1 mm glass cells was used for all spectral measurements. The spectra were obtained with a scan rate of 250 nm/min. The GBC 911A UV-Vis spectrophotometer was connected to a BRAVO AST/286 microcomputer by means of a serial port. The program GBC SCAN MASTER V 1.62 was used for data acquisition and treatment. A COMX PL80 plotter was used for graphical representations. Other apparatus consisted of an Agitaser 2000 rotating bottle agitator, a Selecta Model S-240 desk centrifuge and a Crison Model 2002 pH-meter fitted with a glass-saturated calomel electrode assembly and a temperature probe for pH measurements.

### 2.3. Absorbance measurements

The absorbance (really attenuation) of the PAR–V complex sorbed on the resin was measured in a 1 mm cell at 562 nm (corresponding to the absorption maximum of the coloured species) and 800 nm (the latter is in the range where only the resin absorbs light), compared with a 1 mm cell packed with resin equilibrated with blank solution. The net absorbance was calculated as in a previous report [11].

### 2.4. Procedures

(A) For 100 ml samples, an appropriate volume of sample containing 0.15–2.1 μg (1.5–21 ng/ml) of vanadium(V) was transferred into a 1 l-polyethylene bottle and then 10 ml of $1.47 \times 10^{-5}$ M PAR solution, 10 ml of pH 3.8 HOAc/NaOAc buffer solution and 70 mg of Dowex 1-X8 (200–400 mesh) resin were added, after levelling off to 100 ml.

The mixture was stirred mechanically for 15 min and the coloured resin beads were collected by filtration under suction and, with the aid of a small pipette, packed into a 1 mm-cell together with a small volume of the filtrate. The cell was centrifuged at 5000 rpm for 2 min. A blank solution containing all reagents except vanadium was prepared and treated in the same way as the sample. The absorbance difference between sample and blank, measured as described under Absorbance measurements, provides an estimation of the net absorbance.

(B) For 500 ml samples, an appropriate volume of sample containing 0.125–2.25 μg (0.25–4.5 ng/ml) of vanadium(V) was transferred into a 1 l-polyethylene bottle and then 10 ml of $2.64 \times 10^{-5}$ M PAR solution, 50 ml of pH 3.8 HOAc/NaOAc buffer solution and 70 mg of Dowex 1-X8 (200–400 mesh) resin were added, after levelling off to 500 ml. The mixture was shaken mechanically for 50 min, operating as indicated in the above procedure.

(C) For 1000 ml samples, an appropriate volume of sample containing 0.125–2.4 μg (0.125–2.4 ng/ml) of vanadium(V) was transferred into a 2l-polyethylene bottle and then 10 ml of $3.53 \times 10^{-5}$ M PAR solution, 100 ml of pH 3.8 HOAc/NaOAc buffer solution and 70 mg of Dowex 1-X8 (200–400 mesh) resin were added, after making up to volume. The stirring time was increased to 60 min. Other details were as above.

The calibration graphs were constructed in the same way, using vanadium solutions of known concentration.

### 2.5. Treatment of samples

*Water*

Natural water was filtered through a 0.45 μm membrane filter (Millipore) and collected in a polyethylene container carefully cleaned with nitric acid. The samples were stored at 4 °C until analysis. Analyses were performed with the least possible delay. The usual general precautions were taken to avoid contamination.

*Toadstool tissue (Amanita muscaria)*

Firstly all foreign matter, especially adhering soil, was removed from the sample by means of successive washings with distilled water, 0.1 M HCl and doubly distilled water (we avoided an excessive washing to prevent leaching). The sample was immediately dried into a forced-draft oven for 24 h at 70 °C to prevent decomposition or weight loss by respiration and ground in a hand-mill. A suitable aliquot was weighed (1.0659 g dry material) into a quartz crucible and placed in a cool furnace; the mineralization was carried out by heating slowly to 450 °C for 2 h and holding at this temperature for a further 2 h. The sample was removed and cooled and the ashes were wet carefully with a fine stream doubly distilled water, then adding 1 ml of 4 M NaOH; the crucible was covered with a watch glass, heated cautiously on a hot plate to boiling and finally let stand for a few min. Then, the solution was filtered through Whatman no. 42 paper over a 100 ml standard flask, diluting to volume after addition of 0.75 ml HCl. The vanadium content was determined on an aliquot, as described in the 100 ml procedure.

*Mussel tissue (Mytilus galloprovincialis)*

The sample was dried in a forced-draft oven at 70 °C to constant mass and then ground into a fine powder. A suitable aliquot was weighed (19.6253 g dry material) into a quartz crucible and placed in a cool furnace; the mineralization was carried out by heating slowly to 550 °C for 2 h and holding at this temperature for a further 2 h. The sample was removed and cooled and the ashes were wet carefully with a fine stream doubly distilled water, then adding 2 ml of 4 M NaOH; the crucible was covered with a watch glass, heated cautiously on hot plate to boiling and finaly let stand for a few minutes. Then, the solution was filtered through Whatman no. 42 paper over a 100 ml standard flask, diluting to volume after addition of 0.8 ml HCl. The vanadium content was determined on an aliquot, as described in the 100 ml procedure.

*Petroleum crudes*

A suitable weight of petroleum sample (from 0.501 to 7.529 g, depending on the vanadium content) was treated in a Vycor vessel with sulphuric acid (1 ml for each gram of sample) in a sand-bath with continuous agitation to avoid foam formation, followed by combustion of carbonaceous ash at 525 ± 25 °C. The inorganic residue was treated with 1:1 hydrochloric acid and heated to effect complete dissolution. After concentration, a few drops of nitric and sulphuric acids were added and the solution was heated gently until white fumes were formed and the small carbonaceous residue not ignited was destroyed. After, the Vycor vessel

was washed carefully, the solution was heated to boiling and neutralized and pH was fixed between 3 and 5 with sulphuric acid. Finally, the solution was diluted to 50 ml with doubly distilled water.

### 2.6. Distribution measurements

PAR solution, buffer solution and 70 mg of Dowex 1-X8 (200–400 mesh) were added to a 100 ml water solution containing 3.93 μmol of V(V). After 30 min equilibration, the resin beads were separated by filtration under suction. Then, the equilibrium concentration of V(V) in the solution was determined as described in the 100 ml procedure. The distribution ratio $D$ was calculated from the initial and equilibrium concentrations in the solution. An average value of $(218.2 \pm 3.2) \times 10^3$ ml/g was obtained from five replicate determinations.

## 3. Results and discussion

### 3.1. Absorption spectra in solid phase

PAR reacts with V(V) in solution to give a 1:1 violet complex [12], with an absorption maximum at 533 nm, suitable for colorimetric determination of the latter. Between pH 2 and 8 this complex is sorbed on Dowex 1-X8 anion-exchange resin shifting the absorption maximum at 562 nm. PAR is fixed on this resin showing a yellow-orange colour with an absorption maximum at 409 nm (415 nm in solution). The spectra of the complex in solution and resin phases, from which the increase of the sensitivity in the resin phase is evident are shown in Fig. 1.

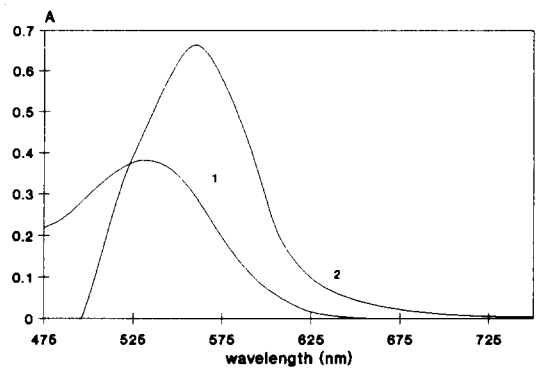

Fig. 1. Net absorption spectra of V(V)–PAR species. (1) in solution $[V(V)] = 1.96 \times 10^{-5}$ M, $[PAR] = 3.93 \times 10^{-4}$ M, pH = 3.9, 10 mm optical path length; (2) on resin. $[V(V)] = 2.94 \times 10^{-7}$ M, $[PAR] = 5.88 \times 10^{-6}$ M, pH 3.9, 70 mg of resin, 1 mm optical path length, stirring time = 15 min, $V = 100$ ml.

### 3.2. Optimization of variables

*pH dependence*

This variable was studied by applying the 100 ml procedure. Optimum pH for the formation and fixation of the species fell in the range 3–4.5 (Fig. 2). At pH values below 3 and above 6 the absorbance decreased significantly. Different buffer solutions ($HCOOH/HCOO^-$, potassium phthalate/HCl, HOAc/NaOAc) were tested. The HOAc/NaOAc buffer (pH 3.8) was found to yield the best results.

Absorbance was independent on ionic strength, adjusted with the buffer solution, up to a concentration of $3.2 \times 10^{-2}$ M. For higher values the absorbance decreased quickly as usual in SPS studies, probably owing to competition between the anions of the buffer for the anionic sites of the resin.

*PAR concentration*

Absorbance increases together with PAR concentration, up to a molar [PAR]/[V(V)] ratio 4 (for 100 ml sample). Consequently, a [PAR]/[V(V)] ratio of 5 was chosen for 100 ml. Similarly, for 500 and 1000 ml molar [PAR]/[V(V)] ratios of 9 and 12 were chosen, respectively.

*Other experimental conditions*

The optimum stirring times were 15, 50 and 60 min for 100, 500 and 1000 ml sample volumes, respectively. The fixed complex was stable for at least 120 min after equilibration. The order of addition of reagents did not affect the results obtained and the one used here was:

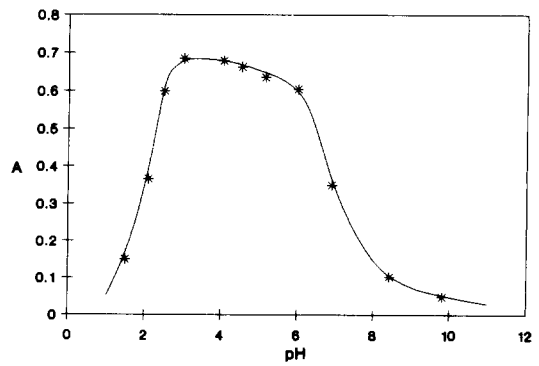

Fig. 2. Influence of pH. $[V(V)] = 2.94 \times 10^{-7}$ M, 70 mg of resin, stirring time = 15 min, $V = 100$ ml, 1 mm optical path length.

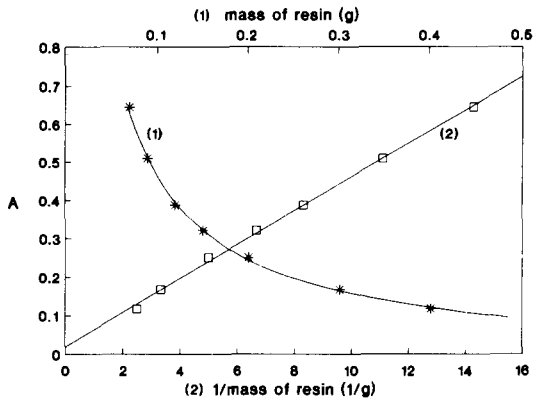

Fig. 3. Influence of the amount of resin. (1) $A$ vs. mass of resin; (2) $A$ vs. 1/mass of resin. $[V(V)] = 2.94 \times 10^{-7}$ M, $[PAR] = 2.94 \times 10^{-6}$ M, pH 3.8, stirring time = 15 min, $V = 100$ ml, 1 mm optical path length.

sample–PAR–buffer–resin. The use of a large amount of resin ($m_r$, in g) lowered absorbance values, as usual [10]. The minimum amount of dry resin required to fill the cell and facilitate handling, i.e. 70 mg, was used for all the measurements. The reduction of absorbance was according to the empirical equation $A_c m_r^{0.958} = 0.051$ (Fig. 3, curve 1). When absorbance $A_c$ is represented vs. $1/m_r$ (Fig. 3, curve 2) we found that absorbance decreased according to the equation $A_c = 0.020 + 0.044/m_r$ ($r = 0.999$).

We can calculate the agreement of the slope with molar absorbance as follows [13]:

$$A_c = \epsilon_c l_R C_o V 1000/(m_r + V/D) \quad (1)$$

where $\epsilon_c$ is the molar absorptivity of the sample species in the ion-exchanger phase (15.700 kg $mol^{-1}$ $cm^{-1}$), $l_R$ the mean light-path length through the solid phase (cm), $C_o$ the initial concentration of V(V) (M), $V$ the volume of sample solution (1), $D$ the distribution ratio (l/g) and $m_r$ the mass of ion-exchanger (g). In our case, owing to the large value of $D$, the fraction $V/D$ can be neglected as compared with $m_r$ for all the values of this latter and then we obtain the equation which relates the absorbance with the mass of ion-exchanger:

$$A_c = \epsilon_c l_R C_o V 1000/m_r = K/m_r \quad (2)$$

where $K = \epsilon_c l_R C_o V 1000$ is the slope of the graphic representation of $A_c$ vs. $1/m_r$. Supposing $l_R = 0.1$ cm, the expected value for $K = 15.700 \times 0.1 \times 2.94 \times 10^{-7} \times 0.100 \times 1000 = 0.046$ which is in excellent agreement with the experimental value 0.044.

*Nature of the fixed complex*

The composition of the fixed V(V)–PAR complex on Dowex 1-X8 resin was studied at the working pH 3.8 using the *molar ratio* [14,15] and the *Job* [16] methods.

The plot $A$ vs. [PAR]/[V(V)] molar ratio, obtained by varying the PAR concentration, showed an inflexion at 1 molar ratio indicating the presence of one molecule of PAR in the fixed complex. Moreover, the *Job* method shows a ratio [PAR]/[V(V)] = 1. Consequently, these results indicated that the stoichiometry is [V(V)]:[PAR] = 1:1 and agreed with those found in aqueous solution [12].

PAR may be considered to act as terdentate ligand having three donor atoms in a plane. The metal is coordinated through the pyridinic nitrogen, the azo nitrogen further from the heterocyclic ring, and the *ortho* hydroxyl group of the reagent [17,18].

Corsini [19] studying the formation of complexes between PAR and various metalic ions in aqueous solution found that the $pK_{a2}$ value of the *p*-OH group of PAR increases notably by the chelation. On the other hand, other authors who have utilized a PAR-like chromogenic reagent in SPS admit that the fixation of the metal–PAR complex on an anion-exchange resin promotes the dissociation of the *para*-hydroxyl group [20].

According to this, the global complexation–fixation process could be presented in this case by the following scheme:

$$VO_2^+ + H_2L + X^- \rightleftarrows VO_2LHX^- + H^+$$

(complexation process)

$$VO_2LHX^- + Cl_m^- R^{m+} \rightleftarrows VO_2LX^{2-}Cl_{m-2}^- R^{m+} + 2Cl^- + H^+$$ (fixation process)

$$VO_2^+ + H_2L + X^- + Cl_m^- R^{m+} \rightleftarrows VO_2LX^{2-}Cl_{m-2}^- R^{m+} + 2Cl^- + 2H^+$$

(global process)

where X represents an unidentate anion, (e.g. $Cl^-$, $AcO^-$), which would be fulfilling the sixth coordination position of the vanadium(V) atom, and $Cl_m^- R^{m+}$ the anionic resin.

In fact, the V(V)–PAR complex is apparently anionic in nature, whereby it is extracted into methyltrioctylammonium chloride solution (Adogen 464) in toluene, whereas it is not extracted into toluene of tetrachloromethane. The above proposed structure for the V(V)–PAR complex in the resin phase is in agree-

Table 1
Analytical parameters for SPS vanadium(V) determination

| | Volume of sample system | | |
|---|---|---|---|
| | 100 ml | 500 ml | 1000 ml |

[b] From Ref. [35].
[c] Vanadium (V) concentration (ng/ml) used for the determination of reproducibility.

ment with that proposed in solution for complexes 1:1 between PAR and metallic ions with coordination index [21].

### 3.3. Analytical data

The analytical parameters are summarized in Table 1. It was verified that one of the main contributions to the RSD comes from the variability of the packing of the ion-exchanger. The relative standard deviation (RSD) was 7.0% without centrifugation for the 100 ml sample and 10 determinations. With centrifugation for 2 min at 5000 rpm before the absorbance measurements were carried out, the RSD decreased at 1.4% and the absorbance values increased at about 9%.

The sensitivity, expressed as apparent molar absorptivity, of the proposed methods, is compared with that of spectrophotometric procedures in the literature (Table 2). It is shown that the increase in sensitivity obtained with the proposed methods is substantial, especially in relation to the solution methods using the same reagent.

According to the equation $A_c = \epsilon_c l_R C_o V 1000/(m_r + V/D)$, the sensitivity in SPS methodology can be enhanced by increasing the sample volume. In our case, the fraction $V/D$ can be neglected as compared with $m_r$ for all the values of $V$ lower than 11 and then we obtain the equation which relates absorbance with sample volume:

$$A_c = \epsilon_c l_R C_o V 1000/m_r = K'V \quad (3)$$

where $K' = \epsilon_c l_R C_o 1000/m_r$ is the slope of $A_c$ vs. $V$ (for $V$ values lower than 11). The expected value for $K' = 15.700 \times 0.1 \times 2.94 \times 10^{-8} \times 1000/0.07 = 0.659\ l^{-1}$.

The increase of absorbance with sample volume can be evaluated by measuring the absorbance of resin equilibrated with different volumes of solutions containing the same concentration of vanadium ($V$) and proportional amounts of the other reagents. Fig. 4 shows the increase in the absorbance with sample volume $V$. Absorbance increases according to the empirical equation $A_c = 0.634V$ ($r = 0.997$), for $V$ values lower than 11. The experimental value of the slope, $0.634\ l^{-1}$, is in excellent agreement with the theoretical value $0.659\ l^{-1}$.

The factor $m_r$ can be neglected compared with $V/D$ at higher sample volume values and then the absorbance becomes independent of sample volume: $A_c = \epsilon_c l_R C_o 1000D = K''$. In practice, absorbance becomes independent of sample volume for $V$ values lower than values predicted theoretically (Fig. 4); probably owing to the stirring time required for high volumes being greater than the experimental one used.

In practice, the increase in the absorbance with sample volume can be also predicted from the slope of the calibration graphs. The sensitivity ratios ($S$) for the samples analysed here are: $S_{1000/500} = 1.92$; $S_{1000/100} = 9.44$ and $S_{500/100} = 4.93$. The theoretical expected values obtained using the distribution ratio value [33] $D$ are 1.94, 9.45 and 4.87, respectively.

The standard deviations of the background absorbance for the blanks, necessary for calculating the IUPAC detection limit (K = 3) [34], measured as the average of 10 determinations and expressed as SD units, were 0.004, 0.002 and 0.002, for 100, 500 and 1000 ml sample volumes, respectively. The detection limits of the proposed methods are similar to those obtained by other sensitive techniques such as

Table 2
Comparison of sensitivities for determination of vanadium(V)

### 3.4. *Effect of foreign ions*

A detailed study of interference effects was carried out for cations and anions, in amounts ranging up to 1000 μg, with 1.5 μg of vanadium. Ions were considered as not interfering if they produced an error of less than ± 5% in the determination of analyte. The tolerance limits for the ions studied are shown in Table 3.

Of the ions tested, the only major interferences were from Co(II) and Cu(II) owing to the formation of complexes with PAR which fix on the solid phase and absorb at the working wavelength [10,36]. Therefore, we can confirm that the proposed methods are sufficiently selective.

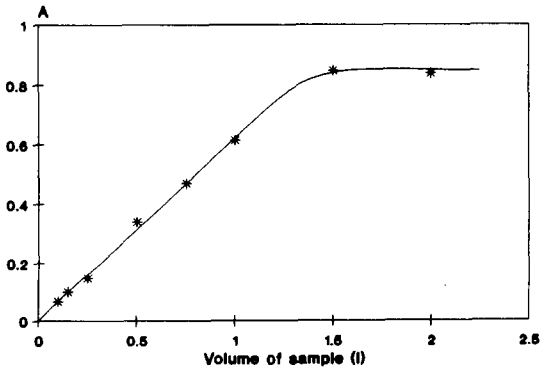

Fig. 4. Influence of the sample volume on colour development. $[V(V)] = 2.94 \times 10^{-8}$ M, $[PAR] = 2.94 \times 10^{-7}$ M, 70 mg of resin, pH 3.8, stirring time = 15–160 min.

### 3.5. Analytical applications

The proposed method has been applied to the determination of vanadium in toadstool tissue, mussel tissue, petroleum crudes and swamp water. The determination of vanadium in toadstool tissue (*Amanita muscaria*) was performed using the standard calibration graph method, since no matrix effect was observed (Table 4). Sample was collected from near the city of Viso del Marqués (Ciudad Real, Spain). Mussel tissue (*Mytilus galloprovincialis*) came from Galicia (Spain) and was analysed by the standard addition calibration graph method (Table 4). The loss of sensitivity caused by matrix effects (evaluated by the slope's quotient between the standard addition calibration graph and the standard calibration graph) was 0.77. The results obtained in both cases are in excellent agreement with those found by EAAS.

The vanadium content in four petroleum samples of different origin, composition and density was analysed by the standard calibration graph method (Table 4). As a reference method, the ASTM procedure, based on tungstophosphovanadic acid formation and absorbance measurement at 436 nm [37], was employed but, in this case, a larger amount of sample than in the SPS method (from 20.050 to 301.180 g) was used. The statistical study of precision and accuracy of the proposed method and the reference ASTM method was made from $F$-criterion and the $t$-test, respectively. The results showed that both methods have the same precision and accuracy.

The method was also applied to the determination of vanadium in Quiebrajano swamp water (Jaén, Spain) by the standard addition calibration graph method obtaining an average content ($n = 3$) of 0.49 ± 0.02 ng/ml of vanadium. The loss of sensitivity caused by the matrix effect (evaluated as indicated above) was 0.68. In this case, in order to check the accuracy of the proposed method a study of recovery was performed. For this, 0.75 and 1.05 ng/ml of vanadium were added to 1000-ml water samples, obtaining recovery precentages of 98.7 and 96.2%, respectively.

Received 3 October 1994; revised 3 January 1995; accepted 3 January 1995

**Abstract**

The stability constants of the complexes of glycinate ion with copper(II), nickel(II) and hydrogen(I) and of nitrilotriacetate ion with calcium(II) and hydrogen(I) and the ionic product of water ($K_w$) were determined potentiometrically. The measurements were carried out at 25.0 °C in four different ionic strengths up to $I\ (=I_c) = 2.50$ and two different ionic media ($KNO_3$ and $(CH_3)_4NNO_3$). Extrapolation of equilibrium constants to zero ionic strength and ionic strength corrections to equilibrium constants were carried out with the data obtained from both media using the TEC (thermodynamic equilibrium constant) equation and computer program. The constants of the potassium complexes with nitrilotriacetic acid at low ionic strength are also given. Successful attempts to predict equilibrium constants for other ionic media using TEC parameters and the procedure of the specific ion-interaction theory (SIT) are given. The variations of equilibrium constants with the ionic strengths and ionic media are demonstrated.

## 1. Introduction

One of the most important tasks in aqueous solution chemistry is speciation, i.e. the exact description of a system with different metal ions and ligands in terms of the concentrations of the species present at given conditions (temperature, ionic strength $I$, and inert salt) and known total concentrations of the components. This is only possible if the equilibrium constants for all the species present in the system at the chosen conditions are known. As this is not always possible, the unknown constants can still be estimated starting from known values evaluated under other experimental conditions. Two of the important parameters affecting the values of the equilibrium constants are the ionic strength and the inert salt. Their dependence may be described using expressions containing terms for the activity coefficients of the species involved in equilibrium [1]. We have recently published a paper [1] introducing the TEC (thermodynamic equilibrium constant) equation for use with such calculations. The results obtained by TEC using the literature data were discussed and compared with those obtained by the SIT (specific ion-interaction theory) equation or its synonym the BGS (Brønsted–Gugenheim–Scatchard) equation.

In this paper, our own experimental results of some simple systems are analysed with the above equation using statistical quantities defined in our earlier paper [1] and given in the footnotes of Table 4. The values of some equilibrium constants with glycinate and nitrilotriacetate ions in presence of two inert salts and a wide ionic strength range have been obtained ($I = 0.050–2.50\ M$). This allows the interpolation of the same stability constants for arbitrary conditions at $I < 3$ and the extrapolation of the same values to $I = 0$. The resulting values are discussed in terms of their precision and reliability as well as the possibility equilibrium constants values in presence of other inert salts.

The practical standard state for a solute B in a solution is a hypothetical solution at the standard state pressure with concentration $c_B = 1\ M$ and activity coefficient $y_B = 1$. To avoid using activity coefficients, the measurements are always done in presence of an inert electrolyte that should not react with the studied species but maintain the activity coefficients of all investigated species as constant. From measurements at different $I$ values, it is often possible to calculate the equilibrium constant at $I = 0$ in the standard state studied by extrapolation using extended Debye–Hückel equations referred to the molar ionic activity coefficients $\gamma_i$.

Recently, a critical survey on equilibrium constant data of glycine and its metal complexes has been published [2]. Some mentioned papers give exact values for the protonation of glycinate ion in solution [3–5] at different ionic strength ($I \simeq 0.01–0.1$) with a few recommended values also for the metal complex formation with the same anion. Another critical survey on equilibrium constants data of nitrilotriacetate and its metal complexes is found in the literature [6] and includes recommended values for the protonation constants of nitrilotriacetate (NTA) at $I = 0.1$(KCl or $KNO_3$) and for the stability constant of the complex with calcium at $I = 0.1(KNO_3)$. In both cases, the number of values is too limited to allow an exact evaluation of the involved constants required for the inert salt concentrations with $I \leqslant 3\ M$.

While a single article appeared on the subject of the $K^+$ complex with glycine [7], a few articles [8–10] have reported a complex of $K^+$ with NTA ($KL^{2-}$ where L = NTA) at $I = 0.1$. Only one article [8] reported the constant of the protonated species $KHL^-$ at the same ionic strength with a large standard deviation. As the stability constants of the potassium complexes are small in magnitude and difficult to be evaluated, it is important to know their values at all ionic strengths because of the applications of potassium salts as supporting electrolytes in potentiometric titrations. Similar remarks can be generalized for $Na^+$ normally forming more stable complexes with polyaminopolycarboxylate ligands than $K^+$ and present in biological systems ($I = 0.15$(NaCl)) and seawater ($I = 0.7$).

## 2. Experimental

### 2.1. Reagents

Glycine (HL) and nitrilotriacetic acid ($H_3L$), Fluka puriss 99%, were checked for purity using elemental analysis. Potassium nitrate, Merck pro analysi 99% was dried in an oven at 80 °C. Potassium hydroxide solution was prepared from a Titrisol Merck ampoule and standardized against three different standard solutions of potassium hydrogen phthalate. The solid potassium hydrogen phthalate was Merck pro analysi titration grade 99.95–100.05%. Nitric acid solutions were prepared from a Titrisol Merck ampoule. The disodium salt of ethylenediaminetetraacetic acid (EDTA) was standardized against standard zinc chloride solution prepared from zinc metal, Fluka 99.999%. Copper nitrate and nickel nitrate, both AnalaR grade, were standardized by titration against standard EDTA solution. Tetramethylammonium nitrate (Fluka), was checked for purity using elemental analysis. Tetramethylammonium hydroxide (Fluka) was standardized against standard potassium hydrogen phthalate. Both tetramethylammonium compounds were checked for the presence of metal impurities. Mercury (Merck) analysis and polarography grade was used.

### 2.2. Potentiometric system

The measuring system consists of a 10 ml thermostated jacket cell (temperature adjusted using a Lauda MS M3 thermostat) containing a micro glass electrode and an external 'homemade' calomel electrode (Pt | Hg, $Hg_2Cl_2$, $xM(N\text{Cl})$, $x'M(N\text{NO}_3)$, where $x = 10\%$ of the total solution concentration $(x + x')M$ and

$N = K^+$ or $(CH_3)_4N^+$) connected to the measuring solution through a salt bridge filled with the aqueous solution of the inert salt alone at the given $I$ ($=x+x'$) value. Its cell potential, $E$, was measured at 25.0 °C using an Orion SA 720 potentiometer. The strong base was added stepwise from a 1.000 ml motor burette (Metrohm 665 Dosimat) to 5.00 ml of the measured acidic solutions. The whole titration system was monitored using an IBM AT computer and the TIT212 data acquisition–titration control software [11].

### 2.3. Procedure

The cell was calibrated by titrating 5.00 ml standard nitric acid solutions at $I = 0.050$, 0.300, 1.00 and 2.50 against either standard potassium hydroxide or tetramethylammonium hydroxide. The calibration parameters (the apparent standard electrode potential $E°'$ and the negative logarithm of the ionic product of water $pK_w$) were computed [12] using the experimental data obtained, i.e. $E$ value for each base addition. An extra term was added to the Nernst equation accounting for the Henderson's liquid junction potential correction [13] owing to $H^+$ and $OH^-$ concentrations. All measured solutions and titrants were maintained at a given ionic strength with the same ionic medium used. During the alkalimetric titration, a reduction in the concentration of the inert salt and $I$ occurs becuase of the neutralization of $H^+$ and dilution. The maximum reductions of the ionic strnegth computed from a strong acid–strong base titration is 0.002 and 0.004 at the ionic strengths of 0.050 and 2.50, respectively. It is in general possible to reach the exact ionic strength in the pH range from which the constants are determined. The calibration parameters were later used to convert the $E$(mV) reading (by the glass electrode) of the measured solutions under investigation to pH. The Nernst slope is set constant to 59.16 mV and the errors obtained for $E°'$ were between $\pm 0.04$ and 0.2 mV corresponding to 0.0007 and 0.003 pH unit, respectively. The deionized water used was previously degassed for 2 h and then saturated with pure argon or nitrogen gas. The gas was first passed through a solution with the same ionic medium and ionic strength of the whole system and then allowed to evolve above the measured solution in the covered measuring cell. The glycinate ion in its fully protonated form ($H_2L^+$) was titrated alone and in presence of copper or nickel metal nitrates, the nitrilotriacetate ion as $H_3L$ was titrated alone and in the presence of calcium nitrate in $KNO_3$ and $(CH_3)_4NNO_3$ media at $I$ values of 0.050, 0.300, 1.00 and 2.50 $M$. The weighted equilibrium constants were then computed using both KONST [14] and SUPERQUAD [15] computer programs. The differences between the constants computed using both programs are negligible (mainly owing to differences in the weighting procedures) and within the uncertainties of the constants. Each equilibrium constant is computed from three or more different solutions and hence three or more different titration curves in ml–mV.

## 3. Extrapolation model

The extrapolation of equilibrium constants to zero ionic strength and the ionic strength correction of equilibrium constants in $KNO_3$ and $(CH_3)_4NNO_3$ were carried out using the TEC approach [1] (Eq. (3)) for equilibrium (1), where ${}^*\beta_{n,p,m}$ and ${}^*\beta°_{n,p,m}$ are the

$$mM + nL + pH_2O \rightleftharpoons M_mL_n(OH)_p + pH^+ \quad (1)$$

$${}^*\beta_{n,p,m} = \frac{[M_mL_n(OH)_p][H^+]^p}{[M]^m[L]^n} \quad (2)$$

$$\log {}^*\beta_{n,p,m} - p \log a_{H_2O} = \log {}^*\beta°_{n,p,m} - \frac{\Delta z^2 A\sqrt{I}}{1 + B\alpha\sqrt{I}} + \Delta CI + \Delta DI^2 + \cdots \quad (3)$$

equilibrium constant and the thermodynamic equilibrium constant, respectively, $a_{H_2O}$ is the activity of water, $\Delta z^2$ ($\Delta z^2 = mz_M^2 + nz_L^2 - z^2_{M_mL_n(OH)_p} - p$) is the net charge, $A$ and $B$ are the Debye–Hückel (D.H.) constants and the quantities $\log {}^*\beta°_{n,p,m}$, $\alpha$, $\Delta C$ and/or optionally $\Delta D$ are adjustable parameters and defined elsewhere [1].

## 4. Results and discussion

### 4.1. Equilibrium constants data at different ionic strengths

The weighted mean equilibrium constants of glycinate ion with hydrogen, copper and nickel and nitrilotriacetate ion with hydrogen and calcium at different ionic strengths in $KNO_3$

and $(CH_3)_4NNO_3$ media at 25.0 °C are collected in Tables 1 and 2, the $pK_w$ are collected in Table 3 and the literature values for the same conditions are given in the footnotes. The individual constants are those computed using SUPERQUAD program. The stability constants of copper and nickel glycine complexes or calcium NTA complexes determined in $KNO_3$ medium and given in Tables 1 and 2 are computed as usual without allowing for the potassium complex with the mentioned ligands.

For glycine (Table 1) it is, however, very difficult to discuss the reliability of the literature data obtained in Ref. [16] with $H^+$. Indeed, the extrapolated data at $I=0$ given in that paper with $\log {}^*\beta^\circ_{1,0,1} = 9.85$ and $\log {}^*\beta^\circ_{1,0,2} = 12.39$ differ strongly from those obtained by different authors [3–5] (all lying within 0.01 log unit) that systematic errors cannot be excluded. The above values are fully beyond the limits of those recommended by the IUPAC [2]: $\log {}^*\beta_{1,0,1} = 9.78 \pm 0.01$ and $\log {}^*\beta_{1,0,2} = 12.14 \pm 0.02$. The other values in the footnotes of Table 1 were given with the classification of the IUPAC critical survey [2]. The three values of $Ni^{2+}$, $\log {}^*\beta_{i,0,1}$ ($i = 1, 2, 3$), at $I = 1(KNO_3)$ lie within the limits given in a publiction [19] based on the measurements of several laboratories for the same system ($\log {}^*\beta_{1,0,1}$: 5.64–5.68; $\log {}^*\beta_{2,0,1}$: 10.24–10.4 and $\log {}^*\beta_{3,0,1} = 13.9$ at $I = 1$(NaCl)). By comparing our own values obtained in both inert salts at the same ionic strength, it was found that, for $I = 0.05$ and 0.3, the same values for all constants with $Cu^{2+}$ and $Ni^{2+}$ are obtained within $\pm 0.04$ log unit. For the equilibrium constant values of nitrilotriacetate ion with hydrogen or calcium, no literature data at the experimentally measured ionic strength in $KNO_3$ or $(CH_3)_4NNO_3$ media were found for comparison. However, interpolated values at $I = 0.1$ and 0.5 using TEC are compared with

| | | | 2, 0, 1 | 15.82(2) (0.07) | | | | |

The values in parentheses are the standard deviations and those beneath them are the confidence intervals at 95% confidence level.

[a] $mM + nL + pH_2O \rightleftharpoons M_mL_n(OH)_p + pH$; L = glycinate.

[b] $\log {}^*\beta_{1,0,1} = 9.721(6)$; $\log {}^*\beta_{1,0,2} = 12.023(8)$ [16].

[c] $\log {}^*\beta_{1,0,1} = 8.38$[D] [17].

[d] $\log {}^*\beta_{2,0,1} = 10.55$[T]; $\log {}^*\beta_{3,0,1} = 14.06$[T] [18].

[e] $\log {}^*\beta_{1,0,1} = 5.33$[D] [17].

The reviewer classification [2] are: [D] = doubtful and [T] = tentative.

the literature data in the next section. For the ionic product of water (Table 3), it is important to find literature values in $(CH_3)_4NNO_3$ or $KNO_3$ ($I \geqslant 0.2$) to be compared with ours. This is also needed to detect any eventual systematic errors due to our glass electrode or the Nernst slope. In dilute solutions ($I \leqslant 0.1$), the activity coefficients of the uni-univalent electrolytes may be considered practically independent of the electrolyte type dissolved. Therefore, the corresponding values for the equilibrium constants should be the same and independent of the inert salt used as far as the ionic strength is the same. Thus the $pK_w$ value obtained with each alkali halide salt at $I = 0.05$ [20] should be identical to those in our two inert salt solutions. The value in $(CH_3)_4NNO_3$ is within the limits of error and that in $KNO_3$ is a little bit low.

Some information about the stability of the potassium complexes with the two ligands can be obtained by comparing the values of $\log {}^*\beta_{1,0,m}$ ($M = H^+$) in presence of the two inert salts (glycine: $m = 1$, 9.589(7); $m = 2$, 11.92(4) in $KNO_3$ and 9.594(1) and 11.958(10) in $(CH_3)_4NNO_3$, respectively; nitrilotriacetic acid: $m = 1$, 9.726(20); $m = 2$, 12.32(6) in $KNO_3$ and 9.867(20) and 12.527(10) in $(CH_3)_4NNO_3$, respectively). Already at $I = 0.050$, for which the medium effect is negligible, low values are found in presence of $K^+$. This may be explained by the formation of $K^+$

Table 2
Experimental stability constants of nitrilotriacetate ion with $H^+$ and $Ca^{2+}$ at different ionic strengths in $KNO_3$ and $(CH_3)_4NNO_3$ media and 25.0 °C

The values in parenthesis are the standard deviations and those beneath them are the confidence intervals at 95% confidence level.
[a] $mM + nL + pH_2O \rightleftharpoons M_mL_n(OH)_p + pH$; L = nitrilotriacetate.

complexes with the ligand species according to Eq. (1). This effect is particularly evident for nitrilotriacetic acid forming, in its deprotonated form, complexes with stability constants that are at least five order of magnitude larger with respect to those of glycine ($\log {}^*\beta_{1,0,1}$ for glycinate [2]: $Ca^{2+} \sim 1.4$ and $Cu^{2+} \sim 8.1$ and nitrilotriacetate [6]: $Ca^{2+} \sim 6.5$ and $Cu^{2+} \sim 13$). On the contrary, in the case of glycine in the two ionic media studied the change of $\log {}^*\beta_{1,0,1}$ is within the estimated errors of the values. For $\log {}^*\beta_{1,0,2}$ the change is larger but always within the estimated errors of the constants. The possible existence of $KHL^-$ may be excluded after examining the data of $Ni^{2+}$ and $Cu^{2+}$ obtained in the two inert salt solutions at $I = 0.050$ that are practically identical. If $KHL^-$ was present in the solution, lower values of ${}^*\beta_{1,0,1}$ for the complexes in $0.050(KNO_3)$ would be expected.

Table 3
The negative logarithm of the ion-product of water, $pK_w$, at 25.0 °C in $KNO_3$ and $(CH_3)_4NNO_3$

| $KNO_3$ | | $(CH_3)_4NNO_3$ | |
|---|---|---|---|
| $I$ | $pK_w$ | $I$ | $pK_w$ |
| 0.050 | 13.808(8) [a] (0.006) | 0.050 | 13.823(5) [a] (0.005) |
| 0.300 | 13.733(2) (0.002) | 0.300 | 13.76(1) (0.008) |
| 1.00 | 13.762(2) (0.003) | 1.00 | 13.93(1) (0.01) |
| 2.50 | 13.953(2) (0.004) | 2.50 | 14.451(8) (0.009) |

[a] At $I \leq 0.1$, the activity coefficients are independent from the inert salt used. Using the data of Harned and Mannweiler [20], for $I = 0.05$: $\log(m_H \cdot m_{OH}) = -13.8285$ which corresponds to $-13.8288$ in the molarity scale.

The use of this large concentration of $K^+$ in detecting its complexes is due to the fact that monovalent alkali ions form weaker complexes with respect to other metal ions of larger charge, i.e. the divalent alkaline earth or 3d metal ions. This is also the reason for using salts of the alkali metal ions as inert salts in ionic equilibrium studies in order to minimize the effect of the components of the inert salts on the equilibria investigated. In case of nitrilotriacetate ion, the stability constants of the potassium complexes at $I = 0.050\ M$ are obtained from the corresponding $^*\beta_{1,0,m}$ with the assumption [21] that the decrease of their values are only due to $K^+$ complex formation giving for $\log([KL^{2-}]/([K^+][L^{3-}])) = 0.83(8)$ and $\log([KHL^-]/([K^+][HL^{2-}])) = 0.47(20)$, with the errors in parentheses calculated at 90% confidence. The percentage of $KHL^-$, calculated using the latter constant, is 12% in 0.050 $M$ $KNO_3$ solution but already 45% in 0.30 $M$ ($KNO_3$) solution. For this reason the constant $^*\beta_{1.0,1}$ with $Ca^{2+}$ (Table 2) at $I = 0.304(KNO_3)$ is only $10^{6.007}$ with respect to $10^{6.245}$ at $I = 0.301((CH_3)_4NNO_3)$.

At $I > 0.1$, the use of different inert salts results in different activity coefficient values specific for each salt. Thus a quantitative determination of a stability constant of $K^+$ complex cnanot be obtained from the results in Tables 1 and 2. The use of a $K^+$ electrode or the solubility measurements with a $K^+$ salt at high ionic strength can give more exact information on this important problem.

A discussion about the reasons of variation of $^*\beta_{n,p,m}$ values with the ionic strength and the inert salt is not a quite simple problem because of the different types of possible interactions among all species present in the given solution. The first problem that needs to be resolved is an explanation of the values of the activity coefficients $\gamma_i$ of single inert salts at different $I$ values. This should also explain the reasons for the different $\gamma_i$ values obtained by changing the inert salt. Indeed the fit of $\gamma_i$ values at different $I$ with the calculated values using the preferred D.H. expression is attained by adjusting some constant parameters in the selected expression. An interpretation of the parameters obtained stand out. The D.H. expressions take into consideration only the electrostatic cation anion interaction without inclusion of other resulting species. Without this preliminary step, each intuitive interpretation of the variation of $^*\beta_{n,p,m}$ with $I$ can only be considered as speculation. On the basis of the known studies in this direction it is not certain that the interpretation of the activity coefficients of pure inert salts at different $I$ values can be considered a fully resolved puzzle.

### 4.2. Extrapolation to zero ionic strength and interpolation to a given I value

The extrapolation of equilibrium constants to zero ionic strength and the ionic strength correction of equilibrium constants in $KNO_3$ and $(CH_3)_4NNO_3$ were carried out using a TEC approach (Eq. (3)) for $\Delta z^2 \neq 0$ and $\Delta z^2 = 0$ [1] as well. The thermodynamic equilibrium constants ($\log {}^*\beta^\circ_{n,p,m}$) computed together with the parameters of Eq. (3) are collected in Table 4.

A comparison of our data with those recommended elsewhere–IUPAC critical survey [2,6] or 'critical' stability constants of Martell and

Values in parentheses are the least-squares unbiased estimates (estimated standard error of the parameters) and the values in parentheses beneath them are the 68.3% confidence or the estimate of $1\sigma$.
SSR = Weighted sum of squared residuals.
$\sigma_{est}$ = Estimated standard deviation of equilibrium constant using the TEC equation.
P = Computed probability based on SSR and the degrees of freedom.
[a] For correction see text.

Smith [22] for given $I$ vlaues–is only possible if the inert salt used is also given. The known experimental data show different ionic strength dependence of the involved constant with the inert salts. Thus the use of the same $^*\beta_{1,0,1}$ value for a constant at the same ionic strength [8] for salts of the same cation (or alkali metal cation) as claimed by Martell and Smith [22] as well as for all salts as assumed by Kiss et al. [2] cannot be accepted. For this reason, their recommended values have scarce importance and are not further considered. On the basis of the literature data given in the IUPAC critical survey, after using statistical estimations of their precision (Table 5a), it was possible to obtain the required quantities for the extraolation and interpolation in other inert salts (Table 5b). The corresponding results for the formation of HL in case of glycine are reproduced in Fig. 1. The values of $\log {}^*\beta^\circ_{1,0,1}$ for the same $I$ value in different inert salts given in the figure show a large variation and are not equal. This is partly due to systematic errors in the different values. In general, the quantity of information given by the authors in the experimental part of the published papers is not complete enough to allow a clear identification of the type of calibration used and the precautions taken to avoid liquid junction potentials errors of some 0.01 pH units. In this context, one has to realize that the more accurate known value for $\log {}^*\beta_{1,01}$ of the system under consideration is 9.778 and values in the limit of $\pm 0.03$ can be considered acceptable in consideration of the large errors of extrapolation and large change of $\log {}^*\beta_{1,0,1}$ caused by small variation of $I$ at $I < 0.1$. By comparing all our values obtained with the accepted ones, it appears that at the lowest $I$ in $KNO_3$ they are lower by 0.02 to 0.03 log unit for the case of glycine ($\log {}^*\beta^\circ_{1,0,1} = 9.718$) and the ionic product of water ($\log {}^*\beta^\circ_{1,0,1} = 13.968$). Increasing our values by 0.025 log unit results (Tables 4 and 6) in an excellent agreement among all data. This can be explained by a small systematic error owing to the strict use of the Nernst value $(RT/F)\ln 10$ that is 59.159 mV for every one pH unit. As shown in Table 6, the agreement of the literature experimental mean values treated statistically and our results is then satisfactory for both glycine and NTA equilibrium systems. Other thermodynamic stability constant values are found in the literature. For glycine [7]: $\log {}^*\beta^\circ_{1,0,1} = 9.75$ and $\log {}^*\beta^\circ_{1,0,2} = 12.08$ extrapolated from a medium in $(C_2H_5)_4NI$. They are in good agreement with our values in Table 6. For NTA [8], the calculated thermodynamic constants are: $\log {}^*\beta_{1,0,1} = 10.39$, $\log {}^*\beta_{1,0,2} = 13.33$ and $\log {}^*\beta_{1,0,3} = 15.31$ extrapolated from media in $(C_2H_5)_4N^+$ or $(C_3H_7)_4N^+$ with the anions of bromide and iodide. They show slight deviation from our values extrapolated in $(CH_3)_4NNO_3$ medium and given in Table 6.

### 4.3. Estimation of $\Delta C$ parameters

The parameter $\Delta C$ of Eq. (3) may be estimated from other individual $C$ parameters. This treatment help estimating equilibrium constants in ionic media other than those measured presuming that the thermodynamic equilibrium constant is known. The combined $\Delta C$ parameters for the equilibrium systems in this work are given in Table 4.

The combined $\Delta C$ parameter of the $pK_w$ in $KNO_3$ and $(CH_3)_4NNO_3$ media may be represented by the following relations,

$$\Delta C = C_{KOH} + C_{HNO_3} \tag{4}$$

$$\Delta C = C_{(CH_3)_4NOH} + C_{HNO_3} \tag{5}$$

From Eq. (5), the individual parameter $C_{(CH_3)_4NOH}$ amounts to 0.35(2) where $C_{HNO_3}$ is computed separately from mean activity coefficient data [23,24] at different ionic strengths and 25.0 °C using the PDHE computer program and the polynomial Debye–Hückel equation (6) for the molar mean activity coefficient $\gamma_\pm$.

$$\log \gamma_\pm = \frac{-Az_+z_-\sqrt{I}}{1 + B\alpha\sqrt{I}} + CI + DI^2 + \cdots \tag{6}$$

The computed parameters of Eq. (6) for 12 common electrolytes are given in Table 7 and are valid in the range $2.50 \geqslant I \geqslant 0$ in molar scale. The activity coefficients required are obtained from those in the molal scale, which are identical with the values in molar scale but setting the concentration $c = (1000 \cdot d \cdot m)/(1000 + M_w \cdot m)$, where $d$ is the density of the involved solution. To avoid confusion in Eq. (6), the molar ionic strength $I_c$ is used. It is noticed that two different parameters $C$ and $D$ are obtained. By examining their values, only the first one is important; the second being 10 times smaller except for the cases of NaCl, KCl and $HClO_4$. For the equilibria investigated, the values of $\Delta D$ in Table 4 are negligible. The standard deviations obtained for $C$ and $D$ de-

pend on their magnitude but in general are much lower with respect to those obtained using $C$ and Eqs. (4), (5) and (7)–(13).

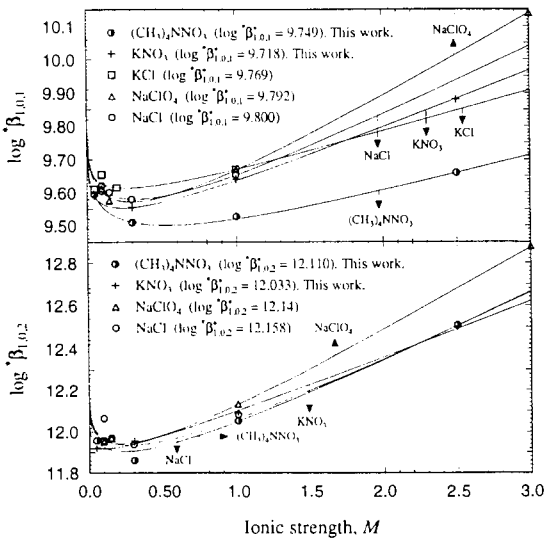

Fig. 1. Variation of stability constants of glycine with ionic strength $I$ and ionic media at 25 °C. Extrapolated data obtained from this work are prompted in the legend of the figures otherwise the data are obtained from the literature and statistically treated to obtain mean values.

The stability constants of copper glycine complexes are relatively high. Their ionic strength dependent parameters $\Delta C$ may be used to retrieve some individual $C$ parameters as an example. For the first and second stability constant of copper glycine complexes, the ionic strength dependent parameters $\Delta C_1$ and $\Delta C_2$ may be represented by the following relations,

$$\Delta C_1 = C_{Cu(NO_3)_2} + C_{NL} - C_{CuLNO_3} \quad (7)$$

$$\Delta C_2 = C_{Cu(NO_3)_2} + 2C_{NL} - C_{CuL_2} \quad (8)$$

where $N = K^+$ or $(CH_3)_4N^+$ and L is the fully deprotonated form of glycine. The difference between $\Delta C_1[(CH_3)_4NNO_3]$ and $\Delta C_1(KNO_3)$, in which $\Delta C_1$ is expressed by Eq. (7), is found to be 0.13(3) l mol$^{-1}$ and is expected to be totally due to the difference between $C_{(CH_3)_4NL}$ and $C_{KL}$. This is ascertained by the difference between $\Delta C_2[(CH_3)_4NNO_3]$ and $\Delta C_2(KNO_3)$ for the same equilibrium system in which $\Delta C_2$ is expressed by Eq. (8). This difference is again believed to be totally attributed to $2C_{(CH_3)_4NL} - 2C_{KL}$ and found to be 0.267 l mol$^{-1}$. Thus $C_{(CH_3)_4NL} - C_{KL}$ is again 0.13(4) l mol$^{-1}$.

The values in parentheses are the estimates of $1\sigma$. All values of TEC are derived from four points ($N = 4$) and have one degree of freedom.
The extrapolated values to $I = 0$ under 'IUPAC publication–$KNO_3$' are calculated from different ionic media.
[a] For correction see text.

