# Biography on Professor Jean-Michel Kauffmann

Professor Jean-Michel Kaufmann

Professor Jean-Michel Kauffmann was born in Arlon, Belgium, in 1954. He became a pharmacist from the Université Libre de Bruxelles, in 1977 and earned a Ph.D. degree in pharmaceutical sciences under Professor G. J. Patriarche in 1983 from the same University. He became Professor and Head of the laboratory of instrumental analysis and bioelectrochemistry at the Institute of Pharmacy of the Université Libre de Bruxelles, in 1992. His research interests include electroanalysis, modified electrodes and biosensors, as well as molecular fluorescence and detector development for flow injection and HPLC analysis. He has published approximately 100 original papers including several chapters related to electroanalysis and biosensors and given more than 140 lectures at national and international meetings. He acted as invited Professor at the Vrij Universiteit Brussel in 1993 and visiting Professor at the University of Extremadura (Badajoz) in 1994. He has been the Treasurer of the International Bioelectrochemical Society since 1989 and became the Vice-President of the Belgian Society of Pharmaceutical Sciences this year. He acts as national representative at the IUPAC—Commission V on electroanalysis. Professor J.-M. Kauffmann is a member of the scientific steering committee of the programme on Artificial Biosensing Interfaces put forward with the support of the European Science Foundation (ESF). He is a member of the Advisory Boards of *Analytical Letters*, *Electroanalysis*, *Talanta* and the *Journal of Pharmaceutical Sciences of Ankara*.

# FORMATION CONSTANTS AT HIGH IONIC STRENGTH—I. POTENTIOMETRIC DETERMINATION OF PROTONATION CONSTANTS FOR SUCCINIC, PROPIONIC AND MONO-METHYL SUCCINIC ACID IN DIFFERENT IONIC MEDIA

GRAHAM E. JACKSON and LISA F. SEYMOUR

Chemistry Department, University of Cape Town, Private Bag, Rondebosch 7700, South Africa

(*Received* 12 *November* 1993. *Revised* 12 *January* 1994. *Accepted* 12 *January* 1994)

**Summary**—The protonation constants, $K_r$, for the ligands succinic acid (SA), mono-methyl succinate (MS) and propionate (PA) have been determined, at 25°C, by glass electrode potentiometry in 3 mol/dm$^3$ ($M$) $NaNO_3$, $KNO_3$, $NH_4NO_3$, $Ca(NO_3)_2$ and $Et_4NBr$ aqueous media. Results are compared with literature constants determined in $3M$ $NaClO_4$. The order of stability was found to be $K_1(SA) > K_1(PA) > K_1(MS) > K_2(SA)$ and for the ligands in the different media $K_r$ followed the general trend with respect to the background electrolyte $Et_4NBr > NaClO_4 > KNO_3 > NaNO_3 > NH_4NO_3 > Ca(NO_3)_2$.

Speciation modelling has been widely used to explain the bioavailability of metal ions in solution.[1–4] In a similar fashion chemical speciation could play a critical role in the emulsifying ability of ionic surfactants. Recently we have become interested in modelling these surfactants which are often used industrially in aqueous solutions of high ionic strength.

As models of the polar headgroups of ionic surfactants, we have chosen propionic acid (PA), succinic acid (SA) and mono-methyl succinic acid (MS). Daniele *et al.* have extensively studied the effect of ionic strength, in the range $0M < I < 1M$, upon the protonation equilibria of carboxylic acids.[5,6] Belavantsev *et al.* have studied the effect of ionic background upon the dissociation constants of monobasic acids.[7] However, as yet no study has been reported of the effect of high ionic strength and background medium upon protonation equilibria. Since these data are necessary in order to model the effect of pH upon the speciation of our model polar head groups, we have undertaken a potentiometric investigation of the protonation equilibria of the above carboxylic acids at high ionic strength ($3M$) and in different background electrolytes ($KNO_3$, $NaNO_3$, $NH_4NO_3$, $Ca(NO_3)_2$, $Et_4NBr$).

## EXPERIMENTAL

Potentiometric titrations were carried out under an atmosphere of high purity nitrogen which was passed through a series of wash bottles to remove any residual $O_2$, $CO_2$ and to humidify the gas. The 50 ml reaction vessel was maintained at $25.00 \pm 0.05$°C and the entire titration apparatus was kept in a room thermostatted at $23 \pm 1$°C. Titrations were repeated using two glass electrodes and a Ag/AgCl reference electrode, connected to the titration solution via a salt bridge. Volumes were dispensed using a Metrohm automatic burette.

All solutions were made up in glass distilled, deionized water, which had been boiled out to remove dissolved $CO_2$. All volumetric flasks used in preparing the solutions were calibrated before use.[8] The strong base solutions were prepared under $N_2$, using Merck titrisols, and were stored in high density polypropylene bottles under an atmosphere of $N_2$.

$NaNO_3$ and $KNO_3$ (Merck GR) were dried under vacuum for 12 hr, at 140°C and 70°C, respectively.[9] $NH_4NO_3$ solutions were standardized using the hydrogen form of a cation exchange resin (Amberlite IR-120) and $Ca(NO_3)_2$ solutions were standardized against EDTA, using magnesium and solochrome black.[8] $Et_4NBr$ (Aldrich-Chemie) was recrystallized from ethanol, dried under vacuum at 100°C for 12 days and stored over $P_2O_5$.[9] Propionic acid (Riedel-de Haën) was purified by distillation, while succinic acid (Merck GR) and mono-methyl succinate (Aldrich-Chemie) were used without further purification.

All solutions were made up to $3M$ ionic strength with respect to the cation of the background electrolyte. The $Et_4NBr$ system was repeated using a background electrolyte concentration of $2.174M$, which is equimolal with $3M$ $KNO_3$. The $HNO_3$ and strong base solutions were standardized against borax and potassium hydrogen phthalate, respectively. With $Ca(NO_3)_2$ and $NH_4NO_3$ as background electrolyte, however, the $HNO_3$ solutions could not be standardized against borax and so were standardized against the strong base of the corresponding system.

In all the six systems studied the strong acid was $HNO_3$. In the case of the sodium and potassium systems, the strong base was NaOH and KOH, respectively. In the ammonium and calcium systems, $Ca(OH)_2$ and $NH_4OH$, could not be used as the strong base, as $Ca(OH)_2$ has low solubility and aqueous ammonia is volatile and has too low a $pK_b$. Similarly, commercially available $Et_4NOH$ proved to have an unacceptable amount of impurity, probably carbonate and, under strongly basic conditions, hydrolysis of the background salt occurred. In these cases therefore the strong base was $1M$ KOH made up to $3M$ $K^+$ with $KNO_3$. Using the base in such a concentrated form resulted in only 0.07% of the background cation being $K^+$ at the end of a titration. As recommended by the IUPAC commission, a summary of the experimental parameters is given in Table 1.[10]

Data were refined using the ESTA suite of programs optimized on weighted emf values.[11–15] A $pK_w$ of 14.18 compiled from 32 references at $3M$, was used throughout.[16] The electrodes were calibrated *in situ* using the refinement option of ESTA. When using ammonium nitrate as the background electrolyte experimental points near the endpoint of the ligand were deleted from the titration data as they had high residuals due to the effect deprotonation of the ammonium ions had on the emf of the solution.

## RESULTS AND DISCUSSION

All the protonation constants determined are shown in Table 2, and have been plotted in Fig. 1 together with literature protonation constants determined in $3M$ $NaClO_4$.[17,18]

The protonation constants, $K_r$, follow the general trend $K_1(SA) > K_1(PA) > K_1(MS) > K_2(SA)$. The differences in protonation constants are due to the different substituents on the carboxylic groups. Substituents which are electron donating weaken the carboxylic acid and hence increase $K_r$, while electron withdrawing groups strengthen the acid and decrease $K_r$. Therefore we would expect carboxylate groups to increase the protonation constant and carboxylic and ester groups to decrease it. These observations, studied in a wide range of acids, provide the basis for the Taft equations and Taft $\sigma^*$ constants which can be used to predict protonation constants.[19] The acid-strengthening ($-\Delta \log K$) electrostatic and inductive effects of representative substituents attached to the $\alpha$-carbon atoms of aliphatic acids have been calcu-

Table 1. Summary of experimental parameters used in the determination of protonation constants for the ligands succinate, propionate and mono-methyl succinate; $T = 25$ °C

| Ligand | Ligand ($mmol/dm^3$) | Major electrolyte ($mol/dm^3$) | pH range | Data points | Number of titrations |
|---|---|---|---|---|---|

lated as a direct function of Taft $\sigma^*$ constants and have been published for a large number of substituents.[19]

For a dibasic acid such as succinic acid there is also a statistical factor which effects the second protonation constant. When the ligand is completely protonated there are two equivalent ways of losing the first proton, therefore $K_2$ should be twice as large as it would be for a closely related monobasic acid. So in predicting the protonation constants, log $K_2$ should be log 2 ($=0.3$) less.

Using the published $\Delta \log K$ values and including the statistical effect, $\Delta \log K_r^{calc}$ can be predicted for the ligands studied. The differences between the experimental protonation constants obtained between the various ligands, $\Delta \log K_r^{expt}$, was taken as the difference between the average protonation constant obtained for the ligand in all media and the average value obtained for propionic acid. Values obtained for $\Delta \log K_r^{calc}$ and $\Delta \log K_r^{expt}$ are given in Table 3. The good correlation obtained between experimental and calculated values lends confidence to our results.

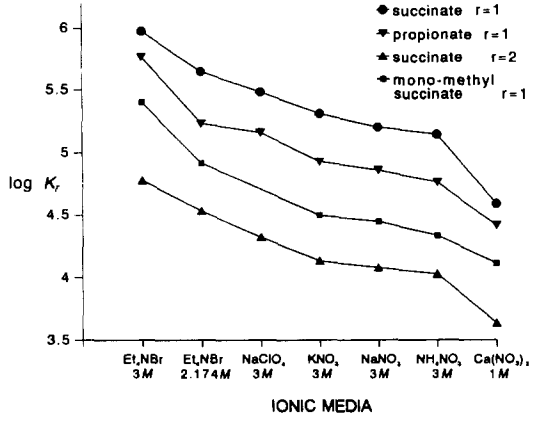

Fig. 1. Protonation constants $K_1$ and $K_2$ plotted for the ligands succinic acid, mono-methyl succinate and propionic acid in different ionic media. The protonation constants determined in 3$M$ $NaClO_4$ were taken from literature.

Figure 1 shows clearly that at high ionic strength, the nature of the background medium has a dramatic effect upon the protonation equilibria of carboxylic acids. De Robertis *et al.* have noted this trend before and have tried to explain it in terms of cation binding to the carboxylate anion, stronger metal binding giving rise to a lower apparent protonation constant.[20–22] This explanation, however, does not account for the consistent difference in protonation constants measured in 3$M$ $NaClO_4$ and 3$M$ $NaNO_3$. Alternatively, in a series of papers, K. S. Pitzer has developed semi-empirical equations for the convenient and accurate description of thermodynamic properties of aqueous electrolytes.[23–26] The Pitzer approach accounts for the change in protonation constant in going from one medium to another in terms of short range interionic forces that are specific

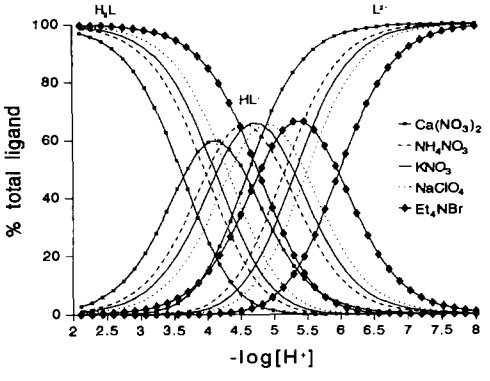

Fig. 3. The speciation of succinate in various 3*M* background electrolytes over the pH range of 2–8. Each species is plotted as a percentage of the total ligand concentration.

to each solute. The Daniele and Pitzer approaches will be examined in more detail in a subsequent paper.

The effect that the nature of the polar head group has on the speciation of model ionic surfactants is shown in Fig. 2. From this we see that in the pH range 4–7 the charge of the carboxylate head groups change from 0 to −1. Similarly, Fig. 3 shows how a change in the background medium affects the speciation of the carboxylic acid. These changes will affect the surface packing of the surfactant and may contribute to the observed pH and medium dependence of emulsion stability.

# FORMATION CONSTANTS AT HIGH IONIC STRENGTH—II. THE IONIC STRENGTH CORRECTION OF FORMATION CONSTANTS USING A SIMPLIFIED PITZER EQUATION

GRAHAM E. JACKSON and LISA F. SEYMOUR

Chemistry Department, University of Cape Town, Private Bag, Rondebosch 7700, South Africa

(*Received* 12 *November* 1993. *Revised* 12 *January* 1994. *Accepted* 12 *January* 1994)

**Summary**—A simplified approach to the correction of equilibrium constants from one ionic strength and/or medium to another is developed. A computer program capable of performing these calculations is presented together with results of its application to the $NH_3/H^+$, $CH_3COO^-/H^+$, $CH_3CH_2COO^-/H^+$, $-OOCCH_2COO^-/H^+$ and $HOOCCH_2COO^-/H^+$ systems.

In recent years the importance of chemical equilibrium modelling has developed from an empirical qualitative tool to a sophisticated quantitative tool in the armoury of chemists.[1–3] Simultaneous with the development of computer modelling, has grown the realization of chemical speciation as being fundamental to many, if not all, biochemical, and industrial reactions.[4,5] Thus the toxicity of mercury is dependent on its chemical speciation, methyl mercury being highly toxic, but mercury in a gold/mercury amalgam being non-toxic. Fundamental to equilibrium modelling is the availability of a suitable database containing thermodynamic data for all the possible reactions occurring in the model. Several such databases have been constructed.[6,7] However, in order to use these databases, it is necessary to convert the data to the conditions of temperature, pressure and ionic strength applicable to the model. Many attempts have been made to convert equilibrium constants applicable at one ionic strength to another. Most of these methods are based on the Debye–Hückel equation which only shows good accuracy up to 0.1 mol/dm$^3$. At higher ionic strength it is necessary to add terms for short range interionic forces that are specific to each solute. This is the approach of Pitzer.[8] However, because of the large number of virial coefficients needed to evaluate the Pitzer equations, this approach which works well even up to an ionic strength of 6 mol/dm$^3$, has not been generally implemented in equilibrium models. However, under the conditions applicable to most simulation models it is possible to simplify the Pitzer equations, which are then easily built into an equilibrium model. In this paper a computer program for converting equilibrium data from low to high ionic strength and from one background electrolyte to another is presented. The accuracy of this approach is evaluated using data for the protonation of ammonia, acetate, propionate and succinate.

## THEORY

In a solution containing metal ions or cations ($M$), ligands ($L$) and protons or hydroxides ($H$), many complexes may be formed in equilibrium with one another. Each complex has associated with it an equilibrium or stability constant. In general for the reaction

$$pM + qL + rH \rightleftharpoons M_pL_qH_r \qquad (1)$$

the thermodynamic stability constant may be defined as

$${}^T\beta_{pqr} = \frac{a_{M_pL_qH_r}}{a_M^p a_L^q a_H^r} \qquad (2)$$

where $p$, $q$, $r$ are the stoichiometric coefficients and $a$ denotes activity.

When $r$ is negative this refers to the removal or addition of hydrogen or hydroxy ions, respectively.

The basis of many of the variables used in potentiometry vary depending on the composition variable and hence the standard state used. In most potentiometric work the standard

state is taken as unit molarity or 1 mole of solute per $dm^3$ solution. This basis is more convenient as most experimental apparatus is calibrated for the dispensing of volumes. In the more concentrated range molality as the composition variable is more popular where the standard state is defined as unit molality or 1 mole of solute per kg solvent. This basis has an advantage as it does not change with temperature and pressure.

In practice, it is easier to determine the concentration of a species than to determine its activity. The activity of a species can be expressed as a product of its composition variable and its activity coefficient, $\gamma$, so that as the concentration approaches zero the activity coefficient tends to unity. Depending on the basis used the activity of the ion, $i$, in solution can be expressed as follows:

$$a_{c,i} = \gamma_{c,i} c_i \quad \text{or} \quad a_{m,i} = \gamma_{m,i} m_i \tag{3}$$

where $c_i$ and $m_i$ are the molar and molal composition variables of the ion, $i$, in solution and the basis of the activity and activity coefficients is given as a subscript.[9]

Stability constants, activity and activity coefficients are all dimensionless but vary depending on the basis used. To avoid inconsistency in units, the activity should be defined as:

$$a_{c,i} c^0 = \gamma_{c,i} c_i \quad \text{or} \quad a_{m,i} m^0 = \gamma_{m,i} m_i . \tag{4}$$

For convenience, the normal convention is to omit the standard state concentration terms, with the understanding that the activity, activity coefficients and stability constants are dimensionless. To prevent confusion care must be taken to define the composition variable used and not to interchange between different bases.

Following from the definition of activity, the thermodynamic stability constant can be defined as the ratio of its stoichiometric stability "constant", $\beta_{pqr}$, and its activity coefficient quotient, $\Gamma_{pqr}$ defined below

$$^T\beta_{pqr} = \frac{\beta_{pqr}}{\Gamma_{pqr}}, \tag{5}$$

where

$$\beta_{pqr} = \frac{[M_p L_q H_r]}{[M]^p [L]^q [H]^r}, \tag{6}$$

and

$$\Gamma_{pqr} = \frac{\gamma_M^p \gamma_L^q \gamma_H^r}{\gamma_{M_p L_q H_r}}, \tag{7}$$

and the square brackets denote molar concentration.

The mean activity coefficient for a given solution is a function of the ionic strength of the solution and can be determined from experimental measurements. For a solution containing cations, $c$, and anions, $a$, it is defined as follows:

$$\gamma_{\pm} = \sqrt[\nu_a + \nu_c]{\gamma_c^{\nu_c} \gamma_a^{\nu_a}} \tag{8}$$

where $\nu_a$ and $\nu_c$ represent the stoichiometric number of cations and anions in the formula.

Many equations have been proposed to account for the change in activity coefficients with ionic strength and temperature.[10] These ionic strength equations have been used to project stability constants measured at one ionic strength and make them applicable at another ionic strength. The degree of accuracy obtained in these corrections is strongly dependent on the method chosen and the reliability of the original stability constants.

Pitzer has developed semi-empirical equations for the convenient and accurate representation and prediction of the thermodynamic properties of aqueous electrolytes including comples mixtures.[8,11-13] These equations can be extended to high ionic strengths, high temperatures and high pressures.[14-17] The various forms of the Debye–Hückel calculation show good accuracy up to 0.1$M$. At higher concentrations account must be taken of short range interionic forces that are specific to each solute. These terms which take into account the kinetic effect of the hard core have been included by Pitzer without disturbing the basic pattern of the Debye–Hückel equation and are presented as interaction or virial coefficients for each solute. The three virial parameters $\beta^{(0)}$, $\beta^{(1)}$ and $C^{\phi}$ have been evaluated from a wide variety of osmotic or activity coefficient data for pure electrolytes. These parameters take into account any ion pairing or weak association that may take place.

When mixing solutes, the additional combinations of coefficients, $\theta_{MX}$, $\theta'_{MX}$ and $\psi_{MNX}$ were added, however these coefficients were found to be small and frequently negligible.[18] Hence in evaluating activity coefficients in mixtures, it was found that the parameters, determined from the single solutes, are able, in most cases, to define the mixture completely. The Pitzer equations allow the prediction, with considerable accuracy, of the properties of mixtures, if the properties of each pure component are known. This is shown in equation (9). The equation is of the same form as that presented by Guggenheim, with the addition of a third virial coefficient. The second virial coefficient $B$,

is now dependent upon ionic strength and the parameters $\theta$ and $\psi$, which have little effect, have been omitted:[19]

$$\ln \gamma_A \gamma_X = (z_A^2 + z_X^2) f^{\gamma} + \sum_a m_a (2B_{Aa} + ZC_{Aa}) + \sum_c m_c (2B_{cX} + ZC_{cX}) + \sum_c \sum_a m_c m_a [(z_A^2 + z_X^2) B'_{ca} + (|z_A| + |z_X|) C_{ca}] \quad (9)$$

$$Z = \sum_i m_i |z_i| \quad (10)$$

$$f^{\gamma} = -A_\phi \left[ \frac{\sqrt{I_m}}{(1 + 1.2\sqrt{I_m})} + \frac{2\ln(1 + 1.2\sqrt{I_m})}{1.2} \right] \quad (11)$$

$$B' = -2\beta^{(1)} \frac{1 - \left(1 + \alpha\sqrt{I_m} + \frac{\alpha^2 I_m}{2}\right) e^{-\alpha\sqrt{I_m}}}{\alpha^2 I_m^2} \quad (12)$$

$$B = \beta^{(0)} + 2\beta^{(1)} \frac{1 - (1 + \alpha\sqrt{I_m}) e^{-\alpha\sqrt{I_m}}}{\alpha^2 I_m} \quad (13)$$

$$C = \frac{C^\phi}{2|z_+ z_-|^{1/2}} \quad (14)$$

where $f'$ is the general "Debye–Hückel" term for long-range forces; $B$ and $C$ are the second and third virial coefficients; and $B'$ is the derivative of $B$. $\beta^{(0)}$, $\beta^{(1)}$ and $C^\phi$ are empirical parameters, $m_i$ and $z_i$ represent the stoichiometric molality and charge of species $i$ and $I_m$ represents the molal ionic strength $= 0.5\ \Sigma m_i c_i^2$. For 1–1 and 2–1 electrolytes $\alpha = 2.0$ and at 25° $A_\phi = 0.391$. Equations (12) and (13) only apply to 1–1, 2–1 and 3–1 electrolytes.

The Pitzer parameters $\beta^{(0)}$, $\beta^{(1)}$ and $C^\phi$ for over 120 electrolytes have been published by the author and other workers in this field.[8,20] These parameters allow the above equation to be applied to a wide variety of mixed electrolytes at room temperature and at ionic strengths up to 6 molal in many cases and occasionally even higher. If measurements do not extend above 2 molal the third virial coefficient, $C$, can be omitted.

The Pitzer equation was converted by Millero to an individual ion form using the mean salt convention. Single ion activity coefficients in halide salt solutions have been successfully calculated.[21,22] The mean salt method used to obtain absolute values of ionic activity coefficients, has limitations when applied to salts which form ion pairs. The method is also limited to solutions of moderate ionic strength.[21] For these reasons we chose to use Pitzer's equation involving salt parameters.

In the experimental determination of solution equilibrium constants, it is normal practice to keep the ionic strength of the solution constants by using a monovalent background electrolyte, $AX$, at a concentration much higher than that of the reacting species. Under these conditions, as the interaction between species is weighted by their concentration, it is reasonable to assume that the activity coefficient of a species will depend only on its interaction with the background electrolyte, *i.e.* interaction with other species in solution are negligible. Using this approximation, equation (7) becomes:

$$\begin{aligned} \ln \Gamma_{pqr} = {} & \xi f^{\gamma} + \xi m_X^2 B'_{AX} + \sigma m_X^2 C_{AX} \\ & + 2qm_X B_{AL} + \xi m_L m_X B'_{AL} \\ & + \sigma m_X m_L C_{AL} + 2qm_X I C_{AL} \\ & + 2rm_X B_{HX} + \xi m_H m_X B'_{HX} \\ & + \sigma m_H m_X C_{HX} + 2rm_X I C_{HX} \\ & + 2pm_X B_{MX} + \xi m_M m_X B'_{MX} \\ & + \sigma m_X m_M C_{MX} + 2pm_X I C_{MX} \\ & - 2m_X B_J + \xi m_S m_X B'_J \\ & + \sigma m_X m_S C_J - 2m_X I C_J \end{aligned} \quad (15)$$

$$\xi = r + pz_M^2 + qz_L^2 - z_S^2, \quad (16)$$

$$\sigma = r + p|z_M| + q|z_L| - |z_S|, \quad (17)$$

for the reaction $pM + qL + rH \rightleftharpoons M_p L_q H_r$ where $M_p L_q H_r = S$. Depending on the charge of the product, the symbol $J$ refers to the salt parameter of the product, $S$, with either anion, $A$, or cation, $X$, of the background electrolyte, *i.e.* if $z_S > 0$ then $J = SX$, if $z_S < 0$ then $J = AS$ and if either $z_L$, $z_M$ or $z_S = 0$ then their relevant virial coefficients are set to zero.

From the activity coefficient quotient and the thermodynamic stability constant, the stoichiometric stability coefficient at any ionic strength can be calculated (equation (18)):

$$\ln \beta_{pqr} = \ln \Gamma_{pqr} + \ln {}^{T}\beta_{pqr}. \quad (18)$$

Note that the activity coefficient of the species $M_p L_q H_r$ depends on its concentration and the concentration of the free components in solution *i.e.* it depends on the speciation of the

solution. Initial estimates of these concentrations can be estimated from uncorrected $\beta$ values and then refined iteratively.

*Computer program*

A Turbo Pascal 6.0 program has been written to convert stability constants from one ionic strength to other ionic strengths. The Pitzer parameters are stored in binary files associated with the program and can be edited and updated. The program runs interactively and calculates the stability constants at ionic strengths specified as input. The results are plotted on the screen together with a curve showing the variation of the stability constant with ionic strength. Experimental stability constant values can also be plotted simultaneously for an evaluation of the calculated relationship. A copy of the program is available, from the authors, upon request.

## RESULTS AND DISCUSSION

Most experimental stability constants have been measured with molarity as basis, while the Pitzer approach is based on molality. Hence the literature stability constants and ionic strengths had to be converted to molality. This conversion is simple if the density of the solution is known. In potentiometric titrations the concentration of the salt is always in excess and the density of the solution approximates to the density of a solution containing the same concentration of pure salt. Hence molar concentrations were converted to a molal scale using equation (19) and the molar based stability constants were converted to a molal scale using the equation (20).

$$m_{AX} = \frac{[AX]}{\rho_{[AX]} - 0.001[AX]M_{AX}} \qquad (19)$$

$$\log \beta_{m,pqr} = \log \beta_{c,pqr} + (p + q + r - 1) \times \log(\rho_{[AX]} - 0.001 M_{AX}[AX]) \qquad (20)$$

where $M_{AX}$ and $m_{AX}$, are the molar mass and molality, respectively of the salt AX.

Density data for a range of aqueous electrolyte solutions at 25°, were taken from the literature.[23–25] A least squares fit of the density variation with molality for each electrolyte gave the following equations (equation (21)), where the value in brackets is the standard deviation in the last position of each number.

$$\rho_{KNO_3}(0\text{–}2.8M) = 0.99713(4) + 0.06181(7)\,[KNO_3] - 0.00099(3)\,[KNO_3]^2$$

$$\rho_{NH_4NO_3}(0\text{–}7.6M) = 0.9974(1) + 0.03149(7)\,[NH_4NO_3] - 0.000263(9)\,[NH_4NO_3]^2$$

$$\rho_{LiNO_3}(0\text{–}5M) = 0.9975(6) + 0.0395(6)\,[LiNO_3] - 0.0002(1)\,[LiNO_3]^2$$

$$\rho_{NaNO_3}(0\text{–}7.2M) = 0.9977(2) + 0.0545(1)\,[NaNO_3] - 0.00053(2)\,[NaNO_3]^2$$

$$\rho_{LiCl}(0\text{–}14M) = 0.9986(4) + 0.0222(1)\,[LiCl] - 0.00008(1)\,[LiCl]^2$$

$$\rho_{NaCl}(0\text{–}5.3M) = 0.9973(1) + 0.0400(1)\,[NaCl] - 0.00056(2)\,[NaCl]^2$$

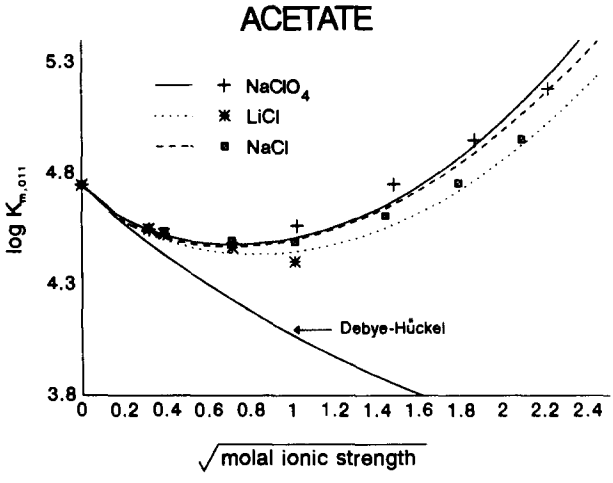

Fig. 1. Protonation constants as a function of ionic strength for various electrolytes. The symbols are experimental data points and the lines were calculated using the simplified Pitzer equation, literature Pitzer parameters and a literature $K^0$. A represents ammonia (log $K^0 = 9.244$) and B acetate (log $K^0 = 4.750$).[6,28]
The Debye–Hückel correction term (equations (11) and (15)), has been included for comparison.

$$\rho_{KCl}(0\text{–}4.1M) = 0.99729(9) + 0.0461(1)\,[KCl] - 0.00068(3)\,[KCl]^2$$

$$\rho_{LiClO_4}(0\text{–}3M) = 0.9973(3) + 0.0631(5)\,[LiClO_4] - 0.0006(2)\,[LiClO_4]^2$$

$$\rho_{NaClO_4}(0\text{–}4M) = 0.9976(8) + 0.078(1)\,[NaClO_4] - 0.0005(2)\,[NaClO_4]^2. \quad (21)$$

The literature Pitzer parameters used in the calculations are given in Table 1.

*Ammonia*

Figure 1(a) shows our simplified Pitzer approach applied to the protonation of ammonia. The symbols are experimental data points while the solid line is the calculated dependence of p*Ka* upon ionic strength. Experimental data were obtained from the literature.[25,26] The Debye–Hückel correction term is shown for comparison. For the uncharged ligand ammonia, the $\xi$ and $\sigma$ terms and hence also the Debye–Hückel term are all zero. As only interactions between ions of opposite sign are included only the *HX* and *SX* interaction

Table 2. Calculated Pitzer parameters

| Salt | $\beta^{(0)}$ | $\beta^{(1)}$ | Salt | $\beta^{(0)}$ | $\beta^{(1)}$ |
|---|---|---|---|---|---|
| Na propionate | 0.1165 | 0.312 | $NH_4$ Propionate | 0.0753 | 0.249 |
| K propionate | 0.1103 | 0.303 | $Et_4N$ Propionate | −0.027 | 1.100 |
| Ca propionate | 0.1061 | 0.921 | $NH_4H$ Succinate | 0.055 | 0.228 |
| NaH succinate | 0.0815 | 0.259 | $Et_4NH$ Succinate | −0.102 | 1.330 |
| KH succinate | 0.0716 | 0.243 | CaH Succinate | 0.0233 | 0.656 |
| Na succinate | 0.250 | 1.417 | $NH_4$ Succinate | 0.218 | 1.105 |
| K succinate | 0.236 | 1.368 | $Et_4N$ Succinate | −0.186 | 3.804 |
| †Ca succinate | 0.527 | 0.527 | | | |

*1–1 electrolyte relationship: $\beta^{(0)} = -0.043 + 0.332\beta^{(1)} + 0.574\beta^{(1)}\beta^{(1)}$. 1–2 electrolyte relationship: $\beta^{(0)} = -0.20(7) + 0.4(1)\beta^{(1)} - 0.03(6)\beta^{(1)}\beta^{(1)}$

†A relationship was not calculated for 2–2 electrolytes. To fit the curve $\beta^{(1)}$ was made equal to $\beta^{(0)}$.

coefficients were used in the ionic strength corrections. The resultant activity coefficient quotient reduces to:

$$\ln \Gamma_{011} = \ln \gamma_{H^+} - \ln \gamma_{NH_4^+}$$

$$= 2m_X(B_{HX} - B_{SX} + IC_{HX} - IC_{SX}). \quad (22)$$

According to the above equation, the cation of the background electrolyte has no affect on the activity coefficient quotient and the same ionic strength relationship was predicted for all nitrate salts. The experimental results for the different nitrates show a similar but not identical trend although the correlation between experimental and calculated results is good for $LiNO_3$ and reasonable for $KNO_3$ and $NaNO_3$.

*Acetate*

Figure 1(b) shows the comparison between the experimental and predicted protonation constants for acetate as a function of $NaClO_4$, LiCl and NaCl concentration.[27–29] Once again the correlation is good over the ionic strength range 0–4 mol/kg. For comparison the results of a Debye–Hückel correction are shown. Clearly the Debye–Hückel equation is not valid above an ionic strength of 0.1 mol/kg.

*Propionate*

For the propionate system not all the necessary Pitzer parameters were available in the literature. However, Pitzer noted a general relationship between the two parameters $\beta^{(0)}$ and $\beta^{(1)}$ for various electrolytes and suggested a

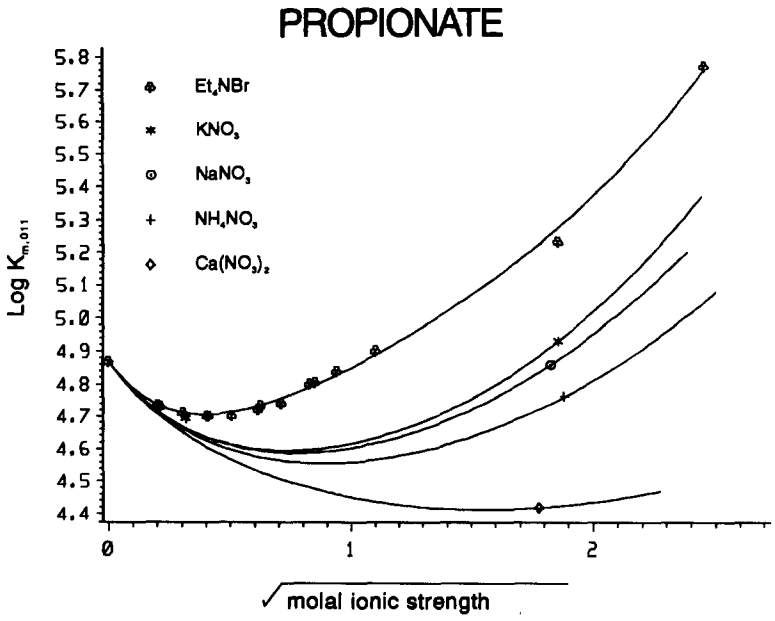

Fig. 2. Propionate's protonation constant as a function of ionic strength for various background electrolytes. The symbols are experimental data points and the solid lines were calculated using the simplified Pitzer equation, literature and calculated Pitzer parameters and a literature $K^0$ ($\log K^0 = 4.868$).

convenient approximation using this relationship to determine $\beta^{(1)}$ and $\beta^{(0)}$ from experimental data, if C is negligible.[30] At the ligand concentrations used to measure protonation constants of propionate, the contribution of terms involving the third virial coefficient to the overall activity coefficient, are small and so may be neglected. Many of the metal–ligand parameters were not available, and when only one protonation constant determined at $3M$ ionic strength, was available, these Pitzer parameters were calculated using the experimental value, the rough approximation method and log $K^0$. When more experimental constants had been determined, or literature values were available, the relevant Pitzer parameters were calculated using a least squares fit of the data. The calculated Pitzer parameters are given in Table 2 and the $\beta$ coefficient relationship used for each electrolyte type is given below the table. For propionic acid, dimerization is also possible but is only apparent at ligand concentrations greater than

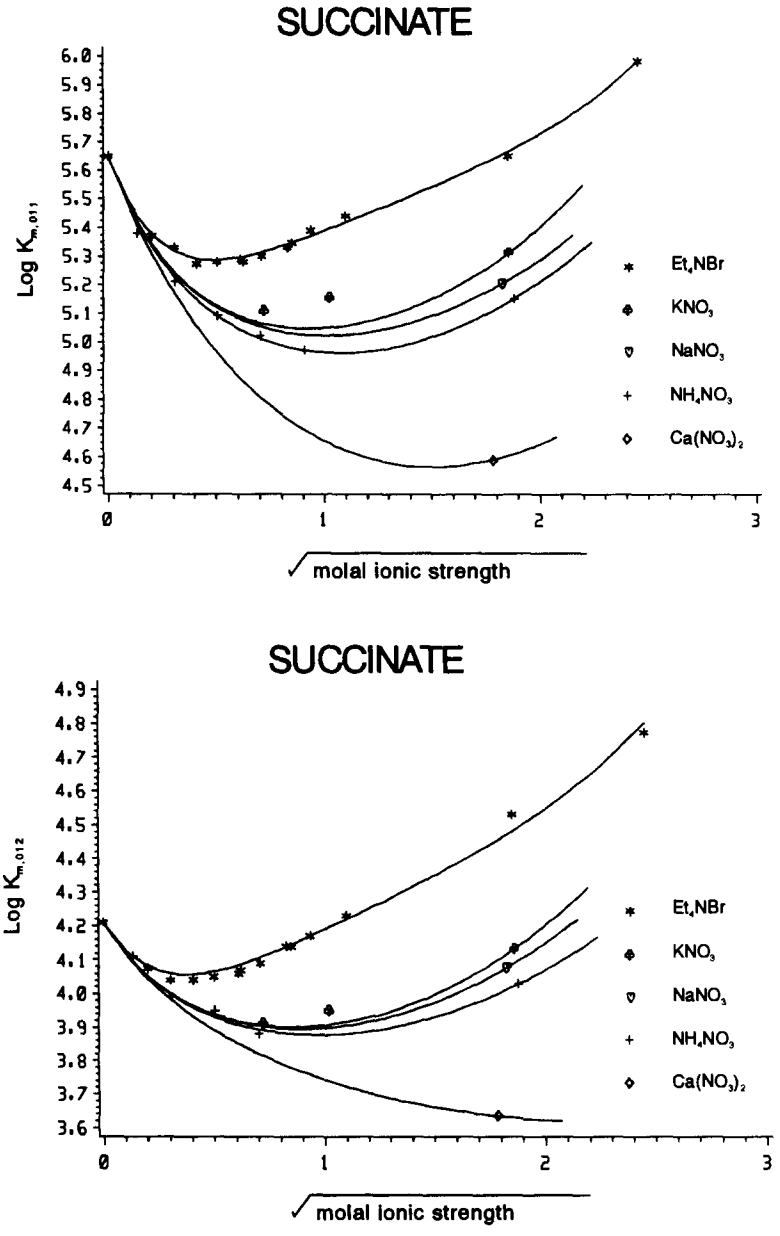

Fig. 3. The first and second protonation constant of succinate as a function of ionic strength for various background electrolytes. The symbols are experimental data points and the solid lines were calculated using the simplified Pitzer equation, literature and calculated Pitzer parameters and a literature $K^0$ ($\log K_1^0 = 5.648$, $\log K_2^0 = 4.209$).

0.05$M$ and so was ignored.[31] Figure 2 shows the experimental protonation constant of propionate measured in different ionic media and at different ionic strengths. Experimental data obtained from the literature have been included in the plot.[32,33] The solid lines in Fig. 2 are the calculated dependence of log $K_{011}$ upon ionic strength and ionic medium based on the parameters listed in Table 2.

### *Succinate*

Succinate presents an interesting example in that the ligand is diprotic and so the solution speciation will depend on the pH of the solution. Once again not all Pitzer parameters were available in the literature and so were estimated from experimental results at 3$M$ ionic strength, using the same procedure as before. The final set of parameters are listed in Table 2. Figures 3(a) and (b) show the experimental data for this system together with the calculated ionic strength dependence. Experimental data obtained from the Jess database and from the literature has been included for comparison.[33–36] These curves show that the simplified Pitzer approach is a good representation of the data.

## CONCLUSIONS

The Pitzer, semi-empirical, method of correcting equilibrium constants from one ionic strength to another or from one ionic medium to another works well for many different electrolytes. However, this method of data correction has not been widely used in equilibrium modelling mainly because of a lack of the necessary parameters for more complex systems. In this paper we have shown that, under the conditions normally used to measure equilibrium constants, that is high background electrolyte concentration relative to reacting species, a simplified Pitzer approach can be used. Using this simplified approach unknown $\beta^{(0)}$ and $\beta^{(1)}$ parameters can be estimated from equilibrium measurements at high ionic strength and then used to predict reliably, equilibrium constants under different modelling conditions. This method should greatly enhance the applicability of chemical equilibrium models.

# PULSED ELECTROCHEMICAL DETECTION OF PENICILLINS USING THREE AND FOUR STEP WAVEFORMS

SELEN ALTUNATA, ROSA L. EARLEY, DANIEL M. MOSSMAN and LAWRENCE E. WELCH*
Department of Chemistry, Knox College, Galesburg, IL 61401, U.S.A.

(*Received* 15 *October* 1993. *Revised* 29 *June* 1994. *Accepted* 8 *July* 1994)

**Summary**—Aided by the construction of a custom potentiostat, a series of different PAD waveforms were compared to find the optimum detector for penicillin oxidation. The waveforms included standard 3-step direct and indirect PAD in addition to reverse-PAD and 4-step PAD. Two new waveforms, the indirect reverse-PAD and the 4-step indirect PAD were examined in the study. Under the solvent conditions of the study (0.01 *M* acetate buffer, pH 4.6) the indirect waveforms yielded the best detectability for penicillin G while the reverse-PAD waveforms yielded the worst performance. The 4-step PAD methods did not improve detectability when compared to the 3-step types, but they did provide output peak profiles with better shapes and less tailing. Although indirect waveforms gave better detectability than direct detection in the 0.01 *M* acetate buffer solution, the limits of detection for each were found to be differing functions of ionic strength. At higher acetate concentrations, direct PAD was more favorable than indirect detection.

The use of amperometric detectors for HPLC offers great selectivity for detection of oxidizable and reducible analytes. Constant potential (DC) amperometry is the simplest form of this detector genre, offering great sensitivity for aromatic organic species and some inorganics.[1,2] The application of DC amperometric detection on noble metal electrodes to aliphatic organic compounds has not proven as fruitful, as both the sensitivity and reproducibility of response are poor.[3–5] This has been attributed to the inability to maintain an active catalytic oxide surface at the working electrode, either by conversion of the oxide to a passive, less catalytic form or by fouling from adsorbates. Adams,[6] noted that electrode ignition, cleaning with chromic or nitric acid, and excursions to potential extremes could all be used in such cases to restore electrode sensitivity. The development of pulsed amperometric detection (PAD) in a sense adapted the potential excursion treatment into one that could be done *in situ* while performing amperometric detection.[7,8] A detection step directly oxidized analytes as in DC amperometry, but was maintained for only a short period of time (typically less than 1 sec). This was followed by a step to a very positive potential to fully oxidize the electrode surface, and then a negative potential step to reduce the surface and provide a clean oxide-free electrode. The entire waveform was repeated at 1–2 Hz, and by use of a lock-in amplifier circuit the current output was sampled only during the detection potential, then held until the next waveform cycle. The use of this original PAD waveform quickly found application for the detection of numerous aliphatic organic compounds.[9–14]

Whereas the original application of PAD oxidized the analyte molecules directly during the detection step, it was found that PAD also would allow some molecules to be monitored indirectly. Using essentially the original PAD waveform, injections into a flowing stream gave "negative" peaks, *i.e.* a decrease in anodic current, for $Cl^-$ in acid, $CN^-$ in base,[15] and for $I^-$ in acid.[3,15] This was attributed to the adsorption of these species, causing a reduction of background current from the formation of electrode surface oxide, with the concurrent absence of any faradaic signal from oxidation of these adsorbates. Indirect PAD was not limited solely to producing "negative" peak response, as $CN^-$ in basic solution can yield enhanced anodic response, *i.e.* "positive" peaks, in an indirect manner.[15] The adsorption of the $CN^-$ causes the kinetics of oxide formation to be altered, creating a potential region where the current from

*Author to whom correspondence should be addressed.

oxide formation is suppressed, and a region where it is enhanced. By selecting a potential in the enhancement region, "positive" response was observed. The absence of $CN^-$ oxidation at this potential led to this method being classified as indirect PAD. Other analytes showing "positive" response were conjectured to be the result of mixed direct and indirect detection.[15]

Early PAD work featured integration of output current for 16.7 msec at the end of the detection potential step, with the original intent being to minimize interference from 60 Hz background signals, but driven in later years by hardware limitations of early generation PAD equipment. An examination of the current integration period found that the use of times longer than 16.7 msec was beneficial for some analytes.[16] The longer integration periods were selected as multiples of 16.7 msec so that the reduction of 60 Hz noise was still effective. Waveforms employing these longer integration periods were originally classified by the title pulsed coulometric detection (PCD), but more recent literature has reclassified them as PAD waveforms.[4]

Polta and Johnson[17] were the first to describe the application of a new PAD waveform with the position of the oxidative and reductive steps following detection inverted. Essentially this eliminated the oxidative cleaning step, as the final oxidative step served to grow the catalytic oxide prior to the detection step in an effort to reduce noise. This waveform yielded better sensitivity than the original PAD method when applied to the detection of thiourea in basic media. The new waveform was not given a title other than PAD in this original work, but a more recent investigation[18] has classified this as a reverse-PAD (R-PAD) waveform to differentiate it from the standard PAD waveform, which was classified as normal-PAD (N-PAD). This recent work studied the R-PAD waveform and concluded that it would be beneficial to use a four step R-PAD waveform. This would insert an anodic cleaning step between the detection step and the cathodic cleaning step while maintaining the final oxidative step to pre-grow surface oxide.

PAD has recently been applied for the detection of penicillins in this laboratory.[5,19,20] Both direct PAD and indirect PAD ("negative" peaks) were found to yield sensitive detection, with the solvent composition determining which of the two gave best results. Direct PAD was best in an aqueous solution of acetate buffer, but when the solvent was altered in preparation for use as an HPLC mobile phase by the addition of organic modifier, the indirect PAD yielded better detectability.[19] It is the goal of this study to examine the use of alternative detection schemes such a R-PAD and 4-step PAD waveforms to determine their practicality for penicillin detection and to understand their function. It should be noted that commerical PAD potentiostats do not allow the use of 4-step waveforms, so their exploration required the construction of a "homemade" potentiostat.

## EXPERIMENTAL

All penicillins were purchased from Sigma (St Louis, MO, USA). All other solutions were made from reagent-grade chemicals from Aldrich (Milwaukee, WI, USA), Baker (Phillipsburg, NJ, USA), or Fisher (Pittsburgh, PA, USA). Water was distilled and deionized before use as a solvent.

Flow injection analysis for the ionic strength variation was done with a Waters 625 LC system (Milford, MA, USA) and a Waters 464 Pulsed Electrochemical Detector. A thin-layer cell was utilized with a single gold working electrode. The counter electrode was a stainless steel block mounted opposing the thin-layer cell, with the flow channel created by a teflon spacer between the two. The reference electrode was a Ag/AgCl. A 50-$\mu$l sample injection loop was employed with this system, and a flow rate of 1 ml/min was standard.

Flow injection analysis for all other experiments described was done using a SSI (State College, PA, USA) Model 300 LC pump with an SSI Model LP-21 pulse dampener and a BAS (West Lafayette, IN, USA) CC-5 flow cell compartment. Potentiostatic control was provided by a Pine Instruments (Grove City, PA, USA) RDE4 potentiostat with external voltage control driven by a Keydata (S. Plainfield, NJ, USA) 486DX2-50 IBM-compatible computer running VIEWDAC 2.1 software from Keithley/MetraByte (Taunton, MA, USA), interfaced with a Keithley DAS-20 interface card and screw terminal board. A dual gold electrode block was used, with the upstream element serving as the working electrode. The counter electrode was a stainless steel block mounted opposing the thin-layer cell, with the flow channel created by a teflon spacer between the two. The reference electrode was a Ag/AgCl. A 50-$\mu$l sample injection loop and a flow

rate of 0.5 ml/min were employed with this system.

A BAS MF-2060 Polishing Kit was used to polish the working electrode; in addition potential cycling to the voltage limits of the system, as defined by the onset of solvent breakdown, was helpful to restore electrode activity following temporary losses of sensitivity. Injected penicillin solutions were all solvent matched with the mobile phase to avoid having a system peak overlapping with the analytical peak. All mobile phases were vacuum filtered through an Alltech (Deerfield, IL, USA) 0.45-$\mu$m nylon filter. Flow injection detector signal polarity was inverted so that increased anodic response would produce peaks rather than troughs on the output plots. All output was filtered through a low-pass frequency filter. Recorded PAD data for quantitative studies was treated with a fourier transform smoothing algorithm to further minimize high frequency noise, and to minimize the impact of regular pump pulsations arising from the lack of back pressure during flow injection trials. Peak heights were used for detection limit and reproducibility calculations. Detection limits ($S/N = 3$) were found by extrapolation from higher concentrations.

## RESULTS AND DISCUSSION

### *Potentiostat development*

The potentiostat used for the waveform optimization work was put together from separate components which are listed above in the Experimental section. The advantage of building this instrument was that it allowed great flexibility in selection of amperometric waveform, which can only be obtained commercially in a very expensive instrument not designed for PAD. The disadvantage of a homemade instrument is that it is likely to suffer from a greater degree of electrochemical noise than a well-made commercial unit. The components that we chose to construct our potentiostat are by no means unique; there are many different options for both software and hardware. One particular concern should be to obtain an interface card that allows both bipolar analog outputs (voltage) and inputs (current); many otherwise very sophisticated and powerful interface cards are only unipolar in nature. Another very important note is that some sample voltage waveforms must be checked with an oscilloscope for validity before the potentiostat can be trusted. We found that some software instructions for a particular potentiostatic function were too cumbersome for the computer to handle in a timely fashion, resulting in slower operation than had been instructed. For example, points to be collected at 1.000 sec intervals may actually be collected at $\sim$1.4 sec intervals if the software is not streamlined. The only way to be certain of the integrity of the user-selected time-dependent operations embedded within a software routine is to check them with an oscilloscope.

Another concern is the need to allow "idle" time to be programmed during the initial phase of an experiment. Whenever an amperometric waveform is initially sent to an electrochemical cell or whenever a significant change in the waveform is made, the current output of the system will change sharply and generally will drift substantially for a number of minutes before the cell reaches an equilibrium state. Any data taken before equilibrium is complete will be suspect; in particular the reproducibility of detector response will be poor. An example of this can be seen in Fig. 1, where the change in output response during equilibration is so acute that the peak polarity inverts for injections of the same solution at differing times following waveform initiation. Although it requires extra programming time, it is essential to produce software that will allow initiation of the desired PAD waveform at the electrochemical cell well before any current data are collected. We found 10 min to be the minimum acceptable idle time with our particular setup.

The potentiostatic software that was developed allowed from one to four potential steps within a waveform, each with a selectable voltage and duration. Current integration always took place during the initial step, although this was not required by the software, and could be done for any length of time desired. Once collected, the raw output data were treated with a low-pass filter and a fourier transform smoothing function as noted in the Experimental section.

### *Waveform optimization*

The names of the waveforms used herein are not completely standardized, so in an effort to clarify the type being used each is illustrated in Table 1 along with a title. 3-step direct PAD (Table 1A) is the standard form of PAD that has been used extensively since the work of Hughes *et al.*[7,8] An oxidative detection step is followed by a step to a more positive potential to provide oxidative cleaning, producing a fully

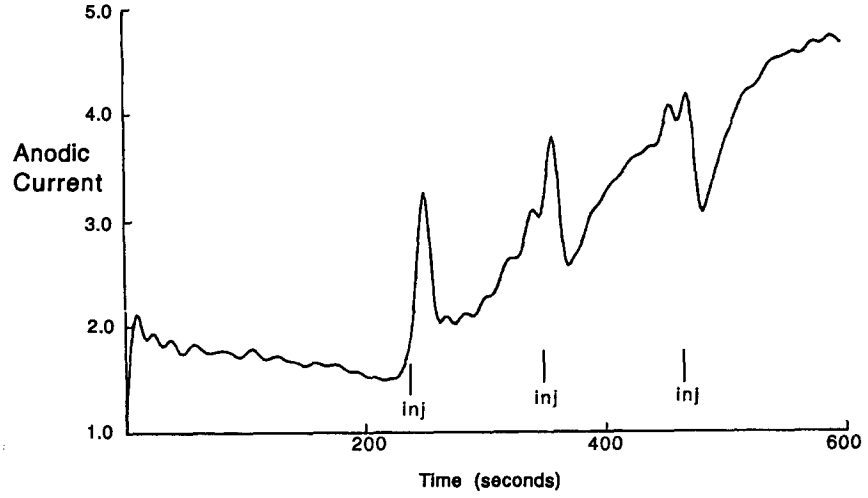

Fig. 1. Detector instability in the absence of a waveform idle period. Flow injection analysis: three injections of $1 \times 10^{-4}M$ penicillin G in a $0.01M$ acetate buffer solvent. Waveform: E1 = 1.1 V for 668 msec, E2 = 1.3 V for 668 msec, E3 = −0.2 V for 835 msec, integrate 17–668 msec.

oxide covered electrode. This is followed by a step to more negative potentials to reduce the surface oxide, providing a clean metal surface which can react with adsorbates. 3-step indirect PAD[5,15] (Table 1B) uses the same basic waveform shape as 3-step direct PAD, although typically the detection step is either less positive, has a shorter duration, or both in comparison to the direct waveform. Indirect PAD results in a change in peak polarity, which is due to suppression of the anodic background signal from the formation of surface oxide at the detection potential. This is suppressed in the presence of an analyte that will adsorb to the electrode surface, resulting in the production of less surface oxide and correspondingly less current from this process. Many adsorbates produce direct PAD response, where the suppression is more than offset by current from oxidation of the adsorbate. However, in indirect PAD the waveform is created to encourage analyte adsorption but to slow its oxidation such that the anodic current produced is not enough to offset the suppressive effect.

Inverse PAD, although not previously used in this lab, has been described by Polta and Johnson,[17] and Roberts and Johnson.[18] The standard form, referred to as direct reverse-PAD (Table 1C) has the anodic and cathodic cleaning steps reversed when compared to 3-step direct PAD. For this to work, the detection potential chosen must be positive enough such that the oxidative cleaning step is not necessary. Following a cathodic cleaning step, a short anodic step is made. This step is designed to "pre-grow" the catalytic oxide necessary for oxidation of the analyte. By forming this oxide prior to the detection step, a reduction in background signal

Table 1

(and noise) during detection can be enabled. The short time of this step is critical, as the catalytic "lower oxide" is transient, and at longer times the lower oxide will be converted to the higher oxide, which is not catalytic for most PAD analytes. It was also possible to do indirect reverse-PAD (Table 1D), which has not been described previously in the literature. This waveform has essentially the same structure as direct reverse-PAD, but as in other indirect waveforms the polarity of reponse shifts as the suppression of the anodic background signal predominates. This would seem to be a very unlikely waveform, as a majority of the anodic current from formation of surface oxide would presumably be occurring during the oxide pre-growth phase in step 3, so would not be available for suppression during the detection step. However, this viewpoint only focuses on sensitivity; whereas the oxide pre-growth should result in a much smaller amount of anodic signal than is available for suppression, the degree of uncertainty of this current level should also be smaller. Thus, the background noise should also be less. When evaluating the waveform based on the $S/N$ of response, it can be envisioned that this waveform could be valuable if the reduction in noise was great enough to offset the loss in sensitivity. The construction of an indirect reverse-PAD waveform from direct reverse-PAD generally requires a shift to less positive detection potentials and shorter times for the oxide pre-growth step.

The ability to program waveforms with greater than three potential steps allows the creation of additional PAD waveforms. 4-step direct PAD (Table 1E) has been proposed as advantageous by Roberts and Johnson.[18] During the discussion of direct reverse-PAD, it was noted that this waveform does not have an oxidative cleaning step, relying on the detection potential for this purpose. The availability of a fourth step in the waveform allows the oxidative cleaning step to be retained while still having an oxide pre-growth step just prior to detection. Finally, Table 1F details a 4-step indirect PAD waveform, which also has not been utilized in any published work. The structure of this waveform is basically the same as the previous one, the difference being that the polarity of the output current is inverted, being controlled by suppression of the anodic background signal. As with indirect reverse-PAD, this waveform will theoretically suffer from poor sensitivity, as the fourth potential step for oxide pre-growth will limit the amount of background signal available for suppression during the detection step. Again, as mentioned above, the possible advantage for this type of waveform lies in the fact that noise should be reduced, perhaps to a greater extent than the loss in sensitivity.

Experiments were run to produce the best example of each of the waveforms mentioned above in terms of $S/N$. These waveforms are listed in Table 2 along with their detection limit for penicillin G and the % relative standard deviation (RSD) of response for a set of five consecutive injections of a $1 \times 10^{-4} M$ penicillin G solution. The solvent system chosen was $0.01 M$ acetate buffer (pH 4.6), which was similar to that used for previous flow injection trials for penicillins in this laboratory.[5] The reader should be cautioned that although the performance of the potentiostat was adequate, it does suffer from higher noise levels than its commercial counterparts. As such, slightly better detection limits can be achieved for the 3-step waveforms using a good commercial instrument. However, the absolute values of the detection limits were less important than their comparison for the different waveforms. Although larger than ideal, the noise should impact the different waveforms to the same degree, allowing them to be compared fairly.

From Table 2, it can be seen that all integration times selected were longer than 250 msec. When the traditional 16.7 msec integration time was tested, it was found to yield worse response for all waveforms in terms of both sensitivity and noise. It is interesting to note that in comparison of 3-step direct and 3-step indirect PAD, both optimized waveforms use the same detection potential. Usually, the indirect method will utilize a slightly smaller potential. However, the variations in the other facets of the waveforms are enough to alter the oxidation kinetics to the degree whereby output polarity is inverted. The performance of the indirect method leads to a superior detection limit when comparing the two; a comparison of the output traces can be seen in Fig. 2. The superiority of the indirect PAD method leads to a seeming paradox when comparing this data with that obtained by Koprowski *et al.*[5] In this work, while also using an acetate buffer solvent, a 3-step direct PAD waveform was found to give better detectability than its indirect counterpart. Although the data sets were obtained with different detectors, which would explain some variation in detection limit, this would not

Table 2. Optimized PAD waveforms for penicillin G injections

| Title | Waveform | % Relative standard deviation | Detection limit ($M$) |
|---|---|---|---|
| 3-step direct PAD | E1: 1.3 V for 501 msec<br>E2: 1.6 V for 668 msec<br>E3: −0.3 V for 668 msec<br>Integrate: 17–501 msec | 2.4 | $2 \times 10^{-6}$ |

reasonably explain why direct PAD would be more favorable on one instrument and indirect PAD on the other.

On close examination of the two experiments, it can be found that although both use acetate buffer solvents, the concentrations are slightly differnt ($0.01M$ here *vs.* $0.2M$ in Ref. 5). A set of experiments were run to examine the possibility that this paradox could be explained by the difference in ionic strength of the acetate buffer. Acetate buffer solutions, all at pH 4.6, were made throughout the range of $0.0005$–$0.3M$. For each different solvent, both a 3-step direct PAD and 3-step indirect PAD waveform were optimized. The optimized waveforms were then used to find a detection limit for solvent-

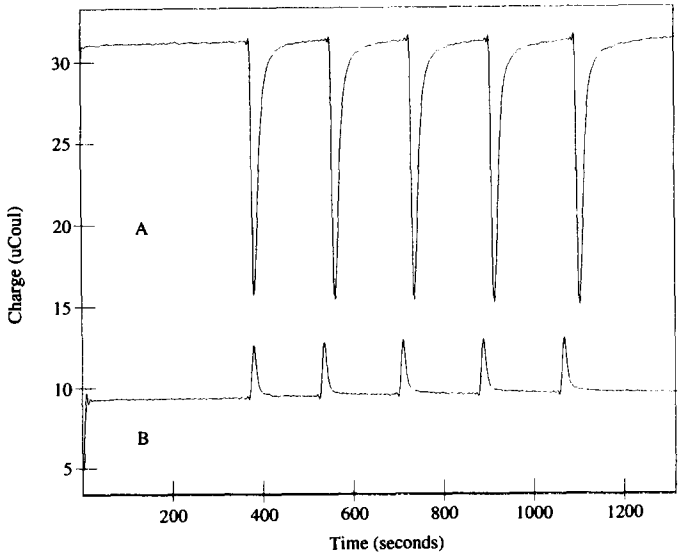

Fig. 2. A comparison of 3-step indirect (A) and 3-step direct (B) PAD. Flow injection analysis: $1 \times 10^{-4}M$ penicillin G in $0.01M$ acetate buffer. Waveforms are given in Table 2.

matched solutions of penicillin G. A plot of the resultant detection limits *vs.* log of acetate concentration is given in Fig. 3. The concentrations were plotted in logarithmic form to allow the variation with concentration to be observed without crowding in the lower region of the concentration scale. At higher concentrations the direct PAD waveform yielded better detection limits, but as acetate concentration is reduced a crossover is observed and the negative PAD produces lower detection limits. This could explain why Koprowski *et al.*,[5] working at high ionic strength, would find positive PAD to be more favorable, while the lower ionic strength used in this work would lead to just the opposite result.

As the electrolyte concentration is reduced, one would expect the oxidation kinetics to be slowed due to the development of an *iR* drop. This problem is noted to be a relatively common occurrence when using a thin-layer electrochemical cell unless a solvent with a high ionic strength is used.[21] The high current requirement for a pulsed waveform and the extreme potentials used to promote penicillin oxidation exacerbate the *iR* drop problem. This has a deleterious effect on direct PAD waveforms, as this tends to attenuate their output response, shifting them toward the crossover to indirect PAD. The application of greater overpotential

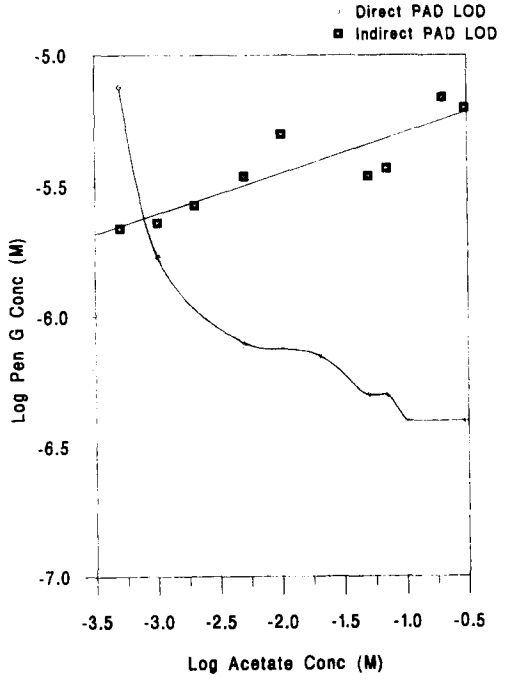

Fig. 3. Penicillin G detectability as a function of acetate concentration in the solvent.

to offset the *iR* drop is not beneficial, as it causes a sharp increase in noise. The *iR* drop caused by the use of a low ionic strength solvent and the resultant slower analyte oxidation kinetics are not a problem for indirect PAD. In fact, it may actually be beneficial since the slowed kinetics are the genesis of the indirect response. High electrolyte concentrations may actually be bad for indirect PAD, as it may be difficult to create a waveform that will produce a slow enough rate of analyte reaction while still forming electrode surface oxide, the growth of which is necessary for indirect PAD. This is illustrated in Fig. 3, as at very high electrolyte concentrations the performance of indirect PAD actually becomes poorer. It is unlikely that the ionic strength effect is a result of a change in analyte adsorption. Adsorption takes place at a separate step in the PAD waveform from detection, and in general the adsorption steps are uniform regardless of waveform type within this work. Since the direct and indirect PAD waveforms feature similar analyte adsorption steps, one would expect that if adsorption was affected by ionic strength it would cause a similar change in both waveforms, rather than the dissimilar one that is observed.

Neither of the reverse-PAD waveforms gave good results. Although the detection limit of the direct reverse-PAD waveform is almost as good as the 3-step direct PAD value, the reproducibility is unacceptable for practical use. The indirect reverse-PAD has a much better RSD, but its detection limit is nowhere close to either of the first two waveforms. It should be noted that reverse-PAD is not universally valuable for all analytes;[22] some analytes respond quite poorly to this type of detection. Most of the analytes that have benefitted from reverse-PAD were sulfur species,[17,22] so it is somewhat of a surprise that the penicillin, with its active sulfide site, was not a better candidate for reverse-PAD.

Neither of the 4-step PAD waveforms offered any gains in detectability. The 4-step direct PAD waveform had virtually the same detection limit as direct reverse-PAD, but this was still three times higher than for 3-step direct PAD. The 4-step indirect PAD, like the 3-step waveforms, gave significantly better output than its direct counterpart. The performance is still slightly poorer than for 3-step indirect PAD, as can be seen in Fig. 4. It can be noted from viewing this figure that the changes in response expected upon moving to a 4-step waveform are indeed present. The added oxide pre-growing

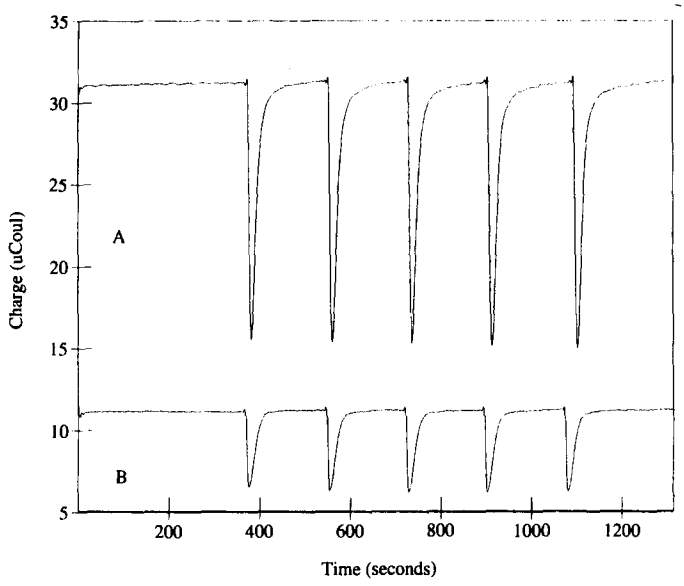

Fig. 4. A comparison of 3-step indirect (A) and 4-step indirect (B) PAD. Flow injection analysis: $1 \times 10^{-4}M$ penicillin G in $0.01M$ acetate buffer. Waveforms are given in Table 2.

step did cause the sensitivity to drop for 4-voltage PAD (16.248 *vs.* 5.080 mean peak heights). The noise level did improve with the addition of the fourth potential step (0.03241 *vs.* 0.01356 standard deviations). Nevertheless, the overall $S/N$ evaluation shows that the 3-step indirect PAD is still superior.

At first glance the data would seem to support the fact that there is no need to produce a potentiostat that can be programmed beyond three potential steps. However, there is a final consideration that does favor the 4-step waveform: peak shape. There is more tailing in the peaks in part A, whereas the 4-step peaks are superior in this regard. The degree of peak distortion can be quantitated by measuring the peak asymmetry factor,[23,24] which gives a value of 4.06 for the 4-step PAD *vs.* 4.24 for 3-step. Although there has been no definitive study detailing the relationship between peak shape and PAD waveform, it has been clearly demonstrated that pulsed electrochemical detection can lead to significant peak tailing,[24] the degree of which is dependent on the waveform design. This is particularly important for indirect PAD, where this has been shown to be more of a problem than for direct PAD.[22] The difference in asymmetry factors is not large, however, it should be noted that the optimization process was based on detectability rather than peak shape. Experience with the two waveforms has shown that the presence of the extra potential step inevitably allows the 4-step waveform to be adjusted to produce better peak shapes than are obtainable with the 3-step. For HPLC experiments where resolution is critical, this new waveform will be a better detector choice than existing 3-step waveforms, as the sacrifice in detectability is small. It should also be noted that although the detectability advantage of the 3-step waveform is clear within the system studied in this project, it is likely that future experimentation with varying solvent systems and sample matrices will uncover conditions for which the 4-step waveform gives the lowest detection limit.

## CONCLUSION

PAD response will vary with ionic strength, even for solutions with the same qualitative composition. This change in electrolyte concentration will change the kinetics of electrochemical response at various PAD waveforms; typically at low ionic strengths the direct PAD response suffers the greatest due to the larger current involved with this process. Indirect PAD waveforms are typically less favorable in the presence of sufficient electrolyte, but at low ionic strengths will become preferable to direct PAD, as the change in oxidation kinetics is less of a problem.

The ability to produce a PAD waveform with four potential steps instead of the traditional three did not result in improved detectability. The detection limit for a 4-step indirect PAD

waveform was only slightly higher than for 3-step indirect PAD, and the obtained peak profiles showed less tailing. The improved peak shapes obtained with the four step waveform will allow improved chromatographic resolution when compared with other forms of PAD.

# SPECIATION OF IRON AND MANGANESE IN DAM WATER PARTICLES USING ELECTRON SPECTROSCOPY FOR CHEMICAL ANALYSIS (ESCA)

MYINT ZAW[1,*] and BARRY CHISWELL[2]

[1]Environmental Science Programme, Australian Nuclear Science and Technology Organization, Private Mail Bag 1, Menai, NSW 2234, Australia
[2]Department of Chemistry, University of Queensland, St Lucia, Qld 4072, Australia

(*Received* 25 *April* 1994. *Revised* 15 *July* 1994. *Accepted* 19 *July* 1994)

**Summary**—The speciation of iron and manganese compounds retained by membrane filtration of dam water samples was studied by use of electron spectroscopy for chemical analysis (ESCA). Samples were taken at various depths and times of year from North Pine Dam near Brisbane, Australia. Both surface and bulk properties of samples representative of the water column profile were investigated. ESCA results showed that iron(III) compounds were found to predominate in the whole water column in any season of the year while the significance of iron(II) species varied in the hypolimnion (the bottom layer). In summer, although various ratios of manganese(II), manganese(III) and manganese(IV) compounds were found to occur down the water column, manganese(IV) compounds were predominant in the epilimnion (the top layer), while both manganese(II) and (IV) compounds predominated in the metalimnion (the middle layer) and the hypolimnion. The majority of Mn(IV) compounds were found throughout the water column after heavy rain and winter season. The ratios of atomic concentrations of iron and manganese as determined by atomic absorption spectrophotometry and ESCA are also discussed.

In our previous studies[1–3] upon manganese and iron in dam waters, work has been concentrated upon speciating the soluble forms of the metals. However, in the environment of natural waters the speciation of particulate forms of these metals has received little attention. This may be due to the speciation techniques being labor intense and expensive in both capital outlay and maintenance of instruments. This work reviews our results to date on the speciation of iron and manganese in dam water particles using electron spectroscopy for chemical analysis (ESCA) [also known as X-ray photoelectron spectroscopy (XPS)] in order to further understand their behaviour in the dam profiles at different times of the year. This is a new and powerful approach to the study of particulates in natural waters.

Modern surface-sensitive analytical techniques, including secondary ion mass spectrometry (SIMS), Auger electron spectroscopy (AES) and ion scattering spectroscopy (ISS), provide a means for obtaining a chemical analysis of the outer five to 10 atomic layers of the surface of a material, as well as an analysis of the underlying material.[4] Consequently these techniques have found widespread use in many areas of material research and fabrication.[5] Quantitative data can be obtained from the spectra by study of peak heights or areas, and identification of chemical oxidation states often can be made from the exact positions and separations of the peaks, as well as from certain spectral contours.[6]

ESCA is potentially an ideal technique for study of the oxidation states of solid iron and manganese compounds. The core electrons of the molecular bonded atoms in compounds are basically in atomic orbitals with their binding energies being characteristic of the atoms. However, an increase in oxidation state produces a slight increase in binding energy, while a decrease in oxidation state will slightly decrease the binding energy.[7]

The atomic concentration routine calculates relative concentrations of iron and manganese (surface elements), while the atomic per cent values are calculated from the measured signals by applying elemental sensitivity factors and normalizing to 100 atomic per cent. The

*Author to whom correspondence should be addressed.

formula[8] used to calculate the atomic concentration values is given below.

$$\frac{n_1}{n_2} = \frac{I_1/S_1}{I_2/S_2}, \quad (1)$$

where $n$ is the number of atoms per unit volume, $I$ is the number of photoelectrons detected (area under the peak) and $S$ is the atomic sensitivity factor.

In environmental sciences,[9] submicron particles (including inorganic and organic colloids, clay minerals and microorganisms) play an important role in natural waters. Physical and chemical sorption processes result in significant amounts of trace elements (including heavy metals) being associated with these particles in aquatic systems. The physical and chemical behaviour of these metals in the environment and their biophysicochemical properties differ from those of the corresponding dissolved species. Electron microscopy is a powerful tool able to morphologically characterize these submicron particles according to their elemental associations. This technique includes analytical electron microscopy (AEM), scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Although SEM cannot directly speciate iron and manganese compounds, it is a powerful tool in the study of different types of algae and bacteria, some of which are directly related to iron and manganese behaviour in the storage dams.

## EXPERIMENTAL

### *Sample preparation and instrumental settings*

Water samples were collected by a Klemmerer-type depth sampler over almost a full year (11/11/87 to 06/09/88) at various depths of North Pine Dam near Brisbane, Australia (actual dates and depths of samples collected are given in Table 4. Samples of sediments were collected using a cylindrical grab sampler, from the top (1–3 cm depth) of the sediment. Samples were filtered through either a 0.45 $\mu$m filter membrane, or a 0.01 $\mu$m filter membrane after prior passage through a 0.45 $\mu$m filter membrane.

Stratification of North Pine Dam commences in early September and lasts until May. During these warmer months the lake becomes fully stratified whilst in the winter (June to August) destratification results in a fully mixed and aerated profile. In a stratified dam the surface and 3 m samples come from the epilimnion, the 10, 11 and 12 m samples all come from the metalimnion and the 15, 27 and 32 m (bottom sediment) come from the hypolimnion. The variation in the depths of sampling the metalimnion and hypolimnion is related to the date of sampling and the depth of water in the dam at the time of sampling.

The methods of sampling and filtration of dam water samples are described in detail in previous papers.[3,10] Duplicate water samples were shaken thoroughly and then transferred into both 100 ml and 1 l. acid-washed polythene containers to yield a series of like samples. For surface analysis at least 1 l. of the dam water sample was filtered through either a 0.45 $\mu$m filter membrane, or a 0.01 $\mu$m filter membrane after prior passage through a 0.45 $\mu$m filter membrane. The particulate matter remaining on the filter membrane was put into a vacuum desiccator for at least one week for drying, before analysis by ESCA and SEM.

For atomic absorption spectrophotometry (AAS) analysis, the corresponding like sample (100 ml) was filtered through either a 0.45 $\mu$m filter membrane, or a 0.01 $\mu$m filter membrane after prior passage through a 0.45 $\mu$m filter membrane. The particulate matter remaining on the filter membrane was digested in 10 ml concentrated hydrochloric acid (BDH, Analar), gently boiling for 30 min and followed by addition of 1.0 ml concentrated nitric acid (BDH, Analar) with boiling for a further 5 min. After acid treatment the solution was cooled down and then made up to 100 ml in a volumetric flask with Milli-Q water and finally analysed for dissolved iron and manganese concentrations by use of Varian AA 875 spectrophotometer. Blank determinations were carried out for each analysis batch.

With SEM analysis the dry sample was cut out and mounted on a specimen stub, sputtered with argon ion (for a few seconds) and coated with gold in a partial argon atmosphere at 100 m Torr. The samples were then examined in a Phillips model SEM 505 scanning electron microscope. All SEM results indicated that filtrate samples collected on membrane filters were uniformly distributed over the membrane surface and that ESCA could be undertaken on a portion of the membrane to give results representative of the whole sample.

ESCA analyses were carried out on a Perkin Elmer PHI Model 560 Multitechnique System. For these analyses, either Al$K\alpha_{1,2}$ X-rays (1486.6 eV) or Mg$K\alpha_{1,2}$ X-rays (1253.6 eV) were used as

the exciting radiation of the photoelectrons. For the measurement of accurate binding energies and the atomic concentrations, the aluminium anode was used (in preference to the magnesium anode) as it shifted interfering Auger peaks up-scale by 233 eV. Such Auger peaks were found to give iron interference in the manganese 2p photoelectron, and oxygen interference in the iron 2p photoelectron regions, respectively, when the magnesium anode was used.

For ESCA analyses the sample membrane was cut to allow it to be mounted on the sample holder and then inserted into the spectrometer. During the analysis the vacuum inside the ESCA chamber was approximately $2 \times 10^{-7}$ Torr due to argon gas flow for the ion etching procedure. The basic pressure in the analysis chamber was typically about $10^{-9}$ Torr. The instrument was calibrated weekly, and the calibration was checked several times each day during data acquisition. The analyser work function was determined assuming the binding energy of the gold $4f_{7/2}$ peak to be 84.0 eV.[11]

The oxidation states of reference iron and manganese metal sheets, a number of iron and manganese oxides and compounds, and the dam water particulate samples on the millipore filter, were all determined before and after argon ion beam etching. The PHI 04-303 ion gun was operated at a beam energy of 4 keV and a beam current of 1.0 $\mu$A. This beam was incident at an angle of 30° to the sample normal, and was rastered over an area 8 × 6 mm to ensure complete etching of the ESCA analysis area (approximately 5 mm diameter). These conditions gave an etching rate of apporoximately 0.25 nm/min for standard $Ta_2O_5$.[12] The etching rate of the particulate (including carbon, standard iron and manganese compounds) in dam water samples on the 0.45 or 0.01 $\mu$m filter membrane

Table 1. Standard iron and manganese compounds for ESCA analysis

| Standard iron compounds | | | Standard manganese compounds | | |
|---|---|---|---|---|---|
| Compound | Purity (%) | Company | Compound | Purity (%) | Company |
| Pure iron sheet | 99.99 | PHI 603965 | Pure Mn sheet | 99.9 | Leico Industry |
| $Fe_2O_3$ | 99.99 | Aldrich | $MnO_2$ | 99.99 | Aldrich |
| $Fe_3O_4$ | 99 | Aldrich | $Mn_3O_4$ | 99.995 | KOH |
| FeS | Technical Grade | Aldrich | $MnCO_3$ | Laboratory reagent | BDH |
| | | | $MnSO_4 \cdot 4H_2O$ | >97% | BDH |
| | | | $Mn(CH_3COO)_2 \cdot 2H_2O$ | >97% | Aldrich |

(after prior passage through a 0.45 $\mu$m filter) relative to $Ta_2O_5$ is unknown, but was assumed to be of similar magnitude.

Iron and manganese $2p_{3/2}$, $2p_{1/2}$ and carbon 1s spectra were recorded, and binding energy measurements were made relative to the carbon 1s spectral peak ($284.8 \pm 0.1$ eV) as a reference value. Carbon is present due to hydrocarbon contamination on the sample surface of the reference material, or is intrinsic to the sample in the case of dam water particulates.

Dam water particulates for the various annual seasons from different depths of North Pine Dam were studied in detail by SEM, while ESCA was used to analyse the oxidation state and binding atoms for iron and manganese present both on the surface and in the bulk of the particulates.

*Data analysis by using curve fitting method*

ESCA measurements involve recording the intensity of emitted electrons as a function of the electron binding energy. The measured spectra consist of peaks at characteristic energies, from which the elemental composition of the sample can be determined. An element is often in several different oxidation states which produces photoelectrons of slightly different binding energies resulting in a composite peak.

Data reduction was carried out using a computer curve fitting program to deconvolute the measured ESCA peaks into the peaks of the individual chemical species.[13] Inputs into the program were the digitized experimental raw data, and the specific peaks shapes (non-Gaussian) for the elements of interest in their various chemical states. The individual peak shapes were obtained from the "Handbook of X-ray Photoelectron Spectroscopy",[14] with the background assumed to vary linearly across each peak. In essence, the computer program calculates an error for each point on the measured curve; such error is the shortest distance between the measured point and the composite curve which is the sum of two or more peaks for particular oxidation states. The program carries out a least squares fit, comparing the measured curve with the sum of the composite curves, systematically varying the intensity and position (within fixed limits) of the composite curves. The final result consists of the raw data, the resolved peaks for the individual oxidation states, the convoluted curve (*i.e.* the sum of the individual peaks) and an error curve which is the difference between the raw data and the convoluted curve.

Each curve-fit was further checked on its suitability with each side of the computer selected error minimum, and each case was further examined to determine if a better fit could be possible using individual peaks with binding energies different from those expected. On the other hand, the slight difference revealed by the rechecking procedures shows that there can be a significant shift in the peak position with ion milling and that this is important when

Table 2. Binding energies for $2p_{3/2}$ line of iron, iron oxides, manganese and manganese oxides as determined by ESCA

| Binding energies (*eV*) | | | | |

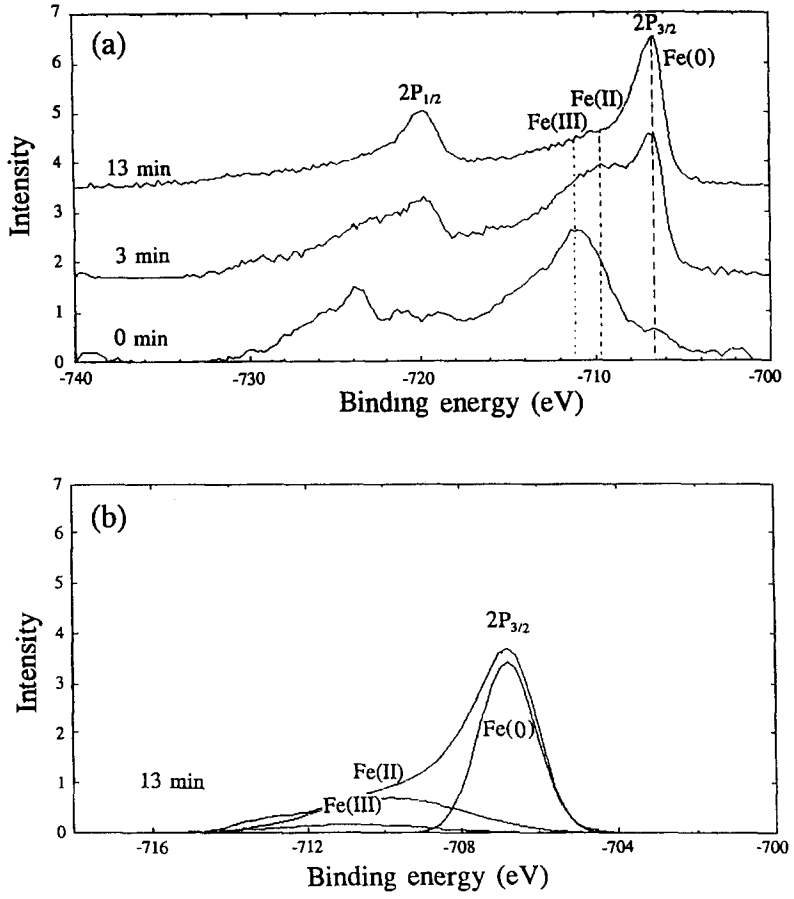

Fig. 2. (a) ESCA spectra of the iron $2p_{3/2}$, $2p_{1/2}$ lines from oxidized iron sheet before (0 min) and after (3 and 13 min) sputtering and (b) curve fitted results of the convoluted iron $2p_{3/2}$ spectra from oxidized iron sheet after 13 min sputtering.

considering the fitting error. Furthermore, the nature of the fit can change depending on the binding energy range chosen. Sometimes these two factors affect each other. The values used are the best fits obtained after these considerations had been taken into account.

## RESULTS AND DISCUSSION

### *Carbon spectrum as a reference peak*

Contamination, which formed on the standard sample surface, consisted mainly of hydrocarbons, water vapour and oxygen, and

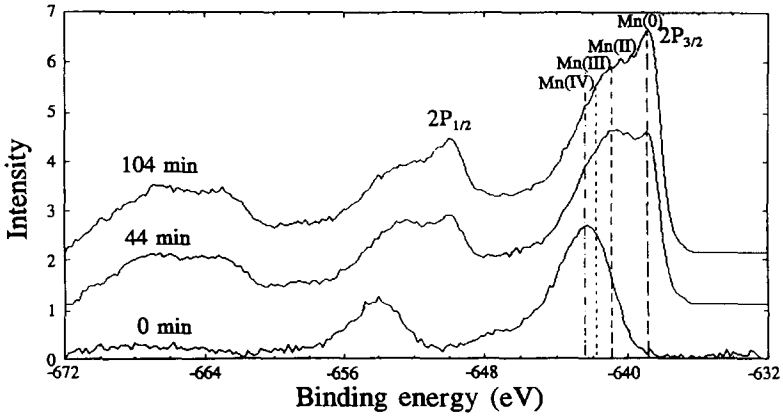

Fig. 3. ESCA spectra of the manganese $2p_{3/2}$, $2p_{1/2}$ lines from oxidized manganese sheet before (0 min) and after (44 and 104 min) sputtering.

originates from exposure to air during the brief period of transfer from the vacuum desiccator to the ESCA apparatus; it can also come from the residual gases within the ESCA chamber.[15] The C 1s peak (284.8 ± 0.1 eV) was observed in all ESCA spectra; however, for the standard samples this peak disappeared after 5 min of ion etching. This was taken to indicate that the carbon contamination on the surface had been removed and any further analysis was representation of the "true" bulk sample. Dam water particulate samples have all the above contaminants; however, most of the carbon in such samples is not contamination but an integral part of the actual sample. The carbon 1s peak for all samples in the unetched state was the most intense spectral peak in comparison with the others, and after ion etching for 5 min, this carbon peak was considerably reduced (Fig. 1). In all the experiments, the carbon 1s spectrum was therefore recorded and used as a reference for charge correction and as a surface contamination removal indicator.[11]

Dilks[16] has claimed that there are five types of bound carbon which can be found from ESCA studies of organic polymer samples, containing carbon and oxygen. These are (1) hydrocarbon ($-CH_x-$), (2) alcohol, ether and peroxide carbon (-C-O-), (3) ketone carbon (>C = O), (4) ester and carboxylic carbon, and (5) carbonate carbon. The binding energies increase from peak 1 to 5 due to the larger dipole difference between carbon and hydrogen or oxygen.

Figure 1(a) shows the ESCA high resolution carbon 1s spectrum both before sputtering and after 5 min sputtering for a 32 m depth sample (bottom sediment) obtained on 06/09/88. Figure 1(b) represents the results of curve fitting for the five differently bound carbon species obtained before sputtering; while Fig. 1(c) is the curve-fitting analysis after 5 min sputtering. These results show that after light sputtering with argon ion on the sample surface, different types of carbon have been removed and their intensity reduced; only the first and second types of carbon have their intensities

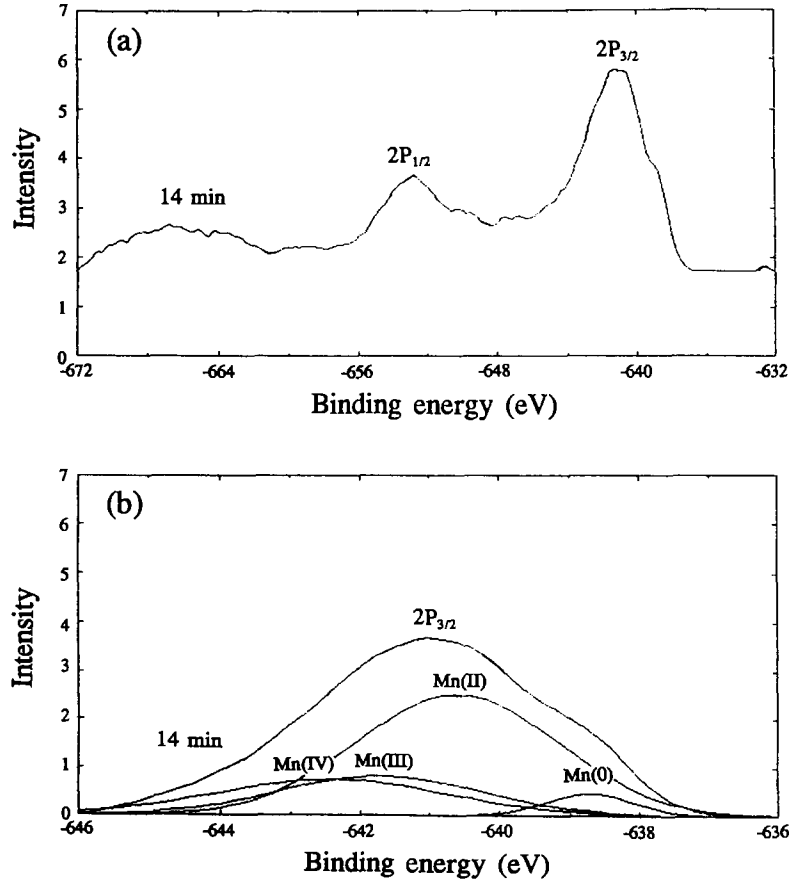

Fig. 4. (a) Raw data and (b) curve fitted results of the convoluted manganese $2p_{3/2}$ spectrum from oxidized manganese sheet.

slightly increased. Also, all the peak positions are slightly shifted to lower binding energies after ion milling by argon ions, which is due to a decrease in sample charging after removal of some of the surface hydrocarbons.

*ESCA measurement on reference iron and manganese metals and compounds*

The iron and manganese oxides and compounds studied by ESCA were commercially obtained high purity powders and crystals (Table 1). Oxide samples were prepared by crushing immediately prior to insertion into the spectrometer. The binding energies for the $2p_{3/2}$ line of standard iron, manganese and their compounds were obtained from a variety of literature sources[7,14,15,17–30] and were confirmed by our own studies as shown in Table 2.

The phenomenon of multiplet splitting associated with photoelectron peaks is due to the presence of unpaired valence electrons, resulting in an exchange interaction which affects differently the remaining spin-up or spin-down core electrons. Another characteristic feature of the oxide spectra, which has been empirically observed for other high spin states of transition metal ions, is the presence of satellite peaks.[31] These shake-up core-level satellites are caused by an incident X-ray photon giving up a discrete portion of its energy to the excitation of a second electron, rather than imparting its entire quantum energy to the primary, photoejected electron. Thus this photoelectron will have lost a small amount of energy and will appear at a slightly higher binding energy than the parent peak. Shake-up peaks are observable for both iron and manganese compounds. These satellite lines have intensities and separations from the parent photoelectron line that are unique to each chemical state. Prominent shake-up patterns typically occur with paramagnetic states including iron(II), iron(III), manganese(II), manganese(III) and manganese(IV) compounds.

An ESCA study on a pure iron metal sheet is shown in Fig. 2(a). After 3 and 13 min heavy sputtering on iron sheet, the iron(III) oxide on the surface can be seen to be almost completely

*B.E.: binding energy.

†FWHM: full width half maximum.

‡The number in parentheses indicates the oxidation number of iron or manganese.

§Normally, a light ion dose ($\leq$5 min sputter) was used to remove only the outer few atomic layers (approximately 1.2 nm) exposing an unaltered sample surface. Much longer sputtering (*i.e.* heavier ion dose) was needed to ensure complete removal of the surface oxidized layers and present a clean metal surface for analysis.

eliminated. This conclusion is reinforced by curve fitting as shown in Fig. 2(b), which clearly indicates the presence of mainly iron(0) at the surface following sputtering.

Figure 3 shows the binding energies of manganese before and after (44 and 104 min) sputtering of manganese sheet metals; the removal of manganese oxide is clearly seen in the growth of the manganese(0) peak with increasing sputtering time. Figure 4(a) and (b) shows results after 14 min sputtering, with the curve-fitted peak of Fig. 4(b) indicating the presence, after this sputtering time, of mainly manganese(II).

Figures 5 and 6 show that, after light sputtering (5 min) of pure $Fe_3O_4$ and $Mn_3O_4$ both the ratios of the concentrations of iron(II) to iron(III) and manganese(II) to manganese(III) are 1:2. These experiments strongly indicate that 5 min light sputtering is just sufficient to remove the surface contamination and not result in any oxide reduction,[7,30] this sputter time was used for all samples. The binding energy for $2p_{3/2}$ line of standard iron and manganese and

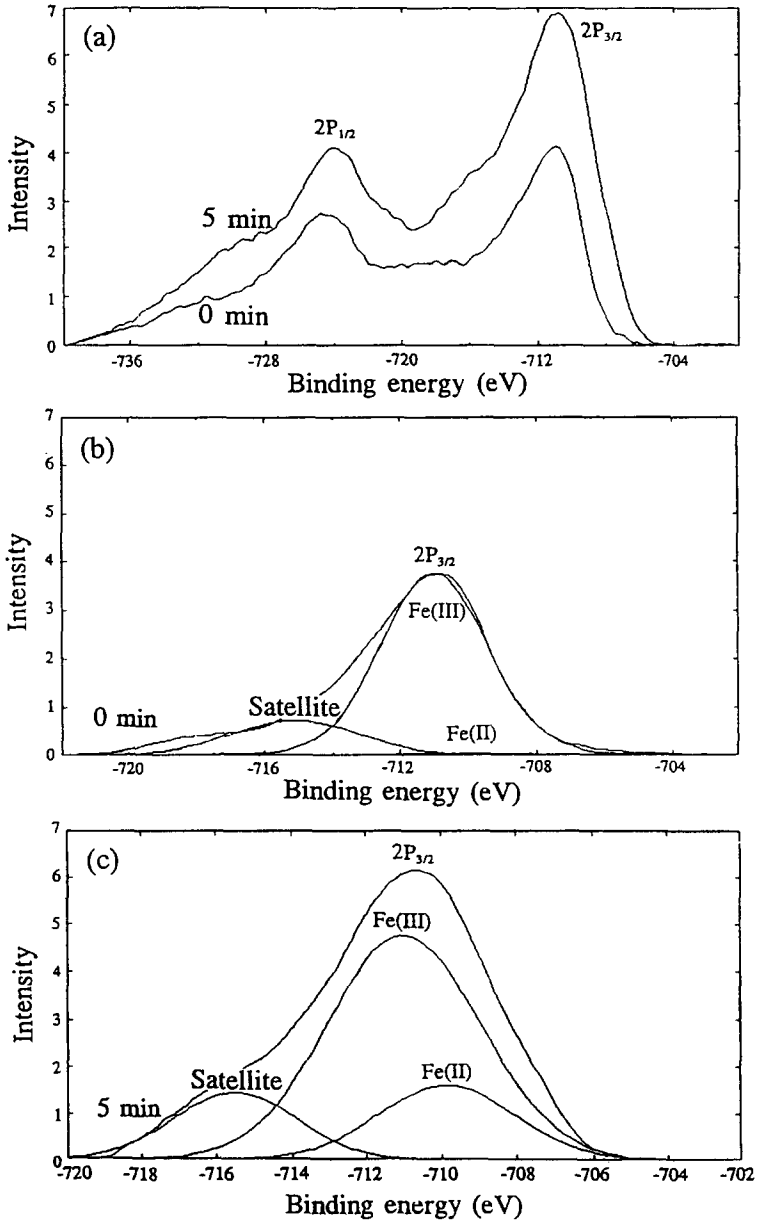

Fig. 7. ESCA high resolution iron 2p data from a North Pine Dam water particulate sample (0.45 $\mu$m membrane filtration) collected on 20/01/88 at a depth of 15 m. (a) Raw data before (0 min) and after etch (5 min); (b) curve fitted data—unetched surface and (c) curve fitted data—etched surface.

its compounds as determined by ESCA are shown in Table 3.

The reference and dam water particulate samples were exposed to the atmosphere when transferred from the vacuum storage desiccator to the ESCA analysis vacuum chamber, therefore, iron(II) compounds might have been oxidized to iron(III) on the outermost surface. However, after light ion beam etching ($\approx$1.25 nm) to remove the normal hydrocarbon surface contamination, any iron(III) surface oxidation layer would also be removed, exposing the true oxidation species present in the bulk. After 5 min of argon ion etching, approximately 1.25 nm (or 2–4 atomic layers) were removed and hydrocarbon, oxygen and other contaminants had been effectively stripped off; as expected the iron(II) concentration was slightly increased. Therefore, the results obtained after etching represent the actual oxidation states of iron and manganese species in the sample. Sullivan and Mills[7] have shown that heavy etching of the bulk iron(III) oxide surface with argon ions leads to a rapid reduction of iron(III) species to iron(II), and, on further reduction finally to iron(0); in heavy etching a large concentration of argon irons are produced with an equal concentration of electrons; these latter will reduce oxidized metal species. A similar situation applies to manganese oxides.[30] For this reason, in all these experiments only a light argon-ion etch was given to each sample surface to prevent

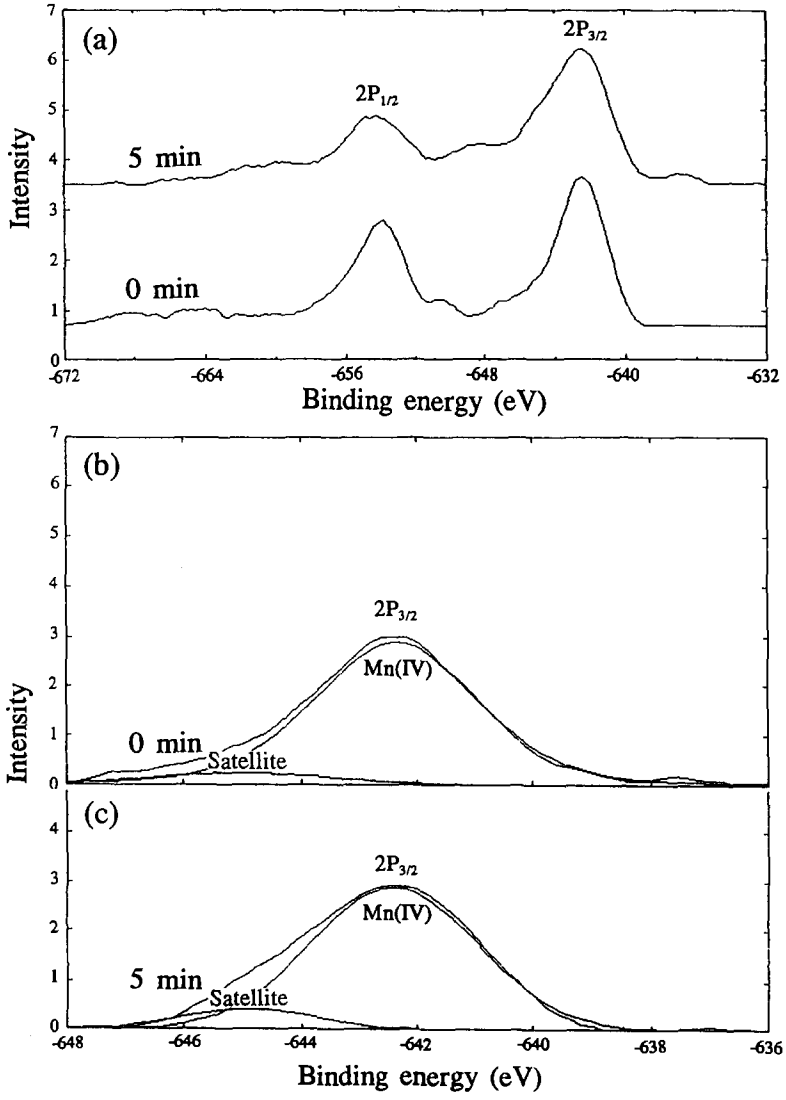

Fig. 8. ESCA high resolution manganese 2p data from a North Pine Dam water particulate sample (0.45 $\mu$m membrane filtration) collected on 13/04/88 at a depth of 21 m. reduction of iron(III) to iron(II) and manganese(IV) and manganese(III) to manganese(II) species.

*ESCA measurement of iron and manganese compounds in dam water particulate samples*

Figures 7 and 8 show the ESCA high resolution data for iron 2p and manganese 2p, obtained from particulate samples collected on 20/01/88 and 13/04/88, respectively. In each case: (a) represents the raw data for the whole 2p region before and after etching, (b) represents the curve fitted results for the $2p_{3/2}$ peak before etching, and (c) represents the curve fitted results for the $2p_{3/2}$ peak after etching. Iron(III) and manganese(IV) oxidation states are mainly predominant in the dam water particulate both before and after sputtering.

The binding energies, oxidation state assignment, and per cent atomic concentration for iron and manganese compounds in particulates of some 16 dam water samples collected at various depths and dates are shown in Table 4. The ratios of atomic concentrations of iron to manganese as determined by AAS and ESCA are also presented in Table 4.

For the purposes of this work, it was anticipated that the species of iron and manganese found in the dam might be dependent upon the region from which the sample was taken. Discussion of results is, therefore, given in terms of speciation in the epilimnion, the metalimnion, the hypolimnion and the sediment.

*Iron and manganese in the epilimnion*

ESCA results (Table 4) show that iron(III) compounds are found to predominate during the year throughout the water column, however, in the epilimnion the ratio between iron(II) and (III) can vary between an insignificant amount of iron(II) (surface sample on 20/01/88) and an approximately 1:3 ratio for iron(II):(III) (3 m on 13/04/88). This indicates that in April, the iron(II) component is far more significant due to the heavy rain effect and the whole water column mixing together. Under these conditions the concentrations of iron are very similar throughout the water column. After one week of heavy rain (662 mm rainfall in first week of April, 1988) the influx of water and associated debris has altered the nature of the dam water significantly (see Table 4; results from 3 to 32 m bottom sediment) and this can be seen clearly from SEM photomicrograph reported elsewhere.[32] The whole water column including bottom sediment contained nearly equal distributions of clay materials, inorganic and organic mineral compounds and algae debris. Further evidence was given from the temperature, dissolved oxygen, pH, iron and manganese depth profiles which were nearly constant values along the water column.[32]

Table 4 shows that manganese(II), manganese(III) and manganese(IV) compounds occur throughout the whole water column, but that manganese(IV) compounds are predominant in the epilimnion. It is clear that the iron(III) and manganese(IV) compounds are predominant in the epilimnion because of the high dissolved oxygen concentrations (7.4–8.0 mg/l.).[32]

ESCA results (Table 4) show that the ratio of iron to manganese is 1.7 (surface sample on 20/01/88), compared to the results from AAS (1.4). All these results indicate that the concentration of iron is at least as great or greater than manganese in the sample.

*Iron and manganese in the metalimnion*

An ESCA study of the iron compounds (Table 4) in the metalimnion (10 to 12 m on 17/02/88 and 12 m on 13/04/88) shows that the iron in the particulate material is composed mostly of iron(III), with the ratio of iron(III):(II) being approximately 2:1. The exception to this is the 11 m sample collected on the 17/02/88 in which the iron(III):(II) ratio is approximately 1:1 with the iron(II) species being slightly in excess.

For manganese collected at the metalimnion on the 17/02/88, the predominant species are the manganese(II) and manganese(IV) moieties, where these two species are almost at the same concentrations. However, for the 12 m sample collected on the 13/04/88 the situation is quite different, with the manganese(IV) species being the only significant species. This collection followed a long period of very heavy rainfall which may account for the observed difference. This indicates that the rain tends to bring oxidized manganese into the dam. The depth profiles of iron and manganese before and after heavy rain, also supported the notion that the heavy rain brought significant amounts of insoluble iron and manganese into the dam.[32] This is further supported by the high levels of particulate manganese(IV) in all levels of the dam after heavy rain (see Table 4; results of 13/04/88 from 3 to 32 m bottom sediment).

In the metalimnion, the ratio of iron to manganese (see Table 4; results from 17/02/88

B, indicates top layer (1 to 3 cm depth) of the bottom sediment sample.

for 10–12 m) increases for all methods of its measurement (AAS and ESCA). ESCA results are different from those of AAS, undoubtedly due to the fact that AAS analyses the total elements in the bulk of the sample, but ESCA gives only the surface concentration.

*Iron and manganese in the hypolimnion*

ESCA results show that the ratio of iron(III) to iron(II) for the 12 and 15 m depths (collected on 17/02/88 and 20/01/88) varies between 2:1 and 3:1. The samples collected from the bottom sediment (27 m, collected on 11/11/87) and 21 m

on 13/04/88 showed a greater variability than this with iron(III) being the only significant species on occasion.

For manganese in the hypolimnic region the predominance of manganese(IV) increases at the expense of manganese(II) compounds (15 m on 20/01/88, 12 m on 17/02/88). This may be due to the adsorbed manganese(II) on the surface of manganese(IV), iron and other particles.[32,33] An anomaly to this trend is found in the 27 m bottom sediment sample collected on 11/11/87 where an unusually large proportion of manganese is present as manganese(III). In previous work,[34] a release of manganese from the sediment has been shown to occur during the spring months, this result may in fact be attributable to this phenomenon.

ESCA results (Table 4) show that the concentrations of iron(III) are slightly greater than iron(II), while for manganese, manganese(IV) compounds predominate in this region, although some manganese(II) compounds are found in the hypolimnion and bottom sediment. The ratios of total iron to total manganese in the hypolimnion (*i.e.* 15 m on 20/01/88; 12 m on 17/02/88) is generally greater than in the epilimnion, due to the significantly increased concentrations of insoluble iron in the hypolimnion.

*Iron and manganese in the sediment*

From the SEM photomicrographs, generally a bottom sediment sample appears to consist of a mixture of algal debris, bacteria, clay materials and inorganic and organic mineral compounds. Concentrations of insoluble iron and manganese are very high, and an ESCA survey gives a strong signal for both iron and manganese.

Table 4 shows that, in general, the bottom sediment samples contain manganese as manganese(IV) (>78%) in winter time (on 09/08/88 and 06/09/88) and after heavy rainfall (on 13/04/88). However various ratios of manganese(II), manganese(III) and manganese(IV) compounds occur in summer time (on 11/11/87). In the case of iron, the majority of material is present as iron(III) (>72%) in the sediment in any season of the year. The ratios of total iron to total manganese in the bottom sediment (Table 4) is significantly greater than in the water column, due to the increased concentrations of insoluble iron compared with insoluble manganese.

*Iron and manganese in winter season*

During the winter destratification, the speciation of iron and manganese takes on a different pattern in the dam. SEM photomicrographs were acquired for samples collected on 0.45 $\mu$m membranes for 09/08/88 and 06/09/88; the general feature of the winter months is the fact that different types of algae bloom down the whole water column depths. There appear to be no colloidal particles.[32]

During this season (Table 4; 09/08/88 and 06/09/88), insoluble manganese(IV) compounds are the predominant form of manganese right down the whole water column. Light sputtering of the ESCA sample to remove surface contamination may be expected to lead to an increase in manganese(II), however, during the destratificated period only manganese(IV) species are observed presumably due to the availability of dissolved oxygen.[32,35] A majority of insoluble iron(III) rather than iron(II) compounds is present consistently over the whole water column. The ratios of iron to manganese (on 09/08/88 and 06/09/88) were very similar over the whole water column (ESCA and AAS values as shown in Table 4). Destratification during this season results in the whole water column becoming homogeneous with respect to temperature, pH and high dissolved oxygen concentrations (3.6–8.2 mg/l.).[32]

## CONCLUSIONS

Surface analysis has been little used for the speciation of particles in natural waters. This may be due to the techniques being labor intense and expensive in both capital outlay and maintenance of equipment. However, these submicron particles play an important role in natural waters and water quality engineering. Physical and chemical sorption processes result in significant amounts of trace elements (including heavy metals) being associated with these particles in aquatic systems. The physical and chemical behaviour of these metals in the environment and their bioavailability differ from those of the corresponding dissolved species. There is no doubt that surface analysis can provide insights into the characteristics of these particles and the information may be applied for water quality improvement and pollution control applications. Our work here has established that ESCA can be used to speciate the oxidation states of solid iron and manganese particles

in dam water and to further understand their behaviour in the dam profiles at different times of the year. Experimental results clearly indicated that during any annual season, iron(III) compounds predominated down the whole water column, however, the significance of the iron(II) species varied in the hypolimnion in summer season. Like iron(III), manganese(IV) compounds also predominated in the whole water column, however manganese(II) species increased in the metalimnion and the hypolimnion in summer time.

# SPECTROPHOTOMETRIC DETERMINATION OF ZIRAM (DITHIOCARBAMATE FUNGICIDE) BY THIOCYANATE AND RHODAMINE 6G METHOD

LATA MATHEW, T. PRASADA RAO,* C. S. P. IYER and A. D. DAMODARAN
Regional Research Laboratory (CSIR), Trivandrum 695 019, India

(*Received* 4 *March* 1994. *Revised* 8 *July* 1994. *Accepted* 20 *July* 1994)

**Summary**—A sensitive spectrophotometric method has been developed for the determination of ziram in water, vegetables and grains. The method is based on the dissociation of dithiocarbamate complex of zinc with thiocyanate and rhodamine 6G at pH 4 to form a pink coloured complex that is stabilized by gelatin. The method is simple and Beer's law is obeyed over the concentration range of 0.05–1 ppm of ziram. The method is free from interference of similar dithiocarbamate fungicides containing $Mn^{2+}$ and $Fe^{3+}$ ions.

Ziram or cuman L is the common name for zinc dimethyldithiocarbamate which is used as an agricultural fungicide because of its low phytotoxicity and is applied in the rubber industry as a vulcanization accelerator and antioxidant.[1] Ziram is relatively nontoxic to plants and is particularly useful in controlling diseases of vegetable crops, such as anthracnose of tomatoes and cucurbits and early blight of tomatoes and potatoes. The compound can cause irritation to the mucous membranes in dust or powder form.[1]

The Clarke method[2] is widely used for the determination of ziram. The method is based on the destruction of dithiocarbamate in acidic medium to liberate carbon disulphide which is absorbed in methanolic KOH solution to give potassium methylxanthate which is titrated iodometrically. Petrascu[3] modified the method of Clarke *et al.*[2] and Rosenthal *et al.*[4] which requires the removal of hydrogen sulphide and liberation of carbondisulphide at a particular temperature. Verma *et al.*[5] reported a method based on the measurement of liberated $CS_2$ using benzylmercaptan. The method is less sensitive (14–150 ppm) and uses toxic mercaptan for the determination of dithiocarbamates. Other methods reported are based on the replacement of zinc with toxic metallic compounds.[6,7] Malik and Rao reported a spectrophotometric procedure for the determination of ziram using diphenylcarbazone. The method not only involves extraction, but also is less sensitive.

In the present communication, a new method is described for the estimation of ziram based on the determination of zinc by formation of a ternary complex with potassium thiocyanate and rhodamine 6G at pH 4. The method is free from interference from $Cu^{2+}$, $Hg^{2+}$, $Fe^{3+}$, $Mn^{2+}$ and $Pb^{2+}$ and does not require the removal of $H_2S$. Beer's law is obeyed from 0.05 to 1.0 ppm of ziram solution. The method has been successfully applied to the determination of ziram in water, vegetables and grain samples.

## EXPERIMENTAL

### *Apparatus*

A Hitachi Model 220 microprocessor controlled double beam spectrophotometer with 1.0 cm quartz cells was used for all spectral measurements. An ELICO Model LI-120 digital pH meter was used for all pH measurements.

### *Reagents*

Ziram solution (Hindustan Ciba-Geigy Ltd). A solution of 1 mg/ml was prepared in hot 25% (v/v) hydrochloric acid.

Rhodamine 6G solution, 0.005%. The reagent (0.05 g) was dissolved (BDH, U.K.) in water and diluted to 1 l.

Potassium thiocyanate solution, 5%. AR grade potassium thiocyanate (5 g) was dissolved in water and diluted to 100 ml with water.

*Author to whom correspondence should be addressed.

Gelatin solution, 1%. Gelatin (1 g) was dissolved in hot water, cooled and diluted to 100 ml with water.

Acetate buffer, pH 4.0. Equal volumes of 2*M* solutions of sodium acetate and acetic acid were mixed and the pH adjusted to 4.0 using a pH meter.

*Procedure*

Suitable aliquots (up to 10 ml) of the sample solution containing not more than 25 $\mu$g of ziram were transferred to a 25 ml volumetric flask, 1 ml of buffer, 2.5 ml of potassium thiocyanate, 5 ml of rhodamine 6G and 1 ml of gelatin were added with mixing and made up to the mark. The absorbance of the solution was measured at 570 nm against a reagent blank. A calibration graph using similar procedure was prepared with a solution containing 2.5–25 $\mu$g of ziram.

## RESULTS AND DISCUSSION

*Effect of pH*

It was found that the ternary complex was fully formed when the solutions were buffered in the pH range 1–5. At higher pH the absorbance of the colour system decreased. Hence, all the subsequent studies were carried out at pH 4.

*Effect of reagent concentrations*

It was found that at least 2 ml of 5% potassium thiocyanate and 4 ml of 0.005% rhodamine 6G solutions were required for constant and maximum absorbance. One millilitre of 1% gelatin was sufficient to prevent the precipitation of ternary complex. The order of addition of the reagents were not found to be critical provided that the gelatin solution was added after the addition of other reagents. The absorbance of the coloured complex was found to be stable for ~2 hr.

*Calibration graph and precision*

The colour system showed linear absorbance in the range of 0–25 $\mu$g of ziram present in 25 ml and passed through the origin. The molar absorptivity was found to be $9.71 \times 10^4$ l. mol$^{-1}$. cm$^{-1}$ and Sandell's sensitivity was calculated to be 0.004 $\mu$g/cm$^2$. The relative standard deviation was found to be $\pm 2.19\%$ in the determination of 10 $\mu$g of ziram solution in 25 ml for repetitive analysis carried out over 7 days.

Table 1. Effect of foreign species (concentration of ziram = 10 $\mu$g/25 ml)

| Foreign species | Tolerance limit* ($\mu$g) |
|---|---|
| $F^-$, $Cl^-$, $SO_4^{2-}$, $PO_4^{3-}$, tartrate | 10,000 |
| $Bi^{3+}$ | 5000 |
| $Mn^{2+}$, $Ni^{2+}$, $Cd^{2+}$† | 2000 |
| $VO^{2+}$, $As^{3+}$, $MoO_4^{2-}$, $Pb^{2+}$,† $Hg^{2+}$,† $Fe^{3+}$‡ | 1000 |
| Thiram, dibam | 1000 |
| $Cu^{2+}$† | 100 |

*Amount of foreign species that caused $< \pm 2\%$ error.
†In the presence of 1 ml of 5% thiourea.
‡In the presence of 1 ml of 5% NaF.

*Effect of foreign species*

The effect of foreign species which are known to coexist with ziram were studied and the results obtained are shown in Table 1. The method is free from interference due to other dithiocarbamate fungicides like thiram and dibam. Equal amounts of $Cu^{2+}$, $Cd^{2+}$, $Pb^{2+}$, $Hg^{2+}$ and $Fe^{3+}$ interfered in the determination of ziram. However, the interference due to these species could be masked with thiourea and sodium fluoride and the tolerance limits are given in Table 1. Hence, the developed method may find application in real samples containing the above species.

*Comparison with other methods*

The developed method has been compared with other reported methods (Table 2). The benzyl mercaptan method[5] makes use of toxic mercaptan and the Methylene Blue method[9] is cumbersome as it requires generation of hydrogen sulphide. The diphenyl carbazone method[8] is less sensitive and requires an additional extraction step. The present method is simple (as it does not require the generation of

Table 2. Comparison with other spectrophotometric methods

| S. No. | Method/ reagent | Max (*nm*) | Beer's law range | Sensitivity ($l.mol^{-1} \cdot cm^{-1}$) | Reference |

*Mean of three replicate analyses.
†Amount of sample = 500 ml.
‡Amount of samples = 200 g.

hydrogen sulphide), highly sensitive and can be applied to real samples in the presence of ferbam and maneb.

*Application of the method*

*Determination of ziram in polluted water.* To check the applicability of the method, the determination of ziram in water from agricultural fields was carried out. These samples were found to be free from ziram. Therefore, known amounts of ziram were added to water samples. Aliquots of spiked water samples were taken in a 25 ml beaker and 2 ml of conc HCl was added followed by 1 ml of buffer and the pH adjusted to 4. These samples were analysed by the recommended procedure. The results are shown in Table 3.

*Determination of ziram in vegetables and grains.* About 200 g of potato, cabbage and wheat grains were taken and blended in a mixer. Known amounts of ziram were added and kept for some time. The blended sample was then digested with 100 ml of 1:1 HCl. The mixture was filtered and aliquots were taken for analysis by the recommended procedure and by standard AAS. The recoveries (Table 3) obtained with the proposed method are comparable with the standard AAS procedure.

*Acknowledgement*—One of the authors (LM) is grateful to CSIR (New Delhi) for the award of a Research Associateship.

(*Received* 4 *March* 1994. *Revised* 11 *July* 1994. *Accepted* 22 *July* 1994)

**Summary**—Gallium chloride is easily extracted from 6*M* HCl by comminuted polyether-type polyurethane foam. After the extraction step, the gallium absorbed by the PU foam can be quantitatively determined by X-ray fluorescence. A procedure for the direct determination of gallium absorbed by PU foam by XRFS is thus described. Gallium is determined at levels as low as 60 ng/ml ($C_L$), with a calibration sensitivity of 424 cps·ml/$\mu$g, within a linear range 0.1–2.30 $\mu$g/ml. The procedure investigated was successfully applied to determination of gallium in aluminum alloys, bauxite and industrial residue samples.

The determination of gallium is not an easy task as several elements which are usually associated with it interfere considerably in the analysis. Thus, gallium is commonly determined after its separation from such elements.[1] The use of polyurethane (PU) foams in the extraction, recovery and preconcentration of various inorganic and organic species in aqueous and non-aqueous media has attracted much attention since Bowen's work on this subject.[2] Many authors have used PU foams to preconcentrate, separate and recover metals to be determined by atomic absorption spectrometry or radiochemical analysis.[3–5] Several authors studied physicochemical parameters related to the sorption mechanisms of metals on the foams.[5–9]

The extraction of gallium from hydrochloric acid solution using polyether-type polyurethane foams has been reported.[10,11] Carvalho[12] studying the same system observed a very high distribution coefficient for gallium ($D \geqslant 10^4$, 6–9*M* HCl), and demonstrated that Al, In, Zn, Ni, and Ti(IV) are not extracted ($D \leqslant 4.5$); Fe(II) and Cu ($D \leqslant 30$) are only slightly extracted from the same medium.

The analytical determination of extracted species when still absorbed in the PU foam has seldom been reported. Radioiodine has been extracted from aqueous solutions[13] and from milk[14] using PU foams, the iodine-131 being determined directly by gamma spectrometry. Open-cell PU foams, loaded with various organic reagents, have been used to detect metal ions directly by comparing the color of the samples thus obtained with standards.[15]

Cobalt has been extracted from 3*M* $NH_4Cl$–1*M* $NH_4SCN$ solution by PU foam discs, and determined by X-ray fluorescence spectrometry (XRFS).[16] The XRFS was employed to determine directly metal thiocyanate complexes of iron, cobalt, zinc, platinum and palladium, extracted on polyether-type PU foam discs.[17] Arsenic[18] and phosphate[19] as arsenomolybdate and molybdoantimonylphosphate, respectively, were also extracted on PU foam and determined directly by XRFS.

This paper describes the direct determination of gallium on open-cell polyether-type polyurethane foam by XRFS, after the extraction of the metal from 6*M* hydrochloric acid solution was performed. This method has been employed to determine gallium in bauxite, alumina, aluminum alloy and residues from the aluminum industry.

## EXPERIMENTAL

### *Apparatus*

A Rigaku-B3 wavelength dispersive X-ray fluorescence spectrometer, with a rhodium tube operated at 40 kV and 30 mA, a LiF crystal, and a scintillation counter was used. Such system is equipped with an automatic unit which drives

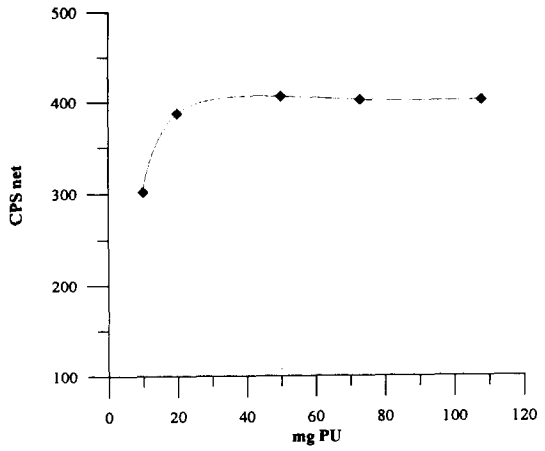

Fig. 1. XRF intensity measured against mass of PU.

the goniometer, sets the discrimination, and acquires the data.

*Reagents*

A gallium stock solution was prepared from its oxide (Johnson Matthey, 99, 99% pure), made 6*M* in hydrochloric acid (Merck, PA), and subsequently standardized with EDTA.[20] Dilute solutions were prepared by appropriated dilution of aliquots from the stock solution with 6*M* hydrochloric acid.

Commercial, open-cell, polyether-type polyurethane foams (Vulcan of Brazil-VCON 202, 42% resilience and 10–12 cells/linear cm) were comminuted in a blender with a large quantity of distilled water. The PU foam was filtered in a vacuum system, squeezed between clean sheets of paper towels and stored in a desiccator.

*General procedures*

A convenient aliquot of the stock solution containing gallium was transferred to stoppered polypropylene flasks. A known amount of comminuted PU foam (previously treated with 6*M* HCl solution for 30 min) was added, and the volume made up to 10.0 ml with 6*M* HCl solution. The system was then shaken mechanically (VKS-100 Mechanical Shaker, 100 cpm) for 1 hr. The PU foam was collected by vacuum filtration (filter paper $\emptyset = 2.0$ cm), covered with a Mylar® film and taken to the XRF spectrometer. The determination of gallium was then made by measuring the gallium $K_\alpha$ line for 40 sec and taking the average of five measurements, after subtracting from each value the measurement corresponding to the blank (CPS net). All experiments were made at $25 \pm 2$°C.

## RESULTS AND DISCUSSION

*Characteristics of the* Ga–*PU*–HCl *system*

As already pointed out,[10–12] gallium can be quantitatively extracted from hydrochloric acid solution by polyether-type polyurethane foams. The efficiency of extraction was found to increase with the hydrochloric acid concentration, reaching a maximum value between 6 and 9*M* HCl, where the system exhibits the highest distribution coefficient ($D \geqslant 10^4$). The extraction is effective after shaking the system for 30 min. In this work the extraction time was always 60 min.

*Effect of the mass of PU on the extraction of gallium from* 6M HCl *media*

The adequate amount of PU foam to be used in the extraction of gallium was found by treating 10.0 ml of 6*M* hydrochloric acid, containing 11.5 $\mu$g of gallium, with masses of comminuted PU foam from 10 to 120 mg. The extraction time was 60 min. A maximal and constant XRF intensity was observed to correspond to masses of PU foam higher than 30 mg (Fig. 1). In this work, $55 \pm 5$ mg of PU foam was selected as optimal mass for the general procedure.

*Analytical characteristics of the method*

For the Ga–PU–6*M* HCl system a linear relationship was found between the gallium concentration and the XRF signal up to 2.3 $\mu$g/ml Ga. The calibration curve was constructed as described under General Procedures. The analytical sensitivity,[21,22] the calibration sensitivity, the limit of detection ($C_L$) and of quantification ($C_Q$),[23] as well as other analytical characteristics of the procedure here described are summarized in Table 1. These analytical characteristics compare favorably with those found on determining gallium by atomic absorption spectrometry, polarography and visual spectrophotometry.[12]

Table 1. Direct determination of gallium by PU–XRFS, analytical characteristics

| Characteristics | Data |
|---|---|
| Calibration sensitivity (*cps ml/μg*) | 424 |

†NIST Certified Values.
‡Fluorimetry.

*Applications*

The procedure investigated was applied for the determination of gallium in aluminum base alloy standards, a bauxite sample and residues from aluminum production plants. The results are compared with the classical fluorimetric method[1] and are presented in Table 2.

The samples were prepared using a mixture of hydrofluoric acid and hydrochloric acid (3:1). For the bauxite sample, sulfuric acid and some drops of hydrogen peroxide was also used. In all cases, the samples were evaporated to dryness or to $SO_3$ fumes, solubilized in $6M$ hydrochloric acid, treated with a small excess of $0.5M$ titanous chloride solution to reduce Fe(III) and the volume adjusted as desired with $6M$ hydrochloric acid.

The paired $t$-test[23] and least-square analysis[21] were used to compare the two methods, the classical fluorimetric method and the procedure proposed in this work. It was found that the calculated slope (1.001) and the intercept (0.09) do not differ significantly from the ideal values of 1 and 0, respectively. Thus, there is no significant difference between the two methods, at the confidence limit of 95% (Table 2).

# PRECISE COULOMETRIC TITRATION OF PRECIOUS METALS—II. DETERMINATION OF PLATINUM(IV) WITH ELECTROGENERATED CHLOROCUPROUS ION IN KCl–Cu–EDTA BUFFER MEDIUM

DONG SHOUAN
Institute of Precious Metals, Kunming 650221, China

(*Received* 20 *June* 1994. *Accepted* 25 *July* 1994)

**Summary**—A method for the precise coulometric titration of platinum(IV) with electrogenerated chlorocuprous ion in KCl–Cu–EDTA buffer medium is described. From 2.7 to 18.7 mg of platinum in pure platinum and platinum alloy are determined with standard deviations of less than or equal to 0.034% using potentiometric end point detection. The method has good accuracy and precision, selectivity and rapidity.

Until now, a direct method for the precise determination of platinum purity, its compounds and alloys has not been reported. For the analysis of platinum with 98–99.9% purity, the spectrographic method applicable to the determination of the total impurity content in pure metal is not usable because of the higher impurity concentration and difficult preparation of the standard sample. For the determination of platinum in compounds such as $H_2PtCl_6$ and $PtCl_4$, the gravimetric method based on the precipitation of platinum as ammonium hexachloroplatinate also have insufficient precision and accuracy. The establishment of a coulometric titration method for platinum provides a good approach to precisely and accurately determining large amounts of platinum in platinum materials.[1] However, methods for the coulometric titration of platinum(IV) with electrogenerated tin(II) were not suited to precise analysis owing to the difficulty of obtaining 100% current efficiency of tin(II) electrogeneration.[2–4]. This author[5] has studied coulometric titration of high amounts of platinum with electrogenerated copper(I) in dilute hydrochloric acid medium and obtained good results. However the hydrochloric acid system, the end point potential break in the titration curve is not very pronounced, so it is difficult to improve precision. For this reason, the titration of platinum, in NaOAc–HOAc buffer medium (pH 4), with electrogenerated copper(I) using a EDTA–Cu(II) complex system was studied. The results demonstrate that the system not only decreases the reduction potential of the Cu(II)/Cu(I) couple, but also improves the reaction of Pt(IV) with Cu(I), increases the end point potential break and enhances the selectivity owing to EDTA complexing with impurity. The proposed method is suitable for precise determination of platinum in pure platinum, some platinum alloys and platinum compounds. The method has a high selectivity.

## EXPERIMENTAL

### *Apparatus*

A Gui-III type precision coulometric analyser was used with constant current output of 1, 10 and 100 mA, the current stability and precision for each grade was $5 \times 10^{-6}$. The timer was a six digit display with a precision of 0.002%. The titration assembler was a new type hermetically sealed electrolytic cell system.[6] An XWT-164 desk autobalance recorder (Shanghai, China) was used.

### *Reagents*

Cupric sulfate, hydrochloric acid and nitric acid were of pure grade. Potassium chloride, sodium acetate and disodium EDTA were of analytical-reagent grade. The anolyte was 0.5*M* cadmium chloride in 0.5*M* potassium chloride. The supporting electrolyte was 0.5*M* KCl–0.02*M* EDTA–0.04*M* Cu in 0.2*M* (HOAc–NaOAc) buffer medium (pH 4). A

standard platinum solution was prepared by dissolving pure platinum in aqua regia and evaporating several times with hydrochloric acid to remove oxides of nitrogen. All distilled water used was secondary distilled water (distilled with quartz distillator).

*Titration procedure*

On adding the test solution to the titration cell and the supporting electrolyte in the pre-titration cell, air was removed from both the test solution (including anolyte) and the supporting electrolyte with pure nitrogen. The supporting electrolyte was pre-titrated to the pre-established endpoint potential, then the supporting electrolyte was placed in the titration cell in which has been added the test solution. Finally, the potentiometric endpoint detection, the coulometric titration was run in the usual manner. The results were displayed and printed by the coulometric analyser.

## RESULTS AND DISCUSSION

*Choice of supporting electrolyte and current efficiency for* Cu(I) *generation*

In the HOAc–NaOAc buffer medium (pH 4), Cu(II) complexed with EDTA and formed a stable complex compound, this is shown when the solution becomes deep blue as EDTA is added. When this solution is electrolysed with a platinum cathode, the complex compound $Cu(II)Y_2$ (Y, EDTA) accepts an electron and produces a cuprous ion. It is well known that fresh cuprous ion is a very strong reductant and will rapidly react with oxidizing substances in solution, because the bare cuprous ion is thermodynamically unstable. The following disproportionation reaction occurs: $2Cu(I) \rightarrow Cu + Cu(II)$, so the platinum cathode will be plated with copper metal. Obviously, it is difficult to obtain 100% current efficiency if this electrolyte system is applied.

In order to obtain 100% current efficiency of Cu(I) electrogeneration, the hydrochloric acid medium has always been applied. It is evident that $Cl^-$ is necessary to obtain stable cuprous ion. However, the buffer system will be destroyed if hydrochloric acid is added to above mentioned $Cu(II)Y^{2-}$ solution in HOAc–NaOAc buffer medium, and the Cu(II) complexes of EDTA will also disintegrate. To establish an optimal condition in which not only the $Cu(II)Y^{2-}$ complex system is maintained but also the cuprous ion electrogeneration was stable, KCl–EDTA–Cu(II) in pH 4 NaOAc–HOAc buffer medium was used as supporting electrolyte instead of dilute hydrochloric acid solution used previously and the titration characteristics of platinum studied. Figure 1 shows voltammetric curves of various media in the presence and absence of EDTA or $Cu^{2+}$. It is observed that, when the current density is a certain value (in the presence of EDTA, $I \leqslant 4$ mA/cm$^2$; no EDTA, $I \leqslant 5$ mA/cm$^2$), 100% current efficiency for Cu(I) generation can be ob-

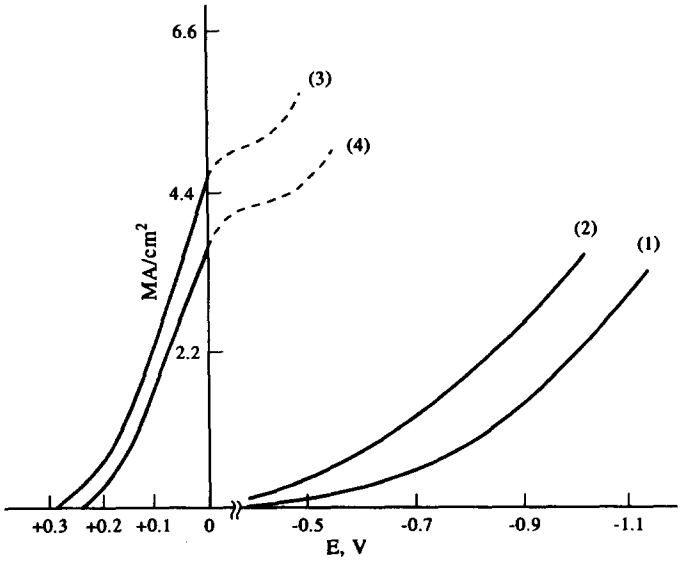

Fig. 1. Platinum cathode voltammetric curves of various media: (1) 0.25*M* KCl + 0.2*M* HOAc–NaOAc, (2) 0.25*M* KCl + 0.02*M* EDTA + 0.2*M* HOAc–NaOAc, (3) (1) + 0.04*M* $CuSO_4 . 5H_2O$, (4) (2) + 0.04*M* $CuSO_4 . 4H_2O$.

tained in either EDTA-containing medium or no EDTA medium. In the presence of EDTA, the density of current allowed became smaller than with no EDTA, and the potential range of curve 4 (electrolyte containing EDTA) in Fig. 1 is more negative than that of curve 3 (no EDTA in the electrolyte), this demonstrates that the reduction potential of the Cu(II)/Cu(I) couple becomes more negative when the electrolyte contains EDTA.

*Mechanism of cuprous chloride generation in the platinum cathode–electrolyte interface and the reaction in solution*

It is well known that the coulometric titrant results from electron transport of ions (or molecules) at the electrode–solution interface when electrolysing. Electron transport in complex systems differs from that in the simple solution, the former usually undergo some intermediate course. In the KCl–Cu(II)–EDTA buffer system, $Cl^-$ is necessary to obtain stable titrant, $CuCl^{2-}$, so it can be deduced that the mechanism of charge exchange in the platinum cathode–solution interface is based on reactions as follows:

$$CuY^{2-} \Rightarrow Cu^{2+} + Y^{4-} \quad (1)$$

$$Cu^{2+} + e \Rightarrow Cu^{+} \quad (2)$$

$$Cu^{+} + nCl^{-} \Rightarrow CuCl_n^{(n-1)-} \quad (3)$$

$$Y^{4-} + 2H^{+} \Rightarrow H_2Y^{2-}. \quad (4)$$

If the electrolyte has no $Cl^-$, above mentioned $Cu^+$ disproportionation reaction will occur instead of reaction (3).

When $CuCl_2$ is produced from the platinum cathode interface in solution, the reactions will occur as follows:

$$PtCl_6^{2-} + 2CuCl_2 \Rightarrow PtCl_4^{2+} + 2Cu^{2+} + 6Cl^{-} \quad (5)$$

$$Cu^{2+} + H_2Y^{2-} \Rightarrow CuY^{2-} + 2H^{+}. \quad (6)$$

It is obvious that coulometric titration of platinum(IV) is based on equation (5).

*Methods of end point detection*

In the above electrolyte solution, the biamperometric method for end point detection is useless with two polarized indicator electrode. However, the potentiometric method for end point detection can obtain good results.

*General potentiometric method* (i = 0). Using a platinum or plated-gold platinum electrode as an indicator electrode (*vs.* SCE), the reduction titration curves of Pt(IV) in various electrolytes were obtained as shown in Fig. 2.

It can be seen from Fig. 2 that the potential break of KCl–$Cu^{2+}$–HOAc–NaOAc system is larger than that of the HCl–$Cu^{2+}$ system. However, the potential break of the EDTA $Cu^{2+}$–KCl–HOAc–NaOAc system is the largest and the potential curve is the most symmetric. Obviously, the concentration of oxidizable Cu(II) decreased owing to formation of $CuY^{2-}$ complex in the electrolyte solution, so the electrode potential of Cu(II)/Cu(I) couple decreased also, and the electrogenerated Cu(I) increased in reducing ability making reaction (5) occur more readily. So the sensitivity and precision for end point detection is improved.

*Bipotentiometer method with two polarized platinum indicator electrodes* ($i \neq 0$). When a small constant current (8.5 $\mu$A) is applied to two identical platinum electrodes (area of either electrode immersed in the electrolyte solution is about 1 $cm^2$), a titration curve graph analogous to that obtained from the classical potentiometric method can be obtained, and the potential break is larger than that of general potentiometric method, so the end point detection is more sensitive. Unfortunately, using this method for end point detection always produced a system negative error, maybe related to reactions on the

indicator electrodes. For this reason, the general potentiometric method for end point detection was still used.

*Experiments for titration of standard platinum(IV) solution and effect of foreign ions*

In order to improve the precision of titration of platinum(IV) with electrogenerated chlorocuprous ions in the KCl–Cu(II)–EDTA buffer medium, the participation of error resulting from inherent inaccuracy of burette readings was minimized by sampling with a precisely (0.1 mg) weighed platinum(IV) test solution. The titration of platinum(IV) standard solution was carried out as mentioned above; the results are shown in Table 1.

Table 1 demonstrates that, for determination of platinum in the range of 2.7–18.7 mg, accurate and precise results can be obtained with the proposed method.

The effect of foreign ions is summarized in Table 2. Many base metals and considerably larger amounts of Fe(III) do not interfere owing to complex formation with EDTA, larger quantities of Ru(III), Ag(I) and Pd(II) do not interfere either. Ir(IV) and Ru(IV) produce a larger positive interference. Au(III) causes a serious positive interference owing to conjugated electrochemical reactions.[7] From the investigation for titration of standard platinum(IV) solution and effect of foreign ions, it is evident that the proposed method is applicable to the precise titration of platinum in platinum materials.

## ANALYTICAL APPLICATION

Platinum of some materials are determined using precise coulometric titration with electrogenerated chlorocuprous in the 0.25*M* KCl–0.2*M* EDTA–0.04*M* Cu(II)–0.2*M* (HOAc-NaOAc) medium. For metallic platinum of 98 to 99.9% purity and platinum alloys, the sample solution is prepared by dissolving these materials in aqua regia and evaporating several times with hydrochloric acid to remove oxides of nitrogen. Results are shown in Table 3. The results obtained for the titration of platinum samples indicated that the proposed method has good precision and convenience, and allows a precision titration of platinum in some materials. The method can be applied to routine assay for platinum compounds.

# REDOX REACTIONS OF HYDROGEN ADDUCTS OF THYMINE: COMPARISONS WITH THE REACTIONS OF HYDROXYL ADDUCTS

S. CHAKRABARTI,* P. C. MANDAL and S. N. BHATTACHARYYA

Nuclear Chemistry Division, Saha Institute of Nuclear Physics, 1/AF, Bidhannagar, Calcutta-700 064, India

(*Received* 29 *March* 1994. *Revised* 25 *July* 1994. *Accepted* 25 *July* 1994)

**Summary**—Hydrogen atoms form two kinds of adducts with thymine (oxidizing and reducing). Redox reactions of these two kinds, popularly known as 5-hydrogenated-6-thyminyl (reducing) and 6-hydrogenated-5-thyminyl (oxidizing), were investigated where ferric ions (oxidizing) and ferrous ions (reducing) were used as the corresponding redox partners. A steady-state gamma radiolytic system was chosen where hydroxyl radicals were scavenged using *t*-butyl alcohol in acidic (pH 1.8) solution. It is inferred that the redox potential of oxidizing hydrogenated thyminyl radicals lies between 0.77 and 1.4 V *vs.* NHE. The reducing hydrogenated thyminyl radical has a redox value less than 0.8 V because it efficiently undergoes electron transfer reaction with Fe(III). A probable range of redox values for hydroxyl adduct of thymine is included for comparison.

Radiolysis of thymine is important in the context of radiation damage of DNA.[1] The radical adducts of thymine as probed by pulse radiolytic study are well known.[2,3] The redox properties of radical adducts of thymine have application for a model study on radiosensitization phenomenon where electron affinity (organic compounds)[4] and redox potentials (metal compounds)[5] are important indices of the capability of the respective compounds using as radiosensitizer. The pulse radiolytic study of thymine has clearly established the dual nature (oxidative and reductive) of the hydroxyl and hydrogen adducts of thymine.[2] However, the electron adduct of thymine is converted only to 6-hydrogenated thymine adduct which is oxidizing in nature and this has been proven by ESR study.[6,7] The 5-hydrogen or hydroxyl adducts of thymine are reducing in nature,[2] yet, little work has been carried out to determine their range of redox potential values. Recently work by Steenken *et al.*[8] has shown that the redox potential of electron adduct of thymine, $T^-$, is of the order of $-1$ V *vs.* NHE. In the present investigation we indicate the redox potential range of hydrogen and hydroxyl adducts of thymine.

## EXPERIMENTAL

Thymine (Koch Light) was recrystallized three times from triply distilled water before use. Solutions were prepared in triply distilled water and the experiments were carried out at acidic pH(1.8) (adjusting by $H_2SO_4$). All the reagents used were of analytical reagent grade. Pure argon gas was used throughout the investigation.

### *γ-Irradiation*

The sample were irradiated in a $^{60}Co$ γ-source following purging with argon gas. The dose rate of the source (9 Gy/min) was determined in a Fricke Dosimeter taking $G(Fe^{3+}) = 15.5$.

### *Procedure*

Thymine solutions ($10^{-3}M$) containing either $5 \times 10^{-4}M$ Fe(III) alum or $10^{-4}M$ Fe(III) alum in the presence of $0.4M$ *t*-butyl alcohol in acidic pH were irradiated at different doses. The formation of Fe(II) was followed spectrophotometrically by its complexation with *o*-phenanthroline and measuring the absorption at 510 nm. The formation of Fe(III) was followed in a spectrophotometer by measuring the absorption at 305 nm. In addition to these, some experiments with dihydrothymine(DHT)($10^{-3}M$) containing $5 \times 10^{-4}M$ Fe(III) alum were

carried out, where formation of Fe(II) was followed spectrophotometrically as above. Blank experiments containing only Fe(II) alum and 0.4$M$ $t$-butyl alcohol were done and the formation of Fe(III) was similarly followed spectrophotometrically at 305 nm.

## RESULTS AND DISCUSSION

### *Reactions of 6-hydrogenated 5-yl thymine*

Figure 1 shows the formation of $Fe^{3+}$ in the presence and in the absence of thymine ($10^{-3}M$) following irradiation of solutions containing $10^{-4}M$ ferrous sulphate and 0.4$M$ $t$-butyl alcohol in an argon saturated condition. It may be noted that the formation of Fe(III) significantly increases with dose and then reaches a plateau in both cases. The yield of the corresponding formation of Fe(III) was calculated from the yield dose plot which shows that $G(Fe^{3+})$ in the absence of thymine is much larger than that in the presence of thymine. The $G(Fe^{3+}) = 6.0$, in the absence of thymine, indicates that the $t$-butyl alcohol radical formed also oxidizes quantitatively ferrous ion and thus the yield of Fe(III) (calculated from the initial slope) becomes the sum of the total yield of OH and H radicals at the experimental pH, *i.e.* $G_{OH} + G_H = 2.7 + 3.6 = 6.3$; which is close to our observed value of 6.0. The corresponding reactions are as follows:

$$R_3COH + H/OH \rightarrow R_2(CH_2)COH + H_2/H_2O$$

(R = $CH_3$ and $R_3COH$ = $t$-butyl alcohol)

$$R_2(CH_2)COH + Fe^{2+} \rightarrow R_2(CH_2)COH^- + Fe^{3+}.$$

But when thymine is present at a concentration of $10^{-3}M$ then because of the higher values of rate constants of thymine with H atom, most of the H will react with thymine forming TH radical ($k_{T+H} = 5.7 \times 10^8 M^{-1}$ sec$^{-1}$).[9] It has been well established that 59.5% of the H atom add to the position 6 of the thymine ring, hence the yield of C(6)-TH should be 2.14.[10] Hence, the initial yield of $G(Fe^{3+})$ in the presence of thymine should be 2.14 + 2.7 = 4.84. In fact, the experimentally observed value of $G(Fe^{3+})$ as obtained from the initial slope was 4.8. It should be pointed out that 37% of $G_H$ is converted to the reducing thymine adduct which will certainly reduce the accumulated Fe(III) formed in the radiolytic system. This is actually corroborated by the results shown in Fig. 1.

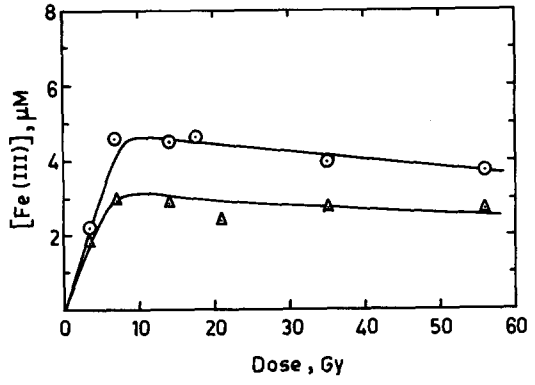

Fig. 1. Formation of Fe(III) at different absorbed doses when radiolysis was carried out with $10^{-4}M$ Fe(II) alum and 0.4$M$ $t$-butanol in presence (△) and absence (○) of thymine ($10^{-3}M$) under argon saturation at pH 1.8.

It is clear from the above that the 6-hydrogenated-5-thyminyl adduct oxidizes ferrous ions. Hence, its redox potential is more positive than the redox potential of the $Fe^{2+}/Fe^{3+}$ couple, *i.e.* 0.77 V *vs.* NHE. However, in our earlier studies we have shown that this oxidizing adduct cannot oxidize $Ni^{2+}$, which has a redox potential value of 1.4 V (for the couple Ni(II)/Ni(III)).[11-13] Hence, the redox potential of C(6)-TH$^{\cdot}$/C(6)-TH$^-$ should lie between these two values, *i.e.* 0.77–1.4 V.

### *Reactions of 5-hydrogenated-6-thyminyl adduct*

In order to follow the reactions of reducing radicals two kinds of experiments were carried out: (i) thymine was radiolysed in the presence of $Fe^{3+}$ and the formation of $Fe^{2+}$ was measured spectrophotometrically at 510 nm by its complexation with $o$-phenanthroline. The yield of $Fe^{2+}$ formation during the radiolysis of thymine in the presence of $Fe^{3+}$ and $t$-butyl alcohol is shown in Table 1. Under the experimental conditions, the concentrations used are such that all the H atoms react with thymine(T) forming TH adduct. It has been reported earlier[10] that only 37% of these TH radicals are reducing and hence the expected yield of $Fe^{2+}$ should be equivalent to the reducing radical yield, *i.e.* 37% of 3.6 = 1.3. This value is very close to the experimental value, 1.4 (Table 1). This experiment clearly indicates that C(5)-TH radical quantitatively reduces $Fe^{3+}$.

$$C(5)\text{-}TH^{\cdot} + Fe^{3+} \rightarrow C(5)\text{-}TH^+ + Fe^{2+}.$$

(ii) The reduction of $Fe^{3+}$ was further evident from an experiment using dihydrothymine(DHT) where only reducing C(5)-TH$^{\cdot}$ radical is formed.[14] Under the experimental concentrations of DHT, $Fe^{3+}$ and $t$-butanol, 81% of the H atom will react with

Table 1. Radiolytic yields of $Fe^{3+}/Fe^{2+}$ formed when solutions containing $10^{-3}M$ thymine or dihydrothymine were radiolysed (in presence and absence of $10^{-4}M$ $Fe^{2+}/5 \times 10^{-4}M$ $Fe^{3+}$) and $0.4M$ *t*-butanol under argon saturated condition at acidic pH (1.8)

| Constituents | $G(Fe^{3+})$* | $G(Fe^{2+})$* |
|---|---|---|
| $10^{-4}M$ $Fe^{2+}$ | 6.0 | — |
| $10^{-4}M$ $Fe^{2+}$ + $10^{-3}M$ thymine | 4.8 | — |
| $5 \times 10^{-4}M$ $Fe^{3+}$ + $10^{-3}M$ thymine | — | 1.4 |
| $5 \times 10^{-4}M$ $Fe^{3+}$ + $10^{-3}M$ dihydrothymine | — | 2.7 |

*1$G$ unit = No. of molecules formed or decomposed/100 eV of energy absorbed = 0.1036 $\mu$mol/J.

thymine forming C(5)-TH$^{\cdot}$. Hence $G(Fe^{2+})$ should be equivalent, *i.e.* 81% of 3.6 = 2.9. The experimental yield of $G(Fe^{2+})$ was 2.7 (Table 1).

From these two reducing radical experiments it can be concluded that the reducing hydrogen adduct of thymine undergoes very efficient electron transfer reaction with $Fe^{3+}$. Hence it can also be concluded that the reducing $TH^{\cdot}/TH^{+}$ couple has a redox potential lower than that of the $Fe^{2+}/Fe^{3+}$ couple, *i.e.* 0.77 V *vs.* NHE.

*Reactions of reducing hydroxyl adduct of thymine*

The electron transfer reaction of the reducing hydroxyl adduct of thymine has been carried out by many workers. The electron transfer from the reducing C(5)-TOH$^{\cdot}$ adduct to electron attracting compounds has been carried out by Kagiya and coworkers.[15] However, the maximum redox values used in their experiment were for the drug 2-methyl-1,4-naphthoquinone, having a redox potential of −0.203 V. However, in our earlier experiments we have shown that the C(5)-TOH adduct can reduce Cu(II)($E_0 = 0.16$ V),[16,17] iron(III)($E_0 = 0.77$ V),[18] but cannot reduce Ni(II) [$E_0 = -2.7$ V for Ni(II)/Ni(I)].[11] It has been reported by Busi *et al.*[19] that the lower domain of the redox value of C(5)-TOH adduct is $< -0.06$ V. Hence the domain of redox potential of this reducing adduct should be $-0.6$ V $< E^0$ C(5)-$TOH^{+}$/C(5)-TOH$^{\cdot}$) $< -0.203$ V.

*Reactions of oxidizing hydroxyl adduct of thymine*

The C(6)-TOH adduct was found to be oxidizing as was evident[2] from the oxidation of TMPD to $TMPD^{+}$. Nishimoto and other coworkers[20] have shown that C(6)-TOH can oxidize transition metal ions such as $FeSO_4$ ($E_0 = 0.77$ V), CuCl ($E_0 = 0.54$ V), $K_2[Fe(CN)_6]$ ($E_0 = 0.36$ V), but cannot oxidize metal ions having $E_0$ values $> 1$ V. Furthermore, we have shown[11] that C(6)-TOH$^{\cdot}$ cannot oxidize Ni(II) to Ni(III) having $E_0 = 1.4$ V. Hence it can be inferred that the C(6)-TOH radical has a redox value of $< 1$ V.

# SEPARATION AND CHARACTERIZATION OF TETROL METABOLITES OF BENZO[a]PYRENE-DNA ADDUCTS USING HPLC AND SOLID-MATRIX ROOM TEMPERATURE LUMINESCENCE

S. W. TJIOE and ROBERT J. HURTUBISE*

Department of Chemistry, University of Wyoming, Laramie, WY 82071-3838, U.S.A.

(*Received* 30 *June* 1994. *Accepted* 27 *July* 1994)

**Summary**—Four tetrols of benzo[a]pyrene-DNA adducts were separated using reversed-phase high performance liquid chromatography. Chromatographic fractions containing a given tetrol were readily characterized with solid-matrix room temperature luminescence techniques. Solid-matrix fluorescence and phosphorescence spectra at picogram amounts of a tetrol were easily obtained. Tetrol fractions collected based on retention times, but with no response from the ultraviolet detector, were characterized by solid-matrix luminescence spectra at very small quantities.

Polycyclic aromatic hydrocarbons are distributed widely in the environment and are known to be associated with the occurrence of cancer in humans and animals.[1] Selkirk *et al.*[2] separated eight metabolites of benzo[a]pyrene (B[a]P) formed by rat liver microsomes via high-performance liquid chromatography (HPLC). They reported that HPLC is an efficient, rapid, and reproducible method for the separation of the metabolites of B[a]P. Rozbeh and Hurtubise[3] reported the reversed-phase chromatographic separation of 14 metabolites of B[a]P using mobile-phase optimization methods. A fluorometric-HPLC assay to quantitate B[a]P metabolites was developed by Rahn *et al.*[4] In their study, isomeric tetrols of B[a]P were liberated by the acid hydrolysis of B[a]P-DNA adducts, separated by HPLC, and the fluorescence of the tetrols was detected in deoxygenated solutions at room temperature. Since the tetrols have high fluorescence quantum yields in deoxygenated solution at room temperature, they can be detected at low levels after separation by HPLC. One B[a]P residue per $10^7$ nucleic bases could be detected as tetrols in 100 $\mu$g of DNA.[4] When applied to B[a]P-DNA adducts, formed under controlled laboratory conditions in the liver and hemoglobin of erythrocyte of the bluegill sunfish, 126 pg of tetrol I-1 could be detected from 195 $\mu$g of isolated DNA.[5] Tromberg *et al.*[6] developed an antibody-based fiber-optic sensor to detect the tetrols. The typical limit of detection for this method was $5 \times 10^{-10} M$ (picomolar range). A fiber-optic antibody-based fluoroimmunosensor for tetrols from B[a]P-DNA adducts in human placenta samples gave a detection limit of 14 amol.[7] However, the characteristic fluorescence spectra of tetrols were not resolvable from these samples at the quantity studied. Tetrols obtained from human lung samples[8] and human urine samples[9] can be quantitated using a combination of immunoaffinity chromatography, HPLC, synchronous fluorescence spectroscopy, and second derivative synchronous fluorescence spectroscopy.

To increase the sensitivity of luminescence detection, after separation of the tetrols, solid-matrices can be used.[10] Solid-matrix room temperature fluorescence (SMRTF) and phosphorescence (SMRTP) are very useful analytical techniques for trace organic analysis.[11–13] In fact, solid-matrix luminescence can give greater fluorescence and phosphorescence quantum yields, in many cases, at room temperature, than the corresponding solution quantum yields at low temperature.[14] Femtomole quantities of tetrols can be detected using various solid-matrices.[15–19]

Corley and Hurtubise[20] reported that the detection limit of a tetrol by SMRTP was 0.38 femtomole/mg using 1:1:8 $\alpha$-cyclodex-

*Author to whom correspondence should be addressed.

trin:$TlNO_3$:$NaNO_3$ as the solid matrix. Tjioe and Hurtubise[19] detected 19 femtomoles of tetrol I-1 by SMRTP on Whatman No. 1 filter paper using thallium acetate as the external heavy atom. The SMRTF dectection limit of tetrol I-1 was 23 femtomoles without the presence of thallium acetate on Whatman No. 1 filter paper.[19] Furthermore, they introduced Whatman 1PS filter paper as a new solid matrix to obtain SMRTP as an alternative to the use of thallium salts which are toxic. The tetrols spotted on 1PS filter paper can be detected at 0.56 and 10.2 femtomoles by SMRTF and SMRTP, respectively.[19] These are among the lowest detection limits reported for a tetrol.

In this work, solid-matrix luminescence was used for the characterization of tetrols after HPLC separation. Whatman No. 1 filter paper was employed for both the SMRTF and the thallium acetate-enhanced SMRTP of tetrol I-1. Whatman 1PS filter paper was also employed to obtain both the SMRTF and SMRTP data for tetrol I-1 without the addition of a heavy atom. There have been very few reports on the use of solid-matrix luminescence for the characterization of HPLC fractions.

## EXPERIMENTAL

### *Chemicals and reagents*

The four tetrols were purchased from the Midwest Research Institute (Kansas City, MO, U.S.A.). Their chemical names and abbreviations are B[a]P-r-7,t-8,9,c-10-tetrahydrotetrol (I-1), B[a]P-r-7,t-8,9,10-tetrahydrotetrol (I-2), B[a]P-r-7,t-8,c-9,t-10-tetrahydrotetrol (II-1), and B[a]P-r-7,t-8,c-9,10-tetrahydrotetrol (II-2). A stock solution for each tetrol was prepared by dissolving 2 mg of a tetrol in 10 ml of absolute methanol (HPLC, Baker, Phillipsburg, NJ, U.S.A.). A standard solution was prepared for each tetrol by adding 100 $\mu$l water (HPLC grade, Baker, Phillipsburg, NJ, U.S.A.) to 100 $\mu$l of the stock tetrol solution in a 1 ml volumetric flask. The contents of the flask were then diluted to 1 ml with methanol:water (55:45, HPLC grade, Baker). A solution which contained the four tetrols was prepared in a similar fashion by adding 250 $\mu$l of each standard tetrol solution to a 1 ml volumetric flask. The concentration for each standard tetrol solution was 20 ng/$\mu$l. The concentration for each tetrol in the four-component solution was 5 ng/$\mu$l. A 500 pg/$\mu$l solution of I-1 was prepared in methanol:water (55:45). Thallium acetate (99.9% pure, Aldrich) solution was prepared by adding thallium acetate and 12 N glacial acid to HPLC grade methanol:water (55:45). This solution was 0.5*M* in thallium acetate and 0.3*M* in acetic acid.

Whatman No. 1 and Whatman 1PS filter paper samples (Whatman Co., Cliffton, NJ, U.S.A.) were developed three times in absolute methanol (Reagent grade, Baker), and dried at 110°C for 30 min. Small circular discs of filter paper were made with a paper punch.

### *Instrumentation*

A Water's Model M-45 or 6000A solvent system was used in conjunction with a U6K universal injector and a Water's Model 440 UV absorbance detector (Milford, MA, U.S.A.). The stationary phase for the reversed-phase chromatographic separation was a Baxter (Burdick and Jackson) octadecyl column (25 cm × 4.6 mm i.d., 5 $\mu$m). The column was kept at ambient temperature during the chromatographic experiments. A Linear Model 1201 (Linear, Reno, NE, U.S.A.) recorder was used to record the chromatograms.

Spectroscopic measurements were performed with a Perkin-Elmer LS-5 fluorescence spectrophotometer. The source employed was a pulsed xenon lamp. The detector was a R777 PMT, and the data were processed with a Perkin Elmer 3600 Data Station.

### *Procedures*

Three chromatographic experiments were performed: (1) To study the retention time of each tetrol, 20 $\mu$l aliquots of each standard tetrol solution were injected into the liquid chromatograph. (2) To study the separation of the four tetrol isomers, 40 $\mu$l aliquots of the four-component tetrol solution were injected into the liquid chromatograph. (3) To study the sensitivity of the solid-matrix room-temperature luminescence techniques, a 1 $\mu$l aliquot of I-1 (500 pg/$\mu$l) solution was injected into the liquid chromatograph and the tetrol fractions were collected.

For the above experiments, injections were repeated three times to ensure reproducibility. Methanol:water (55:45) was used as the mobile phase. The flow rate of the mobile phase was set at 1 ml/min, and the UV detector measured the absorbance of the eluent at 254 nm.

Each chromatographic fraction corresponding to a given tetrol was collected in a test tube. The mobile phase fractions were evaporated to

near dryness by placing the test tubes in a Multi-Block Heater (Model No. 2050, Lab-Line Instrument Inc., Melrose Park, IL, U.S.A.). The temperature at the center of the block heater was set at 110°C. A commercial hot-air dryer was employed to blow a stream of warm air across the openings of the test tubes to assist the evaporation of the solvent. After evaporation, the test tubes were removed from the block heater, cooled to ambient temperature, and diluted with either methanol:water (55:45), or the thallium acetate–acetic acid solution to a specific volume.

The amount of tetrol I-1 recovered in chromatographic experiment 1 (see above) was diluted to 2 ml with methanol:water (55:45), and the quantity of I-1 was calculated from a solution fluorescence calibration curve of I-1. The amount of tetrol I-1 recovered in chromatographic experiment 3 was diluted to 2 ml with the same solvent, and the quantity of I-1 was estimated via comparison of solution fluorescence intensities with a standard solution of I-1 (500 pg/$\mu$l in methanol:water, 55:45). The solution fluorescence of I-1 recovered from chromatographic experiment 3 was examined after the fraction was diluted to 2 ml with methanol:water (55:45). After the solution fluorescence data were obtained, the previous 2 ml solution was evaporated and the residue was dissolved in 30 $\mu$l with methanol:water (55:45). The methanol:water solutions from chromatographic experiments 1 (2 ml) and 3 (30 $\mu$l) were used for SMRTF studies. Samples of I-1 recovered from chromatographic experiment 1 and diluted to 2 ml with thallium acetate–acetic acid were used for SMRTP studies.

To study the solid-matrix room temperature fluorescence and phosphorescence, 1 $\mu$l of I-1 solution (200 pg/$\mu$l) recovered from chromatographic experiment 1 was deposited onto the surface of a Whatman No. 1 filter paper disc which was fitted on top of 4 other pieces of filter paper in a circular depression of a custom-made delrin sample holder. Five microliters of I-1 solution from chromatographic experiment 3 was transferred to the surface of a Whatman 1PS filter paper disc in a separate experiment. The Whatman No. 1 or 1PS filter paper samples in these experiments were dried in the sample holder at 110°C for 30 min and then cooled to room temperature inside the sample compartment of the fluorescence spectrophotometer. A constant stream of dry nitrogen gas was directed into the sample compartment to minimize oxygen and moisture quenching. The sample holder was protected from light during the cooling period which generally required 10 min. The luminescence intensities of tetrol on filter paper were measured by setting the excitation and emission monochromator at the appropriate excitation and emission wavelengths.[19] To measure SMRTF, the excitation and emission wavelengths were set at 346 and 398 nm, respectively. To measure SMRTP, the monochromators were set at 346 and 606 nm, respectively. The SMRTF and SMRTP spectra were obtained in the usual fashion. The limit of detection was obtained as discussed previously.[21]

## RESULTS AND DISCUSSION

### *Retention times of four tetrols*

The four tetrols are stereoisomers and differ from each other in the orientation of the hydroxyl groups covalently bonded to the carbon atoms at the 7, 8, 9, 10 positions.[19] In this work, they gave very good baseline resolution with the HPLC experimental conditions. The separation profile resembled the ones reported in literature.[4,5] The average retention times for the tetrols were: I-1, $11.53 \pm 0.058$ min; II-1, $13.78 \pm 0.058$ min; I-2, $15.97 \pm 0.13$ min; and II-2, $22.37 \pm 0.029$ min. Figure 1 shows a chromatogram for a solution of the four tetrols. Tetrol I-1 and II-1 eluted earlier than I-2 and II-2, indicating less hydrophobic interaction of these two tetrols with the stationary phase. This implied that tetrol I-1 and II-1 are somewhat more polar than I-2. Because tetrol II-2 eluted last, it would be the least polar of the four tetrols. Each peak in Fig. 1 represents an equal quantity of tetrol. Since the peak heights under each chromatographic band were different, the molar absorptivities of the tetrol isomer at 254 nm were not the same. However, the shapes of the chromatographic bands would also contribute to the differences in peak heights. With the experimental conditions presented in Fig. 1, the four tetrol isomers could be completely separated within 24 min.

### *Recovery of I-1*

Fractions of I-1 were collected from the HPLC system with either a M-45 or 6000A pump in the system. The fractions were evaporated to dryness, and then diluted to 2 ml in methanol:water (55:45) as described in the experimental section. The quantity recovered

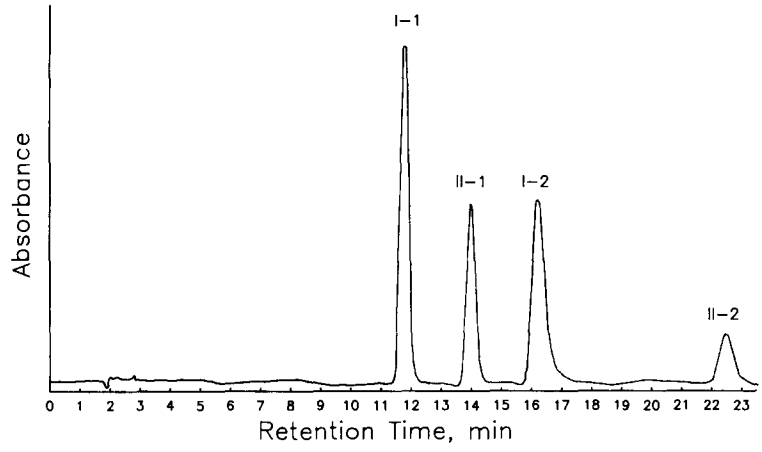

Fig. 1. Chromatogram for the four tetrols. Retention times: I-1 = 11.7 min; II-1 = 13.9 min; I-2 = 16.1 min; II-2 = 22.4 min.

from the liquid chromatograph was calculated using data from a fluorescence calibration curve of I-1. Ninety-one percent of I-1 was recovered. It is assumed that the other tetrols recovered would have similar percent recoveries because identical instrumental conditions were used. The quantity of I-1 recovered from a 20 $\mu$l injection of 20 ng/$\mu$l solution (chromatographic experiment 1) was equal to 0.91 × 400 ng, or 364 ng. The quantity of I-1 recovered from a 1 $\mu$l injection of 500 pg/$\mu$l solution (chromatographic experiment 3) was estimated by comparing the fluorescence intensity of the collected fractions with a standard solution of I-1. Because of the small quantity injected, only 64%, or 0.64 × 500 pg = 320 pg of I-1 was recovered. The solid-matrix luminescence spectra in Figs 2 and 3 were obtained from I-1 (182 pg) recovered from the 20 $\mu$l injections of a 1 ml standard I-1 solution. These figures illustrate that both SMRTF and SMRTP spectra can be obtained easily from picogram levels of I-1 isolated in HPLC fractions.

*Detection limits and smallest quantity for solid-matrix spectra*

The lowest quantity of I-1 detectable by ultraviolet absorbance with the liquid chromatograph was 172 pg. A detection limit of 2.3 pg for I-1 has been reported using a fluorescence detector in conjunction with HPLC.[22] However, the detection limit can be lowered to 0.18 pg, or 0.56 femtomoles, using solid-matrix luminescence techniques reported earlier.[19] This implies that the characterization of tetrols is possible even though no signal would be detected from

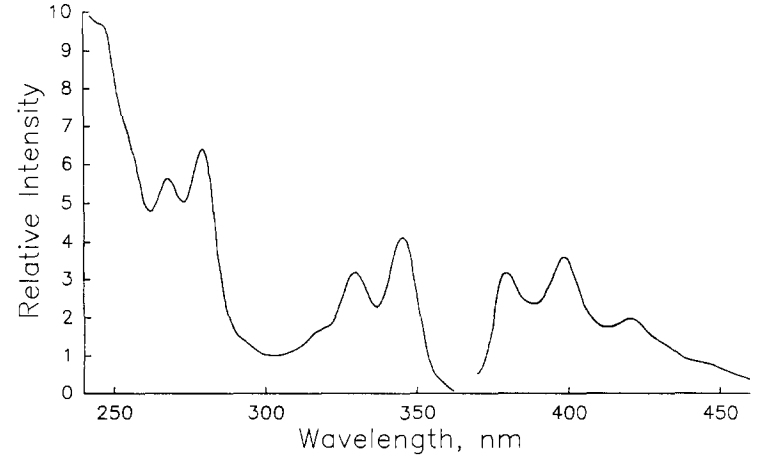

Fig. 2. SMRTF spectra of I-1. One microliter (182 pg) of I-1 spotted on a Whatman 1PS filter paper disc. This solution was recovered from an injection of a 20 $\mu$l aliquot of standard I-1 solution, evaporated, and diluted to 1 ml with methanol:water (55:45).

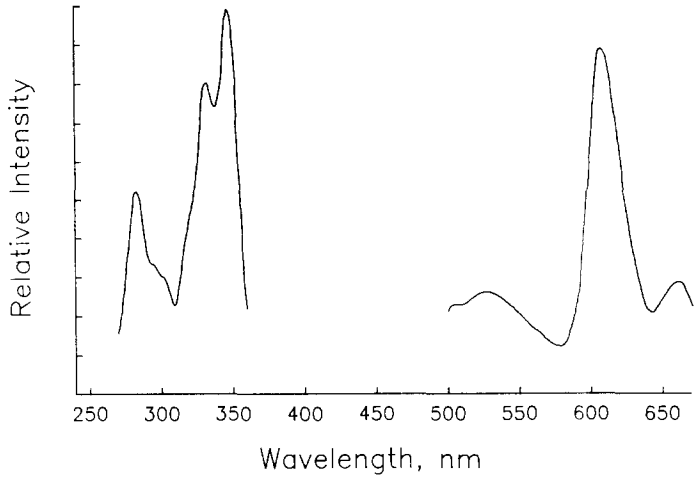

Fig. 3. SMRTP spectra of I-1. One microliter (182 pg) of I-1 spotted on a Whatman No. 1 filter paper disc. This solution was recovered from an injection of a 20 $\mu$l aliquot of standard I-1 solution, evaporated, and diluted to 1 ml with thallium acetate–acetic acid solution.

conventional UV or fluorescence detector. For example, it would be feasible to isolate a tetrol fraction based on the retention time of the tetrol even though the detector did not respond to the tetrol. The isolated fraction could then be characterized by solid-matrix luminescence techniques. In this work, a fraction of I-1 was collected based on its retention time. The fraction gave no response from the UV detector. Poor solution excitation and fluorescence emission spectra of the isolated HPLC fraction were obtained (Fig. 4). However, when the fraction was evaporated and then diluted to 30 $\mu$l (0.16 pg/$\mu$l) in methanol:water (55:45), I-1 could be readily identified by its SMRTF excitation and emission spectra from 53 pg of I-1 adsorbed onto the surface of 1PS filter paper (Fig. 5). As mentioned in reference 19, I-1 deposited on filter paper with thallium acetate solution gave analytically useful SMRTP spectra with only 100 pg on the paper. However, SMRTF gives the lowest limits of detection when 1PS filter paper is used as a solid matrix.[19] For example, SMRTF spectra of I-1 can be obtained with as little as 5 pg on Whatman 1PS filter paper.

## CONCLUSIONS

It was shown that tetrols that were separated by reversed-phase HPLC can be characterized at very low levels by solid-matrix luminescence with Whatman No. 1 or 1PS filter paper. For example, the SMRTF spectra from 53 pg of a recovered tetrol fraction was readily obtained.

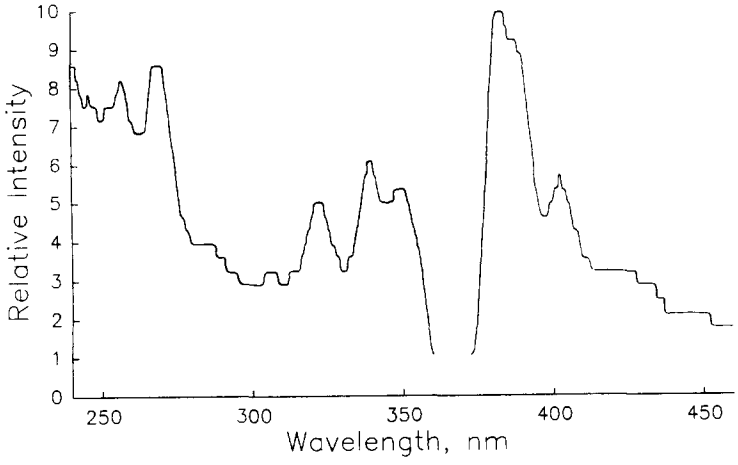

Fig. 4. Solution fluorescence spectra of I-1 (0.16 ng/ml). This solution was recovered from an injection of a 1 $\mu$l aliquot containing 500 pg of I-1.

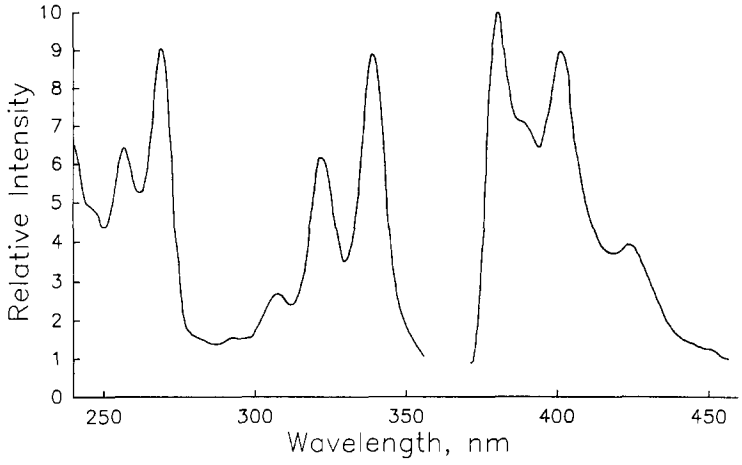

Fig. 5. SMRTF spectra of I-1. The solution in Fig. 4 was evaporated to near dryness. The contents were diluted to 30 $\mu$l with methanol:water (55:45). Five microliters (53 pg) was spotted on a Whatman 1PS filter paper disc.

Solid-matrix luminescence with Whatman 1PS filter paper as the solid matrix was shown to be a very sensitive and convenient method in the trace analysis of tetrol fractions separated by HPLC. The SMRTP of the tetrols on Whatman No. 1 filter paper was also an extremely sensitive approach for the trace characterization of I-1 (and other tetrols) when thallium acetate was used as an external heavy atom. Fractions containing a tetrol can be detected and characterized using solid-matrix room-temperature techniques at a level where conventional solution methods fail.

# SIMULTANEOUS DETERMINATION OF LEAD AND CADMIUM IN VARIOUS ENVIRONMENTAL AND BIOLOGICAL SAMPLES BY DIFFERENTIAL PULSE POLAROGRAPHY AFTER ADSORPTION OF THEIR MORPHOLINE-4-CARBODITHIOATES ONTO MICROCRYSTALLINE NAPHTHALENE OR MORPHOLINE-4-DITHIOCARBAMATE–CTMAB–NAPHTHALENE ADSORBENT

**Summary**—A highly selective, sensitive and rapid differential pulse polarographic method (DPP) has been developed for the simultaneous estimation of trace amounts of lead and cadmium in standard alloys, biological and environmental samples. The morpholine-4-carbodithioates of the samples were absorbed on microcrystalline naphthalene in the pH range of 5–10 for lead and 3.4–11 for cadmium. The metal complexes were desorbed with 10 ml of 1*M* HCl and determined simultaneously with a differential pulse polarograph. These metals can alternatively be quantitatively adsorbed on morpholine-4-dithiocarbamate–cetyltrimethylammonium bromide–naphthalene adsorbent packed in a column and determined similarly. The detection limits are 0.14 ppm for Pb and 0.014 ppm for Cd at minimum instrumental settings (signal-to-noise ratio = 2). The linearity is maintained in the concentration ranges of Pb, 0.7–15 ppm and Cd, 0.07–10 ppm with a correlation factor of 0.9997 and relative standard deviations of 0.95 and 0.81%, respectively. Various parameters such as the effect of pH, volume of aqueous phase, and interference of a number of metal ions on the estimation of lead and cadmium have been studied in detail to optimize the conditions for their simultaneous estimation in various biological and environmental samples.

A survey of the literature reveals that lead may be determined in environmental samples using graphite furnace atomic absorption spectrometry;[1,2] however, chloride, copper and nickel interfere seriously and the method has limited applications in a few environmental and biological samples owing to matrix effect. Differential pulse anodic stripping voltammetry (DPASV) is another technique which may be employed for the determination of metal ions. This technique is sensitive, but less selective for complex materials such as biological and environmental samples having complicated matrix.[3] The anodic stripping voltammetric (ASV) method developed by Aualiitia and Pickering[4] is satisfactory for the simultaneous determination of lead and cadmium, but it involves rigid control of conditions like the constant surface area of the hanging mercury drop electrode (HMDE).

Earlier, much attention was given to the direct polarographic estimation of metals after extraction of their metal complexes into organic solvents.[5–9] Unfortunately, electrochemical methods for the direct determination of reducible substances require that the solvent should have a fairly high dielectric constant so a well defined polarogram can be obtained. In this regard, various workers have mixed the organic phase after extraction with a solvent of high dielectric constant to obtain well defined polarograms.[10,11] The main disadvantages of these methods are that the sensitivity and preconcentration factor are considerably lowered. Thus the aim of the preconcentration and direct determination of a metal is not achieved. A similar situation is observed in the determination of a metal ion after extraction of its metal complex into molten naphthalene.[12]

*Author to whom correspondence should be addressed.

In the present communication, we have developed a simple, rapid, sensitive and economical method for the direct differential pulse polarographic determination of lead and cadmium simultaneously after adsorption of their morpholine-4-carbodithioates on microcrystalline naphthalene. The preconcentration of these metal ions is also possible by passing their aqueous solutions over morpholine-4-dithiocarbamate–cetyltrimethylammonium bromide–naphthalene adsorbent taken in a column. The microcrystalline naphthalene method is rapid but the column method gives a better preconcentration factor (8–10 times). Diethyldithiocarbamates and xanthates normally give anodic wave at $\sim -0.2$ V *vs.* SCE on the DME.[13] However, these are decomposed in the mineral acids below pH 4. Therefore, they do not give any wave under these conditions in the range of 0.0 to $-1.7$ V *vs.* SCE. Thus, a wide range of potential is available. Various parameters such as pH, volume of aqueous phase, reagent concentration, amount of naphthalene and interference of several metal ions on the estimation for lead and cadmium have been evaluated. The procedure developed has been successfully employed for the simultaneous estimation of trace and ultratrace amounts of lead and cadmium in various standard alloys, biological and environmental samples.

## EXPERIMENTAL

### *Apparatus*

Polarograms were recorded with a three-electrode Elico Model CL-90 polarographic analyser outfitted with an X-Y recorder (model LR-108). The glass column used for the preconcentration (Fig. 1) was 60 mm long and had an i.d. of 7 mm. All atomic absorption measurements were made with an atomic absorption spectrometer (Varian AA model 475). An Elico Model L1-120 pH meter was used for pH measurements.

### *Reagents*

Lead and cadmium nitrate solutions were prepared by dissolving analytical grade samples in double-distilled water. These metals were standardized complexometrically using Xylenol Orange as an indicator[14] and were further standardized by the AAS method using AAS standard solutions. Potassium morpholine-4-dithiocarbamate (MCDT) was prepared by the method of Macrotrigiano[15] and a 0.2% solution in distilled water was used. A 10% solution of potassium sodium tartrate in distilled water was used to prevent the hydrolysis of lead. Naphthalene and cetyltrimethylammonium bromide (CTMAB) were of analytical grade. Solutions of alkali metal salts (1%) and various metal salts (0.1%) were used to study the interference of anions and cations, respectively. A 4% solution of $NaBH_4$ (Ubichem. Ltd, Analytical grade) was prepared in 0.2*M* NaOH solution. Sodium acetate–acetic acid (0.2*M*) and aqueous ammonia–ammonium ion (0.1*M*) buffers were used for pH adjustment. Twice-distilled water was used wherever required.

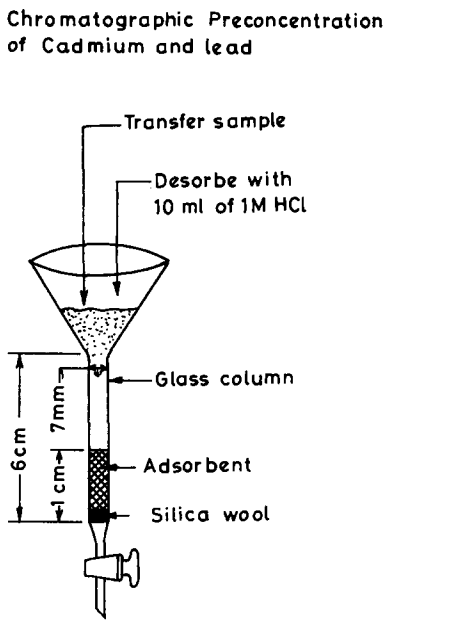

Fig. 1. Separatory column for preconcentration of trace metals.

### *Preparation of MCDT–CTMAB-naphthalene adsorbent*

A naphthalene solution was prepared by dissolving a 10-g sample in 100 ml of acetone followed by 1 l. of distilled water containing 0.050 g cetyltrimethyl ammonium bromide. It was stirred at 25–30°C on a hot plate/stirrer, followed by 100 ml of 0.2% MCDT solution in distilled water. The mixture was stirred for 3 hr and kept for 5 hr at room temperature. The supernatant ligand was aspirated with a siphon and the residue was washed twice with double-distilled water. The final adsorbent was a slurry of MCDT–CTMAB–naphthalene and stored in a bottle for subsequent use.

*Pre-treatment of standard alloys, environmental and biological samples*

The solution of standard alloys was prepared as described in the literature.[16] A 0.01-g sample of each of the standard alloy was dissolved in 50–60 ml of 6*M* HCl by heating on a hot plate, then 3–5 ml of 30% hydrogen peroxide was added. The excess of the peroxide was decomposed by heating. The solution was cooled, filtered if needed, and diluted to 100 ml with distilled water in a calibrated volumetric flask.

Solid environmental samples were dried in an oven at 200°C for 2 hr. A 1.0-g sample of each was decomposed with 50–60 ml of 6*M* HCl,[17] then 3–5 ml of 30% hydrogen peroxide was added. The mixture was heated on a hot plate almost to dryness. The residue was then dissolved in 10 ml of 1*M* HCl and diluted with 10 ml of distilled water and filtered if needed. Finally the solution was made up to 100 ml with distilled water in a calibrated volumetric flask.

A 100-ml sample of each liquid environmental sample was taken and to it added 5 ml of conc $HNO_3$. The solution was heated almost to dryness on a hot plate. The residue was dissolved in 5 ml of 1*M* HCl and finally the solution was made up to 100 ml with distilled water in a calibrated volumetric flask.[18]

A 0.1-g sample of each of the biological samples was dissolved by heating with concentrated nitric and perchloric acids. The solution was cooled and diluted up to a volume of 100 ml with distilled water in a calibrated volumetric flask.[18] In the case of samples of unknown composition cadmium and lead were determined by the AAS method after preconcentration by the proposed method. In this case the naphthalene has to be removed by filtration before aspirating the sample in a flame. In addition, the metals in the unknown samples were also estimated by standard methods reported in the literature.[19]

*General procedures*

An aliquot of lead or cadmium solution (0.5–140 $\mu$g for Cd and 5–200 $\mu$g for Pb) was taken in a 100-ml Erlenmeyer flask with a tightly fitting stopper. To this solution, 2 ml of 10% potassium sodium tartrate and 2 ml of 0.2% reagent solution were added and the mixture diluted to 30–40 ml. The pH of this solution was adjusted by 2 ml of aqueous ammonia–ammonium ion buffer of pH 8.0. The solution was mixed well and allowed to stand for a few seconds. Then, 2 ml of a 20% solution of naphthalene in acetone was added to it with continuous shaking. The solid mass so formed consisting of naphthalene and metal complex was separated by filtration on a Whatman filter paper (No. 1041). The residue was shaken vigorously with 10 ml of 1*M* hydrochloric acid and transferred to the polarographic cell. In the column method, the adsorbent was conditioned to pH 8.0 by passing 5–7 ml of buffer through the column, before the test solution was passed through it at a flow rate of 1–2 ml/min. The column was finally washed with water. Desorption of metal was carried out by passing 10 ml of 1*M* of HCl at flow rate of 1–2 ml/min and the solution was transferred to the polarographic cell. After the addition of 3 ml of 4% $NaBH_4$ solution, the differential pulse polarogram was recorded.

## RESULTS AND DISCUSSION

Preliminary observations indicated that $NaBH_4$ is quite effective for the removal of dissolved oxygen from the solution in a few seconds. Highly purified $N_2$ in contrast takes 5–10 min for the complete removal of $O_2$. Another advantage of using $NaBH_4$ is that it provides $OH^-$ ions and brings the pH in the desired range. Thus, it is helpful for adjusting the pH of a solution (the solution is prepared in 0.2*M* NaOH). There is no need to add extra NaCl as the supporting electrolyte because sufficient quantity is formed in the reaction. Many other supporting electrolytes were also tried without any effect.

*Effect of pH on differential pulse polarograms*

We studied the effect of pH by adding 4% $NaBH_4$ solution, while keeping other variables constant. The shape of the differential pulse polarograms and peak heights were found to be almost constant over the pH range of 0.6–5.0 for both metals (the pH may also be adjusted using NaOH solution). The peak potential ($E_p$) shifted towards more negative values as the pH increased in the range of 5–8, but a plot of $E_p$ *vs.* pH was not linear, indicating that protonation is not taking part in the overall electrode process. The peak heights were considerably decreased above pH 8 in both cases, probably owing to hydroxides formation. Therefore, all studies were carried out at pH $\sim$ 2 since it was conveniently achieved simply by mixing the solutions.

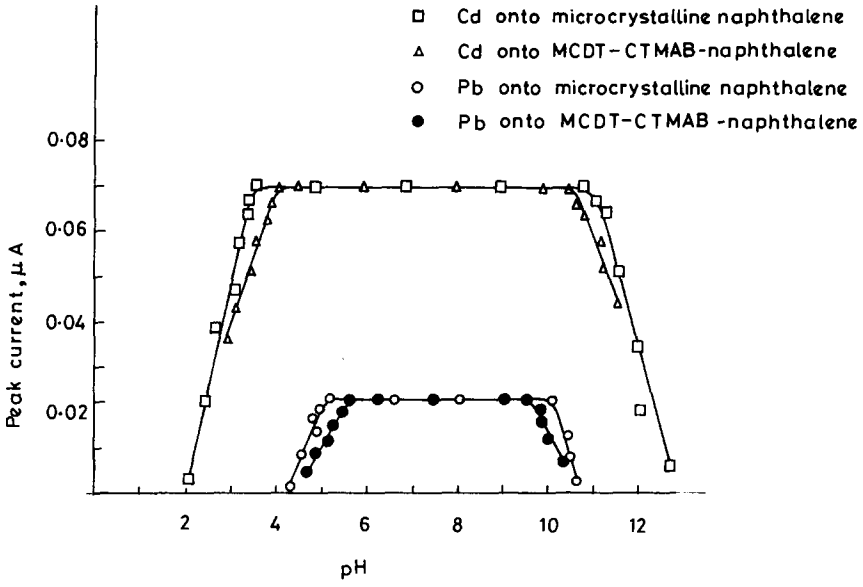

Fig. 2. Effect of pH on adsorption/retention of lead and cadmium complex: lead, 103.5 μg; cadmium, 112 μg; reagent, 2.0 ml; (0.2%) naphthalene, 2.0 ml (20%); reference, reagent blank. Instrumental settings: (a) scan rate = 12 mV/sec; (b) modulation amplitude = 50 mV; (c) drop time = 0.5 sec.

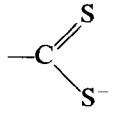
*Effect of pH and buffer on adsorption*

We carried out adsorptions at different pH values, keeping other variables constant. It was found that lead– and cadmium–morpholine-4-carbodithioates were quantitatively retained on naphthalene in the pH ranges of 5–10 and 3.4–11, respectively but in case of column method, lead and cadmium were quantitatively retained on MCDT–CTMAB–naphthalene in the pH ranges of 5.2–9.5 and 4–10.8, respectively (Fig. 2). Addition of 1–5 ml of buffer for adsorption of the complex on microcrystalline naphthalene and 5–15 ml of buffer in the case of the column method did not cause any effect on the adsorption. Therefore, 2.0 ml and 7.0 ml of the aqueous ammonia–ammonium ion buffer were employed in the subsequent determinations in both the cases, respectively.

*Retention characteristics of MCDT*

The chelating agent has the functional group



of the dithiocarbamate molecule which is co-ordinated with the metal. Hence, both the cadmium and lead form the chelate with 2 moles of dithiocarbamate molecule on the surface of microcrystalline naphthalene after passing through the column.

*Retention capacity of MCDT supported on naphthalene*

The retention capacity of morpholine-4-dithiocarbamate supported on naphthalene was determined by the batch method. This experiment was carried out by taking 3 mg of metal ion, 2.0 ml of buffer and a suitable amount of the absorbent in a 100 ml separatory funnel. This mixture was diluted to 30 ml, shaken with a mechanical shaker for 15 min and then filtered through a filter paper. The amount of metal ion in the filtrate was determined by AAS. The naphthalene chelating agent material was dried on a filter paper and the solid mass weighed on a balance. The retention capacity of both the metal ions for this adsorbent depends on the amount of adsorbent. The maximum amount of retention was 4.5 mg for cadmium and 4.1 mg for lead per g of the adsorbent.

*Reaction conditions*

Reaction conditions were established using 103.5 μg of lead and 112 μg of cadmium taken individually.

Preliminary observations indicated that lead and cadmium complexes could be desorbed completely with 10 ml of 0.1–5.0*M* hydrochloric acid, but 1*M* of hydrochloric acid was used instead. The reagent concentration was varied over a range of 0.1–7 ml. It was found that adsorptions were quantitative for 0.5–4.0 ml

of 0.2% reagent of lead and cadmium. Consequently, 2.0 ml of the reagent was used in subsequent studies (2 ml of 0.2% reagent corresponds to $\sim$0.02m$M$, while the metal cadmium 112 $\mu$g and lead 103.5 $\mu$g correspond to 0.001 and 0.0005m$M$, roughly more than 10 and 20 times, respectively. The stoichiometric ratio of the metal:ligand is 1:2. Therefore, the calibration curve can be safely constructed as Cd, 0.9–130 $\mu$g; Pb, 9.1–195 $\mu$g in 13 ml of the final solution.) We added various amounts of naphthalene to sample solutions, keeping other variables constant. It was observed that the peak height remained constant with the addition of 0.4–4.5 ml of 20% naphthalene solution. Therefore, 2 ml of 20% naphthalene was used in subsequent studies. The effect of shaking time on the adsorption indicated that the peak height remained constant over a range of 0.5–7 min. Therefore, 1 min of shaking time was maintained in the present work. While in the case of column method, the flow rate was varied from 0.5 to 8 ml/min. It was found that a flow rate of 0.5–5.0 ml/min did not affect adsorption. A flow rate of 1–2 ml/min was recommended in all experiments. The volume of the aqueous phase was varied in the range of 10–800 ml under the optimum conditions. It was observed that the peak height was almost constant up to 100 ml of the aqueous phase (preconcentration factor of $\sim$6) in case of lead and up to 300 ml of the aqueous phase (preconcentration factor of $\sim$20) in the case of cadmium and then decreased gradually in both the cases. Whereas, in the case of column method, peak height was almost constant up to an aqueous phase volume of 600 ml, for both the metals. Therefore, a preconcentration factor $\sim$40 can be achieved by the column method. However, in all the experiments, 40 ml of the aqueous phase was maintained for convenience.

*Calibration*

A calibration curve (Fig. 3) for the determination of lead and cadmium was prepared according to the general procedure for the optimum conditions developed above. The detection limits were 0.14 ppm for lead and 0.014 ppm for cadmium, at the minimum instrumental settings (signal-to-noise ratio = 2). The linearities were maintained in the concentration ranges of Pb, 0.7–15 ppm and Cd, 0.07–10 ppm (9.1–195 $\mu$g for Pb and 0.91–130 $\mu$g for Cd in 13 ml of the final solution) with a

*Average of five determinations, ±SD.
†After preconcentration by the present method.
‡Column method.
§Microcrystalline naphthalene method.

Cr(III), Zn(II), Mn(II), Ni(II) (50 mg each), V(V), Te(IV), Bi(III), Al(III), As(III), Sn(II), Co(II) and Cu(II) (10 mg each), Os(VIII), Cr(VI), Sb(III), Rh(III), Ru(III) and Pd(II) (5 mg each). Fifteen milligrammes of lead in the case of cadmium and 10 mg of cadmium in the case of lead did not interfere. Only Fe(III), Ir(III) and Tl(I) interfered in both the cases, however, 5 mg of Fe(III) could be tolerated after Fe(III) was masked with triethanolamine while in case of Ir(III), the adsorption was carried out at pH 9.0 since Ir(III) did not absorb above pH 9.0. In addition, EDTA interfered seriously in both cases. Adsorption was almost nil in the presence of EDTA (< 1 mg) undoubtedly owing to the high stability of the lead– and cadmium–EDTA complexes.