The $\Delta C$ constants of nickel glycine may be represented by the following relations,

$$\Delta C_1 = C_{Ni(NO_3)_2} + C_{\mathcal{N}L} - C_{NiLNO_3} \quad (9)$$

$$\Delta C_2 = C_{Ni(NO_3)_2} + 2C_{\mathcal{N}L} - C_{NiL_2} \quad (10)$$

$$\Delta C_3 = C_{Ni(NO_3)_2} + 3C_{\mathcal{N}L} - C_{NiL_3N} \quad (11)$$

The same result was observed for the first stability constant of the relatively strong nickel glycine complex. A difference between $\Delta C_1((CH_3)_4NNO_3)$ and $\Delta C_1(KNO_3)$, in which $\Delta C_1$ is expressed by Eq. (9), is found to be $0.13(4)\,l\,mol^{-1}$. The difference between $\Delta C_2((CH_3)_4NNO_3)$ and $\Delta C_2(KNO_3)$, in which $\Delta C_2$ is represented by Eq. (10), shows slight deviation from the value of 0.13. The actual value is found to be $0.16(4)\,l\,mol^{-1}$. However, this difference is within the estimated errors.

The $\Delta C$ parameters for the system of glycine may be represented by the following relations,

$$\Delta C_1 = C_{HNO_3} + C_{\mathcal{N}L} - C_{\mathcal{N}NO_3} \quad (12)$$

$$\Delta C_2 = 2C_{HNO_3} + C_{\mathcal{N}L} - C_{H_2LNO_3} \quad (13)$$

The difference between $\Delta C_2((CH_3)_4NNO_3)$ and $\Delta C_2(KNO_3)$ in which $\Delta C_2$ is represented by

Table 7
PDHE parameters for some electrolytes at 25.0 °C applicable until $I = 2.50$

| Electrolyte | $a \times 10^8$ | $C$ | $D$ |
|---|---|---|---|
| HCl | 4.596(7) | 0.1063(3) | 0.00772(8) |
| NaCl | 4.42(2) | 0.0197(6) | 0.0060(2) |
| KCl | 3.951(2) | −0.0018(1) | 0.00376(3) |
| $HNO_3$ | 4.767(5) | 0.0633(1) | |
| $NaNO_3$ | 3.84(2) | −0.0405(8) | |
| $KNO_3$ | 3.04(1) | −0.1092(8) | 0.0052(2) |
| $HClO_4$ | 5.31(2) | 0.0862(5) | 0.0212(2) |
| $NaClO_4$ | 4.48(2) | 0.0028(7) | 0.0032(2) |
| NaOH | 3.80(2) | 0.0541(7) | 0.0018(2) |
| KOH | 3.50(1) | 0.0998(6) | 0.0034(2) |
| $Cu(NO_3)_2$ | 4.886(1) | 0.0317(2) | 0.00392(6) |
| $Ni(NO_3)_2$ | 4.855(1) | 0.0587(2) | 0.00265(7) |

Values in parentheses are the least-squares unbiased estimates or estimated standard error of the parameters.
$C_{Cu(NO_3)_2}$ and $C_{Ni(NO_3)_2}$ should be multiplied by three to be compatible with the $\epsilon$ vlaues calculated using the SIT equation.

Eq. (13), should also produce the value of 0.13 l mol$^{-1}$, however, it is found to be only 0.08(4) that is still within the large error limits. The difference between $\Delta C_1((CH_3)_4NNO_3)$ and $\Delta C_1(KNO_3)$, in which $\Delta C_1$ is represented by Eq. (12), is given as follows,

$$C_{(CH_3)_4NL} - C_{KL} - C_{(CH_3)_4NNO_3} + C_{KNO_3} = -0.055(11) \quad (14)$$

Substituting the value of 0.13 in relation (14), the value of $C_{(CH_3)_4NNO_3}$ is obtained. This value is found to be 0.076(31). It is then substituted in Eq. (12), in which $N = (CH_3)_4N^+$, to obtain the value of $C_{(CH_3)_4NL}$. This value is found to be 0.14(3). Consequently, the value of $C_{KL}$ is found to be 0.01(4). Similarly, the value of $C_{CuLNO_3}$ can be readily obtained from Eq. (7) for which $N = (CH_3)_4N^+$ or $K^+$. A value of −0.11(4) is then found. The other individual $C$ parameters for the $Ni^{2+}$ system may be obtained in a similar way. The estimation of $\Delta C$ parameters are necessary to estimate or predict equilibrium constants in other ionic media.

### 4.4. Prediction and estimation of equilibrium constants

The equilibrium constants for a system in a given inert salt at ionic strength $I$ ($\leqslant 3$) can be calculated using Eq. (3) if the thermodynamic constant $^*\beta^\circ_{n,p,m}$ and the parameters $\alpha$ and $\Delta C$ are known. Sometimes $\Delta C$ can be estimated from known values of $C$ for the same or similar electrolytes. In the last case, the knowledge of one suitable $^*\beta_{n,p,m}$ in the range $0.2 < I < 2.5$ is enough to obtain $\alpha$. Otherwise, two values for $^*\beta_{n,p,m}$ are required to obtain the two unknown parameters.

As an example, the $pK_w$ in $NaClO_4$ medium at different $I$ are estimated using the two procedures mentioned above. The $pK^\circ_w = 13.982(9)$ computed from the data in this work measured in $(CH_3)_4NNO_3$ medium and the two literature data of $pK_w$ [25] (13.78(1) at $I = 0.1$ and 13.97(1) at $I = 2$ in $NaClO_4$) are used. In the first procedure, the two TEC equations are solved for $\alpha$ and $\Delta C$. The values found are: $\alpha = 4.14 \times 10^{-8}$ and $\Delta C = 0.241$. The least-squares analysis for the set of literature data given in the ionic strength range of 0.1–3.8 M resulted in the following parameters: $pK^\circ_w = 13.99(2)$, $\alpha = 3.6(6) \times 10^{-8}$, $\Delta C = 0.26(2)$. Thus the calculated parameters from the two data points are within the errors computed by the least-squares analysis. The calculated constants using two data points at $I = 0.10$, 0.50, 1.00, 2.00, 2.99 and 3.80 are: 13.78, 13.73, 13.79, 13.97, 14.18 and 14.35, respectively. They are comparable to the experimental constants at the same ionic strength: 13.78(1), 13.74(1), 13.80(1), 13.97(1), 14.20(1), 14.42(2). The selection of a correct thermodynamic constant $\log {}^*\beta^\circ_{n,p,m}$ is of particular importance. This method can also be used with most of the equations discussed previously [1] although they have not been tested for these procedures; a case that is beyond the scope of this article. The reader is expected to consult Ref. [1] before making the final choice.

In the second procedure, we assume that $\Delta C$ is known along with one equilibrium constant at $I \geqslant 0.5$ and $\log {}^*\beta^\circ_{n,p,m}$. The $\Delta C$ may be calculated from the individual $C$ parameters obtained from Eq. (6) and given in Table 7. For this case, Eqs. (4) or (5) may be used as a guide. For the $pK_w$ system in $NaClO_4$, the estimated $\Delta C = 0.140$ and $\Delta D = 0.023$. The $\alpha$ value may then be calculated using Eq. (15) obtained from Eq. (3) for $p = 0$.

$$\alpha = -\left[\frac{\log {}^*\beta^\circ_{n,p,m} - \log {}^*\beta_{n,p,m} - \Delta z^2 A\sqrt{I} + \Delta CI + \Delta DI^2}{B\sqrt{I}(\log {}^*\beta^\circ_{n,p,m} - \log {}^*\beta_{n,p,m} + \Delta CI + \Delta DI^2)}\right] \quad (15)$$

Thus $\alpha$ is found to be $5.93 \times 10^{-8}$ using the $pK_w$ at $I = 2.0$. The estimated $pK_w$ at $I = 0.10$, 0.50, 1.00, 2.00, 2.99 and 3.80 are: 13.80, 13.75, 13.80, 13.97, 14.20 and 14.43, respectively, to be compared to the experimental values given above. If the $pK_w$ at $I = 0.5$ is used, the calculated $\alpha$ is $5.48 \times 10^{-8}$ and the estimated $pK_w$ at the same ionic strenths are: 13.79, 13.74, 13.78, 13.95, 14.18 and 14.40 to be compared again to the experimental values above. Another possibility for calculating $\alpha$ in this procedure by using the $pK_w$ at $I = 0.10$ and setting both $\Delta C$ and $\Delta D$ to zero in Eq. (15). In this case, $\alpha$ is found to be $5.78 \times 10^{-8}$. It is used beside the other estimated parameters $\Delta C$, $\Delta D$ and $\log {}^*\beta^\circ_{n,p,m}$ in Eq. (3) to estimate the $pK_w$ at the other ionic strengths given earlier.

The choice of the ionic strength value, in which $\alpha$ is calculated, is not arbitrary. This ionic strength is selected in such a way to equal or exceed $I_{crit}$ to a certain limit. In most of the time this is realized in the ionic strength range $1.5 > I \geqslant 0.2$. The range of $I < 0.1$ is avoided because of the large variation of $\alpha$ with the ionic strength and the strong dependence of $C$ on $\alpha$.

When data in the literature are not enough to extract all individual $C$ parameters required for a given system, the first procedure may then be used.

# An optimized on-line preconcentration system for analysis of trace gold in ore samples

P. Di, D.E. Davey *

*School of Chemical Technology, University of South Australia, The Levels, SA 5095, Australia*

Received 12 August 1994; revised 5 December 1994; accepted 27 December 1994

**Abstract**

A flow injection on-line preconcentration technique, combined with graphite furnace atomic absorption spectrometry for the determination of gold in ore samples has been presented. An α-amino pyridine resin (AP) was loaded onto a microcolumn as the preconcentration reagent and a solution of 90% acetone–5% HCl–5% $H_2O$ was used for the gold elution. The Scaled Simplex Method was employed to optimize the flow injection manifold. The selected factors were optimized by the simultaneous consideration of two responses, absorbance and column retention efficiency, with only 12 tests. A detection limit of 0.065 μg Au/l ($3\sigma$) with a relative standard deviation of 4.3%, was achieved. Ore samples containing gold have been analysed successfully using the proposed method.

## 1. Introduction

On-line preconcentration techniques with flow injection analysis (FIA) have significantly increased the sensitivity of flame atomic absorption spectrometry (FAAS) for trace elements [1–4]. The applications of this technique to graphite furnace AAS are few, owing to the necessity of non-continuous flow in the sample introduction stage, which causes difficulties in both the manifold design and the experimental optimization of the FI system. The use of either a fraction collector or an autosampler as the interface between FIA system and GFAAS has been reported [5–9]. Such combinations have disadvantages in being time-consuming, and introduce a high risk of contamination from the equipment and the laboratory environment. In addition, by collecting the total eluate volume and injecting only small part of it into the graphite tube, the effect of the preconcentration is in part lost by the inherent dilution.

Fang and coworkers described a unique FIA manifold for sorbent extraction preconcentration systems using an autosampler arm and capillary as the sample collector and the interface between FIA and GFAAS. A microcolumn with a packing volume of only 15 μl and a very slow elution rate of 0.15 ml/min were used to limit the eluate volume so that the sensitivity was not reduced too much. All the procedures prior to the sample introduction were carried out in an enclosed stream to reduce any contamination risk. The fraction of eluate containing a high concentration of the analyte was introduced into the furnace. Thus, a semi-on-line approach was developed which exhibited all the basic advantages of an on-line procedure [10–13].

Although the combination of the on-line preconcentration technique with the GFAAS is more difficult than that with FAAS or ICP-AES, it is attractive for those systems where matrix influences are significant and where a sensitive determination is required, such as in the analyses of rare or noble metals in mineral samples. As an extension of our previous work for noble metal analysis by on-line preconcen-

*SSDI* 0039-9140(95)01524-8

tration with FAAS [14,15], we have attempted to apply the on-line preconcentration technique to GFAAS detection of trace gold in ore samples. Since the gold content of mineral samples is normally at the parts per million level and gold-containing samples are also expensive, more attention has had to be paid to the column efficiency than previously, to insure that most of the sample treated in the column can be detected. Therefore, a larger column was selected, which has required us to carefully optimize the controlling parameters.

A simplex method was adopted to optimize the FIA section of the manifold. The technique was initially proposed by Spendley [16] and used in analytical chemistry by Long [17]. Since then, some modifications of this method have been presented [18,19] and applications in FIA have also been reported [20–22]. In our experiments, the simplex method has been used to optimise the preconcentration and elution parameters in the FIA manifold, allowing flame AAS to be employed to monitor the changing response. This approach simplifies the operational procedure. The optimized configuration was, then, employed in the GFAAS determination for gold in reference ore samples with acceptable recoveries and precision observed.

## 2. Experimental

### 2.1. AAS determination

A GBC 901 atomic absorption spectrometer fitted with a GBC 900 graphite furnace was used for trace gold analysis, whilst a GBC 905 model flame atomic absorption spectrometer (GBC Scientific Equipment Pty Ltd, Australia) was used in the parameter optimization for the FIA preconcentration stage. Simultaneous background corrections were made using deuterium lamps in both flame AAS and GFAAS. The graphs and data were printed with an Epson RX 80 printer (Epson Corporation, Japan) and the signals from the GFAAS were recorded by a OmniScribe recorder (Houston Instruments, Austin, TX, USA). The GFAAS parameters are listed in Table 1. GBC graphite cups were selected for the GFAAS determination because larger volumes than usual samples were needed (about 50 μl).

### 2.2. On-line preconcentration methodology

The preconcentration FIA-GFAAS technique used in this work employed a single column (Fig. 1) controlled by a Flow Injection Control System (FICS, homemade). Software which allows the time parameters to be set in the computer prior to the analysis was developed to control the operations of both the preconcentration stage and the sample injection into the graphite furnace.

In the sampling stage, pump 2 (P2, Mini-S 860, ISMATEC, Switzerland) started and carried samples through the column (C, homemade). After a selected period of time for sample introduction (60 s in this work), P2 was stopped and pump 1 (P1, multi-speed pump, Gilson, France) ran for 10 s. A 2 M HCl solution was then passed through the column to remove matrix elements (if required). Then, both P1 and P2 were stopped and a 5 s rest period was set to allow manual switching of the four-way rotary valve (V, Rheodyne Incorporated, U.S.A.) from the sampling to the eluting position. P1 was then started again. The analyte was washed out of the column and collected in a PTFE loop (L, 2.0 m in length, 0.5 mm i.d.). The initial fraction of the eluate went to waste, and P1 was stopped when the concentrated fraction of the eluate flowed to the end of the PTFE loop. This time interval obviously needed to be carefully optimised. A manual step was used here to insert the PTFE

| 7 | 20 | Go | Stop | Elution | Remaining eluate to waste |

[a] GC: Graphite cup.

loop into the graphite cup, and then P1 was restarted for 1 s to inject the sample (about 50 μl) into the cup. After the loop was withdrawn for the graphite cup, the heating program could be started. The programmed operation steps are shown in Table 2.

An organic solvent resistant tube (2.06 mm i.d., A.I. Scientific Pty Ltd, Australia) was used for the acetone-based eluent, and Tygon pump tubes (2.06 mm i.d.) for the sample solutions and matrix removal. The sample loading flow rate was 12.6 ml/min, and the elution flow rate, 6.0 ml/min. A microcolumn with the dimensions 3.0 (l) × 50 (i.d.) mm was used in the preconcentration stage. The manifold without the effluent collection loop (L) was used to optimize the preconcentration configuration and the elution step. The Scaled Simplex Method and flame AAS detection were selected for manifold optimization.

### 2.3. Reagents

A 1.00 mg/ml gold solution (BDH Chemicals Ltd, Poole, UK) was used as the stock solution for gold standards. An α-amino pyridine (AP) resin (60–80 mesh, Institute of Polymer Chemistry, Nankai University, China) was employed as the preconcentration reagent. The eluent was a solution of 90% acetone–5% HCl–5% $H_2O$ [23]. The other chemicals used in this work were all analytical-grade.

### 2.4. Ore sample digestion

A 2 g ore sample was first heated in a porcelain crucible at 600 °C in a Muffle Furnace for 3 h. After cooling for 0.5 h, it was transferred into a porcelain evaporating dish, and then 20 ml aqua regia (1:1) was added to the sample. The sample was dissolved on a hot plate in a fume hood and boiled for 1 h with regularly stirring. The dissolved sample was then filtered, and the residues were washed about five times with 0.1 M HCl solution. The sample was finally diluted to the mark in a 100 ml volumetric flask.

### 2.5. Application of scaled simplex method

Although the Modified Simplex Method (MSM) [18] had been successfully applied to our previous work [14], in this present study, the Scaled Simplex Method (SSM) proposed by Morgan and Deming [19] was also used. It is particularly suited where the factors or responses have different units or different regions of interest. The critical idea is one of scaling all factors and responses in such a way that their domains extend from 0 to 1 (or from 0% to 100%). This is accomplished by the equations:

$$X_s = \frac{X_s - X_{al}}{X_{ah} - X_{al}} \quad (1)$$

or

$$R_s = \frac{R_a - R_{al}}{R_{ah} - R_{al}} \quad (2)$$

where $X_s$ or $R_s$, is the scaled value of factor or response; $X_a$ or $R_a$, is the real value used, or obtained, in the experiment; $X_{al}$ or $R_{al}$, is the lowest value; and $X_{ah}$ or $R_{ah}$, is the highest value in the region of interest.

There were two responses used in this study: absorbance ($R1$) and the retention efficiency of the analyte on the column ($R2$). The weights of

these two responses were taken into account in the optimization. The response function used was

$$R_{\text{total}} = R1_s \times 0.7 + R2_s \times 0.3 \quad (3)$$

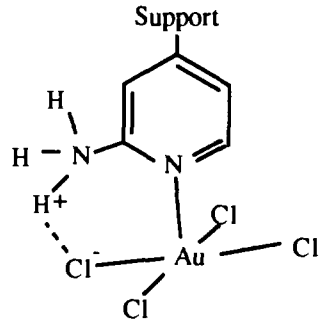
where $R_{\text{total}}$ is the toal desired response, and $R1_s$ and $R2_s$ are the scaled absorbance and the scaled retention efficiency, respectively. Since the absorbance, which reflects sensitivity, was considered more important in this work, the weighting of 70% was given to it, and 30% to the column efficiency.

A computer program which had been developed for the MSM approach described in our recent work [14] was again used here to calculate new factor values by SSM.

## 3. Results and discussion

### 3.1. Preconcentration and elution

The α-amino pyridine (AP) resin is formed by bonding α-amino pyridine to a cross-linked poly-phenylethene support. Li investigated AP resin gold adsorption by infrared spectroscopy and proposed that the mechanism could involve a combination of coordination through the pyridine N lone pair, and ion pair formation via the protonated amine group, $-NH_3^+$, to the complex anion $AuCl_4^-$. The structure could be thus represented as shown.



The planar structure of $AuCl_4^-$ provides sufficient space for the coordinating N, whilst the association of $H^+$ and $Cl^-$ is favoured by the ring arrangement shown, reflecting the strong Au affinity observed for the resin. The adsorptive capacity for gold was found to be 500–600 mg Au/g resin [23].

A fast initial reaction between AP resin and gold was observed by us during on-line preconcentration, and the retention efficiency of the microcolumn was still about 90% even with a fast sampling flow rate of 12 ml/min. The effect of sample acidity on the on-line preconcentration stage was found negligible, there being no change in response with 0.1–4.0 M HCl as sample media. A 0.1 M HCl solution was selected in further experiments.

AP resin had previously been used by us to preconcentrate Pd, Pt and Ir using on-line techniques [15]. A 0.5 M HCl–0.5 M $HClO_4$–0.5 M $Mg(ClO_4)_2$ solution was found suitable on that occasion as a group eluent for Pd, Pt and Ir. This solution could, however, not be used for elution here due to the strong combination of gold with the resin. Even thiourea solution, which had also been successfully used previously as a gold eluent [14], did not perform satisfactorily here. An organic-mixed solution, 90% acetone–5% HCl–5% $H_2O$, studied by some authors [24,25], was then selected as the gold eluent and brought success. Gold, with the concentration range 0.1 ppb–1 ppm, could be fully eluted and the column could be regenerated using this solution. The column also possessed an excellent lifetime (over a hundred reuses). The acetone–HCl eluent was thus selected for all further experiments in this study.

### 3.2. Optimization of the preconcentration manifold

In the optimization study, three factors, column length, sample flow rate and elution flow rate, were chosen, while two responses, absorbance and column retention efficiency, were taken into account. The selection was based on our previous experience, and on precedents in the literature [14].

To determine the column retention efficiency, the loss of gold in the sampling stage was measured. The retention efficiency ($R2$) was than calculated by Eq. (4).

$$R2 = \frac{C_t - C_d}{C_t} \times 100\% \quad (4)$$

where $C_t$ is the total amount of gold carried through the column, and $C_d$ is the gold lost in the sampling stage. The factors, the column length (F1), the sample flow rate (F2), and the elution flow rate (F3), were selected, as stated above. The actual boundary values of the factors ($X_{al}$, $X_{ah}$) and the response values ($R_{al}$, $R_{ah}$) are shown in Table 3. The basic parameters of the simplex optimization are shown in Table 4.

Table 3
Actual boundary values for each factor and response

| Factor | Low value ($X_{al}$) | High value ($X_{ah}$) | Response | Low value ($R_{al}$) | High value ($R_{ah}$) |
|---|---|---|---|---|---|
| F1 (mm) | 5 | 80 | R1 | 0.020 | 0.200 |
| F2 (ml/min) | 2.5 | 13.5 | R2 (%) | 50 | 100 |
| F3 (ml/min) | 1.4 | 6.0 | | | |

Table 4
Parameters of the scaled simplex method

| Factor | Lower limit | | Upper limit | | Step size[b] | | Initial value | | Convergence coefficient |
|---|---|---|---|---|---|---|---|---|---|
| | Actual | %[a] | Actual | %[a] | Actual | %[a] | Actual | %[a] | |
| F1 (mm) | 5.0 | 0 | 80.0 | 100 | 35 (20) | 40 (20) | 27.5 | 30.0 | |
| F2 (ml/min) | 2.5 | 0 | 13.5 | 100 | 6.9 (3.6) | 40 (10) | 5.5 | 27.3 | 0.1 |
| F3 (ml/min) | 1.4 | 0 | 6.0 | 100 | 3.2 (2.1) | 40 (15) | 4.2 | 60.8 | |

[a] % values are scaled by Eqs. (1) and (2).
[b] The values in the parentheses are the small step sizes used in the initial test.

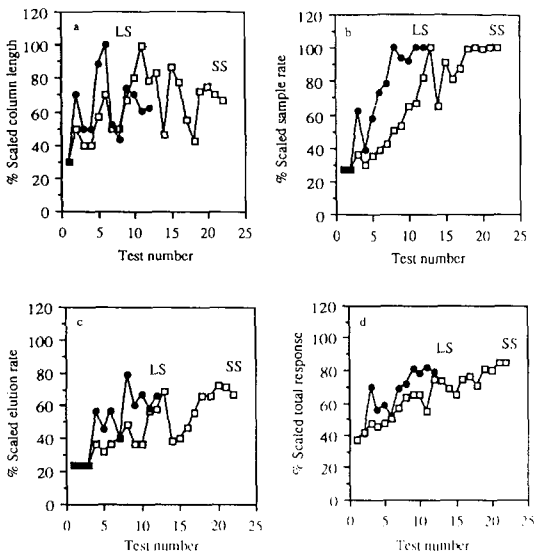


Fig. 2. SSM progression. (a–c) Progress of the factors, (d) total scaled response. LS, large step size; SS, small step size.

As discussed by Yarbro [26] and observed in our earlier work [14] the step size chosen in the simplex method is crucial to success in gaining optimization. In this present study, it was found that rather than starting with an initial simplex using small step sizes, which may prolong the time to reach an optimum, a large initial simplex covering more factor space led quickly to the optimum area. In Fig. 2, the graphs (a–c) show the differences in the optimization of the factor levels by using different step sizes. Although the initial tests were started at the same factor levels, the progress of optimization was slow with small step sizes, and a large step size was found preferable and quickly led to optimization (Fig. 2d). Only 12 tests were needed using this approach. The optimal areas are listed in Table 5. An observed range of 85–94% for the retention efficiency was achieved, while the absorbance was maintained satisfactorily.

### 3.3. Sample injection

The interface between a FIA system and graphite furnace AAS is the critical area in linking these two techniques together, owing to the non-flow-through nature of GFAAS. Initial efforts were made using a vessel to collect sample from the FI stream, followed by normal GFAAS procedures [1,9]. However, an effective loss of sample, and decrease in sensitivity, was observed with a large sample collection and, in fact, only a small portion reached the furnace. A better approach was developed using an autosampler arm as an interface. Only the concentrated portion in the stream was injected into the furnace, and subsequently sensitivity was increased and contamination risk reduced [10–13].

In this study, a PTFE tube was employed to collect and directly introduce eluates into the furnace. The PTFE tube was manually inserted, and all the solutions were kept in an enclosed stream prior to the injection, which both avoided any sample loss or contamina-

Table 5
Optimal factor areas obtained by the scaled simplex method

| | Column length | Sample flow rate | Elution flow rate |
|---|---|---|---|
| Scaled value | 49-73% | 78-100% | 59-78% |
| Actual value | 42-60 (mm) | 11.1-13.5 (ml/min) | 4.1-5.0 (ml/min) |

tion, and kept the manifold and the program simple. We intend to fully automate this step in future work.

It was most important to control the sample injection time into the furnace to insure that sensitivity and precision were not lost. A computer was used to operate the eluent pump (P1) to start and stop the sample injection. The elution curves obtained by determining the eluate during 1 s intervals are given in Fig. 3. It can be seen that each curve has a plateau in the range from 5 s (0.5 ppb) to 10 s (5.0 ppb), which was brought about by the use of a longer column. Although the gold in the plateau region does not in fact contribute to an improved sensitivity, it improves the reproducibility of the determination, and compensates for any variation in the position of the most concentrated fraction of the gold in the sample stream, in turn caused by any variation of flow rate (e.g. as pump tubing wears out). As shown in Fig. 3, the signal became stable after 8 sec elution, i.e. a period of 8 s were needed to elute the gold from the column, and remove the initial fraction of the effluent. Pump 1 was then stopped for 5 s, the PTFE loop inserted into the furnace, and the pump started again for 1 s to inject the sample (see steps 4-6, Table 2).

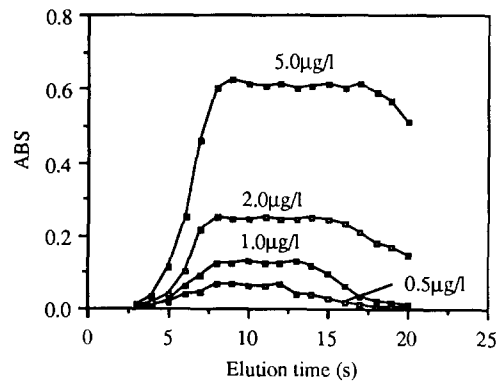

Fig. 3. The elution curves detected by the graphite furnace AAS method. The first sample was injected after 3 sec elution. All the samples were injected for 1 sec.

### 3.4. Interference study

As mentioned earlier, the noble metals, Pd, Pt and Ir, could be eliminated as potential interferents using a 0.5 M HCl-0.5 M $HClO_4$-0.5 M $Mg(ClO_4)_2$ solution [15]. Furthermore, salt matrices such as, $KNO_3$ (4000), NaCl (29 000), $CaCl_2$ (5000), $MgSO_4$ (6000), $AlCl_3$ (800), $Fe(NO_3)_3$ (100), $CrCl_3$ (480), $NiSO_4$ (280), $Pb(NO_3)_2$ (200), and $Cu(NO_3)_2$ (400 mg/l), were studied and found not to markedly affect gold preconcentration or determination by the proposed method. The recoveries of gold in the presence of these elements were above 95%, which was considered satisfactory. All the above matrix elements could be eliminated using 2 M HCl solution prior to the gold elution.

### 3.5. Calibration standard, detection limit and precision

A standard solution series, 0, 0.5, 1.0, 2.0, and 5.0 μg/l, in gold was determined. Each was passed through the column for 60 s and eluted for 8 s, using the graphite furnace AAS method outlined previously. A linear calibration with a good correlation coefficient was obtained, where: absorbance = 0.00206 ($\pm$0.00308) + 0.119 ($\pm$0.00125) Au concentration (μg/l); $R^2 = 0.998$.

A solution containing 0.5 μg/l of gold was determined for 10 replicates. The detection limit found was 0.065 μg/l ($3\sigma$) and the relative standard deviation (%RSD) was 4.3%. In our view, the key source of imprecision in this system was flow rate variation. Although a solvent-resistant pump tube was used in the elution stream, it was observed to soften with acetone contact, causing some stretching and flow rate change over time.

### 3.6. Sample analysis

A mixed composition standard solution and two certified reference ore samples of gold were

Table 6
Analysis results for a prepared mixed standard and ore samples

| Sample | Reference value | | Observed value | |
|---|---|---|---|---|
| | Concentration of Au (g/t) | Standard deviation | Concentration of Au (g/t) | Standard deviation ($n = 6$) |
| Mixed composition standard[a] | 0.50 | — | 0.49 | ±0.02 |
| OREAS 1C[b] | 0.200 | ±0.022 | 0.189 | ±0.032 |
| 7814490[c] | 0.20 | ±0.01 | 0.203 | ±0.015 |

All concentrations are given in g/t for comparison purposes, although the mixed composition standard was prepared in μg/l.
[a] Prepared using a gold standard solution with 10 matrix elements, as listed in the Interference Study section.
[b] Provided by the Chemistry Centre, Western Australia.
[c] Provided by Shandong Geological Exploration Company, China.

determined under the conditions proposed. The results are shown in Table 6. The values obtained corresponded well with the certified values.

## 4. Conclusion

The non-continuous aspect of graphite furnace AAS causes some difficulties in combination with an on-line preconcentration FIA system. This combination is, however, still very attractive for trace element analysis. First of all, pre-matrix removal is a significant advantage of the on-line preconcentration technique. Matrix problems are often encountered in GFAAS determinations, and are removed in the procedure described. Secondly, effective preconcentration reagents and eluents also lead to increased sensitivity. The AP resin described, when combined with an eluent composed of 90% acetone–5% HCl–5% $H_2O$, has epitomized this ideal. Fast sampling and elution speed are added bonuses. Certified Au ore samples have been analysed using the proposed method, and good agreement between the reference values and determined values has been achieved.

Thirdly, the scaled simplex method (SSM) has provided an excellent tool to optimize the control parameters. Although a complicated on-line preconcentration FIA system was involved, SSM allowed more than one response to be considered simultaneously, and significantly simplified the experimental procedure. Larger step sizes were found preferable to quickly reach the optimum area. Only 12 tests were needed to reach the performance plateau. A longer column (50.0 mm) was found beneficial in providing reproducible sample injection and determination.

Finally, an enclosed environment was provided for the sample by simply using the PTFE capillary of the FIA system as the interface between the FIA and GFAAS. FIA methods provided an obvious way to avoid contamination from the laboratory surrounds, and thus furnish the experimenter with a 'poorman's clean room'.

# Technique for the isolation of secondary phases in processed magnesite

P. Arjunan, A. Kumar *, M. Chaudhuri, G. Banerjee

*Central Glass and Ceramic Research Institute, Jadavpur, Calcutta 700 032, India*

Received 3 June 1994; revised 22 December 1994; accepted 27 December 1994

**Abstract**

The study describes a new wet chemical technique, termed ANM, for the isolation of secondary phases in magnesite processed at a temperature of 1650 °C. The major MgO (periclase) phase in processed magnesite was preferentially extracted as ammonium nitrate magnesium double salt by ammonium nitrate in ethanol medium. The residues containing enriched secondary phases were identified by XRD.

## 1. Introduction

Secondary phases and impurities present in small amounts control the behavior of many ceramic materials. Identification of these secondary phases by X-ray powder diffraction is rather difficult owing to their low concentrations in the as-processed samples. Leipold [1] reported a technique for the detection of grain boundary impurities in polycrystalline ceramics through the use of electron beam microprobe (EBM) techniques to determine the distribution of grain boundary impurities like Si, Al, Ca, etc., which are present in ppm levels. The nature of electron techniques do not permit evaluation of the entire matrix owing to the localized nature of the method.

In refractories, secondary phases give rise to critical liquid-forming phase at lower temperatures that control processing behavior. The magnesia system is significantly affected by the presence of such secondary phases, the determination of which are quite difficult [2]. Alper [3] has suggested the use of dilute hydrochloric acid to dissolve the major MgO phase in magnesite refractories in an attempt to concentrate impurities for further analysis and identification through X-ray studies. Methods to isolate metallic and oxide fractions of magnesium in slags have been reported [4]. This paper describes a new wet chemical method to concentrate secondary phases in magnesite which enables easy identification through subsequent XRD.

The method is dependent on ammonium nitrate which has been used for the estimation of uncombined or free MgO (periclase) in cement and cement clinkers by Bogue and Taylor [5]. In the original method, free MgO was extracted from cement clinker as a double salt of ammonium nitrate in the presence of ethanol–glycerol solvent medium. Later, the Bogue–Taylor technique was modified [6] in which only ethanol was used as a solvent. It was observed that use of ethanol as the solvent enhanced the rate of reaction and the extraction period reduced considerably.

The present paper discusses a technique, which has been developed on the basis of previous work [6] in Portland cement, to remove the major MgO phase in processed magnesite through preferential dissolution. The technique is termed the Ammonium Nitrate Method (ANM). The extracted residue can be analyzed

by X-ray powder diffraction to identify secondary phases.

## 2. Experimental

### 2.1. Raw materials

Two natural magnesite samples from two different regions of India were selected for the experiments. The first was Salem magnesite, termed S, from the Salem region of Tamil Nadu, India. This magnesite is rich in silica, present as quartz veins or lenses within the raw magnesite [7]. The other was magnesite from the Almora region of Uttar Pradesh, India, termed A, with iron present as solid solution with magnesite [7].

The magnesities were crushed, ground and pelletized before processing. The pelletized magnesite samples were processed at 1650 °C with 1 h soaking at maximum temperature. This processing reduced the magnesium carbonate to the oxide and produced a compact mass. The compact processed mass was crushed and ground for phase analyses. Phase analyses of these processed samples was done with the help of X-ray powder diffraction technique using Cu K$\alpha$ radiation with Ni filter at a scan speed of 2° 2$\theta$ per minute using a Philips PW-1730 XRD unit. Because these samples contained magnesia (periclase) as the major phase, the secondary phases did not appear in a reasonably identifiable form as will be detailed later. To identify the secondary phases, the processed samples were ground to $-300$ mesh BS ($-52$ μm) and taken for extraction by ANM. After extraction the residue was dried, and the secondary phase were identified using powder XRD.

### 2.2. Apparatus for extraction

Standard chemical laboratory equipment was used for the extraction step in ANM. Refluxing assembly, consisting of a flat-bottom short neck Erlenmeyer flask 500 ml capacity. The water cooler refluxing condenser had a minimum length of 300 mm. The flask and reflux condenser were connected with standard tapered ground glass joints. A heating assembly consisting of a heating mantle with a capacity of 1 l attached with an energy regulator was used. A filtration unit consisting of a standard glass funnel set-up with Whatman No. 41 filter paper was used.

### 2.3. Reagents and materials

The following were used: ammonium nitrate, (AR/GR Grade); ethanol, (purity 99.5%); glass boiling beads; high temperature processed magnesite powder.

### 2.4. Extraction technique

In the ANM, for identification of secondary phases in processed magnesia, the following steps were conducted. About 5 g of powdered ($-52$ μm) sintered magnesia sample was taken in a 500 ml Erlenmeyer flask fitted with a refluxing condenser. About 300 ml absolute ethanol and 20 g of ammonium nitrate and a few small glass beads to aid smooth boiling were added to the sample. The contents were refluxed at a controlled temperature of 70 °C on a heating mantle for about 10–15 h. At regular intervals the flask was shaken well to disturb the settling of fine magnesite powders at the bottom of the flask. Intermittently, the condenser was removed from the flask to release the ammonia formed from the reaction between MgO and ammonium nitrate.

After completion of refluxing the contents were cooled to room temperature and filtered. The glass beads were carefully removed and the residue was washed three to four times in absolute alcohol. The residue was dried at $100 \pm 5$ °C for 1 h and taken for X-ray analysis. If necessary, the filtrate was collected and analyzed complexometrically to determine the total MgO extracted.

## 3. Results and discussion

### 3.1. Phases in as-sintered magnesite

Initial phase analyses of raw materials using XRD and microscopy showed that natural Salem magnesites contain quartz and serpentine as the commonly associated minerals while Almora contains calcite and dolomite and both magnesites contain a minor amount of talc. These associated minerals in the raw material are bound to give rise to secondary phases in magnesite processed at high temperature. The composition of the secondary matrix varies depending on the composition of raw materials. Identification of these secondary phases requires much attention, but at the same time this is difficult owing to the low phase concen-

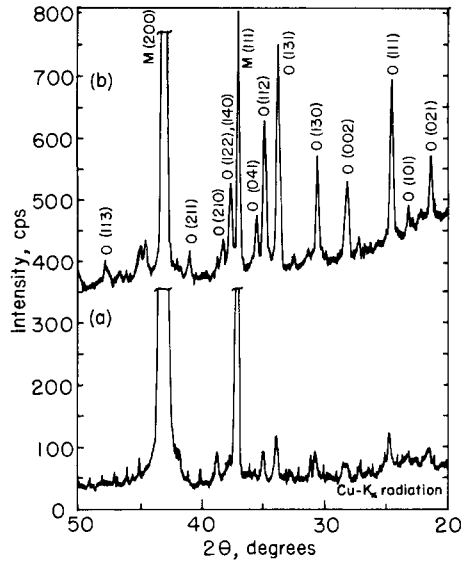

Fig. 1. Powder X-ray diffraction patterns for Salem magnesite processed at 1650 °C. (a) Before and (b) after extraction of the major portion of the periclase phase (M) using ANM showing monticellite (O) to be the crystalline secondary phase.

tration compared to the large amount of periclase grains.

The results of powder XRD analysis of as-fired samples are given in Figs. 1(a) and 2(a). The two patterns show the characteristic (200) and (111) reflections at $d$-spacings of 0.243 and 0.210 nm respectively (at about 43° and 37° $2\theta$ for Cu K$\alpha$ radiation) for periclase (JCPDS 4-0829). The (220) reflection for $d$-spacing of 0.149 nm was identified but this has not been reproduced in the figures for the sake of brevity. Other reflections for secondary phases were present at a low intensity level. It is evident from both figures that the dominant MgO phase does not permit the ready identification of secondary phases. However, even these powder patterns of the as-fired MgO do confirm the presence of secondary phases.

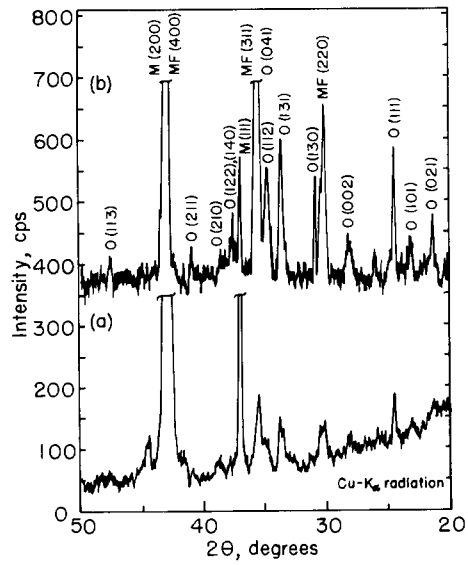

Fig. 2. Powder X-ray diffraction patterns for Almora magnesite processed at 1650 °C. (a) Before and (b) after extraction of the major portion of the periclase phase (M) using ANM showing enhanced magnesioferrite (MF) and monticellite (O) to be the crystalline secondary phases.

Table 1
Periclase, MgO, extracted from processed magnesite

| Sample code | Material | Refluxing time (h) | MgO Extracted (%) |
|---|---|---|---|
| S | Processed Salem magnesite | 9 | 86 |
| A | Processed Almora magnesite | 13 | 89 |

Solvent volume: 300 ml; sample weight: 5 g. Ammonium nitrate: 20 g.

### 3.2. Phases in periclase extracted samples

The results of the chemical extraction using ANM on two samples are given in the Table 1. Alcoholic ammonium nitrate during refluxing with processed magnesite forms a double salt of magnesium with the extracted periclase according to the following equation:

$$MgO + 4NH_4NO_3 \rightarrow Mg(NO_3)_4(NH_4)_2 + 2NH_3 + H_2O \quad (1)$$

An alcoholic solvent was used to prevent possible hydrolysis of magnesium and calcium bearing phases. The ethanol used for the experiments had a water content of less than 0.5%. The processed sample of Almora magnesite with high iron impurity required a longer refluxing period of 13 h compared to samples of processed Salem magnesite which required about 9 h to extract about 85–90% of the sample of MgO (Table 1). This slow reaction time may be attributed to the presence of iron as solid solution in all phases in Almora magnesite preventing easy dissolution of MgO phase.

The solvent volume also affected the extraction time in ANM. The solvent volume below an optimum level increases the extraction period considerably. The optimum solvent level here may be considered as the volume at which

Table 2
Intensity of powder XRD reflections before and after extraction in processed magnesites

| Phases (JCPDS) | *hkl* index | $I/I_0$ | Intensity (*cps*) | | | |
|---|---|---|---|---|---|---|
| | | | Salem | | Almora | |
| | | | Before | After | Before | After |
| Periclase | 200 | 100 | >9000 | >5000 | >5000 | >2000 |
| (4-0829) | 111 | 10 | 850 | 420 | 460 | 200 |
| Monticellite | 131 | 100 | 75 | 360 | 90 | 250 |
| (11-0353) | 130 | 35 | 50 | 170 | 70 | 180 |
| | 111 | 40 | 50 | 280 | 110 | 250 |
| Magnesioferrite | 311 [a] | 100 | — | — | 130 | >700 |
| (17-0464) | 220 | 40 | — | — | 70 | 300 |

[a] Overlaps with monticellite (041) reflection.

the ammonium nitrate dissolves completely at room temperature. According to Eq. (1), 1 g MgO requires 4 g of ammonium nitrate for the reaction. About 20 g of ammonium nitrate were taken for 5 g sample. The optimum solvent volume for 20 g ammonium nitrate was found to be 300 ml ethanol. However, no experiment was conducted to ascertain the effect of solvent volume above the optimum. The non-solubility of phases other than periclase was confirmed by analyzing the resultant filtrate after ANM extraction for elements like Ca, Fe, and Si and none were found. Through repeated trial experiments, it was determined that a minimum refluxing time of about 8 h is required to extract about 80 wt% of the periclase (MgO) phase. Extraction of MgO up to this level of about 80 wt% is considered satisfactory for subsequent identification of secondary phases by XRD.

Phase identification through powder XRD was done after the ANM magnesia extraction to identify the secondary phases present in the sintered magnesites. It was observed that the secondary phases were easily identifiable. The major secondary phase in processed cryptocrystalline Salem magnesite was monticellite with extremely minor amounts of forsterite. The level of forsterite is so low in the material that it is just detectable even after extraction of about 86% of the parent sample as MgO. The major reflections of monticellite (JCPDS 11-0353) are marked O in Fig. 1(b). Dicalcium silicate present as an amorphous mass gave rise to the hump in the XRD pattern at around 20° $2\theta$ Cu K$\alpha$, typical of silicate bearing amorphous phases.

In coarse crystalline Almora magnesite processed material, monticellite and magnesioferrite (JCPDS 17-0464) were the two major crystalline phases revealed after ANM extraction as shown in Fig. 2(b). The iron impurity in this magnesite manifested itself as magnesioferrite after the high temperature processing. XRD of the processed magnesite itself before extraction (Fig. 2(a)) revealed the presence of magnesioferrite and monticellite through the presence of the (311) and (131) reflections of the two phases, respectively. After extraction, the intensity of the various reflections for the two crystalline secondary phases was enhanced considerably as shown in Fig. 2(b). This enhanced XRD pattern through extraction confirmed the absence of significant quantities of any other crystalline secondary phase.

The enhanced intensity of the major secondary crystalline phase reflections and the reduction in intensity of the periclase reflections after the ANM magnesia extraction are given in Table 2. The background noise in the case of Almora magnesite after extraction was high owing to the fluorescence from the relatively large amount of iron in the magnesioferrite. The (200) and (111) reflections for MgO were reduced by over one-half, from over 5000 cps to over 2000 cps and from 460 to 200 cps for the two peaks, respectively (Table 2). The 100% reflection of the monticellite, $CaMgSiO_4$, increased three to five times owing to extraction while magnesioferrite reflections were suitably improved by a factor of four. On the basis of these observations, it can be said that the ANM solution extraction technique was helpful in identification of small amounts of secondary phases in magnesia refractory material.

## 4. Conclusions

A wet chemical technique has been established for the isolation of secondary phases in processed magnesite samples. In this technique, the major MgO phase (periclase) in high temperature processed magnesite was preferentially dissolved by ammonium nitrate in ethanol medium. The filtered residue containing isolated secondary phase concentrate enabled identification of mineral phases when subjected to powder XRD. The technique is easy to perform and requires minimum operational attention during the extraction step.

## Acknowledgments

The authors are grateful to Dr B.K. Sarkar, Director, CGCRI, for his kind permission to carry out this study and publish these results. The authors are greatly indebted to Dr H.S. Maiti, Head, Analytical Chemistry Division, for his kind permission and advice during the entire study.

# Determination of antimony, arsenic, bismuth, selenium, tellurium and tin by low pressure atomic absorption spectrometry with a quartz tube furnace atomizer and hydride generation with air addition

Baogui Zhang *, Yan Wang, Xinsheng Wang, Xulong Chen, Jianxing Feng

*Department of Environmental Science, Nankai University, Tianjin, People's Republic of China*

Received 19 October 1994; revised 11 January 1995; accepted 13 January 1995

**Abstract**

A new method has been developed for the determination of antimony, arsenic, bismuth, selenium, tellurium and tin by hydride generation–atomic absorption spectrometry in an electrically heated quartz tube furnace under sub-atmospheric pressure. The hydride generator, operating at a pressure lower than atmospheric, is used to generate and collect the hydrides of these elements. A certain volume (at atmospheric pressure) of air is then added to the generator after the formation of the volatile hydride. The gaseous mixture of the hydride and air is drawn into an evacuated, heated quartz tube by a vacuum pump. The proposed method gives improved sensitivities and detection limits.

## 1. Introduction

Elements forming covalent hydrides such as antimony, arsenic, bismuth, selenium, tellurium, tin, etc., are often determined after hydride generation by atomization of the hydride and measurement by atomic absorption spectrometry. Quartz tubes are the most widely used atomizers for hydrides. Investigations of many authors showed that addition of oxygen to air to the purge gas increased the sensitivities [1–4] and the highest sensitivities were found for extremely fuel-rich hydrogen–oxygen (or hydrogen–air) flames burning inside unheated quartz tube atomizers [5–7]. Dedina and Rubeska [7] and Welz and Melcher [8] studied the atomization of gaseous hydrides and the effect of oxygen on the sensitivity of hydride-forming elements. They concluded that the atomization of volatile hydride-forming elements was caused by collision with free hydrogen radicals and the role of oxygen was that it was able to increase the concentration of hydrogen radicals, the possibility of collision with hydride molecules and the atomization efficiency.

A method for the determination of antimony, arsenic, selenium and tin by low pressure furnace atomic spectrometry has been established [9–11]. On the basis of these works, a new method for the detemination of antimony, arsenic, bismuth, selenium, tellurium and tin has been developed. The hydrides are generated by adding dilute (1% m/v) sodium borohydride solution to acidified samples in a low pressure (state pressure approx. 9.8 kPa) generator. A certain amount of air is then added to the generator. The gaseous mixture is drawn into an evacuated, heated quartz tube where the atomic absorption occurs. It is most important to optimize the amount of air added so that the sensitivities are not reduced by the liberated hydrogen. The oxygen added reacts with the hydrogen and forms water. This pro-

* Corresponding author.

*SSDI* 0039-9140(95)01526-4

cedure removes the unnecessary hydrogen and reduces the dilution by hydrogen of the atomic concentration of the analyzed elements inside the quartz tube. The effects of various experimental conditions have been thoroughly studied.

## 2. Experimental

### 2.1. Apparatus

A Varian-Techtron AA6 atomic absorption spectrometer was equipped with a Model XWT-200 amplifier-strip chart recorder (Shanghai, China). The recorder has a full-scale pen response of 0.5–0.8 s. This recorder and the Varian AA6 were sufficiently fast to accurately record the transient signals of atomic absorption in our experiments. Varian Techtron hollow cathode lamps were used for all elements. A low pressure hydride generator was employed for the hydride generation and collection. The atomizer was an electrically heated, evacuated quartz tube, which had quartz windows at two sides. The length and the diameter of the tube were 16 and 0.8 cm, respectively. A certain length of capillary pipe used as a damper was connected to the gaseous outlet of the quartz tube. The purpose was to increase the retention period of the analyte atoms inside the quartz tube. If the diameter of the capillary damper was 0.2 cm, the length used was 10–70 cm [9]. A model 2XZ-4 vacuum pump (Shanghai, China) was used to draw out the mixture from the generator into the quartz tube. The limit vacuum of the pump is $6 \times 10^{-5}$ kPa. The apparatus for the low pressure generation of the hydrides and low pressure measurements is shown schematically in Fig. 1.

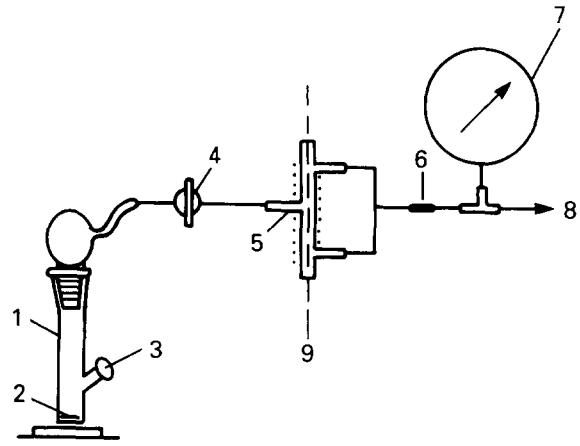

Fig. 1. Schematic diagram of the apparatus for sub-atmospheric pressure hydride generation and measurement in an evacuated, heated quartz tube: 1, hydride generator, 2, magnetic follower; 3, silicone rubber septum; 4, two-way stopcock; 5, electrically heated vacuum quartz tube; 6, capillary damper; 7, monometer, 8, to vacuum pump; 9, optical path.

### 2.2. Reagents

Analytical reagent grade chemicals and doubly distilled water were used throughout. The standard solution contained 1000 μg/ml of ether As, Bi, Sb, Se, Sn or Te. A solution of 1% (m/v) $NaBH_4$ was prepared by dissolving $NaBH_4$ powder in 0.1% (m/v) NaOH, and the solution was filtered through a 0.45 μm membrane filter. The operating conditions for the elements tested are summarized in Table 1.

### 2.3. Analytical procedure

A certain amount of sample solution (about 1–2 ml) and a certain volume of 6 M HCl solution were added to the generator (Table 1). The generator was connected to the apparatus. The two-way stopcock was opened and the air in it drawn out by a vacuum pump for about 20 s. Then the stopcock was closed. A certain volume of 1% $NaBH_4$ solution (Table 1) was injected into the generator through a silicon–

Table 1
Operating conditions and solution specifications

| Element | Wavelength (nm) | Lamp current (Ma) | Spectral bandwidth (nm) | 6 M HCl addition volume (ml) | 1% $NaBH_4$ addition volume (ml) | Air addition volume (ml) |
|---|---|---|---|---|---|---|
| As | 193.7 | 7 | 1.0 | 1.0 | 0.8 | 4 |
| Sb | 217.6 | 5 | 0.2 | 1.0 | 0.5 | 5 |
| Bi | 223.1 | 5 | 0.2 | 0.5 | 0.3 | 4 |

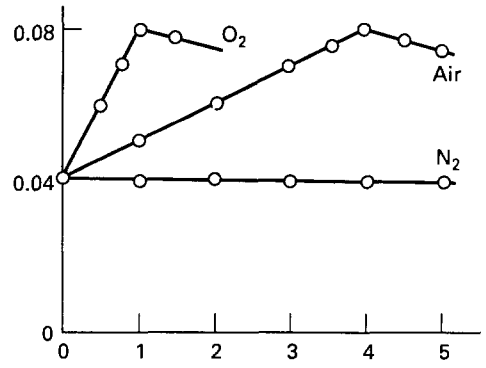

Fig. 3. Effect of the volumes of oxygen, air and nitrogen added on the absorbances of 5 ng arsenic.

rubber septum. The reduction proceded very fast under stirring. After 10 s a certain amount of air was injected into the generator. The stopcock was then opened for drawing out the mixture of the hydride and air into the evacuated, heated quartz tube. The peak absorbance of the sample was recorded instantly.

## 3. Results and discussion

### *3.1. Selection of the temperature inside the electrically heated, evacuated quartz tube*

The temperature inside the central section of the quartz tube was measured using a thermocouple to observe the effect of atomizer tube temperature on the sensitivities of elements. No effect on the results was observed when the temperature was within 800–850 °C. Thus 850 °C is recommended.

### *3.2. Effect of air, oxygen and nitrogen on the sensitivities of elements*

It has been found that the sensitivities of these elements can be increased if a certain amount of air or oxygen is added to the generator, but nitrogen can not be utilized to increase the sensitivities. The experimental results are compared in Figs. 2–7: the sensitivities of antimony, arsenic, bismuth, selenium and telleurium are increased by a factor of approximately two, and the optimum air amounts of these elements are 5, 4, 4, 4, and 3 ml, respectively, whereas the optimum oxygen amounts are 1.2, 1.0, 1.0, 1.0, and 0.6 ml, respectively; this technique is crucial for the determination of tin because the absorbance of 5.0 ng Sn is nearly zero when using the no addition procedure.

### *3.3. Increasing sensitivities by adding oxygen*

When a small amount of air or oxygen is added, a weak flash is seen inside the evacuated, heated quartz tube at the gas inlet. The more air or oxygen is added, the more obvious the flash. This phenomenon is generated by reaction of the hydrogen produced by the decomposition of sodium borohydride with the oxygen added. If air or oxygen is not added, a large amount of hydrogen liberated from the decomposition of sodium tetrahydroborate dilutes the atomic concentration of hydrides.

When air or oxygen is added, the oxygen reacts with the hydrogen and forms water.

$$2H_2 + O_2 = 2H_2O$$

This procedure removes unnecessary hydrogen and reduces the dilution by hydrogen of the atomic concentration of the analyzed elements inside the quartz tube so that the sensitivities are increased.

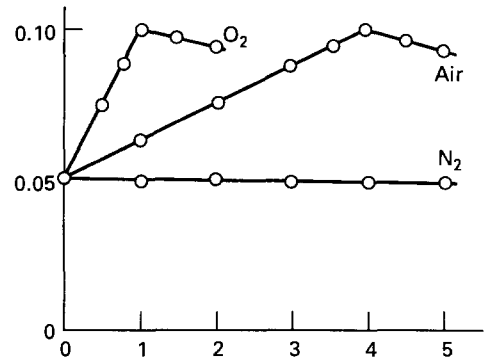

Fig. 4. Effect of the volumes of oxygen, air and nitrogen added on the absorbances of 2 ng bismuth.

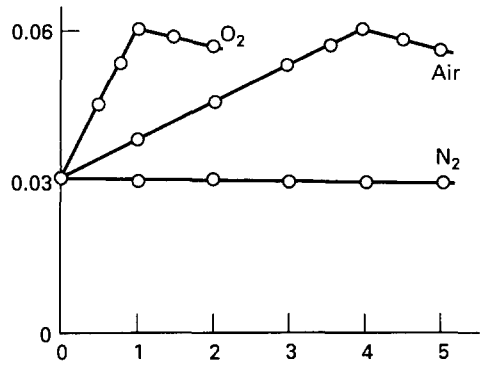

Fig. 5. Effect of the volumes of oxygen, air and nitrogen added on the absorbances of 1 ng of selenium.

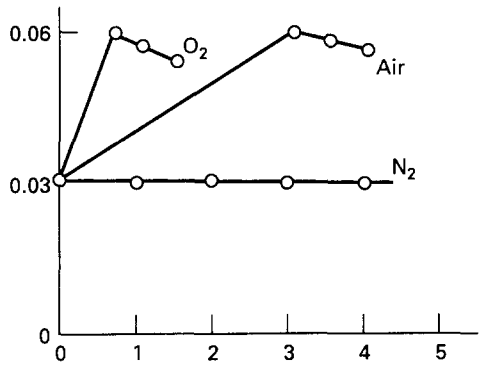

Fig. 6. Effect of the volumes of oxygen, air and nitrogen added on the absorbances of 2 ng of tellurium.

### 3.4. Sensitivity and detection limit

The typical sensitivities of the low pressure technique for arsenic, antimony, bismuth, selenium, tellurium and tin are 290, 80, 90, 73, 140 and 110 pg, respectively; whereas the detection limits ($3\sigma$) of this method for these elements are 610, 100, 50, 60, 26 and 200 pg, respectively.

In order to document the improvement in sensitivity achieved by using a vacuum system, a experiment with carrier gas ($N_2$) has been done. The optimum nitrogen flow-rate was 1.0 l/min for the elements except selenium and tellurium when a flow-rate of 2.6 l/min was used. The other experimental conditions are identical with the vacuam method except for the procedure of adding oxygen or air. The sensitivities of the carrier gas technique for the above elements were 600, 550, 450, 2000, 1600 and 500 pg, respectively. A comparison of the sensitivities between the two methods illustrates that it is beneficial to generate, collect and atomize the hydrides under sub-atmospheric pressure.

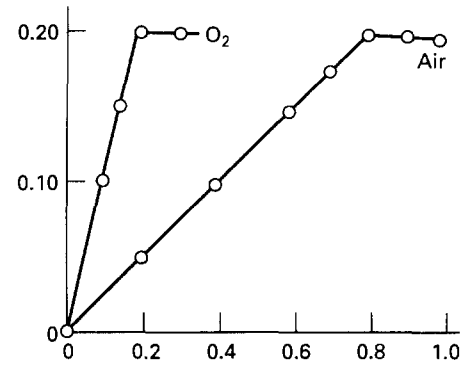

Fig. 7. Effect of the volumes of oxygen, air and nitrogen added on the absorbances of 5 ng of tin.

## 4. Conclusion

As compared with the conventional carrier gas method [12–14], the key features of our method are the hydride generation at less than atmospheric pressure, the vacuum atomization and the elimination of the influence of the hydrogen liberated from the decomposition of sodium borohydride.

# A gas chromatographic method for the determination of nitrite ions in natural waters ☆

I. Sarudi *, I. Nagy

*Department of Chemistry, Faculty of Animal Science, Pannon Agricultural University, Kaposvár, Hungary*

Received 4 November 1994; revised 28 February 1995; accepted 28 February 1995

**Abstract**

Following the treatment of the sample with zinc hydroxide, nitrite reacts with potassium iodide in the presence of acetone and sulphuric acid. The released iodine and the propanone derivative resulting from the acetone are extracted in *n*-hexane. The extract is subjected to gas chromatographic separation and detection using an electron capture detector. The calibration curve was found to be linear up to a concentration of 2.5 mg $l^{-1}$ $NO_2^-$. The detection limit calculated from the threefold noise level and the slope of the calibration curve is 0.008 mg $l^{-1}$. The relative standard deviation (including that of the blank) was less than 8%. The reliability of the method is adequate for practical uses. Amongst the advantages is that the method does not require the use of exceedingly toxic reagents. On the other hand, the method is applicable for samples that even after being subjected to clarification procedures still do not become fully transparent.

*Keywords:* Natural waters; Nitrite ions; Gas chromatography

## 1. Introduction

In the decades that have elapsed since the emergence of flow injection analysis (FIA), several automated methods have been developed for the microquantitative determination of nitrite (FIA spectrometry [1–4], FIA–AAS [5], FIA–voltammetry [6–8], etc.). However, the most widely used practical procedures are still based on spectrophotometric methods [9–12]. Generally the sensitivity of spectrophotometric nitrite determinations satisfies the requirements. However, many of these methods have the drawback that they imply the use of highly toxic and/or carcinogenic chemical reagents [13,14]. Increased precautions are necessary in the case of methods based on the use of azo dyes. Yet another drawback of these methods is that in the case of turbid or opalescent samples, the measurement itself may be hindered, as the clarifying agents used in practice are far from ideal (i.e. the Hungarian Standard [15] recommends the use of zinc hydroxide).

The aim of the present paper is to describe a method that may be used for the determination of the nitrite content in natural waters. The method advocated by us does not require the use of special precautionary measures. On the other hand, our method is applicable even in the cases of samples that, after clarification with zinc hydroxide, still do not provide a transparent, clear solution. The zinc hydroxide treatment of the sample is still recommended, as this happens to be an efficient means of eliminating from the liquid phase interfering heavy metal ions (i.e. $Fe^{3+}$ and $Cu^{2+}$).

## 2. Experimental

### 2.1. Chemicals and reagents

Analytical reagent grade chemicals were used throughout. Distilled water was prepared starting from 2 l of chlorinated tap water, and the chlorine was removed by boiling vigorously for 10 min. After the addition of 2 g of sodium hydroxide, the remaining water was redistilled. All the solutions were prepared using the distilled water obtained according to the above procedure.

Clarifying agents used were 0.6 M $ZnSO_4$ and 2 M NaOH. Other solutions and chemicals were 3.5 M $H_2SO_4$, a mixture of acetone and redistilled water (2:3), $5 \times 10^{-4}$ M KI solution prepared from iodine-free potassium iodide, and finally *n*-hexane. Before use, acetone and *n*-hexane were redistilled and nitrogen gas was bubbled through the KI solution in the test tube for 2 min.

Aqueous standard solutions containing 0.05, 0.10, 0.25, 0.50, 1.00, 1.50, 2.00 and 2.50 mg $l^{-1}$ $NO_2^-$ respectively were prepared by dilution from a 100 mg $l^{-1}$ $NO_2^-$ stock solution which was made up from $KNO_2$.

### 2.2. Apparatus and chromatographic conditions

A Packard-Becker model 419 gas chromatograph was used, equipped with a $^{63}Ni$ electron capture detector and a glass capillary column (30 m × 0.75 mm) coated with SPB-35 (Supelco Inc., USA). The chromatograph was interfaced to a Shimadzu Chromatopac C-R3A integrator. Nitrogen was used as carrier gas at a flow rate of 40 ml $min^{-1}$. The tests were carried out under isothermal conditions. The temperature of the column, inlet and the detector were 110 °C, 170 °C and 300 °C respectively.

### 2.3. Procedure

A portion (2 ml) of $ZnSO_4$ solution and 1 ml of NaOH solution were added to 100 ml of the sample. After sedimentation of the zinc hydroxide precipitate, the clear supernatant was used for the analysis.

A portion (4.5 ml) of the acetone/water mixture, 1.0 ml of the $H_2SO_4$ solution and 2.50 ml of the clarified sample were introduced into a 14 ml vial. Subsequently, nitrogen gas was bubbled through the vial for 2 min, after which 0.5 ml of KI solution and 2.50 ml of *n*-hexane were added to the liquid. The vial was then closed and allowed to stand for 1 h, with vigorous shaking every 15 min. Finally, 5 µl aliquots of the organic phase were manually injected with a micropipette into the gas chromatograph. Three injections were made for each sample. The peak area was used for quantitation and for the calculations. The blank (redistilled water) and the standard solutions were treated in the same manner as the sample. Standard curves were constructed daily.

## 3. Results and discussion

In the above described method, the nitrite ions reacted with iodide ions in the presence of sulphuric acid and acetone, and the released iodine was measured with the GC method of Hasty [16]. Since oxygen oxidizes the iodide ions and this reaction is catalyzed by the NO formed during the reaction between iodide and nitrite, the dissolved oxygen was removed from the sample.

In agreement with the findings of Hasty [16], under the described experimental conditions we also found the existence of a single reaction product, namely monoiodoacetone. The compound 1,1-di-iodoacetone does not appear if the $H_2SO_4$ concentration of the reaction medium is in the range 0.1–1.0 mol $l^{-1}$ (see Refs. [16,17]). The retention time of *n*-hexane and monoiodoacetone were 1.1 and 2.7 min respectively. In reasonable agreement with the findings of other workers [16,18], the partition coefficient of monoidoacetone was found to be 1.85 between *n*-hexane and water at room temperature ($C_{org}/C_{aq}$).

The detector response to monoiodoacetone extracted into *n*-hexane was directly proportional to the $NO_2^-$ concentration of the sample up to a concentration of 2.5 mg $l^{-1}$ of $NO_2^-$. The regression equation of a typical standard curve was $y = 1.93 + 82.54x$, where $x$ is the $NO_2^-$ concentration in milligrams per litre and $y$ is the peak area in arbitrary units. The standard deviation of the regression constant (intercept) and the regression coefficient (slope) were 0.28 and 0.77 respectively. It was shown by the test that the regression constant is significantly different from zero ($p < 0.05$). It appears that the intercept is due to the impurities existing in the reagents.

Table 1
Results of comparative $NO_2^-$ determinations in water samples (mg $l^{-1}$)

| Sample | Gas chromatographic method | | | Spectrophotometric method [a] | | |
|---|---|---|---|---|---|---|
| | $n$ | $\bar{x}$ | SD | $n$ | $\bar{x}$ | SD |
| Rainwater | 7 | 0.069 | 0.005 | 5 | 0.063 | 0.008 |
| Drinking water (unchlorinated) | 5 | 0.078 | 0.007 | 5 | 0.087 | 0.008 |
| Lake water (I) | 6 | 0.103 | 0.008 | 6 | 0.094 | 0.007 |
| Lake water (II) | 7 | 0.329 | 0.024 | 5 | 0.368 | 0.039 |
| Marsh water | 8 | 1.481 | 0.108 | 5 | 1.352 | 0.102 |

[a] Reagents: *N*-(1-naphthyl)ethylendiamine dihydrochloride and sulphanilic acid (see Ref. [21]).

To establish the limit of detection, the blank (redistilled water) was subjected ten times to the complete procedure, including the pretreatment, as previously described, with clarifying agents. The mean and the standard deviation of the obtained signals were 2.51 and 0.22 respectively in arbitrary units. The limit of detection (LOD) was calculated from the standard deviation of the blank signals (noise, $N$) and the slope of the calibration curve ($S$) as follows [19]: $LOD = 3N/S = 0.008$ mg $l^{-1}$ $NO_2^-$ in the water sample. This concentration value calculated corresponds to about 40 pg of $NO_2^-$ ions in the sample if a 5 µl aliquot of the organic phase is injected into the gas chromatograph.

In order to check the reproducibility, the complete procedure described above was repeated seven times with one sample of unchlorinated, poor-quality drinking water. The sample contained 81.6 mg of $Na^+$, 12.1 mg of $K^+$, 248.8 mg of $Ca^{2+}$, 47.3 mg of $Mg^{2+}$, 0.26 mg of $Fe^{2+}$, 0.10 mg of $Mn^{2+}$ and 0.22 mg of $NH_4^+$ cations, as well as 824.3 mg of $HCO_3^-$, 101.2 mg of $Cl^-$, 79.4 mg of $NO_3^-$, 111.9 mg of $SO_4^{2-}$, 16.0 mg of $SiO_3^{2-}$ and 0.003 mg of $SeO_3^{2-}$ anions per litre, while the permanganate index [20] was 6.4 mg $l^{-1}$ of oxygen. The mean and the relative standard deviation (RSD) of the obtained results were 0.347 mg $l^{-1}$ $NO_2^-$ and 5.8% respectively.

To check the day-to-day reproducibility, the $NO_2^-$ concentration of the same water sample as mentioned above was determined once a day for five consecutive days. The mean of the obtained results was 0.328 mg $l^{-1}$ $NO_2^-$ and the RSD was 7.4%. (We have used the same detector and column every time. The sensitivity of the measuring system has a fluctuation of ±5.5% from day to day.)

We investigated the interfering effect of various ions on the determination of 0.75 mg $l^{-1}$ $NO_2^-$. It was found that up to 500 mg $l^{-1}$ level, $F^-$, $Cl^-$, $Br^-$, $H_2PO_4^{2-}$, $SiO_3^{2-}$, and $B_4O_7^{2-}$ ions do not interfere. The upper tolerance limits regarding several potentially interfering ions are as follows: 350 mg $l^{-1}$ for $NH_4^+$, 250 mg $l^{-1}$ for $NO_3^-$, 40 mg $l^{-1}$ for $Mn^{2+}$, 25 mg $l^{-1}$ for $Fe^{2+}$, $Fe^{3+}$ and $Cr^{3+}$, 15 mg $l^{-1}$ for $Cu^{2+}$, 2 mg $l^{-1}$ for $SeO_3^{2-}$, 0.5 mg $l^{-1}$ $AsO_2^-$ and $AsO_4^{3-}$, 0.2 mg $l^{-1}$ for $S^{2-}$ and finally less than 0.1 mg $l^{-1}$ for $ClO^-$ and $IO_3^-$. It is obvious the fairly high tolerance limits for the heavy metal ions is due to the clarification of the sample.

Several water samples were analysed by the method described in the present paper as well as by a widely accepted [21] spectrometric method. As shown in Table 1, the results obtained by the two methods are in close agreement. The difference between the corresponding mean values was not significant at the 5% probability level in either case. The RSD of the gas chromatographic results was lower than 8%.

We intend to apply the described gas chromatographic method for the analysis of various food products, with special emphasis on the analysis of samples difficult to discolour such as fruit juices. In the case of celery juice we have already applied the method developed by us. The nitrite content of the celery juice was determined in the described manner, performing five parallel analyses. The mean value was 1.428 mg $l^{-1}$ and the RSD was 7.3%.

The original nitrite content of celery juice was decomposed quantitatively [5] with the aid of sulphaminic acid, then $KNO_2$ was added to the sample so as to achieve a 1.00 mg $l^{-1}$ concentration of nitrite. Following this procedure we performed three parallel determinations ac-

cording to the above described procedure. The obtained results were 0.92, 0.99 and 1.05 mg $l^{-1}$.

## 4. Conclusions

On the basis of our results we may safely conclude that the gas chromatographic method developed by us proved adequate for the determination of nitrite ions in natural waters and unchlorinated potable waters. The sensitivity and reliability of the method meets the practical requirements. It is worth mentioning that the method does not necessitate the use of highly toxic reagents and the samples do not need to be transparent. We believe that the present method is applicable in food analysis, primarily in the case of samples that are difficult to discolour.

# Determination of Michaelis–Menten and inhibitor constants by an open–closed flow injection approach (Application to the alkaline phosphatase/theophylline system)

M. Sánchez-Cabezudo [1], J.M. Fernández-Romero, M.D. Luque de Castro *

*Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, E-14004, Spain*

Received 11 October 1994; revised 27 December 1994; accepted 20 January 1995

**Abstract**

An automatic method for the estimation of Michaelis–Menten and inhibitor constants in biochemical systems was developed using an unsegmented open–closed flow manifold, and the Lineweaver–Burk and Dixon plot methods. The methods were applied to both the determination of $K_m$ of the enzymatic reaction catalyzed by bovine alkaline phosphatase using 4-methylumbelliferone phosphate as substrate, and the determination of the $K_i$ constant from theophylline as an inhibitor of this biochemical system. The data treatment and comparative results are presented. The values obtained agree with those provided by a conventional method with the biocatalyst in solution.

## 1. Introduction

The development of continuous flow methods coupled with enzymatic reactions has increased the degree of automation in analytical chemistry over the last two decades [1, 2]. However, little attention has been paid to the development of a method for the determination of kinetic constants, stoichiometries, etc. Some papers concerning enzymatic systems (e.g. alcohol dehydrogenase/NADPH dehydrogenase/monooxygenase [3] dihyldrofolate reductase [4], lactic dehydrogenase [5], and glucose oxidase [6]) provide information on enzyme kinetic constants. One of these works deals with the determination of the Michaelis constant of the substrate and antifolate inhibition constant in the NADPH/dihydrofolate reductase system using potentiometric titrations [4].

The applicability of cyclic flow injection systems to non-determination studies has been demonstrated in a variety of methods (e.g. estimation of kinetic [7] and stoichiometry constants [8], amplification methods [9], speciation [10], reaction rate measurements [11–13] and interference removal [14]).

The phenomenon of catalysis inhibition shown by some chemical substances is frequently used to develop methods for the determination of inhibitors [15–27]. Knowledge of the kinetic parameters involved in the biochemical reaction and the inhibitors has contributed to the clarification of inhibition mechanisms.

Inhibitors can influence the enzymatic reaction in such a way that the Michaelis constant ($K_m$) is apparently increased, the maximum reaction rate ($v_{max}$) is apparently decreased or both parameters are apparently changed. The first case is known as competitive inhibition, and the second as non-competitive inhibition. The third type, the special case in which $K_m$ and $v_{max}$ are apparently equally changed, is known as uncompetitive inhibition [28].

The aim of this work was to show the availability of open–closed flow-injection systems for monitoring inhibitory effects using theophylline as an inhibitor of immobilized alkaline phosphatase. The application of different mathematical algorithms (such as the Lineweaver–Burk method [29] and the Dixon plot method [30] to the multipeak recording achieved in the absence or presence of theophylline as inhibitor, permits the estimation of the apparent Michaelis–Menten constants of immobilized alkaline phosphatase and also the determination of the apparent inhibition constants of this system.

The biochemical reaction involved hydrolysis of a 7-hydroxy-4-methylcoumarin derivative [31] (4-methylumbelliferyl phosphate), catalyzed by phosphatase in a basic medium to yield 4-methylumbelliferone and phosphate, according to the following reaction:

4-methylumbelliferyl phosphate + $H_2O$

$$\xrightarrow{\text{Alkaline phosphatase}} \text{4-methylumbelliferone} + HPO_4^{2-}$$

The fluorescence of 4-methylumbelliferone in a basic medium was monitored at $\lambda_{ex} = 365$ nm, $\lambda_{em} = 445$ nm.

Alkaline phosphatase was immobilized on controlled pore glass in preparation to catalyze the conversion of 4-methylumbeliferone phosphate into 4-methylumbelliferone. As the sample passed through the reactor packed with the immobilized biocatalyst, the theophylline present was bound to some groups of the enzyme–substrate complex modifying its catalytic activity; thus the reaction took place to a lesser extent, the amount of 4-methylumbelliferone formed being inversely proportional to the concentration of the inhibitor.

## 2. Experimental

### 2.1. Apparatus and materials

A Kontron Instruments SFM 25 spectrofluorimeter furnished with a Hellma 138.QS flow cell and equipped with a Perkin-Elmer R-100 recorder and a Selecta 382-S recirculating thermostat was used. A Gilson Minipuls-2, four-channel peristaltic pump with a rate selector, a laboratory-made dual injection valve built from two Rheodyne 5041 injection valves, a Rheodyne 5041 injection valve (modified to act as a switching valve) and Teflon tubing of 0.5 mm i.d. were also used. A Zenit ZDS 625 nl PC-Bull System connected via a RS-232 interface was used for absorbance–time data acquisition, processing and delivery.

### 2.2. Reagents

The buffer used was a 500 mmol $l^{-1}$ aqueous solution of tris(hydroxymethyl)aminomethane (Merck N. 8382) adjusted to pH 10 with 1 mol $l^{-1}$ hydrochloric acid (Merck N. 319). A solution of 2.0 mmol $l^{-1}$ 4-methylumbelliferyl phosphate (Sigma M. 8883) was prepared in the above-mentioned buffer. A standard stock solution of alkaline phosphatase (orthophosphoric monoester phosphohydrolase, alkaline optimum, E.C. 3.1.3.1, Sigma P-2897, type I-S from *Bovine intestinal mucose*, 5.8 U $mg^{-1}$) was prepared by dissolving the content of a vial in the 1 mmol $l^{-1}$ theophylline buffer solution (Sigma T. 1633).

The reagents 3-aminopropyltriethoxysilane (Aldrich N. 11, 339-5), glutaraldehyde (Merck N. 820603) and controlled-pore glass (Sigma, CPG-240-200, 120/200 mesh) were used for the biocatalyst immobilization. All solutions were prepared using bi-distilled water of high purity obtained from a Millipore Milli-Q plus system.

### 2.3. Enzyme immobilization

Alkaline phosphatase was immobilized using Masoom and Townshend's method [32,33] and stored at 4 °C in 100 mmol $l^{-1}$ potassium dihydrogen phosphate buffer at pH 7.0. Glass tubes of different lengths and 1 mm i.d. were packed with the support–enzyme conjugate. The alkaline phosphatase reactors preserved their activity for at least 2 months (loss of activity smaller than 2%).

### 2.4. Manifold and procedure

Fig. 1 depicts the open–closed approach used. The theophylline solution (S), diluted to an appropriate extent with tris-HCl buffer, and the substrate solution (R) are simultaneously injected via the dual valve ($IV_1$ and $IV_2$) into two streams of the same buffer (B), and merge at point "a". The inhibitor–substrate plug passes through the valve (SV) and is then trapped in the closed circuit by switching the valve at suitable time interval after injection. The plug passes through the alkaline phos-

phatase reactor where the enzymatic reaction takes place to an appropriate extent. The cycling of the plug into the circuit provides a multipeak recording in which the peak height increases gradually after each new substrate/catalyst contact, thus providing an additional amount of the monitored product. As the buffer solution is injected instead of the theophylline solution the enzymatic reaction occurs to a greater extent and the multipeak recording achieved is used as the blank signal. In the presence of the inhibitor, the catalyzed reaction occurs to a lesser extent. The difference between the signal obtained in the absence and presence of the inhibitor is proportional to the concentration of the inhibitor in the sample.

### 2.5. Analytical signal and data treatment

The iterative passage of the bolus through the immobilized enzyme reactor (IMER) and detector provides the typical recording shown in Fig. 2, in which the successive evolution of the fluorescence signal corresponds to the development of the enzymatic reaction in the absence and presence of the inhibitor (See Fig. 2(A).

The manual method for the determination of $K_m$ involves measurement of the initial reaction rate at different substrate concentrations. The reaction rate vs. substrate concentration plot is a typical exponential curve with a maximum, constant reaction rate ($v_{max}$) at high substrate concentration. $K_m$ is defined as the substrate concentration corresponding to a reaction rate equal to $v_{max}/2$.

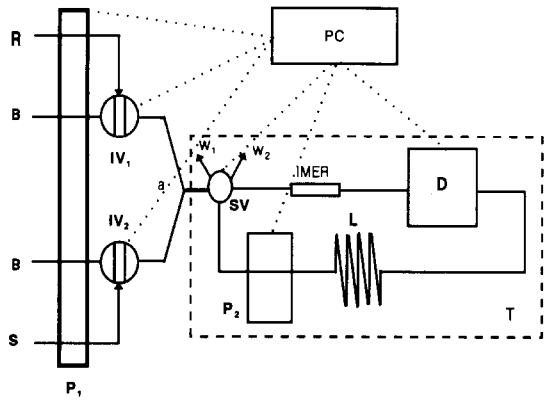

Fig. 1. Open–closed system: R, substrate; B, buffer; S, sample; $P_1$ and $P_2$, peristaltic pumps; $IV_1$ and $IV_2$, double injection valve; a, merging point; SV, switching valve; $W_1$ and $W_2$, waste; IMER, immobilized enzyme reactor; D, detector; L, open reactor; PC, personal computer.

The wealth of information supplied by each recording enables the use of different procedures for obtaining initial reaction rates values.

The multipeak recording in Fig. 2(B) allows different measurements based on fluorescence differences between peaks, whether consecutive or not. Thus, three reaction rate values were obtained from the recording, namely $V_1$, $V_2$ and $V_3$ from the equation $V_i = (A_{i+1} - A_i)/(t_{i+1} - t_i)$, where $A_{i+1}$ and $A_i$ are consecutive maxima or minima obtained at times $t_{i+1}$ and $t_i$, respectively. It is also possible to obtain measurements between non-consecutive peaks, from the equation $V_{31} = (A_3 - A_1)/(t_3 - t_1)$ where $V_{31}$ is the reaction rate calculated from maxima 3 and 1 at times $t_3$ and $t_1$, respectively.

A number of methods [28] have been used to foretell the type of inhibition. However, only two of these methods are widely used; these are discussed below.

(a) A straight line for each concentration of inhibitor is obtained when $1/V_i$ is plotted against $1/[S]$, according to Lineweaver and Burk [29]. These straight lines generally have different slopes for different inhibitor concentrations. Depending on the intercept and the slopes it is possible to predict the type of inhibition. When $1/V$ is plotted against $1/[S]$ in the absence of inhibitor, the constant achieved is the apparent $K_m$ of the enzyme.

(b) A more convenient method is that described by Dixon [30] which enables estimation of $K_i$ by two different procedures: (i) at constant substrate concentration $V_i$ is calculated at several concentrations of the inhibitor, and $1/V_i$ is plotted vs. inhibitor concentration. (ii) $1/K'_m$ is plotted vs. inhibitor concentration ($K'_m$ is the apparent Michaelis constant calculated by the Linewaver–Burk method for each inhibitor concentration). Every type of inhibition provides a straight line for each substrate concentration. In both cases (i and ii) the $x$-axis intercept provides the values of $-K_i$.

## 3. Results and discussion

### 3.1. Optimization of variables

The open–closed approach was optimized using the univariate method. This study was aimed at obtaining the best analytical response of the system in the absence of the inhibitor. The variables were classified into physical, chemical and those characteristic of the hydro-

(B) Types of measurement; $S$, analytical signal; $T$, time; $S_1$, $S_2$ and $S_3$, maxima obtained at times $t_1$, $t_2$ and $t_3$, respectively; $S'_1$, $S'_2$ and $S'_3$, minima obtained at times $t'_1$, $t'_2$ and $t'_3$, respectively; $V_1$, $V_2$ and $V_3$, reaction rate measurements (see text for details).

Table 1
Study of the variables

| Type | Variable | Range studied | Optimum value |
|---|---|---|---|
| Physical | Temperature (°C) | 20–45 | 40 |
| FIA | Flow-rate (ml $min^{-1}$) | 0.6–3.2 | 1.3 |
| | $IV_1$ injection volume (μl) | 50–500 | 225 |
| | | 50–1000 | 500 |
| | $IV_2$ injection volume (μl) | 50–500 | 100 |
| | | 0.1–1.0 | 0.2 |
| | Length of coil $L_1$ (cm) | 40–100 | 70 |
| | Length of IMER (cm) | 0.1–1.0 | 0.2 |
| | Switching time (s) | 6.0–10.0 | 8.4 |
| Chemical | [Tris-HCl] (mmol $l^{-1}$) | | |
| | pH | | |

dynamic system. Table 1 shows the range studied and the optimum values found.

An increase in temperature had a favourable effect on the analytical signal. Over 40 °C the signal did not increase, probably owing to biocatalyst denaturation.

The flow-rate had a marked influence on the evolution of the signal in the closed system, as it conditioned both the dispersion of the plug and the substrate–enzyme–inhibitor contact. Low flow-rates provided high development of the enzymatic reaction, but also a lower number of iterative passages through the enzyme reactor. A flow-rate of 1.3 ml $min^{-1}$ was chosen to obtain sufficient peaks in the multipeak recording. Both substrate and inhibitor injection volumes influenced the development of the multisignal. Substrate injection volumes ($IV_1$) above 225 μl increased the dispersion in the closed system. A 500 μl injection volume of inhibitor ($IV_2$) produced the highest inhibitory response. The IMER length had a strong influence on the analytical response. A long length provided higher development of the enzymatic reaction and a lesser inhibitory effect, probably as a consequence of more active sites in the enzyme reactor. A 0.2 cm long alkaline phosphatase reactor provided the highest difference between blank and sample recording.

At the flow-rate selected (1.3 ml $min^{-1}$), a 100 cm length of coil L and a switching time of 70 s after injection provided the best hydrodynamic conditions for optimal development of the biochemical reactions taking place in the open–closed approach.

Table 2
Calculation of the Michaelis constants

| Method | Type of measurement | Lineweaver–Burk lines | | | Kinetic parameter | |
|---|---|---|---|---|---|---|
| | | Slope | Intercept | $r^2$ | $K_m$ (mmol $l^{-1}$) | $V_{max}$ (mmol $l^{-1}$ $s^{-1}$) |
| Open–closed | Maxima | | | | | |
| | $V_1$ | 2.099 | 5.881 | 0.9972 | 0.357 | 0.170 |

| | $V'_1$ | 0.736 | 3.445 | 0.9985 | 0.211 | 0.287 |
| | $V'_2$ | 1.213 | 4.957 | 0.9930 | 0.244 | 0.207 |
| Conventional | | 2.664 | 6.478 | 0.9982 | 0.411 | 0.154 |

A 0.5 mol $l^{-1}$ tris solution, adjusted to pH 8.5 with 1 M hydrochloric acid, was selected as buffer. All the ingredients of the enzymatic reaction (substrate and inhibitor solutions) were prepared in this buffer.

### *3.2. Determination of the Michaelis–Menten constants*

*(a) By the proposed method*

The Michaelis–Menten constant and the maxima reaction rate were calculated by applying the Lineweaver–Burk method in the open–closed system in the absence of inhibitor. Five 4-methylumbelliferyl phosphate solutions with concentrations between 0.04 and 4.0 mmol $l^{-1}$ were injected in triplicate into the system and the multipeak recording from each solution was obtained. A simple computer processing of the data provided the reaction rate values and also allowed estimation of $K_m$ and $V_{max}$. Table 2 shows the results found using different types of measurement.

*(b) By the conventional method*

The Lineweaver–Burk method [29] was applied to the manual kinetic data for calculation of reaction rates with the enzyme in solution. Five millilitres of the reagent solution containing different concentrations of substrate were added to a test tube containing 100 µl of alkaline phosphatase (10 U $l^{-1}$). The mixture was poured into a conventional cell, placed in the fluorimeter and the fluorescence intensity vs. time was plotted. A data treatment similar to that used in the open–closed flowing method was performed.

*(c) Comparison of the results*

The envelopes of the multipeak signal provided by the open–closed system were quite similar to the kinetic curves obtained using the conventional method. This enables conventional treatment of the information obtained using the automatic method, and comparison of the results obtained with thoses provided by the conventional method.

The linear reaction rate interval achieved in the closed circuit is lower than the linear reaction rate interval obtained by the conventional method. Both the highest linear reaction rate range and the values of $K_m$ and $v_{max}$ closer to the conventional method were obtained when they were based on the average of different reaction rate ranges.

### *3.3. Determination of the inhibitor constants*

*(a) By the proposed method*

The inhibition constants for thephylline were calculated by applying both the Lineweaver–Burk and the Dixon plot methods. Inhibitor solutions containing 0, 0.5, 1.0 and 5.0 mmol $l^{-1}$ were injected in triplicate into the system. The treatment of the data provided information about the type of inhibition and also permitted estimation of $K_i$ from different measurements in the multipeak recording. Figs. 3 and 4, illustrate models of the different types of measurement. Table 3 shows some of the results obtained.

*(b) By the conventional method*

Lineweaver–Burk and Dixon plot methods were applied to the manual kinetic data for calculation of reaction rates with the enzyme in solution. 5 ml of the reagent solution containing different concentrations of substrate were

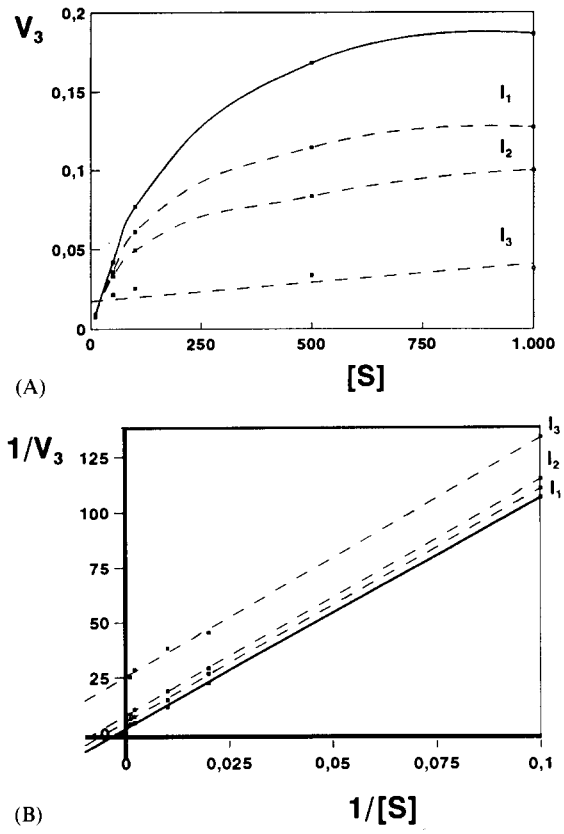

Fig. 3. (A) Reaction rate vs. substrate from $V_3$ measurement: in the absence of theophylline (——) and with different theophylline concentrations $I_1$, $I_2$ and $I_3$ (– – –). (B) Lineweaver–Burk lines from $V_3$ measurements: without theophylline (——) and with different theophylline concentrations $I_1$, $I_2$ and $I_3$ (– – –).

added to a test tube containing 100 µl of standard solution of theophylline were added to a test tube containing 100 µl of standard solution of theophylline (containing 0, 0.5, 1.0 and 5.0 mmol $l^{-1}$) and 100 µl of alkaline phosphatase (10 U $l^{-1}$). The procedure was similar to that used in the manual method previously described.

*(c) Comparison of the results*

Figs. 3 and 4 are typical inhibition plots. The straight lines obtained in all instances denote that theophylline is an uncompetitive inhibitor of bovine alkaline phosphatase. Table 3 summarizes the features of the lines obtained by both the conventional and the proposed open–closed method.

Comparison of the two sets of results shows the correlation found when the Lineweaver–Burk method is applied:

$$Y = 0.65X + 3.37 \qquad (r = 0.9836)$$

where $X$ refers to the conventional kinetic method and $Y$ refers to the open–closed method. The parameters of this equation are as follows:

$$\Sigma_{\text{intercept}} = 0.64$$

$$\Sigma_{\text{slope}} = 0.08$$

$$\Sigma_{y/x} = 0.49$$

which shows an acceptable correlation between both methodologies.

## 4. Final remarks

The study reported here shows the capability of open–closed systems for the implementation of methodologies for predicting the type of inhibition in enzyme-based processes.

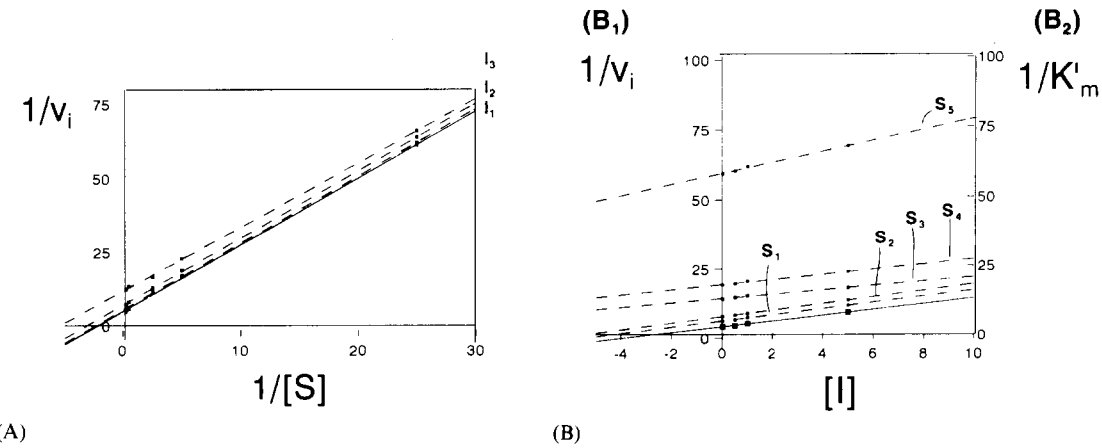

Fig. 4. (A) Lineweaver–Burk lines from $V_1$ measurement: without theophylline (——) and with different theophylline concentrations $I_1$, $I_2$ and $I_3$ (– – –) lines). (B) Dixon plot method: ($B_1$) from [I] vs. $1/v_i$ (at different substrate concentrations $S_1$, $S_2$, $S_3$, $S_4$ and $S_5$); ($B_2$) from [I] vs. $1/K'_m$.

# Prediction of chemical structure of aromatic hydrocarbons by pattern recognition of spectral lines obtained by fluorescence spectrometry in a supersonic jet

Cheng-Huang Lin, Totaro Imasaka *

*Department of Chemical Science and Technology, Kyushu University, Hakozaki, Fukuoka 812, Japan*

Received 14 September 1994; revised 23 January 1995; accepted 24 January 1995

**Abstract**

A technique based on pattern recognition of data obtained by supersonic jet spectrometry is employed for the prediction of chemical structure. The degree of similarity is evaluated quantitatively by calculating a cross correlation factor between sample and reference molecules. A probability density function is determined by fitting the data to a specified equation. The functional group and its position are also predicted by a similar technique. The pattern recognition provides a method for prediction of the chemical structure and is applicable to samples that have not been examined by supersonic jet spectrometry.

## 1. Introduction

Supersonic jet spectrometry provides sharp line structure in ultraviolet and visible spectra [1–4]. This analytical method, therefore, shows selectivity and allows spectrometric differentiation between molecules with similar chemical structures. The application of mass spectrometry after multiphoton ionization gives information relating to the molecular weight of the sample. This information alone, however, is not always sufficient for differentiating between isomers. Although the advantage of supersonic jet spectrometry lies in its well-resolved spectral features, the mass resolution of this technique could be improved by expanding the gas and decreasing its velocity distribution, since a better mass resolution can be obtained by other techniques such as ion cyclotron resonance. It is the sharp spectral features given by supersonic jet spectrometry that are important and useful in the assignment of chemical species and structure.

When a complete database is available, a sample molecule can be accurately identified using the spectral data accumulated for a series of authentic compounds. Recently, a database constructed by accumulating the wavelengths of pure electronic (0–0) transitions was used for the assignment of aromatic hydrocarbons [5–7]. This approach is reliable, because of the sharp line structure of the spectrum. However, there is no straightforward relationship between spectrum and chemical structure. It is, therefore, difficult to assign the chemical species when no standard spectrum is available in the database for that species. It would be useful, therefore, to develop a new method for data analysis, which can be applied to samples whose spectra are not available, i.e. which have not been reported.

One possible approach to this problem involves theoretical calculations of spectral parameters. The energy for the 0–0 transition is estimated by calculation of the molecular orbital by the Pariser–Parr–Pople (PPP) method and by the complete neglect of differential overlap method for spectroscopy (CNDO/S) [8]. These methods are useful for

* Corresponding author. Fax: (81) 92-651-5606.

*SSDI* 0039-9140(95)01536-1

reducing the number of candidates in the assignment. However, the error in the estimation of the wavelength for the 0–0 transition is 1–3%, which is much larger than the error of the peak position obtained experimentally (<0.01%). For more accurate discussion, it is necessary to use a spectral pattern for assignment. In physical chemistry, the spectral profile, i.e. transition energy and intensity, is calculated from the wave function and the Franck–Condon factor by solving a Schrödinger equation. This may give additional information for assignment of the chemical species. However, this approach is not altogether accurate, and the error in the calculation of the vibrational energy sometimes exceeds 10%. In addition, such an approach is complicated and time-consuming even for a single molecule, and as a result is not suitable for applications to analytical spectroscopy. What is ideally needed is a method which will provide sufficient information for the prediction of chemical structure without a standard spectrum of the sample or a complicated theoretical calculation of spectral parameters.

This study describes an approach involving the recognition of patterns of spectral lines which are produced as a result of supersonic jet spectrometry. In order to correlate spectral feature with chemical structure, we calculate a cross correlation factor (CCF) between the spectra obtained for the sample and reference molecules. The line shape in the supersonic jet spectrum is so narrow that almost all the CCF values become zero when they are calculated for different compounds. The data, therefore, were optimized by expanding the spectral line to a specified function, e.g. a gaussian function, thus giving useful information. In order to evaluate the degree of spectral similarity quantitatively, the probability density is plotted against the CCF value for a series of aromatic hydrocarbons. In addition, the spectral data of the 0–0 transition are used for prediction of the chemical structure. The wavelength of the 0–0 transition hardly coincides with that of a different compound, but is correlated quantitatively with a probability density function, providing useful information for structure prediction. The probability densities obtained independently by the above two methods are then multiplied to improve the accuracy of prediction. The advantage of this pattern recognition is demonstrated by differentiation of the anthracene derivatives against non-anthracene compounds. The functional group and its position can also be predicted relatively. The present approach requires neither a standard spectrum of the sample nor a knowledge of complicated quantum chemistry, and it works quite well for assignment of the chemical species in supersonic jet spectrometry.

## 2. Experimental

### 2.1. Calculation

Fig. 1 shows a bar graph of the fluorescence excitation spectra for anthracene and its derivatives obtained by supersonic jet spectrometry. Similar vibrational structure is observed in the spectra of the compounds with similar chemical structure. This is consistent with the fact that vibrational structure is strongly associated with skeletal vibration of the anthracene ring. These similarities can be visually observed, but for quantitative purposes the degree of similarity should be calculated mathematically. It is possible to use a CCF value for evaluation of the similarity between the standard and reference molecules [9]. However, the spectral line is so narrow (<0.01 nm) that almost all the CCF values between different compounds become zero. Therefore, optimization is necessary to evaluate the degree of similarity.

In this study, the signal peak in the supersonic jet spectrum is assumed to have a gaussian distribution:

$$I_k(\nu) = \exp[-(\nu - \nu_k)^2/r^2] \quad (1)$$

where $I_k(\nu)$ is the fluorescence intensity at the excitation frequency of $\nu$ for peak $k$, and $r$ is the linewidth assumed. The spectra of the chemical species $X(\nu)$ and $Y(\nu)$ are represented by

$$X(\nu) = \sum_1^n X_k(\nu) \quad (2)$$

$$Y(\nu) = \sum_1^n Y_k(\nu) \quad (3)$$

where $n$ is the total number of spectral lines. In order to compare the vibrational structure in the excitation spectrum, it is necessary to subtract the frequency of the 0–0 transition from each peak position. The CCF value, $C$, is calculated between the standard and reference spectra by

$$C = \frac{\left[\int X(\nu - \nu_{0X}) \cdot Y(\nu - \nu_{0Y})\, d\nu\right]}{\left[\int X^2(\nu - \nu_{0X})\, d\nu \cdot \int Y^2(\nu - \nu_{0Y})\, d\nu\right]^{1/2}} \quad (4)$$

where $\nu_{0X}$ and $\nu_{0Y}$ are the frequencies of the 0–0 transition for compounds X and Y, respectively. The denominator is a normalization factor. The CCF value is close to unity when the spectral feature of the standard is similar to that of the reference; CCF = 1 when CCF is calculated between the same compounds. In contrast, the CCF value is close to zero when the spectral features are completely different from each other. The CCF value also depends on the parameter $r$. In order to differentiate between the compounds giving similar spectra, this value should be small. However, if it is too small, all the CCF values become zero. Thus, appropriate fuzziness must be introduced by optimizing this parameter.

The CCF value was calculated using a notebook-type personal computer (NEC, PC-9801n). The program was written in BASIC. All the spectral data were cited from the references reported by other authors and from the data measured by ourselves. After digitizing the spectral data (frequency and intensity), the excitation spectrum was calculated using the assumed value for $r$. The CCF value was calculated between the spectra for the standard and reference molecules. The time period of calculation was typically 10 min.

## 3. Results and discussion

### 3.1. Preliminary study

The CCF values are calculated for various anthracene derivatives using 2-ethylanthracene as a standard sample. These results are shown in Table 1. The linewidth, $r$, is changed from 0.1 to 10 $cm^{-1}$. When $r$ is assumed to be 0.1 $cm^{-1}$, it is difficult to evaluate the degree of similarity properly. In the present study, the optimum value of $r$ appears to be between 1 and 10 $cm^{-1}$. The CCF values calculated for alkylanthracenes are significantly larger than those for chloroanthracenes, suggesting that the standard sample contains an alkyl group rather than a chlorine atom. The CCF values for anthracene derivatives substituted at position 2 are larger than those substituted at position 9, indicating a substituent group at position 2. The CCF value is not unity for 2-methylanthracene, indicating that the sample is not 2-methylanthracene. However, the large CCF value for 2-methylanthracene implies that the chemical structure is closely related, structurally, to 2-methylanthracene, and is possibly 2-ethylanthracene. This success in the preliminary study strongly encouraged us to perform further systematic investigations.