*Application to the analysis of alloys, biological and environmental samples*

The accuracy and applicability of the proposed method was evaluated by its application on various alloys, biological and environmental samples. An aliquot of the pretreated standard alloys, biological and environmental sample solution was analyzed by the general procedure after iron was masked with triethanolamine. Tap water from the Department of Chemistry, I.I.T. Delhi, was analysed directly by the general procedure after iron was masked with triethanolamine. The results were also compared with atomic absorption spectrophotometrically after the general procedure had been applied. The data are given in Tables 1, 2 and 3. In the case of samples of unknown composition (Table 3), these metals were also estimated by standard methods reported in the literature.[19]

## CONCLUSIONS

It is difficult to obtain a well defined polarogram in traditional analysis of metals after extraction of their complexes into an organic solvent owing to the low dielectric constant of the organic phase. Sensitivity is lost if it is mixed with another solvent of high dielectric constant. Sometimes a maximum suppressor is also required. Another major disadvantage is the removal of dissolved oxygen which is a tedious and time consuming process and affects the reproducibility of the method owing to partial evaporation of the organic solvent. The reported method has solved most of these problems and tested successfully for the simultaneous estimation of lead and cadmium contents in real samples, *viz.*, biological and environmental samples. Although adsorption onto microcrystalline naphthalene is more rapid, the preconcentration factor is comparatively lower than the column method.

# SENSITIVE SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF PROPOXUR USING 4-AMINOANTIPYRINE

B. VENKATESWARLU and K. SESHAIAH*

Department of Chemistry, Sri Venkateswara University, Tirupati—517502, India

(*Received* 7 *March* 1994. *Revised* 8 *July* 1994. *Accepted* 26 *July* 1994)

**Summary**—The use of 4-aminoantipyrine for the colorimetric determination of propoxur in pesticide formulations and water samples is described. The method is based on the alkaline hydrolysis of the pesticide and the resultant phenol is reacted with 4-aminoantipyrine in the presence of an oxidizing agent. The resultant colored dye is extracted into chloroform and the absorbance measured at 472 nm.

Propoxur (isopropoxyphenyl methyl carbamate) is a carbamate insecticide which has wide applications in controlling numerous species of household and public health pests. It provides control of insects which are resistant to chlorinated hydrocarbons and organophosphates. In view of its wide application there is a need for the development of sensitive and reliable methods for the assessment of quality of insecticide formulations and to quantify the insecticide residues in water. There are spectrophotometric and chromatographic methods for the determination of propoxur. The spectrophotometric methods are based on the alkaline hydrolysis of the insecticide followed by coupling the resultant phenol with reagents such as diazotized 3-nitroaniline-4-sulphonic acid,[1,2] sulphanilic acid,[3] 4-aminoantipyrine,[4] 3,5-dibromo-*p*-benzoquinon chlorimine,[5] 4,4-diaminodiphenyl sulphone,[6] *p*-dimethylamino benzaldehyde and *p*-dimethylamino cinnamaldehyde,[7] 3-methyl-2-benzothia zolinone hydrozone hydrochloride,[8] *p*-dimethylphenylenediamine dihydrochloride[9] and 2-aminobenzophenone.[10] In the above spectrophotometric methods hydrolysed phonolic product is diazotized in aqueous solution as shown in Fig. 1, and the color of the aqueous solution measured. Hence, the sensitivity was less and also there was a possibility of the colored product reacting with other reagents present in the aqueous phase which leads to instability of the compound. We now report a spectrophotometric method based on the reaction of hydrolysed phonolic product with 4-aminoantipyrine in the presence of an oxidizing agent to produce an orange colored dye as shown in Fig. 2. The dye is extracted into organic solvent. Extraction of the dye from aqueous solution into small quantity of organic solvent increased the sensitivity of the method by several-fold compared with the reported methods and also the stability of the colored dye in organic solvents is more when compared with the aqueous phase. The method is extended to the determination of propoxur in commercial formulations and water samples.

## EXPERIMENTAL

### *Reagents*

All chemicals used were of analytical grade.

*Propoxur stock solution* (1000 μg/ml)

Insecticide (0.10 g) was dissolved in 100 ml of carbonyl free methanol. The stock solution was progressively diluted with the solvent to obtain standard solution of desired concentration (0.1 μg/ml).

4-*Aminoantipyrine* (2%)

4-Aminoantipyrine (2 g) was dissolved in distilled water and diluted to 100 ml.

*Sodium hydroxide* (2%)

Sodium hydroxide (2 g) was dissolved in 100 ml of distilled water.

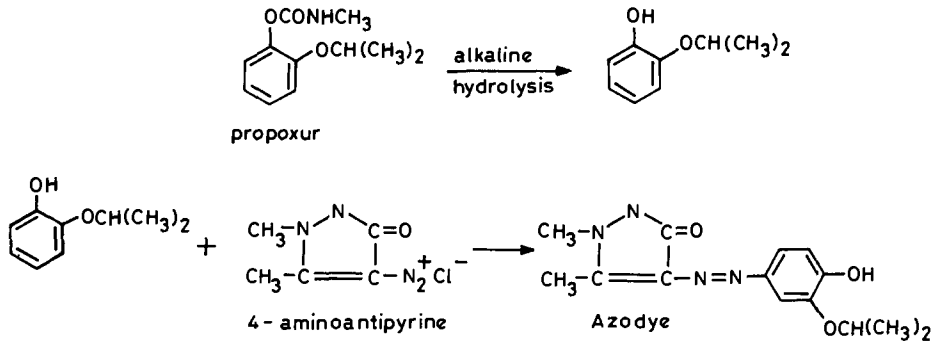

Fig. 1. Coupling reaction of 4-aminoantipyrine with propoxur.

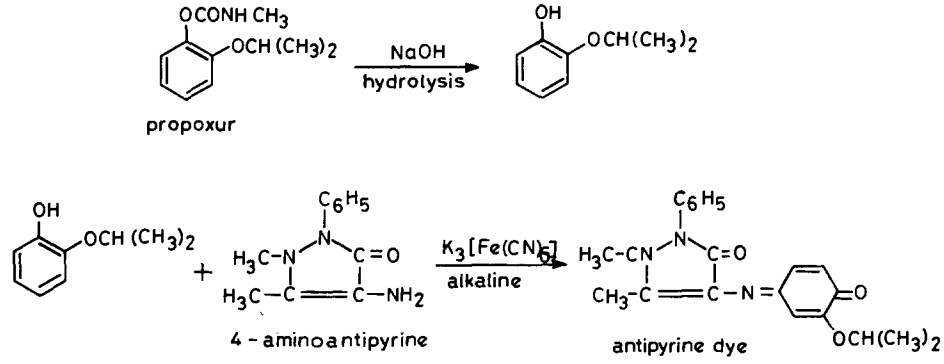

Fig. 2. Reaction mechanism of the antipyrine dye formed with propoxur.

*Buffer solution*

Dipotassium hydrogen phosphate (10.5 g) and 7.3 g of potassium dihydrogen phosphate were dissolved in distilled water and diluted to 100 ml.

*Potassium ferricyanide solution*

Potassium ferricyanide (8 g) was dissolved in distilled water and diluted to 100 ml.

A Shimadzu UV-240 recording spectrophotometer was employed in the studies.

*Procedure*

Insecticide solution (20 ml) was taken in a clean dry 100 ml beaker. Two per cent sodium hydroxide solution (5 ml) was added and allowed to stand for 5 min for complete hydrolysis, the pH of the solution is adjusted to 9.5 by adding 5 ml buffer solution and the requisite amount of HCl and ammonia solution. The solution was transferred to a 50 ml separating funnel and allowed to stand for 2 min and then 3 ml of 4-aminoantipyrine and 3 ml of potassium ferricyanide added and mixed well. The orange colored dye formed was extracted into 10 ml chloroform. The absorbance of the chloroform solution was measured at 472 nm, against a reagent blank.

*Formulations*

Well mixed formulation (equivalent to about 100 $\mu$g of the active insecticide) was shaken with 25 ml of methanol for 5–10 min. The supernatant solution was filtered by decantation into a 100 ml standard flask. The residue was washed twice with 10 ml portions of methanol. The filtrate and washings were diluted to 100 ml with methanol. Analysis was carried out using the above procedure.

Water samples (100 ml) spiked with 2.0, 3.0, 4.0, 5.0 and 6.0 $\mu$g of insecticide were taken, the pH of these samples adjusted to 3–4 with 2% sulphuric acid and 2 g of anhydrous sodium sulphate. The mixture was transferred into a separating funnel and insecticide extracted using approximately 15 ml of chloroform for each extraction by shaking 5–10 min. Combined extracts were washed with 2 ml of 0.1 *M* potassium carbonate to break any emulsion formed during the extraction, then dried over anhydrous sodium sulphate. Finally, chloroform was evaporated and residue dissolved in methanol. Determination was carried out by developing color using the above procedure.

## RESULTS AND DISCUSSION

Propoxur pesticide was hydrolysed and the resultant phenol converted into orange colored dye by reacting with 4-aminoantipyrine in the presence of an alkaline oxidizing agent, potassium ferricyanide.

### *Effect of pH on the formation of colored dye*

The reaction of the phenolic product with antipyrine was carried out in the pH range 6–11. The results are shown in Fig. 3. The absorbance of the colored dye was greater in the pH range 8.5–10. Hence, pH 9.5 was selected for the extraction of dye into organic layer.

### *Effect of solvent*

Extraction of colored dye was carried out in benzene, chloroform, methyl isobutyl ketone and carbon tetrachloride and their absorption spectra are shown in Fig. 4. Absorbance for the benzene extractant was more than the other solvents. The extraction with carbon tetrachloride was less efficient. Though absorbance with the chloroform extraction was slightly less than benzene, chloroform was selected for further extractions because of convenience of extraction.

### *Stability of colored dye*

The stability of the colored dye was studied in different solvents. It was stable for more than 12 hr in chloroform, benzene and methyl isobutyl ketone, but faded quickly in carbon tetrachloride.

Beer's law was obeyed over the concentration range of 0.1 to 1.0 $\mu$g/ml of propoxur and the respective calibration plot is shown in Fig. 5. The molar absorption coefficient of the colored dye was $3.09 \times 10^5$ cm$^{-1}$. The method was applied for the determination of propoxur in commercial formulations, 1% oil-based spray (Baygon spray) and 2% bait (Baygon) and spiked water samples. Results are shown in Table 1. The results indicate that the active insecticide obtained in formulations was in good agreement with the reported results by the manufacturers and the recovery of propoxur from spiked water samples was quite satisfactory. The results further demonstrate that the method is suitable for the analysis of formulations and field water samples.

# SELECTIVE AND SENSITIVE SPECTROPHOTOMETRIC DETERMINATION OF COPPER(II) AND BENZOYLPEROXIDE WITH *N*-ETHYL-2-NAPHTHYLAMINE*

ITSUO MORI,† TSUYOSHI FUJIMOTO, YOSHIKAZU FUJITA and TAKAKO MATSUO
Osaka University of Pharmaceutical Sciences, 2-10-65, Kawai, Matsubara, 580 Osaka, Japan

(*Received* 4 *May* 1994. *Revised* 11 *July* 1994. *Accepted* 26 *July* 1994)

**Summary**—Spectrophotometric determinations of benzoylperoxide (BPO) and copper(II) were, respectively, investigated by using the colour reaction for *N*-ethyl-2-naphthylamine (NENA), BPO and copper(II) as a metal ion in various concentrations of acetonitrile–water mixed solution as acidic media. The calibration graphs were linear in the range of 0–200 $\mu$g BPO with apparent molecular coefficient ($\varepsilon$) of $8.5 \times 10^3 M^{-1}$ cm$^{-1}$ at 530 nm, and 0–2.4 $\mu$g per 10 ml copper(II) with $\varepsilon = 1.72 \times 10^5 M^{-1}$ cm$^{-1}$ at 533 nm, respectively. Additionally, the FIA method for copper(II) was proposed with NENA–BPO. The calibration graph for FIA was linear in the range of 0–7.9 ng copper(II) per 5 $\mu$l at 533 nm. These proposed methods were selective and simple in comparison with previous methods such as cuproin kinetic reactions, especially the spectrophotometry for copper(II) with NENA–BPO was very specific, and the effect of foreign ions was negligible.

Generally, benzoylperoxide (BPO) has been used as a polymerization agent, flour improver, oxidizing and bleaching agent for fats and oils, an organic compound starting material or confirmation agent for hydroxypropylmethyl cellulose, and epispostic pharmaceuticals, *etc.* Various methods for the assay of BPO have been reported; gas chromatography,[1] liquid chromatography,[2] chemiluminescence[3] and spectrophotometry.[4,5] Additionally, many kinetic spectrophotometries of copper(II) with various organic agents such as rhodamine B, eosine and hydrogen peroxide have been reported.[6–9] However, these methods for the assay of copper(II) or BPO lack sensitivity and selectivity. In this paper, with a view to obtaining a more selective and sensitive spectrophotometric method for BPO and copper(II), we have investigated the systematical colour reaction of *N*-ethyl-2-naphthylamine (NENA), BPO and copper(II) in the test tube. The sensitive and selective spectrophotometric determinations for BPO and copper(II) with NENA–BPO in the test tube, and the FIA method for copper(II) were proposed, respectively.

*The application of aromatic amines in analytical chemistry. Part 2.

†To whom correspondence should be addressed.

## EXPERIMENTAL

### *Apparatus and reagents*

The absorption spectrum was recorded on a Shimadzu UV 3100 spectrophotometer with 1.0-cm quartz cells, Hitachi-Horiba Model F-8 and F-11 pHmeters were used. A Shimadzu Model LC-6AD and LC-6A HPLC, and Hitachi 056 recorder were used for the recording of FIA. FIA detection was carried out by a Shimadzu Model SPD-6AV detector. $^1$H NMR spectra were determined with a Varian X1-300 spectrometer in acetone-$d_6$, and mass spectra with a Hitachi M-80 instrument.

All materials and reagents were of analytical grade and were used without further purification. Solutions of $1.0 \times 10^{-1} M$ NENA and $1.0 \times 10^{-3} M$ (NENA–BPO) were prepared by dissolving NENA or (NENA–BPO) in acetonitrile previously synthesized by the Edward method.[10,11] Copper(II) solution was prepared by dissolving copper sulphate in water, and corrected by EDTA titration. Deionized water was used throughout.

### *Standard procedures*

*Determination of BPO.* To a sample solution (0.3 ml) containing 0–200 $\mu$g (0–$8.0 \times 10^{-5} M$)

BPO in a 10-ml calibrated flask, 2.0 ml of pH 5.0 buffer solution (Walpole buffer, acetic acid–sodium acetate mixture) and 0.5 ml of $1.0 \times 10^{-2}M$ copper(II) solution were added. The mixture was diluted to the mark with acetonitrile (final 75% acetonitrile solution) kept at 40°C for 40 min together with a reference solution, and cooled to room temperature or 10–30°C for 5 min. The total amount of BPO was calculated by measuring the absorbance of NENA–BPO–copper(II) solution at 530 nm against a blank [NENA–copper(II) solution] prepared without BPO.

*Determination of copper*(II). (1) Manual method (in test tube). To a solution containing 2.4 $\mu$g copper(II) in a 10-ml calibrated flask, 2.0 ml of pH 5.0 buffer solution and 4.0 ml of $1.0 \times 10^{-3}M$ NENA–BPO acetonitrile solution were added. The mixture was diluted to the mark with water and kept at 25°C for 3 min. The absorbance at 533 nm was measured against water. (2) FIA method. The reaction coil (0.3 mm × 2 m) and the flow rate (1.6 ml/min of $5.0 \times 10^{-4}M$ NENA–BPO acetonitrile solution (carrier 1), and 0.8 ml/min of pH 5.0 acetic acid–sodium acetate buffer solution (carrier 2) were used. The sample solution of 5 $\mu$l containing 0–7.9 ng copper(II) was injected into two mixed carrier streams (carriers 1 and 2), the absorbance at 533 nm monitered, and the output (peak height and area) of the spectrophotometer registered on the chart recorder for the calculation. The amount of copper(II) was found from the calibration graph.

## RESULTS AND DISCUSSION

### *Colouring reaction between naphthylamine derivatives and BPO*

The colour reaction between a secondary naphthylamine such as NENA and BPO as an oxidizing agent were systematically investigated in acetonitrile as weakly acidic media in the presence of copper(II) as a metal ion. As shown in Fig. 1, by heating NENA–BPO and NENA solutions, the difference of absorbances at 530 nm between NENA–BPO and NENA solutions in 75% acetonitrile was proportional to BPO concentration, and its value was stable for 30 min. On the other hand, the reaction products between NENA and BPO, or NENA alone in the absence of copper(II) did not give a coloured product under the conditions investigated.

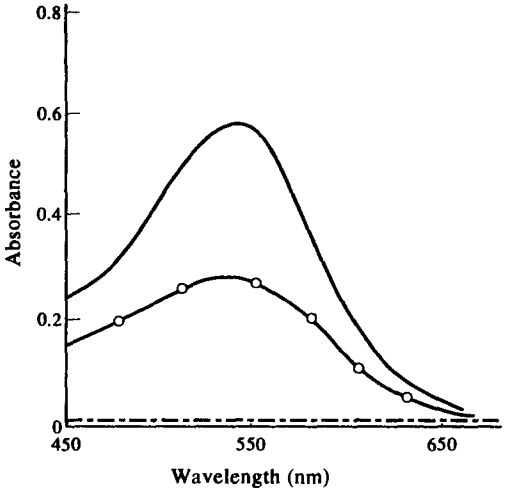

Fig. 1. Absorption spectra of (NENA–BPO–copper(II)) (NENA–copper (II)) and NENA solutions in 75% acetonitrile at pH 5.0. NENA $5.0 \times 10^{-3}M$; copper(II) $2.0 \times 10^{-4}M$; reference, water ——, NENA–BPO–copper(II) solution, BPO (180 $\mu$g); —○— NENA–BPO–copper(II) solution, BPO (90 $\mu$g); – – – – –, NENA–copper(II), NENA solutions.

### *Determination of BPO*

*Effects of solvent and concentration.* The colour reaction among NENA, BPO and copper(II) in acetic acid–sodium acetate medium (apparent pH 5) proceeded readily in acetonitrile, methylalcohol, propylalcohol, dimethylsulphoxide (DMSO), *etc.*, as solvent (mixable solvent with water). Acetonitrile was found to be the optimum solvent for the reaction. In this case, the NENA–BPO colour reaction in large amounts of water was unstable, and

Table 1. Colour reactions among naphthylamine derivatives, BPO and copper(II) in 75% acetonitrile solution

| | Absorbance ($\lambda_{max}$) | | |
|---|---|---|---|
| Naphthylamines (NA) | NA–Cu(II) | NA–BPO | NA–BPO–Cu(II) |
| *N*-Ethyl-1-naphthylamine | None | None | None |
| NENA | None | 0.267 (530) | 1.56 (530) |
| *N*-Phenyl-2-naphthylamine | None | 0.065 (463) | 0.154 (486) |
| *N*-Ethylaniline | None | 0.021 (502) | 0.021 (502) |

Naphthylamines and BPO, $5.0 \times 10^{-4}M$; copper(II), $2.0 \times 10^{-4}M$; reaction time and temperature, at 40°C for 40 min; reference, water.

its absorbance decreased with increasing water concentrations in acetonitrile. Accordingly, the water–acetonitrile (1:3, 75% acetonitrile–water mixture) was used in this colour reaction by considering the amounts of sample (contain water in sample) and reproducibility of absorbance.

*Effects of temperature, heating time and p*H. The colour reaction for NENA, BPO and copper(II) at 50°C for 5–60 min resulted in small absorbance. On the other hand, the colour reaction at 25°C for 120 min exhibited maximum absorbance, but it lacked stability and reproducibility. From these results, the reaction from standing at 40°C for 40 min was used because of the stable and reproducible colour obtained. The absorbance at 530 nm on NENA–BPO in 75% acetonitrile was almost constant at apparent pH 4.5–5.5. In this case, the ionic strength and species of buffer solution did not affect the intensity and stability of the colour reaction.

*Effects of concentration of NENA and copper*(II). From the effect of NENA concentration in the assay of 4.0 or $8.0 \times 10^{-5}M$ BPO, the recommended final concentration of NENA was more than $5.0 \times 10^{-3}M$. In the subsequent procedure, $5.0 \times 10^{-3}M$ NENA was used for the assay of BPO. As the colour reaction between NENA and BPO was catalysed by the coexistence of copper(II) as a metal ion, the coexisting effect of metal ion such as copper(II) was systematically investigated. As shown in Table 2, the coexisting effect of copper(II) as a metal ion was most striking and specific. The optimum copper(II) concentration was $2.0 \times 10^{-4}M$ for the assay of $4.0–8.0 \times 10^{-5}M$ BPO.

*Calibration graph and reproducibility for BPO.* The calibration graph was linear over the wide range from 0 to 200 $\mu$g (0–$8.0 \times 10^{-5}M$) BPO per 10 ml, and the relative standard deviation (RSD, $n = 6$) was 0.6% for 40 $\mu$g BPO in 75% acetonitrile.

Table 2. Effect of metal ions in the colour reaction between NENA and BPO in 75% acetonitrile solution

| Metal ions | Absorbance at 530 nm |
|---|---|
| None | 0.160 |
| Cu(II) | 1.065 |
| Zn(II) | 0.165 |
| Co(II) | 0.205 |
| Ni(II) | 0.145 |
| Pd(II) | 0.003 |
| Fe(III) | 0.131 |
| Mn(II) | 0.163 |

NENA, $5.0 \times 10^{-3}M$; BPO, 400 $\mu$g; pH, 5.0; reference, water.

Table 3. Colour reaction among NENA, BPO and various organic compounds in 75% acetonitrile solution

| Organic substances | Max (*nm*) | Absorbance |
|---|---|---|
| BPO | 530 | 0.418 |
| *m*-Chloroperbenzoic acid | 397 | 0.045 |
| Lauroyl peroxide | 505 | 0.041 |
| *t*-Butylperbenzoic acid | None | None |
| Cumenhydroperoxide | None | None |
| Hydrogen peroxide | None | None |
| Chloramine B | None | None |
| Potassium bromate | None | None |
| Benzoic acid | None | None |
| Benzoyl chloride | None | None |

Organic substances, $5.0 \times 10^{-5}M$; NENA, $5.0 \times 10^{-3}M$; copper(II), $2.0 \times 10^{-4}M$; pH, 5.0; reaction time and temperature, at 40°C for 40 min; reference, water.

*Colour reaction between NENA and other BPO analogues, and effect of foreign substances.* As shown in Table 3, although the colour reaction between NENA, lauroylperoxide and *m*-chloroperbenzoic acid as an oxidizing agent were also recognized, this colour reaction was only one-tenth that of NENA–BPO. On the other hand, other oxidizing agents such as hydrogen peroxide and chloramine B gave no colour reaction.

In this method, the coexistence of various other organic substances scarcely affected the BPO assay.

*Application.* Although further investigation is necessary for the applications for flour samples, *etc.*, the proposed method was applied to a recovery test of BPO in flour; the results were satisfactory, 96.8–98.4% ($n = 3$).

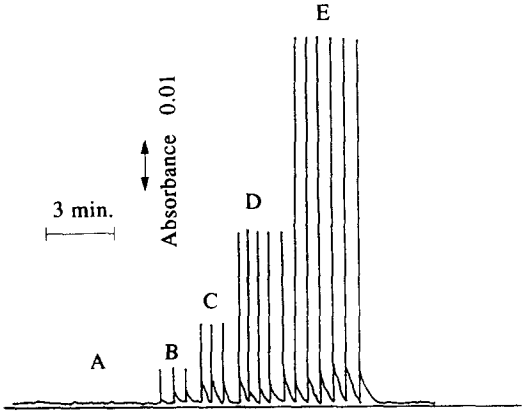

Fig. 2. Calibration peak signal for determination of copper(II) on FIA. Conditions, (NENA–BPO), $5 \times 10^{-4}$ *M*; flow rate of (NENA–BPO) solution 1.6 ml/min; flow rate of buffer solution (pH 5.0) 0.8 ml/min; copper(II) concentrations, A, 0 ng; B, 0.50 ng; C, 0.99 ng; D, 1.99 ng; E, 3.97 ng.

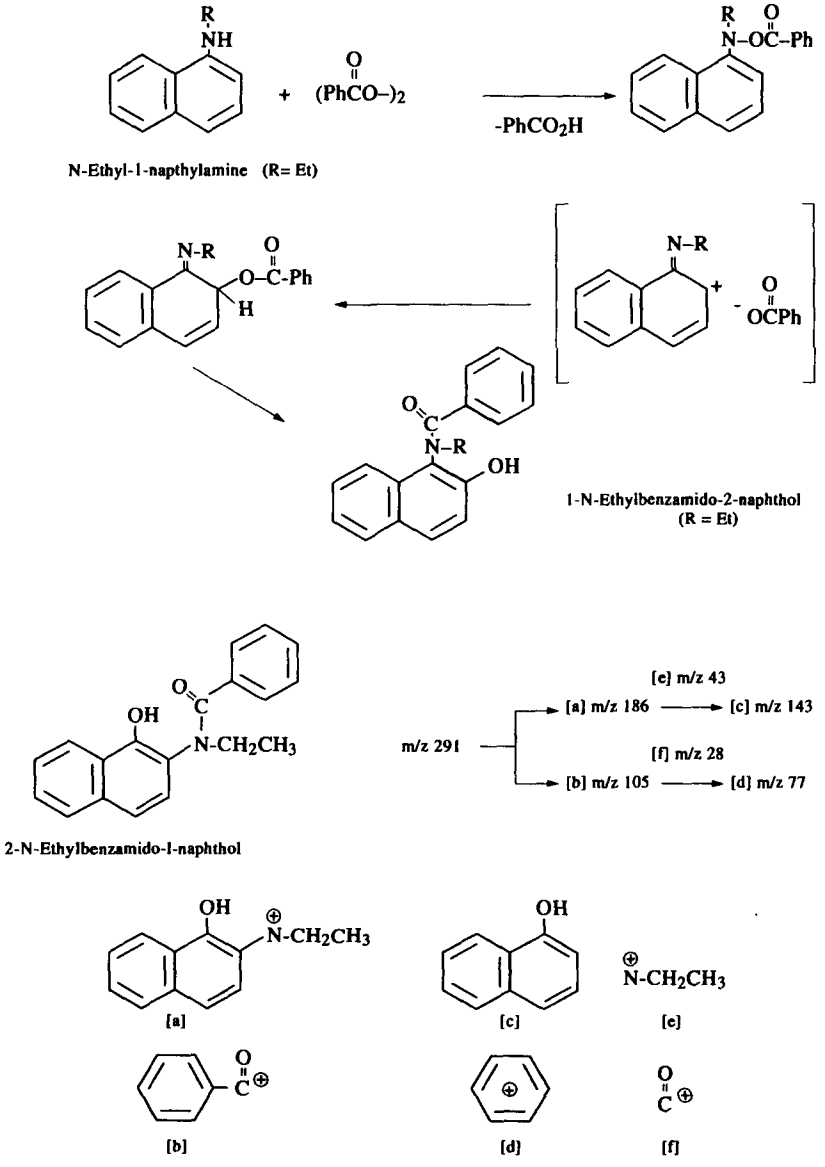
*Reaction between NENA and BPO, and estimation of NENA–BPO*

In previous reports,[10–12] the colour reaction between NENA and BPO was presumed to be *N*-benzolylation and *O*-hydroxylation of NENA; the reaction product (NENA–BPO) was assumed to be 2-*N*-ethylbenzamide-1-naphthol, by the oxidation process shown in Scheme 1. This chemical formula was supported by I mass and $^1$H NMR spectra: $\delta$ 1.17 (3H, *t*, $J = 7.081$ Hz, —$CH_2$—$CH_3$), 3.49 and 4.26 (2H, *dq*, $J = 13.3$, 7.08 Hz, —$CH_2$—$CH_3$), 7.88–8.27 (11H, *m*, arom.H), 8.99 (1H, *br s*, OH).

*Determination of copper*(II)

*(1) Test tube method.* As mentioned above, in the formation of colour reaction product between NENA and BPO in the presence of copper(II), the use of NENA–BPO for measurement was most effective. Accordingly, for the assay of copper(II), NENA–BPO was used.

*Effects of coil length and flow rate.* The peak height lowered and broadened with coil length. Almost constant and reproducible results were obtained with a coil length of 1.5–2.0 m (0.3 mm diameter) and an optimum flow rate of 1.6 ml/min of $5.0 \times 10^{-4} M$



Scheme 1. Reaction between *N*-ethyl-1-naphthylamine and BPO, and mass fragment ions of (NENA–BPO) and (2-*N*-ethylbenzamido-1-naphthol).

Table 4. Effect of foreign ions

| Foreign ions | Added as | Molar ratio | Recovery (%) |
|---|---|---|---|
| None | None | None | 100.0 |
| Fe(III) | Sulphate | 15 | 100.0 |
| Co(II) | Nitrate | 120 | 100.0 |
| Ni(II) | Nitrate | 150 | 100.0 |
| Zn(II) | Chloride | 300 | 100.0 |
| Pb(II) | Nitrate | 1000 | 100.0 |
| Hg(II) | Nitrate | 200 | 100.0 |
| Al(III) | Chloride | 1500 | 100.0 |
| $S_2O_3^{2-}$ | Sodium | 10 | 100.0 |
| | | 100 | 98.0 |
| $F^-$ | Sodium | 20,000 | 100.0 |
| $NO_3^-$ | Potassium | 20,000 | 100.0 |

Copper(II) taken, 0.79 $\mu$g; NENA–BPO, $4.0 \times 10^{-4}M$; pH, 5.0; reaction time and temperature, at 45°C for 40 min; reference, water.

NENA–BPO acetonitrile solution (carrier 1), and 0.8 ml/min of acetic acid–sodium acetate buffer solution (pH 5.0).

*Effects of reaction temperature and concentration of NENA–BPO.* Referring to the above method, the FIA conditions were investigated by changing the flow rate or heating temperature. Optimum and effective temperature and concentration of NENA–BPO solution were respectively 30°C and $5.0 \times 10^{-4}M$ NENA–BPO solution.

*Calibration graph and reproducibility for copper(II) by FIA.* The calibration graph in FIA system showed a good linear relationship over the range 0.5–7.9 ng/5 $\mu$l copper(II) gave a RSD of 1.8% ($n = 5$) (Fig. 2).

*Effect of foreign ions.* The effect of foreign ions was investigated in comparison with the above method. The results were approximately similar to that of the above method.

## CONCLUSIONS

The colour reactions among naphthylamines such as NENA, BPO and various metal ions such as copper(II) were systematically investigated, and a procedure for the assay of BPO was established. By using the selective catalytic action of copper(II) in the colour reaction between NENA and BPO, the selective and sensitive spectrophotometric determination of copper(II) was proposed in 75% acetonitrile. Moreover, the chemical reaction between NENA and BPO (colour reaction) was estimated by $^1$H NMR and mass spectra. The FIA method for the assay of copper(II) was established using the colour reaction of NENA–BPO–copper(II) in 40% acetonitrile solution. The proposed FIA method has the advantages of simplicity, sensitivity and reproducibility; the analytical requirement time was 3 min, and it was little affected by other metal ions.

*Acknowledgements*—The authors would like to thank Mr K. Minoura for NMR measurement, and Mrs M. Fujitake of our University for measurement of mass spectra.

# DECONTAMINATION OF OIL-POLLUTED SOIL BY CLOUD POINT EXTRACTION

GÁBOR KOMÁROMY-HILLER and RAY VON WANDRUSZKA*
Department of Chemistry, University of Idaho, Moscow, ID 83844-2343, U.S.A.

(*Received* 31 *May* 1994. *Revised* 26 *July* 1994. *Accepted* 26 *July* 1994)

**Summary**—An extraction procedure based on cloud point phase separation of nonionic surfactants was used to remove oil contamination from soils. The detergent employed was Triton X-114, and its clouding behavior was monitored by means of a fluorescence probe. Changes in the $I_1/I_3$ ratio of pyrene indicated gradual dehydration of the detergent micelles upon heating. The rate of phase separation, and the volume and water content of the micellar phase were determined. In the practical clean-up, 85–98% of the oil present in the soil was found to enter the micellar phase of the separated washing liquid. A 15-min washing time with 3–5% detergent was found to be sufficient for this degree of contaminant removal from soil containing 0.009–0.017% oil, using a liquid:solid ratio of 5:2. The extraction efficiency decreased with increasing carbon content of the soil. The process holds promise for large-scale treatment of oil-polluted soils.

The solubility of most solutes in water increases with temperature. Aqueous solutions of nonionic surfactants, however, have a lower consolute temperature and become turbid when heated to their characteristic cloud point. At this and higher temperatures, phase separation takes place—the smaller detergent phase contains most of the surfactant and usually sinks to the bottom, while the more voluminous aqueous supernatant has a surfactant content approximately equal to the critical micelle concentration (CMC). Cloud points vary widely among detergents, generally in the range 20°C–90°C.

Clouding is believed to be due to an increase in micellar size and intermicellar attraction.[1-7] It can be explained by the dehydration of the "wet" outer layer of the micelles of nonionic detergents with increasing temperature.[8] The dielectric constant of water decreases rapidly with increasing temperature, making it a poorer solvent for the hydrophilic portion of the detergent molecule.[2] Clouding can be affected by the addition of other substances to the solution of nonionic surfactants. Small amounts of hydrophobic compounds lower the cloud point of detergents by penetrating the micellar interior and thus swelling the micelle. Excessive addition, however, may increase the cloud point.[6,9] Salts can promote or inhibit the dehydration process and therefore either decrease or increase the cloud point. This behavior is believed to be related to the salting-in and salting-out phenomena encountered in protein denaturation.[10,11]

Surfactant clouding has seen limited use in analytical separations.[5,12-19] In most instances, detergents with a polyoxyethylene hydrophilic group, such as the members of the PEO, Brij, and Triton series, were employed. Mostly extractions from aqueous solutions were investigated, but some attempts were made to extract PAHs from solid matrices.[18,19] The goal of the present investigation was to use the extraction capability of nonionic surfactant solutions to clean oil-contaminated soil, and to survey the possibility for large-scale treatment. The impetus for this work was provided by the widely recognized pollution problems presented by leaking underground fuel storage tanks.[20] Hazards and expense associated with large-scale organic solvent extraction, has provided the rationale for exploring this alternative procedure.

Surfactants suitable for decontamination of natural systems should be soluble in water; have a low cloud point (to reduce heating requirement and keep fuel costs low); solubilize pollutants (especially oil); form an easily separable phase; be readily disposable; be

*Author to whom correspondence should be addressed.

inexpensive; have low toxicity; and be biodegradable. So far no single detergent has met all these requirements. However, we have found that Triton X-114 (TX-114), a polyoxyethylene isooctyl-phenyl ether with an average polyoxyethylene chain of eight units, is a promising candidate. It is relatively inexpensive, has low toxicity, and its solutions have a cloud point around 20°C.[13-16] These features and its low volatility make it an attractive extraction medium.

The work described here addresses both the nature of the clouding process and its application to soil decontamination. Pyrene was used as a fluorescent probe to monitor the kinetics and extent of micellar dehydration as the temperature of detergent solutions was slowly increased. For decontamination trials, characterized soil was amended with old engine oil and then washed in a detergent solution. After draining the washing liquid from the soil, cloud point separation was carried out to isolate the contaminant in the detergent phase.

## EXPERIMENTAL

Pyrene (98%) was purchased from Sigma (St Louis, MO, U.S.A.), recrystallized twice from absolute ethanol, and sublimed onto a cold finger. Triton X-114 (Sigma) was used as received. Deionized water, treated with a 0.22-$\mu$m Millipore filter system to 13 M$\Omega$ cm resistivity, was used in all solutions. Pyrene solutions were made by adding an appropriate aliqot of a $5.0 \times 10^{-3}M$ ethanolic solution to a dry 100-ml volumetric flask. The solvent was evaporated, and the residue redissolved in 0.01$M$ TX-114. After sonicating for 3 hr, the flask was filled to the mark, making a $2.0 \times 10^{-6}M$ pyrene solution. It was left to stand overnight before use.

The water content of the micellar phase produced after clouding was determined by drying a known amount to constant weight at $85 \pm 2$°C. Fluorescence measurements were taken with a Perkin–Elmer MPF-66 fluorescence spectrophotometer equipped with a thermostated cell housing. The instrument produces corrected excitation and emission spectra. The solutions were equilibrated at each new temperature level for 10–15 min before measuring the fluorescence intensity. Each data point is the average of three parallel measurements.

Polarity changes in the micellar phase were monitored by means of a fluorescent probe. The variation of the ratio of the first and third emission peaks of the pyrene ($I_1/I_3$) with the polarity of its surroundings is well established.[21,22] It is large ($>1.4$) in polar, and small ($<1.2$) in nonpolar environments. The hydrophobic pyrene molecule is located inside the Triton X micelle, but in close proximity to the phase boundary with the hydrophilic portion.[23-25] We can, therefore, expect that the dehydration of the micelles will change the $I_1/I_3$ ratio of the fluorescent probe.

Two soils, surface collected (0–15 cm), air-dried, and sieved (2 mm), were used in the study: (i) Latahco silt loam, subgroup Argiaquic Xeric Argialboll, pH 6.1, with the following composition (g/kg): organic carbon 41.0; total carbon 41.0; total nitrogen 3.9; clay 159; sand 122; (ii) Portneuf silt loam, subgroup Durixerollic Calciorthid, pH 7.3, with the following composition (g/kg): total carbon 15.6; total nitrogen 1.7; clay 157; sand 48. Soils (10-g samples) were amended with old engine oil by diluting 0.20, 0.40, 1.00 ml aliquots of a stock solution (0.44111 g/ml oil in $CH_2Cl_2$) to 10 ml with methylene chloride, introducing the soil into this solution of the oil, and evaporating the solvent. In the washing procedure, the contaminated soil was agitated for 15 min with the detergent solution by means of a mechanical shaker. The washing liquid was then separated from the soil by centrifugation at 5000 rpm for 20 min, and the volume of the supernatant was adjusted to 25.0 ml with surfactant solution. Phase separation was carried out above the cloud point (at $50 \pm 1$°C), and the solution was kept at this temperature for 2 hr. The separated micellar phase was run off using a separatory funnel and adjusted to 5.0 or 10.0 ml. Standards were made from the stock solution by evaporating the solvent and redissolving the oil in the surfactant solution.

The oil contents of the washing liquid and the micellar phase were determined by thin-layer chromatography using silica plates and a Programmed Multiple Development instrument (Regis Chemical Company). In a typical separation run, eight to 10 development/heating cycles were used, operating in the linear mode. The usual procedure involved an initial development time of 90 sec, extending to 2.5 min in the last cycle, with each elution followed by a 30-sec drying period. The eluent was a 5:3 mixture of hexanes (Fisher Scientific, Class 1B) and absolute ethanol (Midwest Grain Products Co.). The separated oil spots of samples and standards

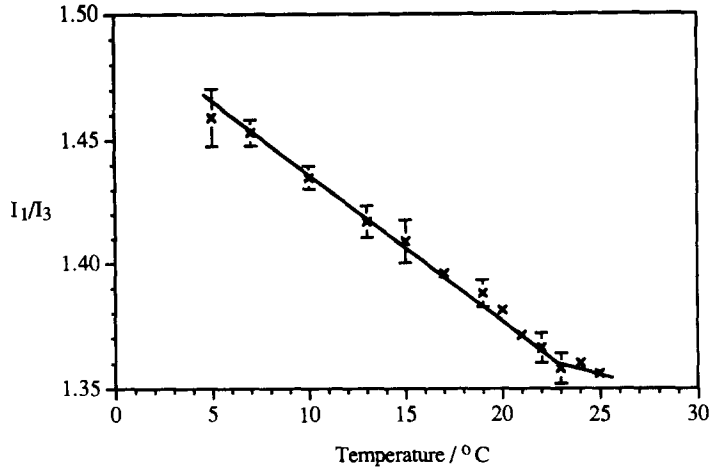

Fig. 1. $I_1/I_3$ ratio of $2.0 \times 10^{-6}M$ pyrene *vs.* temperature in $0.01M$ Triton X-114. Excitation wavelength 336 nm.

were quantified using a polychromatic TLC densitometer (Hoefer Scientific Laboratory). This method was found to give results superior to those obtained with other chromatographic methods, since soil components such as humic materials and mineral colloids did not interfere. All measurements were carried out in duplicate.

## RESULTS AND DISCUSSION

Dong and Winnik[22] have published the Py scale of solvent polarities, based on the ratio of the first and third vibronic band ratio of the pyrene emission ($I_1/I_3$). In our present work with $2.0 \times 10^{-6}M$ pyrene in $0.01M$ TX-114, this parameter showed the polarity of the probe environment at 5°C to be equal to that of 1,2-dichloroethane (1.46). An increase of the temperature to 25°C decreased this polarity to the value of 1,5-pentanediol (1.36). This indicates that the probe molecule, which is known to be located near the hydrated outer layer of the micelle,[23–25] experienced decreasing polarity with increasing temperature. As shown in Fig. 1, the $I_1/I_3$ decrease with temperature was relatively smooth and lacked abrupt changes, suggesting a gradual dehydration process leading up to the cloud point. A similar $I_1/I_3$ change was found when the system was cooled down, indicating that the dehydration and hydration of the polyoxyethylene chains is completely reversible and does not suffer a hysteresis effect.

After the cloud point had been reached, the rate of formation of a separate detergent phase (lower layer) was found to depend on the temperature and the detergent concentration in

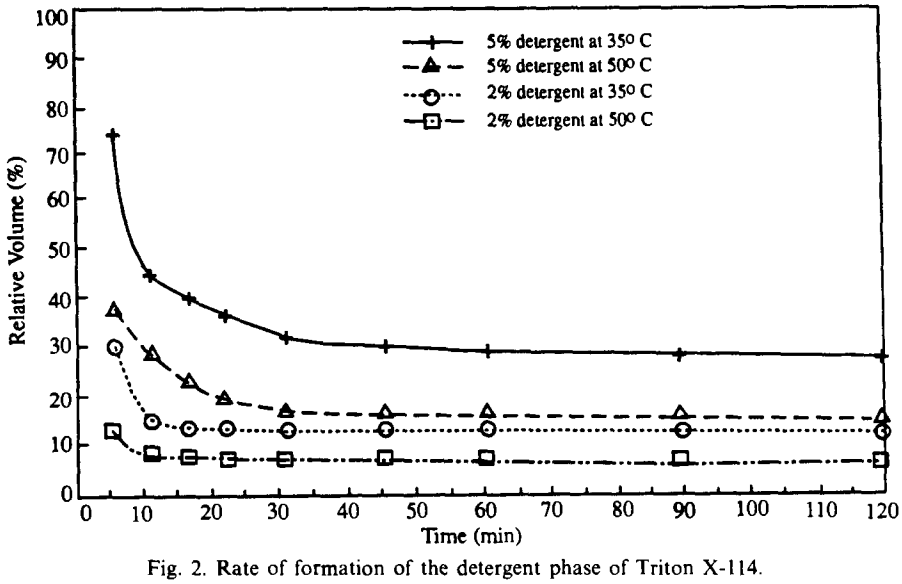

Fig. 2. Rate of formation of the detergent phase of Triton X-114.

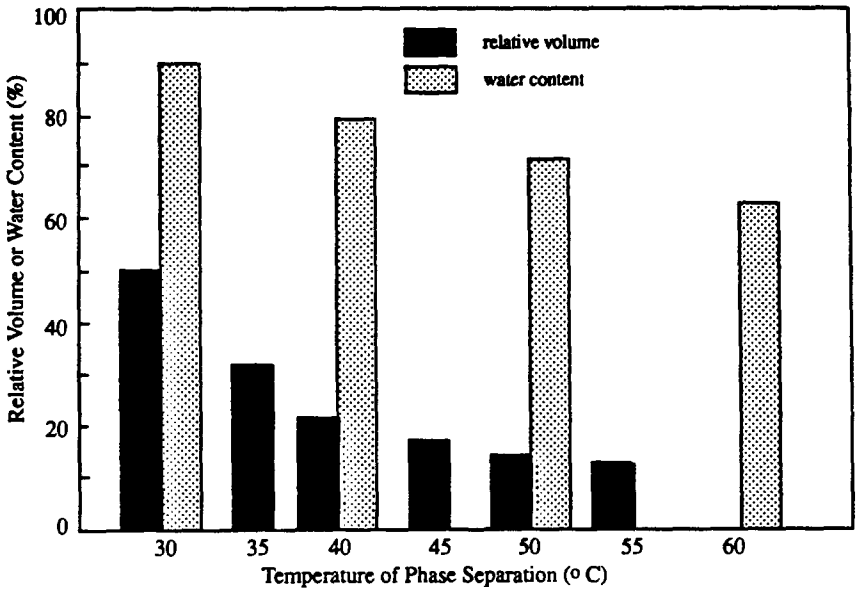

Fig. 3. Relative volume and water content of the detergent phase of 5% Triton X-114 separated at different temperatures. Separation time: 4 hr.

the original aqueous solution. Figure 2 shows the progression of this phase separation. When the detergent-rich layer first became distinct, it had a relatively large volume and water content. As it matured, it shrank through dehydration, reaching a final volume after about 20 min. This was observed by other authors,[13] and seems to be a general trend. The volume decreased with increasing temperature in an exponential fashion (Fig. 3), while the decrease in water content was linear. The water content of the detergent phase was found to be 64% when the phase separation was carried out at 60°C. For practical applications, a small detergent phase would be preferable (*vide infra*), since this minimizes disposal problems. It could be obtained by using low detergent concentrations and high temperatures. At this juncture, both the minimum detergent concentration and the maximum temperature need to be established empirically, depending on the oil concentration in the polluted soil and the admissible energy cost, respectively.

*Treatment of polluted soil*

The effect of agitation time on extraction efficiency of oil from soil is shown in Table 1. With samples of the size indicated, a washing time of approximately 15 min was required. Extending the washing time to 30 min did not significantly improve the extraction efficiency.

The extraction efficiency was found to depend on detergent concentration, washing liquid volume, and oil concentration in the soil (Table 2). As this concentration was increased, the efficiencies of both the extraction into the washing liquid, and the oil migration from the aqueous phase to the detergent phase, decreased. This effect can be ascribed to the detergency of the washing solution—sufficient micelles must be present to solubilize all the oil. To treat soil with high oil concentrations, higher detergent concentrations and/or washing solution volumes must be used (Table 2). With 8900 ppm oil, a 3% Triton X-114 concentration was found to be effective, but at higher oil contamination 5% Triton X-114 was required. With all oil concentrations used (8900–44,300 ppm), a 25 ml volume of washing liquid extracted significantly more oil from 10 g of soil than a 15 ml volume. This suggests that a liquid:solid ratio of 5:2 (w/w) is called for. The organic carbon content of polluted soil did not significantly affect the extraction of oil, but it did have a slightly detrimental effect on the migration of pollutant to the detergent phase (Table 3). Although it is known that surfactant

will be lost due to adsorption to the soil,[19] no attempt was made to quantify this factor in our extraction.

A qualitative study was carried out with uncharacterized soil from a local tanker transfer site which had been subjected to oil spillage for about 40 years. The soil contained approximately 5% (w/w) of weathered oil and showed evidence of extensive pollution by polymerized and oxidized breakdown products. It appeared dark in color, heavily clumped, and of characteristic odor. Treatment with 5% detergent as described above removed these symptoms. The resulting soil was free-flowing, light in colour, and without odor. The age and complexity of the samples precluded quantitative determination of the decontamination efficiency.

## CONCLUSIONS

Cloud point extraction offers an interesting possibility for decontamination of oil-polluted soil. The process is not, as may be expected, unduly impeded by co-extraction of organic matter present in the soil. Likewise, colloidal materials do not appear to constitute a serious problem. The possibility for upscaling to bulk dimensions in which tons of soil can be treated is, therefore, promising. Under no circumstances can a process of this nature be "cheap", but the aqueous character of the washing liquid should make it considerably less expensive than a comparable organic extraction. The low volatility, toxicity, and high biodegradability[26] of the materials are also noted advantages. The detergent phase separated in the clouding process is combustible, despite its relatively high water content. This makes disposal by incineration possible, a process that can be facilitated by the addition of small amounts of low grade ethanol or acetone.[12] The aqueous bulk left after phase separation lends itself to re-use after addition of more detergent. The application of the procedure to other soils and to large-scale pollution remediation is presently under investigation in this laboratory.

# REVERSED-PHASE HPLC DETERMINATION OF Co(II), Ni(II) AND Fe(III) AS THEIR 2-(2-THIAZOLYLAZO)-5-DIMETHYLAMINOPHENOL CHELATES

LI LING YING,* GUI MING-DE and ZHAO YA-QIU
Department of Chemistry, Nankai University, Tianjin, 300071, China

(*Received* 13 *July* 1992. *Revised* 11 *July* 1994. *Accepted* 22 *July* 1994)

**Summary**—The optimum chromatographic separation conditions for Co(II), Ni(II), and Fe(III) chelates with 2-(2-thiazolylazo)-5-dimethylaminophenol (TAM) were investigated. The compositions of chelates were also determined by the HPLC method and thus the possible structure of chelates was given. A precolumn derivatization method was used, followed by separation on an octyl-bonded silica stationary phase with a methanol–tetrahydrofuran–water (40:9:51, v/v/v) mobile phase containing pH 5.8 acetate buffer and $1 \times 10^{-4}M$ TAM. The detection limits of Co(II), Ni(II), and Fe(III) at 560 nm are 0.03, 0.02 and 0.1 ng ($S/N = 2$), respectively. They can be determined by means of the proposed method without interference from other common metal ions and have been determined in five standard alloys with satisfactory results.

The development of HPLC for inorganic compounds has increased rapidly in recent years, because it is not only a sensitive but also a selective and rapid method for separation and determination of metal ions. Many organic chelating reagents have been used widely in HPLC, such as PAN,[1] PAR,[2] dithiocarbamate,[3] $\beta$-diketones,[4] dithizone,[5] 8-hydroxy quinoline,[6] porphyrin,[7] *etc.* However, the use of thiazolylazo reagents is seldom reported in HPLC separations.[8]

2-(2-thiazolylazo)-5-Dimethylaminophenal (TAM) is one of the sensitive reagents used in the spectrophotometric determination of metal ions,[9–12] but its selectivity is very poor. If its chelates can be separated and detected spectrophotometrically by means of HPLC, the reagent would give a highly sensitive and selective HPLC method for the simultaneous determination of some metal ions. We described here the first use of TAM as the chelating reagent in HPLC, and successfully separate the TAM chelates of Co(II), Ni(II), and Fe(III). Among foreign metal ions, only Cu(II) interferes with the determination of Ni(II). By passing $H_2S$ in $0.3M$ HCl to precipitate Cu(II) as CuS, the interference can be avoided.

This method compares to other reverse-phase HPLC by precolum chelating with the similar reagent PAR[2] or 5-Br-PADAP[14] for the separation and determination of heavy metals. This approach has the advantages of high sensitivity (*i.e.* low detection limits), good resolution in a short analytical time and good column efficiency.

## EXPERIMENTAL

### *Apparatus*

LC-4A HPLC equipment (Shimadzu, Japan) was used with a Zorbax-C8 column (5 $\mu$m particle, 150 × 4.6 mm) and an SPD-1 UV-VIS detector. A R-112M registor, C-RIB data processing system, UV-240 type UV-VIS spectrophotometer (Shimadzu, Japan) were used. Stock solutions of Co(II), Ni(II) and Fe(III) in $1M$ $HNO_3$ were prepared from their pure metals (99.99%). A $1 \times 10^{-3}M$ TAM (ICN Pharmaceuticals, U.S.A.) solution was prepared in absolute methanol. The mobile phase was a 40:9:51 (v/v/v methanol–tetrahydrofuran–water ($CH_3OH$–THF–$H_2O$) mixture containing $1 \times 10^{-4}M$ TAM and $0.05M$ acetate buffer (pH 5.8). All reagents used were of A.R. grade. Double-distilled water was used for all solution preparation.

*Author to whom correspondence should be addressed.

*Procedure*

A 3.0 ml portion of 0.05*M* acetate buffer (pH 5.8) and 3.0 ml of $1 \times 10^{-3}M$ TAM solution were mixed with a known volume of the sample solution containing Co(II), Ni(II) and Fe(III), and the mixture was diluted to 10.0 ml with absolute methanol, allowed to stand for 20 min and filtered through a 0.45-$\mu$m filter membrane. For the HPLC analysis, the Zorbax-C8 column was first equilibrated with the mobile phase. A 20-$\mu$l aliquot of the prepared test solution was injected onto the column and the complexes were eluted at a flow-rate of 1.0 ml/min. The peak areas were measured at the detection wavelength of 560 nm.

## RESULTS AND DISCUSSION

*Precolumn derivatization conditions and detection wavelength*

We found by experiment that Co(II), Ni(II) and Fe(III) can be complexed with TAM at pH 4.8–6.1 in 0.05*M* acetate buffer. AT room temperature, all three complexes form rapidly and are stable for 24 hr. The concentration of TAM should be greater than $4.5 \times 10^{-4}M$ for a solution containing 10 $\mu$g/10 ml of each of Co(II), Ni(II) and Fe(III). The wavelengths of the absorption maxma of the CO, Ni and Fe complexes range from 558 to 570 nm (Co 570, Ni 558 and Fe 560 nm). A wavelength of 560 nm was chosen for the determination.

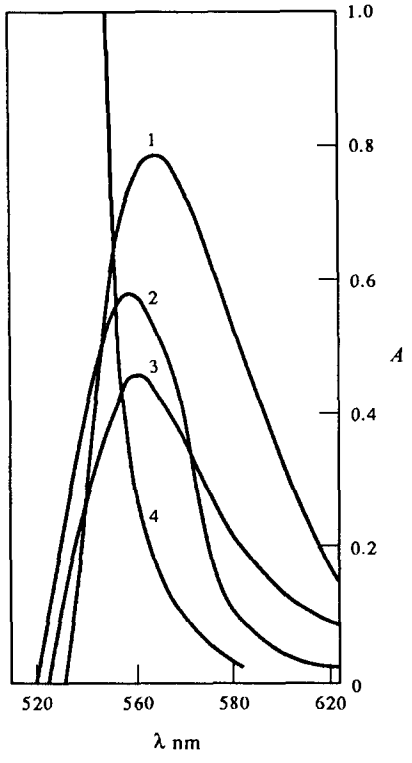

Fig. 1. Absorption spectra: (1) 5.9 $\mu$g/10 ml Co(II) with $3 \times 10^{-4}M$ TAM; (2) 5.8 $\mu$g/10 ml Ni(II) with $3 \times 10^{-4}M$ TAM; (3) 5.6 $\mu$g/10 ml Fe(III) with $3 \times 10^{-4}M$ TAM; (4) $3 \times 10^{-4}M$ TAM. Spectra 1–3 measured *vs.* reagent blank, spectrum 4 measured *vs.* water blank.

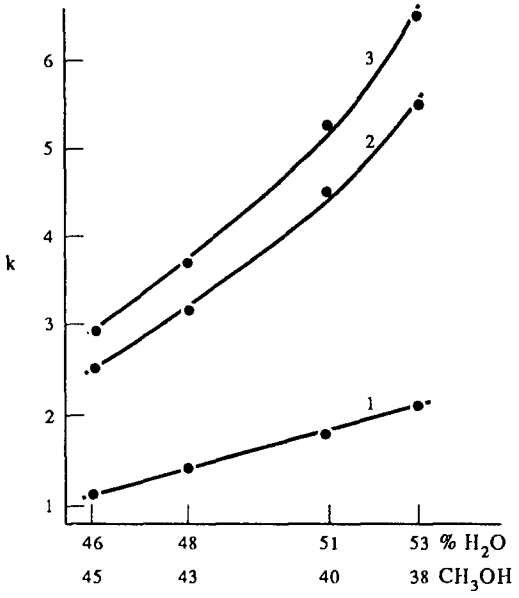

Fig. 2. Effect of the ratio of methanol to water on $K'$ (THF was fixed at 9%). (1) Co–TAM, (2) Ni–TAM, (3) Fe–TAM, pH 5.8 buffer, $1 \times 10^{-4}M$ TAM, concentration of Co(II), Ni(II) and Fe(III) = 10 $\mu$g/10 ml.

*Selection of mobile phase*

The effects of methanol–water, tetrahydrofuran–water and acetonitrile–water used as the mobile phase on the separation of Co, Ni and Fe were investigated. It was found that $CH_3OH$–THF–$H_2O$ was the most suitable mobile phase. To prevent the three complexes from decomposing on the column, the mobile phase had to contain 0.05*M* acetate buffer (pH 5.8) and at least $1 \times 10^{-4}M$ TAM ($1–2 \times 10^{-4}M$ was suitable), otherwise no peak emerged. If there was no excess of TAM in the mobile phase during the elution process, the complex formation equilibrium would shift to the left, and complexes with low stability would decompose. In order to determine the optimum ratio of the three components in the elution for separation, the composition of THF was fixed at 9% and the ratio of methanol to water was varied as shown in Fig. 2. When the ratio of methanol to water was 40:51, *i.e.* the ratio of $CH_3OH$:THF:$H_2O$ was 40:9:51, Co, Ni and Fe complexes were well separated in the least time.

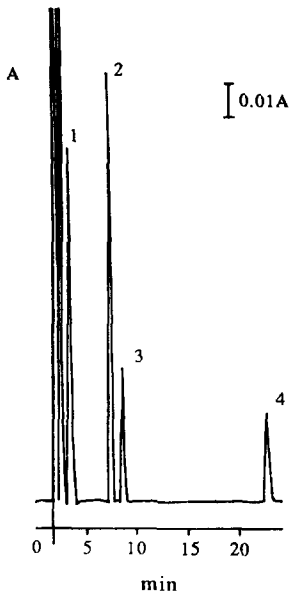

Fig. 3. Separation of Co, Ni and Fe TAM complexes by HPLC. $CH_3OH:THF:H_2O = 40:9:51$ (v/v/v), 0.05*M* pH 5.8 buffer, $1 \times 10^{-4}M$ TAM, concentration of Co, Ni and Fe = 10 μg/10 ml. (1) Co–TAM, (2) Ni–TAM, (3) Fe–TAM, (4) TAM.

*Separation of the* Co, Ni *and* Fe *complexes*

This procedure gave excellent resolution with sharp and symmetrical peaks of the Co, Ni and Fe complexes as shown in Fig. 3. The retention times ($t_R$) were 3.3, 7.3, 8.5, and 22.5 min for TAM, respectively. Linear calibration plots were obtained for Co, Ni and Fe in the ranges of 0–2.0, 0–2.0 and 0–4.0 μg/ml, respectively. Their linear regression equations were as follows:

$$y_{Co} = 0.0946x - 0.004$$

$$y_{Ni} = 0.1180x - 0.0038$$

$$y_{Fe} = 0.0320x - 0.0007.$$

Their regression coefficients were 0.9989, 0.9990 and 0.9995, respectively. The detection limits were 0.03, 0.02 and 0.1 ng ($S/N = 2$) for Co(II), Ni(II) Fe(III), respectively.

Table 1. Effect of foreign ions

| Foreign ions added | Amount of foreign ions tolerated (μg) |
|---|---|
| Al(III), Ca(II), Cd(II), Cr(VI), Ga(III), Hg(II), Mn(II), Pb(II), V(V), W(VI), Ti(IV), Zn(II) | 200 |
| Fe(II), Pd(II) | 100 |
| Cu(II) | 100 [for Co(II)]<br>20 [for Ni(II)]<br>100 [for Fe(III)] |

The effective column efficiency expressed by the number of theoretical plates *N* was calculated for each complex. Using an unretained $KNO_3$ solution, we found that $t_0 = 1.32$ min. According to the formula $N = 5.54 \times ((t_R - t_0)/W_{1/2})^2$ and the chart rate = 2 mm/min, we obtained:

$$N_{eff} = 1595 \text{ for Co–TAM}$$

$$N_{eff} = 17576 \text{ for Ni–TAM}$$

$$N_{eff} = 21309 \text{ for Fe–TAM.}$$

*Effect of foreign ions*

The potential interference of numerous ions was examined by the determination of 10 μg of Co, Ni or Fe in the presence of each foreign ion. The amounts (μg) found to be tolerable (±5% error) as given in Table 1. In fact, all of the foreign ions in Table 1 except Cu(II) did not give a peak at 560 nm, but they consumed the TAM reagent. Their interference can thus be prevented by using excess TAM. Cu(II) interference can be eliminated by passing $H_2S$ into the test solution in advance. Thus only one ion actually interferes with the separation, *i.e.* Cu(II). The $t_R$ of the Cu(II)–TAM complex was 5.6 min, so that the peak of the Cu complex overlaps the peak of the Ni complex.

The use of HPLC to determine the composition of metal complexes has been reported.[13] First, the different TAM peak areas were obtained from different concentrations of TAM

Table 2. Determination of compositions of Co, Ni, and Fe TAM complexes

| Metal ions | Moles of metal ions | Moles of TAM consumed | Mole ratio of metal ion to TAM | Average of mole ratio |
|---|---|---|---|---|
| Co(II) | $3.4 \times 10^{-8}$ | $6.8 \times 10^{-8}$ | 1:2.0 | 1:2 |
| | $3.4 \times 10^{-8}$ | $6.8 \times 10^{-8}$ | 1:2.0 | |
| Ni(II) | $3.4 \times 10^{-8}$ | $6.8 \times 10^{-8}$ | 1:2.0 | 1:2 |
| | $3.4 \times 10^{-8}$ | $6.8 \times 10^{-8}$ | 1:2.0 | |
| Fe(III) | $4.0 \times 10^{-8}$ | $7.9 \times 10^{-8}$ | 1:1.98 | 1:2 |
| | $4.0 \times 10^{-8}$ | $8.0 \times 10^{-8}$ | 1:2.0 | |

Table 3. Results of alloy sample analyses

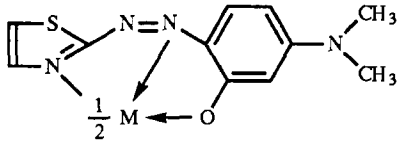
| BY1912-1 | — | 1.00 | 0.17 | 1.00 | — | 1.00 | 1.00 | 0.98 | 1.16 | 100.0 | 98.0 | 99.1 |

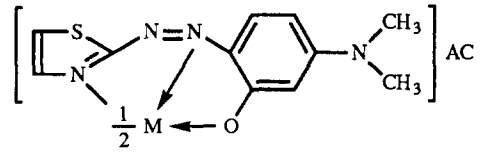
reagent under chromatographic conditions and a plot of TAM peak area *vs.* the concentration of TAM was made. Then a fixed amount of Co(II) or Ni(II) or Fe(III) was mixed with excess amounts of TAM solution, the peak area of the TAM which did not react with Co(II) was measured, and converted to its corresponding concentration from the calibration plot. From these measurements the number of moles of TAM consumed by Co(II) and the mole ratio of Co(II) to TAM could be calculated as shown in Table 2.

The mole ratios of metal ions to TAM in the three complexes were determinated spectrophotometrically by the Job method and the mole ratio method. Results were entirely coincident with those from the above HPLC method.

According to the mole ratios of Co, Ni and Fe to TAM, Co(II) and Ni(II) combine TAM to form a neutral complex, and Fe(III) forms a cation complex first, which then associates with $Ac^-$ to form a neutral association complex. The structures of the three complexes were assumed as follows:



M = Co, Ni



M = Fe

*Analyses of some standard samples*

All the alloy samples used have standard values. They were prepared by the China Steel and Iron Research Institute.

Alloy steel 4j32 (3.32% Co, 33.66% Ni, 0.39% Cu, 62.40% Fe, *etc.*), Cr–Ni–Mn steel 224 (0.031% Cu, 4.86% Ni, 71.40% Fe, etc.), alloy steel 167-2 (0.077% Ni, 0.035% Cu, 99.74% Fe, *etc.*), and low alloy steel BH1311-1A (0.045% Ni, 0.14% Cu, 97.3% Fe, *etc.*) were separately dissolved in 5% $H_2SO_4$, oxidized with 37.5% $HNO_3$ and the excess of $HNO_3$ removed by heating. The solution was transferred to a 100 ml volumetric flask and diluted to the mark with water.

Al–Cu alloy BY1912-1 (57.66% Cu, 3.46% Al, 2.50% Ni, 0.43% Fe, *etc.*) was dissolved in aqua regia, and $HNO_3$ removed by evaporation. The solution was transferred to a 250 ml volumetric flask and diluted to the mark with water. An aliquot of solution was taken to remove Cu(II) by precipitating with $H_2S$ in 0.3*M* HCl, and the precipitate was filtered.

The test solution prepared, following the experimental procedure, were used to determine Co(II), Ni(II), and Fe(III), respectively. Results are shown in Table 3.

# SYNERGIC SOLVENT EXTRACTION STUDIES OF GADOLINIUM USING A COMBINATION OF THE DI(2-ETHYLHEXYL)PHOSPHORIC ACID AND THREE ADDUCTANTS INTO KEROSINE/CHLOROFORM

YOSHITAKA MASUDA* and MD. HASAN ZAHIR

Division of Science of Materials, The Graduate School of Science and Technology, Kobe University, Rokkodai Nada-ku, Kobe 657, Japan

(*Received* 2 *May* 1994. *Revised* 2 *August* 1994. *Accepted* 4 *August* 1994)

**Summary**—The equilibrium extraction behaviour of Gd(III) using a chloroform/kerosine solution containing di(2-ethylhexyl)phosphoric acid (HDEHP), either alone or combined with one of three adductants, 1,10-phenanthroline monohydrate (phen), α,α′-dipyridyl(2,2′-bipyridine) (bipy) or trioctylphosphine oxide (TOPO) is described. The enhancement of the extraction by addition of such neutral adductants is explained in terms of adduct formation of the metal chelate in the organic phase. Among the three synergistic mixtures, 1,10-phenanthroline is the most promising for the extraction of the last member of light lanthanoids, gadolinium. Gadolinium ions are found to be extracted in the absence of phen, bipy or TOPO; the species was $M(HA_2)_3$ but $M(HA_2)_3(phen)_2$ was found when phen was added and $M(HA_2)_3(bipy)$, $M(HA_2)_3(bipy)_2$ was found when bipy was added and $M(HA_2)_3(TOPO)$ was found when TOPO was added. The compositions of the extracted species are obtained from the slope analysis method. $pH_{1/2}$ values were also obtained. The stoichiometry, extraction constants and stability constants of these systems were determined. Synergistic extraction can be carried out at lower pH.

Solvent extraction undoubtedly represents the best of all the various separation techniques because of its simplicity, rapidity, applicability to various concentration ranges and purity of products.[1] Moreover, in synergistic system the extracting power of the mixture exceeds the sum of the extracting powers of its components. This phenomenon of greatly enhanced extraction or synergism owing to a mixture of extractants has attracted considerable attention in recent years. HDEHP is well-known as a powerful extractant, particularly for the 'hard' metal ions such as lanthanides and alkaline earth metals. Numerous studies of its extractant properties with various metal ions are reported in the literature.[2–4]

Handley examined HDEHPDT [di-(2-ethylhexyl)phosphorodithioic acid] as a metal extractant. According to his results, americium and europium could be extracted into dodecane fairly well with HDEHPDT.[5,6] That a 'hard' metal such as $Eu^{3+}$ can be extracted with a 'soft' ligand such as (DEHPDT), was reminiscent of our findings that a nitrogen ligand such as phen seemed to bond with lanthanide chelates at least as readily as with the hydrated lanthanide ions. TOPO is a monodentate phosphine oxide ligand whose basicity is strong enough to form stable adducts with metal chelates.[7] Recently, Komatsu and Freiser have reported extensive investigations on solvent extraction of tervalent lanthanide (Ln) metal ions with mixed ligands. They described the adduct formation of La(III), Pr(III), Eu(III), Ho(III) and Yb(III) with bis(2,4,4-trimethylpentyl) phosphinic acid (HBTMPP) and TOPO, octyl(phenyl)-*N*,*N*-diisosbutylcarbamoylmethyl phosphine oxide (CMPO) or methylenebis(diphenylphosphine) oxide (MBDPO) into chloroform.[8] The solvent extraction of several divalent metal ions with benzoyltrifluoroacetone into chloroform in the presence of tetrabutylammonium and 2-thenoyltrifluoroacetone ions has been studied in detail.[9] In this paper it was observed that the number of the auxiliary reagent molecules ($n$) that attach to the extracted species in time of adduct formation could be evaluated by a $\log D/D_0$ *vs.* log[adductant] plot analysis.

*Author to whom correspondence should be addressed.

Suzuki *et al.*[10] also examined the number of the auxiliary reagent molecules ($n$) by the above slope analysis.

In the present work it was observed that the synergic effect in extraction increases with increasing basicity of the adduct formation, *i.e.* in the order phen > bipy > TOPO. Oxygen bases such as TOPO, a monodentate phosphine oxide ligand are not strongly effective adductants for metal chelates extracted at the low pH ranges, being characteristic of the cation extractants. Instead, the nitrogen bases 1,10-phenanthroline, which have high proton affinity, are appropriate auxiliary ligands. At low pH ranges one molecule of bipy is included in the extracted species. This work gives fundamental information about the adduct formation affinity and enhancement of extraction rate. The role of diluent was also observed for the evaluation of the association constant.

## EXPERIMENTAL

### *Apparatus*

Extraction was done in a Taiyo M incubator at 25 ± 0.1°C. Ultraviolet and visible absorption spectra were measured with a Shimadzu self-recording spectrophotometer (model 240-UV-Vis) with 10 mm optical path glass cells. The pH of an aqueous phase was measured with a Hitachi Horiba M-7II pH-meter. A Kokusan H-200 centrifuge was used for rapid and complete separation of the phases.

### *Materials*

A standard solution of gadolinium nitrate $1 \times 10^{-2}M$ was prepared by dissolution of a suitable amount of the pure oxide (99.99%) (Santoku Chemicals Ltd) in a small volume of concentrated nitric acid, followed by dilution with distilled water. The solution was then heated in order to remove any excess acid. The solution was diluted to 100 ml with distilled water and the concentration, determined as $1 \times 10^{-3}M$. The solution was standardized complexometrically at pH 5.1–5.6 with Xylenol Orange as the indicator.[11] The prepared solution was then stored in a polyethylene bottle.

### *Preparation of di(2-ethylhexyl)phosphoric acid stock solution*

For the preparation of the stock solution of HDEHP, 348 $cm^3$ of chemically pure HDEHP (DP-8R Daihachi Chemicals Ltd) was taken in a clean 1 $dm^3$ volumetric flask and was made up to the mark with chloroform/kerosine so that the solution was 1$M$. This solution was washed three times with 500 $cm^3$ of 6$M$ HCl and three times with 500 $cm^3$ distilled water, after which the solution was left overnight. Since water is slightly soluble in HDEHP, the final HDEHP contains a small amount (1–2%) of water which may be removed using a rotating evaporator at 50°C and 15 mm Hg pressure. A 0.01$M$ phen, bipy, TOPO solution was prepared by dissolving 1.9823 g 1,10-phenanthroline monohydrate, 0.3867 g trioctyl phosphin oxide and 0.156 g 2,2′-bipyridine (Nakarai Chemicals Ltd) in chloroform and diluting it to 100 ml with the same solvent. A 0.001$M$ arsenazoIII solution was prepared by dissolving 0.0776 g of the reagent (Dojin Chemicals Ltd) in 100 ml of distilled water. This solution was freshly prepared each week. Chloroform was used after distillation. All other chemicals used were of analytical grade.

### *pH determination*

The pH was adjusted with hydrochloric acid or sodium hydroxide solution. After equilibration of the two phases the pH was measured precisely in the aqueous solution with a glass electrode pH-meter. Before taking each reading, the pH-meter was standardized by using standard buffers having pH nearly equal to the test solutions. After standardization of the pH-meter, the electrodes were rinsed with distilled water, the residual water present on the surfaces of the electrode was removed by a filter paper. It was then placed in the test solution and kept in such a way for at least 2 min before taking the reading. Higher pH values could not be used as the equilibration led to turbid aqueous solutions probably owing to microemulsion formation that did not clear up even after centrifugation or on prolonged standing. The pH of the aqueous phase was adjusted by the addition of succinic buffer ($2 \times 10^{-3}M$) in conjunction with HCl for lower pH values.

## RESULTS AND DISCUSSION

### *Dependence of extraction on shaking time to reach equilibrium*

The variation of extraction with shaking time was studied at pH 3.5. The data obtained from the shaking time study of gadolinium(III) is plotted in Fig. 1. Figure 1 shows that more than 7 min is required to reach the equilibrium for the Gd(III) under the experimental conditions

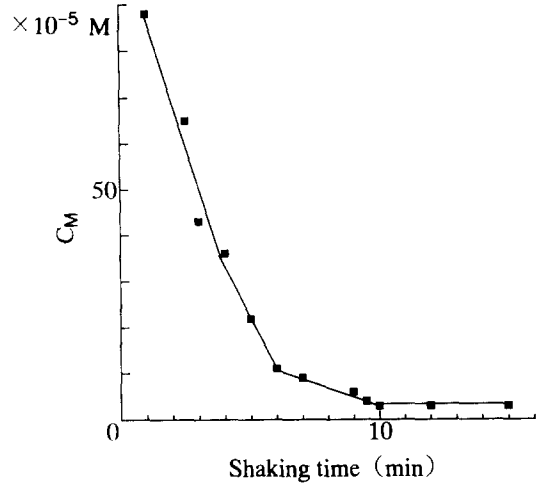

Fig. 1. Determination of the time required to reach equilibrium. Aqueous phase: $[Gd^{3+}] = 1 \times 10^{-4}M$; succinic acid $2 \times 10^{-3}M$. Organic phase: $[(HX)_2] = 2 \times 10^{-3}M$ and $2 \times 10^{-3}M$ phen into $CHCl_3$. Concentration of metal ions in the aqueous phase after extraction as ordinates have been plotted graphically.

stated, at which the $C_M$ *vs.* time plot becomes horizontal, indicating there will be no transfer of Gd(III) from the aqueous phase to organic phase on further shaking.

*Liquid–liquid extraction of metal ions*

The distribution experiments were done at room temperature. An aliquot (10 ml) of the aqueous solution containing the metal ion $1 \times 10^{-4}M$ was taken in a stoppered 50 ml glass tube and that of succinic acid as buffer was $2.00 \times 10^{-3}M$. The ionic strength of the aqueous phase was controlled at $0.1M$ with sodium perchlorate and the extraction was made with HDEHP in the absence of adductants. The extraction of gadolinium–HDEHP alone and with adductants was done in the absence of perchlorate. After the addition of 10 ml of synergistic mixture containing the extractant solution $2 \times 10^{-3}M$ and neutral adductant solution $2 \times 10^{-3}M$ the mixture was shaken for 10 min at 200 strokes/min at $25 \pm 0.1$°C, which was sufficient for equilibration. The mixture was then centrifuged at 2000 r.p.m. for 5 min, the pH of the aqueous phase was measured. The metal content in the aqueous phase was determined spectrophotometrically by the arsenazo III method[12] as was the concentration of gadolinium in the organic phase following back extraction into hydrochloric acid. The concentration of metal ion in the organic phase was determined after back extraction into $6M$ hydrochloric acid for 30 min, 5 ml of strip liquor thus obtained was transferred to a separatory funnel and washed once with 5 ml of pure chloroform to remove the free ligand completely, then the strip liquor was allowed to evaporate. The residue was decomposed and diluted after that the pH was adjusted with 2.5. The solution was transferred into a 10 ml volumetric flask, 0.5 ml of the arsenazo III solution was added and made up to the mark with distilled water. The absorbance was measured at 650 nm. Neither the extractant nor it's complexes in chloroform showed appreciable absorption in the visible region and hence arsenazo III was used in the dual role of calorimetric reagent and scavenger for gadolinium.

*Stripping test*

Stripping tests were carried out with various mineral acids, *viz.* hydrochloric acid, sulphuric acid and nitric acid. The relations between acid concentration and recovery(%) of metal ion are listed in Table 1. These results show that hydrochloric acid with concentrations higher than $4M$ was found to be effective for stripping, while sulphuric acid did not appear to be suitable. Hydrochloric acid was suitable for almost complete stripping.

*Effect of HDEHP concentration*

The effect of HDEHP concentration on the absorbance was studied. This experiment was done in the presence of TOPO, bipy or phen $2 \times 10^{-3}M$, respectively. The effect of neutral adductant concentration on the extraction was also studied. The recommended amount is $2 \times 10^{-3}M$ as shown in Fig. 2.

*Effect of pH on gadolinium(III) extraction systems containing HDEHP and adductant into chloroform/kerosine*

The effective extraction of gadolinium with HDEHP in the presence of phen, bipy or TOPO occurs at the pH of the aqueous phase ranging

Table 1. Relation between the acid concentration and recovery percentage of metal

| Acid | Concentration, $M$ | Recovery percentage |
|---|---|---|
| HCl | 2 | 90 |
| | 3 | 93 |
| | 5 | 98.99 |
| $HNO_3$ | 2 | 85 |
| | 3 | 92 |
| | 5 | 96 |
| $H_2SO_4$ | 2 | 81 |
| | 3 | 88 |
| | 5 | 90 |

from 2.77 to 3.00, 3.45 to 3.79 and 3.45 to 3.70 respectively. Each extraction was kept constant at the log $D$ value of 1.84 for HDEHP(phen), 1.60 for HDEHP(bipy) and 1.30 for HDEHP-(TOPO) synergic extraction systems, respectively, in the pH range from 3.5 to 4.0. It is interesting that the extractability of the gadolinium(III) with HDEHP(phen) synergic extraction process is higher than those of HDEHP(bipy) and HDEHP(TOPO). The optimum pH value to obtain 98% extractability was 2.60 to 3.70 in the case of HDEHP(phen), 97% extraction in the case of HDEHP(bipy) and 95% in the case of HDEHP(TOPO) synergic extraction process, respectively.

The logarithmic distribution coefficients diminished monotonically with increasing aqueous acidities (in the region of pH $>6.0$), implying that the extractions were dominated by the ion-exchange reaction in which hydrogen is liberated. Gaikwad and Damodaran[13] studied the extraction behaviour of Ho(III) with EHPNA(2-ethylhexyl phosphoric acid mono-2-ethylhexyl ester) and they concluded that there is no clear cut separation of phases at higher pH values. The extraction percentage of $Gd^{3+}$ reached a maximum in the case of phen, bipy and TOPO adduct formation at pH 3.00, 3.79 and 3.70, respectively.

*Slope analysis*

A traditional and effective means of obtaining both stoichiometric and equilibrium constant information about extraction processes, called 'slope analysis', is based on an examination of the logarithmic variation of $D$, the distribution ratio, with relevant experimental variables. The log–log plots of the extraction in the form of $D$ vs. a concentration variable indicate the stoichiometry of the formation of the extractable complex and thus lead to the derivation of a suitable equilibrium expression and then to the calculation of equilibrium constants.

*Extraction with HDEHP alone*

The extraction percentage of $Gd^{3+}$ reached a maximum in the case of kerosine and chloroform diluent when extractants were alone at pH 1.95 and 3.00, respectively. Beyond these values the extraction percentage decreased gradually. The plots of log $D$ *vs.* variables such as the pH of the aqueous phase and the logarithm of the concentration of $[(HX)_2]$ were constructed (Figs 3 and 4). Straight lines with a slope of 3 for gadolinium were obtained at the lower levels

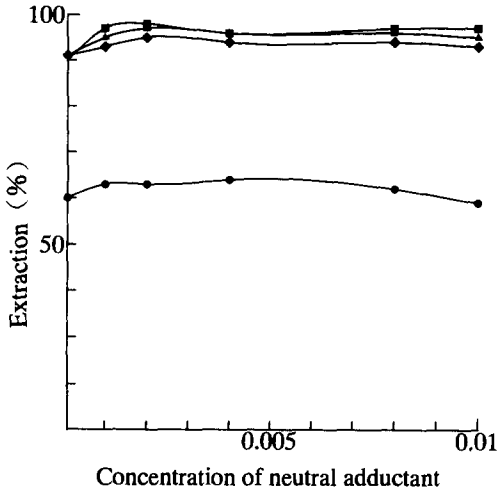

Fig. 2. The effect of HDEHP concentration on extraction in the presence of TOPO, bipy or phen. Organic phase: chloroform containing $1 \times 10^{-2} \sim 1 \times 10^{-4} M$ of di(2-ethylhexyl)phosphoric acid and constant [neutral additive], ● TOPO(kerosine), ◆ TOPO(chloroform), ▲ bipy, ■ phen. The aqueous solution containing gadolinium(III) ion $1 \times 10^{-4} M$, succinic buffer $2 \times 10^{-3} M$; perchlorate absent.

of metal extracted. Thus, the extraction reaction can be written as:

$$M_{aq}^{m+} + m(HX)_{2(O)} \rightleftharpoons M(HX_2)_{m(O)} + mH_{aq}^{+} \quad (1)$$

$$Gd^{3+} + 3(HX)_{2(O)} \rightleftharpoons Gd(HX_2)_{3(O)} + 3H^{+}. \quad (2)$$

Examination of equation (2) leads to the conclusion that the slope of a log $D$ *vs.* pH plot should be 3, indicating that three hydrogen ions are released in the extraction of the metal ion. As seen in Fig. 4, the behaviour of all of the

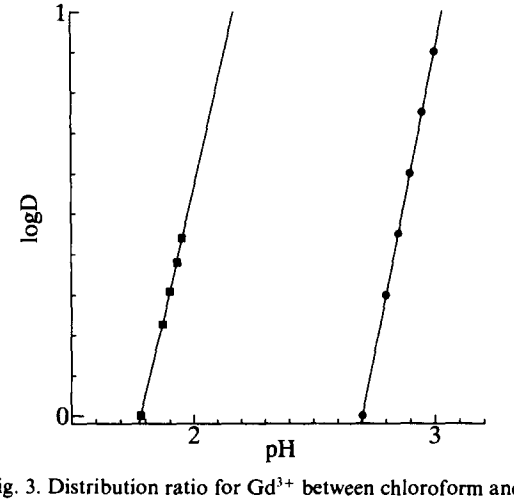

Fig. 3. Distribution ratio for $Gd^{3+}$ between chloroform and aqueous phase as a function of pH in the aqueous phase. Aqueous phase: $[Gd^{3+}] = 1 \times 10^{-4} M$; succinic acid $2 \times 10^{-3} M$. Organic phase: ● chloroform containing $2 \times 10^{-3} M$ HDEHP, ■ kerosine containing $2 \times 10^{-3} M$ HDEHP; perchlorate absent.

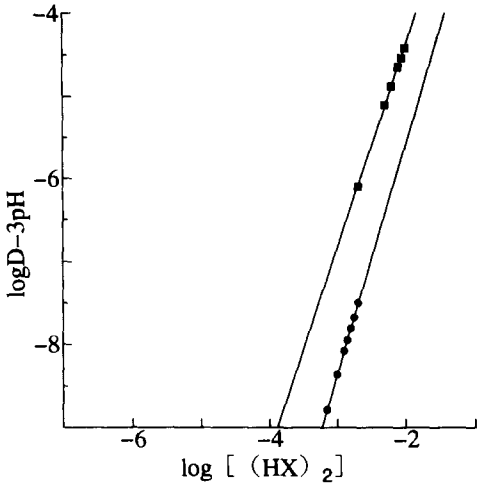

Fig. 4. Distribution ratio of $Gd^{3+}$ as a function of di(2-ethylhexyl)phosphoric acid concentration. Aqueous phase: $1 \times 10^{-4}M$ gadolinium containing no adductants, succinic acid $2 \times 10^{-3}M$. Organic phase as shown in HDEHP into ● chloroform, ■ kerosine.

$Gd^{3+}$ conformed to this simple formulation. In equations (1) and (2) $(HX)_2$ represents the HDEHP dimer. (The subscript O designates concentration in the organic phase.) For the extraction constant, $K_{ex}$, for this reaction refer to equation (3):

$$K_{ex} = [Gd^{3+}(HX_2)_3][H^+]^3/[Gd^{3+}][(HX)_2]^3 \quad (3)$$

or

$$\log K_{ex} = \log D_O - 3pH - 3\log[(HX)_2]. \quad (4)$$

Plots of $(\log D_O - 3pH)$ *vs.* $\log[(HX)_2]_O$ are also linear with slopes of almost +3 in the higher HDEHP concentration range (Fig. 3). +3 indicates the number of molecules of HDEHP combined in the extracted species.

For the kerosine system, the slopes of $\log D_O$ *vs.* pH plots decreased gradually with increasing pH. This type of behaviour was also encountered in the case of the chloroform system, then it was realised that the dependence of HDEHP may be obtained at lower pH values of the aqueous phase.

Thus, from the HDEHP dependence, it can be anticipated that the equation for the extraction reaction for both the chloroform and kerosine systems may be represented by equation (2) at higher acidities or by equation (6) at lower acidities, or by the combination of the two equations

$$Gd^{3+} + 3(HX)_{(O)} \rightleftharpoons [GdX_3]_{(O)} + 3H^+. \quad (6)$$

The applicability of the equations (2) and (6) depends on the assumption that the suppression of ionization of dimeric acid is less than that of the monomeric acid on increasing acidity. Equations (2) and (6) indicate the pH dependence to be +3, but the value obtained were somewhat lower in the case of the kerosine system. The value of $\log K_{ex}$ with chloroform was, unfortunately, smaller than that with kerosine, and this probably reflects the greater HDEHP extractability into chloroform than into kerosine.

*Extraction with a mixture of HDEHP and phen, bipy or TOPO*

As mentioned above the adduct formation of tris-DEHP complexes of $Gd^{3+}$ with oxygen containing monodentate ligand TOPO and bidentate ligand nitrogen containing the chelating agent phen or bipy as representatives of P=O,

$$=N-\overset{\|}{C}-\overset{\|}{C}-N=$$

donor groups, respectively, was studied. It was found that HDEHP complexes showed an exceptionally large tendency to form adducts with nitrogen containing the chelating agent 1,10-phenanthroline. When an auxiliary reagent, such as phen, bipy or TOPO (B), was added to the extraction system, enhanced extraction resulted because of the adduct formation. A per cent extraction (%$E$) pattern of 98.99%(phen) > 97%(bipy) > 95%(TOPO) was obtained into chloroform solvent.

The overall extraction equilibrium and the extraction constant, $K_{ex(B)}$, can be expressed as

$$Gd^{3+} + 3(HX)_{2(O)} + nB_{(O)} \rightleftharpoons Gd(HX_2)_3B_{n(O)} + 3H^+. \quad (7)$$

By subtracting equation (2) from equation (7), the adduct formation in the organic phase can be isolated:

$$Gd(HX_2)_{3(O)} + nB_{(O)} \overset{K_{AD(B)}}{\rightleftharpoons} Gd(HX_2)_3B_{n(O)}. \quad (8)$$

The effect of adduct formation is to increase the extraction equilibrium constant, $K_{ex(B)}$ by a factor given by the adduct formation constants $K_{AD(B)}$.

The adduct formation reaction in the organic phase and the complex stability constant, $\beta_n$ are given by

$$\beta_n = K_{ex(B)}/K_{ex}. \quad (9)$$

In equation (8), $n$ denotes the number of the auxiliary reagent molecules that attach to the

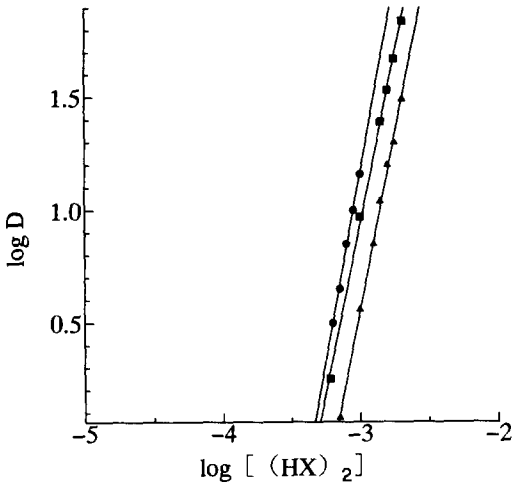

Fig. 5. Distribution ratio for $Gd^{3+}$ as a function of di(2-ethylhexyl) phosphoric acid concentration in the presence of constant adductants ($2 \times 10^{-3}M$) in the organic phase. ■ Phen, ▲ bipy, ● TOPO. Log $D$ *vs.* log[$(HX)_2$] has been plotted graphically according to the condition of Fig. 3.

extracted species. In this paper $n$ was evaluated by the following equation[10,11]

$$\log D/D_O = \log K_{ex(B)}/K_{ex} + n \log[B]_O, \quad (10)$$

where $D$ represents the distribution ratio in time of adduct formation, whereas $D_O$ represents the distribution ratio when HDEHP is alone.

In Figs 5 and 6 the plots of log $D$ *vs.* log$[(HX)_2]_O$ exhibits a slope of +3 and the plots of log $D$ *vs.* pH also have a slope of +3 in the case of the three kinds of synergistic mixture. The results of the extraction of gadolinium using a mixture of HDEHP and phen, bipy or TOPO are shown in Table 2, where it is seen

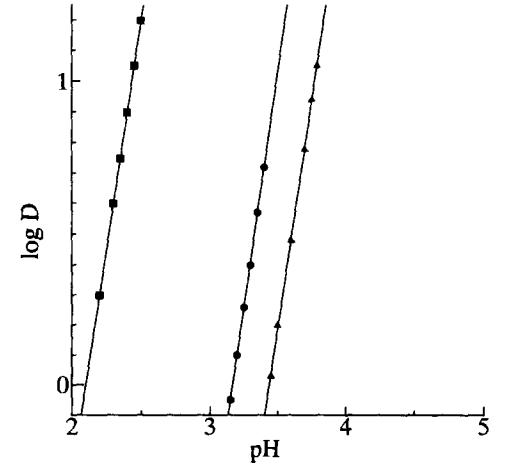

Fig. 6. Distribution ratio for $Gd^{3+}$ as a function of pH in the aqueous phase in presence of ■ phen, ▲ bipy, ● TOPO adductants ($2 \times 10^{-3}M$) in the organic phase.

Table 2. Summary of the results on the extraction of gadolinium with HDEPH and phen, bipy or TOPO

| No | Equation[log $D(y)$] *vs.* pH($x$) | $pH_{1/2}$ |

| 3[p] | $y = (2.10 \pm 0.01)x - (8.55 \pm 0.20)$ | 1.9 |
| 4[p] | $y = (3.20 \pm 0.08)x - (8.10 \pm 0.19)$ | 3.0 |
| 4[a] | $y = (2.13 \pm 0.24)x - (10.64 \pm 0.84)$ | 2.1 |
| 5[p] | $y = (2.10 \pm 0.17)x - (4.58 \pm 0.33)$ | 1.7 |
| 5[a] | $y = (2.62 \pm 0.24)x - (7.28 \pm 0.10)$ | 2.2 |

1 = HDEHP (0.002$M$ dimer) with phen, 2 = HDEPH (0.002$M$ dimer) with bipy, 3 = HDEPH (0.002$M$ dimer) with TOPO, 4 = HDEPH (0.002$M$ dimer) alone into $CHCl_3$, 5 = HDEPH (0.002$M$ dimer) alone into kerosine, [a] = ($ClO_4^-$ absent), [p] = ($ClO_4^-$ present).
All experiments were carried out three times.

from the lower $pH_{1/2}$ (pH of 50% extraction) values that highly enhanced extractions were achieved in the presence of as little as $10^{-3}M$ auxiliary reagent.

Figure 5 shows the distribution ratio of the metal ions as a function of HDEHP concentration when $2 \times 10^{-3}M$ phen, bipy or TOPO was added into the organic phase. In the presence of TOPO the plot is almost similar to that of HDEHP alone in chloroform at the above concentration. As can be seen from Figs 4 and 5, the extraction was enhanced by the addition of phen or bipy. The data in Figs 4 and 5 were calculated on the basis of equations (4) and (8), respectively, by a successive approximation method using a least square computer program. It is very interesting that the values of log $K_{ex(B)}$ with HDEHP are very large compared to those with HDEHP alone into chloroform. This is because the steric hindrance of the synergistic mixture is low. We can easily understand that the effect of phen is much larger in the HDEHP system by comparing values of log($K_{ex}/K_{ex(B)}$). In Table 2, values of $pH_{1/2}$ show that gadolinium can be extracted at slightly lower pH in the HDEHP alone system than in the mixed system under the same extraction conditions, it may be influenced by the distribution constant of the $Gd(HX_2)_3$ complex, and the adduct formation constant $K_{AD(B)}$. In order to clarify the composition of the extracted species, the dependencies of log $D/D_O$ on $[B]_O$ were examined. The plot of log $D/D_O$ *vs.* log$(phen)_O$ (Fig. 7) is linear with a slope of 2, indicating that two molecules of phen are included in the extracted species.

In the case of HDEHP and bipy mixture, the corresponding plot is also linear with a slope of

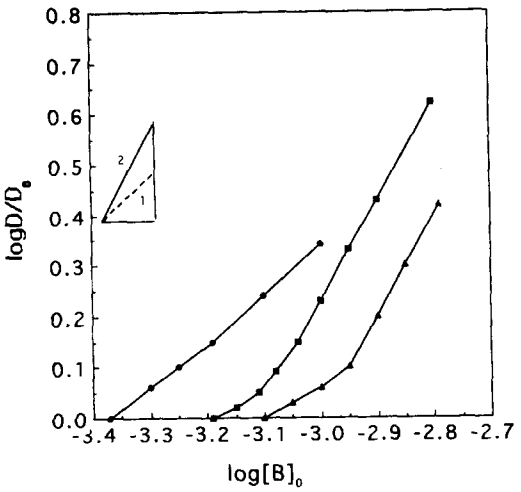

Fig. 7. Plots of $\log D/D_O$ *vs.* concentration of the adductants. From equation (7), $\log K_{AD} = \log D - 3\text{pH} - 3\log(HX_2)_3 - n \log B$. By subtracting $\log K_{ex}$ (equation 4) from $\log K_{AD}$ the following equation was obtained, $\log D/D_O = \log K_{AD}/\log K_{ex} + n \log[B]_O$. The slope of the plot of $\log D/D_O$ *vs.* $[B]_O$ at constant $[(HX)_2]$ and pH gives $n$. The effect of neutral additive concentration to HDEHP on the extraction of $Gd^{3+}$ was observed. Aqueous phase: $[Gd^{3+}] = 1 \times 10^{-4}M$, succinic acid $2 \times 10^{-3}M$. Organic phase: $[(HX)_2] = 2 \times 10^{-3}M$, $B = 2 \times 10^{-3}M$. ■ Phen, ▲ bipy, ● TOPO.

+2 at the higher bipy concentration region, but deviates from the straight line at low bipy concentrations (Fig. 7). This deviation can be explained by considering the extraction of $M(HX_2)_3B$, which takes place in the lower bipy concentration range (dotted lines in Fig. 7). The extraction constant and the stability constant $\beta_n$ are obtained from the linear position of the plot of $\log D/D_O$ *vs.* $\log[\text{phen}]_O$ using equations (8) and (9).

Our data supports the conclusion that TOPO forms a mono adduct extractable species, $Gd(HX_2)_3(TOPO)$, include the finding that the plot of $\log D/D_O$ *vs.* $\log[\text{TOPO}]_O$ have slopes of +1. Thus, it would seem that TOPO reacts as a monodentate ligand.

Generally, in the mixed ligand extraction system of the lanthanides, the decrease of the adduct formation constant may be explained by a diminution of the coordinating power of the lanthanide ion resulting from a stable chelate formation, with a consequently lower stable adduct formation. In addition, the lanthanide ion, to which three molecules of chelating reagent have already coordinated, allows space for the adduct forming reagent, so that steric hindrance for adduct formation increases with atomic number.

For extraction with a mixture of HPMTFP [1-phenyl-3-methyl-4-(trifluoroacetyl)-5-pyrazolone] and MBDPO[methylenebis(diphenylphosphineoxide)], the perchlorate ion was found to have a significant influence.[7] In the absence of the perchlorate ion the slope of the $\log D$ *vs.* pH lines were found to be 2.97 but when the perchlorate ion was present the slope of the $\log D$ *vs.* pH lines was found to be 1.98 for the case of La ion extraction.[7] Table 3 shows the values of the extraction parameters ($\log K_{ex}$) of gadolinium metal ions with HDEHP either alone or combined with phen, bipy or TOPO. Thus the following reaction can be written on the basis of the above findings. In the presence of phen, bipy or TOPO the following extraction may occur:

$$Gd^{3+} + 3(HX)_{2(O)} + 2\text{phen} \rightleftharpoons Gd(HX_2)_{3(O)}(\text{phen})_2 + 3H^+ \quad (11)$$

$$Gd^{3+} + 3(HX)_{2(O)} + 2\text{bipy} \rightleftharpoons Gd(HX_2)_{3(O)}(\text{bipy})_2 + 3H^+ \quad (12)$$

Table 3. Table of equilibrium constants and stability constants at 25°C determined by UV spectrophotometer

| Extractant | Organic phase | $\log K_{ex}$ | $\log K_{ex(B)}$ | $\log \beta_n$ |
|---|---|---|---|---|
| HDEHP alone[p] | $CHCl_3$ | $-0.03 \pm 0.10$ | — | — |

| HDEHP with phen[p] | $CHCl_3$ | — | $6.09 \pm 0.05$ | $6.12 \pm 0.11$ ($n = 2$) |
| HDEHP with bipy[a] | $CHCl_3$ | — | $5.75 \pm 0.01$ | $5.78 \pm 0.02$ ($n = 2$) |
| HDEHP with bipy[p] | $CHCl_3$ | — | $5.00 \pm 0.06$ | $5.03 \pm 0.03$ ($n = 2$) |
| HDEHP with TOPO[a] | $CHCl_3$ | — | $3.31 \pm 0.03$ | $3.34 \pm 0.02$ ($n = 1$) |
| HDEHP with TOPO[p] | $CHCl_3$ | — | $2.89 \pm 0.02$ | $2.92 \pm 0.05$ ($n = 1$) |

[p] = [($ClO_4^-$) present]. [a] = [($ClO_4^-$) absent]. Equation: $\log K_{ex} = \log D_O - 3\text{pH} - 3\log[(HX)_2]$ for HDEHP alone; $Gd^{3+} + 3(HX)_{2(O)} + nB_{(O)} \rightleftharpoons Gd(HX_2)_3B_{n(O)} + 3H^+$ for HDEHP with adductants. $\beta_n = K_{ex(B)}/K_{ex}$ for $\log \beta_n$.

$$Gd^{3+} + 3(HX)_{2(O)} + bipy \rightleftharpoons Gd(HX_2)_{3(O)}(bipy) + 3H^+ \quad (13)$$

$$Gd^{3+} + 3(HX)_{2(O)} + TOPO \rightleftharpoons Gd(HX_2)_{3(O)}(TOPO) + 3H^+. \quad (14)$$

Equations (11)–(14) represent the reactions in the absence of sodium perchlorate.

The values were obtained for $\log K_{ex(phen)} = 6.22 \pm 0.01$ and $\log K_{ex(bipy)} = 5.75 \pm 0.01$, respectively. These results indicate that the ligand 1,10-phen forms complexes that are more stable than those formed by bipy with the same metal ion, as was assumed. It seems reasonable to suggest that this effect is because of phen is more effectively pre-organized for coordination relative to bipy. Bipy is highly strained in the conformer with the nitrogens *cis* to each other, as required for coordination of metal ions,[14] because of the steric hinderance between the hydrogens in the 3- and 3′- positions. However, in phen this problem is overcome by fusing the two rings and forcing the ligand to remain in the correct conformation for coordination to a metal ion.

When sodium perchlorate is present, however, a different extractable species is found.

$$Gd^{3+} + 2(HX)_2 + ClO_4^- + 2(phen) \rightleftharpoons Gd(HX_2)_2(ClO_4^-)(phen)_2 + 2H^+ \quad (15)$$

$$Gd^{3+} + 2(HX)_2 + ClO_4^- + 2(bipy) \rightleftharpoons Gd(HX_2)_2(ClO_4^-)(bipy)_2 + 2H^+ \quad (16)$$

$$Gd^{3+} + 2(HX)_2 + ClO_4^- + (bipy) \rightleftharpoons Gd(HX_2)_2(ClO_4^-)(bipy) + 2H^+ \quad (17)$$

$$Gd^{3+} + 2(HX)_2 + ClO_4^- + (TOPO) \rightleftharpoons Gd(HX_2)_2(ClO_4^-)(TOPO) + 2H^+. \quad (18)$$

When these metals are extracted under increasing concentrations of $NaClO_4$ and adductants, a slope of 2 could be obtained in a plot of $\log D$ *vs.* pH, when $[adductants]_{(O)}$ and $[ClO_4^-]$ were $5 \times 10^{-3}$ and $0.2M$, respectively (Tables 2 and 3). As seen in Table 3, the enhancement was much greater when phen was used than with TOPO or bipy. Thus it would seem than phen forms a diadduct extractable species. In the case of bipy a monoadduct was observed when the concentration range was $<0.1M$. Bipy also formed a biadduct in its higher concentration range.

## CONCLUSIONS

In the mixed complex system containing HDEHP, the donating ability of $(HX)_2$ is insufficient to form an adduct. The effect of three adductants on the extraction of Gd(III) with HDEHP mixtures was examined. From these results, it would appear that the formation of mixed complexes with a mixture of two chelating extractants and adduct formation to mixed complexes like quaternary compound formation successfully enhanced the metal chelate extraction. This is, to some extent, similar to the enhancement of metal chelate extraction by adduct formation in the organic phase through dimer extractant. From these results, it would appear that the adduct formation to mixed complexes may further enhance separation capability in the lanthanide series.

# DETECTION AND SPECTROPHOTOMETRIC DETERMINATION OF COPPER(III) WITH *p*-ANISIDINE

N. KRISHNA MURTHY and B. SREERAMA MURTHY

Department of Engineering Chemistry, Andhra University College of Engineering, Visakhapatnam-530 003, India

(*Received* 4 *April* 1994. *Revised* 2 *August* 1994)

**Summary**—Copper(III) solutions are found to give an instantaneous stable pink-coloured product with 0.2% aqueous *p*-anisidine in the presence of 0.03*N* acetic acid. The wavelength of maximum absorption is 533 nm and obeys Beer's law up to 0.89408 g copper(III). It is also recommended as a spot test for copper(III).

During the course of experiments in search of specific colour reagents for copper(III), we noticed that solutions of copper(III) give an instantaneous stable pink-coloured product with 0.2% aqueous *p*-anisidine in the presence of 0.03*N* acetic acid. The addition of copper(III) solution in 2*M* KOH contributes alkalinity and the effective pH was found to be more than 7, when a stable pink colour was observed. A study of the spectrum of the pink-coloured product and comparison revealed that the pink-coloured product is the oxidized form of *p*-anisidine.[1] Copper(I) and copper(II) and other reagents used did not respond similarly and a survey of the literature indicated that this specific colour reaction between copper(III) and *p*-anisidine has not been previously reported. In view of the importance of the micro determination of copper(III) in non-stoichiometric and super-conducting substances, the above method which is rapid, accurate, simple and specific, will find a wide range of application.

## EXPERIMENTAL

### *Reagents*

*Copper*(III) *solution* (0.02*M*). The solution was prepared from an AnalaR BDH sample of cupric sulphate pentahydrate, by oxidation with potassium persulphate in 2*M* potassium hydroxide media and standardized.[2]

p-*Anisidine* (0.2% *aqueous*). Prepared by dissolving an adequate amount of an AnalaR BDH sample, in double distilled water, standardized against cerium (IV)[3] and stored in amber coloured bottles. All other reagents used were of AnalaR grade only.

### *Apparatus*

A Shimadzu-UV-260 double beam spectrophotometer with recording unit was used for recording the spectra. An ELICO photoelectric colorimeter with filter No.625 (green filter, range 510–590 nm, peak at 540 nm) was used for other experiments.

Preliminary experiments carried out in various acid and alkali media revealed that the pink coloured product obtained by the reaction between copper(III) and *p*-anisidine was instantaneous and stable in the presence of 0.03*N* acetic acid. In view of such experiments the following procedures are recommended.

### *Recommended procedure for the detection of copper*(III) *with* p-*anisidine*

Copper(III) solution (0.05 ml) was mixed with 0.05 ml of 0.1*N* acetic acid and 0.05 ml of 0.2% aqueous *p*-anisidine in the cavity of a white porcelain spot plate, to give an instantaneous pale pink colour. By a systematic quantitative dilution procedure, we found the limits of detection of copper(III) with aqueous *p*-anisidine in the presence of 0.03*N* acetic acid: limit of identification: $0.2 \times 10^{-6}$ g or 0.2 $\mu$g of copper as copper(III); limit of dilution: $1:0.75 \times 10^{6}$.

### *Spectrophotometric estimation of copper*(III) *with* 0.2% p-*anisidine*

Copper(III) solution (1.0 ml) was mixed with 8 ml of 0.1*N* acetic acid and 0.5 ml of 0.2%

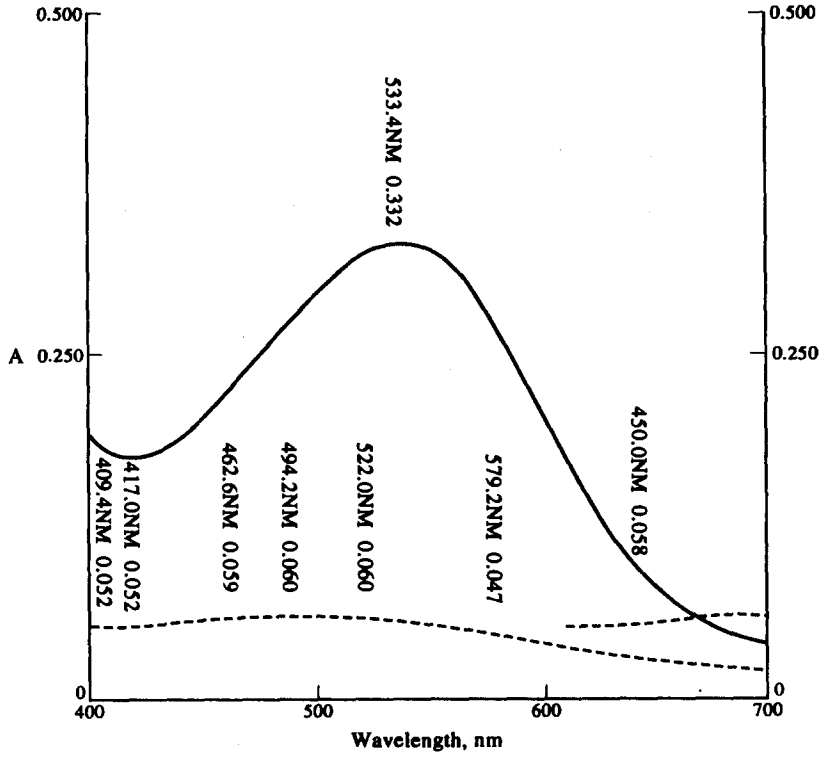

Fig. 1.

aqueous *p*-anisidine to give a stable instantaneous pink-coloured product. The mixture was made up to 25 ml in a volumetric flask and the spectra taken for an aliquot of the solution showed $\lambda_{max}$ at 533 nm (Fig. 1). Solutions of copper(III) and *p*-anisidine have $\lambda_{max}$ as 416 nm

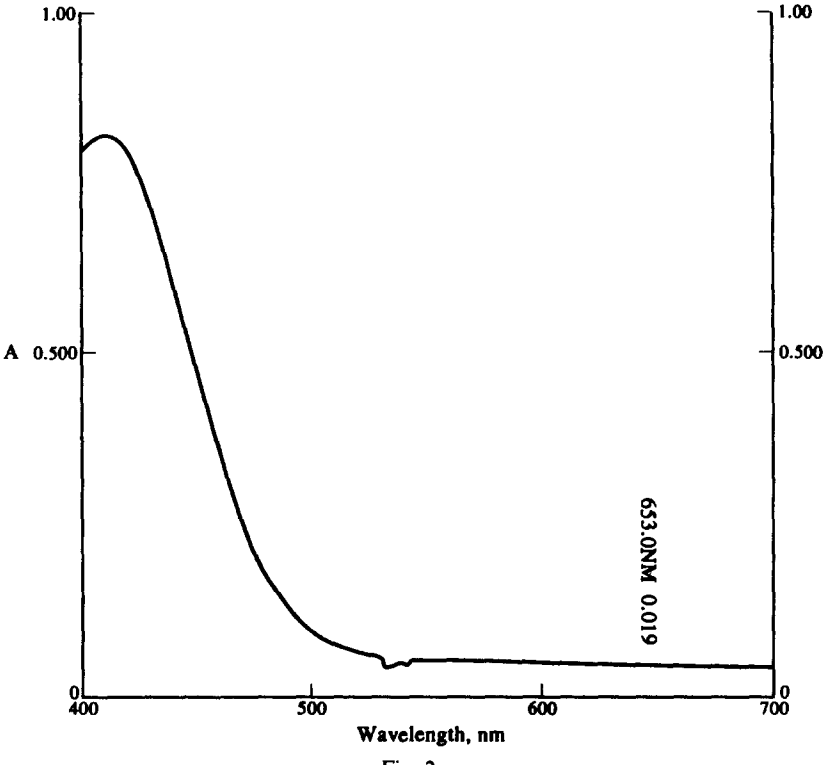

Fig. 2.

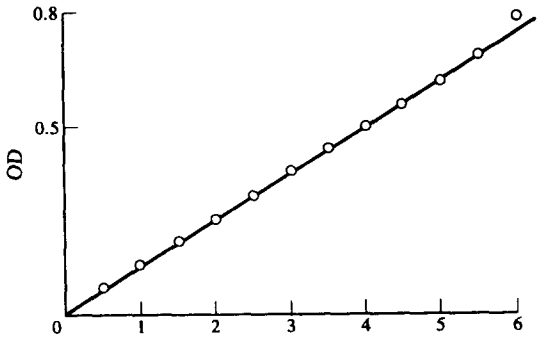

Fig. 3.

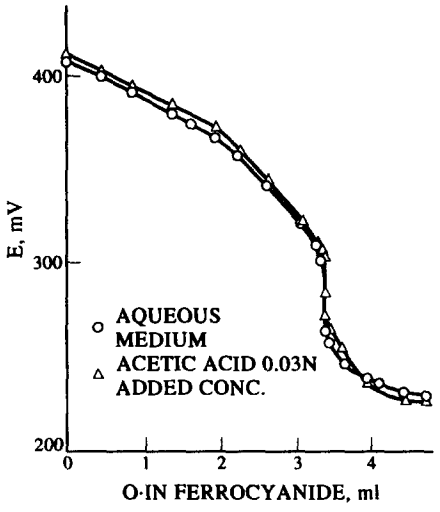

Fig. 4.

(Fig. 2) and 533 nm, respectively, and thus found to have no overlapping.

For the estimation of copper(III), an aliquot volume of copper(III) was mixed with 8 ml of 0.1*N* acetic acid and 2 ml reagent in a 25 volumetric flask to give a stable instantaneous pink-coloured product and the mixture made up to the mark. The solution was taken in an optically matched test tube of an ELICO colorimeter and the optical density measured using filter No. 625 (green filter). The optical density was compared with a standard curve (Fig. 3) and the estimation carried out. Beer's law was found to be obeyed up to 0.89408 g of copper(III).

## DISCUSSION

The specific colour reaction between copper(III) and *p*-anisidine was studied in various acid and alkali media. Copper(III) oxidizes *p*-anisidine to the pink-coloured product [while it is being reduced to copper(II)]. In very low acid concentrations such as 0.1*N* $H_2SO_4$, 0.05*N* HCl, 0.05*N* $H_3PO_4$, an instantaneous pale pink colour was produced, slowly fading away in 5–10 min. It was found that the colour of the product was stable for carrying out further experiments in 0.03*N* acetic acid media. However, even when the concentration of acetic acid was increased over and above 0.06*N*, the intensity of the pink colour and the corresponding optical density were found to decrease. Hence, we used 0.03*N* acetic acid as the optimum condition for the production of oxidized product of *p*-anisidine with copper(III) solution. The $\lambda_{max}$ for the pink-coloured product was 533 nm (Fig. 1) with molar absorptivity, $\varepsilon = 415M^{-1}$ cm$^{-1}$ at 533 nm. There was no overlapping of the spectra of the pink coloured product of *p*-anisidine with other species present in the solution. Beer's law was found to be obeyed up to 0.89408 mg of copper as copper(III).

## CONCLUSION

Copper(III) solutions gave an instantaneous stable pink-coloured product with 0.2% aqueous *p*-anisidine in 0.03*N* acetic acid. The $\lambda_{max}$ was 533 nm for the pink-coloured product with molar absorptivity $\varepsilon = 415M^{-1}$ cm$^{-1}$ at 533 nm. Beer's law was obeyed up to 0.89408 mg of copper and copper(III). This can be used as a spot test for copper(III) with an identification limit of $0.2 \times 10^{-6}$ g and dilution limit of $1:0.75 \times 10^6$. The test and estimation are rapid, easy and accurate.

# SPECTROPHOTOMETRIC DETERMINATION OF DICLOFENAC SODIUM WITH METHYLENE BLUE

JULIO C. BOTELLO and GUADALUPE PÉREZ-CABALLERO*

Facultad de Estudios Superiores Cuautitlán U.N.A.M., Sección de Química Analítica, Campo Uno. Av. Primero de Mayo, s/N Cuautitlán Izcalli, C.P. 54740, Estado de México, México

(*Received* 4 *May* 1994. *Revised* 2 *August* 1994. *Accepted* 4 *August* 1994)

**Summary**—A sensitive spectrophotometric method was established for the determination of Diclofenac sodium (DS) with Methylene Blue (MB) as analytical reagent. It was found that DS reacts with an excess of MB in the pH range 9.2–9.4, to form a chloroform-extractable blue ion-association complex. Good agreement with Beer's law was found in the range of DS concentrations of 0.8–6.4 μg/ml with a detection limit of 0.37 μg/ml. The method was applied for the determination of DS in various tableted forms with a good precision.

2-(2,6-dichloroanilino)Phenyl acetate (Diclofenac sodium) (Fig. 1a) is a nonsteroidal anti-inflammatory agent with potent activity and outstanding tolerability in the treatment of rheumatic diseases.[1,2] It has been measured by a variety of analytical techniques such as ultraviolet[3] and visible spectrophotometry,[4,5] gas[6–8] and liquid chromatography[9–12] and nuclear magnetic resonance spectroscopy.[13]

Spectrophotometric methods provide sensitive, precise and accurate measurements of suitable analytes and they offer practical and economical advantages over other methods. Diclofenac sodium (DS) has been analyzed by spectrophotometric methods using complexation with copper acetate[4] or Methylene Violet[5] followed by extraction, the latter being a more sensitive method than the former. The aim of the present work was to establish an improved extraction and spectrophotometric method with greater sensitivity for the determination of DS using Methylene Blue (MB) (Fig. 1b) in different tableted dosage.

## EXPERIMENTAL

### *Apparatus*

A Beckman DU-65 single beam spectrophotometer with 10 mm glass cells was used for the absorbance measurements. The pH measurements were made with a Corning Model 12 Research pH-meter, calibrated with buffer solution (pH $10 \pm 0.05$).

### *Reagents*

DS (standard drug), 99.46% purity, Voltaren Retard and Flenaken tablets containing 100 mg DS, and Voltaren tablets containing 50 mg DS were analyzed. All other chemicals used were analytical-reagent grade. Deionized water was used to prepare all solutions and in all experiments.

### *Solutions*

A freshly prepared aqueous solution of the pure drug (40 mcg/ml; $1.2573 \times 10^{-4}M$) was used as the standard solution for analytical purposes. A 0.032% w/v ($1.04 \times 10^{-3}M$) aqueous Methylene Blue solution was prepared for these experiments. Ammonium/ammonia buffer solutions covering the pH range from 8 to 11 were made by mixing equal volumes of $1.0M$ ammonia and $1.0M$ ammonium chloride solutions and adjusting the pH with sodium hydroxide or hydrochloric acid.

### *Procedure*

Aliquots of DS solution were transferred into a series of 125 ml separating funnels; then 5 ml of MB solution and 1 ml of buffer (pH 9.4) was added. The total volume of the aqueous phase was adjusted to 10 ml with water. Chloroform (10 ml) was added and the contents shook for exactly 5 min, the separated chloroform layer was collected in a 25 ml volumetric flask. A new

*Author to whom the correspondence should be addressed.

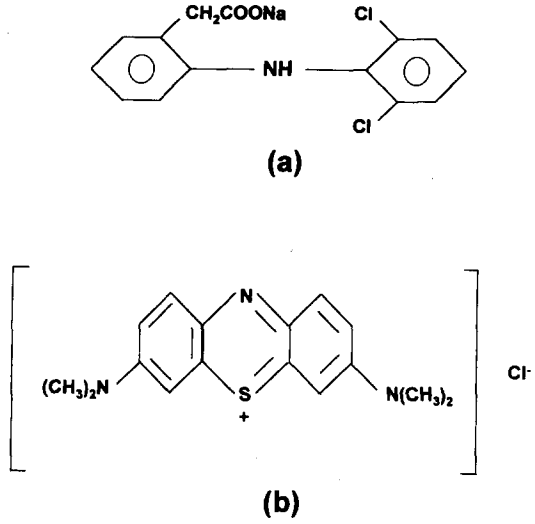

Fig. 1. Structure of (a) Diclofenac sodium and (b) Methylene Blue.

10 ml volume of chloroform volume was added and shook for 5 min, this second extract was combined with the first and this solution diluted to the mark with chloroform. The absorbance of the organic phase was measured against a reagent blank. The reagent blank was prepared exactly like the procedure described above, but in absence of DS.

*Procedure of the assay of tableted dosage*

An amount of tablet powder equivalent to 80 mg of anti-inflammatory agent was weighed accurately and dissolved in water by magnetic stirring. Filtration through a filter paper (Whatman 40) was performed to remove insoluble matter remaining. The solution was diluted to 50 ml with deionized water and treated as described above for the standard drug solution.

## RESULTS AND DISCUSSION

*Absorption spectra*

Diclofenac sodium reacted with MB in aqueous solution in alkaline medium to form a blue ion-association complex which was extracted into chloroform. Figure 2 shows the absorption spectra of this complex and the reagent blank. This complex has an absorption maximum at 653 nm against reagent blank, hence this wavelength was used for all subsequent measurements. Under the same experimental conditions the reagent blank gave a maximum absorption at 642 nm.

*Optimum conditions for complex formation*

In order to establish the optimum pH range, DS was mixed with MB in aqueous solution from pH 8 to 11, and the ion-associated complex absorbance measured. Figure 3 shows that the absorbance increases and reaches a maximum and constant value at 9.2–9.5 pH range. At pH values above 9.5 the absorbance decrease was probably due to the formation of a new ion-associated complex between MB and hydroxyl anion in alkaline medium since experimentally, the reagent blank absorbance increases. Hence, a pH of 9.4 was used in all the subsequent experimental work. The shape of the spectra and maximum position did not vary with pH, so it was concluded that only one complex was formed at this pH range.

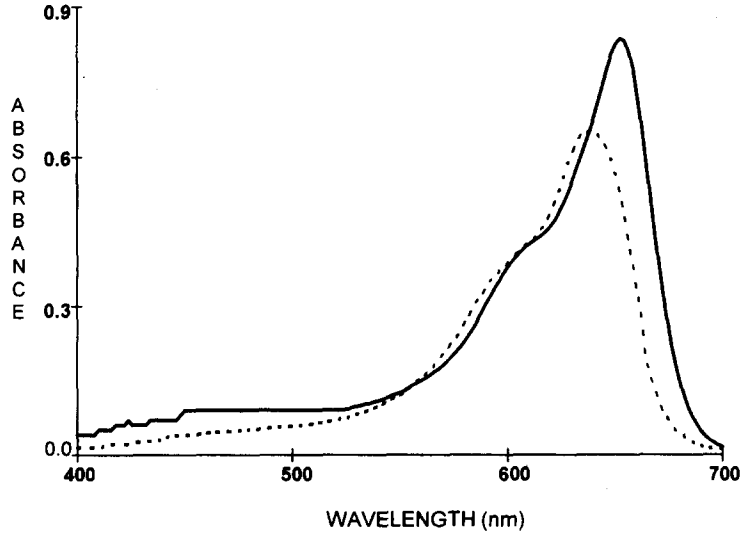

Fig. 2. The absorption spectra of the blank reagent (---), and DS–MB (——) complex formed in the aqueous 0.05$M$ $NH_4^+/NH_3$ buffer containing $5 \times 10^{-4}M$ MB and extracted with chloroform.

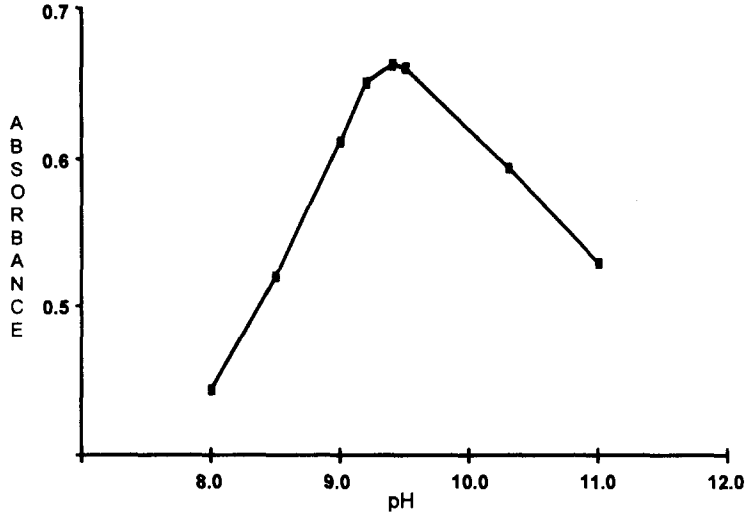

Fig. 3. Variation in absorbance of the DS–MB complex, formed in aqueous 0.05$M$ $NH_4^+/NH_3$ buffer containing $5 \times 10^{-4}M$ MB at different pH values (aborbances were obtained at $\lambda_{653\,nm}$).

The extent of the extraction of the ion-associated complex was found to be affected by the MB concentration. To establish the optimum MB concentration the solution absorbances were plotted as a function of MB concentration (Fig. 4). The absorbance of the system increased in the range of $1–3.5 \times 10^{-4}M$ MB and the absorbance was practically constant in a range of $4–6 \times 10^{-4}M$ MB, hence a concentration of $5.0 \times 10^{-4}M$ MB was used as the optimum concentration. The excess of MB in this system was 25–200 times the concentration of DS.

Two extractions were necessary to achieve a quantitative recovery of the complex. Absorbances of the separated extracts were stable for at least 1 hr. A shaking time of 5 min produced a constant absorbance. An ionic strength of 0.025$M$ was produced by the buffer.

*Linearity*

A calibration curve was obtained under optimum conditions (pH 9.4; $5 \times 10^{-4}M$ MB; ionic strength 0.025$M$), absorbance responses were linear in relation to the calculated concentration of DS over the range 0.8–6.4 mcg/ml ($2.5 \times 10^{-6}–2.5 \times 10^{-5}M$). The equation for one representative calibration curve is:

$$A = (-0.0191 \pm 0.0423) + (0.1789 \pm 0.0105)C,$$

where $A$ and $C$ correspond to absorbance and DS calculated concentration ($\mu$g/ml),

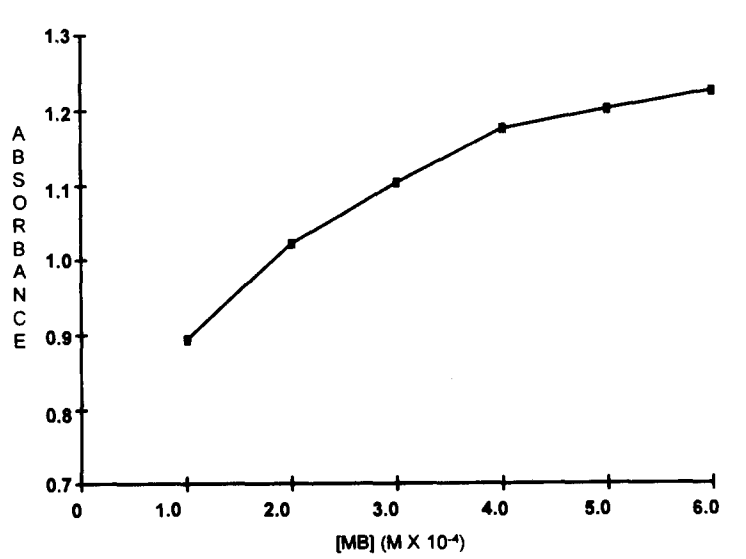

Fig. 4. Variation in absorbance of the DS–MB complex, formed in aqueous 0.05$M$ $NH_4^+/NH_3$ buffer containing different concentrations of MB (absorbances were obtained at $\lambda_{653\,nm}$).

Table 1. Comparison of sensitivity parameters of the different spectrophotometric methods for the determination of Diclofenac sodium

| Analytical reagent | Sandell sensitivity ($mg/cm^2$) | Detection limit ($mcg/ml$) |
|---|---|---|
| Copper acetate | 0.01026 | 1.00 |
| Methylene Violet | — | 72.00 |
| Methylene Blue | 0.006 | 0.37 |

Table 2. Determination of Diclofenac sodium in different tableted dosage

| Drug | Labeled amount ($mg$) | Amount found ($mg$) |
|---|---|---|
| Flenaken | 100.00 | $101.45 \pm 0.42$ |
| Voltaren Retard | 100.00 | $101.35 \pm 0.13$ |
| Voltaren | 50.00 | $49.97 \pm 0.15$ |

Each drug was analyzed eight times.

respectively. The correlation coefficient $(r) = 0.998$ $(n = 8)$, indicating excellent linearity. The molar absorptivity coefficient was $5.7 \times 10^4 M^{-1}$ cm$^{-1}$, and the Sandell sensitivity 0.006 mg/cm$^2$ with a detection limit of 0.37 mcg/ml ($1.2 \times 10^{-6} M$). Table 1 shows that the Table 1 shows that the method reported here has higher sensitivity than other similar methods, in which copper acetate[4] and Methylene Violet[5] are employed as analytical reagents.

*Application*

The applicability of the method to the assay of simple dosage forms was examined by analyzing Flenaken, Voltaren and Voltaren Retard tablets. Table 2 shows the quantities obtained by proposed method and labeled amount. The relative standard deviations are lower than 1% indicating good precision and the independence of the matrix effect over the absorbances measurements.

## CONCLUSIONS

The proposed method is economical, simple, rapid, precise and sensitive. The use of MB as analytical reagent provides a fairly higher sensitivity compared with other similar reagents such as Methylene Violet.

# THE USE OF MACROCYCLES AS ELECTROOSMOTIC FLOW MODIFIERS IN THE SEPARATION OF INORGANIC ANIONS BY CAPILLARY ELECTROPHORESIS

JOHN D. LAMB,* BRAD R. EDWARDS, ROBERT G. SMITH and RICHARD GARRICK
Department of Chemistry, Brigham Young University, Provo, UT 84602, U.S.A.

(*Received* 11 *May* 1994. *Revised* 1 *August* 1994. *Accepted* 2 *August* 1994)

**Summary**—In a novel approach to the use of macrocycles in separation systems, we report the use of macrocyclic ligands as electroosmotic flow modifiers for the separation of inorganic anions by capillary electrophoresis (CE). Inorganic anions were successfully separated through the use of 18-crown-6 or cryptand 2.2.2. as electroosmotic flow modifiers. We found that for our CE system, use of a macrocycle as the modifier resulted in better baseline stability and better efficiency than the commonly used modifier DETA. In our system, the separation efficiency and electroosmotic flow varied according to the pH of the buffer and the affinity of the macrocycle for the buffer metal cation. Results for sodium- and potassium-based buffers show that for the cryptand, pH plays a role in determining the amount of macrocycle–metal complex formed. Separations of a 12 anion standard illustrate these results. In addition, we report the effect of concentration of both macrocycle and metal ion on complex formation and resultant electroosmotic flow modification. Relationships between the macrocycle–metal complex, the buffer medium, the efficiency of separation, and the migration times of the analytes are discussed, and theoretical interpretations presented.

Traditionally, ion chromatography (IC) has been used for the analysis of inorganic ions. However, in recent years capillary electrophoresis (CE) has been explored as an alternate method of inorganic anion and cation separations because it provides several advantages with regard to sample size and separation efficiency. CE separations have resulted in theoretical plate numbers a hundred times greater than those achieved by IC separations.[1]

CE separations are performed by introducing a sample into a buffer-filled capillary by gravity/siphoning or electromigration, then allowing sample ions to migrate based on their respective charge-to-mass ratios in the presence of an electric field. Various separation systems have been developed that take advantage of the high efficiency of CE.[2] Normally buffer flows toward the negative electrode (cathode). This net flow of liquid towards the cathode, called the electroosmotic flow (EOF), is caused by a dielectric layer which forms between the negatively charged silanol groups on the surface of the capillary and the highly mobile cations in the buffer. The motion of the mobile cations results in a net flow of liquid toward the cathode as the buffer solvent is dragged along by the solvated cations.

The migration order, resolution and migration times of sample ions are optimized by the addition of EOF modifiers in the case of anion separations, or complexing agents in the case of cation separations. EOF modifiers are additives that influence the flow of buffer by modifying the dielectric layer at the surface of the capillary wall, slowing or reversing the direction of the bulk flow of liquid in the capillary. This reversal or slowing of the EOF results in shorter anion analysis times and an increase in peak efficiencies over conventional IC separations.[2]

The focus of the research reported herein is the use of crown ethers or cryptands as EOF modifiers in inorganic anion separations by CE. Many applications of macrocyclic molecules have been explored with excellent results.[3–8] Previous articles have described the incorporation of macrocycles as complexing agents, rather than as EOF modifiers, in CE buffer systems for separating cations.[9–13] The well understood ability of macrocyclic ligands to bind alkali metal cations catalyzed our interest in

their potential for use in EOF modification.[14,15] High binding constants between alkali metals and macrocycles[14] (Fig. 1) promote the formation in the buffer of cationic complexes, which can act as EOF modifiers by forming a dielectric layer coupled to the negatively charged silanol groups on the wall of the capillary (Fig. 2). Because of the weakly hydrophobic, cationic nature of the macrocycle-metal complex, the bulk flow of solution is slowed to permit the detection of anions at the anode. The binding strength of a particular buffer metal ion with the macrocycle is a determining factor in the rate of EOF.

## EXPERIMENTAL

### *Apparatus*

Analyses were performed on a Dionex capillary electrophoresis system (CES-1). The CES has five main components: an autosampler for sample selection as well as for injection; a fused silica capillary in which sample separations take place; positive and negative polarity high voltage power supplies capable of 30,000 V; a detector where the anion signal can be measured by direct or indirect UV/Vis detection; and a computer which controls voltage, injection method, injection time, number of samples run, the autosampler, time of analysis and rinses of the capillary. All samples in our analysis were introduced from the autosampler by gravity/siphoning injection into the capillary.

### *Materials*

Reagent-grade macrocycles 12-crown-4, 15-crown-5, 18-crown-6 and kryptofix (cryptand) 2.2.2. were obtained from Aldrich Chemicals (Milwaukee, WI) and reagent grade chemicals were used in preparing all buffers and standards. The structures of these ligands are shown in diagram 1. Water used in the preparation of all buffers and standards was purified to 18 MΩ resistivity using a Millipore Milli-Q water purification system (Waters, Bedford, MA, U.S.A.). Buffers were filtered using 0.45 $\mu$m filters, to remove any particulate matter in the solution, and then degassed by sonication and evacuation.

An ion exchange column packed with cation exchange resin (Dowex MSC-1, 20-50 mesh, Sigma Chemical, St. Louis, MO, U.S.A.) was used to prepare buffers containing different cations. The column was packed in water to

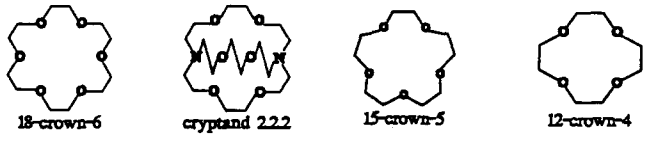

Diagram 1

avoid channeling, and solutions containing the replacement cation were prepared using the nitrate salts of the alkali metals.

The mobility and peak efficiencies of inorganic anions are controlled by matching the background analyte with the species being analyzed. Chromate ion was found to be the most useful in our system, as most of the anions in our standards had high electrophoretic mobilities.[17]

## RESULTS AND DISCUSSION

### *Theoretical*

The relationship between the cation and macrocycle in a chromatographic separation system has been described by Lamb and Smith.[16] The concept behind macrocycle–metal complex formation in a CE system is similar to that described for such an IC system. However, differences arise because the macrocycle incorporated in a CE system is not adsorbed onto a stationary phase, but rather exists in dynamic equilibrium with the metal cation as a solute component of the buffer phase. In an effort to effectively describe the relationships that exist between the various macrocyclic ligands and the metal ions in the buffer system, theoretical calculations were performed for cryptand 2.2.2. and 18-crown-6.

*Cryptand* 2.2.2. The concentration of metal–macrocycle complex in the CE buffer system can be determined for the cryptand 2.2.2. ligand by the following:

$$[L_F] = [L_0] - [ML] - [HL^+] - [H_2L^{2+}], \quad (1)$$

where $[L_F]$ is the concentration of free ligand in the system, $[L_0]$ is the original concentration of ligand, [ML] is the amount of metal–ligand complex formed, and the terms $[HL]^+$ and $[H_2L]^{2+}$ correspond to the first and second protonation steps of the cryptand ligand. Assuming 1:1 stoichiometry, the equilibrium constant for the macrocycle–metal ion complexation is given by the following:

$$L + M^+ \rightleftharpoons ML^+. \quad (2)$$

A combination of equations (1) and (2) yields the equilibrium constant expression:

$$K_m = \frac{[ML^+]}{[L_F][M^+]} \rightarrow \frac{[ML^+]}{([L_0] - [ML^+] - [HL^+] - [H_2L^{2+}])([M_0^+][ML^+])}, \quad (3)$$

where the new $[M_0^+]$ term is defined as the original metal ion concentration. Since the binding of metal ions by the macrocycle occurs in competition with the protonation reaction, we consider the degree to which protonation occurs by incorporating equations (4) and (6) into our overall expression for metal–ligand complex formation. The first expression denotes the protonation of the macrocyclic nitrogens:

$$H^+ + L_F \rightleftharpoons HL^+, \quad (4)$$

which when combined with expression (1) becomes:

$$K_1 = \frac{[HL^+]}{[H^+][L_F]} \rightarrow \frac{[HL^+]}{([L_0] - [ML^+] - [HL^+] - [H_2L^{2+}])([H^+])}. \quad (5)$$

The second protonation constant expression is given by:

$$HL^+ + H^+ \rightleftharpoons H_2L^{2+}, \quad (6)$$

which yields the following expression:

$$K_2 = \frac{[H_2L^{2+}]}{[HL^+][H^+]}. \quad (7)$$

The value of $[H^+]$ was determined by measurement of the pH at equilibrium. The final theoretical solution for $[ML^+]$, the amount of metal–ligand complex in the buffer, is given by a quadratic equation which was used to determine the effect of cation identity, ligand concentration, metal concentration, and pH on the ability of cryptand 2.2.2. to form the metal–ligand complex which would regulate the electroosmotic flow. The theoretical plot of pH *vs.* metal–ligand complex formation is given in Fig. 3, and the effect of ligand concentration on metal–ligand formation is shown in Fig. 4. Each of these factors will be discussed in detail in a later section.

18-*Crown*-6. Macrocycles which cannot be protonated, like 18-crown-6, interact with buffer cations according to the following:

$$L + M^+ \rightleftharpoons ML^+ \quad (8)$$

$$K_m = \frac{[ML^+]}{[L_F][M^+]} \rightarrow \frac{[ML^+]}{([L_0] - [ML^+])([M_0^+] - [ML^+])}. \quad (9)$$

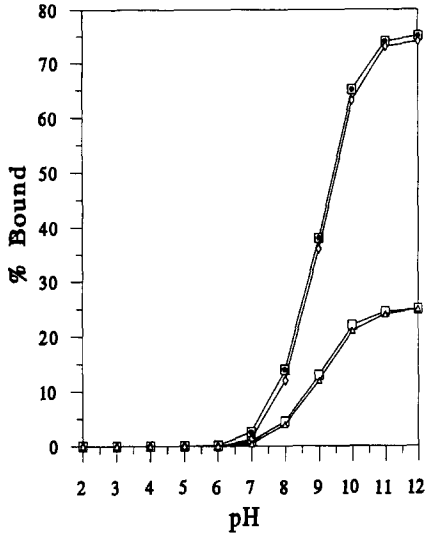

Fig. 3. Theoretical plot of the effect of pH on the binding of cryptand 2.2.2 (2.0 m$M$) to metal ion (6.0 m$M$). ◙ % 2.2.2 bound to $K^+$; ◇ % 2.2.2 bound to $Na^+$; □ % $K^+$ bound to 2.2.2; △ % $Na^+$ bound to 2.2.2.

From these expressions it can be seen that the amount of metal–macrocycle complex formed is not dependent on the pH as was the case for the cryptand 2.2.2. The predicted values for percent ligand and percent metal ion bound under different conditions are shown in Fig. 5. Conditions are given in the figure caption and these results will be discussed in a later section.

Initially four different macrocycles were incorporated into our buffer system as electroosmotic flow modifiers. However, only separations involving 18-crown-6 and cryptand 2.2.2 were extensively explored. The buffers incorporating 15-crown-5 and 12-crown-4 were not pursued after preliminary results (Fig. 6) indicated that analysis times were no longer with these buffers. These results can be compared to those with the 18-crown-6 (Fig. 7) and

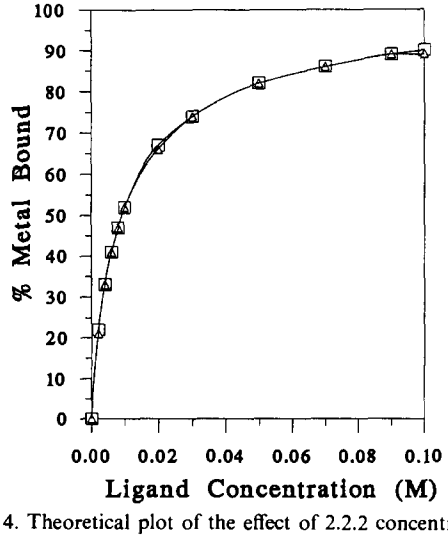

Fig. 4. Theoretical plot of the effect of 2.2.2 concentration on % metal bound at a pH of 10 with a metal ion concentration of 6.1 m$M$. □ % $K^+$ bound; △ % $Na^+$ bound.

Separation of a 12 anion standard with (A) 2.0 m*M* sodium tetraborate, 1.8 m*M* sodium dichromate, 43 m*M* boric acid, and 4.0 m*M* 18-crown-6, pH 7.2; and (B) 2.0 m*M* potassium tetraborate (prepared by ion exchange), 1.8 m*M* potassium dichromate, 43 m*M* boric acid, and 4.0 m*M* 18-crown-6, pH 7.2. Separation conditions: capillary, 75 $\mu$m i.d. × 375 $\mu$m o.d. × 60 cm; injection, gravity, 100 mm for 30 sec at 25 kV, indirect detection at 254 nm. Peak identities: (1) bromide, (2) chloride, (3) iodide, (4) sulfate, (5) nitrite, (6, 7) nitrate and oxalate, (8) thiocyanate, (9) citrate, (10) phosphate, (11) phthalate, (12) acetate. All analyte concentrations are 10 ppm with the exception of chloride which is 3 ppm.

cryptand 2.2.2 (Fig. 8), which are superior in terms of overall speed of analysis.

*Effect of buffer cation on separation and complex formation*

The variation in binding constants for the alkali metal cations with both 18-crown-6 and cryptand 2.2.2 are shown in Fig.1.[15] From these binding constants and from effects seen in macrocycle-based IC separation systems,[16] we anticipated changes in EOF according to the order of buffer cation $K^+ > Rb^+ > Na^+ > Cs^+$ and $Li^+$, regardless of which of the two macrocycles was used. This expected order follows the descending order of affinity of these cations for both macrocyclic ligands.

To the extent possible, buffers were prepared using commercially available chemicals. However, the required $Li^+$, $Rb^+$ and $Cs^+$ salts were not commercially available. A cation exchange system was used to replace the sodium ion in buffers made from sodium salts with each of the other three. However, owing to the availability of the different salts, our research focused on $Na^+$ and $K^+$ buffers only.

18-*Crown*-6. To determine the effect of changing the cation in the buffer system, analyses of an anion standard were performed using 18-crown-6 as the EOF modifier with both $Na^+$ and $K^+$ borate/tetraborate buffers. Comparison of the electropherograms in Fig. 7 shows that significant variation in EOF occurs when the cation in the buffer is changed from $Na^+$ (Fig. 7A) to $K^+$ (Fig. 7B). When $K^+$ is the cation in the buffer (Fig. 7B), the migration times and separation show improvement over the system in which the $Na^+$ is the cation in the buffer. Specifically, the migration times of 12 common anions were longer with the $Na^+$-based buffer than with the $K^+$-based buffer and not all peaks were resolved with the $Na^+$-based buffer. These experimental results correspond to theory, which predicts that $K^+$ binds 18-crown-6 more strongly than $Na^+$ (Fig. 5).[16] This conclusion is in keeping with our stated hypothesis concerning the mechanism of EOF modification by

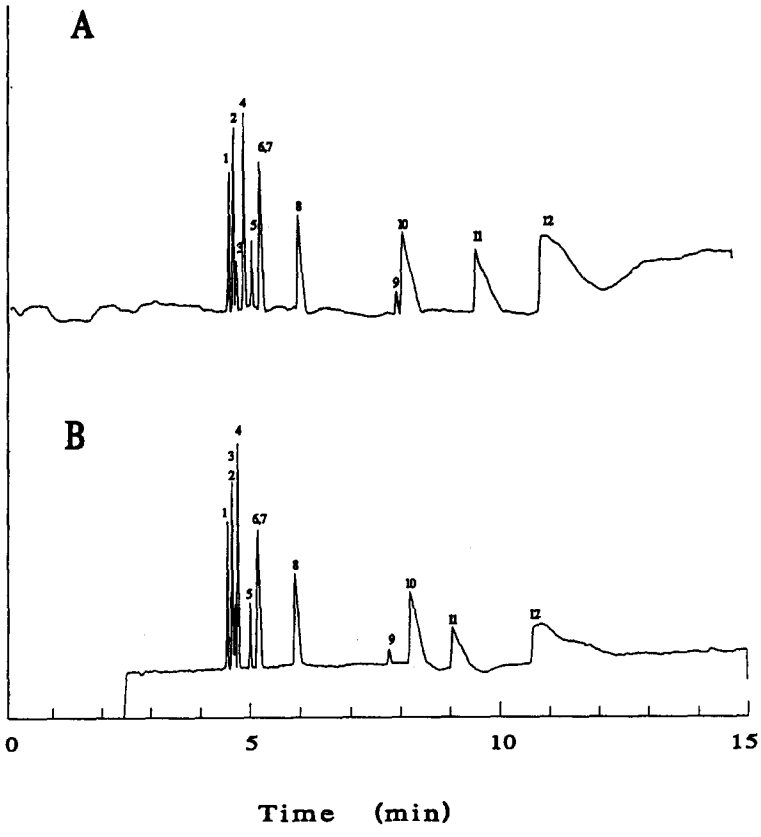

Fig. 8. Separation of a 12 anion standard with (A) 2.0 m*M* sodium tetraborate, 1.8 m*M* sodium dichromate, 43 m*M* boric acid, and 8.0 m*M* cryptand 2.2.2, pH 7.2; and (B) 2.0 m*M* potassium tetraborate (prepared by ion exchange), 1.8 m*M* potassium dichromate, 43 m*M* boric acid, and 8.0 m*M* cryptand 2.2.2, pH 7.2. Separation conditions: capillary, 75 $\mu$m i.d. × 375 $\mu$m o.d. × 60 cm; injection, gravity, 100 mm for 30 sec at 25 kV, indirect detection at 254 nm. Peak identities: (1) bromide, (2) chloride, (3) iodide, (4) sulfate, (5) nitrite, (6, 7) nitrate and oxalate, (8) thiocyanate, (9) citrate, (10) phosphate, (11) phthalate, (12) acetate. All analyte concentrations are 10 ppm with the exception of chloride which is 3 ppm.

macrocyclic complexes. We conclude that the higher population of macrocycle complexes in the presence of $K^+$ is responsible for the superior modification of EOF over the $Na^+$-based buffer.

*Cryptand* 2.2.2. Only above pH of 10 is the cryptand 2.2.2 sufficiently deprotonated for formation of the metal–ligand complex to become important. Above this pH, cation identity and concentration become significant contributors to the degree of EOF modification.

The effect of specific cations on complex formation with the cryptand can be seen in the theoretical plots of Figs 3 and 4. The amount of metal–ligand complex is expected to increase once the second $pK_a$ has been reached for both the $Na^+$-based and $K^+$-based buffers (Fig. 3). It is interesting to note that cation identity does not influence metal–cryptand complex formation (Fig. 4) to the extent seen with the 18-crown-6 system (Fig. 5), even at pH 10. Thus, the modification of EOF expected with the substitution of $K^+$ for $Na^+$ in the buffer system was not as pronounced for the cryptand 2.2.2 as it was for the 18-crown-6. However, the complex formation that occurs with either the $Na^+$ or $K^+$ still results in the expected dielectric layer formation and modification of the EOF.

*Effect of pH on proton ionizable macrocycles*

A plot of pH *vs.* percent cryptand 2.2.2 bound to $Na^+$ or $K^+$ (Fig. 3) illustrates that at pH < 10 the amount of metal–ligand complex is negligible compared to the amount of protonated macrocycle. The modification of the EOF by 2.2.2 in this pH range is based entirely on protonation of the macrocycle rather than the degree of metal ion complexation. At the pH we used in our experiment (pH ≈ 7.2), EOF modification was due to protonation of the nitrogen groups in the macrocyclic ring, and not to the actual binding of the macrocycle with the metal ion.

Table 1. Efficiency and migration times of 3 ppm $Cl^-$ in a borate/tetraborate buffer system

| Ligand concentration (*mM*) | 2.2.2-$Na^+$ | 2.2.2-$K^+$ | 18-crown-6-$Na^+$ | 18-crown-6-$K^+$ | DETA |

| 2.0 | 81542 | 67154 | 57589 | 53569 | 44713 |
| 4.0 | 71244 | 57795 | 25115 | 59481 | — |
| 8.0 | 76065 | 99929 | 37618 | 61832 | — |
| 16.0 | 100787 | 96529 | 55400 | 55400 | — |
| | Time (*min*) | Time (*min*) | Time (*min*) | Time (*min*) | Time (*min*) |
| 2.0 | 4.48 | 4.58 | 4.92 | 4.92 | 4.27 |
| 4.0 | 4.73 | 4.58 | 4.74 | 4.74 | — |
| 8.0 | 4.51 | 4.48 | 5.49 | 4.82 | — |
| 16.0 | 4.50 | 4.40 | 4.98 | 4.98 | — |

Support of this conclusion can be seen in a comparison of the two cryptand 2.2.2 electropherograms seen in Fig. 8. The two are not significantly different even though Fig. 8A was obtained using a $Na^+$-based buffer and Fig. 8B a $K^+$-based buffer, both at a pH of $\approx$7.2. The large difference in the binding constants between $Na^+$ and $K^+$ with this macrocycle causes one to expect a greater modification of EOF evidenced by shorter retention times of the analytes in Fig. 8B. These results conform to the hypothesis that pH, not metal–macrocycle complex formation, was the predominant factor in EOF modification. The protonated, positively charged cryptand 2.2.2 formed a dielectric layer with the walls of the capillary and resulted in a modification of the EOF that was equal or better in many aspects to modifying agents we had previously used in our buffer systems. A comparison of the electropherogram in Fig. 8B with the electropherogram in Fig. 9 shows the baseline improvement and improved efficiency seen with the protonated macrocycle system over a system employing DETA (diethylenetriamine) as the modifying agent.

An experiment was designed in which phosphate buffers, containing either the $Na^+$ or $K^+$ coupled with the cryptand 2.2.2, were adjusted to higher pH in an attempt to correct for this pH dependency. However, when these buffers were used the current became inordinantly high, resulting in a low resistance error in the system.

*Effect of the modifier on migration times, efficiency and resolution*

Table 1 shows the efficiencies and migration times of $Cl^-$ using the borate/tetraborate buffer system, pH 7.2, using different electroosmotic flow modifiers, including both macrocycles and DETA. The $Cl^-$ migration time and its dependence on the modifier is representative of all sample anions. The migration time of $Cl^-$ follows the order DETA < 2.2.2-$K^+$ $\approx$ 2.2.2-$Na^+$ < 18-Crown-6-$K^+$ $\ll$ 18-crown-6-$Na^+$. Table 2 shows the results of efficiency and migration times for $Cl^-$ in a phosphate buffer system, pH 5.0. The migration order for the phosphate system with the various modifiers followed the order 2.2.2-$Na^+$ $\approx$ 2.2.2-$K^+$ < DETA < 18-crown-6-$K^+$ < 18-crown-6-$Na^+$. Migration times for the two buffers are quite different. However, results for either buffer system support the conclusion that the effect on the electroosmotic flow using cryptand 2.2.2 is independent of buffer cation as described above. Based on these $Cl^-$ results, the borate/tetraborate buffer with cryptand 2.2.2 as the modifying agent resulted in the best efficiencies and migration times in our system.

When 18-crown-6 was used as the modifying agent the borate/tetraborate system yielded better efficiency and resolution than the phosphate buffer system. Results for the $K^+$- phosphate/18-crown-6 buffer system are not included in the

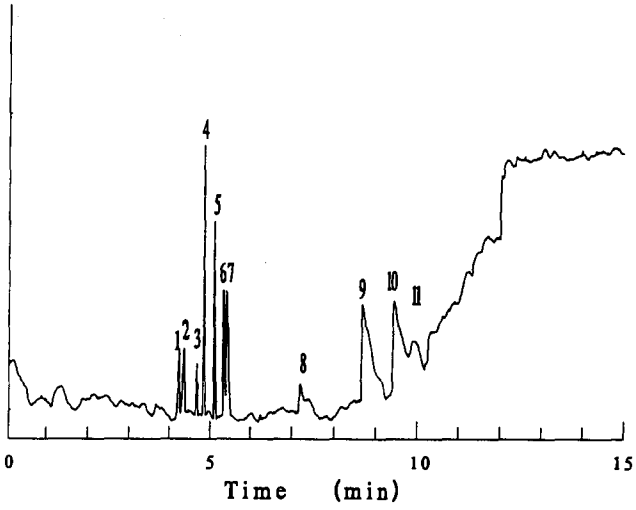

Fig. 9. Separation of a 11 anion standard with (A) 2.0 m*M* potassium tetraborate, 1.8 m*M* sodium dichromate, 43 m*M* boric acid, and 2.0 m*M* DETA, pH 7.2. Separation conditions: capillary, 75 $\mu$m i.d. × 375 $\mu$m o.d. × 60 cm; injection, gravity, 100 mm for 30 sec at 25 kV, indirect detection at 254 nm. Peak identities: (1) bromide, (2) chloride, (3) sulfate, (4) nitrite, (5) nitrate, (6) oxalate, (7) thiocyanate, (8) citrate, (9) phosphate, (10) phthalate, (11) acetate. All analyte concentrations are 10 ppm with the exception of chloride which is 3 ppm.

table as the separation for this system was poor and there was a constant fluctuation in current when this system was employed. A comparison of results for the $Na^+$-borate/18-crown-6 and $K^+$-borate/18-crown-6 buffers for $Cl^-$ ion separation clearly support earlier conclusions that $K^+$, the metal with the higher binding constant, results in the greatest modification of EOF.

As seen in Tables 1 and 2, the efficiency of $Cl^-$ using the macrocycle-based buffers is higher than when using the DETA–borate–tetraborate based buffer. However, the opposite is true when using the phosphate buffer. The migration time results in Table 1 indicate that the DETA–borate–tetraborate buffer yields slightly faster migration times, although higher efficiencies and better baseline stability are observed with a macrocycle as the modifier. The opposite was seen for the phosphate system. The migration times with the phosphate–macrocycle system were faster than with the DETA system, but the efficiency was lower.

In addition to the effects on efficiency and migration times, higher concentrations of the macrocycle resulted in efficiency and resolution improvement when using both the borate and phosphate buffers. The resolution of two peaks as the concentration of cryptand 2.2.2 is increased illustrates this point (Fig. 10).

## CONCLUSIONS

One possible disadvantage of using cryptands as electroosmotic flow modifiers is the expense involved with cryptands. While the current market price of the cryptand 2.2.2 discourages its use in analyses where it is difficult to recover, our results do show that use of macrocycles as electroosmotic flow modifiers in CE buffer systems yields better separations and higher efficiencies than use of DETA. Macrocycles can function as EOF modifiers because the metal–macrocycle complex forms a dielectric layer with the charges on the capillary surface. Theoretical calculations of complexation reactions conform to our experimental results.

One advantage of a macrocycle-based CE system we found is the improved efficiency that can be achieved with the cryptand 2.2.2 over DETA. We also observed an improvement in baseline stability over many analyses we have performed with DETA. Finally, we found that there exists a relationship between the quality of separations and the buffer–macrocycle system used. With phosphate buffer, the migration times of the anions were fast but the efficiencies were poor. With borate–tetraborate buffer the migration times were somewhat slower but efficiencies were much better.

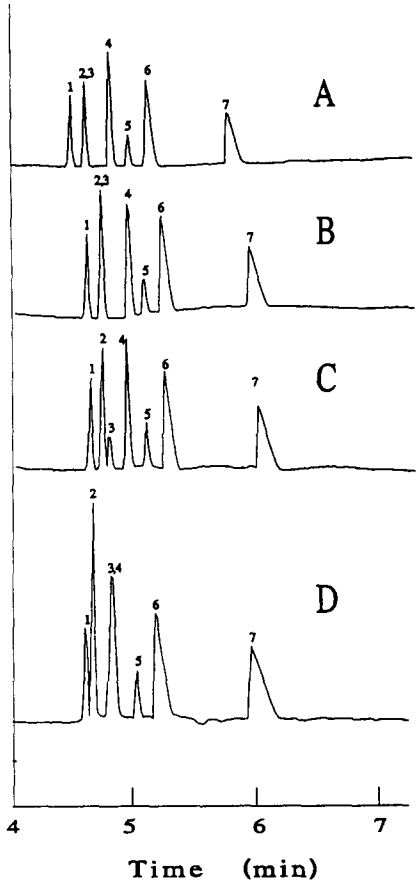

Fig. 10. The effect of changing the modifier concentration is illustrated as the resolution of peaks 2 and 3 is seen as the concentration of the cryptand 2.2.2 changes from: (A, B) 2.0, 4.0 m$M$; peak identities: (1) bromide, (2,3) chloride and iodide, (4) sulfate, (5) nitrite, (6) nitrate, (7) thiocyanate; (C) 8.0 m$M$; peak identities (2) chloride, (3) iodide; (D) 16 m$M$, peak identities: (2) chloride, (3, 4) iodide and sulfate. All analyte concentrations are 10 ppm with the exception of chloride which is 3 ppm.

# USE OF SURFACTANT-MEDIATED PHASE SEPARATION (CLOUD POINT EXTRACTION) WITH AFFINITY LIGANDS FOR THE EXTRACTION OF HYDROPHILIC PROTEINS

TOHRU SAITOH* and WILLIE L. HINZE†

Department of Chemistry, Laboratory for Analytical Micellar Chemistry, Wake Forest University, P.O. Box 7486, Winston-Salem, NC 27109-7486, U.S.A.

(*Received* 15 *June* 1994. *Revised* 29 *July* 1994. *Accepted* 2 *August* 1994)

**Summary**—The feasibility of utilizing a zwitterionic surfactant, 3-(nonyldimethylammonio)propylsulfate, or nonionic surfactant, Triton X-114, mediated phase separation in conjunction with affinity ligands was studied for hydrophilic protein extractions. Below (or above) its critical temperature (so-called cloud point), aqueous solutions of zwitterionic (or nonionic) surfactants separate into two immiscible phases, a surfactant-rich phase and an aqueous phase. Avidin was successfully extracted into the zwitterionic surfactant-rich phase when a small amount of the affinity ligand, *N*-(biotinoyl)dipalmitoyl-L-α-phosphatidyl ethanolamine, was added to the system. It was not possible to extract hexokinase into the surfactant-rich phase of the nonionic surfactant, Triton X-114, even if a considerable amount of octyl-β-D-glucoside was added to the solution as an affinity ligand. In contrast, the use of the zwitterionic surfactant and octyl-β-D-glucoside as an affinity ligand proved to be effective for the extraction of hexokinase. The hexokinase extraction efficiency was found to depend upon the solution pH and the concentration of the affinity ligand in the system. The results clearly indicate that hydrophilic proteins can be successfully extracted with surfactant mediated phase separations (cloud point extractions) via use of the zwitterionic surfactant, 3-(nonyldimethylammonio)propylsulfate, and appropriate affinity ligands. Some advantages of zwitterionic surfactants in such extractive processes relative to that of nonionic surfactants are delineated.

Aqueous solutions of many neutral (nonionic and zwitterionic) surfactant micellar systems, when subjected to temperature alterations, exhibit critical phenomenon.[1,2] That is, nonionic surfactant solutions, when heated, became turbid at the cloud point.[1] Above the cloud point temperature, such solutions separate into two isotropic phases, *i.e.* a surfactant-rich phase (also referred to as micellar-rich or coacervate phases in the literature[1–3]) and an essentially bulk aqueous phase. In contrast, aqueous solutions of certain zwitterionic surfactants display an upper consolute boundary. Thus, their isotropic two-phase region exists at temperatures below (rather than above) their critical temperature.[2]

Normally, the surfactant-rich phase has a very small volume element and hydrophobic species are efficiently concentrated into this phase allowing for their extraction and concentration. This phase separation behavior of nonionic surfactant micellar solutions (so-called cloud point extraction) was first utilized by Watanabe for the extraction and preconcentration of metal ions (as their metal chelates).[4,5] Subsequently, Bordier applied such phase separation behavior of solutions of the nonionic surfactant, Triton X-114, for the extraction and purification of hydrophobic membrane proteins.[6] An important advantage of the latter method is that membrane proteins can be easily separated from hydrophilic peripheral proteins. Since nonionic surfactant solutions are relatively mild, the hydrophobic proteins typically do not undergo any denaturation during the process. As a result, this general technique has experienced increasing popularity since Bordier's initial report.[7,8]

Recently, it has been reported that zwitterionic surfactants can be utilized in an analogous manner for the separation of hydrophobic from

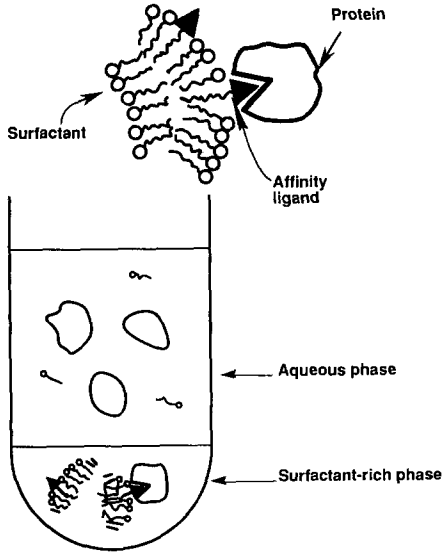

Fig. 1. Schematic representation of the surfactant-mediated phase separation process and affinity ligand partitioning in neutral micellar systems. Note: the surfactant-rich phase in the final phase separated system is not necessarily a micellar aggregate.[1,3,10]

hydrophilic proteins.[9] More important, the general use of zwitterionic (rather than nonionic) surfactants in such an extraction technique appears to offer significant advantages in terms of purer, homogenous surfactant preparation, minimum background absorbance at UV detection wavelengths, the two-phase region occurring at lower temperatures, more rapid phase separation, greater extraction efficiencies and concentration factors among others. A comprehensive review of the theory and applications of surfactant-mediated phase separations in analytical chemistry is available.[10] It should be noted that the phase separation behavior exhibited by aqueous solutions of other molecules, such as derivatized cyclodextrins[11] and polymeric systems,[12] has also been successfully exploited in extractive separations.

As yet, there appear to be no reports in the literature concerning the use of appropriate affinity ligands in conjunction with surfactant mediated cloud point extractions for the subsequent selective extraction and purification of hydrophilic proteins. The idea would be to use a relatively hydrophobic affinity ligand which would be specific for and strongly interact with the desired hydrophilic protein so that the resulting affinity ligand:protein complex would partition to the surfactant micellar aggregate and thus become concentrated in the surfactant-rich phase following phase separation. Figure 1 depicts the affinity cloud point extraction process. The use of affinity ligands in conjunction with the cloud point extraction would thus extend the scope of Bordier's original technique[6] to include selective extraction of hydrophilic proteins. It is rather surprising that this approach has not been previously reported in view of the fact that other extractive separation methods have been developed which employ the affinity interaction between proteins and substrates for efficient protein purification.[13] For example, aqueous polymeric phase separation systems with affinity polymers[12,14,15] as well as reversed micellar solvent extractions with affinity ligands[16] have been examined and developed for large scale protein purifications.

In this paper, we report the preliminary results of a feasibility study concerning the use of affinity ligands in conjunction with the zwitterionic and nonionic surfactant mediated phase separation technique for the extraction of relatively hydrophilic proteins. Avidin and hexokinase were extracted employing alkyl-biotin and octyl-$\beta$-D-glucoside, respectively as the affinity ligands in such cloud point extraction with the zwitterionic surfactant, 3-(nonyldimethylammonio)propyl sulfate (C9-APSO$_4$). In addition, the use of the nonionic surfactant, Triton X-114 in such affinity cloud point extractions was examined.

## EXPERIMENTAL

### *Apparatus*

All absorbance spectra and intensity measurements were made on a Varian Cary 219 UV-visible spectrophotometer. The pH measurements were made on a Corning Model 135 pH/ion meter.

### *Chemicals*

The zwitterionic surfactant, 3-(nonyldimethylammonio)propyl sulfate, (C9-APSO$_4$) was synthesized using a modified literature procedure[2] as recently reported.[9] The corresponding decyl analog (C10-APSO$_4$) is commercially available from Aldrich Chemical Co. (Milwaukee, WI, U.S.A.). The nonionic surfactants, polyethylene(7-8)-*p*-*t*-isooctylphenylether (Triton X-114) and polyoxyethylene(23)dodecanol (Brij-35) were obtained from Sigma Chemical Co. (St Louis, MO, U.S.A.) as 20 and 30 wt% solutions, respectively. The proteins and enzymes, *i.e.* avidin, from egg white; hexokinase, from baker's yeast, type III; concanavalin A, from

*Canavalia ensiformis*, type V; and ribonuclease B, from bovine pancreas, type III-B, were all also purchased from Sigma Chemical Co. and used as received. The affinity ligands *N*(biotinoyl)dipalmitoyl-L-α-phosphatidyl ethanolamine triethylammonium salt (R-biotin) and octyl-β-D-glucoside (octyl-glucoside) were obtained from Molecular Probes (Eugene, OR, U.S.A.) and Boehringer-Mannheim (Indianapolis, IN, U.S.A.), respectively. The water employed in this work was in-house distilled water which was further purified by passage through a Milli-Q System (Millipore Corp.). All other chemicals, reagents, and solvents were of the best commercial grade available.

*Procedures*

*Determination of phase diagrams and phase ratios.* The phase behavior of the zwitterionic surfactant, C9-$APSO_4$, in the presence of different amounts of the affinity ligand, octyl-glucoside, was determined by monitoring the temperature required for clarification of the solution mixture upon heating (or the onset of turbidity upon subsequent cooling). Typically, a 1.00 ml aqueous solution and 0.2000 g total of the surfactant and affinity ligand were thoroughly mixed in a 2.0 ml vial subsequent to being placed in a controlled temperature water bath (Haake, Berlin, Germany). The slope of the temperature change was less than 1°C per 15 min.

In the case of the nonionic surfactant system, a 0.20 ml portion of a 10 g/dl Triton X-114 aqueous solution and varying amounts of a 1.00 g/dl octyl-glucoside solution and methylene chloride were added to a 2.0 ml vial. Enough water was added to this mixture so that the final volume was 1.00 ml. The vial was placed in the controlled temperature water bath and the onset of turbidity (or clarification) temperature determined as described for the zwitterionic system.

The phase ratio (*i.e.* ratio of the volume of the surfactant-rich phase to that of the aqueous phase following phase separation) of the different surfactant micellar aqueous solutions was determined using a calibrated glass tube. The appropriate aqueous surfactant solution was placed into the tube and kept at 4°C for one week in the case of C9-$APSO_4$ (or at 30°C for four days in the case of Triton X-114) prior to measurement of the respective phase volumes. The results reported are the average of triplicate measurements. [Note: this procedure for determination of the phase ratio under different experimental conditions was far more accurate than that determined using centrifuge tubes and direct centrifugation. No detectable effect of centrifugation at 1500 rpm (or even 10,000 rpm) was observed on the determined volume fractions of the aqueous and surfactant-rich phases.]

*Affinity cloud point extraction of avidin with zwitterionic C9-$APSO_4$ and R-biotin as affinity ligand.* A mass (0.00–10.0 mg) of the R-biotin affinity ligand and C9-$APSO_4$ surfactant (190.0–200.0 mg) were placed into a 2.0 ml vial. The total mass of the mixture was kept at 0.2000 g. A 0.950 ml portion of an appropriately buffered aqueous solution was next added to the vial. This solution was sonicated until two clear liquid phases resulted. The vial was placed into an ice water bath in order to maintain a temperature of 0°C. Next, 0.050 ml of an avidin solution (containing 5.0 mg avidin/ml) was added to the vial, the vial mildly stirred for 5 min at 4°C, and then centrifuged at 3000 rpm for 10.0 min. A 0.500 ml aliquot of the bulk aqueous phase of the phase separated system was withdrawn from the vial using a Hamilton microsyringe and mixed well with an equivolume portion of a 1.0 wt% Brij-35 buffered aqueous solution which had been adjusted to the same pH as the extraction solution under study. The concentration of avidin and R-biotin present in the aqueous phase were calculated from absorbance measurements at 282 and 260 nm, respectively. The extraction percentage of avidin as a function of pH was calculated on the basis of the mass balance of avidin and the volume of the aqueous and the surfactant-rich phases.

*Affinity cloud point extraction of proteins with nonionic Triton X-114 and octyl-glucoside as the affinity ligand.* A 0.200 ml aliquot of 10.0 g/dl Triton X-114 aqueous solution (or 10.0 g/dl Triton X-114 solution containing 2.50 g/dl of ocytl-glucoside aqueous solution) was pipetted into a 2.00 ml sample vial. Next, 0.100 ml of 0.05*M* Tris-HCl buffer and 0.600 ml distilled water were added to the vial. After the solution was cooled to 4.0°C, a 0.100 ml portion of an appropriate protein solution (containing 5.0 mg protein per ml) was also added to the vial. The resulting solution was gently stirred for 5 min while the temperature was maintained at *ca.* 4°C. A small amount of methylene chloride was next added in order to promote the phase separation (2 μl in the case of the Triton X-114 only system and 4.3 μl for the Triton X-114-octyl-glucoside affinity system). After the vial

was placed into a constant temperature water bath (30°C) for 5 min, it was centrifuged (at 3000 rpm) for 10 min at room temperature (*ca.* 23°C). An aliquot of the aqueous phase of the phase separated system was withdrawn and the protein concentration determined via use of Lowry's method[17] following appropriate dilution. [Note: The concentration of the surfactants, C9-$APSO_4$ and octyl-glucoside, in the aqueous phase is roughly equal to their critical micelle concentration (CMC). At this concentration level, the surfactants' presence did not interfere with Lowry's method. Some interference was noted due to the buffer components. However, after dilution of the sample, this presented no difficulty.] The protein extraction percentage was calculated on the basis of the material balance and phase ratio of the extraction system.

*Affinity cloud point extraction of hexokinase with C9-$APSO_4$ and octyl-glucoside as affinity ligand.* Portions of octyl-glucoside (0.000–0.0600 g) and C9-$APSO_4$ (0.1400–0.2000 g) were placed in a 2.00 ml vial. The total amount of both materials present was always 0.2000 g. Next, 0.900 ml of buffer solution was added to the vial. The vial was shaken to mix its contents and after a clear homogenous solution (or clear two phase solution) was obtained, the vial was placed into an ice water bath. A 0.100 ml portion of hexokinase (7.5 mg/ml) was added to the system. The contents of the vial were then mildly stirred for 5 min at 4°C after which it was centrifuged (at 3000 rpm) for 10 min at 4°C. A 0.500 ml aliquot of the aqueous phase was collected by use of a microsyringe and mixed with an equivolume buffered 1.0 wt% Brij-35 aqueous solution which was adjusted to the same pH value as that of the original sample solution. The estimation of the extraction percentage of hexokinase was the same as that previously described.

## RESULTS AND DISCUSSION

### *Phase ratios and diagrams*

The phase diagram for the zwitterionic surfactant, C9-$APSO_4$, in the absence of any affinity ligand additives has previously been reported in the literature.[2,9] Figure 2 shows the volumes of the surfactant-rich extractant and aqueous phases as a function of the concentration of the affinity ligand, octyl-glucoside, for the zwitterionic C9-$APSO_4$, surfactant system.

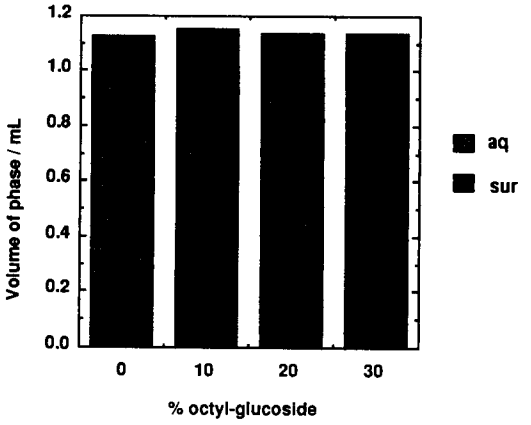

Fig. 2. Volume of aqueous and surfactant-rich phases following phase separation of aqueous mixtures containing C9-$APSO_4$ and octyl-glucoside as a function of the % octyl-glucoside present (*i.e.* [octyl-glucoside]/[octyl-glucoside] + [C9-$APSO_4$]). Conditions: 1.00 ml aqueous solution volume mixed with 0.2000 g total amount of the octyl-glucoside and C9-$APSO_4$ surfactants.

As the amount of the octyl-glucoside increased, the volume of the surfactant-rich extractant phase slightly increased. Additionally, as seen in Fig. 3, the critical temperature for the phase separation of aqueous solutions of C9-$APSO_4$ decreased as the amount of octyl-glucoside present was increased. For example, the critical temperature of an aqueous solution composed of 0.1500 g of C9-$APSO_4$ and 0.1000 g octyl-glucoside was approximately 0°C whereas in the absence of any octyl-glucoside, it was *ca.* 65°C. It may be noted that the critical micelle concen-

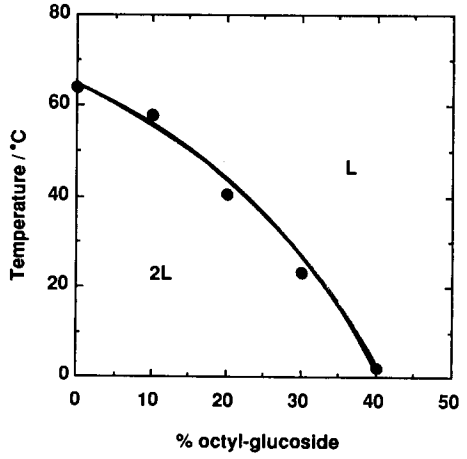

Fig. 3. Cloud point (upper critical temperature) of an aqueous mixed solution of zwitterionic C9-$APSO_4$ surfactant and octyl-glucoside affinity ligand as a function of the % octyl-glucoside present (*i.e.* % concentration ratio of octyl-glucoside [octyl-glucoside]/[octyl-glucoside] + [C9-$APSO_4$]). L refers to the single isotropic solution region, whereas 2L indicates the region where two isotropic phases coexist.

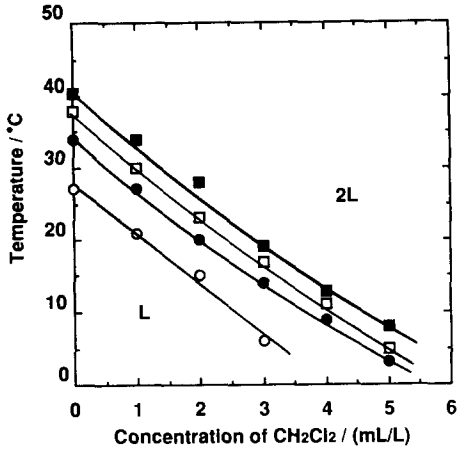

Fig. 4. Cloud point curves for aqueous solutions containing Triton X-114, octyl-glucoside, and methylene chloride as a function of the amount of added methylene chloride. Conditions: [Triton X-114] = 2.0 g/dl with [octyl-glucoside]: (○) 0, (●) 0.20, (□) 0.30, and (■) 0.40 g/dl.

tration (CMC) of C9-APSO$_4$ is 45.0m$M$ in water in the absence of any additives.[9,10]

The cloud point of a 2.00 g/dl Triton X-114 aqueous solution in the absence of any additives is 27°C. This value is in fairly good agreement with literature reports which range from 20 to 30°C for the cloud point of Triton X-114 solutions depending upon the exact surfactant concentration employed.[10] As can be seen from the data presented in Fig. 4, which illustrates the influence of methylene chloride upon the cloud point of Triton X-114 in the presence and absence of different amounts of the affinity ligand, octyl-glucoside, the cloud point temperature of Triton X-114 is drastically altered by additives. If increasing amounts of octyl-glucoside are added to aqueous solutions of Triton X-114, the cloud point increases and higher temperatures are required for the phase separation. This could be detrimental in protein extractions since the activity of many enzymes is known to decrease in the presence of surfactant solutions at or above room temperature.[18,19] However, it is well known that the addition of very small amounts of some relatively hydrophobic organic solvents can cause significant decreases in the cloud point of nonionic surfactant solutions. Thus, as can be observed from Fig. 4, the addition of small amounts of methylene chloride was found to be very effective in that it decreased the cloud point temperature of the Triton X-114/octyl-glucoside affinity system so that protein extractions can be carried out well below room temperature. In addition, its use resulted in the formation of a rigid, surfactant-rich extractant phase. Recently, there was a report in the literature concerning the use of glycerol to decrease the cloud point of Triton X-114 solutions in an analogous manner.[8] In most of our extraction studies the cloud point of the aqueous solutions of Triton X-114 and octyl-glucoside were adjusted to be approximately 7°C by the addition of appropriate amounts of methylene chloride.

The volume of the surfactant-rich phase following phase separation of 1000 ml of an aqueous 2.0 g/dl Triton X-114 solution containing 2 ml/l. methylene chloride was found to be 0.149 ml while that containing 4.3 ml/l. methylene chloride plus 0.50 g/dl octyl-glucoside was 0.178 ml. The CMC value for Triton X-114 in water in the absence of any additives is 0.35m$M$.[10]

*Affinity cloud point extraction of avidin using C9-APSO$_4$ with R-biotin as the affinity ligand*

Figure 5 illustrates the extent of extraction of avidin into the C9-APSO$_4$ surfactant-rich phase as a function of the concentration of the affinity ligand, *N*-(biotinoyl)dipalmitoyl-L-α-phosphatidylethanolamine triethylammonium salt (R-biotin), present. In the absence of any added affinity ligand or at very low R-biotin concentrations, the extraction percentage of avidin was low (*ca.* 10%) and did not significantly increase. However, in the higher concentration region of the R-biotin affinity ligand, the extraction of avidin increased. Thus, the overall shape of the curve for the extraction efficiency of avidin versus concentration of R-biotin is sigmoidal. Although avidin is considered to be a relatively hydrophilic protein, approximately

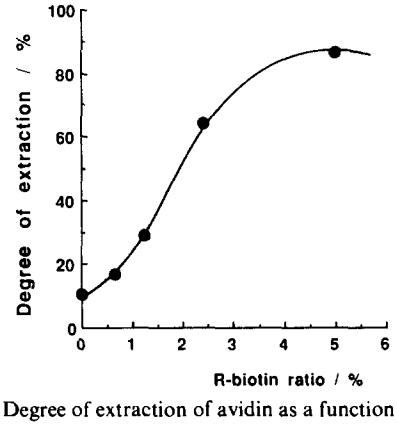

Fig. 5. Degree of extraction of avidin as a function of added affinity ligand, *N*-(biotinoyl)dipalmitoyl-L-α-phosphatidyl ethanolamine (R-biotin) present (*i.e.* [R-biotin]/[R-biotin] + [C9-APSO$_4$]) for the cloud point extraction with the zwitterionic surfactant, C9-APSO$_4$, at 4 C.

88% of the avidin was extracted from the aqueous solution into the C9-$APSO_4$ surfactant phase with only 10.0 mg of the R-biotin affinity ligand being required. The distribution coefficient for avidin (*i.e.* $[avidin]_{surf}/[avidin]_{aq}$) following cloud point extraction with C9-$APSO_4$ was found to be 0.41 in the absence of and 22.5 in the presence of 5.0% of the biotin affinity ligand.

It is well known that the avidin–biotin interaction is very strong. For instance, the avidin:biotin complex reportedly has a dissociation constant ($K_m$) of approximately $10^{-15}M$.[20] The efficient cloud point extraction of avidin can be regarded as resulting from this strong interaction which allows the hydrophobic affinity R-biotin ligand to "drag" the bound avidin into the C9-$APSO_4$ surfactant micellar phase (as illustrated in Fig. 1). The strong avidin–biotin interaction had previously been utilized for several applications in membrane chemistry and molecular biology.[21,22] The developed R-biotin ligand affinity cloud point extraction using C9-$APSO_4$ might also prove to be a useful alternative method in these type of applications.

The described cloud point affinity extraction procedure may not prove to be as useful for the large-scale purification of avidin or avidin-combined protein materials due to the requirements for its subsequent recovery from the extractant phase. In the biotin affinity chromatographic purification procedure for avidin, the conditions required for the subsequent elution of avidin from its biotin-bound state were a combination of low pH (pH 1.5) and a high concentration ($6.0M$) of guanidine hydrogen chloride. However, Orr *et al.*[23,24] have reported that while the free base form of 2-imminobiotin also strongly interacts with avidin ($K_m = 3.5 \times 10^{-11}M$), the cationic form (in the region below pH 4) only interacts weakly ($K_m < 10^{-3}M$). Thus, the use of such alkyl-2-imminobiotin affinity ligand instead of the R-biotin ligand described should prove to be superior for the large scale purification of avidin using the described affinity cloud point extraction method. This is due to the subsequent ease with which the avidin could then be recovered from the extractant surfactant-rich phase.

Under the optimal experimental conditions, the extraction per cent of avidin (*ca.* 88%) was not quite quantitative. This is probably the consequence of the fact that the avidin–biotin interaction is altered by the presence of the C9-$APSO_4$ surfactant present and/or that some of this surfactant still present (after phase separation) in the bulk aqueous phase could solubilize some of the R-biotin affinity ligand (and thus some of the bound avidin). Based on phase diagrams reported by Nilsson *et al.*,[2] the concentration of C9-$APSO_4$ originally present in the extraction system is above 60 wt%. Thus, it would not be surprising if the avidin–biotin binding interaction were affected by this concentrated surfactant solution. Additionally, UV absorbance data show that a small amount of the R-biotin affinity ligand is present in the aqueous phase following the extraction. As some of the zwitterionic C9-$APSO_4$ surfactant is also present in this aqueous phase, its presence may solubilize some of the affinity ligand and thus cause some of the R-biotin to remain in the aqueous phase. Despite the fact that the extraction is not quantitative, the developed cloud point extraction of avidin with R-biotin as the affinity ligand may prove to be a useful method because the preparation of the aqueous–surfactant phase separation system and the extraction procedure are very easy and simple. Additionally, the 88% extraction efficiency achieved is quite good and comparable with other reported extraction schemes for avidin.

*Attempted affinity cloud point extraction of proteins with nonionic Triton X-114 and octyl-glucoside*

Figure 6 illustrates the extent of extraction of the hydrophilic proteins, concanavalin A, ribonuclease B, hexokinase, and cytochrome *c* and the hydrophobic protein, bacteriorhodopsin using the nonionic surfactant, Triton X-114, with octyl-glucoside as the affinity ligand. No apparent extraction was achieved in the case of hexokinase and ribonuclease B and only a very small amount of cytochrome *c* was extracted. As previously reported by Bordier,[6] nearly 100% of the hydrophobic bacteriorhodopsin was extracted with the Triton X-114 in the absence of the octyl-glucoside (as well as in its presence).

Concanavalin A was slightly extracted (*ca.* 12%) by Triton X-114 alone. If the affinity ligand, octyl-glucoside (5 g/l.), was added to the extraction system, then the extent of extraction for concanavalin A increased (Fig. 6). However, the extraction per cent for concanavalin A is still fairly low (*ca.* 28%). This low affinity cloud point extraction efficiency was surprising in view

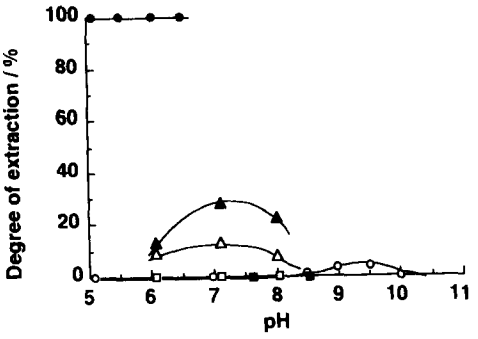

Fig. 6. Degree of extraction for different proteins into the nonionic Triton X-114 surfactant-rich phase using octyl-glucoside as the affinity ligand as a function of pH at 30°C: bacteriorhodopsin (●), cytochrome *c* (○), hexokinase (□), ribonuclease B (■), and concanavaline A in absence (△) and presence (▲) of the affinity ligand. Conditions: for extraction of bacteriorhodopsin and cytochrome [Triton X-114] = 2 g/dl, [octyl-glucoside] = 0.10 g/dl, and 3.0 ml/l. methylene chloride; for extraction of concanavaline A, hexokinase, and ribonuclease B [Triton X-114] = 2.0 g/dl, [octyl-glucoside] 0.50 g/dl, and 4.3 ml/l. methylene chloride; and for extraction of concanavaline A in absence of the affinity ligand [Triton X-114] = 2.0 g/dl and 2.0 ml/l. methylene chloride.

of the fact that it had been reported that the affinity interaction between concanavalin A and octyl-glucoside had been successfully employed for the extraction of concanavalin A into an organic reversed micellar phase at room temperature.[16] Sheu *et al.* found that such reversed micellar aqueous (and thus polar) core region was suitable for the incorporation of proteins (including hydrophilic ones).[25] In contrast, in the case of cloud point extractions, hydrophilic proteins do not appreciably distribute or bind to the relatively hydrophobic surfactant micellar entity.[6] The low extraction efficiency could be due in part to the temperature at which the extraction was conducted (30°C) as it has been reported that the affinity interaction between proteins and substrates decreases as the temperature increases.[26–28] Furthermore, there is the added possibility of denaturation of proteins in such highly concentrated surfactant solutions at high temperature as described previously.[18,28] For instance, solutions of hexokinase, especially type III, were found to be very unstable even if in the presence of suitable stabilizers.[29] Thus, it is thought that successful affinity cloud point extraction systems using nonionic surfactants will require suitable phase separation conditions, *i.e.* a nonionic surfactant–affinity ligand system in which the cloud point is below 0°C and the phases separate well at about 0°C. In this regard, the recent reports on the use of glycerol or Triton X-45 to allow for the low-temperature phase separation of Triton X-114 may prove useful.[8,30]

*Affinity cloud point extraction of hexokinase with zwitterionic C9-$APSO_4$ as surfactant and octyl-glucoside as the affinity ligand*

Figure 7 shows the extent of hexokinase extracted as a function of the solution pH by C9-$APSO_4$ both in the absence and presence of the affinity ligand, octyl-glucoside. In the absence of the affinity ligand, only 4–12% hexokinase was extracted by the C9-$APSO_4$ depending upon the pH employed. As can be seen, at each pH level examined, the presence of the affinity ligand in the zwitterionic surfactant medium led to an appreciable increase in the amount of hexokinase extracted (to over 50%). This fact suggests that the octyl-glucoside was distributed in the surfactant micellar phase and that it acted as an affinity ligand for the hydrophilic protein, hexokinase. A dissociation constant ($K_m = 1 \times 10^{-4} M$) has been reported in the literature for the D-glucose–hexokinase complex.[31] These successful results with the zwitterionic C9-$APSO_4$ surfactant are in sharp contrast with that previously mentioned for the attempted affinity cloud point extraction of hexokinase with the nonionic surfactant Triton X-114 and octyl-glucoside in which no hexokinase was extracted. That a small amount of hexokinase was extracted using just the zwitterionic C9-$APSO_4$ surfactant in the absence of the affinity ligand suggests that the charged head groups of this surfactant might interact with this hydrophilic protein and enhance its extraction efficiency vis-à-vis that

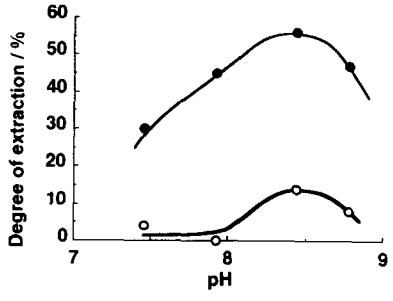

Fig. 7. Dependence of the extraction percentage of hexokinase upon pH for the cloud point extraction using the zwitterionic surfactant C9-$APSO_4$ in the absence (○) and presence (●) of the affinity ligand, octyl-glucoside, at 4°C. Conditions: (○) 0.2000 g C9-$APSO_4$ in 1.00 ml aqueous solution; (●) 0.1600 g C9-$APSO_4$ plus 0.0400 g octyl-glucoside in 1.00 ml aqueous solution.

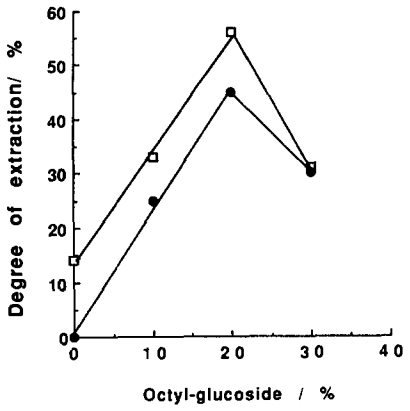

Fig. 8. The effect of the octyl-glucoside affinity ligand concentration ratio (*i.e.* [octyl-glucoside]/[octyl-glucoside] + [C9-$APSO_4$]) upon the extent of extraction of hexokinase at pH 7.92 (●) and 8.44 (□) using the zwitterionic surfactant, C9-$APSO_4$, at 4.0°C.

possible with the uncharged Triton X-114 surfactant system.

Based upon the data in Fig. 7, it appears that the most suitable pH for the affinity extraction of hexokinase with C9-$APSO_4$ is about 8.5. At each pH level between 7 and 9 examined, the maximum extraction efficiency of hexokinase was observed when the concentration ratio of the octyl-glucoside per total surfactant ratio was 20 wt% (see Fig. 8). Strangely, when the concentration ratio of octyl-glucoside was increased to 30 wt%, the extraction efficiency decreased. Bordier has reported that the amount of octyl-glucoside displaced from the surfactant-rich phase of Triton X-114 to the aqueous phase increased as the concentration of octyl-glucoside increased.[6] If the same situation occurs for the zwitterionic C9-$APSO_4$ system, then this might explain the decreased hexokinase extraction efficiency at the highest octyl-glucoside concentration level. It might be noted that under our experimental conditions for the C9-$APSO_4$–octyl-glucoside system, the clear aqueous phase after centrifugation at 4°C turned turbid again if the temperature was lowered to 0°C. This suggests that the aqueous phase still contained both C9-$APSO_4$ and octyl-glucoside. The fact that some of the affinity ligand was still present in the aqueous phase probably explains why the optimum extraction efficiency was only around 58% for hexokinase. Thus, the use of a more hydrophobic alkyl-glucoside affinity ligand possessing a longer alkyl group should be more effective in such affinity cloud point extraction of hexokinase since less of the ligand would be present in the aqueous phase and a clearer phase separation should result.

A significant advantage of the affinity cloud point extraction technique using the zwitterionic surfactant, C9-$APSO_4$, and octyl-glucoside (or other alkyl-glucosides) as affinity ligand is that all procedures, including the extraction of the proteins, can be conducted at low temperature. This is particularly important in the extraction of thermally labile proteins. A more important advantage of this system is that both the extractant surfactant and affinity ligand can be easily removed from the protein sample by subsequent dialysis.[32] This is a consequence of the relatively high CMC values of both of these surfactants (0.045*M* for C9-$APSO_4$[9] and 0.025*M* for octyl-glucoside[33]). In contrast, the CMC of Triton X-114, 0.35m*M*, is too low for the subsequent use of the dialysis technique for its removal from the extracted protein sample. Furthermore, the phase separation occurs much faster for the systems incorporating a zwitterionic surfactant compared to those involving a nonionic surfactant.[9] This quicker phase separation is important not only for handling convenience but also for the potential application of the technique to continuous systems such as a counter-current extraction or a flow injection analysis.

These preliminary results indicate that the affinity cloud point extraction technique is feasible for the purification of hexokinase. This extraction method might also prove useful in those studies concerning determination of the biodistribution of this protein.[34]

## CONCLUSIONS

The preliminary results presented demonstrate the feasibility of employing affinity ligands to extend the scope of Bordier's cloud point extraction technique to include hydrophilic biomaterials in analytical separations. Potential advantages of the approach include experimental convenience, lower cost, and enhanced analytical sensitivity due to the fact that the hydrophilic proteins can be easily extracted from the bulk aqueous solution into the much smaller volume element of the surfactant-rich phase following phase separation. Since zwitterionic and nonionic surfactants are routinely employed in the initial solubilization and fractionation steps of many protein isolation schemes[35,36] means that by judicious selection of that surfactant, the aforementioned affinity

ligand:cloud point extraction procedures can be subsequently employed by mere addition of the proper affinity ligand. Thus, this approach is compatible with the first step in many existing biomaterial separation and purification schemes. The general approach may also prove feasible for the large scale selective separation of some hydrophilic proteins although much more work is required to demonstrate this aspect. A particular advantage in this latter application when employing zwitterionic surfactants will be the ease and rapidness with which its solutions phase separate and the ability to conveniently remove the zwitterionic surfactant from the protein by dialysis as previously mentioned.