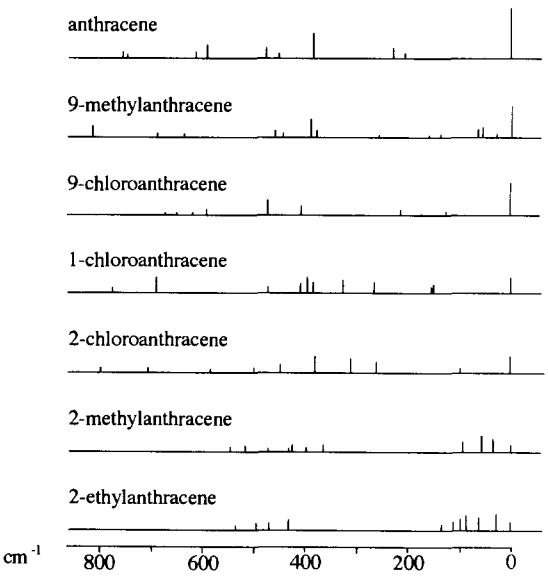

Fig. 1. Fluorescence excitation spectra for anthracene derivatives.

### 3.2. Skeletal structure

The CCF values were calculated for various aromatic hydrocarbons with different skeletons using 9-methylanthracene as a standard sample. A similar study was carried out using 1-methylnaphthalene. The results are shown in Table 2. The CCF values are the largest for the compounds with the same skeletons. Thus the skeletal structure can readily be predicted by this method.

Table 1
CCF values calculated for various aromatic hydrocarbons using 2-ethylanthracene as a standard sample

| Anthracene | 0.080 | 0.605 | $10^{-10}$ | 0.001 | [6] |
| Pyrene | 0.002 | 0.026 | $10^{-5}$ | 0.003 | [16] |

$r$: $cm^{-1}$.

A similar comparison was also carried out using toluene (methylbenzene) as a standard sample. The CCF values calculated for the same aromatic hydrocarbons are shown in lines 1–6 (benzene–pyrene) of Table 3. Surprisingly, the value for benzene is small; the values for pyrene and naphthalene are much larger at $r = 1\ cm^{-1}$ and those of indole and naphthalene at $r = 10\ cm^{-1}$. As a result, the CCF values were also calculated for naphthalene derivatives (7–11, Table 3). However, the CCF values are not so large for naphthalene derivatives. The values for benzene derivatives were also calculated as trials. The results are shown in lines 12–26 of Table 3. Clearly, large CCF values are obtained for benzene derivatives, especially for alkylbenzenes. It should be noted that benzene has a high molecular symmetry ($D_{6h}$) and, as a result, the electronic transition ($^1A_{1g}$–$^1B_{2u}$) is essentially forbidden. Consequently, the spectrum is observed only when the electronic transition is coupled with vibrations breaking $D_{6h}$ symmetry. This situation is completely different from other benzene derivatives. Thus benzene is a special case and is not a representative molecule for benzene derivatives. The compound with an OH or $NH_2$ substituent, e.g. *p*-cresol or *p*-toluidine, gives a small CCF value. Such compounds could be easily differentiated from benzene derivatives which contain only alkyl groups. The effect of substituent groups is further discussed in later sections.

### 3.3. Probability density function

In order to differentiate anthracene derivatives from non-anthracene compounds, the degree of similarity was evaluated by calculating the CCF values for various aromatic hydrocarbons using anthracene as a standard sample. The result is shown in column 2 of Table 4. It is apparent that compounds with an anthracene ring have larger CCF values. Fig. 2 shows the probability density of anthracene derivatives plotted against the CCF value. The solid curve was obtained by fitting the data to the following equation:

The linewidth, $r$, is assumed to be $10\,cm^{-1}$.

$$P = 1 - \exp(-C^2/k^2) \quad (5)$$

where $P$ is the probability of an anthracene derivative, $C$ is the CCF value, and $k$ is the constant obtained by fitting the data to the above equation. This curve is useful for quantifying the "similarity" of the spectrum by calculating the probability from the CCF value using Eq. (5). This "similarity" is listed in the third column of Table 4. The value for 9-hexylanthracene or 9-methylanthracene is 100%, indicating a high spectral similarity, and implying a high probability to be assigned to an anthracene derivative. It should be noted that the curve in Fig. 2 is saturated at high CCF values. In order to differentiate between compounds with closely related structures, the linewidth can be reduced, e.g. to $\approx 1\,cm^{-1}$. It is interesting to note that the first seven compounds are anthracene derivatives in Table 4, but the similarity of other anthracene derivatives such as 9,10-dichloroanthracene and 2-ethylanthracene are much lower than those for non-anthracene derivatives. Thus the reliability given by the present approach is not necessarily perfect.

In order to improve the accuracy of prediction, it is necessary to use an additional, simultaneous parameter, different from the CCF value, in order to discriminate against compounds having different spectral properties.

### 3.4. Wavelength of the 0–0 transition

In the previous section, only the vibrational structure of the spectrum is used for prediction of the chemical structure after subtraction of the frequency of the 0–0 transition. However, this frequency contains important information about the extension of $\pi$ electrons in a molecule, which is related to the ring size. The second column of Table 5 shows the wavelengths of the 0–0 transition for compounds whose excitation spectra have been previously reported. The 14 anthracene derivatives are located between 364 and 387 nm, although two other compounds (pyrene and pyrazine) are also located in this spectral region. This implies that the wavelength of the 0–0 transition can be used to advantage for differentiation of anthracene derivatives. The probability density of the anthracene derivative is plotted against the wavelength of the 0–0 transition in Fig. 3. The probability density increases rapidly at shorter wavelengths and then decays gradually

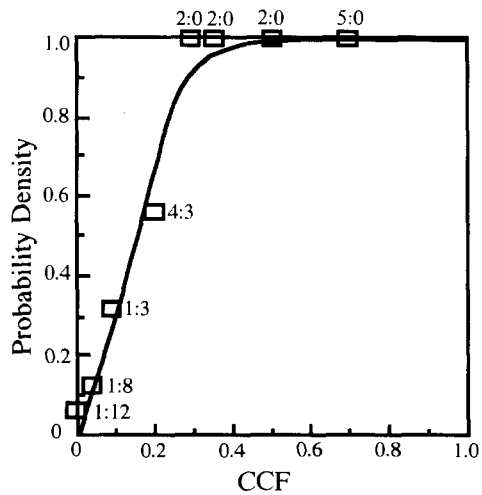

Fig. 2. Probability density of anthracene derivatives versus CCF value. The number in the Figure indicates the number of anthracene (left) and non-anthracene (right) compounds. The solid curve is calculated from Eq. (5) by fitting the experimental data to $k = 0.2$.

| Ovalene | 466.22 | 0.0 | [33] |
| Pentacene | 536.90 | 0.0 | [34] |

at longer wavelengths. These data were fitted to the chi-square distribution function:

$$F_m(x) = [(1/2)\Gamma(m/2)](x/2)^{m/2-1} \exp(-x/2) \quad (6)$$

where $\Gamma(m/2)$ is the gamma function, $m$ is the degree of freedom, and $x$ is the wavelength. The probability to be assigned to an anthracene derivative is listed in column 3 of Table 5. The probabilities for pyrene and pyrazine are rather high, indicating the limitation of this method alone.

### 3.5. Product of probabilities

In order to improve the accuracy of prediction, the probabilities obtained independently (third columns of Tables 4 and 5) may be multiplied. The result is shown in Table 6. It is noteworthy that the first 14 compounds are anthracene derivatives and the probabilities for non-anthracene derivatives are completely zero. Thus, the discrimination of anthracene derivatives from other compounds is perfect for all

the compounds whose spectra are so far available in the reference literature. In this study, anthracene was used simply as a representative molecule of anthracene derivtives in calculation of the CCF values. More accurately, the calculation must be performed using the "averaged spectrum" of anthracene derivatives, which is obtained by accumulating all the spectra for anthracene derivatives. This procedure may further improve the accuracy of prediction.

### 3.6. Functional group

For complete knowledge of the chemical structure, the functional group and its position must also be predicted properly. Table 7 shows the CCF values calculated for various benzene derivatives using toluene as a standard sample. As expected, alkylbenzenes, especially *n*-alkylbenzenes, give large CCF values. Fig. 4 shows the probability of alkylbenzene derivatives plotted against the CCF value. Fig. 5 shows the probability density for alkylbenzenes calculated from the frequency shifts of the 0–0 transitions. The typical shifts by substitution with an alkyl group are 500–1000 $cm^{-1}$. The product of the probabilities is shown for benzene derivatives in column 6 of Table 7. Apparently, ethylbenzene gives the largest value among these compounds, indicating the distinct merit of the present pattern recognition.

A similar comparison was also performed using 9-methylanthracene as a standard sample. As expected, 9-alkylanthracene, i.e. 9-hexylanthracene, gives the largest CCF value, implying the presence of an alkyl group at the 9-position. It is interesting to note that the CCF values for anthracene derivatives substituted at the 2-position with an alkyl group are rather small. This is ascribed to vibrational and rotational motions of the methyl group, providing many split lines due to a shallow potential curve.

Owing to a lack of spectral data, a more accurate discussion is difficult. However, it is generally true that the functional group and its position can be predicted fairly well as the probability is always high when the CCF value is calculated using the standard sample with a closely related chemical structure.

Table 6
Products of probabilities of anthracene derivatives obtained from CCF values and wavelengths of the 0–0 transition

| Compound | Product of probabilities (%) |
|---|---|
| 2-Chloroanthracene | 59.4 |

| *p*-Fluorophenol | 0.001 | 0.0 | 2963.5 | 3.1 | 0.0 |

The linewidth, $r$, is assumed to be $10\,cm^{-1}$.
CCF, cross correlation factor; PC, probability from CCF (%); FS, frequency shift ($cm^{-1}$); PFS, probability from frequency shift (%); $P$, product of probabilities (%).

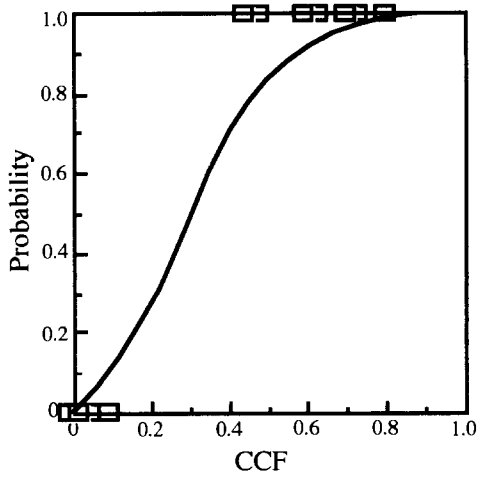

Fig. 4. Probability of alkylbenzenes against CCF value. Owing to the small number of compounds available, the data (0 or 1) are directly plotted in the Figure. The solid curve is calculated from Eq. (5) by fitting the experimental data to $k = 0.4$.

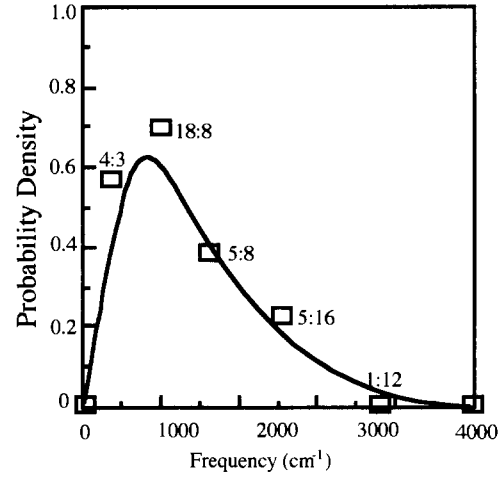

Fig. 5. Probability density of alkylbenzene against the frequency shift of the 0–0 transition from that of benzene. The solid curve is calculated from Eq. (6) by fitting the experimental data to $m = 4$.

## 4. Conclusion

A supersonic jet spectrum contains information concerned with skeletal vibrations, so that the skeletal structure can be well-predicted by pattern recognition. The wavelength of the 0–0 transition also contains information on the chemical structure. Thus the accuracy in prediction is improved by multiplying the above two probabilities obtained independently. Additional data concerned with fluorescence and multiphoton ionization spectra might also be useful for this purpose. Pattern recognition may be applied to analysis of the mass fragment spectrum for more accurate prediction of the chemical structure.

In this study, the determination of functional group position must be regarded as preliminary, since the number of supersonic jet spectra reported is small at the present time. By increasing the number of accumulated data, it will become possible to discuss the effect of other substitutional groups, such as OH or $NH_2$. Their CCF values are quite small when an alkylbenzene is used as a standard sample, suggesting that it may be possible to discrimi-

nate such compounds from other aromatic hydrocarbons, especially alkylbenzene.

For more accurate prediction of chemical structure, it is necessary to accumulate a large number of spectra in the database, as described. For this purpose, it is necessary to develop an instrument which allows measurements of the supersonic jet spectrum in a short time period. For example, the sample should be replaced immediately without changing the conditions of the nozzle and the vacuum system [10]. Further, a widely-tunable laser source may be essential, because the tunable range of the dye laser currently used is very limited and is not suitable for application to unknown samples. A titanium-doped sapphire laser or an optical parameteric oscillator coupled with a frequency conversion system is quite attractive. A multi-frequency laser may be also used to reduce the time for recording a spectrum [11]. Such hardware developments are essential not only for construction of the database, but also for practical use of supersonic jet spectrometry in routine work.

# Photometric assay of 1-naphthylamine by azo dye formation with diazotized sulfisomidine — application to waters

Thaira I. Younis, W.A. Bashir *

*Department of Chemistry, College of Science, Mosul University, Mosul, Iraq*

Received 3 June 1994; revised 5 October 1994; accepted 1 February 1995

**Abstract**

A simple and sensitive photometric method for the trace determination of 1-naphthylamine has been worked out. The method is based on the coupling reaction of the determinand in acidic medium with diazotized sulfisomidine, to form a purplish violet water-soluble mono azo dye that shows maximum absorption at 540 nm with a molar absorptivity of $4.47 \times 10^4$ l mol$^{-1}$ cm$^{-1}$. Beer's law is obeyed over the concentration range 5–70 μg of 1-naphthylamine in a final volume of 25 ml, i.e. 0.2–2.8 p.p.m. with a relative error of −0.7 to +1.7% and a relative standard deviation of 0.35–4.2%, depending on the concentration level. Moreover, the method does not require either temperature control or solvent extraction. Interferences due to foreign species have been examined. The developed method has been applied to the determination of 1-naphthylamine in river water and sea water.

## 1. Introduction

1-Naphthylamine, being a first-class carcinogen, is important from the view point of toxicology [1,2], and therefore its assay is very desirable. The methods available for the determination of 1-naphthylamine are mainly spectrophotometric because of their outstanding features [3]. The commonly used methods for the determination of the intended compound can be grouped into three types. Type I methods involve treatment of 1-naphthylamine with nitrite in acidic medium to form a diazonium cation; this is subsequently coupled with an activated aromatic nucleus in either acidic [4] or basic [5] medium, depending on the nature of the coupling component, to form a colored azo dye for measurement of 1-naphthylamine. These methods are rather time-consuming, not sensitive and involve a several-step procedure. Further, sometimes toxic reagents are used such as 2-naphthol [6].

Type II methods comprise the coupling of 1-naphthylamine with diazotized reagent to form an intensely-colored azo dye. In this respect, diazotized sulfanilic acid [7], diazotized 3,5-dichloraniline [8], diazotized *p*-aminoacetophenone [9], diazotized *p*-nitroaniline [10], and diazotized *p*-aminobenzophenone [11] have been reported for the determination of 1-naphthylamine. Type III methods involve condensation of the determinand with a nitroso aromatic compound to form the corresponding colored azo dye [12]. This technique is time-consuming, insensitive and the reaction medium should be 30% in acetic acid for the performance of the method.

Type II methods are characterized by simplicity, rapidity, and sensitivity, but a review of these methods reveals that the investigations performed using these procedures [9–11] require further study. This paper is devoted to a detailed investigation of the coupling reaction conditions of 1-naphthylamine with diazotized

sulfisomidine. The developed method has proved successful, and has been applied to the assay of 1-naphthylamine in river and sea waters.

## 2. Experimental

### 2.1. Reagents

Caution-gloves are worn in weighing, and all transfers of 1-naphthylamine solutions should be made with a pipette filler.

*Stock 1-naphthylamine solution, 10 mg ml$^{-1}$*

1-Naphthylamine (0.10000 g) (Hopkins and William) is dissolved in ethanol (Fluka), and the volume is then made up to 10 ml in a volumetric flask.

This solution, when stoppered tightly and kept in the refrigerator ($\approx$5 °C), is stable for at least 3 months.

*Working 1-naphthylamine solution, 50 μg ml$^{-1}$*

A 0.5 ml volume of the stock 1-naphthylamine solution is transferred into a 100 ml volumetric flask, and diluted to the mark with distilled water. This solution is stable for at least 1 week.

*Diazotized sulfisomidine solution, 3 mM*

A 22.4 ml volume of 6.7 mM sulfisomidine (Sigma) solution is transferred to a 50 ml volumetric flask. 3 ml of sodium nitrite (BDH) solution (0.0035 g ml$^{-1}$) is then added and, after adding water to 40 ml, the mixture is cooled to 5 °C. A 3 ml volume of 1 M $H_3PO_4$ (Fluka) solution is added, the mixture is stirred occasionally for 10 min and the volume is made up to 50 ml with additional ($\approx$5 °C) cooled distilled water. This solution is stored in darkness over ice and used after 20 min. The reagent when kept in the refrigerator ($\approx$5 °C) is stable for at least 9 days.

*Foreign compound solutions, 1 mg ml$^{-1}$*

These are prepared in either distilled water or ethanol.

### 2.2. Instruments

Absorbance and spectral measurements are performed on a Pye Unican SP 30 UV double-beam digital spectrophotometer using 1 cm optical silica matched cells.

pH measurements (at 20–25 °C) are carried out using a Philips PW 9421 pH meter, reading to three decimal places.

### 2.3. Procedure

To a series of 25 ml volumetric flasks are added 5–70 μg samples of 1-naphthylamine. Distilled water (10 ml) and 3 ml of 1 M $H_3PO_4$ solution are then added, and the mixture is shaken. A 2 ml volume of 3 mM diazotized sulfisomidine solution is then added and the volume is diluted to the mark with distilled water. After standing for 20–30 min, the absorbances are measured against the corresponding blank at 540 nm using 1 cm cells. The apparent molar absorptivity of the wavelength of measurement is $4.47 \times 10^4$ l mol$^{-1}$ cm$^{-1}$. The stability period of at least 30 min is sufficient for many measurements to be made at the same time.

For the subsequent experiments, 50 μg of 1-naphthylamine is taken and the final volumes are 25 ml.

## 3. Results and discussion

### 3.1. Study of the optimum reaction conditions

The effects of various parameters on the absorption intensity of the azo dye are studied and the reaction conditions are optimized.

### 3.2. Choice of diazotized reagent

Several previously unreported diazotized reagents have been examined for the photometric assay of 1-naphthylamine. These reagents are: diazotized sulfisomidine, sulfameter (5-methoxysulfadiazine), sulfamethazine, sulfamethizole, sulfanilamide, sulfanilic acid, sulfapyridine, sulfathiazole, and sulfaisoxazole. Diazotized sulfisomidine has been selected because it satisfies certain requirements [9] (intensity of the azo dye formed and the relatively rapid coupling rate). This reagent is also easily diazotized and remains stable for several days when stored at about 5 °C in darkness. Further, diazotized sulfisomidine gives a water-soluble azo dye with 1-naphthylamine under the experimental conditions, thus avoiding a time-consuming extraction process. The foregoing characteristics recommend diazotized sulfisomidine as a reagent for the assay of 1-naphthylamine.

### 3.3. Effect of acid

It is well-known that aromatic amines couple with diazonium salts in acidic to nearly neutral medium [3]. Different amounts (1–10 ml of 1 M) of different acids (HCl, $HClO_4$, $HNO_3$, $H_2SO_4$, $H_3PO_4$ and $CH_3COOH$) have been examined for their effect on the color intensity of the azo dye. The experimantal data reveal that in the case of strong acids, both the amount and order of the acid (sample + acid + diazotized reagent or sample + diazotized reagent + acid) added affect the intensity of the colored azo dye, and are immaterial when the acids are weak.

### 3.4. Effect of base

Different amounts (1–10 ml of 1 M) and orders (sample + base + diazotized reagent or sample + diazotized reagent + base) of various bases ($CH_3COONa$, $NaHCO_3$, $Na_2CO_3$, $NH_3$, NaOH and KOH) have been investigated for their effect on the color intensity of the azo dye. The color of the azo dye changes from violet in acidic media to orange then to yellowish-brown as the amount of base increases in the reaction medium. In addition, the blank changes from colorless in acidic media to yellow in basic media.

Acidic medium is preferred over basic medium because of: (a) strong color contrast, (b) higher sensitivity, and (c) better expected selectivity of determination because most compounds are activated towards coupling in basic medium.

A 3 ml volume of 1 M $H_3PO_4$ acid (final pH of the reaction mixture $\approx 1.5$) is selected for the subsequent experiments. This is because $H_3PO_4$ can act as a masking agent for cations such as iron(III), aluminium, and calcium, which may be present with the determinand in the same sample and are expected to interfere.

### 3.5. Formation of diazotized sulfisomidine

The diazotization reaction proceeds according to the following equation:

$$ArNH_2 + NaNO_2 + 2HX \xrightarrow{0-5\ ^\circ C} ArN_2X + NaX + 2H_2O$$

From the above equation, it is observed that the formation of diazonium salt is related to three components: the amine, the acid and the nitrite. Therefore, in the subsequent experiments the effect of each has been investigated.

### 3.6. Effect of acid-to-amine ratio

From the above equation, it can be observed that the acid reacts with the amine in a 2:1 ratio to form the diazonium salt. Different ratios of different acids (strong and weak) have been examined for their effect on the yield of the colored azo dye.

The experimental data have drawn the following observations.

(i) The diazotization of sulfisomidine can be carried out equally well in strong acid medium and weak acid medium.

(ii) In general, the absorbance of the colored azo dye becomes independent of the acid-to-amine ratio when the latter is greater than or equal to 2.

(iii) Generally, the absorbance of the colored azo dye becomes independent of the amount of diazotized reagent when the latter is greater than $2 \times 10^{-3}$ mmol per 25 ml final volume.

(iv) The same absorbance is essentially obtained when nitrite and sulfisomidine are mixed (in the absence of acid) and added to the sample solution containing 3 ml of 1 M $H_3PO_4$ per 25 ml final volume. This indicates that the diazotization of sulfisomidine is very fast. However, the 3 ml of 1 M $H_3PO_4$ is omitted and the procedure repeated, only a faint orange–red color is obtained (0.005 A unit).

(v) At a higher acidity ratio in HCl medium, the yield of the colored azo due decreases, probably because nitrous acid will exert an oxidizing rather than a nitrosating effect [14]:

$$2NO_2^- + 2Cl^- + 4H^+ \rightarrow 2NO + Cl_2 + 2H_2O$$

(vi) Phosphoric acid is recommended for diazotization because, in this acid, diazotization is fast, the color of the diazonium salt formed in more faint than in other acids, and the excess which remains can act as a masking agent [15].

### 3.7. Effect of amine-to-acid ratio

Amine solutions of concentrations 1, 3 and 5 mM have been prepared in phosphoric acid at acid-to-amine ratios between 2:1 and 100:1 for the concentrations of the amine. From the results obtained, a 3 mM solution has been selected for the subsequent experiments. This concentration of the diazotized reagent has

been selected as a compromise between sensitivity and stability of the diazonium salt. The stability of diazonium salts decreases as their amounts increase [16].

### 3.8. Effect of nitrite-to-amine ratio

At a constant amine-to-acid ratio of 1:20, the effect of nitrite-to-amine ratio has been evaluated for optimal color intensity using 1, 3 and 5 ml of the prepared diazotized reagent solution. As the ratio of nitrite to amine becomes more than 1:1 and a higher volume of diazotized reagent is used, the color changes from violet to pinkish-orange. Therefore, a 1:1 nitrite-to-amine ratio is recommended for subsequent experiments.

### 3.9. Mode of preparation of diazotized reagent

There are three possible modes for the preparation of diazotized sulfisomidine. Mode II of preparation (amine + $NaNO_2$ then acid) is chosen for subsequent experiments, because the diazonium salt prepared by this mode has the least faint color.

### 3.10. Amount of diazotized reagent

0.5–10 ml of 3 mM diazotized sulfisomidine reagent was examined over the range 5–100 μg of 1-naphthylamine per 25 ml final volume for optimal readings of absorbance. The experimental data reveal that the absorbance increases significantly with increasing amount of diazotized sulfisomidine, and remains approximately constant in the range 2–7 ml of 3 mM diazotized reagent solution. Larger amounts decrease the absorbance and cause hypsochromic shift. The shift may be due to multiple coupling [17]. A 2 ml volume of 3 mM diazotized reagent has been selected for the procedure, because a good correlation between abosrobance and determinand concentration exists. Also, the stability period of the colored azo dye is suitable, the sensitivity of the colored azo due is adequate, and at lower reagent amounts the selectivity of determination will increase.

### 3.11. Effect of temperature

The experimental data show that the absorbance of the azo dye increases as the temperature increases in the range 0–20 °C, reaches a maximum at 20 °C, and remains constant up to 45 °C. Therefore, it has been recommended to carry out reactions at room temperature (20 °C).

### 3.12. Absorption spectra

When a dilute solution of 1-naphthylamine in the presence of phosphoric acid, under the above-established conditions, is mixed with diazotized sulfisomidine reagent, a purplish-violet colored azo dye forms. This shows maximum absorption at 540 nm, in contrast to the colorless reagent blank which shows no absorption at the wavelength of maximum absorption. Fig. 1 shows the absorption spectra of the azo dye and the corresponding reagent blank. The wavelength of maximum absorption at 540 nm has been adapted for the subsequent work.

### 3.13. Kinetics of diazotized sulfisomidine reagent formation

The formation of the diazotized reagent (from its components) has been followed by taking 2 ml of 3 mM solution of the diazotized reagent at various time intervals and measuring the absorbance of the treated standard (according to the recommended procedure). The obtained results indicate that the diazotized reagent solution can be used after 20–30 min from preparation and up to at least 10 days, provided it is kept in the dark at about 5 °C.

### 3.14. Accuracy and precision of the method

To check the accuracy and precision of the method, 1-naphthylamine has been determined at three concentrations. The results are shown in Table 1 and indicate that the method is satisfactory.

Table 1
Accuracy and precision of the method

| Amount of l-naphthylamine taken (μg) | Relative error [a] (%) | Relative standard deviation [a] (%) |
|---|---|---|
| 5 | +1.7 | ±4.2 |
| 30 | −0.7 | ±1.0 |
| 70 | 0 | ±0.4 |

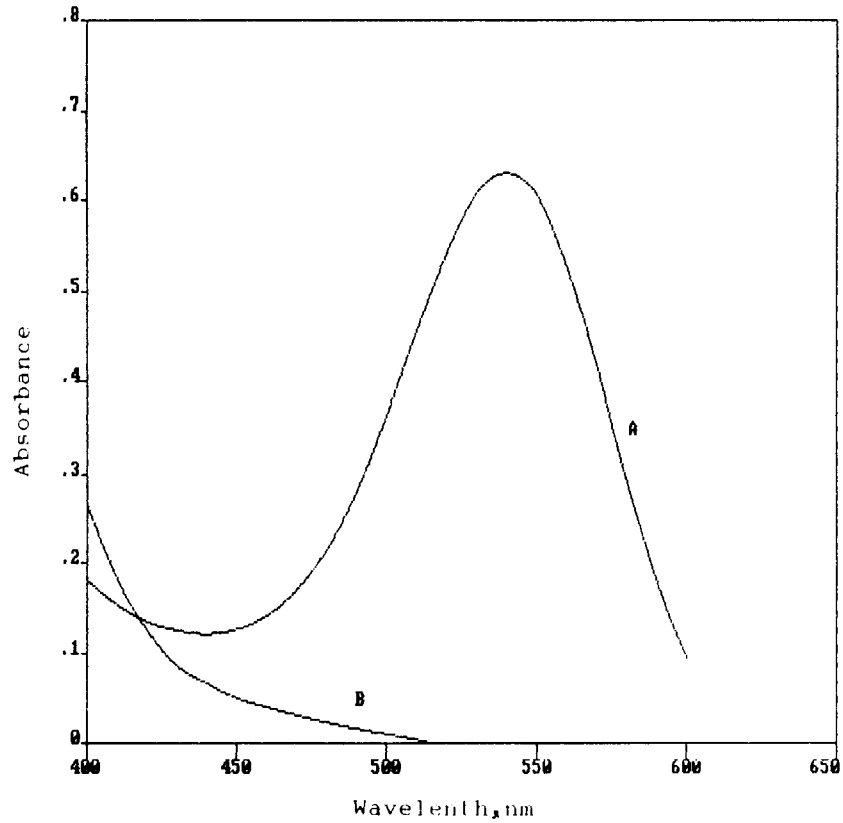

Fig. 1. Absorption spectra of 50 μg of 1-naphthylamine/25 ml measured against: (A) blank; (B) blank against distilled water.

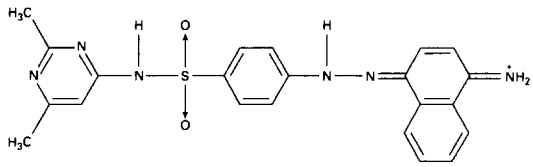
### 3.15. Nature of the dye

The composition of the colored azo dye has been established using Job's method of continuous variation. The results indicate that the dye has been obtained by a 1:1 combining ratio of diazotized sulfisomidine to 1-naphthylamine, revealing a mono azo dye. 1-Naphthylamine couples with diazonium salts at the 4-position, and the structure of the azo dye may be written as follows:



The apparent stability constant has been calculated [18] and is found to be $3.3 \times 10^4$.

### 3.16. Effect of organic solvents

Basic solvents cause hypsochromic shift and sensitivity decrease. Water is shown to be a good medium from the points view of sensitivity and economy. Common immiscible organic solvents only partially (if at all) extract the colored azo dye.

### 3.17. Interferences

In order to assess the possible analytical applications of the present proposed method, the interfering effects of foreign substances (organic and inorganic) at various levels on the determination of 50 μg of 1-naphthylamine by the recommended method have been examined, and the results are given in Table 2.

From the data given in Table 2, it can be observed that some compounds exist that can interfere with the analyte. However, extraction or chromatography can successfully remove these interferences.

### 3.18. Application of the method

*Determination in river water*

1-Naphthylamine may find its way into river water through the discharge of some dye factories. The results for the determination of the compound are shown in Table 3.

Table 2
Effect of foreign compounds on the determination of 50 μg of 1-naphthylamine

| Interferent | Form added | Minimum tolerable amount [a] (μg) |

Received 7 October 1994; revised 31 January 1995; accepted 3 February 1995

**Abstract**

A new functional resin with a long functional side chain was synthesized by modification of aminated macroporous poly(vinyl chloride) resin with cyanoethylene and ethylenediamine. Traces of Au(III), Pt(IV) and Pd(II) in aqueous solution were quantitatively adsorbed in the acidity range of pH $\leqslant 4$ and $C_{H^+} \leqslant 3$ M. The rate of equilibration is high; $Cu^{2+}$, $Fe^{3+}$, $Ni^{2+}$, etc. exhibit little interference on the adsorption of the sought noble metals. The saturated adsorption capacities for Au(III), Pt(IV), Pd(II) and Ir(IV) in 2 M HCl were $\geqslant 4.0$, 1.57, 2.26, 1.85 mmol $g^{-1}$. Adsorbed ions can be quantitatively desorbed by 4% thiourea + 0.25 M $H_2SO_4$. The resin has good reusability, and can be used for preconcentration and separation of Au(III), Pt(IV) and Pd(II) prior to their determination by ICP-AES with satisfactory results.

## 1. Introduction

Adsorption methods are widely used and are the most effective methods for preconcentration and separation of noble metal ions from aqueous solution. Many different adsorbents have been used in this respect [1–8]. However, the mechanisms of adsorption of noble metals are not well defined because of the complication of the form of these elements in aqueous solution. Optimization of the adsorption conditions is also difficult [9]. To date, although a wide variety of different adsorbents used for preconcentration and separation of noble metal ions prior to their determination have been described, the methods do not meet all analytical requirements [3]. In general, adsorption of noble metal ions onto chelating adsorbents takes place on prolonged shaking or heating, owing to their low rate of ligand exchange [10]. Meanwhile, the desorption of these ions is difficult for many adsorbents. In analytical procedures these adsorbents have to be destroyed by ashing at high temperature or heating with a perchloric–sulfuric acid mixture to recover the adsorbed elements [11]. It is valuable to synthesize novel adsorbents with high selectivity, high adsorption rate, and from which adsorbed metal ions can be readily desorbed. We attempt to improve the kinetic characteristic of the adsorbent by increasing the chain length between the macromolecular network and functional groups. This can increase the flexibility of the sidechain which contains the functional group and improve the access of metal ions to the functional groups.

According to Myasoedova et al. [11], functional resins containing nitrogen-heterocyclic groups are highly selective for noble metals. In this work, a macroporous adsorbent which has a long functional sidechain is synthesized. The selectivity of this adsorbent for Au(III), Pt(IV)

* Corresponding author. (ZR-94-004).

*SSDI* 0039-9140(95)01553-1

and Pd(II) is high. Desorption of these ions from the adsorbent is easy. The adsorbent can be successfully applied to the determination of Au, Pt and Pd in a sample.

## 2. Experimental

### 2.1. Instrumentation and reagents

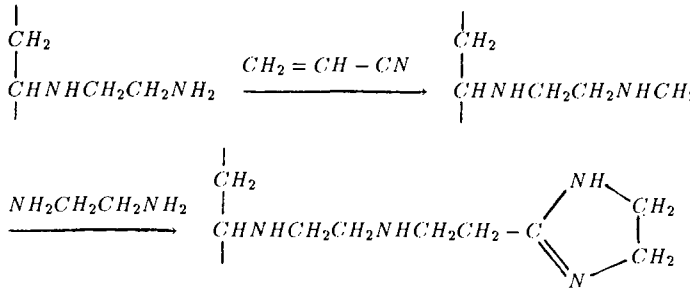
An ICP 6500 inductively coupled plasma optical emission spectrometer (Perkin-Elmer), a Nicolet 170-SX Fourier transform-infrared (FT-IR) spectrometer, a Model pHs-2 precision pH-meter (the second Analysis instrument factory at Shanghai, China) were used. The sorption column was a glass tube (4.5 mm i.d., 10 cm length) in which a small pad of cotton-wool had been placed beforehand. A stock solution of Au, Pt, Pd, Ir and Ru was prepared by dissolving spectroscopically pure $HAuCl_4 \cdot 2H_2O$, $(NH_4)_2PtCl_6$, $PdCl_2$, $(NH_4)_2IrCl_6$, and $(NH_4)_2RuCl_6$ in dilute HCl. All other reagents were analytical grade. Demineralized distilled water was used for preparing aqueous solutions.

### 2.2. Synthesis of adsorbent

The macroporous cyanoethylamino resin (CEA) was synthesized as described previously [12].

Imidazolinyl ethyl amino resin (IEA) was prepared by the following procedure. Twenty grams of CEA, 50 ml ethylene diamine, 40 ml toluene and a little amount of sulfur powder were added to a 250 ml three-necked flask with a reflux condenser, a thermometer, and an agitator. The mixture was refluxed for 7 h. The resulting product was filtered. After washing with ethanol several times the resin was extracted with 75% ethanol until the extract was colorless. The product was dried at 80 °C under vacuum for later use. The nitrogen content of IEA was 11.96%.

The synthetic route of the IEA can be described schematically as



### 2.3. Determination of equilibration rate

Sixty milliliters of 2 M HCl containing Au(III), Pt(IV), and Pd(II) (50.0 μg of each) was added to a vessel fitted with a glass stopper. 0.1 g of IEA resin was added, and the vessel was shaken for the necessary time on a mechanical vibrator. The supernatant was decanted immediately. The metal ions in supernatant were determined by ICP-AES (forward power 1100 W; viewing height 17 mm; argon plasma gas flow rate 14 l $min^{-1}$, argon auxiliary gas flow rate 0.4 l $min^{-1}$, argon nebulizer gas flow rate 1.0 l $min^{-2}$, wave length Au 242.795, Pt 214.423, Pd 229.651, Ir 224.268, Ru 240.272 nm). The rate of adsorption at different shaking times was calculated.

### 2.4. Adsorption procedure

IEA resin (0.1 g) which had been soaked in distilled water for 24 h was loaded into the sorption column and washed with HCl of the same concentration as that in the test solution. The test solution (60–100 ml) was then passed through the column at 0.5–1.0 ml $min^{-1}$, and the resin bed was washed with about 5 ml HCl of the same concentration. The solution which passed the column was evaporated to about 5 ml, transferred into a 10 ml volumetric flask, and diluted to the mark with distilled water. The metal ions in the solution were determined by ICP-AES. The efficiency of adsorption was calculated using $S\% = [(a - CV)/a] \times 100\%$, where $a$ is the initial amount of the metal ion in the test solution (μg) $C$ is the concentration of metal ion in volumetric flask (μg $ml^{-1}$), and $V$ is the volume of volumetric flask (ml).

Adsorbed Au(III), Pt(IV) and Pd(II) were desorbed with preselected eluant and transferred into a 10 ml volumetric flask, diluted to the mark. Metal ions were determined by ICP-AES. Recovery was calculated.

### 2.5. Metal adsorption capacities

A batch equilibrium technique was used to determine metal adsorption capacities. Ten milligrams of IEA resin was added to each of four vessels with glass stoppers. Ten milliliters of 2 M HCl containing different amounts of Au(III) was added to each vessel. These vessels were then shaken on a mechanical vibrator for 10 h. A portion of supernatant was removed and the metal ion was determined by ICP-AES. The adsorption capacity of Au(III) was calculated. The adsorption capacities of Pt(IV), Pd(II) and Ir(IV) were determined by same procedure.

### 2.6. Analysis of sample

A 0.2 g smelter sample was added to a nickel crucible containing a 0.5 g $Na_2CO_3$ and 1.5 g $Na_2O_2$ mixture, and was covered with a little amount of $Na_2CO_3$–$Na_2O_2$ mixture. The sample was then fused in an electric muffle at 700 °C for 10 min. After cooling, it was dissolved in hot water and transferred into a beaker. Conc. HCl was added to adjust the acidity. The solution was boiled for 30 min, and then filtered. The residue and filter paper were washed with 2 M HCl several times. Au, Pt and Pd were adsorbed, and determined following the above procedure.

The standard nickel alloy reference sample (102-A-7) was analyzed following the same procedure after being dissolved in aqua regia.

## 3. Results and discussion

### 3.1. Solution acidity

Fig. 1 shows the effects of pH and acidity on the adsorption of Au(III) (0.82 μg $ml^{-1}$), Pt(IV) (0.86 μg $ml^{-1}$), Pd(II) (0.92 μg $ml^{-1}$), Ir(IV) (1.17 μg $ml^{-1}$) and Ru(IV) (1.00 μg $ml^{-1}$). Pd(II) could be quantitatively adsorbed by the IEA resin at pH ≤ 6.0 and $C_{H^+} \leq 6$ M, Au(III) at pH ≤ 4.0 and $C_{H^+} \leq 6$ M, Pt(IV) at pH ≤ 6.0 and $C_{H^+} \leq 3$ M, and Ir(IV) at pH ≥ 2.

### 3.2. Extraction time

Under batch conditions, the degree of adsorption in 2 M HCl was determined after shaking for between 2 min and 4 h. A quantitative adsorption of microquantities of Au(III), Pt(IV) and Pd(II) was reached in 2 min. The high rate of equilibration may be due to the high flexibility of the functional group and the hydrophilicity of the sidechain. These properties of the adsorbent enabled the ions in aqueous solution to readily approach the functional group.

### 3.3. Desorption conditions

Thiourea and mineral acid mixtures of different concentrations were used as eluants after Au(III), Pt(IV) and Pd(II) had been adsorbed by the IEA resin. The results showed that 4% thiourea + 0.5 M mineral acid could quantitatively desorb the above metal ions. Figs. 2 and 3 show the desorption curves of 4% thiourea + 0.5 M HCl and 4% thiourea + 2% $H_2SO_4$ + 1% KSCN as eluants. Multiple experiments showed that 4% thiourea + 0.25 M $H_2SO_4$ was the best eluant. The recovery of Au(III), Pt(IV) and Pd(II) using this eluant was 96.0%, 99.3% and 99.0%, respectively. Because of the high dissolved solid content of the eluant, the recovery values of the single determination were mostly in the 90–110% region. However, the precision is acceptable in the determination of trace amounts of elements. We also found that after the adsorption of the above metal ions, the desorption must be performed immediately. If the time between adsorption and desorption was more than 6 h, the

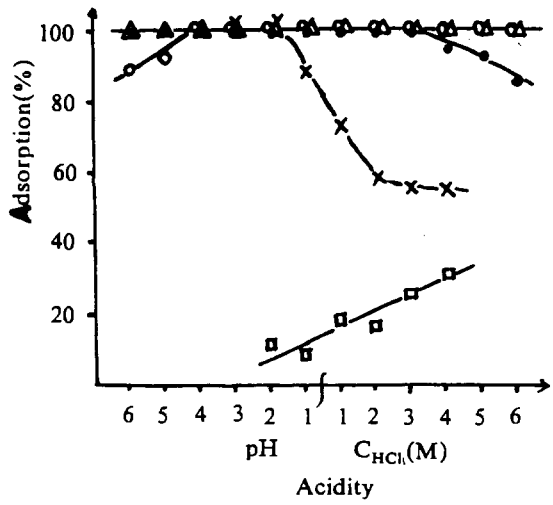


Fig. 1. Effect of acidity on adsorption of 49.4 μg Au(III) (○), 51.6 μg Pt(IV) (●), 55.5 μg Pd(II) (Δ), 70.0 μg Ir(IV) (X), and 60.0 μg Ru(IV) (□) on IEA resin. Solution volume 60 ml, sorbent 0.1 g, flow rate 1.0 ml $min^{-1}$.

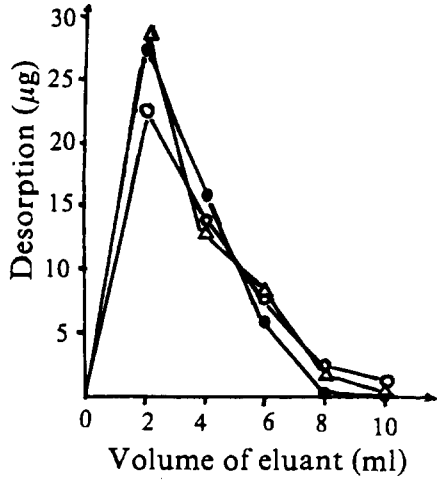

Fig. 2. Desorption curve of 49.4 μg Au(III) (○), 51.6 μg Pt(IV) (●) and 55.5 μg Pd(II) (△) with 4% thiourea + 0.5 M HCl. Sorbent 0.1 g, flow rate 2.0 ml $min^{-1}$.

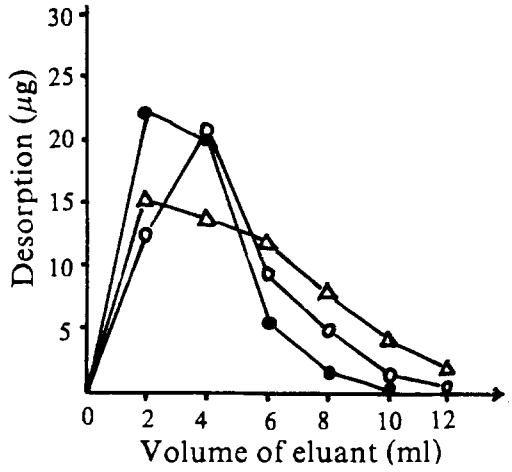

Fig. 3. Desorption curve of 49.4 μg Au(III) (○), 51.6 μg Pt(IV) (●) and 55.5 μg Pd(II) (△) with 4% thiourea + 2% $H_2SO_4$ + 1% KSCN. Sorbent 0.1 g, flow rate 2.0 ml $min^{-1}$.

recovery of Pt(IV) and Pd(II) was less than 90%. If the time was more than a day, only half of Pt(IV) and Pd(II) was desorbed. In addition, determination of Au(III), Pt(IV) and Pd(II) in the eluant by ICP-AES had to be carried out in 2 h. Otherwise, the results would be incorrect, owing to the reduction of these ions by thiourea.

### 3.4. *Effects of accompanying ions*

Table I shows the effects of accompanying ions on the adsorption of Au(III), Pt(IV) and Pd(II) (50.0 μg in 60 ml) by IEA resin. None of these ions caused interference to the adsorption or the determination of Au(III), Pt(IV) and Pd(II). The selectivity of this resin for these noble metal ions is high.

### 3.5. *Adsorption of Au(III), Pt(IV) and Pd(II) from the p.p.b. range*

500 ml of 2 M HCl containing Au(III) 39.6 p.p.b., Pt(IV) 41.2 p.p.b., and Pd(II) 41.4 p.p.b. was passed through 0.1 g of the IEA resin following the above procedure, and was then desorbed with 10 ml 4% thiourea + 0.25 M $H_2SO_4$. The recovery is shown in Table 2.

Au(III) 39.6, Pt(IV) 41.2, Pd(II) 44.4 p.p.b. in 500 ml solution (pH 1.0) containing $Cu^{2+}$, $Fe^{3+}$, $Zn^{2+}$ (100 p.p.m. each), $Ni^{2+}$, $Mn^{2+}$, $Cr^{3+}$, $Ca^{2+}$, $Mg^{2+}$ (10 p.p.m. each) were adsorbed and desorbed following the same procedure. The recovery is also shown in Table 2.

The results showed that at 2 M HCl the recovery of adsorption of Au(III), Pt(IV) and Pd(II) from the p.p.b. range solution was not satisfactory. However, at pH 1.0, in spite of the existence of a large amount of accompanying ions, the p.p.b. range of Au(III), Pt(IV) and Pd(II) could be adsorbed at a high flow rate with acceptable results.

### 3.6. *Stability and reusability of the resin*

In one experiment, Au(III), Pt(IV) and Pd(II) were adsorbed and desorbed following the above procedure, the column was then washed with distilled water until neutral, and another adsorption–desorption cycle was carried out. After 10 cycles of adsorption–desorption, the efficiency of adsorption and recovery of desorption showed virtually no change (Table 3). Thus the stability and reusability of IEA resin is satisfactory.

### 3.7. *Saturated capacity of adsorption*

Fig. 4 shows the results of the determination of the saturated capacity of IEA resin. The amounts of Pt(IV), Pd(II) and Ir(IV) were 1.57, 2.26 and 1.85 mmol per gram of dry resin, respectively. However, Au(III) did not reach saturated adsorption until 8.19 mg Au(III) in solution. This was due to the reduction of Au(III) to Au(0). In these experiments, after the vessels containing Au(III) solution and IEA resin were shaken for several hours, a powder with a golden glitter was observed on the bottom of the vessel and on the surface of the resin.

Table 1
Effects of accompanying ions on recovery (%) of 50 μg Au(III), Pt(IV) and Pd(II)

| | Accompanying ion (mg) | | | | | | | |
|---|---|---|---|---|---|---|---|---|

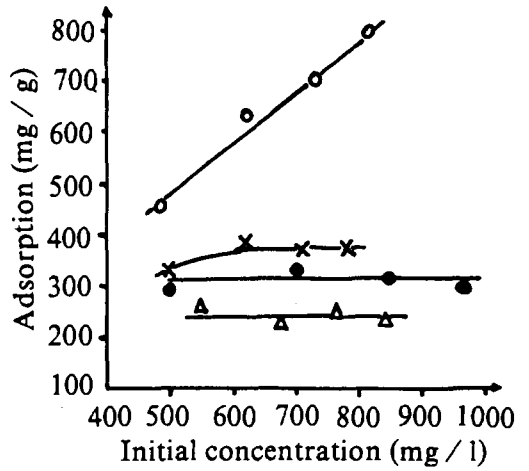

Fig. 4. Effect of concentration on capacity of adsorption of IEA resin for Au(III) (○), Pt(IV) (●), Pd(II) (△) and Ir(IV) (X). Solution volume 10 ml, sorbent 10 mg, shaking time 10 h.

### 3.8. Analytical application

Au, Pt and Pd in a sample from a smelter and a standard nickel alloy reference sample were adsorbed and determined by the above procedure. The reliability of the procedure for the smelter sample was confirmed by the standard addition method (Tables 4 and 5).

### 3.9. IR spectra of the IEA resin and IEA-Pd

The IR absorption bands of IEA resin alone and saturated with Pd(II) ions (IEA-Pd) were assigned according to Refs. [13–15] (Table 6). Absorption at 2244 $cm^{-1}$ of IEA was due to the unreacted cyanogroup. It disappeared after saturation with Pd owing to hydrolysis. After

Table 3
Effects of adsorption–desorption cycles on adsorption of 49.4 μg Au(III), 51.6 μg Pt(IV) and 55.5 μg Pd(II)

| Cycle | Adsorption (%) | | | Desorption recovery (%) | | |
|---|---|---|---|---|---|---|

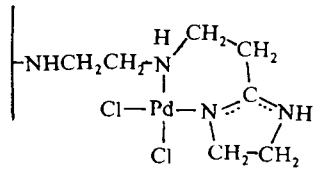
| Pd | 403 ± 4 | 142 | 538 ± 15 | 95.1 | 284 | 687 ± 45 | 100.0 |

[a] Compositions stated by the smelter for the sample were 0.023, 0.066 and 0.040% Au, Pt and Pd, respectively.