*Acknowledgements*—We thank Professor Fawzy S. Sadek (Winston-Salem State University) for providing laboratory space for conducting a portion of this work during which time our building was closed due to an asbestos crisis and Dr Yasuzo Suzuki (Research Institute for Polymers and Textiles, Japan) for helpful discussions. In addition, we thank several anonymous referees for their helpful suggestions. # SIMULTANEOUS DETERMINATION OF PYRIDOXAL AND PYRIDOXAMINE BY DIFFERENT SPECTROFLUORIMETRIC TECHNIQUES

J. J. BERZAS NEVADO, J. A. MURILLO PULGARÍN and M. A. GÓMEZ LAGUNA

Department of Analytical Chemistry and Food Technology, University of Castilla-La Mancha, 13071 Ciudad Real, Spain

(*Received* 8 *February* 1994. *Revised* 1 *August* 1994. *Accepted* 2 *August* 1994)

**Summary**—Binary mixtures of pyridoxal and pyridoxamine can be resolved by using zero-crossing first derivative spectrofluorimetry, first derivative constant wavelength synchronous luminescence spectrometry and first derivative constant energy synchronous luminescence spectrometry. These methods do not require any previous separation steps. The lowest quantization limit is obtained with first derivative constant energy synchronous fluorescence (13.0 and 9.0 $\mu$g/l. for pyridoxal and pyridoxamine, respectively). The measurements were performed in aqueous medium at pH 7.0 provided by adding 0.05*M* phosphate buffer solution. In order to demonstrate the validity of these methods a complete and exhaustive statistical analysis of the experimental data was performed. Pyridoxal and pyridoxamine were determined by these methods in synthetic and real mixtures with good results.

The determination of vitamin $B_6$ and its derivatives is of great interest, but this determination is quite complicated owing to the multiple forms and similar structures of these compounds. Different methods have been reported of characterizing and resolving mixtures of these compounds by microbiological,[1] enzymatic,[2] polarographic,[3] spectrophotometric[4] and fluorimetric methods.[5] However, some prior separation steps are necessary in all of them. Petidier *et al.* reported[6] a method for the simultaneous determination of some derivatives of vitamin $B_6$ by using second derivative fluorescence spectroscopy of these compounds, but it is necessary to use reactions of these compounds with beryllium in ammoniacal medium.

The sensitivity and selectivity of fluorescence is quite useful in analyses, but many spectra of several fluorescence compounds are often impossible to resolve satisfactorily without separation techniques, although each fluorescence compound can be characterized by two wavelengths. Therefore, the development of a technique which is able to improve the selectivity of fluorescence for multicomponent analysis and which does not involve separation steps and is less time-consuming, is of great interest.

In this paper we combined synchronous fluorescence spectroscopy introduced by John and Soutar,[7] with derivative fluorescence technique (described by Green and O'Haver[8]), to resolve binary mixtures of pyridoxal and pyridoxamine, since they showed highly overlapping spectra. Constant wavelength synchronous luminescence spectroscopy implied the simultaneous scanning of both the excitation and emission monochromator at the same scan speed. By using this technique, a reduction in Rayleigh scattering can be obtained.

Inman and Winefordner[9] describe constant energy synchronous luminescence spectroscopy, where a constant energy difference is maintained between the monochromators. This technique avoids interference in Raman scattering.

Synchronous spectra are simpler, narrower, and hence more distinctive than conventional spectra. The combination of derivative and spectrofluorimetric techniques improved the selectivity of the analysis. Thus, the derivative synchronous fluorescence method has been described for the resolution of compound mixtures with spectra of similar characteristics such as those provided by motor oil,[10] or polycycle aromatic.[11] A first study appeared in which constant energy synchronous luminescence was combined with derivative fluorescence technique to determine four polynuclear hydrocarbons.[11] Another work appeared recently on the resolution of binary mixtures of nafcillin and methicillin[12] using these techniques.

This paper describes four methods to resolve the mixture of pyridoxal and pyridoxamine by employing first derivative excitation and emission spectra; and first derivative synchronous fluorimetry (constant wavelength and constant energy). In all cases, the mixtures were resolved by scanning only one spectrum.

## EXPERIMENTAL

### *Reagents*

Pyridoxal and pyridoxamine were purchased from Merck and Sigma, respectively. Stock solutions of 50.0 mg/l. of each one were prepared by dissolving in Milli-Q water. A 0.05*M* buffer solution of pH 7.0 was prepared by mixing suitable amounts of dihydrogen phosphate solution with sodium hydroxide. Stock solutions were stored at 4°C and protected from the light. Under these conditions they showed no sign of decomposition for at least eight days.

### *Apparatus*

Fluorescence measurements were performed on a Perkin–Elmer LS-50 equipped with Xenon Lamp, connected to an Attaio S 3000 ST 386 computer, fitted with Perkin-Elmer F. L. Data Manager (FLDM) software and Epson FX-850 printer. 'FTOTAL'[13] software was used for processing the total luminescence spectra.

Thermostatic equipment and a Crison mod 2001, pHmeter with glass-satured calomel combination electrode were also used.

### *Procedures*

*Determination of pyridoxal and pyridoxamine by first derivative of excitation spectra.* A known volume of stock solution containing 24.0–1000 μg/l. of pyridoxal and 22.0–1000 μg/l. of pyridoxamine was placed in a 25-ml volumetric flask. Immediately afterwards, 2.5 ml of pH 7.0 buffer solution were added to every volumetric flask and diluted to the mark with Milli-Q water. Reagent blank was not necessary.

The excitation spectra were recorded with an emission wavelength at 388 nm to determine pyridoxal in the presence of pyridoxamine and pyridoxamine in the presence of pyridoxal. First derivatives were calculated and the absolute value of the first derivatives were measured at 316 and 325 nm for the determination of pyridoxal and pyridoxamine, respectively.

*Determination of pyridoxal and pyridoxamine by first derivative of emission spectra.* By using this technique both vitamins can be determined when they are found in the range 68.0–1000 μg/l. for pyridoxal and 36.0–1000 μg/l. for pyridoxamine.

The samples were prepared as in the first method. The emission spectra were recorded with excitation at 324 nm for the simultaneous determination of pyridoxal and pyridoxamine. First derivatives were calculated and the absolute values of the first derivative were measured at 376 and 391 nm for the determination of pyridoxal and pyridoxamine respectively.

*Determination of pyridoxal and pyridoxamine by first derivative of constant wavelength synchronous spectra.* This technique allows us to determine pyridoxal and pyridoxamine simultaneously by recording only one synchronous spectrum when these vitamins are found in the range 18.0–1000 μg/l. for pyridoxal and 16.0–1000 g/l. for pyridoxamine.

The sample preparations were thermostatically controlled at 20°C, and the synchronous spectra were recorded by scanning both monochromators together, while maintaining a constant of 56 nm difference between both wavelengths. First derivatives were calculated, and the absolute values of the first derivatives were measured at 316 nm for pyridoxal and 328 nm for pyridoxamine.

*Determination of pyridoxal and pyridoxamine by first derivative of constant energy synchronous spectra.* The synchronous spectra must be recorded maintaining a constant difference of $-4900\ cm^{-1}$ between their wave numbers. The first derivative was calculated and the absolute value was measured at 316 and 325 nm for the determination of pyridoxal and pyridoxamine respectively. Samples were prepared as in the previous methods with pyridoxal and pyridoxamine concentrations varying from 13.0 to 1000 μg/l. for pyridoxal and 9.0 to 1000 μg/l. for pyridoxamine.

## RESULTS AND DISCUSSION

### *Spectra characteristics*

Total luminescence spectra show the best characterization of the fluorescence compound. They were generated by a suitable computer program.[13] These spectra can be plotted as an isometric projection, where excitation spectra, at stepped increments of emission wavelength, are recorded and drawn. Total luminescence spectra can be transformed to a two-dimensional plot of excitation and emission wavelengths by linking points of equal intensity to

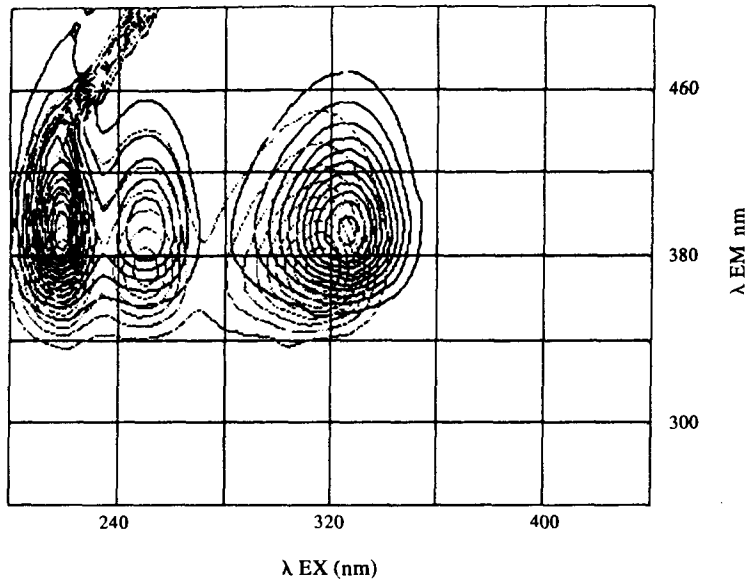

Fig. 1. Contour plots spectra of pyridoxal (---) and pyridoxamine (——).

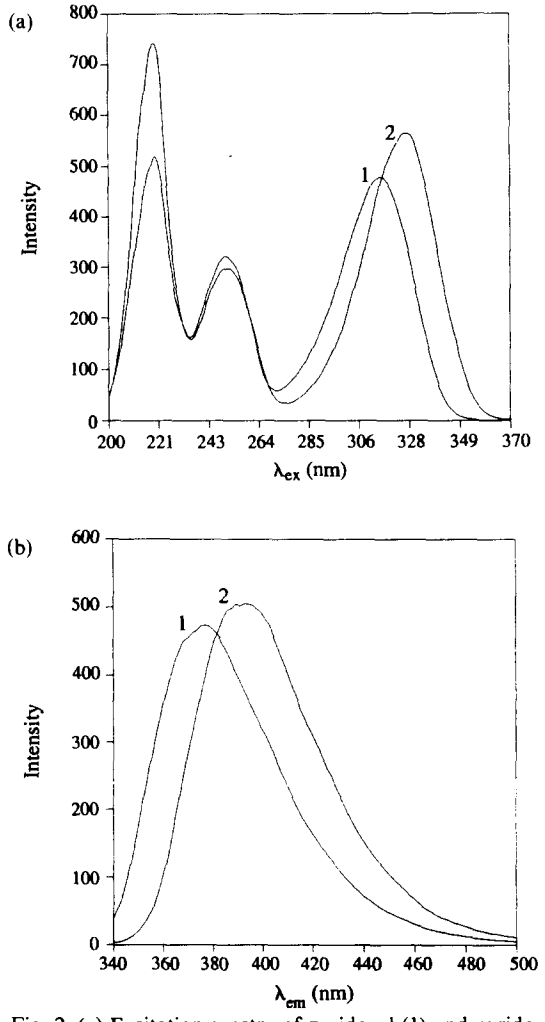

Fig. 2. (a) Excitation spectra of pyridoxal (1) and pyridoxamine (2). (b) Emission spectra of pyridoxal (1) and pyridoxamine (2).

form contours. Contour presentation is more useful than isometric projection due to the presence of hidden excitation peaks shown up by the former. Thus, Fig. 1 presents pyridoxal and pyridoxamine spectra as contour maps.

Pyridoxal exhibits three excitation maxima at 220, 250 and 315 nm, and one emission maximum at 378 nm (Fig. 2A). Pyridoxamine showed excitation maxima at 220, 245 and 327 nm and its emission maximum was at 393 nm (Fig. 2B). For pyridoxal, the wavelengths chosen to work with were 315 and 378 nm for excitation and emission, respectively. For pyridoxamine, 327 and 393 nm were selected for excitation and emission, respectively. In spite of the fact that we do not obtain maximum sensitivity with these, the inner filter effect, which occurs at wavelengths close to 200 nm due to certain inorganic ions, is avoided.

As can be seen in Fig. 3, pyridoxal and pyridoxamine showed highly overlapping fluorescence spectra, so it is not possible to resolve this mixture by conventional fluorescence, and other techniques must be applied.

*Factors affecting fluorescence intensity*

Chemical variables were studied to obtain the best measurement conditions and maximum fluorescence signals. The dielectric constant can modify the fluorescence characteristics of the compound. Thus, the effect of ethanol content in the medium was investigated by preparing samples of both vitamins and varying the ethanol percentage between 0 and 80%. Rela-

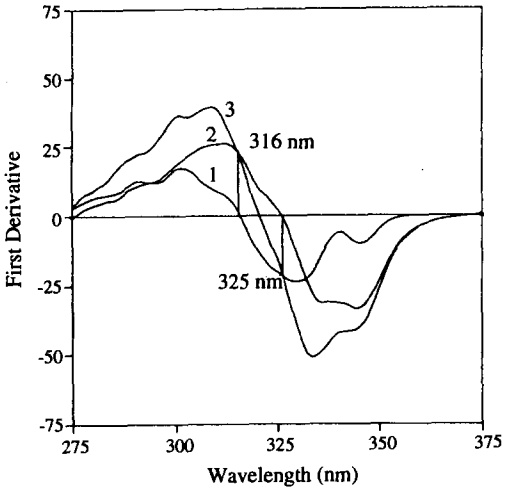

Fig. 3. First derivative excitation spectra of pyridoxal (1), pyridoxamine (2) and their mixture (3).

tive fluorescence intensity decreases as ethanol content in the medium increases, so the final assay samples were made in aqueous solutions as this provided maximum fluorescence intensity.

The influence of pH on the fluorescence intensity was studied by adding different amounts of $HClO_4$ or NaOH solutions. Fluorescence intensities of pyridoxal and pyridoxamine were maximum and constant between pH 5.5 and 9.5, and pH 7.0 was selected as most suitable. pH 7.0 was obtained by adding phosphate buffer solutions. The fluorescence intensities of pyridoxal and pyridoxamine were not affected by the concentration of the buffer. A 0.05*M* concentration of buffer was selected to obtain suitable buffering capacity.

Another factor that affects fluorescence intensity is temperature. Thus, fluorescence intensities show a decrease as temperature increases from 3 to 50°C. Temperature coefficient was of the order of 1.05%°C$^{-1}$ for pyridoxal; this effect can be explained by the higher internal conversion when temperature increased, facilitating non-radiative deactivation of the excited single state.[14] Pyridoxamine showed a temperature coefficient of the order of 1.51%°C$^{-1}$; in this case, the rate of intersystem crossing tends to be highly temperature dependent.[14] Therefore, the use of a thermostat is recommended, choosing a measurement temperature of 20°C, an intermediate room temperature.

In these conditions, the influence of both vitamin concentrations on fluorescence intensity was studied. A linear relation between fluorescence intensity and pyridoxal concentration in the range from 0.05 to 3.0 mg/l. can be observed. For pyridoxal concentration higher than 3.0 mg/l. the intensity decreases due to fluorescence inversion phenomena. Pyridoxamine showed a linear relation fluorescence intensity from 0.05 to 1.5 mg/l.

*Resolution of the mixture of pyridoxal and pyridoxamine*

Contour plots showed highly overlapping spectra, and there are no excitation or emission spectra where the bands were separated (Fig. 1), so when they are together in the same mixture, they cannot be determined by conventional fluorescence. For this reason it is necessary to use another technique.

The first partial derivative of tridimensional spectra in respect of excitation wavelength was calculated. But as it is not possible to resolve the strong overlapping spectra, the zero-crossing technique was applied to them. In order to discover the best instrumental conditions, scan speed and width factor were studied in order to ascertain the most suitable signal-noise ratio. The first derivative was calculated with 60, 240, 720 and 1500 nm/min as scan speed, 240 nm/min was chosen as the most suitable scan speed. The width factor was varied from 2 to 9 (equivalent to 19 points convoluting according to Savitzky and Golay algorithm)[15,16] and 4 was selected as providing the most suitable signal-noise ratio. Although the maximum fluorescence intensities were obtained when the excitation spectra were recorded at 378 and 393 nm as emission wavelengths for pyridoxal and pyridoxamine, respectively, 388 nm was the wavelength chosen because it was possible to determine pyridoxal in the presence of pyridoxamine and pyridoxamine in the presence of pyridoxal by scanning only one spectrum with similar fluorescence intensity and without loss of sensitivity in respect of the maximum for each one. Figure 3 shows the first derivative excitation spectra of pyridoxal, pyridoxamine and their mixture. We selected zero-crossing wavelength 316 and 325 nm for pyridoxal and pyridoxamine.

When first partial derivative of total luminescence spectra in respect of emission wavelength was performed, it was not possible to obtain separate bands in order to determine both compounds simultaneously. By applying the zero-crossing technique to the first derivative emission spectra pyridoxal and pyridoxamine

can be determined by scanning only one emission spectrum at $\lambda_{ex} = 324$ nm.

Although the maximum signal can be obtained when the emission spectra are recorded at $\lambda_{ex} = 315$ nm for pyridoxal and $\lambda_{ex} = 327$ nm for pyridoxamine, 324 nm was chosen as the most suitable excitation wavelength because it was possible to determine pyridoxal and pyridoxamine by scanning one emission spectrum without a significative loss in sensitivity.

The first derivative was calculated with a scan speed of 240 nm/min and a width factor of 4 to provide a suitable signal-noise ratio. The zero-crossings selected were 376 and 391 nm for pyridoxal and pyridoxamine respectively (Fig. 4).

Other fluorescence techniques were used to improve the results: conventional synchronous spectra were used to determine these vitamins by direct measurement of intensity. Figure 5 shows a tridimensional spectra plot of a mixture of pyridoxal and pyridoxamine when scanned at different wavelength intervals (from 5 to 200 nm). The first derivative of these spectra cannot resolve the overlapping spectra, so it was necessary to use the zero-crossing technique to resolve the mixture. The best sensitivity and maximum signal were obtained for pyridoxal when a wavelength interval of 51 nm was used, and 57 nm was used for pyridoxamine. But a wavelength interval of 56 nm was used to determine pyridoxal and pyridoxamine by first derivative of synchronous spectra by scanning only one synchronous spectrum without loss of sensitivity.

Figure 6 shows the first derivative synchronous spectra of pyridoxal, pyridoxamine

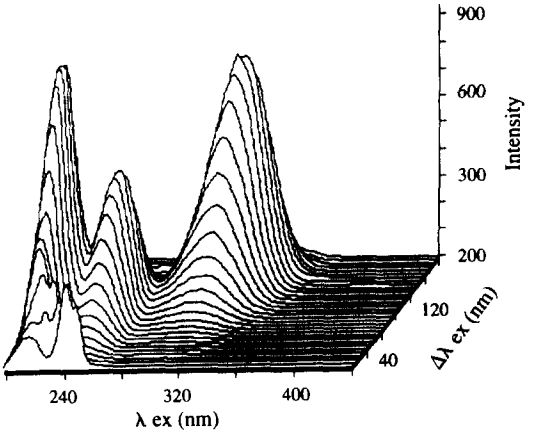

Fig. 5. Tridimensional plots of constant wavelength spectrum of pyridoxal and pyridoxamine mixture.

and their mixture. The selected zero-crossing wavelengths were 316 and 328 nm for pyridoxal and pyridoxamine respectively. Instrumental conditions were the same as described above.

The last method that we used to try to improve the results was constant energy synchronous spectra, where 61 scans of samples of pyridoxal and pyridoxamine were recorded between 200 and 440 nm at different wave number intervals ranging from $-2200$ to $-8300$ cm$^{-1}$. Maximum fluorescence intensity was obtained when the wave numbers $-5300$ and $-5100$ cm$^{-1}$ were used for pyridoxal and pyridoxamine. But $-4900$ cm$^{-1}$ was the most suitable wave number for resolving the mixture of pyridoxal and pyridoxamine by recording only one constant energy synchronous spectrum since suitable fluorescence intensity was obtained without loss of sensitivity. The first derivative

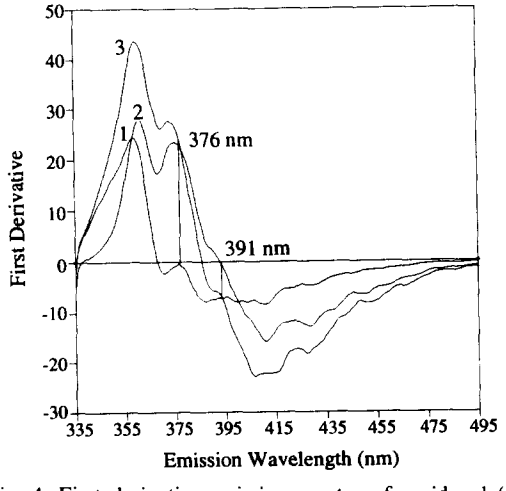

Fig. 4. First derivative emission spectra of pyridoxal (1), pyridoxamine (2) and their mixture (3).

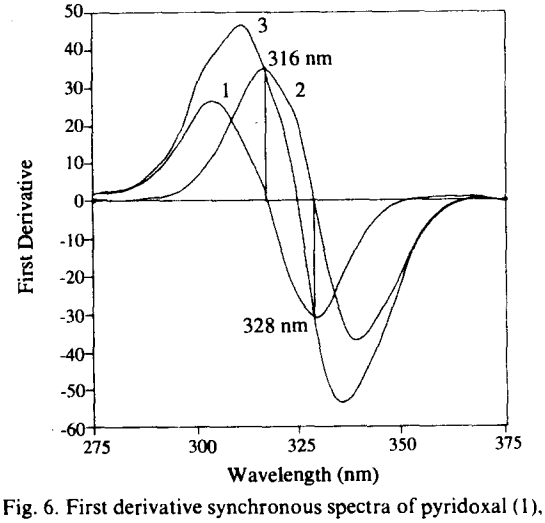

Fig. 6. First derivative synchronous spectra of pyridoxal (1), pyridoxamine (2) and their mixture (3).

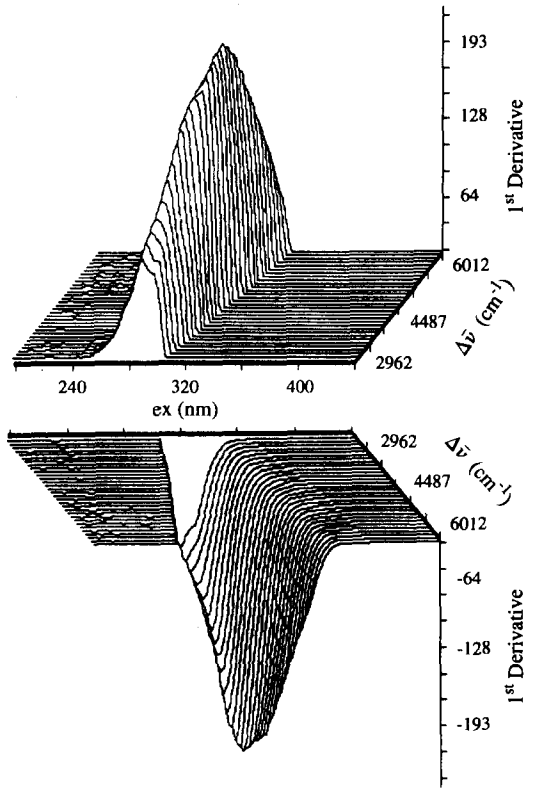

Fig. 7. Tridimensional plots of first derivative constant energy synchronous of pyridoxal and pyridoxamine mixture.

(Fig. 7) was calculated and the zero-crossing technique was also used; in this way, both vitamins were resolved with the greatest sensitivity. Pyridoxal and pyridoxamine concentration were proportional to the signal measured at 316 and 328 nm, respectively.

To provide a suitable signal-noise ratio a scan speed of 240 nm/min and a width factor of 4 were selected.

*Statistical analysis of results*

In order to demonstrate the mutual independence of the analytical signals of pyridoxal and pyridoxamine, we performed an exhaustive statistical analysis of the results in order to test them. We checked whether the zero-crossing wavelengths selected in every method were the most suitable ones or not.

Calibration graphs were constructed from the first derivative signals for standards containing between 20.0 and 1000 $\mu$g/l. of pyridoxal in the absence of pyridoxamine and in the presence of 200, 500 and 800 $\mu$g/l. of pyridoxamine. Similarly, four calibration graphs were prepared for standards containing between 20.0 and 1000 $\mu$g/l. of pyridoxamine in the absence of pyri-

Table 1.

| 1st derivative | Compound | Slope | Intercept | Correlation coefficient | Standard deviation | | Detection limit ($\mu$g/l.) | Quantitation limit ($\mu$g/l.) | Calibration range ($\mu$g/l.) |
|---|---|---|---|---|---|---|---|---|---|
| | | | | | Slope | Intercept | | | |

Pa = Pyridoxal; Pm = Pyridoxamine.

doxal and in the presence of 200, 500 and 800 $\mu$g/l. of pyridoxal.

Linear regression equations ($y = a + mx$) for pyridoxal and pyridoxamine were obtained. The slopes, intercepts, correlation coefficients, standard deviations, detection limits, quantization limits and calibration range obtained for determination of pyridoxal and pyridoxamine by first derivative of excitation, emission, constant wavelength synchronous and constant energy synchronous spectra are summarized in Table 1. The significance of the intercept on the $y$ axis of the obtained regression line was evaluated by applying the Student $t$-test at 95% confidence level. In all the calibration graphs the intercept on the ordinate is negligible, since the experimental $t$-value is smaller than the critical $t$-value. The accuracy of the method can be tested by the use of a statistical technique such as "analysis of variance". Analysis of variance assumes that residual error variance does not change from one sample to another or from one calibration graph to another. The variance ratio (experimental $F$) must be calculated and compared to a theoretical value of $F$, for adequate degrees of freedom at 95% confidence level.

For four series of five standard samples containing 500 $\mu$g/l. of pyridoxal and 500 $\mu$g/l. of pyridoxamine the relative error and standard deviation were calculated for pyridoxal and pyridoxamine, in order to ascertain the reproducibility of the proposed methods. Finally the detection and quantization limits[17,18] were calculated.

To test the accuracy of the method, analysis of variance was applied. The experimental value of $F$, relative errors and standard deviations obtained for determination of pyridoxal and pyridoxamine by first derivative of excitation, emission, constant wavelength synchronous and constant energy synchronous spectra are summarized in Table 2.

## APPLICATIONS

In order to study the validity of the method, and since there are no medicines commercially available which contain these two vitamins, the methods proposed were applied to their determination in physiological serum and glucosed physiological serum, since intravenous injections are usually used for alcohol and pharmacology poisoning. The determination of these vitamins was carried out in commercial preparations of the following companies: "Apiroserum" (Inst. de Biología y Sueroterapia, S.A.) "Pérez Jiménez" (Lab. Pérez Jiménez) and "Grifols" (Lab. Grifols). Three determinations were carried out for each of these sera using pyridoxal and pyridoxamine medicines ("Nervobion" Merck and "Astenolit" Elmu S.A.) Recoveries achieved by means of all the methods proposed are in accordance with the real content of pyridoxal and pyridoxamine in both the physiological serum and the glucosed physiological serum. Recovery percentages achieved in all cases vary between 95.5 and 100.6% for pyridoxal and between 95.3 and 100.9% for pyridoxamine.

## CONCLUSIONS

Molecular fluorescence techniques in combination with derivative techniques resolve binary mixtures of pyridoxal and pyridoxamine without the need for prior separation steps. The use of synchronous fluorescence and constant energy synchronous fluorescence are not sufficient in themselves to separate the bands of these compounds due to the heavy overlap shown by the fluorescence spectra, although, as is to be expected from theory, the spectra are simplified and the bands narrowed. Better separation of the compounds is achieved by applying the first derivative to the different types of fluorescence spectra, but it is still not enough to obtain independent bands.

Table 2.

| 1st derivative | Compound | Experimental $F$ | Theoretical $F$ | Relative error (%) | Standard deviation ($\mu$g/l.) |
|---|---|---|---|---|---|
| Excitation | Pa | 2.01 | 3.07 | 2.81 | 5.1 |
| | Pm | 0.33 | 3.07 | 1.35 | 2.5 |
| Emission | Pa | 3.06 | 3.07 | 2.07 | 8.9 |
| | Pm | 1.56 | 3.07 | 1.11 | 7.1 |
| Constant wavelength | Pa | 0.55 | 3.07 | 2.19 | 8.9 |
| Synchronous | Pm | 2.62 | 3.07 | 1.76 | 7.1 |
| Constant wavelength | Pa | 1.92 | 3.07 | 1.76 | 3.2 |
| Synchronous | Pm | 3.05 | 3.07 | 2.19 | 4.0 |

Pa = Pyridoxal; Pm = Pyridoxamine.

By using the zero-crossing technique it is possible to determine pyridoxal and pyridoxamine simultaneously, both with excitation and emission spectra and with synchronous and constant energy synchronous spectra; in these latter cases greater analytical signals are obtained, which result in better detection and quantization limits. In general due to the similar fluorescent characteristics of vitamin $B_6$ and its derivatives, the methods described involve slow and tedious prior separation. The only fluorimetric method described in the literature which does not involve prior separation is that proposed by Petidier *et al.*,[6] but our methods are more sensitive and faster as it is not necessary to use derivatization reactions or mathematical equations.

# TWO-PHASE POTENTIOMETRIC METAL EXTRACTION TITRATIONS OF SILVER(I), COPPER(II) AND CADMIUM(II) USING SOME CATION-EXCHANGERS AS EXTRACTANTS

BRIAN K. TAIT*

Mineralogy and Process Chemistry Division, Mintek, Private Bag X 3015, Randburg 2125, South Africa

(*Received* 10 *March* 1994. *Revised* 11 *July* 1994. *Accepted* 1 *August* 1994)

**Summary**—The use of two-phase potentiometric metal extraction titrations to study solvent extraction equilibria is described. The method provides a highly reproducible and convenient manner by which to determine extraction behaviour. The system was tested on a number of acidic extractants, namely D2EHPA, Ionquest 801, Cyanex 272, naphthenic acid and Versatic 10 acid. The extraction from an aqueous nitrate medium of silver(I), copper(II) and cadmium(II) was studied. The potentiometric data were used to obtain extraction curves and elucidate the nature of the extracted complexes by slope analysis and non-linear least squares treatment. In general, the following extraction order was obtained: D2EHPA > Ionquest 801 > Cyanex 272 and naphthenic > Versatic 10 for copper(II) and cadmium(II). Organophosphorus acids were shown to form complexes of the nature of $Cu(HA_2)_2$ with copper(II) and carboxylic acids formed dimeric complexes $(CuA_2(HA))_2$. With cadmium octahedral complexes of the form $CdA_2(HA)_4$ occurred. The extraction of silver(I) by Versatic 10 gave a dimeric complex $(AgA(HA))_2$. HA denotes the extractant in the acid form.

Batch-wise extractions require a complete set of mixing, separating, sampling and analyses, which often leads to scattered results. Because the batch technique is laborious, semicontinuous and continuous techniques have been proposed.

The stirred cell semicontinuous technique involves either intermittent vigorous stirring, in which case samples are withdrawn after each complete phase separation, or very mild stirring, allowing samples to be withdrawn continuously.

With the AKUFVE technique,[1,2] mixing and separation are achieved in a mixing vessel and at the inflow into a centrifugal separator. The separated phases pass over on-line detectors for pH measurement and metal ion determination by radiometric techniques.

This investigation sets out to adapt the well-known two-phase potentiometric acid–base titration technique developed by Högfeldt,[3,4] which utilizes a pH electrode to determine the acid or base constants of an extractant. The technique is fully automated, using an automatic titrator for additions of base to vary the pH and two electrode systems, one to measure the pH value, and one to measure the concentration of metal ion in the aqueous phase. Consequently, no samples have to be withdrawn for analysis. A similar technique has been used to study the extraction of silver(I) by Cyanex 471X.[5] This work investigates the extraction of silver(I), copper(II) and cadmium(II) by D2EHPA, Ionquest 801, Cyanex 272, Versatic 10 acid and naphthenic acid. The structures of the extractants are given in Table 1.

## EXPERIMENTAL

### *Electrodes*

A cadmium ISE was made by applying a thin layer of $CdS/Ag_2S$ to the bottom of a graphite rod. The sides of the rod were coated with Teflon. Graphite hydrophobized by Teflon is a conductive powder and thus allows electrical contact between the electroactive surface and a connection to a meter. The layer of electroactive material was polished to close the micropores. The electrode exhibited a Nernstein response, and has been described by Ruzicka *et al.*[6,7]

*Present address: Hickson Chemtech, P.O. Box 118, Roodepoort 1725, South Africa.

Table 1. Structure of extractants used

| | |
|---|---|
| D2EHPA |  |
| Ionquest 801 |  |
| Cyanex 272 |  |
| Versatic 10 |  |
| Naphthenic acid |  |

R = 2-ethylhexyl
R′ = 2,4,4-trimethylpentyl
R″ = unspecified mixture of alkyl groups

A Metrohm copper ISE was used to detect both copper(II) and silver(I). A double-junction silver/silver chloride reference electrode was used with the same internal electrolyte solution that was used as a constant ionic medium in the extraction experiments (1*M* ammonium nitrate or 1*M* sodium nitrate). The electrode assembly was attached to a Hewlett Packard logging multimeter to record the potential at a set time interval.

A Metrohm combined glass electrode, filled with 3*M* sodium chloride, was used to measure pH values.

*Titration procedure*

The organic and aqueous phases were placed in a water-jacketed vessel at 25°C. The organic-to-aqueous phase volume ratio (O/A) was 1 to 5 initially and decreased during the course of the titration. The organic phase contained 0.5*M* extractant in toluene and the aqueous phase 0.01*M* metal ion in 1*M* sodium nitrate or ammonium nitrate.

The stock organic solutions were analysed by potentiometric titration against sodium hydroxide in ethanolic–water medium. The stock aqueous phases were analysed by potentiometric titration against EDTA.

The pH electrode was calibrated against commercial pH 7.00, pH 4.01 and pH 2.01 buffers at 25°C. The ISE assembly was calibrated against standardized metal ion solutions in 1*M* sodium nitrate or ammonium nitrate in the concentration range $10^{-2}$ to $10^{-4}M$.

The inorganic salts were obtained from Saarchem and were of AR grade. The extractants were supplied by the manufacturers, Daihachi, Akulu Marchon, Cyanamid, Shell Chemicals and BDH for D2EHPA, Ionquest 801, Cyanex 272, Versatic 10 acid and naphthenic acid respectively, and used as supplied. Toluene, Merck pro analysi, was used as the diluent.

The titration was performed using a Metrohm 702SM Titrino. The titrant was 0.1*M* sodium hydroxide in 1*M* sodium nitrate or ammonium nitrate, with 0.5 ml additions at 10 min intervals [silver(I) and copper(II)] or at 18 min intervals [cadmium(II)]. This time was sufficient to ensure equilibration of the phases and the potential of the ISE assembly. The pH was allowed to vary in the range 2–8, in which the effect of pH on the potential of the ISE is negligible. After the elapse of the set time interval the pH and potential of the ISE assembly were recorded automatically, and more base was added to the stirred organic and aqueous phases by the Titrino. The titration stopped automatically when the pH value exceeded 8.

*Data treatment*

A spreadsheet was used to treat the potentiometric data. The logarithm of the metal ion concentration was calculated by linear regression from the calibration graph. The concentration of metal ion in the organic phase was assumed to be the difference between the initial concentration (taking dilution effects into account) and the concentration in the aqueous phase at equilibrium. The distribution ratio, *D*, is the concentration of metal ion in the organic phase divided by the concentration of metal ion

in the aqueous phase. The percentage extraction was calculated from

$$\%E = \frac{100D}{D + \frac{V_{aq}}{V_{org}}}, \quad (1)$$

where $V_{aq}$ is the volume of the aqueous phase and $V_{org}$ the volume of the organic phase.

For the generalized extraction equation

$$x\mathrm{M}^{2+} + x\left(\frac{n}{2}+1\right)\overline{\mathrm{H_2A_2}} \rightleftharpoons \overline{(\mathrm{MA_2(HA)}_n)_x} + 2x\mathrm{H}^+, \quad (2)$$

where the bar denotes a species in the organic phase, the concentration extraction constant, $K$, can be expressed as

$$K = \frac{\overline{[(\mathrm{MA_2(HA)}_n)_x]}[\mathrm{H}^+]^{2x}}{[\mathrm{M}^{2+}]^x\overline{[\mathrm{H_2A_2}]}^{x(\frac{n}{2}+1)}}. \quad (3)$$

The extraction constants were calculated by a non-linear least squares technique,[8,9] which required the input of hydrogen ion concentration, percentage extraction and initial metal ion and extractant concentrations.

## RESULTS AND DISCUSSION

### *Extraction of silver* (II)

Silver nitrate solution was found to be unstable in a sodium nitrate medium. Silver(I) was reduced to metallic silver soon after the preparation of the solution, before contact with the organic phase. Since both silver nitrate and sodium nitrate, when used separately under other experimental conditions, presented no problems, it is unlikely that the problem was caused by impurities. The reason for the instability of this solution is unknown.

Consequently, the extraction was investigated from an ammonium nitrate medium. The system also gave unsatisfactory results when the organophosphorus acid extractants or naphthenic acid were used as the extractants because of third phase problems. This was probably due to the formation of ammonium salts of the extractants.

Thus, only the extraction of silver(I) by Versatic 10 acid was studied. The system was used to determine the reproducibility of the titration technique. Figure 1 shows three extraction curves, which fall very close together. It can be concluded, therefore, that the two-phase potentiometric titration technique provides highly reproducible results.

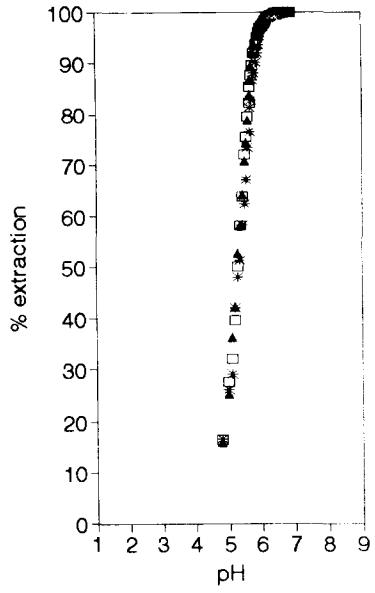

Fig. 1. Extraction of 0.01$M$ silver(I) in 1.0$M$ ammonium nitrate by 0.5$M$ Versatic 10 acid in toluene at 25°C (O/A = 5 initially). The symbols indicate triplicate results.

The $\mathrm{pH}_{0.5}$ value (the pH value at which 50% extraction occurs) for the extraction of 0.01$M$ silver(I) from 1.0$M$ ammonium nitrate by 0.5$M$ Versatic 10 acid in toluene at 25°C is 5.2. An attempt was made to elucidate the extraction stoichiometry by slope analysis. The extraction of silver(I) can be described by

$$x\mathrm{Ag}^+ + \left(\frac{nx}{2}\right)\overline{\mathrm{H_2A_2}} \rightleftharpoons \overline{(\mathrm{AgA(HA)}_{n-1})_x} + x\mathrm{H}^+, \quad (4)$$

where $\mathrm{H_2A_2}$ represents the extractant dimer. It is generally accepted that organophosphorus acids and carboxylic acids form dimers in diluents of low polarity.[10-12]

The extraction constant, $K$, can be expressed as

$$K = \frac{\overline{[(\mathrm{AgA(HA)}_{n-1})_x]}[\mathrm{H}^+]^x}{[\mathrm{Ag}^+]^{x-1}\overline{[\mathrm{H_2A_2}]}^{nx/2}} = \frac{D[\mathrm{H}^+]^x}{[\mathrm{Ag}^+]^{x-1}[\mathrm{H_2A_2}]^{nx/2}}, \quad (5)$$

where

$$D = \frac{\overline{[(\mathrm{AgA(HA)}_{n-1})_x]}}{[\mathrm{Ag}^+]}. \quad (6)$$

By taking logarithms and rearranging, it follows that

$$\log D - \frac{nx}{2}\log[\mathrm{H_2A_2}] - (x-1)\log[\mathrm{Ag}^+] = \log K + x\mathrm{pH}. \quad (7)$$

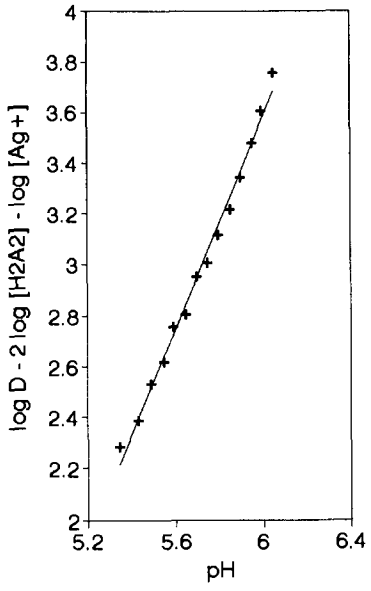

Fig. 2. Slope analysis of silver(I) extraction by Versatic 10 acid. Same conditions as for Fig. 1.

Thus a plot of $\log D - (nx/2)\log[H_2A_2] - (x-1)\log[Ag^+]$ against pH should be a straight line with a slope of $x$ for the correct values of $x$ and $n$. Figure 2 shows such a plot for $x = 2$ and $n = 2$. The slope of the line is 2.07 (correlation coefficient is 0.992) Thus, it can be concluded that the extracted complex is $(AgA(HA))_2$.

*Extraction of copper*(II)

Figure 3 represents the extraction of copper(II) from 1.0*M* sodium nitrate by D2EHPA, Ionquest 801, Cyanex 272, Versatic 10 acid and naphthenic acid in toluene. The $pH_{0.5}$ values under the conditions studied are presented in Table 2. The extraction order is D2EHPA > Ionquest 801 > Cyanex 272 ≈ naphthenic acid > Versatic 10 acid. This order indicates the relative strength of the extractants towards copper(II) extraction.

In general, the extraction of divalent metal ions by organophosphorus acid extractants can be expressed as

$$M^{2+} + n\overline{H_2A_2} \rightleftharpoons \overline{M(HA_2)_2(HA)_{2n-4}} + 2H^+. \quad (8)$$

Thus, a plot of $\log D - n \log[H_2A_2]$ against pH should yield a straight line with a slope of 2 for the correct value of $n$.

In contrast, carboxylic acids often form polymeric extracted complexes with metal ions. For a divalent metal ion

$$xM^{2+} + x\left(\frac{n}{2}+1\right)\overline{H_2A_2} \rightleftharpoons \overline{(MA_2(HA)_n)_x} + 2xH^+ \quad (9)$$

from which it can be deduced that a plot of $\log D - x(n/2+1)\log[H_2A_2] - (x-1)\log[M^{2+}]$ against pH should give a straight line of slope $2x$ for the correct values of $x$ and $n$. The equilibrium dimer concentration was calculated from the initial concentration, taking into account the extractant bound to the metal ion according to the proposed stoichiometry.

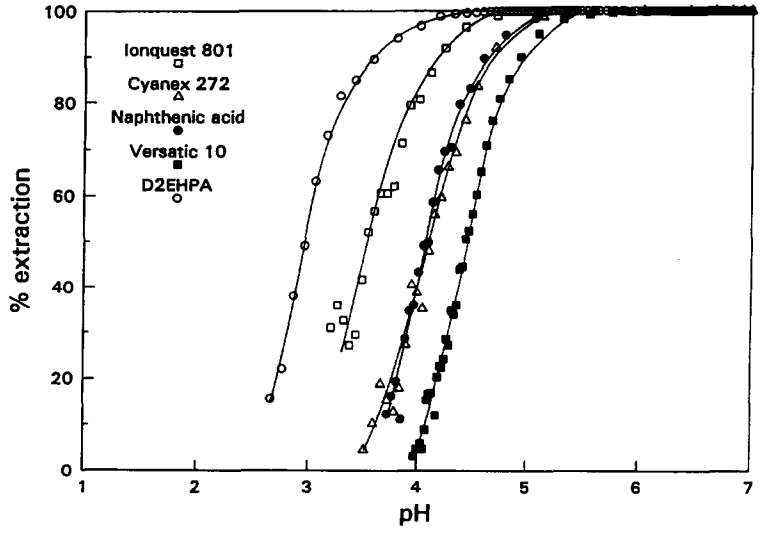

Fig. 3. Extraction of 0.01*M* copper(II) in 1.0*M* sodium nitrate by 0.5*M* extractant in toluene at 25°C (O/A = 5 initially).

Table 2. $pH_{0.5}$ values and results of slope analysis studies for copper(II) and cadmium(II)

| | Copper(II) | | | Cadmium(II) | | |
|---|---|---|---|---|---|---|
| Extractant | $pH_{0.5}$ | slope | $r^2$ | $pH_{0.5}$ | slope | $r^2$ |
| D2EHPA | 3.0 | 1.9 | 0.994 | 3.0 | 1.9 | 0.968 |
| Ionquest 801 | 3.6 | 1.9 | 0.993 | 3.5 | 1.9 | 0.954 |
| Cyanex 272 | 4.1 | 2.0 | 0.998 | 4.3 | 2.2 | 0.972 |
| Versatic 10 | 4.4 | 3.8 | 0.998 | 4.8 | 2.0 | 0.958 |
| Naphthenic | 4.1 | 4.0 | 0.990 | 6.0 | — | — |

The results of the slope analysis studies are consistent with the following extraction equations:

Organophosphorus acids

$$Cu^{2+} + 2\overline{H_2A_2} \rightleftharpoons \overline{Cu(HA_2)_2} + 2H^+, \quad (10)$$

Carboxylic acids

$$2\,Cu^{2+} + 3\overline{H_2A_2} \rightleftharpoons \overline{(CuA_2(HA))_2} + 4H^+. \quad (11)$$

The results are shown in Table 2, and are in agreement with the results of other workers.[10–12] The proposed model was chosen on the basis of the best straight line that gave a slope close to the expected value of 2 or $2x$. Whereas slope analysis was sensitive to the choice of model, the non-linear least squares technique proved relatively insensitive because there was not sufficient variation in the concentration of the extractant. Non-linear least squares treatment of the data was used to calculate the extraction constant, $K$. The results are presented in Table 3. A more rigorous non-linear least squares treatment will require that the extractant concentration is deliberately varied.

The extraction constants confirm the relative extraction order given previously. It should be noted that the constants for organophosphorus acid extractants and carboxylic acid extractants are not comparable because of different stoichiometries (and hence different units). The results of the non-linear least squares treatment show that very good fits of the experimental data were obtained and tend to validate the conclusions drawn from slope analysis studies.

*Extraction of cadmium*(II)

The cadmium ISE built for this set of experiments gave less stable readings than the commercially available copper ISE as it was more sensitive to the presence of organic droplets in the dispersion, and tended to become coated by the organic phase. This problem was solved by stirring the phases slowly. To ensure complete equilibration, measurements were taken at 18 min intervals, as opposed to the 10 min equilibration time used in the previous experiment. The greater instability of the potential measurements resulted in more scatter of the experimental points and this is also reflected in the statistical parameters presented.

The extraction of cadmium(II) from 1.0*M* sodium nitrate by D2EHPA, Ionquest 801, Cyanex 272, naphthenic acid and Versatic 10 acid is presented in Fig. 4. The extraction order D2EHPA > Ionquest > Cyanex 272 and naphthenic > Versatic 10 is the same as obtained with copper(II). The $pH_{0.5}$ values are indicated in Table 2.

Slope analysis studies were consistent with the extraction equation

$$Cd^{2+} + 3\overline{H_2A_2} \rightleftharpoons \overline{CdA_2(HA)_4} + 2H^+ \quad (12)$$

for all extractants except naphthenic acid, for which the stoichiometry could not be determined. The results are shown in Table 2. The same extraction equation for carboxylic acids has been proposed by other workers.[13,14] Grimm[15] has reported the complex $CdA_2(HA)_3$ with D2EHPA and Figuerola[16] proposed the complexes $CdA_2$ and $CdA_2(HA)_3$ with Cyanex 272. Presumably the complexes incorporate water molecules to give a coordination number of four or six.

Non-linear least squares treatment of the data supported the conclusions drawn about the extraction stoichiometry in this work. The extraction constants and related statistics are presented in Table 3.

Table 3. Extraction constants, standard deviation in percentage extraction ($s$) and number of points ($n$) for non-linear least squares treatment of copper(II) and cadmium(II) extraction data

| | Copper(II) | | | Cadmium(II) | | |
|---|---|---|---|---|---|---|
| Extractant | log $K$ | $s$ | $n$ | log $K$ | $s$ | $n$ |
| D2EHPA | $-4.77 \pm 0.01$ | 1.7 | 50 | $-4.48 \pm 0.01$ | 4.4 | 101 |
| Ionquest 801 | $-5.70 \pm 0.01$ | 3.2 | 100 | $-5.27 \pm 0.01$ | 3.9 | 40 |
| Cyanex 272 | $-7.00 \pm 0.01$ | 3.3 | 27 | $-6.83 \pm 0.01$ | 42 | 32 |
| Versatic 10 | $-13.9 \pm 0.01$ | 2.8 | 40 | $-10.3 \pm 0.02$ | 5.9 | 22 |
| Naphthenic | $-12.4 \pm 0.01$ | 2.9 | 40 | — | — | — |

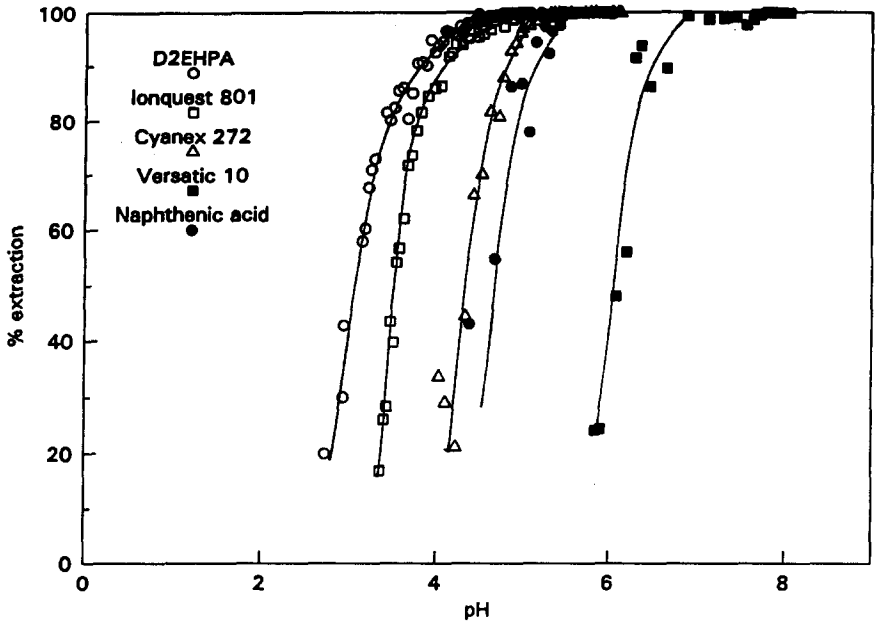

Fig. 4. Extraction of 0.01*M* cadmium(II) in 1.0*M* sodium nitrate by 0.5*M* extractant in toluene at 25°C (O/A = 5 initially).

## CONCLUSIONS

Two-phase potentiometric metal extraction titrations are a convenient and highly reproducible manner in which to obtain extraction–pH curves. Variations can be devised to allow the study of other variables, such as metal ion and extractant concentration. The time taken to produce a curve depends on the number of data points to be collected and the equilibration time chosen.

The method is limited by the number of ISEs available that are sensitive to the metal ion of interest. However, much research is being undertaken to develop new sensors. Although general ion-sensitive electrodes are available, such as the divalent metal ion (water hardness) electrode, these are based on polymer membranes that dissolve in organic solvents. Thus, solid state electrodes or those with a polymer matrix that does not dissolve in the diluent are needed in mixed aqueous–organic systems. Also, because ISEs respond to the activity of the free (aquo) metal ion, investigations must be performed in media in which the metal ion does not complex strongly with the anions in solution.

# BOOK REVIEWS

**The Kirk-Othmer Encyclopedia of Chemical Technology:** Volume 10, Fourth Edition, Explosives and Propellants to Flame Retardants: J. I. KROSCHWITZ and M. HOWE-GRANT (editors), Wiley, New York, Pages: xxviii + 1022. £185.00. ISBN 0-471-52678-9 (v.10).

Well over 10,000 pages of the 4th edition of this encyclopedia have now been published and only the sixth letter of the alphabet has been reached. This indicates both the wide scope of subject matter and the detail in which it is covered.

Volume 10 contains information under 21 separate headings with the largest entry devoted to Fibers. Both natural fibers (of vegetable, animal or mineral origin) and synthetic fibers (natural organic polymers, synthetic organic polymers or inorganic substances) are mentioned. The characteristics, production, and application of Fibers is well covered and a similar treatment is given to the separate entry on Fiber Optics.

Another major topic dealt with in this volume is Explosives and Propellants which uses the reaction rate to to distinguish between the two categories. Here safety aspects, pollutants, performance, manufacture, properties, and applications of these potentially dangerous chemicals are presented.

The two entries on unit operations: extraction and filtration are dealt with in about the same number of pages. As expected extraction covers liquid-liquid (solvent extraction) and liquid-solid extraction and filtration includes vacuum filters, batch pressure filters, continuous pressure filters and centrifugal filters.

The importance of flame retardants—with particular emphasis on antimony (and other inorganics), halogenated and phosphorus flame retardants—is presented and a separate entry on their use with textiles is included. Another group of chemicals—fat and fatty oils—is covered, as are fat replacers. The various fertilizers in use, *e.g.* nitrogen, phosphate, potash, *etc.*, are surveyed and their environmental and economic impact are covered. Also in relation to aspects of farming there are entries on feeds and feed additives, and on feedstocks.

I found the treatise on fine art examination and conservation by L. van Zelst of the Smithsonian Institution to be the most interesting entry in this volume of the encyclopedia. It covers numerous analytical techniques and shows how these are used in conjunction with technological history to examine works of art. The study of deterioration and conservation of important paintings, metal objects, ceramics, textiles, parchments, *etc.*, is truly an area where the worlds of art and science merge. Indeed, after reading this section I found myself somewhat envious of those who work in this domain.

Completing this volume are short entries of extraterrestrial materials, fans and blowers, fermentation, ferrites, ferroelectrics, film and sheeting materials and fillers.

As with all volumes in this encyclopedia a number of different authors have been used, tables of conversion factors, abbreviations, and unit symbols are given and extensive references are appended to each topic covered. A highly desirable acquisition for all good science libraries.

P. J. Cox

**Analytical Chemistry, 5th Edition:** G. D. CHRISTIAN, Wiley, New York, 1994. Pages: xx + 812. £18.95 (softback), ISBN 047105820. £64.00 (hardback).

This text is aimed at undergraduate (college) students majoring in chemistry and related fields and covers the principles and techniques of quantitative analysis. The 5th edition is over 800 pages long, and contains a wealth of information which reflects the authors lifelong involvement in analytical chemistry. This edition has been reorganised compared to the previous versions, and additions reflect developments in the area over the past few years. These include: the statistics of sampling and of small data sets (which are the norm in many analyses), ultramicroelectrodes and chemically modified electrodes, diode array spectrometers, Fourier infrared spectroscopy and near IR instruments, solid phase extraction, supercritical fluid chromatography, capillary electrophoresis and GC-MS, flow-injection analysis principles and experiments, and laboratory applications of PCs, application software and interfaces.

The organisation of the text helps the student new to the area to quickly identify the core information by means of a summary paragraph introducing each chapter which lists the topics covered and gives a broad overview of the content. In addition, key terms are given in boldface type and important equations and concepts boxed for emphasis. Margin notes are used to expand explanations and reinforce important topics.

After an introduction to analytical chemistry in chapter 1, a series of chapters cover topics which, given the excellent organisation and presentation of the information, make this a very attractive introductory text for physical chemistry course modules. These include; statistics (precision, accuracy, correlation coefficient, range, median, non-linear least squares curve fitting etc.), the mole and stoichiometry, chemical equilibria (Gibb's Free Energy, Le Chatelier's Principle, ionic strength, dissociation etc.), solubility product, recrystallisation, acid-base theory leading to titrations, complexometry, chelates, effect of pH on stability/formation constants, and introduction to electrochemical cells and electrode potentials, the Nernst equation.

The 5th edition is over 800 pages long, and contains a wealth of information which reflects the authors lifelong involvement in analytical chemistry. This edition has been reorganised compared to the previous versions, and additions reflect developments in the area over the past few years. These include: the statistics of sampling and of small data sets (which are the norm in many analyses), ultramicroelectrodes and chemically modified electrodes, diode array spectrometers, Fourier infrared spectroscopy and near IR instruments, solid phase extraction, supercritical fluid chromatography, capillary electrophoresis and GC-MS, flow-injection analysis principles and experiments, and laboratory applications of PCs, application software and interfaces.

The organisation of the text helps the student new to the area to quickly identify the core information by means of a summary paragraph introducing each chapter which lists the topics covered and gives a broad overview of the content. In addition, key terms are given in boldface type and important equations and concepts boxed for emphasis. Margin notes are used to expand explanations and reinforce important topics.

After an introduction to analytical chemistry in chapter 1, a series of chapters cover topics which, given the excellent organisation and presentation of the information, make this a very attractive introductory text for physical chemistry course modules. These include; statistics (precision, accuracy, correlation coefficient, range, median, non-linear least squares curve fitting etc.), the mole and stoichiometry, chemical equilibria (Gibb's Free Energy, Le Chatelier's Principle, ionic strength, dissociation etc.), solubility product, recrystallisation, acid-base theory leading to titrations, complexometry, chelates, effect of pH on stability/formation constants, and introduction to electrochemical cells and electrode potentials, the Nernst equation.

This provides a sound basis for chapters on acid-base, precipitation, complexometric and redox/potentiometric titrations. The latter half of the book focuses on instrumental methods. All the major electrochemical, spectroscopic and chromatographic techniques are covered in a clear and concise manner. The closing chapters discuss kinetic methods of analysis (mainly the use of enzymes), laboratory automation and two important application areas (clinical and environmental analysis).

A chapter entitled 'Basic Tools and Operations of Analytical Chemistry' serves as an excellent accompaniment to undergraduate practical courses. This is followed by a collection of 44 selected experiments which illustrate techniques, principles and methods discussed in the preceding chapters. The book also contains six appendices which discuss the analytical literature, review mathematical operations, list important constants, give pH transition values for indicators, discuss safety in the lab, and list answers to even numbered questions, respectively. A comprehensive index completes the text.

The book is not really suited for more detailed instrumental courses (a dedicated instrumental analysis text would be more appropriate—voltammetry and computer interfacing/data processing are not covered in any real detail). However, it is an ideal companion for students studying introductory courses in analytical chemistry or physical chemistry, and for faculty staff looking for new experiments or tutorial questions (for which there is a separate solutions manual available). It is worth buying for the anecdotal information alone, which reflects the author's lifetime dedication to research and teaching in analytical chemistry.

**Instrumentation in Analytical Chemistry:** Volume 2, J. ZÝKA (editor), Ellis Horwood, Chichester, 1994. Pages: 336. £69.00. ISBN 0-13-472226-4.

This book completes the 2 volume series 'Instrumentation in Analytical Chemistry' edited by Jaroslav Zýka and contains 16 chapters by selected authors covering a range of analytical methods. Despite the fact that all the authors are from Prague the English is of a high standard throughout. There is a strong analytical community in the Czech Republic which the editor has tapped to produce a volume of consistent quality (often a problem with multi-author books).

The first 6 chapters are devoted to electrochemical techniques, namely, chemically modified electrodes for potentiometry and voltammetry, advances in electrochemical stripping analysis, adsorptive stripping voltammetry, applications of polarography to the study of surface-active substances, amperometric membrane detectors and electrochemical biosensors. The remainder of the book is devoted to topics on spectroscopy (FTIR and Laser Raman spectrometry), chromatography (identification of bacteria by GC and pyrolysis GC of synthetic polymers), radioimmunoassay, the use of surfactants in analytical chemistry and automatic methods of analysis. All chapters are well illustrated with figures and have extensive bibliographies. The two volume series should be useful to the teacher, the researcher and to more advanced undergraduate/postgraduate students.

B. A. MCGAW

**Electroanalytical Stripping Methods:** KH. BRAININA and E. NEYMAN, Wiley, Chichester, 1993. Pages: xxiii + 198. £49.50. ISBN 0-471-59506-3.

This book is the latest addition to the several monographs on electrochemical stripping analysis published over almost three decades. The two Russian authors have been working in the field for many years and the first one is especially well known in the electroanalytical community. The authors state in the preface to the book that one of their principal aims is to fill an information gap on the pertinent Russian literature and, indeed, the list of 546 references cited in the text is heavily biased in favour of papers published in Russian journals, with an ample proportion of articles by the present authors themselves. Generally this is quite useful, however, the information gap is often a two-way one and certain references to non-Russian literature are undoubtedly missing. Moreover, numerous misprints in the references to non-Russian works considerably decrease the informative value of the book.

Another special feature of the book is a great emphasis on electrochemistry of solids. Electrochemical stripping analysis is at present mostly considered as a method useful primarily for determination and speciation of a few metals and certain organics in the environment. The authors point out its usefulness in studying the structure of solid materials, in phase analysis and detection of structural defects, by mixing the test solid material with carbon for the preparation of carbon paste electrodes and following the electrolytic dissolution processes. In doing this, stripping methods transcend the boundaries of common analysis and enter the field of corrosion and materials science. It should, however, be pointed out that interpretation of the results is difficult and that they should be confronted and supplemented with those obtained by the established spectrometric methods of structural analysis. Nevertheless, this is an uncommon, refreshing view of the method.

The book consists of six chapters, supplemented by lists of abbreviations and symbols and a brief subject index. The first chapter deals with the theory of metal deposition on, and stripping from, solid electrodes. In my opinion, the purely thermodynamic approach adopted represents a gross simplification and the results can only be considered as qualitative. There are some unusual symbols, e.g. $\Omega$ for the coverage of the electrode surface, and some poorly defined parameters such as $\gamma$, which is a "proportionality factor reflecting metal-electrode system peculiarities", essentially serving to improve the matching between the calculated and experimental data (see, *e.g.*, Fig. 1.3). Also the use of the terms "strong and weak interactions" (see page 8) is not particularly fortunate, as it evokes the quantum mechanical terms.

This provides a sound basis for chapters on acid-base, precipitation, complexometric and redox/potentiometric titrations. The latter half of the book focuses on instrumental methods. All the major electrochemical, spectroscopic and chromatographic techniques are covered in a clear and concise manner. The closing chapters discuss kinetic methods of analysis (mainly the use of enzymes), laboratory automation and two important application areas (clinical and environmental analysis).

This book is the latest addition to the several monographs on electrochemical stripping analysis published over almost three decades. The two Russian authors have been working in the field for many years and the first one is especially well known in the electroanalytical community. The authors state in the preface to the book that one of their principal aims is to fill an information gap on the pertinent Russian literature and, indeed, the list of 546 references cited in the text is heavily biased in favour of papers published in Russian journals, with an ample proportion of articles by the present authors themselves. Generally this is quite useful, however, the information gap is often a two-way one and certain references to non-Russian literature are undoubtedly missing. Moreover, numerous misprints in the references to non-Russian works considerably decrease the informative value of the book.

Another special feature of the book is a great emphasis on electrochemistry of solids. Electrochemical stripping analysis is at present mostly considered as a method useful primarily for determination and speciation of a few metals and certain organics in the environment. The authors point out its usefulness in studying the structure of solid materials, in phase analysis and detection of structural defects, by mixing the test solid material with carbon for the preparation of carbon paste electrodes and following the electrolytic dissolution processes. In doing this, stripping methods transcend the boundaries of common analysis and enter the field of corrosion and materials science. It should, however, be pointed out that interpretation of the results is difficult and that they should be confronted and supplemented with those obtained by the established spectrometric methods of structural analysis. Nevertheless, this is an uncommon, refreshing view of the method.

The book consists of six chapters, supplemented by lists of abbreviations and symbols and a brief subject index. The first chapter deals with the theory of metal deposition on, and stripping from, solid electrodes. In my opinion, the purely thermodynamic approach adopted represents a gross simplification and the results can only be considered as qualitative. There are some unusual symbols, e.g. $\Omega$ for the coverage of the electrode surface, and some poorly defined parameters such as $\gamma$, which is a "proportionality factor reflecting metal-electrode system peculiarities", essentially serving to improve the matching between the calculated and experimental data (see, *e.g.*, Fig. 1.3). Also the use of the terms "strong and weak interactions" (see page 8) is not particularly fortunate, as it evokes the quantum mechanical terms.

The second chapter on obtaining an analytical signal is a very brief summary of the measuring methods. Chapter three, equally brief, discusses the electrodes used and electrolysis cells. A great emphasis is placed on solid (especially graphite) electrodes, in accordance with the authors' work. Chapter four surveys stripping analyses in solution, while the last two chapters deal with structural and phase analysis of solids.

The whole book is written more like a journal review than a monograph; therefore, the treatment is rather superficial, non-systematic and appropriate generalizations and conclusions are often missing. In many places the text is not very readable. In my opinion, the book is interesting for specialists because it presents them with an unusual viewpoint and may stimulate them to look beyond the customary boundaries of the method. On the other hand, it would be of little use to the novice in the field.

K. ŠTULÍK

**Flame Chemiluminescence Analysis by Molecular Emission Cavity Detection:** D. A. STILES, A. C. CALOKERINOS and A. TOWNSHEND (editors), Wiley, Chichester, 1994. Pages xiii + 205. £50.00. ISBN 0-471-94340-1.

Molecular emission cavity analysis (M.E.C.A.) shows remarkable sensitivity especially for sulphur, phosphorus and the halides. In addition it is capable of detecting most non-metals and metalloids and can deal with sample types from solid to gaseous. This monograph with contributions from active workers in their respective fields is a welcome coherent summary of this interesting and important field. The topics include the fascinating history of the discovery of M.E.C.A. in Belcher's Birmingham Group in the early 70's (A. Townshend), basic principles (A. C. Calokerinos), instrumentation and automation (N. Grekas) and four chapters on applications. These are grouped under Sulphur, Selenium and Tellurium (E. Henden), Arsenic, Antimony, Boron, Silicon, Germanium and Tin (M. Burguera and J. L. Burguera), Nitrogen, Phosphorus and Carbon (D. A. Stiles and A. Townshend) and Halogens and Metals (D. A. Stiles) and display some interesting aspects of gas phase molecular spectroscopy and selective reaction chemistry in solution or solid phase.

This is a timely and worthy addition to the series "chemical analysis" being produced with the customary attention to layout, quality of diagrams, indexing, *etc.* It is as pleasant to behold as to read. Congratulations to all concerned.

# NEW ADVISORY BOARD MEMBER

The Editorial Board and the Publisher of *Talanta* take pleasure in welcoming the following member of the Advisory Board of the Journal.

JED HARRISON

**Jed Harrison** is a native of Vancouver. He received his B.Sc. in Chemical Physics from Simon Fraser University in 1980, and received the Gordon Shrum Gold Medal upon graduation. He was the recipient of an NSERC Postgraduate Fellowship while undertaking graduate studies in Chemistry at the Massachusetts Institute of Technology. There he worked with Professor Mark Wrighton and graduated with a Ph.D. in 1984. He then joined the Chemistry Department at the University of Alberta, and became a full Professor in 1994. He was the 1993 recipient of the Canadian Society for Chemistry's W.A.E. McBryde Medal, awarded for research in analytical chemistry. In 1994 he received the University of Alberta's first Faculty of Science Research Award.

Harrison is the co-author of over 60 scientific publications, and works with a research group of undergraduate, graduate and Post-doctoral students that numbers about 10. His research interests are generally in electrochemistry, specifically in the development of membranes for chemical and biochemical sensors, and the use of microelectronic fabrication techniques for sensors and sensor systems. This program encompasses the development of new ion-selective electrode membrane matrices suited for use with integrated circuit technology, and the study of transport of ions, neutral molecules and solvents within polymer membrane matrices. Recently his group has begun developing electrophoresis systems on glass "chips". Funding for this research has come from industry and from the Natural Sciences and Engineering Research Council.

Harrison is Associate Editor of a new journal, *Analytical Methods and Instrumentation*. He serves on the program selection committees of the biennial IEEE-sponsored Sensor and Actuator Workshop, and Transducers, the International Conference on Solid-State Sensors and Actuators. He is a member of the Electrochemical Society Sensor Group Executive Committee, and was recently elected a board member of the Society for Electroanalytical Chemistry.

## REVIEW

# HYPHENATED FLOW INJECTION SYSTEMS AND HIGH DISCRIMINATION INSTRUMENTS

M. D. LUQUE DE CASTRO and M. T. TENA

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

(*Received* 2 *February* 1994. *Revised* 2 *September* 1994. *Accepted* 2 *September* 1994)

**Summary**—An overview of the state-of-the-art in flow injection analysis (FIA) coupled to instruments capable of providing either multidetection and/or multi-information is reported. The versatility of FIA endows the hyphenated instruments with analytical capabilities which increase from simple sample introduction to more complex sample handling such as automatic dilution and calibration, solvent exchange, derivatization reactions and on-line separation processes, among others. Unexplored aspects of these powerful problem solvers are also discussed.

Unaffordable analytical problems have found proper solutions since the appearance of 'hyphenated techniques', a term coined by Hirschfield at the beginning of the last decade[1] to name the coupling of two or more powerful techniques or instruments to achieve a synergistic effect of their overall performance with respect to their separate use. Liquid,[2,3] gas[4] and supercritical fluid[5] chromatographic techniques interfaced with mass spectrometric or with atomic spectrometric instruments[6] are examples of the excellent performance of these complex systems, as is the mass spectrometry–mass spectrometry tandem.[7] Most of the cases of hyphenated techniques entail powerful, large, expensive units, whose capabilities compensate for both high acquisition and maintenance costs.

Flow injection analysis (FIA)[8–10] is a simple and inexpensive technique the versatility of which affords for developing steps of the analytical process of rather different complexity. The simplest use of FIA is as a way for introducing samples into a detector, which is far from demonstrating the capabilities of this technique. Nevertheless, this simple use enables the sampling frequency to be dramatically increased and reduce the sample and reagent consumption. More interesting is the use of FIA to implement on-line derivatization reactions,[11] separation processes[12,13] as well as a number of sample handling modes to fit the initial sample conditions to the most suitable for single and multidetection[14,15] or implementation of flow-through (bio)chemical sensors,[16–18] among others.

Most of the detectors coupled to FI manifolds, either for sample introduction or for more complex sample handling, have been conventional instruments (e.g. molecular, atomic optical or electrochemical) capable of providing only two dimensional information. As happened with chromatographic techniques,[19] the first attempts to obtain three dimensional information in FIA were performed using either fast scan electrochemical[20] or diode array detectors,[21] thus enlarging the scope of application of FIA to more complex chemical systems. In a parallel but delayed development of hyphenated systems in chromatography, the coupling of FIA with high discrimination instruments pointed out the maturity of this dynamic technique. This last step in FIA started with the FIA–ICP-AES coupling. The capability of ICP-AES for multidetermination has been aided by FIA in different aspects since the earliest 1980's as listed in Table 1[41–103] and has been reviewed by different authors.[22–24] More recent and less numerous have been the arrangements of FI manifolds with instruments which enable three dimensional information and high

Table 1. FIA–ICP coupling

discrimination capabilities like MS (by direct coupling or through an ICP source), FTIR and NMR, among the most important, which have also been reviewed,[35-40] and whose most significant features are listed in Tables 2[114-151] and 3.[152-175]

Figure 1 shows the dissimilar use of flow injection analysis–high discrimination instrument (FIA–HDI) couplings. For this reason the aim of this work is to give to the analytical community, but particularly FIA users, an overview of the present situation of these hyphenated techniques, emphasizing the advantages involved in them, criticizing their negative aspects and showing the unexplored availabilities of one of the most promising uses of FIA.

## INTERFACES

The connection between a flow injection system and a high resolution detector has a decisive influence on the performance of the hyphenated system, as analytical quality parameters such as reproducibility, accuracy, sensitivity and selectivity are highly dependent on how this coupling is accomplished. The complexity of the interface is very different depending on whether the measurement is performed in solution, plasma or vacuum.

Inexpensive flow-cells (either conventional or demountable micro-flow cells) with KBr windows and different thickness spacers (0.015–0.22 mm, 0.15–9 $\mu$l cell volume) are used in FIA–FTIR coupling when organic solvent carriers are involved.[143-145,159-161] The use of thick spacers yields a higher contribution to the blank measurement from the carrier solvent, so poorer detection limits are obtained. More sophisticated cells are used with uncommon solvents. A 25 $\mu$l-micro-Circle cell equipped with a zinc selenide crystal (0.318 cm diameter) has been used for aqueous samples in FIA–FTIR;[157,158] and a high pressure flow cell (2 $\mu$l, 1 mm optical path length and 2 mm$^2$ cross sectional area) when supercritical $CO_2$ was the carrier.[156]

The design of an NMR flow cell should provide rapid sample displacement without significant degradation of resolution. Cells similar to those in Fig. 2, with a 50 $\mu$l observed volume work well at 1 ml/min flow-rate. The FIA injector can be connected directly to the NMR flow cell with 0.01-in i.d., 1/16-in o.d. tubing.[174] Sufficient premagnetization time of the sample can be accomplished by placing the injector and connectors within the magnetic field.

Special attention has been paid to interfacing FI systems and ICP.[42,44-46,56,57,59,60,132,176-179] A general interface to introduce a liquid into a plasma consists of a nebulizer, a spray chamber and a separator. The main shortcomings of using conventional interfaces in FI–ICP and in LC–ICP couplings related to continuous sample aspiration are the large dead volume and the sample loss involved as well as the band broadening. Efforts have been focused on producing interfaces with high analyte transport efficiency and minimal solvent loading and dead volume in order to decrease detection limits. Low analyte transport efficiency of conventional pneumatic nebulizer/spray chamber systems (only 1–2% of the analyte aspirated actually reaches the plasma) limits the ability to analyse small sample volumes. Miniaturized interfaces have been designed[42,44,45] in order to overcome this drawback. The direct injection nebulizer (DIN)[60] is another approach to minimize the dead volume: a microconcentric nebulizer fits into the central aerosol tube of a conventional ICP torch. Solutions are nebulized directly at the base of the plasma and there is no spray chamber or separator. The microconcentric nebulizer[46,59,60] and thermospray nebulizer[57,176,179] have been the most used. In addition, miniaturized glass-frit nebulizers[45] have been reported to couple FIA and ICP. Solvent loading is identified as a major contributor to plasma instability and poor detection limits. A jet separator,[177] a condenser[57,179] or a membrane dryer separator[132,178] can be used to remove the majority of

the solvent and convert the sample into a dried and desolvated aerosol in a flow of argon. Membrane separators are especially useful for organic solvents.

Flow injection and mass spectrometry have been interfaced either by membrane introduction and ion spray systems. The former consists of a membrane probe directly inserted into the mass spectrometer ion source. The carrier solution flows across the inside surface of the membrane while the outside surface is exposed to the vacuum of the mass spectrometer. This interface is suitable for volatile analytes capable of diffusing through the heated membrane.[163,180]

In ion spray MS the carrier solution is allowed to flow at a rate of 1–500 $\mu$l/min, through a very narrow bore capillary tubing (50–200 $\mu$m) polarized to a high voltage (2–3 kV). Spraying is facilitated by a coaxial flow of nitrogen. The electrically charged droplets found evaporate during their flight to the sampling plate (counter-electrode). The analyte must be present as an ion in solution because there is no ionization process. This injector has been connected to the ionspray interface via a 1 m × 50 $\mu$m i.d. fused-silica tubing.[162]

## SAMPLE INTRODUCTION

Despite the FIA capability to carry out a series of chemical processes, the major use of flow injection-high discrimination instruments (FI–HDI) has been to transport a few $\mu$l of sample to the detector. In addition to this application other more interesting uses are commented on in the following sections.

An extensive use of FIA as a sample introduction tool has been done when coupled to ICP-AES[41–63] and ICP-MS.[114–137] Nevertheless, FIA–ICP hyphenated systems have profited from many other FIA capabilities.

The use of flow injection as a means of sample introduction endows the methods with a number of advantages, namely: reduced sample and reagent consumption, increased sample throughput, higher reproducibility and better detector performance.

The sample saving achievable in FI–ICP is remarkable. Sample volumes in continuous aspiration ICP are usually between 2 and 5 ml, which decreases to 10–500 $\mu$l when coupled to FIA. Continuous aspiration of the sample is too wasteful to be feasible when only a limited sample volume is available (*i.e.* biological, clinical and forensic analysis); so the reduction of sample consumption achievable by FIA is of paramount importance in these fields. By way of example, FIA combined with ICP-AES has been successfully applied to the simultaneous determination of eight elements in 20-$\mu$l serum samples,[54] and acceptable detection limits for the analysis of several metals in biological samples were obtained with the use of *ca.* one-hundreth of the minimum sample volume required for continuous aspiration.[55]

The high sample throughputs achievable by FIA are a consequence of the simple and automatic way of sample introduction, as this can be inserted into the flowing stream and monitored within few seconds, whereas standard NMR methods require at least 45–60 sec before starting monitoring.[174] Flow injection couplings enable near-real time monitoring thus avoiding fraction trapping, which is time-consuming and capable of sample contamination. FI sampling with membrane introduction MS–MS has been used for fully automated monitoring and feedback control of bioreactors.[163] It allows quantification of the major products and metabolites of fermentation and even detection of trace metabolites.

Flow injection is a very reproducible means to introduce a precise volume of sample and also to improve the performance of the detector by minimizing blockage drawbacks in the interface thus favouring the detector stability. The precision of transient signal integration measurements as compared to steady-state integration measurements was found to be at least one of magnitude better for all of the wear metals.[52] The significant improvement in precision is due to reduced carbon build-up (more stable plasma; improved torch stability (no air pockets), constant sample solution flow-rate (use of a pump to avoid problems with viscosity changes) in the coupled FIA–ICP-AES. The ability to use small sample volumes reduces the loading of undesirable matrices on nebulizers and torches, particularly in high salt content samples or organic solvent solutions. An injection volume as low as possible without increasing detection limits must be chosen in order to minimize solid sample deposition on the torch injector tip and on the mass spectrometer sampling interface. Thus, no matrix deposition occurs and therefore reproducibility of a particular measurement is improved. This also provides better long-term stability of the instrument. The flow injection technique enables determinations in samples with total dissolved solid concentration 20–30 times higher than those handled by conventional solution aspiration. The precision of an FIA–ICP-MS approach reported by Vickers *et al.*[114] was found to be *ca.* twice that of a continuous flow mode, whereas Stroh *et al.*[131] have found a mean long-term stability better than 5% RSD for all the elements (10 ng/ml) they have studied in a 3% m/v NaCl matrix.

Memory effects are also minimized in an FIA–HDI coupling as the carrier immediately follows each sample plug, which results in a continuous rinsing effect that dramatically reduces clogging of the interface by deposition of

solid. The rinsing effect of the carrier decreases wash-out times, so the sampling frequency is improved as a result. Since the carrier system is flowing continuously, plasmas which normally extinguish at the air–water interface will no longer do so. In addition, injection of the sample avoids its passage through the flexible tubing of peristaltic pumps, which can adsorb the analyte[116] causing diminished signals and memory effects that severely degrade precision; at the same time, a close control of the flow-rate is accomplished in this way.

The use of FIA–FTIR systems provides simple and rapid sampling and easy cleaning of the flow-cell, and enables the continuous monitoring of the baseline of spectra. Pharmaceuticals[154,158] and pesticide formulations[155] have been determined successfully by FIA–FTIR thus demonstrating the usefulness of this approach.

Detection limits and spectroscopic resolution of FIA–NMR are also better than for static sample measurements.[174] The FI carrier solution provided a suitable medium where stable ion-spray could take place in MS sample introduction.[163]

Solid[181–184] and gaseous[185] samples can also be introduced in FIA–HDI couplings. Despite the capability of FIA for direct introduction of solid and gaseous samples, this potential has not been exploited. Only the direct analysis of solid samples by FIA–ICP-AES has been carried out by electrolytic dissolution[48] and FIA–slurry atomization.[63] Simultaneous determination of Zn, Si, Fe, Mn, Cr, Mg and Cu in aluminium alloys has been accomplished in a few minutes. Gaseous mixtures of compounds containing the elements Br, C, Cl and S were introduced by FIA with various sample loops (15–250 $\mu$l) on the injection valve.[46] Sample gas was added to the loops at *ca.* 10 ml/min, then the sample carrier gas (Ar) was switched through the loops to transport their contents into the ICP.

## SAMPLE HANDLING

This section deals with some simple operations such as automatic mixing of the sample with a dilution, standard or reagent thus completing the step within a short period of time with less sample and diluent, standard or reagent consumption. An additional advantage of the automatic performance of this step is a decrease of sample manipulation and thus of the human errors arose from it.

Dilution is an FIA capability which can be performed in an automatic way, thus achieving dilution factors for samples of standards ranging between 0 and 200. This fact justifies its coupling to HDI instead to other less versatile continuous dilution systems.[70] Different ways have been used to achieve this goal, namely the insertion of a short piece of wide-bore tubing, a delay coil, merging streams, zone sampling approach by using an unstirred or stirred chamber. A dilution step can be mandatory in order to minimize matrix effects in the determination of major components in a complex sample, or to fit the concentration of the analyte(s) within the linear range of determination in concentrated samples. A significant reduction of the mass-dependent interference effects without substantial sacrifice in sensitivity can be achieved by appropriate dispersion in the FI system. Vickers *et al.*[114] have demonstrated the almost complete elimination of signal suppression by using a FI manifold which provides dispersion factors up to 25. Martin and Ihrig[72] have developed an FI–ICP-AES approach for the automatic determination of widely varying elemental composition and concentration in a series of liquid samples without operator intervention. All the samples were appropriately diluted before determination by ICP–AES by using computer-guided sequential dilutions to place all elements within the optimum range. Sample dilution was accomplished by injecting the sample for shorter periods of time (time-based injection). The tandem-injection and merging-streams have also been employed to achieve on-line dilution and steady-state concentrations for ICP-AES and ICP-MS.[64]

### *Automatic calibration*

The ability for on-line development of relatively time-consuming sample pretreatment procedures such as standard additions, internal standard, isotope dilution, and matrix-matching calibration in a simple way, saving both time and sample makes FIA a useful tool for this sample handling.

The standard-addition method has proved to be effective in overcoming matrix effects, one of the main sources of loss in both accuracy and sensitivity in certain types of samples. The FI manifold can be designed either to add the standard to the sample (before, in, or after injection) or to inject the standard into the sample (reversed FIA), among others, thus

avoiding sample and standard contamination and the time-consuming preparation step.

In the reverse-FIA mode the standard-addition method is accomplished by continuous sample pumping to the detector instead of the carrier solution, the detector is zeroed for this baseline value, and the standard solutions are injected in the sample stream. The calibration curve can be run by injecting equal volumes of standards of different concentration; different volumes of the same standard solution, or using any of the FIA alternatives for dilution prior to injection. This method has been proposed to determine benzene in gasoline by FIA–FTIR,[160] and Si in an 85% phosphoric acid sample[65] and rare earth in metal samples[67] by FIA–ICP-AES.

Sample–standard merging before injection is an easy way to implement the standard addition method. A third stream of internal standard can merge after the sample and standard confluence.[141] The standard addition stream is used to add multielement standard solutions of variable concentrations. A complete standard addition can be performed in each sample by changing the standard solution. Unlike the reversed-FIA standard addition method, continuous introduction of the sample matrix into the detector is avoided by the sample standard merging method, which has been successfully used in FIA–ICP-MS[142,113] couplings.

The merging-zone approach has also been used for calibration purposes in the determination of Ni, Cu and Ni in alloys.[68] The system utilized successive injections of the sample, each one accompanied by the injection of a different standard. The limitations of this system include the relatively low sampling rate and the necessity of preparing a series of standards. The latter shortcoming might be overcome by using the zone-sampling mode, which enables controlled dilution of a given standard before its injection into the final standard carrier stream. Standard addition in plant digest samples has been implemented in an FIA–ICP-AES system by merging the sample zone with an aliquot delivered from a trapped standard zone in a modified version of the zone sampling approach. Eleven additions ranging from 3 to 32% of only one standard solution were performed in 5 min.[69] Nine toxic elements in undiluted urine were determined in less than 5 min using an FIA–ICP-MS approach[140] in which the FI manifold, which included a splitter tee, two in-parallel injection valves with different size loops (40 and 500 $\mu$l for standard and sample, respectively) and a mixing tee, was used to inject sequentially three standard solutions into the same sample plug.

Isotope dilution was used by Lasztity, Viczian *et al.* for the determination of lead in various matrices using a merging zones approach with programmable time-based injections.

Matrix matching of sample and standards was implemented in FIA–ICP-AES by Giné *et al.*[71] to minimize the interferences due to easily ionizable elements. Initially the ICP determines the sodium content in the sample and thereafter the computer selects the appropriate sodium addition to match the saline concentration with that of the standards. After having received a suitable amount of sodium, the sample reaches the ICP and the elements are determined.

### *Derivatization*

Flow injection is a suitable tool to carry out on-line chemical reactions in a reproducible and automatic way with a noticeable saving of both sample and reagents. The analyte can be converted into a more suitable form for detection (*e.g.* a volatile species which enhances the selectivity, sensitivity and scope of application of the coupled system). The chemical reactions most widely used in FIA–ICP-AES, FIA–ICP-MS and FIA–MS have been hydride generation and vapour generation.[100–110,148–151,168,169] Getek *et al.*[167] have reported an FIA–MS coupling in which electrochemical and chemical reactions took place. On-line formation and detection of glutathione and cysteine conjugates of acetaminophen were accomplished by interfacing a coulometric cell with a thermospray mass spectrometer in the flow-injection system. The electrochemical information enables the confirmation of *in vivo* reaction mechanisms.

## ON-LINE SEPARATION PROCESSES

One of the more advantageous aspects of FIA is its availability for the development of non-chromatographic continuous separation techniques with minimal complication of the experimental set-up. Flow injection takes advantage of its dynamic nature for an easy, inexpensive implementation of separation techniques involving any of the possible interfaces (liquid–solid, liquid–liquid or gas–liquid). All of them have been implemented in on-line helped by an FI manifold, then hyphenated to a high

capability instrument. The goal of the separation step has been to enhance either the sensitivity of the method by preconcentration of the target analyte(s) or the selectivity by removal of the matrix thus avoiding both its interference on the analytical signal and its passage through the detector, which is of a paramount importance in cases of insufficient or non-discrimination capability. The use of switching valves makes it feasible to lead undesirable species to the waste after separation without passing through the detection point. An additional benefit is an increased reproducibility as distortion of the signal from the analyte is minimized or avoided.

Liquid–solid interfaces have been established in FIA–HDI systems mainly by the use of solid-phase columns packed with either ion-exchange or adsorptive material, particularly with preconcentration purposes. This previous step can improve dramatically the sensitivity of a given method by one or two orders of magnitude. By way of example, the preconcentration FIA–ICP systems described by Hartenstein *et al.* are capable of increasing the signal by 10–15-fold and 20–75-fold per minute of sample loading time for simultaneous multielement integrated and simple element peak height, respectively, giving nearly 100% recovery of spiked analytes in tap and rain run-off waters.[89] Nevertheless, there are two negative aspects of these separation processes, namely: (a) The sample volume used is higher than in the absence of this step (see Tables 1–3). Depending on both the concentration of analyte in the sample and the enrichment factor to be attained the sample volume ranges between 2 and 100 ml, far from the $\mu$l range usual in FIA. (b) The sampling frequency decreases by a factor which depends on the working conditions. In the above example[89] this parameter decreased from 30–60 determinations/hr to 12–20 determinations/hr. This shortcoming can be minimized by using several columns arranged in parallel which work simultaneously and deliver sequentially the eluates to the flow manifold. The location of the column(s) in the dynamic system dramatically affects the overall performance and thus the results obtained. When the column is located in the transport zone of the flow manifold, a switching valve after the column is mandatory in order to waste undesirable sample components, thus avoiding their passage through the detector ($SV_2$ in Fig. 3A) (see Refs 81, 91, 92 and 143 as examples). The main drawback of this arrangement is the continuous

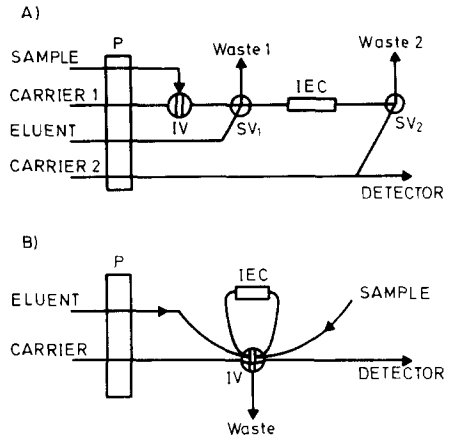

Fig. 3. Schemes of flow injection solid phase separation column coupled to high discrimination detectors. (P) Peristaltic pump; (IV) injection valve; (SV) selecting valve and (IEC) ion-exchange column.

circulation of the liquid in the same direction which tends to compact the packed material in the column and hence increases the pressure within the system. This problem can be overcome by placing the column upright and passing the solution upstream or by carrying out elution in the opposite direction of retention. The implementation of the latter approach is easy if the column is located in the loop of an injection valve (Fig. 3B). (A detailed description of the use of microcolumns in continuous flow systems can be found in Refs 12 and 13.)

In addition to the microcolumn located in any of the commented on above points, other units can be included on-line in the FI manifold to improve the efficiency of the overall process. Such is the case with the desolvation device connected to a microcolumn by Peng *et al.*[91] in the development of a method for the determination of trace elements by FIA–ICP-AES with on-line preconcentration. The authors achieve a desolvation efficiency of 73% at a desolvation temperature of 120 C and apply the method to

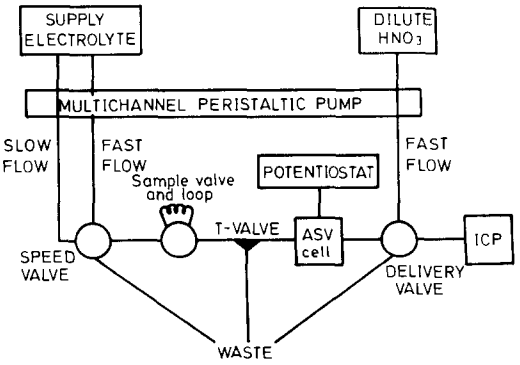

Fig. 4. Scheme of the flow injection-anodic stripping voltammetry inductively coupled plasma (FI-ASV-ICP) approach.

the determination of Al, Cu, Cd, Fe and Mn in serum by separation of the target analytes from various co-existing elements.

A less common liquid–solid interface in FIA–HDI is that created by using an on-line voltammetric stripping cell in the flow manifold such as the arrangement depicted in Fig. 4 which has been used to deposit Cu and Cd at a working electrode, then releasing the analytes for detection by ICP-AES.[147] The deposition step enables the elimination of the sample matrix components that are not electroactive and do not deposit during passage of the sample through the cell, thus being sent to waste by switching the delivery valve. The target analytes were preconcentrated from sample volumes as large as necessary, then stripped for detection into a small volume of liquid of the appropriate characteristics. Detection limits of pg have been achieved for 1-ml urine samples. It must be emphasized that the sampling frequency affordable by a stripping technique is usually higher than by solid columns as both the retention and elution steps are faster. Another additional advantage of stripping is the higher efficiency of the deposition process, which can be 100%.

Liquid–liquid interfaces have seldom been established in FIA–HDI by the use of both extraction and dialysis techniques and in all of the cases the detector has been ICP-AES. In continuous liquid–liquid extraction processes the efficiency of the separation strongly depends on the aqueous–organic flow-rate ratio. One of the earlier papers in this field[98] reported an increase in sensitivity of *ca.* 250-fold in comparison with direct aspiration of an aqueous solution for the determination of Cd by ICP–AES after extraction of its diethyldithiocarbamate into carbon tetrachloride with a detection limit of 4 ng/ml and a sampling frequency of 20 $hr^{-1}$. Indirect methods have also been established in this area, as is the case with the determination of fluoride in water by formation of the lanthanum/alizarin complexone/fluoride ternary complex and its extraction into hexanol containing *N*,*N*-diethylaniline. The introduction of the organic layer into the plasma and measurement of the emission intensity of La III 333.75-nm line enables the determination of the target analyte in a 0.03–1.3 $\mu$g/ml linear range with a sampling rate of 36 samples/hr.[85] Two in-series phase separators are used in order to obtain a pure organic phase to be transferred to the detector.

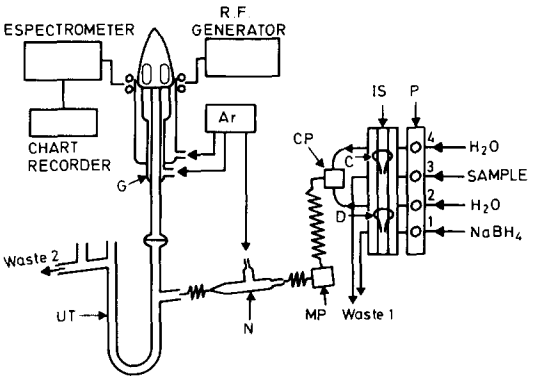

Fig. 5. Scheme of a flow injection–hydride generation–ICP-AES system. (P) Peristaltic pump; (IS) injection system; (CP) confluence point; (MP) mixing point; (N) nebulizer and (UT) U-tube.

A recent combination of flow injection Donnan dialysis with inductively coupled plasma atomic emission spectrometry has proved to yield enrichment factors of over 200 for cations with an 8-min dialysis time, allowing ng/ml level detection limits. These results were obtained for receiver solutions consisting either of Sr(II) or Mg(II), providing complementary free spectral ranges and the applicability of the hyphenated system to trace metal cation analysis for both transition and rare earth elements. The enrichment factors obtained were linear over a wide range of concentrations and limits of detection approximately 100 times lower than for direct aspiration. Additional improvements in enrichment factors were obtained with increases in the dialysis time and/or final sample solution temperature. A signal enhancement factor of 650 with a detection limit of 11 ng/ml for monovalent silver cation was obtained using a 30-min dialysis.[94] These results call for greater attention to be paid to Donnan dialysis as a powerful tool to manipulate the sensitivity of FIA–HDI methods.

Despite the small number of species capable of yielding a gas after reaction, gas–liquid interfaces have gained extensive use in FIA–HDI. Within gas–liquid separation, techniques based on hydride generation are the most common in hyphenated systems, particularly in FIA–ICP-AES and FIA–ICP-MS, where vapour generation has proved considerable enhancement of the analytical capabilities for multielemental determination of volatile vapour-forming elements at ultratrace levels in environmental samples. Very good accuracy and precision in addition to increased sensitivity and avoidance of espectral interferences caused by high salt matrix, as demonstrated in ocean

water samples.[150] An arrangement such as that depicted in Fig. 5 was used in one of the earlier hydride generation–FIA–ICP-AES methods. The determination of arsenic as arsine was performed at a rate of 200 injections/hr with detection limits of 1.4 ng arsenic.[102] Subsequent contributions have been the determination of arsenic in glycerine,[103] that of antimony in waste water,[107] and the simultaneous determination of As, Sb and Se,[108] among others. The simultaneous method,[108] as compared with continuous sample introduction, provides detection limits three times poorer. By contrast, the precision is approximately 150% better with FI due to the reduced pump pulsations. Other advantages of the FI system are the reduced sample size necessary for analysis ($<750$ $\mu$l *vs.* 4–5 ml for the continuous introduction system) and the potential for a greatly increased rate of sample throughput.

One of the scarce contributions on FIA–MS dealing with hydride generation is that reported by Canham and Pacey and consists of preliminary studies of the behaviour of such a system with very promising results.[169] A more complex FIA–ICP-MS arrangement has also been reported for the determination of hydride-generating elements and for the determination of mercury. Several pre-reduction techniques were investigated and applied to the determination of the target analytes (namely, B, Sb, Se, Te, Hg and As) at ultra-trace levels in environmental samples. The detection limits found were in the range 0.5–7.0 pg/ml.

On-line preconcentration and oxidation by hydrogen peroxide were combined to improve the atomic emission limit of detection for iodine. The process was automated by FIA and hyphenated to both ArICP-AES and HeICP-AES for evaluation of the performance of the overall system as a way to circumvent the drawbacks encountered in the batch method, to which $I_2$ is adsorbed onto the peristaltic PVC pump tubing causing a memory effect, and the mixed reagents were only stable for 1 hr. To minimize the memory effect in the batch method, the transfer line was rinsed with a 0.02% solution of sodium thiosulphate in an attempt to reduce $I_2$ (adsorbed on the transfer line) to $I^-$. Although this procedure was effective in reducing the memory effect, its use in routine analysis was limited because of cross-contamination and increased analysis time. To eliminate the cited limitations in the batch method, the reagents were mixed on-line and the formation of $I_2$ took place along the reactor, thus avoiding its passage through the pump tubing. The iodine signal at 183.04 nm was enhanced by a factor of 33 and 100 for ArICP and HeICP, respectively, with detection limits of 5 and 9 ng/ml.[82]

## SPECIATION STUDIES

Speciation has been implemented in FIA–HDI using different capabilities of such arrangements. One of the simpler but more expensive ways to develop speciation is by the use of a detector which allows direct discrimination of the different forms of a given element or compound. This is the case with the FIA–MS–MS tandem, with ion-spray sample introduction and discrimination by selective reaction monitoring of daughter–parent pairs, which has been used for speciation of organotin compounds in sediment and SRM,[162] or the use of molecular emission cavity analysis (MECA) for the speciation of sulphur anions (as sulphide/sulphite/sulphate)[172] and that of phosphorus insecticides[171] and organophosphorus compounds,[170] based on the parameter $t_M$ ($t_M$ is the time elapsed between introduction of the cavity into the flame and analytical achievement of the maximum peak intensity). Speciation can also be implemented in FIA systems coupled to twin in-series detectors with non-capability for speciation. Such is the case with the speciation of phosphorus compounds (as phosphate and total phosphorus) in waste water by FIA and sequential spectrophotometry and ICP-AES. Phosphate was determined as molybdovanadophosphoric acid using a colourimetric method and the solution from the flow cell of the spectrophotometer was directly introduced to an ICP. The determination of total phosphorus was performed by measuring the emission intensity at 177.499 nm. Chromium caused a positive error in the colourimetric determination, but ions commonly existing in waste water did not interfere with the determination of total phosphorus. The sampling throughput was 80 samples/hr. The contributions of FIA to improve the features of the method were the on-line derivatization and the increased sampling frequency.[112]

Discrimination can also be achieved in the FI manifold. Such is the case with speciation of antimony [as Sb(III)/Sb(V)].[107] Antimony was reduced to stibine and determined in 1 *M* malic

acid or 0.5*M* tartaric acid, whereas in either of these media antimony(V) gave little or no signal. Total antimony was separately determined in the presence of 0.1*M* thiourea as pre-reductant.

An on-line separation step can also endow the method with discriminating capability, as in the method proposed for the sequential speciation of chromium [as Cr(III)/Cr(VI)] based on the use of microcolumn of activated alumina in an FIA–ICP-AES arrangement. The column was used to separate and preconcentrate Cr(VI) from Cr(III) before ICP detection at 267.72 nm. Thus, determination limits of 1.4 and 0.20 ng/ml for Cr(III) and Cr(VI), respectively, were obtained.[111]

More complex separation techniques as GC have also been hyphenated to FIA and microwave-induced plasma (MIP) atomic emission spectrometry for organotin speciation analysis. The method was based on the preconcentration of ionic organotin compounds by sorption on bonded silica with octadecyl functional groups followed by on-column ethylation using sodium tetraethylborate. The derivatized species were eluted with 250 $\mu$l of methanol, separated by gas chromatography and detected by MIP–AES. The method was applied to the determination of the target analytes in river samples which were also analysed using a manual liquid–liquid extraction method. The results agreed within 10–15% for concentrations of a few pg/ml.[85]

## CONCLUSIONS

From Tables 1–3 the more extensive use of FI coupled to ICP can be stated. The first of such arrangements exploited the FI manifold only as a means of reproducible transport of the sample into the instrument, with the sole aim of increasing sample frequency. Later it was realized that periodical washing of the nebulizer is beneficial, allowing handling of concentrated samples. These features, together with the feasibility of automated dilution and calibration led to the realization that FIA is the cure of the 'Achilles heel' of ICP. From more recent developments such as FIA preconcentration/separation, FIA speciation and FIA conversion it becomes apparent that FIA can be a more useful problem solver.

The long way ran for full implementation of FIA–ICP coupling seems also to be the way followed by other high discrimination systems, as can be inferred from Tables 2 and 3. In this respect it is noticeable the scarce number of FI–RMN methods proposed so far, despite the fact that interface problems are successfully solved as a result of the previous coupling of RMN with other hydrodynamic systems as is the case with LC-RMN.

Some isolated attempts have been made using these hyphenated systems and should be exploited as they offer interesting perspectives, namely: (a) use of robotic stations for sample pretreatment steps such as weighing and dissolution. The pretreated sample can be introduced directly into the FI manifold,[186,187] thus achieving full automation of the analytical process. (b) Direct introduction of solid samples into the FIA–HDI arrangement. A first attempt has been made in this respect by use of electrical energy for leaching the sample.[181,182] Electrolysis is not the sole way of using solid samples in these dynamic systems, as ultrasounds have also proved their great potential in this context.[183,184] (c) Use of FIA as a 'hyphen' allowing different instrumental techniques to be linked together. The use of a stripping flow-cell for preconcentration purposes is a partial example of this potential, which can also be expanded to its use for preconcentration/determination prior to the high discrimination instrument, thus increasing the information level. Also FIA could be linked to apparatus such as a supercritical fluid extractor and an HDI with accomplishment of the intermediate step (derivatization, separation, *etc.*), which no doubt would improve the overall performance of the method. (d) The scope of non-chromatographic continuous separation techniques coupled to FIA–HDI should be broadened by including prevaporation[188] and continuous precipitation[189] as both have proved their capabilities when coupled to FIA. (e) More attention must be paid to the use of FIA to obtain information in the development of theoretical studies of the dynamics in membrane and membraneless instruments,[180] and to the FIA–HDI coupling interfaced by an autosampler.[190] All these slightly or unexploited aspects of FIA in hyphenated systems can undergo suitable development with the present trend of some manufacturers, which integrate FIA systems in HDI as a means, in principle, of sample handling.

# DECOMPOSITION OF DIPHENYLAMINE IN NITROCELLULOSE BASED PROPELLANTS—I. OPTIMIZATION OF A NUMERICAL MODEL TO CONCENTRATION–TIME DATA FOR DIPHENYLAMINE AND ITS PRIMARY DEGRADATION PRODUCTS DETERMINED BY LIQUID CHROMATOGRAPHY WITH DUAL-AMPEROMETRIC DETECTION

ARNE BERGENS* and ROLF DANIELSSON

Uppsala University, Institute of Chemistry, Department of Analytical Chemistry, P.O. Box 531, S-751 21 Uppsala, Sweden

(*Received* 5 *November* 1991. *Revised* 2 *April* 1993. *Accepted* 4 *April* 1993)

**Summary**—The consumption of diphenylamine (DPA) in two nitrocellulose (NC) based propellants subjected to a heat storage test at 85° has been studied. A previously developed method based on reversed-phase liquid chromatography with dual-amperometric detection was used to monitor the concentrations of DPA, 2-nitro-DPA and 4-nitro-DPA during the test. A numerical model based on first order rate equations was fitted to the obtained analytical data with the use of a specially written curve fitting program. The model implemented in the program describes the initial nitrosation and nitration steps of DPA in aging NC propellants. The use of matrices in the calculation of concentration–time (CT) curves enables the introduction of a general algorithm which can be readily changed in order to simulate any system of first order reactions. The program can therefore be used in other applications such as mechanistic studies in organic synthesis. The general simulation algorithm allows inclusion of unknown (not analysed) components in the reaction mechanism. In this application, it was possible to simulate the course of *N*-nitroso-DPA which is not detectable by the amperometric principle.

The thermal decomposition of NC is a complex process which is believed to be catalyzed by the decomposition products, especially by reactive nitrogen oxides. A frequently used method for stabilization of NC is therefore to add DPA which reacts with the degradation products such as nitrogen oxides, $HNO_3$ and $HNO_2$. The auto-catalytic decomposition of NC is prevented as long as there is a significant amount of stabilizer present in the NC material. Normally, about 1% is normally added depending upon the intended properties of the propellant. The stabilizer will hence be consumed with time under the formation of different nitro and nitroso derivatives of DPA.[1–3] The danger of self-ignition of the NC will, therefore, increase with time and a good estimate of the safe storage time of a propellant batch is, consequently, a matter of great importance.

A properly stabilized NC-propellant is stable for a relatively long period of time (20–50 years) at normal storage conditions. Stability testing must therfore be carried out by storing propellant samples at higher temperatures in order to obtain degradation within a reasonable time. By raising the storage temperature to 90–110°, about 20 years of storage are compressed into one week in the laboratory. Traditionally, the time elapsed until red fumes appear is used as a measure of stability since it indicates the point at which the DPA is fully consumed by the thermal degradation products of NC. By performing heat storage tests at different temperatures (for example 65–100°), it is possible to estimate the time-to-fume at normal storage temperatures but this procedure usually gives estimates impaired by significant errors since an extrapolation is made over a wide temperature range.

Today, the stabilizer consumption during heat storage tests can be readily monitored by chromatographic techniques. In order to correlate results acquired at elevated temperatures with those obtained under normal storage conditions, the rate of stabilizer consumption in the

*Present address: Pharmacia AB, Pharmaceuticals Uppsala, S-751 82 Uppsala, Sweden.

propellant at different temperatures has been used. Assuming first-order kinetics, the time for the stabilizer to be consumed at lower temperatures can be extrapolated with the use of the calculated activation energy. Practice has, however, shown that this method does not give sufficiently precise estimates. This is not surprising since also this approach involves an extrapolation over a large temperature interval and therefore requires extremely precise experimental data. The use of temperatures above the melting point of the stabilizer compound will also introduce errors, as the diffusion conditions for the reacting species in the propellant sample change in the vicinity of the melting point. A properly manufactured NC propellant is, however, stable for at least 20 years at normal storage temperatures which means that stability testing at lower temperatures would require unrealistically long experiments.

Another problem associated with the monitoring of the stabilizer concentration is that a low stabilizer concentration does not necessarily mean that the propellant is unstable. In the case of DPA, for example, a propellant containing less than 0.1% DPA can for instance show acceptable stability according to weight loss or micro-calorimetric measurements for a long time. The stability after that the DPA has been consumed is largely maintained by the initial degradation products, *e.g.* 2-nitro-DPA and 4-nitro-DPA. 2-nitro-DPA is, in fact, a common stabilizing additive used as an alternative to DPA. During the lifetime of a propellant, one DPA molecule can trap six molecules of $NO_x$ before it decomposes to form picric acid.[1] The ability of the nitro-DPA derivatives to trap nitrogen oxides decreases with increasing number of nitroso and nitro groups. The autocatalytic reactions responsible for the red fumes have already started when di-nitro derivatives are beginning to appear.[4] In stability estimations based on stabilizer consumption it should, therefore, be more appropriate to use the time when also the initial degradation products have been consumed.

The objective of this work is to study the initial stages of DPA degradation in a simple single base propellant by the use of a previously developed analytical method[5] for nitro diphenylamines. A further aim is to try to correlate analytical data with a numerical model describing the early stages in the degradation mechanism of DPA. The nitrosation and nitration of aromatic amines such as DPA has been extensively studied and the reaction is described in many organic chemistry textbooks. The attack of $HNO_3$, $HNO_2$ or nitrous gases on the DPA molecule is most likely to appear at the nitrogen in the amino group with the formation of a nitrosamine.[6–8] The nitrosamine can be further converted to 2-nitro-DPA and 4-nitro-DPA by the Fischer–Hepp rearrangement[9–12] and oxidation of the nitroso group. The initial steps in the DPA-degradation in propellants are therefore well understood, and described as the reaction scheme in Fig. 1. The higher nitrated DPA derivatives with two or more nitro groups

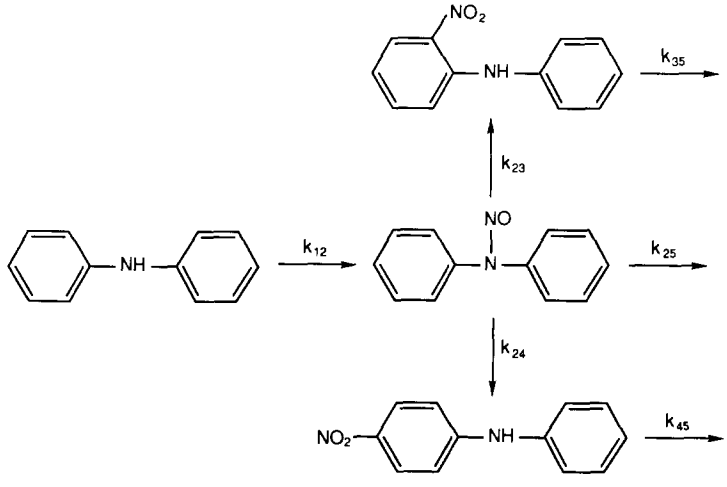

Fig. 1. The dominating reaction routes of the initial DPA degradation in an aging propellant. This reaction mechanism served as a model reaction system for the fitting of CT curves for DPA, 2-nitro-DPA and 4-nitro-DPA. The indexes of the parameters have been chosen on the basis of the numbering of the compounds which is (1) DPA, (2) *N*-nitroso-DPA, (3) 2-nitro-DPA, (4) 4-nitro-DPA and (5) other derivatives with two or more nitro groups.

appear late in the heat storage tests and are therefore only of secondary interest.

A computer program for the simulation of first-order reaction systems has been used to study the degradation mechanism of DPA (Fig. 1). The concentrations of DPA, 2-nitro-DPA and 4-nitro-DPA were monitored during a heat storage test at 85° and the concentraton data obtained were fitted to a model describing the reaction system in Fig. 1. With the dual-amperometric detector used it was, however, not possible to detect and quantify *N*-nitroso-DPA.

## MODELLING AND SIMULATION

The degradation of the stabilizing agent is a complex process, and ideally all components involved should be monitored for a full understanding of the process. In practice only some preselected substances can be analyzed during the experiment, and one has to resort to a model for a more detailed description of the process. Even components of main interest may be unaccessible for analysis, and these must be deduced from what actually can be measured.

This is a situation similar to a complex titration, where a system of equilibrium equations and a set of varying concentrations makes it possible to follow species unaccessible for direct measurements. In our case we need a set of kinetic equations relating the concentration–time (CT) profiles for the different components, when only some of them are experimentally obtained.

A crucial point with this approach is the validity of the model. The fewer components of the proposed reaction scheme that are actually monitored, the higher the demands are put on the precision of the measurements and the degree of fit. There is no simple way of anticipating *a priori* the validity of the results, it is rather a matter of combining chemical reasoning and numerical considerations.

As a tool for this process we have developed a computer program for general use in modelling kinetic reaction schemes described by a set of first-order rate equations. When initial concentrations and rate constants are assigned to the proposed components and selected pathways, the CT curves for all components are simulated. A simplex procedure is then used to make the best least-square fit to the actually measured components.

The simplex method was chosen for optimization of the parameters mainly because the number of calculations required does not increase too rapidly as the number of parameters in the model increases.[13] The simplex algorithm used in the program was based on the modified simplex with variable step length introduced by Nelder and Mead[14] in 1965. No stop criterion for the iterations is included in the program as it is not meant to be operated unattended. When running the program, the progress of the minimization of the square sum is displayed. However, the true progress of the optimization is revealed by visual comparison of the experimental and calculated data.

In the degradation of DPA we are monitoring the origin component and two possible products. The difference between DPA and these two products may be assigned to other products, intermediate as well as final, and to errors of analysis. The simulation makes it possible to separate these contributions, at the expense of the introduction of modelling errors.

The question is then whether the proposed first-order reaction scheme results in assignment of the unexplained amounts to true components or to mere artefacts. In the absence of chemical confirmation we have to rely on sound chemical principles and give preference to simple models. The validity of the model can only be judged by the fit, *i.e.* comparison of the simulated and the recorder CT curves. Attention must also be paid to the uniqueness of the assignment to unmonitored components. If there is insufficient information in the measurements, we should obtain similar degree of fit regardless of the values for the parameters which are related to such components. Inspection of the CT curves for unmonitored components obtained with different starting values for the parameters in the minimization procedure should reveal such problems. Therefore, the development of a fast simulation procedure was an essential step to make such a trial-and-error mode of operation feasible.

It should be emphasised that the optimized parameters are numerically obtained constants. The main purpose of the curve fitting program is to discern which possible reaction mechanisms give the best curve fit to experimentally obtained data. The simulation algorithm uses matrix formalism to calculate the CT curves from the rate equations written in difference

form. For the reaction system given in Fig. 1 these equations are:

$$\frac{\Delta[X_1]}{\Delta t} = -k_{12}[X_1] \quad (1)$$

$$\frac{\Delta[X_2]}{\Delta t} = k_{12}[X_1] - (k_{23} + k_{24} + k_{25})[X_2] \quad (2)$$

$$\frac{\Delta[X_3]}{\Delta t} = k_{23}[k_2] - k_{35}[X_3] \quad (3)$$

$$\frac{\Delta[X_4]}{\Delta t} = k_{24}[X_2] - k_{45}[X_4]. \quad (4)$$

The designations $X_i$ in equations (1)–(4) can be identified from Fig. 1 as: DPA ($i = 1$), *N*-nitroso-DPA ($i = 2$), 2-nitro-DPA ($i = 3$), and 4-nitro-DPA ($i = 4$). The subindex 5 should represent the di-nitro to hexa-nitro derivatives formed later in the storage period. The equation for $X_5$ has been left out since these components were not included in the study.

The concentrations $[X_i]$ are calculated for rather large time intervals $\Delta t$ without loss of accuracy using a novel technique based on matrix exponentiation. This approach enables a computer implementation with short execution time which facilitates the optimization process. The simulation procedure is further described in Appendix 1.

The decomposition of NC is, however, a complicated process with possible unknown steps which might affect the rate of stabilizer degradation. It is, therefore, difficult to obtain CT data with sufficient precision to allow determinations of rate constants since small variations in storage conditions can give rise to large errors in the CT data. The computational approach described here should be more successful for the optimization of coupled rate parameters, for example, in organic synthesis where the surrounding conditions are more easily controlled.

## EXPERIMENTAL

### *Apparatus*

Electrochemical detection at negative potentials suffers from oxygen interferences which therefore have to be minimized. The liquid chromatographic system was, therefore, equipped with a gas tight resevoir for the mobile phase constructed from a 100 ml Merck solvent flask in which the mobile phase could be continuously purged with argon or helium. A small overpressure was maintained inside the reservoir by means of two needle valves regulating the in and outlet gas flows.

The pump used was a Pharmacia LKB, Model 2150 (Pharmacia LKB Biotechnology, Uppsala, Sweden) double-piston pump. The housing of the inlet valves was exchanged with stainless steel housings from two discarded outlet valves in order to allow stainless steel tubing to be used. This was done since the original inlet valves of this pump only allow connection of plastic tubing for the mobile phase supply tube. The walls of the commonly used PTFE tubing are easily penetrated by oxygen which means that stainless steel tubing has to be used exclusively.

The injection of samples were either made with a Millipore Waters Model 712 WISP Sample Processor (Millipore Intertech, Bedford, MA, U.S.A.) or a Carnegie Medicin CMA200 (Carnegie Medicin AB, Stockholm, Sweden) automatic injector. The separations were carried out using a $100 \times 4.6$ mm RP-18 Spheri-5 column obtained from Brownlee labs Inc. (Santa Clara, CA, U.S.A.). The dual electrode amperometric detection system was controlled by two LC-4B potentiostats (Bioanalytical Systems Inc., West Lafayette, IN, U.S.A). The electrochemical cell was used with the electrodes placed in a series arrangement. The reference electrode was an Ag/AgCl electrode and the working electrodes both consisted of glassy carbon. The stainless steel cell body served as counter electrode.

The column, detector cell and waste container were all placed inside a thermostatted shielded box constructed in the laboratory. The temperatures used in this work were 30 and 35°. The temperature was never observed to deviate from the programmed value by more than ±0.1°.

The chromatograms were recorded and processed with a Spectra Physics, Model SP4290 integrator (Spectra Physics, San Jose, CA, U.S.A.). The simulation and simplex optimization algorithms were programmed using the ASYST scientific calculation system (MacMillan Software Company, NY, U.S.A.) and run on an IBM PS/2 model 50 computer equipped with a mathematics co-processor.

### *Chemicals*

The acetonitrile and 2-propanol used in the mobile phase were of Lichrosolv grade (Merck) and could be used without further purification or filtration. *m*-chloroacetic acid was purchased from BDH Chemicals Ltd., Poole, U.K. and

was also used as recieved. The *m*-chloroacetic acid buffer was prepared from a 0.05*M* solution by adjusting the pH to 2.7 with NaOH.

The reference substances DPA (Merck, Darmstadt, Germany, *pro analysi* grade), 4-nitro-DPA (Aldrich-Chemie Gesellschaft GmbH & Co. KG, Steinheim, Germany, specified purity 99%) and 2-nitro-DPA (Aldrich-Chimie, specified purity 98%) were all used as recieved. The internal standard, 4-ethyl-nitrobenzene was also purchased from Aldrich and of 99% specified purity. All standard solutions were prepared weekly and stored in a refrigator.

*Procedures*

*Storage and extraction of propellant samples.* The composition of the two single base NC propellant batches studied in this investigation were 0.5% DPA/99% NC and 0.7% DPA/99% NC. From these two batches, two series consisting of 17 different 4 g samples from each batch were subjected to a heat storage test at 85° according to the Dutch stability test.[15] This test is normally employed for weight loss determinations at temperatures in the interval 95–110°. However, in this investigation the temperature was decreased to 85°, as a lower rate of NC decomposition was desired.

In the Dutch stability test, the samples are placed ungrinded in 160 × 17 mm test tubes with ground glass stoppers. After a predetermined time period, a 1 g portion of the sample is carefully taken out for extraction while the rest is disposed as waste. In this case, the extractions were performed during 4 h using 50 ml of methylene chloride in a Soxhlet extraction unit (Soxtec System 1040 extraction unit, Tecator, Sollentun, Sweden). Methylene chloride was then evaporated at ambient temperature, followed by dissolution and dilution of the residue in acetonitrile to known volume (25–50 ml). It was noticed that the residue needed some time to dissolve and the residue was therefore dissolved using several small portions of solvent. The acetonitrile solutions were then further diluted with mobile phase before transferring them into the automatic injector. Analyses of more than 20 samples were avoided (20 samples correspond to a maximum running time of 6–8 h) because of the unstable 4-nitro-DPA observed in earlier work.[5] With the CMA200 injector the samples were refrigerated to +6°C while stored in the autoinjector.

*Chromatography.* In this investigation two different mobile phase mixtures were used. In the analysis of the nitro derivatives, a mixture consisting of 63% 0.05*M* *m*-chloroacetic acid buffer (pH = 2.7), 13.5% acetonitrile and 23.5% 2-propanol was used at a temperature of 30°. The analysis of DPA was on the other hand performed with a mixture of 60% *m*-chloracetic acid buffer, 13.5% acetonitrile and 26.5% 2-propanol at 35°. In both cases, the mobile phase compositions are given as volumetric percentages. DPA was analysed separately because of the suspected high concentration of DPA and low concentration of nitro derivatives in the beginning of the storage period. The *m*-chloroacetic acid buffer was passed through a 0.45 μm filter (type HVLP, Millipore) before mixing with the organic solvents. As indicated above, the mobile phase was degassed and deoxygenated in its resevoir by purging with helium or argon for 10–15 min before turning the pump on.

All chromatograms were run at flow-rate of 1.1 ml/min and when the chromatographic system was not in use, the mobile phase was left circulating through the system. Since the mobile phase was always kept in an inert atmosphere inside the reservoir flask the start-up time was hereby shortened.

The electrochemical characteristics of 2-nitro-DPA and 4-nitro-DPA have been studied in an earlier report[5] in which the suitable potential settings were found to be W1 = −1.0 V and W2 = +0.4 V *vs.* Ag/AgCl. The potential settings used in the quantification of DPA were on the other hand W1 = 0 V and W2 = +0.9 V. These values were chosen on the basis of literature data[16,17] but were also verified by the recording of hydrodynamic voltammograms.

The injection volumes used were in the range 15–50 μl depending on the concentration level to be analyzed. For the quantification of the nitro diphenylamines, 4-ethyl-nitrobenzene (4-ENB) was chosen as an internal standard since experiments showed that it had similar electrochemical properties as 2-nitro-DPA and 4-nitro-DPA as well as a suitable retention time. In the quantification of DPA an external standard method with a calibration curve was used and the response of the detector was checked at regular intervals by injections of standard solutions. This procedure was employed since oxidation of DPA is suspected to give rise to polymeric products[9] which deactivate the electrode surface by adsorption. Such an effect was, however, never observed during a typical 6–8 hr run including 14–19 samples.

## RESULTS AND DISCUSSION

The electrochemical characterization and evaluation of the analytical conditions for the determinations of 2-nitro-DPA and 4-nitro-DPA have been described in an earlier paper[5] and are therefore only briefly recapitulated. The only reducible substances extracted from the NC-propellants are the different nitro derivatives of DPA. Selective detection of 2-nitro-DPA and 4-nitro-DPA in samples with relatively high amount of DPA present can be achieved with the use of a dual-electrode amperometric detector. In such an arrangement the nitro group is reduced to a hydroxylamine at the first electrode (W1). The latter compound is then oxidized at the second electrode (W2) and it is the current arising form this oxidation that is used as the analytical signal. With the dual-electrode the interference from oxygen in the mobile phase is partly overcome since only some of the hydrogen peroxide formed during the reduction of oxygen is oxidized at the detector electrode.

An example of a chromatogram obtained when analyzing a sample of the 0.7% DPA propellant is shown in Fig. 2(a). The DPA concentration in the injected sample solution was determined to be 19.1 $\mu M$, which corresponds to an injected amount of 0.95 nmol. The concentrations of 2-nitro-DPA and 4-nitro-DPA were determined to be 2.63 $\mu M$ (0.13 nmol injected) and 6.87 $\mu M$ (0.34 nmol), respectively. The oxygen present in the sample solutions gives rise to a peak in the early part of the chromatograms due to oxidation of hydrogen peroxide formed at W1 during the reduction of oxygen. A complete deoxygenation of the samples with any of the two automatic injectors used was found to be difficult. As the hydrogen peroxide peak is not interfering with any analyte peak the problem was, however, left without further attention.

DPA is oxidized at potentials above + 0.7 V at a glassy carbon electrode depending on pH, solvent and the condition of the electrode surface.[16,17] Figure 3 shows a hydrodynamic voltammogram of DPA which reveals that a

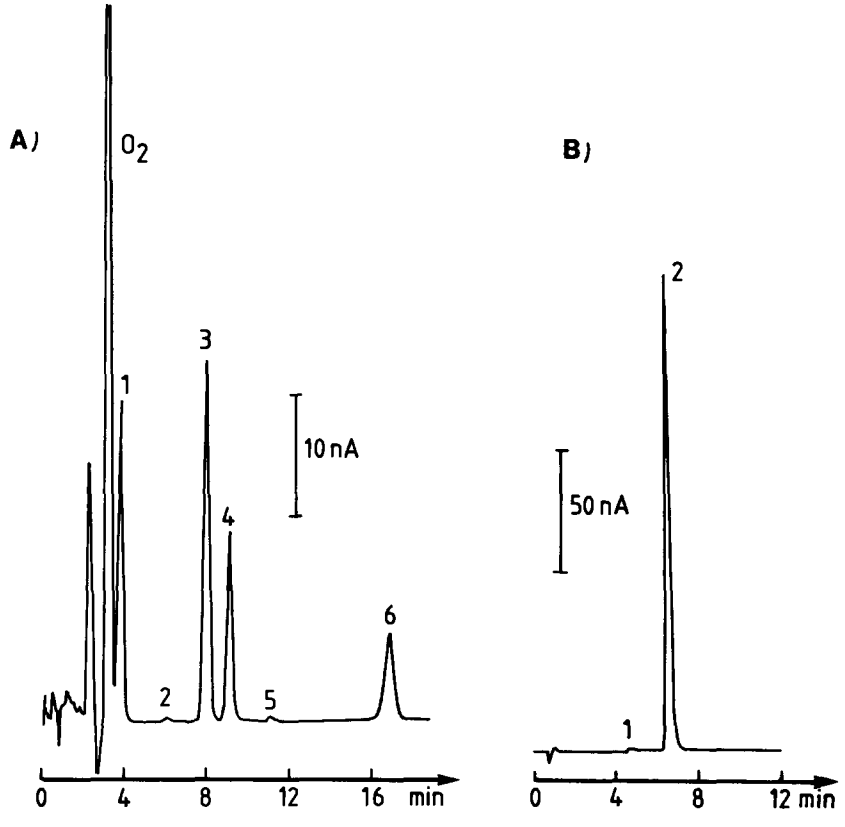

Fig. 2. Chromatograms recorded with dual-electrode amperometric detection with (a) W1 = − 1.0 V, W2 = + 0.4 V *vs.* Ag/AgCl and (b) W1 = 0 V and W2 = + 0.9 V. The sample is a 0.7% DPA propellant stored at 85 for one day. Peak identities in Fig. 1(a): (1, 2) unknown, (3) 4-nitro-DPA, (4) 4-ENB (internal standard), (5) DPA, (6) 2-nitro-DPA. In Fig. 2(b): (1) 4-nitro-DPA and (2) DPA. As explained in the Experimental section, the chromatographic conditions were different in the two cases.

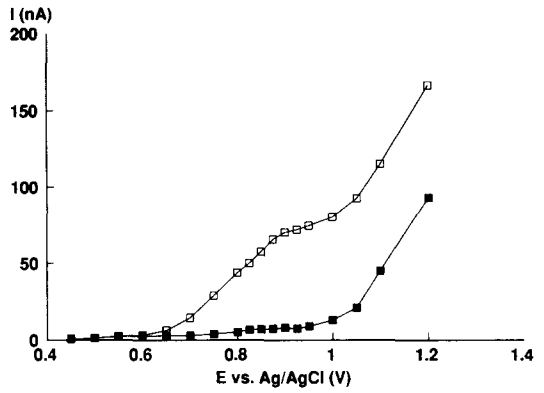

Fig. 3. Hydrodynamic voltammogram for DPA. (□) represents obtained peak currents from injection of 0.2 nmol DPA. (■) represents the background current at the different potentials.

potential of +0.9 V *vs.* Ag/AgCl is necessary in order to obtain a diffusion controlled current. Since the background current rises sharply at potentials more positive than +0.95 V, a detection potential of +0.9 V was chosen. Based on 10 repeated injections, the response for DPA was found to be reproducible within 1%. The calibration graphs were linear in the range of 0.5–11 $\mu M$.

The nitro derivatives of DPA are on the other hand only partly oxidized at +0.9 V *vs.* Ag/AgCl and therefore only give rise to minor peaks. In Fig. 2(b), the oxidation of the eluting 4-nitro-DPA hence only give rise to a small peak at 4.2 min. The different elution times for DPA in Fig. 2(a) and 2(b) stems from the fact that the analyses were carried out with different mobile phases and temperatures.

The results from determinations of DPA, 2-nitro-DPA and 4-nitro-DPA in the two single-base propellants during the heat storage experiment are shown in Fig. 4. As seen in the figure, only a minor part of DPA is converted to 2-nitro-DPA and 4-nitro-DPA, in agreement with previous publications.[1,18] It can further be concluded that the degradation of DPA mainly leads to formation of *N*-nitroso-DPA which in turn is consumed by the NC decomposition products. It can also be seen that 2-nitro-DPA and 4-nitro-DPA are formed simultaneously and that the concentration of 4-nitro-DPA is about twice as high as that of 2-nitro-DPA throughout the whole storage period. At this temperature, the concentrations of 2-nitro-DPA and 4-nitro-DPA reach their maxima after about 15 days of storage.

The solid curves seen in Fig. 4 are those simulated by means of the parameters obtained from the simplex program. Although the assumed first-order kinetics is a simplification, the agreement between the fitted curves and experimental data is good. The theoretical curves for an irreversible first-order reaction system predict asymptotically decreasing concentrations but the measured concentrations decrease more rapidly than the optimized curves predict. This rapid decrease could be caused by an increase of nitrogen oxide formation or indicate that the DPA is involved in other processes.

The three compounds monitored are related to each other as the reaction model implies and the course of one component is dependent on the concentration changes of the others. The concentrations of 2-nitro-DPA and 4-nitro-DPA in the propellant will thus be governed by the change in the *N*-nitroso-DPA concentration through the reactions designated by $k_{23}$ and $k_{24}$. The *N*-nitroso-DPA concentration can, therefore, be simulated by optimizing the parameters in Fig. 1 with respect to the obtained chromatographic data for DPA, 2-nitro-DPA and 4-nitro-DPA. The predicted *N*-nitroso-DPA curve is shown by the dashed curve in Fig. 4.

The guiding principle for the optimizations was to find a reaction system with as few parameters as possible giving a reasonably good curve fit. Parallel routes to 2-nitro-DPA or 4-nitro-DPA with direct nitrosation or nitration at the aromatic rings was considered but did not improve the curve fits. After having tried a number of different mechanisms with parallel reactions, the reaction system originally set up in Fig. 1 was concluded to give the best fits (as shown in Fig. 4) to the experimental data. A general concern in curve-fitting or parameter optimizations based on experimental data is the shape of the response surface. For experimental data in good agreement with a theoretical model the response function (for example the sum of squared residuals) will contain a sharp, well defined, minimum for the parameter set giving the best fit. Complications may, however, arise due to experimental and modelling errors or insufficient data for model validation. Such conditions should give poorly defined parameters of different values depending on the start values used in the optimization of the same data set. The optimization of the parameters $k_{12}$–$k_{45}$ was therefore tested by randomly choosing start values in the interval 0.0001–0.2 day$^{-1}$. In Table 1, the result of 12 such optimizations are presented.

From the min–max ranges of the parameters it can be seen that the optimized parameters $k_{12}$–$k_{45}$ are all relatively well defined by the data sets, with the exception of $[NNODPA]_0$ and $k_{25}$. The latter deviation is, however, not suprising since the parameter $k_{25}$ is related to the *N*-nitroso-DPA component which has not been measured. As already indicated, the optimized parameters in Table 1 can be used to simulate the formation and consumption of *N*-nitroso-DPA during the heat storage test and in Fig. 5, the CT curves for *N*-nitroso-DPA for the 12 different optimizations in Table 1 are shown. The different combinations of parameter values result in different *N*-nitroso-DPA curves which all show realistic shapes according to the assumed reaction mechanism. Whether the curves in Fig. 5 reflect the true course of

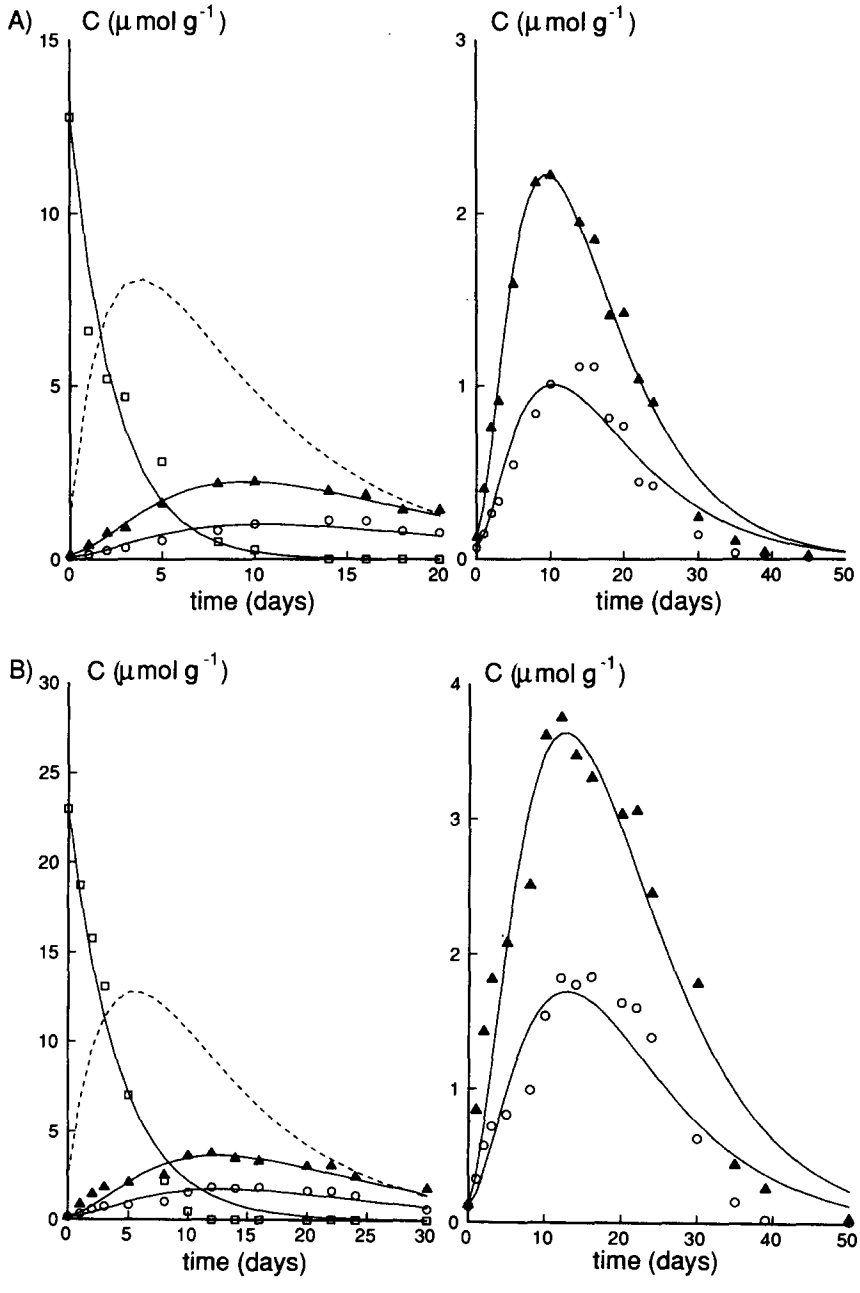

Fig. 4. Resulting curves (solid) for (□) DPA, (▲) 4-nitro-DPA and (○) 2-nitro-DPA from optimizations of the reaction model in Fig. 1 to analytical data of propellants containing (A) 0.5% (30 μmol/g) DPA and (B) 0.7% (41 μmol/g) DPA. To the right the 2-nitro-DPA and 4-nitro-DPA curves are shown with enlarged scales. The data are mean values based on two determinations. The dashed curve is the curve for *N*-nitroso-DPA simulated from the optimized parameters.

The dimensions of rate parameter day$^{-1}$. $[NNODPA]_0$ is the *N*-nitroso-DPA concentration at $t = 0$ given in $\mu$mol/g.

*N*-nitroso-DPA in the propellant, or not, will be investigated in a continuing study.[19] Table 1 and Fig. 5 do not only show that the simplex algorithm converges from different start values, the sizes of the ranges also show that the assumed reaction model is able to explain the experimental concentration data.

A complication discovered in this investigation was that the initial concentration of DPA at $t = 0$ only corresponded to about 50% of the amount used in the preparation. The low concentration could be due to loss by volatilization of DPA during the preparation process or to losses in the extraction step.

The loss of DPA during the propellant production has also been noticed by other authors such as, for example, Schroeder *et al.*[1] In their study which was undertaken at 71°, samples were stored and continuously swept by a stream of air which then passed through two dry-ice cold traps. The analyses of the traps, however, suggested that evaporation is not responsible for the loss of DPA. This is also in agreement with our results obtained at 85°. After four days at 85°, no visible amounts of DPA could be seen on the inside walls of the glass tubes and loss of DPA through evaporation is therefore considered unlikely.

Losses as high as 50% are neither likely to be due to inefficient extraction as methylene chloride is a very good solvent for DPA and its nitro derivatives. Furthermore, the extractions were carried out by Soxhlet extractions which is a well established procedure for extraction of propellant samples.[1,20]

A third possibility for the losses is coupled to the solvent change after the extraction step and the dissolution of the residue in acetonitrile. This step was therefore tested in an experiment in which five 25 ml portions of standard solutions containing DPA, 2-nitro-DPA and 4-nitro-DPA in methylene chloride

B = Amount found in the analysis of the acetonitrile solutions.

were subjected to the same procedure of evaporation and dissolution in acetonitrile as the propellant samples. As seen in Table 2, the results indicate that this step cannot explain the observed loss of DPA. Neither can the losses be explained by a conversion of the DPA into some unknown electroactive compound since there was no unknown peak of the same magnitude as DPA in the chromatograms.

The cause for the significant loss of DPA is presently not fully understood. A remaining possibility is chemical interaction between DPA and NC which could convert DPA into a non-extractable compound or a compound which is not electroactive and therefore not detected. A plausible non-detectable compound is *N*-nitroso-DPA, this compound is namely not reduced within the potential window of the electrochemical detector. By experience from the propellant production, it is known that normally about 5–15% of the DPA is converted into *N*-nitroso-DPA in the preparation process.[20] It is therefore not likely that the observed 50% loss can be fully explained by the formation of *N*-nitroso-DPA.

As other aromatic amines, DPA is known to produce radicals. When heated to about 70° in toluene, the radical diphenylnitrogen ($Ph_2N\cdot$) is formed[7] which readily dimerizes to form tetraphenylhydrazine. Mrzewinski,[21] applied ESR technique to study the transformation of DPA in a NC propellant. According to Mrzewinski, the signal recorded was due to the $Ph_2N\cdot$ radical. In the aging propellant environment the highly reactive $Ph_2N\cdot$ radical could attack the weak nitrate ester bond in the NC.

Several investigations suggest that DPA interacts directly with nitrate esters.[1,2,21–24] The amine nitrogen has two unshared electrons that are easily lost to oxidation agents producting a radical cation, $DPA\cdot^+$ which is quite stable due to the ability for delocalization of the unshared electron to the aromatic rings. The amine functionality together with the delocalized $\pi$-electrons in the aromatic rings make the molecule a very good radical scavenger that could easily react with species having unshared electrons.

Since NC is a widely used material, a number of investigations have been performed concerning its decomposition mechanism. The thermolytic decomposition of NC has been shown to produce radicals in the cellulose polymer. The cleavage of nitrate ester bonds leave alkoxy radicals (RO·) which cause rearrangements and rupture of the cellulose chain.[25–27] The reactivity of DPA towards species with unshared electrons could be regarded as a strong indication that some of the DPA molecules will be incorporated in the NC structure. As already indicated, this could occur either by addition of DPA to the RO· radical sites in the NC structure or by attack of $DPA\cdot^+$ at the nitrate ester bond. The NC-DPA structure formed would probably be equally reactive towards nitrogen oxides as the DPA itself and *N*-nitroso-DPA, 2-nitro-DPA or 4-nitro-DPA could subsequently be released from the NC-DPA structure. A comparable reaction is the reaction between benzoylperoxide and DPA to an O-benzoylhydroxylamine.[28–30] In the latter case, the reaction mixture has been observed to absorb nitrogen oxides from the atmosphere under the formation of *N*-nitroso-DPA.[29,30]

DPA dissolved in acidic media together with an oxidizing agent produces a blue colour and DPA has therefore been widely used as a redox indicator. The blue product is commonly accepted to be a derivative of N, N′-diphenylbenzidine and can also be observed if DPA is oxidized electrochemically. Since nitrous acid is known to be an especially effective oxidizing agent,[8] and also one of the degradation products of NC, it can be expected that the blue oxidation product is formed in the NC-propellant also during storage. An interesting fact in this context is the initial colour change of an aging NC propellant is from yellow to green. The green colour could be produced by a mixture of a

blue DPA oxidation product and the yellow NC polymer. The methylene chloride extracts of green coloured propellant are yellow while the remaining NC-material is green. Most investigations have, however, been focused on the species extracted from the propellant and very little on the remaining NC material after the extraction. Nevertheless, it is known that the amounts of DPA and degradation products never add up to the amount of DPA used in the preparation of the propellant.[20] A study of the material remaining after extraction would therefore be of significant interest.

## CONCLUSIONS

The optimization of rate parameters in a reaction system of pseudo first order can be used as a model for the degradation of DPA in NC based propellants. Surprisingly good agreement between experimental data and theoretical CT curves are obtained, even though NC is a heterogeneous material with different properties depending on the quality of the original cellulose material and the NC preparation procedure. The conditions inside a NC propellant stored at elevated temperatures could provide an environment in which the degradation of DPA follows pseudo first order kinetics. Such an assumption implies that the amount of liberated nitrogen oxides is large compared to the amount of stabilizer added in the propellant. This implication could also be fulfilled because of the large amount of decomposing nitrate ester groups at higher temperatures. The reaction order will, however, change with time as the nitrate ester groups decompose and the formation of nitrogen oxides ceases. In the very early part of the heat storage test, the reaction order would also deviate from first order as the concentration of nitrogen oxides will not exceed that of the DPA. The influence of unknown processes affecting the DPA decomposition hinders the extraction of meaningful rate constant values from the optimizations.

A parallel process which could affect the rate of stabilizer degradation is the oxidation of DPA (*i.e.* oxygen catalyzed radical formation). Such a formation of reactive radicals might further contribute to an increased rate of DPA degradation with time. The influence of oxygen on the formation of reactive radicals is also believed to be the cause for the more rapid consumption of 2-nitro-DPA and 4-nitro-DPA in the later part of the heat storage period.

Although the *N*-nitroso-DPA derivative was not detectable with the amperometric detector used, its CT curve could be simulated from the rate parameter set, given by optimizations based on data for DPA, 2-nitro-DPA and 4-nitro-DPA. In future studies of DPA degradation in NC materials, *N*-nitroso-DPA should also be monitored since most of the DPA is primarily nitrosated at the amine nitrogen and since this compound probably plays an important role for the stability of the NC propellant when the DPA has been consumed. Repeated heat storage tests are needed for a more conclusive interpretation of the ability of the reaction model to predict the course of stabilizer degradation. In part II of this investigation, a study including determination of *N*-nitroso-DPA during a heat storage test at 80°C of the same NC propellants will be presented.

*Acknowledgements*—Acknowledgement is made to Prof. Bengt Nygård for his encouraging support in this work and for reviewing the manuscript. Acknowledgement is also made to the Swedish National Board for Technical Development for the financial support making it possible to complete this work. Finally, the valuable discussions on the mathematics with Professors Svante Jansson and Göran Bergson are gratefully acknowledged.

## APPENDIX

An optimization of a theoretical model to fit experimental data requires an algorithm that can simulate the model according to given parameter values. Here the optimization program will be described in more detail, with emphasis on the mathematical operations used in the simulation algorithm.

For any reaction mechanism assumed to occur under first order conditions, a system of linear differential equations can be set up. This system of first order rate equations can be expressed in a matrix form that enables rapid and convenient calculations of all concentration changes in the reaction system. The principle for the transformation to matrix operations used in the simulation algorithm will be described below for a reversible reaction system containing three components:

$$X_1 \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} X_2 \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} X_3. \qquad \text{(A1)}$$

The time derivatives of compounds $X_1$, $X_2$ and $X_3$ can be written as equations (A2)–(A4).

$$\frac{d[X_1]}{dt} = -k_{12}[X_1] + k_{21}[X_2] \qquad \text{(A2)}$$

$$\frac{d[X_2]}{dt} = k_{12}[X_1] - (k_{23} + k_{21})[X_2] + k_{32}[X_3] \qquad \text{(A3)}$$

$$\frac{d[X_3]}{dt} = k_{23}[X_2] - k_{32}[X_3]. \qquad \text{(A4)}$$

It is possible to solve this equation system and to calculate the CT curves for the given rate parameter values. This can, however, be a very tedious method for more complex reaction mechanisms since the exact solutions rapidly become complicated as the number of reacting components increases.

A different method for calculating the CT relationships was therefore developed for the simulation algorithm used in this investigation. this method is based on difference approximations of the rate equations (A2)–(A4) and the rates of concentration changes for the components are assumed to be constant over a small period of time, $\Delta t$. This assumption is valid if $\Delta t$ is made sufficiently small, but the calculation error rapidly becomes large with increasing $\Delta t$. Calculation of the CT curves with a very small $\Delta t$ leads to a long execution time and is therefore not a practical solution. The difference approximation, however, has the advantage of being readily transformed to matrix formalism which gives condensed formulas for computer programming. The difference approximations of equations (A2)–(A4) can be written as:

$$\frac{\Delta[X_1]}{\Delta t} = -k_{12}[X_1] + k_{21}[X_2], \qquad \text{(A5)}$$

$$\frac{\Delta[X_2]}{\Delta t} = k_{12}[X_1] - (k_{23} + k_{21})[X_2] + k_{32}[X_3], \qquad \text{(A6)}$$

$$\frac{\Delta[X_3]}{\Delta t} = k_{23}[X_2] - k_{32}[X_3], \qquad \text{(A7)}$$

where $\Delta[X_i] = [X_i]^{(2)} - [X_i]^{(1)}$ and $\Delta t = t_2 - t_1$. $[X_i]^{(1)}$ is the concentration of component $i$ at $t_1$ and $[X_i]^{(2)}$ the concentration of component $i$ at $t_2$. The concentrations $X_1^{(2)}$, $X_2^{(2)}$ and $X_3^{(2)}$ after the time $\Delta t$ are then given by

$$[X_1]^{(2)} = (1 - k_{12}\Delta t)[X_1]^{(1)} + k_{21}\Delta t[X_2]^{(1)}, \qquad \text{(A8)}$$

$$[X_2]^{(2)} = k_{12}\Delta t[X_1]^{(1)} + (1 - (k_{23} + k_{21})\Delta t)[X_2]^{(1)} + k_{32}\Delta t[X_3]^{(1)}, \qquad \text{(A9)}$$

$$[X_3]^{(2)} = k_{23}\Delta t[X_2]^{(1)} + (1 - k_{32}\Delta t)[X_3]^{(1)}. \qquad \text{(A10)}$$

By repeated application of equations (A8)–(A10), the concentrations can be calculated for discrete points of time along the time axis separated by the time interval $\Delta t$. The calculations are most easily performed using matrices and the first step in the matrix reformation is to place the concentrations at $t_1$ and $t_2$ of each component as elements in two column vectors $\mathbf{X}^{(1)}$ and $\mathbf{X}^{(2)}$.

$$\mathbf{X}^{(1)} = \begin{pmatrix} [X_1]^{(1)} \\ [X_2]^{(1)} \\ [X_3]^{(1)} \end{pmatrix}, \qquad \mathbf{X}^{(2)} = \begin{pmatrix} [X_1]^{(2)} \\ [X_2]^{(2)} \\ [X_3]^{(2)} \end{pmatrix}.$$

In order to calculate $\mathbf{X}^{(2)}$ from $\mathbf{X}^{(1)}$ we need to introduce a transition matrix, $\mathbf{T}$, which specifies the flow of mass through the system. The matrix $\mathbf{T}$ should contain the $(1 - \Sigma k_{ij}\Delta t)$ and $k_{ij}\Delta t$ factors in equations (A8)–(A10) and will for our reaction system (A1) have the following shape:

$$\mathbf{T} = \begin{pmatrix} (1 - k_{12}\Delta t) & k_{21}\Delta t & 0 \\ k_{12}\Delta t & (1 - (k_{23} + k_{21})\Delta t) & k_{32}\Delta t \\ 0 & k_{23}\Delta t & (1 - k_{23}\Delta t) \end{pmatrix}.$$

The equation system (A8)–(A10) can finally be written in its matrix form:

$$\mathbf{X}^{(2)} = \mathbf{T} \cdot \mathbf{X}^{(1)}. \qquad \text{(A11)}$$

At this stage, the advantage of using matrix formalism becomes obvious. The matrix $\mathbf{T}$ will give an informative view of how the concentrations (or masses) change during the time step $\Delta t$. The rows of $\mathbf{T}$ tells us how the components are formed from the other components of the system while

the columns describe how the mass from one component is distributed to the other components. The first row of **T**, thus, tells us that $X_1$ is formed from the fraction $k_{21}\Delta t$ of $X_2$. On the other hand, the first column of **T** shows that the fraction $(1 - k_{12}\Delta t)$ of $X_1$ remains as $X_1$ and the fraction $k_{12}\Delta t$ is converted to $X_2$.

In the simulation algorithm a sequence of concentration vectors are calculated by repeated operations of the transition matrix **T** according to equation (A11). The operations are initiated with the concentrations determined at $t = 0$ in an initial concentration vector $\mathbf{X}^{(0)}$.

A problem with the difference approximation method is that the time interval $\Delta t$ must be small to keep the calculation error small. The accuracy of the calculated concentrations, however, can be maintained by a refinement procedure in the calculation of **T**.

For this refinement, the time step $\Delta t$ is divided in a large number of substeps, $n$. Let **T′** be the transition matrix calculated for a substep of length $\Delta t' = \Delta t/n$. For computational convenience, the subdivision is performed as a number of bisections, *i.e.* $n = 2^m$. The matrix **T** for the total interval $\Delta t$ is then given by $(\mathbf{T}')^n$ which is readily computed by squaring **T′** $m$ times. The adjusted transition matrix is then used in the relation between the concentration vectors before and after a time step $\Delta t$ (equation (A11)).

For the general case, the adjusted transition matrix **T** is calculated from all possible rate constants $k_{ij}$ in the following way.

(i) Let **R** be a table of the individual rate constants

$$\mathbf{R} - \{k_{ij}\},$$

*i.e.* a square matrix with zero elements for all non-significant reaction pathways.

(ii) Multiply the transpose $\mathbf{R}^{\mathrm{T}}$ with $\Delta t' = \Delta t/m$, where $m = 2^n$. This results in a matrix that defines the transition between components

$$\mathbf{T}' = \mathbf{R}^{\mathrm{T}} \cdot \Delta t'.$$

(iii) So far, the diagonal elements of **T′** are zero. Now they are calculated by subtracting the sum of the corresponding column from unity. According to the law of conservation of mass, the sum of each column must add up to unity for a closed system.

$$\mathbf{T}'_{ij} = 1 - \sum_{i \neq j} \mathbf{T}_{ij}.$$

(iv) Finally, the adjusted **T** is calculated by squaring **T′** $n$ times.

$$\mathbf{T} = (\mathbf{T}')^{2^n} = (\mathbf{T}')^m.$$

Matrix formalism for the solution of complex first-order reaction systems has been described in the literature.[31,32] The system of rate equations

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathbf{X} = \mathbf{K} \cdot \mathbf{X},$$

has the formal solution

$$\mathbf{X}(t) = \mathrm{e}^{\mathbf{K}t} \cdot \mathbf{X}(0).$$

The matrix **K** is the same as the matrix **T′** from step (ii) above, except for the inclusion of ones in the diagonal elements and the multiplication with $\Delta t'$. The meaning of the exponential function of a matrix can be understood from the series expansion, similar to that for a scalar argument:

$$\mathrm{e}^{\mathbf{A}} = \left(\mathbf{1} + \mathbf{A} + \frac{1}{2}\mathbf{A}^2 + \frac{1}{2 \cdot 3}\mathbf{A}^3 + \ldots\right).$$

To arrive at ordinary time functions for the components of **X**, the exponential function of $\mathbf{K} \cdot t$ can be evaluated by eigenvalue diagonalization of **K**.

$$\mathbf{K} = \mathbf{B} \cdot \mathbf{M} \cdot \mathbf{B}^{-1}$$

where **M** is a diagonal matrix with the eigenvalues $m_1, m_2, \ldots$ as diagonal elements and **B** is composed of the eigenvectors.

Now the powers of **K** can be written

$$\mathbf{K}^n = \mathbf{B} \cdot \mathbf{M}^n \cdot \mathbf{B}^{-1}$$

and the power expansion identified as

$$\mathrm{e}^{\mathbf{K}t} = B \cdot \begin{pmatrix} \mathrm{e}^{m_1 t} & 0 & \cdot & \cdot \\ 0 & \mathrm{e}^{m_2 t} & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \end{pmatrix} \cdot \mathbf{B}^{-1}.$$

This leads to solutions for the components $\mathbf{X}_i$ that are linear combinations of exponential functions with apparent rate constants $m_i$.

Numerical values corresponding to a set of rate constants can thus be obtained by solving the corresponding eigenvalue problem and then evaluating the exponentials for each point of time. However, for regular time intervals $\Delta t$, it is sufficient to calculate the single matrix $\mathrm{e}^{\mathbf{K}\Delta t}$ since

$$\mathbf{X}(t + \Delta t) = \mathrm{e}^{\mathbf{K} \cdot \Delta t} \cdot \mathbf{X}(t).$$

Actually, the transition matrix **T** from step (iv) is a numerical approximation of $\mathrm{e}^{\mathbf{K}\Delta t}$. The validity of our approach is demonstrated by an alternate definition of the exponential function:

$$\mathrm{e}^x = \lim_{m \to \infty}\left(1 + \frac{x}{m}\right)^m,$$

with the matrix version

$$\mathrm{e}^{\mathbf{K} \cdot \Delta t} = \lim_{m \to \infty}\left(1 + \mathbf{K} \cdot \frac{\Delta t}{m}\right)^m.$$

The calculation of **T** is nothing but an evaluation of the latter expression for $m = 2^n$. Another possibility would have been to use a number of terms in the series expansion, but the approach taken is more easily implemented and probably more efficient.

# DECOMPOSITION OF DIPHENYLAMINE IN NITROCELLULOSE BASED PROPELLANTS—II. APPLICATION OF A NUMERICAL MODEL TO CONCENTRATION–TIME DATA DETERMINED BY LIQUID CHROMATOGRAPHY AND DUAL-WAVELENGTH DETECTION

ARNE BERGENS*

Uppsala University, Institute of Chemistry, Department of Analytical Chemistry, P.O. Box 531, S-751 21 Uppsala, Sweden

(*Received* 5 *November* 1991. *Revised* 2 *April* 1993. *Accepted* 7 *April* 1993)

**Summary**—A continued investigation of the primary steps in diphenylamine (DPA) decomposition in nitrocellulose (NC) propellants is presented. The study is based on analytical data obtained by reversed-phase liquid chromatographic separation of the initial degradation products of DPA. Spectrophotometric detection, rather than the amperometric detection used in part I of this work (A. Bergens and R. Danielsson, *Talanta*, 1995, **42**, 171), was employed in order to detect *N*-nitroso-DPA as well as DPA, 2-nitro-DPA and 4-nitro-DPA. The results have been studied with the rate parameter optimization program described in part I and simulations suggest that the decomposition of DPA includes unknown reaction steps. More satisfying curve fits were, for example, obtained when the initial reaction for conversion of DPA into *N*-nitroso-DPA was considered to consist of a two step process with an intermediate. This intermediate could act as a stabilizer as well as DPA and *N*-nitroso-DPA, particularly at lower temperatures.

The decomposition of the stabilizer DPA and the degradation products *N*-nitroso-DPA, 2-nitro-DPA and 4-nitro-DPA can be monitored by reversed-phase liquid chromatography (RPLC) and UV/VIS detection during heat storage tests of NC based propellants. Such tests at elevated temperatures, represent a common strategy for the assessment of propellant stability and the time elapsed until red fumes appear is frequently used as a measure of stability. The time-to-fume value can, however, be regarded as a questionable measure of stability since the stabilizer is then totally exhausted and the dangerous rapid decomposition of NC has already proceeded for some time when visible amounts of nitrogen oxides appear. It has also been shown that the rate of gas evolution from a NC propellant is increased as the nitroso and mono nitro derivatives of DPA are depleted.[1] A more relevant measure of propellant stability would, therefore, be the time at which these primary derivatives of DPA have been consumed, or the time when significant amounts of di-nitro derivatives appear, as suggested by Stine.[2]

In part I of this investigation, a method for optimizing concentration–time (CT) curves to analytical data of DPA, 2-nitro-DPA and 4-nitro-DPA was presented. Data were collected during a heat storage test at 85°C employing a previously described method[3] based on RPLC and dual-amperometric detection. By use of a computer program based on simplex optimization of rate parameters in a reaction system, theoretical curves for DPA, 2-nitro-DPA and 4-nitro-DPA could be fitted to the experimental data. The reaction model used was the commonly accepted mechanism for the initial step in DPA degradation in NC based propellants, seen in Fig. 1.[4,5] The theoretical curve for *N*-nitroso-DPA was also simulated on the basis of the rate parameters which describe the assumed reaction system. The *N*-nitroso-DPA acts as an effective stabilizer in the initial part of the degradation process[6] and the results presented in part I also made it desirable to complete the investigation by including *N*-nitroso-DPA as an analyte. Since *N*-nitroso-DPA is not detectable amperometrically it was favourable to replace the electrochemical detection with UV-visible detection.

*Present address: Pharmacia AB, Pharmaceutical Uppsala, S-751 82 Uppsala, Sweden.

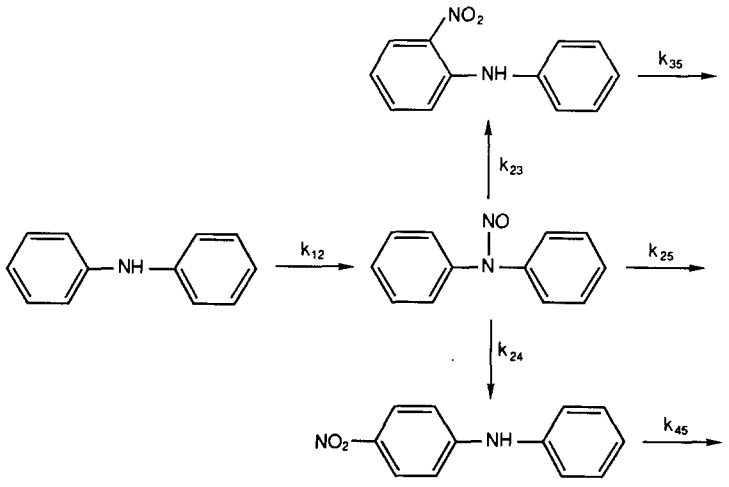

Fig. 1. Reaction scheme for DPA degradation in aging NC propellants. This scheme served as the model system in part I of this investigation.

The present paper is concerned with the results of such a study employing the same mathematical treatment of the experimental data as in part I. The propellant had, however, been subjected to a heat storage test at 80°C rather than at 85°C as in part I.

The reaction mechanisms used in the models of the DPA system have been described with irreversible reaction steps. This was done because the reactions involved in the decomposition of DPA are continuously driven by the excessive formation of nitrogen oxides, and in this sense, the reactions can be described as being irreversible.

## EXPERIMENTAL

### *Apparatus*

The LC-system consisted of a Shimadzu LC-6A pump (Shimadzu Corp., Kyoto, Japan) a Carnegie Medicin CMA200 (Carnegie Medicin AB, Stockholm, Sweden) automatic injector, a home-made column oven and two spectrophotometric detectors placed in series. The first detector was a Kratos Spectroflow, Model 757 (Kratos Analytical Instruments, Ramsey, NJ, USA) while the second was a Shimadzu SPD-6A and the detectors were connected with a 20 cm long piece of PTFE tubing (0.1 mm I.D.) The column used was a 100 × 3.2 mm RP-8 Velosep column (Brownlee labs Inc., Santa Clara, CA, USA).

All chromatograms were recorded and processed with a Spectra Physics, Model SP4290 integrator (Spectra Physics, San Jose, CA, USA) equipped with a dual channel module. The simulation and simplex algorithms were implemented on an IBM PS/2 Model 50 computer using ASYST scientific calculation system (MacMillan Software Company, NY, USA) as described in part I. Spectral characterization of the target compounds was carried out with a Perkin-Elmer Lambda 17 UV/VIS spectrophotometer (Perkin-Elmer Corp., Analytical Instruments, Norwalk, CT, USA) using 1 cm cells and the mobile phase as reference.

### *Chemicals*

The acetonitrile and 2-propanol used as organic modifiers in the mobile phase were obtained from Merck (Lichrosolv grade, Darmstadt, Germany) and used without further purification. The *m*-chloroacetic acid was obtained from BDH Chemicals Ltd., Poole, U.K. and was also used as received. The *m*-chloroacetic acid buffer was prepared from a 0.05*M* solution by adjusting the pH to 2.7 with NaOH.

The reference substances DPA (Merck, pro analysi grade), 4-nitro-DPA (Aldrich Chemie GmbH & Co. KG, Steinheim, Germany, spec. purity 99%) and 2-nitro-DPA (Aldrich Chemie, spec. Purity 98%) were all used as received. *N*-nitroso-DPA was obtained from AB Nobelkrut, Karlskoga, Sweden and found to contain 0.13% DPA.

### *Procedures*

The mobile phase consisted of 71.0% 0.05*M* *m*-chloroacetic acid buffer (pH = 2.7) 19.4% 2-propanol and 9.6% acetonitrile and was filtered and degassed according to the same procedure as in part I. All separations were performed isochratically at a flow rate of

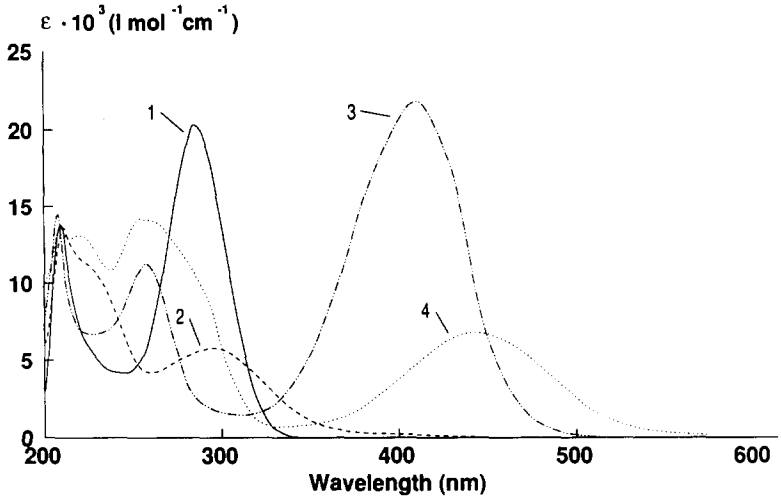

Fig. 2. Spectra of (1) DPA, (2) *N*-nitroso-DPA, (3) 4-nitro-DPA and (4) 2-nitro-DPA. The absorbances have been converted to molar absorptivities for comparison.

0.7 ml/min and at a temperature of 40°C. All compositions are given as volume percentages.

The quantifications were done using calibration curves and injections of external standards were made at regular intervals. The samples were refrigerated at 6°C inside the automatic injector and an injection volume of 15 $\mu$l was used exclusively. The sample solutions were diluted with mobile phase using a dilution factor of 5–10.

*Treatment of propellant samples*

Propellant samples were taken from the two propellant batches investigated in part I having the following specified compositions, 0.5% DPA/99.5% NC and 0.7% DPA/99.3% NC. The compositions correspond to 30 $\mu$mol/g (0.5% DPA) and 41 $\mu$mol/g (0.7% DPA), respectively. The samples were subjected to the Dutch stability test,[7] as described in part I, but the storage temperature was now decreased to 80 C. The DPA and nitro derivatives were extracted during 4 hr in a Soxhlet extraction unit, as also described in part I.

## RESULTS AND DISCUSSION

The results presented in part I of this investigation indicated that *N*-nitroso-DPA may play an important role in the stabilizing function of the DPA system. Spectra for DPA, *N*-nitroso-DPA, 2-nitro-DPA and 4-nitro-DPA obtained with the mobile phase as solvent are shown in Fig. 2. These spectra are in good agreement with published spectra[4] obtained with ethyl alcohol as medium and the choice of mobile phase does, thus, not seem to affect the general spectra characteristics. The spectral differences in Fig. 2 also illustrates the advantage of dual wavelength monitoring. Aromatic nitro compounds absorb in the visible region and 430 nm was therefore chosen as detection wavelength for 2-nitro-DPA and 4-nitro-DPA. *N*-nitroso-DPA on the other hand, shows a maximum at 292 nm which almost coincides with the maximum for DPA and this wavelength was therefore chosen for the detection of these two compounds. Single wavelength detection at, for instance 257 nm, would also have been possible but a better resolution in the chromatographic separation would have been required.

During a heat storage test, the concentrations of stabilizer and degradation products can be expected to change over a wide range. In the early part of the aging process the concentration of nitro derivatives is low compared to that of DPA. Later in the storage period, the DPA concentration is reduced in favour of the nitro derivatives. The situation is illustrated in Figs 3 and 4 in which chromatograms of two samples of the 0.7% DPA propellant are shown prior to and after the heat storage at 80°C. Only small amounts of nitro derivatives and *N*-nitroso-DPA could hence be found for the untreated sample. After 15 days of storage at 80°C (Fig. 4), the concentrations of the nitro derivatives had, however, increased by a factor of about 5 while the DPA concentration had been reduced to about 10% of the value in Fig. 3. As is seen in Fig. 4(b), the dominating derivative at this stage is *N*-nitroso-DPA which is represented by a large peak at 7.5 min in Fig. 4(b).

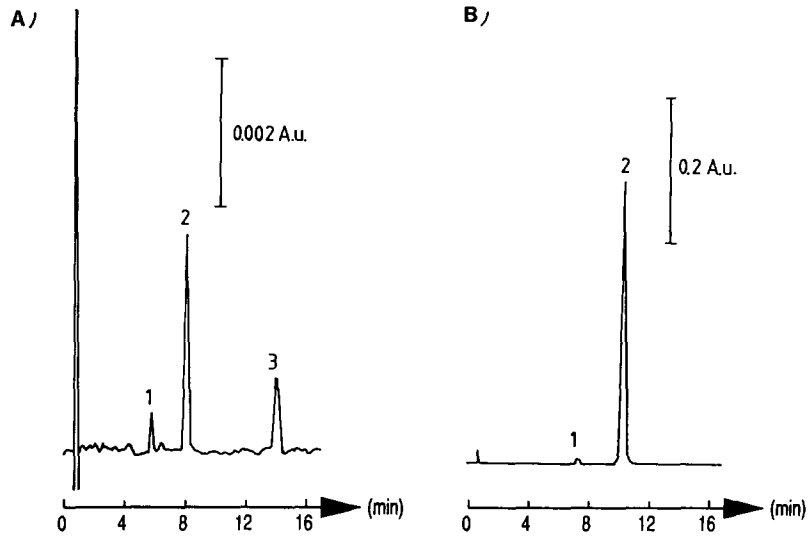

Fig. 3. Chromatograms obtained for an unstored sample with detection at (A) 430 nm and (B) 292 nm. The peaks in (A) correspond to: (1) unknown, (2) 4-nitro-DPA (51 pmol injected which corresponds to 0.14 $\mu$mol/g in the propellant sample), (3) 2-nitro-DPA (59 pmol, 0.15 $\mu$mol/g), in (B): (1) *N*-nitroso-DPA (463 pmol, 1.2 $\mu$mol/g), (2) DPA (9.3 nmol, 24.5 $\mu$mol/g).

The simplex optimization program, described in part I, was then applied to the data obtained from the heat storage test. At first, the proposed scheme for the degradation mechanism used in part I (see Fig. 1) was implemented in the program. The results are shown in Fig. 5(a) and (b) and from the poor agreement between the curves and the experimental data it can be

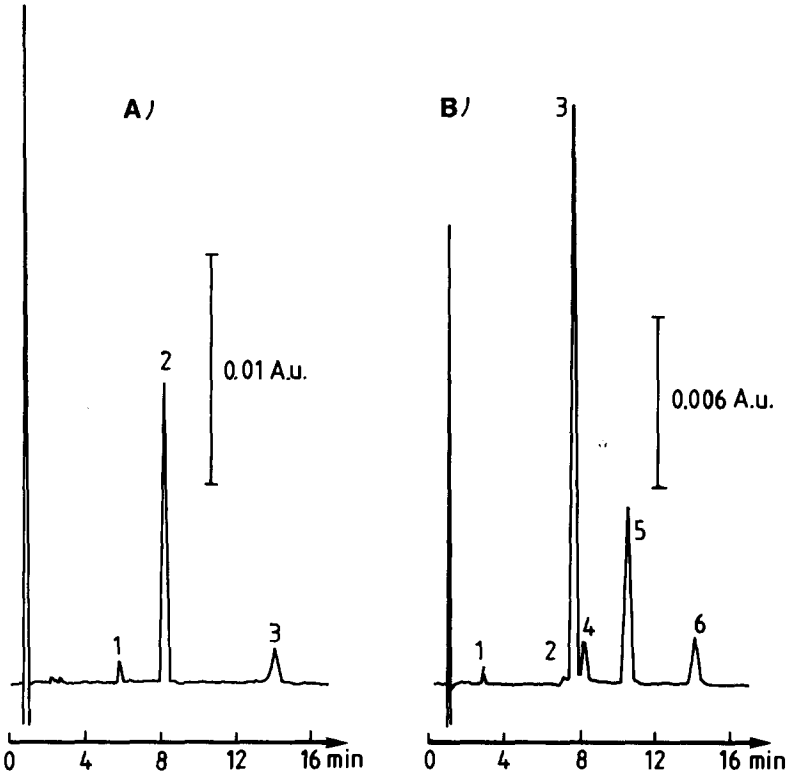

Fig. 4. Chromatograms obtained with detection at (A) 430 nm and (B) 292 nm after 15 days of storage at 80°C. The peaks in (A) correspond to: (1) unknown, (2) 4-nitro-DPA (225 pmol injected which corresponds to 3.0 $\mu$mol/g in the propellant sample), (3) 2-nitro-DPA (88 pmol, 1.2 $\mu$mol/g). In (B): (1) and (2) unknown, (3) *N*-nitroso-DPA (952 pmol, 13.2 $\mu$mol/g), (4) 4-nitro-DPA, (5) DPA (130 pmol, 1.7 $\mu$mol/g), (6) 2-nitro-DPA.

concluded that the assumed reaction mechanism is not applicable for storages at 80°C. The curves in Fig. 5 represent the best possible optimizations obtained after many attempts with different starting values for the initial simplex.

Attempts to optimize CT curves with different values of $k_{12}$ were made but with poor results since it was difficult to find a value for $k_{12}$ compatible with both the rapid decrease in the DPA concentration and the slow increase in the *N*-nitroso-DPA concentration. According to the assumed degradation mechanism, the curve for *N*-nitroso-DPA should also reach a maximum earlier than the 2-nitro-DPA and 4-nitro-DPA curves. Curve fitting experiments with additional parallel routes (*i.e.* direct reactions from DPA to nitro DPAs) did not improve the correlation between the model and the data as all three curves for *N*-nitroso-DPA, 2-nitro-DPA and 4-nitro-DPA passed through their maxima earlier than the experimental data. The fact that the sum of the DPA, *N*-nitroso-DPA, 2-nitro-DPA and 4-nitro-DPA concentrations is decreasing with time indicates that some DPA is lost through an unknown reaction. This reaction could involve thermal radical formation which is common for aromatic amines. The diphenylnitrogen radical is, for example, formed from DPA under influence of heat and oxygen[8,9] and is relatively stable due to the possible electron delocalization. The diphenylnitrogen radical and the radical cation of DPA are also known intermediates in other oxidation reactions of DPA.[8,10–13]

A mechanism that can explain the rapid decrease in the DPA concentration have not yet been elucidated completely. As already stated, the variety of results from different investigations might, however, be explained by competing processes in the aging propellant material. An example of such a side reaction, is oxygen catalyzed oxidation[14,15] by thermally induced radical formation.[8–10,14–17] Opschoor *et al.*[16] have, for instance, shown that the presence of oxygen increases the rate of DPA degradation in NC based propellants significantly and it can therefore be assumed that side reactions of this type will become more pronounced with increasing temperature is increased.

Since this investigation was focused on testing the empirical model presented in part I, we can only speculate on the consumption of DPA in side reactions. As will be shown below, it is, however, possible to modify the degradation scheme in Fig. 1 so that better agreement between the CT data and theoretical curves is achieved at 80°C. The modifications include an intermediate step between DPA and *N*-nitroso-DPA and one additional route for DPA decomposition.

Both chemical[13,18] and electrochemical oxidations[18–24] of DPA are well-known. In acid media, *N*,*N*′-diphenylbenzidine appears to be the major product in electrochemical oxidations of DPA while in neutral to basic media a mixture of tetraphenylhydrazine and *N*,*N*′-diphenylbenzidine is obtained.[21–23] Polymer products resulting from para–para coupling of radicals have also been isolated and characterized after both chemical and electrochemical oxidations.[18–20] The spontaneous thermally induced radical formation of DPA, that could take place in a propellant subjected to high temperatures, must be expected to give a variety of products, not only a straight para–para coupled poly(4-phenylaniline) chain. If the assumed DPA-intermediate is of a polymeric nature the question arises whether this DPA-polymer would degrade into *N*-nitroso-DPA when exposed to nitrogen oxides. Polymerization of DPA would lead to the formation of large aromatic ring systems which probably could trap nitrogen oxides and thereby act as a stabilizer and also result in a decreased rate of *N*-nitroso-DPA formation in accordance with the experimental results. Observations that further support this theory are: the decreasing sum of concentrations in the initial part of aging, and the absence of a peak in the chromatograms which could explain the loss of DPA. For solubility reasons, the polymer could remain in the NC-material even after the extraction with methylene chloride. A large bulky polymer could also be trapped by the NC fibres and therefore not dissolved in the extraction step.

Another suggestion on the stabilizing mechanism of the DPA system made by Urbanski *et al.*[24,25] based on thermal analysis, ESR and IR spectroscopic studies of nitrate esters mixed with aromatic amines and involves the formation of complexes between the aromatic amines and nitrate esters. The complexes could be insoluble in a medium of low dielectric constant such as methylene chloride and probably act as a stabilizer giving nitroso and nitro derivatives of DPA as products.

The reaction model for the optimization program was modified according to the properties of DPA discussed above. The modified reaction

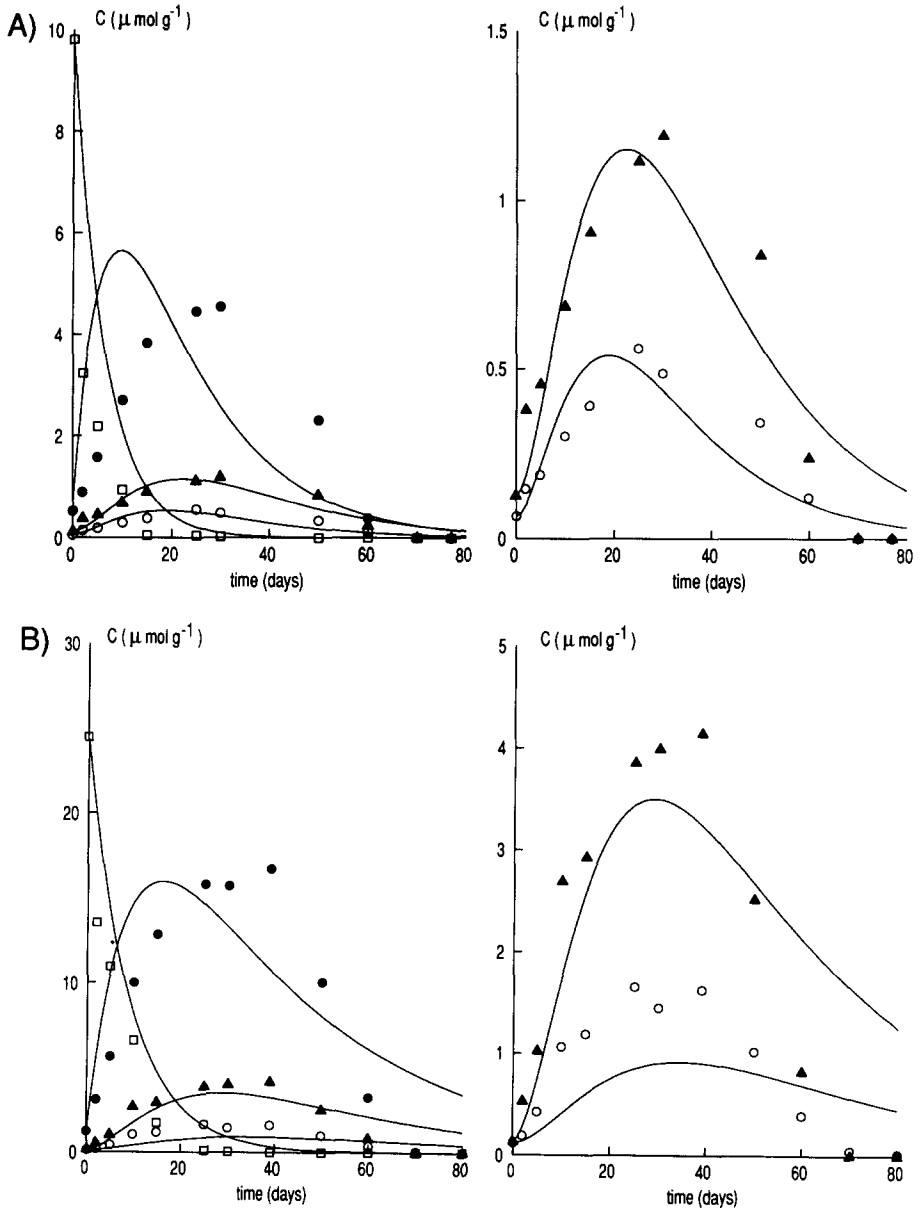

Fig. 5. Resulting CT curves from optimizations of the reaction model in Fig. 1 to data for (□) DPA, (●) *N*-nitroso-DPA, (▲) 4-nitro-DPA and (○) 2-nitro-DPA in (A) 0.5% DPA and (B) 0.7% DPA propellants. The right hand figures show expanded plots for 2-nitro-DPA and 4-nitro-DPA.

scheme is described in Fig. 6 and contains two additional rate parameters when compared with the initial model shown in Fig. 1. If the DPA-intermediate is a resonance stabilized radical it could also give rise to other compounds, not measurable with the analytical procedure used herein. The parameter $k_{27}$ was, therefore, introduced to describe this reaction path. The dashed paths in Fig. 6 were not included in the model since they did not improve the fit. The introduction of an intermediate step in the formation of *N*-nitroso-DPA did, on the other hand, give rise to an improved agreement between the experimental data and the theoretical curves.

In Fig. 7, optimizations of the new model to the data obtained in the heat storage test at 80°C are shown. The poor fits on the consumption side of the curves for *N*-nitroso-DPA, 2-nitro-DPA and 4-nitro-DPA still remain although the overall curve fits for all four analyzed components have been improved. The dashed curves in Fig. 7 represent CT curves for the DPA-intermediate simulated from the optimized parameters. In the optimizations illustrated in Fig. 7, the concentration of DPA-

intermediate at zero time was approximated with the difference between the original DPA content (30 μmol/g for the 0.5% DPA and 41 μmol/g for the 0.7% DPA propellant) and the sum of the DPA, *N*-nitroso-DPA, 4-nitro-DPA and 2-nitro-DPA concentrations at zero time.

The optimization procedure with the new reaction model (Fig. 6) was, therefore, tested with different randomly chosen start values, as in part I. The result is presented in Table 1 and the initial simplex was again defined by start values for $k_{12}$ to $k_{56}$ in the range 0.0001–0.2.

From the width of the ranges given in Table 1 it can be seen that some of the parameters are poorly defined, this applies especially to those parameters which are related to a component lacking in the data sets. The parameter $k_{27}$, thus, exhibits the largest variation since it is only related to the concentration of the DPA-intermediate (*i.e.* component no. 2). The larger variation in $k_{27}$, however, also affects the variation in the other parameters as a result of interaction effects. The parameter $k_{12}$, describing the rate of DPA consumption, is lower for the 0.7% DPA series than for the 0.5% DPA propellant which could indicate that the reaction is not of first order. This could, however, also indicate that the degradation mechanism changes with the DPA concentration but this seems unlikely as the same raw NC material was used in the preparation of both batches. As already stated, the values obtained for the parameters should not be taken as true rate constants since the modified model includes assumed reaction steps.

In spite of the great variations in some of the parameter values, the curve fits were all comparable with those in Fig. 7. Simulations of the CT curves for the DPA-intermediate obtained on the basis of the 12 different parameter sets also showed good agreement with the different optimizations shown in Fig. 8. For the 0.7% DPA propellant, all of the 12 curves coincide even though significant variations in the parameter values between different optimizations were obtained (Fig. 8b). The curves in Fig. 8 indicate that the concentration of the DPA-intermediate increases and goes through a maximum during the first 10 days of the heat storage test. Furthermore, the coinciding curves show that the simplex converges toward solutions that give the same predictions for the DPA-intermediate.

*Optimization to literature data*

There are many reports in the literature where the concentration changes of the stabilizer additive with time have been followed. Only a few of these contain additional data for the subsequently formed nitro derivatives. Curtis and Rogasch[26] published a straight phase LC method for the determination of nitro derivatives formed from DPA during propellant aging. The method was later applied by Curtis[27] in a following study of the DPA degradation in two NC propellants subjected to heat storage at 80°C. The latter report is particularly interesting since it contains data from heat

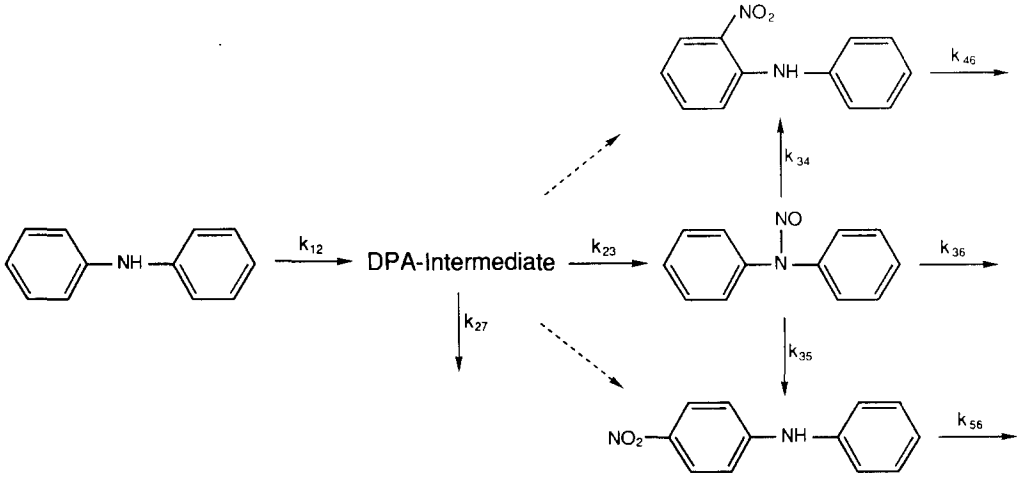

Fig. 6. The modified reaction model used for the optimization to heat storage test data from 80 C. The dashed arrows symbolize the possible reaction paths discussed in the text, but not accounted for in the optimizations for Fig. 7.

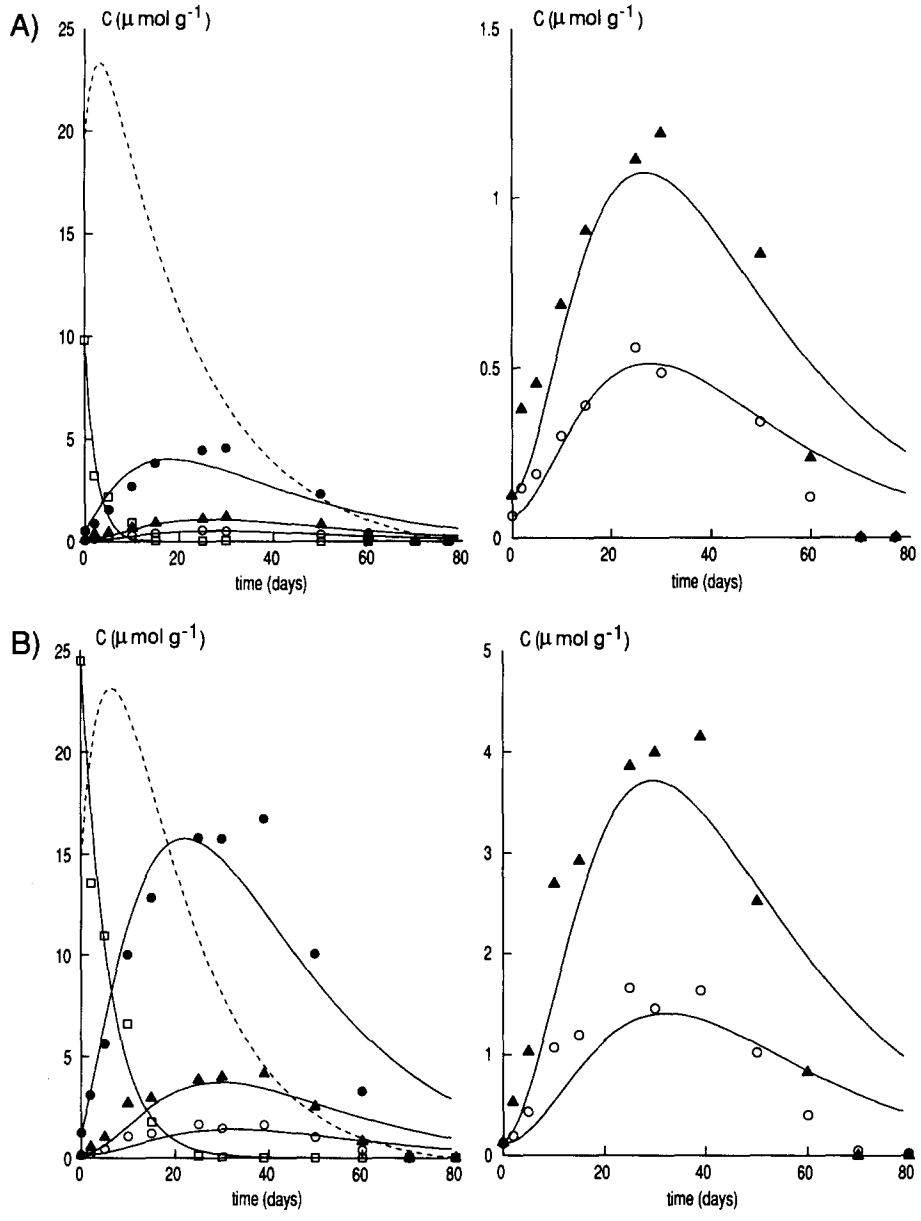

Fig. 7. Resulting curves for the same data sets as in Fig. 5 but for optimizations and curve fittings based on the reaction model described in Fig. 6: (A) 0.5% DPA and (B) 0.7% DPA. The dashed curves are the resulting curves for the DPA-intermediate simulated from the optimizations. The right hand figures show expanded plots for 2-nitro-DPA and 4-nitro-DPA.

storage tests on propellants stored under comparable conditions to this investigation (80°C). It was therefore considered interesting to apply the optimization program on the data reported by Curtis.

In Fig. 9, the optimization of our first assumed model (Fig. 1) to Curtis' set of data is presented. It is noticeable that the decline of DPA concentration does not match the build-up of *N*-nitroso-DPA and the resulting curve shows a poor agreement with the experimental data.

At this stage, it was also interesting to test whether the modification of the reaction scheme from Fig. 6 improves or impairs the curve fit. The inclusion of the intermediate step was found to improve the curve fit for *N*-nitroso-DPA as indicated in Fig. 10.

The improved agreement between the modified reaction model and our CT data can therefore be verified by Curtis' data which have been independently analyzed with no connection at all to our investigation. It is therefore believed that this verification supports the

indication on the existence of an intermediate step in the degradation mechanism.

The existence of the intermediate has therefore to be verified with other experimental techniques since there is no indication on the existence of an intermediate compound with electrochemical or UV/VIS detection. Future investigations should, therefore, be focused on the remaining NC material after the extraction step. As indicated in part I, this material shows interesting colour changes during the heat test which suggests that an investigation with molecular spectroscopic methods might be able to answer the question whether DPA in any form is incorporated or retained in the NC material. In additional to the two previously mentioned DPA-intermediates suggested in the literature, a reaction between the DPA radicals and the radical formed in the NC polymer is also possible. A hypothetical reaction scheme for such a reaction is presented (Scheme I–III).

The steps I–II represent the formations of the known DPA radical cation[8,10,15] and the alkoxyl radical in the NC chain.[28,29] The incorporation of DPA in the NC chain could occur as described by step III in which the DPA can be bound to the NC in two different ways. It is reasonable to assume that the dominating route would be III(b) as the DPA radical cation is stabilized by delocalization of the unshared electron to the aromatic ring. The hypothetical reactions above would not affect the stabilizing action of DPA since the products (NC-DPA) in step III should be as reactive towards nitrogen oxides as DPA itself. In a reaction with nitrogen oxides, the NC-DPA could decompose to give the various nitro and nitroso derivatives of DPA.

The concentrations were monitored during a heat storage test at 80°C. The optimization is based on data from a similar figure presented by Curtis. The data have been transformed to the unit μmol/g from weight-%.

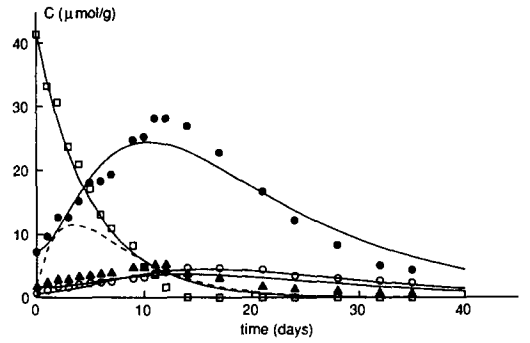

Fig. 10. Optimization of the modified reaction model in Fig. 6 to data from Curtis.[27] Marker identities: (□) DPA, (●) *N*-nitroso-DPA, (▲) 4-nitro-DPA and (○) 2-nitro-DPA. The dashed curve for the DPA-intermediate is calculated from the optimized parameters. The optimization is based on the same data as Fig. 9.