Table 5
Results for determination of the standard reference sample (102-A-7) ($n = 3$) ($\mu g\ g^{-1}$)

| Element | Found | Certified |
|---|---|---|
| Au | 136 ± 8 | 144 |
| Pt | 310 ± 9 | 306 |
| Pd | 183 ± 12 | 189 |

Pd(II) was adsorbed by the IEA, the peak at 3251 $cm^{-1}$ of $\nu$(N–H) became broad. The 1660 and 1592 $cm^{-1}$ peaks of $\nu$(C=C) + $\nu$(C=N) shifted to 1625 $cm^{-1}$, and the 1440 $cm^{-1}$ and 755 $cm^{-1}$ peaks of $\delta$(N–H) shifted to 1442 and 760 $cm^{-1}$, respectively. The 1129 $cm^{-1}$ peak of $\nu$(C–N) shifted to 1169 $cm^{-1}$, and the 995 $cm^{-1}$ peak of the skeletal vibration of the heterocycle shifted to 1045 $cm^{-1}$. All of these indicated that the nitrogen atom participated in the coordination. The new peaks at 533 $cm^{-1}$, 271 $cm^{-1}$ and 319 $cm^{-1}$ were due to $\nu$(Pd–N), $\delta$(N–Pd–N) and $\nu$(Pd–Cl) respectively. Accordingly, the structure formed from IEA resin with Pd(II) might be:



or

| – | 319 | $\nu_{Pd-Cl}$ |
| – | 271 | $\delta_{N-Pd-N}$ |

## 4. Conclusion

IEA resin has high adsorption selectivity for Au(III), Pt(IV) and Pd(II). It can quantitatively adsorb these ions over a wide range of acidities. The adsorbed ions can be readily desorbed by a thiourea and mineral acid mixture. The resin also has the advantage of a high rate of equilibration, low interference, large adsorption capacity, high stability and good reusability. Preconcentration by this resin combined with ICP-AES can be reliably applied to the determination of Au, Pt and Pd in mineral samples.

# Spectrophotometric determination of aluminium by morin

M. Jamaluddin Ahmed *, Jamal Hossan

*Laboratory of Analytical Chemistry, Department of Chemistry, University of Chittagong, Chittagong, Bangladesh*

Received 10 November 1994; revised 31 January 1995; accepted 3 February 1995

**Abstract**

A direct spectrophotometric method for the determination of aluminium with morin has been developed. Morin reacts in slightly acidic 50% ethanolic media (0.0001–0.0015 M $H_2SO_4$) with Al to give a deep-yellow chelate which has an absorption maximum at 421 nm. The average molar absorptivity and Sandell's sensitivity were found to be $5.3 \times 10^3$ l mol$^{-1}$ cm$^{-1}$ and 5 ng of Al cm$^{-2}$, respectively. The reaction is instantaneous and absorbance remains stable for 48 h. The colour system obeys Beer's law from 10 ng ml$^{-1}$ to 5.0 μg ml$^{-1}$ of Al; the stoichiometric composition of the chelate is 2:3 (Al:morin). The interference from over 50 cations, anions and complexing agents has been studied at 0.1 μg ml$^{-1}$ of Al. The method was applied successfully to some certified reference material samples (alloys and steels), environmental waters (inland and surface), biological samples (human blood, urine and gallstone), soils and complex synthetic mixtures.

## 1. Introduction

Aluminium has long been considered as virtually non-toxic and non-absorbable from the gastrointestinal tract. More recent studies on humans, however, expose its acute toxicity [1], including impaired memory, convulsions, characteristic EEG changes, uremia, Shaver's disease (lung) [2], Alzheimer's disease (brain) [3] and also increased risks of cancer [4] of the lung and pancreas, and leukaemia. Al at trace and sub-trace levels in the water used for dialysis can cause brain damage, bone disease and anaemia [5]. All these findings cause alarming concern in public health, demanding accurate determination of this metal ion at trace and sub-trace levels.

Miller and Andelman [6] reviewed methods for the determination of Al species in water. Several recently published spectrophotometric methods [7–18] based on use of various reagents are reported for the determination and detection of the metal ion. Some of these methods are not sensitive [10–14] or suffer from interferences [15–18]. The present paper describes a sensitive spectrophotometric method for the determination of Al using morin. The method is based on the selective complexation of the non-absorbent reagent, morin, in slightly acidic medium (0.0001–0.0015 M $H_2SO_4$) with Al to produce a deep-yellow chelate, followed by direct measurement of the absorbance in 50% ethanolic solution.

## 2. Experimental section

### 2.1. Apparatus

A Shimadzu (Model-160) double beam UV/visible recording spectrophotometer and Philips PW 9418 pH-meter with combination electrodes were used for measurements of absorbance and pH, respectively. Biological samples were analyzed for trace amounts of Al by a Perkin-Elmer Model 560 atomic absorption spectrophotometer at 309.3 nm, using a nitrous oxide–acetylene flame.

### 2.2. Reagents and solutions

All the chemical used were of analytical grade of the highest purity available. Triply-distilled ethanol (from lime) and high-purity deionized water, non-absorbent under UV radiation, were used throughout. High-purity water was obtained by passing tap water through a cellulose absorbent and two mixed-bed ion exchange columns, followed by distillation in a Corning AG-11 unit. The Al level in the high-purity water was found to be below the spectrophotometric detection limit (three times the standard deviation of the blank) of 6 ng $ml^{-1}$. Glass vessels were cleaned by soaking in acidified solutions of $KMnO_4$ or $K_2Cr_2O_7$ followed by washing with concentrated $HNO_3$, and rinsed several times with high-purity deionized water. Stock solutions and environmental water samples (1000 ml each) were kept in polypropylene bottles containing 1 ml conc. $HNO_3$.

*Morin solution, $1.35 \times 10^{-3}$ M*

40.27 mg of morin (BDH Chemicals) was dissolved in 100 ml of triply-distilled ethanol. This solution was diluted further as required.

*Al standard solutions*

100 ml stock solution of Al ($3.71 \times 10^{-2}$ M) was prepared by dissolving 1.7582 g of $AlK(SO_4)_2 \cdot 12H_2O$ (Merck analytical grade) in deionized water. Working standard solutions were prepared after suitable dilutions of the stock solution.

*EDTA solution*

100 ml stock solution of EDTA (0.01%) was prepared by dissolving 10 mg of A.C.S. grade

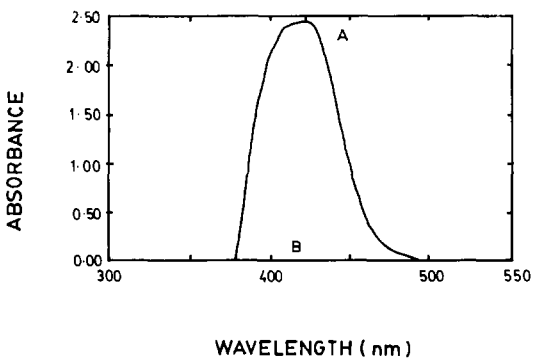

Fig. 1. A and B absorption spectra of the Al–morin system and the reagent blank ($\lambda_{max} = 421$ nm) in 50% ethanolic solutions.

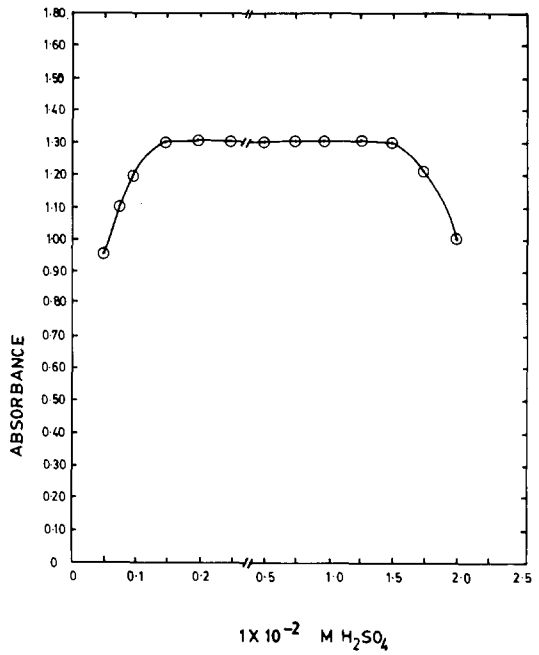

Fig. 2. Effect of acidity on the absorbance of the Al (0.1 μg $ml^{-1}$)–reagent system.

(≥99%) ethylenediaminetetraacetic acid, disodium salt dihydrate in (100 ml) deionized water.

*Tartrate solution*

100 ml stock solution of tartrate (0.01%) was prepared by dissolving 10 mg of A.C.S. grade (99%) potassium sodium tartrate tetrahydrate in (100 ml) deionized water.

*Dilute ammonium hydroxide solution*

A 100 ml solution of dilute ammonium hydroxide was prepared by diluting 10 ml conc. $NH_4OH$ (28–30%, A.C.S. grade) to 100 ml with deionized water. The solution was stored in a polypropylene bottle.

*Other solutions*

Solutions of a large number of inorganic ions and complexing agents were prepared from their water-soluble salts (or the oxides and carbonates in hydrochloric acid); solutions of titanium, zirconium and hafnium were specially prepared from their corresponding oxides (Specpure, Johnson Matthey) according to the recommended procedures of Mukharji [19].

### 2.3. Procedure

To 0.1–1.0 ml of a neutral aqueous (pH 6) solution containing 0.1–50 μg of aluminium in

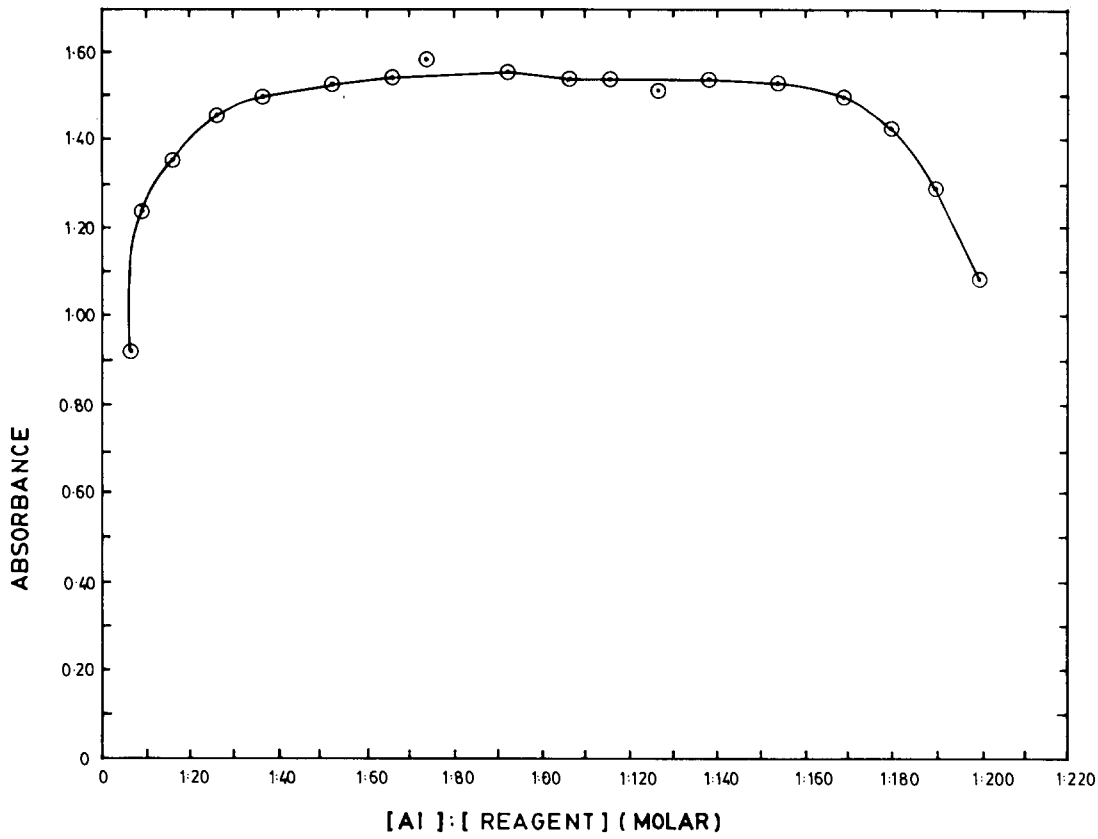

Fig. 3. Effect of the reagent (morin: Al molar concentration ratio) on the absorbance of the Al (0.5 μg $ml^{-1}$)–reagent system.

a 10 ml volumetric flask was added 2.0 ml of $1.35 \times 10^{-3}$ M of the morin reagent solution, followed by the addition 0.2 ml of 0.025 M (0.005 M) sulphuric acid. The solution was mixed well and allowed to stand for 1 min, after which 5 ml of ethanol was added. The mixture was diluted up to the required volume with deionized water. The absorbance was measured at 421 nm against a corresponding reagent blank. A calibration graph was used for unknown samples.

### 2.4. Analytical applications

#### A. Determination of Al in alloys and steels

A 0.1 g amount of an alloy or steel sample containing 3.34–90.5% Al was weighed accurately and placed in a 50 ml Erlenmayer flask. To this was added 5 ml each of concentrated sulphuric and nitric acids, and the mixture was heated gently. 1 ml of perchloric acid (sp. gr. 1.70) was added to the solutions and evaporated until strong fuming occurred. The solution was cooled to room temperature after complete dissolution of the sample. The soluble salts were dissolved in deionized water. The solution was filtered through a Whatman No. 40 filter paper into a 100 ml calibrated flask; the residue (silica and tungstic acid) was washed with a small volume (5 ml) of hot (1:99) sulphuric acid followed by water. The filtrate and washings were collected in the same calibrated flask. The content of the flask was neutralized (pH 6) with dilute $NH_4OH$ in the presence of 1–2 ml of 0.01% (w/v) tartrate and/or EDTA solution, and the volume was made up to the mark with deionized water. An aliquot (1–2 ml) of this solution was pipetted into a 10 ml calibrated flask, and the Al content was determined as described in section 2.3.

#### B. Determination of Al in environmental water samples

Each filtered (through a Whatman No. 40 filter paper) environmental water sample (50 ml) was heated with a mixture of 1 ml conc. $H_2SO_4$ and 2.5 ml conc. $HNO_3$ until sulphur trioxide fumes appeared. After cooling, addition of 2.5 ml conc. $HNO_3$ and heating was repeated until dense white fumes were ob-

served, or until the solution became colourless. The solution was then cooled and neutralized (pH 6) with dilute $NH_4OH$ in the presence of 1–2 ml of 0.01% (w/v) EDTA and/or tartrate solution. It was transferred into a 50 ml volumetric flask and diluted up to the mark with deionized water. 1 ml of the final solution was pipetted into a 10 ml calibrated flask and the Al content was determined as described in section 2.3.

*C. Determination of Al in biological samples*

Human blood (10–20 ml), urine (10–50 ml) or human gallstone (0.1–0.5 g) was added to a 100 ml micro-Kjeldahl digestion flask. A glass bead and 10 ml of conc. $HNO_3$ were added and heated gently on the digester. When the initial brisk reaction was over, the solution was removed and cooled. Conc. $H_2SO_3$ (2.5 ml) was added carefully, followed by the addition of 70% perchloric acid (1 ml); heating was continued until dense white fumes were observed, repeating $HNO_3$ addition if necessary. Heating was continued for at least 30 min, followed by cooling. The content of the flask was neutralized (pH 6) with dilute $NH_4OH$ in the presence of 1–2 ml of 0.01% (w/v) tartrate and/or EDTA solution, transferred quantitatively into a 50 ml volumetric flask and made up to the mark with deionized water. An aliquot (1–2 ml) of the final solution was pipetted into a 10 ml calibrated flask and the Al content was determined as described in section 2.3.

*D. Determination of Al in soil samples*

A 10–20 g amount of air-dried soil sample was weighed accurately and placed in a 100 ml micro-Kjeldahl flask. The sample was digested according to the method recommended by Jackson [20]. The contents of the flask were filtered through Whatman No. 40 filter paper into a 25 ml calibrated flask, neutralized (pH 6) with dilute ammonia and diluted to the volume with deionized water. Suitable aliquots (1–2 ml) were transferred to a 10 ml volumetric flask and the calculated amount of

0.025 M $H_2SO_4$ needed to give a final acidity of 0.0001–0.0015 M was added, followed by 1–2 ml of 0.01% (w/v) tartrate and/or EDTA solution. Al content was then determined as in section 2.3.

## 3. Results and discussion

### 3.1. Development of the method

*Spectral characteristics*

The absorption sepctra of the Al–morin system in 0.025 M $H_2SO_4$ medium was recorded using the spectrophotometer. The absorption spectra of Al–morin as a symmetric curve with maximum absorbance at 421 nm and an average molar absorptivity of $5.3 \times 10^3\ l\ mol^{-1}\ cm^{-1}$ is shown in Fig. 1. The reagent blank exhibited negligible absorbance despite having a wavelength at 421 nm. The reaction mechanism of the present method is as reported earlier [21].

### 3.2. Effect of solvent

Chloroform, benzene, carbon tetrachloride, isobutanol and ethanol were tested as solvents for the system. No absorbance was observed in the organic phase. In 50 ± 2% (v/v) ethanolic medium, however maximum absorbance was observed; hence, a 50% ethanolic solution was used in the recommended procedure.

### 3.3. Effect of acidity

The absorbance was at a maximum and constant when the 10 ml of solution (0.1 $\mu g\ ml^{-1}$)

contained 0.001–0.015 M $H_2SO_4$ at room temperature (25 ± 5°C). Outside this range of acidity, the absorbance decreased (Fig. 2). For all subsequent measurements, 0.2 ml of 0.025 M (0.005 M) $H_2SO_4$ was added.

### 3.4. Effect of time

The reaction is instantaneous. The Al–morin system attained maximum and constant absorbance immediately (within 1 min) after diluting the solution to the final volume, which then remained stable for at least 48 h. A longer period of time was not studied.

### 3.5. Effect of reagent

The excess of reagent is not critical. In tests with 0.5 $\mu g\ ml^{-1}$ Al, the Al/reagent mole ratio was varied from 1:10 to 1:200. Constant maximum absorbance was obtained for mole ratios between 1:40 and 1:170 (Fig. 3). For the different Al concentrations (1 and 0.1 $\mu g\ ml^{-1}$), an identical effect of varying the reagent concentration was noticed.

### 3.6. Calibration graph and Beer's law

Plots of absorbance against Al concentration were linear and passed through the origin for a wide range (10 $ng\ ml^{-1}$ to 5 $\mu g\ ml^{-1}$) of Al concentrations, when different scale expansions were used. The average molar absorptivity and the Sandell's sensitivity [22] were found to be $5.3 \times 10^3\ l\ mol^{-1}\ cm^{-1}$ and 5 ng of Al $cm^{-2}$, respectively.

### 3.7. Precision and accuracy

The precision of the present method was evaluated by determining different concentrations of Al (each analyzed at least five times). Standard deviations in the range 0.001–2.0 for 0.1–50 μg of Al in 10.0 ml were achieved, indicating that this method is highly precise and reproducible. The detection limit (three times the standard deviation of the blank) for Al were found to be 6 $ng\ ml^{-1}$. The reliability of the proposed procedure was assessed by analyzing the Bureau of Analyzed Samples (Table 2) and a series of synthetic mixtures of various compositions (Table 1). Note from Table 2 the good agreement for Al found with the certified values. A few synthetic mixtures of various compositions containing Al and diverse ions of known concentrations were determined by the present method using tartrate and/or EDTA as masking agents, and the results (Table 1) were found to be highly reproducible. The reliability of our procedure was also tested by doing recovery studies. The average recovery obtained for the addition of Al spikes to some environmental water samples was quantitative, as shown in Table 3. The results of the analysis of biological samples by our procedure were found to be in excellent agreement with those obtained by an atomic absorption spectrophotometric method, as shown in Table 4. Hence, the precision and accuracy of the method were found to be excellent.

### 3.8. Effect of foreign ions

More than 50 anions and cations were studied individually to investigate their effect on the determination of 0.1 $\mu g\,ml^{-1}$ of Al. The criterion for an interference was an absorbance value varying by more than 5% from the expected value for Al alone [23]. There was no interference from the following: 1000-fold amounts of tartrate, nitrate, sulphate, citrate, fluoride, bromide, oxalate, alkali metals or acetate; 500-fold amounts of azide, chromium(III), cerium(IV), magnesium, barium or sulphide; 100-fold amounts of tin (II and IV), silver(I) cadmium, manganese(II), bismuth, chromium(VI), copper(II), strontium, vanadium(V), molybdenum(VI), selenium(IV and VI), arsenic(III), uranium(VI) or EDTA. Sodium tartrate prevented the interference of a 100-fold amount of lead(II), iron(II and III), zinc, nickel(II), calcium, mercury(II), tungsten(VI), chloride or cyanide, A 50-fold excess of thiocyanide and thiourea have been tolerated. Interference from persulphate, permanganate or hydrogen peroxide was removed simply by using sodium azide and boiling the solution.

### 3.9. Nature of the complex

Job's method [24] of continuous variation and the molar-ratio [25] method were applied to ascertain the stoichiometric composition of the complex. A 2:3 (Al:morin) complex was indicated by both the methods.

### 3.10. Comparative study

The method is rapid, simple, sensitive and reproducible. It is well suited for routine analysis of trace amounts of Al.

### 3.11. Applications of the method

The proposed method was used to determine the Al content of a series of synthetic environmental samples to test its general/specific applications. The method was also applied to the determination of the Al content in a number of standard samples (alloys and steels), environmental waters (inland and surface), biological samples (human gallstone, blood and urine), and soil samples. In view of the unknown composition of the environmental water samples, the same aliquots were analyzed for their aluminium content, both "spiked" and "unspiked". The mean error and standard deviations for each series of determination were calculated.

A few synthetic mixtures of varying composition containing Al and diverse ions of known concentrations were determined by the present method using tartrate and/or EDTA as masking agents, and the corresponding results are given in Table 1. The reliability of the proposed method was assessed by analyzing the Bureau of Analyzed samples and the corresponding results are shown in Table 2. The analysis of water from various sources for Al is shown in Table 3. The high values for treated waters are probably due to leakage and/or excess addition of alum used as a flocculant in the water-treatment plants. The occurrence of such high values of Al content are also reported in the treated waters of some developed countries [26]. The results of the analysis of biological samples by our procedure were found to be in excellent agreement with those obtained by atomic absorption spectrophotometric methods and are shown in Table 4. The average value of Al in ten different surface soil samples of Bangladesh was found to be 8.5 $\mu g\,ml^{-1}$. The method is very reliable, and the concentration in the $ng\,g^{-1}$ range in 50% ethanolic medium at room temperature ($25 \pm 5$ °C) can be measured in a very simple and rapid way for routine analysis of Al.

## Acknowledgements

The authors acknowledge the gift of some standard samples by Professor B.K. Pal of Jadavpur University, Calcutta, India. We are specially indebted to the authorities of Chittagong Medical College Hospital for their generous help in supplying biological samples. The authors thank Mr. S.M, Amjad Hossain, Deputy Chief Chemist, CUFL, Chittagong for analyzing the biological samples by AAS.

# Determination of strontium at low concentration levels by flame atomic absorption spectrometry associated on-line with continuous coprecipitation preconcentration

Soulin Lin *, Chunsung Zheng, Houjin Zu

*Department of Applied Chemistry, China University of Geosciences, Wuhan 430074, People's Republic of China*

Received 2 August 1994; revised 26 January 1995; accepted 3 February 1995

**Abstract**

A sensitive method for the determination of strontium has been developed. In this work strontium was determined by flame atomic absorption spectrometry using a continuous copreconcentration dissolution procedure based on the formation of lead sulfate followed by elution with hot EDTA solution. Manifold parameters and chemical conditions are described in detail. A concentration factor of up to 61 can be achieved at a sampling rate of 20–30 $h^{-1}$. The detection limit for strontium was 0.9 ng $ml^{-1}$ ($3\sigma$) and the relative standard deviation was 3.5% ($n = 8$) at a concentration level of 100 ng $ml^{-1}$.

## 1. Introduction

It is a matter of fact that the absorption signal for strontium in the air–acetylene flame is depressed in the presence of Al, Si, Ti or phosphates and these effects can be minimized by the addition of releasing agents. In early work reported on the determination of this element with flame atomic absorption spectrometry (FAAS), lanthanum [1] or calcium [2], 8-hydroxyquinoline and lanthanum [3], and EDTA and lanthanum [4] were used to suppress interferences in the air–acetylene flame. Ion exchange procedures were employed by Hofer [5] and David [6] to separate strontium from matrix components for the analysis of phosphate rocks and biological materials respectively. Curnow et al. [7] have reported a method for the determination of strontium. In the method described by these authors, strontium was coprecipitated with calcium oxalate, the precipitate was dissolved in hydrochloric acid and lanthanum chloride was added prior to nebulization. Other than FAAS, methods using spectrophotometric detection have been reported [8,9]. In these methods simultaneous determinations of magnesium and strontium [8], and calcium and strontium [9] were carried out with flow injection (FI) differential kinetic analysis. The determinations were carried out at 40 $h^{-1}$ and the injected sample volumes were 25–250 µl. No detection limits and precision values were reported.

Recently, Gong [10] reported a method for the determination of strontium in rocks. Strontium was coprecipitated with lead sulfate, the precipitate was centrifuged, then dissolved in hot EDTA solution and finally nebulized into the air–acetylene flame. The author claimed that satisfactory results can be obtained with the proposed separation procedure. However, this procedure is laborious and time consuming.

Since 1987, there have been several reports involving the use of on-line precipitation techniques in the FI literature. In 1987, Valcarcel and co-workers published their first paper on the use of on-line precipitation which dealt

(a) Preconcentration position; (b) elution position.

with the separation and preconcentration of lead [11]. In their work, lead in tap water was determined by precipitation with ammonia. A sintered stainless steel filter for solvent filtering in HPLC was used to trap the precipitate, which was then dissolved in a stream of nitric acid to give a transient signal. The technique has also been applied to the determination of copper [12] and cobalt [13] in silicate rocks with dithiooxamide and 1-nitroso-2-naphthol, respectively. In a recent report, the use of disposable membrane filters has been suggested by Tyson and co-workers [14] for the retention of the precipitates of calcium (as oxalate) and copper (as hydroxide). Recently, Fang et al. [15] demonstrated the merit of coprecipitation, which expands the scope of precipitation for separation and preconcentration. This brings the possibility that other sample components and those added externally could aid the collection of analyte species by various processes of coprecipitation. In the paper reported by these authors, the precipitate was collected in an open knotted tube reactor for the determination of lead by coprecipitation with iron(III) by hexamethylene ammonia hexamethylene dithiocarbamate.

In an attempt to improve the performance and to automize the procedure for strontium described above, we have designed a flow system for con-tinuous coprecipitation preconcentration in combination on-line with atomic absorption measurement. In this work, a demountable Perspex glass column with a disposable piece of silk fabric as the filter screen was constructed. The performance of the silk fabric filter is demonstrated by the alleviated pressure in the manifold as well as the rather good precision.

## 2. Experimental

### 2.1. Apparatus and reagents

The flow injection system used was an IFIS-A intelligent flow injection sampler (XIAN Spring Institute, China) comprising an eight-channel rotary injection valve and two three-channel peristaltic pumps. A WFX-1A atomic absorption spectrometer (Beijing Second Optical Instrument Factory, China), a strip chart recorder (PM 8251, Philips, U.K.) and a Sr hollow cathode lamp with an operating current of 6 mA were employed. A fuel-rich air–acetylene flame and a spectral bandpass of 0.2 nm were adopted in all the experiments.

The manifold described in this paper (Fig. 1) has been designed to minimize the dead volumes of the filter and the coils. All transport tubes are of 1.06 mm i.d. Teflon tubing. The heating coil (HC) was made by winding 40 cm of Teflon tubing into coils 30 cm in diameter and placing them in a Thermostat (95 °C).

The construction of the filter is shown in Fig. 2. The demountable column jacket is made of Perspex glass. The total volume of the column is 100 μl (φ2 mm × 32 nm) and is divided by the disposable silk fabric screen. In order to decrease the dispersion of analyte species, the

position of the screen is arranged such that the downstream part of the column for elution is as short as possible. Any super quality silk fabrics with a pore size of approximately 150 μm available in the market may serve as the filter screen.

All reagents are of analytical grade. Water from subboiling distillation was used throughout.

To prepare 10% lead acetate solution, 2.5 g of lead acetate are dissolved in water, 1.5 ml of glacial acetic acid are added and the solution is diluted to 250 ml with water. This solution is diluted further to give a working solution of 2000 μg $ml^{-1}$ of lead. For preparing Sr standard solution, 1.685 g of strontium carbonate are dissolved in a suitable amount of hydrochloric acid, the solution is made up to 80 ml with the same acid, and the resulting solution is transferred to a 1000 ml volumetric flask and is diluted to the mark with water; 1 ml equals 1 mg of strontium. This solution is diluted successively to give a standard series for calibration. Eluting solution, 5% EDTA plus 1% KH phthalate plus 1% NaOH; analytical solution, sample or standard solution plus 0.2% sulfuric acid plus 20% ethanol; wash solution, 2% ammonium sulfate.

### 2.2. Manifold program and time cycle

The manifold program and the time cycle of determinations are shown in Tables 1 and 2, respectively. Values of flow rate corresponding to pump speeds higher than 40 rev $min^{-1}$ can be obtained by extrapolation.

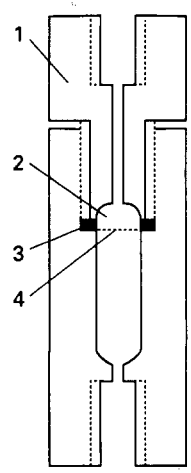

Fig. 2. Construction of the filter. (1) Perspex glass column; (2) cavity; (3) seal ring, (4) silk fabric screen.

Table 1
Manifold program

| Variable | Step | | | | | |
|---|---|---|---|---|---|---|

| Flow rate (ml $min^{-1}$) | 0.35 | 0.72 | 1.4 | 2.1 | 2.8 |

### 2.3. Procedures

*Effect of sulfuric acid concentration*

A series of standard solutions containing the same amount of Sr (200 ng $ml^{-1}$), the same amount of ethanol (20%) and different amounts of sulfuric acid (0.5, 1.0, 2.0, 3.0%) at a pump speed of 50 rev $min^{-1}$ were merged with a solution of 2000 μg $ml^{-1}$ of Pb at a pump speed of 10 rev $min^{-1}$. The dissolving solution stream was 5% EDTA at a pump speed of 82 rev $min^{-1}$.

*Effect of EDTA concentration*

By using the same Sr standard solution of 1% sulfuric acid and flow conditions as were used for investigating the sulfuric acid concentration, the dissolving EDTA solution was varied over a number of concentrations in the range 1–9% at 1% intervals. The dissolving solution was 5% EDTA.

*Effect of pump speed of the sample solution*

With the same dissolving solution at a pump speed of 82 rev $min^{-1}$ and a Sr standard solution of 1% sulfuric acid, the pump speed of the sample solution was varied in the range 40–60 rev $min^{-1}$ at 5 rev $min^{-1}$ intervals.

*Effect of pump speed of EDTA solution*

By using the same solutions as were used for the investigation of the pump speed of the sample solution, the pump speed of the EDTA solution was varied in the range 70–100 rev $min^{-1}$ at 10 rev $min^{-1}$ intervals.

Table 2
Time cycle for determination

| Time (s) | Function |
|---|---|
| 0–15 | PA stops, PB goes, V turns to position a. Wash RC and COL with water. |
| 16–17 | PA and PB stop. Replace water with sample solution. |
| 18–22 | PA and PB go. Rapidly propel water out of RC and COL with the sample and lead acetate solutions. |
| 23–142 | PA and PB go. Start of preconcentration. The precipitate is formed at the confluence point and is subsequently trapped by the filter screen. |
| 143–157 | PA goes, PB stops. V turns to position b. Wash the precipitate with ammonium sulfate. |
| 158–177 | PA stops, PB goes, V remains in position b. Start of elution by flushing a stream of eluting solution. The eluent is propelled into the nebulizer for atomic absorption measurement. |

Key: PA, pump A; PB, pump B; V, valve; RC, reaction coil; COL, column.

*Sample preparation*

*Tea.* Weigh out 0.4 g of the dried sample into a porcelain crucible, ash at 600 °C for 15 min. Dissolve the residue with nitric acid and extract with water. Transfer to a 50 ml volumetric flask, add 10 ml of 5% sulfuric acid and 10 ml of ethanol. Dilute to the mark with distilled water.

*Mineral water.* Pipette 10 ml of the water sample into a 25 ml volumetric flask, and add 5 ml of 5% sulfuric acid and 5 ml of ethanol. Dilute to the mark with distilled water.

*Rock.* Weigh out 0.1 g of the rock sample into a PTFE crucible, and wet with water. Add 0.5 ml of perchloric acid, 5 ml of hydrofluoric acid and 1 ml of hydrochloric acid. Heat on a hotplate to produce copious fumes of perchloric acid. Continue heating until no more fumes appear. Add 1 ml of hydrochloric acid to dissolve the residue and transfer to a 50 ml volumetric flask. Add 10 ml of 5% sulfuric acid and 10 ml of ethanol, and dilute to the mark with distilled water.

## 3. Results and discussion

### 3.1. Optimization of chemical conditions

The selection of the sulfuric acid concentration and the corresponding pump speed are shown in Fig. 3. We can see from the upper curve that a lower concentration (1%) of sulfuric acid gives a higher sensitivity. This can probably be attributed to the formation of finer particles of lead sulfate that are readily dissolved in hot EDTA at this concentration. We used a higher pump speed (50 rev $min^{-1}$) for sample solutions and a lower pump speed (fixed at 10 rev $min^{-1}$) for the lead ions so that a high ratio of strontium to lead, and thus higher sensitivity, can be obtained.

The influence of lead ion concentration on the absorption sensitivity has been studied. As is evident from Fig. 4, it was found that the lead concentration was not critical provided that it was held in the range 1800–2200 μg $ml^{-1}$; 2000 μg $ml^{-1}$ would be the best choice.

Experimental results showed that the absorption sensitivity reached a maximum value and

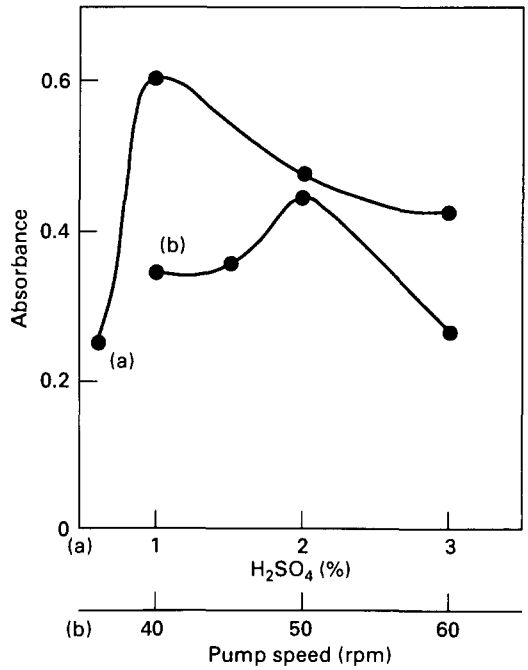

Fig. 3. Effect of $H_2SO_4$ concentration and the corresponding pump speed on the absorption sensitivity. (a) Sr 200 ng/ml, Pb 0.2% (at a fixed pump speed of 50 rpm) and ethanol 20%. (b) Sr 200 ng/ml, Pb 0.2%, $H_2SO_4$ 1% and ethanol 20%.

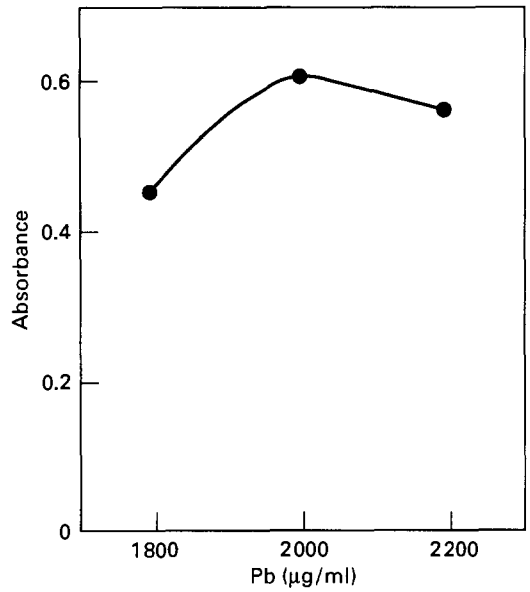

Fig. 4. Effect of Pb concentration on the absorption sensitivity. Sr 200 ng/ml, $H_2SO_4$ 1% and ethanol 20%.

remained constant over a wide range of EDTA concentrations at levels of greater than 5%. In order to avoid the introduction of an excess amount of dissolved solids and to prevent the nebulizer from possible clogging, a concentration of 5% was selected throughout.

The temperature of the EDTA solution is a very critical factor. Lead sulfate can dissolve rapidly in EDTA solution at temperatures higher than 90 °C, while at lower temperatures lead sulfate dissolves much more slowly, yielding a broad signal and much lower peak height.

### 3.2. Interference study

In order to examine the effectiveness of the separation procedure, studies of the effects of coexisting ions have been carried out. With the optimized chemical and flow conditions, no suppression of the absorption signal for 200 ng $ml^{-1}$ of Sr by the following ions (μg/ml) was observed: Al, 100; Ca, 100; Fe, 100; Mg, 100; Si, 20; Ti, 20.

Two reagents were used to improve the analytical performance. Firstly, the sample solutions were made alcoholic by the addition of 20% ethanol to reduce the solubility product of lead sulfate and to accelerate the formation of the precipitate; and secondly, 1% of KH phthalate was added to the eluting solution to eliminate residue interferences, if any [10]. It was shown that KH phthalate was very effective for this purpose. However, the reaction mechanism is not quite understood at present.

### 3.3. Manifold parameters

As lead sulfate was quickly dissolved in EDTA solution at elevated temperature (95 °C), a higher pump speed for the EDTA solution was therefore preferred. This was consistent with the plot in Fig. 5. Nevertheless, the selection of the pump speed was very critical in that it caused a rapid decrease of the absorption signal at values greater than 82 rev $min^{-1}$. The reason was very likely due to the fact that the response of the recorder lagged behind the instantaneous signals.

The absorption sensitivity depends on the preconcentration time, as shown in Fig. 6. A compromise should be made between the two parameters for the concentration levels of interest.

### 3.4. Calibration graph

Calibration graphs were constructed by using Sr standards of 0, 50, 75, 100, 200 ng $ml^{-1}$and 0, 500, 1000, 2000, 3000, 4000 ng $ml^{-1}$ with and without preconcentration, respectively. The data were fitted by the linear equation $y = ax + b$, where $y$ is the peak height in absorbance units and $x$ is the concentration of strontium in nanograms per milliliter. The resulting equations were $y = 2.54 \times 10^{-3}x + 0.003$ (with preconcentration) and $y = 4.70 \times 10^{-5}x + 0.001$ (without preconcentration). The correlation coefficients were 0.998 and 0.997, respectively.

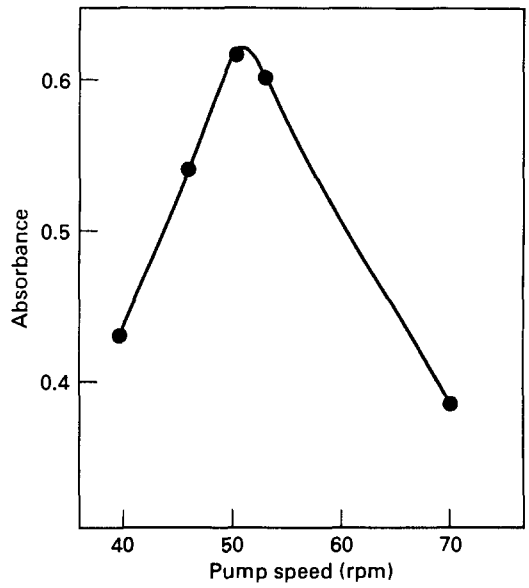

Fig. 5. Effect of pump speed of EDTA on the absorption sensitivity. Sr 200 ng/ml and EDTA 5%.

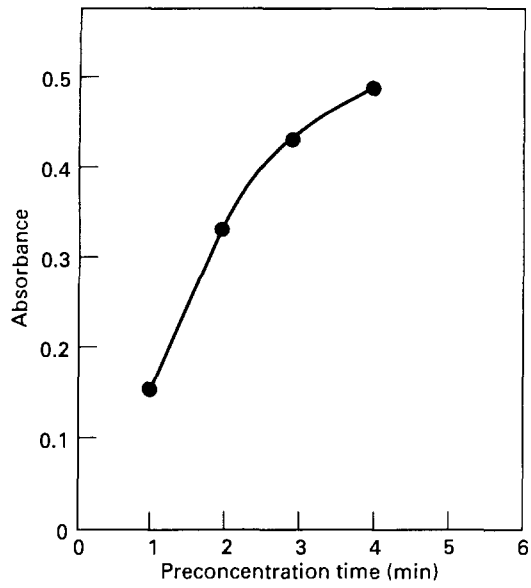

Fig. 6. The absorbance as a function of the preconcentration time. Sr 100 ng/ml, pump speed: 10 rev $min^{-1}$ for sample solutions and 50 rev $min^{-1}$ for Pb.

### 3.5. Sensitivities, detection limits and precision

The analytical performance achieved by the proposed procedure, including sensitivity, detection limit and precision, along with those obtained by direct nebulization, are listed in Table 3. Slopes of the calibration graph were used for comparisons of sensitivities and for calculations of concentration factors. Detection limits were calculated based on $3\sigma$.

### 3.6. Real sample analysis

A variety of samples were analyzed using the proposed procedure to evaluate the reliability and accuracy of the method. Analytical results are listed in Table 4. For rock samples, the analytical data were compared with certified values of standard geological reference materials. For the tea sample, the accuracy was evaluated with a spiked standard and the recovery was satisfactory.

## 4. Conclusion

It has been shown that a simple, inexpensive, disposable and non-metallic filter can be used in a continuous-flow precipitation manifold to collect suspended substances. The FI method described above for the determination of strontium provides a precise and rapid technique that satisfied most of the requirements in routine analysis. An intelligent flow injection sampler equipped with an eight-channel switching/injection valve can serve to control both the precipitation and elution processes automatically.

Table 3
Comparison of analytical performance

| Performance parameter | With preconcentration | Without preconcentration | $S_a/S_b$ | $DL_b/DL_a$ |
|---|---|---|---|---|
| Sensitivity, $A$ (ng $ml^{-1}$) | $2.54 \times 10^{-3}$ | $4.70 \times 10^{-5}$ | 61 | – |
| Detection limit (ng $ml^{-1}$) | 0.9 | 50 | – | 55 |

# Chromium speciation by a surfactant-coated alumina microcolumn using electrothermal atomic absorption spectrometry

Jamshid L. Manzoori *, Mohammad H. Sorouraddin, Farzaneh Shemirani

*Department of Analytical Chemistry, Faculty of Chemistry, University of Tabriz, Tabriz, Iran*

Received 4 November 1994; revised 7 February 1995; accepted 7 February 1995

**Abstract**

A simple and convenient method has been developed for the speciation of chromium(III) and chromium(VI) in aqueous solutions using a sodium dodecyl sulphate coated alumina micro-column (1.5 cm × 5 mm i.d.) and graphite furnace-atomic absorption spectrometry (GF-AAS). Under the optimized conditions (pH 0.6, adjusted with hydrochloric acid; flow rate, 1 ml $min^{-1}$) chromium(VI) is retained on the column and chromium(III) is collected and determined by GF-AAS. Total chromium is directly determined by GF-AAS and chromium(VI) is calculated by difference. The relative standard deviations (10 replicate analyses) at the 20 μg $l^{-1}$ level for chromium(III) and chromium(VI) and at the 40 μg $l^{-1}$ level for total chromium were 1.4%, 3.6% and 1.8%, and the corresponding limits of detection (based on $3\sigma$) were 0.57 μg $ml^{-1}$, 0.61 μg $ml^{-1}$ and 0.35 μg $l^{-1}$ respectively. No large interference effects have been observed from other investigated species and the method has been successfully applied to a range of water samples.

## 1. Introduction

Chromium may exist in many chemical forms and in nature it is usually encountered in the oxidation states III and VI. Chromium(III) probably exists in natural waters in the form of many different species, hydrolyzed, complexed and some even adsorbed on colloidal matter. Such species decompose on the addition of acid, so that in the analysis of water one will have a mixture of anionic chromate and cationic chromium(III) species [1]. Hexavalent chromium finds its way into natural waters, chiefly in the effluents from the electroplating and tanning industries, from dyeing, from sanitary landfill leaching and from water cooling towers [2]. It is well known that each of these oxidation states has very different biological and toxicological properties. Chromium(III) is an essential element for mammals, whereas chromium(VI) is reported to have particularly adverse effects on the lungs, liver and kidneys [3].

A number of papers have described specific analytical procedures for the speciation of chromium ions. However, in spite of the existence of powerful instrumental determination methods, most trace metal analyses performed to date have required some pretreatment of the sample, not only to concentrate the desired trace metals but also to avoid interferences from coexisting elements [4]. Novel combined procedures based on preliminary chelation [5], ion exchange [6,7], solvent extraction [8,9] and electrochemical separation [10] have been developed for the speciation of chromium. All these preconcentration methods introduce additional laborious and time-consuming sample manipulation steps with their associated well-known sources of error. To overcome these problems, an on-line solid sorbent extractions method using a C18 bonded silica reversed-

* Corresponding author.

*SSDI* 0039-9140(95)01556-6

phase sorbent as the column material has been employed for the differential determination of chromium(III) and chromium(VI) in natural waters [11]. A microcolumn of activated alumina in combination with direct current plasma (DCP) [12] or inductively coupled plasma (ICP) [13] atomic emission spectrometry and flame atomic absorption spectrometry [14] has also been used for the sequential determination of chromium(III) and chromium(VI). As a part of our project on trace element determination in environmental samples, we recently described a method for the determination of chromium in serum and lake water samples by electrothermal atomic absorption spectrometry [15]. In this report, a method for the separation and determination of chromium(VI) and chromium(III) using a microcolumn of sodium dodecyl sulphate coated alumina and GF-AAS is described. This method combines the selectivity and separation power of the surfactant-coated alumina with the excellent sensitivity of GF-AAS.

## 2. Experimental

### 2.1. Apparatus

The experiments were performed using a Shimadzu atomic absorption spectrometer model AA 670G with a graphite furnace atomizer GFA-4A, an autosample changer 60G and a graphic printer PR4. A chromium hollow cathode lamp (Hamamatsu Photonics K.K., Japan) and pyrolytic graphite coated graphite tubes were used with sample injection directly onto the tube wall. The sample injection volume was 10 μl in all experiments. The instrumental parameters and temperature programme for the graphite atomizer are listed in Table 1.

### 2.2. Reagents

Analytical reagent-grade chemicals and triply distilled deionized water were used. All glassware was soaked in 5% (v/v) nitric acid for at least 24 h and washed with water.

Alumina powder: alumina (particle size, 10–50 μm; chromatographic grade; Katayama Chemicals, Japan) was purified prior to use by shaking with 5 mol $l^{-1}$ nitric acid, and washing three times with water.

Sodium dodecyl sulphate (SDS): the analytical-grade reagent (Katayama Chemicals) was used without further purification.

SDS-coated alumina: to a 50 ml Erlenmeyer flask were added 1.5 g of alumina, 100 mg of SDS and 50 ml of hydrochloric acid (0.24 mol $l^{-1}$) and the flask was shaken mechanically for 15 min. After this step, the SDS-coated alumina was packed into a microcolumn (1.5 cm × 5 mm i.d.).

Stock solutions of 1000 μg $ml^{-1}$ of chromium(III) and chromium(VI) were prepared from chromium(III) chloride hexahydrate and potassium dichromate, respectively. Working solutions were prepared daily from the stock solutions by serial dilutions with water.

Lake water samples collected from Uromieh Lake, north-west of Iran, were filtered through a 0.45 μm Nucleopore filter prior to storage.

### 2.3. Recommended procedure

A 4 ml portion of sample solution containing chromium(VI) and chromium(III) is transferred to a 10 ml beaker and the pH of the solution is adjusted to 0.6 with 1 mol $l^{-1}$ hydrochloric acid solution. The glass electrode is rinsed with 0.24 mol $l^{-1}$ hydrochloric acid solution and the final volume of the solution is adjusted to 10 ml using 0.24 mol $l^{-1}$ hydrochloric acid solution. The solution is passed through the surfactant-coated alumina with a flow rate of 1 ml $min^{-1}$. The effluent is then collected by suction and chromium(III) is determined by GF-AAS under

the optimized conditions shown in Table 1, using a calibration graph prepared by injecting pure chromium solutions. The total chromium in the sample is directly determined by GF-AAS and chromium(VI) is calculated by difference. In the case of the recovery experiments with spiked water samples (Table 2) total chromium and chromium(III) are determined by GF-AAS using a vanadium(V)–molybdenum(VI) chemical modifier [15].

## 3. Results and discussion

### 3.1. Adsorption of chromium(VI) by SDS-coated alumina

The separation of chromium(III) and chromium(VI) on SDS-coated alumina is attributed to the property of the modified alumina surfaces to adsorb non-ionic compounds in preference to ionic species. Negatively charged SDS is adsorbed on the positively charged alumina surface and forms aggregates know as hemi-micelles or admicelles, which can trap molecules homogeneously. On the addition of a mixture of chromium(III) and chromium(VI) in strongly acidic solutions (HCl; 0.24 mol l$^{-1}$) the latter species, which is in the non-ionic state, is retained quantitatively, while the former species, which is cationic, remains unadsorbed. In the present work an attempt was made to adsorb chromium(VI) on unmodified activated alumina. In spite of the reports of quantitative adsorption of chromium(VI) on alumina at pH 2, no adsorption of chromium(VI) on alumina was observed in aqueous hydrochloric acid medium (0.24 mol l$^{-1}$). This observation indicates the non-ionic nature of chromium(VI), presumably in the form of $H_2CrO_4$ or $HCrO_3Cl$.

In order to avoid chromium(VI) entrapment into the micelles in the aqueous phase, the SDS concentration was fixed at 2 mg ml$^{-1}$, which is below the CMC [16].

### 3.2. Effect of pH

In coating alumina surfaces, the adsorption of SDS on alumina is highly dependent on the solution pH [16]. Negatively charged SDS was more effectively adsorbed on the positively charged alumina surfaces at lower pH values. Almost complete adsorption was achieved at pH 1–4 by shaking SDS solution with alumina for 15 min. The effect of the solution pH on SDS adsorption on alumina is shown in Fig. 1.

In order to study the effect of pH on the adsorption of chromium(VI) on SDS-coated alumina, solutions of different pH in the range 0.0–6.0 containing 50 μg l$^{-1}$ of chromium(VI) were passed through the microcolumn and the percentage of chromium adsorption on the surfactant-coated alumina microcolumn was evaluated. This experiment was repeated for the solutions containing 50 μg l$^{-1}$ of chromium(III). The results are shown in Fig. 2. This figure indicates that at pH 0.6 nearly all the chromium(III) passes through the column while nearly all the chromium(VI) is retained on the column. The decrease in the adsorption of chromium(VI) at pH values greater than 0.8 can be attributed to the transition of chromium(VI) from the non-ionic form to the ionic form, which is not adsorbed on SDS-coated

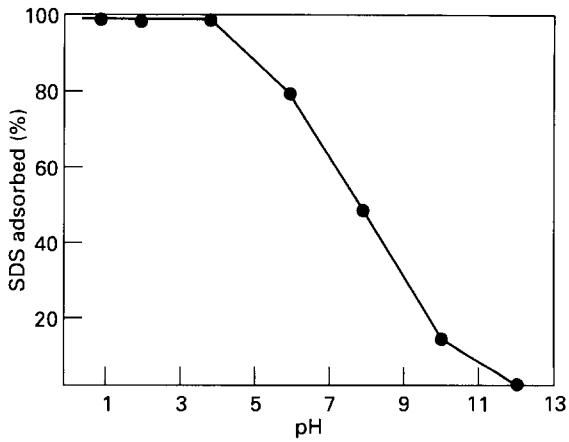

Fig. 1. Effect of the pH on the adsorption of SDS on alumina. (Conditions: 100 mg of SDS and 1.5 g of alumina in 50 ml of hydrochloric acid solution with known pH, mixed for 15 min.)

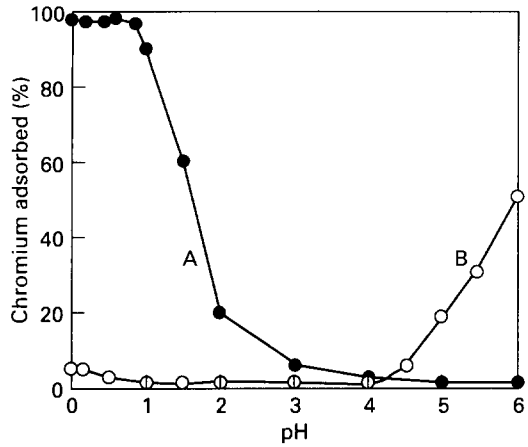

Fig. 2. Effect of the pH on the adsorption of (curve A) chromium(VI) and (curve B) chromium(III) each 50 μg $l^{-1}$ on SDS-coated alumina.

alumina. The increase in the adsorption of chromium(III) at pH values greater than 4.5 is most probably due to the formation of the uncharged $Cr(OH)_3$ species which is easily adsorbed on SDS-coated alumina.

### 3.3. Interference effects

Some experiments were carried out in order to examine the effects of common coexisting ions on the adsorption of chromium(VI) on SDS-coated alumina. In these experiments, solutions of 100 μg $l^{-1}$ of chromium(VI) containing the added interfering ion were treated according to the recommended procedure. The chromium content of the effluents was determined in order to calculate the deposition efficiency of chromium(VI). The tolerances of the coexisting ions, defined as the largest amount yielding a change of less than 5% in the adsorption efficiency of 100 μg $l^{-1}$ of chromium(VI), are given in Table 3. From the results obtained, it can be deduced that the presence of major cations and oxyanions (the most serious interferents on an activated alumina column [14]) have no large influence on chromium(VI) adsorption under the conditions used here.

Table 3
Tolerance limits for coexisting ions in the adsorption of 100 μg $l^{-1}$ of chromium(VI)

| Tolerance limit of ions to Cr(VI) (mg $l^{-1}$) | Coexisting ion |
|---|---|
| 5000 | $K^+$, $Ca^{2+}$, $Mg^{2+}$ |
| 1000 | $Zn^{2+}$, $Cu^{2+}$, $NO_3^-$, $PO_4^{3-}$ |
| 600 | $Mn^{2+}$ |
| 550 | $Al^{3+}$ |
| 500 | $Co^{2+}$, $Fe^{3+}$ |
| 400 | Mo(VI), $SO_4^{2-}$ |

Table 4
Results of chromium(III) and chromium(VI) determinations in synthetic mixtures

| Added (μg $l^{-1}$) | | Found [a] (μg $l^{-1}$) | | |
|---|---|---|---|---|
| Cr(III) | Cr(VI) | Cr(III) | Cr(VI) | Cr (total) |
| 20 | 20 | 20.3 ± 0.3 | 19.9 ± 0.7 | 40.2 ± 0.7 |
| 31 | 21 | 30.6 ± 0.6 | 20.7 ± 0.6 | 51.3 ± 0.8 |
| 22 | 47 | 21.7 ± 0.6 | 48.4 ± 0.7 | 70.1 ± 0.7 |

[a] Average and standard deviation of three determinations

The interferences from high concentrations of matrix ions on chromium(III) and total chromium determinations were overcome by adding vanadium(V) plus molybdenum(VI), 20 μg of each, as chemical modifier.

### 3.4. Calibration, precision and detection limit

The calibration graphs for the determination of total chromium and chromium(III) were both linear up to 100 μg $l^{-1}$ of chromium. The repeatability of the measurements were tested for different amounts of chromium(III) and chromium(VI). At the 40 μg $l^{-1}$ level of total chromium (20 μg $l^{-1}$ with respect to each species), the relative standard deviations (10 replicate analyses) were 1.4%, 3.6% and 1.8% for chromium(III), chromium(VI) and total chromium respectively. This indicates that the precision of chromium(VI) determination is not significantly impaired by the presence of chromium(III). Detection limits defined as three times the standard deviation of a blank determination were 0.57 μg $l^{-1}$, 0.61 μg $l^{-1}$ and 0.35 μg $l^{-1}$ for chromium(III), chromium(VI) and total chromium, respectively, based on ten replicate determinations of the blank.

### 3.5. Application to samples

In order to establish the validity of the proposed procedure, the method has been applied to the determination of some simple mixtures of chromium(III) and chromium(VI). The results are given in Table 4. The reliability of the proposed procedure was also tested by carrying out recovery studies. The average per cent recoveries obtained for the addition of chromium(III) and chromium(VI) spikes to lake, waste and tap water samples are given in

Table 2. The results of Table 2 show that the recoveries of chromium(III) and chromium(VI) were correct to within ±1%.

## 4. Conclusion

A method using a microcolumn of SDS-coated alumina combined with GF-AAS has been developed for the determination of chromium(III) and chromium(VI). Attractive features of this novel method are its good sensitivity, good selectivity and improved simplicity provided by the SDS aggregates. In this method, unlike that using unmodified alumina, there is no need for an additional elution step. Chromium(III) is determined in the effluent while the total chromium concentration is directly determined by GF-AAS, and chromium(VI) is then calculated by difference.

# Characterization of the ionization and spectral properties of sulfonephthalein indicators. Correlation with substituent effects and structural features. Part II

M. Carla Aragoni, Massimiliano Arca, Guido Crisponi *, Valeria M. Nurchi, Roberta Silvagni

*Dipartimento di Chimica e Tecnologie Inorganiche e Metallorganiche, Via Ospedale 72, 09124 Cagliari, Italy*

Received 22 November 1994; revised 13 February 1995; accepted 13 February 1995

**Abstract**

A spectrophotometric study is presented on the first ionization equilibrium of a class of substituted sulfonephthaleins, whose second ionization was the subject of the first part of this work. The present study was more difficult than the previous in that highly acid media and acidity functions had to be used. Nevertheless the results were of sufficient accuracy to allow the dual substituent analysis of Swain and Lupton (C.G. Swain and A.C. Lupton, Jr., J. Am. Chem. Soc., 90 (1968) 4328). Generally speaking, the dependences of equilibrium and spectral parameters on field and resonance parameters found in this and the previous paper were very similar.

## 1. Introduction

Sulfonephthaleins are a class of arylsulfonic acids whose general formula is shown in Fig. 1.

All the indicators are summarized in Table 1. These molecules are characterized by the three following acidic groups: sulfonic, hydroquin-onic and phenolic. The ionizations of these substances can be represented by the equilibria shown below (form 1). The object of the present work is the spectrophotometric measurement of p$K$ values for the first ionization equilibrium and the study of the related spectral features in order to confirm, on these bases, the attribution of this ionization to the hydroquinonic group, the sulfonic groups behaving as stronger acids. A correlation study between the equilibrium and spectral properties and the various substituents characterizing each molecule is proposed. With this information it is possible to complete the data acquisition in this class of indicators reported in a previous work [1] for second dissociation p$K_2$ values. An analogous $^{13}C$ NMR analysis is unworkable because the solubility of

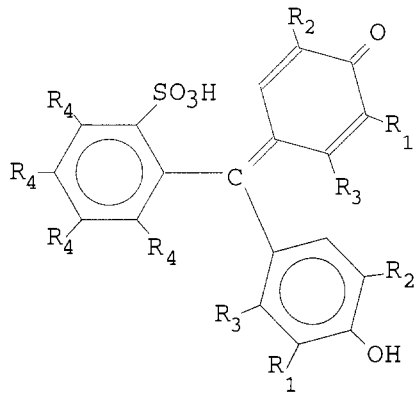

Fig. 1. General formula of sulfonephthaleins.

sulfonephthalein is insufficient in acidic solutions.

The estimation of the $pK_1$ values also requires high acid concentrations. Because of the high concentration of our acidic solutions we had to use a suitable acidity function. The results of this study clarify the behaviour of a class of very versatile indicators with a wide range of colours and p$K$s.

## 2. Experimental

### 2.1. Materials

The studied sulfonephthaleins were Aldrich products, used without further purification. Their purity was checked in the previous work [1] by the appearance of their NMR spectra.

### 2.2. Spectrophotometric measurements

Absorption spectra were recorded at 25 °C, on a Hewlett–Packard 8452 diode array spectrophotometer using a 1 cm quartz cell.

The acid chosen as solvent had to be non-absorbing and strong enough to allow the observation of reliable colour changes (p$K$ values −4.4 to 1.1). Although insufficient to obtain completely the diprotonated form of some indicators, hydrochloric acid proved the most suitable among the acids tried, also in view of its non-oxidizing nature.

A set of 14 HCl solutions from $10^{-2}$ to 11 M were therefore prepared from 37% fuming hydrochloric acid (Merck) and from volumetric standards 1.012 N and 0.1041 N (Aldrich). The titres of the 14 solutions were confirmed potentiometrically.

For each substance 14 samples were then prepared by mixing 0.500 ml of an aqueous solution of approximately $1 \times 10^{-4}$ M indicator and 2.50 ml of the acid solution.

Each sample was then spectrophotometrically analyzed in the range from 190 to 820 nm, obtaining 14 spectra, as for Chlorophenol Red shown in Fig. 2 as an example.

### 2.3. Calculation of ionization constants

Spectral data were analyzed with the program SPECFIT [2] as in the first part of this work [1].

## 3. Results and discussion

### 3.1. Equilibrium data

In the previous study all measurements were made at an ionic strength of 0.1 M $KNO_3$, and $[H^+]$ was adjusted by titrating a mixture of approximately $10^{-2}$ M in different acids. In the present case we had to use much higher acid concentrations. It was therefore no longer possible to control the ionic strength or to use directly the acid concentration; it became neces-

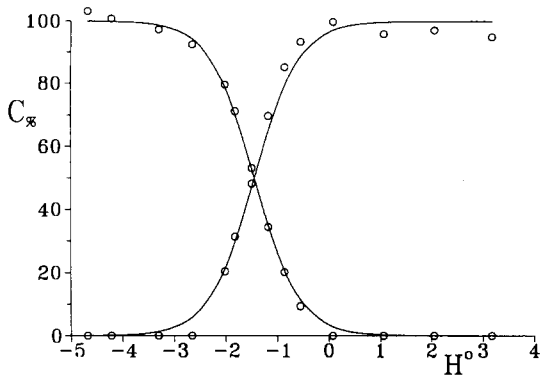

Fig. 5. Distribution curves for the first ionization of Chlorophenol Red.

sary therefore to resort to an acidic function. The $H_0$ function proposed by Hammet and Deyrup [3] was used. The literature [4] values were fitted with a seventh degree polynomial model to extrapolate the values for the hydrogen ion concentrations used, as shown in Fig. 3.

For dilute solutions, $-\log[H^+]$ was used. The experimental absorbance data were analyzed by evolving factor analysis (EFA), using the above $H_0$ function as a continuous variable. As an example we report the experimental spectra of Chlorophenol Red in the $H_0$ range 3.2 to −4.7 (Fig. 2). These data do not present a well-defined isosbestic point. This is presumably to be ascribed to spectral changes connected with the remarkable variation in ionic strength. The same spectra reconstructed taking into account the first two eigenvalues in the factor analysis are presented in Fig. 4. In these spectra all the contributions not determined by ionization were removed.

The evolving factor analysis (EFA) on these data indicates the presence of two absorbing species in the examined range.

Table 2
The $pK_I$ values of the 15 studied sulfonephthaleins

| Compound | $pK_I$ [a] |
|---|---|
| 1 | 1.11 ± 0.01 |
| 1$CH_3$ | 1.42 ± 0.01 |
| 1'$CH_3$ | 1.49 ± 0.01 |
| 2 | 1.16 ± 0.01 |
| 2BR | 0.64 ± 0.01 |
| 2$CH_3$ | 1.57 ± 0.02 |
| 3 | −2.00 ± 0.01 |
| 3$CH_3$ | −1.54 ± 0.01 |
| 3'$CH_3$ | −1.55 ± 0.06 |
| 4 | −1.45 ± 0.01 |
| 5 | −3.6 ± 0.1 |
| 6 | −4.3 ± 0.1 |
| 6Br | −1.4 ± 0.1 |
| 6$CH_3$ | −4.4 ± 0.1 |
| 7 | −4.2 ± 0.1 |

[a] Errors were evaluated as $3\sigma$, where $\sigma$ is the standard deviation furnished by SPECFIT

The distribution curves in Fig. 5 and the spectra in Fig. 6 obtained with EFA without any model assumption are reported as symbols. SPECFIT, moreover, allows a least-squares optimization based on an equilibrium model. We therefore assigned to structures I and II the two absorbing species indicated by EFA, which are connected by a single ionization equilibrium. The relative $pK_I$ estimate was therefore optimized. The resulting distribution curves and spectra are reported as continuous lines in Figs. 5 and 6. With the two procedures, the results are in good agreement. This proves that the experimental measurements were correct. The $pK_I$ values for all the 15 indicators were evaluated with the same procedure outlined above for Chlorophenol Red. These ionization parameters are reported with their respective errors in Table 2. The same $pK_I$

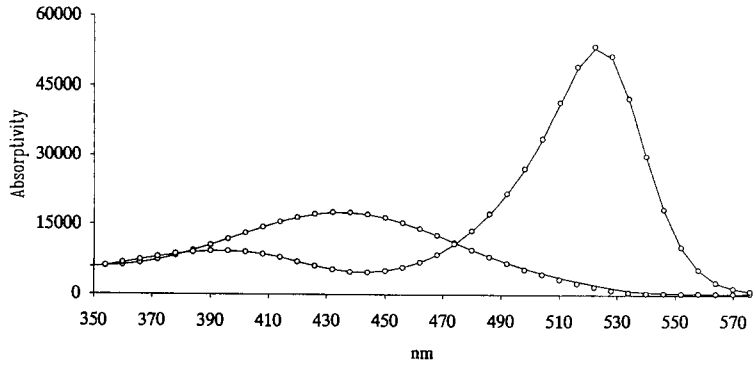

Fig. 6. Absorptivity spectra of the basic and acid forms of Chlorophenol Red.

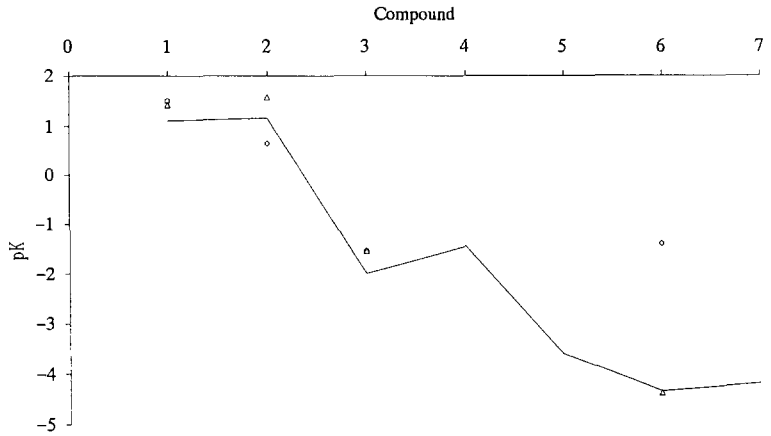

Fig. 7. The p$K_1$ values reported as a substituent function. Continuous line, compounds 1 to 7; △, $1CH_3$, $2CH_3$, $3CH_3$, and $6CH_3$; ○, $1'CH_3$ and $3'CH_3$; ◇, 2Br and 6Br.

values are graphically reported as a function of ortho substituents in Fig. 7. They show a very similar behaviour to that found for the second ionization. The anomalous outlying result for the 6Br compound will be discussed later.

### 3.2. UV-visible spectra

The UV-visible spectra of the 15 indicators, collected as reported above, were decomposed with SPECPEAK [5] and the maximum wavelengths of the component Gaussian peaks in the 300–600 nm range were obtained. These data are reported in Table 3. Peak III was not reported because it is unaffected when the substituents are changed.

Some qualitative observations may be made on the trend of maximum wavelengths reported in Fig. 8 as a function of the substituents.

(i) Indicators 1–7 present a regular trend although maximum wavelengths and p$K_1$ values of indicators 5, 6 and 7 are affected by considerable errors due to their acid strength.

(ii) The $CH_3$ and $CH(CH_3)$ substituents in compounds $1CH_3$, $2CH_3$, $3CH_3$, $6CH_3$, and $1'CH_3$, $3'CH_3$ respectively cause shifts that vary with respect to the trend of related substances with only $R_1$ and $R_2$ substituents.

The presence of Br in position $R_4$ produces a very irregular trend. The basic band at approximately 450 nm, corresponding to the p$K_2$ acid band, confirms a negligible variation with the substituents.

## 4. Concluding remarks

A Swain and Lupton [6] dual substituent analysis was carried out as in the first part of this work [1], but the more recent $\mathcal{F}$ and $\mathcal{R}$ values reported by Hansch et al. [7] were used; the results are reported in Table 4. The $pK_1$ values and maximum wavelengths $\lambda_{max}$ can in fact be well fitted with the equation $y = y^0 + r_1\mathcal{F} r_2\mathcal{R}$, where $\mathcal{F}$ and $\mathcal{R}$ are the sum of the tabulated values for the ortho substituent, since the effects of the $R_1$ and $R_2$ substituents can be considered additive.

Sets 1 and 2 in Table 4 represent the seven (1–7) and six ($1CH_3$–$6CH_3$) compounds respectively. As can be seen the goodness parameters (standard error, $\Sigma r^2$, correlation coefficient) referring to set 1 are very bad con-

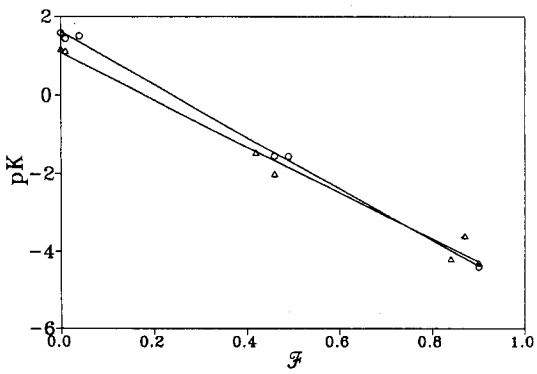

Fig. 9. The p$K$ values of set 1 and set 2 reported as a function of the $\mathcal{F}$ variable.

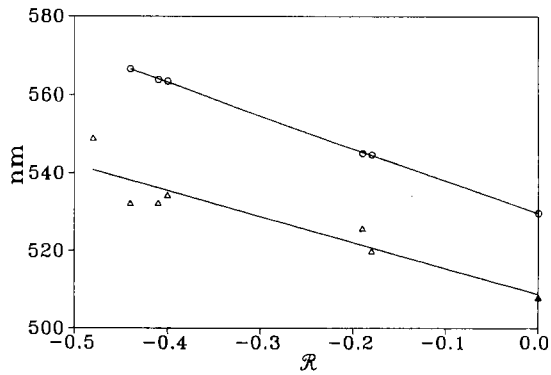

Fig. 10. The $\lambda_{max}$ values for set 1 and set 2 reported as a function of $\mathcal{R}$.

sidering the acidic strength of indicators 5, 6 and 7.

The p$K$ values and the maximum wavelengths of first dissociation depend on the $R_1$ and $R_2$ substituents with a trend analogous to that found for the second equilibrium. Also in this case the $\mathcal{F}$ field variable alone accounts for 86% and 77% of the p$K_1$ variability around the reference value of the unsubstituted compound 2, respectively, for sets 2 and 1. The linear regression with only $\mathcal{F}$ as an independent variable nevertheless shows a standard error and $\Sigma r^2$ very similar to those of the two-variable regression. In Fig. 9 p$K_1$ values versus $\mathcal{F}$ are reported for the two sets: set 1 again is poorer than set 2. The two lines are indistinguishable on the basis of the large errors by which they are affected. Nevertheless, by comparing the most accurate p$K_1$ values of 1 with $1CH_3$ and $1'CH_3$, 2 with $2CH_3$ and 3 with $3CH_3$ and $3'CH_3$, a difference of about 0.5 p$K$ units, corresponding to the meta $CH_3$ effect, can be remarked. These findings are in line with those for the first ionization.

The meta $CH_3$ effect is more significant than that of the ortho substituent because of the steric factor which causes a torsion of the phenolic rings. As can be seen from 1 and 2 or from $1CH_3$, $1'CH_3$ and $2CH_3$ indicators, the ortho substituents do no affect p$K_1$ values. When $R_1$ and $R_2$ are halogens an inductive $-I$ effect causes an increase in acidity as shown in the series 2, 3, and 6 or in the corresponding sequence $2CH_3$, $3CH_3$, $6CH_3$. The trend of maximum wavelengths of the most intense band VI may be seen in Fig. 10. This band was analyzed with the Swain–Lupton method and the parameters shown in Table 4 were obtained. While p$K_1$ values can be evaluated with the $\mathcal{F}$ parameter alone, the band position for both sets shows an 80.5% and an 91% dependence on the resonance $\mathcal{R}$ parameter for sets 1 and 2, respectively. Fig. 10 reports $\lambda_{max}$ values vs. $\mathcal{R}$. A shift of 21 nm between the intercepts of set 2 with respect to set 1 is observed. Analogously to the previous study, the half-bandwidths of set 2 spectra are larger than those of set 1.

In conclusion, it should be pointed out that ionization of the first exchangeable proton takes place at a p$K_1$ value which is normally approximately 7 units lower than the second ionization and the spectral properties of the biprotonated form and of the completely deprotonated form have very similar spectra. This observation substantiates the sequence of ionization equilibria proposed above. In fact the similarity of the spectra is well explained by their assignment to the two symmetric forms I and III, as discussed by Schwarzenbach [8]. The first ionization of the sulfonic group, on the contrary, should give two non-symmetric forms with different spectral properties. This attribution is furthermore supported by the high similarity in the values of the dual substituent analysis on p$K_1$ and p$K_2$.

The difference between the trends of p$K_1$ and p$K_2$ observed when bromine is $R_4$ has to be explained. While p$K_2$ values are not affected, p$K_1$ in fact shows an ambiguous behaviour. The acidity of the 2Br sulfonephthalein increases and that of 6Br decreases. We can tentatively explain this behaviour by a decrease of sulfonic group acidity to $pK \cong -1.4$ due to resonance effects of the four bromine atoms. The ionization order of sulfonic and hydroquinonic groups, which is unaffected in the 2Br compound, is in contrast, reversed in 6Br. The ionization of the hydroquinonic group in the last compound is expected, in fact, at $pK \cong -4$. Further support of sulfonic ionization is given by the spectral features of 6Br which is the only indicator whose acidic species is not coloured.

# Labelling of organotin compounds for fluorimetric detection

C. Leal, M. Granados, M.D. Prat *, R. Compañó

*Departament de Química Analítica, Universitat de Barcelona, Diagonal 647, E-08028 Barcelona, Spain*

Received 25 October 1994; revised 15 February 1995; accepted 15 February 1995

**Abstract**

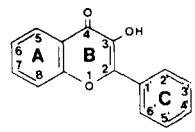
A systematic study of the fluorescence of complexes of some flavone derivatives with organotin compounds in hexane and in an aqueous micellar medium on Triton X-100 is reported. Some relationships between fluorescence intensity and the structure of the fluorogenic reagent or that of the organotin compound can be deduced, and the most suitable reagent for each organotin species can be chosen on the basis of sensitivity and selectivity. Results point out that flavone derivatives are appropriate post-column derivatization reagents for organotin compounds in liquid chromatography.

## 1. Introduction

Aryl and alkyl derivatives of tin are extensively used as PVC stabilizers, biocides, and catalysts and in antifouling paints. The variety of pathways for their entry into the environment, together with their toxicity, has brought about investigations of methods for their separation and detection in environmental samples. Separation is usually carried out by gas chromatography [1,2] or liquid chromatography [3]. For the latter, most detection systems are based on atomic spectroscopic techniques or molecular fluorscence.

As organotin compounds are not intrinsically fluorescent, a fluorogenic derivatization process is needed when detection is performed with fluorimetry. Derivatization can be carried out either pre-column, on-column or post-column, which is the most frequent. Flavone derivatives, which are well-known fluorogenic reagents for inorganic tin [4], have also been proposed for the fluorimetric determination of organotin species [5–7] and they have been used for derivatization in liquid chromatography (LC) [8–14]. However there is a need for systematic study of the relative fluorescence intensities of organotin complexes with flavones in media commonly used in LC, which would allow the selection of the most suitable reagent for each specific problem.

This paper describes a systematic study of the fluorescence properties of several flavone derivatives as labelling reagents for methyltin, butyltin, cyclohexyltin and phenyltin species. In Fig. 1 the structural formulae, the systematic



| SYSTEMATIC NAME | ORDINARY NAME |

names and the ordinary names of the flavone derivatives studied are shown.

Hexane, which is a suitable mobile phase for normal-phase LC of organotin compounds, is one of the reaction media selected. Furthermore, it has been reported that, in comparison with hydro-organic media, non-ionic and cationic surfactants enhance the fluorescence of organotin complexes with flavone derivatives [6,9,15]. Among the micellar media tested, the best results in terms of sensitivity are obtained with non-ionic Triton X-100. Therefore Triton X-100 micellar solutions may be a good alternative for fluorimetric detection of organotin species after chromatographic separation by reverse phase or ion exchange. Thus, the fluorescence of these complexes in 1% (m/v) Triton X-100 was also studied.

## 2. Experimental

### 2.1. Reagents

Solutions were prepared in doubly deionized water (Culligan Ultrapure GS) of 18.3 MΩ cm resistivity.

Triphenyltin chloride (TPhTCl), diphenlytin chloride (DPhTCl), monophenyltin chloride (MPhTCl), tributyltin chloride (TBTCl), dibutyltin chloride (DBTCl), monobutyltin chloride (MBTCl), trimethyltin chloride (TMTCl), and tricyclohexyltin chloride (TCHTCl) were purchased from Fluka or Aldrich (purity above 95%) and were used without further purification. Stock solutions (0.5 g $l^{-1}$ as tin) were prepared with methanol (Merck), except for TCHTCl, which was prepared with cyclohexane. These solutions were stored at 4 °C in dark glass bottles, and working solutions (1–25 mg $l^{-1}$) were prepared freshly prior to use, by dilution with methanol and water, or hexane (Merck).

Ethanol solutions ($3 \times 10^{-4}$–$5 \times 10^{-3}$ M) of flavonol (Aldrich), galangin (Aldrich), kaempferol (Fluka), quercetin (Merck), morin (Merck), fisetin (Aldrich), chrysin (Aldrich) and 7,8-dihydroxy-flavone (Toyko Kasey) were prepared daily.

Buffer solutions of 0.05 M formic acid–solution hydroxide (pH 3–4), 0.05 M succinic acid–sodium hydroxide (pH 5–6) and 0.05 M Tris–hydrochloric acid (pH 7–8) were used; pH values below 3 were adjusted with hydrochloric acid.

A stock aqueous solution of 8.3% (m/v) Triton X-100 (Merck) was used.

### 2.2. Apparatus

Fluorescence measurements were performed on a Perkin-Elmer LS-50 spectrofluorimeter equipped with a xenon discharge lamp and 10-mm pathlength quartz cells. The slit widths were adjusted to 3 or 10 nm in both monochromators depending on the fluorescence of the complexes. Measurements were performed at 20 °C in a thermostatted room. The spectrofluorimeter was calibrated daily using a Perkin-Elmer fluorescence intensity standard of ovalene. All fluorescence data are given without spectral correction.

Spectrophotometric measurements were carried out on a Perkin-Elmer Lambda 19 double-beam spectrophotometer, using 10-mm quartz cells.

A Crison Digilab-517 pH meter equipped with an Orion combined electrode was used for pH measurements. The potentiometric system was calibrated prior to use with buffer solutions, at pH 4.008 and 6.863, prepared from Merck salts according to DIN 19 266.

All glassware used for experiments was previously soaked in 10% nitric acid (Merck) for 24 h and rinsed with doubly deionized water.

### 2.3. Procedures

*Fluorescence measurements*

Hexane medium: transfer 2 ml of the hexane organotin compound solution (1 mg $l^{-1}$) into a 10 ml volumetric flask containing 0.5 ml of the flavone solution ($3.4 \times 10^{-4}$ M) and dilute to volume with hexane. When estimating detection limits, more diluted solutions of organotin compounds were used.

Micellar medium: transfer 1 ml of aqueous organotin compound solution (5 mg $l^{-1}$) into a 25 ml volumetric flask containing 0.5 ml of the flavone solution ($2.1 \times 10^{-3}$ M), 2.5 ml of buffer solution and 3 ml of Triton X-100 solution, and dilute to volume with water.

Immediately after the preparation, excitation and emission spectra were recorded and the fluorescence intensity at optimal wavelengths was read. The fluorescence intensity was read again 1 h later. Blank solutions were prepared and measured at the optimal wavelengths of the complex.

Table 1
Wavelength of the excitation and emission maxima ($\lambda_{ex}$, $\lambda_{em}$) and relative fluorescence intensities ($I_F$) of the complexes of organotin compounds (200 $\mu g\,l^{-1}$) with flavone derivatives in hexane

| Flavone derivative | DBT | | | MBT | | | DPhT | | | MPhT | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | $\lambda_{ex}$ | $\lambda_{em}$ | $I_F$ | $\lambda_{ex}$ | $\lambda_{em}$ | $I_F$ | $\lambda_{ex}$ | $\lambda_{em}$ | $I_F$ | $\lambda_{ex}$ | $\lambda_{em}$ | $I_F$ |
| Flavonol | 396 | 445 | 13 | 400 | 454 | 48 | 396 | 445 | 44 | 400 | 452 | 27 |
| Galangin | 434 | 488 | 0.4 | 416 | 474 | 8 | 429 | 483 | 2 | 418 | 475 | 7 |
| Kaempferol | 420 | 468 | 5 | 428 | 476 | 78 | 426 | 469 | 47 | 429 | 475 | 37 |
| Quercetin | 426 | 482 | 28 | 432 | 487 | 81 | 432 | 486 | 85 | 436 | 485 | 40 |
| Morin | 418 | 488 | 51 | 425 | 498 | 39 | 425 | 491 | 86 | 425 | 495 | 42 |
| Fisetin | 418 | 481 | 97 | 421 | 488 | 43 | 421 | 482 | 100 | 421 | 483 | 45 |

*UV absorption spectra*

Solutions used to obtain the UV absorption spectra were prepared by one of the procedures described above, but using more concentrated solutions of organotin compounds and flavones. The final concentration of the organotin compound was 1 $mg\,l^{-1}$ with a ten-fold excess of reagent. Absorption spectra of the complexes were recorded against a blank.

## 3. Results and discussion

### 3.1. Fluorescence in hexane

The fluorescence intensities (relative to that of the DPhTCl–Fisetin complex, taken as 100), as well as the wavelengths of the excitation and emission maxima, of the complexes of some organotin compounds with six flavone derivatives are given in Table 1. Values corresponding to other species, such as TBT, TPhT, TMT and TCHT, are not given because they exhibited very weak fluorescence with all the flavone derivatives.

In all the cases, both the excitation and emission spectra consisted of a single structureless broad band with the excitation maximum in the range 410–435 nm and the emission maximum in the range 470–500 nm, except for complexes with flavonol ($\lambda_{exc}$ = 390–400 nm; $\lambda_{em}$ = 445–460 nm). The emission intensities did not change significantly for 1 h after the preparation of the solutions.

Values in Table 1 show that, in this medium, the complexes of diorganotin and monoorganotin compounds with the reagents studied are highly fluorescent. Most fluorescent systems, like fisetin or morin complexes of MBT, DBT, MPhT and DPhT, allow limits of detection to be reached at about 0.1 $\mu g\,l^{-1}$, which makes them suitable as labelling reagents in environmental analysis.

The fact that the fluorescence of trialkyl and triaryl complexes in hexane is much less intense than that of monoorganotin and diorganotin compounds, has already been reported by Arakawa et al. [5] and Langseth [16] in the case of morin, and has been attributed to the shielding of the tin atom by the carbon chains of the triorganotin compounds, which hinders the formation of the complex. To confirm this assumption, the UV absorption spectra of solutions containing, respectively, TBT, TPhT, DBT or DPhT and a ten-fold excess of morin or flavonol were compared with the corresponding reagent blanks. No change in the spectrum of the reagent was observed when TBT or TPhT was added to the solution, whereas a new band appeared in the region of 380–430 nm in the case of DBT and DPhT, which suggests that complex formation for triorganotin compounds takes place to a much lesser extent than for diorganotin derivatives. This behaviour agrees with data reported on the complexation of flavonol with butyltin species in methanol, chloroform and toluene [17]. In all the solvents stability constants for TBT were lower than those corresponding to DBT and MBT.

Comparing the emission intensities given by the complexes of the different flavone derivatives (Table 1), some relationships between the structure and the fluorescence of the complex can be deduced. First, the presence of a hydroxyl group at position 3 is essential to fluorescence, as shown by the fact that 7,8-dihydroxyflavone and chrysin do not form fluorescent complexes. On the other hand, the presence of hydroxyl groups in ring A seems to decrease the fluorescence of the complexes, whereas their presence in ring C increases the

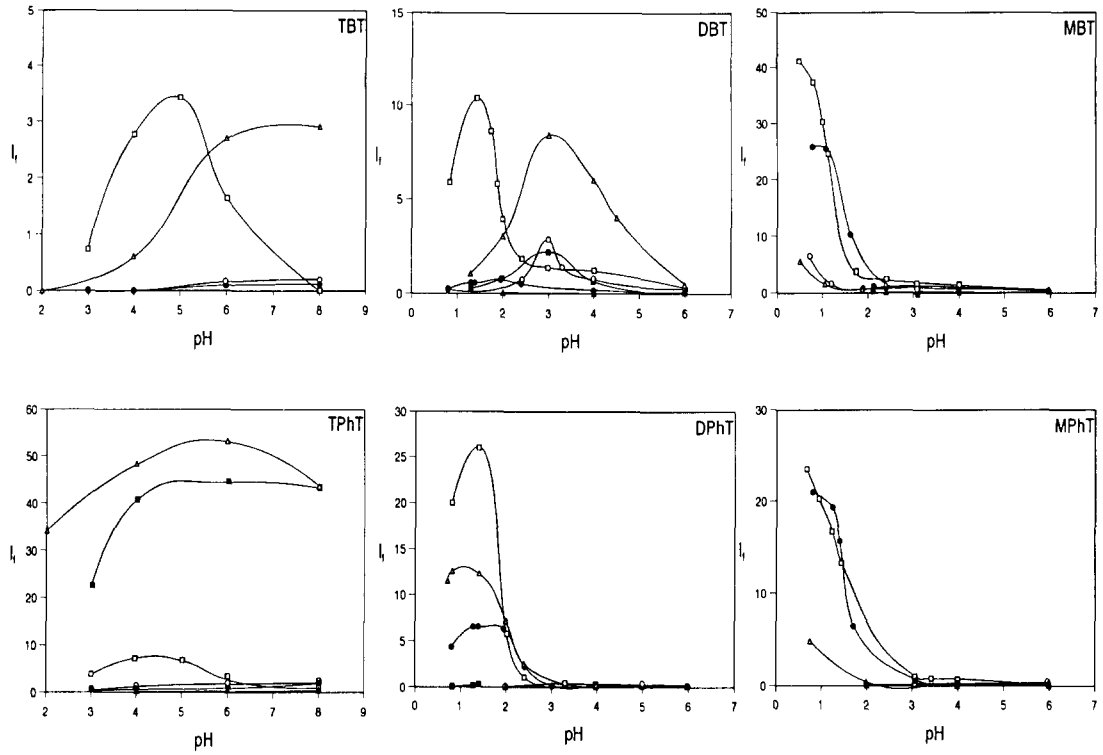

Fig. 2. The pH dependence of the fluorescence intensity of the complexes of organotin compounds in 1% (m/v) Triton X-100. ([Organotin = 200 μg $l^{-1}$].) □, morin; ○, quercetin; ●, kaempferol; ▲, galangin; △, fisetin; ■, flavonol.

emission intensity. In comparison with flavonol, which has no hydroxyl groups in these rings, in galangin, the addition of two OH groups in ring A causes a clear decrease in the fluorescence. In the case of kaempferol, one OH group has been introduced in ring C, increasing the fluorescence of the complexes in relation to galangin. When considering morin or quercetin, which contain two OH groups in ring C, a significant rise in the emission is observed. Finally, fisetin, which has lost a hydroxyl group in ring A, shows the highest fluorescence intensity.

### 3.2. *Fluorescene in Triton X-100 medium*

Fig. 2 shows the influence of pH on the fluorescence of organotin complexes, and in Table 2 excitation and emission maxima wavelengths are given for each complex in 1% (m/v) Triton X-100. Data corresponding to TMT and TCHT are not given, because their complexes exhibit very low fluorescence. As observed in hexane medium, all the spectra show a single broad band.

The fluorescence of organotin complexes in this micellar medium is strongly dependent on pH. As the number of substituents in the tin atom increases, there is a shift of the optimum pH range towards higher values. This behaviour is observed with both butyltin and phenyltin species, and agrees with the data reported [9,15]. On the other hand, in most cases the fluorescence of butyltin species takes place at a slightly higher pH than for the corresponding phenyltin species and this effect is more pronounced for diorganotin species.

No fluorescence was detected from solutions containing chrysin or 7,8-dihydroxyflavone and any of the organotin species tested, in the pH range covered in this study. In order to ascertain whether complexes are formed in these systems, a UV-visible spectrophotometric study was carried out and TPhT was selected as the organotin compound model. From pH 4, significant differences are observed between the absorption spectra of solutions containing TPhT and 7,8-dihydroxy-flavone and those corresponding to the reagent blank. This confirms that complexation takes place, but the new species is not fluorescent. Nevertheless in the system TPhT–chrysin, spectra of the solutions containing both the organotin and the flavone reagent do not show any change in relation to the spectra of the reagent blank, which leads us to conclude that complexes are not formed.

Table 2
Wavelength of the excitation and emission maxima (and relative fluorescence intensities of the complexes of organotin compounds (200 μg $l^{-1}$) with flavone derivatives in 1% (m/v) Triton X-100

[a] Value corresponding to optimum pH for each complex.

The behaviour of 3-hydroxyflavone differs from that shown by the other flavone derivatives. It is an extremely sensitive reagent for TPhT, gives some fluorescence with DBT, and very low or no response with any of the other organotin species tested. A spectrophotometric study pointed out that absorption spectra of solutions containing TPhT and 3-hydroxyflavone show the same trends as those of solutions containing TBT and 3-hydroxyflavone, which reveals that the lack of fluorescence of the TBT solution is not due to poor or no complexation, but to very low quantum yields.

In comparison with the hexane medium, in Triton X-100 solutions the pH is an additional parameter that affects the fluorescence. In consequence, the search for relationships between the fluorescence of the complexes and the structure of the fluorogenic reagent is more difficult. Nevertheless, some of the relationships that have been found in hexane are also valid for Triton X-100 medium. Thus fluorescence is obtained only if the flavone derivative has a hydroxyl group in position 3. On the other hand, as observed in hexane, galangin is the 3-hydroxy derivative that provides the lowest fluorescence intensities, and this behaviour may be related with the presence of hydroxyl groups in ring A, but not in ring B. Finally our data suggest that, in general, reagents that have hydroxyl groups in ring B, such as quercetin, kaempferol, morin and fisetin, provide more intense fluorescence.

The intense fluorescence shown by some of these complexes allows very low limits of detection to be attained. Thus the obtained value for the batch determination of TPhT with flavonol [6] is 0.07 μg $l^{-1}$ and, when this reagent is used as the TPhT labelling reagent after the LC separation [12], the detection limit is 0.1 μg $l^{-1}$ (injected volume, 200 μl). Current studies that we are carrying out show that, when fisetin is used coupled with LC, limits of detection for TBT and TPhT are 4.5 μg $l^{-1}$ and 0.15 μg $l^{-1}$, respectively (injected volume 200 μl). Similar values can also be reached for monoorganotin and diorganotin species with the appropriate reagent.

## 4. Conclusions

The fluorescence intensity values corresponding to a hexane medium show that morin and fisetin are the reagents that provide the highest fluorescence intensities in this solvent with DBT, MPhT and DPhT, and fisetin is slightly superior. The most fluorescent MBT complexes are formed with kaempferol and quercetin, but morin and fisetin complexes of MBT also show strong fluorescence, with values comparable to those of MPhT. From these considerations, and taking into account that all morin and all fisetin complexes have very similar excitation and emission wavelengths, both reagents are suitable for the fluorimetric detection of these organotin species after normal-phase chromatographic separation and they are comparable in terms of sensitivity. Nevertheless, if only MBT, or MBT and MPhT, are to be determined, kaempferol or quercetin is a better choice.

In Triton X-100 solution, morin and fisetin are the most general reagents, and morin is clearly superior for the monoorganotin species, whereas fisetin is the most sensitive reagent for triphenyltin. Kaempferol also provides excellent sensitivity for the monoorganotin species. If a general screening of butyl and/or phenyl

organotin compounds is to be performed by ion-exchange or reverse-phase LC, either morin or fisetin can be used for post-column derivatization before fluorimetric detection. The choice between morin and fisetin depends on the need of sensitivity for monoorganotin vs. triorganotin. In any case, a change of pH of the solution to be detected will be required during the analysis, as optimum conditions for diorganotin and monoorganotin are more acidic (pH below 2) than those required for the detection of triorganotin (pH above 4).

Finally it can be concluded that the fluorescence of the complexes of monoorganotin and diorganotin compounds in hexane is higher than in Triton X-100. In contrast the emission of triorganotin complexes is more intense in the micellar medium, although it is weaker than that of monoorganotin and diorganotin derivatives.

**Abstract**

The equilibrium constants of α,β,γ,δ-tetrakis(1-methylpyridinium-4-yl)porphine (TMPyP) complexes of cadmium(II), lead(II), magnesium(II), and zinc(II) were spectrophotometrically determined using the absorption spectra at the Soret band and the fluorescence spectra. The values of the following constants at 25 °C and ionic strength 0.1 M were evaluated: $K_{Pb-P} = 10^{-8.07 \pm 0.09}$, $K_{Cd-P} = 10^{-7.68 \pm 0.03}$, $K_{Zn-P} = 10^{1.72 \pm 0.08}$, and $K_{Mg-P} = 10^{-7.40 \pm 0.08}$ by the acid hydrolysis reaction of the TMPyP–metal complex at various pHs; $K_{Pb-P} = 10^{-7.80 \pm 0.04}$ and $K_{Cd-P} = 10^{-7.38 \pm 0.04}$ were determined by the ligand exchange reaction between TMPyP and nitrilotriacetic acid.

## 1. Introduction

It is well known that porphyrin compounds form very stable complexes with metal ions such as vanadium(V), cobalt(II), copper(II), etc. With respect to the stability of these complexes, Falk reported the following qualitative order by using the elimination reaction of the metal ion with strong acid [1]: Pt(II) > Pd(II) > V(V) > Ni(II) > Co(II) > Ag(II) > Cu(II) > Fe(II) > Mn(II) > Zn(II) > Mg(II) > Cd(II) > Ca(II) > Sn(II) > Pb(II) > $Li(I)_2$ > Ba(II) > $Ag(I)_2$. Recently, highly sensitive spectrophotometric determinations of various metal ions with water-soluble porphyrins have been developed using the absorption spectra at the Soret band (around $\varepsilon = (20-70) \times 10^4$ $M^{-1}$ $cm^{-1}$ at around 400–500 nm) or the fluorescence spectra at 600–700 nm [2–5].

The investigation of the porphyrin–metal complex in solution chemistry has mainly centered on the kinetics of complexation or adduct formation equilibrium of the porphyrin complex with axial ligands, such as $SCN^-$ for the α,β,γ,δ-tetrakis(1-methylpyridinium-4-yl)-prophine (TMPyP)–cobalt(III) complex [6]. However, systematic studies on the formation equilibria of water-soluble porphyrin complexes are relatively few. Tabata et al. determined the formation constants of the α,β,γ,-δ-tetrakis(4-sulfophenyl)porphine (TPPS) complexes of mercury(II), zinc(II), and cadmium-(II) by using a kinetic model for the metal exchange reaction [7]. Hambright et al. estimated the constant for the TMPyP–cadmium-(II) complex to be $2.0 \times 10^{-8}$ using a spectrophotometric method for the Q band at around 500–700 nm [8].

In this paper, the equilibrium constants ($K$) of TMPyP–lead(II), –cadmium(II), –magnesium(II), and –zinc(II) complexes were determined by a spectrophotometric method using absorption spectra at the Soret band and the fluorescence spectra.

$$M^{2+} + H_2P \rightleftharpoons MP + 2H^+, \qquad K = \frac{[MP][H^+]^2}{[M^{2+}][H_2P]}$$

Moreover, the equilibrium constants for the TMPyP–lead(II) and TMPyP–cadmium(II) complexes were also determined by the ligand exchange reaction with nitrilotriacetic acid.

## 2. Experimental

### 2.1. Apparatus

A Shimazu model UV-365 recording double-beam spectrophotometer with 1 cm glass cells was used for the absorbance measurements. A Hitachi model 850 recording fluorimeter with 1 cm glass cells was used for the relative fluorescence intensity measurements. A Hitachi–Horiba model F-7ss pH meter with Horiba model 6026 glass–Ag/AgCl combined electrode was used. A Komatsu-Yamato model CRT-220 coolnics was used as the water thermostat (25.0 ± 0.1 °C) for the sample solution and the cell holder in the spectrophotometer. An NEC personal computer model PC-9801 was used for the calculation of the equilibrium constant.

### 2.2. Reagents

All reagents used were of analytical-reagent grade unless otherwise described. The synthesis of TMPyP and the preparation of $10^{-4}$ M TMPyP solution was as follows. TMPyP tetratosylate was synthesized and purified as described elsewhere [9]. TMPyP solution was prepared by dissolving 34.9 mg of TMPyP tetratosylate in 250 ml of distilled water. The standardization of TMPyP solution was done by photometric titration (molar ratio method) with a standard copper(II) solution [10]. All standard metal ion solutions ($10^{-2}$M) were prepared from metal nitrates (Wako Junyaku Co.) and the concentrations were determined by EDTA titration. Nitrilotriacetic acid (NTA) (Wako Junyaku Co.) was purifed by the reported method [11]. The $1 \times 10^{-4}$ M solutions of each metal ion and NTA were prepared by dilution with distilled water. The pH buffer reagents, 3-($N$-morpholine)propanesulfonic acid (Mops; Dotaito), tris(hydroxymethyl)-aminomethane (Tris; Wako Junyaku Co.), hexamethylenetetramine (hexamine; Wako Junyaku Co.), sodium tetraborate (borax; Kanto Kagaku Co.), sodium hydroxide, and hydrochloric acid (Wako Junyaku Co.) were used.

### 2.3. Procedure

#### 2.3.1. Determination of equilibrium constants by analysis of pH–absorbacne and pH–fluorecence intensity curves

The dissociation reaction of the porphyrin metal complex was observed for the determination of the equilibrium constant. Each metal complex was prepared by a previous described method [3,12]. Namely, the reaction conditions were as follows. Zinc(II) complex: $[Zn^{2+}]_{Total} = 0.98 \times 10^{-5}$ M, $[H_2P]_{Total} = 4.30 \times 10^{-6}$ M, pH 9.3 (0.1 M borax), reaction time; 30 min (20 °C); magnesium(II) complex: $[Mg^{2+}]_{Total} = 3.99 \times 10^{-5}$ M, $[H_2P]_{Total} = 3.37 \times 10^{-6}$ M, $[oxine]_{Total} = 8.00 \times 10^{-5}$ M, pH 9.3 (0.1 M borax), reaction time, 90 min (95 °C); cadmium(II) complex: $[Cd^{2+}]_{Total} = 0.96 \times 10^{-5}$ M, $[H_2P]_{Total} = 4.30 \times 10^{-6}$ M, pH 9.8 (0.1 M hexamine–0.1 M Tris buffer solution), reaction time, 10 min (20 °C); lead(II) complex: $[Pb^{2+}]_{Total} = 1.82 \times 10^{-5}$ M, $[H_2P]_{Total} = 4.30 \times 10^{-6}$ M, pH 7.66 (0.1 M Mops–0.1 M NaOH buffer solution), reaction time, 30 min (20 °C).

Owing to the dissociation reaction of each complex, 2.5 ml of 2 M $NaNO_3$ solution are added to the system in order to maintain the ionic strength at $I = 0.1$ M, 20 °C. Next, after achieving the prescribed pH with a small amount of 2 M HCl solution, the mixture was diluted with distilled water to the mark in the 25 ml amber volumetric flask. The sample solution was then placed in a 50 ml amber sample bottle, and allowed to stand for the prescribed time at 20 °C in the thermostat. The absorbance of the cadmium(II) complex was measured at 448 nm after 2 days, that of the lead(II) complex at 476 nm after 10 min, the relative fluorescence intensity of the zinc(II) complex at 631 nm (excitation wavelength, 438 nm) after 30 days, and that of the magnesium(II) complex at

648 nm (excitation wavelength, 453 nm) after 27 days.