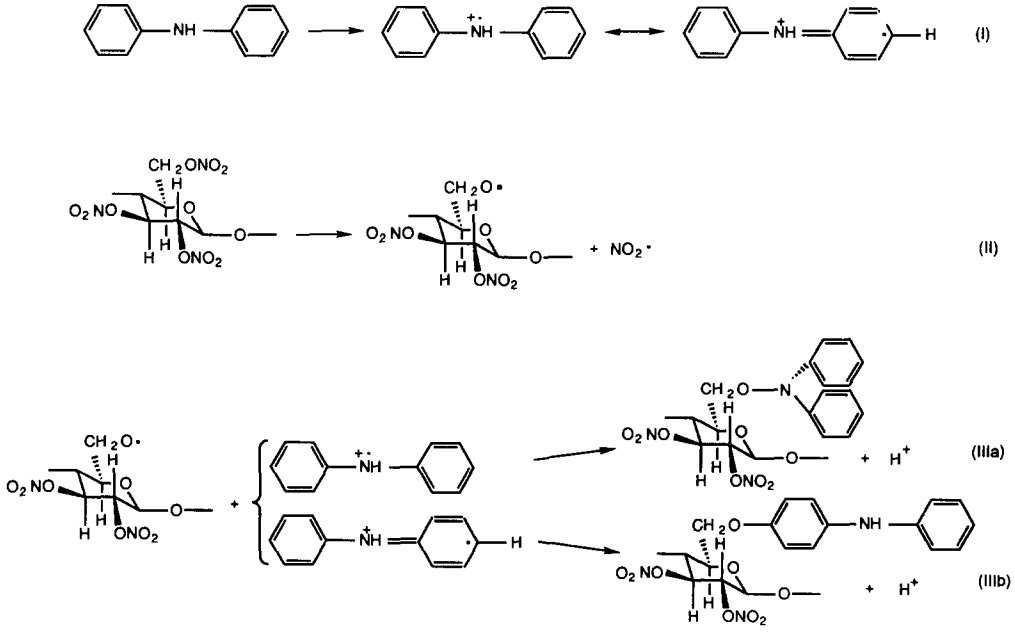
## CONCLUSIONS

The DPA content of a propellant batch usually decreases relatively fast and the stabilizing action after that the DPA has been consumed must, therefore, be attributed to the *N*-nitroso-DPA, 2-nitro-DPA, 4-nitro-DPA and to the possible DPA-intermediate(s). The interesting time to estimate would therefore be the time for consumption of all of these four compounds. However, the curves obtained by the presented optimization procedure fail to predict this time. The reason for this probably lies in the variations in moisture, oxygen and nitrogen oxide concentrations during the course of the heat storage test. In addition, parallel processes involving spontaneous thermal radical formation[17,28] of DPA and nitro derivatives exist. The assumption of first order reactions is therefore not valid over the entire time period for the heat storage test and deviations from the model must therefore be expected. The overall reaction order would be difficult to predict and values in the range 0–1 have been found for the DPA decomposition.[30]

On the basis of the present results it is evident that the mechanism for the initial DPA degradation involves unknown reaction steps which are more significant at lower temperatures. The



Schemes I–III

experimental data in part II indicate the existence of an intermediate step in the nitrozation of DPA. The high stability of a propellant containing less than 0.1% DPA could be explained by the presence of significant amounts of *N*-nitroso-DPA, 2-nitro-DPA and 4-nitro-DPA. The presence of a DPA-intermediate would further increase the stability of a NC propellant with low DPA content. Since most heat storage tests are performed using high temperatures, the aging of the NC material is accelerated to such a high rate that any intermediate reaction steps are difficult to uncover in the stability tests commonly used. The reasonably good fits obtained in part I at 85°C with the initial mechanism shown in Fig. 1 could be a result of the shorter life time of the intermediate compound. The DPA stabilization of NC is also an extremely temperature dependent process since the time-to-fume at 80°C is approximately 120 days while at 25°C it is in the order of 20–50 years. The strong temperature dependence could be an indication that radical species are involved in the mechanism. Furthermore, the diffusion conditions change around the melting temperature of DPA (53°C). As a consequence of the above mentioned aspects on the reaction mechanism, any extrapolations to room temperatures based on monitoring of stabilizer consumption at these high temperatures will be erroneous. The monitoring of DPA or its degradation products can therefore not compete with for example thermal gravimetry or calorimetry as methods for estimating propellant stabilities.

However, the approach with simultaneous curve fitting has shown itself to be useful in mechanistic studies and could be expected to be applicable to, for example, studies of organic synthesis where the experimental conditions are more easily controlled. The approach for computing CT curves makes the optimization program easy to use and changes of reaction mechanisms can be made quickly.

The loss of DPA from the NC material, observed in part I, and the results in the model optimizations in part II make it appropriate to focus future investigations on the NC material remaining after the extraction of the DPA derivatives and there are, at least, three possibilities for the observed loss of DPA which should be investigated in the future. First, the oxidation of DPA into a compound which is either non-electroactive and non-absorbing at 292 or 430 nm, or completely retained on the column. Secondly, the DPA could react to give rise to a product which is insoluble in methylene chloride. This product could be a polymer, as such polymers are known to be formed in both electrochemical oxidations[19,20] and in oxidation due to the presence of oxygen.[8] Finally, DPA could, according to Urbanski *et al.*[24,25] form a non-soluble complex with NC. A study using molecular spectroscopic methods should most likely be able to answer the question of whether DPA is incorporated in the NC material or not.

# DETERMINATION OF ANTIMONY (III) AND (V) BY DIFFERENTIAL PULSE ANODIC STRIPPING VOLTAMMETRY

PAMELA A. WALLER and WILLIAM F. PICKERING

Chemistry Department, University of Newcastle, N.S.W., Callaghan 2308, Australia

(*Received* 6 *December* 1993. *Revised* 12 *April* 1994. *Accepted* 15 *April* 1994)

**Summary**—Re-evaluation of DPASV procedures for determining low levels of Sb (III) and Sb (V) in solution identified several problem areas, *e.g.* anomalous ASV behaviour, possible formation of an intermediate valency state during the analytical cycle, and chemical interactions in acidified test solutions containing both valency states. Specific determination of Sb (III) can be achieved using base solutions composed of 0.2*M* HCl (detection limit 10 n*M*) or acetic acid/acetate buffer (detection limit 600 n*M*). For the determination of Sb (V), analysis in 2*M* HCl is recommended [with response in 0.2*M* HCl being used to correct for any Sb (III) present].

Antimony species are known to be toxic but monitoring of environmental systems for this element is not a common procedure, possibly because the levels tend to be quite low, for example, the terrestrial abundance level of Sb[1] is around 0.7 $\mu$g/g, and sea-water[2] contains 0.1–0.5 $\mu$g Sb/l. [with 70–94% of the total Sb being present as Sb (V) species]. Much higher Sb levels can be found near non-ferrous smelters, *e.g.* near a lead smelter,[3] soil values ranged between 5 and 260 $\mu$g Sb/g, and up to 10 mg/g were found in soils located near a copper smelter.[4]

The analytical procedure used to determine Sb levels in non-polluted systems thus needs to be highly sensitive, and it should also be capable of distinguishing between Sb (III) and Sb (V) species, because the toxicity threshold for antimony species varies with the valency state of the element. One technique which meets these specifications is atomic absorption spectroscopy,[5–10] where detection limits of 0.5 $\mu$g/l. (4 n*M*) have been achieved using hydride generation. Another promising (but not so fully explored) technique is differential pulse, anodic stripping voltammetry (DPASV).

Application of a DPASV procedure[11] to acidified solutions 200 n*M* in Sb (III) or Sb (V) was found to yield sharp signal peaks when a hanging Hg drop electrode was used. The size of the peaks obtained varied with the molarity of the HCl added and the valency state of the Sb present. It was proposed that one could determine the amount of Sb (III) species present by using dilute acid support solutions, and then determine total Sb content using an acidity level of 4*M* HCl, but no experimental data for mixture analyses was presented.

In another ASV study,[12] an acetate buffer solution was used as the supporting electrolyte. With the experimental conditions adopted, the detection limit for Sb (III) was around 600 n*M* (*i.e.* much less sensitive than HCl based systems). Other limitations of this support medium were not evaluated, nor was the behaviour of Sb (V) in this medium examined. To remedy these omissions, further studies have now been made. The determination of Sb in HCl solutions has also been re-examined in some detail, primarily because the responses obtained using Sb (III)/Sb (V) mixtures differed from the results expected (based on single valency state studies).

## EXPERIMENTAL

### *Standards and base solutions*

(a) *Antimony standards.* Standard stock solutions (25 $\mu$*M*) were prepared by dissolving either Univar A.R. potassium antimonyl tartrate (SbT) or Merck A.R. $KSb(OH)_6$ in pure water (from a reverse osmosis unit). A solution saturated with Aldrich Gold Label $Sb_2O_3$ was also prepared [calibration against KSbT

standards indicated the Sb content (*c.* 13 $\mu M$]. Aliquots of these stock solutions were diluted with base electrolyte solution as required to yield test solutions having Sb levels which ranged from 100 n$M$ to 10 $\mu M$.

(b) *Acetate buffer solution.* The 1$M$ $CH_3COOH$, 0.5$M$ $CH_3COONa$ mixture used was prepared from A.R. grade materials.

(c) *Hydrochloric acid solutions.* Base solutions varying in concentration from 0.08 to 4$M$, were prepared by dilution of Univar A.R. HCl with pure water. For some investigations (*e.g.* identification of baseline noise peaks) higher grade acids (such as B.D.H. 'Aristar' brand HCl and 'Volucon' standard solution ampules) were also utilized.

(d) *Hydrazine dihydrochloride.* Small aliquots (*e.g.* 0.1 ml) of a 0.5$M$ stock solution (prepared daily by dissolving A.R. grade salt (Aldrich brand) in pure water) were added (as required) to Sb test solutions (final hydrazine concentration, 0.01$M$).

(e) *Synthetic mixtures containing* Sb (III) *and* Sb (V). Solutions containing antimony in both valency states were prepared by mixing appropriate volumes of the $Sb_2O_3$ saturated solution and standard $KSb(OH)_6$ solutions. The amount of each solution added was varied, in order to obtain mixtures in which the ratio of Sb (III) to Sb (V) was either 5:1, 2:1, 1:1, 1:2 or 1:5. Different total levels of Sb in solution were obtained by using different aliquot volumes and by diluting more concentrated dual valency mixtures with water. Varying volumes of HCl were added to aliquots of these various mixtures (and to aliquots of standard Sb (III) and Sb (V) solutions), in order to prepare test solutions having final acidity levels which ranged from 0.2 to 3.0$M$.

*Analytical procedure*

Each mixture and standard series solution was analysed (by DPASV) and the peak area plotted as a function of the Sb content. The instrument used for the DPASV analysis was an Amel® Polarographic Analyser (model 473), connected to a hanging drop mercury electrode (PAR model 3038, Ag/AgCl reference electrode). The operating conditions used for the HCl base solutions were: Nitrogen purge time, 2 min; Hg drop size, small; deposition potential, −400 mV; deposition time, 1 sec (extended at times to longer values); pause time 3 sec; anodic scan speed, 5 mV/sec; cut-off potential +50 mV; X, Y recorder speed, 100 mV/cm; FSD current, 10, 20, 50 or 100 nA. Similar operating conditions were used with the acetate buffer solutions except that deposition potentials were varied from −400 to −1400 mV.

## RESULTS AND DISCUSSION

*Irregular behaviour of* Sb *in ASV studies*

Some of the results presented in an earlier DPASV study[11] of Sb systems indicated that responses could deviate from the pattern usually observed in ASV determinations of metals such as Pb, Cd, Zn. For example, it was found that repeated scanning of HCl solutions containing Sb (III) or Sb (V), led to peaks which decreased in size (using a hanging drop mercury electrode and 5 min deposition times). Using a thin Hg film electrode only the first voltage scan of Sb (III) solutions yielded a peak and no stripping peak for Sb (V) was detected. The addition of hydrazine to the test solutions modified this behaviour and determination of Sb (V) was achieved using a supporting electrolyte which was 1.2$M$ in HCl, 1.8$M$ in $H_2SO_4$ and 0.01$M$ in hydrazine sulphate.

In our studies, a fresh mercury drop was used for each scan, and the amount of Sb deposited in (or on) the Hg drop was kept small (*e.g.* by using a 1 sec deposition time). Increasing the loading level (by increasing the deposition time) resulted in a disproportionate increase in the stripping peak size, *e.g.* the area enhancement obtained by using much longer times (*e.g.* 300 secs) was relatively small (*e.g.* less than five-fold, cf. Fig. 1).

Calibration series behaviour was also

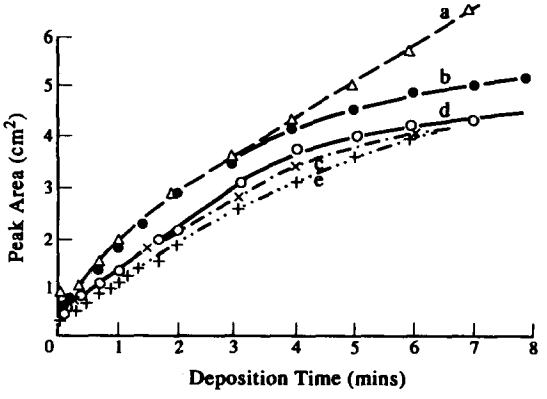

Fig. 1. Effect of deposition time on Sb peak area. (a) 1 $\mu M$ KSbT in acetate buffer; $E_d$ −1.1 V., 20 nA FSD. (b), (c) 5 $\mu$M $Sb(OH)_3$ in 1$M$ HCl; $E_d$ −450 mV, 1 $\mu$A FSD. (d), (e) 50 $\mu M$ $KSb(OH)_6$ in 1$M$ HCl; $E_d$ −500 mV, 200 nA FSD. In systems (b) and (d) hydrazine present.

atypical, because the straight lines which joined the points rarely passed through the origin. For example, the calibration line for Sb (III) in 0.2*M* HCl was defined by the equation: peak area ($mm^2$) = 14 + 63*c*; where *c* is the Sb concentration in $\mu M$ (recorder FSD setting, 50 nA). The magnitude of the intercept value varied with acid molarity and the valency of the Sb salt (*e.g.* in 2*M* HCl, the value for Sb (III) was 25, for Sb (V), 50). Area measurement errors may have contributed to the size of the intercepts, but the marked deviation from zero values suggests that the proportion of analyte reduced at the electrode decreased with increasing concentration. Changing the HCl concentration resulted in small changes in the slope of Sb (III) calibration plots (*e.g.* from 63 in 0.2*M* to 70 in 2*M* HCl), and large changes in the slope of Sb (V) plots (*e.g.* 0.8 in 0.2*M* to 28 in 2*M* HCl).

Abnormal behaviour was most marked in acetate buffer base solutions (discussed in a later section). In this media peak size and shape varied, *inter alia*, with the magnitude of the deposition potential.

The irregular behaviour noted suggests that the processes involved in the ASV deposition stage are more complex than formation of $Sb^0$ (and dissolution in the Hg drop). It appears that some Sb species are adsorbed (or precipitated) on the Hg surface, and during the stripping scan these species influence the size of the current flow.

*Influence of chemical reactions on DPASV responses*

The shape, size and location of the Sb ASV peaks was found to vary with the composition of the base solution, the experimental conditions selected, and the chemical form of the Sb species present. The chemical form of the antimony species introduced into test solutions ranged from being a complex anion (in solutions prepared from potassium antimonyl tartrate), to uncharged molecules or oxycations (in solutions containing dissolved $Sb_2O_3$). Equilibria involved in the dissolution of antimony (III) oxide in water[13] include:

$$Sb_2O_3\ (s) + 3H_2O \leftrightarrow 2Sb(OH)_3 \qquad (1)$$

$$1/2Sb_2O_3 + 1/2H_2O \leftrightarrow SbO^+ + OH^- \qquad (2)$$

$$1/2Sb_2O_3 + 1/2H_2O \leftrightarrow SbO_2^- + H^+ \qquad (3)$$

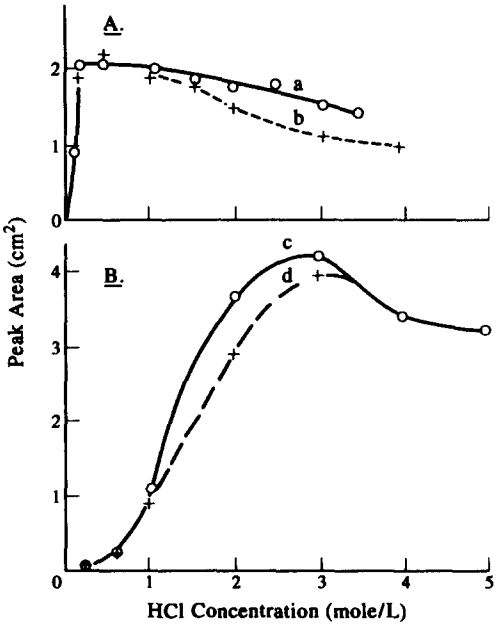

Fig. 2. Effect of HCl concentration and the addition of hydrazine on the DPASV peak areas. $E_d$ −500 mV; deposition time 1 sec; curves (a), (c), symbol o, hydrazine added; curves (b), (d), symbol +, hydrazine absent. (A) Sb (III), 1 $\mu M$ KSbT; recorder setting 20 nA FSD. (B) Sb (V), 50 $\mu M$ $KSb(OH)_6$; recorder setting 500 nA FSD.

The addition of HCl to the $Sb_2O_3$ solutions would have favoured formation of the cation $SbO^+$ (reaction 2), and this transformation was probably near complete at acid levels >0.2*M* (*cf.* plateau region, Fig. 2A). With Sb (V) systems, addition of HCl at levels >0.3*M* was required to achieve a gradual change of the $Sb(OH)_6^-$ ion into a more electro-active species (*cf.* Fig. 2B). The observed differences in Sb (III) and (V) behaviour (*e.g.* HCl concentration effect on peak area, Fig. 2) mainly reflect variations in the deposition stage mechanism, because the stripping peak potential values for Sb (III) and Sb (V) were similar, over a wide range of acid molarity values (*cf.* Fig. 3). It has been concluded that in the stripping cycle, chloro-complexes of similar nature were formed.

The possibility of Sb (IV) species formation during the electro-analytical cycle has been raised in an earlier article.[11] In the deposition stage this could involve processes such as slow oxidation of Sb (III) at the Pt counter electrode and partial (one electron) reduction of Sb (V) compounds. During the anodic stripping stage, oxidation of deposited Sb metal might proceed beyond the Sb (III) state. The Sb (IV) valence state is known[14] to form sparingly soluble compounds, hence formation of this intermediate in the DPASV cycle could result in removal

of some Sb from solution, possibly as partial coatings on the electrodes. It was reported[11] that effects attributed to Sb (IV) could be eliminated by adding hydrazine to the base solutions.

In our investigations, the addition of hydrazine hydrochloride (0.1*M*) to test solutions led to some marginal increases in peak area and slightly sharper peaks, but there were no significant changes in peak potential values. The addition of hydrazine did not promote chemical reduction of Sb (V) [*i.e.* $KSb(OH)_6$] to Sb (III) species. The hydrazine probably acts as a depolarising agent in the electrochemical process, rather than as a chemical reductant.

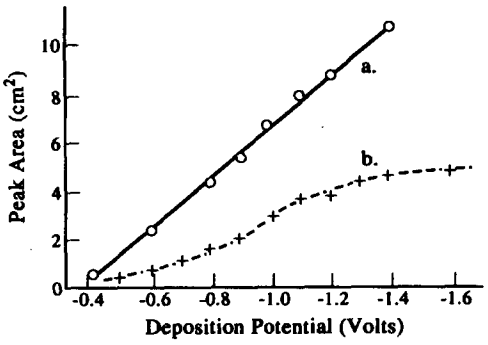

Fig. 4. Graph of effect of deposition potential on peak area values, in acetate buffer solutions. (a) 8 $\mu M$ $Sb(OH)_3$, recorder setting 20 nA FSD; (b) 50 $\mu M$ KSbT, 200 nA FSD.

*Determination of* Sb (III) *in an acetate buffer solution*

No ASV peak assignable to Sb was observed when Sb (V) solutions (50 $\mu M$) were subjected to DPASV analysis, using acetate buffer support solutions. Deposition times ranging from 1 to 360 seconds were examined, and three deposition potentials (−300, −500 and −1100 mV) were used. The scan tracing was the same in the presence, or absence, of hydrazine dihydrochloride. One can, therefore, use an acetate base solution to detect Sb (III) in the presence of pentavalent Sb salts.

For the determination of Sb (III), however, the experimental conditions have to be carefully controlled. It was found, for example, that the area of the Sb peak(s) increased steadily as the negativity of the HMDE was increased from −400 to −1400 mV (as shown on Fig. 4). This suggests that the Sb species present do not dissociate readily under the influence of an applied potential. The shape of the Sb peak also varied. Multiple peaks were found on many of the DPASV traces, *e.g.* applying a potential of −400 mV to buffer solutions containing Sb tartrate yielded two peaks of near equal size (at $E_p$ values of −320 and −270 mV). Using more negative deposition potentials, the −320 mV peak shifted in an anodic direction and the other peak moved in a cathodic direction. Total overlap (*i.e.* a broad symmetrical peak) occurred when deposition potentials of −900 to −1100 mV were used (*cf.* Fig. 5A, curves a–c).

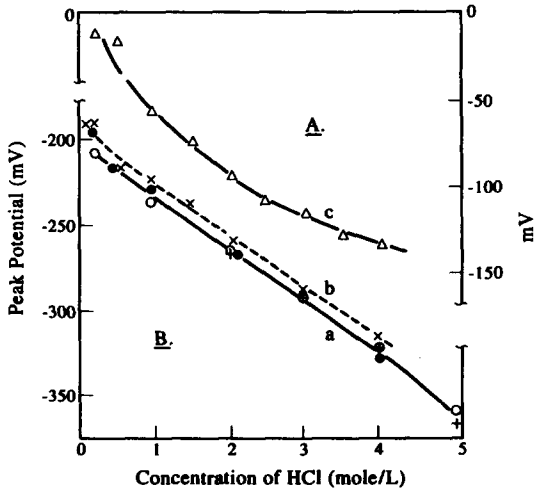

Fig. 3. Effect of HCl concentration on peak potential values. (A) 'acid systems' peaks, curve (c). (B) Antimony peaks. Curve (a) Sb (V): 50 $\mu M$ $KSb(OH)_6$; $E_d$ −500 mV, recorder setting 500 nA FSD, point symbols ○ (closed for hydrazine present). Curve (b) Sb (III): 1 $\mu M$ KSbT; $E_d$ −500 mV, recorder setting, 20 nA FSD; point symbol + (or ×, hydrazine present).

Using longer deposition times did not increase the sensitivity of the procedure proportionally (*cf.* Fig. 5A, curves g–i). Gains in signal size were offset by reduced symmetry of the signals and the appearance of peaks assignable to impurities in the acetate buffer solution (observed when using deposition times >40 secs). One of these impurity peaks ($E_p$ around −300 mV) was not resolved from the Sb peak.

After examining the effect of different variables on the symmetry of Sb peaks (*cf.* Fig. 5A) it was concluded that the optimum operating conditions for quantitative studies would be a deposition potential of −1100 mV applied for one second. Using these conditions, the height (or area) of peaks arising from Sb (III) species was found to be directly related to the concentration present. The detection limit was around 600 n$M$ (10 nA FSD), so the levels of Sb in test solutions should be >1 $\mu M$.

*Determination of* Sb (III) *and* Sb (V) *in* HCl *solutions*

(a) *Effect of* HCl *concentration on DPASV response.* In a previous study[11] of the DPASV responses of Sb (III) and Sb (V) it was found that the size of Sb (III) peaks nearly doubled in size when the level of HCl in the base solution was increased from 0.1 to 1*M*, but little further change in area occurred when the acid level was increased from 1 to 5*M*. Antimony (V) solutions, on the other hand, yielded barely detectable peaks at acidities less than 1*M*; at higher molarities the size of the Sb (V) peaks increased as the level of acid present increased. It was proposed that Sb (III) present in mixtures could be determined using dilute acid (*e.g.* 0.5*M*) support solutions, while for the determination of total Sb contents, a base solution 4*M* in HCl was recommended.

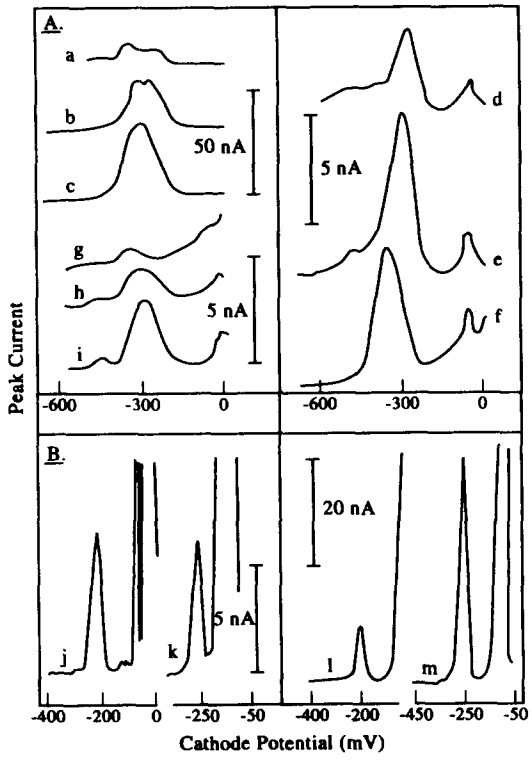

Fig. 5. (A) Typical DPASV curves for Sb (III) in acetate buffer base solution. Effect of deposition potential; Curves (a)–(c), 50 $\mu M$ KSbT; deposition time 1 sec; recorder setting 200 nA FSD. (a) $E_d$ −500 mV, (b) $E_d$ −800 mV, (c) $E_d$ −1.10 V. Curves (d) and (e), 8 $\mu M$ $Sb(OH)_3$; deposition time 1 sec, recorder 20 nA FSD. (d) $E_d$ −600 mV, (e) $E_d$ −900 mV. Curve (f), 10 $\mu M$ KSbT, 0.1*M* in hydrazine; $E_d$ −1.10 V, deposition time 1 sec, recorder 20 nA FSD. Effect of deposition time; curves (g)–(i) 1 $\mu M$ $Sb(OH)_3$, $E_d$ −1.1 V, recorder, 20 nA FSD. (g) 1 sec, (h) 40 sec, (i) 120 sec. (B) Typical DPASV curves for Sb (III) and Sb (V) in hydrochloric acid base solutions. Curves (j) and (k), 1 $\mu M$ Sb (III), $E_d$ −400 mV, deposition time 1 sec, recorder setting 20 nA FSD, in HCl of molarity 0.2 (j) or 1.0. (k) 1.0. Curves (l) and (m), 50 $\mu M$ Sb (V); $E_d$ −500 mV, deposition time 1 sec; recorder setting 50 nA FSD, in acid of molarity 1.0 (l) or 2.0 (m).

Inconsistent responses were obtained when the procedure was applied (in more recent times) to solutions containing the two valency states of Sb. In a bid to identify the problem areas, all aspects of the method were re-examined. Our study, using different instrumental parameters, confirmed that the size of Sb (III) and (V) stripping peaks varied with the molarity of HCl present in the test solutions (*cf.* Fig. 2), but transition point values differed from those previously reported. For example, with Sb (III) solutions, large variations in peak size were restricted to the <0.2*M* HCl region and optimum Sb (III) response occurred in 0.2 to 2*M* acid solutions. The plateau region shown on Fig. 2A had a slight downward slope but this trend had little significance because in calibration plot studies, Sb response in 2*M* acid was marginally larger than in 0.2*M* HCl. In the case of Sb (V) systems, small peaks were observed in 0.5*M* HCl, and size increased with increasing acid molarity until maximum values were reached in solutions 3*M* in acid (*cf.* Fig. 2B). No decline in peak size at higher HCl levels was observed when the Sb (V) concentration was less than 50 $\mu M$. Typical DPASV traces are shown on Fig. 5.

With acid molarities >3*M*, the Sb signal was partially overlapped by the side wing of a large, broad 'system' peak (tentatively attributed to the formation of Hg(II) chlorospecies). Decreasing the molarity of acid present reduced the system peak size (*e.g.* from a peak height of 110 mm in 4*M*, to 5 mm in 0.2*M* HCl), and changed the peak position (*cf.* Fig. 3c). At acid levels less than 3*M*, overlap with the Sb peak became minimal.

Impurities were not a problem when 'Volucon' acid ampules or high purity HCl (*e.g.* B.D.H. 'Aristar' brand) were used to prepare the base solutions, but the A.R. acid used in our study contained a small of impurity (presumably Bi) which had a peak $E_p$ value similar to that of Sb. Correction for this element (via base solution blanks) was most important when analysing solutions containing low levels of Sb (*e.g.* 0.1 $\mu M$). The detection limit for Sb (III) (in 1*M* HCl, using an FSD value of 10 nA) was around 10 nM (*i.e.* 1 $\mu$g/l).

When single valency Sb solutions were repeatedly scanned (or replicates were

analysed), consistent peak area values were usually obtained. The precision of the procedure (expressed as a relative standard deviation) was found to vary with the type of Sb (III) solution being examined. For example, using KSbT standard solutions the RSD value was $\pm 2\%$, with $Sb(OH)_3$ solutions, the RSD value was $\pm 3$–$10\%$.

(b) *Analysis of solutions containing* Sb (III) *and* Sb (V). From the results summarized on Fig. 2 it was concluded that specific determination of the amount of Sb (III) present could be achieved by adjusting aliquots to an acidity level of 0.2 or 0.5*M* HCl. With acid levels $> 1M$, both valency states contribute to the total signal, and for determination of Sb (III) plus Sb (V) values, adjustment of the test solutions to an HCl level of 2.0*M* was selected. [Sb (V) response at this acidity level was less than achieved at higher molarities but the Sb peaks were clearly resolved from any 'acid system' peak]. Since the signal contribution from Sb (III) species varied little with increasing acidity (*cf.* Fig. 2A), any increase in peak area observed using the 2*M* acid solutions could be assigned to the Sb (V) content. Reference to an Sb (V) calibration plot (for the acidity level used) then allows one to convert the difference in peak areas to concentration values.

For this procedure to yield valid results in mixture studies, interaction between the two Sb valency states in acidified solutions must be minimal, and the presence of the second valency state must not alter DPASV response. To test if these conditions were met, synthetic mixtures containing Sb (III) and Sb (V) were prepared, and analysed by DPASV. In the absence of side reactions, the size of the peaks for the various mixtures should match the values obtained by adding together areas which correspond to the concentration of each component in the mixture [as derived from calibration curves prepared for both Sb (III) and Sb (V)].

In one series of studies, the mixtures examined had acid levels adjusted to values ranging from 0.2 to 3.0*M*, and contained equal concentrations of Sb (III) and Sb (V). The concentration of each valency state in the mixtures ranged from 0.8 and 6 $\mu M$. As shown on Fig. 6, the peak sizes varied with acid molarity, and for each level of total Sb content, two plateau regions are discernible on the plots. The first extends from 0.2 to 0.5*M* [contribution of Sb (III) only] and the second embraces the 2 to 3*M* HCl region. These results confirmed that

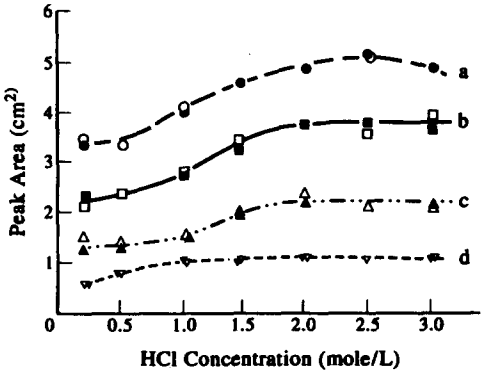

Fig. 6. Effect of acid molarity and amount of antimony present, on the size of the DPASV peak obtained on analysing 1:1 Sb (III), Sb (V) mixtures. Concentration of Sb (III) [and Sb (V)] in the mixtures was (a) 6 $\mu M$, (b) 4 $\mu M$, (c) 2 $\mu M$ (d) 1 $\mu M$. Closed symbol points, mixtures acidified just prior to analysis; Open symbol points, mixtures prepared from antimony standards stored in HCl of different strengths.

analysis in 2*M* HCl was suitable for determining the Sb (V) contribution. Many of the experimental peak area values were higher than 'expected' mixture responses (*i.e.* the sum of calibration curve values for each component), but an equal number were lower. This behaviour suggested that under some conditions the degree of Sb (V) reduction was being enhanced by the presence of Sb (III), while in other conditions Sb was being lost from solution.

In a bid to identify the factors responsible for the varied response, new series of mixtures were prepared. The amount of Sb (III) introduced was again varied between 0.8 and 6 $\mu M$, while the amount of $KSb(OH)_6$ added was adjusted to give mixtures in which the ratios of Sb (III) to Sb (V) were 5:1; 2:1; 1:1; 1:2 and 1:5. These mixtures were analysed by DPASV after adjusting the HCl level to 0.2 or 2.0*M*.

Using test solutions 0.2*M* in HCl [*i.e.* ostensibly determining Sb (III) only] mixture peak areas matched the corresponding points on the Sb (III) calibration plot when the ratio of Sb (III) to Sb (V) in the mixture was 2:1, 1:1 or 1:2. With a marked excess of Sb (III) present (*i.e.* 5:1), the mixture signals were 10% lower (5% if hydrazine added) than the peak areas expected from the Sb (III) calibration plot. This behaviour was attributed to chemical interaction between the valency states, leading to the formation of a small amount of non-reducible (maybe insoluble) Sb species. With excess Sb (V) present [*i.e.* 1:5 mixtures, 4–30 $\mu M$ in

$KSb(OH)_6$], the measured peak areas were about 10% higher than Sb (III) calibration curve values. This behaviour was provisionally attributed to catalysed reduction of some Sb (V) (*e.g.* by Sb/Hg) when the level of this valency state was $>4\ \mu M$. Alternatively, some (or all) of the variance in the mixture analysis results could be assigned to experimental error. The RSD values for the peak area measurements were (on average) larger than those obtained using single valency solutions (with about one fifth having RSD values falling in the 10–15% range).

The results obtained using mixtures $2M$ in HCl are summarized on Fig. 7. One third of the peak area values 'matched' (*i.e.* within $\pm 4\%$)

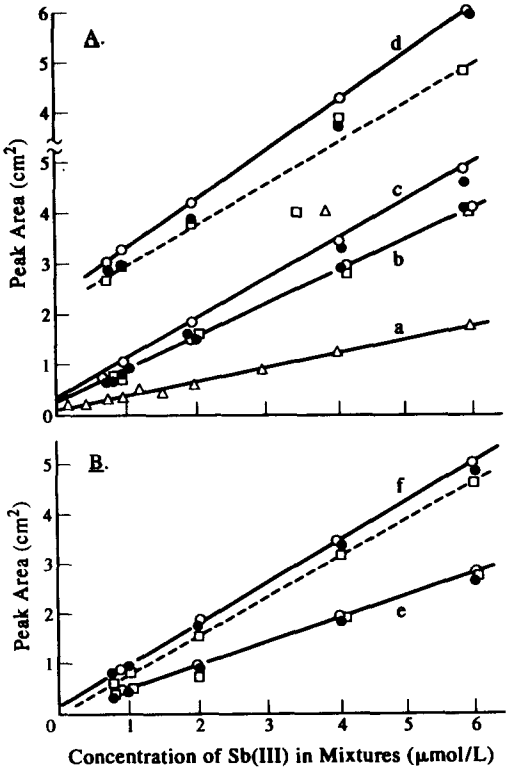

Fig. 7. Effect of Sb concentration on DPASV peak areas, in the presence of $2M$ HCl and differing ratios of Sb (III) and Sb (V). Segment A. Recorder FSD 50 nA; Segment B. FSD 200 nA. System codes: (a) antimony (V) standard solutions, (b) antimony (III) standard solutions, (c) to (e) Sb (III)/Sb (V) mixtures with content ratios of (c) 2:1, (d) 5:1, (e) 1:2 and (f) 1:5. Calibration curves for the different systems are indicated by full lines, and open circle (○) symbols. (For mixtures, calibration point values obtained by adding appropriate areas, drawn from curves (a) and (b), for the concentrations of Sb (III) and Sb (V) present. Experimental peak areas for mixed valency systems which were made $2M$ in HCl just prior to analysis are shown as closed circle (●) points. In another series the mixtures were stored in $2M$ HCl prior to analysis (symbol code □), yielding trends indicated by dashed lines.

the values obtained by addition of $2M$ HCl calibration curve readings [for each specified level of Sb (III) and Sb (V) in the mixture]. Another third of the test solutions yielded results which were 5–10% lower than the calculated value; and the final third [involving mainly mixtures with low Sb (III) contents, *i.e.* 0.8 or 1.0 $\mu M$] had analytical values 15–20% lower than expected (*cf.* closed circles, Fig. 7). The predominance of 'smaller than predicted' peak areas has been attributed to calibration error and/or chemical interactions. The combining of single valency calibration plot points (to yield 'expected' response values) may have led to overestimation of the 'baseline' contribution to mixture signals. [As noted earlier, the intercept value for Sb (V) calibration lines (in $2M$ HCl) was double that found for Sb (III)]. The main cause of smaller DPASV peaks, however, was considered to be formation of an 'ASV inert' Sb species, via a reaction enhanced by the presence of the higher level of acid.

This chemical reaction appears to be a slow process and may only involve one valency state. Peaks 15–30% smaller than expected (*cf.* Fig. 7, dashed lines) were obtained when mixtures (valency ratios 5:1, 2:1 and 1:1) were prepared from Sb (III) and Sb (V) standard solutions which were made $2M$ in HCl several days before being admixed. With an excess of Sb (V) present, the difference between predicted and actual signal size was less (*e.g.* with a valency ratio of 1:5, the values were circa 10% smaller, *cf.* Fig. 7, dashed line f; with mixtures having a valency ratio of 1:2, the analytical results all fell within $\pm 5\%$ of the expected value).

When mixtures were prepared from Sb (III) and Sb (V) standard solutions which were $0.2M$ in HCl, variable DPASV responses were observed. Using 5:1 mixtures, the peaks matched (in size) those obtained using the Sb (III) calibration value. With lower proportions of Sb (III) in the mixture over half of the experimental values deviated from the 'expected' area, with a third being 15–20% higher, and about one fifth lower than expected. The largest deviation (15–20% lower) was found using 1:5 systems.

## CONCLUSIONS

While it is possible to determine both Sb (III) and Sb (V) present in mixtures by control of analyte acidity levels, the speciation data derived from the DPASV studies needs to be

interpreted cautiously, because the accuracy of the analyses can be reduced by secondary chemical processes. For some types of mixtures the values for Sb (III) and Sb (V) may be in error by $\pm 20\%$ of the Sb content, but in most mixture analyses the relative variations should be better than $\pm 10\%$. This error could be reduced by using a two stage calibration procedure (*i.e.* after using single valency calibration plots to obtain the approximate composition of the mixtures, standard mixtures of like composition could be prepared and analysed for both species).

Analytical errors may have less significance when dealing with routine samples (*e.g.* collected from the environment) since preliminary sample treatments can modify the distribution of Sb between valency states. For example, with moist solids, interactions may occur during storage or drying steps. Release of the Sb species from the solids by hot acid extraction, or stabilisation of water samples by adding acid, could also be accompanied by chemical changes (some of which may partially reverse when acid levels are adjusted prior to DPASV analysis).

# THE APPLICATION OF PRINCIPAL COMPONENT REGRESSION ON SIMULTANEOUS MULTICOMPONENT DETERMINATIONS THROUGH A SINGLE CATALYTIC KINETIC RUN

ZHI-CHENG GU* and XIAN DE WANG†

Department of Chemistry, Tongji University, Shanghai 200092, China

(*Received* 27 *January* 1994. *Revised* 3 *June* 1994. *Accepted* 13 *June* 1994)

**Summary**—The kinetic behaviors of Cr(VI) and W(VI), which catalyze a common indicator reaction between $H_2O_2$ and $I^-$, were studied. A new concept, 'Rate Spectrum', is proposed. The two catalysts can be determined simultaneously by analyzing the rate spectra of their mixtures as the rate spectra of each catalyst are linearly independent. Principal Component Regression (PCR) was used to analyze the rate spectra of the mixtures of Cr and W, and in this way the two ions were determined simultaneously through a single kinetic run.

Only a few methods have been proposed to determine catalysts simultaneously through a single kinetic run. Pardue has developed a method for the determination of isoenzymes based on differences in the rate of inhibition.[1] Bromide and iodide were determined simultaneously, using the very large difference in their reaction rate.[2] Nitrite and iodide,[3] Cr(VI) and Fe(III)[4] were determined simultaneously based on their different properties. A method for the simultaneous determination of Ru and Os, based on the difference in the order of the indicator reaction, was carried out recently with multilinear regression.[5] When this method is used, it is necessary that the apparent reaction order for each catalyst is kept constant during the reaction. However, this is not always the case. In order to find a more general method, we studied the application of other chemometrics methods, such as principal component regression (PCR), on the catalytic kinetics. In this paper Cr and W, which catalyze the reaction between $H_2O_2$ and $I^-$,[6,7] were used as an example to investigate the characteristics of applying PCR to simultaneous multicomponent determinations through a single kinetic run. PCR has been used in many cases to resolve spectra of mixtures in chromatography,[8] mass spectrometry[9] and spectrophotometry.[10] The application of PCR in multivariate calibration is more effective than MLR.

## THEORY

A catalyzed indicator reaction can be written as:

$$a\mathrm{A} + b\mathrm{B} \rightarrow x\mathrm{X} + y\mathrm{Y}$$

and its reaction rate equation is:

$$v_i = -\mathrm{d}[\mathrm{A}]/\mathrm{d}t = \mathrm{d}[\mathrm{X}]/\mathrm{d}t = k_i[\mathrm{A}]^{p_i}[\mathrm{B}]^{q_i}[\mathrm{C}_i]. \quad (1)$$

According to stoichiometric relationships:

$$[\mathrm{B}] = [\mathrm{B}]_0 - (b/a)([\mathrm{A}]_0 - [\mathrm{A}]), \quad (2)$$

where $[\mathrm{B}]_0$ and $[\mathrm{A}]_0$ are the initial concentration of B and A, respectively. Substituting equation (2) into equation (1), we have:

$$v_i = k_i[\mathrm{C}_i][\mathrm{A}]^{p_i}\{[\mathrm{B}]_0 - (b/a)([\mathrm{A}]_0 - [\mathrm{A}])\}^{q_i}. \quad (3)$$

For simplification, an approximate equation is used:[11]

$$[\mathrm{B}]^q = \{[\mathrm{B}]_0 - (b/a)([\mathrm{A}]_0 - [\mathrm{A}])\}^q = T[\mathrm{A}]^{p''}$$

and equation (3) becomes:

$$v_i = k_i''[\mathrm{A}]^{p_i'}[\mathrm{C}_i] = f_i[\mathrm{C}_i], \quad (4a)$$

where

$$k_i'' = k_i T,\ p_i' = p_i + p_i',\ \text{and}\ f_i = k_i''[\mathrm{A}]^{p_i'}.$$

Since $k_i''$ is constant under the experimental conditions and $p_i'$ varies with the concentration of A, $f_i$ is the function of concentration of

*Author to whom correspondence should be addressed.

†Present address: Department of Research & Development, Shanghai Jawa Complex, Shanghai 200080, China.

indicator substance A. This is also the case when the product (X or Y) is used as indicator substance, owing to the following relationships:

$$[X] = (x/a)([A]_0 - [A]). \quad (5)$$

A comparison with spectrophotometry is given in the following:
According to Beer's law:

$$A' = \epsilon bC. \quad (6)$$

The absorbance for a mixture of $n$ components is additive. Let $A = A'/b$, we have:

$$A = \Sigma \epsilon_i C_i, \quad (7)$$

where $\epsilon$ can be described as a function of wavelength $\lambda$. While a plot of $A$ *vs.* $\lambda$ is defined as spectrum the simultaneous multicomponent determinations can be carried out when their spectra are linearly independent. Similarly, in catalytic kinetics, when $n$ components behave independently, the reaction rates are additive and equation (4) may be written as:

$$v = \Sigma f_i[c_i]. \quad (8)$$

Compared with equation (7), $f_i$ in equation (8) corresponds to $\epsilon_i$ in equation (7) and concentration of A corresponds to the wavelength. Consequently, the plot of $v$ *vs.* [A] corresponds to the spectrum. We define the plot of $v$ *vs.* [A] as a rate spectrum, and the simultaneous multicomponent determinations by catalytic kinetics can be carried out when the rate spectrum of each component is linearly independent.

When $m$ reaction rate data $v_j$ at $m$ different concentrations of A for each sample are collected, a rate matrix $[v]_{m \times l}$ can be set up, where $j = 1, \ldots, m$, $l$ is the number of samples. And the concentration of the catalysts can be solved from the rate matrix by PCR, as described by Kowalski.[12]

## EXPERIMENTAL

### *Apparatus*

An F7230 spectrophotometer equipped with a thermostat and an IBM personal computer were used.

### *Reagent*

Solutions of 3.0$M$ $H_2O_2$ and 0.1$M$ KI were prepared weekly and diluted freshly before use.

Solutions of 100 $\mu$g/ml Cr and 100 $\mu$g/ml W were prepared and diluted before use.

All the chemicals used were of analytical reagent grade. Redistilled water was used.

### *Procedures*

A suitable portion of KI solution was mixed with sample solution containing Cr and W and diluted to 25 ml with water (solution A).

Solutions of $H_2O_2$, $H_2SO_4$ and starch were mixed to the required concentration (solution B).

After being thermostatted at 20°C for more than half an hour, solutions A and B were mixed in a proportion of 1:2 in a cell as quickly as possible. The absorbance change with time was measured at 580 nm against water. The absorbance at intervals of 10 sec was recorded automatically.

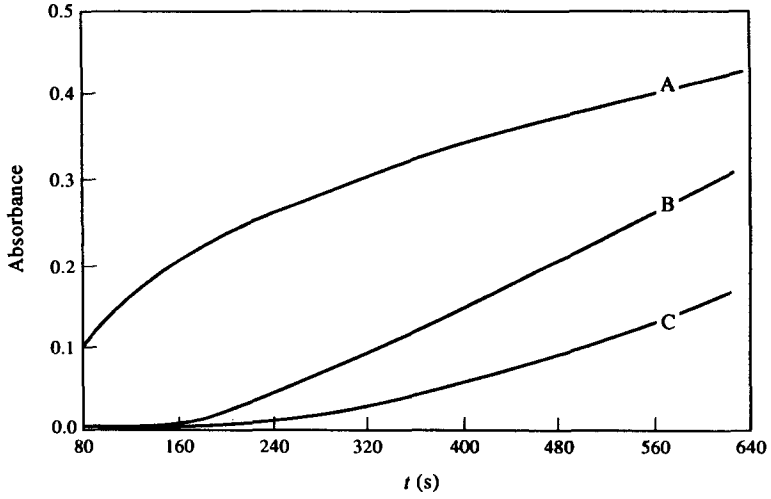

Fig. 1. Absorbance–time curves. $[H_2O_2] = 2.4 \times 10^{-2}$, $[KI] = 6 \times 10^{-4}$, $[H_2SO_4] = 2.7 \times 10^{-2}M$. (A) $[Cr] = 6.41 \times 10^{-6}M$; (B) $[W] = 1.81 \times 10^{-7}M$; (C) blank.

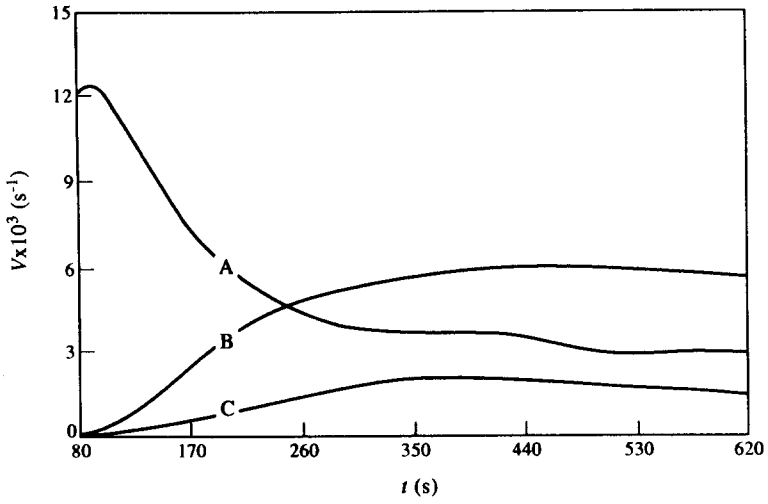

Fig. 2. Reaction rate–time curves. $[H_2O_2] = 2.4 \times 10^{-2}$, $[KI] = 6 \times 10^{-4}$, $[H_2SO_4] = 2.7 \times 10^{-2}M$. (A) $[Cr] = 6.41 \times 10^{-6}M$; (B) $[W] = 1.81 \times 10^{-7}M$; (C) blank.

*Data processing*

The reaction rate $v$ was calculated by the Savitzky–Golay method[13] from the plot of $A$ *vs.* $t$. Based on Beer's law, the absorbance $A$ was used in equation (5) instead of [X]. As described in Ref. 11, the 11 points smooth curve of the second order polynomial were used to derive the first-order derivative, *i.e.* $v$. The rate spectrum was calculated from the plot of $A$ *vs.* $t$ and the plot of $v$ *vs.* $t$. The data of rate matrix was obtained from the plot of $v$ *vs.* $A$ by using the method of linear interpolation. Principal component regression was calculated by PCRRATE program prepared by our laboratory using PASCAL.

## RESULTS AND DISCUSSION

*The possibility of simultaneous determination of Cr and W*

The plot of absorbance $A$ *vs.* time $t$ and reaction rate $v$ *vs.* $t$ are shown in Figs 1 and 2, respectively. The plot of $v$ *vs.* $A$ (the rate spectrum), which is calculated from Figs 1 and 2, is shown in Fig. 3. Obviously the curve B, which is calculated from C and D, is almost overlapped with the experimental one (curve A). It supports the additive assumption, at least under the experimental conditions, and the interaction of the two catalysts can be neglected. The patterns of the curve C and D are quite

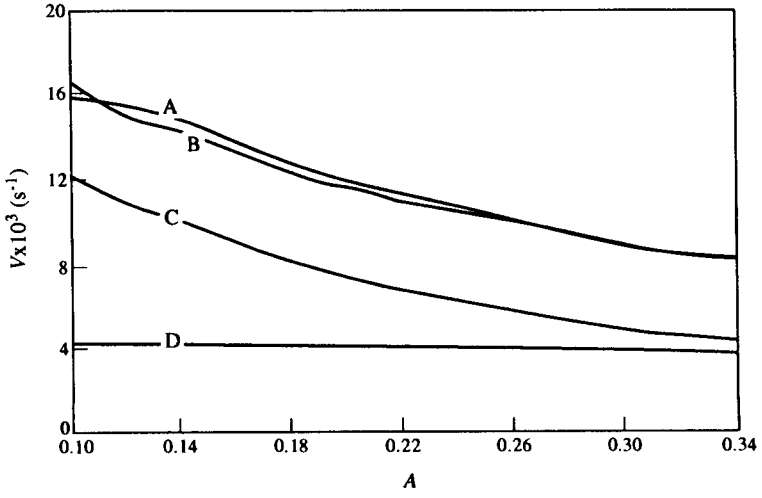

Fig. 3. Rate spectra of the catalyzed reaction. $[H_2O_2] = 2.4 \times 10^{-2}$, $[KI] = 6 \times 10^{-4}$, $[H_2SO_4] = 2.7 \times 10^{-2}M$. (A) $Cr(6.41 \times 10^{-6}M) + W(1.81 \times 10^{-7}M)$; (B) C + D; (C) $[Cr] = 6.41 \times 10^{-6}M$; (D) $[W] = 1.81 \times 10^{-7}M$.

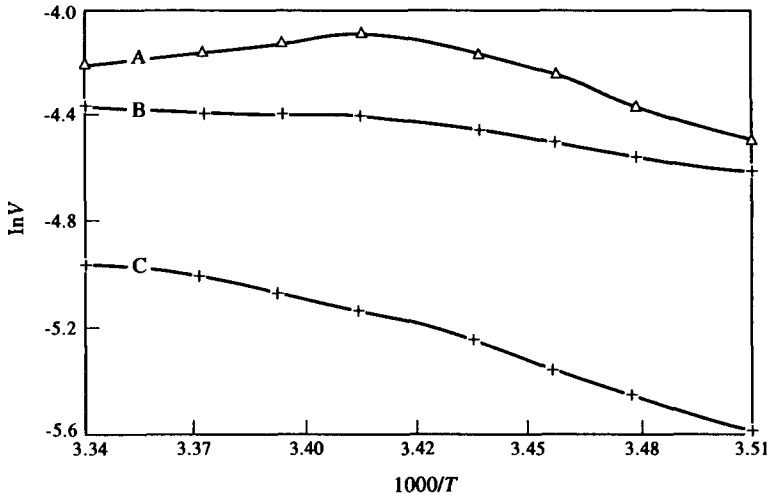

Fig. 4. Active energy curve of the reaction. $[H_2O_2] = 2.4 \times 10^{-2}$, $[KI] = 6 \times 10^{-4}$, $[H_2SO_4] = 2.7 \times 10^{-2}M$. (A) $[Cr] = 6.41 \times 10^{-6}M$; (B) $[W] = 1.81 \times 10^{-7}M$; (C) blank.

different. It suggests that the simultaneous determination of these two catalysts is possible.

*Reaction condition*

The maximum absorption was at 580 nm, so 580 nm is specified as the measuring wavelength in the procedure. The concentration of starch is specified at 0.02%. If the concentration of starch is too high, the blue $I_2$–starch compound will segregate during measuring, and the blank will increase. On the other hand, the sensitivity decreases with decreasing concentration of starch. The effect of temperature on the reaction rate is shown in Fig. 4, 20°C is specified in the procedure.

The rate of W-catalyzed reaction was almost unchanged with $A$ (Fig. 3), while the rate of Cr-catalyzed reaction decreased with the increase of $A$ at the start, and the reaction proceeded with a constant rate after a certain time. This means the kinetic behaviors of W-catalyzed and Cr-catalyzed reaction are different only in the initial period of the reaction. It has also been found that although the rate of the W-catalyzed and the blank reaction varied with the concentration of $H_2SO_4$, $H_2O_2$ and $I^-$, the slope of the plot of $v$ *vs.* $A$ remained unchanged. On the other hand, of the Cr-catalyzed reaction, both the rate and the slope of the plot of $v$ *vs.* $A$ varied with the concentration of $H_2SO_4$, $H_2O_2$ and $I^-$. The plot of $v$ *vs.* $A$ in different reactant ratios is shown in Fig. 5. It shows that the larger $[KI]/[H_2O_2]$ is, the longer the time is in which the reaction rate changed. Obviously the

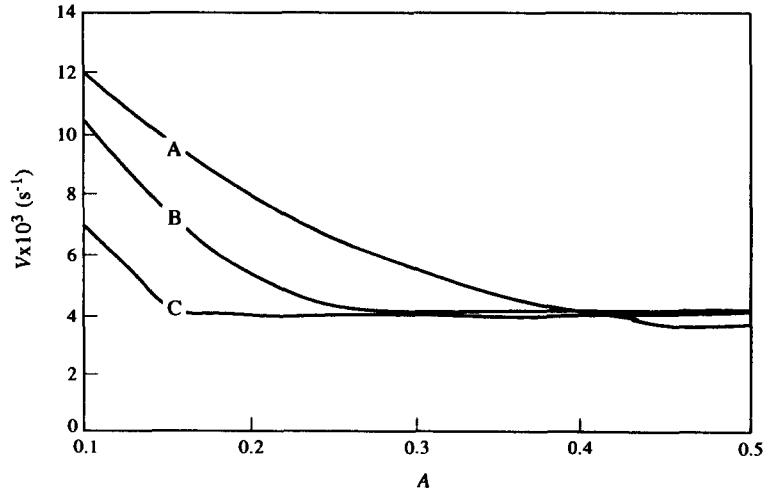

Fig. 5. Rate spectra of Cr-catalyzed reaction at different initial concentration ratios. $[Cr] = 6.41 \times 10^{-6}M$, $[H_2SO_4] = 7 \times 10^{-8}M$. (A) $[H_2O_2]$: $[KI] = 8:15$; (B) $[H_2O_2]$: $[KI] = 8:3$; (C) $[H_2O_2]$: $[KI] = 8:1$.

behavior of the kinetics of Cr and W are different only in the range of time in which the Cr-catalyzed reaction rate changed. So it is favorable to choose the reactant with high $[I^-]/[H_2O_2]$. The length of time in which the reaction rate changed increased with decreasing concentration of $H_2SO_4$, so a low concentration of $H_2SO_4$ seems feasible. However, it is preferable to choose a suitable reaction rate, neither too fast nor too slow. Thus $7 \times 10^{-8}$, $4 \times 10^{-4}$ and $1.5 \times 10^{-8} M$, $H_2SO_4$, $H_2O_2$ and KI, respectively, are specified in the procedure.

*The rate spectrum range for calculations*

The data from $A = 0.1$–$0.34$ was used for calculations. The kinetic behavior of Cr- and W-catalyzed reaction was not additive in the range $A < 0.1$, because the induction time of W-catalyzed reaction was shortened when Cr was present. The difference in their kinetic behavior decreased with increasing $A$. In the range $A > 0.34$ the difference becomes indistinct.

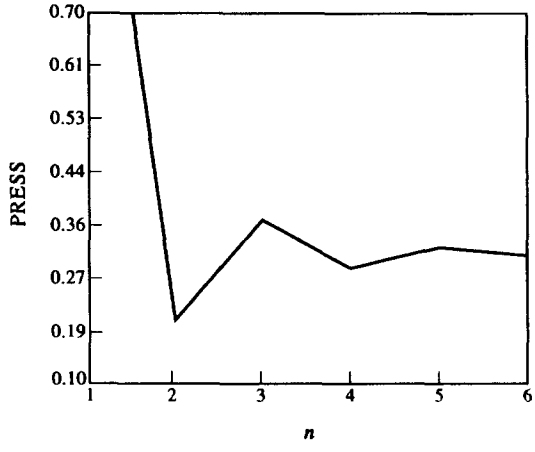

Fig. 6. Dependence of PRESS on number of principal components.

*Error caused by calculation*

The error due to calculation was investigated by computer simulation. Suppose the catalytic effect of the two catalysts $c_1$ and $c_2$ are additive, and the absorbance $A$ is used instead of the concentration of reactant, the rate equation of the mixture can be written as:

$$-dA/dt = k_{11} c_1 A (k_{12} + A) + k_{21} c_2 (A + k_{22}) + k_0, \quad (9)$$

where $k_{11}, k_{12}, k_{21}, k_{22}$ and $k_0$ are constants. After integrating we have $A = f(t, c_1, c_2)$.

Synthetic data sets were obtained using equation (4) and the values of $c_1$, $c_2$ are given in Table 1, $\Delta t = 10$ sec. A set of $A$ at different times was obtained, and the plot of $A$ *vs.* $t$ was set up. Then the rate spectrum and the PCR were calculated by the methods described in data processing. The results are shown in

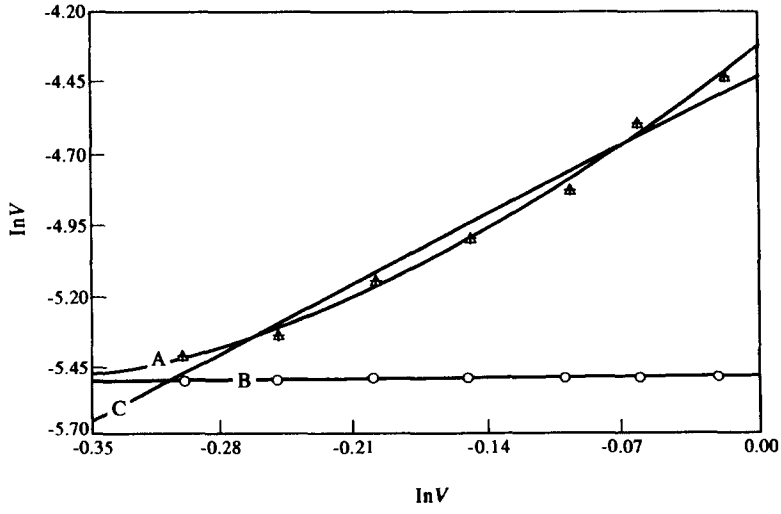

Fig. 7. ln $t$–ln $A$ relationship curves. (A) Cr; (B) W; (C) linear fit of A.

Table 2. The maximum relative error was 0.9%. Thus the error caused by calculation is small compared with the error derived from the experiment.

*Number of principal components*

The number of the principal component can be obtained by cross-validation. The plot of prediction residual sum of squares (PRESS) *vs.* number of components ($n$) is shown in Fig. 6. $n$ is specified as 2 when PRESS gets to its minimum.

*Comparison of the PCR method with multiple linear regression*

The MLR method was described in detail in Ref. 11. When taking the logarithm, equation (4) becomes:

$$\ln v_i = \ln k_i'' + p_i' \ln[\mathrm{A}] + \ln[\mathrm{C}_i], \qquad (10)$$

$p_i'$ and $k_i''$ can be obtained from the plot of $\ln v_i$ *vs.* ln[A] by calibration with standard solutions of $C_i$. For a two-component mixture,

$$v = \Sigma k_i''[\mathrm{A}]^{p_i'}[\mathrm{C}_i] = \Sigma r_i[\mathrm{A}]^{p_i'}, \qquad (11)$$

$r_1$ and $r_2$ can be obtained by two linear regressions of $v$ *vs.* $[\mathrm{A}]^{p_1}$ and $[\mathrm{A}]^{p_2}$ and $[C_i]$ can be solved from $r_i$ and $k_i''$. The prerequisite condition for using this method (MLR) is that the apparent reaction order for each catalyst should be kept constant during the reaction, because accurate data of the parameters $p_i'$ and $k_i''$ can be obtained only if the plot of $\ln v_i$ *vs.* $\ln A$ is linear. The plot of $\ln v$ *vs.* $\ln A$ of both catalysts is shown in Fig. 7. As shown, the plot of the Cr-catalyzed reaction is nonlinear. The parameters give a large error and, consequently, the error of the simultaneous determination of Cr and W is large. However, this is not the case for PCR. When PCR is used, the concentration of both catalysts can be solved from equation (8) which is based on the rate matrix [V] and can be set up using the reaction rate data $v_j$ at several different concentrations of A for each sample as a vector, just as the absorbance matrix set up by the absorbance data at different $\lambda$ in spectrophotometry. One advantage is that it is not necessary to obtain the exact mathematical form of $v$ as the function of [A] and to obtain the parameters $k_i''$ and $p_i'$ in advance; the other is that it can be used whether the apparent reaction order is kept constant or not. As the apparent reaction order for most catalytic reaction is frequently not constant during the changing of the reactant concentration in the reaction, PCR is more suitable for simultaneous determination in kinetics.

Some synthetic samples were prepared and the data were treated with the PCR and MLR[8] methods. The results of analyses with both methods are listed in Table 3. It can be seen that the error of MLR is larger than that of PCR because the $\ln v/\ln A$ plot of the Cr-catalyzed reaction is not linear.

# ON-LINE SORBENT EXTRACTION, PRECONCENTRATION AND DETERMINATION OF LEAD BY ATOMIC ABSORPTION SPECTROMETRY

YANEIRA PETIT DE PEÑA,* MERCEDES GALLEGO and MIGUEL VALCÁRCEL†

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

(*Received* 10 *March* 1994. *Revised* 12 *July* 1994. *Accepted* 1 *August* 1994)

**Summary**—A method for the quantitative preconcentration of lead based on an existing batch process was developed for implementation in a flow system including a flame AAS detector. Lead can be quantitatively preconcentrated as pyrrolidinedithiocarbamate or dithizonate on an activated carbon minicolumn. The chelates are eluted in methyl isobutyl ketone and introduced directly into the nebuliser-burner. An enrichment factor of 50 is typically obtained for a preconcentration time of 2 min (lead can be determined at concentrations between 15 and 400 ng/ml), which results in a throughput of *ca.* 25 samples per hr. The sensitivity achieved with the two reagents is similar, but the selectivity provided by APDC exceeds that of dithizone. Based on the results obtained in the determination of lead in reference materials (minerals and skim milk), the proposed APDC method is applicable to real samples.

Analytical separation techniques play a central role in today's analytical chemistry. They are typically used to enrich one of the sample fractions with a given component in trace analyses, as well as to remove complex matrices for enhanced sensitivity or selectivity, respectively, in common place analytical methods. The preconcentration technique has been used to improve the sensitivity and selectivity of trace analyses by replacing the original sample matrix with a new, non-interfering matrix. The enrichment technique has often been used to collect trace elements on solid surfaces;[1] activated carbon can also be used for the preconcentration of trace elements from acid sample solutions provided the trace elements concerned form neutral chelates in the acid medium. Thus, ammonium pyrrolidinedithiocarbamate (APDC),[2] 8-hidroxyquinoline,[3] potassium ethyl xanthate,[4,5] dithizone,[6] Chrome Azurol S[7] and the ammonium salt of the dithiophosphoric acid *o*-*o*-diethylester,[8] have all been used for chelation of trace metals and back-collection on activated carbon following desorption in a small volume of acid for subsequent measurement of the metal concentration by atomic absorption spectrometry (AAS) or ICP-AES.

On-line preconcentration systems have been used in conjunction with AAS for the determination of lead. Thus, lead traces in tap water can be preconcentrated by using a continuous precipitation–dissolution system[9] and a method based on lead precipitation with ammonia and subsequent dissolution of the precipitate (retained on a filter) with a nitric acid stream; preconcentration factors of up to 700 can thus be achieved with a 250-ml volume. Lead can also be coprecipitated with the iron(II)-hexahydroazepinium hexahydroazepin-1-ylformate complex, collected in a knotted reactor, and dissolved in methyl isobutyl ketone; an enrichment factor of 20 can thus be obtained with 2 ml of sample.[10] Various organic reagents have been used in non-immobilized forms for the extraction of lead as a chelate from aqueous samples. The chelate is sorbed on $C_{18}$ bonded silica and then eluted with methanol; the preconcentration factor thus achieved is 5.3 for 1 ml of sample.[11] A sorbent extraction system including a $C_{18}$ column was also used for the determination of traces of lead and other metals by use of diethyldithiocarbamate and ethanol as chelating agent and eluent, respectively;[12] the sensitivity of the graphite furnace technique was enhanced by a factor of *ca.* 20 for a

40-$\mu$l injected volume with only 3 ml of sample. Lead traces were preconcentrated on a column packed with alga immobilized on controlled pore glass, and eluted with nitric acid to obtain a detection limit of 2.5 ng/ml lead with the sole interference of mercury.[13] A cellulose collector containing immobilized triethylenetetraminepentaacetic acid groups was developed for multi-element preconcentration;[14] however, the recoveries obtained were influenced by inorganic and organic substances present in aquatic samples.

Dithizone is one of the few chelating agents that permits the separation of trace metals from acid solutions; on the other hand, APDC is a chelating agent usually employed for preconcentration of metals in FAAS. Both reagents were previously used for trace enrichment of lead by using a flow system similar to that described above for the preconcentration and determination of copper in water.[15] In the proposed method, the lead chelate is quantitatively preconcentrated on a miniature column packed with activated carbon, prior to its determination by FAAS. The analyte is eluted quantitatively from the column with 200 $\mu$l of methyl isobutyl ketone (MIBK); no dispersion occurs during transfer of the eluate because a water stream is used as the carrier. The time-based sampling mode allows the preconcentration factor to be further increased through an increased analyte volume. The accuracy of the results obtained with APDC was checked by using it to analyse reference materials.

## EXPERIMENTAL

### *Apparatus*

A Perkin-Elmer 380 atomic absorption spectrometer equipped with a bead impact system in the burner chamber and a hollow cathode lead lamp was used. The wavelength and lamp current used were 283.3 nm and 10 mA, respectively. Deuterium arc background correction was employed throughout. The acetylene flow rate was 2.0 l./min and an air flow rate of 21.5 l./min was employed to ensure a clean blue flame. The spectrometer output was connected to a Radiometer REC-80 Servograph recorder. The flow manifold comprised a Gilson-Minipuls-2 peristaltic pump furnished with poly (vinyl chloride) tubes, two Rheodyne 5041 injection valves and a laboratory-made adsorption minicolumn packed with 70 mg of activated carbon. The minicolumn (2.5 cm long $\times$ 3 mm i.d.) was made of PTFE capillary and sealed on one end with a small glass wool bed to prevent material losses. The column was initially flushed with 0.1 mol/l. nitric acid and the subsequent use of methyl isobutyl ketone as eluent in each operational cycle was sufficient to make it ready for re-use. A Hetosicc CD 53-1 Freeze Dryer was also employed.

### *Reagents and standards*

A 1000 mg/l. lead stock solution was prepared by dissolving 1.598 g of lead nitrate in $14.4 \times 10^{-2}M$ nitric acid and diluting to 1 l. with $14.4 \times 10^{-2}M$ nitric acid. Freshly prepared 0.1% (w/v) ammonium pyrrolidinedithiocarbamate (Aldrich, Germany) was also used. A saturated solution of dithizone (Riedel, Germany) was prepared as follows: 4 mg of dithizone was shaken electromagnetically in a 100 ml vessel containing 50 ml of $0.4M$ ammonia for 3 min; the solution was then filtered and the filtrate diluted with water in a 100-ml calibrated flask. Methyl isobutyl ketone (Probus, Spain) was also used. Darco 20-40 activated carbon (Aldrich, Germany) and polygosyl bonded silica reversed-phase sorbent containing octadecyl functional groups (RP-$C_{18}$), 60–100 $\mu$m particle size, from Waters (Millipore, Spain), were employed as sorbents. Standard solutions (100 ml) containing 15–400 ng/ml lead were all freshly prepared in $0.1M$ or $0.01M$ nitric acid by appropriate dilution of a stock standard solution (1000 mg/l).

### *Preparation of samples*

Several reference materials were analysed; minerals were supplied by the Bureau of Analysed Samples (BAS, U.K.) and were Standard Reference Materials (SRM) No. 70b, 41dG and 5g, while the skim milk powder was obtained from the Community Bureau of Reference (BCR) and was material No. 150. The reference standards were dried to constant weight by freeze-drying at 6 Pa (0.04 mm Hg) in the case of spiked skim milk powder and by heating in a furnace at 150°C for 24 hr in the case of the mineral reference materials. Once dry, an accurately weighed amount of *ca.* 50–100 mg (minerals) or 4 g (spiked skim milk powder) was mineralized in a glass vessel as follows: zinc concentrate and lead–vanadium concentrate were mixed with 5 ml of $14.4M$ nitric acid and 2.5 ml of $11.2M$ hydrochloric acid; brass and spiked skim milk powder were mixed with 5 and 20 ml of $14.4M$ nitric

acid, respectively. The vessels were heated at *ca.* 180–200°C in a sand bath until the samples were completely dissolved and nitrogen fumes were given off. The vessels were then allowed to cool and the digestion procedure was repeated (about five times) with multiple additions of the acids until a clear solution remained and nitrogen oxide fumes ceased to evolve. Once cold, the solutions were quantitatively transferred into volumetric flasks of 50, 100 or 500 ml capacity and made to volume with ultrapure (Milli Q) water. Reagent blanks were also prepared in parallel. Sub-samples of 0.5–1 ml (for all minerals) were diluted to 100 or 250 ml, adjusted to pH 1.0 with 2*M* nitric acid and immediately analysed by introducing them into the manifold shown in Fig. 1. The spiked skim milk powder required no further dilution.

*Procedure*

The flow manifold depicted in Fig. 1 was employed for the continuous preconcentration and determination of lead. It operated as follows: the standard or sample solution, containing 15–400 ng/ml of Pb(II) in 0.1*M* (for APDC) or 0.01*M* (for dithizone) nitric acid, was continuously pumped through the system for 2 min and thoroughly mixed with the chelating reagent (0.1% APDC or saturated dithizone in 0.2*M* ammonia). The chelate was retained on the activated carbon minicolumn located in the loop of the injection valve and the sample matrix was driven to waste (W). During the preconcentration step, a water carrier was pumped to the instrument in order to flush the nebuliser after each measurement. In the elution step, both injection valves were switched simultaneously, so 200 $\mu$l of MIBK solvent was passed through the adsorbed chelate to desorb it and sweep the lead to the detector. Peak heights were used as analytical measurements and a blank consisting of 200 $\mu$l of MIBK injected prior to sample preconcentration was also used ($A \simeq 0.020$ units).

## RESULTS AND DISCUSSION

The two reagents, *viz.* 0.1% (w/v) APDC and a saturated dithizone solution in ammonia (4 mg in 100 ml of 0.2*M* ammonia), were tested for lead preconcentration in an acid medium. Elution of the adsorbed chelate from the column was assayed with several organic solvents (ethanol, acetone, 1,2-dichloroethane and MIBK) in an automated configuration similar to that depicted in Fig. 1, and 6.0 ml of standard containing 200 ng/ml of Pb(II) in 0.1*M* and 0.01*M* nitric acid for complexation with APDC and dithizone, respectively, was used. The injected eluent volume was 200 $\mu$l in all instances. The best results (difference between sample and blank signals) were provided by MIBK because the chelate was the easiest to dissolve and hence to desorb; in addition, the blank signal (0.020 units) was the lowest and no dispersion was observed during transfer to the detector since MIBK is water-immiscible. Other extractants provided worse results, either because they water-miscible and the plug dispersed to some extent or because the chelate could not be dissolved. Peak height was selected as the analytical measurement because elution with MIBK was quantitative in 200 $\mu$l of solvent.

*Optimization of experimental variables*

The experimental procedure was optimized by using the univariate method. Chemical variables were studied first; for this purpose, a standard solution containing 100 ng/ml lead was continuously introduced into the flow system. A time-based technique equivalent to using only 6.0 ml of sample (sample flow rate, 3.0 ml/min; pumping time, 2 min) was chosen. The effect of the sample pH, adjusted with dilute nitric acid, was studied between 0.5 and 4.0. The maximum chelate adsorption was achieved at

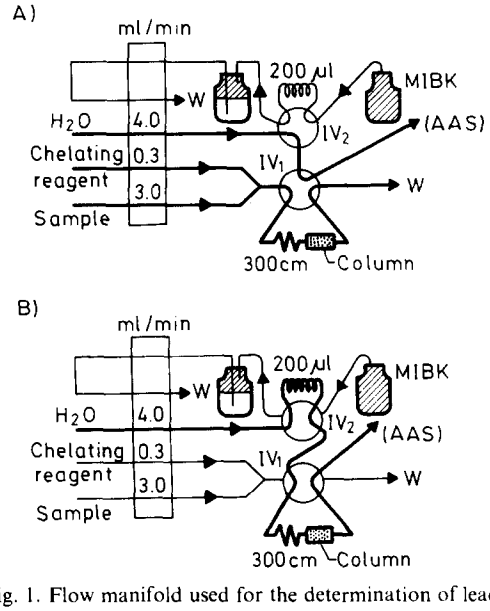

Fig. 1. Flow manifold used for the determination of lead at low concentrations. Bold lines represent channels relevant to the adsorption (A) and elution (B) step. IV, Injection valve; W, waste; MIBK, methyl isobutyl ketone; AAS, atomic absorption spectrometer.

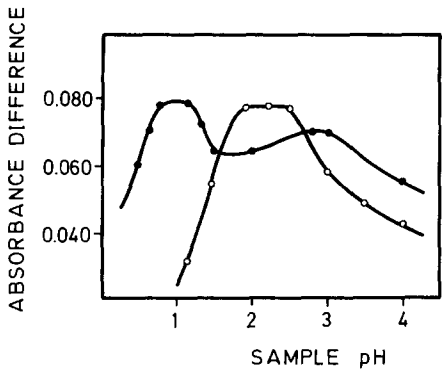

Fig. 2. Effect of pH on lead absorbance following on-line preconcentration with APDC (●) or dithizone (○). Analyte concentration, 100 ng/ml lead.

pH 0.8–1.1 and 1.9–2.5 for APDC and dithizone, respectively (Fig. 2). A further plateau was obtained near pH 3 for APDC that was 10% lower than the first plateau. The influence of various acids used to adjust the sample pH was also studied by using samples containing 100 ng/ml lead at pH 1 and 2 for APDC and dithizone, respectively, adjusted with nitric, hydrochloric and sulphuric acid; the absorbance in hydrochloric and sulphuric acid was 70 and 45% lower, respectively, than that nitric acid, probably because the presence of chloride and sulphate anions hindered the chelate formation by precipitation of their inorganic lead salts. Previous experiments involving a similar flow system[15] had shown the Cu–APDC chelate to be adsorbed as a soluble, precipitated chelate on an activated carbon minicolumn (which acted as a mixing filter/adsorption device); the adsorption increased relative to lead in inorganic salts as a result. Therefore, 0.1 or 0.01*M* nitric acid for APDC or dithizone, respectively, was selected as the optimal medium for sample preparation. The effect of the APDC concentration was studied in the range of 0.001–0.5%; the analytical signal remained constant above 0.05%, so a 0.1% concentration of APDC in water was chosen. The effect of the dithizone concentration was studied in the range $4 \times 10^{-5}$–$4 \times 10^{-4}M$ by dissolving different amounts of the reagent (1–10 mg) in 100 ml of 0.1–0.4*M* ammonia. The signal increased with increasing dithizone concentration up to $1.5 \times 10^{-4}M$ (4 mg of dithizone in 100 ml), above which it remained constant because the solution was saturated; the signal also increased with increasing ammonia concentration up to 0.2*M* at any of the dithizone concentrations tested, but decreased at higher ammonia concentrations through neutralization of the sample. The effect of the dithizone and ammonia concentrations on the lead analytical signal is shown graphically as a three dimensional plot in Fig. 3. Based on the response surface, a dithizone concentration of $1.5 \times 10^{-4}M$ (4 mg in 100 ml) in 0.2*M* ammonia was an experimentally realistic condition, so it was selected for subsequent experiments. Replacing the sample stream with 0.1 or 0.01*M* nitric acid (blanks) or the chelating reagent stream with a water stream (the sample was also circulated) resulted in a similar absorbance in the elution step as that obtained by successively injecting 200 $\mu$l of MIBK solvent before the preconcentration step; no blank was therefore required, and the sample absorbance was obtained by difference from the extractant signal ($A \simeq 0.020$ units).

The flow-rate of sample (6.0 ml of a solution containing 100 ng/ml lead), the effect of which was studied between 0.6 and 4.0 ml/min, resulted in very small variations over the range 1.5–3.0 ml/min. Above 3.0 ml/min, the analytical signal decreased because the residence time also decreased. Increasing the chelating reagent (APDC or dithizone) flow-rate, which was equivalent to increasing the reagent concentration, resulted in concomitant sample dilution and hence in decreased atomic signals. A reagent flow-rate of 0.3 ml/min and a sample flow-rate of 3.0 ml/min were chosen as compromises. The influence of the length of the preconcentration coil (located in the loop of the

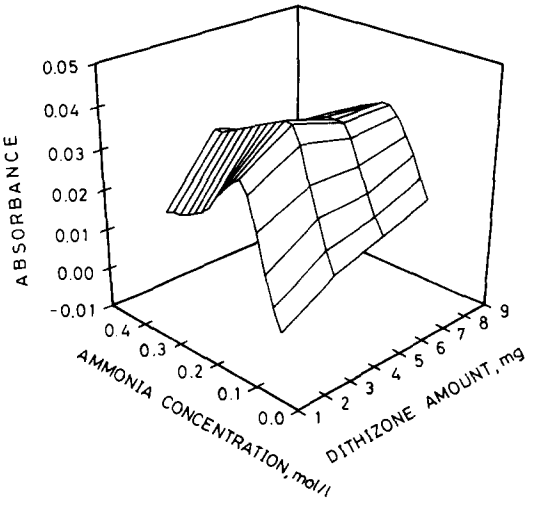

Fig. 3. Response surface for the determination of 50 ng/ml lead at pH 2 and different dithizone and ammonia concentrations.

injection valve before the activated carbon minicolumn) was investigated over the range 50–450 cm (0.5 mm i.d.) by using both chelating reagents. Maximum adsorption was achieved in both instances by using a 300–350 cm preconcentration coil. With coils longer than 350 cm, the chelate formed was carried along the system and probably adsorbed on the inner walls of the PTFE tubing, so it was incompletely dissolved by the injected MIBK, thereby resulting in diminished signals. The effect of the MIBK volume was studied between 25 and 300 $\mu$l. The adsorbed chelate was eluted throughout this range, but some carry-over (incomplete elution) was observed with volumes below 200 $\mu$l. On the other hand, volumes above 200 $\mu$l caused the signal to decrease through dispersion of the analyte in the organic solvent. Based on the above results, flow variables affect the determination of lead to the same extent, whichever chelating agent (APDC or dithizone) is used; therefore, the same flow system can be used for both reagents. A 300 cm long reaction coil (0.5 mm i.d.) and an injected MIBK volume of 200 $\mu$l were selected as optimal for the preconcentration/determination of lead.

*Analytical features*

Several calibration graphs were constructed by introducing the MIBK eluate from the activated carbon minicolumn into the flame using aqueous standard solutions processed along the preconcentration flow system depicted in Fig. 1. Table 1 lists the figures of merit of the graphs and the analytical features of the determination of lead(II) in the range 15–400 ng/ml with a time-based sampling for 2 min, equivalent to a sample volume of 6.0 ml (sample flow-rate, 3.0 ml/min). The detection limit was calculated as three-fold the standard deviation of the peak absorbance for 15 injections of 200 $\mu$l of MIBK (blank). The precision achieved with APDC and dithizone (as relative standard deviation) was checked on 11 standard solutions containing 50 ng/ml lead each.

Automatic preconcentration methods for the determination of lead by AAS are based on sorbent preconcentration by use of minicolumns packed with reversed-phase silica sorbent (RP-$C_{18}$); therefore, a comparative study of the chelate retention on a RP-$C_{18}$ minicolumn was performed. The RP-$C_{18}$ minicolumn was packed with 70 mg, as was the activated carbon minicolumn. The characteristic parameters for the calibration graphs obtained with APDC and dithizone are listed in Table 1. The results allow one to draw the following conclusions: (1) the sensitivity of the method (slope of the calibration graph) does not depend on the chelating reagent used (APDC or dithizone), but only slightly on the minicolumn packing material (thus, it was higher for activated carbon than for RP-$C_{18}$ by a factor of 1.14); (2) the precision was 3.0% or better in all instances; (3) a preconcentration factor of up to 110, calculated as the ratio between the slopes of the calibration graphs obtained with dithizone for a sampling time of 5 min (*i.e.* a sample volume of 15 ml), whether by using the activated carbon minicolumn or by direct aspiration ($A = 0.003 + 1.6 \times 10^{-5}$ [$Pb^{2+}$], lead being given in ng/ml), was achieved.

*Study of interferences*

Under the optimal chemical conditions, the manifold depicted in Fig. 1, an activated carbon minicolumn and a sample volume of 6 ml (sampling time, 2 min) were used to carry out an exhaustive study of potential interferences with both chelating reagents. In previous work,[15] APDC was used for the quantitative preconcentration of copper at pH 1 in the presence of several cations; only $Co^{2+}$ and $Ni^{2+}$ were found to interfere at concentrations 10 times higher than that of Cu. Also, dithizone was found to be less selective than APDC, so it must be subject to a great number of interferences. By using both reagents, the effect of $Zn^{2+}$, $Co^{2+}$,

‡Sampling time 5 min.

$Cu^{2+}$, $Cd^{2+}$, $Hg^{2+}$, $Ni^{2+}$, $Sn^{2+}$, $Fe^{3+}$, $Bi^{3+}$, $Al^{3+}$, and $Mn^{2+}$ was checked. Table 2 lists the tolerated levels of foreign cations for APDC and dithizone. APDC is the better choice for preconcentration of lead because of its higher selectivity relative to dithizone. In fact, with APDC, only $Cd^{2+}$, $Bi^{3+}$, $Ni^{2+}$ and $Hg^{2+}$ interfered at low concentrations (tolerated ratio lower than 5). Zinc(II) was the ion causing the most markedly different effect on the two reagents; thus, it interfered at the same concentration as lead with dithizone but did not interfere at concentrations up to 20 $\mu$g/ml with APDC for 100 ng/ml lead (*i.e.* a Zn/Pb ratio of 200:1). The interference decreased the lead signal in all instances. The effect can be ascribed to the chelating reagent concentration being inadequate for the lead and interferent chelates to be formed (that of the species present at the higher concentration would be preferentially formed); otherwise (if the chelating agent concentration were sufficient and both chelates were formed), the eluent volume used (200 $\mu$l of MIBK) may be inadequate to fully elute the chelates from the minicolumn. In conclusion, dithizone is a scarcely selective reagent for lead determination.

*Determination of lead in reference materials*

The accuracy of the proposed method using APDC for the analysis of reference materials with high metals contents was tested in the determination of lead. Each sample was mineralized in duplicate (in triplicate for the skim milk sample) as described under "sample preparation", together with a similarly prepared blank which allowed the contribution of lead ion present in the reagents to the digestion sample used to be assessed. Each dissolved sample was analysed in triplicate. Blank absorbances corresponded to a lead concentration below the detection limit (10 ng/ml). The results are shown in Table 3. Consistency between the results obtained with the proposed APDC method and the certified values was acceptable in all instances.

Table 2. Tolerated concentrations of foreign cations in the determination of 50 or 100 ng/ml lead with dithizone or APDC method, respectively

| Foreign cation | Tolerated amount (*ng/ml*) Dithizone | APDC |

| $Co^{2+}$ | 50 | 10,000 |
| $Zn^{2+}$ | <50 | 20,000 |

## CONCLUSIONS

Two classical chelating reagents were tested for the preconcentration of lead by adsorption of their chelates on an activated carbon minicolumn. APDC was found to be more selective than dithizone for the determination of lead, probably because the APDC chelate is formed at a lower pH than is the dithizone chelate. Table 4 summarizes the features of alternative preconcentration flow methods for the determination of lead by atomic spectroscopy. Two types of column packing materials were tested for lead preconcentration and matrix removal, *viz.* ion exchangers and sorbent materials such as silica gel $C_{18}$ (no reference has so far been reported to the use of an activated carbon minicolumn for this purpose). The eluting solvent materials used in all of ion-exchange and sorbent-extraction applications are water-miscible, so they result in higher dispersion of eluted lead during transfer to the detector. The preconcentration factors achieved range from 20 to 500; higher preconcentration factors call for larger sample volumes and hence longer sampling times, to the detriment of sample throughput. The preconcentration limit is seemingly determined by the availability of sample solution and the operator's patience. The precision (as RSD) achieved is quite acceptable in all instances. As regards application, all the methods listed in Table 4 were applied to water samples (there are only three uses for soldering smoke, urine and biological materials). The main differences between the proposed method

and existing alternatives using $C_{18}$ minicolumns lie in the preconcentration step, during which both the sample matrix and the eluent are sent to waste in our method; also, the eluent (MIBK) is water-immiscible, so the analyte is not dispersed on transfer to the instrument nebuliser. Finally, the methods listed in Table 4 are generally used for preconcentration and determination of heavy metal (none was investigated in relation to the potential interference of lead).

# MECHANISTIC STUDIES OF METAL ION BINDING TO WATER-SOLUBLE POLYMERS USING POTENTIOMETRY

NEIL V. JARVIS and JUDITH M. WAGENER

Department of Process Technology, Atomic Energy Corporation of South Africa Ltd, P.O. Box 582, Pretoria, 0001, South Africa

(*Received* 15 *March* 1994. *Revised* 20 *June* 1994. *Accepted* 7 *July* 1994)

**Summary**—A method for elucidating metal ion binding mechanisms with water-soluble polymers has been developed in which the polymer is treated as a collection of monomeric units. Data obtained from potentiometric titrations are analysed by the ESTA library of programs and apparent formation constants may be calculated. From this information, predictions may be made as to metal ion separation using complexation–ultrafiltration techniques. The polymer used in this study was Polymin Water-Free and its complexation with Hg(II), Cd(II), Pb(II), Co(II) and Ni(II) was successfully modelled.

Interest in the use of water-soluble polymers in conjuction with ultrafiltration membranes to separate metal ions from aqueous solutions has steadily grown since the work of Geckeler *et al.* was published in the early eighties.[1] The possibility of synthesizing derivatives of commercially available water-soluble polymers such as polyethyleneimine, in order to achieve selective metal ion complexation, was recognized early on. A wide range of applications have been investigated[2] including the nuclear industry[3] and the removal of toxic heavy metal ions such as Pb(II), Cd(II) and Hg(II).[4] As the field of ligand design produces more complicated and selective complexing agents, it has become an attractive option to attach these reagents to polymer backbones in order to minimize losses of expensive compounds.

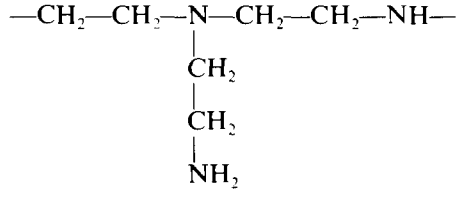
At this time, little effort has gone into the understanding of metal ion complexation mechanisms of water-soluble polymers in aqueous solution. Recent work by Rumeau *et al.*[2] used potentiometry to calculate stability constants of these polymers with metal ions. We have developed a method to elucidate metal ion bonding mechanisms to chelating resins using two-phase potentiometry.[5] In this paper, we extend this method to water-soluble polymers (although the term "two-phase" may not be entirely applicable here). The repeating unit of the polymer is considered to be the ligand and potentiometric data are submitted to the ESTA library of programs.[6] Apparent formation constants may be accurately calculated and this allows predictions to be made on metal ion separation.

The complexation of Hg(II), Cd(II) and Pb(II) were studied and comparisons could be made with previous ultrafiltration studies.[4] The complexation of Co(II) and Ni(II) were also studied in order to make predictions as to the possible use of complexation–ultrafiltration as a method to separate these two metal ions.

## EXPERIMENTAL

### *Reagents*

Polymin* Water-Free, a polyethyleneimine product in which the ratio of primary, secondary and tertiary amine groups is 1:1:1, was obtained from BASF and used as received. The repeating unit is as follows:[1]



All other reagents used were of analytical grade. Where necessary, metal ion solutions were acidified to prevent hydrolysis and standardized by ICP. Standardized sodium hydroxide solutions were obtained by using Merck Titrisol ampoules.

*Polymin is a registered trademark of the BASF company.

*Potentiometry and computing*

Titrations were performed by a Metrohm Titroprocessor 670 using a Metrohm 665 dosimat and a Metrohm combination glass electrode. The titration solutions were contained in a jacketed vessel through which water at $25 \pm 0.1°C$ was circulated from a Grant W14 thermostatted bath. The compositions of the titration solutions are listed in Table 1. These were performed beginning at low and ending at high pH by the addition of $0.050M$ NaOH in $0.95M$ $NaNO_3$. All titration solutions were held at a constant ionic strength of $1.0M$ $NaNO_3$ and vigorously stirred. Nitrogen gas was bubbled through the solutions during the titrations. Under these conditions, it appeared as though equilibrium was attained within a number of minutes (stable EMF readings were obtained). The Titroprocessor was programmed not to add titrant until the electrode drift was less than 0.5 mV/min or a time of 10 min had elapsed. Most data points were obtained using the former criterion. The remaining points were given low weights by the program ESTA2A. Data were submitted to ESTA which was loaded on a mainframe computer. The above repeating unit of Polymin Water-Free was considered to be the ligand. The module ESTA0 was used to calculate the experimental protonation formation function, $\bar{Z}_H$ = the average number of protons bound per ligand; and the deprotonation function, $\bar{Q}$ = the average number of protons released on complexation per metal ion. Where these were insensible, the data points were rejected for refinement. All optimization was done using ESTA2A with the data weighted.[7] Apparent $pK_a$ values obtained in the titrations without metal ions were fixed during optimization of metal ion titrations. Hydrolysis constants and $pK_w$ were obtained from Smith and Martell[8] and also held constant. The electrode constant ($E_0$) was calculated regularly using a strong acid–base titration. Once a model had been obtained, ESTA2A was allowed to refine $E_0$ resulting in small changes with improved standard deviations for $\beta$ values and the Hamilton $R$-factor.

## RESULTS AND DISCUSSION

*Equilibrium modelling*

The results of modelling are given in Table 2. The low standard deviations of the $\beta$ values and Hamilton $R$-factors indicate the applicability of the method. Calculated and experimental formation and deprotonation curves were all in good agreement indicating that the chosen models were plausible.

*Protonation of Polymin Water-Free*

The protonation formation curves (Fig. 1) show no marked inflections indicating that the ligand's deprotonation reactions overlap in the pH region studied. From the species

*All data at 25°C in 1.0$M$ $NaNO_3$. p$K_w$ was fixed at 13.79 under these conditions.[8]
†In these equilibria, charges on metal ions, the ligand and complexes have been omitted for simplicity. L = Monomeric unit of Polymin Water-Free, M = metal ion, H = proton and OH = hydroxide ion.
‡Estimated from Ref. 8.

distribution plot (Fig. 2), it is clear that complete protonation of Polymin Water-Free does not occur in this pH region. This phenomenon has been previously reported.[9] Evidence for possible nearest neighbour interaction in which intramolecular hydrogen bonding is taking place, is given by the presence of species involving two repeating units. Alternatively, when

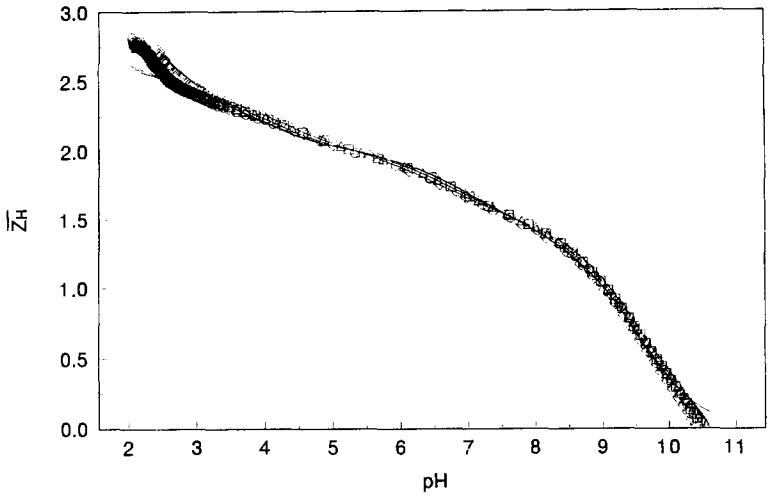

Fig. 1. Experimental (points) and modelled (lines) protonation formation curves for Polymin Water-Free. $\bar{Z}_H$ is the protonation formation function (the average number of protons bound per ligand) and pH is the negative logarithm of the free hydrogen ion concentration. The compositions of the solutions are in Table 1. The titrations are represented by (○) titration 1, (△) titration 2 and (□) titration 3. All solutions were at 25°C and 1.0*M* with respect to $NaNO_3$.

going from low to high pH, the sequence of deprotonation gives some insight as to what is happening at the molecular level. Species involving two repeating units are found between those involving one. This means that, when going from $H_3L$ to $H_2L$ or from $H_2L$ to HL, every second repeating unit becomes deprotonated in preference to each unit giving rise to the intermediate species $H_5L_2$ and $H_3L_2$, respectively. The species $H_6L_2$, $H_4L_2$ and $H_2L_2$, were also submitted to the model but were rejected with ESTA2A preferring to retain species with the same stoichiometric ratios but containing one repeating unit (i.e. $H_3L$, $H_2L$ and HL). Evidence for the species $HL_2$ could not be found.

## Hg(II), Cd(II) *and* Pb(II) *complexation by Polymin Water-Free*

The deprotonation curves (Figs 3–5) show good agreement between observed and calculated values. $\bar{Q}$ values for Hg(II) rise above zero, indicating complexation, at low pH. This is in contrast with Cd(II) and Pb(II) where $\bar{Q}$ becomes sensible above pH 5 and 6, respectively. Thus it may be seen that Hg(II) is more strongly complexed by Polymin Water-Free.

Interpretation of the $\bar{Q}$ curves is difficult—as is often the case. However, with the Hg(II) system, some prediction of complexes for the model is possible. It can be seen (Fig. 5) that at

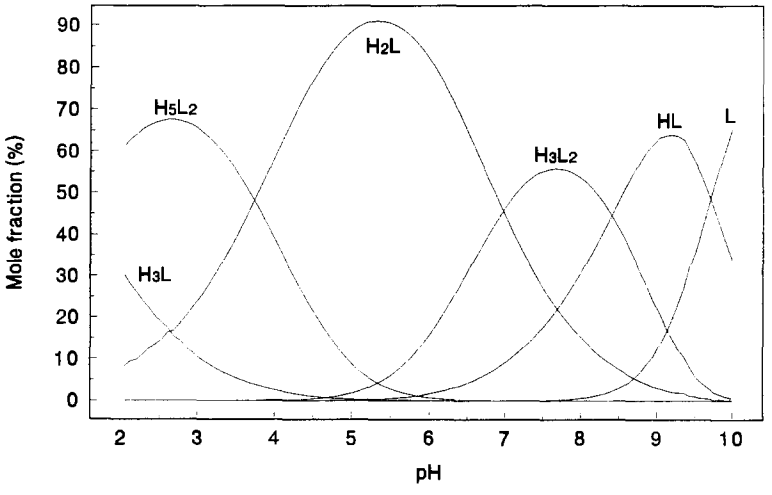

Fig. 2. Species distribution curves for the protonation of Polymin Water-Free at 25 C and 1.0*M* $NaNO_3$, as calculated from the apparent formation constants in Table 2.

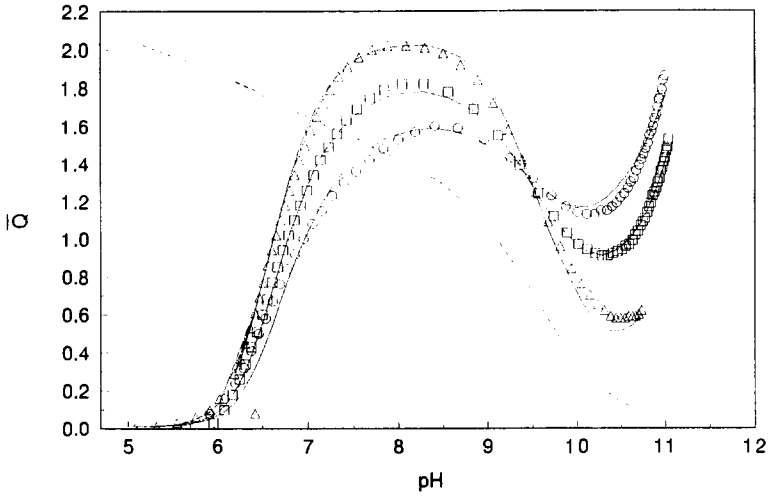

Fig. 3. Experimental (points) and modelled (lines) deprotonation curves for Pb(II) complexation by Polymin Water-Free. $\bar{Q}$ is the deprotonation function (the average number of protons released on complexation per metal ion). The dashed line is the $\bar{n}$ curve, where $\bar{n}$ is the protonation state of the ligand in the absence of the metal ion. The compositions of the solutions are in Table 1. The titrations are represented by (○) titration 1, (△) titration 2 and (□) titration 3. All solutions were at 25 °C and 1.0*M* with respect to $NaNO_3$.

pH 6, the dashed curve which represents $\bar{n}$, the protonation state of the ligand in the absence of the metal ion, is at a value of 2. At this point, $\bar{Q}$ has an inflection at 4. Therefore, the existence of a complex in which a total of five protons have been lost from the ligands in the complex per metal ion is possible. This corresponds to an $ML_2H$ species which was indeed found during modelling.

The $M_2L_3$ species in the Pb(II) system was essential for obtaining a good $\bar{Q}$ fit. The existence of this complex may be due to the large ionic radius of Pb(II) with a repeating unit preferring to bridge two Pb(II) ions.

Species involving one repeating unit in the Pb(II) system were not accepted into the model by ESTA2A. A possible explanation for this may be advanced from comparing the pH values in the deprotonation curves where $\bar{Q}$ rises above zero. It may be seen that Pb(II) is not as well complexed by Polymin Water-Free as Cd(II) or Hg(II). Complexation begins for Pb(II) at pH 6

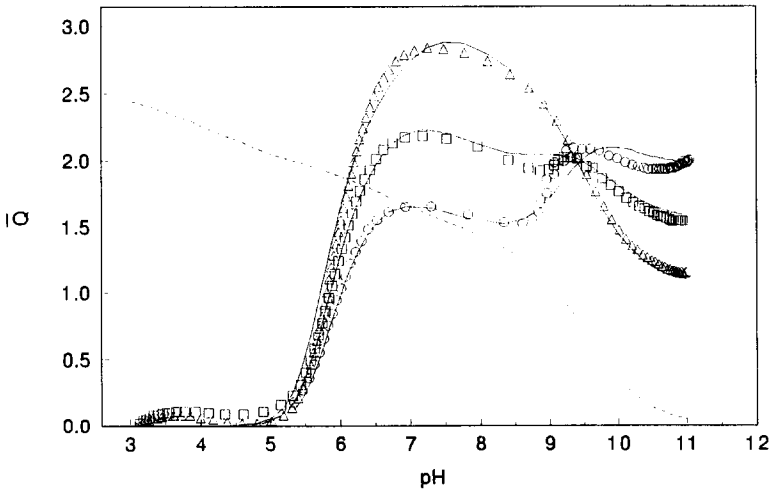

Fig. 4. Experimental (points) and modelled (lines) deprotonation curves for Cd(II) complexation by Polymin Water-Free. The compositions of the solutions are in Table 1. The titrations are represented by (○) titration 1, (△) titration 2 and (□) titration 3. All solutions were at 25 C and 1.0*M* with respect to $NaNO_3$.

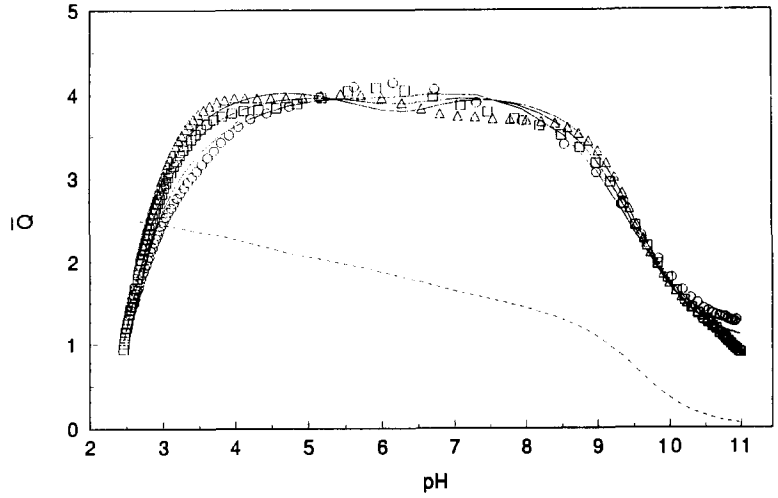

Fig. 5. Experimental (points) and modelled (lines) deprotonation curves for Hg(II) complexation by Polymin Water-Free. The compositions of the solutions are in Table 1. The titrations are represented by (○) titration 1, (△) titration 2 and (□) titration 3. All solutions were at 25°C and 1.0*M* with respect to $NaNO_3$.

where each repeating unit has already lost a proton hence making species involving two repeating units more possible. For Cd(II) and Hg(II) where complexation begins at pH 5 and below pH 2 respectively, species also involving only one repeating unit are possible.

The three metal ions are complexed over a wide pH range. Cd(II) and Pb(II) would be best removed at high pH by ultrafiltration. The pH dependence of Hg(II) removal would not be so critical. These observations are in complete agreement with the complexation–ultrafiltration work performed by Buckley and co-workers.[4]

### Co(II) *and* Ni(II) *complexation by Polymin Water-Free*

Ni(II) is somewhat better complexed by Polymin Water-Free than Co(II). This may be seen by comparing the deprotonation curves (Figs 6 and 7). This is a source of optimism that separation between these two metal ions may be achieved using complexation–ultrafiltration by carefully fixing the pH of the feed stream. However, a more complete picture is obtained by comparing species distribution curves generated by task SPEC in ESTA1. The Co(II)

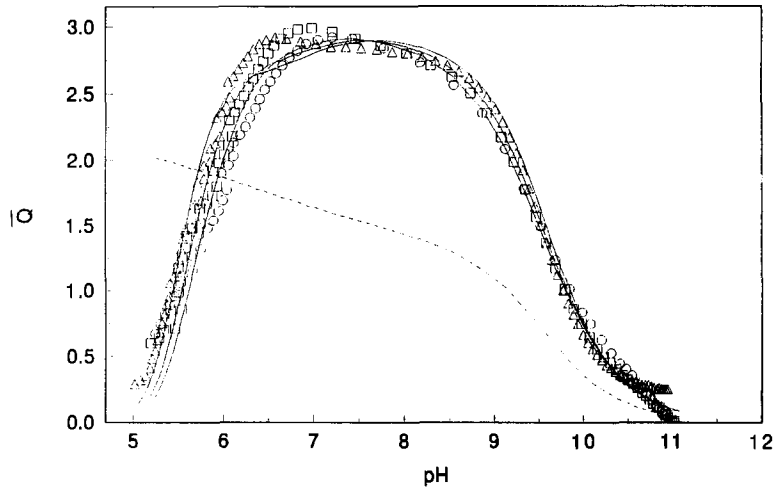

Fig. 6. Experimental (points) and modelled (lines) deprotonation curves for Co(II) complexation by Polymin Water-Free. The compositions of the solutions are in Table 1. The titrations are represented by (○) titration 1, (△) titration 2 and (□) titration 3. All solutions were at 25 C and 1.0*M* with respect to $NaNO_3$.

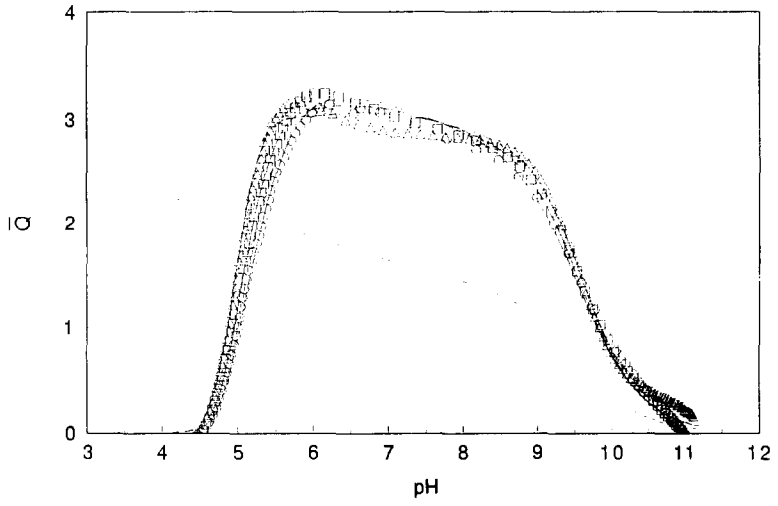

Fig. 7. Experimental (points) and modelled (lines) deprotonation curves for Ni(II) complexation by Polymin Water-Free. The compositions of the solutions are in Table 1. The titrations are represented by (○) titration 1, (△) titration 2 and (□) titration 3. All solutions were at 25 C and 1.0*M* with respect to $NaNO_3$.

system is shown as an example in Fig. 8. If only the curves representing the free metal ions are shown, then plots such as Fig. 9 may be obtained. Here it may be seen that these are close together, making separation difficult. It is, however, hoped that such plots may be used to predict the separation of other metal ions from one another using complexation–ultrafiltration.

For both Ni(II) and Co(II), the $ML_2$ and $ML_2H$ species retained by ESTA2A during modelling are consistent with the deprotonation curve information. It may be seen that $\bar{Q}$ reaches an inflection at roughly a value of three indicating that three protons have been lost on complexation per metal ion. At pH values around 7–8, $\bar{n}$ is close to 1.5. Thus for two repeating units, three protons are lost in the absence of the metal ions. The total number of protons lost for an $ML_2$ species is six which is consistent with the addition of $\bar{Q}$ plus 2 $x$ (total protons on completely protonated repeating unit, $\bar{n}$) which gives a value of six. At lower pH values, where $\bar{n}$ equals two, the same argument may be used to arrive at the $ML_2H$ species. This confirms the best-fitting model reported in Table 2. Species involving one repeating

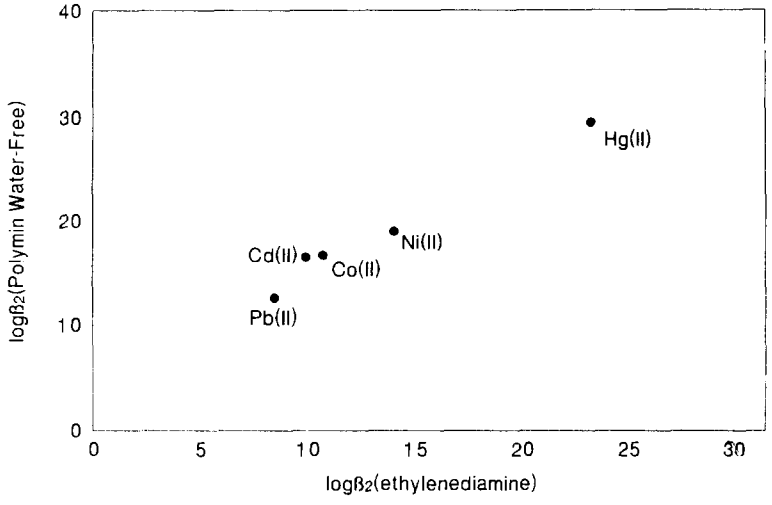

Fig. 10. Plot of $\log\beta_2$(Polymin Water-Free) *vs.* $\log\beta_2$ (ethylenediamine) for the metal ions studied in this paper.

unit were not accepted by ESTA2A into the model.

### *Linear free energy correlations*

A plot of $\log\beta_2$ (Polymin Water-Free) obtained in this study *vs.* $\log\beta_2$ (ethylenediamine)[8] shows a linear correlation (Fig. 10) for the metal ions studied. Such a correlation may be expected. The fact that this was indeed obtained is gratifying and lends credibility to the method of treating the polymer as a collection of monomeric units for modelling purposes.

*Acknowledgements*—The authors wish to thank the Atomic Energy Corporation for permission to publish this work and Annah Rangoaga for performing some of the potentiometric titrations.

(*Received* 22 *April* 1994. *Revised* 11 *July* 1994. *Accepted* 1 *August* 1994)

**Summary**—Oxidized glutathione (GSSG) can be determined after previous accumulation on the HMDE at $E > -0.2$ V (*vs.* the Ag/AgCl reference electrode). GSH is formed during the accumulation, possibly by a mercury-ion-assisted hydrolytic disproportionation of GSSG. In the subsequent cathodic scan GSH is released and catalyses the reduction of nickel ion, giving a peak located at $-0.6$ V. This enables the determination of GSSG by differential-pulse cathodic stripping voltammetry at pH 7.0 in the phosphate acetate or MOPS buffer containing 0.5–1.0 m*M* Ni(II). The detection limit is 10 n*M*. The calibration graph is linear even in the presence of small amounts of human serum albumin, HSA. However, HSA increases the detection limit (20 n*M* for $3 \times 10^{-4}$% HSA). Acetyl-cysteine in small excess or Cu(II) present as reagent impurity do not interfere. Glutathione, cysteine and similar compounds, which accumulate as mercury salts and form stable nickel complexes, will interfere. The method is put forward as a novel alternative stripping voltammetric method to those involving accumulation and determination as mercury or copper salts and complexes, in the knowledge that it may have advantages in particular analytical situations. In particular the method discriminates against compounds which accumulate as mercury salts but which do not form stable nickel complexes.

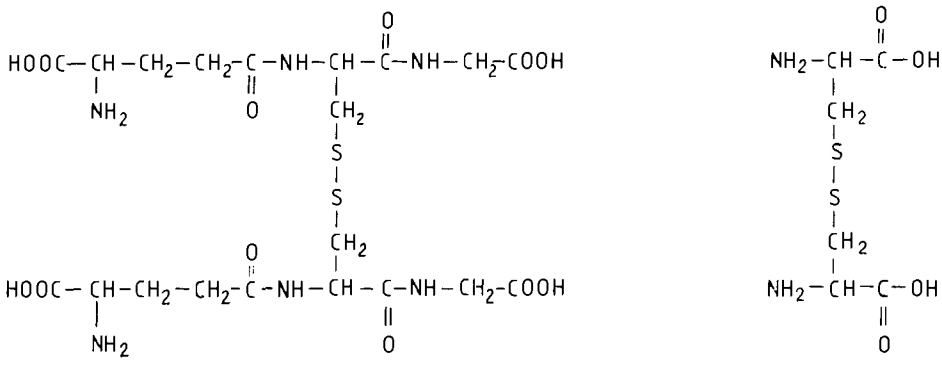
Oxidized glutathione (GSSG, formula I) is an important component of biological media, in close connection with its reduced form, GSH.[1] Owing to their outstanding biological importance, this couple has been extensively studied from both the biochemical and physico-chemical standpoints. The redox reaction (1) makes the electrochemical methods very useful for the investigation of its reactivity, as well as for the analytical determination.

$$GSSG + 2e^- + 2H^+ \rightarrow 2GSH. \qquad (1)$$

The results of early polarographic investigations on GSSG are summarized in Ref. 2. Accordingly, GSSG gives a single reduction wave with a pH-dependent half-wave potential ($E_{1/2} = -0.56$ V at pH 7). The shape of the wave, however, is not in accord with the equation derived under the assumption of a reversible reduction.

The advent of the new polarographic techniques renewed the interest in the polarography of this compound.[3] Particularly, cathodic stripping voltammetry (CSV) of GSSG appeared very promising. The best results are obtained if traces of Cu(II) are present.[4] From this point of view, GSSG mostly behaves as cystine (Cys, formula II).[5] The main characteristic is the breaking of the disulphide bridge during the accumulation step. The plated compound is a metal thiolate, the metal being either Hg(II) or Cu(I) [provided Cu(II) is present at the 50$\mu M$ level]. As in the case of GSH, the stripping peak is due to the reduction of the metal ion in the plated compound. The Cu(I) thiolate is reduced at more negative potentials as compared with the Hg analogue.[4-6]

Although very sensitive, the CSV of thiols and disulphides is less selective, because the accumulation step is based on the general property of cysteine-like compounds to act as monofunctional ligands (through the sulphydryl group) in the complexes with soft metals.[7] It was recently shown that a better selectivity could be achieved by CSV in the presence of nickel ion.[8,9] The analyte (CysH, Cys[8] or GSH[9] is accumulated on the mercury electrode at $E > -0.3$ V. During the subsequent cathodic scan, the thiol



I II

Formulas I and II

catalyses the reduction of Ni(II) giving a characteristic peak in differential-pulse cathodic stripping voltammetry (DPCSV). The same principles are applied in this paper aiming to find the best conditions for the determination of GSSG.

## EXPERIMENTAL

GSSG, GSH, Cys, *N*-acetylcysteine (AcCysH) and human serum albumin (HSA) were Sigma products. Two different buffer systems were used as supporting electrolyte: (1) the phosphate–acetate buffer (PA), which consists of $Na_2HPO4$ and $CH_3COONa$, 0.025*M* each. The pH was adjusted by proper additions of 10% $H_2SO_4$. (2) 0.05*M* 3-(*N*-morpholino)-propanesulphonic acid (MOPS), with the pH adjusted by 10% NaOH.

The Metrohm 663 VA stand in conjunction to the Metrohm 626 Polarecord were employed in the DPCSV experiments. Linear-sweep and cyclic voltammograms were recorded on a PAR 174 instrument. The working electrode was an HMDE (larger size available for the device employed). The cell also included an Ag/AgCl (3M KCl) reference electrode and a glassy carbon rod as auxiliary electrode. The working parameters were as follows: pulse height, 50 mV; pulse interval, 0.5 sec; scan rate, 10 mV/sec. During the pre-concentration step the test-solution was stirred by a Teflon rod usually at the medium speed. Oxygen was expelled by pure nitrogen. Other experimental details are given in Ref. 8.

## RESULTS

### *Behaviour of GSSG in the absence of nickel ion*

Since no previous data on the CSV of GSSG in the buffers here employed are available, its behaviour was tested by several preliminary experiments. Thus, the linear-sweep cathodic stripping voltammograms in Fig. 1 show that after accumulation for 1–2 min at −0.20 V, a cathodic peak forms at −0.47 V. The cyclic voltammogram recorded under similar conditions (Fig. 2) demonstrates that the height of the cathodic peak decreases for successive cycles. On the anodic side, a very small peak appears only during the first scan. It lies in the same potential range as the cathodic one.

The data in Figs 1 and 2 suggest that GSSG is accumulated on the HMDE at potentials close to 0.0 V. In accord with Ref. 4 it may be assumed that the disulphide splits during the plating step and the product of the anodic reaction is a mercury thiolate in the adsorbed state. At more negative potentials this product is reduced and simultaneously the free ligand thus produced desorbs and diffuses back into the bulk of the solution.

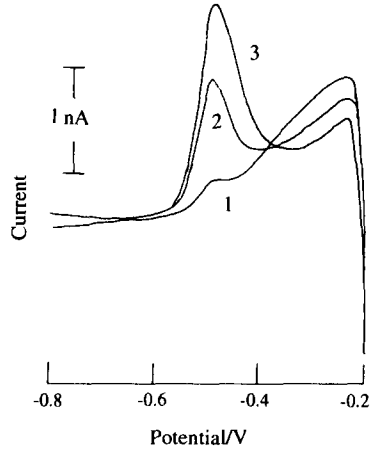


Fig. 1. Linear-sweep cathodic stripping voltammograms (scan-rate, 25 mV/sec) of GSSG (50 n*M*) in the PA buffer (pH 7). Accumulation time (at −0.20 V): (1) 0, (2) 1, (3) 2 min.

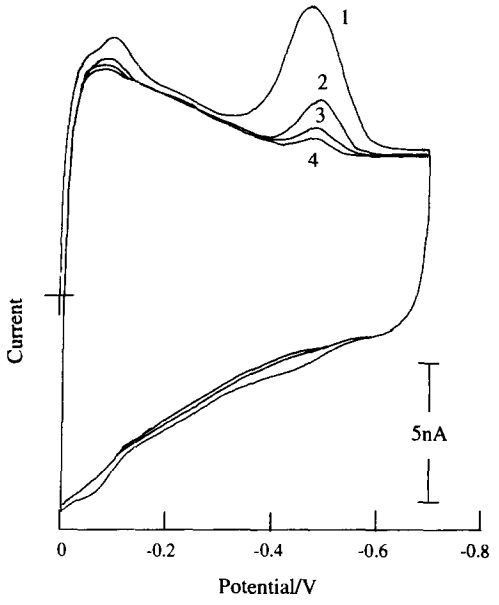

Fig. 2. Cyclic voltammogram of GSSG (50 n$M$) in the PA buffer (pH 7). Start potential, 0.0 V; scan rate, 20 mV/sec. First scan: after 3 min of accumulation at 0.0 V.

DPCS voltammograms recorded under the same conditions also display a symmetrical peak located at $-0.47$ V; as in the case of GSH[9] this will be termed the cathodic stripping peak (CSP). The height of this peak (recorded in the PA buffer) is dependent on the accumulation potential ($E_{acc}$), being slightly larger for $E_{acc} = -0.30$ V, followed by a sharp decrease at more negative values of $E_{acc}$. It vanishes at $E_{acc} \leq -0.45$ V.

*Influence of nickel ion*

As in the case of GSH,[9] the DP cathodic stripping voltammograms recorded in the presence of both GSSG and Ni(II) display a new peak at $-0.60$ V (Fig. 3). It shows a striking analogy with the peak produced under similar conditions by GSH,[9] CysH and Cys.[8] That is why this peak is ascribed to the reduction of $Ni^{2+}$ catalysed by GSH which forms by the splitting of GSSG and will be termed the catalytic cathodic stripping peak (CCSP).

The peak potential is not dependent on Ni(II) concentration. However, as shown in Fig. 4, the DP peak current increases with the rise of NI(II) content, both in the MOPS (curve 1) or PA buffer (curve 2). As usual[8,9] a high excess of Ni(II) is required to achieve good sensitivity. Nevertheless, Ni(II) concentrations higher than 1m$M$ were avoided, because the current due to the diffusion-controlled Ni(II) reduction may overlap the CCSP.

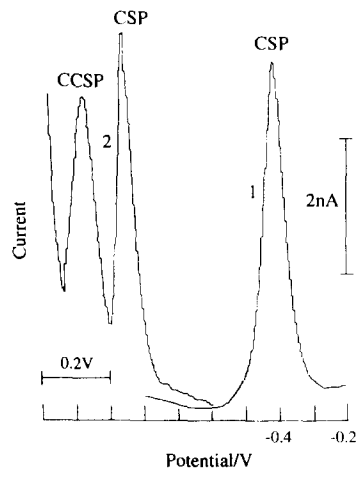

Fig. 3. Effect of nickel ion on GSSG behaviour in DP cathodic stripping voltammetry. MOPS buffer, pH 7.0. GSSG, 50 n$M$. Accumulation: at $-0.20$ V for 2 min. $Ni^{2+}$ (m$M$): (1) 0, (2) 1.

As in the case of GSH[9] the base-line for the measurement of the CCSP current is defined by the lowest level of the voltammogram at the foot of the peak. Tests under various conditions proved that this gives the best relationship between the peak current and GSSG concentration.

The CSP of GSSG is only slightly influenced by Ni(II) (Fig. 3). This behaviour is similar to that of GSH,[9] but strongly contrasts with that of Cys and CysH,[8] whose CSP peaks are suppressed by Ni(II) in high excess.

*Effect of* pH *and buffer composition*

Owing to the competition between proton and Ni(II) for the binding sites in the glutathione molecule, the pH is a very important parameter. In addition, the pH may influence the conversion of GSSG into GSH. Consequently, the effect of pH in the GSSG–Ni(II)

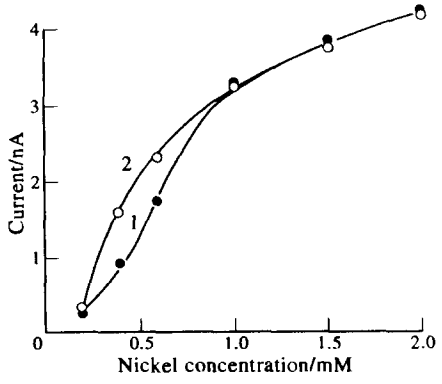

Fig. 4. The dependence of the CCSP DP current on nickel ion concentration. pH 7.0; GSSG 50 n$M$. Accumulation: at $-0.20$ V for 2 min (1) MOPS, (2) PA buffer.

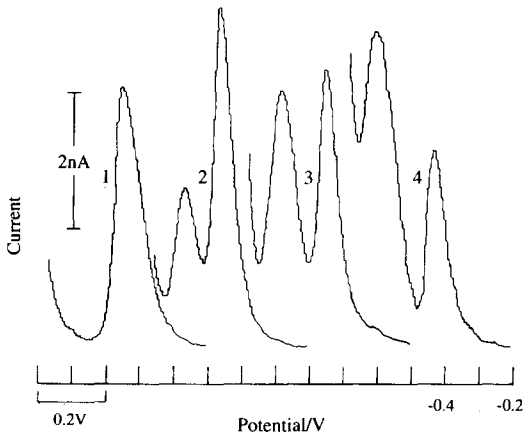

Fig. 5. DP cathodic stripping voltammograms of GSSG (50 n$M$) at various pH-values (MOPS buffer) in the presence of nickel ion (1m$M$). Accumulation: at −0.20 V for 2 min. Potential scale: −0.10 V/div. pH: (1) 6.40, (2) 6.72, (3) 7.00, (4) 7.36.

system was investigated in both the PA and MOPS buffers. Typical DP voltammograms recorded at various pH-values are presented in Fig. 5. Curve 1 in this figure shows that at pH 6.40 only the CSP forms ($E_{peak} = 0.45$ V). The occurrence of the CCSP at −0.60 V requires higher pH-values (curves 2–4). The rise of pH produces a negligible shift in the CCSP potential, but an appreciable increase in the peak height. However, at pH > 7 (curve 4) the catalytic process is partly overlapped by the diffusion-controlled Ni(II) reduction, which slightly shifts towards less negative potentials. This trend was noted in both the PA and MOPS buffer.

The dependence of the CCSP DP current on pH is presented in Fig. 6 for both the MOPS (curve 1) and PA buffer (curve 2). Although pH values higher than 7 seem to offer a better sensitivity, this pH-range was avoided owing to the overlapping effect depicted by curve 4 in Fig. 5. Typically, the pH was adjusted to 7.0 in both buffers. At this pH value, the PA buffer gives a higher peak current, but a better separation of the CCSP from the main nickel peak was noted for MOPS.

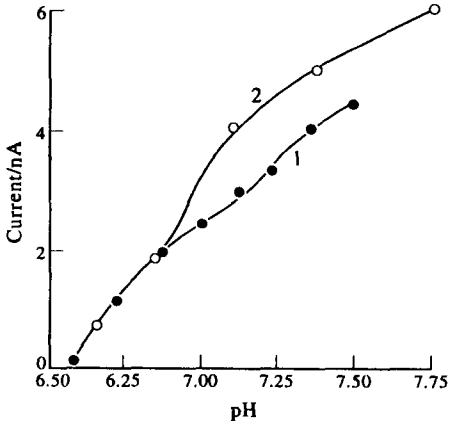

Fig. 6. Dependence of the CCSP DP current on pH in the MOPS (curve 1) or PA buffer (curve 2). Same conditions as in Fig. 5.

*Influence of accumulation conditions*

The effect of $E_{acc}$ in the MOPS buffer on the DP current is presented in Fig. 7a for both the CSP (curve 2) and the CCSP (curve 3). For

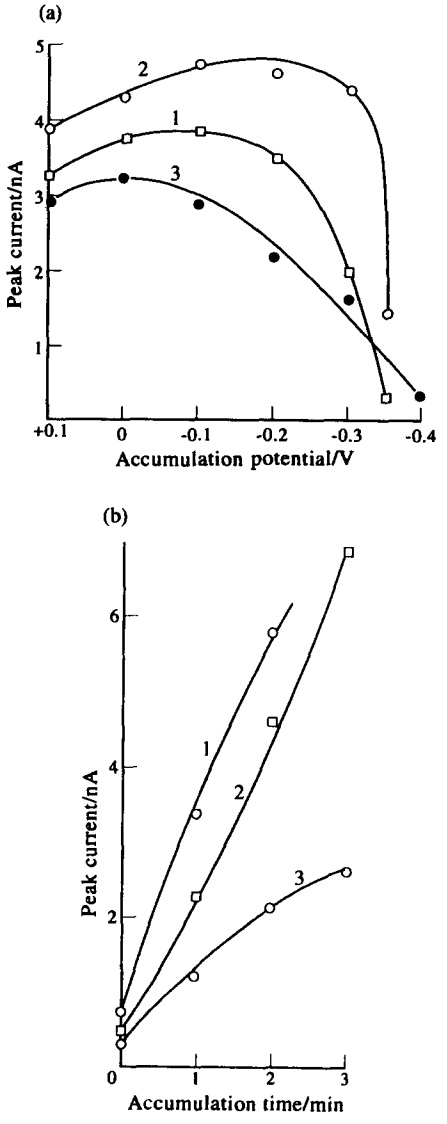

Fig. 7. Effect of accumulation potential (a) and accumulation time (b) on the DP cathodic stripping behaviour of GSSG (50 n$M$) in the MOPS buffer (pH 7.1), in the absence of $Ni^{2+}$ (curve 1) or in the presence of 0.5 m$M$ $Ni^{2+}$ (curves 2 and 3). Curve 2: CSP, curve 3: CCSP. (a) $t_{acc} = 1$ min (curve 1); 2 min (curves 2 and 3). (b) $E_{acc} = -0.20$ V.

comparison, curve 1 in the same figure shows the variation of the CSP in the absence of Ni(II). The CSP sharply decreases for $E_{acc} < -0.25$ V, no matter whether Ni(II) is present or not. Conversely, the CCSP decreased gradually for $E_{acc} < -0.1$ V.

Figure 7b shows the effect of the accumulation time in the MOPS buffer on the DP current. It is seen that the CSP recorded either in the absence (curve 1) or in the presence of Ni(II) (curve 2) strongly increases with the accumulation time. The CCSP current tends to level off after a few minutes' accumulation. The effects of the accumulation conditions in the PA buffer are analogous to those found with MOPS.

*Calibration graph, sensitivity and detection limit*

The CCSP current depends linearly on GSSG concentration. The results of data processing by the least-squares method are summarized in Table 1. From the table it is seen that the intercept of the regression line (peak current *vs.* GSSG concentration, in the form $i = a + bc$) is very small. That is why the parameters of the regression line were also calculated by assuming the direct proportionality (*i.e.* $i = b'c$). These lines were compared by means of the $F$ test, as described in Ref. 9. For all the three sets of data included in Table 1, $F[99\%, 1, (n-2)] > F_{calc}$, proving that the direct proportionality relationship can be accepted.

The values of the slope $b'$ in Table 1 show the influence of some experimental factors on the sensitivity of the method. For instance, the accumulation at 0.00 V (3rd column) brings about a slight improvement in sensitivity as compared with that found for $E_{acc} = -0.20$ V (1st column). As expected, the decrease of the pulse-height from 50 to 10 mV (2nd column) produces a strong decrease in sensitivity, but simultaneously the standard deviation of the fit is much improved. The detection limit in Table 1 is the concentration corresponding to the peak current equal to $3\,s'_0$. The higher value in the 3rd column results from the unfavourable effect of the higher stirring rate on $s'_0$. It is obvious, however, that GSSG may be quantitated even at the level of 10 n$M$, as shown by the data in the 1st and 2nd columns.

Table 1. Parameters of the linear calibration graph for GSSG [$t_{acc} = 2$ min, $E_{acc} = -0.2$ V (1 and 2), 0.0 V (3)]

| | 1 | 2 | 3 |
|---|---|---|---|
| Concn range (n$M$) | 10–200 | 10–130 | 10–200 |

$r$ = Regression coefficient, $s_0$, $s'$ = Standard deviations of the fit; $i$ = peak current (nA), $c$ = analyte concentration (n$M$).

(2): Pulse height = 10 mV; calibration graph bent downward for [GSG] > 130 n$M$.

(3): Maximum stirring speed.

*Interference of some related compound*

Since the CCSP is also produced in the presence of Cys,[8] the effect of this compound on the GSSG–Ni(II) system was investigated. If the CCSP current in the absence of Cys is taken as reference, the peak current increases about two times for a [Cys]/[GSSG] ratio of 0.5 and about three times for this ratio equal to 1. Certainly, this increase is due to CysH which forms by the splitting of Cys.

The mutual interference of GSH and GSSG was also studied. In the presence of each of these compounds the CCSP appears at the same potential. However, under similar conditions, the slopes of the calibration graphs are different, even if it is taken into account that two molecules of GSH could result from one molecule of GSSG.

As in the case of CysH[8] or GSH[9] Ac-CysH has only a minor effect on the CCSP recorded in the presence of GSSG, although, under the same conditions the CSP is strongly enhanced. Thus the CCSP is diminished only by 8% in the presence of a 10 times excess of Ac-CysH.

*Effect of HSA*

The effect of HSA may be typical for some proteins that are present in biological samples. That is why its effect was studied in Ni(II)-containing solutions, both in the presence or in the absence of GSSG.

In the absence of GSSG, after the accumulation at −0.20 V (2 min), HSA gives a shoulder on the DP voltammogram at about −0.6 V (Fig. 8, curve 2). This shoulder is hardly observable for $10^{-4}$% HSA, but sharply increases for higher concentrations. Its height tends to level off for HSA concentrations above $5 \times 10^{-4}$%.

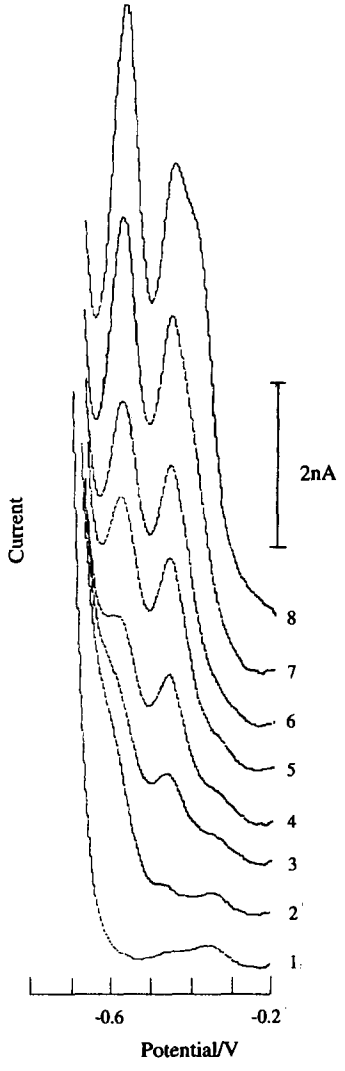

Fig. 8. Effect of HSA on the DP cathodic stripping behaviour of GSSG. pH 7.0 (PA buffer); $Ni^{2+}$, 0.5 m$M$; HSA, $3 \times 10^{-4}$%. Accumulation: at $-0.2$ V, for 2 min. (1) Buffer + $Ni^{2+}$, (2–9) $3 \times 10^{-4}$% HSA added. GSSG, n$M$: (1 and 2) 0, (3) 10, (4) 20, (5) 30, (6) 40, (7) 60, (8) 80.

In the absence of the accumulation step in the stirred solution (but after 30 sec of contact of the quiescent solution with the HMDE), the shoulder is hardly observable. This shoulder may be ascribed to the reduction of Ni(II) catalysed by HSA. Its increase after the accumulation at $-0.20$ V in the stirred solution proves the adsorption of HSA on the HMDE.

At constant concentrations of GSSG (50 n$M$) and $Ni^{2+}$ (0.5 m$M$) the increase of HSA concentration from zero to $6 \times 10^{-4}$% produces a two-fold effect: (1) the CSP is slightly depressed and (2) the CCSP is lifted on the current scale and also its height is increased. By comparing these effects it is observed that the accumulation of GSSG at $-0.2$ V suffers only minor interference from HSA. The main interference occurs in the catalytic reduction of $Ni^{2+}$, in accord with the above-described effect of HSA in the absence of GSSG.

Another experiment was aimed to detect the influence of HSA on the calibration graph. To this end, cathodic stripping voltammograms were recorded at constant concentrations of Ni(II) and HSA and various concentrations of GSSG (curves 2–8 in Fig. 8). Curve 3 in Fig. 8 shows that for 10 n$M$ GSSG the CCSP does not develop properly. However, for higher GSSG concentrations (curves 4–8) the peak assumes the usual shape, enabling the study of the current-concentration relationship. By the same procedure as that described in section, "calibration graph, sensitivity and detection limit" it was found that the peak current is directly proportional to GSSG concentration within the range 20–100 n$M$. The slope is $0.047_1$ nA/nM (standard deviation of the slope, 0.001), and the standard deviation of the fit is 0.20 nA (under the conditions of Fig. 8).

The above data suggest that there is competition for Ni(II) binding between GSH (formed by the cleavage of GSSG) and HSA. This explains the removal of the disturbing effect of HSA at higher values of the [GSSG]/[HSA] ratio.

On the same basis it can be concluded that in the presence of HSA the statistically defined detection limit is unrealistic, the actual one being higher. For example, under the conditions of Fig. 8 the statistical treatment of data gives a detection limit close to 10 n$M$, but at this level HSA strongly disturbs the signal and the actual detection limit (suggested by the examination of voltammograms) seems to be about 20 n$M$.

Despite these disadvantages, it is seen that GSSG can be determined in the presence of a moderate amount of HSA. Moreover, the direct proportionality between the CCSP current and GSSG concentration permits the use of the standard addition method for the analysis of HSA-containing samples.

*Effect of copper ion*

The influence of Cu(II) is similar to that noted in the case of GSH.[9] Thus, for 40 n$M$ GSSG and accumulation at $-0.20$ V, the addition of 0.1$\mu M$ Cu(II) shifts the CSP to $-0.50$ V, partly overlapping the CCSP. For 0.2$\mu M$ Cu(II) the CCSP is almost completely overlapped. The accumulation at more positive potentials (0.0 or $+0.1$ V) diminishes the effect on Cu(II), but its

interference cannot be completely removed in this way. Also, the accumulation at a more negative potential (−0.4 V) does not improve the shape of the voltammogram. Under such conditions, the catalytic reduction of $Ni^{2+}$ gives only a small shoulder, although the peak due to the copper complex is well developed. The interference of Cu(II) is not removed by EDTA even in excess over Cu(II). Nevertheless, traces of Cu(II) present as an impurity in the reagents will not interfere.

## DISCUSSION

A common feature in the CSV of disulphides is that the stripping peak lies at the same potential as that of the corresponding reduced form. This behaviour was noted both in the absence[10,11] or in the presence of Cu(II)[4,5,12] and is explained by the formation of the thiol during the accumulation step of disulphide. In this connection, the occurrence of the CCSP in systems containing either Cys[8] or GSSG (this work) is an additional proof for disulphide cleavage. Usually, the accumulation is effected at a potential too positive to allow the occurrence of disulphide reduction, according to equation (1). The absence of a characteristic peak on the stripping voltammogram demonstrates the absence of such a reaction during the redissolution step. An alternative explanation is founded on the reduction of disulphide by the reaction with mercury[10] or copper amalgam:[5]

$$RSSR + 2M = 2MRS_{ads}, \qquad (2)$$

where M = Hg or Cu. The occurrence of such a reaction has been rejected for both thermodynamic and experimental reasons, at least for mercury.[13]

A more reliable explanation is given in Refs 14, 15, where it is demonstrated that the hydrolytic disproportionation of the disulphide is promoted by Cu(II) ion, according to the reactions:

$$2RSSR + 2OH^- = 2RS^- + 2RSOH \qquad (3)$$

$$2RSOH = RSH + RSO_2H. \qquad (4)$$

In the absence of Cu(II) these reactions occur only at high pH (0.2*M* NaOH).[16] The above reactions occur at pH < 9 for 1m*M* Cu(II) and offer an explanation for the decrease of the cathodic stripping peak of Cys recorded in the presence of Cu(II) when the pH changes from 9.2 to 4.6.[5] Under the typical conditions of CSV (no Cu(II)), the above reactions might be assisted by mercury ions resulting from the anodic oxidation of the mercury electrode. The reaction rate could be sufficiently fast even at pH < 9 owing to the high concentration in the adsorbed state. Another pathway for disulphide degradation leads to *S*-sulphocysteine.[17] This reaction involves an oxidative step with the participation of dioxygen which would not be applicable in CSV.

In conclusion, it may be inferred that both in the case of Cys[8] or GSSG (this work), the disulphide turns into thiol by the mercury ion-assisted mechanism represented by reactions (3) and (4). The plated compound is always a mercury thiol further represented as HgSR (or HgSG).

In connection with the accumulation mechanism it is worth recalling the main difference between glutathione (either reduced or oxidized) on the one hand, and CysH (or Cys) on the other hand. This consists in the effect of Ni(II) on the CSP of the mercury thiolate. The CSP is suppressed by a large excess of Ni(II) in the cases of CysH or Cys[8], but only slight effects are observed for GSH[9] and GSSG (this work). This difference is a consequence of the different kind of Ni(II) binding. Very strong chelates form in the case of CysH, involving both the amino and sulphydryl groups, but much less stable complexes are formed by GSH, which mainly binds by the terminal groups.[18] It can be assumed, therefore, that Ni(II) strongly interferes in the accumulation process involving CysH, no matter whether CysH is initially present in the solution or forms by the cleavage of Cys. Conversely, in the case of GSH the formation of chelates involving the sulfur site is less probable at medium pH.[19] Consequently, as in the case of Ac-CysH, GSH gives a well developed CSP even in the presence of Ni(II). This remark also applies to GSSG in view of reactions (3) and (4).

As shown, even in the case of GSSG, the actual catalyst is GSH produced by reactions (3) and (4), giving only three molecules of GSH from two molecules of GSSG. This characteristic, as well as the sluggishness of reactions (3) and (4), accounts for the difference in sensitivity noted when GSSG is replaced by a two-times higher concentration of GSH.

During the cathodic scan GSH is released according to the reaction

$$GSHg + H^+ + e^- \rightarrow GSH + Hg. \qquad (5)$$

Its catalytic effect must be produced in the same way as previously described.[9] Studies by DC

polarography[20,21] have already proved that GSH is less catalytically active than CysH owing to the differences in the complexing properties. Nevertheless, the CCSP enables the determination of GSSG at the level of 10 n*M* with good accuracy. Only slight interference is produced by Ac-CysH and the determination can be performed even in the presence of small amounts of protein (HSA for example).

The method is not able to distinguish between GSSG and GSH. However, the overall amount of glutathione in the sample could be evaluated after the conversion of one form into the other one by an appropriate reaction. Other compounds which accumulate as mercury salts, and which form stable complexes with nickel, will interfere, and the method presented here does not have a particularly low detection limit, as the catalysis is simply on a one to one basis and does not increase the sensitivity. The method is put forward as a novel alternative stripping voltammetric method to those involving accumulation and determination as mercury or copper salts and complexes, in the knowledge that it may have advantages in particular analytical situations. In particular the method discriminates against compounds which accumulate as mercury salts but which do not form stable nickel complexes. Voltammetric methods, including stripping methods, are being applied increasingly in disposable sensor devices, and accumulation and reduction of nickel complexes might prove advantageous here too.

**Summary**—A sensitive and relatively selective high performance liquid chromatographic method for the determination of Gentian Violet (GV) in human urine and chicken feed is described. The method is based on solid-phase extraction, with subsequent reversed-phase chromatographic separation on a cyano column and amperometric detection using a carbon fibre microelectrode flow cell operated at +1.3 V. The peak currents were directly proportional to GV concentration over the concentration range 1–30 ppb (for urine samples analysis) and 1–20 ppm for poultry feed analysis. Using this method, the minimum detectable concentration was estimated to be 0.5 ppb. The method was applied successfully to the determination of GV in human urine and in chicken feed, and it was concluded that the method could be applied to the quantitative analysis of GV in the presence of its major metabolite, leuco GV. In the proposed procedure, the occurrence of matrix effects during urine analysis was significant. The electrochemical pretreatment regime described in this paper was used to overcome these effects. Recovery studies were performed on both the human urine and chicken feed samples. The recovery of GV ranged from 92 to 96% in both matrices, with a relative standard deviation of less than 5.5%.

Gentian Violet (GV; hexamethyl pararosaniline; also known as Crystal Violet) is classified as a triphenylmethane dye, and has been marketed since 1951 for a variety of uses. It has anthelmintic properties and has been used in the treatment of strongyloid infestation.[1] The compound has also been used in humans, as an antimicrobial agent in the treatment of burn victims, to treat umbilical cords of infants as a vaginal cream, for various purposes in veterinary medicine, and as a pH indicator substance. At present, the U.S. Food and Drug Administration (FDA) permits the use of GV (8 ppm) in poultry feeds as a mould inhibitor. GV has however been determined to be mutagenic to *Bacillus subtilis*, *Escherichia coli*, and *Salmonella typhimurium*,[2] and cytotoxic to mammalian cells.[3] Au *et al.*[4,5] demonstrated its genetic cytotoxicity to Chinese hamsterovary (CHO) cells. Concern about the health risks and carcinogenicity associated with the use of GV requires that a routine laboratory method be developed to monitor the drug and its metabolite.

Typical approaches for determining GV have involved the use of potentiometry,[6] spectrophotometry[7] and mass spectrometry,[8] and lately by HPLC with amperometric detection using macroelectrodes such as the glassy carbon electrode.[9] The virtues of microelectrodes are well known,[10–12] and the advantages of studying their steady-state voltammograms are well documented.[13,14] Use of microelectrodes (typically micron to submicron sizes) has recently made inroads into the use of LC-EC in clinical applications. The main advantage is the ability to construct extremely low volume cells (as low as a few picolitres for a carbon-fibre microcylinder electrode).[15] Other advantages include: (1) detection limit improvements, as reported in the determination of norepinephrine (sub-pmol) using a carbon fibre electrode;[16] (2) a lower dependency on flow rate, and thus lower noise associated with flow-rate fluctuations;[16,17] (3) higher current densities, time-independent

*Author to whom all correspondence should be addressed.

currents and better signal-to-noise ratios; (4) the possibility of using very high scan rates or simpler instrumentation, and (5) the capability of carrying out measurements in solutions with very low conductivity.[18,19] The major drawback with microelectrodes is that fabrication difficulties increase as the size of the microelectrode decreases,[20] and so far they have relatively limited commercial availability. Hence, most workers normally prepare their own microelectrodes by sealing thin wires or fibres in glass capillaries, either by melting the glass or by using an epoxy resin.[21–23] Sealing wires or fibres into glass is technically demanding, and there is always a risk that the relatively high temperatures needed to melt the glass might change the characteristics of the electrode material. It has been reported that carbon fibres which had been in contact with a flame were more fragile and needed longer electrochemical conditioning.[24] It is necessary, therefore, to ensure the highest possible activity of the electrode surface, by establishing the most suitable and convenient pretreatment procedures for the electrochemical detector, following studies relating to the features of the analyte and sample matrix to be dealt with.

This paper describes the development of a LC-EC method using a microelectrode flow cell based on a carbon fibre working electrode, for the determination of GV at concentration ranges of 1–30 ppb in human urine, and at 1–20 ppm in poultry feed. The method could also determine GV in the presence of its major pharmacologically active metabolite (leuco Gentian Violet).

## EXPERIMENTAL

### *Reagents and materials*

Carbon fibres, 14 $\mu$m in diameter, were obtained from Avco (Lowell, MA, U.S.A.). Chemicals were used without further purification. All chemicals were of analytical-reagent grade, unless otherwise indicated. Gentian Violet (USP,[25] Crystal Violet 96%) and leuco Crystal Violet were obtained from Sigma and were used to prepare reference standards.

Chicken basal diet containing GV at 0 ppm and fortified feed containing GV at 2.5, 5.0 and 10.0 ppm were kindly supplied by the National Food Centre (Dublin, Ireland). Human urine for control and recovery analyses were provided by healthy volunteers. The urine specimens were collected in polycarbonate bottles and were stored at −4°C until analysis. Stock standard solutions equivalent to 0.20 mg/ml GV were freshly prepared in LC grade methanol, mixed and then stored in a cool place (*ca.* 4°C) and protected from light. These were diluted and added to GV-free urine aliquots to generate spiked urine standards in the concentration range 1–30 ppb. The "spiked" samples were left for at least 1 hr before they were analysed to

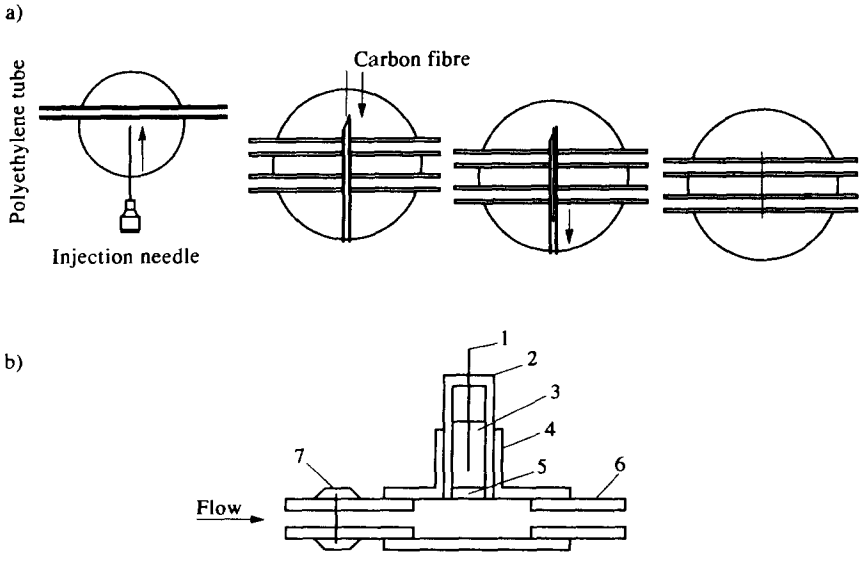

Fig. 1. (a) Method of fixing a carbon fibre into polyethylene tube. (b) The structure of the carbon fibre microelectrode flow cell consisting of: 1, silver wire coated with $Ag_3PO_4$; 2, reference electrode body; 3, internal reference solution; 4, T-tube; 5, ceramic rod; 6, stainless steel counter electrode; 7, carbon fibre flow electrode.

permit any possible interactions between the drug and urine constituents.

*Fabrication of microelectrode flow cell*

The method of inserting the carbon fibre into a polyethylene tube is shown in Fig. 1. An injection needle (o.d. 0.4 mm, i.d. 0.2 mm) was inserted through the centre of a 15-mm piece of polyethylene tube (o.d. 2 mm, i.d. 0.5 mm). A carbon fibre (diameter 14 $\mu$m) was inserted into the injection needle, which was then removed from the tube, leaving the fibre behind. The needle holes were sealed by gentle heating with an electric iron. A copper wire of 0.5 mm diameter was wound around the sealed area for a few turns. The area was then covered with a layer of silver epoxy resin. The resin was diluted with ethyl acetate to a suitable viscosity before application to the tube. After 1 hr the electrode was ready for use. The copper wire was used as a lead for electrical connection. The silver phosphate reference electrode was prepared by connecting a silver wire (0.1 mm in diameter) to the anode and a platinum electrode to the cathode of a 1.5 V battery, while immersing the assembly for 2 min in a solution of 1*M* phosphoric acid. The wire was then inserted into a polyethylene tube, which was 15 mm long and 1 mm in diameter, and a porous rod (2 mm long and 1 mm in diameter) was fitted to one end of the polyethylene tube. The reference electrode tube was then filled with an internal reference solution containing 1*M* phosphoric acid, and this end was closed by heating. A length (2 cm) of stainless steel tubing (1 mm × 0.2 mm i.d.) served as the counter electrode. The working, reference, and counter electrodes were mounted in a T-tube arrangement, and the working electrode was connected to the outlet of the HPLC column (downstream of the working electrode). Hence the mobile phase eluent passed first through the working electrode and then via the counter electrode to waste.

*Cyclic voltammetry*

Cyclic voltammetric experiments were initially recorded on blank solutions of 0.05*M* acetate buffer, followed by solutions containing $1 \times 10^{-3}M$ GV dissolved in 0.05 acetate buffer solution (pH 5.5) at a glassy carbon electrode. Voltammetric conditions were as follows: initial potential 0 V; final potential 1.6 V and scan rate 50 mV/sec. Prior to scanning, the electrode was cleaned by washing with distilled water, polishing the surface with aluminium oxide powder (0.3 $\mu$m), rinsing again with distilled water followed by acetone and finally drying with a tissue-paper. The glass cell and the counter electrode were soaked in $HNO_3$ solution, and then rinsed thoroughly with triply-distilled water. The presence of any adsorption process was investigated by multiple CV scanning without pretreatment of the glassy carbon electrode.

*Extraction and clean-up procedures*

*Poultry feed.* The sample preparation and clean-up procedures were reported previously by Roybal *et al.*[9] Blank chicken feed and sample feed were ground to pass through a 1 mm sieve (Pascal Engng Co. Ltd, Crawley, U.K.), stored in a quart glass jar, and kept in a cool, dry place. Ground feed (20 g) was then accurately weighed into a 500 ml centrifuge bottle, 200 ml methanol/1*M* HCl (99:1) was added and the mixture was shaken vigorously for 1 hr on a mechanical shaker, then left to stand overnight. An appropriate aliquot of the supernatant was then pipetted into a 15 ml centrifuge tube according to the following schedule: GV (ppm), aliquot (ml): 10 ppm, 1 ml; 5 ppm, 2 ml and 2.5 ppm, 4 ml. The aliquot was then diluted to 10 ml with mobile phase and mixed. The solution was then filtered through a disposable, 5 $\mu$m polytetrafluoroethylene (PTFE) membrane (Millipore Corp., Bedford, MA, U.S.A.) into a 25 ml Erlenmeyer flask. Then 20 $\mu$l of filtered solution was injected into the liquid chromatograph. The concentration of GV (ppm) in feed was calculated as follows:

$$\text{ppm} = (P/S) \times (C/W) \times (D),$$

where $P$ = peak height (mm) obtained from injection of filtered solution, $S$ = average peak height (mm) obtained from injection of standard, $C$ = concentration (ppm) of injected standard, $D$ = final volume (ml) of filtered solution, and $W$ = initial weight of feed sample taken for analysis.

*Human urine.* The procedures for extracting GV from urine specimens were based on the work of Rushing and Bowman.[26] A 100 ml portion of spiked human urine in a 165 ml culture tube was adjusted to pH 7.0 with 6*M* NaOH. After the addition of 50 ml of dichloromethane the tube was gently shaken by hand for 3 min with care taken to prevent emulsification of the contents. The tube was then centrifuged for 5 min at 500 rpm and the dichloromethane layer removed by syringe,

percolated through 20 g of sodium sulphate in a glass funnel (3.0 cm diameter), and collected in a 250 ml round-bottom flask. The extraction process was repeated with two additional 20 ml portions of dichloromethane, the sodium sulphate washed with 5 ml of dichloromethane, and the combined extracts evaporated to dryness on a 30°C water bath using water pump vacuum. The dry residue was transferred to a 50 ml round-bottom flask by using four successive 1 ml rinses of the dichloromethane which were then evaporated to dryness as described. The residue was finally dissolved in 1.0 ml of methanol and 100 $\mu$l were injected for analysis.

The stability of the urine samples at room temperature was tested by making 10 consecutive injections of the same urine sample over a period of approximately 5 hr. There were no significant changes in the peak current between the first five and the last five samples. In addition, urine samples spiked with the test compound were stable for more than 5 days at $-4$°C.

*HPLC*

The HPLC separation used in this study for the chromatographic separation of the triphenylmethane dye is similar to those reported by Roybal *et al.*[9] The system consisted of a stainless steel column (250 × 4.6 mm i.d.) packed with cyano packing material (particle size 5 $\mu$m) (Hichrom Ltd, Reading, U.K.). The mobile phase was acetonitrile–acetate buffer (60:40); the acetate buffer was prepared by adjusting 0.1*M* sodium acetate solution (8.2 g sodium acetate/1 l. deionized water) to pH 4.5 with glacial acetic acid (*ca.* 8 ml). Sample injections to the column were introduced via a syringe-loading Rheodyne valve (Cotai, CA, U.S.A.). The analytical column was protected by a 20 mm direct-connect guard column, (LC-18-DB, Supelco, Inc., Bellefonte, PA, U.S.A.) packed with CN packing material (Lichrosorb 10 CN, HPLC Technology, Macclesfield, U.K.). All solvents used in the HPLC system were filtered through a disposable 0.5 $\mu$m fluoropore filter (No. FHLP 04700, Millipore, Bedford, MA, U.S.A.). Oxidative amperometric measurements were performed using an EG&G Princeton Applied Research Model 400 EC potentiostat connected to the flow cell by crocodile pins. GV was detected amperometrically by employing a potential of +1.3 V at the working electrode. The resultant signals were recorded on a Philips Model PM8261 X-t recorder (Eindhoven, The Netherlands) at a chart speed of 300 mm/hr.

The peak currents as a function of concentration were then measured for quantitative analysis. Operating conditions: LC mobile phase at room temperature; the mobile phase flow rate was maintained at 1.0 ml/min through the analytical column: column temperature, ambient; column pressure, *ca.* 1500 psi; the normal operating current range was set at 2 and 20 nA for full-scale deflection for the analysis of GV in human urine and poultry feed respectively.

## RESULTS AND DISCUSSION

*Cyclic voltammetric behaviour*

A typical cyclic voltammogram for a $1 \times 10^{-3}M$ solution of GV obtained using a glassy carbon working electrode in 0.05*M* acetate buffer (pH 5.5) supporting electrolyte is shown in Fig. 2. The voltammogram showed one peak on anodic scanning between 0 and +1.4 V, with no peak on the reverse scan. The appearance of a single anodic peak in the first cycle only, with no cathodic peak on the reverse scan, is indicative of the irreversible nature of the oxidation process. Further cycling without reactivation of the electrode (scan B) showed complete suppression of the anodic peak indicating that the reaction product is strongly adsorbed on the electrode surface.

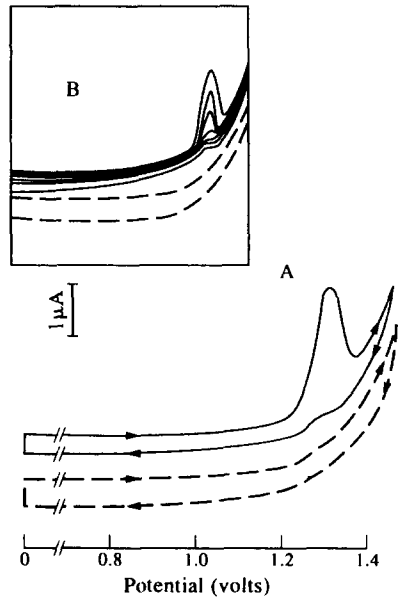

Fig. 2. Cyclic voltammogram of $1 \times 10^{-3}M$ GV in 0.05*M* acetate buffer (pH 5.5) at a stationary glassy carbon electrode (A). The inset in (B) shows the cyclic voltammograms obtained after recycling without intervening activation of the electrode.

*Optimization of LC-EC conditions*

In order to determine the optimum applied potential for amperometric detection following liquid chromatography, a hydrodynamic voltammogram was constructed for GV (Fig. 3) by injecting 100 $\mu$l of 30 ppb GV standard solutions of the compound and recording the detector response at intervals of 0.10 V over the range +0.40 V to 1.40 V. The voltammogram verifies that GV undergoes a single oxidation within this potential range. The maximum currents were achieved at a potential of +1.40 V; however, the magnitude of the background current was about 0.004 nA at this applied voltage. It was found that reducing the potential to +1.30 V afforded a significant reduction in background current, which resulted in better signal-to-noise ratios; therefore, an applied potential of +1.30 V was selected for the remainder of the LC-EC studies. Using cyclic voltammetric data, existing HPLC information and the hydrodynamic voltammogram, the chromatographic system was developed to meet the requirement of both separation and detection of GV in poultry feed and in human urine.

*Pretreatment of the carbon fibre working electrode*

The electrode response is usually affected by the features of the sample matrix. Urine is a complex medium that contains many complex biological materials that can interfere with the performance of the analysis. In the proposed procedure, the occurrence of matrix effects (defined as the relative sensitivity in the presence of a matrix to that in the absence of a matrix)

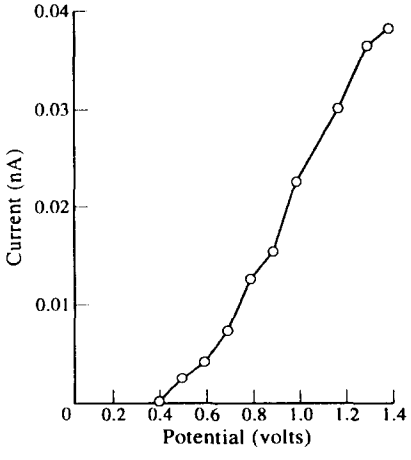

Fig. 3. Hydrodynamic voltammogram obtained for 30 ng/ml GV standard solution. Mobile phase: acetonitrile–acetate buffer (60:40), pH 5.5; working electrode: 14 $\mu$m carbon fibre.

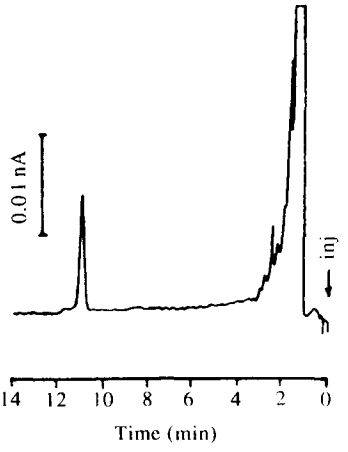

Fig. 4. Chromatogram obtained by analysis of human urine extract spiked with 5 ppb GV. Chromatographic conditions (see text).

during urine analysis was significant. It was necessary to counteract the matrix effect when the carbon fibre electrode surface became contaminated. Electrochemical pretreatment was used to solve this problem. The working electrode was treated by applying −1.40 V for 40 sec and then +1.40 V for 40 sec (*vs.* $Ag/Ag_3PO_4$) followed by equilibration for 3 min. When the upper potential limit was extended to +1.5 V, many fibres were either broken or provided noisy and erratic oxidation peaks. When this pretreatment procedure was applied to the analysis of the urine specimens obtained from healthy volunteers, the interferences from other urinary constituents were effectively eliminated. The pretreatment regime also improved the correlation coefficient for the calibration graph and the sensitivity of the method; making the pretreatment of the electrode an essential step for the determination of GV using the microelectrode flow cell. A similar improvement was observed when the pretreatment procedure was applied during the analysis of the animal feed. One explanation of this behaviour is the increase of the effective rates of electron transfer by generating electrocatalytic functional groups at the surface of the electrode due to pretreatment.

Chemical pretreatment of the carbon fibre electrode were also tried. The working electrode was immersed for 20 min in $HNO_3$, $H_2SO_4$, $H_2O_2$ and concentrated acid dichromate solution. In all these cases the resulting test voltammograms showed poor defined peak shapes. The flow system used provides short contact between the sample and the active surface allows minimal contamination of the electrode surface.

Table 1. Precision of the assay in (a) urine and (b) chicken feed

| Concentration spiked (*ppb*) | Mean concentration found* (*ppb*) | RSD (%) |
|---|---|---|
| (a) | | |
| 4.0 | 3.6 | 3.5 |
| 7.5 | 7.1 | 2.3 |
| 10.0 | 9.4 | 5.1 |
| (b) | | |
| 2.5 | 2.4 | 4.2 |
| 5.0 | 4.7 | 2.5 |
| 10.0 | 9.6 | 1.7 |

*$n = 5$.

*Determination of Gentian Violet in human urine and poultry feed*

The analytical procedure was then applied to control human urine and poultry feed samples to establish the limit of detection and recovery of the method.

*Linear range.* A series of external GV standards were prepared in a mixture consisted of methanol:water (95:5), and a calibration graph based on the mean ($n = 5$) detector response values was constructed by injecting between 1 and 30 ppb of GV for standard solutions for urine samples analysis and between 1 and 20 ppm for poultry feed analysis. Peak currents were measured and graphs of peak current *vs.* amount injected were constructed. The linear calibration curves indicated that the oxidation of GV at the carbon fibre working electrode is reproducible over these ranges using the micro-electrode flow cell and the chromatographic conditions, with correlation coefficients of greater than 0.996 for both studies. The characteristics of these curves were slope: $2.1 \times 10^{-3}$ nA/ppb and $9.1 \times 10^{-2}$ nA/ppm, and intercept $1 \times 10^{-3}$ and $2 \times 10^{-3}$ nA for human urine and poultry feed analysis, respectively. These calibration ranges were considered suitable for the applications being undertaken in this study. The limit of detection was taken to be the concentration at which the signal was three times greater than the noise of the base line. The minimum detectable concentration was found to be 0.5 ppb.

Table 2. Recovery of (a) GV from spiked urine specimens and (b) chicken feed

| Sample | GV concentration (*ppb*) | | |
|---|---|---|---|
| | Present | Mean amount found* | Mean recovery (%) |
| (a) | | | |
| A | 2.0 | 1.8 | 90 |
| B | 5.0 | 4.6 | 92 |
| C | 15.0 | 14.1 | 94 |
| (b) | | | |

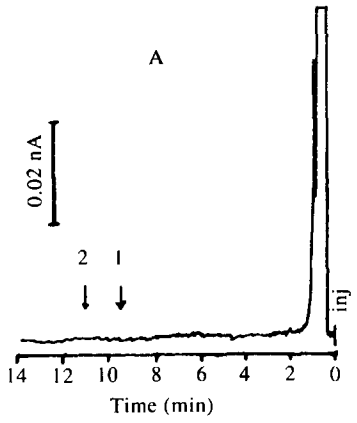
*$n = 5$.



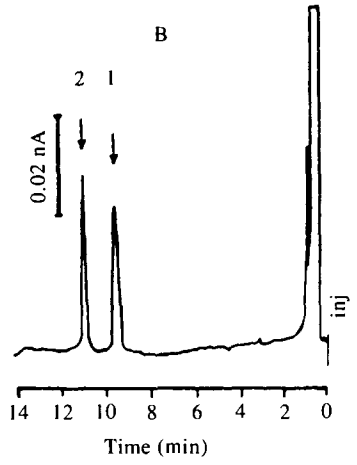


Fig. 5. Typical chromatogram of the separation of leuco Gentian Violet and Gentian Violet at +1.3 V for (A) blank urine extract and (B) spiked human urine containing 15 ppb of (1) leuco and (2) chromatic form of Gentian Violet.

*Precision.* The method described has been applied to a number of samples of human urine and poultry feed. The LC-EC chromatograms obtained for GV extracted from human urine and chicken feed as described earlier, showed a well defined peak for GV with a retention time of 11.0 min (Fig. 4). The precision was measured as the relative standard deviation of a repeated injection of the same quantity of a sample at 4, 7.5, and 10 ppb urine samples and at 2.5, 5, and 10 ppm feed samples. The results summarized in

Table 1(a) and (b) display an acceptable level of accuracy and precision, with the RSD ranging between 1.9 and 4.2%. These results are in good agreement with those published by other authors.

*Recovery studies.* The extraction procedures produced a "clean" extract and consequently good recoveries of GV. Table 2(a) and (b) show the overall recovery of GV, which was assessed by comparing the representative peak currents for spiked urine specimens and poultry feed sample taken through the study with the peak current for corresponding standards. The recoveries of GV from spiked urine blanks and from chicken feed ranged from 91.69 to 94.09% at ppb levels and from 94.85 to 95.70% at ppm levels and averaged 94.06%. These recovery levels are satisfactory, and the concentration of the "spiked samples" did not appear to influence the recovery of GV residues in urine specimens.

*Interference study.* In many cases quantitation of metabolites in addition to the parent drug will be required if these metabolites are pharmacologically active. Intestinal microflora, under anaerobic conditions, are capable of metabolizing GV by reduction to its leuco (colourless) form.[27] According to the U.S.A. National Centre for Toxicological Research,[28] this leuco derivative (LGV) is then "structurally similar to the classical aromatic carcinogens". The possible potential interference of the leuco derivative in the determination of GV was tested using the proposed method.

Figure 5 shows the chromatogram observed for simultaneous determination of spiked human urine containing 15 ppb of GV and LGV. It can be seen from this figure that both forms are well resolved and there were no significant effects due to the added interferent. This metabolic product would not be expected to interfere in real samples as the level of spiking was considerably higher than that normally found in human urine.

## CONCLUSION

This research describes a sensitive LC-EC method for quantitative analysis of GV in human urine and chicken feed using an electrochemical microelectrode flow cell. The detector has been found to exhibit a considerable improvement in the limit of detection over a previously reported method which involved amperometric detection using a glassy carbon macroelectrode.[9] The use of the carbon fibre overcame many problems associated with the use of glassy carbon electrodes. The method eliminates interferences from other urinary constituents and provided a reliable and fairly precise tool for biological monitoring of GV. The ability of simultaneous determination of the parent drug (GV) in presence of its major demethylated metabolite (LGV) could be of great importance in studying the biotransformation of GV into its leuco form. It is considered that the method will be useful for both clinical and pharmacokinetic studies.

# POTENTIOMETRIC DETERMINATION OF AMINAL STABILITY CONSTANTS

P. D. TAYLOR

Department of Chemistry and Biological Chemistry, University of Essex, Wivenhoe Park, Colchester, Essex CO4 3SQ, U.K.

(*Received* 7 *June* 1994. *Accepted* 1 *August* 1994)

**Summary**—Potentiometric titration was used to determine the logarithms of the stepwise equilibrium constants for the species formed between morpholine and formaldehyde in aqueous solution, ionic strength 0.5 and 2.5*M* (KCl) at 25°C. The instrumental and computational techniques developed for metal–ligand stability constant determination were applied. Formaldehyde is equivalent to the metal-ion and is represented by M while neutral morpholine is equivalent to the ligand and is represented by L. The stability constants of the following equilibria were determined by non-linear regression (figures in parentheses are at ionic strength 2.5*M* KCl): $M + L \rightleftharpoons ML$ (hemi-aminal) $\log K_1 = 2.90 \pm 0.02$ ($2.980 \pm 0.004$); $ML + L \rightleftharpoons ML_2$ (bis-aminal); $\log K_2 = 1.3 \pm 0.2$ ($1.41 \pm 0.07$); $MLH \rightleftharpoons ML + H^+$ (protonated hemi-aminal) $pK_a = 5.87 \pm 0.01$ ($6.411 \pm 0.005$); $ML_2H \rightleftharpoons ML_2 + H^+$ (protonated bis-aminal) $pK_a = (7.6 \pm 0.2)$. The $pK_a$ of the protonated bis-aminal could only be determined at the higher ionic strength. The results are in good agreement with reported values determined using the classic formol titration. The automated titration system acquired the full time course of the pH change upon each titrant addition allowing a kinetic analysis to be performed as well as an equilibrium analysis. The forward and reverse rate constants for $M + L \rightleftharpoons ML$ were $0.77M^{-1}$ sec$^{-1}$ and $8.1 \times 10^{-4}$ sec$^{-1}$, respectively.

The species known to form when formaldehyde and a secondary amine are mixed in aqueous solution are shown in Scheme 1. The equilibrium constants of this system have been determined by Kallen *et al.* using the formol titration.[1] This involves measurement of the change in pH of amine/aminium compositions as a function of formaldehyde concentration. The analysis of data in that work involved a number of elegant graphical extrapolations and linearisations. The high pH at which formaldehyde–morpholine solutions undergo changes in speciation simplifies the algebra because the free proton concentration can be neglected in conservation equations. However, it is useful to recognise that the multi-component formaldehyde–morpholine equilibrium system is described by a set of conservation equations and equilibrium equations in an identical fashion to metal–ligand equilibrium systems. Multi-parametric non-linear regression of potentiometric titrations has been widely used to determine metal–ligand stability constants and a number of sophisticated algorithms and computer programs have been developed to handle this type of data analysis.[2] This work examines the application of the experimental and computational techniques developed for metal–ligand stability constant determination to the entirely organic formaldehyde–morpholine system. (See over for Scheme 1).

The set of conservation equations 1–3 and the equilibrium equations 4 describe the system. $M_t$, $L_t$ and $H_t$ are the total analytical concentrations of formaldehyde, morpholine and proton; $m$, $l$ and $h$ are the free concentrations of formaldehyde, morpholine and proton at equilibrium and $p_j$, $q_j$ and $r_j$ are the stoichiometries of formaldehyde, morpholine and proton in the $j$th complex species $S_j$ with formation constant $\beta_j$ and $K_w$ is the ion product of water. The notation is consistent with most metal–ligand titration studies if formaldehyde is considered to be the metal-ion ligated by morpholine.

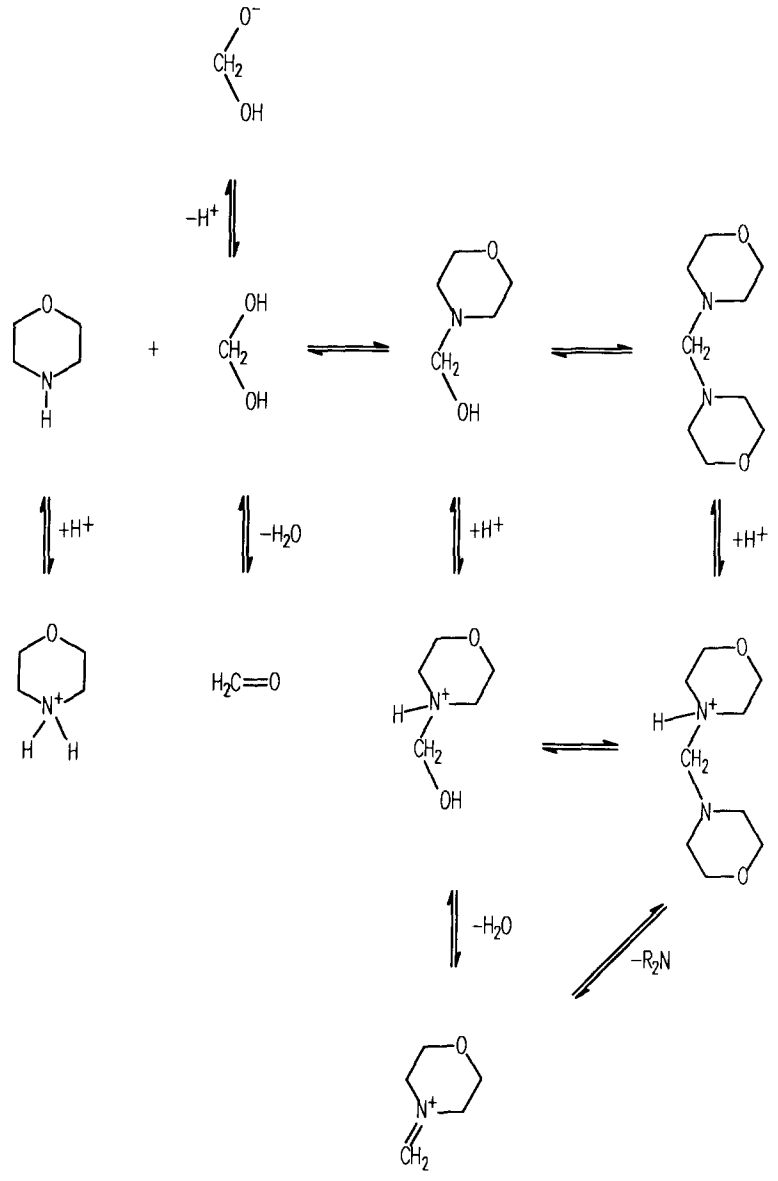
$$M_t = m + \Sigma p_j S_j \quad (1)$$

$$L_t = l + \Sigma q_j S_j \quad (2)$$

$$H_t = h + \Sigma r_j S_j - K_w/h \quad (3)$$

$$S_j = \beta_j m^p l^q h^r. \quad (4)$$

The set of equations can be solved by Gauss–Newton iteration in the three variables $m$, $l$ and $h$ as described in many previous publications on potentiometric



Scheme 1

titrations of metal–ligand equilibria.[3,4] The stability constants and other parameters describing the model system may then be optimized non-linearly by least squares regression analysis of the potentiometric data. The use of these equations in the non-linear regression program NONLIN15 (QuickBasic 4.5) has been described previously.[3]

The only potential difficulty is the slow kinetics of the formaldehyde morpholine system compared with many metal–ligand systems. An automated potentiometric titration system developed for metal–ligand titrations was modified to allow acquisition of pH *vs* time after each titrant addition to ensure that equilibrium had been achieved. The glass electrode response is relatively rapid (about 5 sec to reach a stable reading in calibration titrations of HCl with KOH) so the pH variation after 5 sec reflects the kinetics of hemi-aminal and bis-aminal formation. This slower change is experimentally found to be exponential as expected for a small amplitude perturbation from equilibrium. Fortunately, the half-times of the exponentials obtained in the formaldehyde–morpholine system are short enough to make the titrimetric technique practical. The time course, together with the speciation determined from the equilibrium pH titration permitted the determination of some of the rate constants involved.

## EXPERIMENTAL

Data were collected by an automated titration system operated by a PC and software developed to permit pH to be recorded with time for each titrant addition. The instrument comprises a stepper motor driven, micrometer mounted 1 ml syringe (Agla) and a Corning Δ250 pH meter. The computer program which controls the titrator continues to acquire values of pH until the slope of pH against time, plus twice the standard error of the slope is less than 0.0002 pH units per second. The water jacketed titration vessel was maintained at 25.0°C ± 0.01 by a Grant-Barrington thermocirculator. Stock solutions of formaldehyde and morpholine were all maintained at the same ionic strength (0.5 or 2.5*M* KCl). Formaldehyde solutions were prepared from 37% w/w solution containing 10% methanol stabilizer (Aldrich); morpholine from the free base (Aldrich). A glass electrode and calomel reference electrode were used. Acid was HCl (1.022 or 5.00*M*) base was KOH (0.984 or 5.00*M*) both Aldrich standard solutions. Water was distilled and deionized (18 MΩ/cm).

### *Typical titration procedure*

KCl (10 ml) was acidified with 100 μl of 1.022*M* HCl and titrated with 200 μl of 0.984*M* KOH to calibrate the electrodes. Then 400 μl of HCl and 1 ml of the morpholine solution were added and titrated with 470 μl of KOH in 10 μl aliquots. Thereafter, acidification and titration were repeated after additions of 30, 170 and 1800 μl of formaldehyde solution. Thus all titrations were performed by additions to the same solution without removing the glass electrode.

## RESULTS

### *Stability constants*

Titrations with fixed morpholine and increasing concentrations of formaldehyde are shown in Fig. 1. Introduction of formaldehyde leads to a decrease in pH in the buffer region because the hemi-aminal (ML) and bis-aminal ($ML_2$) are weaker bases than the free morpholine. The $pK_a$ of the hemi-aminal (5.87) is 2.7 units below that of morpholine itself (8.545) while the $pK_a$ of the bis-aminal is only 1.5 units below morpholine so the decrease in pH that results from formation of bis-aminal is less dramatic than that resulting from hemi-aminal formation. Increasing the formaldehyde concentration gives a buffer region of progressively lower pH with the limiting buffer region of $pK_a$ 5.87 corresponding to quantitative formation of the hemi-aminal. The $pK_a$ of formaldehyde hydrate (12.78) becomes significant at high formaldehyde concentrations (Fig. 1, curve 4). This ionization is entirely analogous mathematically with the hydrolysis of metal-ions to metal-hydroxides and is dealt with as such by the computational analysis. Speciation for the titration curve 2 is shown in Fig. 2. High concentrations of formaldehyde and morpholine were required to give concentrations of bis-aminal and the protonated aminals ($ML + H^+$, $ML_2 + H^+$) which could be detected. A correspondingly high concentration of KCl was required in these titrations to keep the ionic strength constant. The parameters optimized by non-linear regression are summarized in Table 1. The sequence of analysis was as

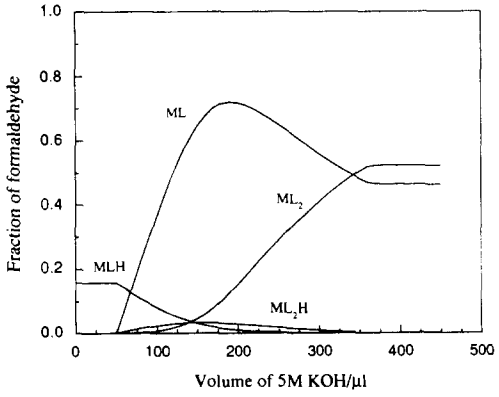

Fig. 2. Speciation of formaldehyde morpholine solution during titration curve 2 (◇) of Fig. 1. Species are shown as the mole fraction of formaldehyde involved.

follows. The calibration titration and the morpholine titration were optimized globally to determine the electrode zero, the p$K_a$ of morpholine, the concentration of morpholine, the value of p$K_w$ and the initial acid concentration. Two titrations containing formaldehyde (30 and 200 $\mu$l) were than analysed holding the parameters above constant and globally optimizing only the values of log $K_1$ and log $K_2$, the p$K_a$ value of the protonated bis-aminal, the initial acid concentration, the added acid concentration. Finally the two titrations containing 200 $\mu$l and 2 ml of formaldehyde were analysed optimizing the p$K_a$ of the protonated hemi-aminal, initial acid concentration and added acid concentration. At the lower formaldehyde–morpholine concentration (titration conducted in 0.5$M$ KCl) the concentration of the bis-aminal was too low to determine its p$K_a$.

*Kinetics*

The ability of the instrumentation to record the full time course of the change in pH after each titrant addition (Fig. 3) allows some kinetic analysis. The time course is well modelled by a single exponential (Fig. 4). For a small perturbation of the system shown in Scheme 1, assuming that all proton exchanges are rapid, a two exponential relaxation is expected, one for each equilibrium that is not a proton transfer reaction. Under conditions where [ML] far exceeds [$ML_2$], the amplitude of the second exponential

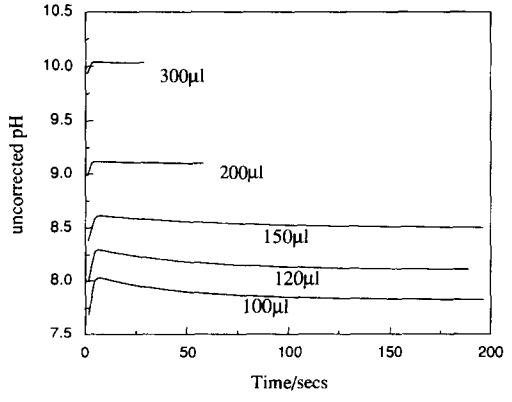

Fig. 3. Variation of pH with time at the titrant volume indicated. The data corresponds to curve 2 (◇) in Fig. 1. The rapid pH change completed in the first 5 sec is the equilibration of the glass electrode with the solution. The slower change is the equilibration of formaldehyde and morpholine with aminal. The slower change is an exponential relaxation with a half-time which varies with pH. The pH is uncorrected and includes an electrode zero of 0.782.

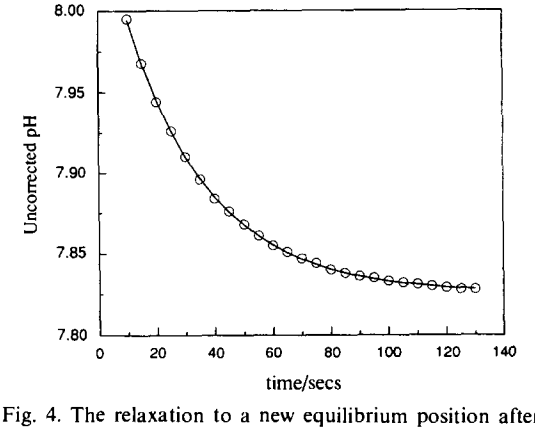

Fig. 4. The relaxation to a new equilibrium position after each titrant addition is a single exponential under conditions where [ML]≫[$ML_2$]. The solid line is simulated from the value of $k_{obs}$ optimized by non-linear regression using a single exponential function. The data corresponds to the addition of 10 $\mu$l of 0.2$M$ KOH to give the 100 $\mu$l titration point of curve 2 (◇) in Fig. 1. The first 10 sec have been truncated to remove the initial response of the glass electrode to the changed pH.

will be negligible and the single remaining exponential should have a rate constant that is dependent on the concentration of free formaldehyde ([M]) and morpholine ([L]) as shown by equation 7.

$$M + L \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ML \quad K_1 = 954$$

$$k_{obs} = k_2 + k_1([M] + [L]) \tag{5}$$

$$K_1 = [ML]/[M][L] = k_1/k_2 \tag{6}$$

$$k_{obs} = k_1(1/K_1 + [M] + [L]). \tag{7}$$

The concentrations, $[M]$ and $[L]$, for each relaxation, were obtained from the speciation calculated from stability constants determined in the previous section. A plot of $k_{obs}$ against $1/K_1 + [M] + [L]$ should then give a straight line through the origin with a gradient of $k_1$ (Fig. 5). Linear regression to this model gives a value of $k_1 = 0.77M^{-1}\text{sec}^{-1}$. Since $k_1/k_2 = 954M/\text{sec}$, $k_2$ must be $k_1/K_1 = 8.1 \times 10^{-4}$ sec$^{-1}$. In principle the same approach could be used to determine the rate constants comprising $K_2$.

## DISCUSSION

The results are generally in agreement with Kallen and Jencks but are likely to be of greater accuracy mainly because analysis of full pH titration curves allows the use of internal calibration of the glass electrode zero, total morpholine concentration and total acid concentration. The introduction of the protonated bis-aminal, led to a significant improvement in the fit, although the standard error of this parameter is large.

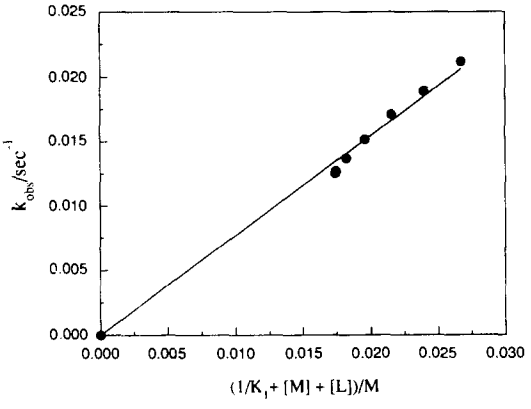

Fig. 5. The value of $k_{obs}$ at each titration point from 120–180 $\mu$l, curve 2 (◇) in Fig. 1, against $1/K_1 + [L] + [M]$ where [L] is the concentration of free neutral morpholine and [M] that of free formaldehyde calculated from the speciation at each point. The solid line is drawn from the slope optimized by linear regression to equation (7). This gives a value for $k_1$ of $0.77M^{-1}$ sec$^{-1}$.

The stability constants of the hemi-aminal and bis-aminal are not altered greatly by a five-fold increase in ionic strength. This is to be expected since both species have no net charge. However the p$K_a$ of the morpholinium ion and of the protonated hemi-aminal increase by 0.57 and 0.54 respectively. Because the p$K_a$ of the protonated bis-aminal could only be determined at the higher ionic strength, the effect of ionic strength on its value is not known. It presumably increases by a similar amount to the hemi-aminal. The result of increased ionic strength is thus to decrease the concentration of hemi-aminal and bis-aminal while the concentration of morpholinium, protonated hemi-aminal, and probably also the protonated bis-aminal, should increase slightly in concentration.

The kinetics of approach to equilibrium at each titration point provides valuable additional information from which rate constants can be readily determined.

Metal–ligand potentiometric studies have led to a large number of computer oriented algorithms and programs which exploit them. The majority of these should be applicable without any modification to the analysis of formaldehyde–amine equilibria if formaldehyde is recognized as playing the role of the metal-ion while the amine is the ligand. Examples are the non-linear regression programs NONLIN15,[3,4] TITFIT[5] and BEST.[6] Most of these programs can also be used to generate simulated speciation.

The stability constants reported in this work and the effect of ionic strength on them, are important in the analysis of reaction rates involving hemi-aminals and bis-aminals as a function of pH and ionic strength. For example, the bimolecular aromatic Mannich reaction in aqueous media probably proceeds via electrophilic attack of hemi-aminals and bis-aminals on phenols. The determination of equilibrium speciation has recently enabled the author to determine, for the first time, the rate constants for the individual species in the Mannich reaction of the 3-hydroxy-4-pyrone, kojic acid.

# AN ION-EXCHANGE METHOD FOR SELECTIVE SEPARATION OF PALLADIUM, PLATINUM AND RHODIUM FROM SOLUTIONS OBTAINED BY LEACHING AUTOMOTIVE CATALYTIC CONVERTERS

ROMULUS GAITA* and SARGON J. AL-BAZI†

Department of Chemistry, Northeastern Illinois University, Chicago, IL 60625, U.S.A.

(*Received* 17 *May* 1994. *Revised* 15 *August* 1994. *Accepted* 16 *August* 1994)

**Summary**—An ion-exchange method has been developed for the separation of palladium, platinum and rhodium from a solution that is highly acidic and contains a considerable amount of lead, aluminum, iron and cerium, obtained by leaching a used honeycomb type automotive catalytic converter. A column of Amberlite IRA-93 anion-exchange resin was found appropriate to recover platinum metals from the pregnant solution. Selective stripping of these metals from the resin was achieved by eluting rhodium first with 6.0*M* hydrochloric acid, then palladium with a 1% ammonia solution at ambient temperature, and platinum with 5% of the reagent at elevated temperatures. Optimum conditions for leaching these metals from the catalyst were 5.0*M* hydrochloric acid and 0.4*M* sodium chlorate at 70°C. This method can be applied to both analytical as well as large scale operations. It is simple, economical, and relatively safe for human exposure and the environment.

There are two common automotive catalytic converter catalysts in use.[1] The so-called 'low-loading' form contains about 370 ppm of platinum and about 160 ppm of palladium, and the 'high-loading' form contains approximately 60% more of each of these elements. There is also an 'extra high-loading' catalyst which contains about 850 ppm of platinum and 350 ppm of palladium and even some varieties which contain more palladium than platinum. These palladium–platinum catalysts are usually referred to as 'two-way' catalysts since they cause the oxidation of both carbon monoxide and hydrocarbons.

Rhodium has been introduced into catalytic converters. Since then, approximately 73% of the world production of rhodium is consumed in the production of autocatalysts.[2] These monolithic automotive catalysts are typically Cordierite type honeycombs with platinum, palladium and rhodium. These catalysts are called 'three-way' catalysts, since they not only oxidize carbon monoxide and hydrocarbons but also various nitrous oxides.

The average loading of platinum group metals per catalytic converter has been 0.05 troy ounces of platinum, 0.02 troy ounces of palladium and 0.005 troy ounces of rhodium.[3] Each year, approximately 10 million automobiles are scrapped in the United States. Based on an equivalent number of converters, it is estimated that 500,000 troy ounces of platinum and 200,000 troy ounces of palladium and 50,000 troy ounces of rhodium will be wasted annually just in the United States. The annual world consumption of these metals for autocatalyst use could double or triple the above numbers. Since these metals are in limited supply, a successful process for their recovery from catalytic converters will play an important part in their future availability and prices.

Dissolution of palladium, platinum and rhodium presents special problems owing to their generally high ionization potential (the first ionization potential of Pd = 8.3 eV, Pt = 9.0 eV and Rh = 7.5 eV). This coupled with the complex variety of elements in the used catalytic converter makes it difficult to leach these metals from the catalyst, and to isolate them from the pregnant solution. Furthermore, the increasing variety of catalysts produced, the apprehension over industrial pollution, and

*Present address: Allied Signal Research & Technology, Des Plaines, IL 60017, U.S.A.