*2.3.2. Determination of equilibrium constants based on ligand exchange reaction*

The preparation of the lead(II) or cadmium(II) complex solution was as follows. A 2.5 ml sample of $10^{-4}$ M lead(II) or cadmium(II) standard solution was allowed to stand for 30 min at room temperature after achieving a pH of 10.7 with 2 ml of 0.1 M borax–0.1 M Tris–0.1 M NaOH mixed buffer solution. Next, 2.5 ml of 2 M $NaNO_3$ solution are added in order to set the ionic strength at $I = 0.1$ M, and 5 ml of $10^{-4}$ M NTA standard solution, and small amounts of 2 M HCl solution to achieve the prescribed pH were added, respectively. The sample solution was then placed in a 50 ml amber bottle, and allowed to stand for the prescribed time at 20 °C in the thermostat. The absorbance at 476 nm of the lead(II) complex and that at 448 nm of the cadmium(II) complex were measured after 2 days.

The concentration of $H_2P$ was determined by measuring the absorbance at 423 nm or the relative fluorescence intensity at 641 nm (excitation wavelength, 423 nm) in both the above procedures.

## 3. Results and Discussion

Many methods have been reported for the determination of the equilibrium constant of complexation. In this paper, a highly sensitive and reproducible spectrophotometric and fluorescence method was used. The absorption spectra in the Soret band and the fluorescence spectra of each metal complex are shown in Figs. 1 and 2, respectively. Since the Soret bands of the zinc(II) complex and the magnesium(II) complex significantly overlap with that of free reagent, the fluorescence spectra were used for their concentration measurements. The complexation of the metal ion (M) and free-base type porphyrin ($H_2P$) is given as follows

$$M + H_2P \overset{K}{\rightleftharpoons} M\text{–}P + 2H$$

$$K = \frac{[M\text{–}P][H]^2}{[M][H_2P]} \quad (1)$$

where $K$ is the equilibrium constant. The species charge was omitted.

*3.1. Equilibrium constants for TMPyP–cadmium(II), –magnesium(II), –lead(II), and –zinc(II) complexes*

*3.1.1. Cadmium(II), magnesium(II), and lead(II) complexes (pH 5.5–7.5)*

The hydrolysis species of the metal ion (MOH, $M(OH)_2$) was considered and the concentration [M] of the unreacted metal ion and side reaction coefficient (herein after, the $\alpha$ coefficient [13]) were defined

$$[M]_{Free} = [M] + [MOH] + [M(OH)_2]$$

$$\alpha_M = \frac{[M]_{Free}}{[M]} = 1 + \frac{[MOH]}{[M]} + \frac{[M(OH)_2]}{[M]}$$

The $\alpha_M$ coefficient was calculated by using a constant with respect to the hydrolysis reaction

Cd [14]:
$$\beta_1^{Cd} = \frac{[CdOH][H]}{[Cd]} = 10^{-7.92}$$

$$\beta_2^{Cd} = \frac{[Cd(OH)_2][H]}{[CdOH]} = 10^{-11.38}$$

Mg [15]:
$$\beta_1^{Mg} = \frac{[MgOH][H]}{[Mg]} = 10^{-11.40}$$

Pb [16]:
$$\beta_1^{Pb} = \frac{[Ph(OH)][H]}{[Pb]} = 10^{-8.84}$$

$$\beta_2^{Pb} = \frac{[Pb(OH)_2][H]}{[PbOH]} = 10^{-7.11}$$

From these $\alpha_M$ coefficents, the equilibrium constant $K$ of Eq. (1) was as follows

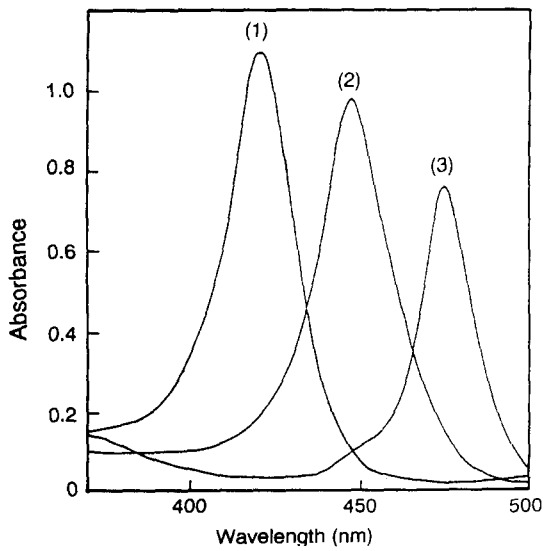

Fig. 1. Absorption spectra of TMPyP, TMPyP–cadmium(II) and TMPyP–lead(II) complexes. Curve (1), TMPyP; curve (2), TMPyP–Cd(II); curve (3), TMPyP–Pb(II). (Measurement conditions: pH 9.30; 20 °C; $[TMPyP]_{Total} = 4.30 \times 10^{-6}$ M; $[Cd^{2+}]_{Total} = 0.96 \times 10^{-5}$ M; $[Pb^{2+}]_{Total} = 1.82 \times 10^{-5}$ M.)

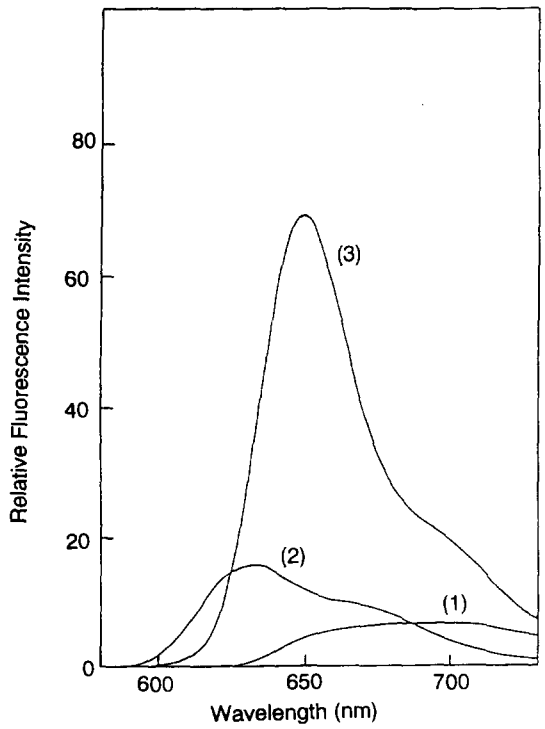

Fig. 2. Fluorescence spectra of TMPyP, TMPyP–magnesium(II) and TMPyP–zinc(II) complexes. Curve (1), TMPyP (excitation wavelength $\lambda_{ex} = 423$ nm); curve (2), TMPyP–Zn(II) ($\lambda_{ex} = 438$ nm); curve (3), TMPyP–Mg(II) ($\lambda_{ex} = 453$ nm). (Measurement conditions: pH 9.30; 20 °C; $[TMPyP]_{Total} = 4.30 \times 10^{-6}$ M; $[Zn^{2+}]_{total} = 0.98 \times 10^{-5}$ M; $[Mg^{2+}]_{Total} = 3.99 \times 10^{-5}$ M.)

$$K = \frac{[M-P][H]^2}{[M]_{Free}[H_2P]}\alpha_M \qquad (2)$$

where $[M]_{Free} = [M]_{Total} - [M-P]$, and $[P]_{Total} = [H_2P] + [M-P]$. The concentration of M–P and $H_2P$ were determined by measuring the absorbance and relative fluorescence intensity at their respective maximum wavelenghts. Based on these data, the equilibrium constant $K$ of Eq. (2) was calculated.

### 3.1.2. Zinc(II) complex (pH 1.0 ~ 3.0)

Species of $H_3P$ and $H_4P$ and $H_4P$ for TMPyP are considered and the side-reaction coefficient ($\alpha_P$) was defined. Also, the side-reaction coefficient ($\alpha_M$) due to hydrolysis of the metal ion was neglected in this pH range.

$$[P]_{Free} = [H_2P] + [H_3P] + [H_4P]$$

$$\alpha_p = \frac{[P]_{Free}}{[H_2P]} = 1 + \frac{[H_3P]}{[H_2P]} + \frac{[H_2P]}{[H_2P]}$$

The $\alpha_p$ coefficient was calculated by using the acid dissociation constant [17]

$$Ka_3 = \frac{[H_3P]}{[H_2P][H]} = 10^{2.06} \quad Ka_4 = \frac{[H_4P]}{[H_3P][H]} = 10^{0.80}$$

From this $\alpha_p$ coefficient, the equilibrium constant $K$ in Eq. (1) because

$$K = \frac{[M-P][H]^2}{[M][P]_{Free}}\alpha_p \qquad (3)$$

where $[M] = [M]_{Total} - [M-P]$, $[P]_{Free} = [P]_{Total} - [M-P]$

The concentration of M–P was determined by measuring the relative fluorescence intensity. The equilibrium constant $K$ of Eq. (3) was then determined. Results of sections 3.1.1. and 3.2.2. are shown in Table 1 and Fig. 3.

### 3.2. Determination of equilibrium constant of lead(II) and cadmuim(II) complexes by ligand exchange reaction

Nitrilotriacetic acid ($H_3Y$) was selected as the reagent for the ligand exchange reaction. The material balance equation for the metal ions is given by

$$[M]_{Free} = [M] + [MOH] + [M(OH)_2] + [M-Y]$$
$$= [M]_{Total} - [M-P] \qquad (4)$$

where $[M-Y] = K_Y[M][Y]_{Total}/K_Y[M] + \alpha_Y$. The side-reaction coefficent of NTA ($\alpha_Y$) is given by

$$\alpha_Y = 1 + \frac{[HY]}{[Y]} + \frac{[H_2Y]}{[Y]} + \frac{[H_3Y]}{[Y]}$$

Therefore, Eq. (4) can be rearranged to

$$[M]_{Free} = [M] + \frac{\beta_1^M}{[H]}[M] + \frac{\beta_1^M\beta_2^M}{[H]^2}[M] + \frac{K_Y[M][Y]_{Total}}{K_Y[M] + \alpha_y} \qquad (5)$$

and the value of $\alpha_Y$ was then calculated from the acid dissociation constants of $H_3Y$ [18]

$$Ka_1^Y = \frac{[HY]}{[Y][H]} = 10^{9.73} \quad Ka_2^Y = \frac{[H_2Y]}{[HY][H]} = 10^{2.49}$$

$$Ka_3^Y = \frac{[H_3Y]}{[H_2Y][H]} = 10^{1.89}$$

The hydrolysis constants of $\beta_1^{Pb}$, $\beta_2^{Pb}$, $\beta_1^{Cd}$, and $\beta_2^{Cd}$ are the same as that previously mentioned. The $K_Y$ value was calculated from the formation constants of the NTA metal complex

$$K_Y^{Cd} = \frac{[CdY]}{[Cd][Y]} = 10^{10.0}\ [19]$$

$$K_Y^{Pb} = \frac{[PbY]}{[Pb][Y]} = 10^{11.47}\ [20].$$

[a] $A = [M-P]/[H_2P][M]$ was calculated from Eqs. (2) or (3) with the observed parameters

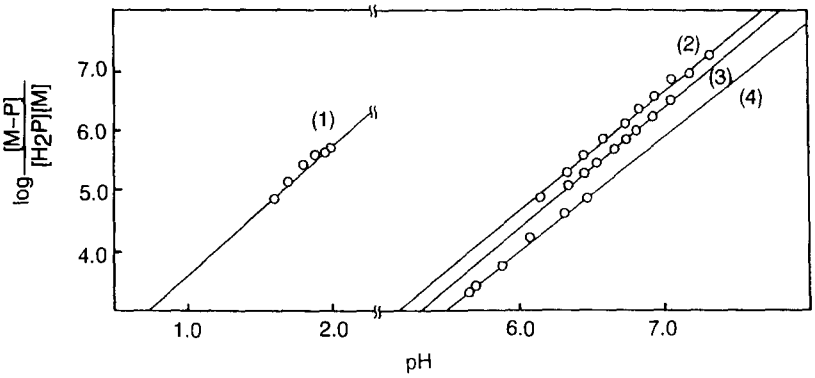

Fig. 3. Plots of log [M–P]/[$H_2$P][M] vs. pH for the dissociation reaction of TMPyP–metal(II) complexes at 20 °C and $I = 0.1$ M ($NaNO_3$). Line (1), TMPyP–Zn(II) (slope, 2.11); line (2), TMPyP–Mg(II) (slope, 1.99); line (3), TMPyP–Cd(II) (slope, 2.00); line (4), TMPyP–Pb(II) (slope, 1.90).

The solution of the quadratic Eq. (5) for [M] was calculated; $K$ can be determined by substituting this solution in Eq. (1)

The results are shown in Table 2 and Fig. 4. The equilibrium constants obtained in this study are summarized in Table 3. The values of log $K$ in Figs. 3 and 4 were also obtained from the $y$-intercept in the relationship log $A$ vs. pH. In Fig. 3, this analysis method gave the following values: $\log K_{TMPyP-Pb} = -7.44$ (slope, 1.90); $\log K_{TMPyP-Cd} = -7.71$ (slope, 2.00); $\log K_{TMPyP-Mg} = -7.32$ (slope, 1.99); and $\log K_{TMPyP-Zn} = 1.53$ (slope, 2.11). Moreover, similarly in Fig. 4, the values were $\log K_{TMPyP-Pb} = -7.93$ (slope, 2.01) and $\log K_{TMPyP-Cd} = -7.05$ (slope, 1.96). However, this method was not adopted, because the pH region of the experimental points was narrow and the slope of the straight line obtained by the least-square method slightly deviated from the 2.00 theoretical value. The average value of $K$ obtained from each experimental point was adopted as an equilibrium constant of the porphyrin complex in this study. The order of stability for each metal complex agreed well with that (Zn(II) > Mg(II) > Cd(II) > Pb(II)) reported by Falk [1]. With respect to the lead(II) complex, the measurement of the equilibruim constant based on the ligand exchange reaction is useful because of being able to reduce the influence of hydrolysis. As a result, the straight line (slope, 2.01) in Fig. 4 was better than that in Fig. 3 (slope, 1.90), since that in Fig. 4 is close to the theoretical value (slope, 2.00) of the two-proton reaction. Compared with the equilibrium constant in this study and those of Tabata et al. [7], reported for the TPPS–cadmium(II), –zinc(II) and

# Dopamine sensing and selectivity of Nafion-coated plant tissue powder sensors

Y. Chen, T.C. Tan *

*Department of Chemical Engineering, National University of Singapore, 10, Kent Ridge Crescent, 0511 Singapore*

Received 22 July 1994; accepted 1 November 1994

**Abstract**

Dopamine tissue sensors were prepared using biofilms containing pretreated tissue powder of potato, banana, mushroom and apple. These sensors showed good stability, reproducibility and service life span of more than 200 days involving 300 to 500 measurements. Overlaying the sensors with a Nafion coating considerably improved the sensor selectivity for dopamine by effectively precluding neutral and anionic solutes from entering the biofilm thus removing the interference of most of the 23 solutes examined in this study. The response of the Nafion-coated apple powder sensor in a mixture containing dopamine and the three strong interferents (arterenol, histidine and tyrosine), at concentrations within their respective linear calibration range, was linear with respect to the concentration of each of the solutes. The sensitivity of each of the components in the mixture was higher than the corresponding single component linear range sensitivity.

## 1. Introduction

Polyphenolase, an enzyme present in many fruits, fungi and vegetables, catalyses the oxidation of phenolic and allied compounds including dopamine [1,2], an important neurotransmitter associated with Parkinson's disease, muscular immobility and tumour when its concentration deviates from its normal level [3]. Polyphenolase sensors have been prepared with biofilm fabricated from tissues of apple [4–6] banana [5,7,8] potato, mushroom [5,9] and avocado [9]. In most cases, fresh tissues were used either by themselves [4,7,9,10] or mixed with a conductive material such as carbon paste [8]. They were characterized by very short service life owing to microbial degradation. They were normally stored at 4 °C to −10 °C when they were not being used. Tan and Chen [4,5] overcame the deterioration problem by removing water-soluble biodegradable materials from the tissue prior to its use for the biofilm preparation. They reported a service life of more than 3 months and were stored in phosphate buffer at room temperature when they were not in use. The sensors also showed better reproducibility, stability and sensitivity than the untreated tissue sensors. Polyphenolase also catalyses the oxidation of many other biogenic amines, amino acids and phenolic compounds. As a result, polyphenolase based biosensors generally showed poor selectivity. The selectivity problem is more serious with tissue sensors since the tissue also contained many other types of enzymes besides polyphenolase. Dopamine selectivity has been enhanced by overlaying the sensor with functional membranes such as base-hydrolysed cellulosic film to preclude larger molecule interferents [11], protonated poly(4-vinylpyridine) film to remove cationic interferents [12] and Nafion to remove anionic interferents [6,13]. Enzyme inhibitors and activators have also been used to improve the selectivity of tissue-based adenosine sensor [14].

This paper reports the effects of overlaying four different tissue powder sensors with a Nafion film on their efficacy and selectivity for dopamine sensing.

## 2. Experimental

### 2.1. Materials and preparation

All the chemicals used in this study were analytical reagent grade. Stock solutions of 0.05 M disodium hydrogen phosphate ($Na_2HPO_4 \cdot 2H_2O$, Merck) and 0.05 M sodium dihydrogen phosphate ($NaH_2PO_4 \cdot 2H_2O$, Merck) were prepared. Appropriate amounts of the two stock solutions were mixed when required to give 0.05 M phosphate buffers of pH ranging from 4.89 to 8.49. The pH was measured using a Hanna pH meter (Model 8417). Altogether 22 compounds of various biogenic amines, catecholamines, amines, amino acids and phenolic compounds were used to examine the sensitivity of the tissue sensors relative to dopamine. All compounds except phenol (BDH) were obtained from Sigma. Solutions of unstable and easily oxidizable compounds such as biogenic amines were prepared as required using nitrogen-deaerated deionized water.

### 2.2. Sensor fabrication and experimental procedure

Four Nafion-coated tissue power sensors were prepared using biofilms containing approximately the same mass of immobilized potato, banana, mushroom and apple pretreated powder according to the procedure described in an earlier paper [6]. The fabrication involved pretreating the tissue to remove water-soluble biodegradable solutes, immobilizing the tissue powder on polycarbonate membrane, coating Nafion on a polycarbonate membrane and finally securing these membranes over a dissolved oxygen probe (YSI Model 50, Yellowstone Instrument).

The sensor was placed in a jacketed beaker containing 50 ml of 0.05 M phosphate buffer of known pH and constant temperature. The solution was saturated with dissolved oxygen by bubbling air continuously through it. A Pine AFRDE4 potentiostat maintained the dissolved oxygen probe at $-0.8$ V and the current output was monitored continuously on a HP 3466A digital multimeter and simultaneously recorded on a Rikadenki chart recorder. At steady-state, the baseline current, $I_0$ was noted. A known amount of the test solute was added to the buffer. The new steady-state current, $I_s$ was recorded. The difference, $\Delta I$ $(=I_0 - I_s)$, was noted as the sensor response corresponding to the concentration of the test solute in the buffer solution. The response time for the system to equilibrate after the addition of the test solute was also recorded. The sensor was removed, washed with deionized water and returned to the jacketed beaker which was refilled with 50 ml of fresh buffer solution. The recovery time for the sensor current to return to its baseline value was noted before starting the next measurement. Measurements were carried for each of the four sensors at different pHs, temperatures and concentrations of dopamine and other solutes. To obtain good reproducibility and stability, the sensor has to be preconditioned when new or has been left unused for several weeks, and also each time the pH or temperature of the solution was changed. This was done by repeating the measurement procedure several times in the new environment with the same solute concentration until the results were reproducible.

The selectivity and interference effects of the 22 compounds were examined at 298 K and at the respective optimum pH of the sensor by comparing the sensor response of the solute with dopamine at the same concentration of 40.1 μM. Solutes showing a relative sensitivity (response) with respect to dopamine equal or greater than 10% were considered as strong interferents. For the sensor which showed the least number of such strong interferents, linear range calibration was carried out for each of the strong interferents. Measurements were also made in solutions containing different concentrations of dopamine and these strong interferents.

## 3. Results and discussion

### 3.1. Effect of pH

The response of the four Nafion-coated sensors generally increases with decreasing pH of the solution with a slight maximum shown by the apple sensor at pH about 5.56 (Fig. 1a). Without the Nafion coating, the sensors showed optimum response at pH 6.50 for

potato, 5.56 for apple and banana and 7.40 for mushroom [5]. A similar pH effect is shown in Fig. 1(b) on the ratio of the response of Nafion-coated sensor ($\Delta I_c$) to that without the Nafion coating ($\Delta I_u$). All the data for the uncoated sensors were obtained in a previous study [5]. These observations may be attributed to the increased swelling of the Nafion film at lower pH [15] resulting in higher solubility and diffusivity of the solute and hence better mass transfer [16]. Although Alhaique et al. [15] reported no pH effect on the permeability of cationic exchange Nafion film towards positively charged species such as dopamine, the diffusion rate of dopamine through the Nafion film would nevertheless vary with pH by virtue of its effect on the hydrolysis of dopamine in the solution. Since lower pH favours the hydrolysis of dopamine, the concentration of its positively charged species would, therefore, increase with decreasing pH. Its diffusion rate through the Nafion film would increase, resulting thereby in a higher sensor response. In the absence of the Nafion coating, the hydrolyis of dopamine has no effect on its diffusion through the polycarbonate membrane. The reduced sensor response of the Nafion-coated sensors is, however, a measure of the mass transfer resistance and the cationic exchange activity of the Nafion film.

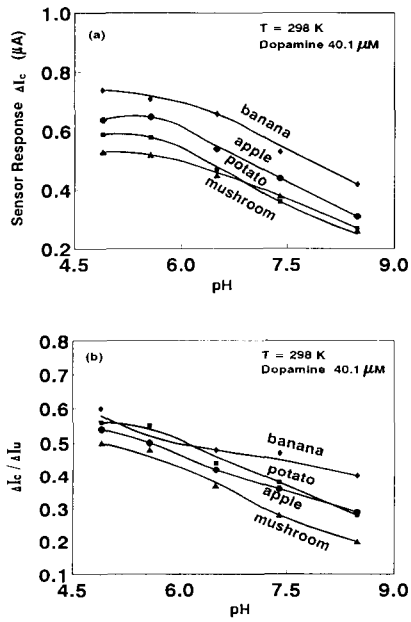

Fig. 1. pH effect on sensor response to dopamine.

TAL 42-8-H

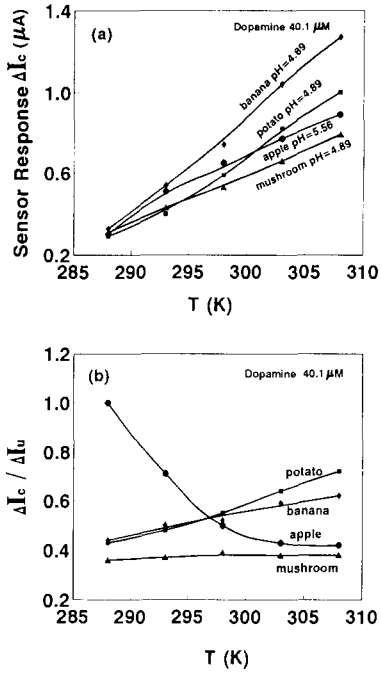

Fig. 2. Temperature effect on sensor responses of Nafion-coated sensors and the ratio $\Delta I_c/\Delta I_u$.

### 3.2. Effect of temperature

The response of all the four sensors increased monotonically with temperature increasing from 288 to 308 K (Fig. 2a). The data for the uncoated sensors were obtained in a previous study [5] at their respective optimum pH. The response of the Nafion-coated sensors relative to the uncoated sensors is shown in Fig. 2(b). Only the apple sensor showed a decreasing trend. Since measurements using the apple sensor with and without the Nafion coating were made at the same pH, the temperature effect on the reaction constant and diffusion through the polycarbonate membrane and biofilm should be the same for both cases. The decrease in the relative response is, therefore, a measure of the temperature effect on the hydrolysis of dopamine, the extent of swelling and the cation transport property of the Nafion film. In the other three cases, the increase in the relative response with temperature would also include the effects due to operating the Nafion-coated sensors at lower pH.

### 3.3. Response and baseline recovery

The response time of the Nafion-coated sensors generally increased with increasing dopamine concentration. The response time at 298 K was about 3–14 min in the linear concentration range of pH 5.56 for apple and 4.89

Table 1
Sensing characteristics for dopamine in 0.05 M phosphate buffer

| Parameters | Potato | Banana | Mushroom | Apple |
|---|---|---|---|---|

| | (7–30) | (7–13) | (5–12) | (10–30) |
| Service life (day) | >240 | >235 | >206 | >214 |

Figures in parenthese are for the uncoated sensors obtained from Ref. [5].

for the other three sensors (Table 1). These were comparable with the response time (values in parentheses in Table 1) of those without the Nafion coating and operating at their respective optimum pH and higher linear concentration range [5]. The negligible change in the response time with the addition of the Nafion film could be due to the lower concentration involved and operating at lower pH (except for apple). Carr [17] and Chen and Tan [5] found that the response time is longer with lower operating temperature, higher concentration and lower diffusivity of the substrate.

Good reproducibility, stability and service life span were obtained by leaving the sensor after each measurement in a fresh phosphate solution to allow it to return to its baseline value. The baseline recovery time for the Nafion-coated sensors varied from 2–27 min compared with 5–30 min for the uncoated sensors [5] for the same reasons of lower substrate concentration in the biofilm and pH.

### 3.4. *Reproducibility, stability and service life*

The stability and reproducibility of the four sensors with and without the Nafion coating was examined over a period of more than 200 days by repeating the steady-state measurement in a 0.05 M phosphate buffer containing 40.1 μM dopamine at 298 K and at their respective operating pH. The sensors were used in between these measurements for other parametric studies involving more than 300 measurements for the mushroom sensor and more than 500 measurements for the other three sensors. They were stored in substrate-free phosphate buffer at room temperature when they were not in use. The time plot of the relative response expressed as per cent of the initial value corresponding to the first steady-state measurement immediately after its preconditioning is shown in Fig. 3. All the four sensors showed a mean relative response of 100.1–104.1% with a standard deviation of 1.46–4.25 and a coefficient of variation (CV) of 1.5–4.1%. These results showed conclusively that the pretreated tissue powder sensors have

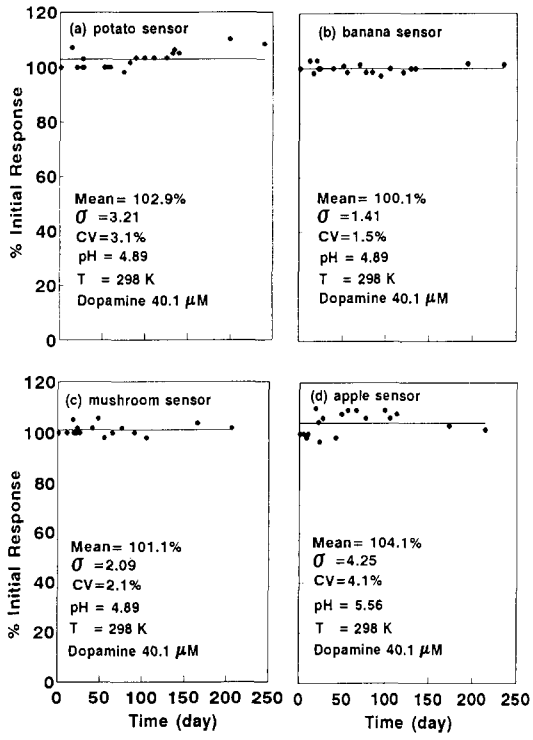

Fig. 3. Stability and reproducibility of the sensor response.

considerably better stability, reproducibility and longer service life compared with sensors using untreated tissues [4,7,9,10] or purified tyrosinase [18]. Moreover, the storage of the present sensors when they were not in use was considerably more convenient in phosphate buffer at room temperature compared with −10° to 4 °C storage conditions for the untreated tissue sensors. The Nafion coating further reduced the contamination and deactivation of the enzyme in the tissue powder by precluding most of the interferents from entering the biofilm.

### 3.5. Calibration against dopamine

The results of the calibration of the four Nafion-coated sensors against dopamine at 298 K and pH 5.56 for the apple sensor and 4.89 for the other three sensors are given in Table 1. Corresponding values for the uncoated sensors obtained in a previous study [5] are given in parentheses for comparison. Linear response was observed over the concentration range of 4–40.1 μM for potato and banana sensors and 4–79.9 μM for mushroom and apple sensors with sensitivity of about 0.0137–0.0183 μA/μM compared with 0.0271–0.0344 μA/μM reported earlier for the uncoated sensors [5]. The presence of the Nafion film, therefore, reduced the sensitivity to about half that of the uncoated sensors. A similar drop in sensitivity was observed by Gerhard et al. [19] and Harrison et al. [20] for their Nafion-coated sensors.

### 3.6. Selectivity and interference

The response of the four sensors to 22 solutes relative to their response to dopamine at the same concentration of 40.1 μM at different pHs are shown in Fig. 4(a–d). The data for the uncoated sensors [5] given as PU 6.5 in Fig. 4(a), BU 5.56 in Fig. 4(b), MU 7.4 in Fig. 4(c) and AU 5.56 in Fig. 4(d) were included for comparison. The anionic repulsion property of the Nafion film significantly reduced or totally eliminated the interference of anionic interferents including amino acid with p$I$ values less than the pH of the solution such as DOPAC (Dc), homovanillic acid (H), vanillymandelic acid (V), L-histidine (Hd), L-tryptophan (Tp), L-DOPA (Da), L-tyrosine (Ty), L-cysteine (Ce), L-cystine (C) and 3-indolylacetic acid (I). On the other hand, its cationic exchange property enhanced the sensor sensitivity towards cationic solutes while the reduced sensitivity towards the neutral solutes such as catechol (Ct) could be due to its mass transfer resistance. The exclusion of anions and neutral molecules reduced the contamination and deactivation of the enzymes in the tissue and further improved the stability, reproducibility and service life span of the sensor. Among the four sensors, dopamine sensing by the apple powder sensor was affected by the least number of interfering solutes and the number was further reduced by the Nafion coating. The present sensors showed significantly lower sensitivity to the interferents reported for a purified mushroom tyrosinase sensor [18].

The effect of concentration on the extent and nature of interference was studied using the Nafion-coated apple sensor at a pH of 5.56. The results showed that increase in the solute concentration did not affect the interference of epinephrine (E), H, V, tryptamine (T), C, I, phenol (P), ascorbic acid (Aa), 3-methoxytyramine hydrochloride (M), serotonin (S), Tp, Da, adenine (Ad), riboflavin (R), DOPEG (Dg) and Ct up to a concentration as high as 100 μM. The results confirmed that these solutes have little or no interference on dopamine sensing within the linear calibration range of dopamine. However, the relative selectivity of uric acid (Ua) with respect to dopamine at the same concentration decreased from 17% at 40.1 μM to 3% at 98.3 μM. This showed that the sensitivity of dopamine is more concentration dependent than that of uric acid outside the linear range. Linear calibration was carried out for arterenol (Ar), Dc, Ty, Hd and Ce. The results are given in Table 2. The linear range sensitivity of arterenol, histidine and tyrosine to dopamine was about 11–12% that of dopamine. Their interference in a mixture with dopamine was examined by determining the sensor response at different concentrations of the four components in the mixture. The concentration of each of the components was limited to within its linear calibration range. The experimental sensor response–composition data were correlated assuming linear interaction and the results obtained given by:

$$\Delta I_{\text{mixture}} = 0.0178C_{\text{dopamine}} + 0.0033C_{\text{arterenol}} + 0.0037C_{\text{histidine}} + 0.0023C_{\text{tyrosine}}$$

The correlation showed a mean fractional error of 0.088 with a standard deviation of 0.12 and

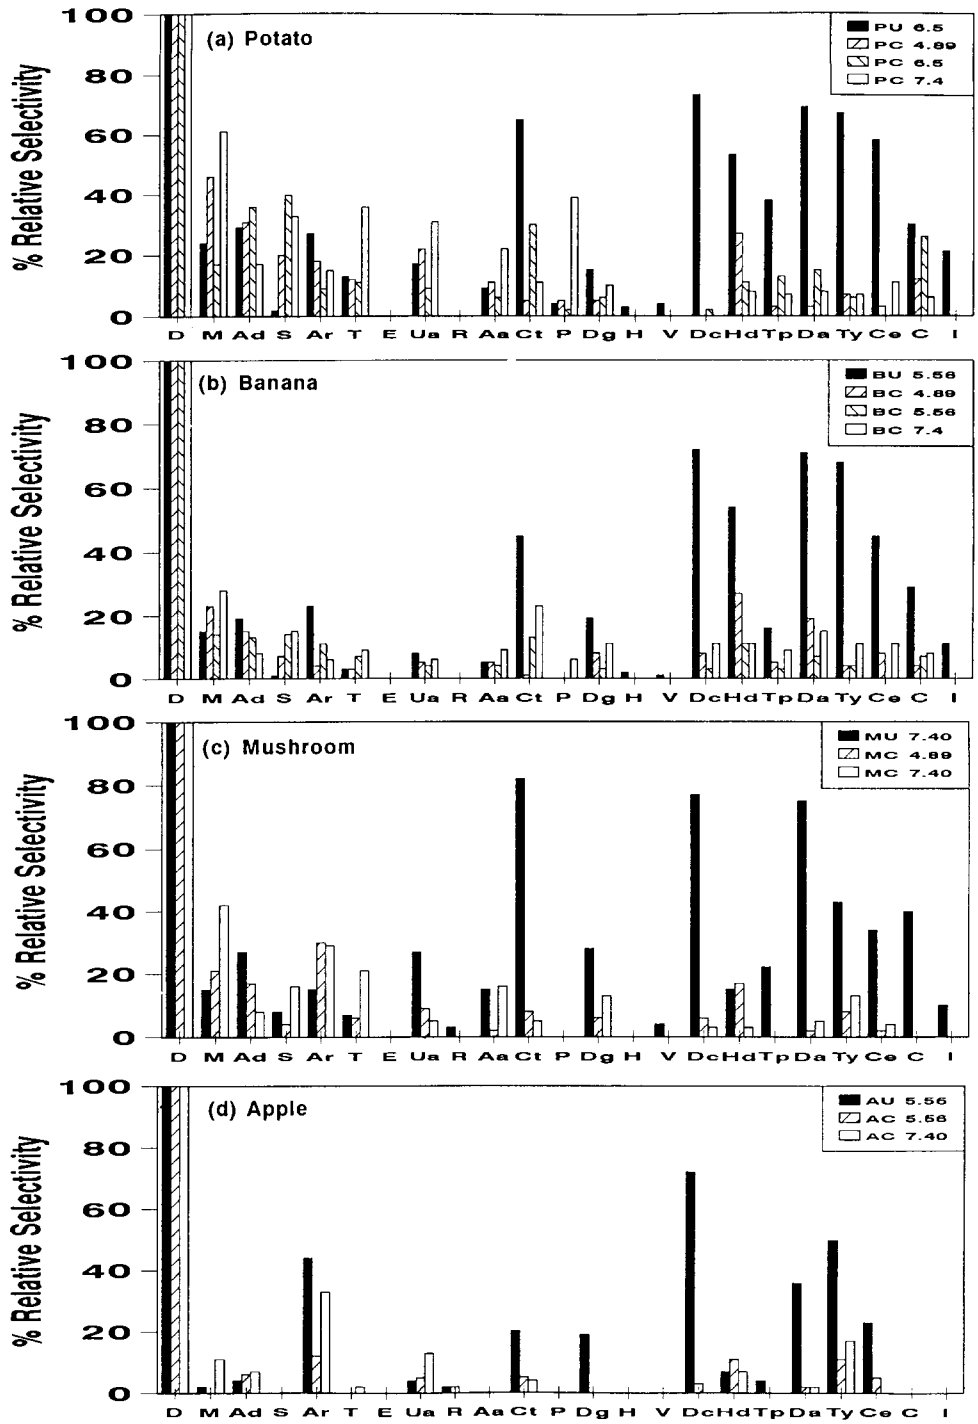

Fig. 4. Relative selectivity of sensors with and without the Nafion coating for 22 solutes with respect to dopamine—D(dopamine), M(3-methoxytramine hydrochloride), Ad(adenine) S(serotonin), Ar(arterenol), T(tryptamine), E(epinephrine), Ua(uric acid), R(riboflavin), Aa(ascorbic acid), Ct(catechol), P(phenol), Dg(DOPEG), H(homovanillic acid), V(vanillylmandelic acid), Dc(DOPAC), Hd(histidine), Tp(tryptophan), Da(DOPA), Ty(tyrosine), Ce(cysteine), C(cystine) and I(3-indolylacetic acid). (The data for the uncoated sensors were obtained from Ref. [5].)

a mean ratio of calculated to experimental response of 1.064 with a standard deviation of 0.135. The component sensitivity in a mixture was higher than the corresponding pure component sensitivity for all the components. The increase is in the order of decreasing molecular weight of the components: dopamine (MW 189.6) increased by 5.4%, tyrosine (MW 181.2)

Table 2
Calibration and relative selectivity of apple tissue powder sensor

| Solute | Linear range (μM) | Sensitivity (μA/μM) | % relative selectivity coated (uncoated) |
|---|---|---|---|
| Dopamine | 4–79.9 | 0.0169 | 100.0(100.0) |
| Arterenol | 4–95.0 | 0.0019 | 11.6(51.7) |
| Histidine | 4–60.0 | 0.0018 | 10.8(12.0) |
| Tyrosine | 4–40.3 | 0.0018 | 10.5(49.8) |
| Cysteine | 4–23.7 | 0.0012 | 7.4(22.8) |
| DOPAC | 4–40.2 | 0.0005 | 3.0(72.0) |

by 32.3%, arterenol (MW 169.2) by 71.7% and histidine (MW 155.2) by 107.8%. Solute diffusing in the same direction mutually increased their mass transfer rates and the increase was higher with smaller molecules. This would, therefore, explain the mutual increase in the response and sensitivity of the components in the mixture. The increase may also be attributed to the difference in the affinity of the Nafion film for the various components depending on their positivity at the operating pH.

## 4. Conclusions

Four Nafion-coated tissue powder sensors were fabricated using tissues of potato, banana, mushroom and apple which have been pretreated to remove the water-soluble biodegradable solutes contained in the tissue. They showed good stability, reproducibility and service life span of over 200 days involving 300–500 measurements compared to the few days life span of untreated tissue and purified polyphenolase sensors. The sensors were stored in phosphate buffer at room temperature unlike the raw tissue sensors which have to be stored at 4 to −10 °C. Overlaying the sensors with a Nafion coating considerably increased sensor selectivity for dopamine and decreased the number of interferents among the 22 solutes examined in this study by effectively precluding the neutral and anionic solutes from entering the biofilm. This further reduced the contamination and deactivation of the enzymes in the tissue. Apple tissue powder sensor showed the least number of interferents. Its response to a mixture of dopamine and three other strong interferents (arterenol, histidine and tyrosine) was linear with respect to the concentration of the components. The component sensitivity of all the components in the mixture was higher than the respective single component sensitivity. The long service life span of these sensors and the effectiveness of Nafion coating in reducing interference of most of the solutes have enhanced their potential applications in clinical analysis of dopamine in physiological fluids and as a detector for liquid chromatograph.

## Acknowledgements

The authors gratefully acknowledge the funding of the sensor project by the National University of Singapore and the award of a research scholarship to Y. Chen for her graduate study.

# Book reviews

***Information Theory in Analytical Chemistry***, by K. Eckschlager and K. Danzer, Wiley, Chichester, 1994, xv + 275 pp., £54.00. ISBN 0-471-59507-1.

Imagine, if you will, a book on relativity that does not mention Einstein. It would be hard to take very seriously as a work of authority. Eckschlager and Danzer's book is concerned with information theory, a subject which was pioneered by Claude Shannon and developed in numerous areas of physics by Ed Jaynes. These men are the giants of the field, and indeed, major contributors to 20th century science, but Shannon receives only a passing reference, and Jaynes is ignored altogether! This sets the tone for what I regard as a very unsatisfactory book.

It is unsatisfactory first of all because of a tendency to gloss over key issues. For example, the use of entropy in an information theory context is still a subject of controversy, yet this problem is completely ignored: "*Entropy is a universally valid measure of uncertainty, disorder, irrespective of the system whose order is characterised by it*" state the authors. This is their belief, but at the very least there should be some references to the literature here from which the reader can explore this rich seam of controversy.

Bayes' theorem (called rather quaintly "*Bayes' relation*" in the book) is a key ingredient in the use of information theory. It enables you to code into the calculations suitable prior knowledge of the parameters being sought. It too gets scant attention. This is another unsatisfactory tendency; information theory is presented as an isolated edifice. There are numerous discussions of increases in information content when certain mathematical techniques are used, but often it is just traditional statistics in another guise, when what is needed is a Bayesian method in which the entropy functional is used in conjunction with Bayes' theorem.

The reader will have noticed that the English of the quotation in paragraph two above is rather stilted; this is characteristic of the whole book. Sentences are not grammatically incorrect in general, but they are rather unusual in their grammar and use of words; the text does not flow easily. So if you are an analytical chemist looking for a useful book on information theory, this is not the one, but if you do purchase it be aware that the method is much more wide ranging and intellectually stimulating than this.

***Quality Assurance for Biopharmaceuticals***, by J.F. Huxsoll, Wiley, New York, 1994, 206 pp., £49.50. ISBN 0-471-03656-0.

This book is an excellent, instructive, concise, easily readable, reference source on quality assurance (QA). It deals with general basic principles and the particular problems associated with manufacture and control to assure the quality of biopharmaceuticals. Testing, documentation, labeling, validation, audit, training, safety and waste management — all have their place in the book. The frequent use of lists summarising the requirements for, e.g. QC, documentation, validation, etc., and lists explaining the multitude of abbreviations used in QA literature is to be commended. All who work in QA know that statistical analysis is required. The relevant chapter represents a basic, concise guide to all the statistical methods required in the control of QA processes. For those with an interest in marketing biopharmaceutical products in the USA, Europe and Japan, the last three chapters in the book deal with the regulatory issues and variations in requirements between these three major markets.

All eleven chapters in the book are written in the same concise style. All contain appropriate references at the end of each chapter for further reading. A minor criticism, from the point of the reader outside the USA, is that the book

***Pharmaceutical and Biomedical Applications of Liquid Chromatography***, edited by C.M. Riley, W.J. Lough and I.W. Wainer, Elsevier, Oxford, 1994, x + 379 pp., £85.00. IBSN 0-08-041009-X.

As is outlined in the Introduction, this text is a sequel to a previous volume edited by I.W. Wainer on Liquid Chromatography in Pharmaceutical Development. As such it is a valuable addition to the literature in this area since it deals with developments in LC which have been developed or which have assumed greater importance since the publication of the earlier book.

The book is divided into four parts, each dealing with different aspects of a general area. Part 1 deals with two aspects of on-column separations namely the very general amine-containing compounds such as primary amines, amino acids and peptides and also methods of obtaining fast separations of enantiomers. The chapter on capillary electrophoresis with which this part begins could usefully have been omitted. Half of it is devoted to standard electrophoretic theory and the remainder is a very general overview which requires to be dealt with in much greater detail to be useful.

Part 2 consists of four chapters each dealing with a topic representing a variant on sample pretreatment. The chapter on solid phase extraction, while short, is a good general account of the process. The chapter on on-line microdialysis pretreatment combines good treatment of theoretical considerations with numerous specific applications of the technique. This part of the text concludes with a short but readable account of column switching as applied to chiral separations.

The third part of the book focuses on the use of liquid chromatography as a preparative method. One chapter deals generally with the problems of obtaining pure samples of drugs for evaluation studies using liquid chromatography. The other is concerned specifically with the purification of naturally occurring biomolecules. This chapter reviews different chromatographic modes of operation as well as discussing the different retention mechanisms which have been employed for proteins and peptides.

The concluding part contains two chapters each concerned with the validation of assays based on liquid chromatography. The first of these, Chapter 10, deals with the strategic aspects of developing a separation and this is followed with a short account of validation parameters. Here the separate validation requirements for main component and impurity assay are nicely distinguished. The last chapter is a much more in-depth account of assay validation including useful flow charts and necessary statistical relationships.

Overall this is an excellent companion volume to the previous Liquid Chromatography in Pharmaceutical Development. Most practising chromatographers will find chapters directly relevent to their own current interests. In addition, the coverage of the developments which have taken place over the last few years is so well balanced that all of us will find this book useful in obtaining at least a nodding acquaintanceship with areas outside our direct interest as well as providing a useful range of references for further reading.

***Reviews on Analytical Chemistry — Euroanalysis VIII***, edited by D. Littlejohn and D. Thorburn Burns, The Royal Society of Chemistry, Cambridge, 1994, x + 365pp., £75.00. ISBN 0-85186-982-3.

The compilation of papers which go together to make this book represents 25 of the invited lectures presented at the Euroanalysis VIII conference held in Edinburgh in 1993. They consist of a very diverse range of subjects and vary in their style from reviews to more research-based papers. The editors have attempted to give some structure to the chapters, but the text covers a wide range of subject areas and by its nature lacks cohesion. Readers are advised to look closely at the contents of the book as many major areas of analytical science were obviously not presented as papers at the conference. Nevertheless, given that the text was prepared as a summary of the papers at Euroanalysis VII, it clearly achieves its aim, with a set of well written and easy-to-read papers. I would question, however, the review aspects of some of the chapters and this may be a misleading feature of the title.

is aimed at a USA public and thus the text uses USA legislative requirements for illustrative examples.

***Reviews on Analytical Chemistry — Euroanalysis VIII***, edited by D. Littlejohn and D. Thorburn Burns, The Royal Society of Chemistry, Cambridge, 1994, x + 365pp., £75.00. ISBN 0-85186-982-3.

The compilation of papers which go together to make this book represents 25 of the invited lectures presented at the Euroanalysis VIII conference held in Edinburgh in 1993. They consist of a very diverse range of subjects and vary in their style from reviews to more research-based papers. The editors have attempted to give some structure to the chapters, but the text covers a wide range of subject areas and by its nature lacks cohesion. Readers are advised to look closely at the contents of the book as many major areas of analytical science were obviously not presented as papers at the conference. Nevertheless, given that the text was prepared as a summary of the papers at Euroanalysis VII, it clearly achieves its aim, with a set of well written and easy-to-read papers. I would question, however, the review aspects of some of the chapters and this may be a misleading feature of the title.

Chapter 1 gives a historical perspective of Scottish analytical chemistry and contains many facts, elucidating many of the relationships between alchemy, scientific chemistry and analytical science. Individual sections describe the life and work of some notable chemists and contain many interesting anecdotes. With the growing importance of validation and data quality it is not surprising that papers 2 and 3 focus on this subject. *Traceability to the Mole: A New Initiative by CIPM* might not seem a wildly attractive title to the analyst but the text is an excellent review on calibration techniques mainly using isotope dilution mass spectrometry. The third paper is a very provocative view of the quality of analytical methods and demonstrates an interesting analogy to the presence of towers on the Dutch landscape. The next two papers focus on initiatives to improve the quality of food analysis and in particular the regulatory requirements. Paper 6 looks at water quality standards, identifying the good and the bad guys and states what effluents should or should not contain. Factors that influence elemental species in sediments form the basis of a detailed review whilst the speciation of organic sulphur in hydrocarbons is given a very thorough discussion in a complimentary paper. The final four papers in the book deal with clinical applications of analytical science, mainly the use of capillary electrophoresis as a diagnostic tool, magnesium determinations, the use of stable isotopes in clinical studies and assays based on antibody screening. The remaining 12 papers tend to be orientated mainly towards techniques rather than applications and include a review on plasma mass spectrometry and the use of mass spectrometry in process analysis. These topics based papers continue with laser induced molecular luminescence, a most interesting review of high resolution imaging techniques, neural networks including the use of fuzzy logic, electrochemical applications including microelectrodes, modified electrodes for sensor and in-vivo monitoring, and two reviews on flow analysis. The papers vary in length but are very readable taking anything from 20 to 40 minutes to complete any one article. Each paper is packed with information and high quality tables and diagrams can be found throughout the text. There is a limited index for reference purposes, but the real value of the book does not lie in its reference capability, but in the fact that it offers a snapshot 'state of the art' view on particular topics and how they are developing. As indicated earlier many of the more traditional aspects of analytical chemistry are not covered in the book, but those included are recommended to the reader who wishes to consolidate their current knowledge or just browse into other areas of analytical methodology.

S.J. Haswell

***Handbook of Surfactants***, 2nd ed., by M.R. Porter, Blackie, London, 1994, xii + 324 pp., £75.00. ISBN 0-7514-0170-6.

As implied in the title, this is a practical book aimed at those who work with surface-active agents. Compared to the first edition the book has been updated and extended and the chapters on surfactant theory and polymeric surfactants have been completely rewritten.

Following a short introduction, a general approach to using surfactants in formulations is given. The author's experience is very much in evidence both here and in the following chapter on information sources where his opinions on certain published works and databases are confidently stated, e.g. "By far the best book on. . . ", "Good but more theoretical than practical", and "Does not quite live up to title".

There then follows a comprehensive chapter (63 pp.) on surfactant theory which is superbly illustrated with 59 diagrams and contains many up-to-date references from the 1990s. This chapter presents a very good, non-mathematical description of surfactant theory, with details such as the definition of HLB number and the experimental observation (by light scattering) that there are about 71 sodium lauryl sulphate molecules in a micelle at 23 °C.

The following four chapters, which make up more than half of the book, are devoted to the four main classes of surfactant: anionic, nonionic, cationic and amphoteric. These chapters start with an introduction and then the main types are discussed under sub-headings such as Nomenclature, Description, General properties, Applications, and Specification. As expected, the chapter on anionics (70 pp.) is dominated by the sulphates and sulphonates but the carboxylates, isethionates, phosphates, sulphosuccinates, sulphosuccinamates and taurates are also mentioned. A total of 15 sub-divisions are made to cover the nonionic surfactants (79 pp.) with the Tweens and Spans (Atlas trade names) discussed under Sorbitan derivatives. The chemistry of ethoxylation is also given in this chapter.