†Author to whom correspondence should be addressed.

concern with human exposure to chemicals is making the development of new processes to recover these metals from the catalysts more difficult.

The method commonly employed for a selective separation of palladium, platinum and rhodium from the solution obtained by leaching catalytic converters is based on 'wet chemical' procedures.[1,4] Platinum is precipitated as ammonium hexachloroplatinate(IV) and rhodium as ammonium hexachlororhodate(III) by saturating the decomposed mother liquor with ammonium chloride. Palladium is precipitated as ammonium hexachloropalladate(IV) after oxidation to palladium(IV). This method is considered inefficient by today's standards in terms of the degree of separation achieved, the yields obtained, and the complexity of the operation. Solvent extraction methods[5–7] have ben developed to overcome the problems related to traditional practice. However, this technique is characterized by very slow kinetics[8] and selective back-extraction does not appear to be easily achieved.[9–12] Furthermore, the utilized organic solvents tend to be volatile, flammable and toxic which may introduce pollution to the environment.

The purpose of this study was to develop an ion-exchange method for the selective separation of palladium, platinum and rhodium from the solution obtained by leaching them from the honeycomb type catalytic converter. The optimum conditions for leaching these metals from the catalyst were also investigated.

## EXPERIMENTAL

### *Reagents*

Anion-exchange resins Amberlite IRA-68 (20–30 mesh particle size) and Amberlite IRA-93 (20–30 mesh particle size) both from Alfa Products, and Amberlite IRA-400 (16–50 mesh particle size) of Aldrich Chemical Company, were used in their chloride forms. These resins were equilibrated with 10% hydrochloric acid before use. Palladium, platinum and rhodium stock solutions of 1000 ppm were prepared by dissolving a weighed amount of palladium(II) chloride (Aldrich Chemical Company), platinum(II) chloride (Johnson Matthey) and rhodium(III) chloride (Aldrich Chemical Company) in 10% hydrochloric acid solution. A stock solution of 10.0*M* lithium chloride and 0.45*M* lanthanum nitrate hexahydrate (Li/La) was prepared in deionized water. All other reagents were of analytical grade. A used honeycomb type automotive catalytic converter ground to minus 60 mesh particle size was obtained from Catalytic Converter Refining Co., Northlake, IL.

### *Apparatus*

A glass chromatographic column (18 cm long and 4.8 mm inner diameter) was used. Palladium, platinum and rhodium were determined with a Spectraspan IV (Beckman Instruments) direct coupled plasma atomic emission spectrometer. The flow rate was controlled by an Econo peristaltic pump (Bio-Rad, California). An ATC autosampler (Techni Lab, NJ) was used to collect 2 ml fractions.

### *Leaching procedure*

The schematic diagram for leaching palladium, platinum and rhodium from the catalytic converter is shown in Fig. 1. A 20.0 g sample in a 250 ml beaker was treated with 95.0 ml of the desired concentration of hydrochloric acid. With continued stirring, the heterogeneous mixture was heated (see discussion for details) and then a small amount of sodium chlorate was added slowly from a 50.0 ml buret. After cooling to room temperature in an ice bath, the solution was filtered into a 100 ml volumetric flask and distilled water added to the mark. This

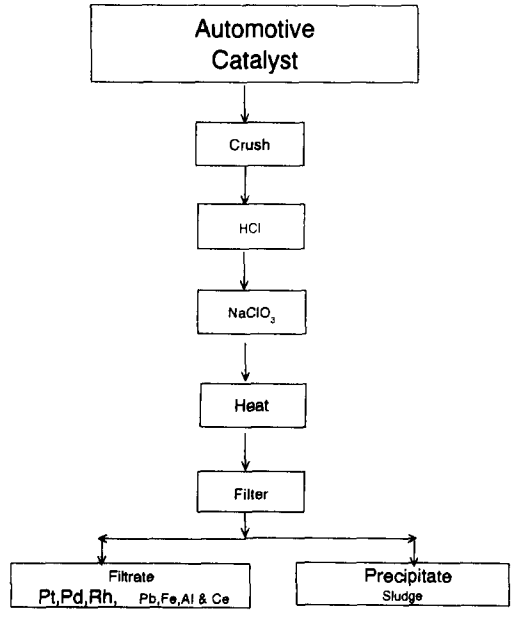

Fig. 1. Flow diagram for leaching palladium, platinum and rhodium from automotive catalyst.

solution was then divided into two 50.0 ml portions. To one portion, 2.50 ml of the Li/La solution was added to suppress interferences and improve detection limits. This portion was then used for the analysis of palladium, platinum and rhodium. The other portion was used to determine the acidic content.

*Recovery and stripping procedure*

*Batch ion-exchange procedure.* Resin (1.0 g) and 10.0 ml solution of palladium, platinum and rhodium were stirred moderately for 2.5 hr at room temperature in a 25 ml beaker. After equilibration the solution was filtered through a Whatman # 2 filter paper. The loaded resin was then washed for 5 min with 10.0 ml deionized water, filtered and mixed with 10.0 ml of the stripping solution for 1.5 hr at room temperature. To the filtrate from the recovery and stripping experiments, 0.50 ml of the Li/La solution was added and the filtrate solution then analyzed for palladium, platinum and rhodium.

*Column ion-exchange procedure.* The column was filled with a slurry of the resin until the settled resin bed reached the top of the column (2.0 g of dry resin). A 25.0 ml portion of the pregnant solution was passed through the column at a flow rate of 1 ml/min controlled by the peristaltic pump. The platinum metals were then selectively eluted from the column with the stripping solution. In both studies, 2 ml fractions of the eluate were collected with auto sampler, treated with 0.10 ml of the Li/La solution, and analyzed for palladium, platinum and rhodium.

## RESULTS AND DISCUSSION

The optimum conditions for leaching palladium, platinum and rhodium from the used catalytic converter were established by investigating the effects of various parameters.

*Effect of sodium chlorate concentration*

Varying the concentration of sodium chlorate from zero to 1.1*M* (Fig. 2) indicating that at zero sodium chlorate, less than 5.0 ppm of palladium, 0.5 ppm of platinum and 1.1 ppm of rhodium were recovered. Leaching increased sharply with increasing sodium chlorate to a maximum of 32.5 ppm palladium, 290 ppm platinum and 7.0 ppm rhodium at 0.4*M* sodium chlorate and then decreased slowly. The effect of sodium chlorate on the concentration of hydrochloric acid of the leached solution was linear; acid concentration decreased with increasing sodium chlorate (fits the least-squares equation $[HCl]_{final} = -1.878\ [NaClO_3]_{initial} + 3.624$). The decrease in acid concentration may explain the decrease in palladium, platinum and rhodium leached beyond 0.4*M* sodium chlorate concentration.

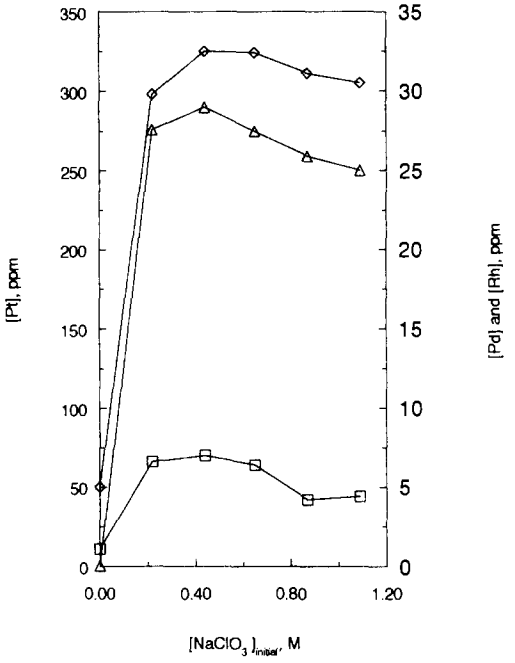

Fig. 2. Effect of sodium chlorate concentration on leaching palladium, platinum and rhodium: autocatalyst weight = 20.0 g, $[HCl]_{initial} = 4.8M$, temperature = 70°C, heating period = 1 hr: (◇) Pd, (△) Pt, (□) Rh.

*Effect of hydrochloric acid concentration*

Leaching palladium, platinum and rhodium from 0.4*M* sodium chlorate solutions increased from 2.0 ppm at zero concentration to a maximum of 31.4 ppm at 1.8*M* hydrochloric acid (Fig. 3). The amount of platinum leached increased sharply from 0.8 ppm at zero concentration to 327 ppm at 7.2*M* and then remained constant at higher concentrations of acid. About 0.1 ppm rhodium was leached in the absence of hydrochloric acid and 5.5 ppm at 1.8*M* which further increased to a maximum of 8.1 ppm from a 5.4*M* solution. The increase in the amount of palladium, platinum and rhodium leached with increasing acid concentration may be related to the formation of chlorocomplexes of these metals [$PdCl_4^{2-}$, $PtCl_6^{2-}$ and $RhCl_6^{3-}$] which are much more stable than their aquocomplexes [$Pd(H_2O)_4^{2+}$, $Pt(H_2O)_6^{4+}$ and $Rh(H_2O)_6^{3+}$].

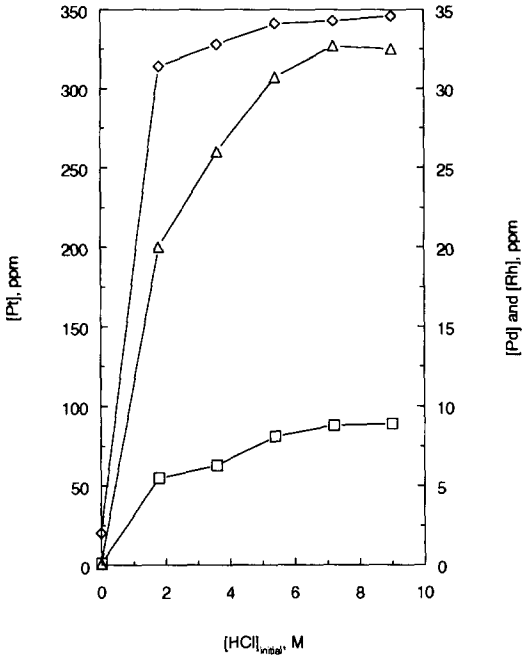

Fig. 3. Effect of hydrochloric acid concentration on leaching palladium, platinum and rhodium: autocatalyst weight = 20.0 g, $[NaClO_3] = 0.4M$, temperature = 70°C, heating period = 1 hr: (◇) Pd, (△) Pt, (□) Rh.

*Effect of temperature*

Palladium leaching was independent of the temperature (Fig. 4), while platinum leaching increased from 176 ppm at room temperature to a maximum of 325 ppm at 95°C. Rhodium leaching increased from 3.3 ppm at room temperature to a maximum of 9.5 ppm at 95°C. The effect of temperature on the hydrochloric acid content of the leached solutions showed a linear decrease in acid concentration with temperature which can be expressed by the following regression equation $[HCl]_{final} = -0.043\ t + 5.104$ over the temperature range of 32° to 95°C studied. Because hydrochloric acid evaporates at elevated temperatures, a temperature of 70°C was recommended for optimal leaching.

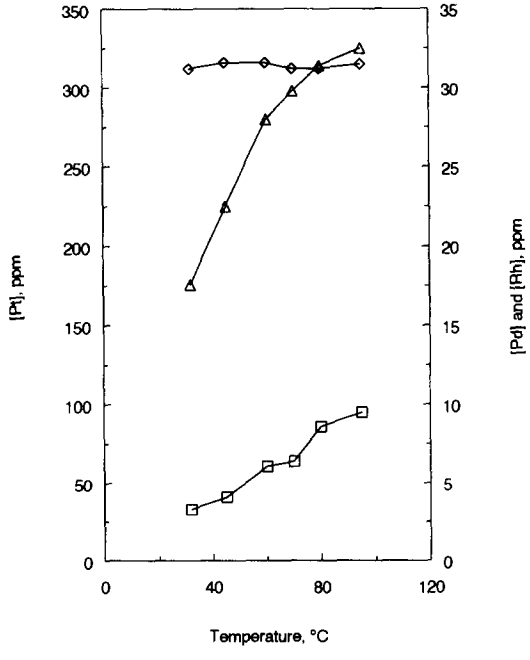

Fig. 4. Temperature effect on leaching palladium, platinum and rhodium: autocatalyst weight = 20.0 g, $[HCl]_{initial} = 4.8M$, $[NaClO_3] = 0.4M$, heating period = 1 hr: (◇) Pd, (△) Pt, (□) Rh.

*Separation of palladium, platinum and rhodium*

*Evaluation of anion-exchange resins.* Three anion-exchange resins, Amberlite IRA-400, Amberlite IRA-93 and Amberlite IRA-68 were tested using a batch procedure to select a resin that is efficient in both recovery and stripping of palladium, platinum and rhodium. Recovery of these metals from a $4.0M$ hydrochloric acid solution containing a synthetic mixture of 25 ppm of each metal, and stripping with 5% $NH_3$ solution were investigated. Although the quantitative recovery of palladium and platinum could be achieved with both Amberlite IRA-400 and Amberlite IRA-93 resins, the latter exhibited more favorable results in the recovery of rhodium and its stripping with platinum (Table 1).

*Recovery of* Pd, Pt *and* Rh. The recovery of palladium, platinum and rhodium from a pregnant solution that was made 280 ppm platinum, 340 ppm palladium, 380 ppm rhodium and which contained 6450 ppm aluminum, 1610 ppm iron, 947 ppm cerium and 397 ppm lead showed a recovery of 99% palladium, 97% platinum and 61% rhodium (Table 2). The results also indicated that 13% aluminum, 32% iron, 18% cerium and 80% lead were retained by the resin. The decomposition of $RhCl_6^{3-}$ in

aqueous solution to $[RhCl_{6-x}(H_2O)_x]^{x-3}$ types may be the major problem in its recovery.[13]

*Elution of rhodium.* In an attempt to strip rhodium selectively, the resin was treated with 25.0 ml of 6.0*M* hydrochloric acid solution at 1 ml/min at room temperature. Palladium and platinum remained on the resin whereas 80% of the rhodium was eluted (Table 2). Therefore, a complete elution of rhodium can be achieved by controlling the volume of hydrochloric acid. When the stripping solution was tested for aluminum, cerium, iron and lead, both aluminum and cerium were quantitatively eluted while 84% of the lead and 44% of the iron were eluted under these conditions. These two metals were removed completely with 25.0 ml deionized water at 1 ml/min.

*Elution of palladium.* When the resin from previous investigation was treated with 25.0 ml of 5% $NH_3$ solution (flow rate 1 ml/min), 98% palladium was eluted with only 7% platinum (Table 2).

Elution of palladium and platinum from the resin with different volumes of 5% $NH_3$ solution was studied by passing the eluent through the column loaded with these metals and treated with 25.0 ml each of 6.0*M* hydrochloric acid and deionized water (Fig. 5). A 4.0 ml of 5% $NH_3$ solution was sufficient to strip palladium completely with only a small amount of contaminating platinum. To improve the selectivity of eluting palladium, different percentages of ammonia solution from 1 to 10% (25.0 ml volume) were studied. Less than 2% of ammonia solution was sufficient to strip palladium selectively (Fig. 6). Furthermore, concentrations below the limits of analytical detection were obtained when the eluted solution was tested for iron, lead, aluminum and cerium.

*Elution of platinum.* The stripping of small amounts of platinum from the resin (Figs 5, 6) may be related to the slow rate of formation of $Pt(NH_3)_6^{4+}$ in comparison to $Pd(NH_3)_4^{2+}$ com-

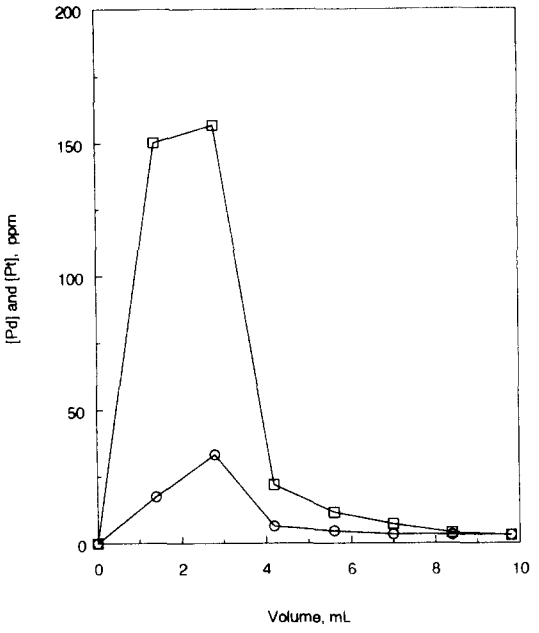

Fig. 5. Elution curves for palladium and platinum: 5% $NH_3$ solution (v/v), flow rate = 1 ml/min (□) Pd, (○) Pt.

plex.[14] In an attempt to improve the stripping efficiency for platinum, the effect of column temperature was studied. The column was packed with resin and loaded with platinum, then immersed completely in a water bath maintained at 65°C. An aliquot of 25.0 ml solution of 5% $NH_3$ (heated to 65°C) was passed through at a flow rate of 1 ml/min. The percentage of platinum recovered increased from 7% at room

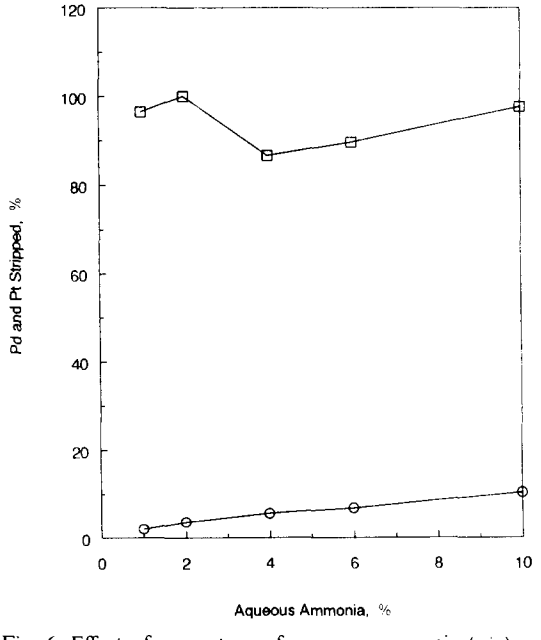

Fig. 6. Effect of percentage of aqueous ammonia (v/v) on stripping palladium and platinum: solution volumes = 25.0 ml, flow rate = 1 ml/min: (□) Pd, (○) Pt.

temperature to 42% at 65°C. When this experiment was repeated at a flow rate of 0.5 ml/min, the per-cent of platinum eluted further improved to 65%. This indicates that a complete recovery of platinum from the resin can be accomplished by controlling the percentage of ammonia solution, its flow rate and the column temperature.

*Capacity of Amberlite IRA-93 for* Pd *and* Pt *uptake*

The capacity of the resin to retain palladium and platinum was estimated from a breakthrough study: 275 ml of 4.0*M* hydrochloric acid containing 350 ppm platinum and 275 ppm palladium were passed through the column (packed with 2.0 g of the resin) at a flow rate of 1 ml/min. From the plot of concentration of the metal unretained versus volume of the solution collected (Fig. 7), capacities of 0.44 mol platinum/kg resin and 0.85 mol palladium/kg resin were calculated. Owing to these high resin capacities, Amberlite IRA-93 may be of practical value in recovering palladium and platinum from a solution obtained by leaching these metals from automotive catalytic converters.

*Recommended process for macro scale recovery of* Pd, Pt *and* Rh

A recommended process for leaching palladium, platinum and rhodium from the automotive catalytic converter and their selective recovery from the leached solution using Amberlite IRA-93 is summarized in Fig. 8. A 5.0*M* hydrochloric acid solution is mixed with the catalyst sample and then heated to 70°C. At this temperature, a 0.4*M* sodium chlorate solution is added slowly and the mixture is filtered. The pregnant solution is then passed through the resin. The column is washed with 6.0*M* hydrochloric acid solution followed by deionized water. The hydrochloric acid solution (containing non-saturating amount of rhodium) is saved for reuse. The resin is then treated at room temperature with 1% $NH_3$ solution to strip palladium followed by 5% of the reagent at elevated temperatures and a slow flow rate to elute platinum. The separation of palladium and platinum from the eluted solution could then be processed either by reduction to metal or precipitation as $(NH_4)_2PdCl_4$ and $(NH_4)_2PtCl_6$ by hydrochloric acid.[15] The original leaching solution is then adjusted to 5.0*M* hydrochloric acid, heated to 70°C and reused several times to leach platinum metals from a new batch of the catalytic converters and passed through the resin again. After several recycling processes, the leaching solution becomes rich in rhodium. This recycled solution can then be passed through the resin many times to recover rhodium. After each cycle, the resin is washed with the saved hydrochloric acid solution to strip rhodium which then can be recovered by a selective reduction to metal.[2]

## CONCLUSIONS

The described ion-exchange method, using Amberlite IRA-93, for selective separation of palladium, platinum and rhodium from acidic solutions obtained by leaching honeycomb type catalytic converter can be considered an efficient technique for the separation of these metals on

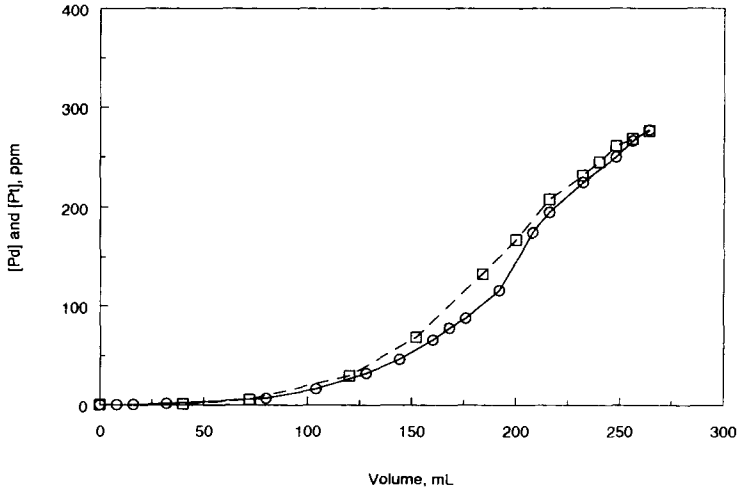

Fig. 7. Breakthrough curves for palladium and platinum: [Pd] = 275 ppm, [Pt] = 350 ppm, [HCl] = 4*M*, solution volume = 275 ml, flow rate 1 ml/min: (□) Pd, (○) Pt.

an analytical scale and could be applied to large scale operations. This method is not restricted solely to automotive catalysts but is also applicable to petrochemical catalysts, ores, and industrial wastes. It is noteworthy that owing to the nontoxicity, nonvolatility, and nonflammability of the ion-exchange resin, this method may present fewer environmental hazards than the currently adopted solvent extraction and precipitation techniques.

# A FLOW INJECTION ANALYSIS TECHNIQUE FOR THE DETERMINATION OF CHLORIDE USING REFLECTANCE DETECTION

RICHARD H. TAYLOR and JAY W. GRATE
Pacific Northwest Laboratory, K2-12, P.O. Box 999, Richland, WA 99352, U.S.A.

(*Received* 5 *May* 1994; *Revised* 12 *August* 1994. *Accepted* 16 *August* 1994)

**Summary**—A flow injection (FI) determination for chloride has been developed using the light reflectance of the precipitate formed by the reaction of chloride with silver(I) as the method of detection rather than turbidimetry, as in the previous FI method using this reaction. The dynamic range of the analysis is increased to 0–10 m*M* chloride with a 10 m*M* silver(I) reagent and to 0–50 m*M* chloride with a 50 m*M* silver(I) reagent by using this mode of detection. The ability to select the injected reagent from an option of two concentrations via the control program is incorporated into the FI system, enhancing the versatility of the analysis.The dynamic range is further extended to 100 m*M* chloride by measuring the signal levels at the trailing portion of the response curve. The consumption of reagent is kept to a minimum by merging injected zones of sample and reagent instead of using a constant reagent stream.

The determination of chloride concentration was one of the earliest applications of flow injection analysis (FIA) to the analysis of environmental waters.[1,2] These analyses used the formation of an iron(III) thiocyanate complex to determine the chloride spectrophotometrically, after the reaction of chloride with mercury thiocyanate.[1–5] These reports state an initial range up to 75 mg/l.,[3,4] which, through the application of stream splitting[1,2] or pre-injection dilution,[5] was extended up to 800 mg/l. Another method employing photometric detection used the formation of a silver chloride precipitant, by the reaction of chloride with the silver(I) ion, as a method of chloride analysis by FIA.[6] In this study, turbidimetry was used as the method of detection, and a range of 0–14 mg/l. was given.

This report describes the development of a flow injection (FI) method for the determination of chloride. The method has five main features. First, the previously mentioned silver(I)–chloride chemistry, which forms a white precipitate, is used. Second, reflectance rather than turbidimetry is used as the detection method. Reflectance is measured by using a flow cell with a bifurcated optical fiber bundle. The system flow and cell geometry forces the particulate to remain suspended while passing through the flow cell. Third, the ability to select, through the control program, from two silver(I) reagent solutions of differing concentrations is provided. This extends the dynamic range of the analysis when sample concentrations are determined from the maximum reflectance peak height. Fourth, the dynamic range of the analysis is further extended by measuring the signal levels at the trailing portion of the response curve. Concentrations up to 3500 mg/l. were measured by this method, far higher than the previous method using this chemistry. Moreover, this measurement can be done in spite of the increasing solubility of silver chloride at high chloride concentrations. Fifth, the method was developed in such a manner as to minimize the amount of silver reagent used by co-injecting reagent and sample rather than injecting sample into a continuous reagent stream. The advantages of this new method include the extended dynamic range, the avoidance of a mercury-containing reagent, and the minimization of the silver reagent.

## EXPERIMENTAL

### *Reagents*

All solutions were prepared in deionized water. Chloride samples in the range of 2–100 m*M* were prepared with potassium chloride (Mattheson Coleman and Bell) and the reagents were 0.010 and 0.050*M* silver nitrate (Cascade Silver Co.). The carrier for both sample and reagent streams in the determination of chloride

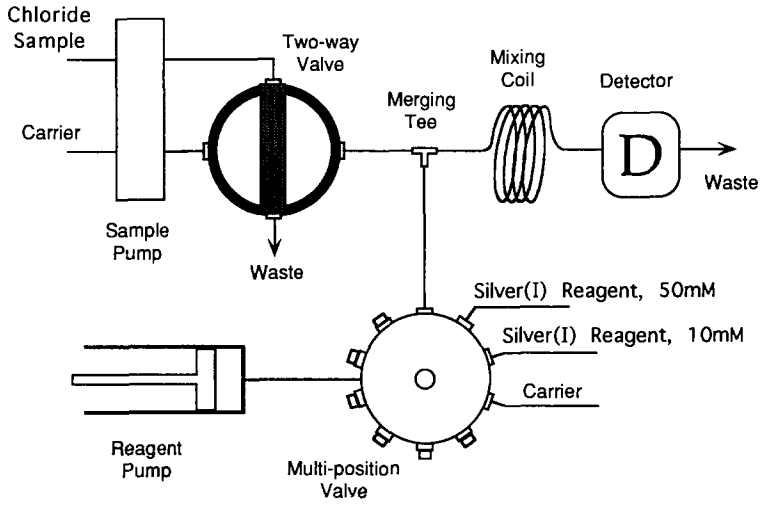

Fig. 1. Schematic of the chloride system.

was deionized water, which was also used as the blank solution for the analysis. When determining the overlap of the sample and reagent zones 0.01*M* borate solution (Aldrich) was used as carrier, and 0.004% Bromothymol Blue (BTB) (Aldrich) was injected in place of sample and reagent.

*Apparatus*

A schematic of the FI system for the determination of chloride is shown in Fig. 1. The system was assembled using an Alitea Modular Injection System Type MIS-1B (housing the peristaltic sample pump and the multi-position reagent stream valve); an Alitea Model S2-V piston pump for the reagent stream; a Valco 10-port 2-way sample injection valve; and an Alitea ODS-1 detection system, which used a Brinkman PC 701 colorimeter. The colorimeter was used without an interference filter installed and was connected to the flow cell (Fig. 2) by a bifurcated fiber optical bundle. The flow cell was modified by the removal of the internal reflecting plate. The direction of flow through the cell was vertical with the lower opening as the inlet. This, along with the force of the flow prevented the accumulation of the precipitate within the flow cell light path. All components were controlled and data collected using the FIALab control program (Alitea) running on a Northgate® 486ZXP computer equipped with a Real Time Device ADA1100 data acquisition board.

Tygon® tubing of 1.02 mm inside diameter was used in the peristaltic pump for both the sample and the sample stream carrier, and a 5 ml syringe was used in the reagent stream pump. The sample injection valve had a 24$\mu$l sample loop. Tubing upstream of the PEEK merging tee was 0.82 mm inside diameter PTFE (Upchurch). The tubing downstream of the tee, which formed the mixing coil, was a 45 cm length of 0.5 mm inside diameter Tygon® tubing.

*General procedure*

Prior to performing the analysis the control program was selected which directed the multi-purpose valve to the port of the reagent with the desired concentration. The selected silver(I) reagent, using the piston pump and the multi-position valve, and the chloride sample, using the peristaltic pump and the 2-way valve, were injected into separate deionized water carrier streams. These two zones were propelled to a tee where they were merged and then sent through the mixing coil to the detector flow cell, where

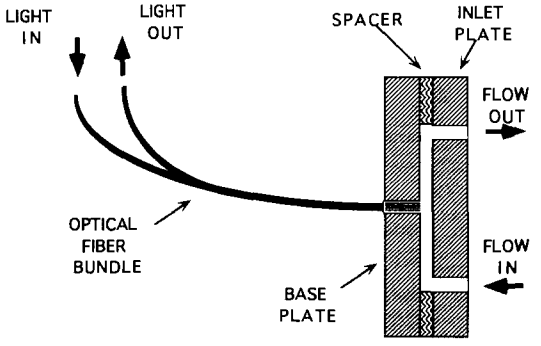

Fig. 2. Cut-away schematic of the detector flow cell. The reflector plate, normally located between the spacer and the inlet plate for absorbance measurements, was removed.

the reflectance of the silver chloride precipitate was measured.

The analysis was initiated by filling the syringe of the piston pump with 0.62 ml of deionized water. The multi-position valve was then directed to the selected reagent line, and 67$\mu$l of the silver(I) reagent of the desired concentration was drawn into the system. At this point the multi-position valve was redirected, and the direction of the piston pump reversed, sending the isolated volume of silver(I) reagent toward the merging tee. At the same time, the peristaltic pump started, and the sample loop of the 2-way injection valve was flushed with the chloride-containing sample for 6 sec before 24 $\mu$l of the chloride sample were injected into the sample stream. Both reagent and sample streams had a flow rate of 1.0 ml/min, creating a flow of 2.0 ml/min downstream of the merging tee, through the mixing coil and the detector flow cell.

*Adjustment of the reagent zone*

In order to form the maximum amount of precipitate possible it is necessary that the entire chloride sample zone come in contact with the silver(I) reagent. The volume of the chloride sample zone was physically fixed by the sample loop on the injection valve. The volume of the silver(I) reagent zone, however, was determined by the length of time the multi-position valve was directed to the reagent line and the flow rate of the piston pump during that time. Varying these parameters involved only software commands, requiring no physical alteration of the system. The silver(I) reagent volume and the time of injection were adjusted such that the silver(I) reagent zone was larger than and completely overlapped the chloride sample zone when the two streams merged. This was determined by injecting BTB dye in lieu of each solution in turn and observing the detector response. This approach provides information on both the timing and dispersion of the zones. The degree of overlap and comparative dispersion of the two zones as determined by this method are illustrated in Fig. 3.

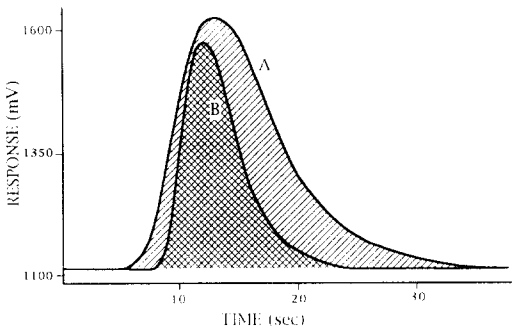

Fig. 3. Representation of the overlap of the reagent zone (A) of the sample zone (B), determined by the injection of 0.004% BTB dye for each zone individually and then combining the two data sets.

## RESULTS AND DISCUSSION

Chloride solutions of varying concentration were injected into the sample stream, and a 0.010 or 0.050$M$ silver nitrate solution was used as reagent. The separate streams merged to mix the two solutions, forming a zone of silver chloride precipitate. This zone passed through the detector flow cell and the reflectance of the white precipitate was measured.

The intensity of the light source was adjusted such that the baseline response corresponded to the reflected light intensity giving a reading of 80% T on the detector meter. The increase of the intensity of the reflected light as the reaction precipitate moved through the flow cell resulted in an increase in the detector response output voltage, and could be viewed on the detector meter as an apparent increase in transmittance. This increase in the detector output voltage was compared with the chloride concentration of the injected sample.

In the range from 0–10 m$M$ (0–354 mg/l.) a linear proportionality between maximum response peak height and the chloride concentration of the sample was obtained using the 0.010$M$ silver(I) reagent. The found line had a slope of 0.0255 m$M$/mV and an intercept of $-0.065$ m$M$, giving a correlation coefficient of 0.998. The non-zero intercept is due to the refractive index change which occurs when the silver(I) reagent zone passes through the flow cell.

Using the 0.050$M$ silver(I) reagent a linear proportionality between maximum response peak height and the chloride concentration of the sample was obtained in the range from 0–50 m$M$ (0–1770 mg/l.). The found line had a slope of 0.0303 m$M$/mV and an intercept of 0.66 m$M$, giving a correlation coefficient of 0.998.

Although the sample undergoes greater dispersion than the reagent (Fig. 3) due to less volume being injected, above a certain chloride concentration (approximately 12 and 60 m$M$ when using the 0.010 and the 0.050$M$ silver(I) reagent, respectively) the silver(I) reagent

becomes the limiting reactant. This is expected to produce a maximum response level which would not be exceeded, forming peaks which had a level plateau on the top, with an increase in peak width with increasing chloride concentration. It was observed, however, that along with the increase in width, the peaks began to 'invert' at the top and that the maximum height decreased as the chloride concentration increased (Fig. 4). Two factors may contribute to the observed effect. First, the solubility of silver chloride increases with the chloride concentration above chloride concentrations of approximately 10 m$M$ [7] due to the formation of soluble silver complexes such as $AgCl_2^-$ and $AgCl_3^{2-}$.[8,9] Second, it is possible that the aggregation and reflectance properties of the precipitate vary depending on which species, silver(I) or chloride, is in excess. The surface charge of the precipitate particles, and hence any particle/particle repulsions, depend on the ions adsorbed on the particle surfaces.

Nevertheless, the varying chloride concentration of the dispersed sample zone creates an area of the merged reactants in which the chloride concentration is less than that of the silver reagent, and signal levels are still proportional to the chloride concentration. Using the detector response after the inverted portion of the response, where the desired sample to reagent ratio is achieved, a convenient correlation between detector response and chloride concentration can still be found. The response levels using the 0.010$M$ silver(I) reagent at delay times of 22 and 24 sec after injection were examined (Fig. 4). These times were determined by observation of the detector response to the injected sample of highest concentration (100 m$M$ $Cl^-$). At a delay time of 22 sec a linear relationship was found with a slope of 0.765 m$M$/mV, an intercept of −0.843 m$M$, with a correlation coefficient of 0.998. At a delay time of 24 sec a linear relationship was found with a slope of 1.77 m$M$/mV, an intercept of −2.10 m$M$, with a correlation coefficient of 0.999.

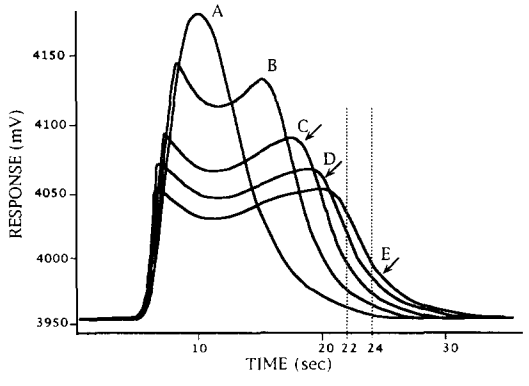

Fig. 4. Representation of the response curves of an injected sample of 10–100 m$M$ chloride reacted with 0.010$M$ silver(I), showing the reduction of response which occurred at higher concentrations. The signal level at delay times of 22 and 24 sec were used to extend the dynamic range of the analysis. (A = 10 m$M$, B = 20 m$M$, C = 50 m$M$, D = 75 m$M$, E = 100 m$M$).

The time required to perform a single analysis was 82 sec, which includes the time to fill the syringe. This gives an analysis frequency slightly greater than 40 $h^{-1}$. Multiple analyses ($\geq 3$) were performed for each sample, with a relative standard deviation (RSD) of less than 1.5% for samples in the range of 0–10 m$M$ $Cl^-$ and less than 3% for samples 10–100 m$M$ $Cl^-$ with the 0.010$M$ silver(I) reagent and an RSD of less than 3.5% for all analyses using the 0.050$M$ silver(I) reagent. This precision is comparable with FI methods using the mercury thiocyanate–iron chemistry which have reported RSD values of 1.2 and 1.3%.[2,5] The automated method introduced here compares favorably with manual titrimetric methods which have reported RSD values of 4.2% by Mohr's method (titration with silver nitrate with a potassium chromate indicator) and 3.3% by mercuric nitrate titration.[10]

## CONCLUSIONS

A flow injection method for the analysis of chloride, with a dynamic range of 0–100 m$M$ (0–3500 mg/l.), using the reaction with Ag(I), and performing detection by reflectance, was devised. This approach greatly increases the dynamic range of the former FIA method using this chemistry, which used turbidimetry as the method of detection. It also avoids the use of mercury containing reagent, which has formerly been used in other FIA photometric determinations of chloride. The silver reagent, although less of a hazard than the mercury reagent, is a controlled waste, and the method is designed such that its use is minimized, thus reducing its consumption and its concentration in the waste generated.

The dynamic range of the analysis can be adjusted in two ways. First, for analyses where the sample concentration is determined from the reflectance peak height, the silver reagent must be present in excess. This can be achieved by

selecting a silver reagent solution of appropriate concentration using the multi-position valve, as we have demonstrated. The possible choices of silver reagent concentration are limited only by the number of valve ports available. Alternatively, when chloride concentrations exceed silver reagent concentrations, the chloride concentration can be determined from trailing portion of the response curve. In this case, the dynamic range is limited by the width of the silver reagent zone that the chloride sample is merged into. The silver reagent zone width can be increased simply by increasing the volume of the silver reagent injected, which can be easily achieved through the manipulation of the flow program. The ability to either select the concentration of the analytical reagent and/or the width of the reagent zone through the control program enhances the overall versatility of the assay. Although the described method was developed to analyze samples with a chlorine concentration up to 100 m*M*, which satisfied the needs of this laboratory, it can be seen that either of these two techniques could allow for further expansion of the dynamic range.

# DETERMINATION OF GOLD IN BIOLOGICAL MATERIALS BY ELECTROTHERMAL ATOMIC ABSORPTION SPECTROMETRY WITH A MOLYBDENUM TUBE ATOMIZER

KIYOHISA OHTA,* TIKARA ISIYAMA, MASAYOSI YOKOYAMA and TAKAYUKI MIZUNO
Department of Chemistry for Materials, Faculty of Engineering, Mie University, Tsu, Mie 514, Japan

(*Received* 3 *June* 1994. *Revised* 16 *August* 1994. *Accepted* 19 *August* 1994)

**Summary**—Electrothermal atomic absorption spectrometry (ETA-ASS) of gold with a molybdenum tube atomizer has been investigated. A sensitive ETA-AAS method was developed. The gold absorption signal became higher with the heating rate of the tube atomizer and as the ratio of hydrogen in the argon purge gas decreased. The optimal heating rate and the optimal gas flow rate were 5.5°C/msec and Ar 480 ml/min + $H_2$ 20 ml/min, respectively. The absolute characteristic mass (the mass of element giving 0.0044 abs.) of gold by the atomizer was 1.8 pg and the detection limit was 130 pg/ml ($3S/N$). These values were > 10 times better than those obtained with graphite atomizers, ICP and ICP-MS. The interferences caused by large amounts of interferents were evaluated. The addition of thiourea served to eliminate severe interferences. The recovery of spiked gold in biological materials was in the range of 101–106%.

Gold compounds have been used in the treatment of rheumatoid arthritis.[1] However, they are fundamentally toxic for a living body. The determination of gold in biological materials is, therefore, of interest. Several methods have been used to determine gold concentrations including graphite furnace atomic absorption spectrometry (GFAAS),[2–9] inductively coupled plasma emission spectrometry (ICP)[9,10] and flame AAS.[11,12] Although ICP has high sensitivity, the method has severe optical and chemical interferences.[9,11] Flame AAS has poor sensitivity for measuring trace levels of gold in biological materials.[12] GFAAS is in much more general use throughout the world. There is, however, a problem of chemical interference. In order to eliminate the interferences from biological matrices, electrophoretic separation,[2] standard addition method,[5] chemical modification,[6,8] co-precipitation,[13] liquid–liquid extraction[14] and silica gel adsorption of chelate[15] have been used for gold determination in biological and geological materials.

Electrothermal atomization AAS (ETA-AAS) with metal tube atomizers, developed recently,[16–18] has better sensitivity for most metal elements than other analytical instruments, the ability to use smaller sample sizes, and relatively low power and low cost. Despite the advantages, there is a little information on the application of the metal tube atomizer to ETA-AAS.

In the present work, we report a determination of gold in biological materials by ETA-AAS with a molybdenum tube atomizer. Atomization characteristics for gold in the atomizer were evaluated. Interference studies for the gold absorption signal were also performed.

## EXPERIMENTAL

### *Apparatus*

An atomizer consisting of a molybdenum tube (20 mm long and 2.0 mm i.d.) and two supporters (5 mm wide and 20 mm long) was made from a molybdenum foil (0.05 mm thick and 99.95% purity, Rembar Co.). A 0.3 mm diameter hole was drilled at the midpoint of the tube to inject sample solution. Gold AA signals were measured at 242.80 nm (Au-hollow cathode lamp, Hamamatsu photonics Co.) using a monochromator (Nippon Jarrell-Ash 0.5 m Ebert-type), an amplifier, a storage oscilloscope (Iwatsu MS-5021), and a microcomputer (Sord M223). The electric power for heating the atomizer was supplied with two

*Author to whom correspondence should be addressed.

transformers (Yamabishi volt-slider, S-130-30, Cap. 3 k VA). Two pinhole apertures were placed in front of and in the rear of the atomizer, in order to collimate the light beam and eliminate the radiation from the atomizer surface. Background absorption was checked with a deuterium lamp (Original Hanau D200F). The absorption signal from the amplifier and the output signal from a photodiode for the measurement of atomizer temperature were simultaneously fed into the microcomputer. Calibration of the temperature of the atomizer was done against the photodiode voltage using an optical pyrometer (Chino Works) with microcomputer programming.

*Reagents*

A standard stock solution (1 mg/ml, 1*M* HCl solution) of gold (spectroscopic purity) was obtained from Nacalai Tesque Inc. (Kyoto, Japan). Solutions of the matrix elements for the interference study were prepared as chlorides in 0.1–6*M* hydrochloric acid. Standard solutions with concentrations appropriate to the atomic absorption measurements were diluted from the stock solutions with water immediately before use. All other chemicals used here were of analytical grade purity.

*Procedures*

An accurately weighed biological sample (about 0.1 g) was treated with 3 ml of nitric acid (14*M*) and 1 ml of hydrogen peroxide (30%) in a Uni-seal decomposition vessel and heated for 3 hr in an electric oven at 120°C. After the decomposition, the solution was transferred into a Teflon beaker and evaporated by heating in a polyethylene glycol bath (110°C). Then the residue was dissolved in 5 ml of 6*M* hydrochloric acid on the bath. The evaporation was repeated twice more with addition of hydrochloric acid in between. The solution, in which the residue was dissolved, was diluted to 5 ml with 6*M* hydrochloric acid. The resultant solution was diluted to adequate volume (10–20 ml) with a 10 mg/ml thiourea solution for AA measurements.

For the atomization characteristics, the interference study and the determination of gold in biological materials, a 1 $\mu$l portion of the sample solution containing Au (250 pg) was pipetted into the molybdenum tube atomizer. The sample was dried at 80°C for 20 sec, 720°C (410°C for the atomization characteristics) for 10 sec and heated to atomize at 2240°C for 3 sec. The atomizing temperature corresponded to a heating rate of 5.5°C/msec.

## RESULTS AND DISCUSSION

*Effect of heating rate*

Atomic absorption is related to the density of the atomic vapour. The atomization rate of an atomizer affects the density as reported in previous papers[16–18] and hence the effect of the atomization rate, 1.5–5.5°C/msec, on the gold AA-profile was investigated. At more than 5.5°C/msec, the lifetime of the metal atomizer was very short (< 100 firings).

The absorption profile of gold was characterized by a sharper and narrower peak with the increase of the heating rate, as shown in Fig. 1. The appearance temperature of the gold signal (1150°C), which is defined as the temperature of atomizer giving an absorbance of 0.0044, was independent of the heating rate. However, the temperature at the maximum AA signal (peak temperature) was 1910°C at 5.5°C/msec, 1860°C at 4.2°C/msec, 1700°C at 3.0°C/msec, 1630°C at 2.5°C/msec and 1350°C at 1.5°C/msec, and thus, the peak temperature of the signal was found to be dependent on the heating rate. These phenomena are the same as those observed for the absorptions of silver.[17] Gold in the stock solution is in the form of the tetrachloroaurate ion. The chloride ($AuCl_3$) dissociates to give AuCl and $Cl_2$ at high temperature (254°C) and converts to gold metal during the dry stage.[19,20]

The appearance temperature of gold in the molybdenum atomizer is close to the melting point of gold metal (1064°C), but far from the

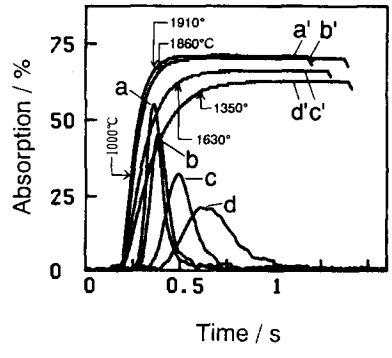

Fig. 1. Effect of heating rate of the molybdenum atomizer on atomic absorption of gold. (a and a') 5.5 C/msec; (b and b') 4.2 C/msec; (c and c') 3.0 C/msec; (d and d') 1.5 C/msec; (a–d) atomization profiles; (a'–d') temperature increasing; Au 250 pg. Purge gas was 480 ml/min Ar + 20 ml/min $H_2$. Pyrolysis temperature: 410 C.

boiling point (2808°C).[19] The vapor pressure for gold metal is $1.47 \times 10^{-7}$ atm, corresponding to $5.20 \times 10^{10}$ atoms in the metal tube atomizer, at 1150°C.[19]

Consequently, 5.5°C/msec heating rate was recommended, in view of the highest peak and the lifetime of the metal atomizer.

*Effect of hydrogen*

Hydrogen added to the argon purge gas is necessary to protect the metal atomizer from oxidation by residual traces of oxygen in the atomizer chamber or in the argon gas cylinder. Therefore, the absorption signal for gold (250 pg) was evaluated in argon–hydrogen purge gas at the heating rate of 5.5°C/msec. In pure argon gas, the highest AA signal for gold was obtained, as shown in Fig. 2. A small addition of hydrogen to the argon purge gas provided the low AA peak. The peak height of the gold signal decreased with increasing ratio of hydrogen. In pure hydrogen, the AA signal became extremely small and shifted to the lower temperature region. The peak temperature for the AA signal was 1610°C in pure argon, 1910°C in Ar 480 ml/min and $H_2$ 20 ml/min, 2000°C in Ar 400 ml/min and $H_2$ 100 ml/min, and 1900°C in pure hydrogen. Thus, the peak temperature of the signal was dependent on the hydrogen ratio in the purge gas. These phenomena are specific for gold and the reason could not be seen clearly, though we discussed it on the grounds of the literature values.

Since gold hydride does not exist at room and high temperatures,[20] the lower peaks of gold given by the addition of hydrogen are a result of the large specific heat of hydrogen.

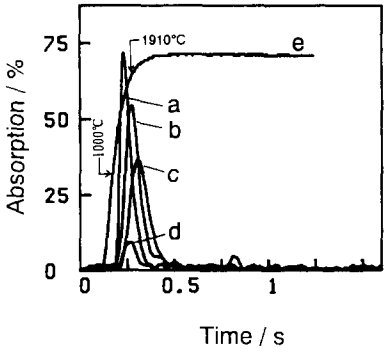

Fig. 2. Effect of hydrogen on atomic absorption of gold. (a) 500 ml/min Ar; (b) 480 ml/min Ar and 20 ml/min $H_2$; (c) 400 ml/min Ar and 100 ml/min $H_2$; (d) 500 ml/min $H_2$; (e) temperature increasing; Au 250 pg; heating rate was 5.5°C/msec. Pyrolysis temperature: 410 C.

The optimal purge gas flow rate for the absorption signal was Ar 480 ml/min and $H_2$ 20 ml/min, considering the lifetime of the molybdenum atomizer.

*Effect of pyrolysis temperature*

It has been reported that the pyrolysis temperature on ETA-AAS sometimes affects the AA peak height in the determination of some element.[16-18] Therefore, the effect of pyrolysis temperature on the absorbance of gold in the molybdenum tube atomizer was investigated. The results are shown in Fig. 3. The highest absorbance for gold in the metal atomizer was obtained at a pyrolysis temperature of about 410°C. Over 410°C, the absorbance decreased significantly. Though the shape of the pyrolysis temperature curve in the presence of thiourea is similar to that obtained without thiourea, the curve shifted to a lower temperature region. This phenomenon is presumably related to the lower decomposition temperature of the sulfide rather than that of the chloride.

On GFAAS, the sensitive pyrolysis temperatures for gold are 780°C,[2] 450°C,[3] 600°C,[5] 1200–1300°C,[6] and 1300°C.[7] The temperature (410°C) in the metal atomizer was very different from those, except one, of the graphite furnace atomizers. The difference may result from the lack of formation of gold carbide in the metal tube. Consequently, 410°C was selected as an optimal pyrolysis temperature for atomization characteristics. For the interference study and the determination of gold in biological materials, 720°C was selected considering the matrix interferences.

*Detection limit, characteristic mass and reproducibility*

The characteristic mass of gold, which was defined as the mass of element giving an

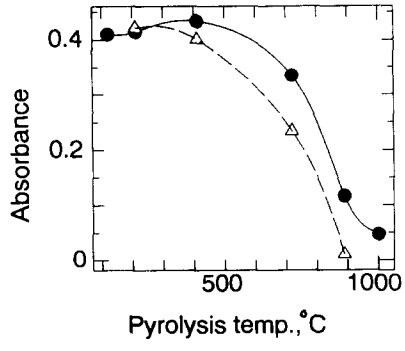

Fig. 3. Effect of pyrolysis temperature on atomic absorption signal of gold. Solid line: Au 250 pg; broken line: Au 250 pg + thiourea.

absorbance of 0.0044, by the atomizer was 1.8 pg. The detection limit, which was the weight of analyte which gave an atomic absorption signal equal to three times the standard deviation of the background, obtained from the measurement of a solution blank, was calculated from the height of gold absorption signal. The detection limit of gold by use of the molybdenum tube atomizer was 1.3 pg, corresponding to 130 pg/ml, given at 10 $\mu$l sample. These values were several times better than the characteristic mass (4.782 pg[7]) and the detection limit (400 pg/ml[6]) obtained with a graphite atomizer, and those with ICP (10 ng/ml[11]) and ICP-MS (200 pg/ml[11]).

A reason for the better sensitivity in the molybdenum atomizer may be the nonporous atomizer wall differing from a graphite furnace and the formation of the Mo-alloy with a low bonding energy.

The reproducibility of the use of the molybdenum atomizer was investigated. The relative standard deviation for 250 pg of gold was 2.9% for 10 measurements. In the case of thiourea addition, the RSD was 2.5%.

*Interference study*

Interferences by some matrix elements in the determination of gold in biological materials by GFAAS have been observed.[2-8] In particular, the interference problems from chloride salts were important.[4] Therefore, the influences of Ca, Cu, Fe, K, Mg, Pb and Zn (0.25–2.5 mg metal/ml), which are included as major elements in biological materials, on a gold absorption signal were investigated in the molybdenum tube atomizer. These coexisting elements were naturally used as chloride salts.

Despite the sensitivity not being optimal, the gold samples were pyrolyzed at 720°C because of the molecular absorption formed from the matrix at the time of atomization after the low temperature pyrolysis. The gold signal in the presence of these elements was measured in terms of both the peak height and the peak area. The peak area measurement method was more unsuitable than the peak height method because of the larger interfering tendency and the inconvenience. The gold signal (250 pg) was influenced by Ca, Cu, Fe, K, Pb and Zn. The interference of potassium was especially severe. Royal[21] found serious depression of the gold signal in the presence of alkali on the determination of gold by GFAAS. In flame AAS, interference owing to copper, iron and sodium was reported.[22] In the metal tube atomizer, interference phenomena observed were similar to those obtained in GFAAS. The effect of copper on the determination of gold by ETA-AAS with a GF has been found to be troublesome, with suppression of the absorbance signal for gold.[13] However, in the molybdenum atomizer, copper enhanced the gold signal.

Matthew and McGaham[8] reported that cysteine served as a matrix modifier for gold determination in biological fluids and tissues. Cysteine is a sulfur compound and hence, in order to eliminate the interferences, thiourea being a sulfur compound was tried as a matrix modifier for gold. A typical effect of thiourea on the gold signal in the presence of calcium is shown in Fig. 4. By the addition of thiourea, the gold signal was little affected by the coexistences of 2.5 mg/l of Mg, 0.25 mg/ml of Ca, Cu, Fe, K, Pb and Zn. The interference reducing effect by thiourea may result from sulfide formation of gold and the coexisting elements.

*Determination of gold*

Since it was found that thiourea was useful for the recovery of gold AA signal in the presence of interferent, a matrix modifier method was applied to the determination of gold in biological materials. The samples were spiked with 200–400 ng Au/g. Following the digestion of biological samples, the samples with thiourea were analyzed by ETA-AAS with the metal atomizer under optimal conditions. Table 1 shows the results obtained for some biological materials (NIST). The recovery of spiked gold in biological materials was in the range of 101–106%. The relative standard

*NIST standard.
Five analyses were carried out.

deviations were better than 14% at five replicate analyses. The analytical results obtained with the addition of thiourea can be considered satisfactory for the determination of gold in biological materials.

As described above, for the determination of gold in biological materials the addition of thiourea served to eliminate severe interferences. Moreover, the use of molybdenum tube atomizer and an argon–hydrogen atmosphere has large benefits such as high sensitivity and longer lifetime (more than 5000 firings) over a graphite furnace (200–250 firings). Therefore, the performance characteristics of the molybdenum tube atomizer will serve to provide accurate and sensitive determinations of gold in complex samples.

# DIRECT DETERMINATION OF TRACES OF Ag, Cd, Pb, Bi, Cr, Mn, Co, Ni, Li, Be, Cu AND Sb IN ENVIRONMENTAL WATERS AND GEOLOGICAL MATERIALS BY SIMULTANEOUS MULTI-ELEMENT GRAPHITE FURNACE ATOMIC ABSORPTION SPECTROMETRY WITH ZEEMAN-EFFECT BACKGROUND CORRECTION*

J. G. SEN GUPTA† and J. L. BOUVIER

Geological Survey of Canada, Ottawa, Ontario, Canada K1A OE8

(*Received* 16 *May* 1994. *Revised* 30 *August* 1994. *Accepted* 31 *August* 1994)

**Summary**—A method was developed for direct determination of minor and trace amounts of Cr, Mn, Cu, Ni, Co, Li, Pb, Cd, Bi, Sb, Be and Ag in silicate rock, lake and stream sediments using a microwave oven dissolution method and a multi-element graphite furnace atomic absorption spectrometer equipped with a Zeeman-effect background correction device. The measurement technique was also suitable for direct determination of trace and ultra-trace amounts of these elements in drinking and seawater samples. A rock or sediment sample was brought into solution in a Teflon vessel by heating in a microwave oven with a mixture of hydrofluoric acid and aqua regia, followed by a further heating with a mixture of boric acid and ethylenediaminetetraacetic acid. The specified elements were directly determined in a group of four elements in one firing and eight elements in two firings from this solution or from a diluted solution using the optimum operating parameters developed in this work. The method, tested with 23 international reference rocks and sediments and seven international quality control and reference water samples, showed good to excellent agreement with the recommended values.

There is a great demand from scientists of the Geological Survey of Canada (GSC) for determination of minor and trace elements in silicate rocks, rock-forming minerals, and lake and stream sediments for ore genesis studies, and for geochemical prospecting. Determination of trace and ultra-trace elements in environmental water samples is also required by geochemists and others for ascertaining their toxicity levels for drinking purposes, industrial pollution levels and for searching for ore deposits.

The classical colorimetric[1] and titrimetric[2] methods used previously in the GSC for trace analysis have now been replaced by modern spectrometric techniques. Among these, flame atomic absorption spectrometry (FAAS) suffers from lack of sufficient sensitivities and good precision for certain elements such as Ag, Cd, Pb, Bi, Li, Be, Sb and Co in the ng/g and low $\mu$g/g levels present in most rocks, sediments and environmental water samples.

To improve the detection limits for trace elements and eliminate interferences from associated major elements, extraction of suitable complexes of the analytes into organic solvents before FAAS determination was previously favoured by analysts.[3,4] A widely used method for Pb, Cd, Bi and Zn was chelation with ammonium pyrrolidine dithiocarbamate (APDC) and extraction of the complexes with methyl isobutyl ketone (MIBK), followed by back-extraction with an acid into the aqueous phase before determination by graphite furnace atomic absorption spectrometry (GFAAS).[5,6]

Because of the interference from major quantity of iron, the first author used isopropyl ether to separate it from a silicate rock digest in $HF$–$HNO_3$–$HClO_4$. From the remaining solution, Pb and Cd were extracted along with some other trace elements such as Mn, Ni, Co, Bi and Zn with APDC–oxine–MIBK system.

*Paper presented at 39th Canadian Spectroscopy Conference, University of Laval, Quebec City, 16–18 August 1993. Geological Survey of Canada Contribution No. 33892.

†Author to whom correspondence should be addressed.

After back-extraction with an acid into the aqueous phase, these elements were determined by single-element GFAAS.[7]

Attempts to determine Pb and Cd in geological materials by single-element GFAAS were found in the works of Bettinelli *et al.*[8] who used $HCl$–$HNO_3$–$HClO_4$ to decompose samples, and Alvarado and Petrole[9] who employed boric acid to complex excess HF after decompostion by $HCl$–$HF$–$HNO_3$. However, it is our experience that the use of $HClO_4$ is detrimental to the life expectancy of a graphite cuvette used in GFAAS determination.

Deuterium background correction device used with a single-element GFAAS failed to eliminate emission and molecular interferences in direct determination of trace elements in rock sample solutions decomposed by conventional methods with acids and fusion. This was due to the presence of associated major elements and high concentration of salts in solutions.

Neutron activation, and more recently inductively coupled plasma atomic emission spectrometry (ICP-AES) and inductively coupled plasma mass spectrometry (ICP-MS) have been used for trace analysis in geological materials. However, neutron activation and ICP-MS instrumentations are very expensive, and ICP-AES suffers from lack of sufficient sensitivities and interference effects in the determination of some trace elements such as Ag, Pb, Cd, Bi, Sb and Li in silicate rocks and environmental water samples.

The reasons for choosing multi-element GFAAS in the authors' laboratories were: (1) high sensitivities for trace elements present in silicate rocks and environmental water samples, (2) freedom from interference effects from the associated major elements because of the use of Zeeman-effect background correction technique, (3) elimination of the spectral complexity associated with ICP-AES, and (4) the limitations which molecular Cl species impose through isobaric interferences in selecting a decomposition scheme for ICP-MS analysis. Many schemes use HCl and/or $HClO_4$ to dissolve samples and, therefore, require extensive correction for isobaric interferences, if the concentration ratios between the interferent and the analyte permit making the correction at all.

Since a single-element graphite furnace even with the capability of sequential determination and Zeeman background correction would be too slow to be used for routine determination of 12 elements as presented in this work, it was decided to use a relatively inexpensive multi-element graphite furnace atomic absorption spectrometer equipped with a Zeeman-effect background correction device for simultaneous determination of four elements. This instrument, which could be programmed for automatic determination of eight elements in two firings, was successfully used by the first author for multi-element determination of scandium, yttrium, eight rare-earth elements,[10] and seven noble metals[11] in rocks and several candidate reference materials of Canadian Certified Reference Materials Project (CCRMP) after preconcentration by ion-exchange.

A microwave digestion procedure found effective for decomposition of most silicate rocks and naturally occurring sediments in our laboratories was used in this work. This involved heating the sample in a Teflon bomb (in a microwave oven) first with a mixture of HF and aqua regia, followed by second heating with a mixture of boric acid and ethylenediaminetetraacetic acid (EDTA). Compared to the regular method of sample decomposition in the GSC,[10] which uses $HF + HNO_3 + HClO_4 + HCl +$ EDTA (ammonium salt) plus fusion of any insoluble residue with $Na_2CO_3$ and $Na_2O_2$, this method does not use $HClO_4$ which needs to be evaporated in a special fume hood and whose presence even in trace amounts is harmful in GFAAS determination. Since the time of decomposition and steps are shorter in the microwave oven digestion method, it is much faster for routine use. The method is also economical since less acid consumption is required and environmentally friendly because no evaporation of acids is involved.

In the microwave digestion method, boric acid was used to complex the excess HF, and EDTA to dissolve any insoluble material not completely attacked by the HF + aqua regia mixture. The suitability of EDTA to dissolve insoluble materials of silicate rocks such as barite and strontianite was established in two earlier papers.[12,13]

After microwave digestion and dilution with $HNO_3$, an aliquot of the sample solution was directly injected into the graphite tube furnace of the multi-element atomic absorption spectrometer and atomized for simultaneous determination of up to four elements. The elements were chosen in groups of four primarily for their compatible ash and atomization temperatures; however, their expected abundances in samples also played a role in this choice. The results of these investigations carried out with a variety of international geochemical reference materials and several reference water samples showed good agreement with the recommended values.

After sample solution preparation, concentration of four elements in about 100 samples could be simultaneously determined in one day.

## EXPERIMENTAL

### *Apparatus*

A Hitachi Z-9000 simultaneous multi-element atomic absorption spectrometer equipped with a Zeeman-effect background correction device, built-in autosampler (72 samples holding capacity), plotter and data recorder was used. The instrument was cooled during heating by water maintained at 17°C employing a Neslab Model CFT-33 refrigerated recirculator. Pyrolytic graphite coated graphite tube (part No. 190-6003) and argon gas (UHP, 99.999%, predried by passing through a Matheson Model 6406 gas purifier and pressure maintained at 44 psi) were used throughout this work.

A Milestone microwave oven Model MLS-1200, equipped with six Milestone pressure decomposition Teflon vessels of capacity 100 ml each, a microwave digestion rotor (HPR 1000/6) and a remote control panel, were used for decomposition of samples.

*High purity 2% nitric acid.

ACS grade reagents (unless stated otherwise) were used throughout the work.

*Standard solutions.* A 100 $\mu$g/ml standard solution of each element was prepared by diluting 1000 $\mu$g/ml Plasma Chem ICP standard solutions (Cd, Pb, Bi, Mn, Co, Ni, Cr, Li, Be, Cu and Sb) and Fisher Scientific standard solution (Ag) with 2% nitric acid (Seastar High purity). The above standard solutions were mixed in appropriate amounts and diluted to volumes with the high purity 2% nitric acid to obtain synthetic standard mixtures to be used for preparation of calibration curves (see under Procedure for further details). All standard solutions were stored in tightly stoppered nalgene bottles.

*Mixed solution of boric acid (2.2%) and EDTA (0.165%).* 1.65 g EDTA was dissolved in concentrated ammonia solution, 22 g boric acid was added, and stirred to dissolve and diluted with water to 1 l. It was stored in a nalgene bottle.

*Palladium–magnesium modifier.* A 15 ml solution of 1000 $\mu$g/ml Pd solution was mixed with 50 ml of 1000 $\mu$g/ml Mg solution (both as nitrates) and diluted to 100 ml with 2% nitric acid (Pd:Mg = 0.3). This solution (16.7 ml) was diluted to 100 ml with 2% nitric acid and stored in a nalgene bottle. The diluted solution ($\sim$10 $\mu$l) was used during determination of Pb and Cd (along with Ag and Bi) by the autosampler programme.

## *Recommended procedure*

*Silicate rock, lake or stream sediment sample decomposition.* The finely powdered sample (0.5 g) (−200 mesh) was transferred to a

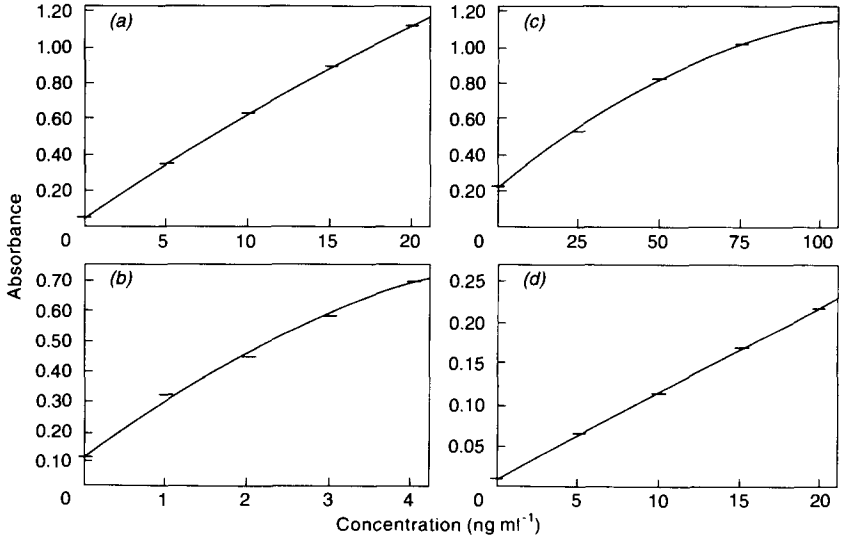

Fig. 1. Calibration graphs for (a) Ag; (b) Cd; (c) Pb (wavelength 283.3 nm) and (d) Bi at atomization temperature of 2200 C (40 $\mu$l soln. of each standard of Group 1 of Table 4). Quadratic correlation: Ag, 0.9998; Cd, 0.9909; Pb, 0.9849; and Bi, 0.9996.

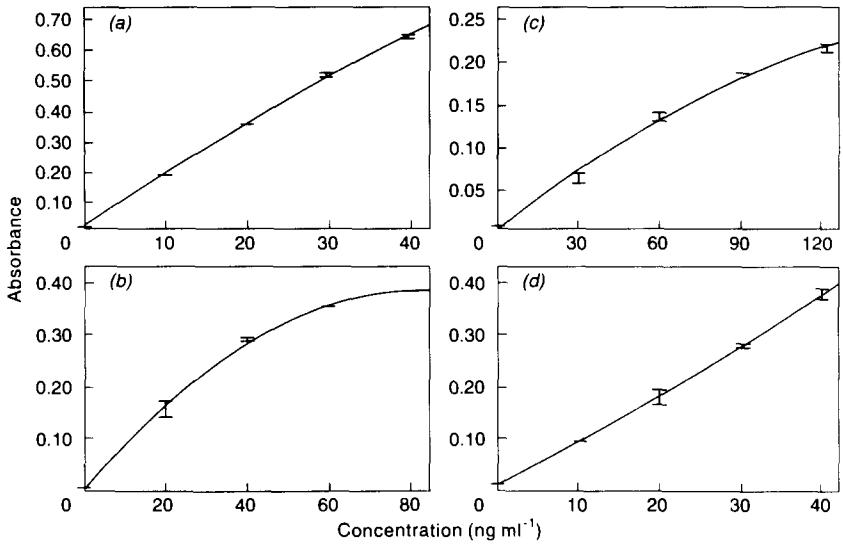

Fig. 2. Calibration graphs for (a) Mn (wavelength 403.1 nm); (b) Co; (c) Ni; and (d) Cr (wavelength 425.4 nm) at atomization temperature of 2400°C (40 $\mu$l soln. of each standard of Group 2 of Table 4). Quadratic correlation: Mn, 0.9991; Co, 0.9616; Ni, 0.9886; and Cr, 0.9993.

Milestone Teflon decomposition vessel (note 1). A total of 2.5 ml 40% hydrofluoric acid was added dropwise while shaking the vessel to allow a smooth reaction to take place and prevent excessive local overheating and loss by sputtering. Concentrated nitric acid (3 ml) was added and stirred thoroughly with a Teflon rod, breaking the lump to a slurry. A total of 9 ml concentrated hydrochloric acid was slowly added while stirring the solution, and finally rinsing the outer side of the Teflon rod into the vessel. The Teflon rod was set aside and the vessel was covered with the lid and the spring assembly. The vessel was then placed inside the protection shield and after six sample vessels had been assembled in the rotor, the screw caps were tightened with the T bar using two $\frac{1}{4}$ rotations towards the end (care was taken not to overtighten to prevent cracking of the Teflon spring cover).

Placing the rotor with the assembled sample vessels inside the microwave oven, the door was closed and it was heated gradually (3 min.) to maximum power (1000 W). It was then further heated at 600 W for 2 min. and 250 W for 10 min. It was allowed to vent until the program was ready and the power shut off automatically.

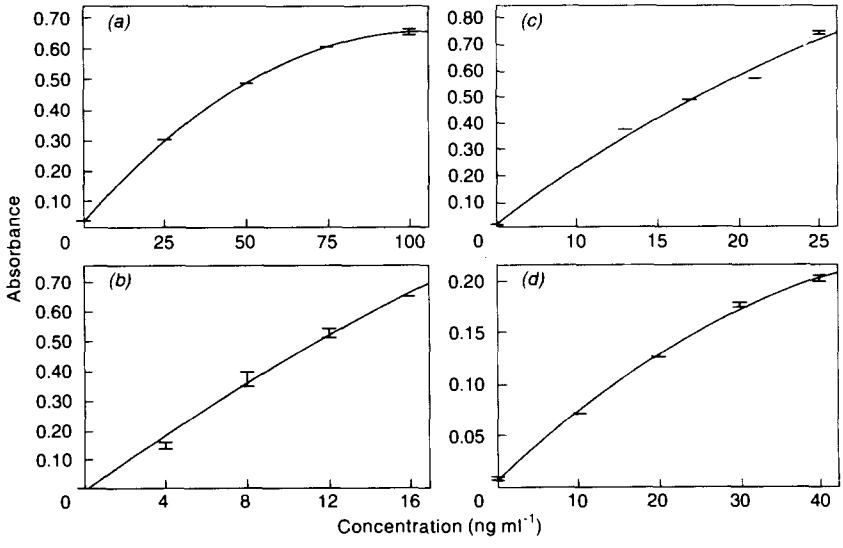

Fig. 3. Calibration graphs for (a) Li; (b) Be; (c) Cu; and (d) Sb at atomization temperature of 2300 C (40 $\mu$l soln. of each standard of Group 3 of Table 4). Quadratic correlation: Li, 0.9648; Be, 0.9947; Cu 0.9915; and Sb, 0.9896.

Table 5. Sensitivities of elements as obtained with a pyrolytic graphite coated graphite tube furnace using the Hitachi Z-9000 simultaneous multi-element atomic absorption spectrophotometer

| Element | Wavelength (*nm*) | Atomization temperature (°C) | Sensitivity* (*pg*) |
|---|---|---|---|
| Ag | 328.1 | 2200 | 3 |
| Cd | 228.8 | 2200 | 0.9† |
| Pb | 217.0 | 2200 | 4.6 |
| | 283.3 | 2200 | 13† |
| Bi | 223.1 | 2200 | 16 |
| Mn | 279.5 | 2400 | 1.5 |
| | 403.1 | 2400 | 10 |
| Co | 240.7 | 2400 | 22 |
| Ni | 232.0 | 2400 | 65 |
| Cr | 357.9 | 2400 | 13 |
| | 425.4 | 2400 | 19 |
| Li | 670.8 | 2300 | 19 |
| Be | 234.9 | 2300 | 4 |
| Cu | 324.7 | 2300 | 5 |
| Sb | 217.6 | 2300 | 29 |

*Defined as the mass of the element in picograms that produces a change in absorbance, compared with a pure solvent or blank, of 0.0044.
†In the presence of a palladium–magnesium modifier (see under Reagents in the text for concentration).

The rotor assembly was removed from the oven, placed on the stand and allowed to cool to room temperature (note 2). Carefully unscrewing the spring cap with the T bar, with $\frac{1}{4}$ rotation at a time until some gas was vented and the top screw was loose, the vessel was removed from the rotor and the lid opened cautiously.

A mixture (30 ml) containing 2.2% boric acid and 0.165% EDTA (note 3) was added, the cover and inner upper side of the vessel were rinsed. The vessel with the cover was inserted

*Mean of two values.
†Reported in a compilation of data in Ref. 23.
‡'Total element' as reported in Ref. 23.
§'Partial extraction element in concentrated $HNO_3$ + concentrated HCl' as reported in Ref. 23.

*Determination of elements in sample solutions.* Using 10–40 $\mu$l of a sample solution (rock, sediment or water sample), or from a diluted solution, as necessary to bring the absorbance values within the limits of calibration curves, the concentration of the unknown was determined using the appropriate operating parameters and calibration curves (note 4). Blank values, if any, were corrected for (note 5).

*Notes*

1. Six samples were always run simultaneously in one batch to prevent excessive pressure build up within each vessel.
2. If necessary, quick cooling can be effected by inserting the whole rotor assembly inside a bath of cold water, or running cold tap water on the outer tube.
3. An automatic dispenser was used in the authors' laboratory to expedite this process.
4. Dilutions were necessary for some sample solutions containing high Pb, Cr, Mn, Ni, Cu, Cd and Li. Also, alternative absorption lines for Pb (283.3 nm), Cr (425.4 nm) and Mn (403.1 nm) were used to reduce sensitivities where needed, particularly for some rock and sediment sample solutions containing high amounts of these elements.
5. Blank reagent values were negligible if appropriate care was taken to clean the decomposition vessels thoroughly with acids, alconox soap and water before use.

## RESULTS AND DISCUSSION

*Sensitivities*

The sensitivities for the 12 elements studied in this work are given in Table 5. Alternative less sensitive lines for Pb (283.3 nm), Cr (425.4 nm) and Mn (403.1 nm) were chosen

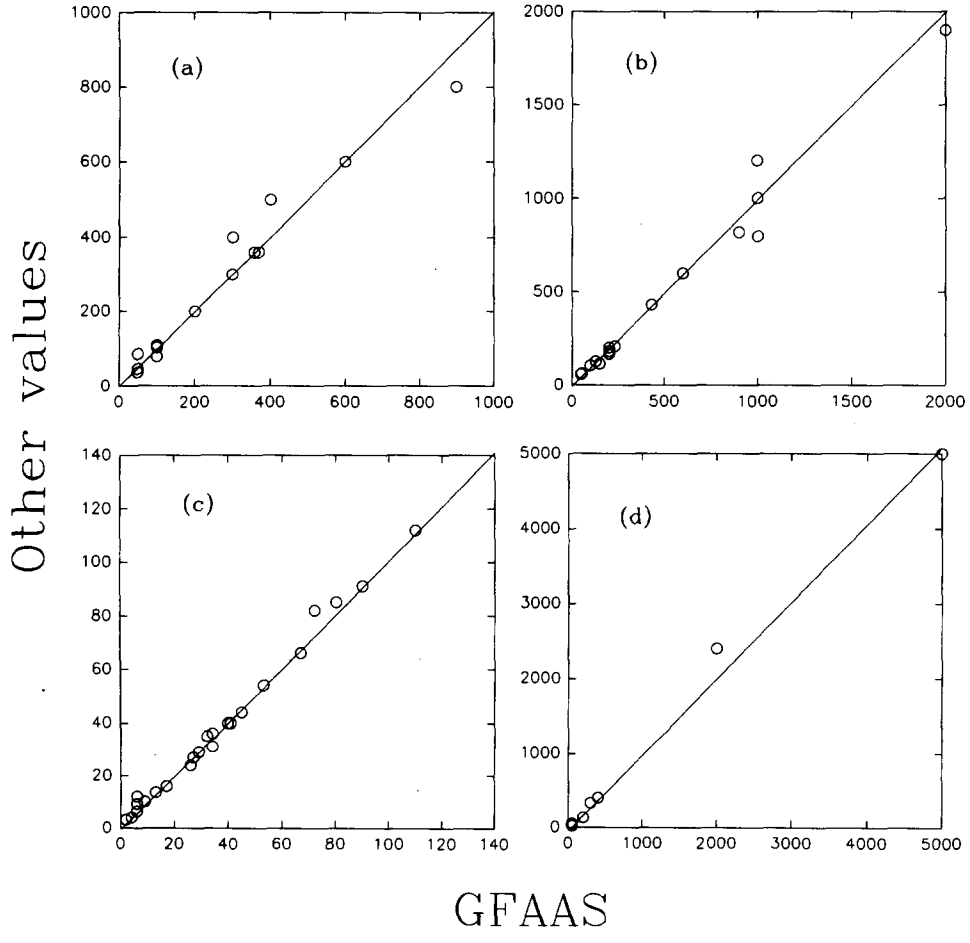

Fig. 4. Correlation plots for multi-element GFAAS *vs.* other values for some international reference rocks and sediments: (a) Ag; (b) Cd; (c) Pb; and (d) Bi. Analyte concentrations for Ag, Cd and Bi in ng/g and for Pb in $\mu$g/g.

for determination in rock and sediment samples since these elements were normally present in higher concentrations than other trace elements. The sensitivities of the primary wavelengths for Pb (217.00 nm), Cr (357.9 nm) and Mn (279.5 nm) are also included in Table 5; these lines were used where high sensitivities were needed for determination of ultra-trace amounts of these elements, *e.g.* in water samples.

*The use of palladium–magnesium modifier for* Pb *and* Cd

Palladium and magnesium chlorides have been used as matrix modifiers to prevent losses of lead in the presence of alkali and alkaline halides during charring.[14] Stabilization of cadmium by addition of magnesium nitrate or phosphate has also been reported by Slavin *et al.*[15] However, in order to lower the blank absorbance values, a lower concentration of palladium–magnesium modifier than reported by these authors[14,15] was used in this work to increase the atomization temperature for Pb and Cd to 2200°C without losses. It was found that in the presence of the specified amount of the modifier (see under Reagents and standard solutions) the ash and the atomization temperatures for Pb and Cd could be increased to 800° and 2700°C, respectively, without any losses. Therefore, using this modifier, Pb and Cd could be simultaneously determined with two other elements (*e.g.* Li and Sb) which required higher atomization temperatures than 2200°C. In this work, Pb and Cd were determined simultaneously with Ag and Bi; however, the modifier did not have any effect on the blank or absorbance values for the latter two elements.

*Analyses of reference materials for trace elements*

The validity of the proposed simultaneous multi-element GFAAS method for trace elements was tested with National Institute of Standards & Technology (NIST) reference water

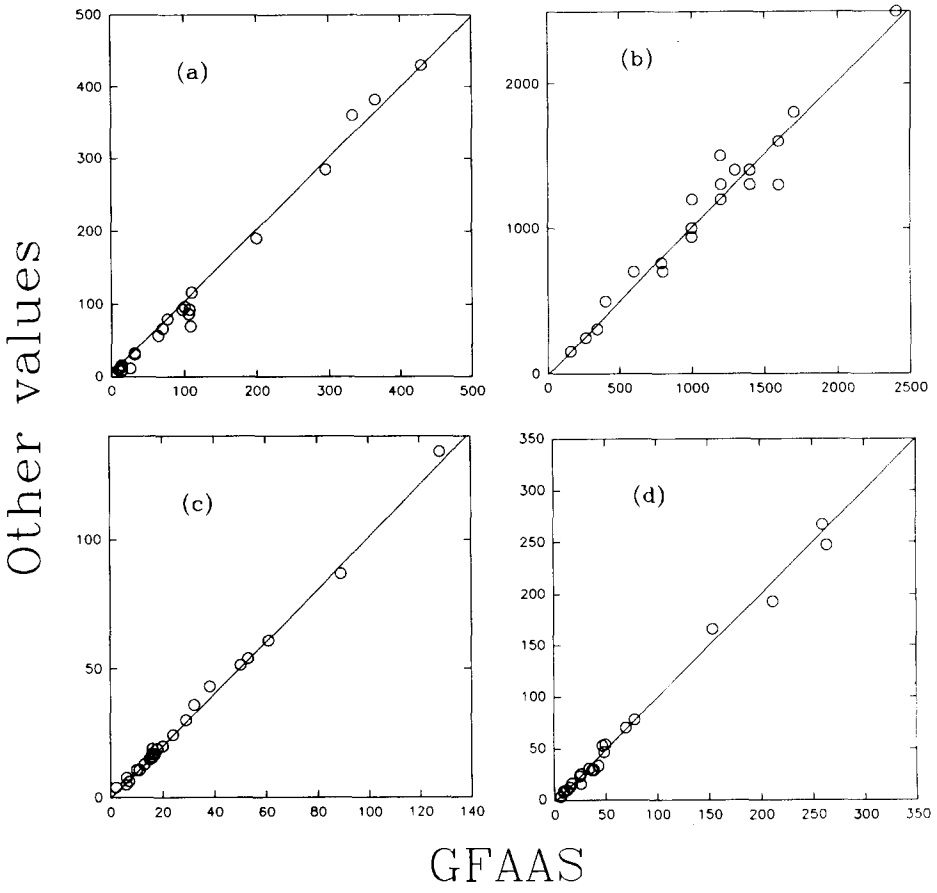

Fig. 5. Correlation plots for multi-element GFAAS *vs.* other values for some international reference rocks and sediments: (a) Cr; (b) Mn; (c) Co; and (d) Ni. Analyte concentrations in $\mu$g/g.

sample 1643c, U.S. Environmental Protection Agency (USEPA) quality control (QC) water samples (concentrates 1, 2, 6 and ICAP 19), National Research Council (NRC) of Canada reference water samples SLRS-2 (riverine water) and CASS-1 (near shore seawater), and a variety of international geochemical reference rocks and sediments issued by Canadian Certified Reference Materials Project (CCRMP), United States Geological Survey (USGS), National Institute for Metallurgy (NIM) (South Africa), International Working Group (IWG) (France) and Institute of Geophysical and Geochemical Exploration (IGGE) (China).

The results for replicate determinations of trace elements in NIST, USEPA and NRC reference water samples, given in Table 6, show good precision and excellent agreement with the expected values in most cases.

Twenty-three international reference rock and sediment samples were decomposed by the Recommended procedure and the specified elements were determined directly either from the solutions thus prepared (sample concentration 0.01 g/ml in each) or from further diluted solutions in groups of four as described above. The averages of two values for Ag, Cd, Pb, Bi, Cr, Mn, Co, Ni, Li, Be, Cu and Sb of this work in these samples are given in Tables 7–12 and compared with other values ('consensus', 'working', 'usable', 'recommended' and 'provisional') quoted from the literature.[16–24]

For each of Ag, Cd and Bi the determination limit (lowest possible amount that could be detected with certainty) of this work was 50 ng/g; it was 2 $\mu$g/g for Be.

In the case of minor and trace elements (*e.g.* Cr, Mn, Pb, Cu, Co, Ni, Cd, Be and Li) of the reference rocks and sediments, the average values of duplicate determinations of this work either agree with or fall within the limits of 'accepted values' (*cf.* Tables 7–12).

For ultra-trace elements (*e.g.* Ag, Bi and Sb) in these samples, the other values are near the determination limits of the GFAAS method, and in some cases (*cf.* Table 7) only one or two other values available in the literature are not even certified. Also, other Ag and Bi values in

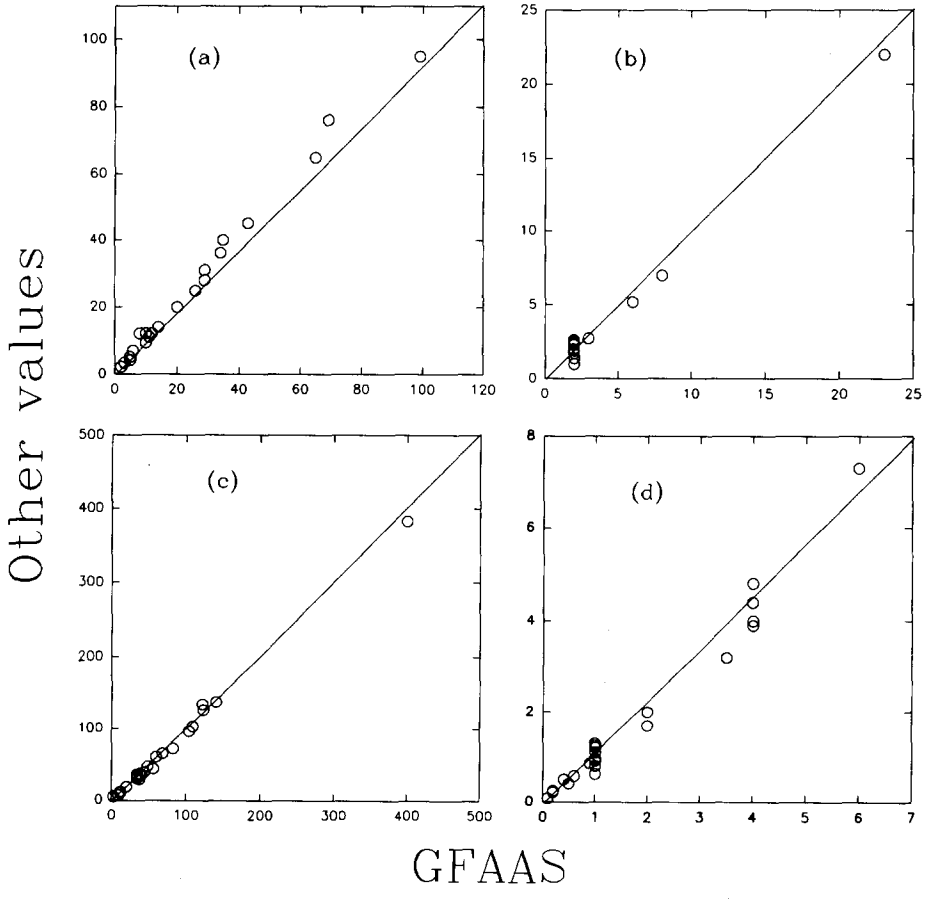

Fig. 6. Correlation plots for multi-element GFAAS *vs.* other values for some international reference rocks and sediments: (a) Li; (b) Be; (c) Cu; and (d) Sb. Analyte concentrations in $\mu$g/g.

SY-2, and Bi value in LKSD-1 to LKSD-4 and STSD-1 to STSD-4 are not available in the literature. Therefore, more data on these elements in the specified samples by other methods are needed for a valid comparison with the GFAAS values.

Where possible, the results of this work are also compared graphically with other recommended values (without standard deviation) in Figs 4–6. With the exceptions for few samples, the data points for these elements in these figures fall reasonably close to the 45° line, demonstrating fair agreement between multi-element GFAAS and other values.

Chromium in DTS-1 (dunite) was found to be lower than the 'consensus value' probably owing to the presence of a significant amount of chromite which was not completely attacked by the decomposition method. A fusion of this partially insoluble chromite residue with $Na_2O_2$ would be required to obtain better results. However, the results for other elements in this sample showed good agreement in most cases with the 'consensus values' and hence justified their inclusion in this work.

## CONCLUSIONS

The direct simultaneous multi-element GFAAS determination of trace and ultra-trace amounts of Ag, Cd, Pb, Bi, Cr, Mn, Co, Ni, Li, Be, Cu and Sb from environmental waters and geochemical sample solutions is relatively rapid and results are of acceptable quality. Low operating and virtually nil maintenance costs make the instrument ideally suited for a laboratory with a small budget. At a lower cost, the multi-element GFAAS results on the common trace and ultra-trace elements in water, rocks and related materials are comparable in quality with those of other more costly instrumental techniques such as ICP-AES and ICP-MS. Therefore, this technique is ideally suited not only for internal routine production work, but also useful for certification of trace elements in international reference samples of water, rocks and related materials.

# THE COMPARISON OF CAPILLARY ZONE ELECTROPHORESIS AND ATOMIC SPECTROSCOPY FOR THE DETERMINATION OF THE CATION CONTENT OF A STANDARD REFERENCE MATERIAL IAEA-A-11 MILK POWDER

EMMA L. PRETSWELL,* BRIAN A. MCGAW and ANDREW R. MORRISSON
School of Applied Sciences, The Robert Gordon University, St Andrew Street, Aberdeen AB1 1HG, U.K.

(*Received* 25 *February* 1994. *Revised* 12 *September* 1994. *Accepted* 12 *September* 1994)

**Summary**—Alkali and alkaline earth metals were separated and quantified by Capillary Zone Electrophoresis using a previously developed method. CZE combined with indirect detection has received considerable attention over the last few years. Methods for the determination of inorganic and organic cations and anions have been reported although few of these include quantitative application to real samples. All of these methods are characterized by high efficiencies and high capacity. Application of the method to the determination of the major cation content of an International Atomic Energy Agency (IAEA) standard reference material is described. Complete resolution and quantitation of the ions ($Na^+$, $K^+$, $Ca^{2+}$, $Mg^{2+}$) was achieved with calibration curves, for the individual components, having correlation coefficients ($r^2$) ranging from 0.996 to 0.999 and detection limits (two times the baseline noise) of 10 ppb for potassium and magnesium and of 2.5 ppb for sodium and 2 ppb for calcium were achieved. Comparable results were achieved when employing analysis by Atomic Spectroscopy. The accuracy of this method was tested by comparison with standard flame Atomic Absorption cation analysis. Statistical analysis of the instrumental results indicate that there is no evidence suggesting systematic differences between the methods. In addition, a number of potential advantages of CZE for cation analysis are discussed.

Capillary zone electrophoresis (CZE), a form of CE where separation is mainly based on differences in solute size and charge at a given pH, offers a rapid, high resolution method for the determination of inorganic and organic ions. Ions are separated according to their relative ionic mobilities in an electric field. CE is characterized by the use of narrow bore capillaries (10–100 $\mu$m) operated at high applied potentials (10–30 kV) and is fast becoming a technique complementary to High Performance Liquid Chromatography (HPLC) and Ion Chromatography (IC).

The origins of the use of CE for ion analysis can be traced to 1967[1] but more recently CZE has been demonstrated to be a high efficiency technique for the separation, with indirect detection, of inorganic anions,[2–6] amino acids,[7] organic acids,[8] cations[9] and alkali metals.[10] In 1981 Nukatsuka *et al.*[11] described the use of α-hydroxyisobutyric acid (HIBA) as a complexing agent in an isotachophoretic separation of lanthanides. The use of HIBA and acetic acid were reported by Hirokawa.[12] In 1990 Foret *et al.*[13] reported separation of rare earth metals and lithium, sodium, potassium and magnesium by CZE. In this method, indirect detection was utilized using HIBA and creatinine–acetate buffer. More recently several papers were published by Jandik, Jones *et al.* of Waters Ion Analysis Department[14–17] relating to similar principles of separation of alkali and alkaline earth cations. Although many method development and optimisation papers have been published few applications have been discussed.

This paper describes a comparison of CE cation analysis with standard Flame Atomic Spectroscopy. Using the system reported by Foret *et al.*[13] the simultaneous quantitation of Na, Mg, K and Ca in an International Atomic Energy Agency (IAEA) standard reference material (powdered milk) was performed.

This CE technique relies on indirect photometric detection which can be used for the detection of compounds that have no optical absorbance. When using indirect detection

*Author to whom correspondence should be addressed.

methods with CZE, an absorbing ion, in this instance creatinine, is incorporated in the electrolyte to produce a background signal. Cations present in the sample displace the absorbing cation in the electrolyte and produce a negative peak.

The IAEA standard reference powdered milk sample contains a number of major cations which are routinely determined, the standard analytical methods employed include spectroscopy, XRF and possibly ICP-MS. The IAEA-A-11 powdered milk sample was chosen as it represented a matrix rich in four major cations at varying concentrations. Powdered milk is a major source of cations for formula fed infants and it is, therefore, important for the availability of rapid methods to quantify the cation content in such matrices, with new improved methodology being continually sought. In addition this paper reports the potential advantages of CE for the multi-component analysis of major cations in real samples.

## EXPERIMENTAL

### *Apparatus*

Quantitative and qualitative work was performed with polyimide coated fused-silica capillary tubes (Dionex UK) with an effective length of 65 cm to the detector window. A Dionex CES-1 (Dionex UK, Camberley, Surrey, U.K.) with indirect detection at 220 nm was used for all of the analyses. The instrument was operated at 10 kV with the detector at the cathodic side. The sample solution was loaded onto the capillary under gravity (elevated at 100 mm for 30 sec). Data acquisition was carried out on the CES-1 with a Waters Maxima 820 Chromatography Workstation (Waters Chromatography Division, Watford, U.K.). The AA system employed was the Perkin Elmer PE3100 (Perkin Elmer, Post Office Lane, Beaconsfield, Berks, U.K.).

### *Materials and reagents*

CE electrolyte solutions were prepared from AnalaR-grade chemicals (Merck, Poole, Dorset, U.K.). When preparing the electrolyte, 4.5240 g of creatinine and 1.014 g of HIBA (α-hydroxyisobutyric acid) were added to a beaker containing 500 ml water, the pH was then adjusted to 3.5 by the addition of Aristar grade acetic acid and made up to 1000 ml with 18 MΩ water (Elga Ltd, High Street Lane End, High Wycombe, U.K.). This operating buffer was then vacuum filtered through a 0.45 μm cellulose nitrate filter which also degasses the solution. Glassware for all the analysis was soaked overnight in 2% Decon and thoroughly washed in 18 MΩ water.

The standard reference material milk powder IAEA-A-11 was obtained from the International Atomic Energy Agency (Vienna, Austria).

### *Preparation of standards and samples*

All standard solutions were prepared by a dilution of 1000 ppm stock solutions (BDH AA Standards Poole, Dorset, U.K.) containing a single ion, freshly prepared every month and stored in 500 ml plastic flasks. All mixed ion standards were freshly prepared for each experiment. Elga 18 mΩ water and plastic flasks were used throughout. A standard addition method was employed for the spectroscopic analysis as shown in Table 1a.

Calibration curves for the CE analysis for each of the cations of interest were prepared as mixed standards (BDH AA Standards). Six replicates were performed and the reproducibility of the response factors were expressed as a

function of concentration and the correlation coefficient of the lines obtained with accuracy and precision stated.

Six weighings of 200 mg of IAEA standard reference sample were prepared. After weighing, one of the six samples was dried in an oven at 80°C for 48 hr to drive off any associated water. This was used as a blank for weight correction. The process used for the dry-ashing is a standard technique[18] as used in all methods for cation analysis and is the rate determining step common to all instrumental procedures. Reduction of the dry-ashing stage may be possible by the implementation of microwave digestion techniques.[19] The samples were then taken up in concentrated nitric acid and made up to volume with deionized water in 10 ml standard flasks to give a 7% nitric acid solution. Subsequent dilutions were carried out prior to injection.

A blank was prepared by analysing the 7% mineral acid identically to the sample analysis. Atomic spectroscopic sample solutions were prepared from dilutions of the digested samples made up in mineral acid. As the analysis is single component, samples were prepared for analysis of individual components as shown in Table 1a.

*Procedure for capillary preparation and handling*

Prior to extended use, the capillary was filled with 1*M* sodium hydroxide and allowed to stand for 1 hr. This solution was replaced with 0.1*M* sodium hydroxide, allowed to stand for 30 min, washed with deionized water before filling with running buffer by pressure injection. The capillary was used for a maximum of 12 injections before regeneration by pressure injection of 0.1*M* sodium hydroxide for 5 min and running buffer for 15 min. This was done during unattended operation (overnight) to ensure good baseline stability and to minimise the chance of capillary blockage. During monitored operation many more runs were achieved before regeneration was required. At the end of each operating day the capillary was flushed with running buffer and left filled.

*Calculation method*

The values quoted for the results obtained are the experimental values corrected after weight and background contribution was taken into consideration. Weight correction was performed by scaling the actual result to a value appropriate for an accurate weighing of 200 mg, this value was also background corrected by subtracting the value obtained for the blank, to remove any contribution from the acid.

*Instrumental operation*

The CES-1 system incorporates three modes of injection into the capillary: hydrostatic, pressure and electromigration. All injections for this study were performed in the hydrostatic mode as non-preferential loading was required. Pressure injection was performed as part of the rinse cycle where buffer was pressure injected onto the capillary. Gravity injection was utilized and the sample was elevated at 100 mm for 30 sec and a running voltage of 10 kV (positive potential) applied. A 40-sample carousel was used with Dionex 2 ml microvials. Indirect UV-detection at 220 nm was employed for the CE work.

The spectrometer was used in both modes of operation, emission and absorption. The conditions employed for the spectroscopic analysis are shown in Table 1b.

## RESULTS AND DISCUSSION

CE calibration graphs for $Na^+$, $K^+$, $Mg^{2+}$, $Ca^{2+}$ showed a linear dependence of the response factor measured in terms of peak area as a function of the concentration of the individual cations, with correlation coefficients ($r^2$) of 0.998, 0.996, 0.999 and 0.998, respectively, and LODs calculated (as two times baseline noise) as 10 ppb for potassium and magnesium, as 2.5 ppb for magnesium and as 2 ppb for calcium (Fig. 1). Correlation coefficients for the spectroscopic analysis were also calculated being 0.997, 0.996, 0.998 and 0.996, respectively.

Figure 2 shows the electropherogram of a standard mixture containing 20 ppm of sodium, potassium, calcium and magnesium with an elution order of $K^+$, $Na^+$, $Ca^{2+}$ and $Mg^{2+}$. It can be seen that complete resolution and detection were achieved within 16 min. Much lower migration times have been demonstrated,[14,16,17] however in this instance the fluctuating baseline and more pronounced baseline noise was accentuated at high applied field strength. This was possibly due to Joule heating in the capillary hence a low operating voltage of 10 kV was applied leading to increased migration times. Manipulation of the control voltage does allow a decrease in the elution time resulting from a faster Electroosmotic Flow (EOF). A compromise is necessary to achieve well defined chromatography and speed of analysis.

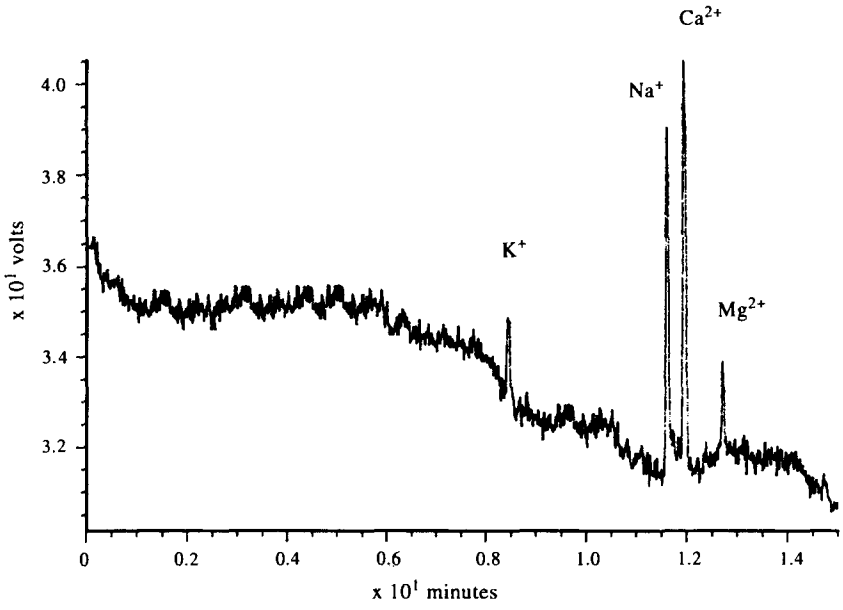

Fig. 1. Electropherogram showing the response factor for a 10 ppb standard solution of the major cations found in the milk powder matrix.

Optimization of the electrolyte system used in the CE analysis was achieved by altering the concentration of the complexing agent (HIBA). This was measured in terms of baseline resolution of the peaks. The stability of the chelant–cation complex formed varies depending on the cations present and the concentration of the chelant itself. The greater the stability of the complex, the more retarded the ion is in the capillary allowing greater separation of components. When analysing samples with disparate concentrations it may be necessary to use a stronger more specific chelant, for example a crown ether (E. Pretswell and K. Cook, personal communication). The crown ether, being highly specific, will strongly complex a specific ion, retarding it and hence changing the elution order of the solutes.

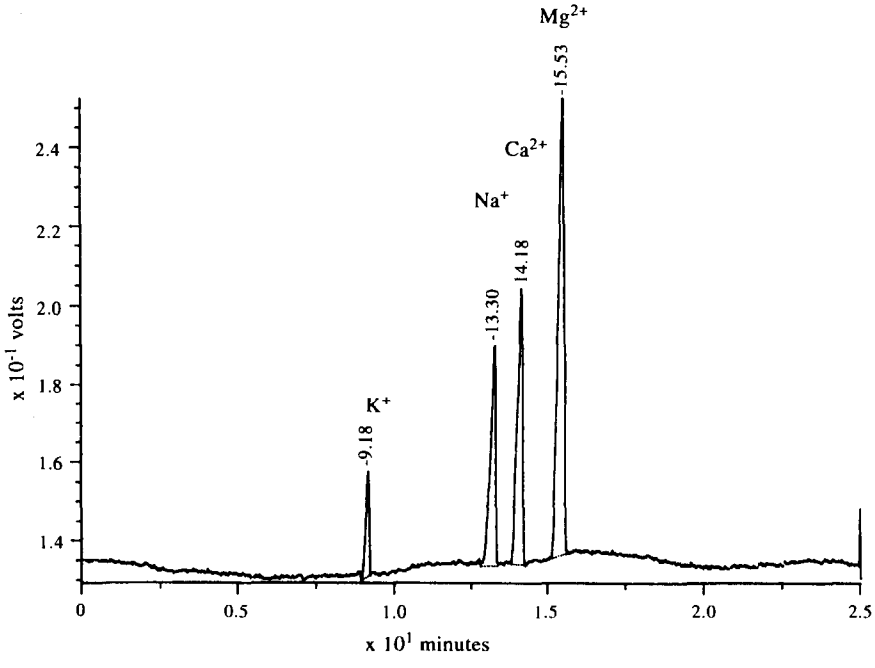

Fig. 2. Electropherogram of the major cations found in a 20 ppm standard solution.

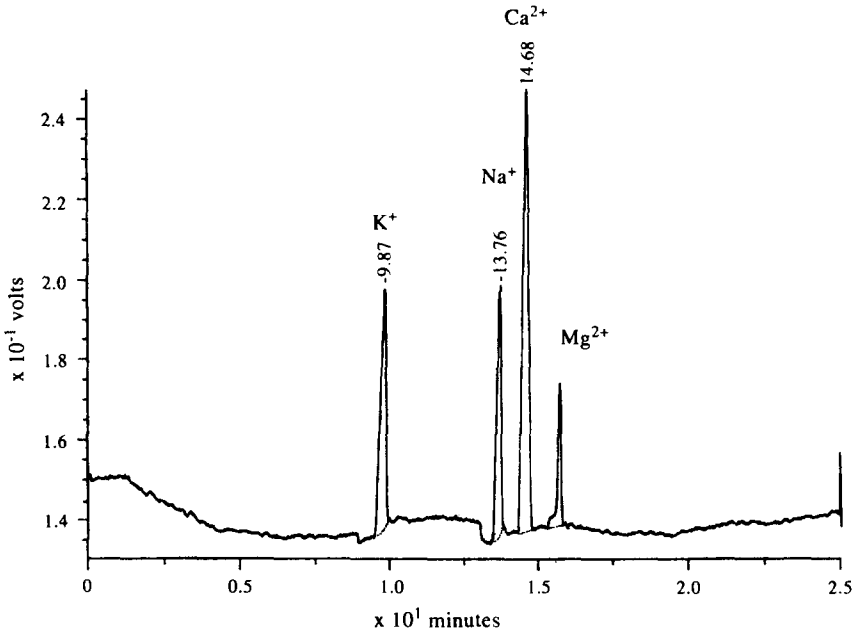

Fig. 3. Electropherogram of the major cations found in the IAEA standard reference sample.

Figure 3 illustrates the optimized separation for the analysis of the IAEA A-11 standard reference milk sample by CE. From the electropherogram the mobility of the last eluting ion varies significantly from the mobility of the buffer ions as peak fronting is observed. This is possibly due to the interference of the sample matrix on the separation pattern (real samples *vs.* laboratory standards) or the presence of nitric acid in the sample on the complex formation between the cation and HIBA. This may cause a shift in the equilibrium and hence alter the mobility of the cation. A shift in the retention time of the standard reference analytes is also observed, one explanation for this may be due to the higher pH of the sample compared to that of the standards. The sample pH may also be responsible for the dips seen in the baseline prior to the sample peaks. The plug flow characteristics of CE and the minimum EOF in the capillary prohibit sample mixing. At the sample-buffer interface a pH gradient exists causing changes in the absorbance of the zone passing the detection window resulting in the characteristic dips in the baseline. It is also possible that the presence of nitric acid may give a positive UV absorbance when passing the detection window resulting in dips in the baseline. This effect was not apparent when analysing the standard cation solutions, but was apparent when the blank nitric acid sample was analysed indicating further evidence that the presence of the nitric acid may be the cause of the undulating baseline.

There was no requirement for trace enrichment of the samples so gravity injections were used throughout because this mode of injection has the high precision of electromigration, but is nondiscriminatory, *i.e.* gives non-preferential loading of individual cation species.

The concentration of $Na^+$, $K^+$, $Mg^{2+}$ and $Ca^{2+}$ were calculated by both instrumental methods for the IAEA A-11 with instrumental

Table 2. Concentrations obtained by Instrumental analysis and those cited by IAEA for the cations analysed (statistical instrumental error quoted)

| | IAEA | CE | AA |
|---|---|---|---|
| Component | (*mg/kg*, error %)* | (*mg/kg*, $r^2$) | (*mg/kg*, $r^2$) |
| Calcium | 12,900 (6.2) | 13,000 (1.27) | 13,020 (1.67) |
| Potassium | 17,200 (5.8) | 17,300 (1.45) | 17,290 (1.56) |
| Sodium | 4420 (7.5) | 4390 (1.86) | 4410 (1.91) |
| Magnesium | 1100 (7.3) | 1090 (1.63) | 1090 (1.74) |

*95% confidence interval for the mean.

Table 3. Table showing the calculated results from the statistical comparison of the methods

| | Method tested | |
|---|---|---|
| Method compared | Spectroscopy | IAEA |
| Capillary electrophoresis | Slope, 0.999<br>Intercept, −0.06<br>$r^2$ −0.995 | Slope, 0.995<br>Intercept, 0.033<br>$r^2$, 0.998 |
| Spectroscopy | | Slope, 0.996<br>Intercept, −0.08<br>$r^2$, 0.999 |

and analytical precision tested and shown in Table 2.

Regression lines were used to compare analytical methods.[20] A statistical comparison was performed between AA and the IAEA cited values and between the CE and the cited values. Statistical analysis of the results is shown in Table 3. From Table 3 it is apparent that there is no evidence for systematic differences between the methods as the calculated slope and intercept do not differ significantly from 1 and 0, respectively.

## CONCLUSIONS

CE offers a rapid and reproducible method for the determination of alkali and alkaline earth metals by capillary zone electrophoresis (CZE) with indirect UV detection. The method gives excellent agreement for four major cations in a certified reference material (IAEA A-11). CE has advantages over spectroscopic analysis namely, simple calibration standards, sample preparation, simpleness of operation, fully automated, multi component analysis, easy operation and implementation. Disadvantages include poor sensitivity for trace element analysis, which may be improved with isotachophoretic stacking of the samples,[21] and loss of resolution when analysing mixtures of disparate concentrations. Conductivity detection has been demonstrated[22–25] where narrow bore capillaries attached to specially designed potentiometric detectors have been able to detect traces ($10^{-9}$ mol/l). Unfortunately, these systems are not widely available commercially.

This paper concludes that CZE can be applied to the analysis of cations in complex matrices and give results comparable to standard methods. This indicates that CE may be an optimal extension of classical methods of cation analysis with sensitive detection at low ppm/high ppb range and may be used reliably as a multi component method for quantifying major cations in food matrices. Application of the method to a wide variety of sample matrices is easily attainable suggesting the versatility and reliability of the method.

*Acknowledgements*—We would like to thank Dr K. Cook and Mr K. Divan of Dionex UK for their invaluable help during the work. In addition we would also like to thank Dr J. S. Park of Procter and Gamble Ltd for his continued support and finally Procter and Gamble Ltd for funding the work.

**Summary**—An electroanalytical method for determination of the anti-inflammatory agent aceclofenac at the ppb level using adsorptive stripping voltammetric techniques on conventional and surfactant chemically modified electrodes is developed. In this electroanalytical study a process of aceclofenac adsorption on carbon particles has been identified. In order to improve the aceclofenac determination, a chemical modification of the carbon paste was carried out employing several hydrophobic substances such as phospholipid and fatty acids, as well as several surfactants such as the non-ionic Triton X-100 and Triton X-405 and anionic sodium dodecyl sulfate. The influence of parameters such as pH, preconcentration time, carbon/Nujol ratio, surfactant/carbon ratio, potential scan rate, *etc.*, on sensitivity of the method were widely studied. The proposed method was applied to the determination of the active compound in tablets.

Aceclofenac (AC), 2-((2,6-dichlorophenyl)-amino) phenylacetoxyacetic acid, is a new non-steroidal anti-inflammatory agent produced by Prodesfarma (Spain). Experimental studies have demonstrated its ability to reduce prostaglandin synthesis in inflamed areas both in animals and humans.[1,2] Experimental pharmacokinetic studies with animals showed rapid adsorption when administered orally, distribution mainly in the gastro-intestinal tract, liver and kidneys and elimination according a biocompartmental model, with no accumulation when administered in repeated doses.[3–5]

AC is scarcely soluble in n-hexane and water and quite soluble in dimethylformamide, acetone, methanol (96%), ethanol (96%), acetonitrile, chloroform, acetic acid, acetyl acetate and alkaline solutions. It is weakly acidic ($pK_a = 4.7$). In experiments with animals, AC demonstrated an important analgesic and anti-inflammatory effect, similar to that of diclofenac (DC) and stronger than other non-steroidal anti-inflammatory agents.

In humans, using $^{14}C$ radioactivity measurements, according to Chassaud *et al.*[6] and Bastida *et al.*[7] the following metabolites were found: *o*-[(2,6-dichlorophenyl)amine]-phenyl acetic acid (4–7%), 4′-hydroxy-*o* [[(2,6-dichlorophenylamine)]phenyl acetic acid] (10–16%), 4′-hydroxyaceclofenac 'lactam' (11%) and the rest as unchanged AC.[6] These metabolites are mainly in a conjugated form with glucoronic acid, which combines with toxic metabolites.[7]

Regarding the analytical aspects of drugs in general, several papers show an important role played by the electrode used. Patriarche[8] reviews electrode modification, concerning all types of electrodes. According to Patriarche and to the literature,[9–14] solid electrode surface modification generally affects the selectivity and the kinetics of eletrochemical reactions, owing to the presence of intermediate catalyst immobilized onto the electrode surface. Moreover, the solid electrode modification can produce an important preconcentration effect of drugs onto the electrode surface with an enhancement of sensitivity.[15–17]

Analytical determination methods for AC are potentiometric using the acidic properties of this drug[7] and chromatographic using of HPLC[7,18] and by thin layer[7] for identification only. Additionally, the use of the carbon paste electrode in electroanalytical chemistry has permitted its

*Author to whom correspondence should be addressed.

easy modification with a wide variety of modifiers.[19,20] The use of phospholipids and fatty acids as modifier was carried out by Patriarche and co-workers[21,22] and the use of surfactants as modifier was first initiated by Mottola *et al.*[23] by dipping carbon paste electrodes in a surfactant solution, and by us[24] by incorporating a solid state modifier into the paste. Recently, several reviews, concerning chemical modifications of carbon-based electrodes[25] as well as their use in liquid chromatography detection,[26] have appeared.

## EXPERIMENTAL

### *Apparatus*

To obtain voltammograms, a Potentiostat Autolab PSTAT 10 and a GPES software ECO-CHEMIE (Holland) were used.

Electrodes were Ag/AgCl, KCl saturated as reference electrode, a Pt wire as auxiliary electrode and a Metrohm 6.1204.000 carbon rotating disc electrode (diameter = 3 mm) as working electrode (in which a hole, by pressing a carbon disc, was made to be readily filled with carbon paste).

An ultrasonic bath Selecta (Spain) was employed as graphite powder mixer.

### *Reagents*

Graphite powder (200 mesh and spectroscopically pure) was from Johnson Matthey (Paris, France). AC, pure product and tablets, named Airtal, were provided by Prodesfarma (Spain). These tablets had the composition given in Table 1.

All surfactants used were supplied by Serva Feinbiochemica (Heidelberg, Germany) and employed without purification.

Nujol oil was a Merck reagent and all other chemical reagents were of analytical grade and furnished by different firms.

The 2,6-dichloro-*p*-aminophenol was supplied by Aldrich-Chemie.

### *Procedures*

We used two types of carbon paste electrodes: (a) the conventional carbon paste electrode (CPE); (b) the modified carbon paste electrode (MCPE). These types of electrodes were previously prepared by us,[24] but in this case the C (g)/nujol (g) ratio was 68:32, and the surfactant (g)/C (g) ratio was 5:95. In both electrodes, carbon powder/Nujol oil, as well as carbon powder/Nujol oil/chloroform surfactant solution (added to facilitate the modifier dispersion and evaporation), were homogenized by an ultrasonic bath.

The preliminary studies on electroactivity of AC were only carried out on CPE.

The adsorption studies were carried out on both types of electrodes at open circuit before stripping, using the following types of solutions: (a) preconcentration solution, formed by the analyte and the pH buffer; (b) stripping solution, formed by pH buffer and the supporting electrolyte.

In order to develop an electroanalytical deter-

Table 1. Composition of aceclofenac tablets

| Ingredients | Formula of aceclofenac tablet 100 *mg** (*mg*) |

| Total tablet weight | 214 |

*Ethanol is used in the manufacture of the tablet core and dichloromethane and ethanol in the film coating stage; levels in the final product are low.

†Average: none.

‡The composition of Sepifilm 752 white is: hydroxylpropyl methylcellulose, 68–70%; polyoxyl-40 stearate, 6–10%; titanium dioxide, 18–22%.

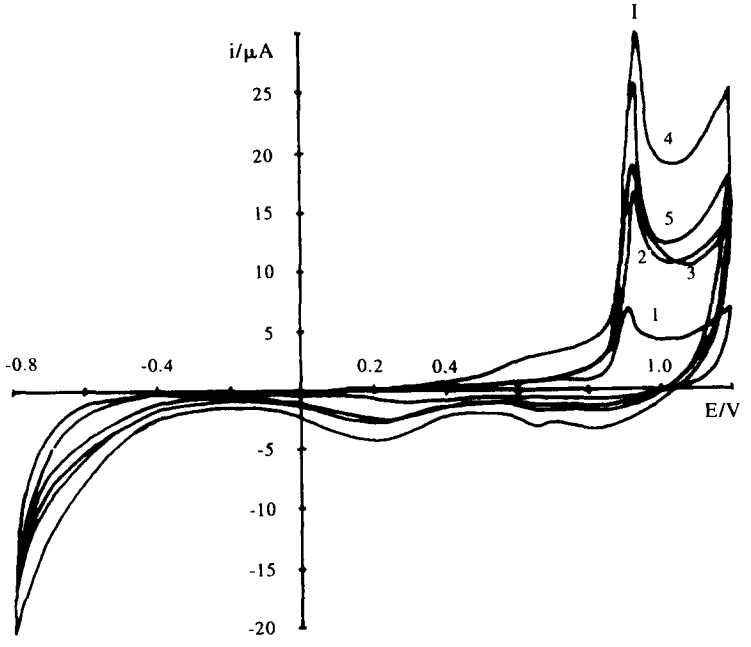

Fig. 1. Voltammogram of $10^{-5}M$ AC at pH 1 ($HClO_4$ $0.1M$) at different scan rate: (1) 1 V/sec; (2) 2 V/sec; (3) 3 V/sec; (4) 4 V/sec; (5) 5 V/sec; starting potential: 0.00 V; first scan forward +1.20 V, reverse up to −0.70 V and reverse up to 0.00 V to complete the cycle; conventional carbon paste electrode.

mination method of AC, the influence of several parameters on voltammetric peak height, such as potential scan rate, pH, preconcentration time, analyte concentration, carbon/Nujol oil (g/g) ratio, surfactant/carbon/Nujol oil (g/g/g) ratio and solution alcohol concentration, were studied. In all the cases, after each experiment, the electrode surface was renewed.

In order to develop an AC electroanalytical method using the conventional CPE, the following experimental conditions were employed. Preconcentration solution: $0.1M$ $HClO_4$ + AC, stripping solution: $0.1M$ $HClO_4 + 0.1M$ $KNO_3$, Nujol oil (g)/carbon (g) ratio: 32/68, preconcentration time: 8 min, potential scan rate: 4 V/sec, solution stirring rate: $10^3$ tpm. In the case of CMCPE the same experimental conditions as above were employed, but in this case a surfactant (g)/carbon (g) ratio of 5/95 was utilized.

## RESULTS AND DISCUSSION

### *Preliminary studies on CPE*

In order to determine if AC was electroactive (no reference about its electrochemical behaviour was found), its electrochemical profiles at different pH (acidic media of $HClO_4$, $AcO^-$/AcOH and $HPO_4^{2-}/H_2PO_4^-$, weakly alkaline medium, $NH_3/NH_4^+$, and strongly alkaline medium, NaOH) were obtained, without and with preconcentration step.

Voltammograms obtained, with a $1 \times 10^{-5}M$ AC solution, at pH 1 ($HClO_4$ $0.1M$) without a preconcentration step, scanning the potential from 0.0 V, up to 1.2 V, and then back to −0.8 V *vs.* Ag/AgCl, KCl satd, at different scan rates (1–5 V/sec), are plotted in Fig. 1. Only one well defined oxidation peak appears at 0.993 V. Its height increases with scan rate up to 4 V/sec, and then decreases at 5 V/sec, probably owing to high cell constant value. The height of this peak increases linearly with AC concentration and with $v^{1/2}$, therefore, it is a diffusion controlled peak. It also appears as a cathodic peak at +0.2 V whose height increases slightly with the scan rate.

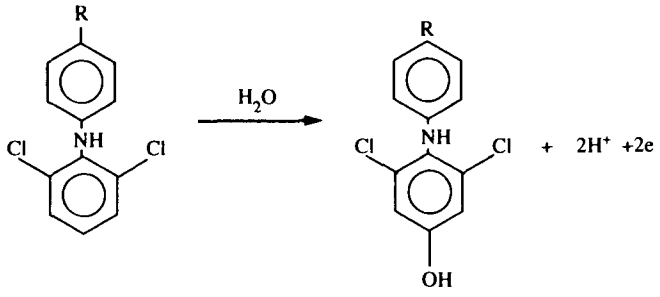
Following a preconcentration step, employing the same AC solution but at pH 1.7 ($HClO_4$ $2.10^{-2}M$), the same voltammogram was obtained, in which we observe that the anodic peak is near the electroactivity limit and, therefore, it is difficult to analyse.

In order to obtain a fairly easy to use voltammogram, we proceeded as follows. Without a preconcentration step: with the same AC solution, we completed a whole cyclic voltammetric cycle from +1.00 V to −0.100 V and back to +1.0 V. The voltammogram obtained is plotted in Fig. 2. In this figure, a very suitable analytical peak at +0.5 V and other small peaks (at +0.7, +0.65 and +0.15 V) without analytical significance, are observed. This analytical peak is probably a result of oxidation of a

substance obtained by a series of previous electrochemical and chemical reactions described as follows.

*Analytical peak characterization*

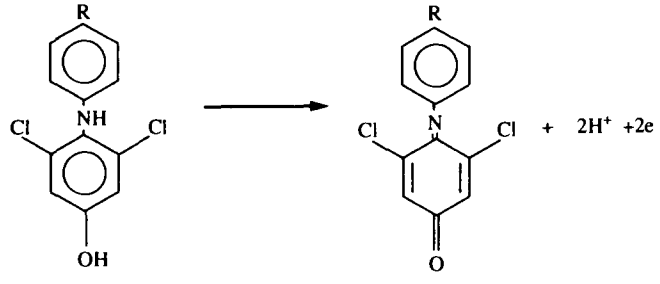
In order to characterize the peak, a series of voltammograms were obtained. These voltammograms have been interpreted according to Adams.[27] Thus, we think that the first step in the electrochemical oxidation of AC is the following reaction (where R is $—CH_2—CO_2—CH_2—CO_2H$, in the aceclofenac formula):



Scheme 1.

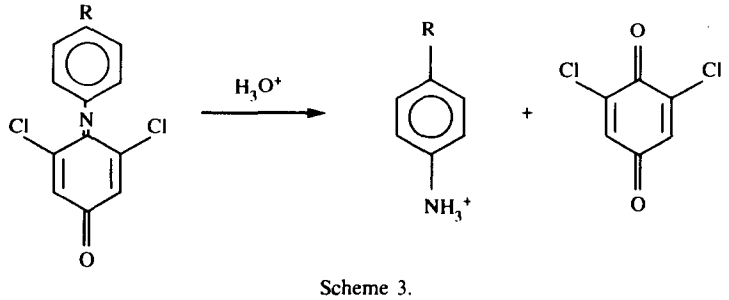
obtaining peak I of Fig. 2.

The aminophenol formed is further oxidized in peak I, giving a quinoneimine R derivative:



Scheme 2.

This quinoneimine is easily hydrolysed in acidic media according to Adams[27] giving the following compounds:



Scheme 3.

The quinoneimine and quinone forms might correspond to the redox peak couple III/III′ and II/II′, respectively.

In order to verify this, we studied the electrochemical behaviour of the commercially available compound 2,6-dichloro-*p*-aminophenol, and the results obtained indicate that its behaviour is similar to that of AC. However, the commercial compound is just slightly adsorbed onto the carbon paste electrode (Fig. 3), corresponding to the case in which a $1 \times 10^{-5}M$ 2,6-dichloro-*p*-aminophenol solution was in contact with a CPE for 8 min.

We also studied $1 \times 10^{-5}M$ 2,6-dichloro-*p*-aminophenol in solution, that is to say without a preconcentration step, by cyclic voltammetry, scanning the potential at 4 V/sec, obtaining the voltammogram plotted in Fig. 4, in which a

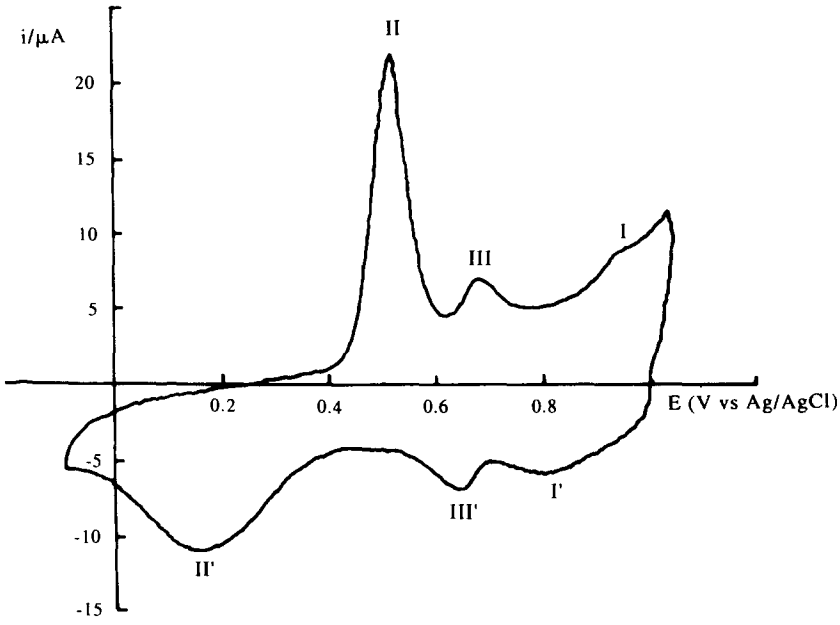


Fig. 2. Voltammogram of $10^{-5}M$ AC at pH 1.7 ($HClO_4$ $10^{-2}M$); starting potential: +1.00 V; first scan up to −0.10 V, reverse up to 1.05 V and finally up to 1.00 V to complete the cycle; scan rate: 4000 mV/sec; conventional carbon paste electrode.

quasi-reversible behaviour of this compound is observed, with an anodic peak developed at about +0.5 V.

We think that the quinone formation is the most probable electrochemical transformation of AC according to Adams.[27] Therefore, we can conclude that the analytical peak of AC obtained must correspond to the anodic oxidation of adsorbed 2,6-dichlorohydroquinone previously produced by electrochemical and chemical processes on AC after its strong adsorption on the carbon paste electrode.

All of the following studies on the electroanalytical behaviour of AC were carried out using

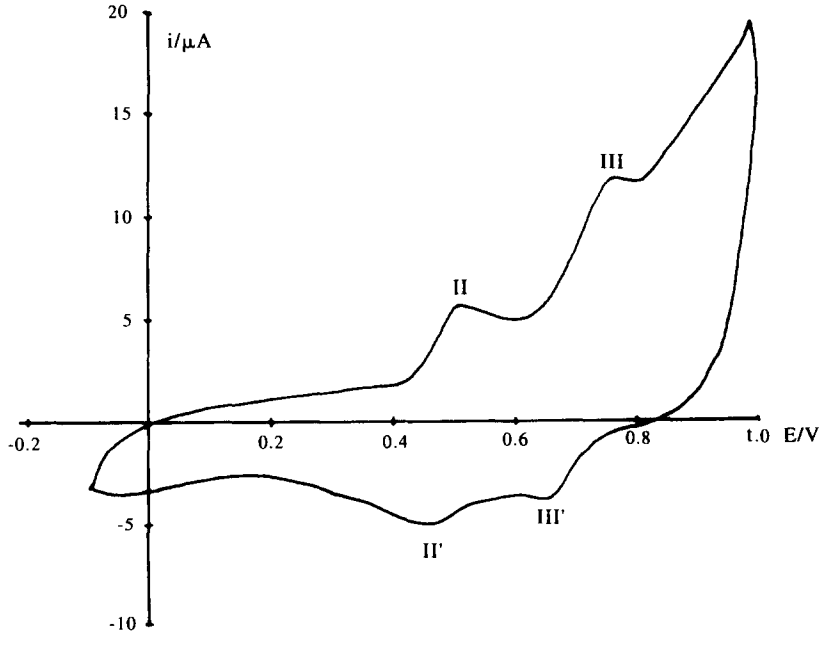

Fig. 3. Voltammogram of 2,6-dichloro-*p*-aminophenol solution after contact with the carbon paste electrode for 8 min; pH 1 both in preconcentration and stripping cells.

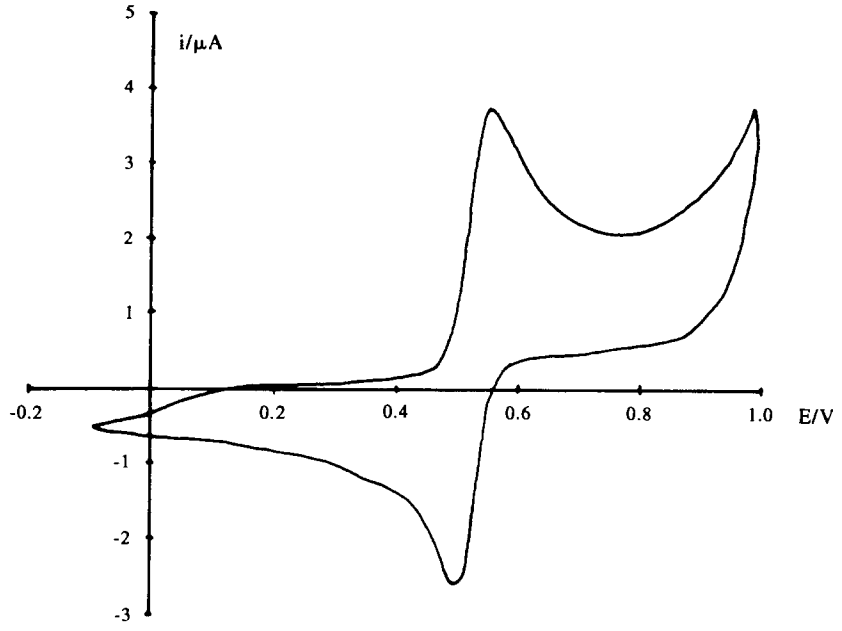

Fig. 4. Voltammogram of a $10^{-5}M$ 2,6-dichloro-*p*-aminophenol solution at pH 1 on a conventional carbon paste electrode; scan rate 4 V/sec (without preconcentration step).

adsorptive voltammetric techniques on CPE and MCPE. For this, two solutions were used: (1) preconcentration solution; (2) stripping solution, as we have previously indicated in Procedures. Several preliminary parameters, such as the water/alcohol ratio of the AC solutions as well as the Nujol oil/carbon ratio of the CPE, were studied.

As AC is sparingly soluble in water we prepared a $1 \times 10^{-2}M$ AC solution in pure ethanol. Nevertheless, according to the AC structure, we think that protons must play an important role

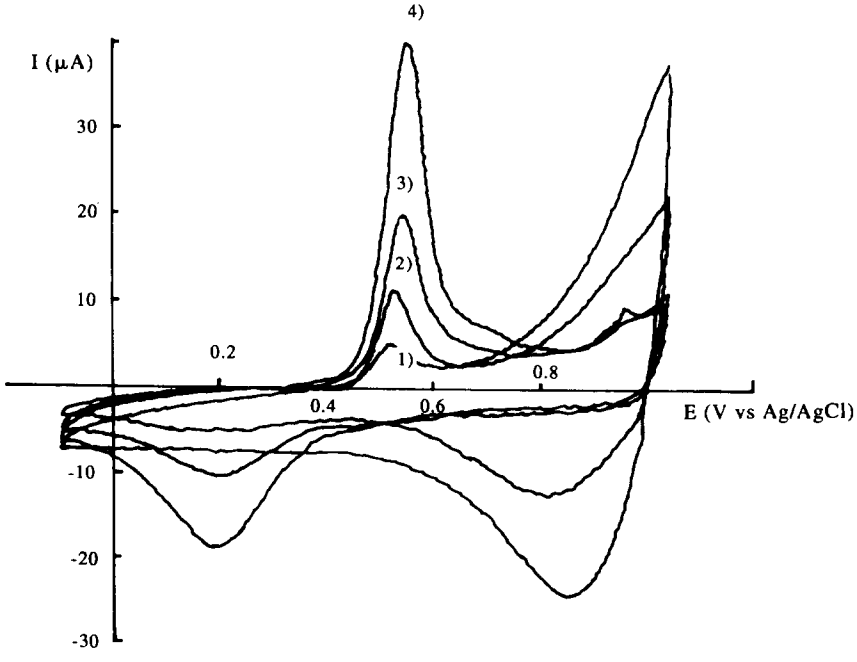

Fig. 5. Voltammograms of $10^{-5}M$ AC at pH 1 ($HClO_4$ $0.1M$). Influence of ethanol/$H_2O$ (v/v) ratio of preconcentration solution on peak height; (1) 3:2; (2) 2:3; (3) 1:4; (4) 0:5; scan rate: 4 V/sec; conventional carbon paste electrode; ad-accumulation time: 8 min.

Table 2. Influence of carbon (g)/Nujol oil (ml) on $I_p$ ($\mu$A), $E_p$, $E_{p/2}$, $E_p - E_{p/2}$ (V) of aceclofenac peak height (ad-accumulation time: 8 min, ad-accumulation pH: 1.0; potential scan rate: 4 V/sec)

| C (g)/Nujol (g) | $I_p$ ($\mu A$) | $E_p$ ($V$) | $E_{p/2}$ | $E_p - E_{p/2}$ |
|---|---|---|---|---|
| 3:1.23 | — | | — | |
| 3:1.32 | 17.04 | 0.548 | 0.548 | 0.035 |

| 3:1.76 | 2.60 | 0.539 | 0.503 | 0.036 |

in the reduction mechanism of this drug, therefore, the influence of percentage water and pH must be studied.

*Influence of alcohol/water ratio on peak height.* By varying the ethanol/water ratio, we observe that the lower the ethanol/water ratio, the higher the voltammetric peak height. The influence of ethanol/water ratio on AC peak height is plotted in Fig. 5. These experiments were carried out with a $1 \times 10^{-5}M$ AC solution, at pH 1 into both the preconcentration and stripping solutions, with a preconcentration time of 8 min and a potential scan rate of 4 V/sec. In this figure, we observe that despite the high scan rate, the height of the AC peak can be easily measured.

*Influence of Nujol/carbon ratio on aceclofenac peak height.* This study had a double purpose. Firstly, to obtain a more intense analytical signal, and, secondly, to ascertain if AC is adsorbed on carbon particles or extracted by the Nujol oil used as binder in this type of electrode. The influence of the C (g)/Nujol (g) ratio on $I_p$ ($\mu$A), $E_p$ (V), $E_{p/2}$ and ($E_p - E_{p/2}$) of aceclofenac voltammetric peak height can be seen from Table 2.

The higher the carbon/Nujol (w/w) oil ratio, the higher the peak height, therefore, we can conclude that AC is adsorbed on carbon particles and not extracted by the Nujol oil, as we have found in another work on another substance.[22] By increasing the Nujol oil/carbon (w/w) ratio the CPE electroactive area decreases and so the AC peak height also decreases, that is to say, by decreasing the polarity of the electrode surface the AC adsorption also decreases. We can also observe that both $E_p$, $E_{p/2}$ and $E_p - E_{p/2}$ remain almost invariable with the C (g)/Nujol (g) ratio. As Nujol oil is necessary to bind the carbon particles, an optimal Nujol oil/carbon ratio of 32/68 (w/w) was chosen for all the following experiments.

*Stripping of AC at the CPE*

In this part, a study of several experimental parameters was carried out in order to establish an AC stripping method based on a drug adsorption phenomenon on carbon particles, *i.e.* by using a carbon paste electrode without modification. The studied parameters were scan rate, ad-accumulation time, pH of the preconcentration and stripping solutions, solution stir-

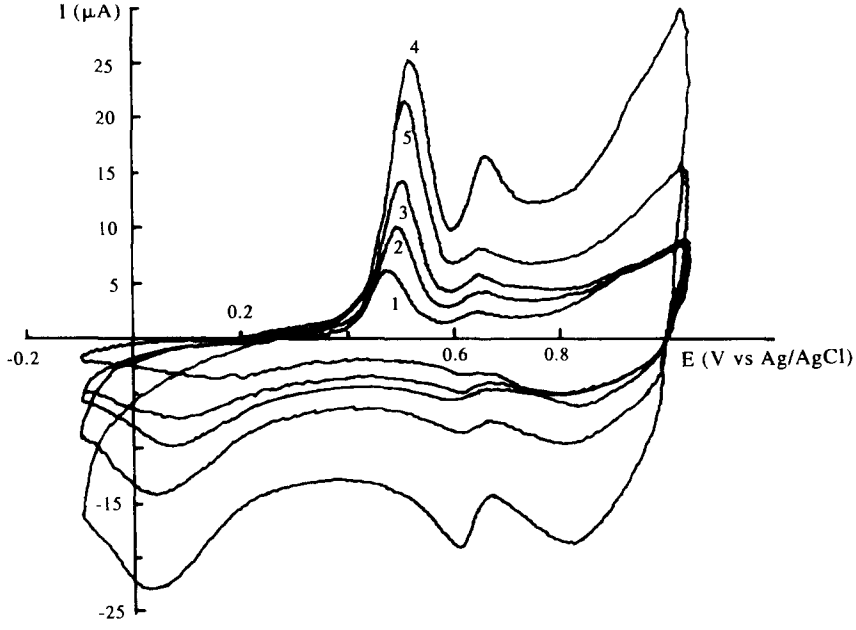

Fig. 6. Voltammograms of $6.10^{-5}M$ AC at pH 4.5 both in preconcentration and stripping cells. Influence of scan rate; (1) 1 V/sec; (2) 2 V/sec; (3) 3 V/sec; (4) 4 V/sec; (5) 5 V/sec; conventional carbon paste electrode; ad-accumulation time: 4 min.

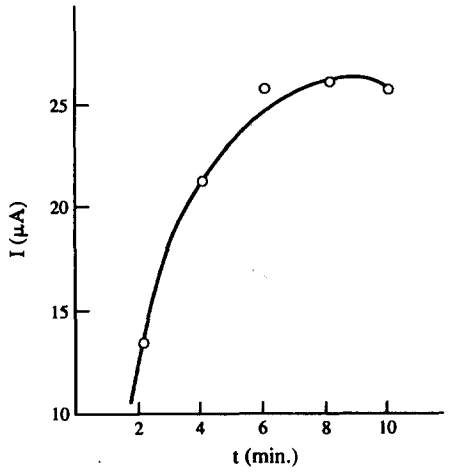

Fig. 7. Influence of ad-accumulation time on peak height of $6 \times 10^{-5}M$ at pH 4.5 ($HAc/Ac^-$ $0.1M$) in preconcentration cell and 1 ($HClO_4$ $0.1M$) in stripping cell; scan rate: 4000 mV/sec; conventional carbon paste electrode.

ring rate, and analyte concentration influence on AC anodic peak height.

*Scan rate influence.* The preconcentration solution was formed by a $6 \times 10^{-5}M$ AC solution and a buffer to give pH 4.5 ($HAc/Ac^-$ $0.1M$), and the stripping solution was formed by $0.1M$ $KNO_3$ solution and a buffer to give pH 4.5 ($HAc/Ac^-$ $0.1M$). Scanning cyclically the potential between 1.05 and $-0.1$ at different scan rates, several voltammograms, plotted in Fig. 6, were obtained, showing that the optimal value was 4 V/sec. In addition, a peak height decrease is observed at 5 V/sec. This 'anomalous result' may be explained by the fact that, at very high scan rate, the percentage of 2,6 dichloro-*p*-hydroquinone formation, from the AC, must decrease.

*Ad-accumulation time influence.* For these experiments the preconcentration solutions and the stripping solutions were the same as above. The scan rate was 4 V/sec and the ad-accumulation time was between 2 and 10 min. The results obtained are plotted in Fig. 7, where optimal values were reached from 8 min of ad-accumulation.

*pH influence.* For these experiments the preconcentration solution pH was firstly varied between 1 and 8.5, whilst the pH stripping solution was constant and equal to 1.7. The scan rate and ad-accumulation time had the optimal values obtained as above, and the AC concentration was also $6 \times 10^{-5}M$. The results obtained are plotted in Fig. 8, where the optimal pH value is 1.0. In this figure we can observe a slight peak potential shift of about 6.6 mV/pH between pH 8.5 and 1.0, whilst the peak height differences are greater, explaining the importance of pH in the ad-accumulation of 2,6-dichloro-*p*-benzohydroquinone according to the AC electrochemical and chemical transformations mentioned above, but especially in the stripping step.

If the pH of the preconcentration solution is maintained at a value of 1, and the pH of the

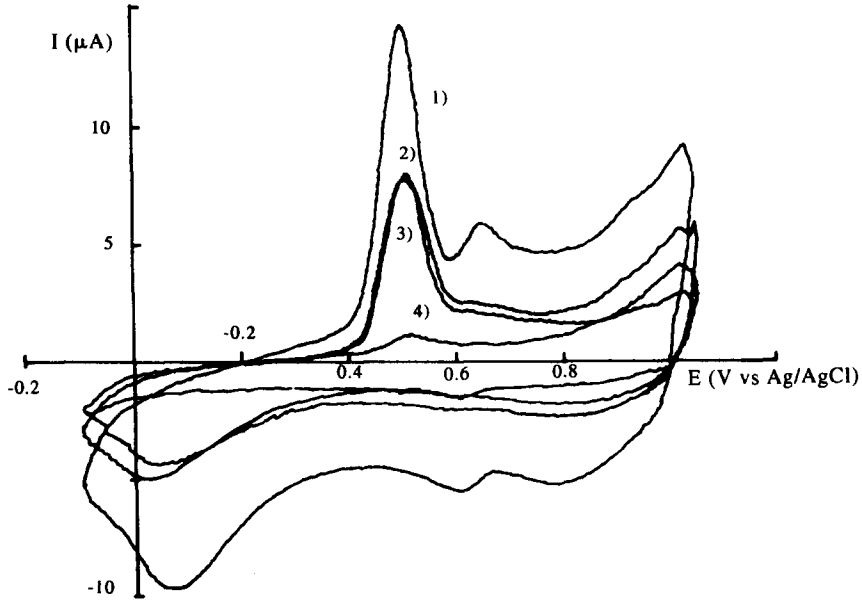

Fig. 8. Influence of the preconcentration cell pH on $6.10^{-5}M$ AC solution peak height; (1) 1.0; (2) 2.3; (3) 5.9; (4) 8.5; stripping cell pH: 1.7; scan rate; 4000 mV/sec; ad-accumulation time: 8 min; conventional carbon paste electrode.

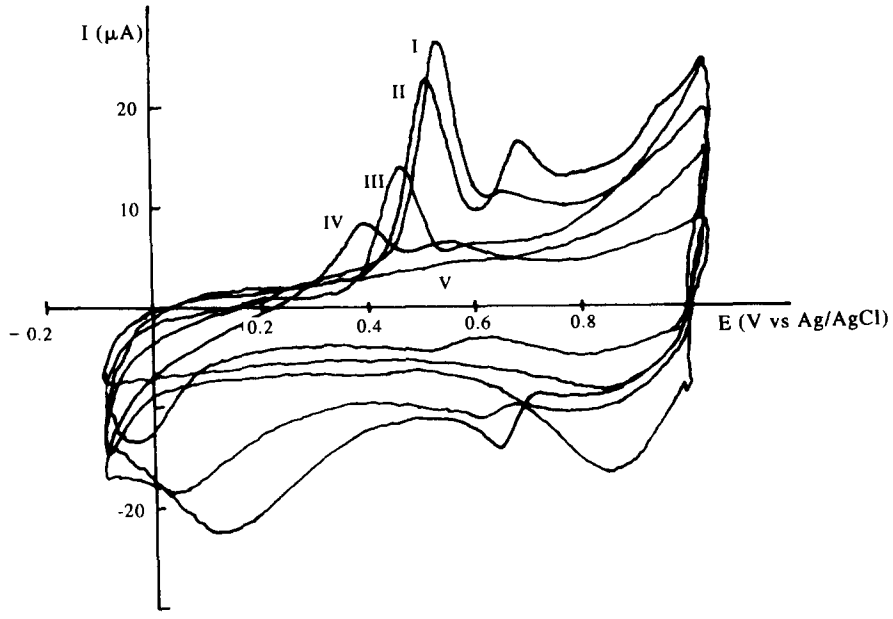

Fig. 9. Influence of the stripping cell pH on $6.10^{-5}M$ AC solution peak height; (I) 1.0; (II) 1.7; (III) 3.0; (IV) 4.7; (V) 6.7; preconcentration cell pH: 1; scan rate: 4000 mV/sec; ad-accumulation time: 8 min; conventional carbon paste electrode.

stripping solution is varied between 1 and 6.7, the higher the pH value, the lower the AC peak height, and the more negative the $E_p$ (Fig. 9).

Although the preconcentration step was carried out at pH 1 in all cases (at open circuit), the oxidation and reduction processes were carried out at different pH (from 1 to 6.7), therefore the formation of electroactive species to give peak II was depleted and the obtained anodic peaks were of different heights, therefore we might affirm that the pH is an important parameter in the mechanism of the AC oxidation on CPE, as we have observed above.

These experimental results confirm our hypothesis that by AC electrochemical oxidation, a molecule of 2,6-dichloro-*p*-benzoquinone is produced. This compound is reduced to 2,6-dichloro-*p*-hydroquinone, causing a higher stripping solution pH, and lower $E_p$ and peak current, because the 2,6-dichloro-*p*-benzoquinone preconcentration depends upon the medium acidity. Also, the lower the pH the higher the $E_p$, according to the electrochemical equilibria shifting laws.

We have also studied the preconcentration solution stirring rate influence on voltammetric peak height, and an optimal value of 1000 rotations/min was obtained.

*Analyte concentration influence.* Finally, in order to apply the proposed AC determination method, by using a stripping voltammetric technique of the CPE, the influence of analyte concentration on voltammetric peak height was studied. For this, the corresponding data are given in the experimental conditions.

After plotting the corresponding voltammetric peak currents *vs.* analyte concentration, a straight line was obtained. By its adjustment by the least square method, the following equation was obtained:

$$I_p(\mu A) = 7.1 \times 10^{-2} + 2.82 \times 10^{6} C\,(M)$$

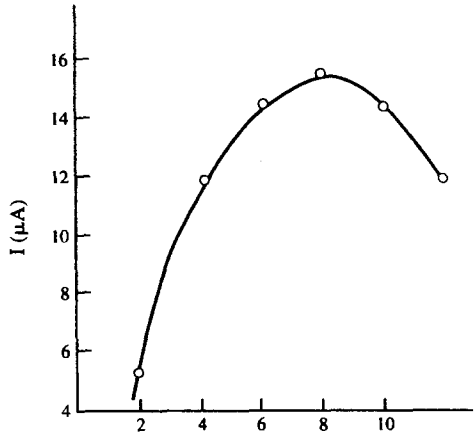

Fig. 10. Influence of preconcentration time of $10^{-6}M$ AC solution peak height; pH 1 in both cells; scan rate: 4000 mV/sec; modified carbon paste electrode with Triton X-405; surfactant/carbon (w/w) ratio of 5/95.

Table 3. Results of AC determination in Airtal R tablets obtained by our adsorptive stripping method and its comparison with a potentiometric one

| Sample | Stripping ($mg \pm s$)* | Potentiometric ($mg \pm s$)* | mg/tablet ($mg$) | $t_m$† |
|---|---|---|---|---|

| 2 | 98.63 ± 1.38 | 98.79 ± 1.77 | 100.00 | 0.21 |
| 3 | 98.52 ± 1.54 | 98.78 ± 1.82 | 100.00 | 0.33 |

*These data are the average of nine measurements.

†These data are the Student's $t$ measurements. The Student's $t$ tabulated is 2.12 for $n_1 + n_2 - 2 = 16$ freedom grades for a confidence level of 95%.

with a correlation coefficient of 0.9998 and a detection limit, of $5.4 \times 10^{-8}M$ (19 ppb), according to Miller and Miller.[28]

*Electroanalysis of aceclofenac at the modified CPE*

In order to improve the analytical results obtained at the CPE, a chemical modification of this electrode was carried out. This modification was made by mixing the carbon powder with different surfactants, such as the non-ionic Triton X-100 and X-405, and the anionic sodium dodecyl sulfate (SDS), as well as different hydrophobic substances, such as asolectin (phospholipid) and stearic acid (fatty acid). Interesting improvements were observed only in the case of Triton X-405.

With this type of electrode, prepared as has been indicated in Procedures, we studied the influence of only three parameters: optimal surfactant/carbon (w/w) ratio [obtaining a value of 5/95 (g/g)], optimal preconcentration time and analyte concentration on aceclofenac oxidation peak current. Other parameters, such as Nujor oil/carbon (w/w) ratio, preconcentration time, potential scan rate, *etc.*, are the same as indicated in the case of the CPE.

*Preconcentration time influence.* In Fig. 10, the influence of preconcentration time on peak height has been plotted, in which the maximal preconcentration time was reached at 8 min. From this value, the higher the preconcentration time, the lower the drug reduction peak height as obtained in other works.[24,29]

*Analyte concentration influence.* To study this parameter we employed the conditions given in the Experimental. The AC concentration range studied was between $1 \times 10^{-7}$ and $1 \times 10^{-6}M$. Plotting AC reduction peak current *vs.* analyte concentration a straight line was obtained, whose equation was

$$I_p(\mu A) = 0.95 + 1.2 \times 10^7 C(M)$$

with a correlation coefficient of 0.9997 and a detection limit, according to Miller and Miller,[28] of $1.93 \times 10^{-8}$ (7 ppb), *i.e.* almost one-third of the one obtained in the case of the conventional carbon paste electrode.

From these results, we can confirm that the presence of certain surfactants in the CMCPE improves the AC electroanalytical determination, owing to the increase of chemical affinity between the two types of molecules, as we have found elsewhere by using phospholipids as modifiers.[22]

*Application of our method to drug formulation control.* In order to check our AC determination method, we applied it to determine AC in a drug formulation, Airtal R, which is presented as tablets of about 200 mg, in which, according to the manufacturer, there is 100 mg of pure aceclofenac per tablet and an excipient constituted by several ingredients (Table 1).

To carry out the AC determination we prepared three groups of five tablets, which were well ground and mixed separately in an agate mortar. From each solid sample we took an amount sufficient to prepare a volumetric flask of 25 ml of about $1 \times 10^{-2}M$ aceclofenac* after filtration of the residue. From each solution, a new AC solution of about $1 \times 10^{-4}M$ aceclofenac* was prepared. From each one of these last solutions, three samples of 26 $\mu$l were taken and added to three volumetric flasks of 25 ml, obtaining, after dilution with the appropriate solution, an AC concentration of $1 \times 10^{-7}M$*. With these solutions, a series of voltammograms were obtained according to our proposed method using a surfactant MCPE. In each case, four standard additions of 50, 100, 150 and 225 $\mu$l of $1 \times 10^{-4}M$ AC standard solution† were made, obtaining a series of results, from which an equivalent mean volume is deduced. The results are given in Table 3.

*Certified by the manufacturer.

†Standard prepared by us.

In order to validate our method, a comparison of our results with the one obtained by another method employed by the AC manufacturer to control the AC contents in the tablets, was carried out. The manufacturers normally employ potentiometric or chromatographic techniques. We have chosen the potentiometric technique as a validation method. For this, from each $10^{-2}M$ AC solution, three other solutions 20-fold more diluted ($5 \times 10^{-4}M$) were prepared and then titred with NaOH standardized *vs.* an acid–base standard, the $C_6H_4(COOH)COOK$. The results obtained are given in the third column of Table 3: $t_m$ (measured value) is less than 2.12 (tabulated value), therefore there is no significant difference between the two methods, according to Miller and Miller.[28]

## CONCLUSIONS

The electrochemical behaviour of AC has been studied for the first time in this paper using voltammetric techniques on conventional as well as on surfactant MCPEs, observing a well developed analytical oxidation peak at +0.5 V (Ag/AgCl, KCl satd).

To obtain this peak it was necessary previously to oxidize the compound by starting the potential scan at sufficiently high values, *e.g.* +1.00 V (Ag/AgCl, KCl satd), and then to reduce it at sufficient low potential values, *e.g.* −0.1 V (Ag/AgCl, KCl satd).

An explanation of the AC electrochemical and chemical reactions on CPE and CMCPE is given according to the literature.[27]

AC can be adsorbed on carbon particles of conventional carbon paste electrodes and not extracted by the Nujol oil used as binder, at least in strong acidic media (pH 1). The drug can be also adsorbed on surfactant MCPEs, mainly when the modifier is Triton X-405. On the contrary, this compound does not adsorb on phospholipid chemically modified carbon paste electrode nor on fatty acid chemically modified carbon paste electrode (at least in the case of asolectin).

Adsorptive stripping voltammetric method of AC determination, on conventional and surfactant chemically modified electrodes, is proposed in the present paper, obtaining a very sensitive response (a detection limit of 7 ppb) in the case of surfactant chemically modified electrode, this method being applied to AC control in tablets.

The method is also quite accurate as we have shown by comparing our results with the ones obtained by potentiometry. In this sense our electroanalytical method has been validated *vs.* the potentiometric one based upon a classic acid–base reaction potentiometrically followed by a glass electrode.

*Acknowledgements*—This work has been carried out under the financial support of the Ministerio de Educación y Ciencia of Spain under Project PB 89-0361-C03-01. The authors thank the Prodesfarma Research Center of Barcelona (Spain), especially Dr E. Carrasco, researcher of this Center, for the kind provision of the pure substance, the drug formulations to apply to the proposed method, as well as data about this drug formulation.

# DEVELOPMENT OF A HIGHLY SENSITIVE GALVANIC CELL OXYGEN SENSOR

HIROSHI OGINO* and KIYOTAKA ASAKURA

Toyo Sanso Co. Ltd., Technical Research Laboratory, 3-3, Mizue-cho, Kawasaki, Kanagawa 210, Japan

(*Received* 10 *January* 1994. *Revised* 16 *March* 1994. *Accepted* 1 *August* 1994)

**Summary**—A highly sensitive galvanic cell oxygen sensor was successfully developed for determining parts per billion of oxygen in high purity gases such as nitrogen, argon, *etc.* The response of this improved sensor was proportional in the range of oxygen concentrations from 10.0 ppm to the detection limit. The response speed in this study was improved to within 90 sec for a 90% response. The detection limit was tentatively found to be less than 0.4 ppb corresponding to $S/N = 2$.

In high technology industries such as the manufacture of semi-conductors, the requirement for quality control of gases used as inert and atmospheric gases is becoming more important. The requirement for a highly sensitive oxygen analyzer has increased for gas suppliers and users. There are many types of commercially available oxygen analyzers for the determination of oxygen in gases: (1) galvanic cell type,[1–8] (2) zirconia type,[9] (3) luminescence type,[10] (4) others.[11] However, based on sensitivity and accuracy of the sensor and handling safety, as well as ease of calibration, the galvanic cell oxygen sensor could be considered the most sensitive and reliable sensor for accomplishing the continuous determination of trace levels of oxygen in hydrogen, nitrogen, argon, helium, *etc.*[1–8]

Recently, the purity control management of high purity inert gases such as nitrogen and argon has become more important. It is required to continuously determine and control the concentration of impurities at levels of several parts per billion (ppb, v/v) in high purity gases.

The authors have previously developed and reported a trace oxygen analyzer with a detection limit of 10 ppb.[8] In this paper, the characteristics of an improved galvanic cell oxygen sensor (GOS), which has the capability of a detection limit in the sub-ppb level for the determination of trace levels of oxygen in nitrogen, argon, helium, and hydrogen, are described.

## EXPERIMENTAL

### *Apparatus and reagents*

The cross-sectional view of the GOS is shown in Fig. 1. The GOS consists of lead rod (anode) and silver screen mesh (cathode) electrodes as follows,

Pb/Zeolite (KOH sol.)/PE/POF/Ag

When oxygen contacts with the cathode, the GOS produces an electric current via the following reactions: at the cathode (Ag), $O_2 + H_2O + 2e^- \rightarrow 4OH^-$; at the anode (Pb), $Pb + 4OH^- \rightarrow 2Pb(OH)_2 + 2e^-$. The anodic electrode (Pb) was 5 mm diameter × 65 mm long and the cathodic electrode (Ag) was a screen mesh of 0.5 mm thickness. The PE was an 8 mm i.d. × 10 mm o.d. × 70 mm long tube made from sintered porous polyethylene with the pore size of $< 100\ \mu m$ and the POF was a

20 $\mu$m thick polyolefin film with *ca.* 0.1 mm diameter holes (50 holes/cm$^2$). The zeolite (*e.g.* MS-5A, 60/80 mesh), which was admixed with agarose, was used to retain 5*M* KOH alkaline solution.

Assembled GOSs were impregnated with 5*M* KOH solution for an adequate time after assembly in order to retain much more alkaline solution. The GOS is installed in a detector box which was made from a polymethacrylate-based resin. The detector box has a humidifier, which can hold *ca.* 350 ml of alkaline solution. The alkaline solution is required as the source of the water for humidifying the GOS and also as the electrolyte solution for the oxygen generator. The GOS requires moisture at a constant level to avoid sensor dryness. For both requirements as described above, the detection system was designed as shown in Fig. 2.

The water content in the electrolyte was reduced by evaporation of water during the sample flow and gas purges. Therefore, refilling with deionized (or distilled) water was required every 4 weeks.

The detection system including the detector box and gas pipeline was heated to 35°C to prevent condensation of water in the pipelines. The coulombic yield of this type sensor can be related to the flow rate of the gas sample, the spacing between the internal surface of the sensor holder and the silver mesh of the GOS, the wetting of the GOS, *etc.*

Stainless steel tubing with a 1/8 inch diameter and stainless steel diaphragmed valves with 1/8 inch VCR fitting (Advanced Pressure Technology, AP-2600, CA, USA) were used: they were very effective for obtaining a faster response and reducing the purge time of oxygen that remained in the analytical system. The alkaline solution was continuously purged with oxygen-free nitrogen (100 ml/min) to completely remove any dissolved oxygen.

The alkaline solution in the humidifier was prepared by mixing 34.5 g KOH (Kanto Chemical, guaranteed purity >85 wt %, Tokyo, Japan) and one l. of deionized water: an alkalinity of 3 wt % KOH was required for stable oxygen generation by water electrolysis.

Nitrogen gas evaporated from liquid nitrogen was used as the sample gas in order to evaluate sensor responses such as sensitivity, stability, zero and span calibration, *etc.* The sample gas was divided into two gas lines: one line was used to produce oxygen-free nitrogen (zero gas), which was purified by passing it through an oxygen absorber to remove trace amounts of oxygen in the nitrogen gas, and the other was used as a sample gas without purification. Both flow rates were controlled using mass flow controllers. The flow rates of the sample and purge gases were regulated at 100 ml/min by the mass flow controllers within $\pm 1\%$ deviation. Oxygen-free nitrogen was prepared by passing nitrogen through an oxygen absorber (Gasclean, Nikka Seikou, Tokyo, Japan), which could remove oxygen to at least the 2–3 ppb level or below: the concentration of residual oxygen in the purified nitrogen was separately and previously confirmed using an atmospheric pressure ionization mass spectromer[11] (API-MS, UG-240 APN, Hitachi, Tokyo, Japan) in the Technical Research Laboratory (Toyo Sanso).

For the experiments at ppb levels of oxygen, a getter type purifier (Saes PureGas, Inc., Model, MonoToor, phase-II, CA, U.S.A.) was used: this getter could remove oxygen to less than 0.1 ppb. The sample gases containing low levels of oxygen in nitrogen were prepared with a standard gas generator (STEC, SGGU-6000, Kyoto, Japan), which has the capability of dilution rates between 1/10 and 1/10,000. The desired oxygen concentration in a sample gas could be provided in the range of ppb to ppm. An amplifier and microcomputer system, which had been installed in a trace oxygen analyzer (GOT-20, Toyo Sanso),[8] was used in this experiment.

## RESULTS AND DISCUSSION

### *Calibration system*

The accurate calibration of the sensor is one of the most important factors for obtaining reliable analytical values: an accurate determi-

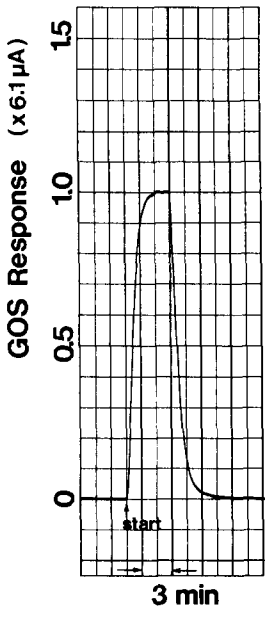

Fig. 3. Typical recording profile of 1 ppm oxygen gas generated by the water electrolysis.

nation depends on how the sensor can be precisely calibrated. The detector box has an internal oxygen generation system[1,4] for the calibration of the GOS: the constant current method was used for water electrolysis in order to generate a small amount of oxygen. In these experiments, the calibration of the GOS was carried out using an oxygen standard gas generated by water electrolysis as described above. The evolution of oxygen is proportional to the amount of electric current based on the Faraday's law.[1] The generated oxygen is mixed with 100 ml/min of oxygen-free nitrogen (zero gas). The oxygen concentration is inversely proportional to the flow rates of the diluting gas. The amount of current is calculated from the following equation.

$$I = 0.263 \,.\, V \,.\, C,$$

where $I$, $V$ and $C$ are the electric current ($\mu$A), the flow rate of the zero gas (ml/min) and the concentration of oxygen (ppm), respectively. The cathodic and anodic electrodes for the water electrolysis were 1 mm diameter × 10 mm long and 0.5 mm diameter × 1 mm long platinum wires, respectively. The cathodic electrode was covered with an anion exchange resin tube to prevent the electrochemical deposition of impurity metals from the electrolyte alkaline solution.[8] The lifetime of the electrode, therefore, could be prolonged so that the electrode could be used for at least several months without cleaning, if the calibration was done once a week. With these improvements, a standard oxygen gas could be accurately provided at the level of ppm in inert gases such as nitrogen and argon using this method. In the experiment to be described, the GOS could be calibrated with 1 or 5 ppm oxygen standard gases in nitrogen. If necessary, an oxygen standard gas from a cylinder could be used for the calibration of the sensor. A typical sensing profile of the GOS for the generation of 1 ppm span gas is given in Fig. 3.

*Stabilization of the GOS*

For stabilizing the GOS response, the electrolyte medium must be in a stable and homogeneous state. As one possibility, agar could be expected to make the zeolite powders homogeneously disperse. However, agar could not be used for this purpose because it was unstable in the strong alkaline solution. On the other hand, agarose was not only stable in the alkaline solution, but also its gelatin was slightly soluble in this solution. Thus, agarose was chosen as the dispersing material of the zeolite and retaining alkaline solution; when admixed with the zeolite powder, it formed a stable gel in the strong alkaline solution to avoid a heterogeneous reaction between the surface of the lead electrode and the zeolite powder.

To demonstrate the effect of agarose addition, a set of experiments for the evaluation of these electrolyte media were separately carried out with two electrolyte media; one (A) was zeolite saturated with 5*M* KOH solution and the other (B) was zeolite–agarose saturated with 5*M* KOH solution. Galvanic cells were constructed with a piece of lead plate, 5 mm width × 20 mm long × 1 mm thickness, as the anodic electrode and a 10 mm width × 35 mm long silver screen mesh as the cathodic electrode. The anodic electrode was dipped into the electrolyte medium. The cathodic electrode was placed on the surface of electrolyte medium and could be exposed to atmospheric air.

The two galvanic cells were allowed to stand under atmospheric air at room temperature for a week. When the galvanic cell was constructed without the agarose, the zeolite was in direct contact with the lead and was deposited on and in the surface of the lead electrode as shown in photograph (A) of Fig. 4. The result from the galvanic cell (A) suggests that the lead plate reacted with the zeolite so that the reaction should take place inside the lead and part of the zeolite could directly react with the lead elec-

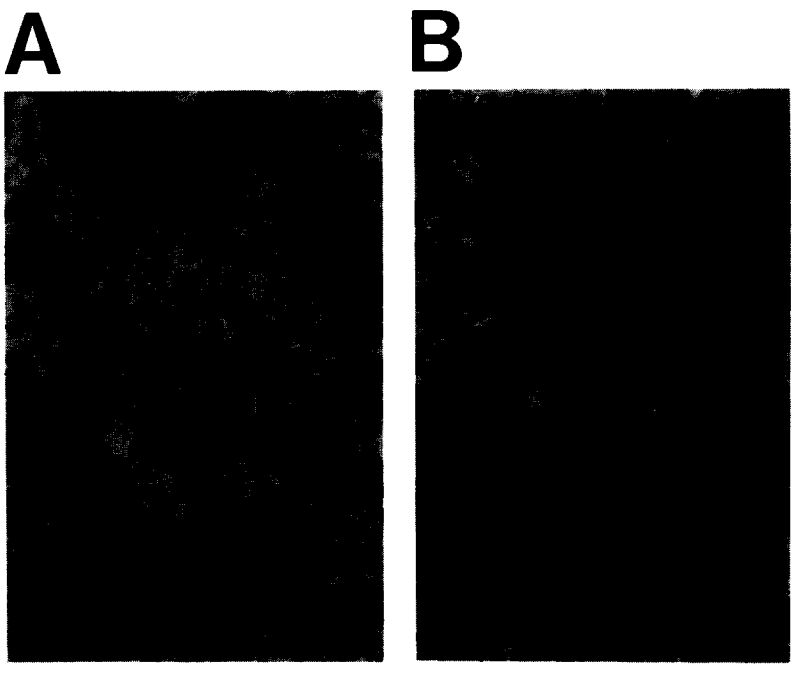

Fig. 4. Photograms of lead plate reacted with the zeolite. (A) Electrolyte medium without agarose, (B) with agarose. Both plates were sonicated for approximate 15 min and rinsed with distilled water.

trode. Its instability and undesirable capability might be largely a result of such a phenomenon: a homogeneous gel could make the electrochemical reaction more stable. On the other hand, if the agarose was used as a gelling reagent, it is clear that the surface would be kept clean as shown in the photogram (B). On the basis of these results, it could be expected that the zeolite was covered with the agarose and the electrolyte medium could retain much more alkaline solution and that the dead volume inside the sensor could be reduced or eliminated.

*Characteristics of the GOS*

In order to evaluate the characteristics of the GOS, several GOSs were made in the same way as previously described. They were fully submerged in 5*M* KOH solution overnight in order to provide enough alkaline solution in the sensor. The measurements were started after the GOS was installed in the detector box. The air remaining inside the GOS and dissolved oxygen in the alkaline solution could be purged with oxygen-free nitrogen for a couple of hours. If the GOS was operated after adequate purging and the response of the GOS was in the stable state, the GOS signal output should be less than 0.1 $\mu$A for oxygen-free nitrogen. It is very difficult for the response of the GOS to reach zero current owing to the residual current of the GOS and the residual oxygen in the zero gas. It takes several hours until the determination of trace oxygen at the ppb level can be done. In order to quantitatively evaluate the response time for the improved and ordinary (without the addition of agarose) GOSs, three GOSs were tested using oxygen-free nitrogen and nitrogen containing 0.63 ppm oxygen. Two GOSs were made by the use of agarose and the other without agarose. Figure 5 is a typical profile for the response change in the GOS (A) between zero gas and reference gases (nitrogen containing 0.63 ppm oxygen). The response profiles were obtained by alternately turning the six port rotary valve from the zero gas line to the sample gas line. The obtained results are summarized in Table 1. The GOSs (A, B) admixed with agarose had a response time of 90 sec for a 90% response and the other (R) without agarose had a response time of 120 sec: the response of the improved GOSs was faster and more stable than that prepared without the agarose.

In order to demonstrate the capability of sensor installed in the prototype oxygen analyzer, the sensor response was recorded stepwise for different oxygen concentrations in nitrogen, which were provided by the use of the standard gas generator. After the GOS was calibrated with the 1 or 5 ppm span gas, the working curves were obtained in the concentration range

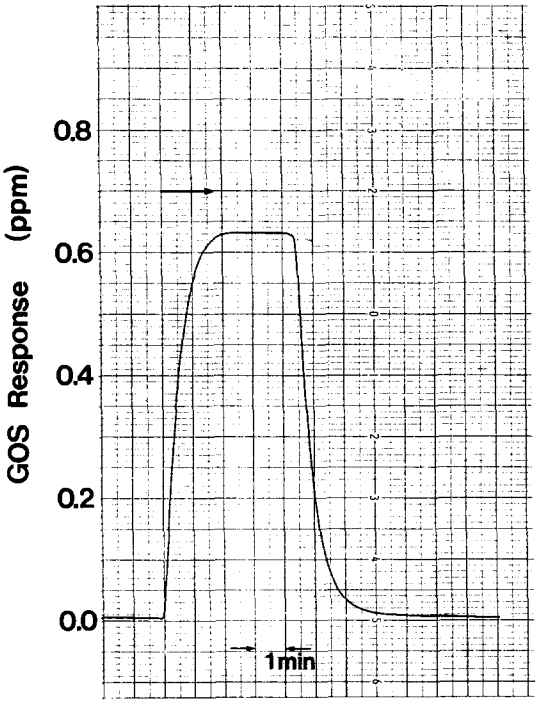

Fig. 5. Typical profile of GOS response speed. The response profile was obtained from sample gases having 0 and 0.63 ppm $O_2$ in nitrogen.

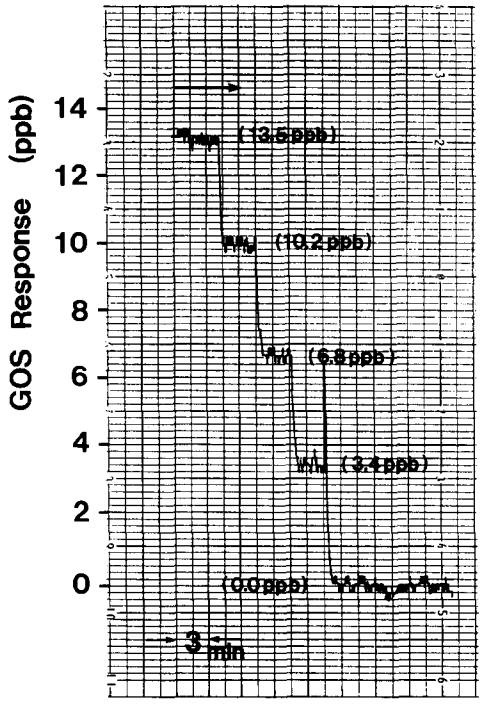

Fig. 6. Typical profile of GOS response ranging from 0 to 13.5 ppb $O_2$ in nitrogen.

of 0–10 ppm. The results showed that the GOS response is linear within experimental error in the range examined.

The typical performance of the GOS response is shown in Fig. 6. The response profile indicated that the GOS could be used for practical monitoring even in the range of 0–20 ppb of oxygen with an accuracy of $\pm 2\%$ deviation to full scale.

*Typical profile of continuous monitoring*

The profile of the continuous monitoring of oxygen in nitrogen, which was supplied from a cold evaporator charged with liquid nitrogen, is shown in Fig. 7. In Fig. 7, several small variations found in the period from 12 to 7 p.m. were a result of pressure changes in the gas supply pipeline. The result shows that when large amounts of nitrogen were used elsewhere for other purposes such as line purging, the GOS could monitor a few ppb of oxygen concentration fluctuations owing to small pressure changes and so on. The obtained profile indicates that the GOS would be reliable and suitable as an oxygen sensor for determining trace levels of oxygen in high purity industrial gases because the GOS has a high sensitivity and long term stability.

## CONCLUSIONS

The results obtained from the prototype trace oxygen analyzer showed that the GOS could have the capability to determine trace levels of oxygen in the sub-ppb and several ppm range. At present, a highly sensitive oxygen analyzer

Table 1. Comparison of the response of GOS constructed with and without agarose

| Sensor | Time at 90% response | | Average (*sec*) | Rel. response (%, $R = 100$) |
|---|---|---|---|---|
| | Up (*sec*) | Down (*sec*) | | |
| A | 80 | 88 | 84 | 63.6 |
| B | 84 | 87 | 85 | 64.4 |
| R | 138 | 126 | 132 | 100.0 |

These data were obtained from sample gases containing 50–70 ppb oxygen in nitrogen.

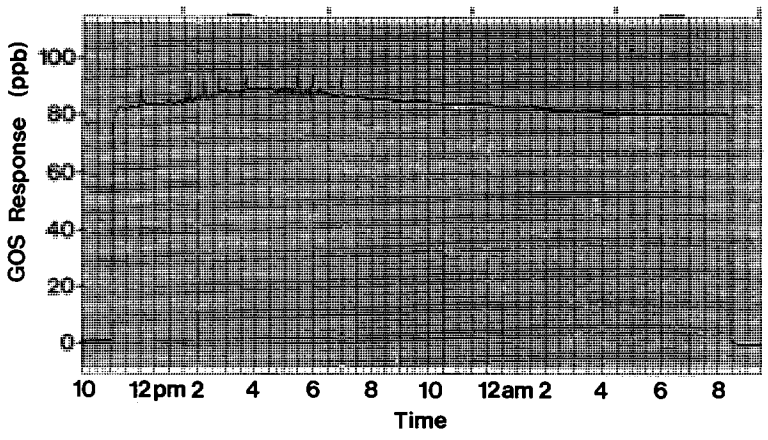

Fig. 7. Continuous monitoring profile for trace oxygen in nitrogen.

(Toyo Sanso, GOT-30, Tokyo, Japan), which was installed in the GOS, has been successfully developed in cooperation with Toyo Sanso Co. Ltd and DKK Corp. (Tokyo, Japan): the full range of determination, 0–10 ppm; detection limit, $\pm 1$ digit corresponding to 1 ppb oxygen concentration. These highly sensitive oxygen analyzers have been used for determining and monitoring ppb levels of oxygen in gas mixtures and for quality control of ultra high purity gases such as nitrogen, argon and helium in Toyo Sanso's manufacturing facility for the past several years.

*Acknowledgements*—The authors are grateful to Mr M. Goto of DKK Corporation and the staff of the Technical Research Laboratory, Toyo Sanso Co. Ltd. for their valuable contribution.

# EXTRACTIVE SPECTROPHOTOMETRIC DETERMINATION OF SOME FLUOROQUINOLONE DERIVATIVES IN PURE AND DOSAGE FORMS

C. S. P. SASTRY,[1]* KOLLI RAMA RAO[1] and D. SIVA PRASAD[2]

[1]Foods and Drugs Analysis Laboratories, School of Chemistry, Andhra University, Visakhapatnam 530 003, India; [2]Department of Biochemistry, Andhra University, Visakhapatnam 530 003, India

(*Received* 12 *April* 1994. *Revised* 29 *July* 1994. *Accepted* 2 *August* 1994)

**Summary**—Two simple and sensitive extractive spectrophotometric methods for the determination of some fluoroquinolone derivatives (norfloxacin, NRF; ciprofloxacin, CPF; ofloxacin, OFL; and enrofloxacin, ERF) with Supracene Violet 3B (SV 3B, method A) and tropaeolin 000 (TP 000, method B) are described. The methods are based on the formation of ion-association complexes of fluoroquinolones with these dyes, which are extracted into chloroform and have absorption maxima at 575 nm (SV 3B) and 485 nm (TP 000). The methods obey Beer's law and the precision and accuracy of the methods were checked by UV reference methods. The detection limits were 5.0 μg/ml for NRF and 2.5 μg/ml for CPF in method A and 2.5 μg/ml for OFL and ERF in methods A and B.

The fluoroquinolone derivatives norfloxacin [1-ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-3-quinoline carboxylic acid], ciprofloxacin [1-cyclopropyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-3-quinoline carboxylic acid], ofloxacin [9-fluoro-2,3-dihydro-3-methyl-10-(4-methyl-1-piperazinyl)-7-oxo-7H pyrido(1,2,3 de)-1,4-benzoxazine-6-carboxylic acid] and enrofloxacin [1-cyclopropyl-7-(4-ethyl-1-piperazinyl)-6-fluoro-1,4-dihydro-4-oxo-3-quinoline carboxylic acid] are used as broad spectrum antibacterial agents. Norfloxacin and ciprofloxacin are official in the U.S.P.,[1] whilst ofloxacin and enrofloxacin are not official on any pharmacopoeia. A number of visible spectrophotometric methods for the determination of fluoroquinolones such as norfloxacin (NRF),[2–8] ciprofloxacin (CPF)[7,9–13] and ofloxacin (OFL)[8,14,15] are reported in the literature. No spectrophotometric method for the determination of enrofloxacin (ERF) has been reported. Even though extraction spectrophotometric procedures are popular for their sensitivity in the assay of drugs,[16] there is only one report [13] for the determination of ciprofloxacin using the acid dyes, Bromocresol Purple and Bromophenol Blue. The aim of the present work is to provide simple and sensitive methods for the estimation of fluoroquinolones which are basic, in pure and dosage forms. In preliminary experiments, in view of developing methods of analysis suitable for assaying small quantities of fluoroquinolones, we tried seven anionic dyes namely, SV 3B, TP 000, Alizarin red S, Nigrocin water soluble, Fast Green FCF, Congo Red and Bromopyrogallol Red as the colour producing agents at various pH ranges, by a dye salt partition technique. Two visible spectrophotometric estimations using SV 3B (CI No. 60730) for all fluoroquinolones and TP 000 (CI No. 14600) for OFL and ERF were selected as being the most suitable and are described herein.

The proposed extractive spectrophotometric methods are based on the formation of ion-association complexes with SV 3B ($\lambda_{max}$ 575 nm) and TP 000 ($\lambda_{max}$ 485 nm) and their complexes are quantitatively extracted into chloroform. Structures of SV 3B, TP 000 and their chloroform soluble complexes with fluoroquinolones (*e.g.* Enrofloxacin) are shown in Fig. 1.

## EXPERIMENTAL

### *Apparatus*

A Milton Roy spectronic 1201 UV-visible spectrophotometer with 1 cm matched quartz cells was used for all the absorbance measurements. An Elico model LI-120 digital pH meter was used for pH measurements.

*To whom correspondence should be addressed.

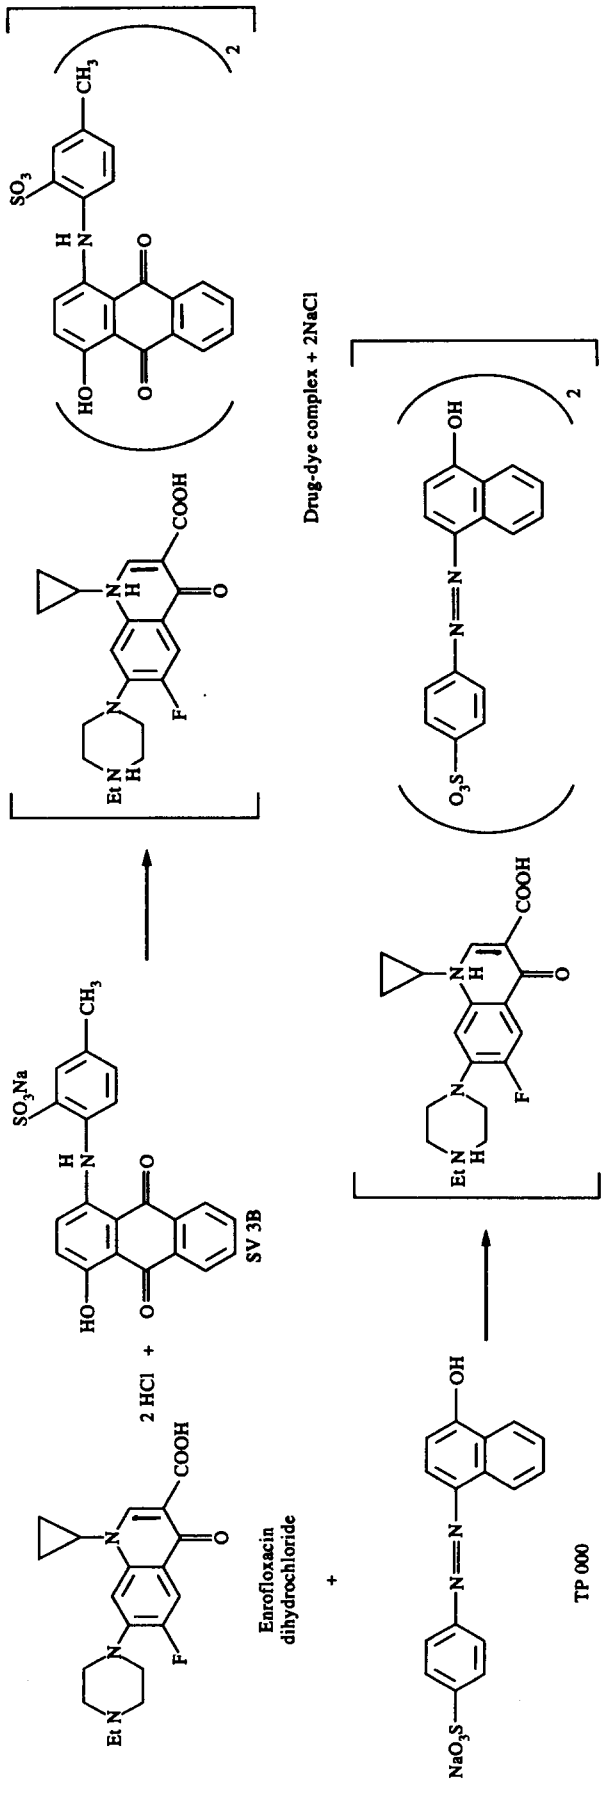

Fig. 1. Structures of Supracen Violet 3B, tropaeolin 000 and their respective complexes with enrofloxacin dihydrochloride.

*Reagents*

Chemicals of analytical grade were used. All solutions were prepared in double distilled water. Aqueous solutions of SV 3B (0.2%, chroma), TP 000 (0.2%, Fluka) and 0.1*M* HCl were prepared.

A buffer solution of pH 1.3 was prepared by mixing 226 ml of 0.1*M* glycine (Loba, 7.507 g of glycine + 5.85 g of NaCl, dissolved in 1 l. of distilled water) and 774 ml of 0.1*M* HCl.

*Standard drug solutions*

Stock solutions of (1 mg/ml) NRF, CPF, OFL and ERF were prepared in 0.01*M* HCl. The working standard solutions were prepared by suitable dilution of the stock solutions with distilled water.

*Analysis of bulk samples*

*Method A.* Drug aliquots of NRF (0.5–4.0 ml, 100 μg/ml), CPF (0.5–6.0 ml, 50 μg/ml), OFL (0.5–5.0 ml, 50 μg/ml) and ERF (0.5–5.0 ml, 50 μg/ml) were placed in a series of 125 ml separating funnels. Then 6.0 ml of buffer (pH 1.3) and 2.0 ml of SV 3B solution were added to each separating funnel. The total volume of aqueous layer in each separating funnel was brought to 15 ml with distilled water. A 10 ml portion of chloroform was added to each and the contents were shaken for 2 min. The two phases were allowed to separate and the absorbance of the separated chloroform layer was measured at 575 nm against a reagent blank within the stability period (1 min–10 hr) at laboratory temperature (28 ± 5°C). The amount of drugs was computed from their calibration graphs.

*Method B.* Aliquots of aqueous OFL (0.5–6.0 ml, 50 μg/ml), ERF (0.5–4.0 ml, 50 μg/ml) were transferred into a series of 125 ml separating funnels. Then 6.0 ml of 0.1*M* HCl and 2.0 ml of TP 000 were added to each separating funnel. The total volume of aqueous phase was adjusted to 15 ml in each separating funnel with distilled water. Then 10 ml of chloroform was added to each and the contents were shaken for 2 min and the two phases were allowed to separate and the absorbance of the separated chloroform layer was measured at 485 nm against a reagent blank within the stability period (1 min–10 hr) at laboratory temperature (28 ± 5°C). The amounts of OFL and ERF were computed from their respective calibration graphs. Method B is not suitable for the determination of NRF and CPF, as they do not form chloroform soluble complexes with TP 000.

*Analysis of formulations*

Twenty tablets were weighed and powdered. The powder equivalent to 100 mg of active ingredient was treated with 100 ml of 0.01*M* HCl and the insoluble residue filtered to obtain a solution of 1 mg/ml. The stock solutions were further diluted with distilled water to obtain working standard solutions and were analysed as described under the procedure for bulk samples.

For the determination of drugs in intravenous (i.v.) fluid and eye/ear drops, the weight of the drug per ml was determined. A quantity of i.v. fluid or eye/ear drops equivalent to 10 mg of the drug was transferred to 100 ml of volumetric flask and diluted to the mark with distilled water to obtain a concentration of 100 μg/ml. This solution was further diluted to the requisite concentration.

As the dosage forms were not available in the local market for ERF, we prepared our own according to the literature methods.[17,18] The results for NRF, CPF, OFL and ERF were compared with their respective UV spectrophotometric procedure as under NRF.[19]

A quantity of cream equivalent to 25 mg of CPF HCl was dissolved in about 50 ml of chloroform and transferred to a separating funnel. The chloroform solution was extracted with 0.01*M* HCl (3 × 25 ml). The aqueous phase in the separating funnel was collected into a 100 ml volumetric flask. The chloroform solution was then washed with 0.01*M* HCl and the washings were collected into the flask and made up to the mark with 0.01*M* HCl to obtain a solution of 250 μg/ml of CPF. This stock solution was diluted stepwise with distilled water to 50 μg/ml working standard solution and analysed by the procedure of method A.

## RESULTS AND DISCUSSION

The absorption spectra of the reaction products in methods A and B showed characteristic $\lambda_{max}$ values (Figs 2 and 3). The experimental conditions were established by varying one parameter at a time and observing its effect on the absorbance of the coloured species.

In method A, in order to establish optimum pH range, the drugs were allowed to react with SV 3B in aqueous solution buffered to pH 1.0–1.5 and the complex formed was extracted

into chloroform for measurement. Constant absorbances were obtained over the pH range 1.1–1.5 in glycine–HCl buffer, hence a pH of 1.3 was used. A 2.0 ml portion of SV 3B solution was found to be optimal. Constant absorbance was obtained for shaking periods between 1 and 5 min, hence a shaking time of 2 min was selected for use. Chloroform was preferred for its selective extraction of the drug–dye complex from the aqueous phase. A ratio of 3:2 of aqueous to chloroform phases was required for efficient extraction of the coloured species.

In method B also, to establish the experimental conditions, the drugs were allowed to react with TP 000 in dilute HCl ranging from 0.05 to 1.5*M* and the complex was extracted into chloroform layer. Constant absorbances were obtained with 0.08–0.12*M* HCl, hence 0.1*M* HCl was used. A 2 ml portion of TP 000 solution was found to be optimal. Shaking times of 0.5–4 min produced constant absorbance, hence a shaking time of 2 min was chosen for use. A ratio of 3:2 of aqueous to organic phases was required for efficient extraction of the coloured species.

*Analytical data*

The Beer's law limits, molar absorptivity, Sandell's sensitivity, regression equation and correlation coefficient obtained by linear least squares treatment of the results are given in Table 1. The precision and accuracy of the two methods were tested by estimating six replicates of the drugs within the Beer's law limits. The per cent standard deviation and the per cent range of error at 95% confidence level are given in Table 1.

The values obtained by the proposed and reference methods for dosage forms are compared in Table 2 and are in good agreement. The results of the recovery experiments by the proposed methods are listed in Table 2. The fluoroquinolones, being basic in nature, forms an ion-association complex with the acidic dye, SV 3B (for NRF, CPF, OFL and ERF) or TP 000 (for OFL and ERF) which are extractable

into chloroform from the aqueous phase. The stoichiometric ratio of the fluoroquinolones to SV 3B or TP 000 was determined with the slope ratio method and found to be 1:2.

The quantitative measure of the effect of complexation on acid–base equilibrium is most likely to be interpretable in terms of electronic, steric and other effects of complexing. The fluoroquinolone (1 mole) and oppositely charged form of the dye (2 moles) behave as a single unit being held together by electrostatic attraction.

The proposed methods are advantageous when compared to many of the reported methods in having higher $\lambda_{max}$ values and sensitivity. This is a decisive advantage since the interference from the associated ingredients shall be generally far less at higher wavelengths than at lower wavelengths. The methods are sensitive enough to permit the determination even up to 2.5 $\mu$g/ml. A significant advantage of an extractive spectrophotometric determination is that it offers distinct possibilities in the assay of a particular component in a complex dosage formulation. In the present study, some fluoroquinolone derivatives were estimated successfully as pure compounds as well as components in representative dosage formulations. The commonly used additives and excipients in the dosage forms of fluoroquinolones such as starch, lactose, talc, stearic acid, hydroxy propyl methyl cellulose, glycerine, titanium dioxide, tartrazine, white soft paraffin, liquid paraffin, sodium chloride, lactic acid and EDTA were found not to interfere in the analysis. Thus the proposed methods are simple, rapid with reasonable precision and accuracy when compared to many of the reported

methods. They offer the advantage that individual compounds can be determined in a multicomponent mixture.

*Acknowledgements*—The authors are grateful to NATCO fine pharmaceuticals Pvt. Ltd, Hyderabad for generously providing gift samples of fluoroquinolones and also to the university grants commission for providing financial assistance to one of us (KRR).

# DETERMINATION OF STABILITY CONSTANTS OF COPPER(II) COMPLEX OF GLYCINE IN WATER + ALCOHOL MIXED SOLVENTS WITH ION SELECTIVE ELECTRODE TECHNIQUE

JING FAN

Department of Chemistry, Henan Normal University, Xinxiang, Henan 453002, P.R. China

(*Received* 24 *February* 1994. *Revised* 8 *August* 1994. *Accepted* 12 *August* 1994)

**Summary**—The first stability constants ($\log \beta_1$) of the copper(II) complex of glycine in water and in 13 water + alcohol (isopropanol, tert-butanol, 1,2-propylene glycol and glycerol) solvents have been determined at 25°C and an ionic strength of 0.10, from pH and pCu measurements of cells containing copper(II) ion selective electrode. It has been shown that as the proportion of the alcohol increases, the stability constants become increasing positive in all of the mixed solvents examined. An almost linear relation between $\log \beta_1$ and the mole fraction of alcohol was found for the complex in aqueous solutions of isopropanol, tert-butanol and glycerol. The response of the copper(II) ion selective electrode in water and in water + alcohol mixed solvents was also investigated. The advantages of using an ion selective electrode to determine the stability constants in mixed solvents are discussed.

The stability constant of a complex is one of the important basic datum in analytical chemistry. In many analytical methods it may be used to prejudge the interfering elements and to choose the optimum analytical conditions.[1,2] For example, if a complexing agent is used as precipitant in gravimetric analysis, the optimum conditions of precipitation (pH, concentrations, etc.) can be found by equilibrium calculations. It may be predicted whether quantitative precipitation or separation can or cannot be obtained under given conditions.

In recent years, non-aqueous and mixed solvents have been widely used in analytical chemistry with the rapid development of non-aqueous analytical techniques and methods. Although a considerable amount of data on stability constant of complexes in water are available in the literature,[3–5] data in non-aqueous or mixed solvents are limited. In particular, few studies have been reported on the determination of stability constants in non-aqueous or mixed solvents using the ion selective electrode (ISE) method.[6] As a part of the continuing studies on the use of ISE in mixed solvents,[7–10] we report here the first stability constants of the copper(II) complex of glycine in water and in water + alcohol mixed solvents. The alcohols used in this work were isopropanol (IPA), tert-butanol (TBA), 1,2-propylene glycol (PG) and glycerol (GL). The stability constants were determined from pH and pCu measurements of cells containing copper(II) ion solid membrane electrode at 25°C and ionic strength $I = 0.1$. The variation of $\log \beta_1$ with concentrations of the alcohol in a given mixed solvent is illustrated. In addition, the response of the copper(II) ion selective electrode in water and in mixed solvents is discussed.

## EXPERIMENTAL

### *Materials*

IPA, TBA, PG and GL (A.R., all from Shanghai Chem. Co., China) were used after drying over 4 Å type molecular sieves. Glycine (A.R., Beijing Chem. Co., China) was purified by recrystallization from aqueous solution of ethanol and dried under vacuum. Pure copper (99.99%, Shanghai Chem. Co.) and purified glycine were used to prepare the stock solutions of copper(II) nitrate ($0.1182M$) and those of glycine ($0.0100M$) in appropriate solvents, respectively. Water + alcohol mixed solvents were prepared by weight with twice distilled water. The ionic strength in all solutions was supported with $0.1M$ potassium nitrate.

*Apparatus*

The potentiometric titrations were performed at $25 \pm 0.05$°C in a water jacketed glass cell. A copper(II) ion solid membrane electrode (Jiangsu, type 306) was used together with a saturated calomel reference electrode (Jiangsu, type 801) for measurements of the copper(II) ion activity in solution; the pH was measured with a pH glass electrode (Shanghai, type 231) against the same reference electrode. The cell potential and the pH values were recorded by means of a precise pH meter (pH S-2D, Chengdu). Before measurements, the glass electrode was calibrated against standard buffers in water. The Nernstian response of the copper(II) ion selective electrode was checked in aqueous copper(II) nitrate solutions at $I = 0.1$.

*Procedure*

A series of standard solutions of copper(II) nitrate ($10^{-2}$ to $10^{-6}M$) in a given solvent was prepared by successive dilution of the respective stock solution with $0.1M$ potassium nitrate solution. Potentials of copper(II) ion electrode in the standard cooper(II) nitrate solutions were measured. Readings were taken when potential was constant within 0.5 mV for at least 5 min. Then, a standard curve of pCu *vs.* $E$ (potential) was constructed for each given solvent.

A 30.00 ml glycine solution ($0.0010M$) and a 15.00 ml copper(II) nitrate solution ($0.0010M$) were added to the cell. After thermal equilibrium was reached, the cell solution was titrated with small additions of $0.10M$ potassium hydroxide up to pH > 6.4. During titrations, the reaction solution was stirred magnetically. After each titration, the pH value and potential of the copper(II) ion electrode were recorded. Using potential values of the copper(II) ion electrode obtained, values of pCu in reaction solution can be easily found from the standard pCu *vs.* $E$ curves.

In order to reduce the influence of the liquid junction, $0.1M$ potassium nitrate in the same solvent as the reaction solution was used as filling solution for the external salt bridge of the saturated calomel electrode. For example, if the reaction medium is an aqueous solution of 16.3 wt% TBA, a $0.1M$ potassium nitrate solution in this mixed solvent would be the correct filling solution. Otherwise, it is difficult to obtain a stable cell potential.

The response of the copper(II) ion electrode was measured over a range of concentrations of copper(II) ion extending typically from $10^{-1}$ to $10^{-6}M$. The procedure used was similar to that described by Coetzee and Istone.[11]

## RESULTS AND DISCUSSION

The stability constants for the copper(II)-glycine complex in water have been investigated by Hansen and Ruzicka.[12] According to these authors, there are only two possible equilibriums in the reaction solution in the case of pH ≪ 6.9.

$$\underset{(HL)}{H_3N^+CH_2COO^-} \overset{K_2}{\rightleftharpoons} \underset{(L^-)}{H_2NCH_2COO^-} + H^+$$

and

$$Cu^{2+} + L^- \overset{\beta_1}{\rightleftharpoons} CuL^+.$$

Therefore, the first stability constant for the copper(II)-glycine complex can be expressed by equation (1):

$$\beta_1 = [CuL^+]/([Cu^{2+}][L^-]), \tag{1}$$

where

$$[L^-] = (C_L^0 - [CuL^+])/\alpha_{L(H)} \tag{2}$$

and

$$\alpha_{L(H)} = 1 + [H^+]/K_2, \tag{3}$$

here $C_L^0$ is the initial concentration of glycine in the reaction solution, $\alpha_{L(H)}$ the side reaction function of glycine in reaction with hydrogen ion, and $K_2$ the second dissociation constant of glycine under given conditions.

Inserting equations (2) and (3) into equation (1) and taking logarithms, it follows that

$$\log \beta_1 = pCu + \log(1 + [H^+]/K_2) - \log(C_L^0 - [CuL^+])/[CuL^+]. \tag{4}$$

Since $C_L^0$ was known exactly in a given experiment and $[Cu^{2+}]$ was determinable experimentally, the value of $[CuL^+]$ in equation (4) can be calculated from the initial and free concentrations of copper(II). However, the measured pH values in the mixed solvents have to be transformed to hydrogen ion concentrations in order to calculate $\log \beta_1$ using equation (4). In doing so, the procedure proposed by Van Vitert and Haas[13] was closely followed.

Because the ionic strength was kept to be 0.1 in the present work, $K_2$ values involved in equation (4) should be those at $I = 0.1$. Therefore, the thermodynamic second dissociation

Table 1. pH and pCu values for the determination of the first stability constant of the Cu(II) complex of glycine in aqueous solution of 16.3 wt% TBA (25°C, $I = 0.1$)

| $pH_{obs}$ | $pH_{cor}$ | $E$/mV | pCu | $\log \beta_1$ |

| Coefficient of variation | | | | 0.11% |

constants ($K_{a2}$) of glycine in water and in water + alcohol mixed solvents reported in the literature[14–19] have been corrected to the values at $I = 0.1$ in the solvents concerned, using equation (5) or (6)

$$K_{x2} = K_2 \gamma_{\pm}^2 \quad (K_2 = c_{H^+} c_{L^-}/c_{HL},\ \gamma_{\pm}^2 = \gamma_{H^+}\gamma_{L^-}) \qquad (5)$$

$$K'_{x2} = K'_2 \gamma_{\pm}^2 \quad (K'_2 = m_{H^+} m_{L^-}/m_{HL},\ K_2 = K'_2 \rho) \qquad (6)$$

and mean activity coefficients ($\gamma_{\pm}$) of electrolyte $H^+L^+$ calculated from Davies equation[20]

$$\log \gamma_{\pm} = -A I^{1/2}/(1 + I^{1/2}) + 0.3 A I, \qquad (7)$$

where $\gamma_i$ is the activity coefficient of ion. The activity coefficient of glycine (HL) is assumed to be equal to unity. $m_i$ is the molality of species defined per kg of (water + alcohol) solvent. $A$ is the Debye-Hückel constant given by

$$A = 1.8246 \times 10^6/(DT)^{3/2}. \qquad (8)$$

The required values of the dielectric constant $D$ and density $\rho$ for the mixed solvents are taken from previous studies.[15–18,21,22]

The potentiometric titrations were carried out in the range of pH 4–6.5 for each experiment. It was found that in the case of pH < 5 and >6, the determined $\log \beta_1$ values are not constant and changed greatly with pH. The same experimental phenomena for the same reaction in water was observed by Hansen and Ruzicka.[12] This is a result of the limited stability of the 1:1 ($CuL^+$) complex in acid solutions when pH < 5. When pH > 6, there is a possible formation of a 1:2 ($CuL_2$) complex. In view of this fact, only the experimental data in the range of pH 5–6 were used to calculate the stability constants in all cases. The final result is the average of all the determinations in this pH range. Table 1 lists the observed potentials of the copper(II) ion electrode, pCu, pH and calculated $\log \beta_1$ values for the complexation in aqueous solution of 16.3 wt% TBA, along with the standard deviation and coefficient of variation for $\log \beta_1$. Values of $\log \beta_1$ for the complex in water and in water + alcohol mixed solvents are given in Table 2. For all other systems, the standard deviation and coefficient of variation in $\log \beta_1$ were not greater than 0.03 and 0.4%, respectively. In addition, some critical experiments were repeated several times, reproducible results were obtained in all cases.

The value for $\log \beta_1$ in water obtained in this work was 8.19, which is in excellent agreement with the values 8.07, 8.15 and 8.36 reported previously.[5,12,23] No stability constant data on the complex in aqueous solutions of alcohols has been reported in the literature to the best of our knowledge.

It is evident from the table that the first stability constant of the copper(II) complex of glycine increases with the concentration of alcohols in all the mixed solvents investigated. This experimental fact can be partially explained

Table 2. The first stability constants ($\log \beta_1$) of the Cu(II)-glycine complex in aqueous solutions of alcohols (25°C, $I = 0.1$)

| | $\log \beta_1$ | | | |
|---|---|---|---|---|
| Alcohol wt% | $H_2O$ + TBA | $H_2O$ + IPA | $H_2O$ + PG | $H_2O$ + GL |
| 0.0 | 8.19 | 8.19 | 8.19 | 8.19 |
| 8.0 | 8.26 | 8.25 | — | — |
| 10.0 | — | — | — | 8.21 |
| 16.3 | 8.38 | 8.35 | — | — |
| 18.2 | — | — | 8.44 | — |
| 25.0 | 8.55 | 8.54 | — | — |
| 30.0 | — | — | — | 8.24 |
| 31.9 | — | — | 8.57 | — |
| 34.2 | 8.77 | 8.73 | — | — |
| 43.8 | 8.86 | — | — | — |
| 50.0 | — | — | — | 8.31 |

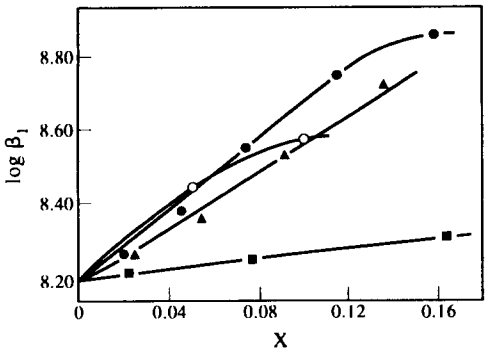

Fig. 1. Variation of the stability constants (log $\beta_1$) with mole fraction (X) of alcohols in mixed solvents. (●) TBA; (△) IPA; (○) PG; (■) GL.

from the decreasing dielectric constant of the mixed solvents,[21] because the lower dielectric constant of the mixed solvents in comparison with that of water would cause the electrostatic contributions to the bond formation to increase with increasing percentage of alcohol in the solvent mixtures. A further analysis of the results reveals that in aqueous solutions of IPA, TBA and GL, $\log \beta_1$ changes almost linearly with the mole fraction of alcohols (Fig. 1). However, this is not true for the complex in aqueous solutions of PG, as illustrated in the same figure.

The response of the copper(II) ion selective electrode was investigated at constant ionic strength of 0.1 in water and in water + alcohol mixtures. In all solvents, at copper(II) ion concentration extending from $10^{-5}$ to between $10^{-2}$ and $10^{-1}M$, the response was linear and Nernstian (slope of response was $29.6 \pm 0.6$ mV/decade). The lower detection limit was about $10^{-6}M$. At higher concentrations, the response became increasingly sub-Nernstian with increasing concentration. At lower concentrations, the response became increasingly sub-Nernstian with decreasing concentration. Very similar results have been reported by Coetzee and Istone[11] from copper(II) ion selective electrode in a variety of organic solvents and their mixtures with water.

In most of the solvents, the slope of response decreases slightly with increasing concentration of alcohol in mixed solvents. For example, the slope of response determined in water was 30.2 mV/decade. It decreases gradually to 29.0 mV/decade when 8.0, 16.3, 25.0 and 34.2 wt% IPA were added to water. Furthermore, we have examined whether the lower detection limit for copper(II) ion in water could be extended by adding alcohols. However, no obvious changes were observed for the lower detection limit in different mixed solvents compared with that in water. This observation is generally in agreement with those previously reported by Rechnitz for methanol and acetone as solvents[24] and Coetzee and Istone[11] in a variety of organic solvents and their mixtures with water.

Finally, a small comment can be made on the applicability of ISE in the determination of stability constants in mixed solvents. The present investigation suggests that ISE can be used successfully for the determination of stability constants of complexes in water + organic solvents under given conditions. This method is characterized by good accuracy, reproducibility and simplicity of the measurement techniques. By using ISE, two parameters, pH and pM (M refer to metal ion), can be measured. Therefore, the determination of stability constants is greatly simplified and the results obtained are more reliable compared with the pH-titration technique.

**Summary**—Soil collected from a disused cattle dip in northern New South Wales was studied with the aim of developing an inexpensive, yet effective method for quantitative determination of arsenic(III), arsenic(V) and total organic arsenic in a contaminated soil. Hydrochloric acid extractions were used as a method for removal of the arsenic from the soil in a form suitable for speciation. It was found that the extraction efficiency varied with the ratio of soil to acid, and the concentration of the acid. Arsenic(III), as arsenic trichloride, was selectively extracted into chloroform from a solution highly concentrated in hydrochloric acid. This was followed by back-extraction of the arsenic into water. Total inorganic arsenic was determined in a similar manner after the reduction of arsenic(V) to the trivalent state with potassium iodide. Arsenic(V) was determined by the difference between the results for arsenic(III) and total inorganic arsenic. All analyses for the various arsenic species were performed by hydride generation–atomic absorption spectroscopy; concentrations of total arsenic in the soil were confirmed using X-ray fluorescence spectrometry. It was found that all the arsenic in the soil was present as inorganic arsenic in the pentavalent state. This reflects the ability of arsenic to interchange between species, since the original species in cattle dipping solution is arsenic(III).

As a result of the injudicious use of arsenic in herbicides, pesticides, tanning solutions and timber preservatives, there are in excess of a thousand arsenic contaminated soil sites in the state of Queensland, Australia alone. Owing to the increases of urbanization, many of these sites are now being used for residential, community and recreational purposes.[1] Because of the toxic nature of arsenic, it is desirable to develop a cost effective method for remediation of such contaminated sites. Before this is possible, it is necessary to have an understanding of which species of arsenic are present in a given soil and how these will be affected by certain conditions.

Probably the most significant work in speciation of arsenic in a soil has been done by Takamatsu *et al.*[2] By use of high performance liquid chromatography anion exchange and an extraction process using 1*M* hydrochloric acid, the so-called bioavailable portion of the arsenic was speciated. However, for the work of this project it was desirable to speciate all of the arsenic present in a soil. For this reason, it was decided to extract the arsenic from the soil with concentrated hydrochloric acid and to speciate using solvent extractions.

The proposed method utilizes the observation that arsenic(III) can be selectively extracted into an organic phase from a strongly acidic phase. This can then be back-extracted into water for analysis.[2–4] It would appear that inorganic arsenic in solution, is most stable in its hydrolysed form.[5] However, in the presence of an excess of hydrochloric acid, chlorination of the arsenic will occur, yielding arsenic trichloride and arsenic pentachloride. It has been shown that arsenic trichloride is a covalent molecule while arsenic pentachloride probably exists as the complex ions, $[AsCl_4]^+[AsCl_6]^-$.[5] If this is the case, then it is quite obvious that the trivalent arsenic can be extracted into an organic phase such as chloroform or benzene, while arsenic pentachloride is excluded owing to its ionic properties. The arsenic contained in the organic phase can be easily recovered by back-extraction with water. As previously stated, inorganic arsenic is most stable in solution in its hydrolysed form. Therefore, when the arsenic comes into contact with water, hydrolysis occurs, excluding the arsenic from the organic phase.

## EXPERIMENTAL

### *Reagents and glassware*

Stock solutions for arsenic compounds were prepared from arsenic trioxide ($As_2O_3$, 99.8%, BDH Chemicals Ltd) and arsenic pentoxide ($As_2O_5 . 5H_2O$, 99.9%, Aldrich Chemicals). Concentrations of arsenic(V) solutions were confirmed by calibration against arsenic trichloride standard solution (BDH Chemicals Ltd). All other chemicals were of analytical grade and dilutions were performed with distilled water.

All glassware was soaked for at least 24 hr in 4*M* nitric acid after cleaning in X-tran (BDH Chemicals Ltd), a phosphate-free detergent. Final rinsing was performed with milli-Q water.

### *Preparation of soil*

All soil samples were prepared according to the procedure outlined in AS1289.1(1991).[6] In summary, the soil was dried at 50°C for at least 24 hr. The dried material was ground lightly with a mortar and pestle and sieved through a 2.36 mm sieve, removing foreign bodies such as twigs and stones. In addition to the requirements of AS1289, the fraction which passed the sieve was ground to a fine powder in a tungsten-carbide swing mill. The resulting powder was homogenized by shaking for approximately 30 min.

### *Determination of total arsenic concentration in soil*

Prior to speciation work, the total concentration of arsenic in the soil was determined by X-ray fluorescence spectrometry (XRF) on loose powders. The conversion of an XRF intensity to a concentration is subject to errors due to matrix effects, principally by absorption of the fluorescent (secondary) radiation by the matrix elements. Therefore, it was necessary to initially determine the major and minor components in the soils studied so that a matrix correction factor ($\mu$) could be calculated for each soil. The major and minor components of silicate matrices such as soils consist of the following elements, expressed as oxides: $SiO_2$, $Al_2O_3$, $Fe_2O_3$, MgO, CaO, $Na_2O$, $K_2O$, $TiO_2$, $P_2O_5$, MnO, $SO_3$, SrO and loss on ignition (LOI). These were determined by XRF according to the method of Norrish and Hutton.[7] In summary, a portion of the finely ground sample is fused with a borate based flux containing lanthanum oxide ($La_2O_3$), a heavy absorber, and the resultant melt is pressed to yield a glass bead. XRF intensities are collected from the bead and concentrations are calculated from the Norrish/Hutton algorithm as follows:[8]

$$C_i = D + ER(1 + \Sigma\mu_{ij}C_j),$$

where $C_i$ = concentration of element $i$, $D$ = intercept expressed as a percentage, $E$ = slope, $R$ = intensity of element $i$ (from XRF spectrometer), $\mu$ = matrix correction factors and $C_j$ = concentration of interfering element.

Once the major and minor elements are determined, the matrix correction factor for any analyte radiation, in this case arsenic K-$\alpha$ radiation, can be calculated as shown below:

$$\mu_i = \Sigma M_j W_j,$$

where $\mu_i$ = matrix correction factor for element $i$, $M_j$ = mass absorption coefficient for element $j$ and $W_j$ = weight fraction of element $j$. Having obtained $\mu_{As}$, it is now possible to accurately determine, with full matrix correction, arsenic in the soils under scrutiny. Table 1 outlines the operating parameters of the XRF spectrometer and it should be noted that background intensities are also collected.

Table 1. XRF operating parameters

| | Arsenic | Lead |
|---|---|---|
| Analyte line | *K*-$\alpha$ | *L*-$\beta$ |
| X-ray tube | Rhodium | Rhodium |
| Power | 60 kV; 40 mA | 60 kV; 40 mA |
| Detector | F + S | F + S |
| Crystal | LIF 200 | LIF 200 |
| Peak 2-$\theta$ angle | 33.96 | 28.22 |
| Backgrounds | +0.6; −0.5 | +0.4; −1.2 |
| Counting time (sec)* | 100 | 100 |
| Pulse height discrimination | UL75; LL25 | UL70; LL30 |
| Collimation | Fine | Fine |
| Mask | Small | Small |

*Counting time refers to the time expended on each line, *i.e.* 100 sec for each background and peak.

One complication in the XRF determination of arsenic is that lead overlaps with the arsenic $K$-$\alpha$ analyte line and it is therefore necessary to correct for the lead interference. The calculation for the conversion of the intensity of arsenic $K$-$\alpha$ radiation into a concentration is outlined as follows:

$$C_{Pb} = K_1 R_{Pb} \mu_{Pb}$$

$$C_{As} = (K_2 R_{As} \mu_{As} - (LC_{Pb})),$$

where $C_{Pb}$, $C_{As}$ = concentrations of lead and arsenic, respectively (mg/kg), $K_1$, $K_2$ = calibration slope constants for lead and arsenic, respectively, $R_{Pb}$, $R_{As}$ = net intensities for lead and arsenic, respectively (background corrected), $\mu_{Pb}$, $\mu_{As}$ = matrix correction factors for lead and arsenic analyte lines, respectively, and $L$ = lead line overlap correction factor. It will be noted that the concentration of lead needs to be pre-determined.

As with most forms of modern analysis, XRF requires a calibration procedure to be undertaken before meaningful results can be obtained. This is effected by the use of international standard reference materials (SRM's), containing known amounts of arsenic and lead. The accuracy of the method employed is approximately $\pm 5\%$ with a precision in the order of 1–2%. The lower limit of detection is approximately 1 mg/kg.[1]

*Extraction of arsenic from soil*

Arsenic was removed from the soil by treatment with concentrated hydrochloric acid. A 5 g sample of soil was accurately weighed into a centrifuge tube and 20 ml of 10$M$ hydrochloric acid was added. The extraction was assisted by shaking vigorously for about 30 min. The resulting slurry was centrifuged at 3000 r.p.m. for approximately 5 min and the supernatant was gravity filtered (Whatman 44) into a 100 ml volumetric flask. This procedure was repeated a further two times on the same 5 g sample of soil. When the extraction was complete, the soil was washed into the filter paper with water and the solution diluted.

*Speciation of trivalent arsenic*

A 10 ml aliquot of the arsenic extract was transferred to a 100 ml separating funnel and 80 ml of 10$M$ hydrochloric acid was added, adjusting the acid concentration to greater than 9$M$. This was followed by extraction of arsenic(III) into chloroform with $4 \times 10$ ml washings. At this stage the strongly acidic aqueous phase was discarded. The arsenic was then back-extracted from the organic phase into $2 \times 20$ ml aliquots of water and diluted to 100 ml.

*Speciation of total inorganic arsenic*

A separate 10 ml aliquot of arsenic extract was transferred to a large test tube and 10 ml of 50% potassium iodide was added. The tube was then covered and immersed in a water bath at 60°C for about 30 min. After the solution had cooled, it was diluted to 50 ml, 10 ml of which was transferred to a 100 ml separating funnel. After adjusting the acid concentration to greater than 9$M$, extraction for inorganic arsenic was performed as for arsenic(III).

## RESULTS AND DISCUSSION

*Extraction of arsenic from soil*

Initially, the arsenic was extracted from 1 g of cattle dip soil with 20 ml of hydrochloric acid. The mixture was shaken for about 30 min and the resulting slurry gravity filtered. Consequent analysis revealed that this method yielded 85% of the total arsenic present. In order to achieve a higher extraction efficiency, it was decided to try a multiple extraction. When performing liquid–liquid extractions, it is common practice to extract two or three times to ensure a complete transition between the phases. This same principle was applied to the extraction of arsenic from soil with acid. A three-fold extraction procedure on 1 g of cattle dip soil yielded 97% of the total arsenic present.

The ratio of acid to soil and the concentration of the acid also affects the extraction efficiency. In the first instance, it was found that when applying the extraction technique to 5 g of soil, 86% of the arsenic was removed compared with 97% when extracting 1 g of soil. It is not surprising then that the concentration of hydrochloric acid should also affect the extraction efficiency. During the developmental stages of the process, extractions were attempted using water and 1$M$ hydrochloric acid as well as concentrated hydrochloric acid. Extraction with water yielded less than 5% of the total arsenic while the 1$M$ hydrochloric acid extraction yielded 56% of the total arsenic. Such an effect has also been noted by other workers.[9,10]

Table 2. Reduction of $As^{5+}$ to $As^{3+}$ *vs.* HCl strength[13]

| Normality of HCl | Reduction (%)* |
|---|---|
| 4.0 | 96.29 |
| 5.0 | 96.98 |
| 6.0 | 97.49 |
| 7.0 | 95.68 |
| 7.5 | 31.90 |
| 8.0 | 11.26 |
| 9.0 | 11.98 |

*Reduction performed as follows: (i) adjust the acid strength to approximately 6*N* with HCl, (ii) add 4 ml of 50% $SnCl_2$ solution, (iii) add 5 ml of 15% KI solution and (iv) leave to stand at room temperature for 15 min.

*Importance of acid concentration*

The success of the proposed method is highly dependent upon careful monitoring of the concentration of hydrochloric acid. Trivalent arsenic will only be completely extracted into an organic solvent from a solution which is highly concentrated in hydrochloric acid. Beard and Lyerly[11] employed a similar solvent extraction technique to separate arsenic from antimony and bismuth using benzene as the extracting solvent. It is claimed that the extraction of arsenic(III) into benzene was almost non-existent until the hydrochloric acid concentration reached 4*M*. The efficiency of extraction then rose sharply with increasing acid concentration, yielding a 100% extraction at acid concentrations of 9*M* or greater. Other researchers observed similar results using chloroform as the extracting solvent.[3,12]

The concentration of hydrochloric acid also has a significant effect on the reduction of arsenate to arsenite. This method utilized potassium iodide as a reducing agent. Literature suggests that reduction by this method requires the concentration of hydrochloric acid to be at least 1*M*.[13,14] However, it was found that at acid concentrations above 7*M*, the reduction efficiency decreases significantly. Hydrochloric acid concentrations of 1, 6 and 9*M* were used in the reduction of a 100 mg/l. arsenic(V) solution with potassium iodide. Reduction efficiencies of 93, 95 and 15% were obtained, respectively. Forehand *et al.*[13] performed a more comprehensive study of the dependence of reduction upon concentration of hydrochloric acid when using a potassium iodide/stannous chloride mixture as the reducing agent. Their results clearly show a dramatic decrease in reduction at an acid concentration above 7*M* (Table 2).

*Efficiency of solvent extraction*

Prior to investigation of soil samples, the solvent extraction technique was applied to 100 mg/l. solutions of arsenic(III) and arsenic(V) to ascertain the efficiency of the method. The mean and standard deviation results from eight determinations demonstrated that the method was accurate and precise for both trivalent and pentavalent arsenic (Table 3).

*Fate of organic arsenic during speciation*

The two major forms of organic arsenic are monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA). Neither of these compounds will be extracted into chloroform under the conditions described in this paper.[2] However, one must also consider the fate of these two compounds during reduction of inorganic arsenic(V) with potassium iodide. It is possible that MMA and DMA will be reduced by potassium iodide to $CH_3AsI_2$ and $(CH_3)_2AsI$, respectively.[15] If these compounds are formed and can be extracted into chloroform, then the results for the total inorganic arsenic and hence the inorganic arsenic(V) will be erroneous. However, it would seem that the reduction of DMA to $(CH_3)_2AsI$ is very slow and will not occur to any significant level during the time scale of this experiment.[15] The reduction of MMA to $CH_3AsI_2$ is much faster but the organic arsenic(III) product is not likely to be soluble in chloroform to any appreciable extent.[16] Therefore, it was concluded that only inorganic arsenic(III) would be extracted into the chloroform.

*Results for speciation of arsenic in cattle dip soil*

X-Ray fluorescence spectrometry, based on triplicate analyses, revealed that the cattle dip soil contained $1145 \pm 57$ mg/kg total arsenic. Experiments were then conducted to determine the quantity of soil required to yield meaningful speciation results. The speciation procedure was applied to both 1 and 5 g masses of soils and it was found that the mean results for both masses

Table 3. Solvent extraction of arsenic species in solution

| Arsenic species | Extraction efficiency (%) | Standard deviation (%) |
|---|---|---|
| Arsenite | 97 | 3.4 |
| Arsenate | 95 | 3.6 |

Table 4. Speciation results for cattle dip soil*

| | 5 g of soil | 1 g of soil |
|---|---|---|
| Concentration of arsenic obtained from XRF (*mg/kg*) | 1145 ± 57 | 1145 ± 70 |
| Average concentration of arsenic determined by HCl extraction (*mg/kg*) | 985 ± 70 | 978 ± 70 |
| Extraction percentage | 86% | 85% |
| Concentration of inorganic arsenic (*mg/kg*) | 945 ± 94 | 921 ± 270 |
| Concentration of arsenic(III) (*mg/kg*) | 3 ± 0.3† | 3 ± 1 |
| Concentration of arsenic(V) (*mg/kg*) | 942 ± 94 | 918 ± 270 |
| Concentration of organic arsenic (*mg/kg*) | 40 ± 4 | 64 ± 13 |

*Means and their associated errors are calculated from at least six determinations.
†Calculated but not statistically meaningful standard error.

of soils were similar, but the precision for the lower mass was poor (Table 4). Therefore, it could be generalized that for soils with arsenic concentrations of 1000 mg/kg or greater, at least 5 g aliquots must be used, as it would appear that precision increases with the amount of arsenic being speciated. It follows that for concentrations of less than 1000 mg/kg of arsenic, even larger aliquots would be required. Speciation of arsenic in 5 g of cattle dip soil revealed that all or nearly all the arsenic is present in the inorganic, pentavalent state.

Based on the observation that arsenite and arsenate are more than 99.9% soluble in hydrochloric acid at the concentrations encountered in the method, it was assumed that As(III) and As(V) are extracted from the soil with equal efficiency. On this basis, it can be claimed that 96% of the arsenic is in the pentavalent state and about 0.3% is present as As(III). Therefore, while only 86% of the arsenic was extracted from the soil, nearly 100% of the extracted arsenic was speciated; thereby forming a representative view of the species present in the soil. The results for both organic arsenic and arsenic(III) fall within experimental error and can, therefore, be approximated to zero concentrations. This infers that all or nearly all of the arsenic present in the soil is inorganic and pentavalent. Of course, the above assumption will not hold for all soils. For instance, under reducing conditions, sulfur rich soils can contain arsenic(III) as an acid insoluble sulfide.[17] Therefore, it is necessary to consider each soil sample separately before making such extrapolatory calculations.

Aliquots of the cattle dip soil were spiked with known quantities of arsenite and arsenate (Table 5). The speciation procedure was performed on these spikes. If the method is valid, the results for each of the species present should increase by the amount of the relevant arsenic species added. Table 6 lists the results for speciation of the arsenic extracted from the soil with hydrochloric acid. If it is assumed that the extracted arsenic for the cattle dip soil forms a representative sample of the total arsenic in the soil, then theoretical values can be calculated for the speciation of the total amount of arsenic present (Table 7).

In preparing CDS(III), arsenite was added so that the total concentration of arsenic in the soil increased 83 mg/kg (Table 5). Speciation of CDS(III) yielded an arsenic(III) concentration of 84 mg/kg, an increase of 81 mg/kg when compared with the cattle dip soil (Table 7). This provides strong evidence that the amount of arsenic(III) found in the cattle dip soil is valid. Similarly, preparation of CDS(V) involved the addition of arsenate so that the total concentration of arsenic in the soil increased by 84 mg/kg (Table 5). Speciation of CDS(V) resulted in an arsenic(V) concentration of 1178 mg/kg; an increase of 79 mg/kg when compared with the unspiked cattle dip soil (Table 7). This provides strong evidence that the amounts of arsenite and arsenate determined for the cattle dip soil are valid.

Table 5. Spiked samples of cattle dip soil*

| Soil code | Spike material | Concentration of arsenic (*mg/kg*) |
|---|---|---|
| CDS† | — | 1145 ± 57 |
| CDS(III) | arsenic(III) | 1228 ± 61 |
| CDS(V) | arsenic(V) | 1229 ± 61 |

*Means and their associated errors are calculated from three determinations by XRF.
†CDS: Cattle dip soil.

Table 6. Speciation results for cattle dip spikes*

| Soil code | Total arsenic extracted (mg/kg) | Concentration of arsenic(III) (mg/kg) | Concentration of arsenic(V) (mg/kg) |
|---|---|---|---|
| CDS | 985 ± 70 | 3 ± 0.3† | 945 ± 94 |
| CDS(III) | 1032 ± 72 | 71 ± 7 | 942 ± 94 |
| CDS(V) | 1045 ± 73 | 3 ± 0.3† | 1002 ± 100 |

*Means and their associated errors are calculated from at least six determinations.
†Calculated but not statistically meaningful standard errors.

Table 7. Calculated values for speciation of total amount of arsenic in cattle dip soil*

| Soil code | Total arsenic extracted (mg/kg) | Concentration of arsenic(III) (mg/kg) | Concentration of arsenic(V) (mg/kg) |
|---|---|---|---|
| CDS | 1145 ± 80 | 3 ± 0.3† | 1099 ± 109 |
| CDS(III) | 1228 ± 86 | 84 ± 8 | 1121 ± 112 |
| CDS(V) | 1229 ± 86 | 4 ± 0.4† | 1178 ± 117 |

*Means and their associated errors are calculated from at least six determinations.
†Calculated but not statistically meaningful standard errors.

Since the data in Table 7 are similar to the expected results, yet are calculated from the percentage of arsenic(III) and arsenic(V) in the soil extract, it can be claimed that the extract provides a representative sample of the arsenic present in the soil.

## CONCLUSIONS

The aim of this research project was to develop an inexpensive, efficient method for quantitative determination of arsenic species in a contaminated soil. In order to achieve this, a soil from an abandoned cattle dip site in northern New South Wales was investigated. Satisfactory results were obtained, revealing that nearly all of the arsenic present was in the pentavalent state. Validation of this result was achieved by spiking the cattle dip soil with known amounts of arsenite and arsenate.

Speciation of the cattle dip soil indicated that all of the arsenic was in inorganic forms, within experimental error. However, the method for speciation should also be applicable to organic forms of arsenic, although in this work, validation of the results was focused on the determinations of arsenic(III) and arsenic(V). Speciation of the cattle dip soil after spiking with known amounts of organic arsenic should result in a total arsenic concentration greater than the inorganic arsenic concentration; thus yielding the amount of organic arsenic by difference.

Determination of total arsenic and its species, in a 5 g aliquot of soil, requires the use of about 230 ml of hydrochloric acid. This equates to a cost of slightly less than $1(A) for the acid per sample. The cost of other chemicals, such as potassium iodide and chloroform, is no more than $1(A) per sample. Therefore, at a total reagent cost of approximately $2(A) per sample, this method is inexpensive even on large scale investigations. A major advantage of the proposed method over other techniques lies in the amount of arsenic extracted from the soil. As stated previously, Takamatsu *et al.*[2] speciated the arsenic which they extracted from soil using 1*M* hydrochloric acid. However, of the 12 soils analysed by them, between 3.6 and 53.2% of the total arsenic present was extracted. The method here described yields a similar quality of results, but has a total arsenic extraction of between 80 and 100%.

# ADSORPTIVE STRIPPING VOLTAMMETRY OF TRACE MANGANESE IN THE PRESENCE OF 2-(5′-BROMO-2′-PYRIDYLAZO)-5-DIETHYLAMINOPHENOL (5-Br-PADAP)

JOSEPH WANG* and JIANMIN LU

Department of Chemistry and Biochemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 28 *June* 1994. *Revised* 9 *August* 1994. *Accepted* 9 *August* 1994)

**Summary**—Trace levels of manganese can be determined by voltammetry after controlled adsorptive accumulation of the manganese-2-(5′-bromo-2′-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) complex on a hanging mercury drop electrode. Optimal conditions include an ammonia buffer solution (pH 8.8) containing $1 \times 10^{-5}M$ 5-Br-PADAP and an accumulation potential of $-1.20$ V. The technique offers enhanced sensitivity over analogous measurements of the manganese-Eriochrome Black T chelate. The detection limit is 0.2 $\mu$g/l with 1 min accumulation. The new adsorptive approach is characterized with new selectivity dimensions (compared to the Eriochrome Black T scheme), and is not affected by large excess of commonly coexisting calcium and magnesium cations (which severely interfere in the Eriochrome Black T procedure).

Because of the importance of manganese, highly sensitive analytical methods are required for its determination in biological and environmental matrices. Neutron activation and atomic absorption spectroscopic measurements of trace levels of manganese usually require tedious enrichment steps (such as co-precipitation and extraction).[1,2] The highly sensitive electroanalytical technique, stripping analysis, can also be employed for trace measurements of manganese.[3,4] However, conventional stripping measurements of manganese suffer from difficulties associated with the low solubility of manganese in mercury, large hydrogen evolution background current, the formation of intermetallic compounds, and an irreversible redox process. Such problems may be addressed using an alternative stripping mode based on non-electrolytic preconcentration. Yet, only one adsorptive stripping voltammetric procedure, involving the adsorptive accumulation of the manganese/Eriochrome Black T complex, has been reported.[5]

This article describes an extremely sensitive adsorptive stripping voltammetric method for the quantitation of trace amounts of manganese, in which preconcentration is accomplished by adsorption of the manganese chelate with 2-(5′-bromo-2′-pyridylazo)-5-diethylaminophenol (5-Br-PADAP). The formation of surface active chelates of 5-Br-PADAP with vanadium, iron, or chromium has been utilized recently for measuring low levels of these metal ions.[6–8] The characterization, optimization, and advantages of the manganese–Br-PADAP adsorptive stripping procedure are elucidated in the following sections.

## EXPERIMENTAL

### *Apparatus and reagents*

An EG&G PAR Model 264A voltammetric analyzer, a PAR 303A static mercury drop electrode, and a PAR 0073 X-Y recorder were used to obtain the voltammograms. A medium-size hanging mercury drop electrode, with an area of 0.016 cm$^2$ was employed in connection with the 10 ml cell.

All solutions were prepared with doubly distilled water. A 1000 ppm stock manganese solution (atomic adsorption standard, Aldrich) was diluted as required. Stock solutions ($10^{-2}M$) of 5-Br-PADAP (Aldrich) were prepared in ethanol (Quantum Chemical Co.). A $1 \times 10^{-2}M$ ammonia/ammonium chloride buffer (pH 8.8) served as supporting electrolyte.

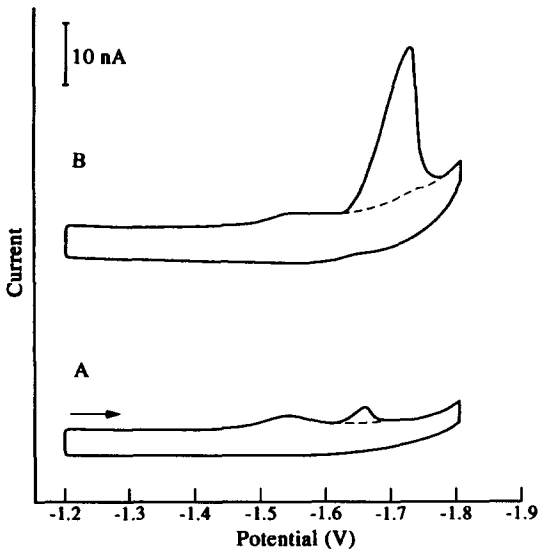

Fig. 1. Cyclic voltammograms for 20 $\mu$g/l. manganese without (A) and with (B) 60 sec prior stirring at $-1.2$ V. Dotted lines are the corresponding curves for the blank solution (0.01 M ammonia buffer, containing $5 \times 10^{-6}M$ 5-Br-PADAP, and 10% ethanol). Scan rate, 50 mV/sec.

### *Procedure*

The supporting electrolyte solution (10 ml), containing $1 \times 10^{-5}M$ 5-Br-PADAP and 10% ethanol was pipetted into the cell and deaerated with nitrogen for 8 min. The preconcentration potential (usually $-1.20$ V) was applied to a fresh mercury drop while the solution was stirred. Following the preconcentration step, the stirring was stopped and after 15 sec the voltammogram was recorded by applying a negative-going differential pulse scan (with 10 mV/sec scan rate and 25 mV amplitude). The scan was terminated at $-1.80$ V. Aliquots of the manganese standard solution were introduced after recording the background voltammograms, and the cycle was repeated using a new mercury drop. Throughout this operation, nitrogen was passed over the solution. All data were obtained at room temperature.

## RESULTS AND DISCUSSION

Figure 1B displays a cyclic voltammogram for 20$\mu$g/l. manganese, in the presence of $5 \times 10^{-6}M$ 5-Br-PADAP, recorded after 1 min preconcentration at $-1.20$ V. A large and well defined cathodic peak is observed at *ca.* $-1.72$ V. No peaks are observed in the anodic branch. Subsequent scans exhibit a rapid diminution of the peak (to a stable value with 15 runs), indicating rapid desorption from the surface (not shown). Voltammogram A displays the analogous response without accumulation. A substantially lower (*ca.* 10-fold) peak, representing the solution species, is observed. The latter is similar to that observed following the desorption. The effect of potential scan rate (v) was evaluated for the surface-confined Mn-5-Br-PADAP complex. A plot of log $i_p$ *vs.* log $v$ was linear over the 5–100 mV/sec range, with a slope of 0.81, indicating deviation for an ideal behavior of adsorbed reactants. Unlike the manganese/Eriochrome Black T voltammetric measurements, which involve the reduction of the ligand electroactive (azo) moiety,[5] the manganese/5-Br-PADAP reduction process

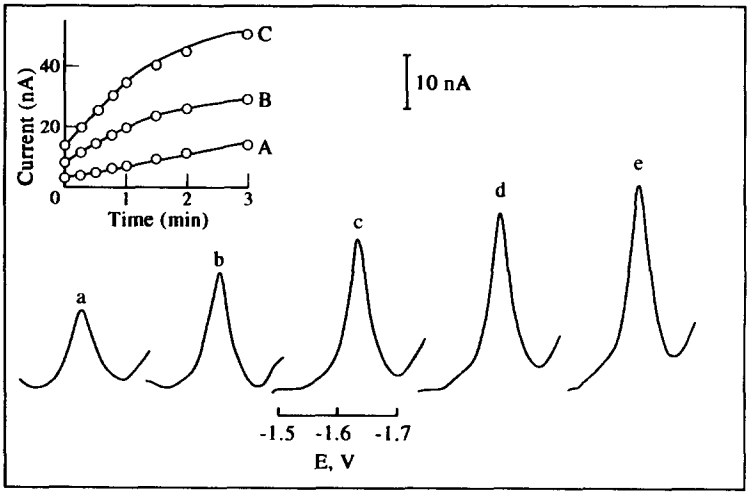

Fig. 2. Differential pulse voltammograms for 10 $\mu$g/l. manganese after different preconcentration times: 0 (a), 15 (b), 30 (c), 45 (d) and 60 (e) sec, with 300 rpm stirring. Inset shows current *vs.* preconcentration plots for 2 (A), 5 (B) and 10 (C) $\mu$g/l. manganese. Accumulation at $-1.2$ V; scan rate, 10 mV/sec; pulse amplitude, 25 mV; solution, as in Fig. 1.

involves the metal center in the complex. This is supported by the fact that measurements without the ligand yielded a small manganese peak, at a similar potential; the peak was greatly (20-fold) enhanced upon adding the 5-Br-PADAP (not shown). Analogous vanadium measurements also involved reduction of the metal center.[9]

Highly sensitive adsorptive stripping voltammetric measurements can be realized utilizing the effective interfacial accumulation of the Mn–5-Br-PADAP complex. For example, Fig. 2 displays differential pulse voltammograms for 10 $\mu$g/l. after different preconcentration periods from 0 to 60 sec (a–e). Larger peak currents are observed for longer accumulation periods. Yet, even without a preceding preconcentration, a well-defined peak is observed (reflecting the strong chelate adsorption during the slow differential pulse scan). Also shown in Fig. 2 (inset) are plots of peak current *vs.* preconcentration time at three manganese levels: 2 (A), 5 (B) and 10 (C) $\mu$g/l. While the 2 $\mu$g/l. experiment yields a linear increase of the peak current, a curvature (above 1 min period) is observed using the 5 and 10 $\mu$g/l. manganese solutions.

Figure 3 examines the influence of various experimental variables upon the stripping response of the Mn–5-Br-PADAP complex. Increasing the pH from 8 to 8.8 results in a gradual increase in the peak height; a sharp decrease in the response is observed as the pH is raised further (A). The optimal pH (8.8) is much lower than that for the eriochrome procedure,[5] which is advantageous considering the higher stability of the dissolved form of the metal. A similar pH was employed in the Fe-5-Br-PADAP procedure,[7] while acetate buffer solutions (of lower pH) were used for the quantitation of vanadium and chromium.[6,8] The peak increases rapidly upon raising the ligand concentration from $2 \times 10^{-6}$ to $8 \times 10^{-6} M$, above which it starts to level off (B). Similar (micromolar) 5-Br-PADAP levels were employed in analogous schemes for iron, vanadium and chromium.[6-8] The dependence of the current on the preconcentration potential was examined over the range from $-0.9$ to $-1.50$ V (C). An optimal behavior was observed around $-1.20$ V. Substantially lower potentials were used in earlier procedures using 5-Br-PADAP.[6-8] The chelate peak also increased upon increasing the ethanol content to 10% (v/v), and then it levelled off (not shown). Such a profile reflects the increased solubility of 5-Br-PADAP. Because of

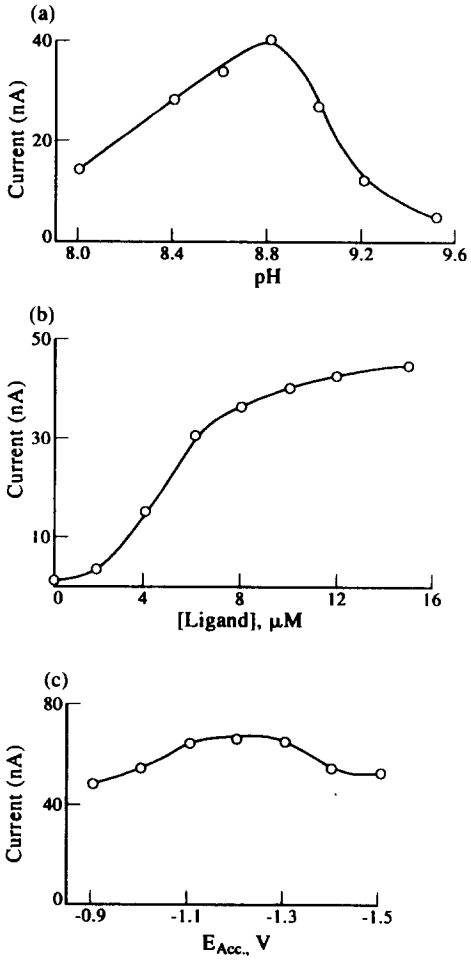

Fig. 3. Effect of pH (A), ligand concentration (B), and accumulation potential (C) on the adsorptive stripping peak current for manganese [10 $\mu$g/l. (A, B), 20 $\mu$g/l. (C)]. Accumulation for 30 (A, C) and 60 (B) sec. Other conditions, as in Fig. 2.

the long desorption time, a new drop was used in each cycle. Both the linear scan and differential pulse modes yielded a well defined stripping response with the latter offering slightly improved signal-to-background characteristics. Best results were obtained with a 25 mV pulse amplitude and 10 mV/sec scan rate.

Figure 4 shows stripping voltammograms obtained for manganese solutions of increasing concentration in 2 $\mu$g/l. steps after a 60-sec preconcentration time. Well-defined peaks, which increase linearly with the manganese concentration, are observed. Also shown in Fig. 4 (insets) are calibration plots over wider concentration ranges [2–14 (A) and 10–90 (B) $\mu$g/l.] following 60 and 30 sec accumulation, respectively. A curvature is observed above 50 $\mu$g/l. with a leveling off above 80 $\mu$g/l. The linear portions are characterized with slopes of 4.3 (A)

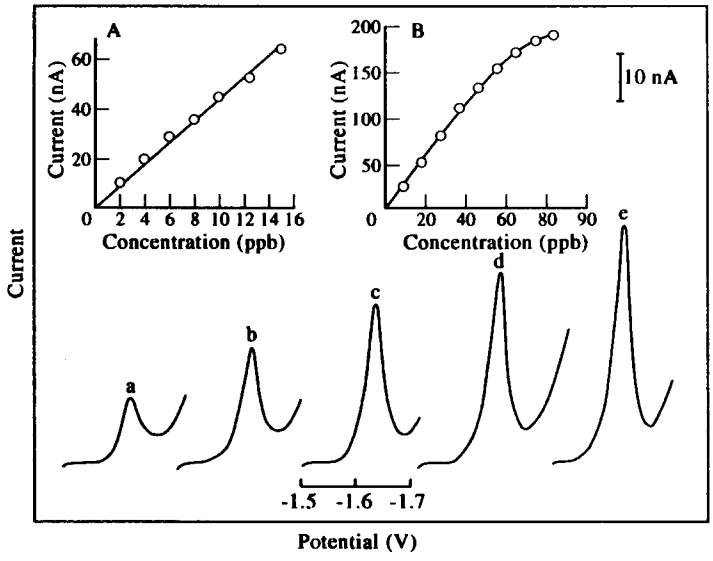

Fig. 4. Stripping voltammograms for solutions of increasing manganese concentration, 2–10 $\mu$g/l. (a–e). Preconcentration for 60 sec; conditions, as in Fig. 2e. Also shown (inset) are calibration plots over the 2–14 (A) and 10–90 (B) $\mu$g/l. ranges, following 60 and 30 sec accumulations, respectively.

and 2.7 (B) nA l./$\mu$g. The detection limit was estimated (from curve a) to be 0.2 $\mu$g/l. ($3 \times 10^{-9} M$). The precision was estimated from 15 successive measurements of the 2 $\mu$g/l. manganese solution (60-sec accumulation); the mean peak current was 9.8 nA (range 9.5–10.3 nA and relative standard deviation of 4.0%).

The inherent sensitivity of the method is apparent from comparison with the earlier procedure based on the manganese/dihydroxyazo-dyes complexes.[5] Figure 5 compares voltammograms for 10 $\mu$g/l. manganese in the presence of 5-Br-PADAP (A) to those obtained in the presence of the azo dye Eriochrome Black T (B) and Solochrome Violet RS (C). Both dihydroxyazo dyes yield a defined manganese peak, superimposed on a decaying background peak (associated with the reduction of the free ligand). A sharper and larger peak, and a lower baseline response, are observed in the presence of 5-Br-PADAP. Even more profound sensitivity improvements were observed using a differential pulse excitation waveform, for which the manganese–azo dyes peaks were obscured by those of the ligand while that of the

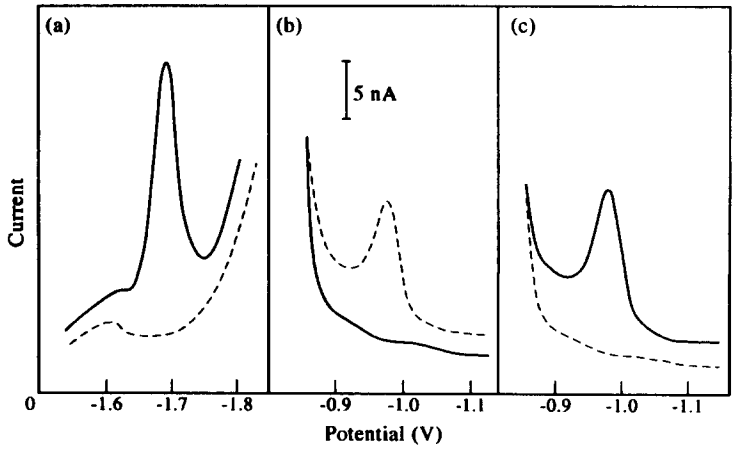

Fig. 5. Stripping voltammograms for 10 $\mu$g/l. manganese in the presence of 5-Br-PADAP (A), Eriochrome Black T (B), and Solochrome Violet RS (C). Conditions, (A) as in Fig. 2e, with $1 \times 10^{-5} M$ 5-Br-PADAP; (B, C), 0.02$M$ PIPES (pH 12) solution, containing $5 \times 10^{-6} M$ of the azo dye, using 60 sec accumulation at $-1.2$ V.

Mn–5-Br-PADAP complex was well defined (as in Fig. 4e).

The following metal ions (20 $\mu$g/l.) were tested and found not to affect the 2 $\mu$g/l. manganese response: Al(III), Bi(IIII), Sb(III), Ni(II), Cu(II), Zn(II), Cd(II), Pb(II), In(III), Ca(II), Mg(II), Ir(III) or Tl(I). It should be pointed out that analogous manganese measurements in the presence of Eriochrome Black T suffer from severe Cu(II), Zn(II), Ca(II) and Mg(II) interferences.[5] The lack of calcium and magnesium interference is of great significance because of their common presence in biological and environmental matrices (*e.g.* mg/l. level in natural waters). Even larger (500-fold) excess of these ions did not affect the manganese response. The insensitivity to copper is also significant considering severe copper–manganese intermetallic problems in conventional stripping measurements.[4] Depressions of the 2 $\mu$g/l. manganese peak were observed in the presence of 20 $\mu$g/l. uranium(VI), Fe(III), Ti(IV), V(V), Cr(III) and La(III). A separation step would be required in the presence of an excess of these metals. Organic surfactants that compete with the chelate on the surface sites represent another source of interference. While 1 mg/l. gelatin or sodium dodecyl sulphate did not affect the 10 $\mu$g/l. manganese peak (60 sec accumulation), 4 mg/l. of these surfactants caused 30 and 70% diminutions of the response, respectively.

In conclusion, the present study describes an effective means for the measurement of trace levels of manganese. Quantitation at the $\mu$g/l. level is feasible with short preconcentration times. The 5-Br-PADAP based approach offers a new selectivity dimension and enhances the signal-to-background characteristics, compared to an early adsorptive stripping procedure. Yet, an even more selective ligand is desired to address remaining selectivity problems. The attractive performance of the 5-Br-PADAP–Mn system should lead to various environmental or clinical applications, and may offer new information related to the speciation of manganese.

# PRECONCENTRATION OF IRON (III), COBALT (II) AND COPPER (II) NITROSO-R COMPLEXES ON TETRADECYLDIMETHYLBENZYLAMMONIUM IODIDE–NAPHTHALENE ADSORBENT

BAL K. PURI and SANJAY BALANI

Department of Chemistry, Indian Institute of Technology, Hauz Khas New Delhi—110016, India

(*Received* 6 *December* 1993. *Revised* 8 *August* 1994. *Accepted* 16 *August* 1994)

**Summary**—Iron, cobalt and copper form coloured water soluble anionic complexes with disodium 1-nitroso-2-naphthol-3-6-disulphonate (nitroso R-salt). The anionic complex is retained quantitatively as a water insoluble neutral ion associated complex (M-nitroso R-TDBA) on tetradecyldimethylbenzylammonium iodide on naphthalene ($TDBA^+I^-$-naphthalene) packed column in the pH range of: Fe(III): 3.1–6.5, Co: 3.4–8.5 and Cu 5.9–8.0 when their solutions are passed individually over this adsorbent at a flow rate of 0.5–5.0 ml/min. The solid mass consisting of an ion associated metal complex along with naphthalene is dissolved out of the column with 5 ml dimethylformamide/chloroform and metals are determined spectrophotometrically. The absorbance is measured at 710 nm for iron, 425 nm for cobalt and 480 nm for copper. Beers law is obeyed in the concentration range 9.2–82 $\mu$g of iron, 4.2–7.2 $\mu$g of cobalt and 3.0–62 $\mu$g of copper in 5 ml of final $DMF/CHCl_3$ solution. The molar absorptivities are calculated to be Fe: $7.58 \times 10^3$, Co: $1.33 \times 10^4$ and Cu: $4.92 \times 10^4 M^{-1}$ cm$^{-1}$. Ten replicate determinations containing 25 $\mu$g of iron, 9.96 $\mu$g of cobalt and 3.17 $\mu$g of copper gave mean absorbances 0.677, 0.450 and 0.490 with relative standard deviations of 0.88, 0.98 and 0.92%, respectively. The interference of large number of metals and anions on the estimations of these metals has been studied. The optimized conditions so developed have been employed for the trace determination of these metals in standard alloys, waste water and fly ash samples.

Disodium 1-nitroso-2-naphthol-3,6-disulphonate (nitroso R-salt) was introduced in 1921 by Van Klooster for the detection of cobalt[1] and then subsequently used by various investigators for the determination of small quantities of this metal in plant and animal tissues,[2–7] soils,[8–10] grasses,[11,12] steels and carbides.[13] Preliminary experiments indicated that metalions like $Fe^{3+}$, $Co^{2+}$ and $Cu^{2+}$ also react with this reagent and form coloured water soluble anionic complexes. These anionic complexes in the presence of tetradecyldimethylbenzylammonium cation form coloured water insoluble ion associated complexes which can be easily adsorbed on microcrystalline naphthalene.

In the present communication we have synthesized tetradecyldimethylbenzylammonium iodide–naphthalene as an adsorbent and used it for the preconcentration of iron (III), cobalt (II) and copper (II) using nitroso R-salt as the chelating agent. This adsorbent is very easy to synthesize (simply by mixing the solutions) and is highly economical and gives a preconcentration factor $\sim 100$ for these metals. The interference of a large number of metal ions and anions has been studied in detail and the optimized conditions so developed have been employed for the preconcentration and determination of iron, cobalt and copper from the large volume of their aqueous solutions in alloys, waste water and fly ash samples. After preconcentration by this method, these metals may also be determined by atomic absorption spectrometrically by aspirating their DMF solution in a flame. However, the spectrophotometric method is much more economical (since it is cheaper than AAS and does not require any gas or maintenance), sensitive and free from matrix effect. The sensitivity and the selectivity of the developed method has been compared with recent methods reported in the literature (Tables 1 and 2). Except iron, the method is fairly sensitive for cobalt and copper but the preconcentration factor $\sim 100$ is a highly favourable factor for the trace estimation of these metals from a large volume of their aqueous solutions. The selectivity of the method is much better than most of the recent methods.

Table 1. Comparison of sensitivities of various methods

| Metal | Reagent | $M^{-1}\ cm^{-1}$ | Ref. |

## EXPERIMENTAL

### *Reagents*

Standard iron, cobalt and copper solutions were prepared from analytical grade ferric ammonium sulphate, cobalt (II) chloride and copper (II) sulphate in double distilled water and standardized by known methods. Sodium acetate/acetic acid and ammonia/ammonium acetate solutions were used to adjust the pH. Naphthalene, chloroform and dimethylformamide were checked spectrophotometrically before use. Double distilled water was used wherever needed. To study the interferences of various ions, a solution containing 25–30 mg of anion or 1 mg of cation were prepared in distilled water.

### *Preparation of tetradecyldimethylbenzyl-ammonium iodide–naphthalene*

A solution of naphthalene was prepared by dissolving 10 g in 100 ml of acetone. This solution was transferred to a beaker containing 0.8 g KI in 1000 ml of distilled water in a fast stream with continuous stirring. An aqueous solution of tetradecyldimethylbenzylammonium chloride ($TDBA^+Cl^-$) was prepared by dissolving 0.4 g in 250 ml of distilled water. This solution was transferred to the beaker containing the above solutions and stirred for 5 h. The supernatant solution was drained off by decantation. The residue was washed twice with distilled water. The final adsorbent $TDBA^+I^-$ supported on naphthalene was stored in a bottle for subsequent use.

### *Apparatus*

An Elico pH meter, Lambda 3b UV/VIS spectrophotometer and a Pye Unicam 191 atomic absorption spectrometer were used.

### *General procedure*

An aliquot of a metal ion solution, Fe: 9.2–8.2 μg, Co: 4.2–72 μg, and Cu: 3.0–62 μg was taken in a 100 ml beaker and to it, 0.2–4.0 ml of 0.20% solution of nitroso-R salt was added. The pH of these solutions was adjusted by adding a suitable volume of buffer solution (sodium acetate/acetic acid, ammonia/ammonium acetate) or dilute solutions of hydrochloric acid or sodium hydroxide (3–5 ml) to adjust the pH; Fe: 3.1–6.5, Co(II): 3.4–8.5 and Cu(II): 5.9–8.0. The metal complex solution was passed over the adsorbent (tetradecyldimethylbenzylammonium iodide–naphthalene, 0.2 g placed to height of 1.2 cm in a column) at a flow rate of 0.5–5.0 ml/min. Metal–nitroso R-TDBA complex along with naphthalene was dissolved out of the column with 5 ml of chloroform in the case of Fe(III) and 5 ml of DMF in the case of Co(II) and Cu(II). The absorbances were measured in a 1 cm cell at 710 nm for iron, 425 nm for cobalt and 480 nm of copper against the reagent blank prepared similarly.

## RESULTS AND DISCUSSION

### *Absorption spectra*

The absorption spectra of metal complexes were recorded in chloroform/dimethyl-

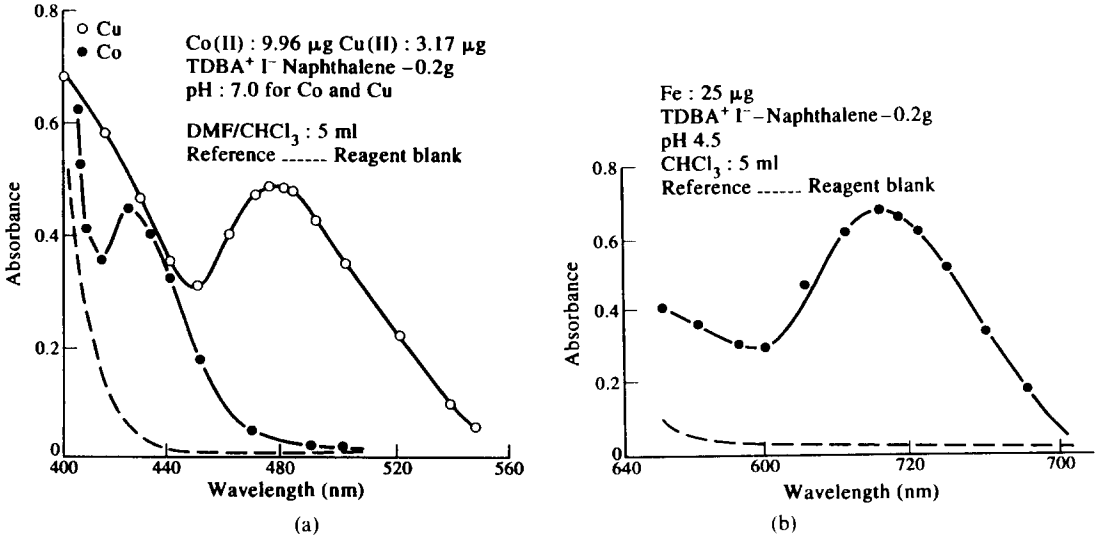

Fig. 1.

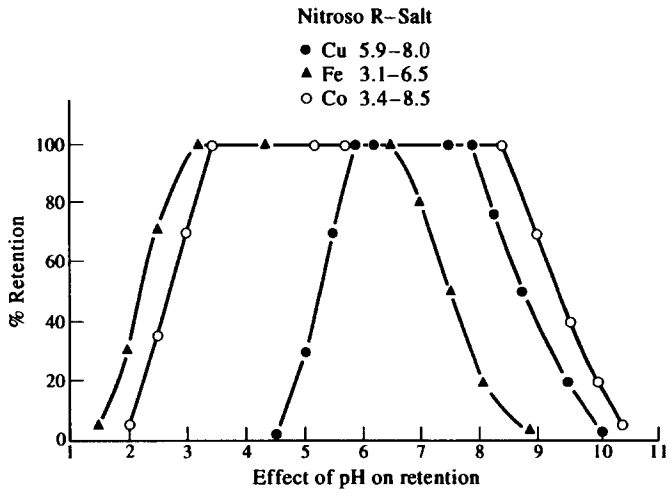

Fig. 2.

formamide against the reagent blank and the reagent blank against water (Fig. 1a, b). These complexes show absorption maxima, iron at 710 nm, cobalt at 425 nm and copper at 480 nm.

*Effect of pH*

Adsorption was carried out at different pH keeping other conditions constant. Adsorption was found to be maximum and constant in the pH range Fe(III): 3.1–6.5, Co(II) 3.4–8.5 and Cu(II): 5.9–8.0 (Fig. 2). Adsorption for each metal chelate anion was carried out by adding different volumes of buffer solutions. It was found that 1.0–5.0 ml of a buffer solution did not affect the percentage of retention of the metal complex on the adsorbent.

*Reaction conditions*

The reaction conditions were established taking 25.00 $\mu$g of iron, 9.96 $\mu$g of cobalt and 3.17 $\mu$g of copper.

Adsorption was maximum and constant when 0.1–1.2 g of tetradecyldimethylbenzylammonium iodide–naphthalene (adsorbent) and 0.2–4.0 ml of 0.20% (w/v) of the reagent (nitroso-R salt) were used. The volume of the aqueous phase containing the metal ion was varied from 20 to 500 ml. It was observed that the adsorbance was constant when the aqueous phase did not exceed 400–500 ml in all the cases (preconcentration factor of ~80–100).

Absorbance of metal–nitroso-R TDBA complex in chloroform/dimethylformamide was constant for 24 hr in all the cases.

Sodium chloride, sodium nitrate and sodium perchlorate when added in the concentration range of 0.01–0.1$M$ had no effect on the adsorption.

The affect of flow rate on adsorption was examined in the range of 0.5–10 ml/min. Adsorption was maximum and constant when the flow rate was between 0.5 and 5.0 ml/min. Above 5 ml/min, the percentage retention of the metal complexes decreased gradually. The percentage retention was decreased by 14% for iron, 8.8% for cobalt and 5% for copper at a flow rate of 10 ml/min.

A flow rate of 1 ml/min, was chosen for subsequent studies for convenience. In cases of larger aqueous phase volume, a flow rate of 5 ml/min may be maintained.

*Beer's law*

Beer's law was obeyed in the concentration range, Fe: 9.2–82 $\mu$g, Co: 4.2–72 $\mu$g and Cu: 3.0–62 $\mu$g, in 5 ml of final solution. The concentration range as given by a Ringbom plot (in ppm) was Fe: 1.84–6.0, Co: 0.8–3.6 and Cu: 0.2–1.27. The molar absorptivities for these complexes were calculated to be ($M^{-1}$ cm$^{-1}$) Fe: $7.58 \times 10^3$, Co: $1.33 \times 10^4$ and Cu $4.92 \times 10^4$. The sensitivity of the developed method is better than many of the recent methods reported in Table 1. Ten replicate determinations containing Fe: 25.00 $\mu$g, Co: 9.96 $\mu$g and Cu: 3.17 $\mu$g gave mean absorbances of 0.677, 0.450 and 0.492 with relative standard deviations of 0.88, 0.98 and 0.92%, respectively. The accuracy of this method was checked by the determination of these metal ions in standard alloys, waste water and fly ash samples.

*Composition of the metal complex*

The composition of the metal–nitroso R complex was studied by Job's method and mole ratio method. Peaks at 0.50 mole fraction for iron, 0.25 for cobalt and 0.33 for copper and a break at 1:1 for iron, 1:3 for cobalt and 1:2 for copper suggested the formation of $Fe(C_{10}H_5O_8NS_2)_2$, $Co(C_{10}H_5O_8NS_2)_3$ and $Cu(C_{10}H_5O_8NS_2)_2$. The structure of the metal–nitroso R-TDBA complex was confirmed by infrared analysis in which $-OH$ stretching was prominent at 3100–3450 $cm^{-1}$ in the free ligand but disappeared completely after the metal complex formation.

*Retention capacity of chelating agent supported on naphthalene*

The retention capacity of the chelating agent supported on naphthalene was determined for each metal ion by a batch method. This experiment was carried out by taking 350 $\mu$g of metal ion, 3–5 ml of buffer, 0.5–4.0 ml of 0.20% reagent (nitroso-R salt) and a suitable amount of the adsorbent in a 100 ml separatory funnel. This mixture was diluted to 30 ml. It was shaken with a mechanical shaker for 15 min and then filtered through a filter paper. The amount of the metal ion in the filtrate was determined by AAS. The retention capacity of metal ion was found to be proportional to the amount of TDBA on naphthalene and also on nitroso R-salt. The maximum capacity was found to be Fe: 1.2 mg, Co: 1.4 mg and Cu: 1.8 mg per g of adsorbent.

*Effect of diverse ions*

The interference of various ions on the estimation of these metal ions has been studied in detail. Generally, 30 mg of the alkali metal salts of anions and 1.5 mg salt of cations were added individually to the solution containing 25 $\mu$g of iron, 9.96 $\mu$g of cobalt and 3.17 $\mu$g of copper, respectively and the general procedure applied. Among the anions examined (Tables 3 and 4) large amounts of chloride, bromide, nitrate, acetate, carbonate and sulphate could be tolerated (30 mg each). Citrate, oxalate, orthophosphate, tartrate and EDTA interfered in all the cases. Except EDTA, a relatively low amount of these anions could be tolerated (Table 3). Obviously the stability constants of these metal–EDTA complexes must be higher than their metal nitroso R-salt complexes. Of the metal ions examined (Table 4), many did not interfere up to mg levels. $Rh^{3+}$, $Ru^{3+}$, $Pd^{2+}$ Os and V interfered, however relatively low amounts could be tolerated. The interference of copper in the determination of iron and cobalt was eliminated by adding 1 mg of thiourea during adsorption. Iron was masked with 3 ml of 5% NaF solution in the determination of copper and cobalt. $Ag^+$ was masked with 3 ml of 1% $Na_2S_2O_3$ in all cases. Interference of cobalt and nickel in the estimation of iron was

Conditions same as in Table 1

*Iron was masked with 3.0 ml of 5% sodium fluoride.

†Copper was masked with 1 *mg* of thiourea.

eliminated by pre-adsorption of cobalt and nickel at pH 8.4 where iron did not adsorb on the adsorbent and then after the removal of nickel and cobalt, iron was determined. At pH 8.4 iron does not interfere in the determination of cobalt.

*Determination of cobalt and copper in alloys*

A sample of an alloy (0.1–1.0 g) was dissolved in 10–15 ml of aqua regia on a water bath. After cooling, 3–5 ml of hydrogen peroxide (30%) was added. The excess of peroxide was decomposed by heating the solution on a water bath. The mixture was cooled and filtered if needed and then diluted to 250 ml with distilled water in a calibrated flask. An appropriate volume of this solution was taken, copper and cobalt were determined by the general procedure. The results are given in Table 5.

*Determination of iron and copper in fly ash and waste water sample*

A sample of fly ash (460–600 mg) was taken in a platinum crucible and 250 mg of $Li_3Bo_3$ was added. The crucible was heated at 700°C for an hour and then cooled. The contents of the crucible were transferred to a beaker containing 2.2*M* hydrochloric acid and diluted to 300 ml in a calibrated flask. An aliquot of this solution was taken and iron and copper were determined by the general procedure. Similarly, a waste water sample (100 ml) was treated with 2*M* HCl and heated to 200°C, it was allowed to cool, filtered and diluted to 50 ml in a calibrated flask and iron and copper were determined by general procedure. The relative standard deviation for five determinations in each case did not exceed ±1.3%. The results obtained by this method were found to be in good agreement with those obtained by standard methods reported in the literature.

## CONCLUSION

A solid ion pair produced from tetradecyldimethylbenzylammonium iodide on naphthalene provides a simple, rapid and economical method for column preconcentration of iron, cobalt and copper in alloys, waste water and fly ash sample using nitroso R-salt as the complexing agent. The proposed adsorbent is highly effective for the trace determination of these metal ions from a large volume of their aqueous phase (preconcentration factor 80–100). The method is relatively sensitive and selective as compared to recent methods re-

ported in the literature. This adsorbent may also be employed for any metal ion which forms an anionic complex with a complexing agent. Instead of using spectrophotometry as a tool for the estimation of metals, atomic absorption or pulse polarography may also be employed after the preconcentration step. The sensitivity and selectivity of this method may be further improved by using derivative spectrophotometry.

# POTENTIOMETRIC STUDY OF REACTION BETWEEN PERIODATE AND IODIDE AS THEIR TETRABUTYLAMMONIUM SALTS IN CHLOROFORM. APPLICATION TO THE DETERMINATION OF IODIDE AND POTENTIOMETRIC DETECTION OF END POINTS IN ACID–BASE TITRATIONS IN CHLOROFORM

M. H. POURNAGHI-AZAR* and KH. FARHADI
Faculty of Chemistry, University of Tabriz, Tabriz, Iran

(*Received* 22 *March* 1994. *Revised* 22 *August* 1994. *Accepted* 22 *August* 1994)

**Summary**—A potentiometric method for the titration of tetrabutylammonium iodide (TBAI) in chloroform using tetrabutylammonium periodate (TBAPI) as a strong and suitable oxidizing reagent is described. The potentiometric conditions were optimized and the equilibrium constants of the reactions occurring during the titration were determined. The method was used for the determination of iodide both in chloroform and aqueous solutions after extraction into chloroform as ion-association with tetraphenylarsonium. The reaction between TBAPI and TBAI was also used as acid indicator for the potentiometric detection of end points of acid–base titrations in chloroform.

The high dissolving power and extracting property of chloroform against natural products, organic, organometallic and pharmaceutical compounds make it an excellent solvent and the study of electrochemical behaviour of these compounds in chloroform is interesting in order to develop new electroanalytical methods.

Peover was the first worker who employed polarography for the study of organic molecular complexes in chloroform.[1] In our previous works we have studied the electrochemical behaviour of quinones, anthraquinones and phenothiazines at a Hg electrode,[2–5] ferrocene at bare solid electrodes[6] and hydroquinone at polypyrrole-coated Pt electrode.[7] On the basis of results obtained from these studies, polarography was used for the determination of K group vitamins, anthracycline group anticancer and phenothiazinic drugs in pharmaceutical preparations,[5,8,9] 9,10-anthraquinone in paper samples, black liquors[4] and some naturally occurring hydroxy derivatives of 9,10-anthraquinone in medicinal plants.[10]

In aprotic solvents of low permittivity like chloroform ($\epsilon = 4.8$) all chemical reactions, including proton-transfer, electron-transfer and complex formation are greatly complicated by ion-association leading to ion-pairs of various types. Therefore, incomplete dissociation of electrolytes should be taken into account in potentiometric and, particularly, conductimetric measurements. Rumeau was the first worker to use potentiometry for studying the redox and complex formation reactions in chloroform and developed redox molecular scales in this solvent.[11] Golabi *et al.*[12] applied potentiometry for the detection of equivalence points in oxidimetric titrations of phenothiazinic drugs by bromine solution in chloroform. Recently we have developed the quinhydrone electrode in chloroform and used this electrode as acid indicator for the potentiometric detection of end points in acid–base titrations. A method for the calculation of the equilibrium constants of acid–base reactions in this solvent was proposed.[13]

The aim of this work was to study the reaction between tetrabutylammonium periodate and iodide in chloroform in order to develop a potentiometric titration method for iodide and use the redox system $IO_4^-/I_2$ as an acid indicator for the potentiometric detection of end points of acid–base titrations in this medium.

## EXPERIMENTAL

### *Reagents*

The solvent used was chloroform G.R. from E. Merck or Janssen, tetrabutylammonium periodate (TBAPI), iodide (TBAI) and perchlorate (TBAP) were from Janssen or Fluka. (TBAI) was purified from a mixture of etheracetone. Other chemicals were P.A. grade from E. Merck or Fluka. A 0.001*M* solution of periodate was used. Chloroform solutions of perchloric and sulfuric acids were prepared by shaking a 10 ml portion of each concentrated acid and 20 ml chloroform in a separatory funnel for 30 min. The concentration of acids in the extracts was determined potentiometrically using a quinhydrone electrode as acid indicator and a standard solution of $(But)_3N$ in chloroform.[13] The other acid solutions were prepared by direct dissolving of required amount of pure acids in chloroform.

### *Apparatus*

Potentiograph E 536 equipped with an E 578 titration stand (Metrohm) or a Video titrator Vit 90 (Radiometer) coupled with a Toshiba P321SL printer were used to plot the normal and differential forms of the titration curves. The potentiometric cell was thermostated at $25 \pm 0.1°$ using a double membrane cell (Metrohm) and an Eyela UA-10 (Japan) thermostat.

The reference electrode Ag/AgCl (satd) 0.05*M* TBACl and 0.50*M* TBAP in chloroform prepared in a separated compartment with a dense ceramic plug in the bottom was used, the indicator electrode was Pt wire.

### *Procedure*

Tetrabutylammonium iodide 0.005 M (10 ml) was pipetted into the reaction cell, a suitable strong acid added up to 0.2*M*, and titrated by 0.001*M* tetrabutylammonium periodate at 0.5 ml/min.

## THEORETICAL

### *Equations of the potentiometric titration curves*

By gradual addition of periodate to iodide solution in chloroform, the reaction pathway between periodate and iodide may be two successive electron transfer steps forming $AI_3$ and $I_2$, respectively. In strongly acidic medium as 0.2*M* *p*-toluenesulfonic acid ($TSO_3H$) the first step of reaction can be shown as follows:

$$11AI + AIO_4 + 8TSO_3H \rightleftharpoons 4AI_3 + 8ATSO_3 + 4H_2O, \quad (1)$$

where A is the tetrabutylammonium cation. Assuming that the chloroform is saturated with $H_2O$ the equilibrium constant of reaction (1) is:

$$K_1 = \frac{[AI_3]^4[ATSO_3]^8}{[AI]^{11}[AIO_4][TSO_3H]^8}. \quad (2)$$

Before the equivalence point of reaction 1, the half cell reaction at the Pt electrode at 25°C can be shown as:

$$AI_3 + 2e + 2A^+ \rightleftharpoons 3AI$$

$$E = E_1^\circ + \frac{0.059}{2}\log\left(\frac{[AI_3][A^+]^2}{[AI]^3}\right). \quad (3)$$

Because of the ion-pair formation in chloroform the dissociation equilibria for $A^+I^-$, $A^+I_3^-$, $A^+TSO_3^-$ and $A^+IO_4^-$ should be considered.

$$AI \rightleftharpoons I^- + A^+ \quad K_{d_1} = \frac{[A^+][I^-]}{[AI]} \quad (4)$$

$$AI_3 \rightleftharpoons I_3^- + A^+ \quad K_{d_2} = \frac{[A^+][I_3^-]}{[AI_3]} \quad (5)$$

$$ATSO_3 \rightleftharpoons TSO_3^- + A^+ \quad K_{d_3} = \frac{[A^+][TSO_3^-]}{[ATSO_3]} \quad (6)$$

$$AIO_4 \rightleftharpoons IO_4^- + A^+ \quad K_{d_4} = \frac{[A^+][IO_4^-]}{[AIO_4]}, \quad (7)$$

from equations (4)–(6) we have:

$$[A^+] = [I^-] + [I_3^-] + [TSO_3^-]$$

$$= \frac{K_{d_1}[AI]}{[A^+]} + \frac{K_{d_2}[AI_3]}{[A^+]} + \frac{K_{d_3}[ATSO_3]}{[A^+]}. \quad (8)$$

According to the following equation:

$$-\log K_d = C^{te} + \frac{0.43Z_1Z_2Ne^2}{(r^+ + r^-)RT} \times \frac{1}{\epsilon},$$

in which the cation radii ($r^+$) is constant and large for ion-pairs $A^+B^-$, the influence of the anion radii ($r^-$) change upon the log $K_d$ can be neglected and in a first approximation we can assume that:

$$K_{d_1} = K_{d_2} = K_{d_3} = K_{d_4} = K_d.$$

Thus equation (8) can be written as:

$$[A^+]^2 = K_d([AI] + [AI_3] + [ATSO_3]). \quad (9)$$

Considering:

$$x = \frac{\text{added amount of } AIO_4}{\text{required amount of } AIO_4 \text{ until the first equivalence point}} = \frac{\text{added } AIO_4}{C_0/11},$$

where $C_0$ is initial concentration of AI solution. At any point of the titration, we have:

$$F = V/(V+v);$$

$$[AI] = FC_0(1-x);$$

$$[AI_3] = 4FxC_0/11$$

$[ATSO_3] = 8FxC_0/11$ and equation (3) can be shown as:

$$E = E_1^0 + \frac{0.059}{2} \times \log\left[\frac{K_d[FC_0(1-x) + 4FxC_0/11 + 8FxC_0/11](4FxC_0/11)}{[FC_0(1-x)]^3}\right], \quad (10)$$

where $V$ is initial volume of AI and $v$ is added volume of $AIO_4$ or:

$$E = a_1 + \frac{0.059}{2}\log\left(\frac{x(x+11)}{F(1-x)^3}\right), \quad (11)$$

where:

$$a_1 = E_1^0 + \frac{0.059}{2}\log K_d + \frac{0.059}{2}\log(4/121C_0). \quad (12)$$

For a Nerstian behaviour of potential variation, the plot of $E$ *vs.* $\log[x(x+11)/F(1-x)^3]$ should be a straight line with a slope of $0.059/2V$.

The second step of the oxidation reaction is attributed to the oxidation of $AI_3$ formed in the first step to $I_2$ as:

$$7AI_3 + AIO_4 + 8TSO_3H \rightleftharpoons 11I_2 + 8ATSO_3 + 4H_2O \quad (13)$$

$$K_2 = \frac{[I_2]^{11}[ATSO_3]^8}{[AI_3]^7[AIO_4][TSO_3H]^8}. \quad (14)$$

Before the second equivalence point the half cell reaction at the Pt electrode in this step will be:

$$3I_2 + 2e + 2A^+ \rightleftharpoons 2AI_3$$

$$E = E_2^0 + \frac{0.059}{2}\log\left(\frac{[I_2]^3[A^+]^2}{[AI_3]^2}\right). \quad (15)$$

Considering the dissociation equilibrium of $AI_3$ (equation 5) and $ATSO_3$ (equation 6), equation (15) can be written as:

$$E = E_2^0 + \frac{0.059}{2}\log\left(\frac{K_d([ATSO_3] + [AI_3])[I_2]^3}{[AI_3]^2}\right). \quad (16)$$

According to reaction (13) in the interval of $1 < x < 11/7$, ($x = 11/7$ corresponds to second equivalence point) and considering that the concentration of produced AI in first step is $4FC_0/11$, we have:

$[AIO_4]$ added in this step $= F(xC_0/11 - C_0/11)$

$$[AI_3] = FC_0(1 - 7x/11)$$

$$[I_2] = FC_0(x-1)$$

$$[ATSO_3] = 8xC_0F/11.$$

Therefore, equation (16) can be rewritten as:

$$E = E_2^0 + \frac{0.059}{2} \times \log\left(\frac{11F^2C_0^2K_d(x-1)^3(11+x)}{(11-7x)^2}\right) \quad (17)$$

or

$$E = a_2 + \frac{0.059}{2}\log\left(\frac{F^2(x-1)^3(11+x)}{(11-7x)^2}\right), \quad (18)$$

where

$$a_2 = E_2^0 + \frac{0.059}{2}\log K_d + \frac{0.059}{2}\log 11C_0^2. \quad (19)$$

A plot of $E$ *vs.* $\log(F^2(11+x)(x-1)^3/(11-7x)^2)$ must be a straight line with a slope of $0.059/2$ $V$.

After the second equivalence point the half cell reaction in this interval is:

$$2AIO_4 + 14e^- + 16TSO_3H \rightleftharpoons I_2 + 2ATSO_3 + 14TSO_3^- + 8H_2O$$

$$E = E_3^0 + \frac{0.059}{14}\log\frac{[AIO_4]^2[TSO_3H]^{16}}{[I_2][ATSO_3]^2[TSO_3^-]^{14}}. \quad (20)$$

From equation (6)

$$[TSO_3^-]^2 = K_{d_3}^2[ATSO_3]^2/[A^+]^2, \quad (21)$$

since

$$[A^+] = K_{d_3}[ATSO_3] + K_{d_4}[AIO_4] = K_d([ATSO_3] + [AIO_4]). \quad (22)$$

Therefore,

$$[TSO_3^-]^2 = K_d[ATSO_3]^2/([ATSO_3] + [AIO_4]), \quad (23)$$

considering

$$[AIO_4] = (FxC_0/11 - FC_0/7),$$
$$[I_2] = 4FC_0/7,$$
$$[ATSO_3] = 8FC_0/7$$
$$[A^+]^2 = K_d FC_0(11 + x)/11$$

we can write

$$E = a_3 + \frac{0.059}{14}\log(7x - 11)^2(11 + x)^7/F^8, \quad (24)$$

where

$$a_3 = E_3^0 - \frac{0.059}{14}\log C_0^8 - \frac{0.059}{2}\log K_d + 0.0671 \log[TSO_3H] + 0.049. \quad (25)$$

A plot of $E$ *vs.* $\log(7x - 11)^2(11 + x)^7/F^8$ should be a straight line with a slope of $0.059/14$ $V$.

*Potentiometric determination of equilibrium constants*

During the gradual addition of $AIO_4$ to the AI in chloroform the redox reactions of (1), (13) and complex formation reaction of (26) can simultaneously occur as follows:

$$I_2 + AI \rightleftharpoons AI_3 \quad (26)$$

$$K_c = \frac{[AI_3]}{[I_2][AI]} \quad (27)$$

and their equilibrium constants may be determined potentiometrically.

*Determination of* $K_c$

This constant may be obtained as follows: subtracting equations (12) and (19) leads us to:

$$a_2 - a_1 = E_2^0 - E_1^0 + \frac{0.059}{2}\log(332.75C_0^3). \quad (28)$$

Since the potentials of the half cell at the Pt electrode in this interval $(0 < x < 1)$ given by equations (3) and (15) are the same, one can conclude that:

$$E_2^0 + \frac{0.059}{2}\log\frac{[I_2]^3[A^+]^2}{[I_3A]^2} = E_1^0 + \frac{0.059}{2}\log\frac{[AI_3][A^+]^2}{[AI]^3}$$

or

$$E_2^0 - E_1^0 = 0.0885 \log K_c. \quad (29)$$

Inserting equation (29) into equation (28) leads us to:

$$a_2 - a_1 = \frac{0.059}{2}\log(332.75C_0^3) + 0.088 \log K_c. \quad (30)$$

$a_1$ and $a_2$ are determined by means of plots of $E$ *vs.* $\log(x(11 + x)/F(1 - x)^3)$ for $0 < x < 1$ and $E$ *vs.* $\log(F^2(x + 11)(x - 1)^3/(11 - 7x)^2)$ for $1 < x < 11/7$ using the experimental potentiometric titration curves of the known solutions of AI by $AIO_4$.

*Determination of* $K_1$

$K_1$ is accessible from the experimental measurement of $a_1$ and $a_3$: subtraction of equations (25) and (12) leads us to:

$$a_3 - a_1 = E_3^0 - E_1^0 - \frac{0.059}{14}\log C_0 + 0.0591 \log K_d = +0.067 \log[TSO_3H] + 0.093 \quad (31)$$

and according to the equations (2), (3), (20) and (6)

$$E_3^0 - E_1^0 = 0.059 \log K_d - \frac{0.059}{14}\log K_c + \frac{0.059}{7}\log K_1. \quad (32)$$

By inserting equation (32) in equation (31)

$$a_3 - a_1 = -\frac{0.059}{14}\log C_0 + \frac{0.059}{7}\log K_1 - \frac{0.059}{14}\log K_c + 0.067 \log[TSO_3H] + 0.093. \quad (33)$$

$a_3$ can be obtained from the plot of $E$ *vs.* $\log(7x - 11)^2(x + 11)^7/F^8$ for the last segment of the titration curve $(x > 11/7)$ and $\log K_1$ may be calculated from equation (33).

*Determination of* $K_2$

This may be calculated by subtraction of equations (19) and (25)

$$a_3 - a_2 = E_3^0 - E_2^0 - \frac{0.059}{14}\log C_0^{22} - 0.059 \log K_d + 0.067 \log[TSO_3H]. \quad (34)$$

According to equations (15), (20), (5) and (6) we have:

$$E_3^0 - E_2^0 = 0.059 \log K_d + \frac{0.059}{7} \log K_2. \quad (35)$$

Inserting equation (35) in equation (34) gives equation (36) and $\log K_2$ can be determined:

$$a_3 - a_2 = -\frac{0.059}{14} \log C_0^{22} + \frac{0.059}{7} \log K_2 + 0.067 \log[TSO_3H] + 0.018. \quad (36)$$

## RESULTS AND DISCUSSION

The potentiometric curve for the titration of 10 ml 0.005*M* TBAI by a 0.001*M* solution of TBAPI in the presence of a suitable strong acid such as $TSO_3H$ in chloroform is shown in Fig. 1. Two equivalence points corresponding to reactions (1) and (13), are discernible. The color of the titrating solution before the first equivalence point ($0 < x < 1$) was yellowish ($AI_3$ formation) which tended to orange ($AI_3$ and $I_2$ mixture) between the first and second equivalence points ($1 < x < 11/7$). Finally its color changed to violet ($I_2$) after the second equivalence point.

*Influence of acid*

The potentiometric titration plots for a 0.005*M* solution of TBAI were recorded in the presence of various organic and inorganic strong acids. During the titration, $HClO_4$ reacts as an oxidizing agent and the stoichiometry of the reactions according to (1) and (13) was not verified. On the other hand methanesulfonic acid with a moderate concentration, is not strong enough for a quantitative proceeding of reaction (13). The titration curve in the presence of trichloroacetic acid was not reproducible, the electrode potential suffers from a loss of stability during its measurement and the first equivalence point is a poor one. A well defined and reproducible curve was recorded in the presence of *p*-toluenesulfonic and sulfuric acids. Two illustrative curves are shown in Fig. 2. On the other hand the precision and accuracy of the titrations were influenced by the titration speed. More precise and accurate results were obtained with a speed of 0.5 ml/min. The detection of equivalence points is more precise by inflection mode potentiometry.

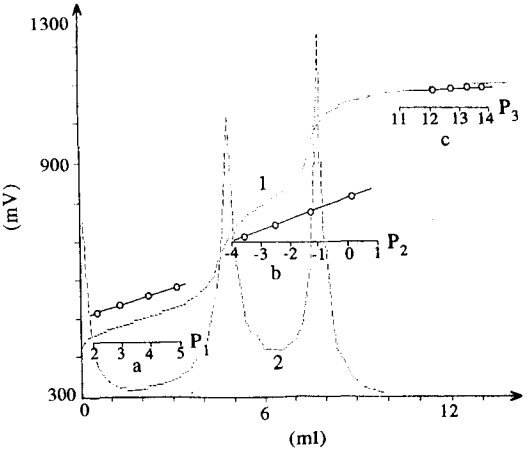

Fig. 1. Potentiometric titration of 10 ml 0.005*M* TBAI + 0.2*M* $TSO_3H$ with 0.001*M* TBAPI solution. (1) Plot of *E vs.* $V_{IO_4}$, (2) plot of $\Delta E/\Delta V$ *vs.* $V_{IO_4}$. (a) Plot of *E vs.* $P_1 = \log[x(11+x)/F(1-x)^3]$, (b) plot of *E vs.* $P_2 = \log[F^2(x-1)^3(11+x)^2/(11+7x)]$, (c) plot of *E vs.* $P_3 = \log[(7x-11)^2(x+11)^7/F^8]$.

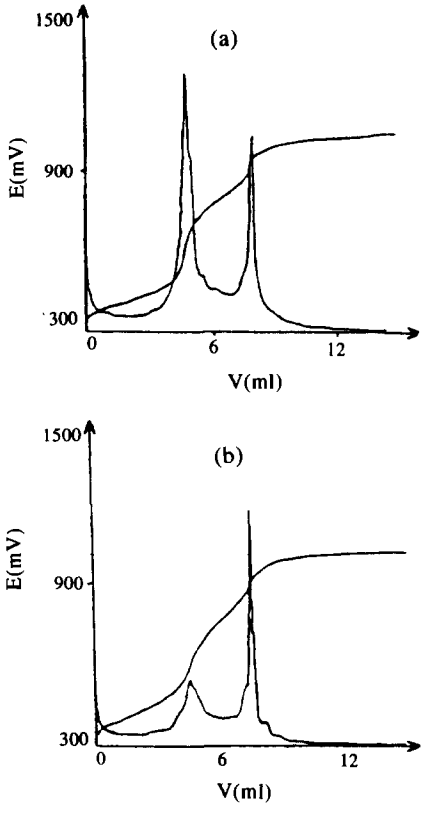

Fig. 2. Titration curves of 10 ml TBAI 0.005*M* by 0.001*M* solution of TBAPI, in the presence of 0.2*M* (a) toluenesulfonic acid, (b) methanesulfonic acid.

*Influence of water*

The addition of a few drops of water to the sample solution (IA) or using an aqueous concentrated solution of $HClO_4$ and $H_2SO_4$ gives rise to second phase formation and the extraction of $I_3^-$, produced during the first step (1), into the aqueous phase. The potential measured

in this condition did not agree with the relationships developed in chloroform (see Theoretical section). In addition, the curves obtained were not verified.

*Influence of the tetrabutylammonium salts*

Potentiometry in the presence of 0.5*M* TBAP shows that the electrode potential is more stable and two well defined equivalence points were observed. But in the presence of $TSO_3H$–$ATSO_3$ and $H_2SO_4$–$AHSO_4$, the solution was buffered, the oxidation reactions became less quantitative and the second step of AI oxidation cannot proceed.

*Determination of the equilibrium constants of reactions*

To prevent intervening of ion-pairs dissociation equilibrium of TBAP, with unknown equilibrium constants, in a thermodynamic analysis of the electrode potential changes, we used potentiometric titration curves recorded in the absence of this salt in spite of its influence on the stability of the potentials measured. The plots of $E$ *vs.* $\log[x(11+x)/F(1-x)^3]$ for the first segment of the titration curve ($0 < x < 1$), $E$ *vs.* $\log[F^2(x-1)^3(11+x)/(11-7x)^2$ for the second segment ($1 < 11/7$) and $E$ *vs.* $\log[(7x-11)^2(x+11)^7/F^8]$ for the last segment were straight lines with slopes of 0.030, 0.031 and 0.005 (Fig. 1a–c), respectively. These agree with the proposed stoichiometry for the titration reactions and equations (30), (33) and (36) allowed the calculation of $K_c$, $K_1$ and $K_2$, respectively. The results obtained are shown in Table 1.

*Analytical applications*

*Determination of iodide concentration.* Since the tetrabutylammonium iodide is used as a phase-transfer catalyst for some organic syntheses in the water–chloroform system,[14,15] the proposed potentiometric method was conveniently used for the determination of this catalyst in chloroform. In addition at pH 1–12 the iodide was extracted from aqueous solutions into chloroform as ion association with tetrabutylammonium chloride,[16] tetraphenylarsonium chloride[17] or tetraphenylphosphonium chloride[18] and then titrated potentiometrically. The method is selective in the presence of bromide and the relative standard deviation for three determination at 0.005*M* concentration level was 1.5%. A typical example of the titration curve for iodide, after its extraction from a 0.005*M* aqueous solution of $I^-$ and $Br^-$ with tetraphenylarsonium chloride into chloroform is shown in Fig. 3. The titration curve exhibits one equivalence point and the concentration of iodide can be determined.

Table 1. Calculated equilibrium constants

| | | | |

| Equilibrium* constants | $\log K_c = 5.5$ | $\log K_1 = 62.2$ | $\log K_2 = 1.1$ |
| SD | 0.08 | 0.78 | 0.06 |

*Mean of three determinations.

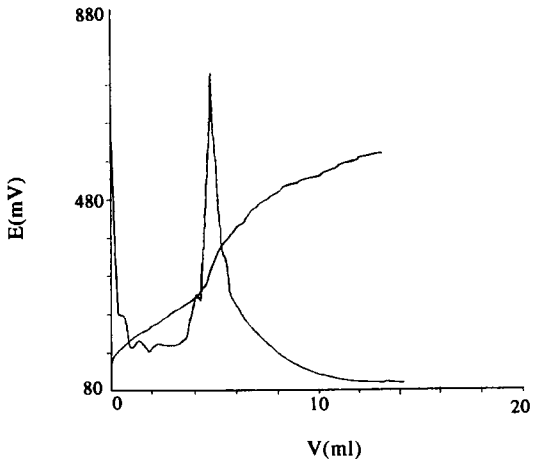

Fig. 3. Potentiometric titration curve for 10 ml chloroform solution of iodide (extracted from an aqueous solution of $I^-$ and $Br^-$ each 0.025*M* as ion association with tetraphenylarsonium into 25 ml chloroform). The titrant solution was a 0.001*M* TBAPI.

*Potentiometric detection of end points in acid–base titrations.* The reaction between periodate (TBAPI) and iodide (TBAI) may be utilized (i) for the potentiometric titration of strong acids and (ii) as a potentiometric indicator for the detection of end points of acid–base titrations in chloroform.

*Titration of Strong Acids*

On the basis of results obtained from potentiometric titration of TBAI with TBAPI, only strong acids seem to be titrated by this way. This can be carried out according to three different procedures as follows: (i) titration of a known solution of TBAI in the presence of TBAPI (excess amount) by the sample acid solution. (ii) Titration of TBAI solution in the presence of the acid sample by TBAPI. (iii) Titration of TBAPI solution in the presence of the acid sample by TBAI. Of the three proposed pro-

cedures only (i) gives a precise and accurate result. A typical example of the titration curve for *p*-toluenesulfonic acid solution is presented in Fig. 4. These behaviors are predictable from the values obtained for $K_c$, $K_1$ and $K_2$ and competition between the various chemical reactions occurring in the titration process.

*Detection of End Points of Acid–base Titrations*

This can be carried out only in the case of the acidimetric mode. The titration plots for 10 ml 0.01*M* solution of various organic bases, by 0.01*M* solution of some organic acid having a different strength are recorded in the presence of $5 \times 10^{-5}M$ TBAI and $2 \times 10^{-2}M$ TBAPI in chloroform. The potential ranges from 0.300 to 1.100 *V vs.* reference electrode with a large rise in the region of the equivalence point for strong acids and bases. The relative standard deviation for three assays of $10^{-2}M$ of the acids or bases was 1–2% depending on the strength of the analyte. Note that the precision and accuracy of the method depend on the concentration of TBAI and titration speed. The most reliable results were obtained with $5 \times 10^{-5}M$ of TBAI and 0.5 ml/min. Typical examples of the titration plots are shown in Fig. 5.

## CONCLUSIONS

On the basis of the results obtained, the chloroform solution of TBAPI in the presence of a suitable strong acid can be used as a powerful and stable reagent for oxidimetric titration in chloroform. The titration reactions were rapid in acidic medium and among the various strong organic and inorganic acids, *p*-toluenesulfonic was convenient for this purpose. The equilibrium constants of the titration reactions may be determined potentiometrically and the reaction between TBAPI and TBAI may be used as a potentiometric indicator for the detection of acid–bases titrations in chloroform.

# SIMULTANEOUS REDUCTION OF ARSENIC AND LEAD TO HYDRIDES BY SODIUM TETRAHYDROBORATE(III) FOR INDUCTIVELY COUPLED PLASMA-ATOMIC EMISSION SPECTROMETRY: AN INVESTIGATION INTO THE REACTION MEDIUM

HENGWU CHEN[1], JIANZHI WU[2] and IAN D. BRINDLE[3]*

(*Received* 16 *June* 1994. *Revised* 30 *August* 1994. *Accepted* 31 *August* 1994)

**Summary**—Nitroso R salt and potassium ferricyanide, in hydrochloric acid, have been used as the reaction medium for simultaneous generation of arsine and plumbane, combined with inductively coupled plasma-atomic emission spectrometric detection. Both of the reagents enhance the lead signal and neither reagent inhibits the arsenic signal, provided that the potassium ferricyanide is mixed on-line with the analyte solution. Potassium iodide, which is used to prereduce As(V) to As(III), does not interfere with plumbane generation in both reaction systems. Various parameters affecting the signals have been studied, and the hydrochloric acid–potassium ferricyanide system has proved to be a better reaction medium. Detection limits of lead and arsenic are 1.1 and 2.8 ng/ml, respectively, have been obtained in the HCl–$K_3Fe(CN)_6$ system at a sample uptake rate of 1.5 ml/min.

The contents of arsenic and lead in the environment is of great concern because both of them are recognized as cumulative poisons to animals and people. In addition, arsenic has been identified as a potential human carcinogen. Therefore, determination of trace arsenic and lead in various samples is of great interest of analysts and environmental chemists.

Among the various techniques, inductively coupled plasma-atomic emission spectrometry (ICP-AES) is favored because of its capability for multi-element analysis. However, the sensitivity of ICP-AES by solution nebulization cannot meet the needs of determining As and Pb at low trace and ultra-trace concentrations. The combination of ICP with mass spectrometry does provide excellent detection limits for arsenic and lead of less than 1 ng/ml,[1] but the expense of such equipment has prevented their being commonplace in analytical laboratories.

Since Thompson and co-workers combined ICP-AES with hydride generation[2] in 1978, this technique has received considerable attention by analysts because the sensitivity and detection limit could be greatly improved, compared to those obtained by conventional solution nebulization into an ICP source. Thus, methods of sequential or simultaneous determination of hydride forming elements,[3] and simultaneous determination both hydride forming elements and non hydride forming elements[4,5] have been developed. Nevertheless, it is difficult to find reasonable compromise conditions required for the simultaneous determination of all eight of the hydride forming elements because of their different requirements for hydride formation. Thompson *et al.* reported that germanium and tin could not be reduced satisfactorily by sodium tetrahydroborate(III) under the high acid conditions necessary for the reduction of arsenic, antimony, bismuth, selenium and tellurium and hence had to be separately reduced in a low acid medium.[6]

Oxidation state of the analytes is another important factor affecting the hydride formation. Trivalent arsenic and antimony, quadrivalent selenium and tellurium are more easily reduced to hydrides in comparison to the corresponding species of higher oxidation state.[7] Therefore, prereduction reagents, such as potassium iodide,[8] potassium iodide plus ascorbic acid,[9] and L-cysteine,[10] have been used to

*Author to whom correspondence should be addressed.

convert arsenic(V) to arsenic(III) before hydride generation. On the other hand, efficient generation of plumbane from lead(II) requires the presence of strong oxidizing reagent such as potassium dichromate,[11,12] hydrogen peroxide[12,13] and ammonium peroxodisulfate.[12] It has been assumed that the lead(II) was converted to metastable lead(IV) by the oxidant before it was reduced to plumbane.[13] The introduction of strong oxidizing reagents into the reaction medium prevented simultaneous reduction of other hydride forming elements, as reported by Zen and his co-workers:[5] the enhancement of lead signal, owing to the presence of $H_2O_2$ and $(NH_4)S_2O_8$, was obtained at the sacrifice of 99, 98, 70 and 32% decrease in the signals from selenium, tellurium, arsenic, and antimony, respectively. The conflicting requirements for the reaction medium lead to difficulties in the simultaneous and efficient generation of arsine and plumbane for ICP-AES determination.

Recently, chelating reagents such as nitroso R salt[14] and 1-(2-pyridylazo)-2-naphthol-6-sulphonic acid (PAN-S), *etc.*[15] were found effective in enhancing the lead signal of hydride generation-atomic absorption spectrometry (HG-AAS) Potassium ferricyanide, a mild oxidizing agent, was also found to be an excellent reagent to enhance efficiency of plumbane generation. (H. Chen, R. Zhu and J. Wu, unpublished results).[16,17] It was assumed that the chelation[14,15] or coordination[17] of lead by these reagents might exert a critical influence in the enhancement of lead signal. Because the conditions for the generation are so mild, it seemed likely that a method could be developed which would enhance the lead signal without depressing the arsenic signal. This paper reports the main results of a detailed investigation into the determination of lead and arsenic using reaction media containing nitroso R salt or $K_3Fe(CN)_6$ for the simultaneous generation of arsine and plumbane, followed by determination with ICP-AES.

## EXPERIMENTAL

### *Apparatus*

A Leeman Labs PLASMA-SPEC inductively coupled plasma-atomic emission spectrometer was use to obtain emission signals.

The continuous hydride generation system, shown schematically in Fig. 1, was constructed by modification of the liquid sample introduction assembly of the plasma source. The pneumatic nebulizer was removed from the Teflon cap of the spray chamber, and was replaced by a rubber septum with the similar dimensions containing two 1 mm i.d. × 30 mm glass tubes. The upper glass tube was connected to the argon carrier, and the lower tube which was positioned above the drain port of the spray chamber, was connected to the reaction tubing (1 mm i.d. × 10 cm) where hydride formation occurred. A PTFE tube (1 mm i.d. × 150 mm) was used to mix the acidic test solution and $K_3Fe(CN)_6$ solution. The three channel peristaltic pump originally attached on the ICP machine was used to propel the analyte, reductant and $K_3Fe(CN)_6$. A second peristaltic pump was used to drain the waste.

### *Reagents*

Arsenic(III) standard solution (1000 μg/ml) was prepared by dissolving 0.1320 g of $As_2O_3$

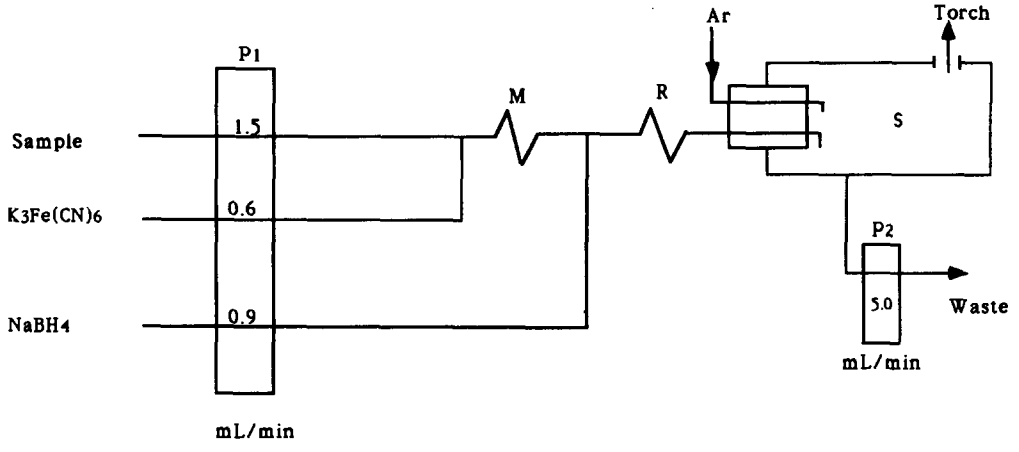

Fig. 1. Manifold of the continuous hydride generation–separation system. M: Mixing tube, $P_1$, $P_2$: peristaltic pumps, R: reaction tube, S: spray chamber.

(analytical grade, The Second Chemical Factory, Tianjin, P. R. China) in 4 ml of 2 mol/l. NaOH solution followed by the addition of 50 ml water and 5 ml of 2*M* HCl. The solution was diluted to 100 ml with deionized distilled water.

Arsenic(V) standard solution (1000 $\mu$g/ml) was prepared by dissolving 0.4179 g of $Na_2HAsO_4 . 7H_2O$ (AnalaR, BDH, Poole, U.K.) in 100 ml deionized distilled water, and was standardized against As(III) standard solution by conventional aspiration into the plasma.

Lead(II) standard solution (1000 $\mu$g/ml) was prepared by dissolving 0.1000 g granular lead (analytical grade, The Third Chemical Factory, Tianjin, China) in nitric acid and was diluted in 100 ml with deionized distilled water.

Sodium tetrahydroborate(III) solution (2.5% m/V) was prepared daily from powder (Merck) by dissolution in 0.2% m/V sodium hydroxide solution and filtered through a filter paper before use.

Nitroso R salt solution (1.6% m/V) was made by dissolution of the reagent (Analytical grade, Beijing Chemical Factory, Beijing, China) in hot deionized distilled water, the solution was cooled to room temperature before use.

Potassium ferricyanide (5% m/V) was made by dissolving 10 g of the salt (Analytical grade, Cuihau Chemical Co., Shanghai, China) in 200 ml deionized distilled water and was kept in a brown bottle.

All other reagents used are analytical grade or better.

*Operating parameters, Plasma-Spec*

Operating conditions for the Plasma Spec were as follows: coolant flow rate, 14 l. Ar/min; carrier gas, 0.6 l Ar/min (optimized); applied powder (measured as oscillator current), 0.52 A ($\approx$1.1 kW); viewing height was aligned on the zone where the best signal to background ratio for lead is obtained. Wavelengths for the determinations were: Pb 220.35 nm, As 234.98 nm (except where stated). Sample flow rate, 1.5 ml/min; $NaBH_4$ flow rate, 0.9 ml/min; $K_3Fe(CN)_6$ flow rate, 0.6 ml/min. Integration tine: 3 sec.

## RESULTS AND DISCUSSION

The sample introduction system of the Leeman Labs Plasma-Spec was equipped with a dual platinum grid nebulizer, which was used for on-line hydride generation by Watling and Collier.[18] Using this device, the spent solution, together with the hydride and by-product gas, was aspirated into the plasma. This created problems for the present work. When nitroso R salt was used as reagent, the introduction of aerosol containing the organic compound into the torch caused the deposition of carbon particles at the tip of the torch injector, which resulted in deterioration of the plasma stability. Therefore, the dual platinum grid nebulizer was simply replaced by a rubber septum with two inlet ports, as described in the Experimental section. With this arrangement, the spray chamber acted as a gas–liquid separator with a large dead volume. Although it is evident that the continuous hydride generation–separation system would be significantly improved by the use of a gas–liquid separator, this device allows rapid conversion of the sample introduction mode from conventional solution nebulization to hydride generation and vice versa.

According to the manual, the spectrometer can undertake a search for the best zone in which to view the plasma. For multi-element analysis by solution nebulization, the manufacturer recommends that the optimal viewing zone be aligned on the area where the most intense signal from nickel is obtained. For the present study, however, since lead and arsenic were the only analytes, the alignment was performed during simultaneous generation of plumbane and arsine. Thus, the viewing zone must be aligned on either lead or arsenic. Tests indicated that the viewing zone for lead was a better compromise condition with respect to signal-to-noise characteristics.

*Hydrochloric acid–nitroso R salt system*

The hydrochloric acid–nitroso R salt system was first chosen as a reaction medium for the simultaneous generation of arsine and plumbane because no oxidizing reagent existed in the system. In the tests, nitroso R salt solution was directly added to the acidic sample solution, and the pump line for $K_3Fe(CN)_6$ solution in the manifold (Fig. 1) was omitted. Figure 2 shows the influence of the nitroso R salt on the arsenic and lead signal. With the increase of the reagent concentration up to 1.0% m/V, the final concentration in the test solution, the lead signal increased steadily while the arsenic signal was not affected. After an initial sharp rise between 0 and 0.4% m/V, the lead signal climbs relatively slowly. Further

increase of the reagent beyond 1.4% was restricted by its solubility (approximately 1.5% m/V). Considering both sensitivity and the expense of the reagent, 1% m/V nitroso R salt was chosen for the following study.

Figure 3 shows the effect of acidity on the signal. As can be seen, the lead signal reached a maximum at the HCl concentration of 0.3 mol/l, beyond which it decreased. The optimum acid concentration for plumbane formation was also suitable for arsine formation, since the change in arsenic signal was small after the acid concentration exceeded 0.2*M*. Tests also revealed that changing the length of the reaction tubing in the range of 10–35 cm and changing the $NaBH_4$ concentration over the range of 2–6% m/V had no significant effect on either arsenic or lead signals.

The reagents used for prereduction of As(V) to As(III) were examined to determine whether they had any harmful impact on plumbane generation. Anderson *et al.* reported that reduction of As(V) to As(III) by potassium iodide was incomplete if the acid concentration was less than 0.3 mol/l. Therefore, prereduction of As(V) was carried out in 3 ml of 2*M* HCl, into which 0.25 g KI (or 0.25 g KI plus 0.25 g ascorbic acid) had been added, for 1 hr. The solution containing both Pb(II) and prereduced As(V) was diluted to 25 ml with a solution of 1.2% m/V nitroso R salt for the following hydride generation. The influence of prereducing reagents on the signals from lead, As(III) and As(V) are summarized in Table 1. Thus, without any prereducing reagent, As(V) could not produce the same signal as did As(III). When KI was used, both As(V) and As(III) produced almost the same signal while the lead signal did not change. If the test solution, which had been diluted with nitroso R salt to the acidity required for hydride generation, stood for 1 hr, no change was observed in either the lead or the arsenic signals. Introduction of ascorbic acid, which is recommended to eliminate the formation of free iodine, owing to the oxidation of iodide by dissolved oxygen,[9] caused partial depression of the lead signal. Therefore, potassium iodide was selected as the prereducing reagent for the study.

Despite the fact that the nitroso R salt interfered with neither generation of arsine nor prereduction of As(V) to As(III), its enhancing effect on the lead signal was limited, as can been seen in Fig. 2. As a result, the detection limit for lead, defined as three times the standard deviation of the signals from a blank solution, is high (see Table 2). The poor sensitivity for lead in the present system was not a result of arsenic interference, since the lead signal obtained in the presence of arsenic was the same as that in its absence. Zhang *et al.* obtained a satisfactory sensitivity of atomic absorption spectrometric determination of lead by using batch-wise plumbane generation in the medium of HCl–

Table 2. Comparison of detection limits obtained in various reaction media

§Sample flow rate 1.5 ml/min, this work.

nitroso R salt.[14] Thus, the poor sensitivity for lead in the present work was assumed to be related to the continuous flow generation mode that might be kinetically unfavourable for the generation of plumbane in the nitroso R salt medium.

*Hydrochloric acid–potassium ferricyanide system*

When potassium ferricyanide is used, its redox behaviour should be considered. It is a mild oxidant with a standard electrode potential of +0.36 V that is much lower than those of As(V)/As(III) (+0.559 V) and $I_2/I^-$ (+0.5355 V).[19] However, in 1 mol/l. HCl, the formal electrode potential of $K_3Fe(CN)_6$ rises to +0.700 V. Therefore, $K_3Fe(CN)_6$ may be able to oxidize As(III) to As(V) and iodide to iodine in strongly acidic media. This was verified by tests. If $K_3Fe(CN)_6$ was added to the test solution containing Pb(II), As(III) and KI, the arsenic signal steadily decreased as the solution was allowed to stand. Therefore, on-line addition of $K_3Fe(CN)_6$ was adopted for the determinations, which would minimize the contact time between the reagent and the arsenic(III). With the manifold shown in Fig. 1, $K_3Fe(CN)_6$ solution (5% m/V) was mixed on-line with the test solution, resulting in no influence on the As(III) signal, whether KI was added to the test solution or not. Changing the length of the mixing tube from 10 to 80 cm caused no change in either lead and arsenic signals. Therefore, the following tests were made with this manifold.

The influence of $K_3Fe(CN)_6$ concentration on lead and arsenic signals is shown in Fig. 4. From the figure, one can see that $K_3Fe(CN)_6$ greatly enhanced the lead signal while having no impact on the arsenic signal. It should be noted that the lead concentration used in this work was 0.5 μg/ml compared with 1 μg/ml lead used when nitroso R salt was investigated. Moreover, in a wide range of $K_3Fe(CN)_6$ concentration (1.25–10% m/V), both lead and arsenic signals remained constant. Therefore, it is an ideal reagent for simultaneous generation of plumbane and arsine. Figures 5 and 6 show the influence of HCl concentration and that of $NaBH_4$ concentration, respectively. From these figures, one can concluded that 0.3 mol/l. HCl, 2% m/V $NaBH_4$ and 5% m/V $K_3Fe(CN)_6$ are the best compromise conditions for the determination of arsenic and lead.

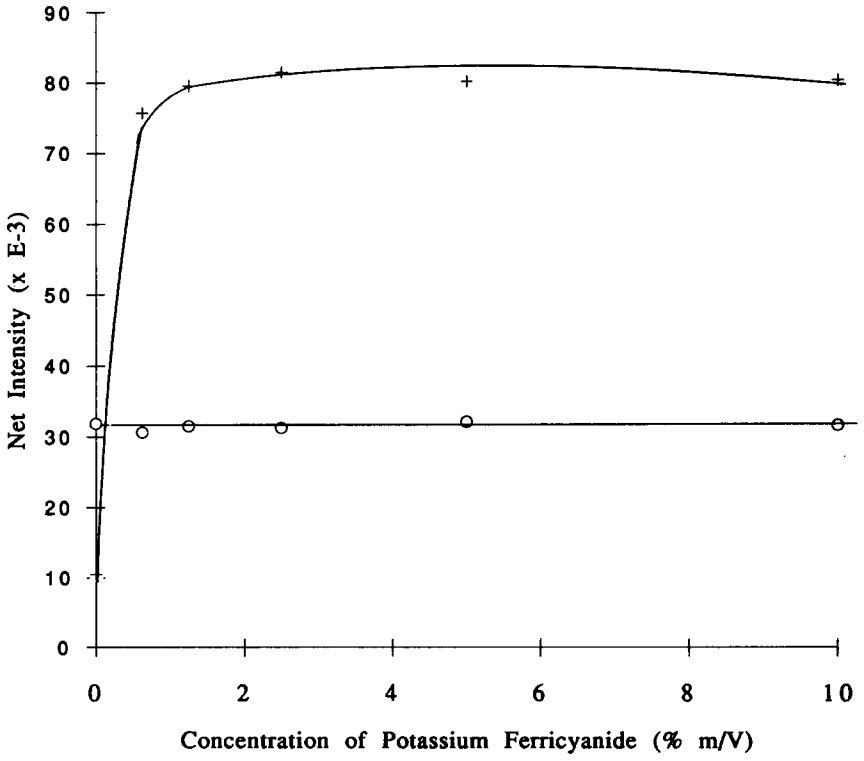

Fig. 4. Influence of $K_3Fe(CN)_6$ concentration on arsenic and lead signals. 0.5 μg/ml Pb (+) and 0.5 μg/ml As(III) (○) in 0.30*M* HCl. 2% m/V $NaBH_4$ as reductant.

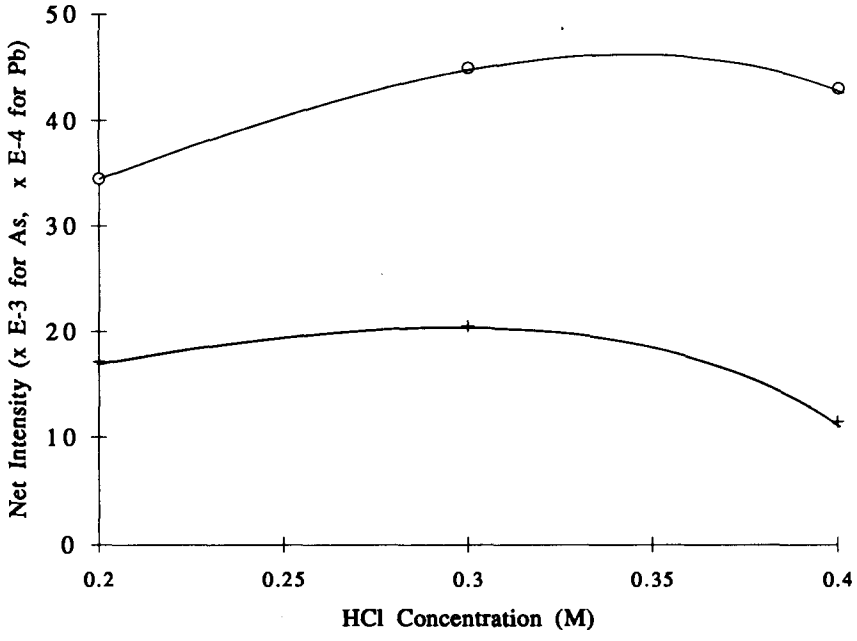

Fig. 5. Influence of HCl concentration on arsenic and lead signals in the HCl–$K_3Fe(CN)_6$ system. 1 μg/ml Pb (+) and 0.5 μg/ml As(III) (○) in 5% m/V $K_3Fe(CN)_6$. 2% m/V $NaBH_4$ as reductant.

Prereduction of As(V) to As(III) was carried out in the same way as with the nitroso R salt system. After prereduction, the test solution was diluted with deionized water to volume, and pumped to mix with $K_3Fe(CN)_6$ solution for hydride generation. The data listed in Table 3 show the influence of the relevant reagents on signals. Ascorbic acid could not be used because it severely inhibited the lead signal. When 1.3% m/V KI was used alone, As(V) could be

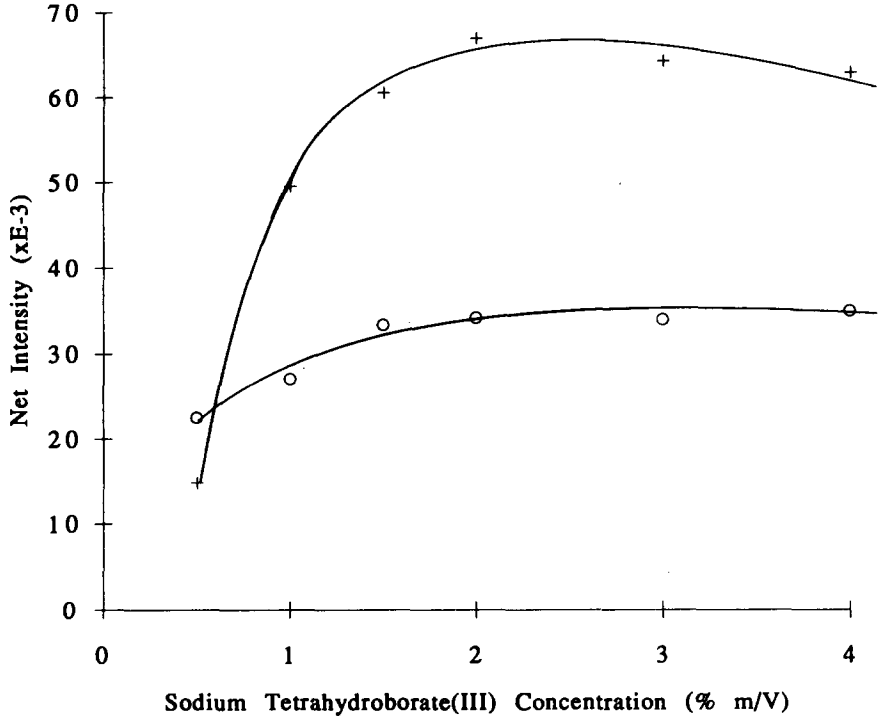

Fig. 6. Influence of $NaBH_4$ concentration on arsenic and lead signals. 0.5 μg/ml Pb (+) and 0.5 μg/ml As (III) (○) in 0.3*M* HCl, mixed on-line with 5% m/V $K_3Fe(CN)_6$.

Table 3. The influence of reagents on the signals* of Pb(II), As(III) and As(V) in $HCl$–$K_3Fe(CN)_6$ medium

| Reagent concentration | | | Relative signals | | |
|---|---|---|---|---|---|
| $K_3Fe(CN)_6$ | KI | Ascorbic acid | Pb(II) | As(III) | As(V)/As(III) |
| 5.0 | 0 | 0 | 1.00 | 1.00 | 0.11 |
| 5.0 | 1.3 | 0 | 1.00 | 0.99 | 0.96 |
| 5.0 | 1.3 | 1.3 | 0.31 | 1.05 | 1.00 |

*0.5 μg/ml Pb(II) and 0.5 μg/ml As(III) [or 0.5 μg/ml As(V)] made 0.3*M* in HCl.

completely reduced to As(III), while the lead signal was not affected. Hence, the $HCl$–$K_3Fe(CN)_6$ system, coupled with KI for prereduction of As(V), is an ideal reaction medium for the simultaneous generation of arsine and plumbane.

The detection limits obtained in the $K_3Fe(CN)_6$ system are listed in Table 2. For comparison, we have compared values for the detection limit, obtained by other groups, in various reaction media. Thus, the detection limits for arsenic and lead obtained in the $K_3Fe(CN)_6$ system are comparable, not only to those obtained in multi-element determination,[1,4] but also to that obtained in determination of lead alone.[20] Since it is well know that faster sample uptake rate usually results in higher sensitivity, it may be possible to improve further the detection limits of the $HCl$–$K_3Fe(CN)_6$ system if a higher sample uptake rate in conjunction with a higher input power for ICP source is applied.

## CONCLUSION

Arsenic and lead can be simultaneously reduced to the hydrides in hydrochloric acid–nitroso R salt and hydrochloric acid–potassium ferricyanide media by means of sodium tetrahydroborate(III) reduction. The latter is preferable owing to the fact that lower detection limits for both arsenic and lead can be obtained by inductively coupled plasma-atomic emission spectrometry in combination with hydride generation. It is well known that hydride generation, especially plumbane generation, is subject to interferences from transition metals and hydride forming elements. Further work on developing an understanding of these interferences occurring in the recommended media and on the way to eliminate these interferences will be necessary before the technique can be applied to analyze real samples with complex matrices. It is very likely that better detection limits would be obtained if a superior gas–liquid separator were used, or, as a reviewer has suggested, an axially viewed ICP system.

# APPLICATION OF ANALYSES ON THE BASIS OF CHARACTERISTIC MASS: DETERMINATIONS OF INDIUM, SILVER AND THALLIUM IN DRAINAGE SEDIMENT AND GEOCHEMICAL SAMPLES

YANSHENG ZHENG* and YUQI WANG

Department of Chemistry, Jilin University, Changchun 130023, China

(*Received* 23 *March* 1994. *Revised* 24 *August* 1994. *Accepted* 31 *August* 1994)

**Summary**—When Pd and EDTA ammonium salt are used as a common matrix modifier, the establishment of a common furnace programme for the determinations of indium, silver and thallium would greatly simplify routine analysis. The continuous determination of indium, silver and thallium by the analyses on the basis of characteristic mass and the graphite furnace with the V-shaped boat is described. The possibility of the proposed method for application to continuous determination of indium, silver and thallium in real sample is discussed. The continuous determination of indium, silver and thallium in drainage sediment and geochemical samples by the analyses on the basis of characteristic mass is carried out and the results of sample analyses are in good agreement with the expected values.

Theoretical characteristic masses $m_0$ (cal) were calculated and compared with experimental values $m_0$ (exp) by L'vov *et al.*[1,2] for 32 elements measured under STPF conditions, the mean value of $m_0$ (cal)/$m_0$ (exp) was found to be 0.85 with a SD of 0.10. For the other elements vaporized from the furnace wall or the platform $m_0$ (cal)/$m_0$ (exp) deviated from the ideal value of 1 by a factor of 2–10. The discrepancies may be accounted for by the formation of thermostable gaseous carbides and monocyanides or partial ionization of the atoms. Baxter and Frech[3] have pointed out that temperature gradients over the length of tube may be a limiting factor for absolute analysis by GFAAS. They[4] defined $m_0$ (cal)/$m_0$ (exp) as the calculated atomization efficiency and studied the temperature dependence of calculated atomization efficiencies of some elements in a two-step atomizer, and showed that the calculated atomization efficiency for most elements reaches a plateau, often in the higher temperature region.

There are only a few reports about the absolute analysis applying to the determination of an element in a real sample. Slavin *et al.*[5] reported the possibility of standardless analysis applied to determinations of the elements in real samples. They showed that the stabilized temperature platform furnace (STPF) equipped with Zeeman background correction satisfied the requirements for standardless analysis in GFAAS, and this method was based on the stability of characteristic mass. As the characteristic masses must be determined using standard solutions, the method of Slavin *et al.* is not quite a standardless analysis. However, the analysis on the basis of characteristic mass is simpler and more convenient than applying a calibration curve and the method of Slavin *et al.* accelerates the development of absolute analysis. Recently, Zheng *et al.*[6–8] and Ma *et al.*[9,10] reported the determinations of Ag, Cd, Cr and In in real samples with analyses on the basis of characteristic mass. At the same time, Zheng *et al.*[6] showed that it was an important condition to use a matrix modifier to eliminate interferences for application of analysis on the basis of characteristic mass in real sample. Shan *et al.*[11–13] have reported that the addition of some metal salts result in improved sensitivity for the determinations of indium and thallium, and they found Pd to be the best matrix modifier. Moreover, when ammonium salt of EDTA was used as a matrix modifier, the interference of perchloric acid, which was used for decomposition of sample, was suppressed completely.[14]

In graphite furnace atomic absorption spectrometry, the establishment of a common

*Author to whom correspondence should be addressed.

furnace programme suitable for most elements would greatly simplify operating procedure and reduce test time. Welz *et al.*[15–17] reported use of $Pd(NO_3)_2$–$Mg(NO_3)_2$ as matrix modifier and a uniform furnace programme for determinations of some elements in real samples. Berglund *et al.*[18] have studied the feasibility of using a single set of atomizer conditions for a suite of elements covering a wide range of volatilities using a platform-equipped, integrated-contact furnace and a palladium modifier. Moreover, Harnly *et al.*[19,20] pointed out that simultaneous multielement furnace conditions were accomplished using compromise atomization parameters in multielement GFAAS.

This work aims to establish a common furnace programme suitable for the determinations of indium, silver and thallium. The feasibility of the continuous determination of indium, silver and thallium in real sample using analysis on the basis of characteristic mass is discussed. The proposed method was applied to the continuous determination of indium, silver and thallium in drainage sediment and geochemical samples and satisfactory results were obtained.

## EXPERIMENTAL

### *Apparatus*

A Hitachi 180-50 atomic absorption spectrometer with a GA-3 graphite furnace and a XWT-164 (made in China) strip chart recorder was used. Pyrocoated graphite tubes (made in China) and a V-shaped boat (made in our laboratory)[21] were used. The spectral band width was 1.3 nm. Hollow cathode lamps (made in China) of Ag, In and Tl were used as a light source and operated at 7.5, 7.0 and 6.0 mA, respectively. A deuterium arc background system was used throughout. $N_2$ was used as the purge gas at a flow rate of 150 ml/min and the purge gas was stopped at atomization step. The 328.1, 303.9 and 276.8 nm lines of Ag, In and Tl respectively, were employed for all measurements and read out as peak area, respectively. Sample solution was injected into graphite tube with a 20$\mu$l Eppendorf micropipette. The temperature of the furnace was corrected with a MT-2 optical pyrometer (made in China). The common graphite furnace operating parameters for indium, silver and thallium were: drying 80–120°C, 30 sec; ashing 500°C, 30 sec; atomization 2200°C, 7 sec; cleaning 2600°C, 3 sec.

### *Reagents*

Stock solutions (1 mg/ml) of indium, silver and thallium were prepared by dissolving a suitable amount of metal indium (S.P. grade), $AgNO_3$ (analytical reagent grade) and $Tl_2(SO_4)_3$ (analytical reagent grade) in water obtained from a quartz flask in a sub-boiling still, with metal indium in 10 ml of 6 mol/dm$^3$ nitric acid. It was boiled to expel nitrogen oxide and diluted with sub-boiling distilled water. Working solutions were prepared by appropriate dilution with sub-boiling distilled water.

A 5% (w/v) solution of EDTA ammonium salt was prepared by dissolving 5.00 g EDTA (analytical reagent grade) in sub-boiling distilled water and added 15 ml of 25% aqueous ammonia (analytical reagent grade) to dilute to 100 ml with sub-boiling distilled water.

A solution of palladium (10 mg/ml) was prepared by dissolving a suitable amount of $PdCl_2$ (analytical reagent grade) in concentrated nitric acid, with the addition of several drops of concentrated hydrochloric acid, and diluting with sub-boiling water.

### *Procedures and sample decompositions*

In each case the blank signal was subtracted from the experimental result. The peak area absorbance values of each measurement were the mean of five measurements. The experimental values of characteristic mass were calculated from the average value of peak area absorbance obtained from the aqueous standard solution of the determined element using the formula

$$m_o = (0.0044/A_i)m_a, \qquad (1)$$

where $A_i$ is the average peak area absorbance, and $m_a$ is the mass of analyte in picograms for a particular element. The experimental values of $m_o$ for indium, silver and thallium determined under the operating conditions of the common furnace programme above are listed in the footnote of Table 1.

Standard drainage sediment and geochemical reference samples (made in China) were used in this study. A weighed amount of sample was transferred into a polyfluorotetraethylene crucible, usually 0.1–0.2 g, and 5, 3 and 5 ml of 67% $HNO_3$, 72% $HClO_4$ and 35% HF, respectively were carefully added. The mixture was then heated on a sand bath until it was nearly dry. The residue was dissolved in 0.02*M* solution of nitric acid, and 0.5 ml of 5% (w/v) EDTA ammonium salt and 1.25 mg Pd as a

matrix modifier were added. The solution was made up to the final volume of 25 ml, and the continuous determination of indium, silver and thallium under the operating conditions of the common furnace programme above by GFAAS with the V-shaped boat was carried out.

## RESULTS AND DISCUSSION

### *Establishment of a common furnace programme*

It is an important task to establish a common furnace programme suitable for determining indium, silver and thallium. It is reported[21] that the characteristic masses of some elements in a furnace with a V-shaped boat were lower than that in a furnace with a platform. Palladium is the best matrix modifier for determinations of indium and thallium and EDTA ammonium salt can completely suppress the effect of perchloric acid.[11–14] The experimental results show that use of 50 μg/ml Pd and 2% (v/v) EDTA ammonium salt as a common matrix modifier for determination of indium, silver and thallium was the best choices. Ashing temperature tests for indium, silver and thallium in the presence of Pd and EDTA ammonium salt were carried out. The experimental results show that the highest allowable ashing temperatures of thallium, silver and indium were 500°, 700° and 900°C, respectively. In order to prevent loss of thallium at the ashing step, a common ashing temperature for the continuous determination of indium, silver and thallium was chose to be 500°C.

It was reported[22] that the experimental values of characteristic mass of indium and silver were stable in the ranges of 2200–2400° and 1600–2500°C, respectively. Moreover, the experimental results of atomization temperature show that in the range of 1600–2300°C, not only the experimental value of characteristic mass for thallium was stable, but also its calculated atomization efficiency value [$m_0$ (cal)/$m_0$ (exp)] was close to 100%. The detailed results will be given separately. It must be emphasized that the establishment of a common atomization temperature did not have a negative effect on sensitivity and is regarded as greatly facilitating routine analysis. The calculated atomization efficiency values of indium, silver and thallium at 2200°C were larger than 80% on the basis of the above tests. Therefore, a common atomization temperature was chosen to 2200°C.

After a lapse of over two years we checked the experimental values of the characteristic mass for indium and silver with aqueous standards of the corresponding element once again. The characteristic mass of silver at 2200°C was 0.67 pg and it was in good agreement with 0.68 pg reported in Ref. 22. However, the characteristic mass of indium at 2200°C was 9.6 pg, slightly larger than 6.5 pg reported in Ref. 22. It must be noted that it is possible that the expected characteristic mass of indium is slightly different from the value previously reported because the amount of Pd and ashing temperature used in this study are different from Ref. 22. As shown in Ref. 6 a frequent check of characteristic mass will be a key to assuring accurate analytical results for the application of analysis on the basis of characteristic mass in a practical sample. Moreover, the experimental value of characteristic mass for thallium has appeared to be basically stable for three months.

### *Interference studies*

It has been shown that the use of a matrix modifier to eliminate interference is a necessary condition for application of analysis on the basis of characteristic mass in a practical sample. In order to examine the applicability of the proposed method of analysis on the basis of

Table 1. Determinations of indium, silver and thallium in samples

Characteristic mass ($m_0$) of Ag, In and Tl was 0.67, 9.6 and 9.4 pg, respectively. *GSD-2 and GSD-8 are drainage sediment samples (China). GSr-3 and GSS-4 are geochemical reference samples (China). †This value is the average values of four separate determinations.

characteristic mass for continuous determination of indium, silver and thallium in a real sample, a series of experiments was undertaken to test the interference effects of a variety of foreign ions. The interference effect of each foreign ion was estimated by reference to the peak area absorbance obtained by the same amount of corresponding analytical element standard. It was found that there were no interferences in the presence of 0.2*M* $HClO_4$ and $HNO_3$, a 1000-fold excess of K, Na, Ca, Cd, Co, Ba, Mg, Ni, Pb, Si, Ze, Al and Fe when Pd and ammonium salt of EDTA was used as a common matrix modifier. It would appear that the Pd–EDTA ammonium salt is the best choice and it can fulfil the above condition.[6]

*Determinations of indium, silver and thallium*

The continuous determination of indium, silver and thallium in the standard drainage sediment and geochemical reference samples by a graphite furnace with V-shaped boat and the use of 50 μg/ml Pd and 2% (v/v) EDTA ammonium salt as a matrix modifier was carried out. The graphite furnace operating conditions and sample decomposition were described in the Experimental section. Analyses on the basis of characteristic mass, *i.e.* the mass of indium, silver and thallium in the sample were calculated from equation (1) on the basis of characteristic mass value of the corresponding element which was determined by use of the aqueous standard and listed in the footnote of Table 1. In order to examine the accuracy of analysis on the basis of characteristic mass, the calibration curve method for indium and silver was also carried out. The analytical results of samples are listed in Table 1. The calibration curve method is a calibration prepared with the aqueous standard of the corresponding element, It indicated that the continuous determination of indium, silver and thallium in the drainage sediment and geochemical reference samples by analyses on the basis of characteristic mass produces satisfactory results. In conclusion, the proposed Pd and EDTA ammonium salt as modifier makes continuous determination of Ag, In and Tl by analyses on the basis of characteristic mass under study possible, not only with a common modifier, but also using a common furnace programme. Our current experiment indicates that the method can simplify operating procedure and reduce time. It is favourable to routine analysis.

(*Received* 5 *May* 1994. *Revised* 24 *August* 1994. *Accepted* 31 *August* 1994)

**Summary**—A rapid, highly selective and simple method has been developed for the quantitative determination of pyro-, tri- and orthophosphates. The method is based on the formation of a solid complex of bis(ethylenediamine)cobalt(III) species with pyrophosphate at pH 4.2–4.3, with triphosphate at pH 2.0–2.1 and with orthophosphate at pH 8.2–8.6. The proposed method for pyro- and triphosphates differs from the available method, which is based on the formation of an adduct with tris(ethylenediamine)cobalt(III) species. The complexes have the composition $[Co(en)_2HP_2O_7]4H_2O$ and $[Co(en)_2H_2P_3O_{10}]2H_2O$, respectively. The precipitation is instantaneous and quantitative under the recommended optimum conditions giving 99.5% gravimetric yield in both cases. There is no interferences from orthophosphate, trimetaphosphate and pyrophosphate species in the triphosphate estimation up to 5% of each component. The efficacy of the method has been established by determining pyrophosphate and triphosphate contents in various matrices. In the case of orthophosphate, the proposed method differs from the available methods such as ammonium phosphomolybdate, vanadophosphomolybdate and quinoline phosphomolybdate, which are based on the formation of a precipitate, followed by either titrimetry or gravimetry. The precipitation is instantaneous and the method is simple. Under the recommended pH and other reaction conditions, gravimetric yields of 99.6–100% are obtainable. The method is applicable to orthophosphoric acid and a variety of phosphate salts.

Of all the condensed phosphates, sodium triphosphate (STP) (also known commercially as sodium tripolyphosphate) and tetrasodium pyrophosphate are of industrial importance. Owing to its extensive use in the manufacture of detergents, anhydrous triphosphate is also of great commercial importance. Because of complexities in controlling the conditions for thermal condensation of orthophosphate to triphosphate, the commercially available anhydrous triphosphate is always contaminated with other phosphates, *viz.* orthophosphate, trimetaphosphate and pyrophosphate.[1]

Chromatographic[2] and infrared spectroscopic techniques[3–5] have been employed for the identification and for the estimation of phosphate compounds. A method based on tris(ethylenediamine)cobalt(III) species forming a solid adduct with pyrophosphate and triphosphate at pH about 6.5 and 3.5, respectively, is widely used for the quantitative estimation of these two compounds gravimetrically.[6] Hexamminecobalt(III) chloride has also been suggested as precipitant for use in the determination of pyrophosphate and triphosphate,[6] but this reagent suffers from nonselectivity when employed to estimate an admixture of pyrophosphate and triphosphate, and is hence not a very valuable reagent. In this paper, a rapid and simple method for the determination of pyrophosphate and triphosphate by forming a coordination complex with aqueous bis(ethylenediamine)cobalt(III) species at pH 4.2–4.3 and 2.0–2.1, respectively, is described. By physicochemical studies, it was found that the solid complexes formed correspond to $[Co(en)_2HP_2O_7]4H_2O$ and $[Co(en)_2H_2P_3O_{10}]2H_2O$, respectively.[7] Gravimetric yields of 99.5% were obtained in the case of pure pyro- and triphosphates.

Various analytical methods for the determination of orthophosphoric acid and phosphate salts have been reported.[8] They include direct titrimetric,[9–11] complexo titrimetric,[12] potentiometric,[13–16] complexo gravimetric,[11,17] colorimetric,[11,18–21] chromatographic[22–27] and atomic absorption spectroscopic techniques.[28] Orthophosphates are also known to form complexes

*Author to whom correspondence should be addressed.

with Co(III), Cr(III), *etc.*, containing other ligands such as ethylenediamine and ammonia. It was found that bis(ethylenediamine)cobalt(III) species also forms complex with orthophosphate anion under specific pH and other reaction conditions. Several phosphato complexes of cobalt(III) of the type $[Co(NH_3)_4PO_4]$, $[Co(NH_3)_5PO_4]$, $[Co(NH_3)_4H_2O \cdot HPO_4]^+$, $[Co(en)_2PO_4]$, $[Co(en)_2H_2O \cdot HPO_4]^+$, $[Co(en)_2OH \cdot HPO_4]$, $[Co(en)_2OH \cdot PO_4]^-$, $[Co(en)_2H_2O \cdot H_2PO_4]^{2+}$ and $[Co(en)_2H_2O \cdot H_3PO_4]^{3+}$ have been reported and characterized. Their hydrolytic properties have also been studied.[29] Although the synthesis of $[Co(en)_2PO_4]$ was reported starting from transdichloro bis(ethylenediamine)cobalt(III) perchlorate,[30] it has not been exploited for the quantitative estimation of orthophosphates.

The above method for the estimation of pyro- and triphosphates is extended for the quantitative estimation of orthophosphate based on the complex formation of orthophosphate anion with acidified solution of (carbonato)-bis(ethylenediamine)cobalt(III) chloride. The precipitation is quantitative between pH 8.2 and 8.6 under the recommended reaction conditions. The solid complex formed corresponds to $[Co(en)_2PO_4]$.[7] The method is also applicable to salts such as $NaH_2PO_4$, $Na_2HPO_4$, $Na_3PO_4$, $(NH_4)_2HPO_4$, $KH_2PO_4$ and other similar salts of orthophosphoric acid. Gravimetric yields of 99.6–100% are obtainable in the case of orthophosphoric acid and its salts. The method was employed for the phosphate estimation of commercial matrices such as tricalcium phosphate, dicalciumphosphate, *etc.* The *cis*- and *trans*-dichlorobis(ethylenediamine)cobalt(III) chloride were also tried as alternative reagents for the quantitative determination of orthophosphate anion. The results were not encouraging.

## EXPERIMENTAL

### *Reagents and instruments*

(Carbonato)bis(ethylenediamine)cobalt(III) chloride was prepared by a known method.[31] It was recrystallized and air-dried. The purity of the compound was checked by chemical analysis. This complex (75 mg) was acidified with 1*M* hydrochloric acid (1 ml) to decompose the carbonate and obtain the aqueous bis(ethylenediamine)cobalt(III) species which was used as the reagent for the precipitation reaction. Tris(ethylenediamine)cobalt(III) chloride was prepared by a known method.[32] It was recrystallized and dried at 110°C before use. A 4% aqueous solution was used for all the experiments. One drop of toluene was added to inhibit mold growth. *cis*- and *trans*-Dichlorobis(ethylenediamine)cobalt(III) chloride were prepared by a known method.[27] These complexes are water soluble and 7% aqueous solutions were used as reagents. Sodium pyrophosphate, analytical reagent tetrasodium pyrophosphate, $Na_4P_2O_7 \cdot 10H_2O$ (Koch-Light, U.K.) was used as a standard pyrophosphate. Sodium triphosphate, from the commercially available anhydrous sodium triphosphate (Ballarpur Industries Ltd, Karwar, India), its hexahydrate was prepared.[34] Sodium trimetaphosphate was prepared by thermal dehydration of $NaH_2PO_4$ under controlled conditions. The condensation polymerization was carried out between 500 and 600°C for about 5 hr, followed by slow cooling.[35] From this product, the monohydrate was prepared by precipitating it from aqueous solution with ethanol at 40°C and then air-dried. Orthophosphoric acid, analytical reagent grade orthophosphoric acid (E. Merck) was used. Orthophosphates, analytical reagent grade $NaH_2PO_4 \cdot 2H_2O$, $Na_2HPO_4$, $Na_3PO_4 \cdot 12H_2O$, $KH_2PO_4$ and $(NH_4)_2HPO_4$ of BDH and Sarabhai chemicals were used. Sodium acid pyrophosphate ($Na_2H_2P_2O_7$) was prepared by a known method[36] by heating $NaH_2PO_4$ to 250°C for 5 hr. It was recrystallized from ethanol. Detergent powders, commercially available spray-dried premier detergent powders of Indian origin were employed.

Model 3B Perkin Elmer double beam electronic spectrophotometer, model 2380 Perkin Elmer atomic absorption spectrophotometer and a model 361 microprocessor pHmeter (Systronics) were used.

### *Procedure*

A known amount of pure tetrasodium pyrophosphate (about 150 mg) in a 100 ml beaker was taken. Distilled water (15 ml) followed by 15 ml of propanol was added, 2–3 ml of bis(ethylenediamine)cobalt(III) reagent was then added and precipitation occurred immediately. The pH of the solution was adjusted to between 4.2 and 4.3 using 1*M* sodium hydroxide and the contents of beaker were stirred for 10–15 min. The precipitate was filtered quantitatively through a G-3 sintered crucible. The filtrate was used for the complete transfer of the precipitate

to the crucible. The precipitate was washed with 1:1 ethanol. It was dried at 110°C for 1 hr and weighed. The same procedure was used for the precipitation of triphosphate except that in this case, the pH was adjusted to between 2.0 and 2.1. In the case of orthophosphate, the reagent requirement was 8 ml and the pH was adjusted to between 8.2 and 8.6. The precipitate was washed with absolute ethanol instead of 1:1 ethanol. Since this complex is hygroscopic, immediately after drying the crucible is kept in a vacuum desiccator and weighed as soon as it attains ambient temperature.

Using the same procedure, *cis*- and *trans*-dichlorobis(ethylenediamine)cobalt(III) chloride were used as precipitating agents for orthophosphates instead of the acidified solution of (carbonato)bis(ethylenediamine)-cobalt(III) chloride. The use of the aquo complex of *trans*-dichlorobis(ethylenediamine)cobalt(III) chloride, obtained by the overnight aquation of the *trans*-dichloro bis(ethylenediamine)cobalt(III) chloride was also attempted.

## RESULTS AND DISCUSSION

The electronic spectra of acidified solution of $[Co(en)_2CO_3]Cl$ and the filtrates of the precipitation experiments showed an absorption maximum at 494 nm. Stoichiometrically for each mole of pyro-, tri- and orthophosphates, one mole of bis(ethylenediamine)cobalt(III) species is required. It was also confirmed by the ratio of Co:P obtained by the analysis of the respective precipitates.

### *Effect of pH*

In a series of beakers, the same amount of pure pyrophosphate (about 150 mg) was taken and the precipitations were carried out at different pH. Similarly, the effect of pH on the precipitation of triphosphate and orthophosphate were also studied. The plots of pH *vs.* mean yield values of pyro-, tri- and orthophosphates are shown in Figs 1–3, respectively. The results indicate that pH 4.2–4.3, 2.0–2.1 and 8.2–8.6 are optimum for the quantitative determination of pyro-, tri- and orthophosphates, respectively, and maximum yields of 99.5–100% are obtainable under these optimum conditions. The advantages of the present method are that it is simple, rapid and more accurate than the available method. The available method requires buffering and seeding for initiation of precipitation and takes 30 min for the precipitation to go to completion in the case of pyro- and triphosphates. However, the addition of a non-aqueous solvent, preferably propanol, is needed in the described method. A few precipitations were carried out by adding excess water during precipitation and without adding propanol before precipitation, to study the effect of dilution and absence of propanol on the quantitative estimations. Precipitations were also carried out using methanol and ethanol instead of propanol. Dilution with water and absence of propanol in the reaction mixture during the precipitation gave lower yields. Although methanol and ethanol could be used, propanol is preferred for the best results. The completeness of the precipitation was confirmed by the absence of phosphate in the mother liquor.

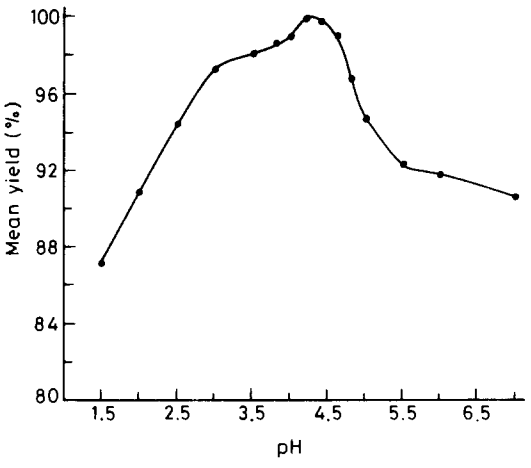

Fig. 1. Effect of pH on the estimation of pyrophosphate.

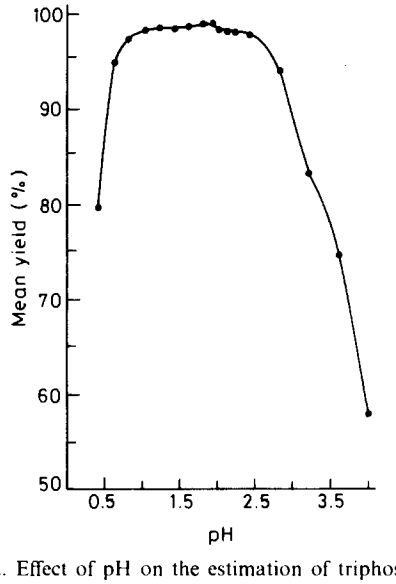

Fig. 2. Effect of pH on the estimation of triphosphate.

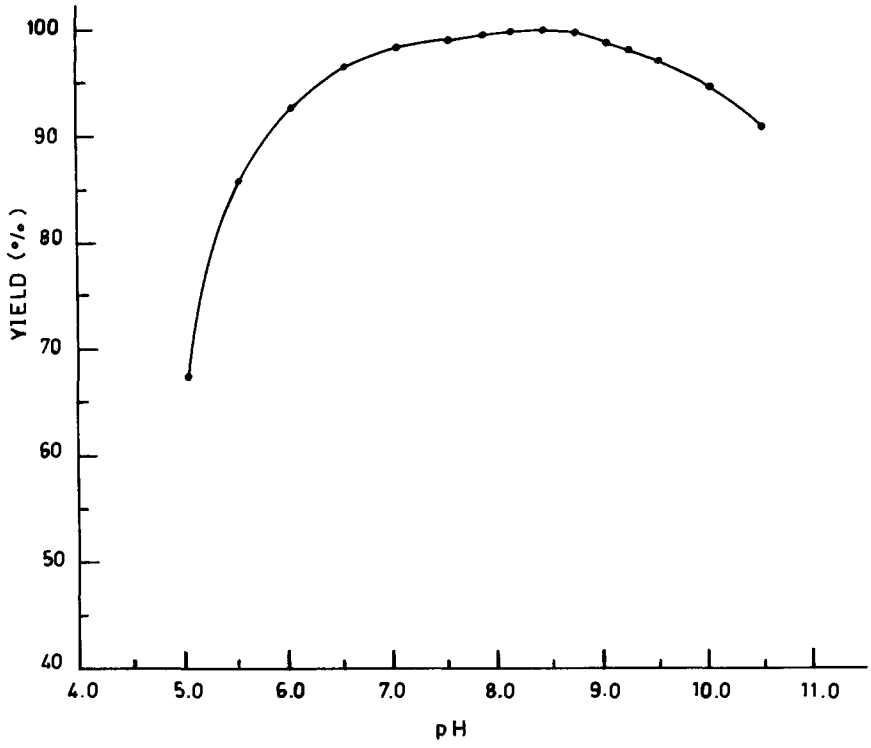

Fig. 3. Effect of pH on the estimation of orthophosphate.

*Determination of excess reagent*

Since the reagent, bis(ethylenediamine)-cobalt(III) is coloured, pyrophosphate and triphosphate were precipitated using a known amount of the reagent and then the excess reagent was measured spectrophotometrically. A calibration curve was made by diluting a known amount of the acidified solution of $[Co(en)_2CO_3]Cl$ and measuring the absorbance. Similarly, the filtrates of pyrophosphate and triphosphate precipitations were collected and diluted to a known volume with water. Absorbances of all these solutions were measured at 494 nm using cells of 1 cm path length. From the calibration curve, the quantity of excess reagent in the filtrate and hence the net amount of the reagent consumed for complexation was determined. From the reagent consumption, condensed phosphate present in a given aliquot was calculated.

The results of the spectrophotometric determination of excess reagent are presented in Table 1. Although the quantity of pyro- and triphosphates could be calculated by determining spectroscopically the quantity of the reagent consumed, the accuracy of the results obtained would depend upon the quantitative collection of filtrate. However, the yield was calculated based on the quantity of precipitate in all further experiments.

*Effect of ortho-, trimeta- and pyrophosphates in triphosphate estimation*

Phosphate solutions of known concentrations were prepared and a known amount of it was added to a known quantity of triphosphate (for fractional volumes, microburette was used) so that the total phosphate in the aliquot was 150 mg. A series of precipitation experiments were carried out using the proposed procedure on binary and quaternary mixtures containing varying amounts of ortho-, trimeta-, pyro- and triphosphates to determine the interference of these components and their effect on the estimation of triphosphate. Similarly, the effect of varying amounts of sodium sulphate in triphosphate estimation was investigated.

The results of interference of ortho-, trimeta- and pyrophosphates in the binary mixtures of each with triphosphate are shown in Tables 2–4. The results indicate that there is no interference up to 10% of orthophosphate in the mixture. However, as noted above, orthophosphate also forms a complex with the new reagent, the precipitation starts at pH 6.5, and it is quantitative between pH 8.2 and 8.6.

Table 1. Determination of tri- and pyrophosphates by excess reagent method

| Sample number | STP/pyrophosphate taken (*mg*) | Reagent added (*mg*) | Reagent in filtrate from absorbance (*mg*) | Reagent consumed for complexation (*mg*) | STP/pyrophosphate found (*mg*) | Deviation (%) |
|---|---|---|---|---|---|---|
| 1 | 150.00 (STP) | 120.00 | 9.00 | 110.00 | 149.00 | −0.66 |
| 2 | 120.00 (STP) | 120.00 | 27.00 | 93.00 | 124.00 | +3.30 |
| 3 | 90.90 (pyro) | 150.00 | 57.00 | 93.00 | 90.10 | −0.88 |
| 4 | 87.20 (pyro) | 150.00 | 58.00 | 92.00 | 89.10 | +2.10 |

Table 2. Effect of orthophosphate in the estimation of triphosphate

| Sample number | Triphosphate taken (*mg*) | Orthophosphate added (*mg*) | In the mixture | | Found* | | |
|---|---|---|---|---|---|---|---|
| | | | Triphosphate (%) | Orthophosphate (%) | I (%) | II (%) | Mean (%) |
| 1 | 150.00 | Nil | 100.0 | Nil | 99.4 | 99.8 | 99.6 |
| 2 | 148.50 | 1.50 | 99.0 | 1.0 | 99.4 | 99.6 | 99.5 |

*Calculated as $[Co(en)_2H_2P_3O_{10}]2H_2O$.

Trimetaphosphate also does not interfere in the precipitation of triphosphate. It is interesting to note that trimetaphosphate does not precipitate as a complex with an acidified solution of bis(ethylenediamine)cobalt(III) species at all pHs. The yields of triphosphate are quantitative, if pyrophosphate present in the mixture is less than 5%. When the pyrophosphate present in the mixture is higher than 5%, owing to the co-precipitation of pyrophosphate complex, the yields were unrealistic, over 100%. This is contrary to the observations made in the literature method, wherein the precipitation is said to be incomplete at increased levels of pyrophosphate.[6]

The results of the studies on the interference of sodium sulphate in triphosphate estimation are presented in Table 5. It was found that sodium sulphate does not interfere up to 10% in the binary mixture with triphosphate.

The results of the determination of triphosphate in the quaternary mixtures containing ortho-, trimeta- and pyrophosphates are presented in Table 6. The results indicate that there is no interference from these up to 5% each of the components in the triphosphate estimation. This study of the multicomponent system was carried out keeping in view the composition of the commercially available sodium triphosphate.

*Accuracy*

The reproducibility of the results by the described method was determined by carrying out five replicate determinations of five different commercial triphosphate samples and a standard sample. Five replicate determinations of triphosphate in all the six samples were also made using the known method.[6] Based on the results, mean and standard deviations have been calculated (Table 7). From the results, it is observed that standard deviations of the present method are lower than those of the available method, showing that more accurate and precise results are obtainable from the present method.

Table 3. Effect of trimetaphosphate in the estimation of triphosphate

| Sample number | Triphosphate taken (*mg*) | Trimetaphosphate added (*mg*) | In the mixture | | Found* | | |
|---|---|---|---|---|---|---|---|
| | | | Triphosphate (%) | Trimetaphosphate (%) | I (%) | II (%) | Mean (%) |

In the case of orthophosphates, the reproducibility of the results by the described method was determined by carrying out six replicate determinations on six samples of analytical reagent grade orthophosphate salts. The mean and standard deviations have been calculated and the results are given in Table 8. It shows that the standard deviations of the present method are low, demonstrating the precision and accuracy of the results obtainable by the described method.

Since the total $PO_4^{3-}$ content present in the aliquot is complexed, it is difficult to distinguish between various types of orthophosphates present in the admixture. However, in the case of a single component pure orthophosphate system, such as $NaH_2PO_4$, $Na_2HPO_4$, *etc.*, it can be distinguished by the weight of the complex, since different orthophosphates contain different weight percentage of $PO_4^{3-}$.

In the case of *trans*-dichlorobis(ethylenediamine)cobalt(III) chloride and also its aquo form as complexing agent, the yields were about 98% for $PO_4^{3-}$ ion. The adjustment of pH was rather difficult owing to the gradual decrease of the pH of the solution with time. The precipitates obtained in these cases were amorphous in nature and the filtration was extremely slow. The same situation was observed in the case of *cis*-dichlorobis(ethylenediamine)cobalt(III) chloride. Hence, these reagents are not suitable for the quantitative estimation of orthophosphates.

Table 6. Effect of ortho-, trimeta- and pyrophosphates in the estimation of triphosphate

| Sample number | Triphosphate taken (*mg*) | Orthophosphate added (*mg*) | Trimetaphosphate added (*mg*) | Pyrophosphate added (*mg*) | In the mixture | | | | Found* mean (%) |

*Standard triphosphate namely $Na_5P_3O_{10}6H_2O$ (77.3% $Na_5P_3O_{10}$).

*Application of the method for pyro-, tri- and orthophosphates in commercial matrices*

*Estimation of triphosphate in commercial samples.* The present method was employed for the estimation of triphosphate samples obtained from four different manufacturers spread over four different countries. The estimations were carried out in replicate using both the present and the reported methods. The results are given in Table 7. There are some differences in the results for the triphosphate content in the samples and they can be accounted for by the variations in the raw materials used and conditions for thermal condensation of orthophosphate during the manufacture of triphosphate by different manufacturers. In all the determinations, the results obtained by the known method[6] are lower than the results obtained by the described method. This is also in agreement with the yield obtainable (98–99.5%) by the reported method.[6]

*Estimation of pyrophosphate.* Under the optimum conditions recommended for the precipitation of pyrophosphate, it was found that the present method gives a yield of 99.5% which is in contrast to a maximum yield of 93% obtainable by the known method. The absence of phosphate in the filtrate in all the precipitation experiments by the present method confirmed the completion of precipitation. Generally, commercial samples of pyrophosphate do not contain triphosphate or any other polyphosphates. However, a series of experiments were conducted to study the effect of triphosphate up to 30%, in the determination of pyrophosphate by the described method (Table 9). It is observed that with up to 5% of triphosphate, the yields were as expected. Furthermore, it was found that in the presence of 10, 20 and 30% of triphosphate, the yields were unrealistic, over 100%. Above 30% of triphosphate, the precipitate was sticky in nature at room temperature, which upon cooling to 10 °C turned solid. The present method was also applied to the determination of pyrophosphate in sodium acidpyrophosphate ($Na_2H_2P_2O_7$) prepared by a standard method.[36] The results were found to be good. The replicate experiments showed the purity to be 99.4–99.8%.

*Determination of triphosphate in commercial detergent powders.* The present method was utilized for the determination of triphosphate in premier detergent powders of Indian origin. Detergent powders, in general, are complex and multicomponent systems. The samples for the analysis were prepared by dissolving the detergent powder in 95% ethanol to remove anionic detergent. The alcohol insoluble phosphates were then dissolved in water and used for the estimation.[1] Determinations were made in triplicate for each sample, employing the known and the described methods (Table 10). It is observed that the results of both the methods are in good agreement.

Table 8. Analysis of orthophosphoric acid and its salts by the present method

| Sample | Purity of sample obtained (in wt%) 1 | 2 | 3 | 4 | 5 | 6 | Mean dev. (%) | Standard dev. (%) |

†The yield could not be accurately determined owing to the sticky nature of the precipitate.

Table 10. Comparison of the present method with the known method for the determination of triphosphate in commercial detergent powders

| Manufacturer's code number | Triphosphate content | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Reported method[6] | | | | This method | | | |
| | I (%) | II (%) | III (%) | Mean (%) | I (%) | II (%) | III (%) | Mean (%) |
| A | 19.9 | 20.9 | 20.1 | 20.3 | 20.6 | 21.3 | 20.2 | 20.7 |
| B | 27.9 | 27.9 | 27.0 | 27.6 | 28.5 | 27.5 | 27.3 | 27.8 |
| C | 16.8 | 18.9 | 18.0 | 17.9 | 18.2 | 16.9 | 17.0 | 17.4 |

*Determination of orthophosphate in commercial matrices.* For this purpose, some commercial tricalcium and dicalcium phosphates were taken. Since these are water insoluble, acid extract of these samples were used for the estimation. It was found that calcium severely interferes. At the optimum pH, precipitation of calcium phosphate occurs preferentially over the precipitation of $[Co(en)_2PO_4]$, resulting in a mixture of both the precipitates. Masking of calcium by EDTA followed by precipitation of the phosphate complex by acidified solution of (carbonato)bis(ethylenediamine)cobalt(III) chloride did not give the desired results.

# ELECTROTHERMAL ATOMIC ABSORPTION SPECTROMETRIC DETERMINATION OF ULTRA-TRACE AMOUNTS OF TIN BY *IN SITU* PRECONCENTRATION IN A GRAPHITE TUBE USING FLOW INJECTION HYDRIDE GENERATION WITH ON-LINE ION-EXCHANGE SEPARATION

GUANHONG TAO* and ZHAOLUN FANG†

Flow Injection Analysis Research Centre, Institute of Applied Ecology, Chinese Academy of Sciences, Box 417, 110015 Shenyang, China

(*Received* 17 *January* 1994. *Revised* 11 *July* 1994. *Accepted* 17 *August* 1994)

**Summary**—A method was developed for the ultra-trace determination of tin by *in situ* preconcentration in a graphite tube using a flow injection hydride generation technique with on-line ion-exchange separation. The sample was prepared in 2*M* hydrochloric acid before being passed through an incorporated micro-column packed with a strongly basic anion-exchanger D-201. The tin was retained as its chlorostannate complex and subsequently eluted by de-ionized water into the hydride generation system. The hydride and hydrogen gases evolved were separated from the liquid phase in a gas–liquid separator and transferred into a palladium-coated graphite tube pre-heated to 300°C to collect the analyte, which was later atomized at 2300°C. With the reported system, tin was determined at a sampling frequency of 30/hr with a detection limit ($3\sigma$) of 0.01 μg/l. using 10.7 ml sample. The precision was 1.5% RSD at the 0.5 μg/l. level. The proposed method was applied to the determination of tin in tap water, hair, serum samples and geological reference samples.

Recently the *in situ* preconcentration of vapour-forming analytes in a graphite furnace following vapour generation reactions has aroused considerable interest as a new technique for ultra-trace analysis using electrothermal atomic absorption spectrometry (ETAAS). Originally developed for the preconcentration of hydride-forming elements, most recently the technique has been extended also to the preconcentration of mercury.[1,2] Several attempts were made to automate the preconcentration procedure under batch or continuous flow configurations to improve the efficiency as well as to decrease human intervention. The latter is helpful in minimizing contamination risks in the ultra-trace determinations. The implementation of flow injection (FI) techniques in the automation of on-line preconcentration systems for atomic absorption spectrometry (AAS) was frequently shown to provide significant advantages over other approaches.[3] This is also true for *in situ* preconcentration with hydride generation. In a recent application of the FI technique to the determination of germanium in environmental samples in our group using *in situ* preconcentration ETAAS,[4] apart from automation of the system and decreases in contamination, the system featured large improvements in the tolerance to interferences, in comparison to batch procedures. Hitherto, FI *in situ* preconcentration has been applied successfully to germanium,[4] arsenic[5] and tin.[6]

The determination of tin in environmental samples is of importance owing to its biological interest.[7–9] Hydride generation AAS is one of the most commonly used methods owing to its high sensitivity and selectivity,[10–15] but the methods suffer strong influences from acidity in the sample matrix.[10–12] Recently, Fang *et al.*[16] described an on-line modification of the acid matrix of sample digest by incorporation of an anion-exchanger column in an FI system prior to the hydride generation reaction. The analyte was initially converted into its chlorostannate complex, retained on an ion-exchange column and subsequently eluted by diluted nitric acid

under strictly controlled conditions. Reproducible conditions for hydride generation reaction were achieved, with 3.5-fold gain in sensitivity.

Although detection limits as low as 0.08 $\mu$g/l. for tin were reported using hydride generation approaches,[16] the sensitivity is often insufficient for the precise determination of tin at ultra-trace levels in some samples, such as natural waters. More recently, *in situ* preconcentration of tin in a graphite furnace by FI hydride generation was used successfully by Zhang *et al.*[6] to improve the performance of ETAAS procedures. A detection limit of 7 ng/l. was achieved with a precision of 3–5% RSD at the 1.0 $\mu$g/l. level. However, no systematic studies on the influence of acidity were given. In order to enhance the sensitivity, 10 ml sample were used, resulting in a long collection (preconcentration) step of 145 sec at 300°C in the graphite furnace programme.

In this work, an attempt was made to apply the FI on-line ion-exchange sample matrix modification technique to the *in situ* preconcentration of tin in a graphite tube to create robust conditions for hydride generation, with the aim of providing a reliable and sensitive method for the determination of tin. The feasibility of this approach was illustrated by its application to the determination of trace amounts of tin in biological samples and geological reference samples.

## EXPERIMENTAL

### *Apparatus*

A Perkin-Elmer Model 2100 atomic absorption spectrometer with a deuterium lamp background corrector was used with a Perkin-Elmer Model HGA-700 graphite furnace. A wavelength of 286.4 nm was used with a spectral band pass of 0.7 nm. A tin hollow cathode lamp was operated at 30 mA. Pyrolytic graphite coated polycrystalline graphite tubes were used with similarly coated L'vov platforms. The graphite furnace temperature programme is given in Table 1. Integrated absorbance (peak area) was used for evaluating the results throughout this work. The analyte absorption peaks were recorded by a PC computer, presented on a high-resolution screen, and printed out using an Epson EX-800 printer.

A Perkin-Elmer Model FIAS-200 system with a 5-port FI-valve was used with the hydride generation accessories.[17] The rotation speed of the two multichannel peristaltic pumps, their stop and go intervals and the actuation of the injector were programmed and automatically controlled by a separate PC computer, independent of the spectrometer. The outlet of the gas-liquid separator, consisting of a 50 cm length of PTFE tubing, was connected to a 5 cm long × 1.5 mm o.d. × 0.5 mm i.d. quartz capillary with a short piece of silicone-rubber tubing. The quartz capillary was loaded on a laboratory-made rotating arm that could be used to swing the tip of the capillary into the sample introduction port of the graphite tube and functioned as a hydride introduction probe during the *in situ* collection (preconcentration) stage.

The ion-exchange column used for separation was made by packing a strongly basic macroporous anion exchanger D-201, 60–100 mesh (Shenyang Organic Chemicals Co.) into a 3 mm i.d. × 30 mm long column whose construction was described previously.[18] The column was connected to the FI-valve via threaded fittings.

Tygon pump tubing was used to deliver all solutions. All reaction coils and connections were made with 0.7 mm i.d. poly(tetrafluoroethylene) (PTFE) tubing. A chemifold plastic connector block (Perkin-Elmer) furnished with W-configuration conduits was used for merging of the reagent and carrier streams.

Plastic containers were used for the samples.

### *Reagents*

A 1000 mg/l. tin stock standard solution was prepared by dissolving the appropriate amount of $SnCl_2 . 2H_2O$ in 2*M* hydrochloric acid. A series of working standard solutions were

Table 1. Furnace programme for *in situ* preconcentration and atomization

| 4. Atomization | 2300 | 0 | 5 | 0 |
| 5. Cleaning | 2650 | 1 | 3 | 300 |

prepared by three-stage dilutions of the stock standard solution with 2*M* HCl.

Ultra-pure reagent grade hydrochloric acid (Beijing Chemical Factory) was further purified by iso-thermal diffusion, as described in the Procedures.

Sodium tetrahydroborate solution (0.1–0.5%, v/v) was prepared using purified $NaBH_4$ (Merck, Schuchardt, Germany) and purified as described under *Reagent purification*. The concentration of sodium hydroxide in the reagent solution was 0.05*M*.

De-ionized water was used throughout. Nitric acid was of ultra-pure reagent grade (Beijing Chemical Factory, Beijing, China). Palladium solution 500 mg/l. was prepared by dissolving 0.166 g of palladium chloride in 10 ml of nitric acid and diluting to 100 ml with de-ionized water. All other chemicals were of analytical, or ultra-pure reagent grade.

*Procedures*

*On line ion-exchange preconcentration.* The FI manifold used for on-line ion-exchange separation hydride generation ETAAS is shown in Fig. 1, together with the optimized operating parameters. The manifold was almost the same as that for hydride generation AAS applications described previously,[16] except the stannane formed (Fig. 1b) was introduced into the graphite furnace for collection instead of the heated quartz tube for atomization. The graphite furnace temperature programme in Table 1 also shows the various stages of operation for the *in situ* collection.

Before each hydride generation and collection cycle, 20 $\mu$l of 500 mg/l. Pd was pipetted into the furnace. Then the furnace programme and FI system were initiated simultaneously. The Pd solution was dried and the furnace was heated to 300°C and held constant at that temperature for 20 sec to complete the pre-treatment. The sample loading procedure of the FI system was performed in parallel with the drying and pyrolysis/pre-treatment steps. In the loading step (Fig. 1a), pump 1 was stopped, and pump 2 actuated to propel the sample in 2*M* hydrochloric acid through the ion-exchange column at 8 ml/min. The chlorostannate complex was sorbed on the column and the effluent emerging from the column was discarded. This step lasted 80 sec which coincided with the drying and pyrolysis/pre-treatment steps of the furnace programme.

At the end of the loading period, which was also the end of the pyrolysis/pre-treatment step, the tip of the quartz capillary probe was inserted through the sample introduction port at the centre of the graphite tube by manually swinging over the arm on which the probe was fixed, and was kept in contact with the graphite platform throughout the collection period. The valve was then actuated automatically, directing the eluent flow into the column. The sorbed chlorostannate complex was eluted by de-ionized water into the hydride generation manifold and merged with the tetrahydroborate reductant solution. The residual acidified sample solution remaining in the column provided the acid conditions for the hydride generation reaction.

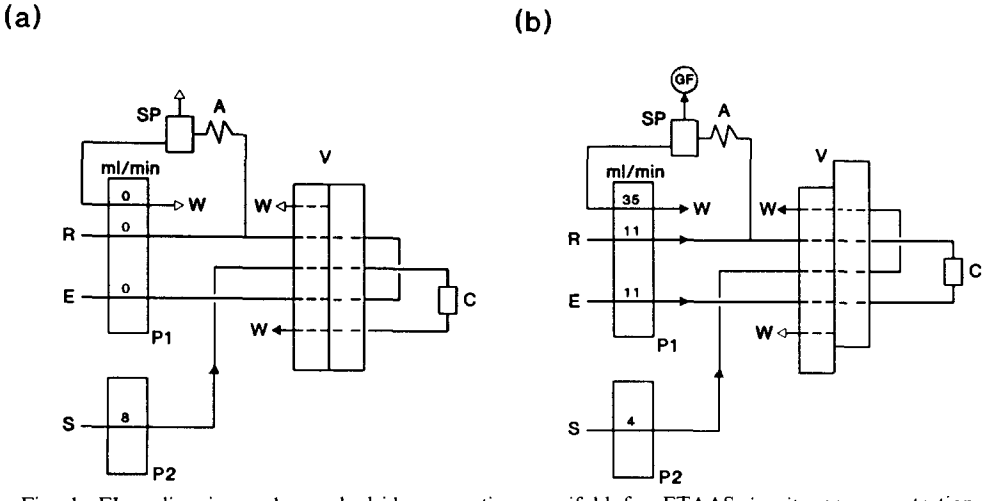

Fig. 1. FI on-line ion-exchange hydride generation manifold for ETAAS *in situ* preconcentration determination of tin: (a) sample loading; and (b) eluting and collecting. (A) Reaction coil; (C) ion-exchange column; (E) de-ionized water; (GF) graphite furnace; (P1,P2) peristaltic pumps; (R) 0.5% $NaBH_4$; (S) sample; (SP) gas–liquid separator; (V) injector valve; (W) waste.

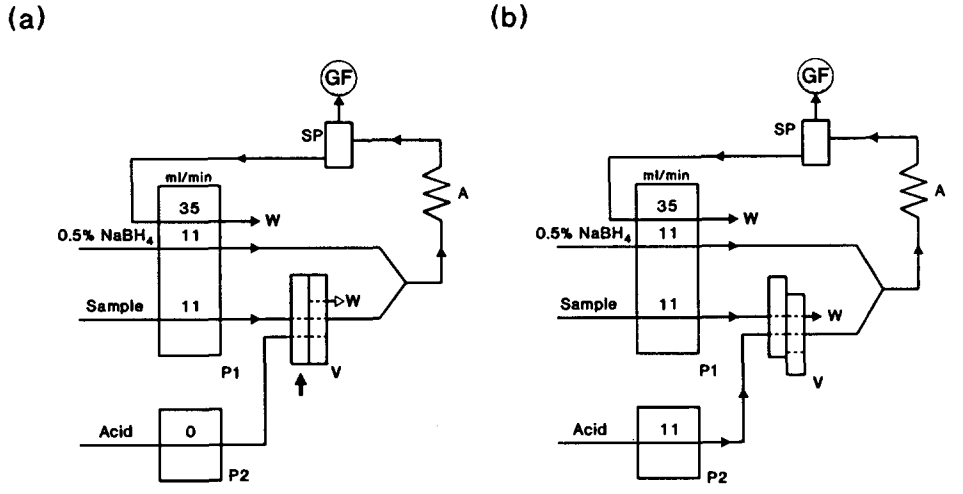

Fig. 2. FI manifold for investigation on effects of the hydride generation media for the *in situ* preconcentration determination of tin: (a) collection; and (b) washing and sample changing. (A) Reaction coil; (GF) graphite furnace; (P1,P2) peristaltic pumps; (SP) gas–liquid separator; (V) injector valve; (W) waste.

After passing through a 30 cm length of reaction coil (A), the gas–liquid mixture was guided into the gas–liquid separator where the waste was pumped out at a flow-rate of 35 ml/min. The stannane generated was separated and transferred by the evolved hydrogen gas into the Pd-coated graphite tube and tin was collected in the furnace following decomposition. The elution procedure was 20 sec. During this stage the next sample was introduced into the uptake line at a reduced rotation speed and ready for the next determination. The FI system was stopped automatically at this point. After an interval of 10 sec for the withdrawal of the quartz capillary probe from the graphite tube, giving a total of 30 sec at the 300°C collection temperature, the graphite furnace was heated to the atomization temperature at 2300°C, using maximum power with interrupted internal argon flow, and the absorbance signals were recorded. Finally, the furnace temperature was increased to 2650°C for 3 sec to clean the furnace.

*Studies on the effects of acidity.* For the studies on the effects of the hydride generation media, the FI manifold shown in Fig. 2 was used. It is very similar to that reported previously[4] for the *in situ* preconcentration determination of germanium. The procedures were also similar to those in the previous system. After the drying and pyrolysis/pre-treatment steps were completed, the tip of the quartz probe was inserted into the graphite furnace and the FI system was actuated immediately. This initiated the collection sequence. The acidified sample was merged with the tetrahydroborate reductant, both propelled by pump P1 at 11 ml/min. The stannane formed was separated and transferred into the Pd-coated graphite tube. After a 30 sec generation (collection) period, the valve was automatically actuated to the washing and sample change position. An acid rinsing solution, propelled by pump 2, was run for 10 sec to expel the residual sample in the reaction coil to the separator in order to prepare the system for the next sample and collect the remaining fraction of stannane evolved from the residual sample after the termination of the sampling period. Meanwhile the next sample was introduced into the sample uptake lines. After the withdrawal of the quartz probe from the graphite tube, the analyte was atomized. The furnace temperature programme was the same as that used in the FI on-line ion-exchange separation hydride generation ETAAS system.

*Reagent purification.* For purification of HCl, 3000 ml HCl were introduced into a 30 cm i.d. desiccator. A 500 ml PTFE beaker containing

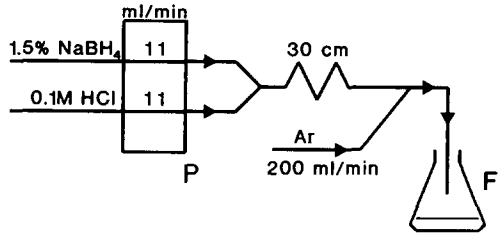

Fig. 3. Schematic diagram for purification of $NaBH_4$. (P) Peristaltic pump; (F) flask.

300 ml de-ionized water was placed on the porcelain shelf of the desiccator. The desiccator was kept sealed at room temperature for 10 days. The final concentration of the purified HCl in the beaker was obtained by titration.

The schematic diagram for the purification of $NaBH_4$ is shown in Fig. 3. The manipulation was conducted in a ventilated hood. Both 1.5% (v/v) $NaBH_4$ solution and 0.1*M* HCl were delivered by a peristaltic pump at flow rates of 11 ml/min. The two solutions merged and reacted in a 30 cm long reaction coil. Analyte contaminant in $NaBH_4$ was transformed to stannane and released from the solution with the aid of an argon stream. The concentration of $NaBH_4$ was about 0.5% after purification.

*Sample pre-treatment.* Geological samples: 0.5 g samples were treated with 5 ml of a nitric acid–hydrofluoric acid mixture (7 + 3 v/v) in PTFE beakers. The vessels were heated on a hot plate at 140°C and gently boiled nearly to dryness. A further 2 ml of acid mixture were added and the solutions were again taken nearly to dryness. After cooling, the digests were diluted to 50 ml. A 1 ml volume was taken and diluted further to 100 ml with 2*M* HCl.

Hair and serum samples: 0.2 g hair or 1 ml serum sample was digested gently in PTFE beakers with 5 ml of a nitric acid–perchloric acid mixture (3 + 1 v/v) on a hot-plate at 140°C until near dryness. A further 1 ml of acid mixture was added and the solution was taken nearly to dryness again. After cooling, the digest was diluted to 50 ml with 2*M* HCl.

Tap water samples were filtered and acidified to 2*M* HCl with concentrated HCl.

## RESULTS AND DISCUSSION

### *Effect of hydride generation reaction medium on* in situ *preconcentration ETAAS signal response for tin*

It has been demonstrated by several authors that the stannane generation efficiency is strongly dependent on the acidity at which the reaction is performed and also on the acid species. Various acidity conditions for the hydride generation determination of tin have been proposed.[10–12,19–21] Thompson and Pahlavanpour[19] observed a distinct maximum of the analytical signal at approximately 0.1*M* HCl. De Doncker *et al.*[11] found that 0.09*M* of $H_2SO_4$ gave optimum sensitivity for the generation of stannane. A mixed reaction medium of 0.4*M* nitric acid and 0.2*M* tartaric acid was used by Legret *et al.*[10] as the optimal condition. By means of radio tracers, Petrick and Krivan[20] showed that the stannane efficiency was close to 100% for 0.5*M* HCl. A model for hydride generation was proposed by Wang and Barnes[21] and they concluded that stannane could be generated only within a critical range in the vicinity of pH 1.0, referring to the final acidity. In the above studies, batch-wise or continuous-flow approaches were used for hydride generation. However recently Fang *et al.*[16] pointed out that influences from acidity were more pronounced in FI approaches than in the batch mode. In their FI application, Welz *et al.*[12] used 0.1*M* HCl in saturated boric acid as reaction medium and observed that sensitivity increased significantly with decreasing HCl concentration in saturated boric acid solution down to 0.1*M* and no reliable signals could be obtained for the concentrations lower than 0.1*M* owing to hydrolysis of tin. In the recent FI hydride generation *in situ* preconcentration application, Zhang *et al.*[6] used 0.5 or 2.0% HCl as the hydride generation medium; but no detailed effects of the acidities and acid species were reported. In their previous work,[13] they reported the efficiency of stannane generation for 0.5% HCl (0.17*M*) was higher than 2.0%.

Therefore, an attempt was made in this work to investigate the effect of hydride generation medium on the sensitivity for the *in situ* preconcentration ETAAS system. Hydrochloric, nitric, and sulphuric acids were studied using the FI manifold shown in Fig. 2. The influence of varying acid concentrations on the signal is shown in Fig. 4. The sensitivity depended strongly on the concentration, but the maximum signals were quite similar for all three

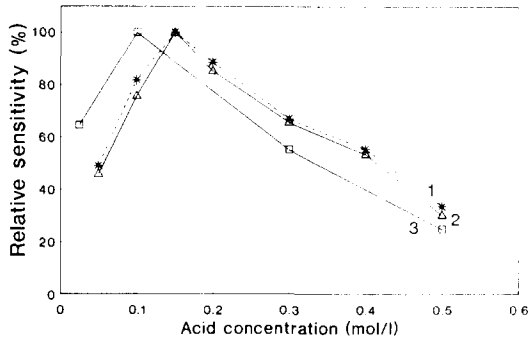

Fig. 4. Effect of acid concentrations on the tin signal expressed in % integrated absorbance, using the manifold shown in Fig. 2 and taking the maximum absorbance as 100% for all the acids studied. (1) Nitric acid; (2) Hydrochloric acid; (3) Sulphuric acid. The concentration of tin was 0.5 μg/l. Other conditions are as shown in Fig. 2.

acids. This observation was quite similar to that reported by Thompson *et al.*[19] and de Doncker *et al.*[11] Although it is not difficult to adjust the sample acidity to 0.15*M* to produce maximum sensitivity, no stable region of influence on sensitivity could be found, which would imply lack of robustness for the method. Therefore, the on-line modification of the acid matrix of sample solutions using an incorporated ion-exchange column proposed by Fang *et al.*[16] was adopted in this work, in order to create more reliable conditions for the hydride generation.

*Optimization of experimental parameters for FI on-line ion-exchange separation* in situ *hydride preconcentration system*

FI hydride generation AAS coupled with on-line ion-exchange separation and preconcentration system has been used successfully in the determination of tin in canned food.[16] The manifold was adapted to the *in situ* preconcentration ETAAS system, resulting in the FI manifold shown in Fig. 1.

In their previous studies,[16] Fang *et al.* used 0.1*M* nitric acid as the eluent and found its concentration very critical for the system's performance. Therefore, a detailed investigation of the acid concentration under different sodium tetrahydroborate concentrations was carried out. The flow-rates for sample, eluent and reductant solutions were adopted mainly based on previously established experimental conditions for FI on-line ion-exchange separation and preconcentration of tin[16] and other hydride-forming elements.[22,23] The results are shown in Fig. 5. The absorbance remained almost constant in the nitric acid concentration range of 0 (de-ionized water)–0.2*M* at all $NaBH_4$ concentrations tested. This phenomenon was different from that reported in Ref. 16 where the peak height absorbances dropped dramatically with an increase in acid concentration from 0 to 0.4*M*. This is because the readouts for the *in situ* preconcentration system were not based on transient signals produced during the hydride generation reaction but on integrated readings from the electrothermal atomization process. The readouts will remain identical as long as the amount of analyte trapped on the tube during the collection period are identical. This is in agreement with the observation of Fang *et al.*[16] that for the transient eluate signals, when the peak height increased with a decrease in acid concentration, the peak width decreased, producing approximately the same peak area. The explanation for the responses using de-ionized water as eluent is that the residual acidified sample solution remaining in the column following sample loading provided the acid conditions for the hydride generation reaction. The sensitivity increased with an increase in tetrahydroborate concentration (Fig. 5). However the reaction became so violent when the concentration was higher than 0.5% that trouble-free gas–liquid separation could no longer be ensured. Since lower reductant concentration also provides reduced blank values. A de-ionized water eluent and 0.5% $NaBH_4$ were used in subsequent studies.

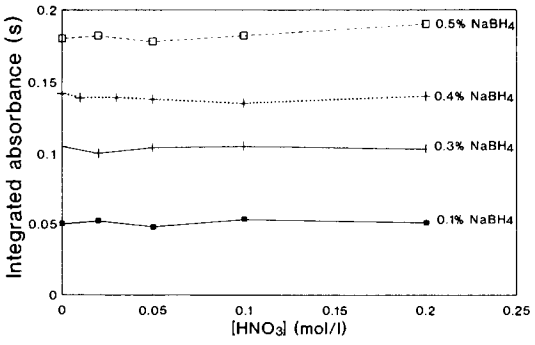

Fig. 5. Effect of nitric acid concentrations on integrated absorbance under different $NaBH_4$ concentrations. The concentration of tin was 0.5 μg/l. Other conditions are as shown in Fig. 1.

In most hydride generation AAS and recently *in situ* preconcentration systems, carrier gases, normally argon, were used to strip and transport the hydrides into the atomizer or graphite tube. However, recent studies by Tao and Fang[4] showed that effects from the carrier gas flow-rate were negligible in the *in situ* preconcentration system. In their system, no carrier gas was used. The hydride was transported into the graphite furnace by the hydrogen generated during the reaction. This produced about 10% higher sensitivity apart from a saving in the argon gas supply. Therefore no argon carrier was used in the present work following this experience. No unfavourable effects were found by doing so. However, no increase in sensitivity was observed either.

The optimum operating conditions for ETAAS are given in Table 1. The catalytic reactivity of palladium was reported to promote low temperature deposition of the hydride by dissociative chemisorption[24–26] and, therefore, palladium was used for coating the furnace tube in the present work. It was found that 20 μl of 500 mg/l. Pd were sufficient for trapping and

stabilizing the collected product on the substrate at a temperature of 300°C. An atomization temperature of 2300°C recommended by the manufacturer for conventional ETAAS,[27] was used in this study.

*Interference studies*

Interferences studies on possible interferents both in the ion-exchange process and in the hydride generation reaction showed considerable high tolerance to a wide range of coexisting ions (Table 2). Cu(II) and Ni(II) were frequently reported to be two of the most significant transition metal interferences in the determination of tin. In their studies,[19] Thompson *et al.* reported that 1 mg/l. Cu(II) and 1 mg/l. Ni(II) could depress responses of tin by 40 and 65%, respectively. In this study, up to 5 mg/l. Cu(II) and 10 mg/l. Ni(II) could be tolerated without any significant adverse effects on the integrated absorbance. Other potential interferents such as Fe(II), Fe(III) did not interfere seriously up to higher levels. Since the stability of the chloro-complexes of these metal ions in 2*M* hydrochloric acid are considerably lower compared to the chlorostannate complex, their introduction into the hydride generation manifold were partially impeded owing to decreased retention on the ion exchanger. The hydride forming elements such as As(III) As (V), Ge(VI) and Se(IV), Se(VI) were also investigated, and neither of these interfered up to at least $2 \times 10^4$-fold excess concentrations. In their FI hydride generation *in situ* preconcentration system,[6] Zhang *et al.* reported that the system could tolerate these hydride forming elements at 200-fold excess. Table 2 also shows that the anions tested exhibit no serious interferences on the determination of tin.

generation *in situ* preconcentration ETAAS system are summarized in Table 3. A sampling frequency of 30/hr was achieved owing to the short hydride collection period (30 sec) made possible by the on-line ion-exchange separation system used. With an 80 sec loading period, corresponding to a consumption of 10.7 ml sample solution, and using the proposed conditions, the detection limit ($3\sigma$) was found to be 0.01 μg/l., which was about a factor of eight better than FI hydride generation with ion-exchange separation without collection in a furnace.[16] The detection limit was also similar to that reported in Ref. 6 (0.007 μg/l.), where an electrodeless discharge lamp was used instead of the hollow cathode lamp used in this study. The favourable reproducibility ensured a low detection limit and showed effective control over the conditions for stannane generation through the ion-exchange matrix modification.

Although several purification measures were taken, the high tin blank still remained to be the main obstacle for further improving the detection limit. Iso-thermal diffusion has shown to be an effective method for the purification of HCl. However, it was difficult to purify $NaBH_4$ although several other methods, including filtration,[14] and $BaSO_4$ co-precipitation[28] were tested. Smith[29] and Castillo[14] ascribed the high blank to the contamination of $NaBH_4$ which is usually packed in a plastic bag inside a tin container. Detailed investigations on further reducing tin blank values in $NaBH_4$ are underway.

The characteristic mass of the present method was compared with that of the conventional ETAAS method to evaluate the overall collection efficiency of the ion-exchange separation, hydride generation and *in situ* preconcentration procedures, taking the efficiency of conventional ETAAS as 100%. The overall collection efficiency was 59% since the ion-exchanger could retain only 61% of the analyte (Table 3). The deposition efficiency (overall collection efficiency/retention efficiency) was 96%, which implied complete stannane generation and hydride deposition on the platform. To assess the accuracy of the proposed method, geochemical reference samples were analyzed. The results shown in Table 4 are in good agreement with the recommended values. Determination of tin in tap water, serum and hair samples were also satisfactory (Table 5).

## CONCLUSIONS

The combination of on-line ion-exchange separation with FI hydride generation *in situ* preconcentration was shown to be capable of producing an efficient system for ultra-trace analysis of tin in waters and biological samples. The on-line sample matrix modification technique improved the selectivity and robustness of the method, and significantly reduced the hydride collection time, resulting in higher sample throughput. The detection limit of the system might be further improved by using a tin electrodeless discharge lamp and purer reagents.

*Acknowledgements*—The authors are grateful to Bodenseewerk Perkin-Elmer, Überlingen, Germany, for partial financial support and for the loan of AAS and FI equipment, to Shenyang Organic Chemicals Co. for donating the ion-exchanger.