Chapter 1 gives a historical perspective of Scottish analytical chemistry and contains many facts, elucidating many of the relationships between alchemy, scientific chemistry and analytical science. Individual sections describe the life and work of some notable chemists and contain many interesting anecdotes. With the growing importance of validation and data quality it is not surprising that papers 2 and 3 focus on this subject. *Traceability to the Mole: A New Initiative by CIPM* might not seem a wildly attractive title to the analyst but the text is an excellent review on calibration techniques mainly using isotope dilution mass spectrometry. The third paper is a very provocative view of the quality of analytical methods and demonstrates an interesting analogy to the presence of towers on the Dutch landscape. S.J. Haswell

***Handbook of Surfactants***, 2nd ed., by M.R. Porter, Blackie, London, 1994, xii + 324 pp., £75.00. ISBN 0-7514-0170-6.

As implied in the title, this is a practical book aimed at those who work with surface-active agents. Compared to the first edition the book has been updated and extended and the chapters on surfactant theory and polymeric surfactants have been completely rewritten.

Following a short introduction, a general approach to using surfactants in formulations is given. The author's experience is very much in evidence both here and in the following chapter on information sources where his opinions on certain published works and databases are confidently stated, e.g. "By far the best book on. . . ", "Good but more theoretical than practical", and "Does not quite live up to title".

There then follows a comprehensive chapter (63 pp.) on surfactant theory which is superbly illustrated with 59 diagrams and contains many up-to-date references from the 1990s. This chapter presents a very good, non-mathematical description of surfactant theory, with details such as the definition of HLB number and the experimental observation (by light scattering) that there are about 71 sodium lauryl sulphate molecules in a micelle at 23 °C.

The following four chapters, which make up more than half of the book, are devoted to the four main classes of surfactant: anionic, nonionic, cationic and amphoteric. These chapters start with an introduction and then the main types are discussed under sub-headings such as Nomenclature, Description, General properties, Applications, and Specification. As expected, the chapter on anionics (70 pp.) is dominated by the sulphates and sulphonates but the carboxylates, isethionates, phosphates, sulphosuccinates, sulphosuccinamates and taurates are also mentioned. A total of 15 sub-divisions are made to cover the nonionic surfactants (79 pp.) with the Tweens and Spans (Atlas trade names) discussed under Sorbitan derivatives. The chemistry of ethoxylation is also given in this chapter.

The short chapter on cationic surfactants (10 pp.) briefly discusses quaternary ammonium, amine and imidazoline salts and I recognised Cetrimide BP (an antiseptic detergent) as being in this category. Amphoterics (18 pp.) covers betaines, glycinates and amino propionates and mentions their mildness on skin and mucous membrane compared with other types of surfactants. A further short chapter is concerned with speciality surfactants and includes Bolaform surfactants (polar groups at both ends of the hydrophobic group) and Gemini surfactants (two surfactant molecules linked with an organic spacer via the two hydrophilic groups). The final chapter covers polymeric surfactants and is followed by two appendices — the first on names of hydrophobes and average composition of fats and oils and the second on the all important ecological and toxicity requirements.

Overall, I found this book very detailed. Having read it from cover-to-cover I find it difficult to retain all the information offered and I will have to revert to using it as intended, i.e. as a handbook. It includes much practical information such as details of surfactant mixtures and compatibilities and the theory and practical chapters compliment each other extremely well. It will be a very worthwhile purchase for all those involved with surfactants.

***Principles and Applications of Electrochemistry***, by D.R. Crow, Chapman and Hall, London, 1994, xi + 282pp., Softback, £16.99. ISBN 0-7514-0168-4.

This well known text is now into its 4th edition. It has undergone extensive revision but has maintained a traditional approach in bringing the text up-to-date with the content requirements of modern undergraduate courses in chemistry. The book is divided into two parts. Part I (153 pp.) covers the principles of ionic interactions, ionic equilibria, conductivity, interfacial phenomena, electrochemical cells and electrode processes. The author's teaching experience shows in the clear and lucid way in which the fundamental principles are presented and appropriately illustrated with suitable diagrams, tables or problems. Part II (98 pp.) gives the applications which have as their basis the theoretical considerations given in Part I. These include equilibrium constant determinations by both conductivity and pH measurement, polarography, amperometric titration and coulometric methods. The last but one chapter gives a brief overview of electrochemical sensors and in the final chapter, the exploitation of electrode processes, e.g. as sources of energy in industry, is explained and exemplified.

As an aid to understanding the text, problems are given at the end of each chapter and answers in an Appendix. Each chapter also has suggestions for further reading. In this day and age where self study is becoming more important a text such as this is recommended.

***Analysis of Addictive and Misused Drugs***, edited by J.A. Adamovics, Dekker, New York, 1994, viii + 671pp., US$195.00. ISBN 0-8247-9238-6.

Approximately half of this text consists of separate chapters devoted to individual analytical techniques used for the quantification of drugs. The remainder of the book, some 300 pages, consists of an appendix in the form of a reference table of analytical methods for approximately 400 compounds listed as controlled substances by the U.S. Drug Enforcement Agency or as banned drugs by the International Olympic Committee. The data provided in this appendix include, for each compound, the matrix, analytical technique, any sample pretreatment required, stationary and mobile phases for chromatographic analyses (which constitute the vast majority of the methods cited), detection method, comments including additional references and original literature reference.

This section will be useful as a source of analytical information for those requiring to undertake analysis of such durgs in that it assembles information into a concise and useable format. While this appendix is not exhaustive, it does serve the more general purpose of indicating the relative degree of use of different analytical techniques in this field. In this sense it shows current usage of the different techniques discussed in the individual chapters. It is stated in the text that the purpose of the appendix is to complement the material in individual chapters. It seems approproate, there-

The short chapter on cationic surfactants (10 pp.) briefly discusses quaternary ammonium, amine and imidazoline salts and I recognised Cetrimide BP (an antiseptic detergent) as being in this category. Amphoterics (18 pp.) covers betaines, glycinates and amino propionates and mentions their mildness on skin and mucous membrane compared with other types of surfactants. A further short chapter is concerned with speciality surfactants and includes Bolaform surfactants (polar groups at both ends of the hydrophobic group) and Gemini surfactants (two surfactant molecules linked with an organic spacer via the two hydrophilic groups). While this appendix is not exhaustive, it does serve the more general purpose of indicating the relative degree of use of different analytical techniques in this field. In this sense it shows current usage of the different techniques discussed in the individual chapters. It is stated in the text that the purpose of the appendix is to complement the material in individual chapters. It seems approproate, there-

fore, that each of the analytical methods in these chapters is treated from a different standpoint.

In Chapter 1 the principles of enzyme immunoassays are covered together with some of the commercially available technology while in Chapter 2 biosensors based on enzyme reactions and bioaffinity are described in general terms. Chapter 3 is an account of a single commerical TLC system. Chapter 4 provides considerable information on the general principles of obtaining LC separations including choice of stationary and mobile phase composition. Numerous applications of these to forensic situations are described. The relative state of use of capillary electrophoresis is shown in Chapter 5 in that the majority of information is concerned with explaining the principles of separation in the various modes of CE and limiting examples to essentially bulk material. Chapter 6 is an amalagam of TLC and coupled GC–MS. These appear to have been included in a single chapter in order to describe the principle of initial screening for abused drugs in biological fluids and subsequent confirmation. This chapter also contains a large tabulation of TLC and GC–MS data for different drugs.

The last two chapters are somewhat extraneous to the main thrust of this text. The chapter on drug testing of athletes is basically a detailed account of particular screening and confirmation procedures. Likewise, that on drug analysis in South America, describes operating procedures rather than extending the analytical content of the book. These chapters will have a much less general appeal than the rest of this text which will be a useful addition to the analytical literature concerned with testing for drug abuse and misuse.

Review

# Recent developments in derivative ultraviolet/visible absorption spectrophotometery

C. Bosch Ojeda, F. Sanchez Rojas, J.M. Cano Pavon *

*Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, 29071 Málaga, Spain*

Received 11 October 1994; accepted 10 March 1995

**Abstract**

The instrumental development and analytical applications of derivative ultraviolet/visible region absorption spectrophotometry produced in the last seven years (since 1987) are reviewed.

## 1. Introduction

In a review published some years ago [1] we exposed the theoretical aspects, instrumental devices and analytical applications of derivative ultraviolet/visible spectrophotometry (DS) until 1986. Although this technique does not really constitute a very important innovation, its ability to solve problems, especially for binary and ternary mixtures of compounds whose spectra show considerable overlapping, have made its use grow spectacularly over the last few years, especially in pharmaceutical, clinical and biochemical, as well as in inorganic and organic analysis.

The purpose of this paper is to review the publications on instrumental and theoretical aspects of derivative spectrometry and its use in the diverse fields of applications published since 1987, in order to fill the gap existing since the publication of our first review.

## 2. Theoretical and instrumental aspects

Over the last few years, the use of digital differentiation by means of computers to obtain derivative spectra has been the usual procedure. Higher order derivatives can easily be obtained. General principles of these methods have been reviewed [2], and diverse interferences for coupling conventional spectrophotometers to microcalculations have been developed [3]; diverse algorithms (such as those of Fourier and Savitzky–Golay) are often used for obtaining the derivative spectra [4].

Diode-array spectrophotometers are actually widely used owing to their speed. Different computer-based data-acquisition systems for use with diode-array spectrophotometers have been described [5]. Diverse programs were developed to control the system and to process the results. Program functions usually included: (i) acquisition of data and correction for diode sensitivity, (ii) correction for positional shifts in array, (iii) creation of the data-base, (iv) fitting of the baseline, location of peaks, conversion to wavelength and identification of elements present, (v) display of raw and enhanced data from individual arrays, and (vi) use of an artificial intelligence approach to identify components of a sample [6].

The attained derivative spectra have been assayed by other procedures, e.g. by subtrac-

* Corresponding author.

tion of delayed spectra. In this procedure, production of a derivative spectrum is achieved with the use of a single data system without the creation of noise and without the need for computer software; the spectrum is stored in one half of the memory. A small horizontal shift is made, the size of which is not critical, and the resultant is transferred to the second half of the memory; the derivative spectrum is then created by subtraction of one half from the other [7].

An inconvenience of the derivative technique is that the signal-to-noise ratio (S/N) becomes progressively worse for higher orders. For this reason, practical derivative techniques include some degree of low-pass filtering or smoothing to control the increase in noise. Over the last few years, this problem has usually been solved by three types of digital filtering: ensemble averaging, least-squares polynomial smoothing and Fourier smoothing. Several computer programs were written for the actual applications of the concepts of these digital filters on UV/visible spectrophotometer systems; as a result, ensemble averaging could not be applied as a routine operation for the spectrophotometer used; the maxima S/N enhancement factors achieved by least-squares polynomial smoothing were 6.17 and 7.47 for the spectra of Gaussian and Lorentzian distribution models, and 16.42 and 11.78 by Fourier smoothing for the spectra of the two models, respectively [8]. Talsky concludes that, in general, the more favourable S/N was obtained from four to six orders of derivative when electronic differentiation combined with diverse filtering systems was used [9].

The precision and accuracy in derivative spectrophotometry have been evaluated in a wide variety of situations. Using a computerized numerical method, it has been concluded [10] that if the spectrophotometric measurements are accurate to four significant figures, the relative error of the first numerical derivative is 0.6%; if measurements are accurate to three significant figures, the relative error of the first numerical derivative is 6%. Compared with conventional spectrophotometry, the first derivative from a recording spectrophotometer caused an average error of $\approx 4\%$, but at the peak of the first derivative the error was $\approx 2\%$. Kimbrell et al. [11] recently developed a theoretical study on the multiple interacting factors which determine precision in derivative spectrometry. According to this work, the precision varies by close to an order of magnitude when reasonable combinations of factors levels are used; the derivative order typically interacts strongly with the polynomial degree of the smoothing and derivatizing functions, and with the window width of these functions.

Enhancement of the precision and accuracy in derivative spectrophotometry of highly absorbing samples has been investigated using transmittance-ratio methods [12]. The precision and accuracy obtained in multi-component determinations have also been considered, especially in mixtures of pharmaceuticals [13,14]. Detection limits have been evaluated for different substances using diverse derivative orders [15]; in general, no appreciable differences from conventional photometry are observed.

### 2.1. *Multicomponent analysis*

Derivative UV/visible spectrophometry has been widely used over the last few years in the analysis of multicomponent mixtures. For this reason, diverse procedures for the resolution of overlapped derivative peaks have been applied. Thus, the zero-crossing method has been used for the first- and second-derivative spectra in diverse mixtures [16]. Another procedure used is the named "$K$-ratio" method, in which the $K$-coefficient dual wavelength spectrophotometric method is taken as the mathematical model in order to resolve the difference $n$th-derivative spectral data at one wavelength for determining diverse two-component systems with zeroth-derivative and $n$th-derivative spectra that were seriously interfered with [17,18].

Diverse computer programs have been applied to the analysis of multicomponents using derivative spectra. Delaye et al. [19] developed a program (DESPI) for the computerized recognition of the spectral components in known binary mixtures, whereas Park et al. [20] describe another program (SPECMAN PLUS), written in Pascal, which provides automated spectral comparison techniques, utilizing the value of the root-mean square (RMS) of each difference; this comparison routine of the program can deal with spectra of compounds of different concentrations and different spectral recording resolutions. Recently, a multivariate statistical tool, the partial least-squares (PLS) method, has been applied to derivative data with good results [21]; the PLS technique has a calibration step where the relationship is estimated from a set of reference samples, and this

step is followed by prediction in which the results of the calibration are used to predict or estimate the component concentration from the unknown sample spectrum.

Other procedures for multicomponent analysis using computer calculations have also been reported. The FDAS-SL method [22], which is a means of measuring the shift-length (SL, nm) of the maximum absorption wavelength of a compound by utilizing the first-derivative absorption spectrum (FDAS), was used in the simultaneous determination of binary mixtures; this method utilizes the shift of the absorption spectrum of a compound at surfactant concentrations above the critical micelle concentration and the mixed molar ratio is obtained from the shift-length; each concentration of the compound is calculated by Beer's law. Karstang and Kvaleim [23] describe a technique based upon regression modelling of spectra for accurate estimation of the concentration of analytes in the presence of background constituents; this novel technique gives reliable predictions, while all the contaminated samples are detected as outliers in the conventional approach.

### *2.2. Combination of DS with flow injection, liquid chromatography and kinetic analysis*

The advent of a multi-dimensional detection system and the affordability of personal computers provided with software that allows storage and subsequent processing of data has fostered developments of new experimental procedures in which DS is used in combination with dynamic techniques, such as flow-injection and liquid chromatography.

The simultaneous determination of compounds in two-, three- and four-component mixtures with completely overlapping spectra was achieved by flow-injection with a diode-array detection system, using the third-derivative spectra in the range 214–290 nm. The absorbance spectrum of each solution was recorded 10.7 s after sample injection with an integration time of 0.4 s [24].

In liquid chromatography, the information supplied by derivative spectroscopy used as a detection system has been exploited in three different ways, namely: (i) using the first derivative of the elution profile obtained at the wavelength of the absorption maximum; in theory, the derivative should be zero at this point and therefore the disappearance of the main peak reveals the presence of other constituents with different absorption features; this procedure is called the "null spectral derivative technique"; (ii) using the complete derivative obtained by recording the elution profile; this procedure is known as the "spectral derivative mapping technique" [25,26]; (iii) using the derivative spectra of the components obtained around the maxima signal of the overlapped chromatographic peaks; the detector was set to collect a spectrum every 1 s, over an adequate wavelength range; this procedure makes possible the easy transformation of a chromatographic problem in a spectrophotometric problem [27].

Derivative techniques have also been used in kinetic analysis. A selective empirical data processing method based on a modification of the conventional kinetic derivative method has been reported [28]. The method is based on parameters not directly correlated with the initial rate, but which are similar to those used in derivative spectrometry as the distance between two peaks or the value of the derivative at a single time. Two types of kinetic curves were tested, namely curves with and without induction periods. Different-order derivatives were obtained by numerical differentiation using the Savitzky–Golay method. The proposed method is shown to provide improved selectivity.

## 3. Applications

### *3.1. Inorganic analysis*

The use of DS in inorganic analysis, especially in the determination of mixtures of metal ions, has undergone an appreciable increase in the last few years. Diverse chromogenic reagents (EDTA, dithizone, 8-hydroxyquinoline, some hydrazones, etc.) have been proposed. The different determinations achieved are described in Table 1. However, the analysis of anions has hardly been investigated; only the simultaneous determination of nitrite and nitrate in water using linear regression DS has been described [76].

### *3.2. Organic compounds*

Binary and ternary mixtures of organic compounds have been widely analyzed using DS. Although pharmaceutical formulations are the mixtures most frequently assayed, and are es-

Table 1
Determination of metal ions

| Elements | Reagents | Remarks | Ref. |
|---|---|---|---|
| Al, Fe(III), Cu, Ti, Ni | 8-Hydroxyquinoline | 1st deriv., extraction into chloroform; binary, ternary and quaternary mixtures were analyzed | 28 |
| Be | Beryllon III | 3rd deriv. | 29 |
| Be, Al | 5,8-Dihydroxy-1, 4-naphthoquinone | Simultaneous determination; 7.2–396 and 10.8–1080 ng $ml^{-1}$, respectively | 30 |
| Co | 8-Hydroxyquinoline | 1st deriv., cobalt is oxidized by air only in the presence of Fe(III) or V(V), extraction into chloroform is used | 31 |
| Co, Fe(II) | 3-(4-Phenyl-2-pyridinyl)-1,2,4-triazine | 1st deriv., simult. determ., extraction into dichloroethane, 57–2000 and 2–200 ng $ml^{-1}$, respectively | 32 |
| Co, Cu | Methylenediamine tetraacetic acid | 1st deriv., simult. determ. | 33 |
| Cu, Fe(III) | 2-(5-Bromo-2-pyridylazo)-5-diethylaminophenol | Simult. determ., 2–10 μg $ml^{-1}$ of each ion | 34 |
| Cu, Ni | Sodium cyanide | 3rd deriv., simult. determ., 0.55–5.8 and 0.55–6.8 μg $ml^{-1}$, respectively | 35 |
| Cu, Ni | – | 1st deriv., aqueous solutions of both metal ions were analyzed | 36 |
| Cu, Zn | 5,10,15,20-Tetrakis-(4-trimethylammonio-ohenyl)porphine | 4th deriv., determinations were performed in the presence of sodium dodecylsulphate | 37 |
| Cu, Zn, Mn(II) | 2-(5-Bromo-2-pyridylazo)-5-diethylaminophenol | 1st and 2nd deriv., simult. determ., using the equation set of solutions and the least-squares method | 38 |
| Fe(III) | EDTA | 1st and 2nd deriv. | 39 |
| Fe(II) | 1,10-Phenanthroline | 2nd deriv., 1–12 μg $ml^{-1}$, iron is determined in bronze | 40 |
| Fe(III), Bi | EDTA | 1st deriv., 0.5–8.0 and 0.1–35.7 μg $ml^{-1}$, respectively | 41 |
| Hg | Iodide + Pyronine G | 3rd deriv., 0.04–0.8 μg $ml^{-1}$ | 42 |
| Hg, Co | Benzyl-2-pyridylketone-2-quinolylhydrozone | 1st deriv., simult. determ. | 43 |
| Ir, Rh, Pt, Ag | Sulfochlorophenoazo-rhodanine | | 44 |
| La, Pr, Nd, Sm, Eu, Ho, Er | Triethylenetetramine-hexaacetic acid (TTHA) | 3rd deriv. | 45 |
| Mn | $(NH_4)_2S_2O_8$ + Ag(I) | 1st deriv., manganese is oxidized to permanganate | 46 |
| Mo | Bromopyrogallol red | 3rd deriv., simultaneous determ. | 47 |
| Mo, Ti | Salicylfluorone + hexadecylmethylammonium bromide | 3rd deriv., simult. determ. | 48 |

Table 1 (continued)

| Elements | Reagents | Remarks | Ref. |
|---|---|---|---|
| Nd | Tiron | 3rd deriv. | 49 |
| Nd | Ascorbic acid | 5th deriv., Nd is determined in magnesium alloys | 50 |
| Nd, Er | 5,7-Dibromoquinolin-8-ol | 3rd deriv., simult. determ., Trition X-100 is used as surfactant, up to 18 $\mu g\ ml^{-1}$ of Nd and up to 21 $\mu g\ ml^{-1}$ of Er | 51 |
| Nd, Er | 5-Sulfo-7-iodoquinolin-8-ol (ferron) + diethylamine | 3rd deriv., up to 14 $\mu g\ ml^{-1}$ for Nd and up to 13 $\mu g\ ml^{-1}$ for Er | 52 |
| Nd, Er | 4-Benzoyl-3-methyl-1-phenylpyrazolin-5-one | 3rd deriv., simult. determ., 5.8–29 and 6.7–40 $\mu g\ ml^{-1}$, respectively | 53 |
| Nd, Er | 8-Hydroxyquinoline + diethylamine | 3rd deriv., 3–18 and 4.5–21 $\mu g\ ml^{-1}$, respectively | 54 |
| Nd, Sm, Eu, Gd, Tb, Dy | HCl | 1st deriv. | 55 |
| Ni, Co | 2-(4,5-Dimethyl-2-thiozolylazo)-5-dimethylaminobenzoic acid | 1st deriv., simult. determ., the method makes possible the determination of both elements in nickel minerals | 56 |
| Ni, Co | Benzyl-2-pyridylketone-2-quinolylhydrazone | 1st deriv., 480 and 512 nm, simult. determ. | 57 |
| Ni, Cu, V | 2-(5-Bromo-2-pyridylazo-5-diethylamino)phenol | 1st deriv., simult. determ., these elements have been determined in petroleum samples | 58 |
| Ni, Cu, Zn | 4-(2-Pyridylazo)resorcinol | 1st deriv., simult. determ., Kalman filter is used | 59 |
| Ni, Cu, Zu | 1-(2-Pyridylazo)-2-naphthol | 2nd deriv., simult. determ., 0.3–2.0, 0.5–3.0 and 0.5–3.0 $\mu g\ ml^{-1}$, respectively | 60 |
| Pb | 1,10-Phenanthroline + Rose Bengal | 4th deriv., extraction of the complex into chloroform | 61 |
| Pd, Pt | Dithizone | 5th deriv., simult. determ., extraction into carbon tetrachloride | 62 |
| Pd, Pt | *N*,*N*-Diethyl-4-nitrosoaniline | 1st deriv., simult. determ., 567.5 and 549.2 nm, respectively | 63 |
| Pd, Nd, Sm, Eu, Ho, Er | EDTA and oxalic acid | 2nd and 4th deriv., Sm and Eu can be determined in the presence of other metals | 64 |
| Pr, Nd, Eu, Ho, Er, Tm | 2-Thenoyltrifluoroacetone and 2,6-dimethylpyridine | 2nd deriv. | 65 |
| Pr, Nd, Dy | – | 2nd deriv., spectra in acid solutions were measured | 66 |
| Sm, Gd, Dy, Nd | | 2nd deriv., 4th deriv., spectra in acid solutions ($HClO_4$) were measured | 67 |
| Ta | 5-Bromo-2-(2-pyridylazo)-5-diethylaminophenol | 1st deriv., Ta is determined in nickel-based alloys containing niobium | 68 |

Table 1 (continued)

| Elements | Reagents | Remarks | Ref. |
|---|---|---|---|
| Ti | Hydrogen peroxide | 2nd deriv., up to 10 μg ml$^{-1}$, Ti is determined in steels | 69 |
| U, Th | Carminic acid | 1st deriv., simult. determ., 2–50 and 1–40 μg ml$^{-1}$, respectively | 70 |
| U, Th | 4-(2′-Thiazolylazo) resacetophenone oxime | 1st deriv., simult. determ. | 71 |
| V, Co | 4-(1′*H*-1′, 2′,4′-Triazol-3′-ylazo)-2-methylresorcinol | 2nd deriv., simult. determ., 0.10–1.02 and 0.12–1.18 μg ml$^{-1}$, respectively | 72 |
| W, Mo | Sacilylfluorone and cetyltrimethylammonium bromide | | 73 |
| Zn | *meso*-Tetrakis (3,5, dibromo-4-hydroxyphenyl)porphyrin (T(DBHP)P) | 2nd deriv., up to 0.24 μg ml$^{-1}$, zinc can be determined in biological samples | 74, 75 |

pecially considered in the next paragraph, other diverse mixtures (antioxidants, pesticides, herbicides, etc.) have been determined with good results. Table 2 shows the diverse procedures described since 1987. Li and Shi [100] reviewed years ago the articles published on organic compounds (including pharmaceuticals and clinical samples) until 1988.

### 3.3. Pharmaceutical analysis

The application of DS in pharmaceutical analysis has undergone explosive growth over the last 5 years. This fact is due to the easy application of this technique to pharmaceutical formulations, which are usually mixtures of two or three components of different chemical structures, and therefore show UV/visible spectra with different peaks and/or different amplitudes. DS has also proved particularly useful in eliminating matrix interferences, including those of aromatics, which have weak absorption in the near ultraviolet.

More than a hundred methods for pharmaceutical mixtures have been described over the last few years [101–215], and are shown in Table 3. Particularly numerous are the determinations referring to mixtures of antidepressives and transquilizers, as well as to formulations containing caffeine with other stimulants and antihystaminics, or mixtures of diverse sulphamides or antibiotics.

### 3.4. Analysis of amino acids, proteins and other biological compounds

DS has been widely used in the analysis of binary and ternary mixtures of amino acids. Mixtures of phenylalanine, tyrosine and triptophane have been especially studied. Procedures described since 1987 [216–235] are shown in Table 4.

### 3.5. Clinical and forensic analysis

DS has been proposed for the identification of compounds in mixtures of special interest in clinical and forensic analysis, and diverse general reports have been published in recent years [236,237]. Specific procedures are summarized [238–257] in Table 5. Diverse procedures using second derivative spectra have been described for the determination of haemoglobin and carboxyhaemoglobin in blood, as well as for the analysis of diverse pharmaceutical compounds in biological fluids.

### 3.6. Food analysis

Procedures involving the application of UV/visible DS to food analysis are summarized [258–271] in Table 6. In general, derivative technique has been especially used in the determination of additives (colouring, flavour enhancers) in foods.

Table 2
Determination of organic compounds

| Compounds | Remarks | Ref. |
|---|---|---|
| Alkaloids | Total alkaloids of Coptis chinensis were extracted in HCl–MeOH and determined | 77 |
| Antioxidants (butylated hydroxyanisole, butylated hydroxytoluene and Pr gallate) | 3rd and 4th deriv. was used | 78 |
| Carbaryl and chlorpyrifos | PLS was also applied to simultaneous determination | 79 |
| Carbendazim | 2nd deriv., the compound is determined in Kolfugo extra formulations | 80 |
| Chlorophenols | 1st deriv., two-, three- and four-component mixtures were possible using multivariate calibration | 81, 82 |
| Chlorpromazine and $\beta$-cyclodextrin | 2nd deriv., the binding constant between both compounds in aqueous solution was determined by means of an iterative calculation method | 83 |
| Cocaine | 1st and 2nd deriv., the compound (up to 10 $\mu g\ ml^{-1}$) is determined in methanol | 84 |
| 2-Furfuraldehyde, 5-hydroxymethyl furfuraldehyde and malonaldehyde | Simult. determ., the three chemicals were reacted previously with 2-thiobarbituric acid, PLS analysis is used | 85 |
| 5-Hydroxyflavonoids | 1st deriv. | 86 |
| Indulin C | 2nd deriv., spectra are used for studies of degradation of lignin | 87 |
| Indazole-3-carboxylic acid | 2nd, 3rd and 4th deriv., several isomers $N_1$ and $N_2$ substituted were identified using this technique | 88 |
| Nicotine | 1st and 2nd deriv., nicotine is determined in tobacco products | 89 |
| Paeonol | 1st deriv., the derivative values at 279 and 242 nm were used for quantification of paeonol, and their difference was proportional to up to 10 $\mu g\ ml^{-1}$ of this substance | 90 |
| Phenol compounds | 1st and 2nd deriv., mixture of to up to nine phenols (phenol and halogen, nitro-, methoxy- and methyl-derivatives, 1–100 $\mu M$) were determined with use of the mathematical algorithm MULTI3 | 91 |
| Phloroglucinols | 2nd deriv., flow-injection analysis coupled with liquid chromatography and a diode array detector was used | 92 |
| Piperonyl butoxide, neopynamine, permethrin and fenitrothion | 2nd deriv., binary mixtures can be resolved | 93 |
| Polymers | 1st and 4th deriv., polystyrene and mixtures of several prepolymers were studied | 94 |
| Polymers | 2nd deriv. | 95 |
| Salicylaldehyde and *para*-hydroxybenzaldehyde | 2nd deriv., simult. determ. | 96 |

Table 2 (continued)

| Compounds | Remarks | Ref. |
|---|---|---|
| Salicylaldehyde, 3-hydroxybenzaldehyde and 4-hydroxybenzaldehyde | 1st deriv., simult. determ. | 97 |
| Tocopherols | 2nd deriv., individual $\alpha$-, $\beta$-, $\gamma$- and $\delta$-tocopherols were determined | 98 |
| Trifluralin, benfluralin, isopropalin and oryzalin (herbicides) | 1st deriv., detection range found was 1–7 $\mu g\ ml^{-1}$ | 99 |

Table 3
Methods described for the analysis of compounds in pharmaceutical formulations

| Compounds | Remarks | Ref. |
|---|---|---|
| Acetylsalicylic acid and chlormezanone | 4th deriv., 0.02–0.2 $mg\ ml^{-1}$ for each compound | 101 |
| Acetylsalicylic acid and paracetamol | 276, 286, 304 and 314 nm for acetylsalicylic acid; 256 and 320 nm for paracetamol. Regression equations must be used | 102 |
| Aliphatic thiol drugs | 2nd and 3rd deriv., 4-(6-methylnaphthalen-2-yl)4-oxobut-2-enoic acid is used as reagent | 103 |
| Acetaminophen and orphenedrine, ibuprofen or chlorzoxazone | Binary mixtures only | 104 |
| Aminazine and diprazine | 250–255 nm | 105 |
| 4-Aminophenol | 2nd deriv., 224 nm, 0.5–38% of 4-aminophenol can be determined in the presence of paracetamol | 106 |
| Aminodarone hydrochloride | 1st and 2nd deriv. | 107 |
| Amitriptyline and chlordiazepoxide or perphenazine | 1st deriv. | 108 |
| Amoxycillin | 2nd deriv., 280 nm, 3.3–55.4 $\mu g\ ml^{-1}$ | 109 |
| Amoxycillin and cephalexin | 2nd deriv., up to 90 $\mu g\ ml^{-1}$ for amoxycillin (276 nm) and up to 60 $\mu g\ ml^{-1}$ for cephalexin (267.5 nm) | 110 |
| Ascorbic acid and analgin | 1st deriv. | 111 |
| Asparaginase | 259 nm, 0.05–0.125 $mg\ ml^{-1}$ | 112 |
| Benzalkonium HCl | 2nd deriv., 255–275 nm, determination can be achieved in the presence of pilocarpine, hypromellose and polivinyl alcohol | 113 |
| Benzodiazepines | 1st and 2nd deriv., single compounds only | 114 |
| Benzodiazepines and/or their metabolites | 2nd deriv., 19 compounds can be clearly identified, whereas four can only be differentiated two by two (diazepam–prazepam and alprazolam–estazolam) | 115 |
| Benzodiazepines and benzophenones | Determination in biological fluids | 116 |

Table 3 (continued)

| Compounds | Remarks | Ref. |
|---|---|---|
| Bretylium tosylate, hyoscine Bu bromide, oxyphenonium bromide, cetrimide and benzalkonium chloride | 1st deriv., picric acid is used as reagent, 5–20 $\mu g\ ml^{-1}$ for each compound | 117 |
| Bromazepam | 2nd deriv., 237–247 nm, up to 30 $\mu g\ ml^{-1}$ | 118 |
| Bufotoxin lactone | 2nd deriv., 359 and 376 nm, determination is made in Houzhenwan (traditional chinese antipyretic) | 119 |
| Caffeine and amidopyrine | 1st deriv., 275–296 nm, linear regression method of multiwavelength is used | 120 |
| Caffeine and antihistaminics | 1st deriv. | 121 |
| Caffeine and sodium benzoate | 9–33 $\mu g\ ml^{-1}$(269 nm) for caffeine and 6.5–19.5 (241 nm) for sodium benzoate | 122 |
| Canrenone | 2nd deriv., 300 nm, 2–10 $\mu g\ ml^{-1}$, determination in the presence of spironolactone | 123 |
| Carbimazole and methimazole | 3rd deriv., 265 and 295 nm, respectively | 124 |
| Cephalosporins and their degradation products | 2nd deriv., 4–24 $\mu g\ ml^{-1}$ | 125 |
| Clomiphene citrate and tamoxifen citrate | 1st deriv. | 126 |
| Chlorpheniramine maleate | 2nd deriv., 228–260 nm, 4–36 $\mu g\ ml^{-1}$ | 127 |
| Chlorpheniramine maleate and phenylephrine–HCl | | 128 |
| Chlorphenoxamine and caffeine | 225, 232 nm for chlorphenoxamine and 256, 283 nm for caffeine | 129 |
| Chlorpromazine and its sulphoxide | 3rd deriv. | 130 |
| Clotrimazole | 1st deriv., 266 nm | 131 |
| Captotril and hydrochlorothiazide | 1st deriv., 228–248 nm | 132 |
| Cytarabine and acyclovir | 1st and 2nd deriv., 268 and 272, respectively | 133 |
| Danthron and phanquone | 1st deriv., previous formation of complexes with metal ions | 134 |
| Diazepam and oxazepam | 4th deriv. | 135 |
| Diazepam and otilonium bromide | 1st deriv., 264 and 406–408 nm, respectively | 136 |
| Dicloxacillin and ampicillin | 2nd deriv., up to 60 $\mu g\ ml^{-1}$ for each compound | 137 |
| 2,6-Diisopropylphenol | 2nd deriv., 0.10–0.25 $\mu g\ ml^{-1}$ | 138 |
| Diphenhydramine or naphazoline, and methylene blue | 2nd deriv., extraction into chloroform | 139 |
| Diphenhydramine | 2nd deriv., 215 or 251 nm | 140 |
| Diphenhydramine, ephedrine and pentoxyverine | 1st and 4th deriv. | 141 |

Table 3 (continued)

| Compounds | Remarks | Ref. |
|---|---|---|
| Diloxanide furoate and metronidazole | 1st and 2nd deriv., 0.02–0.1 mg $ml^{-1}$ (262 nm) and 0.04–0.2 mg $ml^{-1}$ (248 nm), respectively | 142 |
| Domperidone | 1st deriv. | 143 |
| Enalapril maleate | 4th deriv. | 144 |
| Estradiol and progesterone or testosterone | | 145 |
| Estrone, equilin, 17-α-estradiol and 17-α-dihydroequilin | 1st, 2nd, 3rd and 4th deriv., 280 and 338 nm | 146 |
| Ethinyl oestradiol and norethisterone | 1st and 2nd deriv. | 147 |
| Famotidine | 2nd deriv., 304 nm | 148 |
| Febuprol | 276 and 280 nm | 149 |
| Fendiline HCl and other related compounds | 2nd deriv., 0.25–1 g $l^{-1}$ | 150 |
| Glibenclamide, mebeverine and clopamide | 2nd deriv., determination can be achieved in the presence of their degradation products | 151 |
| Hydrochlorothiazide and amiloride HCl | 1st deriv., 284.7 nm | 152 |
| Hydrocortisone, dexamethasone, prednisolone and prednisone | 1st deriv. | 153 |
| 4-Hydroxyphenoxymethyl penicillin | 4th deriv., 304–314 nm, 0.06–0.30 mg $ml^{-1}$ | 154 |
| Imipramine and amitriptyline | 1st and 2nd deriv., 0.62–10.14 μg $ml^{-1}$ and 0.63–10.40 μg $ml^{-1}$, respectively | 155 |
| Imipramine, trimipramine, amitriptyline, dothiepin and cyproheptadine | 1st and 2nd deriv. | 156 |
| Insulin | 7th deriv., bovine and porcine insulin can be discriminated | 157 |
| Isoniazid and pyridoxine or thiacetazone | 1st deriv., 8.2–41.1 μg $ml^{-1}$ and 7.1–23.6 μg $ml^{-1}$ | 158 |
| β-Lactam antibiotics | Determination in turbid solutions containing liposomes | 159 |
| Levamisole hydrochloride | 1st deriv., 239 nm | 160 |
| Levodopa | 2nd deriv., 267 nm | 161 |
| Levodopa | 2nd deriv., 280–290 nm, 2.4–120 μg $ml^{-1}$ | 162 |
| Lidocaine | 3rd deriv. | 163 |
| Methylene blue, hexamethylene tetramine and resorcinol | 1st deriv., 273, 221 and 300 nm, respectively | 164 |
| Minoxidil and retinoic acid | 1st deriv., 290 and 351 nm, respectively | 165 |
| Nifedipine | 1st deriv., 402 nm | 166 |
| Nitofurantoin and phenazopyridine | 1st deriv., 335 and 317 nm, respectively | 167 |
| Notriptyline and perphenazine | 4th deriv., 239.6 and 268.8 nm, respectively | 168 |

Table 3 (continued)

| Compounds | Remarks | Ref. |
|---|---|---|
| Oestradiol | 3–12 μg ml$^{-1}$ | 169 |
| Oxytetracycline | | 170 |
| Parabens | | 171 |
| Paracetamol | 2nd deriv. | 172 |
| Paracetamol and chlorzoxazone | 2nd deriv., 270.8 and 278.9 nm, respectively | 173 |
| Paracetamol and methocarbamol | 2nd deriv., 250.2 and 227.6 nm, respectively | 174 |
| Paracetamol and phenylpropanolamine HCl | 1st deriv., 256.7 and 242.8 nm, respectively | 175 |
| Penicillins and cephalosporins | 1st, 2nd and 3rd deriv., 13 penicillins and five cephalosphorins in different combinations were assayed | 176 |
| Perphenazine and amitriptyline | 1st and 2nd deriv., 1–8 μg ml$^{-1}$ and 1–30 μg ml$^{-1}$, respectively | 177 |
| Perphenazine and amitriptyline | 1st and 2nd deriv., other tranquilizers and antidepressants were also assayed | 178 |
| Phenothiazines | 1st and 2nd deriv. | 179 |
| Phenothiazines | 2nd and 4th deriv. | 180 |
| Phenothiazines | 2nd deriv., binary mixtures | 181 |
| Phenylephrine | 1st deriv., determination is in the presence of chlorapheramine, sulphacetamide or prednisolone | 182 |
| 1-Phenylethylamine | Determination is in the presence of fosfomycin | 183 |
| Phenylephrine HCl and carbinoxamine maleate | 1st deriv., 275 and 237 nm, respectively; related compounds were also assayed | 184 |
| Phenytoin and phenobarbital | 2nd deriv. | 185 |
| Phenytoin | 2nd deriv., 4.5–160 μmol l$^{-1}$ | 186 |
| Prazosin and polythiazide | 2nd deriv., 346 and 236 nm, respectively | 187 |
| Prenylamine lactate and other related compounds | 2nd deriv. | 188 |
| Propofol | 2nd deriv., 286 nm, 0.1–0.25 mg ml$^{-1}$ | 189 |
| Pseudoephedrine and chlorpheniramine | 1st deriv. | 190 |
| Pseudoephedrine, chlorpheniramine and dextromethorphan | 2nd deriv., 240–300 nm | 191 |
| Puerarin | 1st deriv., 3.2–16 μg ml$^{-1}$ | 192 |
| Rifamixin | 2nd deriv. 2–40 μg ml$^{-1}$ | 193 |
| Salbutamol | 1st deriv., 286 nm | 194 |
| Salbutamol | 2nd and 4th order, 1–80 μg ml$^{-1}$, determination is in the presence of gelatine | 195 |
| Salicylic and salicyluric acids | 1st deriv., 2.6–52 μg ml$^{-1}$ and 2.1–42 μg ml$^{-1}$ | 196 |
| Simvastatin | | 197 |

Table 3 (continued)

| Compounds | Remarks | Ref. |
|---|---|---|
| Spironolactone and hydrochlorothiazide | | 198 |
| Sulfamethoxazole and trimethroprim | 280 and 290 nm, respectively | 199 |
| Sulfacetamide, sulfadimidine and sulfathiourea | 1st deriv. | 200 |
| Sulfonamides | 1st and 4th deriv., Bratton–Marshall reaction combined with derivative photometry is used | 201 |
| Sulphamethizole | 1st deriv., up to 43 μg $ml^{-1}$, determination is in the presence of nitrofurantoine | 202 |
| Sulphaquinoxaline and pyrimethamine | 1st deriv., 1–25 mg $ml^{-1}$ and 1–50 mg $ml^{-1}$, respectively | 203 |
| Synephrine | 1st deriv. | 204 |
| Tetracyclines | 2nd deriv. | 205 |
| Theophylline | 1st deriv., 284, nm | 206 |
| Thiamine, riboflavine, nicotinamide, pyridoxine and ascorbic acid | Multiple linear regression analysis is used | 207 |
| Thiamine, riboflavine, nicotinamide, pyridoxine and calcium pantothenate | 1st deriv., multicomponent program is used | 208 |
| Thiobarbituric acid | 2nd deriv., determination is in the pressure of reactive products of lipid peroxidation in plants | 209 |
| Thioxanthenes | 1st deriv., 4–40 μg $ml^{-1}$ | 210 |
| Tocopherols | $\alpha$-, $\beta$-, $\gamma$- and $\delta$-tocopherols were determined at 298, 302, 304 and 306 nm, respectively | 211 |
| Tolazoline, atropine homatropine, tetrahydrozoline and xylometazoline | 1st deriv., picric acid is used as reagent, extraction is made into chloroform | 212 |
| Triamterene and hydrochlorothiazide or xipamide | 1st deriv. | 213 |
| Triamphenicol glycinate and *N*-acetylcisteine or 4-hydroxyisophthalic acid | 2nd deriv., 274–278 nm, 6–55 μg $ml^{-1}$ for triamphenicol | 214 |
| Trimethroprim and sulfamethoxazole | | 215 |

### 3.7. *Environmental analysis*

A few applications of derivative UV spectrophotometry to environmental analysis have been described over the last few years. High-order derivative absorption spectrophotometry has been used in the determination of oil in waste water to avoid complex sample extraction and to eliminate interference by other chemical species; the calibration curve varied rectilinearly up to 100 mg $l^{-1}$ of oil, with 0.05 N $H_2SO_4$ as reference standard and light petroleum as blank [272].

Derivative spectrophotometry has also been used in combination with thermal soil desorption in the field screening of benzene–toluene–

Table 4
Methods for the analysis of amino acids and proteins

| Compounds | Remarks | Ref. |
|---|---|---|
| Adenine and thymine | 2nd deriv., adenine and thymine were determined in DNA (not more than 10 μg DNA is required) | 216 |
| Amino acids | 2nd deriv., aromatic amino-acids were tested | 217 |
| Amino acids | 2nd deriv, and size-exclusion HPLC were combined and applied to the determination of aromatic amino acids of polypeptides | 218 |
| Chlorophylls a and b | 1st deriv., 671 nm for a and 467 nm for b | 219 |
| Metaloporphyrins | 3rd deriv., the method is based on variation of the Soret band wavelength with the type of functional group structure of the 20-carbon porphyrin chromophore | 220 |
| Phenylalanine, tyrosine and triptophane | Factorial analysis procedure for interpreting derivative spectra is proposed; application is made to the determination of these compounds in the presence of aromatic chromophores content in mitochondrial proteins | 221 |
| Ibidem | 2nd deriv. | 222 |
| Ibidem | Phenylalanine is determined in the presence of the other compounds by means of the negative derivative peak near 258 nm | 224 |
| Phospholipids | HPLC 2nd deriv. is used; phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine and phosphatidic acid were characterized | 225 |
| Phosphotyrosine | HPLC 2nd deriv. is used, phosphatyrosine residues in peptides were identified | 226 |
| Polynucleotides | Conformational isomerizations of polynucleotides are studied by means of 4th deriv. spectrophotometry | 227, 228 |
| Proteins | HPLC deriv. spectrophotometry is used for the separation and detection of proteins and peptides | 229 |
| Proteins | 4th deriv. is used for protein quantification during purification | 230 |
| Proteins | Size-exclusion HPLC derivative spectrophotometry is used | 231 |
| Proteins and phenol | Detection of diverse proteins and phenol were achieved in DNA samples | 232 |
| Somatotropin | 2nd deriv., proteolysis of native bovine somatotropin is studied | 233 |
| Tryptophan | 2nd deriv., presence of tryptophan in peptides is studied | 234 |
| Tryptophan and tyrosine | 2nd deriv., both amino acids were determined in synthetic peptides | 235 |

Table 5
Clinical and forensic analysis

| Substances | Type of sample | Remarks | Ref. |
|---|---|---|---|
| Allopurinol and uric acid | Urine | 1st and 2nd deriv. (284 and 243 nm, respectively), 2–12 μg $ml^{-1}$ | 238 |
| Bile salts | | 2nd deriv., critical micellar concentrations of bile salts were determined | 239 |
| Bilirrubin, methaemoglobin and oxyhaemoglobin | Cerebroespinald fluid | 1st and 2nd deriv., simultaneous determination, effects of turbidity are minimized | 240 |
| Carboxyhaemoglobin | Blood | 2nd deriv., 418 nm | 241 |
| Carboxyhaemoglobin | Blood | Soret region of the UV spectrum is used, method has been applied in postmortem blood samples | 242 |
| Ceftizoxime | Plasma | 2nd deriv., 281 nm, 1–100 μg $ml^{-1}$ | 243 |
| Clonazepam | Urine | 3rd deriv., limit of detection is 150 ng $ml^{-1}$ | 244 |
| Haemoglobin | Plasma or serum | 1st deriv. | 245 |
| Haemoglobin (total) and carboxyhaemoglobin | Blood | 3rd deriv., carboxyhaemoglobin shows a maximum at 565 nm, and oxyhaemoglobin crosses the zero line at 565 nm | 246 |
| Haemoglobin and urinary porphirins | Plasma | 2nd deriv., limits of detection are 0.060 μmol for haemoglobin and 10 mmol $l^{-1}$ for coproporphyrin and uroporphyrin | 247 |
| Imipenem | Plasma | 3rd deriv., 306–312 nm, detection limit is 3 μg $ml^{-1}$ | 248 |
| Lipids | Plasma | 2nd deriv., lipid dienes as markers of lipid peroxidation in heptane extracted from plasma from patients with arthritis are analyzed | 249 |
| Lipids | Plasma | Lipid peroxidation is used, and hydroperoxidienes formed were studied by derivative spectrophotometry | 250 |
| Myoglobin | | 2nd deriv., myoglobin is determined in the presence of haemoglobin; diverse algorithms were used | 251 |
| Nitrazepam and clorazepam | Biological fluids | 5th deriv., limits of detection are 1 μg $ml^{-1}$ and 1.5 μg $ml^{-1}$, respectively | 252 |
| Paracetamol and salicylate | Plasma | 2nd deriv., recovery is slow | 253 |
| Pesticides | Serum and gastric juice | 2nd deriv., 245 nm, carbamate pesticides were analyzed, detection limit for carbaryl is 250 μg $ml^{-1}$ | 254 |
| Phenylbutazone and oxyphenbutazone | Plasma | 4th deriv., 1–5 μg $ml^{-1}$ for phenylbutazone and 3–8 μg $ml^{-1}$ for oxyphenbutazone | 255 |
| Porphyrins | Urine | 2nd deriv. | 256 |
| Rifampicin | Plasma | Binding of rifampicin by plasma proteins is studied | 257 |

Table 6
Food analysis

| Substances | Type of sample | Remarks | Ref. |
|---|---|---|---|
| $\alpha$- and $\beta$-acids | Hops | 2nd deriv., simult. determ. | 258 |
| Chlorogenic acids | Instant coffee | 2nd deriv., 325 nm, chicory does not interfere | 259 |
| Enzymes | Red fruited pears | 4th deriv., of peroxidase, esterase and acid phosphatase were determined | 260 |
| Flavour enhancers | Food preparations | 1st and 2nd deriv., partial least-squares and principal component regression modelling of spectrophotometric data have been used | 261 |
| Food colours (synthetic) | Foods | 2nd deriv., Amaranth, Tartrazide, New Coccine, Sunset Yellow and Brillant Blue were determined in binary mixtures | 262 |
| Food colours (synthetic) | Foods | 1st deriv., Acid Blue, Food Red, Acid Red and Food Yellow were determined simultaneously | 263 |
| 2-Furfuraldehyde and 5-(hydroxymethyl)-2-furfuraldehyde | Orange juice | 1st deriv., thiobarbituric acid is used as reagent, 436 and 414 nm were used | 264 |
| Lipid oxidation products | Vegetable oils | 2nd deriv., degree of rancidity of diverse vegetable oils (peanut, sunflower, corn, soybean, grape seed) was determined | 265 |
| Pigments | Orange-drink powder | 1st deriv., carminic acid and citron yellow were determined at 468 and 548 nm, respetively | 266 |
| Quinine | Soft drinks | 4th deriv., limit of detection is 5 ng $ml^{-1}$ | 267 |
| Refined oil | Virgin olive oils | 2nd deriv., interfering oxidizing products were removed with alumina | 268 |
| Saccharin, benzoic acid and ethyl-4-hydroxybenzoate | Beverages | | 269 |
| Seed oils | Olive oils | 2nd deriv., peanut, sunflower, corn, soybean, grapeseed oils were determined | 270 |
| Sorbic and benzoic acids | Soft drinks | 2nd deriv., 1–7 $\mu g\ ml^{-1}$ | 271 |

ethylbenzene–xylene in solids [273]. Another method has been developed for the analysis of environmental polycyclic aromatic hydrocarbons (PAHs) utilizing an algorithm in which the samples spectrum was used to build a vector containing the second to fifth derivatives; this was multiply regressed against similar vectors containing the corresponding derivative of the unit molar UV spectra of the target PAH; the PAHs selected in this step were used for a second multiple regression filter, fitting all possible compounds into a

single Beer's law model; a third filter, based on sensitivity analysis, selected the significant components of the sample system [274].

Finally, a second-derivative UV spectrophotometry method is described for the determination of nitrate in soils; ammonium nitrite and urea may be determined in the same experiments [275].