# AMPEROMETRIC DETECTION FOR CAPILLARY FLOW INJECTION ANALYSIS

JOSEPH WANG* and LIANG CHEN

Department of Chemistry and Biochemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 9 *September* 1994. *Revised* 11 *September* 1994. *Accepted* 11 *September* 1994)

**Summary**—Ultrasmall-volume measurements of oxidizable compounds have been accomplished by coupling a capillary flow injection system with amperometric detection. Remarkably low (femtomole) mass detection limits result from the combination of nanoliter sample volume and the inherent sensitivity of the wall-jet detector. A substantial economy of reagent consumption and disposal accrues from the operation of the nl/min flow regime. Variables influencing the physical dispersion in the capillary flow injection system, including capillary length, sample volume or flow rate, are explored and optimized.

Flow injection analysis (FIA) has proved highly useful in practical applications in fields as varied as environmental monitoring, process analytical chemistry or clinical diagnostics.[1–3] The technique offers distinct advantages in versatility, reproducibility, and sample throughput over conventional (wet-chemistry) methods. Typical sample volumes and flow rates are of the order of 20–50 $\mu$l and 0.5–2.0 ml/min, respectively. Yet, substantial reduction in the carrier consumption and sample volume are highly desired for addressing environmental concerns on reagent/waste disposal or the growing needs for assays of ultrasmall (nanoliter) biological samples. One approach to reduce the flow rate and sample size is to employ miniaturized FIA systems, such as those based on integrated microconduits[4] or micromachined silicon structures.[5] Another promising avenue for ultraflow-volume FIA is to replace the traditional Teflon interconnecting tubing with fused-silica capillary tubes. Liu and Dasgupta[6] reported on a capillary FIA system with calorimetric detection and electroosmotic pumping. Olesik *et al.*[7] employed an infrared-absorption detector for a capillary FIA system with supercritical $CO_2$ as the carrier fluid.

The present note aims at characterizing capillary FIA systems with amperometric detection and elucidating the dispersion phenomena in such systems. Amperometric detection, which has been extremely useful for microscale separations and in other microenvironments,[8] holds great promise for capillary FIA. During the course of this investigation, Matysik and Werner[9] reported on the stripping voltammetric assay of tear samples in connection with capillary FIA. In the following sections we will illustrate how a detailed understanding of the dispersion phenomena and the use of amperometric detection can lead to reliable assays of nanoliter sample volumes, to a million-fold reduction in the flow rate (compared to conventional FIA) and to remarkably low mass detection limits (at the femtomole level).

## EXPERIMENTAL

### *Apparatus*

The capillary FIA system is shown in Fig. 1. It consisted of a sample and carrier reservoirs (D, E), a 52 $\mu$m i.d., 120 cm long, fused-silica capillary (Polymicrotechnologies Inc., F), supported by a glass tube (G), and a large-volume wall-jet detector. Glassy carbon or platinum 2 mm diameter disks (BAS, Models MF-2012 and MF-2013, respectively), placed at a 1 mm distance from the capillary outlet, served as the working electrode (A). The platinum disk was employed in connection with the detection of hydrogen peroxide and hydrazine. The reference electrode (Ag/AgCl, BAS Model RE-1,B) and the platinum wire auxiliary electrode (C) were

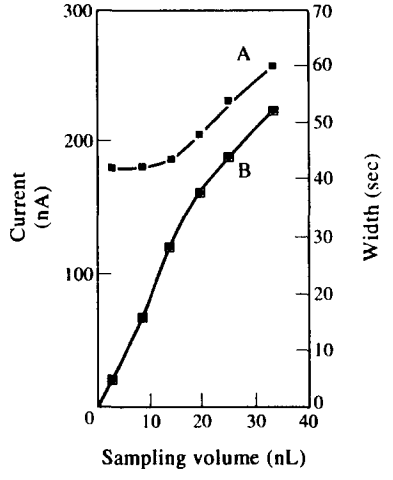

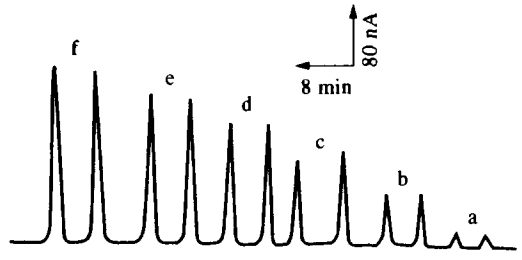

Fig. 2. Capillary-FIA amperometric peaks for different sample volumes: 3(a), 8(b), 14(c), 19(d), 25(e) and 33(f) nl. Analyte, $K_4Fe(CN)_6$ at $1 \times 10^{-3}M$; operating potential, +0.4 V; flow rate, 32 nl/min; capillary length, 120 cm; carrier and electrolyte, 0.05*M* phosphate buffer (pH 7.4). Also shown, the resulting plots of the peak current (B) and width (A) against the volume.

inserted through the cell cover. Amperometric measurements were carried out with an EG&G PAR Model 264A voltammetric analyzer, in conjunction with a Houston Omniscribe strip-chart recorder.

*Reagents*

All chemicals were reagent grade, and solutions were freshly prepared with double-distilled water. Potassium ferrocyanide, hydrazine (Baker), hydrogen peroxide (Aldrich), dopamine and acetaminophen (Sigma) were used without further purification. Phosphate buffer (0.05*M*, pH 7.4) served as the carrier solution.

*Procedure*

Capillary flow injection experiments were performed at room temperature after applying the desired potential and allowing the transient current to decay. The sample introduction was accomplished by switching between the carrier and sample reservoirs under conditions of gravity flow. The sample volume thus varied with the introduction time. Most experiments employed a flow rate of 32 nl/min and a 15 sec sample introduction, *i.e.* a sample volume of 8 nl.

## RESULTS AND DISCUSSION

High-voltage electroosmotic pumping, proposed for capillary FIA with colorimetric detection(6), is not readily compatible with amperometric detection. Gravity flow, in contrast, has been found in the present work to offer a very attractive capillary-FIA/amperometric behavior. Unlike electroosmotic pumping for which flow-induced dispersion is nonexistent[6], the gravity flow induces a significant dispersion of the sample plug. Factors influencing the physical dispersion in capillary FIA systems, and hence the resulting amperometric response, were thus elucidated.

Figure 2 displays flow injection amperometric peaks for different volumes of the ferrocyanide solution, ranging from 3 to 35 nl (a–f). Such volumes are ca. 3 orders of magnitude less than those common in FIA/amperometry. Well-defined peaks are observed inspite of these ultrasmall volumes. The peak current increases rapidly with the volume at first, and then more slowly. Significant dispersion is indicated from

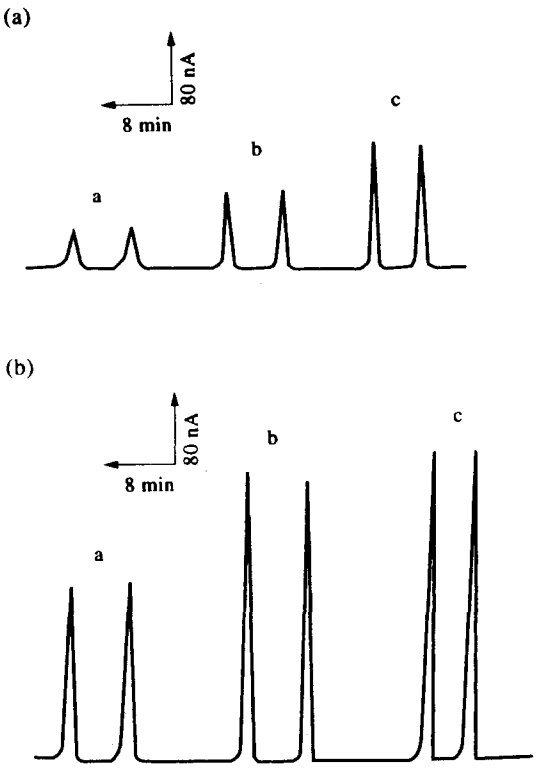

Fig. 3. Effect of capillary length (a) and volume flow rate (b) upon the amperometric response to $1 \times 10^{-3} M$ $K_4Fe(CN)_6$. Sample volume, 8(a) and 22(b) nl; capillary length, 120 (a)a, (b), 95 (a)b and 76 (a)c cm; flow rate, 33 (a), (b)a, 46 (b)b and 66 (b)c nl/min. Other conditions, as in Fig. 2.

the resulting peak widths (43–60 sec). Sample throughputs in the order of 45–75 $hr^{-1}$ can thus be realized. Such frequency, which is similar to that of macro FIA systems, reflects the long residence times of the sample zone. The influence of the capillary length and flow rate is shown in Fig. 3 (a) and (b), respectively. The higher dispersion, expected for longer capillaries, lead to smaller and broader current peaks. Increasing the flow rate not only decreases the dispersion, but also enhances the analyte flux towards the wall-jet detector. The net result is a doubling of the sensitivity between 33 and 66 nl/min. Note that while these flow rates are ca. 5 orders of magnitude lower than those normally employed in FIA/amperometry, the linear flow rate is remarkably high (being inversely proportional to the cross-sectional area of the capillary). The sample plug impinging on the wall-jet detector surface thus leads to remarkable sensitivity despite the ultrasmall volume (22 nl) employed. (Since the jet issuing from the capillary outlet remains intact over larger capillary–electrode separations, there is no apparent advantage to employ an on-capillary detector, a task difficult to implement even with ultramicroelectrodes). Since the wall-jet detector dead volume is effectively the boundary layer, and in the absence of connecting tubing, a detector-induced dispersion is nonexistent. Overall, the influence of the above parameters upon the dispersion of the sample zone is similar to that encountered in conventional FIA systems.

The extremely low flow rates of capillary FIA assure also a highly stable amperometric response. Figure 4(a) displays amperometric

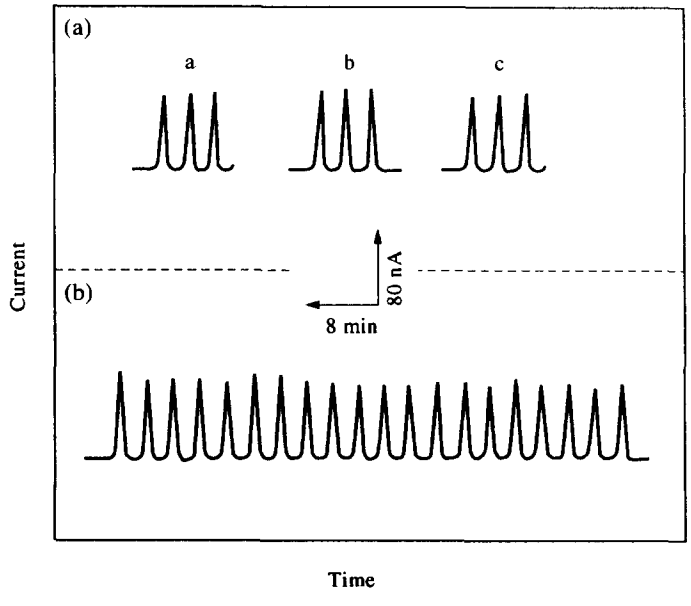

Fig. 4. Flow injection peaks for $1 \times 10^{-3} M$ $K_4Fe(CN)_6$ recorded (a) in 4-day intervals (a, b, c) and (b) during the 10th day of continuous flow. Other conditions, as in Fig. 2(b).

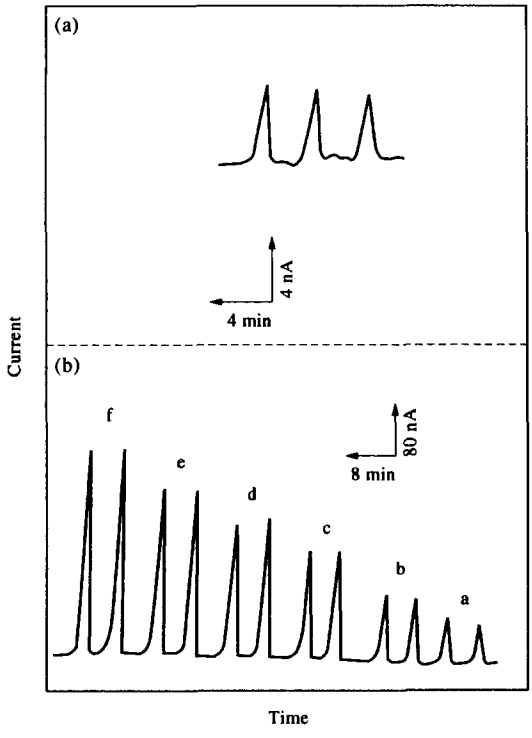

Fig. 5. FIA peaks for $5 \times 10^{-6}M$ hydrogen peroxide (a) and for dopamine solutions of ascending concentration ($2.5 \times 10^{-4}$–$1.25 \times 10^{-3}M$, (b) a–f. Operating potential, +0.75 (a) and +0.70 (b) V. Other conditions, as in Fig. 2(b), except that a platinum working-electrode was used in (a).

peaks recorded during the 1st, 4th and 9th day of a continuous carrier flow. the reproducible response is attributed to the negligible change in the gravity head during this prolonged period. The total volume of the carrier solution consumed during the entire 9 day period corresponds to nearly 500 $\mu$l! Conventional FIA/amperometry, in contrast, would require 20–50 l. over the same period. Also illustrated in Fig. 4(b) is the reproducibility of the data during the 10th day of the operation. This series of 20 successive runs yielded a relative standard deviation of 4.9%.

The coupling of the inherent sensitivity with the ultralow sample volumes of capillary FIA results in remarkably low mass detection limits. Figure 5(a) displays flow injection peaks for an 8 nl sample containing 1.38 pg (i.e. $5 \times 10^{-6}M$) hydrogen peroxide. A detection limit of $2 \times 10^{-6}M$ can be estimated based on the signal-to-noise characteristics ($S/N = 3$) of these readouts. This value corresponds to 540 fg or 16 fmol in the nanoliter sample. Slightly higher detection limits of 0.7, 1.3 and 8.0 pg were estimated from injections of hydrazine, catechol and acetaminophen solutions, respectively. Ordinary FIA/amperometric systems, in contrast, commonly offer detection limits at the low nanogram level. Figure 5(b) illustrates the concentration dependence of the capillary-FIA/amperometric operation. Injections of 8 nl dopamine solutions of increasing concentration ($2.5 \times 10^{-4}$–$1.25 \times 10^{-3}M$, a–f) were used for this purpose. The peak current shows excellent linearity with the injected concentration (slope, 261 nA/m$M$; correlation coefficient, 0.998). Highly linear calibration plots were obtained also for analogous measurements of acetaminophen and ferrocyanide (not shown).

In conclusion, data presented in this article clearly illustrate that the coupling of capillary FIA and amperometric detection provides a powerful analytical tool. The resulting system permits highly sensitive measurements in extremely small sample volume, in connection with ultralow carrier flow rates. The femtomole quantitation is thus coupled with extreme economy in terms of solution consumption. Significantly higher flow rates, at the $\mu$l/min regime, and $\mu$l samples, characterized micromachined FIA systems,[5] as well as the recent capillary-FIA/stripping operation[9]. While the concept is presented in terms of direct amperometry at ordinary electrodes, it could be extended to highly selective amperometric probes based on coverage with biological or chemical recognition layers. For example, the remarkable sensitivity towards hydrogen peroxide holds great promise for many oxidase-based enzymatic assays. Such selective detectors would address the lack of separation power in the FIA system (in comparison with microcolumn separation techniques). There is no fundamental barrier to further downscaling of the FIA/amperometric system to the picoliter sample domain and sub-nl/min flow regime via the use of smaller-diameter capillaries. Such downscaling should push the detection limits even further down to the attomole level. Additional improvements are anticipated by designing more elaborate capillary FIA systems, possessing sample-manipulation and liquid-handling capabilities.

# FLOW INJECTION FLUORIMETRIC DETERMINATION OF THIOUREA

TOMÁS PÉREZ-RUIZ,* CARMEN MARTÍNEZ-LOZANO, VIRGINIA TOMÁS and ROCIO CASAJÚS
Department of Analytical Chemistry, Faculty of Chemistry, University of Murcia, Murcia, Spain

(*Received* 10 *June* 1994. *Revised* 23 *September* 1994. *Accepted* 23 *September* 1994)

**Summary**—A flow injection configuration for the fluorimetric determination of thiourea is proposed. The procedure is based on the rapid oxidation of thiourea by thallium(III) with concomitant formation of fluorescent thallium(I). Linear calibration graphs were obtained between $5 \times 10^{-7}$ and $1 \times 10^{-5} M$, with a sampling rate of 90 samples/hr. The usefulness of the method was tested in the determination of thiourea in fruit juices and fruit peels.

Thiourea(TU) and several TU derivatives have various industrial, agricultural and analytical applications. They are widely used in the rubber industry as accelerators, in photography as fixing agents and to remove stains from negatives, and in agriculture as fungicides, herbicides and rodenticides. The use of an aqueous solution of TU as a leaching agent for gold has been widely reported in the literature. TU is also used as a spectrophotometric reagent for the determination of several metals.[1]

The presence of TU in urine was reported to be a non-specific indicator of cancer.[2] TU is toxic owing to its influence on the metabolism of carbohydrates.[3] Moreover, TU has been labelled as having carcinogenic activity[4] and so, all work with this compound should be performed with the greatest of care to prevent direct exposure of researchers and contamination of the environment.

Various methods have been proposed for the determination of TU such as titrimetry with haloamines,[5] *N*-bromosuccinimide,[6] iodine[7] or mercury(II) nitrate,[8] Raman spectrometry,[9] spectrophotometry,[10] polarography,[11] stripping voltammetry,[12,13] high-performance liquid chromatography,[14] kinetic methods,[15,16] ion selective electrode potentiometry[17] and piezoelectric detection.[18]

Despite the large number of manual methods available, there are few automated procedures. In recent years, flow injection analysis has been used in the determination of TU. Flow injection procedures involve the catalyzed iodine–azide reaction using the amperometric[19] and photometric[20] detection of iodine or the electrochemical detection of TU using pulsed amperometry.[21]

In this paper the development of a spectrofluorimetric flow injection method for the determination of TU and its application to routine analysis is presented. The determination is based on the oxidation of TU by thallium(III) and the parameter measured is the fluorescence of the thallium(I) formed. This violet fluorescence has been attributed to the existence of the $TlCl_3^{2-}$ anionic complex[22] and hence the reaction is carried out in the presence of hydrochloric acid. The procedure is very simple, inexpensive and fast and allows the determination of TU in fruit juices and fruit peels.

## EXPERIMENTAL

### *Apparatus*

A SLM-Aminco Bowman Series 2 spectrofluorimeter was used for recording spectra; excitation and emission spectra were corrected. The detector used in the flow system was a Perkin Elmer model 3000 spectrofluorimeter with a Hellma 176.052 QS flow cell (inner volume 25 $\mu$l). A Gilson Minipuls-4 peristaltic pump and an Omnifit rotary valve were also used. Except for the pump tube (Tygon), PTFE tubing (0.5 mm i.d.) was used throughout the manifold.

*Author to whom correspondence should be addressed.

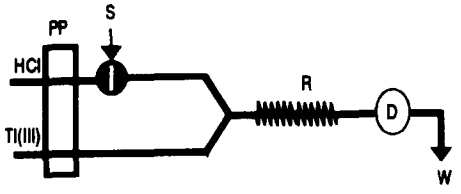

Fig. 1. Schematic diagram of the flow injection system for fluorimetric determination of thiourea. (PP) Peristaltic pump; (S) point of sample injection; (R) reaction coil (30 cm); (D) fluorimeter; (W) waste.

*Reagents*

All reagents were of analytical grade unless otherwise stated. All-glass apparatus was used to produce doubly distilled water, which was used throughout.

Stock thiourea solution ($1 \times 10^{-3}M$) was prepared by dissolving 0.0190 g of thiourea (Merck) in water and diluting to 250 ml in a calibrated flask; this solution remained stable for 1 week if kept refrigerated. Working solutions of lower concentration were prepared daily by appropriate dilution of the stock solution.

Thallium(III) stock solution ($1 \times 10^{-3}M$) in $1M$ hydrochloric acid was prepared from thallium(III) nitrate trihydrate (Merck). Solutions of lower concentration were prepared by dilution with $1M$ hydrochloric acid.

*Manifold*

The schematic diagram of the instrumental set up is shown in Fig. 1 with conditions as stated. The sample is introduced at point S with the aid of the Omnifit rotary valve with a 235-$\mu$l loop. The reagent streams are pumped at the same flow rate in order to achieve effective mixing of both solutions. The reaction is started by injection of the sample and, as the sample zone reaches the flow cell, the fluorescence of thallium(I) formed is measured ($\lambda_{ex} = 227$ nm; $\lambda_{em} = 419$ nm).

## RESULTS AND DISCUSSION

TU is rapidly oxidized by thallium(III) to form fluorescent thallium(I). The fluorescence spectra of a solution containing $1 \times 10^{-4}M$ Tl(III), $1 \times 10^{-5}M$ TU and $1M$ HCl are shown in Fig. 2. The excitation maximum occurs at 227 nm and the fluorescence emission maximum at 419 nm. The fluorescence intensity increases with increasing chloride and ion hydrogen concentrations up to about $0.9M$, above which it remains constant. A $1.0M$ hydrochloric acid was selected for further investigations. Alternatively, TU can be easily oxidized in a flow system by injection into a thallium(III) solution flowing on line. The manifold in Fig. 1 was used to investigate the effect of chemical and flow-injection variables on the peak height.

*Influence of manifold parameters*

The variables studied were flow-rate, volume injected and length of the reaction coil. The reagent concentrations used in these experiments were as follows: thallium(III) line, $2 \times 10^{-4}M$ and hydrochloric acid line, $1M$. The mixing ratio between both streams was always 1:1.

The sample volume was varied between 35 and 285 $\mu$l. The peak heights increased with increasing volumes injected up to 235 $\mu$l, above which they remained virtually constant. A sample volume of 235 $\mu$l was chosen for further experiments.

The peak height obviously depends on the residence time of the sample zone in the system, i.e. on the total flow rate and the tube length. The effect of the flow rate was checked over the range 0.4–2.0 ml/min. The lower flow rates gave higher fluorescence intensities although, up to 0.5 ml/min, peak-height reproducibility was poor and the peaks were so broad that sample throughput was very low. A flow rate of 0.6 ml/min (0.3 for each channel) was selected as the best compromise between reproducibility, sensitivity and throughput.

Reaction coils measuring of 0–150 cm were tested. There was little increase in fluorescence intensity with increased reactor lengths up to 30 cm, above which the signal decreased slightly. The length chosen for the reactor was 30 cm.

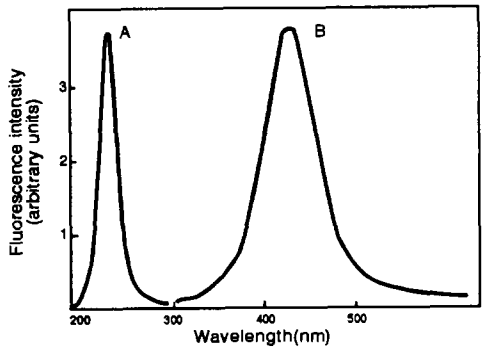

Fig. 2. Excitation (A); and emission spectra (B). [Tl(III)] = $1 \times 10^{-4}M$; [thiourea] = $1 \times 10^{-5}M$; [HCl] = $2M$.

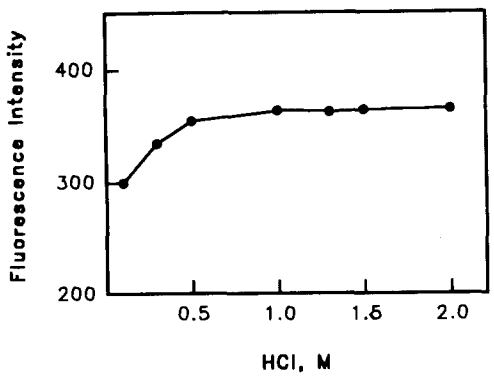

Fig. 3. Effect of hydrochloride acid concentration on the peak height.

*Influence of reagent concentrations*

The effect of varying concentration of thallium(III) and hydrochloric acid were tested in the optimized flow system. The fluorescence intensity increased slightly as the hydrochloric acid concentration was increased from 0.1 to 1.0*M*, above which it remained virtually constant (Fig. 3). The peak height increased steeply with an increase in thallium(III) concentration up to $4 \times 10^{-5}M$, and was constant at higher concentrations (Fig. 4). The reagents used were $1 \times 10^{-4}M$ thallium(III) and 1.0*M* hydrochloric acid.

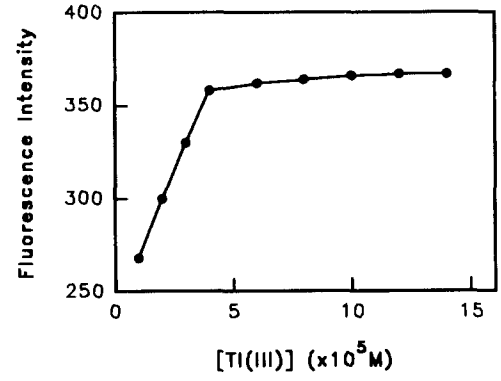

Fig. 4. Effect of thallium(III) concentration on the peak height.

*Calibration graph and reproducibility*

A series of standard solutions of TU were injected into the manifold under the selected conditions to test the linearity of the calibration graph. A linear relationship between TU concentration and fluorescence intensity was obtained over the range $5 \times 10^{-7}$–$1 \times 10^{-5}M$. Regression analysis of the linear portion of the calibration graph gives a standard deviation of 1.6% for the slope and a correlation coefficient of 0.9993. The precision of the method was established by repeated assays ($n = 10$) using $3 \times 10^{-6}$ and $8 \times 10^{-6}M$ solutions of TU. The relative standard deviations were 2.3 and 1.2%, respectively. The sampling rate was about 90 samples/hr.

*Interference studies*

In order to assess the possible analytical applications of the flow injection procedure described above, the effect of concomitant species on the determination of TU in real samples was studied by analysing synthetic sample solutions containing $5 \times 10^{-6}M$ of TU and various excess amounts of the food additives commonly found in fruit juices and fruit peels, inorganic compounds and organic acids. A substance was considered not to interfere if the variation in the peak height of TU was less than 3%. The results are shown in Table 1.

*Analytical applications*

The proposed method was applied to the determination of TU in fruit juices and fruit peels. TU is often added to citrus as a fungicide to assist in its conservation during cold storage. The recoveries from the samples spiked with different amounts of TU are shown in Table 2.

Table 1. Tolerance to different species in the determination of thiourea*

| Species added | Maximum tolerable molar ratio |
|---|---|

| $Bi^{3+}$, $Cu^{2+}$, $I^-$, cysteine | 0.1 |

*Thiourea concentration, $5 \times 10^{-6}M$.
†Maximum ratio tested.

Table 2. Recovery of thiourea in fruit juices and fruit peels

| Sample* | Amount added | Amount found† | Average recovery (%) | Found by Reference method[10]‡ |
|---|---|---|---|---|
| Lemon juice | 8.0 | 7.65 ± 0.62 | 95.6 | 7.82 |
| (μg/ml) | 15.0 | 14.43 ± 0.49 | 96.2 | 14.64 |
| | 30.0 | 28.95 ± 0.37 | 96.5 | 29.20 |
| Orange juice | 8.0 | 7.68 ± 0.51 | 96.0 | 7.74 |
| (μg/ml) | 15.0 | 15.04 ± 0.35 | 100.3 | 14.86 |
| | 30.0 | 28.71 ± 0.47 | 95.7 | 29.30 |
| Orange peel | 5.0 | 5.02 ± 0.63 | 100.5 | 4.86 |
| (mg/kg) | 10.0 | 9.58 ± 0.55 | 95.8 | 9.81 |
| | 15.0 | 14.61 ± 0.47 | 97.4 | 15.2 |

*Ascorbic acid was previously eliminated by heating the solution in alkaline medium at 50°C for 30 min.

†Average values of four determinations ± SD.

‡Average of two determinations.

As can be seen, the assay results for all the samples were in good agreement with the values for the nominal contents and with those obtained using the manual photometric method recommended by AOAC.[10]

## CONCLUSIONS

The results obtained demonstrate the utility of measuring the fluorescence of the thallium(I) formed in the reaction between TU and Tl(III) for the determination of TU at trace levels. The proposed method is suitable for determining TU derivatives, which are also oxidized by thallium(III). This scheme would be useful as a postcolumn on-line reaction for the simultaneous determination of several thioureas using high performance liquid chromatography.

# CURRENT THEORIES IN THE CALCULATION OF ACTIVITY COEFFICIENTS—II. SPECIFIC INTERACTION THEORIES APPLIED TO SOME EQUILIBRIA STUDIES IN SOLUTION CHEMISTRY

M. P. ELIZALDE and J. L. APARICIO

Departamento de Química Analítica, Universidad del País Vasco, Apartado 644, 48080 Bilbao, Spain

(*Received* 10 *May* 1994. *Revised* 19 *September* 1994. *Accepted* 19 *September* 1994)

**Summary**—The adequation of the current theories for calculating activity coefficients has been studied for a series of ionic equilibria in analytical chemistry: the water ionic product as well as two reactions of complex formation and oxidation–reduction. In all the cases, the specific interaction theory (SIT) has proved to be adequate and simple to apply in a restricted interval (0.5–3*M*), whereas Pitzer's theory is outstanding for its high precision in reproducing experimental behaviour and to correlate values of equilibrium constants for different conditions and media.

Most of the equilibrium constants values reported in analytical chemistry are referred to given ionic medium conditions owing to the dependence of these values on the nature and ionic strength of the ionic medium. Consequently, in most cases a previous selection and extrapolation of these known equilibrium constants values to different experimental conditions is needed. For this purpose, the activity coefficients of the species involved in the reactions should be determined.

The corresponding calculations are often restricted to the use of the Debye–Hückel theory[1,2] or the Davies equation,[3] in spite of their short range of validity. However, some authors have applied the so-called specific interaction theory, SIT,[4–6] to correlate equilibrium constant data and an evaluation of the different theories for calculating mean activity coefficients has been reported.[7]

In a previous publication,[8] the specific interaction and ionic associations theories for calculating mean activity coefficients for 2:1 and 2:2 electrolytes have been applied and criticised. In this work, two representative theories, SIT[9] and Pitzer,[10–13] for calculating single-ion activity coefficients have been compared in terms of their applicability in the prediction and correlation of equilibrium data in different media and ionic strengths. For this purpose, the following examples of general interest in solution chemistry have been selected: the ionic product of water, the formation constant of the diaminsilver complex and the redox potential of the $Hg_2^{2+}/Hg$ pair.

Table 1 shows the general SIT and Pitzer equations for the calculation of single-ion activity coefficients in mixtures of electrolytes. In Table 2 the values of the parameters needed to perform the calculations presented in this work are shown. All the calculations have been carried out by means of the program LETAGROP-MODEL FUNCTION.[14] In this program the function to be minimized is the error square sum, $U$, defined as

$$U = \sum_N (A_{exp} - A_{calc})^2,$$

where $A_{exp}$ is the experimental function and $A_{calc}$ the corresponding magnitude calculated by the program, $N$ is the number of experimental points. The best fit is that which gives the lowest values for both $U$ and the mean standard deviation, $\sigma$. The statistical factor, $R = U/\Sigma A_{exp}^2$ is also given by the program.

## RESULTS

### *The ionic product of water* ($k_w$)

The dependence of $k_w$ on temperature is emphasized in most textbooks whereas the influence of the medium and ionic strength is usually omitted. However, this variation can be appreciable as seen in Fig. 1, where $k_w$ values in LiCl,

Table 1. General expressions of SIT and Pitzer theories for calculating single-ion activity coefficients

SIT

$\log \gamma_M = -z_M^2 D + \Sigma\epsilon\,(M^{z+}, X^-)m_x$

$\epsilon\,(M, X, I) = (|z_M + z_X|^2/4I)(\log \gamma^0_{MX} + |z_M z_X| D)$

$D = A\sqrt{I}/(1 + 1.5\sqrt{I})$, $A = 0.5109$,[7]

$\gamma^0_{MX}$: mean activity coefficient of the pure MX electrolyte.

Pitzer

$\log \gamma_M = z_M^2 f\gamma + 2\Sigma m_a\{B_{Ma} + (\Sigma mz)C_{Ma}\} + 2\Sigma m_c\theta_{Mc} + + \Sigma\Sigma m_c m_a\{z_M^2 B'_{ca} + z_M C_{ca} + \Psi_{Mca}\}$

$\Sigma(mz) = \Sigma m_c z_c = \Sigma m_a |z_a|$

$f\gamma = 0.392\{(\sqrt{I}/1 + 1.2\sqrt{I}) + (2/1.2)\ln(1 + 1.2\sqrt{I})\}$

$B_{MX} = \beta^{(0)}_{MX} + (\beta^{(1)}_{MX}/2I)\{1 - (1 + 2\sqrt{I})\exp(-2\sqrt{I})\}$

$B'_{MX} = (\beta^{(1)}_{MX}/2I^2)\{-1 - (1 + 2\sqrt{I} + 2I)\exp(-2\sqrt{I})\}$

$C_{MX} = C^{\phi}_{MX}/(2|z_M z_X|^{1/2})$.

NaCl and KCl media reported by Harned and Owen[15] have been plotted as a function of the ionic strength. This figure proves that the value $k_w = 10^{-14}$ usually adopted is not adequate and, therefore, extrapolations to given experimental conditions should be carried out, specially when accurate calculations are needed.

The acidity reaction of water was firstly considered with the following relationship between the equilibrium constant at infinite dilution, $k^0_w$ ($10^{-14}$ at 298 K), and the corresponding stoichiometric equilibrium constant, $k_w$:

$$pk_w = pK^0_w + \log \gamma_H + \log \gamma_{OH} - \log a_w, \quad (1)$$

$\gamma_H$ and $\gamma_{OH}$ being the single-ion activity coefficients and $a_w$ the water activity, which can be calculated from:

$$a_w = -0.00784 v\phi m, \quad (2)$$

or taken from literature.[15] In equation (2), $v$ is the stoichiometric index, $\phi$ the osmotic coefficient of the solution and $m$ the molality.

The application of SIT and Pitzer equations shown in Table 1 leads to the following theoretical expressions for $pk_w$ in LiCl, NaCl and KCl media:

SIT:

$$pk^I_w = pK^0_w - 2D + \{\epsilon\,(H^+, Cl^-) + \epsilon\,(OH^-, M^+)\}m_{MCl} - \log a_w \quad (3)$$

PITZER:

$$2.30pk^I_w = 2.30pK^0_w + 2f^{\gamma} + 2m\{B_{HCl} + B_{MOH} + m(C_{HCl} + C_{MOH})\} + m^2(2B'_{MCl} + 2C_{MCl} + \Psi_{HCl-MCl} + \Psi_{MCl-MOH}) + 2m(\theta_{HCl-MCl} + \theta_{MCl-MOH}) - \log a_w, \quad (4)$$

where M refers to $Li^+$, $Na^+$ or $K^+$.

The suitability of SIT and Pitzer theories for calculating single-ion activity coefficients can be evaluated through the comparison of calculated $k_w$ values (using the parameters listed in Table 2) and the corresponding experimental values reported by Harned and Owen.

The results obtained are illustrated in Fig. 1 as $k_w = f$(ionic strength) for the three ionic media. It can be appreciated that at low values of ionic strength both theories approximately predict the experimental behaviour, whereas on increasing the ionic strength the differences are significant. SIT theory qualitatively reproduces the experimental function, whereas Pitzer equation gives rise to an excellent prediction of the experimental behaviour. For comparison, in the same figure, values of $k_w$ derived using the extended Debye–Hückel equation for the value $B \cdot a = 1$ are represented.

Table 2. Values of the known SIT and Pitzer parameters for the calculations

| Interaction coefficient, $\epsilon$[9] | | $\beta^{(0)}$[11] | $\beta^{(1)}$[11] | $C^{\phi}$[11] |

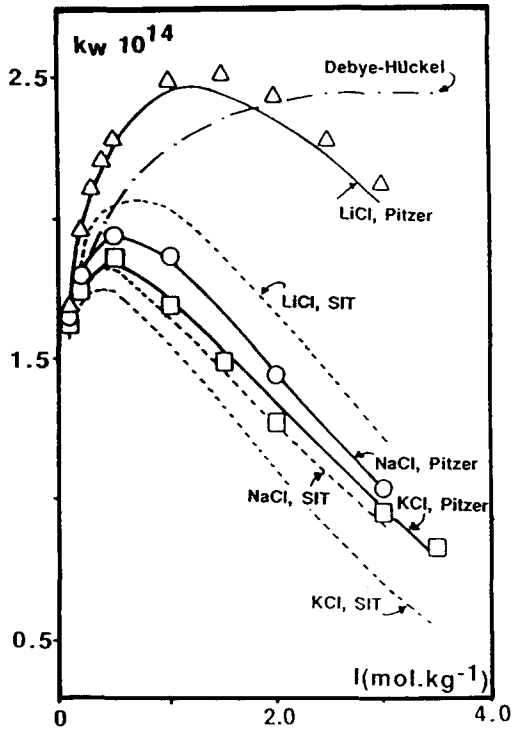

Fig. 1. $k_w$ values in LiCl, NaCl and KCl media as a function of the ionic strength.[14] Lines represent the predicted $k_w$ values using SIT and Pitzer theories.

*The formation constant of the diaminsilver complex*

The diaminsilver formation equilibria has been extensively studied in different media and ionic strengths because of its importance in analytical chemistry. Consequently, there is a significant number of different formation constant values reported for this equilibrium.[16,17]

In this case, the application of SIT and Pitzer theories should allow to correlate the different equilibrium constant values as well as to extrapolate to given experimental conditions. The precision in the correlation will indicate the degree of suitability of both theories.

Besides the stoichiometric equilibrium constant values, $\beta_2^{\mathrm{I}}$, reported in the literature in $NaClO_4$, $KNO_3$, $NaNO_3$ and $LiNO_3$ for the reaction:

$$Ag^+ + 2NH_3 \Leftrightarrow Ag(NH_3)_2^+ \qquad (5)$$

it is necessary to consider the corresponding values, $k_a^{\mathrm{I}}$, reported for the equilibrium:

$$NH_4^+ \Leftrightarrow NH_3 + H^+. \qquad (6)$$

These values can be related to the corresponding at infinite dilution, $\beta_2^0$ and $k_a^0$ by:

$$\log \beta_2^{\mathrm{I}} = \log \beta_2^0 + \log \gamma_{Ag(NH_3)_2} - \log \gamma_{Ag} - 2 \log \gamma_{NH_3} \qquad (7)$$

and

$$\mathrm{p}k_a^{\mathrm{I}} = \mathrm{p}K_a^0 - \log \gamma_{NH_4} + \log \gamma_{NH_3} + \log \gamma_H, \qquad (8)$$

where the calculation of the activity coefficient for the neutral species $NH_3$ is needed. The activity coefficient for this compound can be calculated by means of the Long and McDevit equation:[18]

$$\log \gamma_{NH_3} = s(NH_3, E)m, \qquad (9)$$

where $s(NH_3, E)$ is the so-called salting coefficient of the neutral species $NH_3$ in the ionic medium E, and $m$ is the molality.

Prior to considering the diaminsilver formation equilibrium, $s$ should be evaluated through equations (8) and (9). For the sake of simplicity, the SIT theory has been used to determine the salting coefficients and $\mathrm{p}K_a^0$ values:

$$\mathrm{p}k_a^{\mathrm{I}} + \{\epsilon(NH_4^+, X^-) - \epsilon(H^+, X^-)\}m = \mathrm{p}K_a^0 + sm, \qquad (10)$$

where X refers to $NO_3^-$ or $ClO_4^-$.

The plot of the first member in equation (10) as a function of $m$ is shown in Fig. 2. From the obtained straight line, the value of $\mathrm{p}K_a^0 = 9.25 \pm 0.01$ is concluded and within the experimental error, $s(NH_3, NaNO_3) \approx s(NH_3, NaClO_4) \approx s(NH_3, LiNO_3) \approx 0$ can be derived. These results agree with experimental data reported by Maeda *et al.* indicating that the activity coefficient of ammonia in salt solutions is constant and close to unity.[16]

Therefore, the application of SIT theory to equation (7) leads to:

$$\log \beta_2^{\mathrm{I}} - \epsilon(Ag^+, X^-)m = \log \beta_2^0 - \epsilon(Ag(NH_3)_2^+, X^-)m. \qquad (11)$$

If this equation is valid, the experimental function $\log \beta_2^{\mathrm{I}} - \epsilon(Ag^+, X^-) = f(m)$ should yield two different straight lines, one for the three different nitrate media and another for perchlorate medium, with the same $Y$-axis

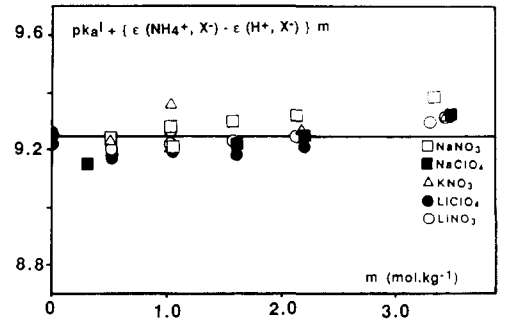

Fig. 2. The application of SIT theory to literature $\mathrm{p}k_a$ ($NH_4^+$) data at different ionic media.

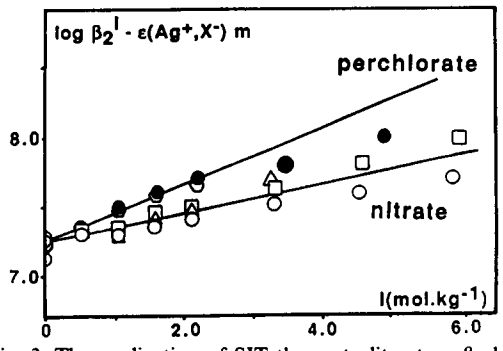

Fig. 3. The application of SIT theory to literature $\beta_2$ data at different ionic strengths and media.

intercept. As seen in Fig. 3, the prediction is fulfilled in the range 0.5–3.0 mol/kg. As the ionic strength increases, deviations between the experimental data and the theoretical functions are higher. From the function expressed in equation (11), the parameters collected in Table 3 were obtained.

On the other hand, the application of Pitzer theory to equation (7) has been restricted to data in nitrate media because the required Pitzer parameters in perchlorate media are not available. The following expression can be derived for the diaminsilver formation constant in nitrate media:

$$\ln \beta_2^I = \ln \beta_2^0 + 2m\{B_{AgNO_3} - B_{Ag(NH_3)_2NO_3} + m(C_{AgNO_3} - C_{Ag(NH_3)_2NO_3}) + \theta_{AgNO_3-MNO_3} - \theta_{Ag(NH_3)_2NO_3-MNO_3})\} + m^2(\Psi_{AgNO_3-MNO_3} - \Psi_{Ag(NH_3)_2NO_3-MNO_3}), \quad (12)$$

where M refers to $Li^+$, $Na^+$ or $K^+$.

In this equation, the function $B_{AgNO_3}$ and the parameter $C_{AgNO_3}$ shown in Table 1 can be evaluated taking into account the values of the parameters $\beta^{(0)}_{AgNO_3}$, $\beta^{(1)}_{AgNO_3}$ and $C^{\phi}_{AgNO_3}$ collected in Table 2. Therefore, in equation (10) there are seven unknown parameters which can be grouped as follows:

$$\ln \beta_2^I - 2m(B_{AgNO_3} + mC_{AgNO_3}) = \ln \beta_2^0 - 2m(\beta^{(0)}_{Ag(NH_3)_2NO_3} + \theta_{Ag(NH_3)_2NO_3-MNO_3} - \theta_{AgNO_3-MNO_3}) - m^2(C^{\phi}_{Ag(NH_3)_2NO_3} + \Psi_{Ag(NH_3)_2NO_3-MNO_3} - \Psi_{AgNO_3-MNO_3}) - \beta^{(1)}_{Ag(NH_3)_2NO_3}\{1-(1+2\sqrt{I})\exp(-2\sqrt{I})\}, \quad (13)$$

where $I \approx m$.

This function has been plotted in Fig. 4 where it can be seen to give a good fit in the range $I = 0$–6 mol/kg. In this case the deviations observed with SIT theory as high ionic strengths do not appear. The value $\log \beta_2^0 = 7.22 \pm 0.01$ can be obtained from the intercept on $Y$-axis as well as the Pitzer parameters collected in Table 3. The similarity of the parameters $\theta$ in $NaNO_3$ and $KNO_3$ media as well as the significant difference with those in $LiNO_3$ medium can be concluded from these results.

As it can be appreciated in all the cases the deviations obtained with Pitzer theory are much lower than those obtained by SIT. However, the application of SIT theory gives rise to acceptable results up to 3 mol/kg, specially if its only parameter involved in comparison with the seven parameters needed in Pitzer equation is considered.

Table 3. Values of the calculated values for SIT and Pitzer parameters, as well as equilibrium constant/potential redox values at infinite dilution, and results of the numerical fits for the data treatment of the formation constant values of the diaminsilver complex (2) and the redox potential data of $Hg_2^{2+}$/Hg pair (3)

*The redox potential of the* $Hg_2^{2+}$/Hg *pair*

Several authors[19–21] have measured the conditional potential values for the $Hg_2^{2+}$/Hg redox couple as a function of $H^+$ concentration by means of potentiometric measurements of the cell:

$$H_2(g)/HClO_4, C_H/HClO_4,$$
$$C_H//Hg_2(ClO_4)_2, C_B/Hg,$$

where $c$ is the molar concentration, and $C_B \cdot C_H \ll 1$.

The measured potential corresponding to the reaction:

$$H_2(g) + Hg_2^{2+} \Leftrightarrow 2H^+ + 2Hg \qquad (14)$$

can be expressed by

$$E = E^0 + 29.58 \log(C_B/C_H^2) + 29.58 \log \gamma_{Hg_2}\gamma_H^2. \qquad (15)$$

The application of SIT theory to this equation leads to the following function:

$$E - 29.58 \log(C_B/C_H^2) + 59.16D = E^0 + 29.58\{\epsilon(Hg_2^{2+}, ClO_4^-) - 2\epsilon(H^+, ClO_4^-)\}m_{HClO_4}. \qquad (16)$$

The linear plot $E - 29.58 \log(C_B/C_H^2) + 59.16D = f(m_{HClO_4})$ is shown in Fig. 5, from which values of $E^0$ and $\epsilon(Hg_2^{2+}, ClO_4^-)$ collected in Table 3 were obtained. On the other hand, the Pitzer theory applied to this system can be expressed by the equation:

$$E - 29.58 \log(C_B/C_H^2) = E^0 - (29.58/2.30)\{-2f^{\cdot\cdot} + 2m_{ClO_4}(2B_{HClO_4} + 2C_{HClO_4}m_{HClO_4} - B_{Hg_2(ClO_4)_2} - C_{Hg_2(ClO_4)_2}m_{HClO_4}) + 2(2m_{Hg} - m_H)\theta_{HClO_4 - Hg_2(ClO_4)_2} + 2m_{Hg}m_{ClO_4}(B'_{Hg_2(ClO_4)_2} + C_{Hg_2(ClO_4)_2} + \Psi_{HClO_4 - Hg_2(ClO_4)_2}) - m_H m_{HClO_4}(4B'_{HClO_4} + 2C_{HClO_4} + \Psi_{HClO_4 - Hg_2(ClO_4)_2}). \qquad (17)$$

Taking into account that $m_H \approx m_{ClO_4} \approx I \approx m$, and $m_{Hg} \ll m_H$, equation (17) can be transformed into:

$$Y = (4.60/59.16)E - 2.30 \log C_B \cdot C_H^{-2} - 2f^{\cdot\cdot} + 4mB_{HClO_4} + m^2C^{\phi}_{HClO_4} - 4m^2B'_{HClO_4} = (4.60/59.16)E^0 + 2m(\beta^{(0)}_{Hg_2(ClO_4)_2} + \theta_{Hg_2(ClO_4)_2 - HClO_4}) + \beta^{(1)}_{Hg_2(ClO_4)_2} + \{1 - (1 + 2\sqrt{I})\exp(-2\sqrt{I})\} + m^2 \times \{(1/\sqrt{2})C^{\phi}_{Hg_2(ClO_4)_2} + \Psi_{HClO_4 - Hg_2(ClO_4)_2}\}, \qquad (18)$$

where the parameters $\beta^{(0)}$ and $\beta^{(1)}$ included in the functions $B_{HClO_4}$ and $B'_{HClO_4}$ as well as the parameter $C^{\phi}_{HClO_4}$ are known (Table 2).

Experimental data $Y = f(m)$ have been plotted in Fig. 6 together with the theoretical function from which the parameter values summarized in Table 3 were derived.

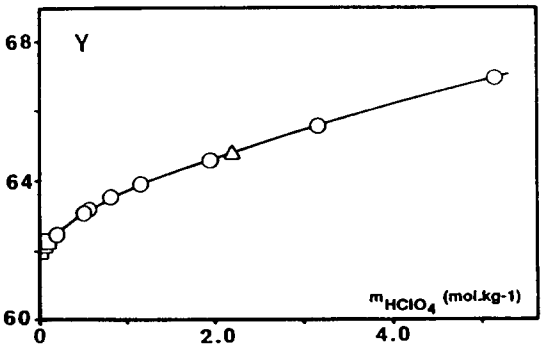

Fig. 6. The application of Pitzer theory to literature redox potential data of the $Hg_2^{2+}$/Hg pair at different ionic strengths.

## DISCUSSION

Values for the determined parameter values derived for the three cases studied are summarized in Table 3 together with the values of the mean standard deviation $\sigma$ and the statistical factor $R$. From the obtained results, the possibility to overcome the difficulty derived from the different equilibrium constant values collected in the literature for a given reaction can be concluded first. In fact, the application of SIT and Pitzer theories allows the selection of the appropriate equilibrium constant values as well as the extrapolation to given experimental conditions with more or less accuracy.

Thus, in the case of the water acidity equilibrium, it should be noted that the use of SIT and Pitzer theories for calculating $H^+$ and $OH^-$ activity coefficients can predict the appreciable variations of experimental $k_w$ values with the ionic media. Especially with the use of Pitzer equations, numerical experimental values for $k_w$ in different media may be deduced with minimum error.

The formation of the diaminsilver complex has been selected as representative of complex formation equilibria. Values of the interaction coefficients ($\epsilon$) of diaminsilver and nitrate or perchlorate agree acceptably with literature values reported for these parameters.[16] The zero mean values of the salting coefficients for $NH_3$ at the different ionic media considered are in agreement with literature values for this parameter.

Although Pitzer parameter values are much more scarce in the literature in relation to complex formation equilibria, it is noteworthy to point out that values obtained for diaminsilver nitrate are within the interval from the upper to the lower values reported by Pitzer for 1:1 electrolytes in nitrate media. Thus, the $\beta^{(0)}$ value varies from 0.1 to $-0.1$, $\beta^{(1)}$ from 0.3 to $-0.4$ and $C^\phi$ from 0.007 to $-0.006$.[11]

The application of SIT theory leads to good results in the range $I = 0.5$–$3.0M$, while with Pitzer theory a good fit is obtained in the range considered (up to $6M$). The deviations observed at the highest ionic strength values can be attributed to the lack of consideration in the SIT theory of the same sign ionic interactions which are appreciable at high values of ionic strength.

The redox potential of the $Hg_2^{2+}/Hg$ couple can be reported as an example of treatment of redox potential data which are scattered and sometimes confused in the literature. Both SIT and Pitzer theories give similar values for $E^0$ magnitude and good fits are obtained, specially in the case of Pitzer equation.

The Pitzer parameter values in perchlorate media for the 2:1 $Hg_2(ClO_4)_2$ electrolyte are within the interval for $\beta^{(0)}$, $\beta^{(1)}$ and $C^\phi$ for this type of electrolyte, 0.8 to $-0.44$ for $\beta^{(0)}$, 2.9 to 2.1 for $\beta^{(1)}$ and 0.04 to $-0.06$ for $C^\phi$, respectively, reported by Pitzer.[11]

The comparison between the results obtained by SIT and Pitzer theories in the prediction or correlation of equilibrium constant and redox potential data in different media clearly indicates the suitability of Pitzer equations for this purpose. On the other hand, the application of SIT theory gives rise to acceptable results up to $3M$, especially if its simplicity, only one parameter ($\epsilon$) is used in the calculations, is taken into account.

(*Received* 24 *June* 1994. *Revised* 19 *September* 1994. *Accepted* 19 *September* 1994)

**Summary**—A method for the extraction–spectrophotometric determination of palladium with 3,4,4a,5-tetrahydro-3,3,4a-trimethyl-7-(substituted)-pyrimido(1,6-*a*)benzimidazole-1-thiol (PBT) is described. PBT–Pd(II) complex is extracted from an acidic aqueous solution (0.01–0.5*M* $HClO_4$) into a chloroform layer. The absorbance is measured at 438 nm and the molar absorptivity found to be $1.033 \times 10^4 M^{-1}$ $cm^{-1}$. The complex system conforms to Beer's law over the range 1.9–28.5 $\mu$g/ml palladium(II). The effects of pH (2–6), $HClO_4$ concentration, PBT concentration and shaking time were studied. The ratio of metal ion to ligand molecules in the coloured complex was found to be 1:4. The tolerance limit for many metals have been determined. Finally, the method has been applied successfully to the determination of palladium in synthetic mixtures and in the standard palladium carbon powder (palladium catalyst).

Palladium is one of the platinum group metal. It is a good catalyst and is used widely for hydrogenation and dehydrogenation reactions. Owing to its corrosion resistance nature and alloying ability, palladium and its alloys are used in dental and medicinal devices, and in jewellery manufacture.

Various organic compounds such as 2-hydroxy acetophenone thiosemicarbazone,[1] 1-amino-4hydroxy anthraquinone,[2] 2-hydroxy-4-methoxy-5′-chlorochalcone oxime,[3] di-2-pyridyl methanone-2-(5-nitro)pyridyl hydrazone,[4] 2-carboxy-2′-hydroxy-5-methyl-azobenzene,[5] 5,6-dimethyl-1,3-indanedione-2-oxime,[6] isonitrosomalone dianilide[7] and 3,5-dichloro-2-(2,4-diamino-phenyl) pyridine[8] have been reported as spectrophotometric reagents for the determination of palladium(II). Some organic reagents bearing mercapto group have also been explored for the determination of palladium(II), viz. 2-mercaptobenzoxazole,[9] mercaptoacetic acid-$\beta$-naphthylamide,[10] 8-mercaptoquinoline,[11] $\beta$-mercaptroresorcylic [4-hydroxy-2-mercapto-benzoic] acid,[12] 2-mercaptoacetoacetanilide,[13] 2*N*-(2-mercaptophenyl)-1,2,3-benzothiadiazoline[14,15] and 2-mercaptobenzamide.[16] However, the reported methods suffer from limitations such as longer extraction period,[4,8,9,14,15] less satability,[8] interferences from other commonly associated ions[4,5,12,16] and negligible extraction.[1,2,6,9,12]

Anti-parasitic and anti-inflammatory activity evaluation of pyrimido benzimidazoles[17,18] and their derivatives[19,20] have been reported in the recent literature. The analytical applications of pyrimido benzimidazoles have not been explored so far.

In the present investigation 3,4,4a-5-tetrahydro-3,3,4a-trimethyl-7-(substituted)-pyrimido (1,6-*a*)benzimidazole-1-thiol (**Ia–c**) has been explored as a new reagent for the separation, extraction and determination of palladium. Among the transition metal ions tested the reagent reacts with Pd(II) and Hg(II). But the conditions for the extraction of Hg(II) are different from that of palladium. Hence no interference from Hg(II) is observed during the determination of Pd(II).

## EXPERIMENTAL

### *Reagents*

*Synthesis of* 3,4,4*a*,5-*tetrahydro*-3,3,4*a*-*trimethyl pyrimido*[1,6-a]*benzimidazole*-1-*thiol*(**Ia**) (PBT). o-Phenylene diamine (2.16 g, 0.02 mol) was dissolved in methanol (20 ml) and to it was

*Author to whom correspondence should be addressed.

added 4-methyl-4-isothiocyanato-2-pentanone (3.50 g; 0.022 mol) and 2 drops of conc sulphuric acid (pH ~ 6). The reaction contents were heated under reflux for 8 hr. Solvent was removed under reduced pressure and the residue left behind was basified with sodium carbonate solution. Solid so obtained was filtered, washed with water and air-dried. The crude product was recrystallized[21] from THF to give 3,4,4a,5-tetrahydro-3,3,4a-trimethyl pyrimido[1,6-*a*]benzimidazole-1-thiol (**Ia**), yield 86% mp 223°C, $^1$H NMR (300 MHz; DMSO-$d_6$): $\delta$ 1.2 (*d*, 6H, $CH_3 + CH_3$), 1.35 (*s*, 3H, $-CH_3$), 2.10 (*s*, 1H, $J_{gem.} = 15$ Hz), 2.32 (*d*, 1H. $J_{gem.} = 15$ Hz), 6.5 (*m*, 3H, one H exch. -NH + 2H Ar), 6.80 (*t*, 1H, Ar), 8.3 (*s*, -C-NH, exch.), 8.55 (*d*, 1H, Ar). HR MS *m/z* (rel. int.%), 247.1148 ([M]$^+$, 51.84). Calcd. for $C_{13}H_{17}N_3S$ 247.1143. Elemental analysis found C, 63.00; H, 7.00; N, 17.10; Calcd. for $C_{13}H_{17}N_3S$ C, 63.15; H, 6.88; N 17.00.

Pyrimido[1,6-*a*]benzimidazoles (**Ib** and **c**) were prepared by condensing 4-methyl 1,2-phenylene diamine and 4-methoxy-1,2-phenylene-diamine with 4-isothiocyanato-4-methyl-2-pentanone (Sahu, Guptu and Sondhi, unpublished results).[18] Both these compounds, were purified by recrystallization and purified compounds gave correct $^1$H NMR, HRMS and elemental analysis (within an error of $\pm$0.4%).

### Pd(II) *Standard solution*

A $1.9 \times 10^{-3}M$ stock solution was prepared by dissolving 0.0334 g palladium(II) chloride (Johnson Mathey, London) in a few drops of conc hydrochloric acid and diluting to 100 ml with double distilled water. The stock solution was standardized[22] with dimethyl glyoxime.

All the reagents and chemicals used were of analytical grade. Solutions of other ions were prepared by dissolving the corresponding salts in double distilled water.

### *Apparatus*

Absorbance measurements were carried out with a Shimadzu UV-260 recording spectrophotometer with 1 nm band width and 10 mm matched silica cells. A CL-46 Toshniwal, digital pH meter with a combined glass electrode was used for pH-measurements. For the determination of palladium(II) in aqueous phase, inductively coupled plasma-atomic emission spectrometer, model 8040 Plasma Labtum (Australia) was used.

### *Procedure*

An aliquot of the solution containing 190 $\mu$g palladium(II) was taken in a separatory funnel and mixed with an adequate amount of perchloric acid to have the desired acidity. The aqueous phase was made up to 10 ml with double distilled water. This was shaken for 90 sec with 10 ml of organic phase containing 1.5 ml of PBT-**Ia** (0.01*M*) and 8.5 ml chloroform. The yellow-coloured organic phase was separated and 1 g of anhydrous $Na_2SO_4$ added to remove traces of water. The absorbance of the organic phase was measured at 438 nm against reagent blank.

## RESULTS AND DISCUSSION

### *Spectral characteristics*

Absorption spectra of Pd(II) PBT (**Ia–c**) complexes in chloroform medium against reagent blank were recorded. Maximum absorbance was observed in the case of Pd(II)–PBT-**Ia** complex (Table 1). The absorption spectra of the yellow coloured complex formed between Pd(II) and PBT-**Ia** and the reagent blank are shown in Fig. 1. The palladium complex and reagent have $\lambda_{max}$ at 438 and 340 nm, respectively. In order to minimize the effect of reagent blank, the absorbance of the complex was measured at 438 nm where reagent blank shows negligible absorbance.

### *Choice of acid and effect of acidity*

Choice of acid and its concentration are important in the extraction of Pd(II) with substituted pyrimido[1,6-*a*]benzimidazoles (**Ia–c**). Different acids, viz. $HClO_4$, $HNO_3$, $H_2SO_4$ and HCl, were tried. Nitric acid could not be used because the ligand is oxidized at higher acid concentration (>4*M* $HNO_3$) and up to 4*M* $HNO_3$ extraction is not complete. Amongst the other acids ($H_2SO_4$, $HClO_4$ and HCl) perchloric acid is the most suitable because maximum absorbance is obtained with $HClO_4$ and only a single extraction is required to extract Pd(II) completely from perchloric acid medium. Thus

Table 1. Absorption characteristics of Pd(II)–PBT complexes in chloroform

| Reagent | $\lambda_{max}$ (*nm*) | ($M^{-1}$ $cm^{-1}$) | Acid concentration (*M*) |
|---|---|---|---|
| PBT-**Ia** | 438 | 10,331 | 0.01–0.5 |
| PBT-**Ib** | 438 | 9994 | 0.01 |
| PBT-**Ic** | 434 | 5816 | 0.01–0.1 |

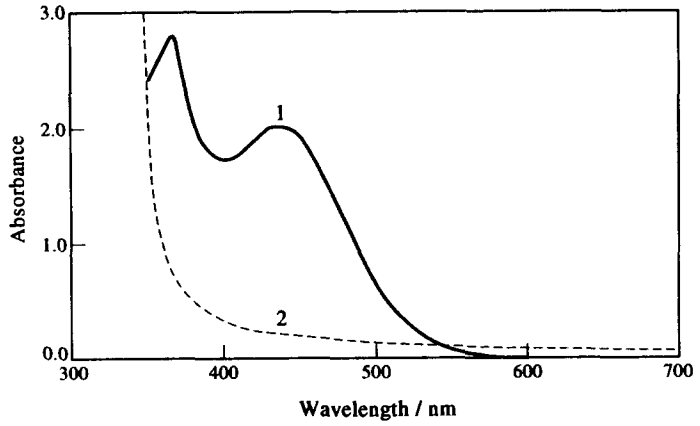

Fig. 1. Absorption spectra of Pd(II)–PBT-**Ia** complex in chloroform. PBT-**Ia** = $1.5 \times 10^{-3}M$; acid concentration $0.1M$; (1) 19 $\mu$g/ml of palladium(II) extracted into chloroform *vs.* reagent blank and (2) reagent blank *vs.* chloroform.

extraction studies were carried out for all the three derivatives from perchloric acid medium.

PBT-**Ia** is the more suitable ligand, as quantitative extraction is obtained with this ligand in the range 0.01–0.5$M$ $HClO_4$. Whereas with PBT-**Ib** quantitative extraction is achieved only at 0.01$M$ $HClO_4$. With PBT-**Ic** the highest percentage extraction obtained is only 52%. Thus PBT-**Ia** was selected for all further studies. Results are illustrated in Fig. 2.

*Calibration, sensitivity and precision*

A calibration curve was drawn for the Pd(II)–PBT-**Ia** complex. The coloured system obeyed Beer's law over the range 1.9–28.5 $\mu$g/ml of palladium(II). The molar absorptivity and Sandell sensitivity for log $I/I_0 = 0.001$ were $1.033 \times 10^4 M^{-1}$ cm$^{-1}$ and 0.009 $\mu$g/cm$^2$, respectively. Coefficient of variation was 0.056% for the determination of 19 $\mu$g of palladium(II).

*Effect of PBT concentration*

The absorbances of a series of solutions containing 190 $\mu$g of palladium(II) and various concentrations of PBT-**Ia** ($1.0 \times 10^{-3}$–$5.0 \times 10^{-3}M$) were measured keeping all other parameters constant. Maximum absorbance was observed at $1.5 \times 10^{-3}M$ PBT-**Ia** concentration. This reveals that the concentration of PBT-**Ia** must be at least 7.5 times greater than that of palladium(II) concentration for full colour development.

*Composition of the extracted species*

The ratio of metal ion to PBT-**Ia** in the extracted species was determined by the log–log plot of distribution ratio *vs.* PBT-**Ia** concentration at a fixed pH. A straight line with a slope of *ca.* 4 was obtained, indicating a 1:4 metal-to-ligand ratio in the extracted complex (Fig. 3).

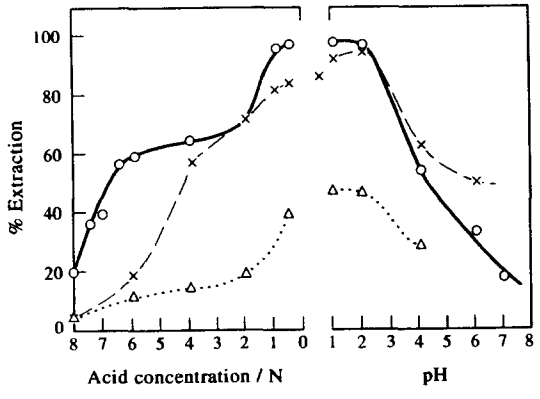

Fig. 2. Effect of pH on the extraction of Pd(II)–PBT complexes. Pd(II), 19 $\mu$g/ml; PBT = $1.5 \times 10^{-3}M$. —○— PBT-**Ia**, — × — PBT-**Ib**, —△— PBT-**Ic**.

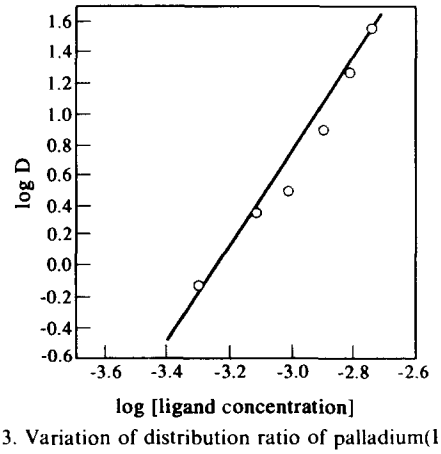

Fig. 3. Variation of distribution ratio of palladium(II) as a function of PBT-**Ia** concentration at constant acid concentration ($0.1M$) and constant metal ion concentration [Pd(II) = 19 $\mu$g/ml].

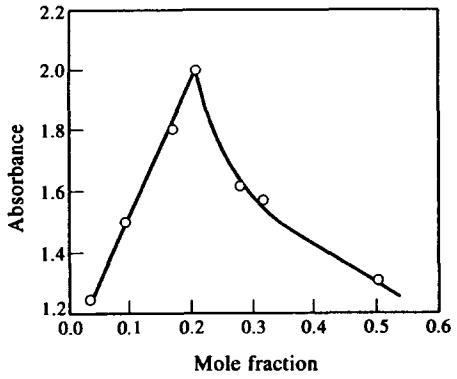

Fig. 4. Plot of composition of the extracted species by Job's continuous variation method. Total concentration of Pd(II) and PBT-**Ia** = $5.0 \times 10^{-4} M$.

The composition was also verified by Job's method of continuous variation (Fig. 4). The results reveal a monodentate behaviour of the ligand. Similar results have also been reported by Singh *et al.*[23]

*Choice of solvent*

Different solvents were tried for the extraction of Pd(II)–PBT-**Ia** complex (Table 2). Out of the eight tested solvents chloroform is the most suitable solvent as maximum absorbance is achieved with this solvent. Thus chloroform was selected for further studies.

*Shaking time and stability*

The shaking time for the extraction was varied from 30 to 300 sec. Minimum shaking time for complete extraction of 19 $\mu$g/ml of palladium(II) with chloroform is 60 sec at $25 \pm 2°C$. Therefore, a 90 sec shaking time was adopted for all further studies. The absorbance of Pd–PBT–**Ia** complex is stable for at least 30 hr at 438 nm.

Table 2. Extraction of Pd(II)–PBT-**Ia** complex with various organic solvents

| | Solvent | $\lambda_{max}$ (nm) | %$E$) | ($M^{-1}$ $cm^{-1}$) |
|---|---|---|---|---|
| (1) | Carbon tetrachloride | — | 0.0 | — |
| (2) | Benzene | — | 0.0 | — |
| (3) | Toluene | — | 0.0 | — |
| (4) | Xylene | — | 0.0 | — |
| (5) | Nitrobenzene | 431 | 95.0 | 8193 |

*Effect of diverse ions*

In order to study the effect of various ions on the determination of the Pd(II)–PBT-**Ia** complex, a fixed amount (10 $\mu$g/ml) of palladium(II) was taken with different amounts of foreign ions and the recommended procedure was followed. The results are summarized in Table 3. An error of $\pm 3\%$ in the absorbance was considered tolerable. Cobalt(II), copper(II) and platinum(IV) are tolerated when present in equimolar

Table 4. Determination of palladium(II) in the synthetic mixtures

| Composition of synthetic mixture ($\mu g$) | Pd(II) found by the present method in organic phase* ($\mu g$) | Co(II), Ni(II) and V(V) remaining in the aqueous phase (determined by A.A.S.*) ($\mu g$) |
|---|---|---|
| Pd(100); Co(100); Ni(100) | 97.8 | Ni(88.9); Co(100.2) |
| Pd(200); V(200); Ni(1200) | 199.5 | Ni(1196.5); V(198.6) |
| Pd(100); Pt(200) | 98.9 | Pt(199.2) |

Table 5. Determination of Pd(II) in palladium–charcoal

| Sample | Taken ($\mu g$*) (as determined by ICP) | Found ($\mu g$) | Recovery (%) |
|---|---|---|---|
| Pd–Charcoal (E. Merck) | 18.00 | 17.84<br>17.80<br>18.02 | 99.37 |
| Pd–Charcoal (Aldrich) | 28.00 | 27.63<br>27.74<br>27.80 | 99.01 |

*Determined by ICP-AES in aqueous phase.

concentration. The interferences from 10-fold excess of these ions can be masked with 1,10-phenanthroline, EDTA and oxalate, respectively. Iodide and citrate interfere at low concentration Gold(III) and $CNS^-$ interfere seriously in the determination of palladium(II).

*Application of the method to real samples and synthetic mixtures*

In order to confirm the usefulness of the proposed method, it was applied to the determination of palladium(II) in the synthetic mixture and Pd–charcoal. The results of synthetic mixture are given in Table 4. Results indicate a clear separation of Pd(II) from Co(II), Ni(II) and V(V) leaving these metal ions in the aqueous phase. After extraction of Pd(II) concentrations of Ni(II), Co(II) and V(V) were determined in the aqueous phase by A.A.S. (Table 4).

To prepare a solution of Pd–charcoal, 0.1 g of the palladium charcoal was weighed and dissolved in conc $HNO_3$. The solution was evaporated nearly to dryness, extracted with 10 ml of 0.05*M* HCl, filtered and diluted to 100 ml with distilled water. An aliquot of this solution was analysed for palladium(II) by the proposed method. The results were tested by ICP-AES. There was a good agreement between the amount of Pd(II) estimated by this method and that determined by ICP-AES (Table 5).

The palladium(II) in the organic phase can be stripped quantitatively with 10*M* $HClO_4$. Thus the proposed method provides a simple, rapid and selective method for the extraction, separation and spectrophotometric determination of palladium(II).

*Acknowledgements*—The authors gratefully acknowledge the assistance of Dr N. K. Saini and Dr P. P. Kapoor of Wadia, Institute of Geology, Dehradun in some of the I.C.P. measurements.

# PREDOMINANCE-ZONE DIAGRAMS OF Fe(III) AND Fe(II) SULFATE COMPLEXES IN ACIDIC MEDIA. VOLTAMMETRIC AND SPECTROPHOTOMETRIC STUDIES

ADRIÁN F. GIL, LEONARDO SALGADO, LAURA GALICIA and IGNACIO GONZÁLEZ*

Universidad Autónoma Metropolitana-Iztapalapa, Depto de Química, Area de Electroquímica, Apdo. Postal 55-534, 09340 México D.F., Mexico

(*Received* 1 *March* 1994. *Revised* 14 *June* 1994. *Accepted* 23 *September* 1994)

**Summary**—A thermodynamic study based on concepts of generalized species and equilibria, was used to understand the distribution of Fe(III) and Fe(II) species in the Fe(III)/Fe(II)/$H_2SO_4$/$H_2O$ system. The two-dimensional predominance zone diagrams (TDPZ) and Pourbaix type diagrams thus obtained permitted the selection of optimum experimental conditions, to differentiate the chemical species involved in this system. The existence of the different predominant chemical species for Fe(III): $Fe^{3+}$, $FeSO_4^+$ and $Fe(SO_4)_2^-$ was evidenced by spectrophotometrical studies for $pSO_4'$ values from 4 to 0 units in a buffered solution of pH 0.5. Additionally, voltammetric studies performed on Pt, Au and carbon paste electrodes confirmed that the electron exchange between Fe(III)/Fe(II) in $H_2SO_4$ media occurs by an inner Helmholtz layer mechanism. It was also possible to show that the representative couples at $pSO_4' = 0$ (buffered) are: (a) for pH < 0 $FeSO_4^+/FeHSO_4^+$ and (b) for pH > 1.0: $Fe(SO_4)_2^-/FeHSO_4^+$. The last couple presents a coupled chemical reaction in the electrochemical mechanism; this reaction is associated with the different coordination numbers of Fe(III) and Fe(II).

The importance of iron chemistry in geological, environmental, metallurgical, industrial, catalytical and biological contexts makes its understanding of fundamental significance. In connection with applications, it is very important to study the behavior of iron (III) species in weakly acidic solutions. For example, it is well known that the corrosion of metallic iron is strongly accelerated by the presence of sulfate ions.[1–4]

In many of the previous studies on the electrochemical behavior of Fe(II)/Fe(III) couple, two main features have been reported: (a) the dependence of the normal potential values on the supporting electrolyte attributed to the different iron coordination sphere,[2,3,5] and (b) the dependence of the iron redox potential on the solution pH and on the supporting electrolyte anions owing to its complex redox mechanism.[2,4,6]

Despite extensive research on the Fe(II)/Fe(III) couple, few studies have considered the existence of the sulfate–iron complexes in sulfuric acid media in order to explain the electrochemical behavior of this couple. This is a result of the difficult detection of the chemical species involved in the redox equilibria,[7,8] since the formation constants of the iron–sulfates are small.[9,10]

In this work, the Fe(III)/Fe(II)/$H_2SO_4$/$H_2O$ system is studied in several ways: Firstly, a method based on concepts of generalized species and equilibria,[11,12] is used to understand the thermodynamic distribution of Fe(III) and Fe(II) species in sulfuric acid system. This method allows for the construction of two-dimensional predominance zone diagrams and Pourbaix-type diagrams which consider all chemical species present in solution.

From these diagrams, it is possible to explain the spectrophotometric behavior of the solution containing $2 \times 10^{-4} M$ Fe(III) at pH 0.5 with variable sulfate concentration. The Pourbaix diagram constructed by using generalized species allows us to discuss the differences in the electrochemical behavior of Fe(III)/Fe(III) system in sulfuric acid solutions at different pH values (at $pSO_4' = 0$).

## CONSTRUCTION OF THE TWO-DIMENSIONAL PREDOMINANCE ZONE (TDPZ) AND POURBAIX-TYPE DIAGRAMS

The stability of the Fe(III) and Fe(II) species was studied separately by TDPZ diagrams of

*Author to whom correspondence should be addressed.

the corresponding generalized species. The calculations were carried out by analyzing the generalized equilibria[11,12] of the type:

$$Fe(III)' + SO_4' \leftrightarrows Fe(SO_4)' \quad (1)$$

$$Fe(SO_4)' + SO_4' \leftrightarrows Fe(SO_4)_2' \quad (2)$$

as well as the generalized dismutation equilibria:

$$2FeSO_4' \rightleftarrows Fe(SO_4)_2' + Fe(III)', \quad (3)$$

where $Fe(III)'$ represents all the Fe(III) species complexed with ligands other than $SO_4'$: (e.g. $Fe(III)' = \Sigma_i\ Fe(OH)_i$); $SO_4'$ represents all the chemical species containing $SO_4$, except those corresponding to the $FeSO_4$ complexes (e.g. $SO_4' = \Sigma_r\ SO_4(H)_r$), and $FeSO_4$ represents all the chemical species of $FeSO_4$ complexed with species other than $SO_4$ (e.g. $\Sigma_k\ FeSO_4(H)_k$). Where electrical charges are omitted for simplicity.

The definition of generalized species and their relationship with the complexation coefficients ($\alpha$) have been previously discussed in detail.[11,12]

For the system $Fe(III)$–$H_2SO_4$–$H_2O$ the concentrations of the generalized species are defined in such a way that:[11,12]

$$[Fe(III)'] = \sum_{i=0}^{m} Fe(OH)_i = [Fe^{3+}]\alpha_{Fe(H)} \quad (4)$$

$$Fe(SO_4)_j' = \sum_{k=0}^{n} FeH_k(SO_4)_j = [Fe(SO_4)^{3-2j}]\alpha_{(FeSO_4)_j(H)} \quad (5)$$

where $j \in \{0, 1, 2\}$,

$$SO_4' = \sum_{r=0}^{r} H_rSO_4 = [SO_4^{2-}]\alpha_{SO_4(H)}. \quad (6)$$

The generalized species are defined by the same method for the $Fe(II)$–$H_2SO_4$–$H_2O$ system. $\alpha_{FeSO_4j(H)}$ and $\alpha_{SO_4(H)}$ are the complexation coefficients dependent only on the $[H^+]$ buffering[12] (*e.g.* $\alpha_{FeSO_4(H)} = 1 + \Sigma_k K^{FeSO_4.kH}_{Fe(SO_4)_k} H^k$).

The generalized equilibrium is associated with Ringbom-type conditional constants[11,12] (dependent only on the $[H^+]$ buffering) called generalized constants.

$$K^{SO_4'}_{Fe(SO_4)_j'} = K^{SO_4}_{Fe(SO_4)_j} \frac{\alpha_{Fe(SO_4)_{(j+1)}(H)}}{\alpha_{Fe(SO_4)_j(H)}\alpha_{L(H)}} = \frac{[Fe(SO_4)_{(j+1)}]}{[Fe(SO_4)_j'][(SO_4)']}. \quad (7)$$

The method for the construction of predominance-zone diagrams (TDPZ) consists of the following steps.[11-13]

(1) Analysis of the ampholyte's stability: if the generalized dismutation constant of equilibrium (3) is $\geqslant 1$, $Fe(SO_4)'$ cannot predominate in the system, consequently, only the following equilibrium must be considered:

$$Fe(III)' + 2(SO_4)' \leftrightarrows Fe(SO_4)_2'. \quad (8)$$

(2) Study of the predominance of generalized species ($Fe(SO_4)_2'$, ($Fe(SO_4)'$ and $Fe(III)'$) with the following condition: $pSO_4' = -\log K^{(SO_4)'}_{Fe(SO_4)'}$ and $pSO_4' = -\log K^{(SO_4)'}_{Fe(SO_4)_2'}$ where $[Fe(III)'] = [Fe(SO_4)']$ and $[Fe(SO_4)_2'] = [Fe(SO_4)']$, respectively.

(3) Graphical representation in the $pSO_4' = pH$ space with borderlines selected from the conditions just described.

(4) Establishment of the limits for TDPZ imposed by the stabilization of the solid species ($Fe(OH)_3$, $Fe(OH)_2$). The method which considers the condensed phases in TDPZ has been described elsewhere.[14] The stability regions of the $Fe(OH)_2$ and $Fe(OH)_3$ depend upon the Fe(II) and Fe(III) concentrations selected for each case. In the following example, the total Fe(II) and Fe(III) concentrations are $2 \times 10^{-3} M$.

The total sulfates concentration $[SO_4']$ is the sum of $HSO_4^-$ and $SO_4^{2-}$ and is called the generalized sulfate concentration. The values of thermodynamic formation constants for the chemical species employed in this work are reported in Table 1.[9,10]

The TDPZ diagrams for $Fe/H_2SO_4/H_2O$ system are shown in Fig. 1. Figure 1a shows the predominance zones of the $Fe^{III}(SO_4)'$ species (*e.g.* $Fe(SO_4)^+$, $Fe(SO_4)_2^-$, $FeHSO_4^{2+}$) and Fig. 1b shows those of the $Fe^{II}(SO_4)'$ species (*e.g.* $Fe^{2+}$, $FeHSO_4^+$) as a function of $pSO_4'$ and pH, with the same degree of oxidation. Thus, these diagrams do not consider electron exchange. (Fig. 1a only considers the region be-

Table 1. The values of thermodynamic formation constants for iron–sulfate complexes[9,10]

| Ion | Equilibrium | log K |
|---|---|---|
| | $L = SO_4^{2-}$ | |
| $H^+$ | $H + L \rightarrow HL$ | 1.94 |
| $Fe^{3+}$ | $M + HL \rightarrow MHL$ | 1.8 |
| | $M + L \rightarrow ML$ | 4.0 |
| | $M + 2L \rightarrow ML_2$ | 5.8 |
| $Fe^{2+}$ | $M + HL \rightarrow MHL$ | 2.2 |
| | $L = OH^-$ | |
| $Fe^{3+}$ | $M + L \rightarrow ML$ | 11.0 |
| | $M + 2L \rightarrow ML_2$ | 21.9 |

| $Fe^{2+}$ | $M + 2L \rightarrow ML_2$ | 15.1 |

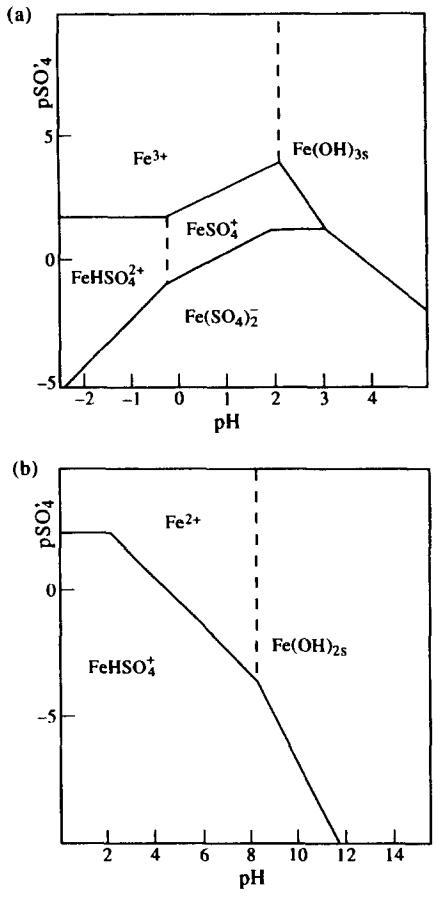

Fig. 1. Two-dimensional predominance zone diagrams ($pSO_4'$/pH) of Fe(II)/Fe(III) chemical species constructed for $C_{Fe(III)} = C_{Fe(II)} = 2 \times 10^{-3} M$, [$SO_4'$] represent the generalized sulfate concentration. (a) Fe(III) chemical species, (b) Fe(II) chemical species.

tween pH $-2$ and 5, since this is the pH range of practical interest.) The solid lines represent the variation of the logarithm of the generalized constants described by equation (7), and the described Fe–$SO_4$ exchange. The dashed lines represent the borderline of the predominance zone of species with the same M–L stoichiometry but different degree of protonation. From this diagram (1a), only $Fe(OH)_3$ and $Fe(SO_4)_2^-$ are present at higher pH values. The region at pH $< 0$ is not useful in our case because it can no longer be considered as dilute. The complete diagram is important for theoretical purposes only.

From the diagram, it can be concluded that in highly acidic media, the Fe(II) and Fe(III) sulfates-complexed species equilibria are predominant. At the conditions of the electrochemical studies previously reported,[2-4] Fe(III) and Fe(II) ions are complexed. For example, at $0 <$ pH $< 4$ and $pSO_4' = 0$ (total sulfate $= 1M$) it may be observed that the Fe(II) ions are the predominant species, mainly as $FeHSO_4^+$, while Fe(III) ions are in the form of $FeSO_4^+$ or $Fe(SO_4)_2^-$. This is a graphical way to analyze the behavior of processes involving only the complexation and hydrolysis reactions (these diagrams may be useful in the study of hydrometallurgical processes such as solvent extraction and ion-exchange). The electron exchange reactions are only considered in Pourbaix type diagrams.

In order to discuss the redox properties of Fe(III)/Fe(II) couple, considering hydrolysis effects on the cations and the formation of sulfate complexes, it would be necessary to construct a three-dimensional Pourbaix type diagram, $E''$–$pSO_4'$–pH. This diagram can be constructed considering the generalized electrochemical equilibria for the $Fe/H_2SO_4/H_2O$ system;[13]

$$Fe(III)'' + 1e^- \leftrightarrows Fe(II)'' \qquad (9)$$

with

$$E'' = E^0_{Fe^{3+}/Fe^{2+}} + \frac{RT}{F} \ln \frac{[Fe(III)'']}{[Fe(II)'']} \qquad (10)$$

where [Fe(III)''] represents the generalized concentration of Fe(III) species complexed with $SO_4$, OH and H.

However, the construction of such diagrams is rather time consuming and complicated. Therefore, to correlate thermodynamic predictions with the experimental results in an adequate manner, two-dimensional Pourbaix type diagrams have been constructed, considering either the $pSO_4'$ or else the pH constant. These diagrams correspond to a slice-cut of the corresponding three dimensional diagrams (as shown in Fig. 2).

The solid lines in Fig. 2 correspond to the variation of the formal potential of Fe(III)/Fe(II) with the $pSO_4'$ buffered at $1M$ or else at buffered pH 0.5. The dashed lines correspond to the border lines of the predominance zones of the different species with the same oxidation degree as a function of pH or $pSO_4'$. In Fig. 2a the potential–pH (or Pourbaix type) diagram for this system at buffered $pSO_4' = 0$ is shown (see below) and the potential–$pSO_4$ (Pourbaix type diagram) for the system buffered at pH 0.5 is shown in Fig. 2b. In Fig. 2b, it is evident that the equilibrium potential of the Fe(III)/Fe(II) couple is practically constant and similar to that of $Fe^{3+}/Fe^{2+}$ couple (0.77 V) even

though the chemical nature of the species involved is not the same (owing to the change in $pSO_4'$). This may be the reason why most authors do not consider the existence of sulfate-complexed Fe(III) ions in their works.[7,8]

The TDPZ diagrams of Fig. 1a and b show that the predominant species of Fe(III) and Fe(II) depend on the pH and $pSO_4'$ values which provoke a change in the redox properties of the system as shown in the Pourbaix-type diagrams of Fig. 2a and b.

In order to verify the chemical changes of the Fe(III) species with pH and $pSO_4'$, electrochemical and spectrophotometrical studies under buffered conditions were performed. The results of these studies prove, as shown below, that the changes in the electrochemical behavior of Fe(III)/Fe(II) system can be associated with modifications in the coordination sphere.

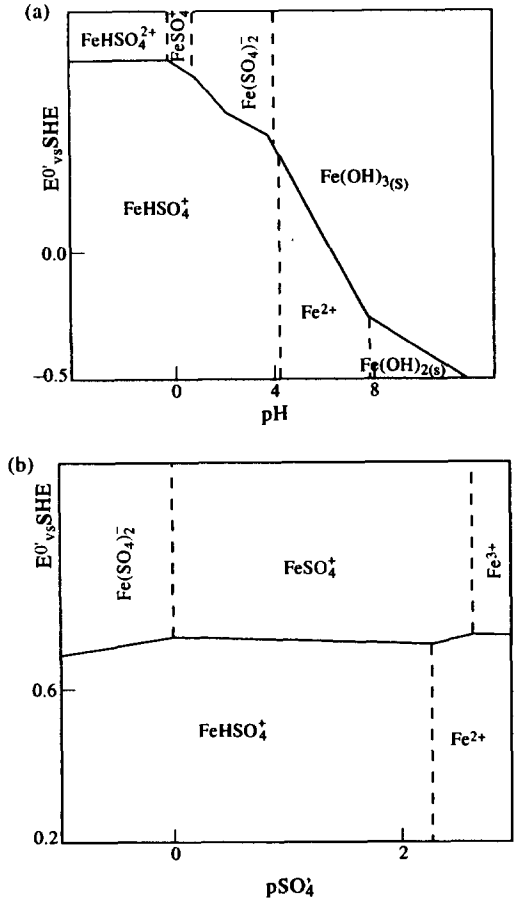

Fig. 2. Pourbaix type diagrams for the Fe(III)/Fe(II)/$SO_4'/H_2O$ system constructed from Fig. 1 and $C_{Fe(III)} = C_{Fe(II)} = 2 \times 10^{-3} M$. The Fe(III), Fe(II) diagrams are constructed for different buffered generalized species. (a) Potential ($E^0$/SHE)–pH diagram under buffered generalized sulfate $[SO_4'] = 1M$. (b) Potential ($E^0$/SHE)–$pSO_4'$ diagram at (buffered) pH 0.5.

## EXPERIMENTAL

The Fe(III) $2 \times 10^{-3} M$ solutions, were prepared by dissolving $Fe_2(SO_4)_3.H_2O$ (Laitz A. R.) in hot $1M$ $H_2SO_4$. The $1M$ $H_2SO_4$ solution was prepared from $H_2SO_4$ (Merck A. R.) and tridistilled water. In all experiments the solutions were previously saturated with $N_2$ and maintained under this atmosphere during each experiment. The pH and $pSO_4'$ were fixed by solid NaOH and $Na_2SO_4$ additions. For the solutions at $pH > 0$, the pH values were measured with a glassy electrode Corning model 240. The $pSO_4'$ were calculated by using the values of the solid $Na_2SO_4$ addition. For the $1M$ $H_2SO_4$ solution, it is not possible to measure the pH with a glassy electrode; in this case we have simply assumed that $pH < 0$.

The electrochemical studies were performed in a three-electrode cell. The working electrodes were Pt, Au and carbon paste (CP) rotating disk electrodes. Carbon paste electrodes were prepared by mixing Aldrich graphite powder with silicone oil, using a carbon rod as the electric contact. A mercury–mercurous sulfate electrode (MSE) was used as the reference, and a high area graphite rod as the counter electrode. All potentials in this work are given with respect to the normal hydrogen electrode (NHE).

The electronic system consisted of a PAR model 173 Potentiostat-Galvanostat, a PAR model 175 Universal Programmer, a Sefram X–Y Plotter and HP 3478A Multimeter. The spectrophotometric experiments were performed using a UV-Visible Hitachi spectrophotometer model 200.

### *Spectrophotometric measurements*

In order to verify the chemical changes in the Fe(III) coordination sphere predicted by the diagram (Fig. 1a), absorbance studies were carried out as a function of $pSO_4'$. It was not possible to perform such studies for the Fe(II) species, owing to the fact that these species easily oxidize in oxygen-containing aqueous solutions[2] and they present small molar extinction coefficients in aqueous solutions in the UV-Visible region.[6,15]

The UV-Visible spectra of the different Fe(III)–sulfate complexes are similar and they present absorption peaks in the 320–350 nm region.[6,15,16] For this reason it is very difficult to differentiate among these complexes by using this technique. However, it is possible to distinguish between Fe(III)–sulfate complexes and

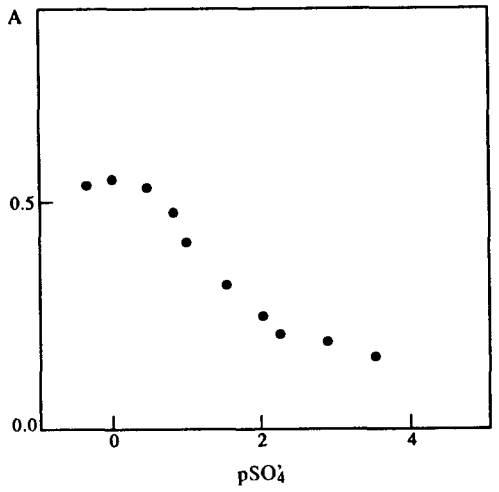

Fig. 3. Variation of absorbance ($\lambda = 318$ nm) as a function of $pSO_4'$, for a solution containing $2 \times 10^{-4} M$ Fe(III) and pH 0.5 (buffered). The sulfate concentration is modified by addition of $Na_2SO_4$.

other Fe(III)–aqueous complexes, because other Fe(III)–aqueous complexes present very small molar extinction coefficients in this region.

The variation of absorbance at $\lambda = 358$ nm as a function of $pSO_4'$ ($pHSO_4$) for pH 0.5 buffered solutions is shown in Fig. 3. The decrease in absorbance with increasing $pSO_4'$ indicates a variation of the coordination sphere of the Fe(III) species even at pH 0.5. Obviously, the absorbance corresponds to the sum of the absorbances of all the Fe(III)–$SO_4$ species in solution. At $pSO_4' < 0.8$, the absorbance is constant and as predicted by the diagrams can be interpreted to be owing to the predominant species $Fe(SO_4)_2^-$.[6,16-18] In the region $0.8 < pSO_4' < 2.2$, the absorbance decreases owing to the decrease in the $Fe(SO_4)_2^-$ molar fraction even though the $FeSO_4^+$ molar fraction increases (predominance of $FeSO_4^+$); this effect is caused by the fact that the $FeSO_4^+$ molar extinction coefficient is lower than that of $Fe(SO_4)_2^-$.[6] For pH > 2.2, the absorbance practically does not change because $Fe^{3+}$ is the predominant chemical species and it absorbs very little at this wavelength (358 nm).[6]

The spectrophotometric behavior of the Fe(III)–sulfate solution is not a definite proof of the presence of the various complexes of Fe(III)–$SO_4$; however, the variation of absorbance with $pSO_4'$ can be predicted by means of the information from Fig. 1a. Figure 1a predicts that $[Fe(SO_4)_2^-] = [FeSO_4^+]$ for pH 0.5 at $pSO_4' = -0.04$, and $[FeSO_4^+] = [Fe^{3+}]$ for pH 0.5 at $pSO_4' = 2.56$. This fact is an indication of the validity of the assumption discussed above, concerning the Fe(III)–$SO_4$ complexes. Unfortunately, the proof of the presence of the different sulfate complexes with iron in aqueous solution is a very difficult task when attempting to use other experimental techniques.

*Voltammetric measurements*

The electrochemical behavior of the Fe(III)/Fe(II) system is predicted by the Pourbaix-type diagram and involves different redox couples of soluble species as a function of pH at buffered $pSO_4'$ (Fig. 2). From the results discussed above, it is clear that pH changes provoke variations in the coordination sphere of Fe(III) but not in that of Fe(II).

According to the selected pH region, four representative electrochemical reactions exist involving soluble species for Fe(II) and Fe(III):

Region I: high acidity
$FeHSO_4^{2+} + 1e^- \rightleftarrows FeHSO_4^+$
Region II: $-0.26 \leqslant pH \leqslant 0.54$
$FeSO_4^+ + H_3O^+ + 1e^- \rightleftarrows FeHSO_4^+ + H_2O$
Region III: $0.54 \leqslant pH \leqslant 1.98$
$Fe(SO_4)_2^- + 2H_3O^+ + 1e^- \rightleftarrows FeHSO_4^+ + HSO_4^+ 2H_2O$
Region IV: $1.98 \leqslant pH \leqslant 4.0$
$Fe(SO_4)_2^- + H_3O^+ + 1e^+ \rightleftarrows FeHSO_4^+ + SO_4^{2-} + H_2O$.

In order to analyze the influence of the change in the coordination sphere of Fe(III) on the electrochemical behavior of the redox couples considered, a voltammetric study of the Fe(III) reduction on stationary disk electrodes was performed at buffered $pSO_4'$ and different values of pH. For this work, two pH regions were chosen: (a) pH < 0 ($1 M$ $H_2SO_4$) and (b) pH > 1. These were selected because they place the system in definite predominance regions of each chemical species (Fe(III): $FeSO_4^+$ and $Fe(SO_4)_2^-$, respectively). Furthermore, since the molar fractions $FeSO_4^+$ and $Fe(SO_4)_2^-$ are similar within the range $0 < pH < 1$, the electrochemical behavior cannot be associated with only one predominant Fe(III) species.

The voltammetric experiments at a stationary electrode (Pt, Au and CP), were carried out at different potential scan rates ($40 < v < 200$ mV/sec) for each pH value. A typical voltammogram obtained for the Fe(III) reduction is shown in Fig. 4. From these curves, cathodic ($E_{pc}$) and anodic ($E_{pa}$) potential peaks and associated currents ($i_c$ and $i_a$) were obtained. The determination of voltammetric parameters was made using stabilized voltammograms (after 3 or 4 cycles). The voltammetric behavior

is similar for different solutions whose pH falls in the same pH region.

Figure 5 shows the variation of $(E_{pa} - E_{pc}) = \Delta E_p$ as a function of $\ln v$ (sweep rate) for the three electrodes used in this work, for the electrochemical process of Fe(III)/Fe(II) in $1M$ $H_2SO_4$.

For both pH regions, $\Delta E_p$ changes with electrode material[19] at the same pH and sweep rate, this means that the heterogeneous rate constant ($\kappa_s$) for Fe(III)/Fe(II) processes is different on each electrode. This fact indicates that the electron transfer of Fe(III)/Fe(II) in sulfuric acid media performed by an "inner Helmholtz layer mechanism"[19] as has been evidenced by other authors.[3,5] The variation of $\Delta E_p$ with the scan rate[20] become more important in solutions at higher pH values. The $\kappa_s$ values could be calculated from the variation of $\Delta E_p$ with scan rate, however it is not possible to attempt this in the scan rate range considered in this work.

On the other hand, the $(E_{pa} + E_{pc})/2$ (generally associated with $E^0$) does not vary with scan rate, and its value is practically independent of the electrode material in solutions with pH < 0. Meanwhile, $(E_{pa} + E_{pc})/2$ varies markedly with the scan rate, and depends on the electrode material in solutions with pH > 1. These facts indicate that the kinetic mechanisms are different in the two pH regions, probably owing to the different predominant species of Fe(III).

Anson[3] reported that the decrease in $\kappa_s$ when the pH increase in sulfate medium is mainly a result of the formation of sulfate complexes with lower exchange current densities. However, Anson has not identified the sulfate complexes involved in the redox mechanism.

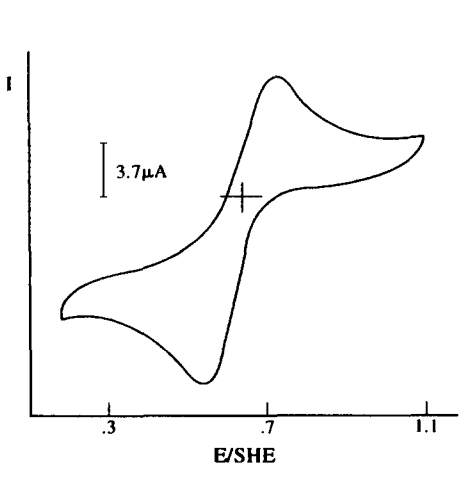

Fig. 4. Typical voltammogram for reduction of Fe(III) in $1M$ $H_2SO_4$ on platinum disk electrode, sweep rate 25 mV/sec.

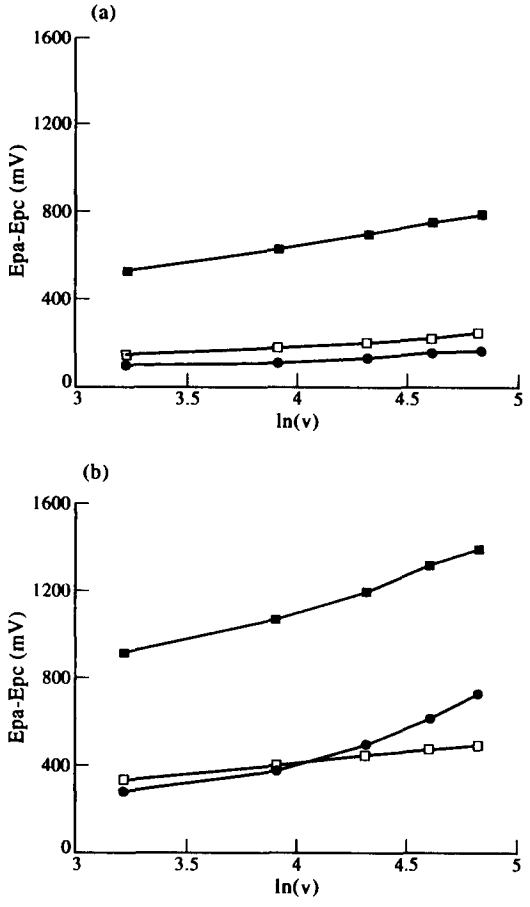

Fig. 5. The variation $E_{pa} - E_{pc}$ as a function of the scan rate potential ($\ln v$) for the Fe(III)/Fe(II) system from voltammetric curves obtained in different disc electrodes: (●) gold, (□) platinum and (■) carbon paste electrode. The electrolytic solution is $1M$ $H_2SO_4$ at different pH: (a) pH < 0, (b) pH > 1.

Figure 6 shows a typical variation of $i_a/i_c$ ratio as a function of $\log v$. For pH < 0 (Fig. 6a) the $i_a/i_c$ ratio varies smoothly with scan rate ($v$), and is essentially equal to unity for the Pt, Au and CP electrodes in the scan rate range considered. However, for pH > 1, the $i_a/i_c$ ratio is different to one, and varies in a distinct manner for Pt, Au and CP electrodes. The electron transfer at pH < 0 is performed between $FeSO_4^+/FeHSO_4^+$; meanwhile, at pH > 1 the couple $Fe(SO_4)_2^-/FeHSO_4^+$ is involved in the process. When the number of sulfate ligands associated with Fe(III) and Fe(II) is the same, the electrochemical behavior is typical of an inner Helmholtz layer mechanism. However, when the number of sulfate ligands is different in Fe(III) and Fe(II), the adsorption processes of Fe(III) inside the inner Helmholtz plane and the rearrangement of Fe(III) complexes are very different to those occurred at pH < 0. These facts are evidenced

by the kinetical complication observed in Fig. 6b.

These differences in electrochemical behavior with pH for the Fe(III) reduction may be attributed to the presence of different chemical species of Fe(III) in solution. The voltammetric results are not complete enough to establish the redox mechanism; however, it is possible to observe the modification in the electron transfer mechanism with the change in the pH of the solution.

Considering that electron transfer between Fe(III) and Fe(II) occurs by an inner Helmholtz layer mechanism, the chemical species involved in the mechanism would have the same coordination sphere; this is the case for the solution at pH < 0 here the predominant species are: ($FeSO_4^+$/$FeHSO_4^+$). Meanwhile, the different coordination numbers of Fe(III) and Fe(II) in the region pH > 1 here, the predominant species are: ($Fe(SO_4)_2^-$/$FeHSO_4^+$) may be related to the chemical complication observed in the voltammetric studies.

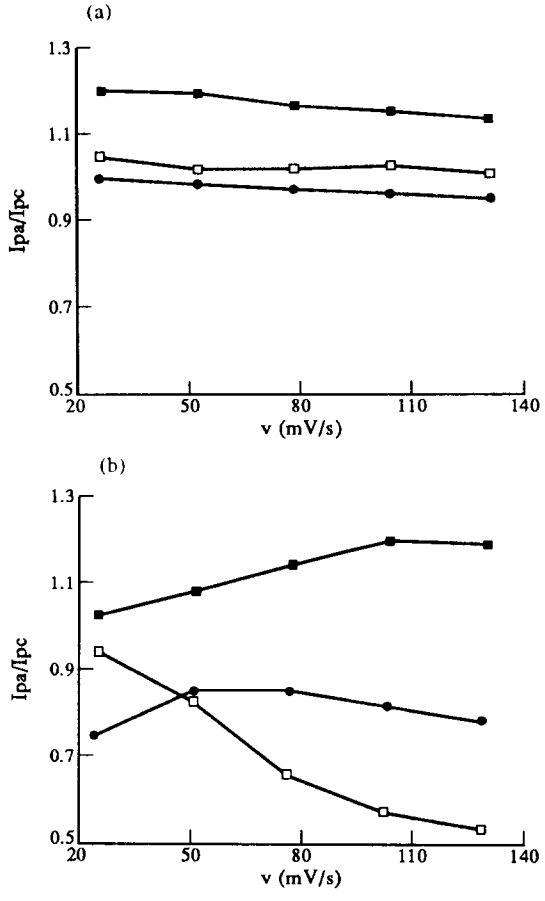

Fig. 6. The variation of the anodic–cathodic peak current ratio ($i_a/i_c$) as a function of the potential scan rate ($v$) for the Fe(III)/Fe(II) system from voltammetric curves obtained in different disc electrodes: (●) gold, (□) platinum and (■) carbon paste electrode. The electrolytic solution is 1*M* $H_2SO_4$ at different pH: (a) pH < 0, (b) pH > 1.

## CONCLUSIONS

A method based on the concept of generalized species and equilibria is used to represent the thermodynamic distribution of Fe(III) and Fe(II) species. The diagrams thus generated facilitate the selection of experimental parameters in order to establish specific equilibrium conditions. On the other hand, this selection permits a more realistic interpretation of the experimental results in complicated systems, similar to the one presented in this work.

This study permitted the selection of optimum experimental conditions since it is possible to identify different chemical species of Fe(III) and Fe(II) and of the redox couples Fe(III)/Fe(II). The spectrophotometric results showed the existence of the different chemical species for Fe(III) in the range of $0 < pSO_4' < 4$. In a similar manner, the electrochemical studies confirmed that the electron exchange transfer occurs by an inner sphere mechanism because the electrochemical behavior is different for the three electrodes used. Other authors have observed this behavior,[5] although to the best of our knowledge none has proposed that the iron–sulfate complexes are involved in the mechanism.

The electrochemical reduction of Fe(III) in $H_2SO_4$ was found to be complicated owing to the presence of different complexes on the electrode surface as a function of pH.

# HIGH PERFORMANCE LIQUID CHROMATOGRAPHIC DETERMINATION OF ALUMINIUM IN NATURAL WATERS IN THE FORM OF ITS LUMOGALLION CHELATE

CHAO YAN ZHOU,[1] JUN WU,[1] HUA CHI,[1] MING KEONG WONG,[1]* LIP LIN KOH[1] and YEOW CHIN WEE[2]

[1]Department of Chemistry, National University of Singapore, Lower Kent Ridge Road, Singapore 0511

(*Received* 1 *June* 1994. *Revised* 16 *September* 1994. *Accepted* 23 *September* 1994)

**Summary**—A high performance liquid chromatographic method for the determination of ultra trace amount of aluminium in natural waters has been developed using lumogallion as a precolumn reagent for fluorimetric detection. The highly fluorescent Al–lumogallion chelate ($\lambda_{ex}$ 500 nm, $\lambda_{em}$ 574 nm) was separated on a LiChrosorb RP 18 column with an eluent containing 3:7 acetonitrile/0.02*M* potassium hydrogen phthalate buffer (pH 4.7) containing $10^{-5}M$ lumogallion. The proposed system provides a simple, quick, selective and sensitive method for the determination of ultra-trace amount of aluminium in water samples. The detection limit defined as three times the standard deviation of the blank signal, was 0.05 $\mu$g/l. in water samples for 100 $\mu$l injection. The tolerance limits were 5 mg/l. for Fe(III) and $F^-$ and over 10 mg/l. for other foreign ions. The sensitivity of the method was independent of salinity. This method had been used for the direct determination of aluminium in both tap and coastal sea-waters without any preconcentration steps.

Aluminium was until recently believed to be relatively harmless, but evidence has grown to implicate it in a variety of potential toxicity in man.[1,2] Al is a minor component of natural water, its typical levels range from 0.5 to 140 $\mu$g/l.[3–5] There is thus an urgent need for the development of sensitive techniques to measure Al in low concentrations. So far, literature values for trace Al in natural waters are relatively scarce. This is mainly owing to analytical difficulties. The most commonly used analytical techniques are graphite furnace atomic absorption spectrometry (GF-AAS) and inductively coupled plasma atomic emission spectrometry (ICP-AES). The detection limits of these methods are about 1 $\mu$g/l., but their precision is poor in this range.[6–8]

The use of high performance liquid chromatographic (HPLC) separation and determination of Al in the form of chelates have been gaining popularity in recent years.[9–13] Spectrophotometric and electrochemical detections are most widely used in HPLC systems for the detection of Al chelates. However, they have poor performance at the $\mu$g/l. level.[9,10,13] Uehara *et al.*[12] recommended salicylaldehydebenzoylhydrazone (SAB) as a precolumn reagent. As SAB forms a chelate with Al, which is sensitive to fluorimetric detection, the detection limit for Al was reported to be 40 pg/ml in a 100 $\mu$l injection. Unfortunately, SAB is not commercially available and the synthesis and purification are inevitable. The success of the SAB method led us to conduct a systematic study on commercially available precolumn reagents for the HPLC analysis of Al with highly sensitive fluorimetric detection.

Fluorimetric analyses of Al with lumogallion as a chelating reagent have gained widespread acceptance.[14–17] Lumogallion has the advantages of high reaction ability, short reaction time, the formation of a stable resolvable chelate with Al at pH 4–5 and the chelate has high sensitivity for fluorimetric detection. However, in those normal fluorimetric analyses of Al using lumogallion as the chelating reagent,[15,17] the interferences from Fe(III) and $F^-$ are appreciable. Thus it was thought that combining HPLC with fluorimetric detection would provide a good solution to the problem. Different metal–lumo-

*Author to whom correspondence should be addressed.

gallion chelates in a sample solution can be separated with HPLC and thus the interferences in Al fluorimetric analyses can be eliminated and the low detection limit of fluorescence method can be achieved.

The aim of the present study is to develop a simple, selective and sensitive HPLC method for the determination of Al using fluorimetric and spectrophotometric detections with lumogallion as a precolumn reagent. The method was applied to the direct determination of Al at sub-ppb level in tap and coastal sea-waters.

## EXPERIMENTAL

### *Reagents and solutions*

The sodium hydroxide pellets from BDH (UK) were of "Aristar" 98.0% grade. All the chemicals used were of analytical reagent grade, unless otherwise indicated. Throughout the study, all glass and polypropylene apparatus were washed with 5% nitric acid and deionized distilled water.

Stock standard aluminium solution containing 1000 mg/l. Al in aluminium nitrate form for atomic absorption spectrometry was bought from BDH. All working standard Al solutions were prepared by serial immediate dilution with 0.2% nitric acid solution. Lumogallion was bought from Tokyo Kasei Kogyo Co. Ltd (Japan) and its solution (0.1 w/v %) was prepared by dissolving 0.1 g of the solid in 100 ml deionized distilled water. Potassium hydrogen phthalate (from BDH) solution (0.2*M*) was obtained by adding 1.02 g of the reagent into 50 ml deionized distilled water. The buffer solution was prepared by dissolving 2.04 g potassium hydrogen phthalate and 0.0017 g lumogallion in 500 ml deionized distilled water and the pH of the solution was adjusted to 4.7 with 1*M* NaOH solution.

### *Apparatus*

HPLC analysis was performed on a Waters Powerline™ HPLC system, including a Waters 600E Multisolvent Delivery System Controller, a Waters 470 Scanning Fluorescence Detector, a Waters 486 Tunable Absorbance Detector, a Waters 700 Satellite WISP™ Autosampler. The Waters Maxima™ 825 HPLC software was used for qualification. A LiChrosorb RP18 10 $\mu$ (25 cm × 4.6 mm i.d.) column from Hichrom Limited (U.K.) was used for the separation.

### *Pretreatment of water sample*

Tap water from the Singapore tap water supply system and coastal sea-water collected from the west coast of Singapore were treated by the following two procedures:[18,19] (A) for the determination of original dissolved Al: after collection, the samples were filtered immediately with cellulose filter (Millipore), pore size 0.45 $\mu$m, and then stored in polypropylene bottle at room temperature and analyzed within one week; (B) for the determination of dissolved Al after acid treatment: after collection, the pH of the sample was immediately adjusted to 1.5 by adding an appropriate amount of hydrochloric acid and the sample filtered with the cellulose filter prior to analysis. The samples were stored in polypropylene container.

### *Analytical procedure*

Pretreated water sample (5 ml) was transferred into a 10 ml polypropylene test tube, and 1 ml of 0.2*M* potassium hydrogen phthalate solution was added. After the pH of the mixture was adjusted to 4.7 by adding an appropriate amount of 1*M* NaOH solution, 0.5 ml of 0.1 w/v % lumogallion solution was added and the volume of the solution made up to 10 ml with deionized distilled water. The mixture was left at room temperature (about 25°C) for 15 min, then a 100 $\mu$l aliquot of the solution was injected into the HPLC.

## RESULTS AND DISCUSSION

### *Detection wavelengths*

Lumogallion reacted readily with Al ion. The UV absorption spectra of lumogallion and its Al chelate in a buffer solution at pH 4.7 are shown in Fig. 1. Lumogallion and its Al chelate gave maximum absorption at around 410 nm. However, the absorption maximum of the chelate was shifted slightly towards longer wavelength. After background subtraction, which was obtained by placing the solution containing lumogallion in the reference cell and the solution containing the chelate in the sample cell, a maximum absorbance related to the chelate appeared at 497 nm. The fluorescence spectra of the chelate and lumogallion are shown in Fig. 2. The optimum excitation and emission wavelengths of the Al-lumogallion chelate were found to be 500 and 574 nm. These wavelengths were used in later experiments.

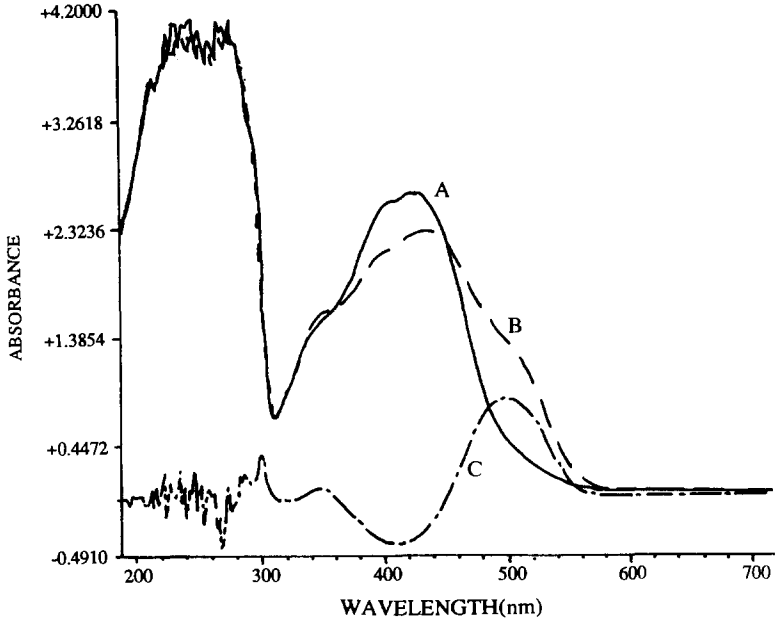

Fig. 1. The UV spectra of: (A) lumogallion; (B) Al–lumogallion chelate; (C) Al–lumogallion chelate with background correction. For A, a buffer solution containing 0.02*M* potassium hydrogen phthalate adjusted to pH 4.7 was used in the reference cell and the buffer solution spiked with 0.005% lumogallion was used in the sample cell; for **B**, the buffer solution in the reference cell and the buffer solution spiked with 0.005% lumogallion and 500 $\mu$g/l. of Al in the sample cell; for C, the buffer solution spiked with 0.005% lumogallion was used in the reference cell and the buffer solution spiked with Al (500 $\mu$g/l.) and lumogallion (0.005%) was used in the sample cell.

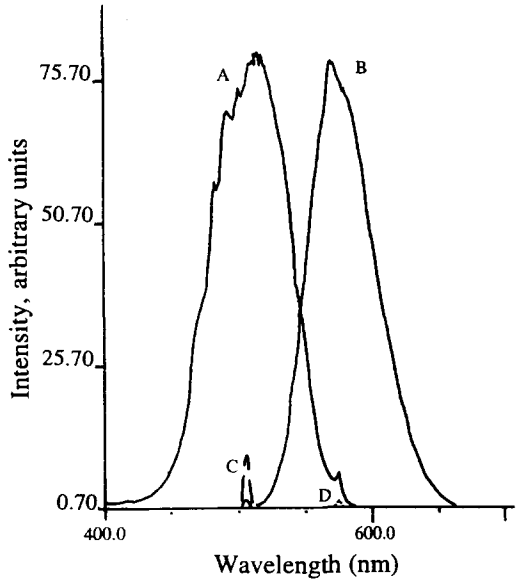

Fig. 2. The fluorescence spectra of 0.005% lumogallion solution containing 0.02*M* potassium hydrogen phthalate at pH 4.7 and the chelate solution containing Al (500 $\mu$g/l.), lumogallion (0.005%) and 0.02*M* potassium hydrogen phthalate at pH 4.7. (A) The excitation spectrum of the chelate solution with emission at 574 nm; (B) the emission spectrum of the chelate solution with excitation at 505 nm; (C) the excitation spectrum of lumogallion solution with emission at 574 nm; (D) the emission spectrum of lumogallion solution with excitation at 505 nm.

*Effects of reaction pH, temperature and time*

For the formation of the Al–lumogallion chelate, optimum pH values were reported to be from 3.8 to 5.0[14-16] Our experimental results were in agreement with the reported pH range. A pH value of 4.7 was chosen in later experiments. The effects of reaction time and temperature in the formation of the chelate were also studied. Following normal analytical procedures, samples containing 20 $\mu$g/l. of Al were prepared, then heated immediately in water bath set at different temperatures for 15 min and then analyzed. Results are shown in Table 1. From Table 1, it is seen that temperature had little effect on the formation of the chelate. For subsequent experiments, 25°C (room temperature) was used. When the temperature was fixed at 25°C, a sample containing 20 $\mu$g/l. of Al was prepared and then analyzed several times within 24 hr. According to the results shown in Table 2, the reaction of Al with lumogallion was completed in 15 min at room temperature and the chelate was stable for at least 24 hr.

*Chromatogram*

The typical chromatograms obtained from a serial injections of the solutions containing

Table 1. Effect of temperature on the formation of the chelate

| $T$ (°C) | 25 | 40 | 50 | 60 | 70 | 80 | 90 |
|---|---|---|---|---|---|---|---|
| Peak height† | 22.7 | 23.4 | 23.8 | 23.9 | 22.1 | 22.8 | 23.2 |

*The water bath temperature.

†The peak height in fluorimetric detection, unit, $10^3$ $\mu$V. Conditions: Al concentration 20 $\mu$g/l., pH 4.7, 0.02$M$ potassium hydrogen phthalate, 0.005% lumogallion; column, Lichrosorb RP 18; mobile phase, 30% acetonitrile and 70% aqueous containing 0.02$M$ potassium hydrogen phthalate, $10^{-5}M$ lumogallion; flow rate, 1.0 ml/min; detection, 500 nm and 574 nm for excitation and emission in fluorimetric detection; injection, 100 $\mu$l.

different Al concentrations are shown in Fig. 3. In the initial study, methanol and acetonitrile were added to the buffer solution as an eluent to separate the chelate and ligand. When methanol was used, poor separation of chelate and ligand was obtained. Addition of acetonitrile to the buffer solution improved the separation. In order to obtain a good separation of the compounds and to save the analysis time, a mobile phase containing 70% buffer and 30% acetonitrile was chosen in the later experiments. Under this condition, potassium hydrogen phthalate, Al–lumogallion chelate and the ligand are well separated as shown in Fig. 4.

*Linear range, precision and detection limit*

In the fluorimetric detection mode, both peak area and peak height of the chelate are increased linearly up to 500 $\mu$g/l. The repeatability (RSD) of the method was 2.43% for six replicate analyses of 50 $\mu$g/l. Al solution. The detection limit (taken as the concentration equivalent to three times the standard deviation of the blank) was 0.05 $\mu$g/l. for fluorimetric detection. Even with UV detection (at 497 nm), the detection limit was 0.3 $\mu$g/l. It was easy to quantify the Al concentration by the peak height method in fluorimetric detection at high concentration level. However, at low concentration level, the peak area method was found to be more accurate. The major sources of extraneous Al were glassware or other containers, reagents and solvents used. It was widely suggested that in the determination of ultra-trace Al, the use of glassware was to be avoided.[3,12,14,15] In our procedure, polypropylene apparatuses were used. Thus the main contamination sources were from reagents, potassium hydrogen phthalate was chosen to prepare the buffer solution. The pH of its solution was 3.9, hence only a small amount of sodium hydroxide solution was needed to adjust the pH to 4.7. In procedure A, the sample solution was filtered without any addition of other chemicals, and the blanks were found to be around 0.02 $\mu$g/l. While in procedure B, higher blank values were obtained around $\mu$g/l. which were caused by extraneous Al from added chemicals.

*Effects of foreign substances*

Iron is known to interfere with the standard lumogallion procedures[15,17] for fluorimetric analysis even at the $\mu$g/l. level. Experiments were, therefore, carried out to assess whether it remained so in the present method. Standard solutions containing 50 $\mu$g/l. of Al were spiked with Fe(III) at levels from 0 to 10 mg/l. and then analyzed. The results are listed in Table 3. When the concentration of Fe(III) reached 0.5 mg/l., the color of the solution changed from light yellow to light brown and the color became deeper with the increase of Fe(III) concentration. As shown in Fig. 5, the chromatogram obtained from UV detection method was influenced strongly and the lumogallion peak was very low, indicating that the Fe(III) in the solution consumed most of the free lumogallion ligand. However, the chromatogram from fluorimetric detection did not change until Fe(III) concentration was over 5 mg/l. The results indicate that Al–lumogallion chelate is more stable than Fe(III)–lumogallion chelate and the two chelates are separated by HPLC.

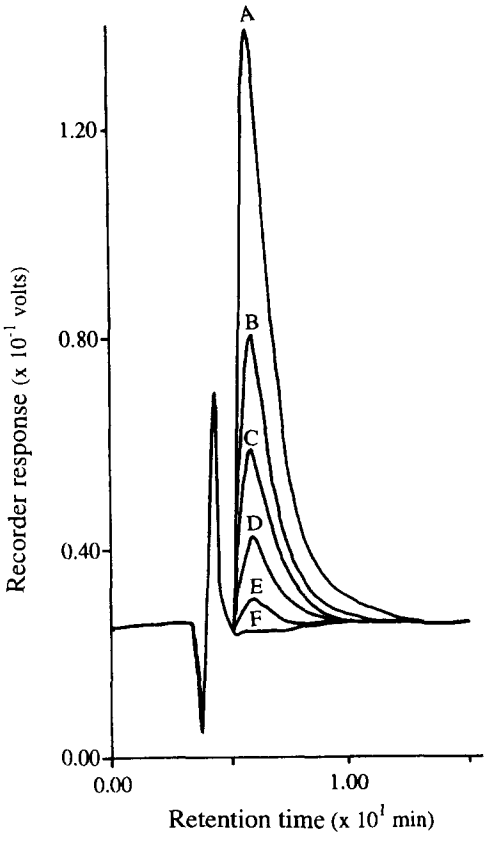

Fig. 3. Typical chromatograms of fluorimetric detection with different Al concentrations: (A) 200 $\mu$g/l.; (B) 100 $\mu$g/l.; (C) 60 $\mu$g/l.; (D) 30 $\mu$g/l.; (E) 10 $\mu$g/l. and (F) 0 $\mu$g/l. The chelate was formed in the solution at pH 4.7 containing 0.02*M* potassium hydrogen phthalate and 0.005% lumogallion; column, Lichrosorb RP 18; mobile phase, 30% acetonitrile and 70% aqueous containing 0.02*M* potassium hydrogen phthalate and $10^{-5}$*M* lumogallion; flow-rate, 1.0 ml/min; detection, 500 nm and 574 nm for excitation and emission in fluorescence detection; injection, 100 $\mu$l.

The second known interference in the conventional fluorimetric assay is that of fluoride.[15,17] Standard solutions of Al (50 $\mu$g/l.) were spiked with fluoride at levels from 0 to 10 mg/l. and analyzed according to the recommended procedure. The results are given in Table 4, which indicated that at below 5 mg/l., fluoride did not interfere with the Al analysis.

Other common metal ions in natural waters such as Ni(II), Co(II), Zn(II), Sn(II), Cu(II), Mo(VI), Pb(II) were also studied. The ions did not interfere in the proposed method at under 10 mg/l. level. Na(I), Mg(II), K(I) and Ca(II) did not interfere with the Al analysis at concentrations present in sea-water. The interferences of foreign ions in the proposed method were 10 times lower than those in fluorimetric methods with lumogallion. Potential interferences from diverse metal ions present in large excess are thought to be caused by the consumption of lumogallion reagent under precolumn derivatization conditions rather than by peak overlap. Such interferences can be overcome by adding sufficient amount of lumogallion, or by diluting the sample prior to derivatization. In the present method, lumogallion was used at a higher concentration than that used in the fluorimetric methods[15,17] in order to eliminate the interference from salts present in natural water samples. The linear range was also increased in the proposed method.

*Practical application*

The proposed method had been successfully applied to the determination of Al in fresh- and sea-water samples. Table 5 summarizes the results obtained by our proposed method and the GF-AAS method for water samples, and samples spiked with the metal standards to ascertain the validity of the analytical data. The good recovery of the spiked Al ion indicates that the procedure is valid.

Sample pretreatment methods would normally influence the final analytical results.[10,18-20] In procedure A, the concentrations of Al in the water samples were at the ppb level, hence the results were obtained by measuring the peak areas and the standard addition method was used. The results are shown in Fig. 6. The concentration values obtained from procedure A represent the original dissolved Al that could form chelate with lumogallion without acid treatment. The Al concentrations obtained from procedure B correspond to the dissolved Al in water after acid treatment. Hence the Al concentrations would include original dissolved Al and Al from particles and colloids which was released during acid treatment. Typical HPLC chromatograms of the tap water, sea-water and their spiked samples from procedure B are

shown in Fig. 7. Our data (Table 5) show that the proposed HPLC method can be used successfully to determine Al in natural water samples and that there is no interference from matrixes such as alkali and alkaline-earth metals in sea-water. The recoveries of the proposed method were 100 and 96% for tap water and sea-water samples. The results from GF-AAS and the proposed HPLC method were in agreement for tap water and its spiked samples.

| B† | Sea-water + 100 $\mu$g/l. Al(III) | $306 \pm 5.3$ | $320 \pm 16$ |

*The values were obtained from standard addition method.
†The values were obtained from average of four measurements.
The analytical conditions of HPLC method as in Fig. 3.

However, differences were found in sea-water and its spiked samples. Higher values of Al concentration were found in sea-water and its spiked samples by the GF-AAS method compared with that from the HPLC method. Owing to the high salt content in sea-water, the background correction used in GF-AAS may not be able to compensate completely for the background contribution.

## CONCLUSIONS

Lumogallion is a commercially available reagent which reacts cleanly with aluminium, forming a stable and highly fluorescent complex. These characteristics permit the use of lumogallion in the determination of Al in ultra-trace levels. Coupled with HPLC, which functions as a clean-up procedure, interferences from other ions are eliminated. The technique permits trace analysis of aluminium in sub-ppb to 500 ppb level in both fresh and saline waters. The complicated procedures, such as preseparation and matrix-matching that are otherwise needed for the removal of matrix effects are thus eliminated. The proposed method may also be applicable to clinical, environmental and industrial analyses.

# OPTIMAL ACIDITY OF COMPLEXES BY SOLUTION OF POLYNOMIALS AND BY ITERATION

B. W. BUDESINSKY*

Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

(*Received* 21 *June* 1994. *Revised* 2 *September* 1994. *Accepted* 13 *September* 1994)

**Summary**—The methods for optimal acidity of complexes $M_xL_y(OH)_mH_n$ based on direct iteration or solution of polynomials are described and discussed. Then, by a direct straightforward method of computation (that does not require any iteration) the complexes $M_xL(OH)_mH_n$ and $ML_y(OH)_mH_n$ are treated (where $1 \leqslant x \leqslant 3$ and $1 \leqslant y \leqslant 3$). Finally, the conditions leading to formation of polynuclear complexes are shown and discussed. The importance of study of polynuclear complexes for solving of biochemical problems is pointed out. Practical examples are given for each method.

The optimal acidity of a complex is the acidity for which the concentration of complex formation is reaching its maximum. The optimal acidity of complexes $M_xL_y(OH)_mH_n$ is usually determined by iteration.[1] Among methods of iteration we can even include such methods like regula falsi (or secant *m.*) and the Newton–Raphson method[2] because these methods also require some kind of iteration, just the mechanism of iteration in these methods is different.

Relatively little attention has been paid to polynomial methods like cubic and quartic equations. It is assumed that those methods lead to many complex conjugate roots so that it is difficult to find out the correct result. In this paper I will show that it is not necessarily so. On the contrary, the traditional iteration methods are connected with larger error. However, I do not intend to underrate the iteration methods, whose far reaching universality is of great advantage.

In combination with a sufficiently general method of iteration the optimal acidity of complexes $M_xL_y(OH)_mH_n$ (where $1 \leqslant x \leqslant 4$ and $y$ is any reasonable integer) can be determined. This is particularly useful for problems in biochemistry.

Finally, the conditions are shown that lead to the formation of polynuclear complexes. They are illustrated on the complex formation of chrome azurol S, eriochrome cyanine R, Xylenol Orange and triethylenetetraminehexaacetic acid with ions like $Fe^{3+}$, $Th^{4+}$, $Hg^{2+}$, $La^{3+}$ and $Cu^{2+}$.

## THEORETICAL

### *Single complex formation* $M_xL_y(OH)_mH_n$

If $[M_xL_y(OH)_mH_n] = c$, then the material balance is

$$c_M = xc + [M]\alpha_{MOH} \quad \text{and} \quad c_L = yc + [L]\alpha_{LH}, \tag{1a, b}$$

where $\alpha_{MOH}$ and $\alpha_{LH}$ are the coefficients of side reactions of the metal with OH ions and of the ligand L with protons H, respectively. We have

$$\alpha_{MOH} = \Sigma\beta_{t'}[OH]^{t'} = \Sigma\beta_{t'}K_w^{t'}[H]^{-t'} = \Sigma\beta_{t'}^{*}[H]^{-t'} \tag{2}$$

$$\alpha_{LH} = \Sigma\beta_t[H]^t, \tag{3}$$

where $K_w$ is the autoprotolytic constant of water ($=[H][OH] = 10^{-14}$ at 25°C). The conditional stability constant $K$ of the complex $M_xL_y(OH)_mH_n$ is given by

$$\begin{aligned} K &= c\,(c_M - xc)^{-x}(c_L - yc)^{-y} \\ &= c\,([M]\alpha_{MOH})^{-x}([L]\alpha_{LH})^{-y} \\ &= \beta_{xynm}\alpha_{MOH}^{-x}\alpha_H^{-y}[OH]^m[H]^n, \end{aligned} \tag{4}$$

where $\beta_{xynm}$ is the overall stability constant of the complex $M_xL_y(OH)_mH_n$. Taking logarithms of equation (4) we obtain

$$\begin{aligned} \log K = \log\beta_{xynm} &- x\log\alpha_{MOH} \\ &- y\log\alpha_{LH} + m\log K_w \\ &- (m-n)\log[H]. \end{aligned} \tag{5}$$

The conditional constant $K$ is reaching its maximum for the optimal acidity of the complex $M_xL_y(OH)_mH_n$. Therefore, we have

$$(\mathrm{d}\log K)/(\mathrm{d}\log[\mathrm{H}]) = 0 \qquad (6)$$

so that if we differentiate equation (5) under the conditions of (6) we obtain

$$x(\mathrm{d}\log\alpha_{\mathrm{MOH}})/(\mathrm{d}\log[\mathrm{H}]) + y(\mathrm{d}\log\alpha_{\mathrm{LH}})/(\mathrm{d}\log[\mathrm{H}]) + m - n = 0. \qquad (7)$$

Furthermore, we have

$$(\mathrm{d}\log\alpha_{\mathrm{MOH}})/(\mathrm{d}\log[\mathrm{H}]) = -(\Sigma t'\beta_t^*[\mathrm{H}]^{-t'})/(\Sigma\beta_t^*[\mathrm{H}]^{-t'}) = -\bar{t}' \qquad (8)$$

$$(\log\alpha_{\mathrm{LH}})/(\mathrm{d}\log[\mathrm{H}]) = (\Sigma t\beta_t[\mathrm{H}]^t)/(\Sigma\beta_t[\mathrm{H}]^t) = \bar{t}. \qquad (9)$$

Combining equations (7)–(9) results in

$$-x\bar{t}' + y\bar{t} + m - n = 0, \qquad (10)$$

which is the final equation for the optimal acidity of a single complex $M_xL_y(OH)_mH_n$. This shows that it is only a function of the composition of the complex and the extent of the side reactions, the metal M with hydroxide anions and the ligand with the protons. It is not a function of the stability of the complex.

If two complexes between M and L are formed, the stabilities of both are required to determine their optimal acidity, or at least one proceeding by the procedure described below.

*Many complexes of* $M_xL_y(OH)_mH_n$

Taking into account the fact that quartic equations can still be solved directly, the system of complexes, the optimal acidity of which we are trying to determine, is described by the material balance equations

$$[\mathrm{M}]^4A + [\mathrm{M}]^3B + [\mathrm{M}]^2C + [\mathrm{M}]D + E = 0 \qquad (11)$$

$$[\mathrm{M}]'^4A' + [\mathrm{M}]'^3B' + [\mathrm{M}]'^2C' + [\mathrm{M}]'D' + E' = 0, \qquad (12)$$

where

$$A = \Sigma\Sigma\Sigma p\beta_{4pef}[L]^p[\mathrm{OH}]^e[\mathrm{H}]^f,$$
$$B = \Sigma\Sigma\Sigma q\beta_{3qgh}[\mathrm{L}]^q[\mathrm{OH}]^g[\mathrm{H}]^h \qquad (13a, b)$$
$$C = \Sigma\Sigma\Sigma r\beta_{2rij}[\mathrm{L}]^r[\mathrm{OH}]^i[\mathrm{H}]^j,$$
$$D = \Sigma\Sigma\Sigma s\beta_{1smn}[\mathrm{L}]^s[\mathrm{OH}]^m[\mathrm{H}]^n \qquad (14a, b)$$
$$E = [\mathrm{L}]\Sigma\beta_t[\mathrm{H}]^t - c_{\mathrm{L}} \qquad (15)$$
$$A' = \Sigma\Sigma\Sigma 4\beta_{4pef}[\mathrm{L}]^p[\mathrm{OH}]^e[\mathrm{H}]^f,$$
$$B' = \Sigma\Sigma\Sigma 3\beta_{3qgh}[\mathrm{L}]^q[\mathrm{OH}]^g[\mathrm{H}]^h \qquad (16a, b)$$
$$C' = \Sigma\Sigma\Sigma 2\beta_{2rij}[\mathrm{L}]^r[\mathrm{OH}]^i[\mathrm{H}]^j,$$
$$D' = \Sigma\Sigma\Sigma\beta_{1smn}[\mathrm{L}]^s[\mathrm{OH}]^m[\mathrm{H}]^n \qquad (17a, b)$$
$$E' = -c_{\mathrm{M}}. \qquad (18)$$

As a measure of the accuracy of iteration, we have introduced

$$A^* = 1 - [\mathrm{M}]/[\mathrm{M}]', \qquad (19)$$

where $|A^*| < 0.001$ throughout.

As a measure of concentration, the molar per cents of the total metal concentration were used:

$$P_{xyur} = 100x\beta_{xyur}[\mathrm{M}]^x[\mathrm{L}]^y[\mathrm{OH}]^u[\mathrm{H}]^r. \qquad (20)$$

Within direct iteration, both material balance equations (11) and (12) are transformed into a form explicit for [M] and [M]′. These two equations are combined with the accuracy equation (19), and the iteration started with the quantity [L] until the condition of accuracy are met. In doing that, another basic rule of iteration is followed, iterating with a quantity which has the most complicated form in the given system.

The mechanism of direct iteration is presented in Fig. 1. It is useful to start the iteration at higher pH since then the interval of permissible [L] values is wider.

There is no need to give the equations for determination of optimal acidity in mono- and binuclear systems. They are evident from equations (11), (12), (14a, b), (15), (17a, b), (18) and (19).

For systems of trinuclear complexes, the equations that hold are

$$P = D/B - (C/B)^2/3 \qquad (21)$$

$$Q = (C/B)^3 2/27 - (CD/B^2)/3 + E/B \qquad (22)$$

$$[\mathrm{M}] = [-Q/2 + (Q^2/4 + P^3/27)^{1/2}]^{1/3} - (C/B)/3 + [-Q/2 - (Q^2/4 + P^3/27)^{1/2}]^{1/3}, \qquad (23)$$

where (23) is the well known Cardano equation.[3] Since that equation has real roots only if

$$Q^2/4 + P^3/27 \geqslant 0, \qquad (24)$$

that does not cover all real roots of cubic equations (11) and (12) ($A = A' = 0$), so that some real roots of (11) and (12) must correspond to (24) even if it is negative. This leads to the equation

$$[\mathrm{M}] = 2(-P/3)^{1/2}\cos\varphi/3 - (C/B)/3 \qquad (25)$$

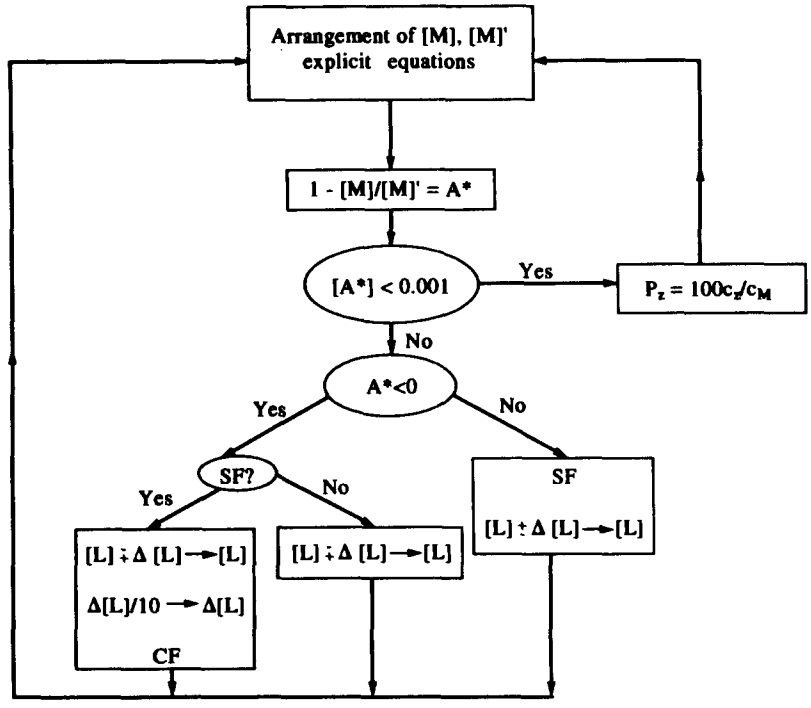

Fig. 1.

where

$$\cos\varphi = -Q/2(-27/P^3)^{1/2}. \quad (26)$$

For derivation of equation (25) see Appendix A.

Under these conditions, equation (23) yields just one real and positive root; if it does not, then (25) takes over. In that way we find the solution of cubic equations (11) and (12).

For systems of tetranuclear complexes, the solution is based on the solution of a quartic equation. We have

$$P^* = BD/A^2 - 4E/A - (C/A)^2/3 \quad (27)$$

$$Q^* = -(C/A)^3 2/27 + (BCD)/A^3 - 4(E/A)/3 - (D/A)^2 - (B/A)^2 E/A + 4CE/A^2 \quad (28)$$

$$y = [-Q^*/2 + (Q^{*2}/4 + P^{*3}/27)^{1/2}]^{1/3} - (C/A)/3 + [-Q^*/2 - (Q^{*2}/4 + P^{*3}/27)^{1/2}]^{1/3}. \quad (29)$$

Because that solution can be rarely found correctly published, it is given in Appendix B.

The condition to obtain positive real roots is again

$$Q^{*2}/4 + P^{*3}/27 \geqslant 0. \quad (30)$$

From Appendix B we have

$$\alpha^2 = (B/A)^2/4 + y - C/A;$$

$$\beta^2 = y^2/4 - E/A \quad (31a, b)$$

so that, for the conditions of complexation, the only acceptable positive real root is given by equation (32). Since the solution of a quartic

$$[M] = (\alpha - B/2A)/2 + [(\alpha - B/2A)^2/4 + \beta - y/2]^{1/2} \quad (32)$$

equation includes the solution of the cubic equation (29), our program must include the selection between (23) and (25), both with asterisk quantities.

Complexes $ML_y(OH)_uH_v$ and $M_xL(OH)_uH_v$. For these complexes no iteration is necessary and the computation of [M] and [L] is a straight operation employing the equations

$$[M]([L]^3U + [L]^2V + [L]W + 1) - c_M = 0 \quad (33)$$

$$[M](3[L]^3U + 2[L]^2V + [L]W) + [L]\alpha_{LH} - c_L = 0. \quad (34)$$

Combination of equations (33) and (34), with elimination of [M], results in

$$[L]^4\alpha_{LH}U + [L]^3(\alpha_{LH}V - c_LU + 3c_MU) + [L]^2(\alpha_{LH}W - c_LV + 2c_MV) + [L](\alpha_{LH} - c_LW + c_MW) - c_L = 0, \quad (35)$$

where $1 \leqslant y \leqslant 3$ and $U = \Sigma\Sigma\beta_{13ef}[OH]^e[H]^f$, $V = \Sigma\Sigma\beta_{12gh}[OH]^g[H]^h$, $W = \Sigma\Sigma\beta_{11ij}[OH]^i[H]^j$.

The situation is similar with complexes $M_xL(OH)_uH_r$. We have again

$$[L]([M]^3U' + [M]^2V' + [M]W' + \alpha_{LH}) - c_L = 0 \quad (36)$$

$$[L](3[M]^3U' + 2[M]^2V' + [M]W') + [M] - c_M = 0. \quad (37)$$

Combining equations (36) and (37) with elimination of [L] we get

$$[M]^4U' + [M]^3(V' - c_MU' + 3c_LU') + [M]^2(W' - c_MV' + 2c_LV') + [M](\alpha_{LH} - c_MW' + c_LW') - c_M\alpha_{LH} = 0, \quad (38)$$

where $1 \leqslant x \leqslant 3$ and $U' = \Sigma\Sigma\beta_{31mn}[OH]^m[H]^n$, $V' = \Sigma\Sigma\beta_{21pq}[OH]^p[H]^q$, $W' = \Sigma\Sigma\beta_{11rs}[OH]^r[H]^s$.

## RESULTS AND DISCUSSION

The conditions of the single complex method are met only seldom in real solutions. Nevertheless, that method gives useful preliminary information about probable behavior of the complex.[4] Some illustrative results and a comparison with the most advanced method as described in this paper are given in Table 1. Similar results, sometimes even more closely related to the facts, can be obtained with buffer ligands described by $\alpha_{MX}$ and $\alpha_{XH}$ (where $X = NH_3$, $CH_3COO^-$, etc.).

The optimal acidities for particular complexes were determined by computing the dependence between the actual concentration of the complex (in Tables the numbers are in parentheses) and the acidity of the coexisting solution. This was done over the whole acidity scale for every complex of the known composition and stability.

Thus Table 2 shows the effect of different total concentration of metal and ligand on the optimal acidity and actual concentration of complexes. Furthermore, Table 2 shows different behavior of the tetradentate ligand (CAS and ECR) and of the octadentate ligand (XO). Thus in the case of XO, only at very low pH, when most of the ligand is blocked by hydrogen complexes and, therefore, the free metal ions are in huge excess, is the binuclear complex $M_2LH_2$ formed. At higher pH (5.8–6.2), when the donors of the ligand are activated and the ligand itself is present in excess, the main complex formed is $M(LH_2)_2$. In between, understandably, there are conditions for the complex $MLH_2$.[5] On the other hand, owing to the presence of two relatively independent chelating systems and the donor deficiency, CAS and ECR form the binuclear complexes $M_2L$ and $M_2L_2$. Only at low pH, when one side of the ligand is blocked by hydrogen, is the complex MLH formed. Ueno *et al.*[6] discussed the conditions of complex formation between $Fe^{3+}$ and CAS. Complexation of CAS and ECR is in good agreement with the theory of binuclear complex formation (see below).

The results of the straightforward method (SFM), employing the quartic equation and cubic equation as a sub-method, are presented in Table 3. The computation shows, that if we have a system of complexes with overall stability constants $\beta_1, \beta_2, \ldots, \beta_z$ then if $\beta_1^z \doteq \beta_z$, the computation runs predominantly via Cardano equation (23). On the other hand, if $\beta_1^z > \beta_z$, it

*The numbers in parentheses refer to the per cent of particular complex; $c_M$ and $c_L$ are the total concentration of the metal and of the ligand, respectively.

runs via the goniometric variant (25). Table 3 also shows the comparison of SFM with the direct iteration method. Both methods give very similar results, but SFM is slightly more accurate. Many times the iteration gives the same concentration of individual complexes in the pH interval 5–6.

Table 4 shows the optimal acidity of metal complexes of TTHA (triethylenetetraminehexaacetic acid). Since it is $y = 1$ throughout, the SFM and direct iteration were used. Again as in Table 3 the SFM gives slightly better results. TTHA forms a wide scale of binuclear complexes.

The conditions of polynuclear complex formation can be summed up as follows: (a) the complexing reagent must contain several relatively independent chelating systems. (b) The primary mononuclear complex is usually a mixed metal–hydrogen–ligand complex. (c) As a

$2c_L = c_M$. See also the footnotes for Table 2: $c_L = 0.01M$.

measure of nuclearity the fraction $F$, equation (39), can be used.

$$F = [M_xL]/[M_{x-1}LH] = \beta_x[M]/(\beta_{x-1}[H]), \quad (39)$$

where $\beta_x$ is the overall stability constant of the complex $M_xL$ and $\beta_{x-1}$ the stability constant of the mixed complex $M_{x-1}LH$. The actual concentrations [M] and [H] should be taken in the conditions of optimal acidity of the complex $M_xL$. The values of $\log F$ for complexes $M_2L$ from Table 4 are listed in Table 5.

Biochemistry is the most fruitful field where polynuclear complexes can occur. One problem is, for example, why rigid and planar polypeptides form only the *trans* configuration of mutual location of nitrogen and oxygen atoms.[7] The presence of a metal ion like $Cu^{2+}$ would favor the *cis* configuration. Tripropylene- or tributylenetetraminohexaacetic acid can be used as model for investigation of tetranuclear complexes.

Table 5. Fraction F in the conditions of optimal acidity

| Metal ion | log F | Metal ion | log F | Metal ion | log F |

## APPENDIX A

*Goniometric variant of Cardano equation*[9]

The Cardano equation (23) with imaginary components reads

$$[M] = [-Q/2 + i(Q^2/4 + P^3/27)^{1/2}]^{1/3} + [-Q/2 - i(Q^2/4 + P^3/27)^{1/2}]^{1/3} - (C/B)/3. \quad (A1)$$

According to the Moivre theorem we have

$$(\cos x \pm i \sin x)^n = \cos nx \pm i \sin nx \quad \text{(A2)}$$

and introducing

$$\cos x = -Q/2(-27/P^3)^{1/2} \quad \text{(A3)}$$

we obtain

$$[M] = 2(-P/3)^{1/2} \cos x/3 - (C/B)/3, \quad \text{(A4)}$$

where $x = \varphi$. Then (A4) is identical with (25).

## APPENDIX B

*Solution of the quartic equation*[10]

The general equation

$$x^4 + ax^3 + bx^2 + cx + d = 0 \quad \text{(B1)}$$

is squared for its two members by writing

$$(x^2 + ax/2)^2 = x^4 + ax^3 + (a/2)^2x^2 = [(a/2)^2 - b]x^2 - cx - d. \quad \text{(B2)}$$

Furthermore, if we add to each side $(x^2 + ax/2)y + y^2/4$ we get

$$(x^2 + ax/2 + y/2)^2 = x^4 + (a/2)^2x^2 + y^2/4 + ax^3 + x^2y + (a/2)xy. \quad \text{(B3)}$$

That is

$$[(a/2)^2 - b + y]x^2 + (ay/2 - c)x + (y/2)^2 - d = \alpha^2x^2 + 2\alpha\beta x + \beta^2, \quad \text{(B4)}$$

where

$$\alpha^2 = (a/2)^2 - b + y, \quad \beta^2 = (y/2)^2 - d, \quad 2\alpha\beta = ay/2 - c, \quad \text{(B5a, b, c)}$$

so that by mutual combination of (B5, a, b, c) we obtain

$$y^3 - by^2 + (ac - 4d)y - (c^2 + a^2d - 4bd) = 0 \quad \text{(B6)}$$

which is the resolvent of (B1). Since it is a cubic equation, it may be solved by the methods for cubic equations. Thus we get by combination of (B4) and (B5, ab)

$$x^2 + (a/2 - \alpha)x + y/2 - \beta = 0 \quad \text{(B7)}$$

or

$$x = (\alpha - a/2)/2 + [(\alpha - a/2)^2/4 + \beta - y/2]^{1/2} = [M]. \quad \text{(B8)}$$

# DETERMINATION OF EQUILIBRIUM CONSTANTS OF ALKALINE EARTH METAL ION CHELATES WITH DOWEX A-1 CHELATING RESIN

LEO HARJU and TOWE KROOK
Department of Analytical Chemistry, Åbo Akademi, FIN-20500 Åbo, Finland

(*Received* 26 *April* 1994. *Revised* 29 *September* 1994. *Accepted* 29 *September* 1994)

**Summary**—A complexation chemistry model is applied to chelating ion-exchange systems and a method is presented for the determination of equilibrium constants for metal ion chelates with these resins. Protonation constants for the iminodiacetic based chelating resin Dowex A-1 were determined from potentiometric pH-data. Equilibrium constants were determined for 1:1 beryllium, magnesium, calcium, strontium and barium chelates with the resin in a wide pH range by measuring the concentrations of respective metal ions in the aqueous phase with direct current plasma atomic emission spectrometry (DCP-AES). A batch technique was used for the equilibrium experiments. At pH below 7 protonated 1:1 species were also found to be formed with the resin. From the obtained equilibrium constants, theoretical distribution coefficients were calculated as function of pH for respective metal ion resin system.

The synthesis and use of selective chelating resins in chemistry and industry have rapidly increased during the last years. Comprehensive reviews have been written about the synthesis, properties and uses of chelating resins.[1-3] Chelating resins have, for instance, found use for removal of trace metal ions from reagents, biochemical and physiological fluids. The main use in analytical chemistry is for preconcentration and separation, *e.g.* of heavy metal ions from sea-water. In environmental chemistry the resins have been used for speciation studies. One of the present authors has previously utilized Dowex A-1 for separation of Zn-65 isotopes from a large excess of copper ions.[4]

Dowex A-1, the resin studied in this work, has iminodiacetic acid (IDA) as a functional group anchored to the styrene divinylbenzene matrix. Thus the chelating group is tridentate containing one amino and two carboxylate oxygens as donor atoms. Like the monomer aminocarboxylic acids it has a zwitterionic structure. The iminodiacetic acid based resin is also known by several other trade names such as Chelex 100, Diaion CR-10, Duolite ES-466, Lewatit TP-207 and Wofatit MC50.

Equilibrium constants are necessary for the development, theoretical treatment and optimization of, *e.g.* analytical methods and industrial processes. This holds also for ion-exchange systems, like chelating resins. However, in the literature[5-9] equilibrium constants can be found only for a few metal ions. Harju and Perus[7] have reported equilibrium constants for copper(II) chelates with the Dowex A-1 resin.

## EXPERIMENTAL

The chelating resin studied in this work was Dowex A-1 (Fluka, 50-100 mesh). The resin was dried for 1 h at 70°C and stored in an exsiccator until used. A batch technique was used for the determination of equilibrium constants. The measurements were carried out at 25°C (±1°C) and the ionic strength was adjusted to 0.1 *M* by adding potassium nitrate. An inert atmosphere was obtained by outgasing the solutions with nitrogen or argon gases.

The stock solutions of the metal ions studied were prepared from pro analysis reagents and standardized by complexometric titrations against EDTA according to a procedure described earlier.[10] Magnesium ions were titrated at pH 10 with Eriochrome Black T as indicator. Ca, Ba and Sr ions were also titrated at pH 10 with Eriochrome Black T as indicator, but a small amount of Mg-EDTA was added to give a sharp transition. For accurate titrations and standardizations a Metrohm E 457 $\mu$-buret was used.

The cation exchange capacity, $C$, of the resin was determined by two different methods. One

direct method was based on Kjeldahl analysis of the nitrogen content of the dry resin. By assuming that one functional group contains one nitrogen atom, the method gave a capacity of 2.3 mmol/g for the resin in sodium form.

In the second method the resin was allowed to equilibrate with an excess of zinc ions at a pH sufficiently high to guarantee a quantitative sorption of zinc ions. The concentration of zinc in the solution phase was determined by complexometric titrations with a standard EDTA solution at pH 5.3 using Xylenol Orange as indicator. This method gave a capacity of 2.2 mmol/g. The capacity 2.3 mmol/g was used in the calculations in this work.

A Metrohm model 654 pH/mV meter equipped with a Metrohm combined pH electrode was used for the pH measurements. The pH electrode system was calibrated to give hydrogen ion concentrations, [H], according to a procedure described earlier.[11] For very accurate measurements, mV values were recorded and recalculated to $-\log[H]$ values using Nernst's law.

The equilibrium constants were determined using the following procedure: 100 mg of the dry resin was mixed with 100 ml of aqueous phase having an exactly known concentration of the metal ion studied. Appropriate pH values were adjusted with KOH and $HNO_3$, and the mixtures were allowed to equilibrate for 48 hr under constant stirring. No extra buffer agents, which could interfere with the ion-exchange equilibria, were used for adjustment of pH. The final pH of the aqueous phase was measured and the concentration of the metal ion in the filtrate determined. Direct current plasma atomic emission spectrometry (DCP-AES) was used for the determination of the analytical concentrations of metal ions studied in the equilibrium studies. A Spectra span III B spectrometer (Spectrametrics Inc., Andover, MA) was used. Five to seven standards were used for the calibration of the analytical methods for each metal ion studied. $KNO_3$ ($0.1M$) was added to each standard in order to control the matrix effects.

In order to minimize problems with activity calculations and corrections, the determination of equilibrium constants was carried out at constant ionic strength ($\mu = 0.1$) in the solution phase. The ionic strength was adjusted to 0.1 with $KNO_3$. Concentrations of species were determined and calculated and the equilibrium constants are given as concentration constants. The concentrations of the species in the resin phase are expressed as mmol/g and in the aqueous phase as $M$.

## RESULTS AND DISCUSSION

### *Study of time needed for equilibration*

Because of the slow kinetics of Dowex A-1 a test was made to find out the minimum time needed for equilibration with alkaline earth metal ions. In Fig. 1 pCa is plotted as a function of time. The concentration of calcium in the aqueous phase was monitored in suitable time intervals by DCP-AES in presence of an excess of the chelating resin. After about 5 hr of equilibration the pCa values are relatively constant. However, for the determination of equilibriation constants in the present work the mixtures were allowed to equilibrate for 48 hr under constant mixing before the final analytical measurements. According to Sides and Kenner,[12] 6 hr of shaking gave constant distribution coefficients for alkaline earth metals with Dowex A-1. The kinetics of the chelating resin Dowex A-1 has been very thoroughly studied by Schmuckler.[13]

### *Determination of protonation constants*

The experimental data for the determination of the protonation constants of the chelating resin Dowex A-1 are presented as a potentiometric curve in Fig. 2. Each data point in the figure represents a batch experiment where the total volume and total concentration of the resin were kept constant with various volumes of standard acid added. The pH curve exhibits two buffer regions corresponding to the protonation of the amino respective carboxylic group. From these two buffer regions, which are well apart, the protonation constants can be calculated.

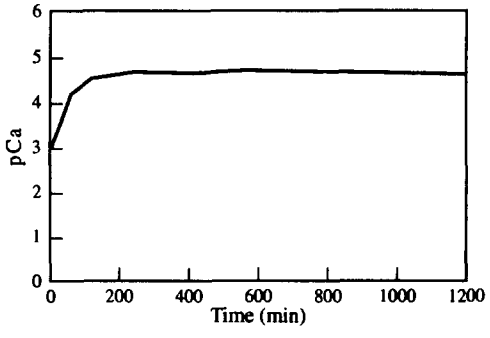

Fig. 1. pCa as function of time for the Ca-Dowex A-1 system at pH 9.51. Volume = 200 ml, $m_R = 200$ mg, $C_{Ca} = 10^{-3.00}M$, $\mu = 0.1$ ($KNO_3$).

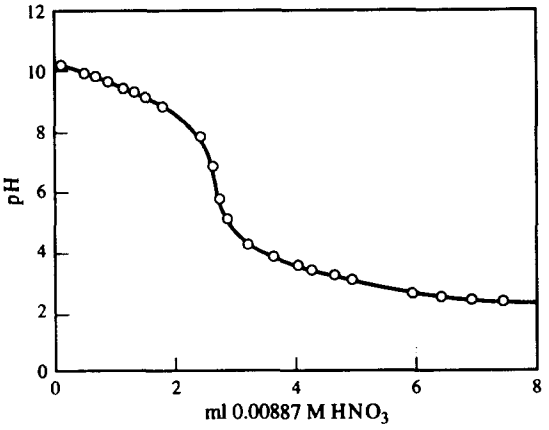

Fig. 2. Potentiometric pH-curve for the chelating resin Dowex A-1. 100.0 mg resin, volume = 50.0 ml, $\mu = 0.1$.

For the protonation of the resin we have the following reactions and stepwise equilibrium constants

$$R + H \rightleftharpoons HR \quad (1)$$

$$HR + H \rightleftharpoons H_2R \quad (2)$$

$$K_{HR}^{H,R} = \frac{[HR]}{[H][R]} \quad (3)$$

$$K_{H_2R}^{HR,H} = \frac{[H_2R]}{[H][HR]}. \quad (4)$$

The ionic charges are omitted for the sake of simplicity. The determination of the first protonation constant, $K_{HR}^{H,R}$, is given in Table 1. The calculation of the concentrations of the protonated and nonprotonated form of the resin is based on the following expressions

$$[R] = \frac{n_R}{m_R} \quad (5)$$

$$n_R = (V_{eq} - V_{HNO_3}) \cdot C_{HNO_3} - V \cdot [OH^-] \quad (6)$$

$$[HR] = C - [R], \quad (7)$$

Table 1. Determination of the first protonation constant, $K_{HR}^{H,R}$, for the resin Dowex A-1 (100.0 mg resin, $\mu = 0.1$, volume = 50.0 ml pH was adjusted with 0.0887$M$ $HNO_3$)

| $-\log[H]$ | $V_{HNO_3}$ ($ml$) | [R] ($mmol/g$) | [HR] ($mmol/g$) | $\log K_{HR}^{H,R}$ |
|---|---|---|---|---|
| 9.71 | 0.80 | 1.56 | 0.74 | 9.38 |
| 9.64 | 0.90 | 1.48 | 0.82 | 9.38 |
| 9.40 | 1.10 | 1.31 | 0.99 | 9.28 |
| 9.33 | 1.30 | 1.13 | 1.17 | 9.35 |
| 9.18 | 1.40 | 1.05 | 1.25 | 9.26 |
| 9.15 | 1.50 | 0.96 | 1.34 | 9.29 |

Mean value of $\log K_{HR}^{H,R} = 9.32$.
Standard deviation 0.05.

where $V_{HNO_3}$ is volume of the standard acid added (ml); $V_{eq}$ the volume of acid added at the first equivalence point (2.59 ml in Fig. 2); $V$ the total volume of the aqueous phase (ml); $C_{HNO_3}$ the concentration of the standard acid ($M$); $m_R$ the mass of the resin (g) and $C$ the capacity of the resin (mmol/g). The concentrations of $H^+$ and $OH^-$ ions at the first equivalence point of the potentiometric curve (Fig. 2) are of no practical significance for the calculations and can be omitted in equation (6).

The following protonation constants were determined in this work: $K_{HR}^{H,R} = 10^{9.32}$ (Table 1) and $K_{H_2R}^{HR,H} = 10^{3.25}$. There are great variations in the values of protonation constants published in the literature for Dowex A-1. Leyden and Underwood[8] have reported $K_{HR}^{H,R} = 10^{8.55}$ and $K_{H_2R}^{HR,R} = 10^{2.95}$. The first protonation constant is clearly below the value obtained in this work. Szabadka[9] has obtained $K_{HR}^{H,R} = 10^{9.12}$, $K_{H_2R}^{HR,R} = 10^{3.12}$ and $K_{H_3R}^{H_2R,H} = 10^{1.44}$, which are in satisfactory agreement with protonation constants obtained by the present authors. From a practical point of view, the first protonation constant is of greatest interest, because most equilibrium constants in this work were determined at pH above 5, where the second protonation constant will not have any influence on the calculations.

*Determination of equilibrium constants of alkaline earth metal ions*

Harju and Perus[7] have shown that copper(II) ions predominantly form 1:1 chelates with the functional group of the Dowex A-1 chelating resin in a large pH region (2.8–9.4). A similar 1:1 model has been reported by Loewenschuss and Schmuckler.[5] The functional groups in the resin are well spaced and it is unlikely that biligands (1:2) are formed with the resin matrix.

The reaction of alkaline earth metal ions with the chelating resin can thus generally be written as

$$M' + R' \rightleftharpoons (MR)', \quad (8)$$

which is defined by the conditional constant

$$K_{(MR)}^{M',R'} = \frac{[(MR)']}{[M'][R']} = K_{MR}^{M,R} \cdot \frac{\alpha_{MR}}{\alpha_M \cdot \alpha_R}. \quad (9)$$

$K_{MR}^{M,R}$ is the usual 1:1 stability constant expressed by

$$K_{MR}^{M,R} = \frac{[MR]}{[M][R]}. \quad (10)$$

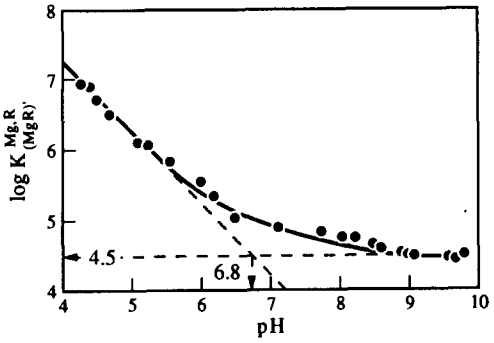

Fig. 3. Log $K^{Mg,R}_{(MgR)'}$ plotted as a function of pH.

The total metal ion concentration in the solution phase, [M′], is determined by direct current plasma atomic emission spectrometry (DCP-AES). The concentration of (MR)′, which also includes the concentrations of protonated 1:1 chelates, can be calculated from the following equation

$$[(MR)'] = \frac{(C_M - [M'])V}{m_R}, \qquad (11)$$

where $C_M$ is total concentration of metal ions added to the solution and $V$ is volume of the solution phase (ml).

For the concentration of resin not bound to metal ions we have the expressions

$$[R'] = C - [(MR)'] \qquad (12)$$

and

$$[R] = \frac{[R']}{\alpha_{R(H)}}. \qquad (13)$$

The α-coefficients are used as defined by Ringbom.[14] $\alpha_{R(H)}$ is defined by the equation

$$\alpha_{R(H)} = 1 + [H]K^{H,R}_{HR} + [H]^2K^{2H,R}_{H_2R}. \qquad (14)$$

The side reactions of metal ions can be considered by the equation

$$[M] = \frac{[M']}{\alpha_M}. \qquad (15)$$

As a demonstration of the theoretical principles used in the present work, Fig. 3 presents log $K^{Mg,R}_{(MgR)'}$ plotted as a function of pH. The almost horizontal course of the curve at pH above 8 indicates that the nonprotonated chelate MgR dominates and $K^{Mg,R}_{MgR}$ equals $K^{Mg,R}_{(MgR)'}$ in this pH region. This region, where the interfering effect from hydrogen ions are still quite small, is optimal for calculation of $K^{Mg,R}_{MgR}$, which is presented in Table 2.

Mean value of log $K^{Mg,R}_{MgR}$ = 4.52.
Standard deviation 0.07.

Table 3. Determination of $K^{H,MgR}_{MgHR}$

| −log[H] | −log[Mg] | [(MgR)′] (*mmol/g*) | [R′] (*mmol/g*) | −log[R] | log $K^{Mg,R}_{(MgR)'}$ | log $\alpha_{MgR(H)}$ | log $K^{H,MgR}_{MgHR}$ |
|---|---|---|---|---|---|---|---|
| 6.49 | 3.135 | 0.243 | 2.057 | 2.514 | 5.034 | 0.518 | 6.85 |
| 6.07 | 3.128 | 0.240 | 2.060 | 2.937 | 5.445 | 0.928 | 6.94 |
| 5.89 | 3.136 | 0.253 | 2.047 | 3.120 | 5.658 | 1.141 | 7.00 |
| 5.43 | 3.098 | 0.187 | 2.113 | 3.568 | 5.939 | 1.421 | 6.83 |
| 5.11 | 3.085 | 0.162 | 2.138 | 3.886 | 6.180 | 1.663 | 6.76 |
| 4.97 | 3.072 | 0.137 | 2.163 | 4.023 | 6.230 | 1.714 | 6.68 |
| 4.57 | 3.071 | 0.136 | 2.164 | 4.435 | 6.640 | 2.123 | 6.69 |
| 4.40 | 3.078 | 0.149 | 2.151 | 4.617 | 6.870 | 2.353 | 6.75 |
| 4.29 | 3.089 | 0.169 | 2.131 | 4.739 | 7.055 | 2.538 | 6.83 |
| 4.18 | 3.077 | 0.146 | 2.154 | 4.855 | 7.097 | 2.580 | 6.76 |
| 4.15 | 3.073 | 0.139 | 2.161 | 4.887 | 7.101 | 2.584 | 6.73 |

Mean value of log $K^{H,MgR}_{MgHR}$ = 6.80.
Standard deviation 0.10.

At pH below 7 there is a rise of the curve in Fig. 3 and this indicates the formation of protonated species. An approximate constant $K_{MgHR}^{MgR,H} = 10^{6.8}$ can be obtained from the figure as the intercept between the horizontal line ($\log K_{MgR}^{Mg,R} = 4.5$) and the tangent of the slope $-1$ to the rising curve, according to a method described earlier by Ringbom and Harju.[15] A more exact calculation of $K_{MgHR}^{MgR,H}$ is given in Table 3, based on the following equations derived from the general expressions for $\alpha_{MR(H)}$

$$K_{MHR}^{MR,H} = \frac{[MHR]}{[MR][H]} = \frac{\alpha_{MR(H)}}{(1+[H])}, \quad (16)$$

where

$$\alpha_{MR(H)} = \frac{K_{(MR)'}^{M,R}}{K_{MR}^{M,R}}. \quad (17)$$

The equilibrium constants determined in this work are summarized in Table 4. For beryllium no constant could be determined for the protonated chelate. The precision obtained for the logarithmic equilibrium constants expressed as standard deviations are mostly about 0.1, which must at least be considered as satisfactorily. In the literature, no equilibrium constants could be found for alkaline earth metal ion complexes with the IDA based chelating resin. In a recent paper Pesavento *et al.*[16] report the formation of a protonated species $Ca(HR)_2$ at pH below 7.

*Calculation of distribution coefficients from the equilibrium constant*

Distribution coefficients are not equilibrium constants because they depend both on pH of the aqueous phase and the load of the resin. The distribution coefficient, $D$, is defined by the equation[14]

$$D = \frac{\text{mmol of metal ion/g dry resin}}{\text{mol/l of metal ions in solution}}. \quad (18)$$

According to the law of mass action the distribution coefficient can at certain pH be calculated from equilibrium constants by the following equation

$$D = \frac{[(MR)']}{[M']} = K_{MR}^{M,R} \cdot \frac{[R'] \cdot \alpha_{MR(H)}}{\alpha_{M(OH)} \cdot \alpha_{R(H)}}, \quad (19)$$

Table 4. Equilibrium constants of alkaline earth metal ion chelates with Dowex A-1 (R)

| | $\log K_{MR}^{M,R}$ | SD | $\log K_{MHR}^{H,MR}$ | SD |
|---|---|---|---|---|
| Be | 6.85 | 0.29 | | |
| Mg | 4.52 | 0.07 | 6.80 | 0.10 |
| Ca | 4.75 | 0.14 | 6.53 | 0.05 |
| Sr | 4.61 | 0.10 | 6.90 | 0.08 |
| Ba | 4.20 | 0.09 | 7.43 | 0.08 |

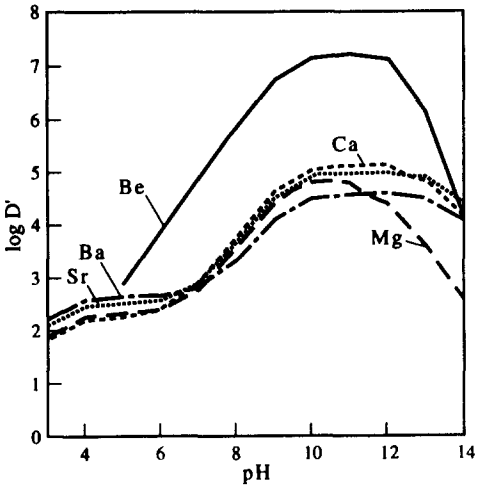

Fig. 4. Theoretically calculated distribution coefficients for alkaline earth metal ions with Dowex A-1.

where

$$\alpha_{MR(H)} = 1 + [H^+] \cdot K_{MHR}^{MR,H}. \quad (20)$$

Figure 4 gives distribution coefficients for the alkaline earth metal ions calculated from equilibrium constants according to the above equation. It is assumed that the metal ions are present in trace quantities and [R′] equals the capacity of the resin. The log $D$ curves plotted for the alkaline earth metal ions show a maximum at pH above 10 and at lower pH a strong pH dependence.

Distribution coefficients for alkaline earth metal ions with Dowex A-1 have been reported by several groups.[8,12,17] The studies have mostly been restricted to pH values below 8 and the results showed large divergences. The formation of protonated chelates in the resin phase explains the unexpected high distribution ratios obtained experimentally by several authors for calcium and other alkaline earth metal ions at lower pH values.

## CONCLUSION

Equilibrium constants for chelating resins are quite difficult to determine, which is reflected by the small number of papers published on the topic in the literature. The slow reactions make the equilibrium studies very time-consuming. The capacity and protonation constants of the resin are not easy to determine. According to Eger *et al.*[6] small amounts of organic material, most likely benzyliminodiacetic acid molecules, are liberated to the aqueous phase due to decomposition of the resin. This will to some

degree affect the equilibria. Potassium, used for the adjustment of the ionic strength will also have a slight diminishing effect on the equilibrium constant. No extra pH buffer, which could affect the equilibria, were used in this work.

The alkaline earth metal ions form relatively weak chelates with the Dowex A-1 resin. Equilibrium constants determined in a wide pH range show that predominantly 1:1 chelates are formed. The optimal region for determination of equilibrium constants for these metal ions is at pH above 8, where the interfering effects of hydrogen ions are small. At pH below 7 the alkaline earth metal ions form protonated 1:1 chelates with the resin. The precision and reliability of the method can be considered as good.

The complexation chemistry model and the equilibrium constants presented in this work for the chelating resin Dowex A-1 can be quite useful for practical purposes, where ion exchange equilibrium data are the basis when developing and optimizing separation procedures. The experimental results showed that the law of mass action and the equilibrium model proposed is valid over a wide pH range for IDA-based chelating resins. As natural ion-exchange resins also can contain carboxylic and amino groups as functional groups, equilibrium studies of this type can contribute to an increased understanding of ion-exchange processes taking place in our environment.

# CHEMILUMINESCENCE DETERMINATION OF NITRATE WITH PHOTOCHEMICAL ACTIVATION IN A FLOW INJECTION SYSTEM

LIU RENMIN, LIU DAOJIE, SUN AILING and LIU GUIHUA

Department of Chemistry, Liaocheng Teachers College, Shandong, P.R. China

(*Received* 17 *May* 1994. *Revised* 19 *September* 1994. *Accepted* 23 *September* 1994)

**Summary**—A chemiluminescence flow injection system is described for the determination of nitrate, involving use of a laboratory-built flow-through photochemical reactor. Optimum analytical conditions were established. The linear range for nitrate is $7 \times 10^{-8}$–$1 \times 10^{-4}M$. The sampling frequency is 60 samples per hour. The relative standard deviation for $1 \times 10^{-7}$, $1 \times 10^{-6}$ and $1 \times 10^{-5}M$ nitrate is 0.97, 0.84 and 0.76%, respectively. The method has been applied to the determination of nitrate in natural water samples, and recoveries of 96–103% have been attained.

## INTRODUCTION

Photochemical analysis is based on the utilization of photochemical reaction in the process of analysis. It has been increasingly used in various fields, owing to its high sensitivity and selectivity. Flow injection analysis (FIA) offers high throughput, cost-effective performance and versatility. The combination of FIA technique with photochemical analysis provides a novel means for studies of photochemical analysis.[1–7] The amperometric determination of oxalate based on the photochemical reaction taking place in the reaction coil of a FIA system that was irradiated with visible light has been reported.[1] A second approach to the photochemical determination of this analyte was based on the use of an amperometric flow cell with several optical fiber, which irradiated the sample only in the flow cell.[2] A similar use of a photochemical reaction in FIA, with unstable compounds such as phenothiazines under ultraviolet radiation was reported.[3] The simultaneous determination of chlorprolazine and promethazine using different configurations for implementation of the photochemical reactions was also reported.[4] Another FIA system involving photochemical reaction is on-line photochemical oxidation of organoarsenicals to inorganic arsenic.[5] In our previous work, a flow-through photochemical reactor was constructed and used in a FIA system for the determination of nitrite based on its inhibitory effect on the photochemical reaction between iodine and ethylenediaminetetraacetic acid.[6] A second approach of our work to photochemical determination in a FIA system was simultaneous determination of iron(II) and iron(III) based on the photochemical reduction of iron(III)-1,10-phenanthroline complex to iron(II)-1,10-phenanthroline complex.[7]

When an acidified nitrate solution is irradiated with ultraviolet light, species like peroxonitrite are formed in the solution, which are the oxidants of luminol. Chemiluminescence was found to appear after mixing an alkaline luminol solution and an acidified nitrate solution initially irradiated with a mercury lamp. A conventional chemiluminescence method was established by Kalinichenko *et al.*[8]

In the present work, a flow-through photochemical reactor was constructed and used for the study of determination of nitrate in a FIA system, based on the photochemical activation and chemiluminescence reactions. The proposed method shows high sensitivity, selectivity and speed.

## EXPERIMENTAL

### *Reagents*

A standard stock solution of nitrate was prepared at $0.1M$ with analytical pure sodium nitrate. The working solution was prepared by diluting the stock solution with a sulfuric acid solution at pH 5.0.

The carrier solution was sulfuric acid solution, pH 5.0.

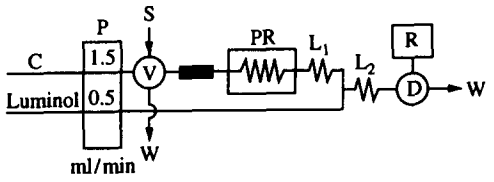

Fig. 1. Schematic diagram of the FIA system. P, Peristaltic pump; S, sample; V, injection valve; PR, photochemical reactor; L1, L2, connection tube; D, detector; R, recorder; C, carrier; W, waste.

The luminol reagent solution was $5 \times 10^{-5}M$ with $0.1M$ potassium hydroxide.

*Apparatus*

The flow injection manifold used is shown in Fig. 1. The peristaltic pump, injection valve and chemiluminescence detector are a FICT-8604 chemiluminescence analyzer (Jiangsu Electroanalytical Instrument Plant). The chemiluminescence signal was recorded with an XWT-S platform recorder (The Third Automatic Instrument Plant of Shanghai). A photochemical reactor (made in this laboratory, Fig. 2) was used in the FIA system. A iminodiacetyl ligand exchange resin column was used in the FIA system to remove the interference of $Fe^{3+}$, $Cu^{2+}$, $Co^{2+}$ and $Ni^{2+}$.

*Procedure*

The FIA system was connected up with PTFE tubing (0.8 mm i.d.) according to the arrangement shown in Fig. 1. The flow-rates of carrier and luminol reagent were adjusted according to the parameters given in Fig. 1. The sampling time was 20 sec and the injection time 40 sec. So the sampling frequency was 60 samples/hr. The chemiluminescence signal was recorded with the recorder. Nitrate was determined according to the peak height.

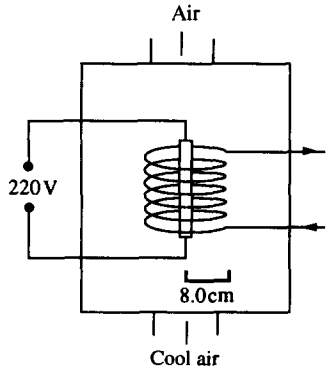

Fig. 2. Schematic diagram of the flow-through photochemical reactor.

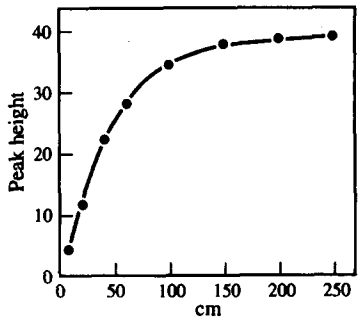

Fig. 3. Influence of the length of reaction tube of the photochemical reactor.

A series of nitrate standard solution was prepared and injected into the carrier before and after the sample runs.

## RESULTS AND DISCUSSION

*Photochemical reactor*

The main parts of the photochemical reactor are the light source and reaction tube. Nitrate has an absorption peak at 202 nm ($\varepsilon = 9500$) and an absorption peak at 304 nm ($\varepsilon = 9$). When the acidified nitrate solution is irradiated with ultraviolet light, species like peroxonitrite are formed, which are oxidants of luminol. A GGZ-125W high-pressure mercury lamp was used as the light source for the photochemical reactor.

An auger-type quartz tube was used as the reaction tube of the photochemical reactor. Its length was found to have a significant effect on the photochemical activation. Higher sensitivity can be obtained when a longer reaction tube is used. Figure 3 shows the influence of the length of reaction tube on the determination of $1.0 \times 10^{-6}M$ nitrate. It can be seen from Fig. 3 that the chemiluminescence intensity basically reached the maximum when a 200 cm long

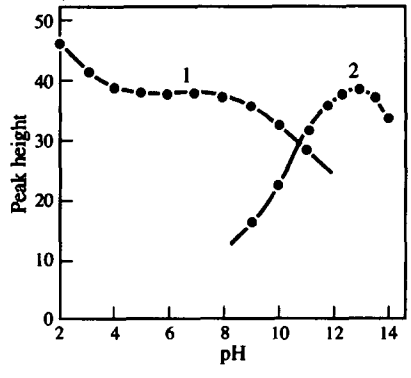

Fig. 4. Influence of pH. (1) Carrier; (2) luminal reagent.

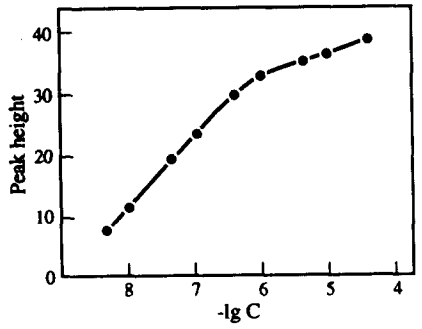

Fig. 5. Influence of the concentration of luminol.

reaction tube was used. In the following experiments, a 200 cm long reaction tube was used.

*Connection tube $L_1$ and $L_2$*

The lifetime of the photochemical product, like peroxonitrite, and the chemiluminescence between the product and luminol is relatively short. Hence, the length of the connection tubes $L_1$ and $L_2$ must be short. In the following experiments, the length of $L_1$ is 15 cm, and $L_2$ is 5 cm.

*Effect of pH*

Keeping the pH of the mixture of carrier and luminol reagent solution constant, the influence of the pH of the carrier on the determination of $1 \times 10^{-6}M$ nitrate was studied. Keeping the pH of the carrier constant, the influence of luminol reagent solution on the determination was studied. All the results are shown in Fig. 4. In the following experiments, the pH of the carrier was controlled at 5.0, and that of luminol reagent solution at 13.0.

*Concentration of luminol*

The influence of the concentration of luminol on the determination of $1.0 \times 10^{-6}M$ nitrate (Fig. 5). Figure 5 shows that high chemiluminescence intensity can be attained when a luminol of high concentration is used. However, a spill-over signal is given out by the chemiluminescence analyzer when the concentration of luminol is higher than $1 \times 10^{-4}M$, and this made the determination impossible. In the following experiments, a $5 \times 10^{-5}M$ luminol solution was used.

Table 1. Effect of foreign ions on the determination of $1.0 \times 10^{-6}M$ nitrate

| Foreign ion | Tolerated molar ratio (ion:nitrate) |
|---|---|
| $Cl^-$, $F^-$, $SO_4^{2-}$, $ClO_4^-$, $PO_4^{3-}$ | 10,000 |
| $Al^{3+}$, $Zn^{2+}$, $Cd^{2+}$, $Fe^{2+}$ | 1000 |
| $Br^-$, $VO_3^-$, $WO_4^{2-}$, $NH_4^+$ | 30 |
| $Mn^{2+}$ | 15 |
| $Fe^{3+}$ | 10 |
| $I^-$, $ClO_3^-$, $CrO_4^{2-}$, $NO_2^-$ | 2 |
| $Cu^{2+}$, $Co^{2+}$, $Ni^{2+}$ | 1 |
| $BrO_3^-$, $IO_3^-$, $MoO_4^{2-}$ | 0.5 |
| $Fe^{3+}$ | 0.1* |
| $Cu^{2+}$, $Co^{2+}$, $Ni^{2+}$ | 0.01* |

*No iminodiacetyl ligand exchange resin column in FIA system.

*Calibration*

According to the proposed procedure, the calibration graph was established with standard solutions of nitrate. The linear range for nitrate is from $7.0 \times 10^{-8}$ to $1.0 \times 10^{-4}M$. The precision for the determination of nitrate was measured by analysing $1.0 \times 10^{-7}$, $1.0 \times 10^{-6}$ and $1.0 \times 10^{-5}M$ nitrate standard solution 11 times. The relative standard deviations were 0.97, 0.84 and 0.76, respectively.

*Interference of foreign ions*

The interference of a number of foreign ions was studied by addition of such ions to $1.0 \times 10^{-6}M$ nitrate. The results listed in Table 1 show the high selectivity of the method (with a relative error of less than 5%).

*Applications*

Natural water samples were determined by the proposed method and the cadmium column

Table 2. Determination of nitrate in natural water samples

| Sample | Data obtained by the proposed method (*mg/l.*) | Data obtained by cadmium reduction method (*mg/l.*) | Relative (%) |
|---|---|---|---|
| Tap water | 0.64 | 0.67 | −4.5 |
| River water | 1.14 | 1.12 | 1.8 |
| Lake water | 2.06 | 2.10 | 1.9 |
| Well water | 0.88 | 0.90 | −2.2 |
| Deep well water | 1.26 | 1.23 | 2.4 |

Table 3. Recovery of nitrate from natural water samples

| Sample | Nitrate found (*mg/l.*) | Total nitrate present after addition (*mg/l.*) | Recovery (%) |
|---|---|---|---|
| Tap water | 0.64 | 1.66 | 102 |
| River water | 1.14 | 2.10 | 96 |
| Lake water | 2.06 | 3.09 | 103 |
| Well water | 0.88 | 1.86 | 98 |
| Deep well water | 1.26 | 2.26 | 100 |

reduction method.[9] The results are listed in Table 2.

Table 3 shows the results obtained with the proposed method for natural water samples to which 1.0 mg/l. nitrate was added. It can be seen from Table 3 that recoveries of 94–103% can be attained.

**Summary**—Application of the unified physicochemical approach to the description of the dissociation properties of Laurentide fulvic acid, extracted from peat, has shown that five predominant acidic moieties may account for the observed potentiometric titrations in aqueous medium. Information from non-aqueous titrations and titrations in presence of excess metal ions, *e.g.* $Cu^{2+}$ and $Eu^{3+}$, has shown that three of the acidic moieties are carboxylic in nature while the other two are of alcoholic nature. A comprehensive description of the dissociation properties of natural organic acids, as ligands, is advocated as a pre-requisite step towards understanding their interaction with metal ions in the environment.

The dissociation properties of humic substances have been shown to be complicated by two factors, *i.e.* heterogeneity with respect to molecular size leading to 'ionic strength' effects and functional group heterogeneity.[1] Recent advances have considerably influenced the conceptualization of humic substances in modeling efforts.[2–4] Modeling the role of humic substances in the distribution and mobility of trace metals in the environment, however, requires the identification of the factors that perturb the solution chemistry of these substances. In this paper, methods for the identification of these complicating factors developed earlier[5] have been employed for the Laurentide fulvic acid, a peat-extracted sample obtained from Concordia University, Canada.[6] In the unified physicochemical approach employed here, the humic substances are conceptualized as an assemblage of amphiphilic moieties with varying molecular size and acidic functionalities composed of four to five predominant acidic groups.[7] These sites have varying acidic strengths but they may be averaged. The usefulness of such an approach to identifying the complicating factors in the proton equilibria of humic substances has an analogy in coordination inorganic chemistry where adequate characterisation of the ligand is a pre-requisite for meaningful description of its interaction with metal ions.[8]

## EXPERIMENTAL

Details of reagents and extraction procedure are described elsewhere.[5] Potentiometric titrations performed in aqueous medium as function of ionic strength are employed to estimate the ionic strength effects. A combination of titrations in non-aqueous media using an internal reference compound, parahydroxybenzoic acid, and titrations in aqueous media with varying amounts of $Eu^{3+}$ and $Cu^{2+}$ has facilitated an estimation of the relative abundances of the different acid groups present in the fulvic acid.[9,10] Insights into the ionic strength effects and functional group heterogeneity and combination thereof, have made possible the assignment of the predominant acidic moieties determining the dissociation properties of the fulvic acid, as before.[5]

## RESULTS

### *The effect of ionic strength on the measurable acid dissociation properties of Laurentide FA*

The acid dissociation properties measured for the Laurentide FA at three different FA concentration levels (50, 100 and 250 ppm) in sodium nitrate solutions at five different salt

concentration levels (0.0010, 0.010, 0.10, 1.0 and 5.0$M$) are shown in Fig. 1. In this figure, representative data that were compiled at the conditions specified are expressed as plots of $p(K_a^{app})_\alpha$, defined by the equation below

$$p(K_a^{app})_\alpha = pH - \log\left(\frac{\alpha}{(1-\alpha)}\right) \quad (1)$$

*vs.* $\alpha$, the degree of association measured at each step in the titration with standard base. In equation (1) $(K_a^{app})_\alpha$ refers to the overall dissociation constant of the Laurentide FA measured at a particular $\alpha$ value. The overall degree of dissociation, $\alpha$, is obtained from the following expression:

$$\alpha = \frac{\Sigma A_e^-}{\Sigma HA_i} \quad (2)$$

where $\Sigma A_e^-$ is defined as

$$\Sigma A_e^- = bV_b + h_e V_s \quad (3)$$

and $\Sigma HA_i$ is the total titratable acid capacity of the fulvic acid. In equation (3), $V_b$ is the volume in ml of b molar base added and $h_e$ is the proton concentration, while $V_s$ is the total volume of the solution in ml.

The fact that the $p(K_a^{app})_\alpha$ *vs.* $\alpha$ plots obtained at salt concentration levels of 1.0 and 5.0$M$ $NaNO_3$ are almost superimposable in Fig. 1, as they were for the Armadale FA[5] shows once again that a Donnan potential term is no longer operative at these concentrations. At these higher salt concentrations, the concentration of the counter ion in the solution is practically identical to its concentration in the solvent sheat domain of the fulvic acid molecules. The increase in $p(K_a^{app})_\alpha$ with $\alpha$ at these elevated salt concentration levels can, on this basis, be attributed solely to the functional group heterogeneity of the fulvic acid.[5] By subtracting this curve, $p(K_a^{app})_\alpha$ *vs.* $\alpha$ at $NaNO_3$ concentration $\geqslant 1.0M$, from similar separate curves resolved at the lower salt concentration levels ($[NaNO_3] = 0.0010$, 0.01 and 0.1$M$), the unique contribution of the Donnan potential term, $\Delta pK_a^{app}$, to the measurable acid dissociation properties of the Laurentide fulvic acid at the three different salt concentration levels is made accessible (Fig. 2).

The observed response to each 10-fold change in salt concentration is, as it was for the Armadale Horizon Bh fulvic acid,[5] sizeably smaller than the value of unity projected for molecules exhibiting macromolecular properties.[11] This discrepancy has been attributed to the fact that only a fraction of the soil fulvic acid molecules is large enough to develop the separate phase properties operative in the Gibbs–Donnan based model. The molecular size

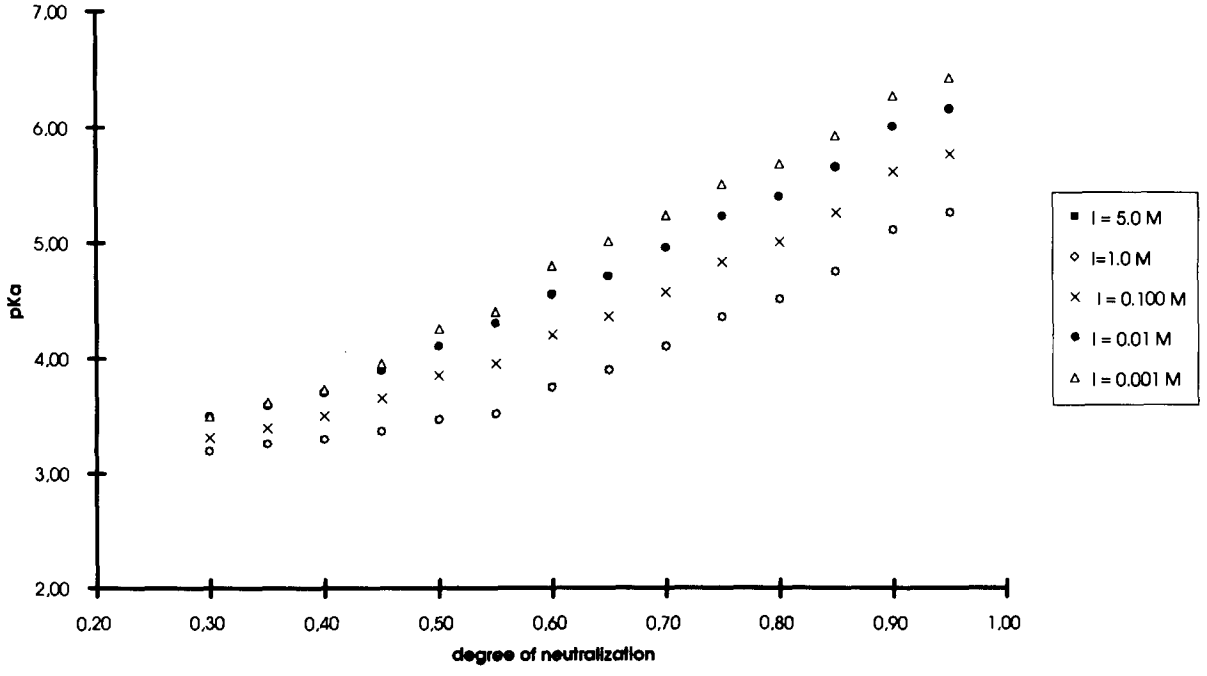

Fig. 1. Plots of $p(K_a^{app})_\alpha$ *vs.* $\alpha$ for Laurentide fulvic acid, LFA, as a function of ionic strength and FA concentration. (Note: $I = 1.0$ and $I = 5.0M$ curves were exactly superimposable.)

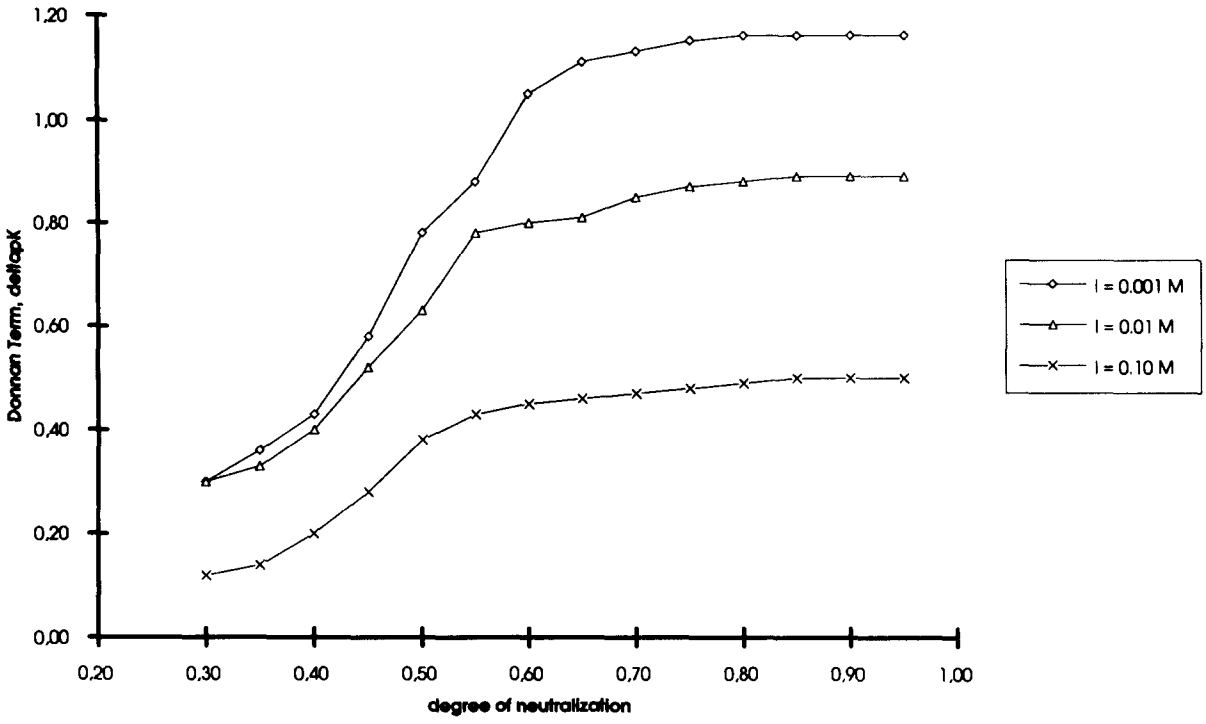

Fig. 2. Variation of the Donnan potential term, $\Delta pK_x$, with degree of dissociation of Laurentide fulvic acid at three different ionic strengths.

heterogeneity existent in humic substances has been exhibited by a number of molecular weight measurements.[12-14]

The $\Delta pK_a^{app}$ values resolved in this research are somewhat smaller than those measured earlier for the Armadale Horizons Bh fulvic acid.[5] On the basis of the Gibbs–Donnan-based interpretation of these changes in the Donnan potential term, one can conclude that the fraction of fulvic acid molecules large enough to exhibit macromolecular properties is smaller in the Laurentide FA over the salt concentration range examined. The fact that the rate of increase in $p(K_a^{app})\alpha$ for each 10-fold increase in salt concentration ($M_{s,2} = 10M_{s,1}$) is larger for the Laurentide FA, however, is believed to show that the Laurentide FA is, on a relative basis, polydispersed to a greater extent than the Armadale FA.[15]

*The employment of acid dissociation studies in non-aqueous media to determine the relative abundances of carboxylic* (R-COOH) *and alcoholic* (R'-$CH_2$-OH) *moieties that constitute the weak acid site heterogeneity of the Laurentide fulvic acid*

The results that were obtained in a representative experiment carried out with *para*-hydroxybenzoic acid, the internal reference standard used in the non-aqueous acid dissociation studies of the Laurentide fulvic acid source, are summarized in Table 1. They show that the measurable acid content in non-aqueous media is identical with the 7.72 mmol/g

Table 1. Functional group analysis of Laurentide fulvic acid in DMF using pHBA as an internal reference standard

| Acid used (*g*) | | Equiv. *ml* of T-nBAH | | Capacities (*meq*/*g* of acid) | | |

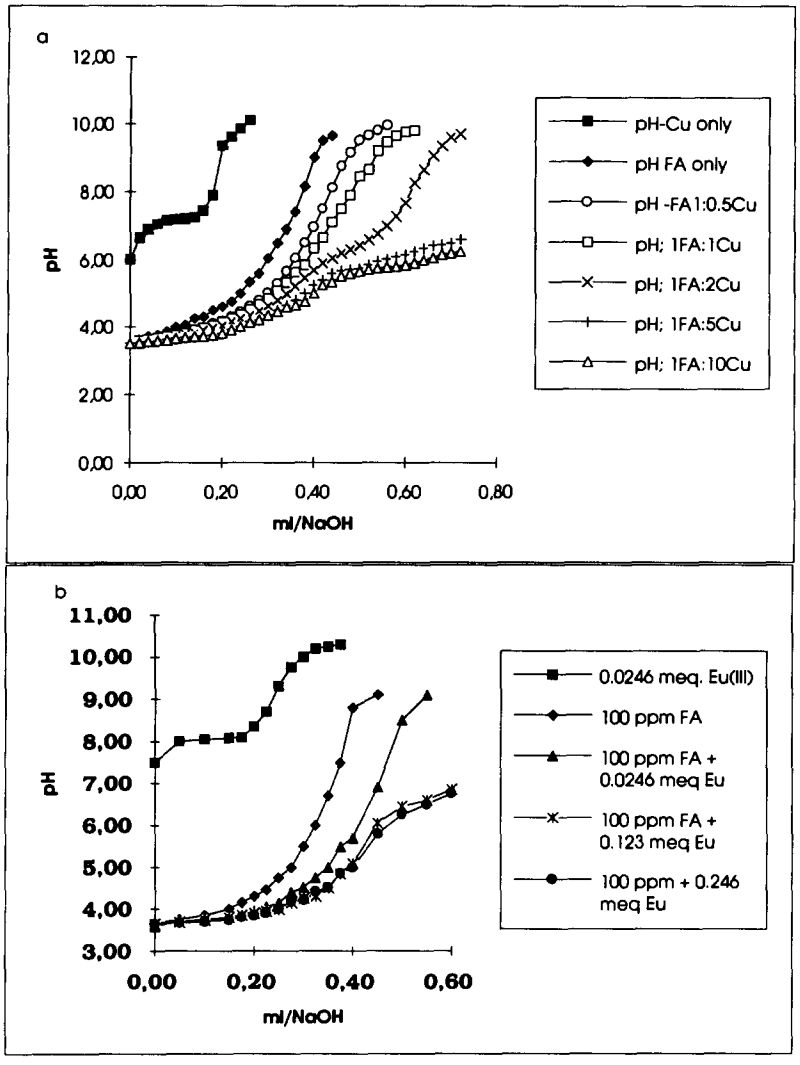

Fig. 3. The enhancement of proton release affected in LFA by increasing amounts of (a) $Cu^{2+}$ and (b) $Eu^{3+}$.

value reached in the aqueous media studies. Slightly more than 73.4% of the acid sites are attributable to carboxylic acid (RCOOH) moieties while the remaining weak acid functionalities are alcoholic ($R'CH_2OH$).

*Studies of proton release enhancement affected in Laurentide fulvic acid samples by the presence of excess* $Cu^{2+}$ *and* $Eu^{3+}$ *ion to provide additional site heterogeneity insights*

The enhancement of proton release affected in Laurentide fulvic acid samples by increasing the presence of $Cu^{+2}$ and/or ($Eu^{+3}$) from zero to greater than a two-fold excess, on a molar charge basis, may be observed by referring to Fig. 3a and b. The plots of p{H} *vs.* aliquots of standard base added that are presented in these figures also include p{H} data compiled during addition of base to the metal ions alone. Referring first to the neutralization studies carried out to study the extra proton release in the presence of Cu(II): when Cu(II) ion alone is titrated with base, the pH immediately rises from 5.5 to 7.0. Further addition of base results in a slow rise in pH. The system remains buffered until the first hydrolysis step $[Cu(II) + nOH = Cu(OH)_n]$ is complete. At this point the pH rises steeply to about 10.5. In systems where FA greatly exceeds the Cu(II), the titration curves resemble those of FA alone but with the equivalence point shifted to higher volumes of NaOH. When FA and Cu(II) are present in equivalent amounts on a millimoles of charge basis, there is a narrow buffered region between pH 6 and 7 owing to the hydrolysis of the small quantity of uncomplexed Cu(II).

In the presence of excess Cu(II), the shape of the titration curve remains unaffected up to a pH of 6.0. At this point the hydrolysis of uncomplexed Cu(II) produces an extended pH-buffered region. From careful extrapolation of the curves which are made to follow the general shape of the FA titration curve, the extra $H^+$ released by chelation of Cu(II) has been estimated to be $45 \pm 3\%$.

In the titration of Eu(III) alone with NaOH, buffering occurs at a pH of about 8; the system remains buffered until inception of the final hydrolysis step where the pH rises sharply to about 10. In titrations of FA where FA exceeds Eu(III) sizeably [5FA:1 Eu(III) in millimoles], the complete removal of Eu(III) by complexation is indicated by the absence of a buffered region. When the ratio is approximately 1FA:1Eu in mmoles, the titration curve exhibits the same shape as the FA titration curve up to a pH of 6.5; a flattened region from pH 7.0 to 7.5 persists until the hydrolysis of Eu(III) is complete. The sharp pH rise to about 10 when this happens is not shown. Analysis of the appropriate curves in this figure indicates that the extra release of $H^+$ ion by chelation of Eu(III) is approximately $26.6 \pm 3\%$. The extra release of protons observed in the presence of excess Cu(II) and Eu(III) arises from the coordination of these multivalent metal ions to ligand combinations that yield complexes of extremely high stability. Such coordination possibilities are facilitated by the close proximity of the very weak phenolic OH acid groups, not otherwise detectable in the FA molecule with standard neutralization procedures, to a fraction of the weak acid functionalities that are detectable in standard neutralization methods.

Since the release from the Laurentide FA of extra protons by Cu(II) is almost a factor of two greater than by Eu(III) just as it was for the Armadale FA, one can deduce as before[5] that, of two bidentate components of the FA molecule accessible to these metal ions, only one complexes both of them strongly enough to affect such a release of extra protons. In the literature the dihydroxyl groups are strongly bound to both Cu(II) and Eu(III)[16] and a dihydroxy moiety has, on this basis, been identified as the likely bidentate functionality in the FA molecule from which the release of extra acidity can be affected by both Cu(II) and Eu(III) ions.[5]

Reference to the literature[16] influences the tentative assignment of the second bidentate group to a salicylic acid-like moiety. The stability constant of the Cu-salicylate chelate is $4.6 \times 10^{10}$, more than six orders of magnitude greater than the analogous Eu-salicylate complex ($3 \times 10^4$). The free energy of formation of the Cu(II) chelate is large enough to promote release of $H^+$ ions from the -OH group ($pK = 13$) *ortho* to the carboxylic acid ($pK = 3$). The extra release of protons in the presence of excess Cu(II) ions is thus compatible with the above assignment of the second bidentate group in the FA molecule as it was for the Armadale Horizons FA.[5]

*Analysis of functional site heterogeneity of the Laurentide fulvic acid via abundance and acid strength assignments*

It has been shown that the acid dissociation feature provided by plots of $p(K_a^{app}{}_{I \geq 1.0})_\alpha$ *vs.* $\alpha$ are completely attributable to the site heterogeneity of the Laurentide fulvic acid.[5] With such information made available, the assignment of acid strengths to functional site possibilities, as well as the selection of suitable abundance for them, become feasible. The quantities of carboxylic and hydroxyl acidity in a particular FA source, accessible from the non-aqueous acid dissociations studies, present a starting point for these estimates. The proton release enhancement studies further facilitate this task.

The additional release of proton ($26 \pm 3\%$) in the presence of excess Eu(III) is about equal to the quantity of weak acid assignable to the OH functionality ($\sim 26.6\%$) in the nonaqueous titrations; much more weakly acidic OH, unaccessible to both the aqueous and non-aqueous studies, can be presumed to be in a position *ortho* to this OH moiety to account for the extra proton release through highly favored chelation reactions with both the Cu(II) and the Eu(III).

The additional proton release of $\sim 17\%$, observed in the presence of excess Cu(II), can be attributed to salicylic acid-like sites whose phenolic OH group, $p(K_a) \sim 13$, would also be expected to escape detection in the aqueous and non-aqueous studies. The fact that the formation constant of Cu(salicylate) is six orders of magnitude larger than the formation constant of Eu(salicylate)$^+$ would account for this result, as pointed out earlier.

On the basis of the above reasoning, the abundance of the acidic alcohol assigned to the FA molecule was assumed to be $\sim 26\%$. The

$pK_a$ of approximately 6 initially assigned to this site facilitated resolution of the abundance and $pK_a$ assignments eventually made. The estimate that a salicylic acid-like group was responsible for the ~17% increase in proton release in the presence of excess Cu(II) led to a $pK_a$ assignment of approximately 3 for the carboxylic acid group presumed to be associated with it. From the acid dissociation studies in aqueous media, it was also noted that approximately 30% of the acidity had to be associated with a fairly strong carboxylic acid ($pK_a \approx 1.7$) moiety. Trial and error estimates of abundances and acid strengths, influenced by the above information, were examined much as they had been in an earlier study.[5] It was found necessary to introduce a third carboxylic acid group with a $pK_a$ of ~4.2 and a second hydroxyl group with a $pK_a$ smaller than the single value of 6 initially assigned to approximate the dissociation properties experimentally measured for the Laurentide fulvic acid in $NaNO_3$ solution at a concentration level of 1.0*M* or higher. The Hendersson-Hasselbalch equation was used to facilitate selection of optimum site parameters. In the program developed for this purpose, the experimental p{H} range encountered in the fulvic, acid dissociation studies at $I \geqslant 1.0M$ was examined in a sequence of steps listed below. First $\alpha_n$, the degree of dissociation of the $n$th acid site at a selected p{H} value was evaluated with equation (1a) employing the dissociation constant assigned to the $n$th site for the series of computations:

$$\log\left(\frac{\alpha_n}{(1-\alpha_n)}\right) = p(K_{a_n}^{intr}) - pH. \qquad (1a)$$

Each of the five $\alpha_n$ values resolved at the selected p{H} value was then multiplied by $A_n$, the fractional abundance assessed for each of the corresponding $n$ sites. To compute the overall degree of dissociation, $\alpha^o_{calc}$, for comparison with the experimental value, $\alpha^o_{exp}$, at each p{H} value selected the $\alpha_n A_n$ values were added together as shown in the following equation

$$\alpha^o_{calc} = \Sigma \alpha_n A_n. \qquad (4)$$

The trial and error adjusted $pK_{a,n}$ and $A_n$ parameters eventually used and the $\alpha^o_{calc}$ values that they resolve are listed in Table 2. The $\alpha^o_{exp}$ values are presented in this table as well, for comparison with the $\alpha^o_{calc}$ values to show the excellent agreement reached between them by the approach that has been described.

## CONCLUSIONS

The dissociation properties of Laurentide FA, isolated from peat, have been studied by following the unified physicochemical approach developed earlier.[1] In such an exercise, it was determined that the observed dissociation properties of the Laurentide fulvic acid may be described by considering five predominant acidic moieties (three of carboxylic nature and

Table 2. Comparison of experimentally based overall degree of dissociation, $\alpha^o_{exp}$, of Laurentide fulvic acid in 1.00*M* $NaNO_3$ with the summation of computed contributions of five different acid sites to overall degree of dissociation, $\alpha^o_{calc}$

two of alcoholic OH). The smaller effect of bulk electrolyte on its dissociation properties has permitted the postulation that a smaller fraction of the Laurentide fulvic acid is large enough to exhibit macromolecular properties, as compared to the Armadale Horizons.[1] The approach employed in this study to characterise the acidic properties of Laurentide FA is recommended as an incumbent step towards understanding the interaction between natural organic acids and metal ions. Its compatibility with already existent chemical speciation programs cannot be overemphasized.

## SHORT COMMUNICATION

# DEVELOPMENT OF A HIGH-PERFORMANCE LIQUID CHROMATOGRAPHIC SYSTEM WITH ENZYME REACTORS FOR THE DETERMINATION OF *N*-ACETYL BRANCHED-CHAIN AMINO ACIDS

NOBUTOSHI KIBA, YUKIO OYAMA and MOTOHISA FURUSAWA

Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan

(*Received* 19 *July* 1994. *Revised* 26 *September* 1994. *Accepted* 27 *September* 1994)

**Summary**—Immobilized enzymes were used as column reactors in a high-performance liquid chromatographic system for the specific detection of *N*-acetyl branched-chain amino acids (AcBCAs) such as *N*-acetyl-L-valine (AcVal), *N*-acetyl-L-leucine (AcLeu) and *N*-acetyl-L-isoleucine (AcIle). Aminoacylase and leucine dehydrogenase were immobilized onto poly(vinyl alcohol) beads. The AcBCAs were separated as three peaks on a Capcell $C_1$ SG120 column with 0.03*M* phosphate buffer (pH 8.0). Aminoacylase was capable of hydrolysing the AcBCAs to amino acids, which react with β-nicotinamide adenine dinucleotide ($NAD^+$) in the presence of leucine dehydrogenase. The reduced nicotinamide adenine dinucleotide (NADH) produced was monitored fluorimetrically. The calibration graphs were linear from 4 to 200μ*M* for AcVal and AcLeu, and from 5 to 300μ*M* for AcIle; detection limits for AcVal, AcLeu and AcIle were 2, 2 and 3μ*M*, respectively. The immobilized aminoacylase reactor should be renewed every 5 days owing to a poor stability of aminoacylase.

## INTRODUCTION

*N*-Acetylation is a reaction of amino acid metabolism, and the increase in the AcBCSs levels in body fluids is known to occur in maple syrup urine disease which is caused by inborn errors of metabolism of branched-chain amino acids (BCAs).

Usually, *N*-acetyl amino acids are determined by gas chromatography–mass spectrometry.[1–3] In a second approach, *N*-acetyl amino acids are hydrolyzed, and the resulting amino acids are quantitated by high-performance liquid chromatography (HPLC) using *o*-phtalaldehyde precolumn derivatization.[4,5] Recently, Kawakami *et al.*[6] developed a HPLC method based on the pre-column derivatization with 9-anthryldiazomethane and fluorimetric monitoring. However, the pre-column techniques are time-consuming.

This paper described the use of immobilized enzymes as post-column reactor in an HPLC system for the selective determination of AcBCAs. The AcBCAs from separation column were hydrolyzed in immobilized aminoacylase reactor and the BCAs formed were mixed with $NAD^+$ solution. The $NAD^+$ was reduced to NADH in the immobilized leucine dehydrogenase reactor and the NADH formed was monitored by fluorescence detection.

Immobilized aminoacylase reactors have been used for the resolution of racemic mixtures of *N*-acetylamino acids and for the preparation of amino acids,[7,8] but there is no paper concerning their application to the determination of the compounds. Leucine dehydrogenase from *Bacillus sphaericus* was immobilized and used in flow-injection systems[9,10] and in HPLC system[11] as reactor for the determination of BCAs. In this work, leucine dehydrogenase from *Bacillus stearothermophilus*[12] that is stable at higher temperature was used.

## EXPERIMENTAL

### *Chemical and reagents*

*N*-acetyl-L-valine, *N*-acetyl-L-leucine and *N*-acetyl-L-isoleucine were purchased from Sigma. Aminoacylase (EC 3.5.1.14, from Porcine kidney, grade III, AA), was obtained from Sigma

with an activity of 110 U/mg with AcLeu as substrate at pH 8.0 at 30°C. Leucine dehydrogenase (EC 1.4.1.9, from *Bacillus stearothermophilus*, LeuDH) was purchased from Unitika (Osaka) with an activity of 42 U/mg with Leu as substrate at pH 10.5 at 30°C. Poly(vinyl alcohol) beads were GS-500 (13 $\mu$m diameter) and were obtained from Showa Denko (Tokyo). $NAD^+$ (98%, free acid) and NADH (disodium salt, 98%) were from Kohjin (Tokyo) and Capcell $C_1$ SG120 was from Shiseido (Tokyo). All other chemicals were of analytical reagent grade.

Phosphate buffer (pH 8.0) consisting of 0.03*M* potassium dihydrogen phosphate–0.03*M* disodium hydrogen phosphate was prepared. $NAD^+$ solution [20m*M* $NAD^+$ in 0.03*M* phosphate buffer (pH 7.0)] and 0.3*M* carbonate buffer (pH 10.0) consisting of 0.3*M* sodium carbonate–sodium hydrogen carbonate were prepared daily.

*Preparation of enzyme reactors*

AA and LeuDH were immobilized onto the poly(vinyl alcohol) beads. The method of amination of the beads was similar to that described by Matsumoto *et al.*.[13] The beads (2 g) were suspended in 50 ml of 50% chloromethyloxirane in 3*M* sodium hydroxide solution at 50°C for 1.5 hr, followed by reaction with concentration aqueous ammonia (50 ml) at 40°C for 3 hr. The attached amine amounted to 3.0 meq./g dry beads. The aminated beads were packed into columns. Glutaraldehyde solution (4%) in 0.1*M* sodium hydrogen carbonate was pumped through the columns at 0.3 ml/min for 3 hr at *ca.* 20°C and the columns were washed with deaerated water at 0.5 ml/min for 30 min. AA solution (20 mg in 10 ml of 0.1*M* phosphate buffer, pH 7.0) was recycled through the column (50 × 4 mm i.d., stainless-steel) for 6 hr at 0.2 ml/min at about 15°C. During the immobilization procedure the enzyme solution was kept at 2–5°C in an ice-box. After the immobilization procedure, AA activity in the solution was measured with AcLeu as substrate at pH 8.0 at 30°C. AA was immobilized with a 46% yield; it was assumed that inactivation of AA during the immobilization process did not occur. LeuDH solution (3 mg in 10 ml of 0.1*M* phosphate buffer, pH 7.0) was circulated through the column (2 cm × 4 mm i.d., stainless-steel) for 3 hr at 0.2 ml/min at about 20°C. LeuDH activity in the solution was measured with Leu as substrate at pH 10.0 at 30°C. LeuDH was immobilized with a 98% yield; it was assumed that inactivation of LeuDH during the immobilization did not occur.

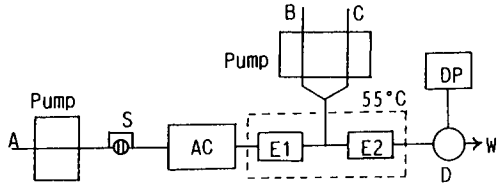

Fig. 1. Flow diagram of liquid chromatographic system for the determination of *N*-acetyl branched-chain amino acids. (A) Mobile phase (0.03*M* phosphate buffer, pH 8.0), 0.4 ml/min, (B) 20 mM $NAD^+$ solution (0.2 ml/min), (C) 0.3*M* carbonate buffer (pH 10.0), 0.2 ml/min, (S) injection valve with a 30 $\mu$l loop, (AC) analytical column (250 × 4 mm i.d.), (E1) immobilized aminoacylase reactor (50 × 4 mm i.d.), (E2) immobilized leucine dehydrogenase reactor (20 × 4 mm i.d.), (D) fluorimeter (*Ex* 340 nm, *Em* 465 nm), (DP) data processor, (W) waste. E1 and E2 were kept at 55 °C.

*HPLC system*

A schematic diagram of the system is shown in Fig. 1. The system consisted of a LC pump (Hitachi L-6000) and a reagent-delivery pump (Kyowa Seimitsu KHU-W-52), an injection valve (Sanuki SVI-6M2) equipped with a 30-$\mu$l loop, an analytical column (250 × 4 mm i.d., stainless-steel column), an immobilized AA reactor, an immobilized LeuDH reactor, a spectrofluorimeter (Jasco FP-210) [*Ex* 340 nm, *Em* 465 nm] equipped with flow-through cell (15 $\mu$l) and a data processor (System Instrument Chromatocorder II). The analytical column was filled with Capcell $C_1$ SG120 (5 $\mu$m). The reactors were kept constant at 55°C in a water bath. The mobile phase was the 0.03*M* phosphate buffer (pH 8.0), which was pumped at 0.4 ml/min and $NAD^+$ solution and the carbonate buffer were pumped at 0.2 ml/min each.

A serum sample was filtered through an ultrafiltration membrane (Advantec 0Q100, nominal molecular weight cut-off 10,000). The filtrate (30 $\mu$l) was injected into the system.

*Reference method*

The AcBCAs content in serum samples was determined for comparison with gradient cation-exchange chromatographic method with post-column derivatization with *o*-phthalaldehyde and fluorimetric detection.[14] The separation column was TSK gel SCX (5 $\mu$m) (30 cm × 7.8 mm i.d.). Serum (200 $\mu$l) was mixed with 0.6*M* ice-cold perchloric acid (400 $\mu$l). The mixture was centrifuged and the clean supernatant was filtered through the ultrafiltration

membrane. For the determination of BCAs a part of the filtrate (10 $\mu$l) was injected into the liquid chromatographic system, and the other portion (300 $\mu$l) was mixed 1.5$M$ tris(hydroxymethyl)aminomethane solution (700 $\mu$l) and 20 $\mu$l of AA solution (10 mg of AA in 1.0 ml of 0.1$M$ phosphate buffer) and was incubated 60 min at 35°C. After the hydrolysis the solution was filtered and for the determination of BCAs plus AcBCAs the filtrate (40 $\mu$l) was injected into the liquid chromatographic system.

## RESULTS AND DISCUSSION

### *Properties of immobilized enzyme reactors*

The properties of immobilized LeuDH were first evaluated without using the analytical column or the immobilized AA reactor. The influence of pH on the enzyme reaction was studied over the pH range 9–11 with carbonate buffer. A standard solution of Leu (20$\mu M$) was injected into the carrier stream (0.03$M$ phosphate buffer, pH 8.0) and mixed with a mixture of $NAD^+$ solution and 0.3$M$ carbonate buffer at various pH values before reaching the reactor. The optimum pH for the enzyme reaction was about 10.0. The reactor was placed in a waterbath and the temperature was varied between 45 and 70°C. The reactor exhibited the highest activity at 60°C. The effect of the concentration of $NAD^+$ in the reactor was examined in the range 1–6m$M$. The peak height was constant at concentrations greater than 4m$M$. The peak height decreased linearly as the flow-rate was increased from 0.6 to 1.2 ml/min. With 4m$M$ $NAD^+$ in carbonate buffer (pH 10.0) at 55°C and at a flow-rate of 0.8 ml/min, 50$\mu M$ Leu was converted by LeuDH with a 89% yield. Under the same conditions, the relative activities of the immobilized LeuDH for Leu, Ile and Val were 100, 100, 95, respectively. The reactor was used for 8 hr/day and was stored at 4°C in 0.1$M$ phosphate buffer (pH 7.0) when not in use. The activity remained at 95% of the initial value for 4 weeks. The peak heights were plotted against the concentrations of the amino acids. The concentration range of linear response was from 1 to 300$\mu M$. The detection limit was 0.7$\mu M$.

The immobilized AA reactor was used in the flow injection mode by omitting the analytical column to evaluate the efficiency of amino acids production from each AcBCA at various temperatures. The reactor was placed in a water bath and the temperature varied from 45 to 70°C in 0.03$M$ phosphate buffer (pH 8.0) at a flow-rate of 0.4 ml/min. The peak height of the liberated amino acid was determined by injecting AcVal, AcLeu and AcIle standards (10$\mu M$). A conversion efficiency of 100% was obtained above 50°C for all AcBCAs. The efficiencies for AcVal, AcLeu and AcIle were maintained at a constant value for 17, 15 and 5 days, respectively, when the reactor was used for 8 hr per day and was stored at 4°C in 0.1$M$ phosphate buffer (pH 7.0) when not in use.

### *Separation of the AcBCAs*

The separation of mixtures of AcVal, AcIle and AcLeu was carried out by reversed phase chromatography on a Develosil ODS-HG-5 (5 $\mu$m) column (150 × 4.6 mm i.d.) with 0.03$M$ phosphate buffer (pH 8.0)–methanol (95:5, v/v) as mobile phase. The use of the mobile phase led to the inactivation of immobilized AA within 2 days, because AA is denatured by methanol. Separation of the AcBCAs was effected on a Capcell $C_1$ SG120 (5 $\mu$m) column (250 × 4 mm i.d.) with 0.03$M$ phosphate buffer (pH 8.0) as mobile phase. By using the mobile phase a stable and reproducible chromatogram was obtained (Fig. 2). The peak height ratio for AcVal,

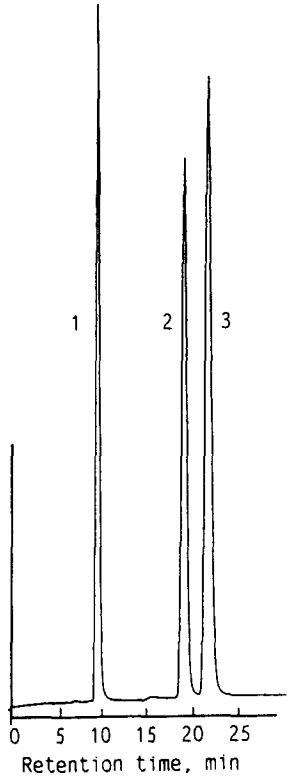

Fig. 2. Chromatogram of standard mixture (each of 20$\mu M$). (1) *N*-Acetyl-L-valine, (2) *N*-acetyl-L-isoleucine, (3) *N*-acetyl-L-leucine.

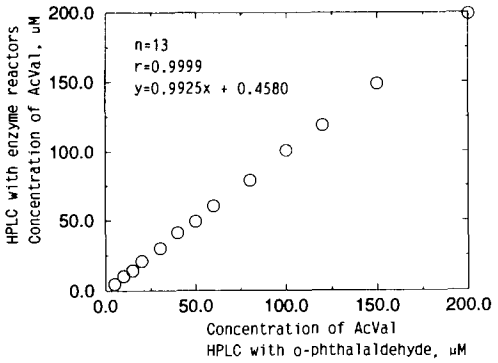

Fig. 3. Comparison of *N*-acetyl-L-valine concentration determined by HPLC with enzyme reactors and by HPLC with *o*-phthalaldehyde.[14]

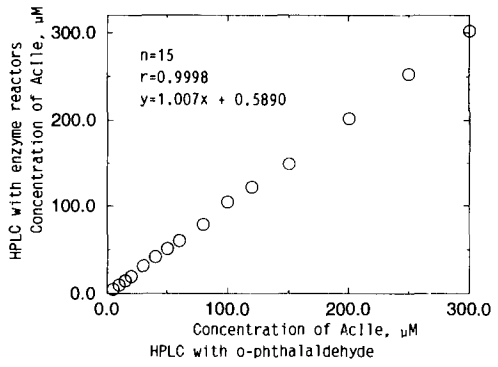

Fig. 5. Comparison of *N*-acetyl-L-leucine concentration determined by HPLC with enzyme reactors and by HPLC with *o*-phthalaldehyde.[14]

AcIle and AcLeu was 100:78:90. The peak height was plotted against the concentration of the compounds. The concentration ranges of linear response were from 4 to 200$\mu M$ for AcVal and AcLeu and from 5 to 300$\mu M$ for AcIle. The detection limits (signal-to-noise ratio = 3) for AcVal, AcIle and AcLeu were 2, 3 and 2$\mu M$, respectively.

*Application*

This system was used to determine the amount of AcVal, AcLeu and AcIle in serum. A sample of normal human serum was filtered on the ultrafiltration membrane. The filtrate (30$\mu$l) was injected into the system. Since no naturally occurring free AcBCAs were found in the serum by this method, the pooled serum was supplemented with AcVal, AcLeu and AcIle to give final concentrations of 5–200$\mu M$ AcVal, 5–300$\mu M$ AcIle and 5–200$\mu M$ AcLeu. Results obtained using this system compared well with a cation-exchange high-performance liquid chromatographic method.[14] The results are summarized in Figs 3–5. The calculated linear regressions and correlation coefficients for AcVal, AcIle and AcLeu were $y = 0.9925x + 0.4580$ and $r = 0.9999$, $y = 1.007x + 0.5890$ and $r = 0.9998$, and $y = 0.9898x + 0.3774$ and $r = 0.9999$, respectively.

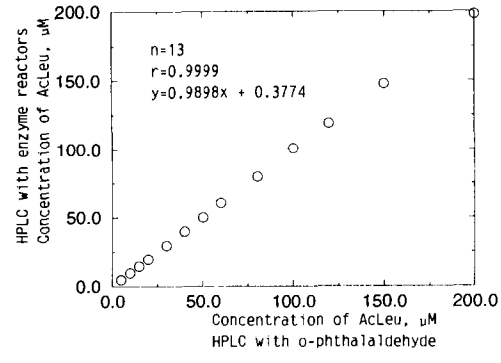

Fig. 4. Comparison of *N*-acetyl-L-isoleucine concentration determined by HPLC with enzyme reactors and by HPLC with *o*-phthalaldehyde.[14]

## CONCLUSIONS

We have shown that immobilized acteylacylase reactor and leucine dehydrogenase reactor are useful for the simultaneous detection of AcVal, AcIle and AcLeu using reversed-phase HPLC and fluorimetric detection. This method proved to be simple and selective for the determination of AcBCAs. However, it should be noted that the immobilized aminoacylase reactor should be renewed every 5 days, and that this is a disadvantage of the proposed technique.

# COLORIMETRIC DETERMINATION OF LOW pH WITH MALACHITE GREEN

ELIZABETH W. BAUMANN

Westinghouse Savannah River Company, Savannah River Technology Center, Aiken, SC 29808, U.S.A.

(*Received* 6 *October* 1993. *Revised* 15 *April* 1994. *Accepted* 15 *April* 1994)

**Summary**—A spectrophotometric method was developed for determination of concentration-based pH values from 0 to 2 with Malachite Green indicator. A quadratic model equation was based on the ratio of the absorbances of the peak at 618 nm and the isosbestic point at 518 nm. Normalization to the isosbestic point was used to stabilize the response because the color faded; the useful time interval was within 5 min after indicator addition. Model and verification sets agreed within ±0.02 pH units between pH 0.3 and 1.8. This excellent precision makes the colorimetric method useful for acid determinations with a relative precision of > ±5%. The presence of salts at a salt/acid equivalent ratio >0.1 caused a low pH bias.

Use of color indicators provides a convenient alternative to potentiometric pH measurements for determination of acidity. Modern instrumentation such as diode array spectrophotometry and computerized data reduction has converted this classical technique[1] into one that is practical for field and online applications. Color indicators offer the option of either simple visual estimation or quantitative determination by spectrophotometry, with fiber optics or flow injection interfaces. Mathematical fitting or modeling of the spectral data can provide instant output values. In this work, preparation of models with standard solutions of known hydrogen ion concentrations makes the measured pH one that is based on hydrogen ion concentrations (*i.e.* $-\log[H^+]$), rather than on hydrogen ion activities.

Although many pH indicators are available,[2] only a few have suitable spectra for analytical applications, particularly at the extremes of the pH range. Earlier work described azoviolet indicator for colorimetric pH determinations of solutions such as the concentrated waste solutions with pH > 11 at the Savannah River Site.[3] The present work describes a similar application of Malachite Green to solutions with pH < 2 for other process streams. Normalization of the data to the isosbestic point and development of a quadratic model provides a sensitive method that overcomes the limitations of the indicator due to color fading.

This paper was prepared in connection with work done under Contract No. DE-AC09-89SR18035 with the U.S. Department of Energy. ## EXPERIMENTAL

The calibration/model was developed by making absorbance measurements with standard solutions of 0.01–1*M* $HNO_3$. These solutions were prepared from a 1*M* stock solution standardized against the primary standard tris(hydroxymethyl)aminomethane.[4] The dilutions were confirmed by nitrate determinations with ion chromatography. Spectra for the acid and base forms of the indicator were established with 2*M* $HNO_3$ and 0.1*M* $KNO_3$, respectively. Samples were prepared and analyzed by the same procedure as the standards. A reference spectrum of the test solution without indicator was used for each measurement.

The Malachite Green solution was 0.1 w/v% of Malachite Green hydrochloride [$(CH_3)_2NC_6H_4C(C_6H_5):C_6H_4:N(CH_3)_2Cl$; CAS No. 569-64-2. Baker P451.03 or equivalent] dissolved in water. The solution was filtered. The pH of the indicator solution was about 3. The usual pH adjustment to midrange (about pH 1) was not made because the indicator is unstable at the lower pH, and the acid

contribution of the indicator to the test system is negligible.

*Procedure*

Four millilitres of solution was pipetted into a vial and 50 $\mu$gl of Malachite Green solution added. The solution was transferred to a 1-cm cuvette and between 0.25 and 5 min after addition of the Malachite Green, the absorbance of solution was measured from 400 to 700 nm (618 nm and 518 nm are the specific wavelengths of interest) with a Hewlett Packard Diode Array Spectrophotometer, or equivalent. The collected data was used to create a model or to determine pH from the established model, as described below.

## RESULTS AND DISCUSSION

*Malachite Green indicator*

Figure 1 shows Malachite Green spectra from pH 0.01 to 2.1. The base form has a strong sharp peak at 618 nm (blue-green), which was used for the analysis. The acid form has a broader, less suitable, peak in the 425–450 nm (yellow) range. The isosbestic point occurs at 518 nm. Kolthoff reported that triphenylmethane dyes, such as Malachite Green, were considered to be of no practical value as pH indicators because of instability and salt errors.[2] Normalization with the isosbestic point absorbance overcame the instability problem; salt error limitations are discussed below. Anionic halide complexes with certain metals (Cd, Co, Ta, Ga, In, Rh, Sn, Zn) are reported to bond with Malachite Green into extractable ion pairs,[5] but this possible interference was not investigated because these metals were not significant in our process streams.

*Collection and interpretation of data*

Spectra were collected at intervals of approximately 0.25, 2.5, and 5 min after the indicator was added. Spectra at the extremes of the indicator pH range were similarly obtained with $2M$ $HNO_3$ and $0.1M$ $KNO_3$. Ratios of absorbances at the peak (618 nm) and at the isosbestic point (518 nm) were used for modeling and for pH determinations from the model.

The color of the Malachite Green faded with time, particularly in more acidic solutions. Normalization to the isosbestic absorbance provided a parameter that was independent of measurement time for the 5 min interval after the indicator was added. Figure 2 shows average values and % relative standard deviations (RSD) for the normalized absorbances taken 0.25, 2.5, and 5 min after addition of indicator. %RSD values were $<1\%$ except at the lowest pH (0.009), where the %RSD rose to 3.5%. The variables $DX_n$, $DA_n$, and $DB_n$ are the ratios of the peak to isosbestic absorbances for the un-

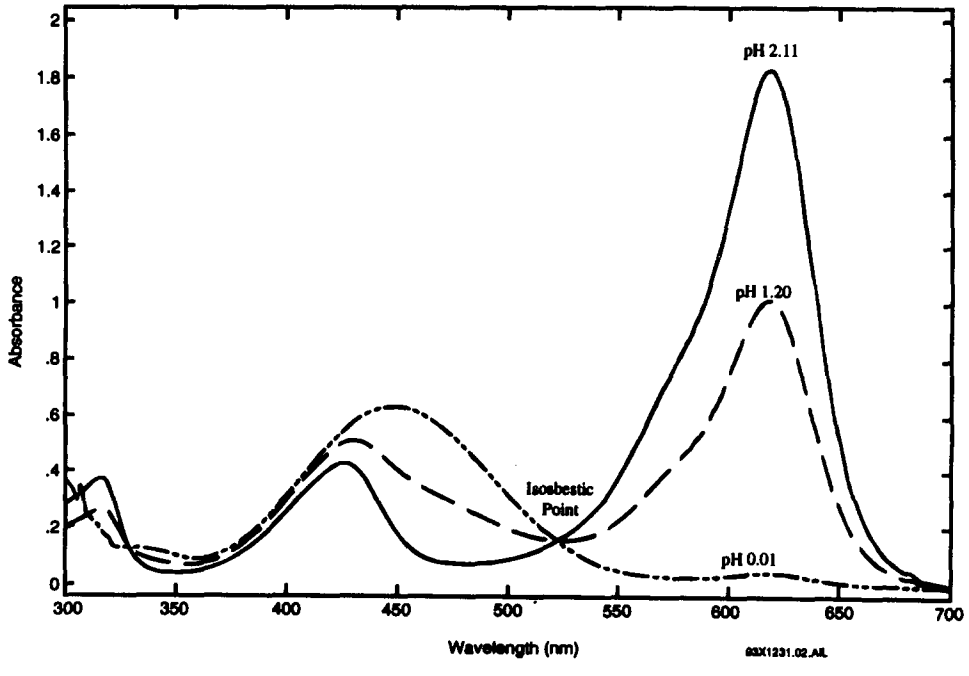

Fig. 1. Effect of pH on the absorption spectrum of Malachite Green. Spectra were taken 0.25 min after addition of indicator. The concentration of Malachite Green was $3.4 \times 10^{-5}M$.

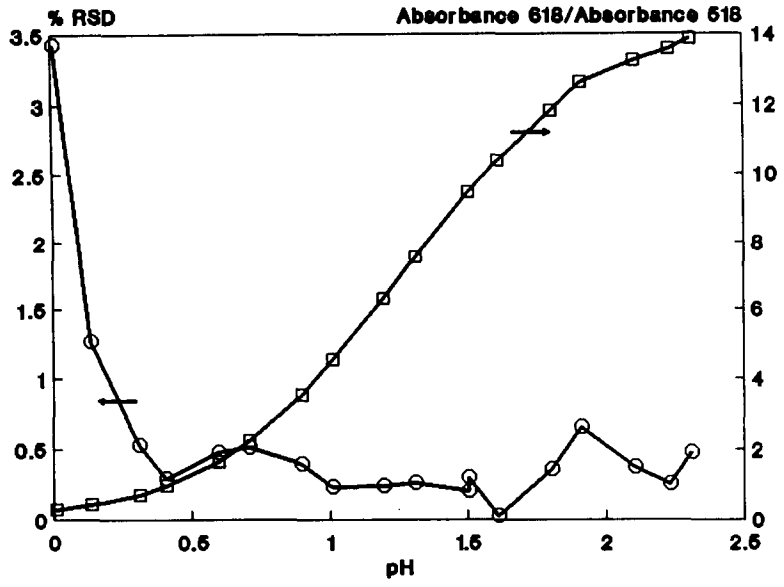

Fig. 2. Average values of $DX_n$, the ratio of absorbances at 618 and 518 nm, for different times. The ratios were averaged for measurements 0.25, 2.5, and 5 min after indicator addition. □ = average $DX_n$; ○ = % relative standard deviation.

known, the acid form and the base form, respectively.

Normalization to the isosbestic point also made the determination nearly independent of indicator concentration. Table 1A shows $DA_n$ and $DB_n$, over a three-fold range of indicator concentrations. The peak absorbance at 618 nm for $DB_n$ with 50 μl of indicator was >3, too high for accurate response.

*Development of model*

The relationships for fitting single peak data were similar to those used earlier.[1,3] $DADB_n$ is defined in equation (1a) in terms of α, the fraction of the indicator in the base form, and in equation (1b) in terms of ($DB_n$), ($DA_n$), and $DX_n$).

$$DADB_n = \alpha/(1-\alpha) \quad (1a)$$

$$=(DX_n - DA_n)/(DB_n - DX_n). \quad (1b)$$

The model was developed with a set of 18 nitric acid standards and was verified with measurements of a newly prepared set of these 18 standards. Three sets of data, collected approximately 0.25, 2.5, and 5 min after the indicator was added, were averaged for the model. $DA_n$ and $DB_n$ values for the model-building (calibration) set and for the verification set were the average of six experimental values (two samples

Table 1. Summary of $DA_n$ and $DB_n$ values

measured at three different times) for that test. Average $DA_n$ and $DB_n$ and their pooled standard deviations are included in Table 1B.

The model equation, which had an $R$ squared value of 0.999465, was:

$$\text{pH} = 1.298192 + 0.815108\ (\log DADB_n) \\ 0.069844\ (\log DADB_n)^2. \qquad (2)$$

The good agreement of the model with the test set is shown in Figure 3. Between pH 0 and 1.8, differences between calculated and known values were $<0.02$ pH unit. The reason for the trend in the data, with a positive bias at pH $< 1$ and a negative bias at pH $> 1$, is not known.

*Salt error*

The salt error was investigated with solutions that contained hydrolyzable ions or simple salts. In one set of experiments the solutions were standard 0.1$M$ nitric acid containing 0.1$M$ nitrates of aluminum, uranium, iron, thorium, or chromium, cations of interest in our process streams. Limits of the salt effect were investigated with the aluminum–nitric acid system with progressively less aluminum, down to 0.0125$M$ aluminum nitrate. The free acid content of these solutions was determined by standard addition in the presence of KSCN[6] or by titration in the presence of KF. Solutions of 0.1$n$ nitric acid or hydrochloric acid solutions spiked with their respective sodium salts were also analyzed.

The spectra of the solutions with hydrolyzable ions (Fig. 3) showed that, with the exception of iron, the presence of the metals did not affect the shape of the spectra. The results of these studies (Fig. 4) demonstrated that the salt error was related to the number of equivalents of salt present. Equivalent amounts of salt and acid caused a low bias of about 0.06 pH units. To achieve a precision of $\pm 0.02$ pH units the salt/acid equivalent ratio must be $<0.1$.

*Application to determination of acid concentrations*

The model was developed for pH defined in terms of hydrogen ion concentration, not for hydrogen ion activity. The excellent precision of $\pm 0.02$ pH units suggested that this colorimetric method might be useful for determination of acid concentrations in systems where a relative precision of $> \pm 5\%$ is adequate.

Table 2 shows application of the model to determination of the acidity of process solutions that contained up to 0.1$M$ $UO_2(NO_3)_2$. Confirming analyses were performed by titration with NaOH in KF medium and/or by standard additions in KSCN medium.[6] Both these methods determine hydrogen ion concentration. Within the range of the model, the colorimetric method gave comparable results. These determinations also demonstrated that in this low-salt system the method could be extended to more concen-

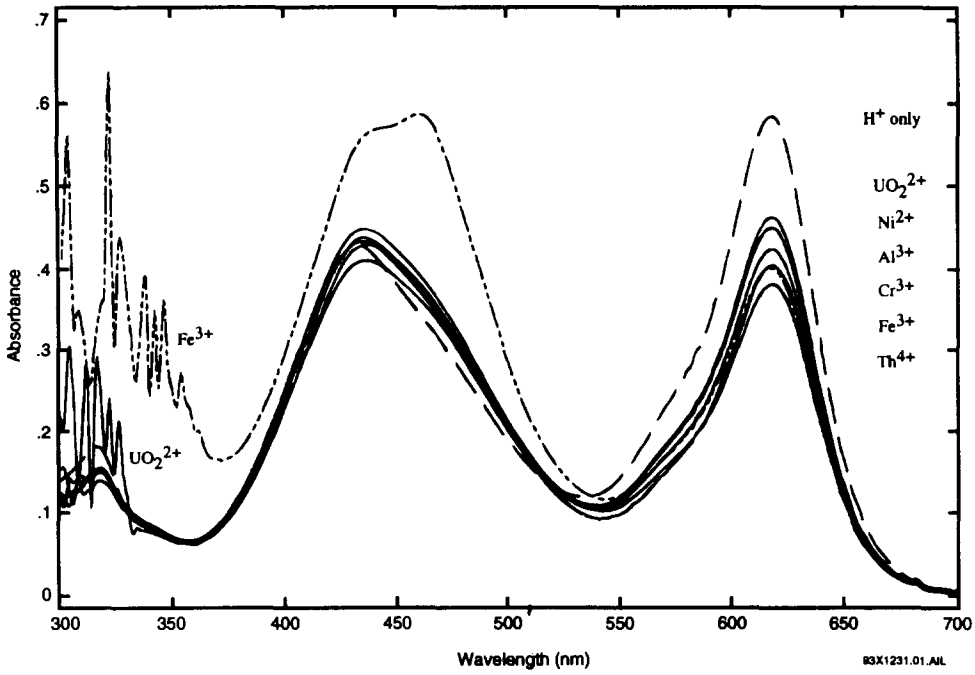

Fig. 4. Effect of hydrolyzable salts on absorption spectrum of Malachite Green. Solutions were 0.1*M* $HNO_3$ + 0.1*M* metal nitrate. Spectra were taken 2.5 min after addition of indicator. Malachite Green concentration was $3.4 \times 10^{-5}M$.

trated acid solutions by making dilutions as large as 10-fold.

*Comments on implementation*

Concentration-based pH determinations are useful for many applications. Sometimes the difference between hydrogen ion activity and acid concentration can be compensated. At the higher pH range of the method, samples may be sufficiently dilute that activity coefficients approach unity. For samples with similar ionic strengths, indicator and electrode pH values will be proportional to one another throughout the range.

The model equation in this paper is intended to serve as a guide for application and performance of the method. For actual implementation, a model for the system of interest should be

developed. A model that includes the full spectrum can be developed by partial least squares or other techniques, as was done in the previous work with high pH systems and azoviolet indicator.[3] While the full-spectrum model may or may not improve the precision, it most certainly would be useful in flagging inappropriate samples through goodness-of-fit calculations.

# DISPOSABLE SCREEN-PRINTED ELECTRODES FOR MONITORING HYDRAZINES

JOSEPH WANG* and PRASAD V. A. PAMIDI

Department of Chemistry and Biochemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 10 *May* 1994. *Accepted* 22 *July* 1994)

**Summary**—Disposable amperometric sensors for hydrazines have been fabricated by a judicious tailoring of the surface of screen-printed electrodes. Strong electrocatalytic action towards the oxidation of hydrazines is achieved by incorporating cobalt phthalocyanine within the carbon inks or by covering the printed surface with a mixed valent ruthenium cyanide coating. The electrocatalytic behavior, sensor optimization and analytical performance are reported. The new sensor strips should facilitate on-site environmental and industrial monitoring of hydrazine compounds.

Because of the environmental and toxicological significance of hydrazine compounds, a reliable method is required for their quantitation. Portable instruments, coupled with small sensing probes, are preferred for facilitating environmental field screening or on-site industrial monitoring of hydrazines. Controlled-potential electroanalytical procedures, particularly those relying on electrocatalytic modified electrodes, have been developed for the detection of hydrazine compounds. In particular, glassy carbon electrodes coated with cobalt phthalocyanine (CoPC) or mixed-valent ruthenium (III,II) cyanide (mvRuCN) layers have been shown to catalyze the oxidation of various hydrazines.[1,2] The adaptation of such schemes for mass-producible environmental or industrial sensors is thus a logical extension of their capabilities.

The present work describes disposable modified screen-printed sensors for measurements of hydrazine. The screen-printed (thick film) technology represents an ideal route for large-scale fabrication of highly reproducible and yet inexpensive electrochemical sensors.[3–5] For example, commercial single-use enzyme electrodes are commonly being used for self-testing of blood glucose levels.[6] We have previously used the screen-printing technology as the basis of disposable sensors for metals (such as lead or uranium).[7,8] Cobalt–phthalocyanine based screen-printed electrodes were employed by Wring and Hart[9] for facilitating the determination of biomolecules such as reduced glutathione. In the following sections we will characterize and apply CoPC and mvRuCN modified sensor strips for decentralized testing of hydrazines.

## EXPERIMENTAL

### *Apparatus*

Amperometric and voltammetric measurements were carried out with a Bioanalytical Systems (BAS) CV-27 voltammetric analyzer in connection with a BAS Model VC-2 10 ml cell. The screen-printed working-electrode strip, the Ag/AgCl reference electrode (BAS Model RE-1) and platinum wire auxiliary electrodes were introduced to the cell through its Teflon cover.

A semi-automatic screen-printer (Model TF-100, MPM Inc. Franklin, MA, U.S.A.) was used for fabricating the electrode strips. A group of 25 electrodes was thus printed onto the alumina ceramic base (of 10 × 3.4 cm). Each electrode consisted of a 1 × 6 mm working area. The carbon ink was obtained from Gwent Electronic Materials Ltd (No. C10903D14, Gwent, U.K.). The CoPC modified ink was prepared by thoroughly mixing 0.1 g of CoPC with 4.0 g of the carbon ink. The mixing was facilitated by a 15-min sonication period. Coating of the unmodified strip with a mvRuCN layer was accomplished by cycling the potential between 0.4 and 1.0 V (at 50 mV/sec for 30 min) in the

presence of a 0.2*M* $K_2SO_4$ solution (pH 2.0) containing 2.5 m*M* $RuCl_3$ and 2.5 m*M* $K_4Ru(CN)_6$.

*Reagents*

All solutions were prepared with double-distilled water. Hydrazine solutions were prepared from hydrazine sulfate (Baker) and 1,2-dimethylhydrazine (Aldrich). The surface modifiers, CoPC and ruthenium chloride/potassium hexacyanoruthenate, were purchased from Aldrich and Alpha, respectively. The supporting electrolytes were 0.2*M* $K_2SO_4$ and 0.2*M* NaOH in connection with the ruthenium- and CoPC-modified strips, respectively. Ground water and tap water samples were collected at the Hanford Site (Richland, WA, U.S.A.) and the NMSU Chemistry and Biochemistry building (Las Cruces, NM, U.S.A.).

*Procedure*

Quantitation of the hydrazine compounds was accomplished in chronoamperometric experiments (with stepping the potential from open-circuit to +0.1 and 1.0 V for the CoPC- and mvRuCN-based strips, respectively). The current was sampled 210 sec following the potential step. Calibration data were achieved by spiked aliquots of the hydrazine standard solution to the cell.

## RESULTS AND DISCUSSION

Because of the large overvoltage for the electrooxidation of hydrazines at ordinary carbon strip electrodes, modified sensor surfaces are required to catalyze the oxidation process. Two such catalytic surfaces, based on modification with CoPC or mixed-valent ruthenium cyanide (mvRuCN), are known for their catalytic activity toward hydrazines at conventional carbon paste and glassy carbon electrodes,[1,2] and are thus assessed below in connection with the disposable carbon strips. While CoPC can be added to the carbon ink suspension prior to the printing process, the mvRuCN film is grown electrochemically after completing the fabrication.

The electrochemical deposition of the mvRuCN layer on the printed carbon surface is illustrated in Fig. 1. Repetitive cyclic voltammograms reveal two anodic peaks (at $\sim +0.62$ and $\sim +0.88$ V), corresponding to the $Ru^{2+,3+}$ and $Ru(CN)_6^{3-,4-}$ couples, respectively. A cathodic peak, at $\sim +0.66$ V, corresponding to the $Ru(CN)_6^{3-,4-}$ couple, is also observed. Similar peaks, at slightly different potentials, were reported for the analogous modification of glassy carbon electrodes.[10] All peaks gradually increase upon repetitive scanning, reflecting the continuous growth of the mvRuCN film.

Figure 2 displays hydrodynamic voltammograms (HDVs) for $4 \times 10^{-5}M$ dimethylhydrazine (a) and hydrazine (b) at both mvRuCN (A) and CoPC (B) modified strips, as well as the corresponding response at the unmodified sensor (open squares). Different media, $K_2SO_4$ (A) and NaOH (B), as commonly used with mvRuCN[2] and CoPC[1] modified electrodes, were employed. (Owing to its limited anodic potential window of NaOH media and the high potential of the mvRuCN couple, NaOH was not employed in connection with this modifier.) At the mvRuCN-coated strip, the anodic detection of both hydrazines is starting at +0.7 V, reaches a maxima around +1.0 to +1.1 V, and decreases at higher potentials. Similar profiles were reported for mvRuCN-coated glassy carbon electrodes.[2] No response is observed, over the entire potential range, for analogous measurements at the bare strip. At the CoPC-containing strip, the oxidation starts at −0.1 V, with the current increasing slowly up to +0.3 V

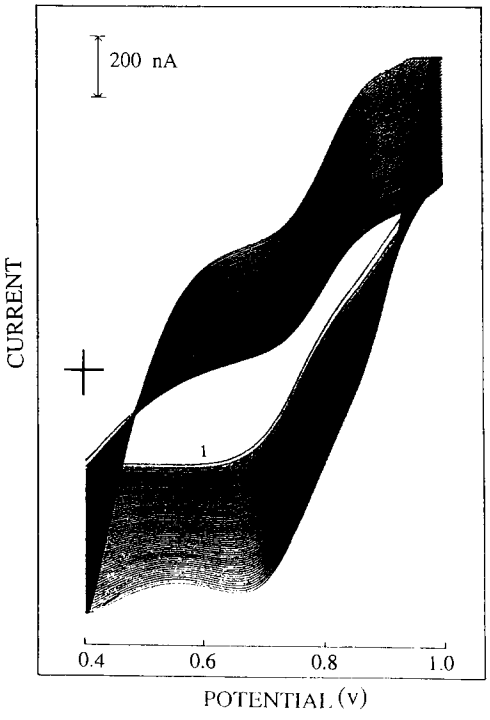

Fig. 1. Repetitive cyclic voltammograms at a screen-printed carbon electrode, dipped in a 0.2*M* $K_2SO_4$ solution (pH 2.0) containing 2.5 m*M* $RuCl_3$ and 2.5 m*M* $K_4Ru(CN)_6$ for 30 min. Scan rate, 50 mV/sec.

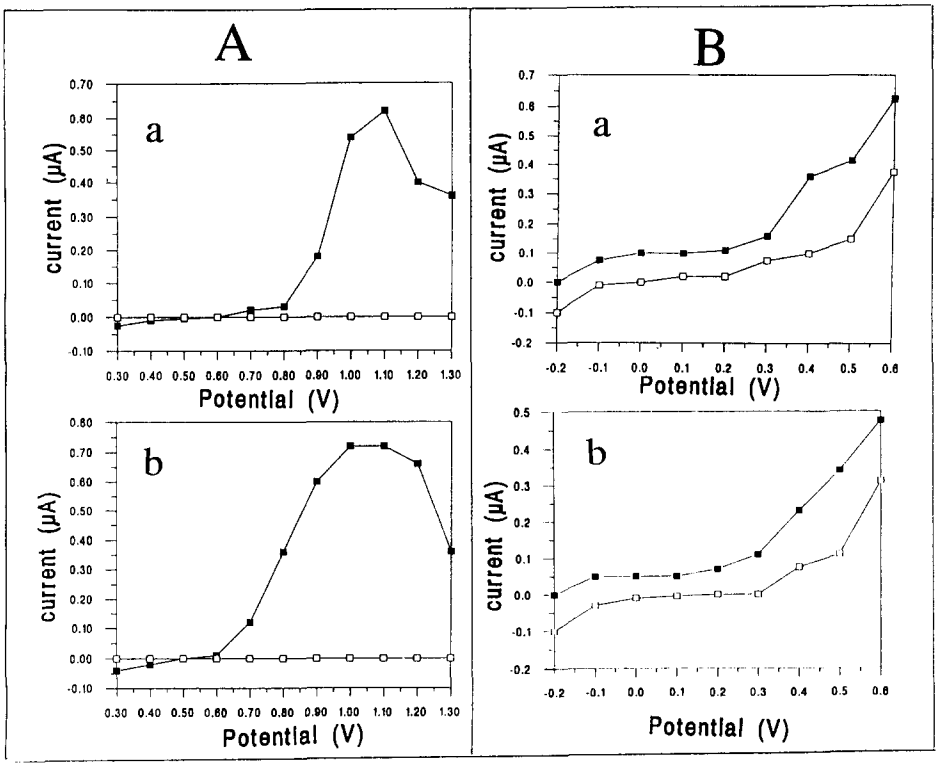

Fig. 2. Hydrodynamic voltammograms for $4 \times 10^{-5}M$ 1,2-dimethylhydrazine (a) and hydrazine (b) at mvRuCN (A) and CoPC (B) modified carbon strips. Electrolytes, $0.2M$ $K_2SO_4$ (A) and $0.2M$ NaOH (B). The individual points were obtained by chronoamperometry.

and then more rapidly. Note that (upon using the NaOH solution) the bare electrode is also responding to these hydrazines, but yields significantly smaller currents. Two oxidation processes (at $-0.2$ and $+0.1$ V) were reported for hydrazine at phthalocyanine-coated glassy carbon electrodes.[1]

The HDVs of Fig. 2 indicate that an optimum strip performance could be achieved around $+0.1$ V (CoPC) and $+1.0$ V (mvRuCN). Considering that quiescent sample droplets are likely to be placed onto the strip surface, chronoamperometry was selected for all subsequent quantitative work. Figure 3 shows chronamperograms for hydrazine solutions of increasing concentration ($4 \times 10^{-5}M$ increments) at the mvRuCN (A(a)) and CoPC (B(a)) modified strips, along with the corresponding response of the naked strip surface (b). Both strips offer convenient quantitation at the micromolar concentration level, as well as an extremely low background response (shown as dotted line). Note also that in accordance with the HDV data of Fig. 2, the unmodified electrodes yield only a negligible response towards the analyte. The resulting calibration plots (not shown) were linear in the case of the mvRuCN-coated strip (slope $8.5 \pm 0.01$

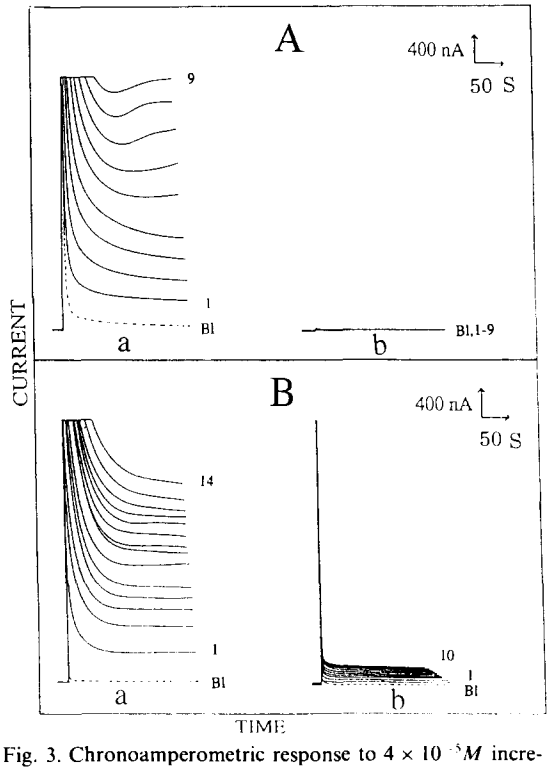

Fig. 3. Chronoamperometric response to $4 \times 10^{-5}M$ increments in the hydrazine concentration, along with the corresponding blank response (dotted line) at the mvRuCN (A(a)) and CoPC (B(a)) modified strips. Also shown (b) the corresponding response at the unmodified strips (b). Potential steps to $+1.0$ V (A) and $+0.1$ V (B). Electrolytes, as in Fig. 2.

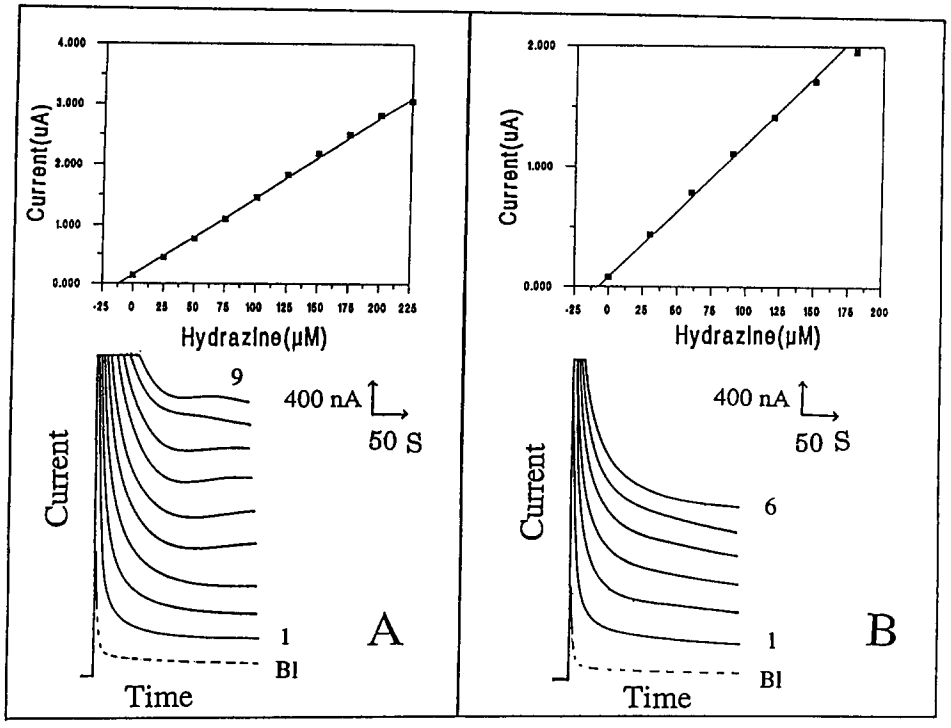

Fig. 4. Chronoamperometric response of the mvRuCN strip to ground water (A) and drinking water (B) samples spiked with increasing hydrazine concentration in $2.5 \times 10^{-5}M$ steps. Also shown (as dotted lines) are the blank sample responses; 8 ml sample +2 ml $0.2M$ $K_2SO_4$. Other conditions, as in Fig. 3A.

mA/$\mu M$, correlation coefficient, 0.997) but displayed a curvature (above $8 \times 10^{-5}M$) for the CoPC-containing sensors (correlation efficient, 0.986). Detection limits of $4 \times 10^{-6}$ and $5 \times 10^{-6}M$ hydrazines can be estimated from the signal-to-noise characteristics ($S/N = 3$) of the response at the CoPC- and mvRuCN strips, respectively. Convenient quantitation was obtained also for analogous measurements of 1,2-dimethylhydrazine, with both sensors displaying nonlinearity, with a leveling off above $1.5 \times 10^{-4}M$ (not shown).

Because of their extremely low cost, the new hydrazine sensors are aimed mainly at single-use applications. Yet, such electrodes hold promise also for use as reusable devices. Long runs of 20 successive runs of $1 \times 10^{-4}M$ hydrazine yielded relative standard deviations of 10 and 12% for the mvRuCN and CoPC modifications, respectively (not shown). A gradual decrease in the response characterized these prolonged series. Electrode-to-electrode reproducibilities of 5% RSD were observed for both modification schemes (conditions: 10 strips of the same batch, using a $1 \times 10^{-4}M$ hydrazine solution; other, as in Fig. 2).

Figure 4 demonstrates the suitability of the mvRuCN sensor strip for direct measurements of hydrazine in ground water (A) and drinking water (B) samples. Small (25 $\mu M$) increments in the hydrazine concentration of both samples yield a well-defined chronoamperometric response, and linear standard additions plots (shown as insets). The extremely low blank response (dotted lines) indicates lack of major interferences in these environmental samples. Whenever needed, improvement in the selectivity can be achieved by covering the strip surface with a size-exclusion coating (permeable mainly to the very small hydrazine species).

In conclusion, this paper demonstrates that effective sensor strips for hydrazines can be fabricated by coupling thick-film and surface modification technologies. Effective electrocatalytic detection of hydrazine compounds can thus be achieved through a judicious tailoring of the strip surface. While requiring different operating conditions (*e.g.* potential, supporting electrolyte), both CoPC- and mvRuCN-based strips offer convenient quantitation of micromolar hydrazine concentrations. The selection of the most appropriate strip for a given analytical task should thus depend primarily on selectivity considerations (based on the different reactivities of these modifiers).

Although the present work deals with printing of the working electrode strip, self-standing hydrazine sensors (suitable for handling small sample volumes) can be easily achieved via coprinting of the reference electrode. Future coupling of such low-cost sensors with portable, battery-operated, instruments should facilitate on-site and real-time environmental and industrial monitoring of hydrazine compounds.

# ELECTROPOLYMERIZED *m*-PHENYLENEDIAMINE AS A MEANS TO IMMOBILIZE ACTIVE PROTEIN ON THICKNESS-SHEAR-MODE QUARTZ CRYSTAL

SI SHI-HUI, XU YUAN-JIN, NIE LI-HUA and YAO SHOU-ZHUO*

New Material Research Institute, Hunan University, Changsha, 410082 P.R. China

(*Received* 23 *May* 1994. *Revised* 9 *September* 1994. *Accepted* 12 *September* 1994)

**Summary**—Electropolymerized *m*-phenylenediamine was used as an active coating for immobilizing urease and lectin on a gold-plated thickness-shear-mode (TSM) crystal. To enhance effectiveness of immobilization, a bilayer polymer film composed of polyaniline and poly-*m*-phenylenediamine was proposed. Compared with single poly-*m*-phenylenediamine film, the bilayer polymer film gave better results in terms of immobilizing capacity, stability and reproductivity. On this bilayer-film-coated TSM quartz crystal, the amount of immobilized lectin was estimated about 1.8 $\mu$g/cm$^2$. Detection of purified human erythrocytes is demonstrated as an example of potential application of this lectin-modified TSM biosensor in clinic.

In recent years, applications of thickness-shear-mode (TSM) quartz crystal in solution chemistry have been developing rapidly.[1–3] Because the TSM sensor offers many advantages such as high sensitivity, simplicity of use and cost of effectiveness, some investigators have applied this device to immunosensors.[4] Immunoglobulins were detected with antibody[5,6] or protein A-modified crystal.[7] Microbes,[8] haptens[9,10] or protein antigen[11] were also detected by a similar method. Recently, much attention has been paid to the development of new biological coatings and new film-forming techniques.[12] For the development of a TSM immunosensor, a key step is to immobilize biological species (e.g. enzyme, antibody) effectively on the surface of the TSM crystal. Usually, the surface of the TSM crystal is precoated with functional polymer (e.g. polyethyleneimine[13]) by the dip-coating method. To our knowledge, few electropolymerized films have been used to immobilize biological species on the surface of TSM devices.

Electropolymerized films have been a subject of active investigation owing to their possible utility for a variety of applications including electrocatalyst, selective electrodes and surface modification.[14,15] With electropolymerization it is much easier to control the parameters of film thickness, homogeneity, and reproducibility. Glucose oxidase electrodes have been developed for polyaniline (PAn) or poly-*o*-phenylenediamine coating.[16,17] It is known that PAn can produce adherent and conducting film of uniform thickness on the gold matrix, but no functional group in the PAn structure can be modified with a bifunctional reagent which couples proteins such as antibodies and enzymes.

In this paper, the possibility for immobilizing active protein on the poly-*m*-phenylenediamine-coated TSM crystal is investigated. It was found that the poly-*m*-phenylenediamine (PmPD) coating on PAn matrix gave better results in terms of immobilizing capacity and stability.

## EXPERIMENTAL

### *Apparatus*

AT-cut 6 MHz gold-plated quartz crystal was used (area of electrode, 0.28 cm$^2$). A home-made IC-TTL oscillator was designed to drive the crystal at its resonant frequency,[18] and the frequency of the oscillator was monitored by a universal counter (Iwatsu, Model SC-7201). The experimental data were treated with a Hewlett Packard 9153C computer. The electrochemical quartz crystal microbalance (EQCM) experimental arrangement was similar to Ref. [19]. The QCM electrode facing solution was used as the working electrode, a commercial saturated

Table 1. Frequency responses to lectin and urease immobilized on three different coatings (average of five experiments)

| Coating | Urease | Lectin |
|---|---|---|
| $\gamma$-APTES | $-68 \pm 19$ Hz | $-52 \pm 11$ Hz |
| PmPD* | $-45 \pm 6$ Hz | $-42 \pm 8$ Hz |
| PmPD and PAn† | $-137 \pm 7$ Hz | $-118 \pm 9$ Hz |

*The frequency response to PmPD coating is about 400 Hz.
†The frequency responses to PmPD coating and PAn coating are controlled about 300 and 200 Hz, respectively.

calomel electrode (SCE) and a platinum mesh were used as the reference electrode and the auxiliary electrode, respectively. XJP-821 B model polargraph and X-Y recorder were used in EQCM measurements, and all potentials were quoted *vs.* SCE. The admittance measurements of the TSM crystal were performed using a HP 4192A impedance analyser. The temperature was controlled by the thermostat water bath at $15 \pm 0.1$°C except where otherwise stated.

*Materials*

Blood specimen obtained from a healthy man was anti-coagulated with EDTA, and centrifuged at 150 ***g*** for 10 min. The erythrocytes were washed three times with 0.9% NaCl, and suspended in phosphate buffer (pH 7.2, 0.2*M*). Urease (biochemical reagent, BDH Chemical Ltd, Poole, U.K.): 2 mg of urease was dissolved in 1 ml of phosphate buffer (pH 7, 0.2*M*). Lectin (biproducts of WuHan Biological Institute, purified from soybean) was diluted with phosphate buffer (pH 7.2, 0.2*M*), to a concentration of about 2 mg/ml. Glutaraldehyde (GA) was of biochemical reagent grade, from which 3% (pH 7) solution was prepared. $\gamma$-Aminopropyltriethoxysilane ($\gamma$-APTES, Aldrich) was used. *m*-Phenylenediamine was purified by recrystallization from dichloromethane and aniline was distilled under reduced pressure.

*Surface modification*

(a) *Thin silane coating.* After treatment with chloroform and acetone, the TSM crystal was dipped in a 5% solution of $\gamma$-APTES in acetone for 1 hr at 25°C, then air-dried and washed several times with acetone.

(b) *Bilayer polymer coating.* The gold-plated TSM crystal was mounted at the bottom of a well-type cell, and one side of the crystal was kept out of the solution. The TSM crystal electrode facing solution was washed with acetone and distilled water before modification. With steady state scanning from $-0.2$ to 0.8 V in 0.1*M* aniline and 1.2*M* sulfuric acid, the polyaniline coating was deposited on the gold-plated TSM crystal. Then the obtained PAn-coated crystal was washed with distilled water and put into a solution containing 0.12*M* *m*-phenylenediamine and 1.2*M* sulfuric acid, and further treated by electrolysing at 0.70 V to obtain PmPD coating.

*Immobilization*

The polymer-coated TSM crystals were washed thoroughly with distilled water, then treated with 3% GA solution for 2 hr. After washing with phosphate buffer, a steady frequency of GA-treated crystal ($f_1$) was measured in phosphate buffer. Subsequently, the lectin or the urease solution was added into detector cell, and the frequency monitored. When the immobilization completed, the protein-modified crystal was washed with phosphate buffer, and the second steady frequency ($f_2$) was remeasured in phosphate buffer. The values of frequency shift corresponding to immobilized lectin and urease ($f_2$-$f_1$) were obtained (Table 1).

## RESULTS AND DISCUSSION

*Modified gold-plated TSM crystal with PAn and PmPD*

The frequency response for aniline electropolymerization recorded concurrently with the CV sweep is shown in Fig. 1. During CV scanning, the resonant frequency decreases, which means the PAn film is depositing on the surface of gold-plated TSM crystal. When a

solution containing 1.2*M* sulfuric acid and 0.1*M* aniline was chosen as the polymerizing medium, an excellent cohesive film was obtained on the TSM device. In order to obtain new functional polymer coating, the property of electropolymerized *m*-phenylenediamine coating on gold matrix was investigated. The cyclic voltammograms observed during *m*-phenylenediamine electrolysis reaction in various acidity polymerizing solutions are shown in Fig. 2. It can be seen that the shape of the CV profiles is affected by the change of the medium acidity, and at high potential oxidizing polymerization can occur. The results monitored by the TSM device show that the rate of PmPD depositing on gold matrix is slow during *m*-phenylenediamine electrolysis at constant potential (Fig. 3). However, when the PAn-coated TSM device was used as working electrode, and the electrolysis was carried out in solution containing 1.2*M* sulfuric acid and 0.1*M* *m*-phenylenediamine, a cohesive dark film was easy to obtain on the PAn matrix. As can be seen in Fig. 3, the depositing rate of PmPD is larger on PAn matrix than on gold matrix. Perhaps, it can be attributed to the electrocatalysis property of PAn and the much higher surface area provided by the PAn. With PmPD depositing, the rate of frequency change gradually decreases, which suggests electroinactivation and low conductivity of PmPD film. From the results of CV scanning, it was also found that the electrochemical response of PAn was different in the medium with and without *m*-phenylenediamine, new current peaks show that electrochemical reaction occurred on the PAn matrix (Fig. 4).

On the basis of the electrical equivalent circuit model, it has been demonstrated that the changes of resistance ($R$), inductance ($L$), and capacitance ($C$) components correspond to those of viscosity, mass, and elasticity of the film on the TSM device.[20] Usually, determination of these parameters, especially conductance $G$ ($G = 1/R$), provides useful information about chemical and/or physical properties of the film on the TSM device. While the polymer films are depositing on the surface of the TSM crystal, the $f_{G_{max}}$ decreases, but a very small change is observed in $G_{max}$, which suggests the electropolymerized films are not viscous (if the film were acting as a viscous medium, the $G_{max}$ would decrease[21]) (Fig. 5). It is well known that the width of the half-height of the conductance maximum of the TSM crystal should broaden if the viscoelastic properties of the film affect the resonant frequency. From the conductance spectra of TSM crystal in solution, no detectable difference was found between the bare

crystal and the polymer-coated crystal. Therefore, those electropolymerized films behaved as a rigid layer under the experimental conditions.

*Comparison of immobilizing capacity*

Owing to the presence of amine groups in the PmPD structure, the polymer-coated piezoelectric crystal can be remodified with GA, and this reaction usually finished within 2 hr at 15°C. To obtain the value of frequency shift corresponding to immobilized protein, the steady frequency of TSM device was measured in the same medium before and after the protein immobilization. The values of frequency shift ($f_2$-$f_1$) are given in Table 1.

It can be seen that the crystal modified with electropolymerized film provided better reproducible results than organic film for the protein immobilization. Compared with single PmPD film or $\gamma$-APTES coating, the bilayer polymer (PAn and PmPD) film dramatically enhanced the amount of immobilized protein. It is known that the electropolymerized aniline usually forms a fibril structure film, in which some enzymes were entrapped,[22] so it can be deduced that the PmPD film deposited on PAn matrix posesses a larger surface area, and provides a rich active site for immobilizing protein. During the growth of film, it was found that the initial depositing rate of the PmPD did not change further if the frequency response to the PAn coating was more than 300 Hz. The immobilizing protein results show that it is not necessary for the PmPD coating to be very thick. Considering the immobilizing capacity and the stability of coating, the thickness of bilayer polymer coating was optimized as: the frequency responses to PAn coating and PmPD coating were controlled about 200 and 250 Hz, respectively. Assuming film density of 1.2 g/cm$^3$,[23] the thickness of bilayer polymer coating was about 11 nm.

In order to test the stability of modification layer, the unreacted aidehyde groups were blocked with 0.1$M$ glycine in phosphate buffer (pH 7, 0.2$M$). Subsequently, the lectin-modified TSM crystal was immersed in phosphate buffer, and the frequency was monitored. The experimental results showed that only at initial time (about 10 min) the frequency of crystal slightly increased (perhaps resulting from the removal of the nonspecifical adsorption), then became steady. The frequency variation of bilayer-polymer-coated TSM device with immobilized lectin was $\pm$4 Hz for observation intervals of 1 h.

Since it was observed that the value of $G_{max}$ decreased when the lectin was immoblized on the surface of TSM device (Fig. 6), the immobilized lectin layer behaved viscoelastically, and the mass of immobilized lectin could not be calculated by Sauerbrey equation. In order to estimate the amount of immobilized lectin on the bilayer polymer-coated TSM device, the experimental relationship between frequency shift and mass of added lectin was obtained as follows: first, the steady frequency ($F_1$) of polymer-coated TSM device (air-dried) was measured. Then, each time 2 $\mu$l of lectin solution (1 mg lectin in 2 ml distilled water) was placed on the surface of polymer layer, and air-dried. Finally, the second steady frequency ($F_2$) was remeasured. The relationship between $F_2$-$F_1$ and the mass of added lectin is shown in Fig. 7.

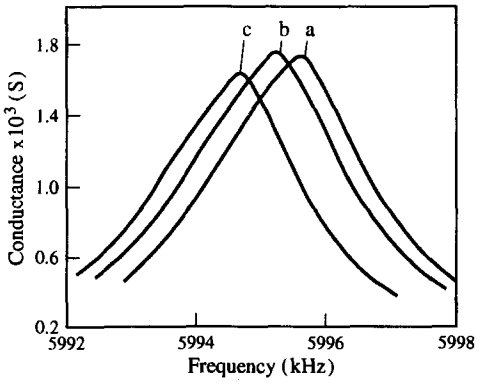

Fig. 6. Conductance spectra of the TSM oscillator in phosphate buffer observed in the course of immobilizing lectin. (a) Polymer-coated TSM crystal; (b) GA-treated TSM crystal; (c) TSM crystal with immobilized lectin.

The frequency response to immobilized lectin was also obtained by a similar method. After the GA-treated crystal was washed with water and air-dried, a steady frequency ($F_1$) was measured. Subsequently, the GA-treated crystal was immersed in the lectin solution. When the immobilization completed (about 3 hr at 15°C), the lectin-modified TSM crystal was washed with water and air-dried. Finally, the second steady frequency ($F_2$) was remeasured. The value of $F_2$-$F_1$ was $-112$ Hz (average of six experiments). According to Fig. 7, the mass of immobilized lectin was estimated about 1.8 $\mu$g/cm$^2$.

*Application of lectin-modified TSM device*

Lectins are very useful for the study of cell-initiated differentiation of cells and the topography of cell surface constituents[24] and, in order to demonstrate the possible utility of this lectin-modified TSM sensor in clinical applications, we have investigated its frequency response to the human erythrocytes. Upon addition of erythrocyte suspension, the frequency of TSM device decreases, which means that erythrocytes combinate to the lectin-coated TSM crystal, and the immobilized lectin is active (Fig. 8). The detection limit is about $10^5$ cells/ml. The experimental result showed that the adsorbed erythrocytes can be removed by 0.2*M* glycine HCl (pH 2.2), and the lectin-modified TSM sensor was reused five times with 8% decreased signal. It was found that over a incubation temperature range from 10° to 35°C, the affinity between the immobilized lectin and the erythrocyte was affected by the temperature. The frequency response to the adsorption of erythrocytes was greater at a higher incubation temperature. But the experimental result also shows that the reusability of this sensor readily dropped off when the temperature was over 35°C. Further studies about the frequency response of lectin-modified TSM sensor are being pursued.

## CONCLUSIONS

The results described above demonstrate that on the basis of electropolymerized *m*-phenylenediamine coating, lectin and urease can be immobilized on the surface of TSM quartz crystal with glutaraldehyde. Since the regeneration of piezoelectric crystal is easy, the TSM biosensor based on this modification technique becomes economically feasible, it may open up the way to immobilize biological species effectively on the TSM crystal.

# APPLICATION OF PATTERN RECOGNITION AND PIEZOELECTRIC SENSOR ARRAY FOR THE DETECTION OF ORGANIC COMPOUNDS

GYÖRGY BARKÓ, BALÁZS PAPP and JÓZSEF HLAVAY*

University of Veszprém, Department of Analytical Chemistry 8201, Veszprém, P.O. Box 158, Hungary

(*Received* 20 *January* 1994. *Revised* 26 *August* 1994. *Accepted* 16 *September* 1994)

**Summary**—Organic vapours were measured by an array of piezoelectric crystal detectors. Quartz crystals were coated by different GC stationary phases. Four coated crystals were placed in an array and pattern recognition was used for identification of the compounds including acetone, benzene, chloroform and pentane. A computer program was developed for the measurement of the frequency changes and data processing. Pattern recognition method using feature extraction was applied for identification of analytes.

The determination of organic compounds can mostly be accomplished by gas chromatography (GC), however, some other chemical sensors have also been used.[1] These sensors could be applied for the monitoring of the organic vapours at trace concentration. Two kinds of chemical sensors have mostly been applied: the metal-oxide semiconductor gas sensors,[2] and the piezoelectric quartz crystal sensors. The quartz crystal might be used as surface acoustic wave (SAW)[3] or as piezoelectric quartz crystal microbalance (PQM).[4] The frequency of the SAW sensor ranges from 30 to 200 MHz, while that of the PQM lies from 8 to 15 MHz.

Owing to the Sauerbrey equation the change of frequency of a quartz crystal is proportional to the change of the mass deposited on the surface of crystals.[5]

$$\Delta F = -2.3 * 10^6 * F^2 * \frac{\Delta M}{A}, \qquad (1)$$

where $\Delta F$ is the change in frequency (Hz), $F$ is the basis frequency of the quartz crystal (MHz), $\Delta M$ is the change in mass (g), $A$ is the area coated ($cm^2$). In the development of the piezoelectric chemical sensors, the first work of King[6] included the investigation of some liquid-coated crystals that can be operated by partition of the analyte between the gas and liquid phases. From equation (1), King estimated a detection limit of $10^{-9}$ g.[7] Guilbault and Tomita[8] developed a piezoelectric device sensitive for the organophosphorus compounds and pesticides. They found a mixture of 3-PAD, Triton X-100 and sodium hydroxide that had excellent selectivity and fast response. Karmarkar and Guilbault[9] used iridium(I) complex as a coating material for aromatic hydrocarbons in air. Hahn and co-workers[10] developed a crystal detector for the determination of the acetoin in air. The quartz crystal was coated with semicarbazide. Ho[11] developed a portable device with the piezoelectric crystal coated by Carbowax-550. This sensor was used for the monitoring of the toluene in ambient air. Edmonds and West[12] built a detector for the determination of the hydrocarbons using Pluronic 64 GC stationary phase as coating material. Two crystals were applied: a coated crystal for measurements and an uncoated reference one. It was found that the coating substance has given poor selectivity for hydrocarbons. Coating such as Pluronic L64, Carbowax 20M and squalane, although sensitive, were not particularly selective, and adsorbed many different organic compounds. An array of detectors was suggested providing that the sensitivity of each detector to each analyte was known, and the signal from each detector could be analysed mathematically and the concentration of each component could be estimated, even in multicomponent mixtures. Fraser and co-workers[13] developed a multisensor piezoelectric crystal detector system for the determination of airborne contaminants such as ammonia. Klinkhachorn and co-workers[14] designed a PQM system that was able to detect

*Author to whom correspondence should be addressed.

nanogram level mass changes of sorbed compounds. Five oscillator modules were used to construct an array of four sensors and pattern recognition was applied for the multi-component analysis. Chang[15] has developed an odour sensing system with PQM using a number of different lipid-coated crystals. The identification of odorant has been found to be dependent on the species of lipids. Schmautz[16] used a quartz sensor array with non-selective but different sensitive coating material for the analysis of the anaesthetic gases. The sensor signals were processed with pattern recognition methods. Carey[17] applied pattern recognition methods for selection of stationary phases. A generally useful procedure was proposed, tested, and the best sensitive coating materials were selected. The major problem using PQM sensors is the interference of water vapour. Most of the sensing compounds are also sensitive to moisture, so it has to be removed from the air without the reduction of the analyte vapours. Among many different solutions, one effective method is the application of the Nafion tubing with a 13X molecular sieve as drying agent packed on the outside of the membrane in a closed container.[20] Others include the use of chromatographic column filled with silica gel or molecular sieves, this has to be set into the sample introduction line.[4,8]

In our work a sensor array has been developed for detection of the organic vapours. It consists of four quartz crystals coated by GC stationary phases. Pattern recognition method using feature extraction has been applied for identification of the analyte. Model experiments were carried out to find the optimal conditions for the analysis of organic contaminants in different workshops.

## EXPERIMENTAL

Analytical grade benzene, *n*-pentane, acetone, chloroform, cyclohexane, toluene and methanol (Reanal, Hungary) were used. Nine MHz AT-cut quartz crystals, resonating in thickness-shear mode, were used. Silver electrodes were deposited to the both sides of the crystals. The crystals were manufactured by Gamma Co., Hungary. Stationary phases of OV1 and OV275 (Supelco), ASI50 (Applied Science Laboratories Inc.), and the polyphenilether (Carlo Erba) were used. The oscillator and data handling system was home-built. The sensor array consisted of four crystals (Fig. 1). The four crystals were coated with stationary phases and the coated area was 0.2 $cm^2$. The thin film of the coating was formed by solvent evaporation. The mass of the coating caused a frequency shift of about 8 kHz. The crystals were placed in a dry nitrogen stream for about 2 hr and then were built into the sensor array. Coatings were purged with dry nitrogen until the resonant frequency of the crystals reached a steady state. Organic vapours of standard compounds were injected into the nitrogen carrier gas. The nitrogen (T 45, supplied by Messer Griesheim, Hungary) contained only 30 ppm water vapour and was dried with $CaCl_2$ to remove the traces of water. The flow rate was measured by rotameter and kept at 20 l./hr (Fig. 2). Thermostatted sample holders were applied and the concentrations of the organic compounds were calculated using the ideal gas law. The vapours of the compounds were injected by a syringe into the flow of the carrier gas and the analytes reached the four crystals simultaneously in the detector. The decrease of the frequency proportional to the change in weight was recorded (equation 1). Frequencies of the crystals were measured with a four channel frequency counter, and compared to the clock of a computer as reference frequency. A computer program was developed for the measurement of the change in frequency and for the application of the pattern recognition method. The pattern recognition uses feature extraction and the K-nearest neighbour method for the processing of the saved frequency files.[18] An IBM AT386 DX2 computer with math coprocessor was used and an AX5216 counter/timer board (AXIOM) was used for the frequency measurement.

## RESULTS AND DISCUSSION

The responses of four quartz crystals coated by different GC stationary phases were investigated as an organic vapour sensor. A characteristic response was given by each sensor placed in the array. Seven different organic vapours were measured. The changes of raw frequency values of a quartz crystal coated by OV1 for 25 $\mu$mol organic compounds as a function of time are listed in Table 1. Adsorption and, consequently desorption, took place in only some hundreds of msec. As can be seen from the data, the recovery rate was the same for all volatile compounds. The reversibility, selectivity and sensitivity of the piezoelectric sensors to vapours rely on the

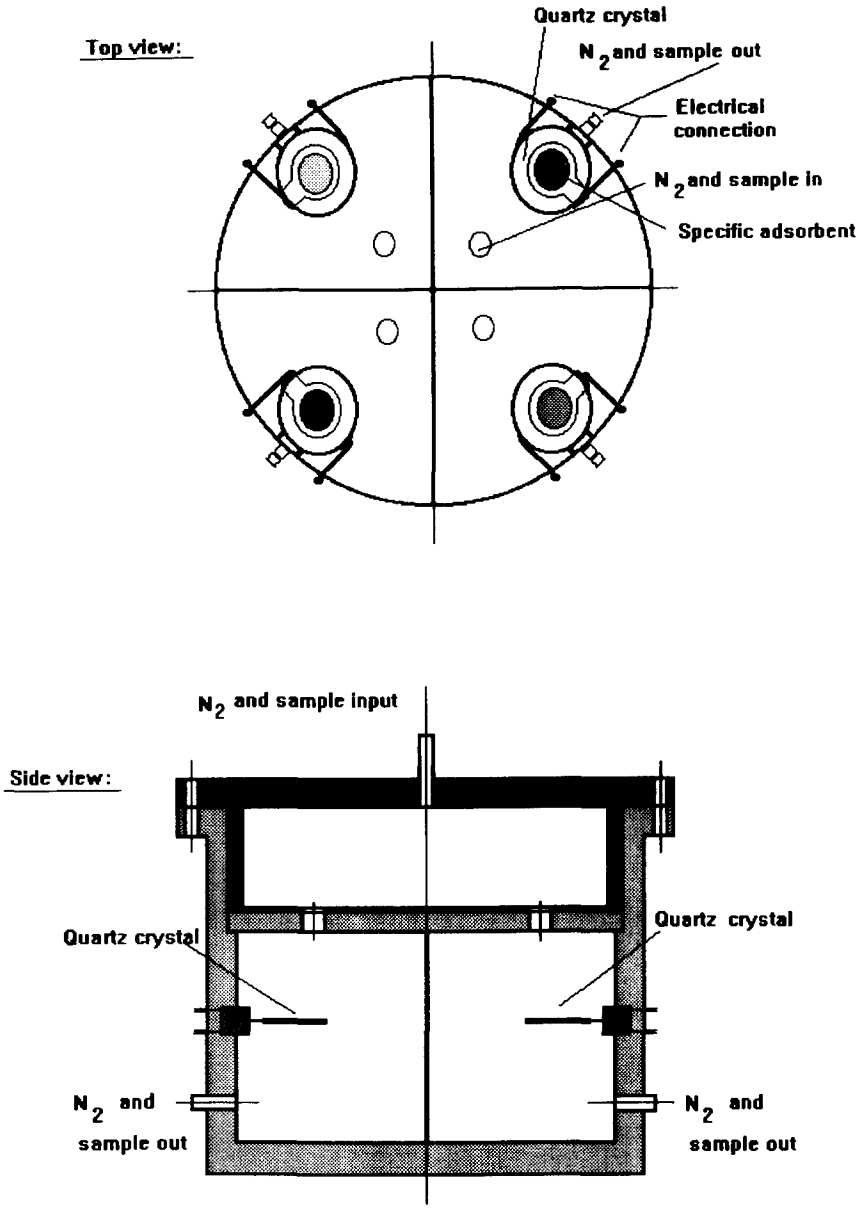

Fig. 1. Piezoelectric sensor array.

coating materials. The recorded frequency change was equilibrium response, and it depends greatly on the flow rate of gas mixture. However, the flow rate was kept constant (20 l./hr) for the reproducible responses. The maximum frequency change of the quartz sensors is listed in Table 2.

The GC stationary phases show different sensitivity to organic vapours. From the results four compounds were chosen for the characterization of the group of the organic materials. Benzene was applied as a representative compound of the aromatic hydrocarbons, acetone for ketones, *n*-pentane for the hydrocarbon groups, and chloroform for the chlorinated hydrocarbons. The frequencies of the compounds have been drawn as a bar chart[19] (Fig. 3). These values were used for the preparation of the data matrices. The frequency was converted to pattern with feature extraction. The feature extraction method consists of signal processing. The PQM sensor signal can be processed by extraction of the most distinctive feature parts of the signal. The lowest and highest frequencies of four crystals were converted into the feature space (see Table 1). Not only the highest frequency change, but also the lowest one contains valuable information concerning the reaction between the coating materials and analytes.

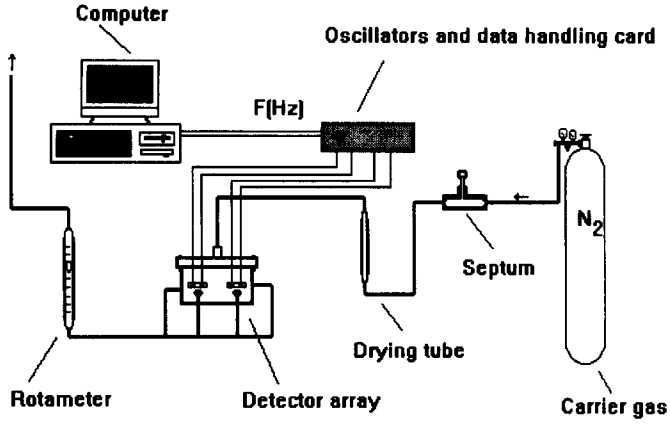

Fig. 2. The experimental set-up.

The feature space presents data files in the computer's memory. In the present case it consists of eight frequency values (two for each sensor). For classification of vapours the signals of the sensor array were transformed into a concentration independent plane. Linear transformation was applied for normalization of the signal. The process is shown by equations 2 and 3.

where $X^+$ is the position of the cluster at the highest value in rows (1 . . . 32); $Y^+$ the position of the cluster at the highest value in columns (1 . . . 4) (OV1 = 1, ASI50 = 2, OV275 = 3 and PPh-ether = 4, see Fig. 4); $\Delta F^+_{\text{OV1}}$ the highest value of the measured frequency on crystal coated by OV1; $\Delta F^+_{\text{ASI50}}$ the highest value of the measured frequency on crystal coated by ASI50;

$$X^+ = \text{INT}\left(\frac{\Delta F^+_{\text{OV1}}}{\Delta F^+_{\text{OV1}} + \Delta F^+_{\text{ASI50}} + \Delta F^+_{\text{OV275}} + \Delta F^+_{\text{PPh-ether}}} \cdot R\right) \tag{2}$$

$$Y^+ = 1,$$

| 7 Chloroform | 150 | 120 | 178 | 450 |

$\Delta F^{+}_{OV275}$ the highest value of the measured frequency on crystal coated by OV275; $\Delta F^{+}_{PPh\text{-}ether}$ the highest value of the measured frequency on crystal coated by PPh-ether, $R$ the resolution of the feature extraction ($R = 32$) and

$$X^{-} = \mathrm{INT}\left(\frac{\Delta F^{-}_{OV1}}{\Delta F^{-}_{OV1} + \Delta F^{-}_{ASI50} + \Delta F^{-}_{OV275} + \Delta F^{-}_{PPh\text{-}ether}} \cdot R\right) \qquad (3)$$

$$Y^{-} = 1,$$

where, $X^{-}$ is the position of the cluster at the lowest value in rows (1 . . . 32); $Y^{-}$ the position of the cluster at the lowest value in columns (1 . . . 4) (OV1 = 1, ASI50 = 2, OV275 = 3 and PPh-ether = 4, see Fig. 4); $\Delta F^{-}_{OV1}$ the lowest value of the measured frequency on crystal coated by OV1; $\Delta F^{-}_{ASI50}$ the lowest value of the measured frequency on crystal coated by ASI50; $\Delta F^{-}_{OV275}$ the lowest value of the measured frequency on crystal coated by OV275; $\Delta F^{-}_{PPh\text{-}ether}$ the lowest value of the measured frequency on crystal coated by PPh-ether and $R$ the resolution of the feature extraction ($R = 32$). It can be seen that each transformed response is calculated as the ratio of the summary of the four sensor replies. The patterns of the benzene are shown in Fig. 4.

This method could eliminate the effects of absolute amounts of vapours on pattern recognition. The patterns were stored as binary data set. The data set gives a value of 1 when a cluster has been found in the column of a sensor. In any other case the values are 0. The size of the saved pattern file was about 10% of the file of frequencies recorded. The number of columns of the data set was equal to the number of the sensors (Fig. 4). The number of rows of the data set was proportional to the resolution of the feature extraction. With an increasing resolution the calculation time of pattern recognition should considerably be increased. However, large differences in the frequency changes are not necessary for the distinction of the patterns.[16] The repeatability of the patterns has been found to be the most important criteria of the appropriate recognition.

The pattern recognition approach can be seen in Fig. 5a and b. At first, the computer program was taught. Sample of organic vapours was injected and the changes in the frequencies of

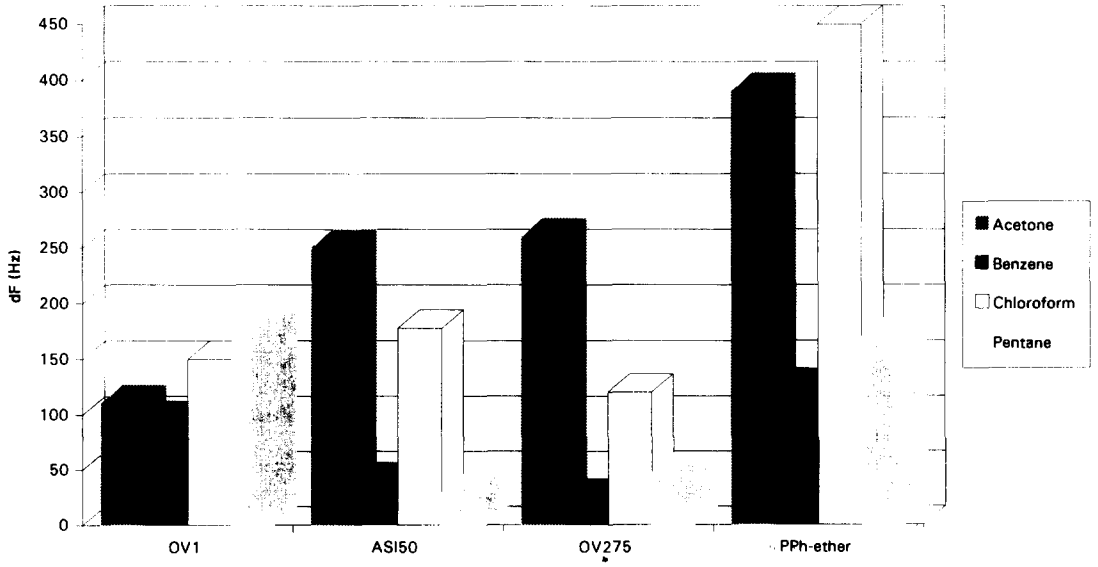

Fig. 3. Frequency changes of piezoelectric quartz crystals for organic vapours coated by different GC stationary phases.

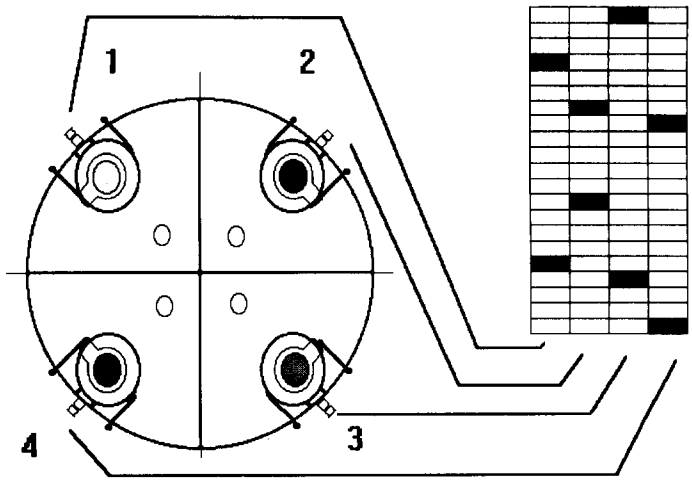

Fig. 4. The piezoelectric sensor array and the pattern for benzene.

the crystals were measured, converted to patterns and saved in the memory (Fig. 5a). After the teaching process, the unknown organic vapour was measured. The pattern of unknown compound was compared with the learned patterns. The two binary data sets were processed by the K-nearest neighbour method. The unknown sample set was grouped to its nearest neighbour learning point. During the learning process the data base of organic compounds can be formed by the given sample set. The maximum score was saved to the matched pattern and the unknown organic compound was identified (Fig. 5b).

The partition of a solute vapour between the surrounding gas phase and the coating material is represented by the adsorption of organic vapour into the sensitive layer.[17] The solubility coefficient, $K$, is a parameter to compare different coating materials referred to the sensitivity of test vapours:

$$\Delta F = k * V_c * C_c = \frac{\Delta F_c}{\rho_c} * C_g * K \tag{4}$$

$$K = \frac{\Delta F * \rho_c}{C_g * \Delta F_c}, \tag{5}$$

where $\Delta F$ is the change in frequency (Hz); $\Delta F_c$ the frequency shift of the coating (Hz); $\rho_c$ the

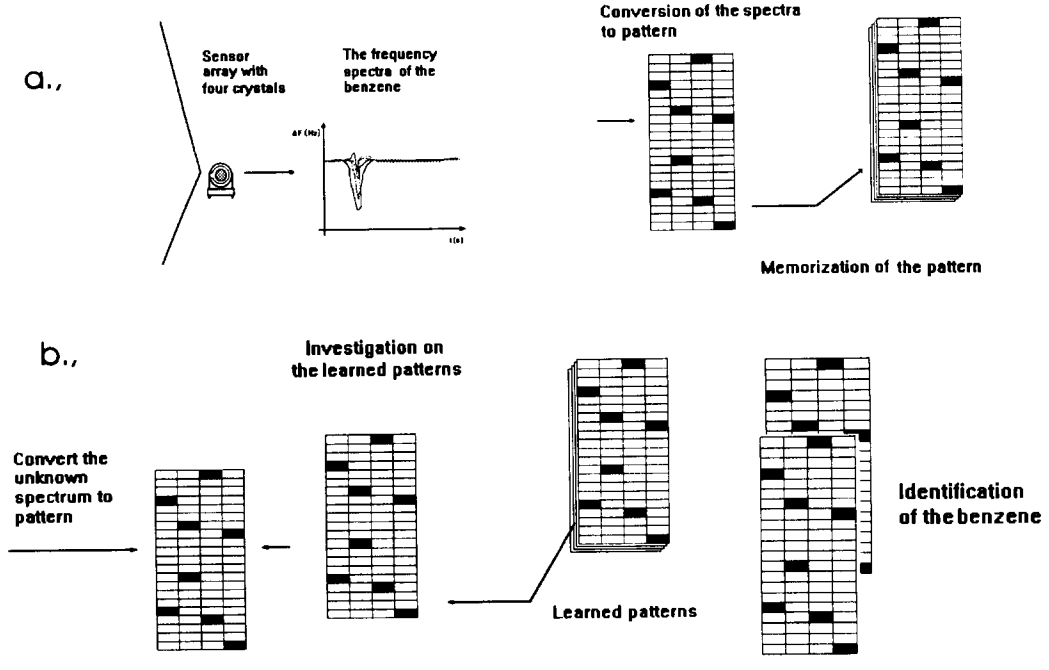

Fig. 5. The process of pattern recognition for identification of benzene.

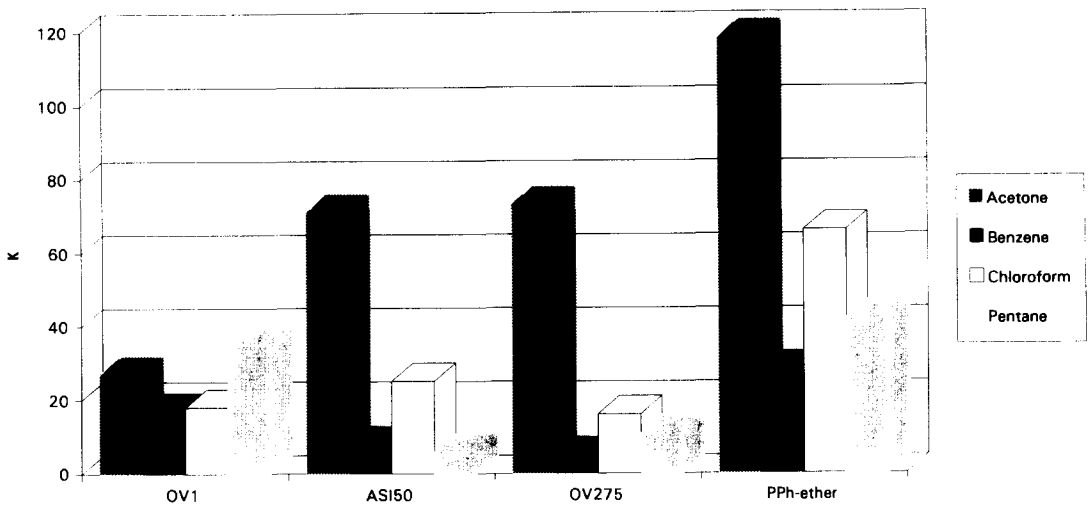

Fig. 6. Solubility coefficients calculated for different GC stationary phases.

density of the coating (g/cm$^3$); $C_c$ the vapour concentration in the coating (g/cm$^3$); $C_g$ the vapour concentration in the gas phase (g/cm$^3$); $k$ is a constant and $V_c$ the gas volume in the coating (cm$^3$). The values of $C_g$ were calculated by the ideal gas law.

The solubility coefficients of the coating materials were compared and the results are shown in Fig. 6. Comparing the values of the $dF$ and $K$ (Figs 3 and 6), it can be seen that only the PPh-ether shows a different pattern. This coating proved to be the most sensitive material for the organic vapours. The ASI50 and the OV275 gave poor sensitivity to the aromatic compounds and the hydrocarbons, but they were found to be sensitive coatings for acetone. The OV1 is generally used in GC for the separation of compounds having different polarity. Therefore, the analytes can appropriately be differentiated by the $K$ values on the four coatings for the pattern recognition.

## CONCLUSIONS

The array of piezoelectric quartz crystals coated with gas chromatographic stationary phases may be a suitable sensor for identifying selected compounds of organic vapours. A computer program was developed for the measurement of the frequency changes and data processing. The array of the chemical sensor consisted of four coated quartz crystals and the model system can be used for detection of different vapours. On the basis of the results of model experiments the identification of several pollutants may be carried out and characterization of a polluted environment may be performed. The application of the chemical sensor developed needs the removal of moisture content of the sample. The sensing elements are usually sensitive to water vapours. The effect of this interference can be overcome by incorporating a drying unit set into the analysis line. Further improvements can be expected by using further crystals coated with different GC stationary phases and applying calibration curves for the determination of the amount of the compounds in air.

# A NOVEL OXYGEN AND/OR CARBON DIOXIDE-SENSITIVE OPTICAL TRANSDUCER

MING FAT CHOI* and PETER HAWKINS

Faculty of Applied Sciences, University of the West of England, Coldharbour Lane, Frenchay, Bristol BS16 1QY, U.K.

(*Received* 2 *September* 1994. *Accepted* 12 *September* 1994)

**Summary**—A novel oxygen ($O_2$) and/or carbon dioxide ($CO_2$)-sensitive transducer for the measurement of both gaseous $O_2$ and $CO_2$ over the concentration ranges of $O_2$, 0–100% and $CO_2$, 0–10% has been described employing a solution of 10.6 $\mu M$ fluorescein (FL) and 190 $\mu M$ potassium hydroxide in a solvent mixtures of 1:1 (v/v) *N,N'*-diethylaniline (DEA) and *N,N*-dimethylformamide. Increasing $O_2$ concentrations cause the absorbance of the solution at a wavelength of 400 nm to increase owing to a contact charge transfer reaction existing between $O_2$ and DEA molecules, and increasing $CO_2$ concentrations produce a non-linear fall in absorbance at 520 nm as the colour of FL changes from its orange dianion form to the colourless neutral, lactonic form. Both processes are independent of each other and reversible. The response to changes in $O_2$ concentrations is in good agreement with Beer–Lambert's law and the response to changes in $CO_2$ concentrations in non-linear. A fibre optic sensing system based on this solvent–dye solution has been set up for continuous and reversible determination of both gaseous $O_2$ and $CO_2$. Possible applications include environmental and physiological monitoring of $O_2$ over the ranges of 0–100% and $CO_2$, 0–10%.

Oxygen ($O_2$) can be considered to be one of the most important elements in our nature with an enormous chemical and biochemical reactions involving $O_2$ as reactants or products. Carbon dioxide ($CO_2$) is usually a by-product of many industrial processes and it is believed to aggravate the greenhouse effect of our environment. Medical diagnosis and treatment of critically ill patients in intensive care units and operating theatres often requires monitoring of $CO_2$ and $O_2$ partial pressures of arterial blood. Consequently, the determination of both $O_2$ and $CO_2$ is of considerable importance in environmental, biomedical analysis and analytical chemistry. Considerable effort has been devoted over many years to the development of new techniques for the measurement of $O_2$ and $CO_2$ concentrations. Amperometrical determination of $O_2$ by a Clark-type electrode[1] has been commonly used in the past which suffers from the drawback of $O_2$ consumption. The detection of $CO_2$ is usually based on an infrared detector[2,3] and a Severinghaus electrode[4] with bulky and expensive devices being used. With the advent of fibre optics technology, there is a growing interest in the development of fibre optics $O_2$ and/or $CO_2$ sensors. The attractive features of fibre optics sensors include: immunity to electrical interference; ease of miniaturization; comparatively inexpensive device; remote and *in situ* sensing; and high information carrying capacity (multiwavelength transmission), etc. There have been many publications on single optical fibre $O_2$ sensors[5–8] based on the fluorescent quenching of a dye by molecular $O_2$ and $CO_2$ sensors[9–14] based on the pH modulation accomplishing with the colour change of a dye. Several electrochemical multi-sensors have also been reported for the simultaneously detection of both $O_2$ and $CO_2$. Albery and Barron[15] applied the electroreduction technique for the amperometric determination of $O_2$ and $CO_2$ in which two electrolytes and two applied potentials were used. Arquint *et al.*[16] and Gumbrecht *et al.*[17] employed amperometric and potentiometric techniques for the detection of pH, $pO_2$ and $pCO_2$. Individual pH, $pCO_2$ and $pO_2$ sensors were fabricated and positioned on a miniaturized microchip. Recently, there have been a few combined fibre optic $O_2$ and $CO_2$ sensors described in the literature. Gehrich *et al.*[18] and Miller *et al.*[19] arranged three individual pH, $pCO_2$ and $pO_2$-sensitive optical fibres together in a catheter. Similarly, oxygen-sensitive material

*Author to whom correspondence should be addressed.

and $CO_2$-sensitive material were entrapped in separate gas-permeable membranes and attached to the distal end of a bifurcated optical fibre for sensing gaseous $O_2$ and $CO_2$.[20] In all the above instances, individual sensitive-material was often used for each gas. To the best of our knowledge, not a single sensing medium for both $O_2$ and $CO_2$ have been reported to date.

It has been known that some organic solvents exhibit contact charge transfer absorption (CCTA) bands when in contact with $O_2$.[21] Tsubomura and Mulliken[22] explained that this is caused by the formation of CCT pairs between the organic solvents and molecular $O_2$. The CCTA bands lie in longer wavelength regions if the solvents have lower ionization potentials, like some amine compounds, and usually appear as extensions to the long wavelength edge of the absorption spectra of the deoxygenated solvents. The CCTA intensity of the organic solvents is also related to the partial pressure of $O_2$ in the gas mixtures above the solvents and the reaction between the solvents and $O_2$ is reversible.[23]

Fluorescein (FL) dye immobilized in poly(ethylene glycol) has been successfully applied for fibre optic sensing of $CO_2$.[24] With the combination of organic solvent and dye, a single transducer can possibly be employed for the determination of both $O_2$ and $CO_2$. In this paper, we apply this approach and report here a single $O_2/CO_2$-sensitive transducer in which both gaseous $O_2$ and $CO_2$ can be detected independently based on the CCTA of *N,N'*-diethylaniline (DEA) with $O_2$ and the colour change of FL upon exposure to $CO_2$.

## EXPERIMENTAL

### *Chemicals and reagents*

DEA (>99%), *N,N*-dimethylformamide (DMF > 99.9%, HPLC grade), *n*-heptane (99%, spectrophotometric grade), methanol (>99.9%, HPLC grade) and FL dye (98%) were purchased from Aldrich Chemical Co. Ltd, U.K. Potassium hydroxide (KOH, AnalaR grade) was obtained from BDH Chemical Ltd, U.K. Solutions of 10.6 $\mu M$ FL and 190 $\mu M$ KOH in DMF, and 10.6 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture were prepared by adding 20 $\mu$l of a concentrated methanolic KOH solution (KOH concentration was determined by standard acid–base titration[25]) and 70 $\mu$l of a concentrated FL in DMF solution (concentration of FL solution was determined spectrophotometrically by employing the molar absorptivity of $FL^{2-}$ dianion[26]) into DMF and 1:1 (v/v) DEA/DMF solvent mixture, respectively. Similarly, a solution of 0.10 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture was prepared for fluorescence studies. All reagents were used as received. Nitrogen gas ($N_2$), $O_2$ gas, 10% (v/v) $CO_2$ in $N_2$ gas mixture and $CO_2$ gas were supplied by Distillers MG, U.K.

### *The gas mixing system*

Different $O_2$ (in the range of 0–100%) or $CO_2$ concentrations (in the range of 0–10%) in a gas stream were produced by controlling the flow rates of either $O_2$ gas or 10% $CO_2$ in $N_2$ gas mixture and the diluent $N_2$ gas entering a mixing chamber. The gas mixture was passed through a portable $O_2$ meter (Oxywarn 100I from Draeger Manufacturing, U.K.) or $CO_2$ detector (LFG 10 Landfill Gas Analyser from Analytical Development Company Ltd, U.K.) where the $O_2$ or $CO_2$ concentrations in the gas mixture were determined before bubbling through the investigating solvent or solvent–dye solution contained in a 1 cm path-length quartz cuvette.

### *Instrumentation*

The CCTA spectra were measured on a Perkin-Elmer Lambda 15 Spectrophotometer, fluorescence excitation (EX) and emission (EM) spectra were recorded on a Perkin-Elmer LS-5 Luminescence Spectrometer.

In the fibre optic detecting system of $O_2$ and $CO_2$, a home-made optical arrangement was set up. A modulated beam of light with known wavelength was produced by a 100 W quartz halogen lamp (Bentham Instruments Ltd, U.K.) stabilized by a Bentham 505 current stabilized filament lamp power supply, a Bentham 218 optical chopper at a frequency of 141 Hz and a Bentham M300 monochromator controlled by a Bentham SMD3B stepping motor drive unit before being launched into a plastic optical fibre (1 m long and 2 mm diameter from RS Components, U.K.). The transmitted light from the fibre irradiated the front surface of a 1 cm quartz cuvette containing 1 ml of solvent or solvent–dye solution with gaseous $O_2$ or $CO_2$ standards at a flow rate of about 50 $cm^3$/min continuously passing through it. A second plastic optical fibre (0.5 m long, 2 mm diameter) was positioned on the back surface of the cuvette to collect the transmitted light. The other end of this fibre led directly onto the front surface of a

100 $mm^2$ silicon photovoltaic detector (RS Components, U.K.) and the output signal was amplified by a Bentham 277 current pre-amplifier and a Bentham 223 lock-in amplifier which was synchronized to the modulated light beam by a reference signal provided by the light chopper. The amplified signal was recorded on a Linses 1S chart recorder (Electroplan, U.K.) and displayed on a LED display (Bentham 217 digital unit). To avoid a slight drift caused by a small evaporation of the solvent, the solvent–dye solution was replaced with a fresh one at approximately 2 hr intervals.

## RESULTS AND DISCUSSION

### *Development of $O_2/CO_2$-sensitive transducer*

*N,N'*-Diethylaniline has a strong broad CCTA band lying in the ultraviolet/visible regions and there is an increase in absorbance as the $O_2$ concentration increases (Fig. 1). The CCTA band disappears when the dissolved $O_2$ is removed by purging DEA with $N_2$ or $CO_2$. Note that the reference is air-saturated DEA ($[O_2] = 21\%$ approx.) which explains why DEA has negative absorbances when their $O_2$ concentrations are less than the air-saturated value. A graph of absorbance (abs) at 400 nm against applied $[O_2]$ is plotted where abs = absorbance of DEA saturated with a given applied $[O_2]$ – absorbance of DEA saturated with $N_2$. A linear straight line is obtained which agrees with Beer–Lambert's law having absorbance directly proportional to the applied $[O_2]$. Similarly, the CCTA spectra for different mol percentage (%) mixtures of DEA/*n*-heptane mixture were also recorded (Fig. 2). There is an increase in absorbance as the mol% of DEA in DEA/*n*-heptane mixture increases. *n*-Heptane has no CCTA band at the wavelengths investigated. A graph of abs at 400 nm against mol% of DEA in DEA/*n*-heptane mixture is plotted and a linear straight line is found which indicates that the CCTA is directly proportional to the concentration of DEA in DEA/*n*-heptane mixture. The change of absorbance arises from the CCTA of the DEA and $O_2$ complex and the reaction is reversible.

$$\mathrm{DEA} + \mathrm{O_2} \rightleftarrows \mathrm{DEA}\cdots\mathrm{O_2} \overset{h\nu}{\rightleftarrows} (\mathrm{DEA}\cdots\mathrm{O_2})^*.$$

It is possible that DEA can serve as a sensing medium for $O_2$.

It has also been observed that some pH-sensitive dyes change colour upon exposure to gaseous $CO_2$. The presence of water is crucial for response to $CO_2$ which is based on the following equations:

$$\mathrm{CO_2} + \mathrm{H_2O} \rightleftarrows \mathrm{H_2CO_3}$$

$$\mathrm{H_2CO_3} + \mathrm{H_2O} \rightleftarrows \mathrm{HCO_3^-} + \mathrm{H_3O^+}$$

$$\mathrm{HCO_3^-} + \mathrm{H_2O} \rightleftarrows \mathrm{CO_3^{2-}} + \mathrm{H_3O^+}$$

$$\underset{\text{(colour A)}}{\mathrm{DH}} + \mathrm{H_2O} \rightleftarrows \underset{\text{(colour B)}}{\mathrm{D^-}} + \mathrm{H_3O^+},$$

where DH and $D^-$ are the protonated and deprotonated forms of the dye, respectively. The

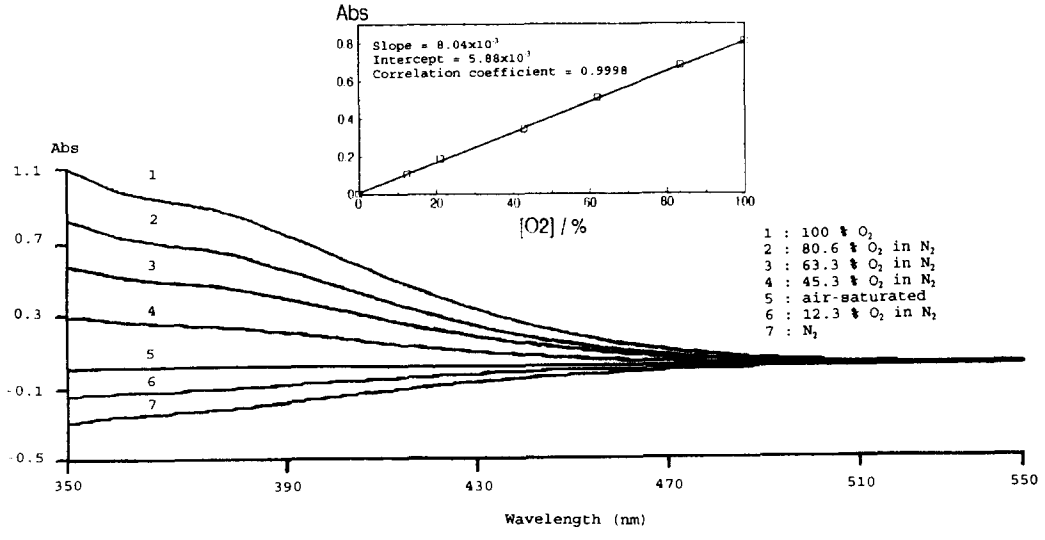

Fig. 1. The effect of different $O_2$ concentration on the CCTA spectrum of DEA. Inset shows the calibration plot of absorbance at 400 nm against $[O_2]$ using the data of the spectra. The optical pathlength is 1 cm and the reference is air-saturated DEA.

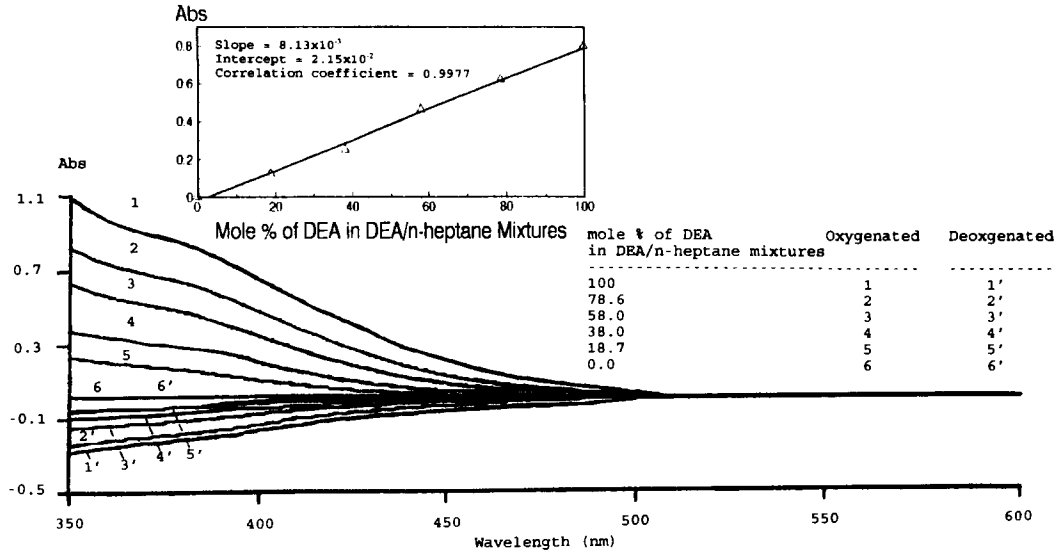

Fig. 2. The CCTA spectra of DEA/*n*-heptane solvent mixtures. Solvent mixtures are in mol%. Inset shows the calibration plot of absorbance at 400 nm against mol% of DEA in DEA/*n*-heptane solvent mixture. The measurement conditions are the same as in Fig. 1.

colour change of the dye is sensitive to pH change of its environment. A solution of 10.6 $\mu M$ FL and 190 $\mu M$ KOH in DMF was tested for its response to $CO_2$ (Fig. 3). It is assumed that FL exists only as $FL^{2-}$ ions in this highly alkaline solvent. Neutral form of FL can occur in three different tautomers, i.e. zwitterion, quinoid and lactone. However, it has been reported that colourless lactonic form is usually the dominant tautomer present in organic solvents.[27] The change of absorbance arises from the conversion of the orange dianion form of FL to the colourless, neutral lactonic form upon exposure to $CO_2$. These changes were brought about from the change of the pH of the solution with the dissolution of $CO_2$ in DMF and can be envisaged in the following reactions:

$$CO_2 + OH^- \rightleftarrows HCO_3^- \quad (1)$$

$$H^+ + OH^- \rightleftarrows H_2O \quad (2)$$

$$2H^+ + FL^{2-} \rightleftarrows H_2FL. \quad (3)$$

Dissolved $CO_2$ removed the $OH^-$ ions in DMF: as a result, the $H^+$ ion concentration is increased which shifts the equilibrium of equation (3) from left to right. A plot of abs at 520 nm against $[CO_2]$ is shown in Fig. 3 and increasing $[CO_2]$ cause a non-linear fall in

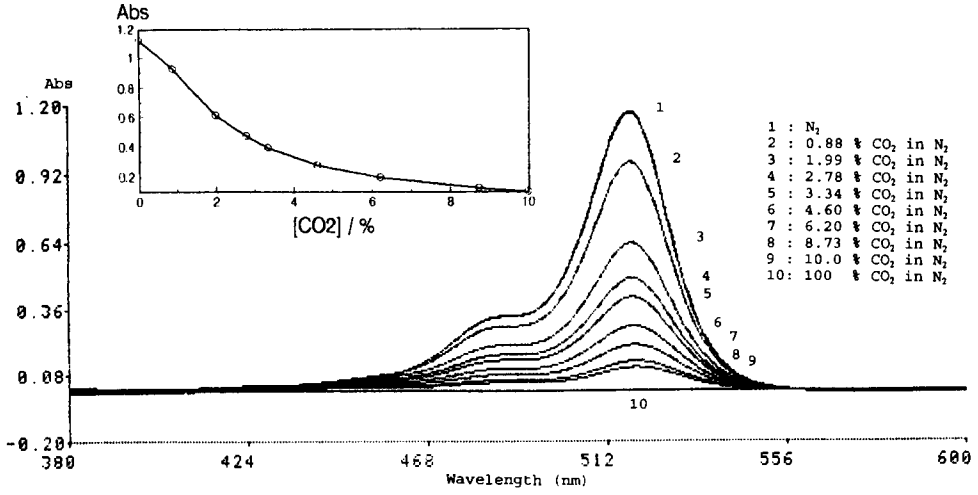

Fig. 3. The effect of different $CO_2$ concentration on the absorption spectrum of a solution of 10.6 $\mu M$ FL and 190 $\mu M$ KOH in DMF. Inset shows the plot of abs against $[CO_2]$ using the data of the spectra. The optical pathlength is 1 cm and the reference is a solution of air-saturated 190 $\mu M$ KOH in DMF.

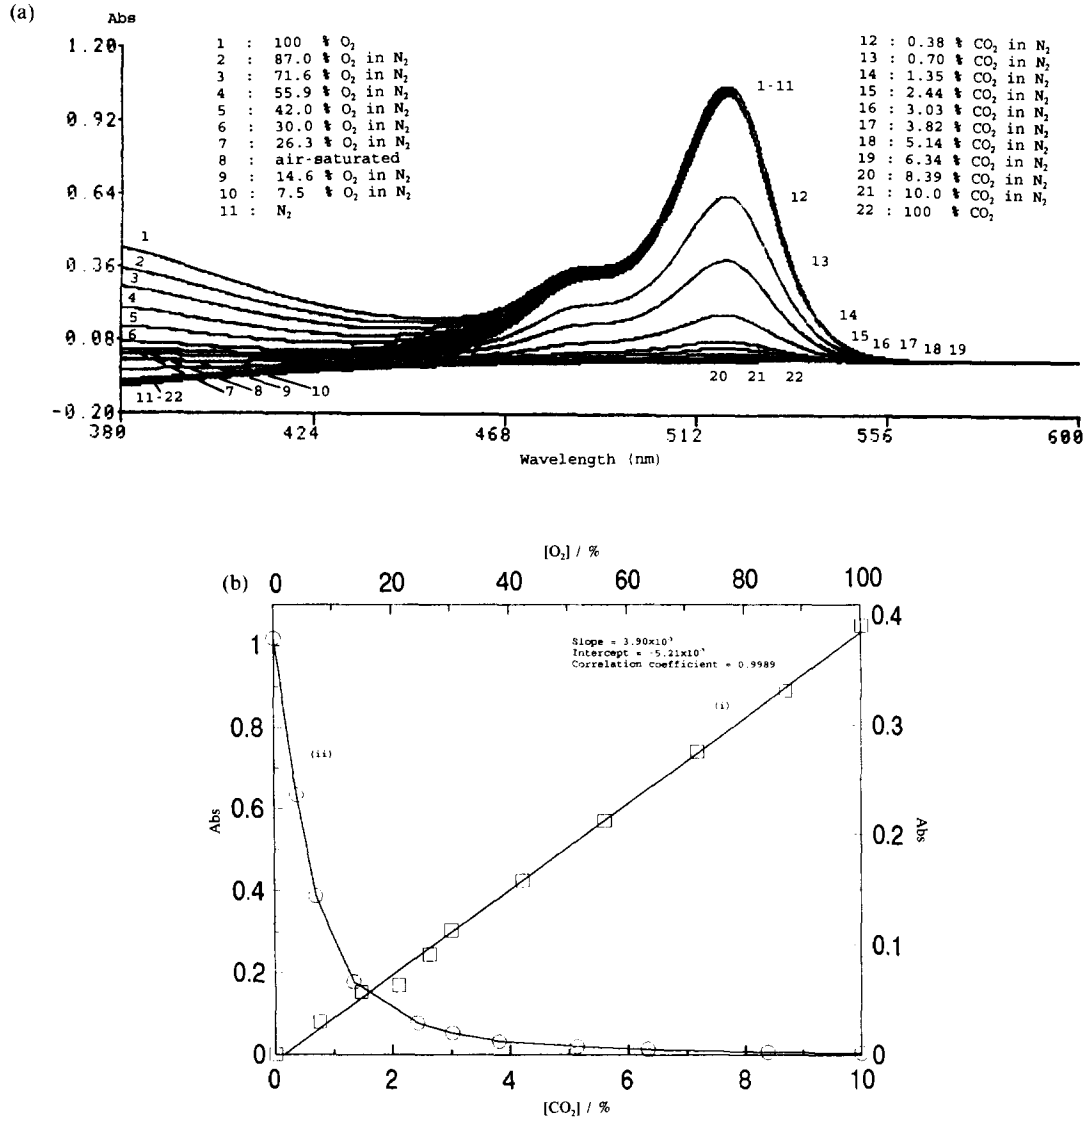

Fig. 4. (a) The effect of $O_2$ and $CO_2$ on the absorption spectrum of a solution of 10.6 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture. Optical pathlength: 1 cm; reference: air-saturated 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture. (b)(i) Plot of abs against $[O_2]$ at 400 nm using the data in (a). (ii) Plot of abs against $[CO_2]$ at 520 nm using the data in (a).

absorbance with a 91% change in absorbance from 0 to 10% $CO_2$.

We observed that a solution of FL in DEA changes colour on exposure to $CO_2$ but that the change is not entirely reversible which may be probably owing to DEA being an almost completely non-aqueous solvent. As mentioned above, a solution of FL in DMF responds reversibly to gaseous $CO_2$ as DMF contains a small amount of dissolved water (about 0.03%). Unfortunately, DMF has a CCTA spectrum which is too far into the ultraviolet region to be of practical use for future fibre optic sensor development. After further investigation, we devised a way around this problem by using a solution of FL dye and KOH in a 1:1 (v/v) DEA/DMF solvent mixture for the independent and reversible measurements of $CO_2$ (using colour changes of the FL dye) and $O_2$ (using the CCTA of the DEA with $O_2$). The observed changes in absorption spectrum of the solvent-dye solution as a function of $[O_2]$ and $[CO_2]$ are shown in Fig. 4a which demonstrates that there are no cross-interference between the two gases. A graph of abs at 400 nm against applied $[O_2]$ is plotted in Fig. 4b(i). The results agree with Beer–Lambert's law and the absorbance is linearly proportional to the applied $[O_2]$. The

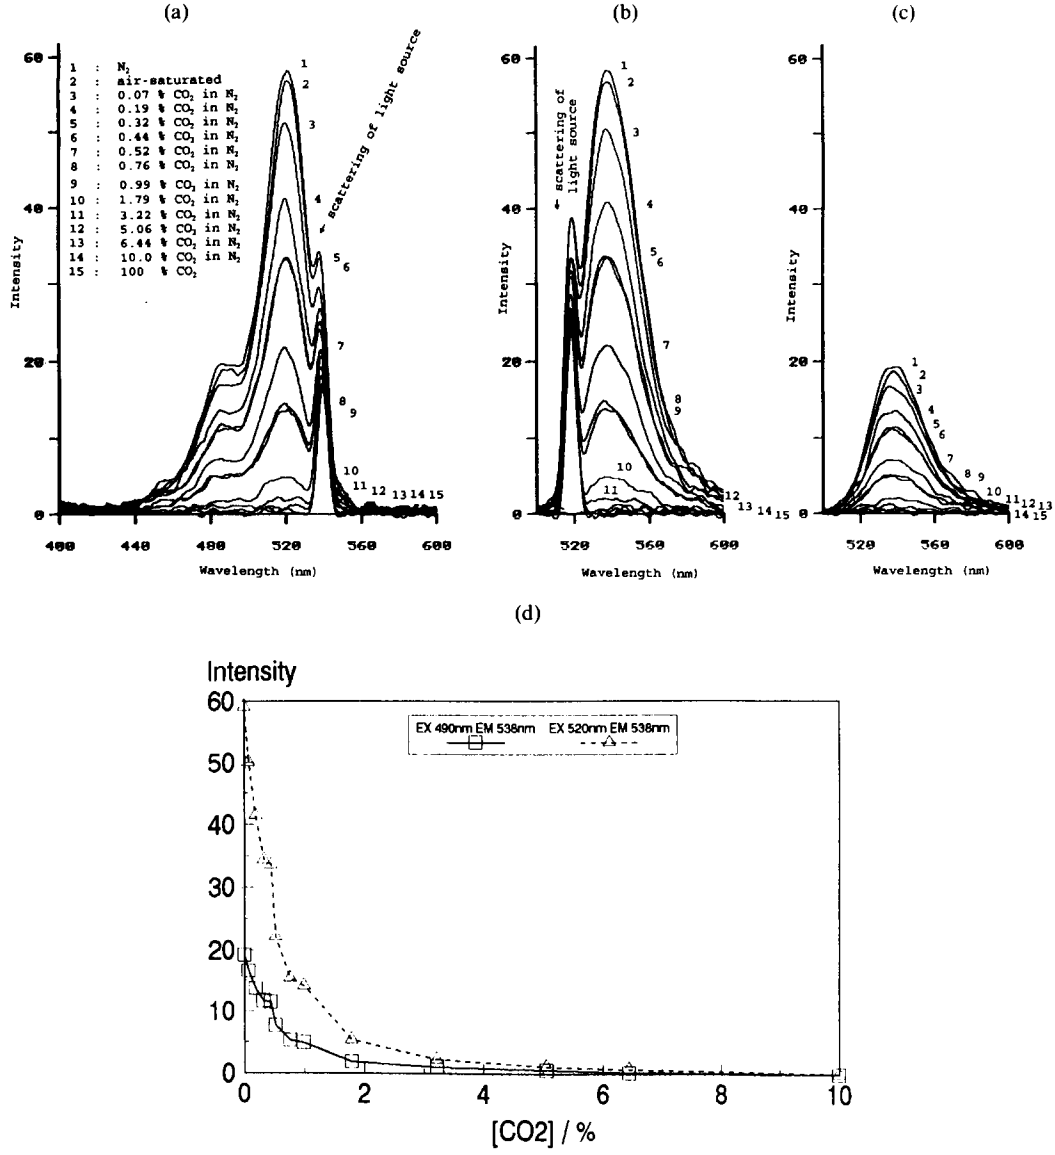

Fig. 5. Fluorescence excitation (EX) and emission (EM) spectra of 0.10 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture. Optical pathlength:1 cm. (a) EX spectra with EM wavelength at 538 nm. (b) EM spectra with EX wavelength at 520 nm. (c) EM spectra with EX wavelength at 490 nm. (d) Plot of intensity against applied [$CO_2$] using the data of the spectra.

change of absorbance is again caused by the CCTA of the DEA and $O_2$ complex. A plot of abs at 520 nm against applied [$CO_2$] is shown in Fig. 4b(ii) and increasing [$CO_2$] produce a non-linear fall in absorbance. The change of absorbance arises from the conversion of the orange dianion form of FL to the colourless, neutral lactonic form upon exposure to $CO_2$.

The fluorescence EX and EM spectra of 0.10 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture is shown in Figs. 5a–c. The fluorescence intensity is decreased when the $CO_2$ concentration is increased. Unlike $FL^{2-}$ ion which is a strongly fluorescent molecule, the neutral lactonic form of FL is non-fluorescent. As explained above, $FL^{2-}$ ions in the solution are probably converted to neutral lactonic form of FL upon exposure to $CO_2$ (equations 1–3). The plot of intensity against applied [$CO_2$] is shown in Fig. 5d which shows that increasing [$CO_2$] generates a non-linear fall in fluorescence intensity.

*Fibre optic sensing system for $O_2$ and $CO_2$*

The experimental results demonstrate that FL dye and KOH in DEA/DMF solvent mixture is a promising $O_2$ and $CO_2$-sensitive transducer to be used for the development of a sensing system

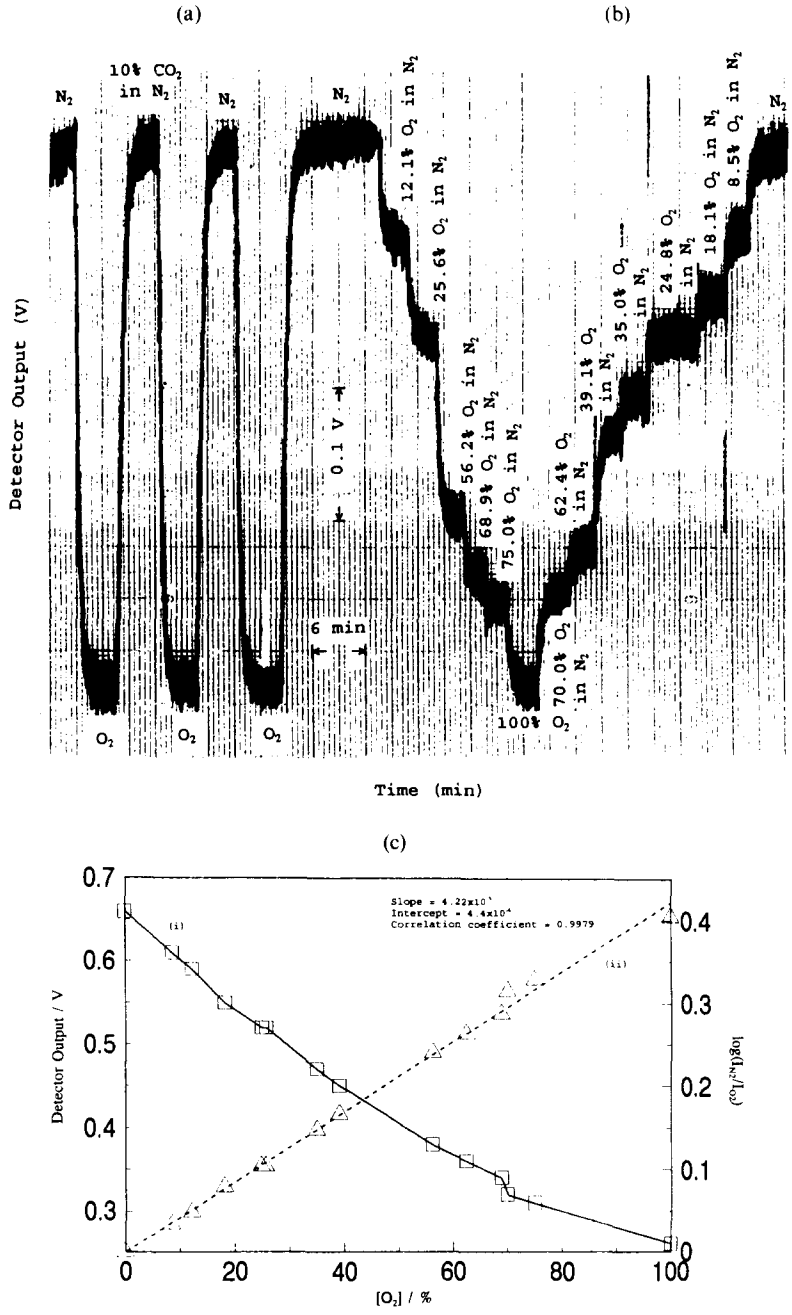

Fig. 6. (a) The response time, reproducibility and total signal change of the fibre optic sensing system when subjected to changes between: $N_2 \rightarrow O_2 \rightarrow$ 10% $CO_2$ in $N_2 \rightarrow O_2 \rightarrow N_2$. 1.0 ml of a solution of 10.6 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture in a 1 cm cuvette was used with a wavelength of 400 nm and a gas flow rate of 50 $cm^3$/min. The amplification is about 10 times that used in Fig. 7. (b) The response of the fibre optic sensing system when subjected to different $O_2$ concentrations. (c) The response of the fibre optic sensing system with $O_2$. (i) Plot of detector output against $[O_2]$. (ii) Plot of $\log(I_{N_2}/I_{O_2})$ against $[O_2]$ using the data in (b).

for both $O_2$ and $CO_2$. The solvent mixture has a CCTA spectrum extending well into the visible region so it can be used with inexpensive plastic optical fibres. Wavelengths at 400 and 520 nm were chosen to monitor the concentrations of $O_2$ and $CO_2$. Although plastic fibres have substantial attenuation around 400 nm, the experimental set-up mentioned above is still sensitive enough for $O_2$ detection. Fluorescence measurement of $FL^{2-}$ ions, in principle, can be adapted to detect $CO_2$. However, we found that there was a cross-interference on $CO_2$ from $O_2$

owing to the fluorescent quenching effect of molecular $O_2$ on $FL^{2-}$ ions. In addition, the determinations of $O_2$ and $CO_2$ can be accomplished easily by only switching between the monitoring wavelengths. Thus, all the measurements were based on the absorption spectroscopic technique. Using the experimental set-up described earlier, the response, reproducibility and total signal change of the sensing system monitoring at 400 nm and a gas flow rate

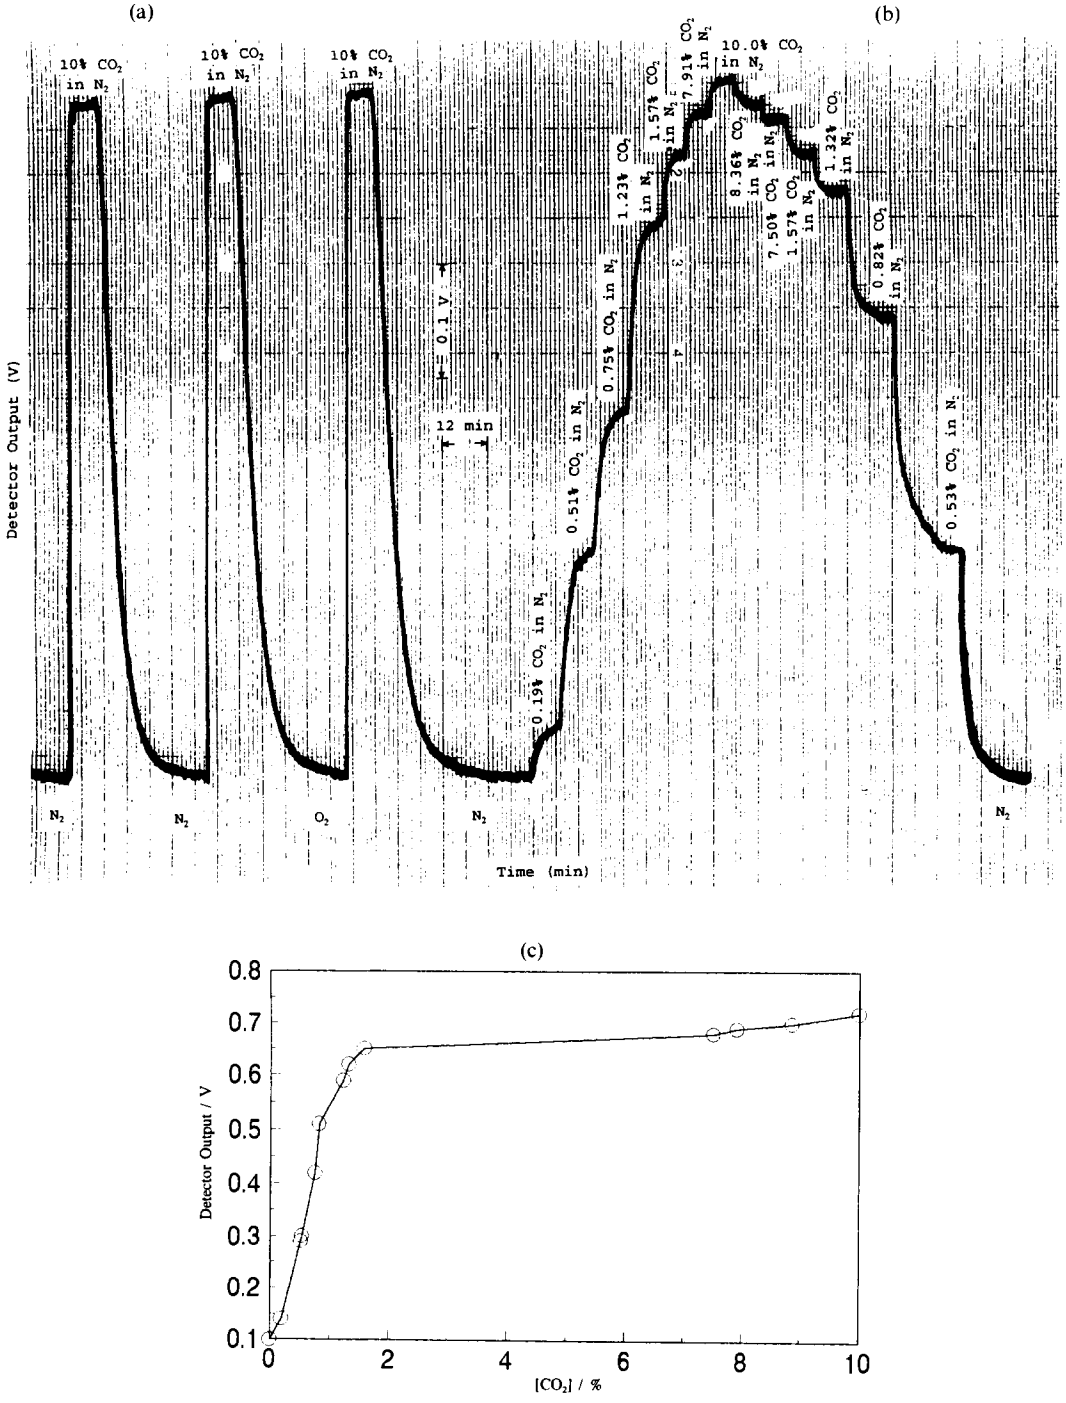

Fig. 7. (a) The response time, reproducibility and total signal change of the fibre optic sensing system when subjected to changes between: $N_2 \rightarrow$ 10% $CO_2$ in $N_2 \rightarrow O_2 \rightarrow$ 10% $CO_2$ in $N_2 \rightarrow N_2$. A solution (1.0 ml) of 10.6 $\mu M$ FL and 190 $\mu M$ KOH in 1:1 (v/v) DEA/DMF solvent mixture in a 1 cm cuvette was used with a wavelength of 520 nm and a gas flow rate of 50 $cm^3$/min. (b) The response of the fibre optic sensing system when subjected to different $CO_2$ concentrations. (c) Plot of detector output against $[CO_2]$.

of 50 $cm^3$/min through the solvent–dye solution in a 1 cm path-length cuvette were investigated. Figure 6a shows the response of the sensing system to step changes in gas concentrations from 100% $N_2$ to 100% $O_2$, from 100% $O_2$ to 10% $CO_2$ in $N_2$, from 10% $CO_2$ in $N_2$ to 100% $O_2$ and again back to 100% $N_2$. The reversibility of the sensing system is good and there is no cross-interference from $CO_2$. The response time is 0.75 and 1.5 min for a 90% signal change from $N_2$ to $O_2$ and from $O_2$ to $N_2$, respectively. The response of the sensing system when subjected to different levels of $O_2$ was investigated (Fig. 6b). The decrease in signal level with increasing $O_2$ concentrations is non-linear [Fig. 6c(i)] and the sensitivity (indicated by the slope of the graph) decreases as the concentration of $O_2$ increases with about a 35% change of signal level from 0 to 25% $O_2$. The sensing system responds over the range of 0–100% $O_2$ with a response which is in agreement with Beer–Lambert's law so that a linear graph [Fig. 6c(ii)] is obtained when $\log(I_{N_2}/I_{O_2})$ is plotted against $[O_2]$ where $I_{N_2}$ is the signal level recorded in $N_2$ only (i.e. $[O_2] = 0$) and $I_{O_2}$ is the level recorded in a gas mixture having an $O_2$ concentration of $[O_2]$. The response, reproducibility and total signal change of the sensing system monitoring at 520 nm were investigated. Figure 7a shows the response of the sensing system to step changes in gas concentrations from 100% $N_2$ to 10% $CO_2$ in $N_2$, from 10% $CO_2$ in $N_2$ to 100% $O_2$, from 100% $O_2$ to 10% $CO_2$ in $N_2$ and again back to 100% $N_2$. The reversibility of the sensing system is good and there is no cross-interference from $O_2$. The response time is 0.41 min and 10.0 min for a 90% signal change from $N_2$ to 10% $CO_2$ in $N_2$ and from 10% $CO_2$ in $N_2$ to $N_2$, respectively. The response of the sensing system when subjected to different concentrations of $CO_2$ was investigated (Fig. 7b) and was shown to be reversible. The increase in signal level with increasing $CO_2$ concentrations is non-linear (Fig. 7c): as a result, a non-linear calibration graph has to be plotted when using the sensing system for $CO_2$ determination over the range of 0–10% $CO_2$.

## CONCLUSIONS

This study demonstrated the use of a single solvent–dye solution as an $O_2$ and $CO_2$-sensitive transducer for the determination of both gaseous $O_2$ and $CO_2$. This detecting system has several advantages: inexpensive plastic optical fibre can be used; DEA and FL are inexpensive and readily available; preparation of solvent–dye solution is simple and fast. Possible applications include environmental and physiological monitoring of $O_2$ over the ranges of 0–100% and $CO_2$, 0–10%. The sensing medium however, still suffers from several drawbacks such as photo-bleaching of the dye, possibly cross-interference from other acidic or alkaline gases and also other electron acceptors like nitric oxide.[28]

Furthermore, we expect the response of the solvent–dye solution to $CO_2$ will be humidity dependent because of the aforementioned reasons. The presence of water is crucial for the response of the solvent–dye solution to $CO_2$ and thus, increasing the water concentration in the solvent–dye solution is likely to shift the equilibrium of equation (2) from right to left and lowering the pH of the solvent–dye solution with a concomittant effect on the equilibrium of equation (3). The water content will certainly vary with the water vapour concentration in an applied gas mixture since DMF is a hydrophilic compound with a propensity to absorb water vapour. Secondly, we have observed that there is a hypsochromic shift of the absorbance band of $FL^{2-}$ in DMF when the water content increases.[29] In order to circumvent this effect, the applied gas mixture can pass through some drying agent such as a molecular sieve before bubbling through the solvent–dye solution.

In addition, the sensing schemes are based on the concentration of dissolved $O_2$ and $CO_2$ in the solvent–dye solution. Any variation of temperature will change the Henry's law constant of these gases and the solvent–dye solution. Although we do not have the gas solubility data of these gases in DMT/DMF solvent mixture, it has been reported that there is a 11.6% decrease in solubility of $CO_2$ in aniline[30] and the solubilities of $O_2$ in carbon tetrachloride, chlorobenzene, benzene and acetone increase by 2.00, 2.79, 4.35 and 4.02%, respectively, from 20 to 30°C.[31] Consequently, we expect the response of the solvent–dye solution to $CO_2$ will be strongly dependent on temperature with a less marked dependence for $O_2$.

Finally, we are now planning to design a $O_2/CO_2$ fibre optic sensor by employing a similar design of Kar and Arnold.[32] Briefly, the solvent–dye solution is entrapped inside a segment of thin-wall poly(tetrafluoroethylene) (PTFE) tubing. A single optical fibre directs the

incident light into the solvent–dye solution through one end of the tubing and the transmitted light is collected by another optical fibre through the other end. Oxygen and $CO_2$ gases can readily diffuse through the thin-wall PTFE tubing into the solvent–dye solution for the reactions.

*Acknowledgements*—The authors would like to express their thanks to Dr A. Tubb for using his oxygen and carbon dioxide detectors and to the University of the West of England, Bristol for providing the financial support.

# BOOK REVIEWS

**Chemistry and Physics of Carbon—Volume 24:** P. A. THROWER (editor), Dekker, New York, 1994. Pages: xv + 316. $165.00. ISBN 0-8247-9091-X.

This is the latest volume in a series which has earned a deservedly high reputation in the carbon community. Each volume contains contributions by leading experts and in this book, four quite diverse topics are brought together to form another authoritative account of some currently topical aspects of the chemistry and physics of carbon.

The opening section, comprising some 40 pages, deals with the early stages of pitch carbonization and provides a description of the kinetics of pitch polymerization leading to mesophase formation and development. By focusing on the polymerization process during mesophase formation, the mechanism of the growth of the mesophase spheres from the isotropic phase is also described. Brief descriptions are included of the key analytical methods and procedures used to derive the data on which these descriptions are based, and a good set of references is provided in this very clear expose of recent work of the UCAR Carbon Company in this field. The second chapter deals with the quite different subject of the thermal conductivity of diamond. With the recent advances in the development of diamond films and bearing in mind that diamond has a higher thermal conductivity than copper, this chapter is certainly timely. After an outline of the theoretical background of the thermal conductivity of non-metallic solids, the published data on the thermal conductivity of single crystal diamond and chemically vapour-deposited films follows in successive sections. This provides a thorough review of the available data and leads to a concluding section which highlights the advances made in the past 5 years and indicates where further research is required. The statement that "the thermal conductivity of diamond is one of the most important physical parameters of this fascinating and potentially technologically important forms of carbon" is well justified by this chapter.

The remaining two chapters are of roughly equal length and in total comprise nearly two thirds of the book. "Chemistry in the production and utilization of needle coke" is a contribution from Japanese workers under the leadership of Isao Mochida and is an excellent review covering the properties and structure of needle coke, commercial production procedures and the relevant carbonization chemistry. It is comprehensive, detailed and highly informative and will undoubtedly become essential background reading for anyone starting work in this area. The final chapter examines the role of physical, solid-state analytical and electro-chemistry in the study of carbon surfaces. The authors cited their objective as being to provide a more unified and comprehensive review of carbon surface properties and to illustrate the importance of these properties in some applications such as catalysis and gasification. They must be satisfied with the result of their efforts and they have produced an authoritative account of a topic which has been the subject for a very large number of published papers as evidenced by the extensive references provided.

In keeping with previous books in this series, this one is well produced with clear script and illustrations and is well bound in hard-back form. At $165 it is not cheap but it is an excellent contribution to the subject and will be a valuable acquisition for libraries and indeed for all individual carbon scientists who can afford it.

J. W. PATRICK

**Advances in Steroid Analysis '93:** S. GÖRÖG (editor), Akadémiai Kiadó, Budapest, 1994. Pages: xiii + 623. £85.00.

This book is a record of the fifth in a series of symposia held in Hungary, involving a total of sixty-five papers from contributors in twenty countries. Less than a third of the papers are from the host country. Steroid hormones form the main focus, but analysis of complex mixtures of sterols, bile acids, and the vitamins D, also figure prominently.

The biochemical flavour of these texts increases inexorably, as does the clinical dimension, at the expense of chemical and pharmaceutical aspects of steroid analysis. Accounts of receptor binding studies and immunoassay methods outnumber those concerned with chromatographic methods and spectroscopy (HPLC, HPTLC and GS-MS) and a substantial chapter is devoted to steroid hormone biosynthesis, metabolism and enzymology. In contrast to previous volumes in this series, there is a dearth of novel methodology, testifying no doubt to the success of methods developed in the 1980's for the determination of trace amounts of anabolic steroids.

The final third of the volume is devoted to clinical studies, and a special session entitled "environment, steroids and cancer", in which epidemiology and endocrinology come to the fore. The latter chapter is of the "review-lecture" type and concentrates mainly upon breast cancer and prostatic cancer, and the possible role of dietary habits in influencing the incidence of these diseases.

The book is fairly free of trivial errors and is reasonably uniform in style, in spite of its being reproduced directly from such a large number of authors' manuscripts. It again represents excellent value for money.

A. B. TURNER

**Infrared Characteristic Group Frequencies, Tables and Charts—Second Edition:** G. SOCRATES, Wiley, Chichester, 1994. Pages: xii + 249. $60.00. ISBN 0-471-94230-8.

Infrared spectroscopy is used to identify substances by examining the characteristic absorptions of functional groups. Absorption bands in the region 4000–200 $cm^{-1}$ are normally considered and the technique is used for both qualitative and quantitative analysis. As stated in the introduction to this work, correlation tables and charts, relating frequency intervals to functional groups, have been derived empirically over many years by the careful and painstaking work of very many scientists.

The second edition of this very comprehensive book is in landscape style to facilitate the presentation of charts although some of the tables are printed sideways in portrait format. There is an introduction which includes useful information on spurious bands, 19 chapters on functional groups or classes of compounds, and a chapter on the near infrared region (14,000–4000 $cm^{-1}$). Included in the text are 13 different charts covering 39 pages, numerous tables, 3 figures, an appendix detailing further reading and a useful index.

I found the print size on many of the charts to be very small especially when the characters are superimposed on a 'graph paper' background and I wondered if my days of not wearing spectacles were coming to an end. All the useful charts of a general nature are included in the introduction, these are: regions of strong solvent absorption, negative correlations (absence of band equals absence of group), positions of bands in relation to type of vibration and the main chart (13 pages) of characteristic bands of groups and compounds. The familiar abbreviations are given on the charts; *e.g.*, w—weak, m—medium, s—strong, str—stretch, sym—symmetric, *etc.*, and all such symbols are clearly stated. Similarly the use of thick lines to indicate important band ranges is explained. Most of the remaining charts and tables are more specifically related to functional groups or chemical classes. These are: band positions of alkenes, carbonyl groups, substituted benzenes, ions, hydrides, complexes/ligands/other groups, and transition metal-halides. A chart relating to absorptions in the near infrared region is also included.

The individual chapters are excellent, for example, the chapter on the important carbonyl group covers numerous chemical classes for which a strong absorption band due to the C = O stretching vibration is observed in the 1850–1550 $cm^{-1}$ region. This chapter, at 41 pages the largest in the book, includes 41 tables and 179 references. Other chapters are devoted to alkanes, double-bond compounds, triple-bond compounds, the X = Y = Z group, the O-H group, ethers, and the -O-O- group. Other compounds covered in separate chapters include: amines *etc.*, aromatics, 6-membered heterocyclic compounds, 5-membered heterocyclic compounds, organic nitrogens, organic halogens, sulphur and selenium compounds, organic phosphate compounds, organic silicon compounds, boron compounds and finally inorganic compounds and coordination complexes.

I decided to use the book to examine IR data ($cm^{-1}$) on a couple of compounds that I have been studying. First a FTIR spectrum of a novel organophosphorus carbohydrate with bands at 3213 (OH), 3078-3061 (aryl C-H), 2914-2837 (aliphatic C-H), 1481 (aryl C-H), 1230 (P = O), 1093 and 1041 (C-O), 760 and 717 (monosubstituted aromatic ring). As I also examined the compound by X-ray crystallography, all the groups assigned by IR can be confirmed as present. Next an IR spectrum (lower resolution) of a known compound, gallic acid (3,4,5-trihydroxybenzoic acid), isolated from a herb used in Chinese medicine which gave bands at: 3480 (OH), 1655 (C = O), 1545 and 1440 (aryl C-H), 1270 (C-O) and 728 (aryl C-H). Again all seems to be okay. Many known compounds can, of course, also be identified by comparison with the well-known compilations of standard spectra and brief details of these collections (both book and computer based) are presented in this work.

Overall this book is a welcomed valuable addition to any laboratory engaged in infrared spectroscopy and is highly recommended.

**Experimental Mass Spectrometry:** D. H. RUSSELL (editor), Plenum, New York, 1994. Pages: xiii + 311. US$79.50. ISBN 0-306-44457-7.

Mass spectrometry has advanced so rapidly in the last decade that it has become increasingly difficult to keep abreast of developments—especially in the area of biological mass spectrometry. Although technical innovations form a major part of these advances much has also been achieved by the nonspecialist. Indeed many mass spectrometers are now operated routinely by bioscientists, clinicians, *etc*; a situation difficult to imagine 10 years ago. It is in these laboratories where we can arguably expect to see the greatest potential for further development so it is critical for the mass spectrometrists and the bioscientists to interface with one another and learn to communicate across the 'divide'.

The editor, a mass spectrometrist, has done an admirable job in producing a book which he intends as a guide for the nonspecialist in the expanding field of experimental mass spectrometry. The book has eight chapters dealing with diverse areas: negative ion chemistry, organo-alkali metal ions, collision induced dissociation (CID) of ions, Fourier transform ion cyclotron resonance (FTICR) mass spectrometry, protein structure by time-of-light MS, electrospray ionisation and tandem MS of large biomolecules and LC/FAB MS.

This book provides a timely update for both specialist MS operators and for the nonspecialist in some of the most important developments in mass spectrometry. As mentioned in the preface equally important areas have not been covered, notably: in depth coverage of tandem MS, matrix-assisted laser desorption ionisation (MALDI) and, dare I say it, inorganic mass spectrometry. For reasons lost in the mists of time few books on mass spectrometry (and this is no exception) include chapters on inorganic MS which has seen equally important advances in the last decade in terms of applications to the biomedical field.

**Infrared Characteristic Group Frequencies, Tables and Charts—Second Edition:** G. SOCRATES, Wiley, Chichester, 1994. Pages: xii + 249. $60.00. ISBN 0-471-94230-8.

## REVIEW

# A REVIEW ON THIOCYANATE METHODS FOR THE ESTIMATION OF MOLYBDENUM BY MOLECULAR ABSORPTION SPECTROSCOPY

A. C. BASAK, K. C. GHOSH, A. R. PAUL, S. BHATTACHARJEE* and L. P. PANDEY
Analytical Chemistry Division, National Metallurgical Laboratory, Jamshedpur, 831 007, India

(*Received* 3 *March* 1994. *Revised* 2 *September* 1994. *Accepted* 21 *September* 1994)

**Summary**—A review is presented on thiocyanate methods for the estimation of molybdenum in a wide variety of samples. They include conventional thiocyanate methods in which molybdenum forms an orange red complex with the thiocyanate ions and improved thiocyanate methods where the sensitivity is increased through the formation of ternary ion association complex.

The estimation of molybdenum by thiocyanate method is one of the most commonly used techniques. Molybdenum forms an orange red complex with thiocyanate ions in acid media in the presence of reducing agents. Mo(VI) is reduced to Mo(V) which forms the coloured complex and it has an absorption maximum in the range of 460–470 nm. Normally the complex is extracted into an appropriate solvent for absorbance measurement.

The reaction has been known for a long time; the analytical utility of the molybdenum thiocyanate complex was first shown by Braun who used this technique to detect molybdenum in minerals.[1,2] Its use has grown, though rather slowly, over time.[1–128] The mechanism of the colour reaction is complicated and the system may contain several Mo(V) complexes. The Mo:SCN ratio has been assigned as 1:3, though yellow 1:2 and colourless 1:1 complexes have also been advocated.[11,12] As the reaction involves a number of parameters the reaction conditions must be rigorously maintained for precision and accuracy. Attempts have been continually made to improve the sensitivity and selectivity by judicious choice of solvents, reducing agents and acid concentrations.

The present review aims to assimilate the extensive literature on thiocyanate methods which have been used for the estimation of Mo in a wide variety of samples. A literature search was carried out primarily through *Analytical Abstracts* for the period 1972–1992. While an attempt has been made to be as exhaustive as possible for the period mentioned, the citations before 1971 were collected mostly as cross-references.

The review has been organized in the following manner. It primarily deals with two types of thiocyanate methods, the conventional and the modified type. Section 1 describes the conventional thiocyanate methods which include reducing agent, solvents used for extraction, sensitivity and interference from foreign ions. The modified thiocyanate methods have been listed in a tabular form in Section 2. Section 3 describes the application of both conventional and modified thiocyanate methods followed by conclusions in Section 4.

## 1. CONVENTIONAL THIOCYANATE METHODS

This section describes those methods in which Mo(VI) is first reduced to Mo(V) by using an appropriate reducing agent. The reduced Mo(V) is then allowed to form an orange red complex with the thiocyanate ions under regulated experimental conditions. Subsequently the coloured complex is extracted with a solvent for absorbance measurement at 470 nm.

### 1.1. *Reducing agents*

The role of reducing agent is most important in any thiocyanate method as Mo(VI) must be

*Author to whom correspondence should be addressed.

reduced to Mo(V) to form a complex with the thiocyanate ions. Therefore, the reducing agent should be mild enough not to reduce Mo(VI) below Mo(V). Ascorbic acid has been extensively used for this purpose.[14,27,42,45–48,52,62,63,69,71,73,75,78,81,83,84,86,87,90,94,95,103,104,107,113–115,118,119,122,128] Sn(II) has also been a popular choice.[6,21,44,53,57,61,77,120,121] However, its use has been restricted because of the fact that Sn(II) has a tendency to reduce Mo(VI) below Mo(V) and is not an entirely satisfactory reductant.[4,9,13,52] Also, the sensitivity and precision are poor in the absence of Fe(III). Other reducing agents include, iodide,[5,10,13] hydrazinium sulphate,[55] K-ethyl xanthate,[58] mercaptoacetic acid,[41] ferrocene,[66] CuCl–ascorbic acid,[99] thiourea,[28] titanium,[3] tin and titanium,[34] potassium iodide in the presence of Cu(I)[10] and sulphite.[5] Thiocyanate itself reduces Mo(VI) under the catalytic influence of copper.[18]

### 1.2. *Solvents*

A wide variety of solvents have been used to extract the Mo–SCN complex in the conventional thiocyanate methods. They include butyl acetate,[41] tributyl phosphate in chloroform,[46,47] 4-methyl pentan-2-ol in benzene,[49] amyl alcohol,[52] isoamyl alcohol + carbon tetrachloride,[8] tribenzylamine in chloroform,[55] tributyl phosphate + benzene(1:1),[57] acetophenone,[58] acetic acid,[66] isoamyl alcohol,[77] ethyl acetate,[82] ethyl methyl ketone,[92] butyl acetate,[96] isobutyl methyl ketone,[99] chloroform[110] and hexadecylmethyl ammonium bromide in chloroform.[121] Absorbance measurement in the aqueous medium has also been reported.[9]

### 1.3. *Sensitivity*

The molar extinction coefficient of the conventional thiocyanate complex is $2.0 \times 10^4$ at 470 nm in isoamyl alcohol, $1.45 \times 10^4$ at 465 nm[66] in aqueous acetic acid and $2.0 \times 10^4$ at 470 nm[82] in ethyl acetate.

### 1.4. *Interference*

The conventional thiocyanate methods are prone to interference from many cations and anions. Most common of them is Fe(III). However, under the normal reaction conditions it is reduced to Fe(II) which does not interfere. Interference from niobium may be corrected by measuring the absorbance simultaneously at 390 and 470 nm.[47] Tungsten is masked with oxalic acid,[49] $KHF_2$.[55] Cd, Fe, Cr, Ni, Mn, Cu, Zn, V, U may be tolerated in < 100-fold but Ti and Sn interfere.[41] Fe, V, W and Nb interferences have been overcome in rock samples by acid decomposition and extraction of Mo into xylene with tributylphosphate.[52] Ti, U, Bi, Ru, Mn, Ni, Fe, Co, Cr, V, W, Nb, Ce and Re interferences are overcome by washing the organic phase with $SnCl_2$ solution in acid medium,[55] but Pd, Pt and Os interfere. No interferences have been observed from 1000-fold amount of Zr, Nb, W or Re.[66] Large amounts of Re may be removed by potassium ethyl xanthate.[58] Methods of removing coextracted Fe, Co, Cu and Ti from the organic phase have been discussed but Pd, Hg, fluoride, citrate and oxalate interfere.[92]

## 2. MODIFIED THIOCYANATE METHODS

In this category, in addition to thiocyanate, another reagent is added which forms a ternary ion association complex followed by the solvent extraction of the complex for absorbance measurement. The additional reagent either enhances the efficiency of extraction or it pushes the absorption maximum to higher wavelength thus making it more selective. In both cases, the final objective is to increase the sensitivity and/or selectivity of the conventional thiocyanate methods. In the ternary ion association complex, the metal ion reacts with a ligand to produce a charged binary complex with a second ligand of opposite charge, usually a dyestaff. A ternary complex so formed normally exhibits enhanced selectivity, precision and sensitivity over the equivalent binary complex.

A large number of methods have been reported which adopt this approach.[42,44,48,53,54,56,58,59,60–64,68–75,78–81,83,85–88,90,95,97,102,104–107,110–116,118,119,122–124,126–128] They have been listed in Table 1. The organization of Table 1 is as follows: the second column under the head reagent shows the reagent which is necessary for forming the ternary ion association complex in addition to thiocyanate. In the column headed 'conditions of measurement', informations are given about the absorbance maximum ($\lambda_{max}$), molar extinction coefficient ($\epsilon$) and the metal, thiocyanate and reagent mole ratio ($M:SCN^-:R$), sequentially subject to the availability. The fourth column gives the reducing agent and the fifth and the sixth columns give the solvents and additional reagents and the analytical range, respectively. The column under 'interference' notes a brief summary of foreign ion 'interference' and probable ways to overcome them. The column headed 'matrix' gives the nature of samples where Mo has been estimated by the listed

Table 1. Thiocyanate methods involving ternary ion association complex

| | Reagent | Conditions of measurement $\lambda_{max}/\epsilon$/ M:$SCN^-$:R | Reducing agent | Solvent/ Additional reagent | Analytical range | Interference | Matrix | Ref. |
|---|---|---|---|---|---|---|---|---|
| 1. | Crystal violet | 595 | Ascorbic acid | Toluene +Ethanol | 0.5–4 μg/10 ml | Nb, V, Ti, In, Ga, W, Zr, Co and Zn interfere | | 42 |
| 2. | 1,10-Phenanthroline | 525 | $SnCl_2$ | Dichloroet hane, Methanol | 1–10 μg/ml | 10-fold excess of Fe or V and 100-fold excess of W, P or silicate is tolerated | | 44 |
| 3. | 2-Benzylamino pyridine | 440; 1:3:2 | Ascorbic acid | Chloroform | | | Mo in steel | 48 |
| 4. | 2-Mercaptobenzo-γ-thiopyrone | 470 | $SnCl_2$ | Acetophenone | | Of 40 ions studied only fluoride, thiosulphate, Ni, Cu, Ag and Co interfere | Mo in steel | 53 |
| 5. | Diphenyl guanidine | 470; 21,200 | | Chloroform | 0.7–70 μg/10 ml | 5- to 10-fold of Nb or Bi and 200-fold of Cr, Mn, Ni, Zr, Cu, Ti, W, Re and Co do not interfere | Mo in steel | 54 |
| 6. | 4-Benzylpyridine | 465 | | | | | | 56 |
| 7. | Ethyl xanthate | 470 | | Acetophenone | 1.2–13.8 μg/ml | Na, K, Ba, Ca, Mg, Al, Mn, Cr, Sb, As, Zr, Ti, Pb, Sn, Ce, La and Fe do not interfere in 1000-fold | Mo in steel and Re | 58 |
| 8. | Antipyrene | 440; 19,000 | | Chloroform | 0.1–130 μg/5 ml | Alkali and alkaline earth metals, lanthanoids, Ni, Zn, Cd, Al, Mn, As, Sb and Sn do not interfere. Interference from Fe, Cu, Ti, Nb, Ta, Bi, W, Cr, U, V and Co may be prevented by masking, by reduction or by changing acidity | Mo in steel | 59 |
| 9. | Triethyl amine | 460; 28,000 | | Chloroform | | Alkali, alkaline earth metals, rare earths, Zn, Cd, Ni, Hf, Al, As, Zr, Pb, Bi, Sn, Co, Cu(80-fold), Ta(30-fold), Ti(15-fold), Nb(20-fold), W(40-fold), do not interfere. Thiourea may be used for masking Cu, KF for Ta, Ti, Nb and citric acid for W | Mo in soil | 60 |
| 10. | Quinoline | 470 | $SnCl_2$ | Nitrobenzene | | Cu, Co, Fe, Ti and W interfere. Cu, Co, Fe and Ti are removed by precipitation with NaOH. W is masked with citrate | Mo in steel | 61 |
| 11. | Tetraphenyl arsonium chloride | 470; 17,400 | Ascorbic acid and Ti(III) | Chloroform and quinol | | Cu, Zn, Cd, Al, Sn, Pb, V, Cr, Mn, Co, Ni do not interfere. Oxalic acid can mask 40-fold W and 10-fold Nb | Mo in low alloy steel and tungsten tool steel | 62 |

*continued overleaf*

Table 1—*continued*

| | Reagent | Conditions of measurement $\lambda_{max}/\epsilon$/ M:$SCN^-$:R | Reducing agent | Solvent/ Additional reagent | Analytical range | Interference | Matrix | Ref. |
|---|---|---|---|---|---|---|---|---|
| 12. | Octyl (α-anilino benzyl) phosphate | 470 | Ascorbic acid | Chloroform | 0.7–28 μg/L | Few ions that interfere can be separated or reduced with ascorbic acid | | 63 |
| 13. | Rhodamine B | 600 | Ascorbic acid | | 0.1–10 μg/25 ml | Interference from Fe(III) and tungstate may be masked with ascorbic acid and tartarate, respectively | Mo in soil and plants | 64 |
| 14. | Tetrabutyl ammonium ion | 465; 27,000; 1:4:3 | | Chloroform | 0.2–18 μg/ml | V, Co, Cr, Fe and Cu do not interfere if masked with ascorbic acid | Mo in industrial Cu–$MoS_2$ mixture | 68 |
| 15. | Tetraphenyl phosphonium chloride and tetraphenyl arsonium chloride | 470 | Ascorbic acid | Chloroform | 0.05–0.1 mM | Of 41 species only Ti interferes strongly but it may be masked by the addition of fluoride in the aqueous phase | | 69 |
| 16. | *N*,*N*′-Diethyl aniline perchlorate | 470 | Ascorbic acid | Dichloroethane | 1–10 μg/ml | No interference from 5000-fold Ni, 1000-fold Cu or Mn, 500-fold Fe or V and 300-fold Cr | Mo in steel | 70 |
| 17. | Dialkyl anilinium perchlorate (alkyl = methyl, ethyl, propyl, butyl or octyl) | 470; 15,000 | Ascorbic acid | Dichloroethane | 1–10 μg/ml | Interference by Fe is masked by ascorbic acid | Mo in steel | 71 |
| 18. | Benzoic-α-oxime | 490 | $SnCl_2$ | Isopropyl ether | | Tungsten interferes | | 72 |
| 19. | Crystal violet | 590 | Ascorbic acid | Toluene | | Tungsten interferes | Mo in high purity metallic niobium | 73 |
| 20. | Hexamethyl phosphoramide | 460 | | Chloroform | 0.75–5 μg/ml | Fe is separated by solvent extraction. No interference from 1 mg of U, V, Ta or Zr. 500 mg of Re, Nb and Ta were masked with NaF, Cu with thiourea and W by adding excess ammonium thiocyanate | Mo in alloy steel | 74 |
| 21. | Chlorpromazine hydrochloride | 465; 1:4:1 | Ascorbic acid | Chloroform | 5–50 μg/10 ml | | | 75 |
| 22. | ε-Caprolactum | 475; 20,000; 1:5:4 | Ascorbic acid | Aqueous | 3–18 μg/ml | Mg, Al, Ca(1000-fold), Ba, Mn (500-fold), Ag, Zn, Co, Cr, Fe(100-fold), Ni(50-fold), V, Zr(10-fold), Nb, Cu, Pb, Sn and W interfere | | 78 |
| 23. | $N^1$-(4-chlorophenyl)-$N^2$-(4-chloro-*o*-tolyl)-$N^1$-Hydroxybenzamidine hydrochloride | 470; 4500 | | Benzene | 2–20 μg/ml | No interference from most of the metals normally associated with Mo | | 79 |

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| 24. | $N^1$-(4-chlorophenyl)-$N^1$-hydroxy-$N^2$-(2,3-xylyl)-*p*-(toluamidine)-Hydrochloride | 470; 4000; 1:2:2 | | Benzene | 2.8–14 μg/ml | | | 80 |
| 25. | Mepazine(pecazine)hydrochloride | 465; 17,000 | Ascorbic acid | Chloroform | 0.9–5.4 μg/ml | About 24 cations normally associated with Mo and 8 anions may be tolerated | Mo in alloy steel | 81 |
| 26. | Thiocyanate-hydroxyamidine[$N^1$-hydroxy-$N^1$-*p*-tolyl-$N^2$-3,4-xylylbenzamidine] | 470; 1:2:2 | Ascorbic acid | Benzene | 9–18 μg/ml | No interference from Ni, Co, Cu(II), Mn(II) | Mo in steel and ores | 83 |
| 27. | Rhodamine 6G | 570 | | Aqueous gelatine solution | 0.04–0.24 μg/ml | Interference of 40 foreign ions (except Co and Zn) may be overcome by the addition of thiourea, ascorbic acid and tartarate | | 85 |
| 28. | Nitron | 465 | Ascorbic acid | Chloroform | 1.2–12 μg/ml | Mn, Ti(IV) and peroxide interfere at all concentrations. W(2-fold), Cr, Co, Fe, Pt, U, V(20-fold) and 200-fold amounts of 30 other species do not interfere | Mo in steel | 86 |
| 29. | *NN'*-Diphenyl-*p*-tolyamidine hydrochloride | 470 | Ascorbic acid | Benzene | 0.4–5 μg/ml | Many foreign ions do not interfere | | 87 |
| 30. | (Ethoxy carbonyl pentadecyl) trimethyl ammonium bromide (CPTA) | | | Chloroform, isobutyl alcohol | 0.1–7.0 μg/ml | Interference from several metals can be reduced by the addition of small amounts of citric acid. Interference of 10-fold Fe(III) can be prevented by an appropriate addition of ascorbic acid | Mo in sediments | 88 |
| 31. | *NN'*-Diaryl benzamide | 465; 1:2:1 | Ascorbic acid | Benzene | 0.4–5.4 μg/ml | At least 20,000 ppm of $Cl^-$, $Br^-$, $NO_3^-$, $SO_4^{2-}$, Li, Na, K and 6000 ppm of Be, Mg, Ca, Ba and Sr do not interfere. 12,000 ppm Ni, 1000 ppm Mn, 8000 ppm Cr, 7000 ppm Al may be tolerated. Interference of other ions are also listed | Mo in ores and alloy steels | 90 |
| 32. | Amides (*N*-phenyl acetamide, *N*-*p*-tolyacetamide, *N*-phenyl propionamide and benzamide) | 475; 13,000–18,000; 1:2:1 | Ascorbic acid | Benzene | 0.3–5.2 μg/ml | Nb interferes but may be masked with oxalate. Alkali metals, chloride, bromide, nitrate and sulphate do not interfere at concentration $\leqslant 2M$ | Mo in ores, alloy steel and synthetic mixtures | 95 |
| 33. | Imidoyl derivatives *N*-(*N*-phenylbenzimidoyl)-thiourea, *N*-phenyl-*N*-(*N*-phenyl benzimidoyl)-thiourea and I-(*N*-phenyl benzimidoyl)-thiosemicarbazide | 465 | L-Ascorbic acid | | 0.8–6.5 μg/ml | | Mo in ores and steel | 97 |

*continued overleaf*

| | Reagent | Conditions of measurement $\lambda_{max}/\epsilon/$ M:$SCN^-$:R | Reducing agent | Solvent/ Additional reagent | Analytical range | Interference | Matrix | Ref. |
|---|---|---|---|---|---|---|---|---|
| 34. | Adogen(methyl trioctyl ammonium chloride) | 467; 21,300 | $SnCl_2$ | Toluene | 2.5–50 μg | | Mo in steel | 102 |
| 35. | Acetone thiosemicarbazone | 472; 19,000; 1:4:2 | Ascorbic acid | Chloroform | 0.1–9.5 μg/ml | 4000 ppm Zn may be tolerated for 3 ppm Mo. Bivalent Pd, Rh show the lowest tolerance of 12 μg/ml | Mo in molybdenum steel | 104 |
| 36. | Perazinedimalonate {10-[3-(4-methyl 1-peparizinyl)propyl]*p* henothiazine dimalonate} | 460; 10,600; 1:1:4 | | Aqueous | 0.1–14 μg/ml | Tl, Fluoride and Zn do not interfere. V, Mn and Cr are eliminated by oxalate, Fe by ascorbic acid. Cu must be removed by extraction with dithiazone | Mo in alloy steel, ores and synthetic mixtures | 105 |
| 37. | Rhodamine B | 580; 150,000 | Ascorbic acid | Aqueous, polyvinyl alcohol, $CuSO_4$, thiourea, citric acid | | | Mo in steel, high speed steel and tungstate | 106 |
| 38. | Ethyl isobutrazine hydrochloride | 460; 38,600 | Ascorbic acid | Chloroform | 0.05–5.6 μg/ml | About 24 cations normally associated with Mo and 8 anions do not interfere | Mo in steel | 107 |
| 39. | Methotrimeprazine | 465; 16,000 | Ascorbic acid | Chloroform | 0.02–6 μg/ml | Tolerance levels of metals usually associated with molybdenum and common anions have been listed. A 100-fold excess of tungsten and a large excess of base metals and anions do not interfere. A large excess of iron may be tolerated in the presence of ascorbic acid. Sodium oxalate may be used to mask interference caused by V and Mn | Mo in steel | 110 |
| 40. | Malachite green | 640; 100,000; 1:5:2 | | | $\leqslant$400 *n*g/ml | | Trace Mo in ore | 111 |
| 41. | Pyrogallol | 465; 100,000; 2:3:2 | | Isobutyl methyl ketone | 0.04–1 μg/ml | | | 112 |
| 42. | 4-Acetyl-2-(acetylamino-5-dimethyl-$\Delta^2$-1,3,4-thiadizole-[5-acetamide-3-acetyl 2,3-dihydro-2,2-dimethyl 1,3,4-thiadiazole] | 470; 20,100 | Ascorbic acid | Chloroform | 0.06–2.5 μg/ml | Ten-fold amounts of Au, Pd and V and slightly higher amounts of Nb, Pt and Ta may be tolerated | Mo in steel | 113 |

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| 43. | 2-Chloro-*NN'*-bis (4-chlorophenyl)-*N*-hydroxybenzamidine | 470; 3300 | Ascorbic acid | Benzene | 3 24 $\mu$g/ml | Chlorine, bromine, nitrate, sulphate, urea, triethanolamine, alakli and alkaline earth metals do not interfere up to 3000 *ppm*. Fe(III), Cd(II) and fluoride (1000 *ppm*), Al(III), Ni(II), Co(II) and Zn(II) (2500 *ppm*), Cr(III) and Mn(II) (1800 *ppm*), Ti(IV) and Zr(IV) (200 *ppm*), Nb(V) and Ta(V) (150 *ppm*), V(V) (50 *ppm*), W(VI) (20 *ppm*) and Cu(II) (3000 *ppm*) do not interfere | Mo in steel ores | 114 |
| 44. | 2-Chloro-*N'*-4-chlorophenyl-*N*-*m*-tolyl benzamidine hydrochloride | 470; 18,000 | Ascorbic acid | Benzene | 0.4–5.4 $\mu$g/ml | 34 foreign ions show no serious interference | Mo in steel and fertilizer dusts | 115 |
| 45. | Ethyl Violet | 580; 900,000 | | Polyvinyl alcohol | $<6$ $\mu$g/50 ml | | Mo in steel and ores | 116 |
| 46. | Vanilline thiosemicarbazone | 470; 19,800 | Ascorbic acid | Chloroform | 0.1–4.6 $\mu$g/ml | | Mo in molybdenum steel | 118 |
| 47. | Rhodamine B | 570; 380,000; 1:6:3 | Ascorbic acid | Polyvinyl alcohol | 12 220 *n*g/ml | Fe and Ni do not interfere | Mo in Fe-Ni-Mo thin film | 119 |
| 48. | Neotetrazolinium chloride | 470; 24,700 | Ascorbic acid | Chloroform, ethanol | $<146$ $\mu$g/ml | | Mo in river water | 122 |
| 49. | Nile Blue | 630; 180,000 | | Polyvinyl alcohol, Arabic gum | $<1.2$ $\mu$g/ml | | Mo in steel | 123 |

| 51. | *N*-Octyl *N'*-phenyl benzamidine | 465; 19,500 | Ascorbic acid | Benzene | | Interference by Nb is masked by oxalate | Mo in rock, alloy steels, ores, ash and fertilizer | 126 |
| 52. | Malachite Green | 652; 380,000 | Ascorbic acid | Aqueous, cyclodextrin, Arabic gum | $<0.2$ $\mu$g/ml | Interference by 18 foreign ions may be tolerated | Mo in minerals | 127 |
| 53. | Thioacetanilide | 470; 19,000 | $SnCl_2$, ascorbic acid | Benzene | | Free from interference by metals normally associated with Mo | Mo in steel, coal ash, ores and waste waters | 128 |

method and the last column gives the reference number.

A number of modified thiocyanate thiocyanate methods have been reported which use ionic[62,68,69,75,81,88,102,107,121,122] nonionic[100,117] surfactants for sensitization.

### 3. APPLICATION

The thiocyanate methods have been applied for estimating Mo in a wide variety of samples, the majority of them being steel samples.[22,23,25,26,48–50,53,54,59,61,62,70,71,74,81,101,102,104,106,107 113–115,118,120,123,124,128] The thiocyanate method has also been used for estimating Mo in rocks,[52] chloroplatinic acid,[46] uranium and uraniferrous compounds,[17,41,51] soil,[7,32,60] alloys containing Nb,[66] concentrated NaCl medium,[72] oxide films,[82] ores and alloy steel,[90,95,105,110,111,116,120] sediment,[88] air,[94] battery grade $MnO_2$,[96] seawater,[31,98] sewage sludge and soil,[99] catalyst,[108] synthetic corrundum and lithium niobate,[121] ash and fertilizers,[126] plant materials,[8,77] soil and plants,[64] rhenium compounds,[14] beryllium,[16] aluminium alloys,[20] copper ores,[27] lead,[24] niobium and tantalum[26] and tungsten and its compounds.[10,14,26]

### 4. CONCLUSIONS

Thiocyanate methods are primarily of two types, the conventional and the modified ones. In the conventional types, Mo(IV) is reduced to Mo(V) by an appropriate reducing agent which forms an orange red complex with the thiocyanate ions. The complex is subsequently extracted by a solvent for absorbance measurement. In the modified type, in addition to thiocyanate, a third reagent is added which forms a ternary ion association complex. The complex either enhances the sensitivity or pushes the absorbance maximum to a higher wavelength thereby enhancing the selectivity. Ascorbic acid and $SnCl_2$ have been the most popular reducing agents. Molar extinction coefficients ($\epsilon$) in the conventional type range from 1.5 to $2.5 \times 10^4$, whereas in the modified type $\epsilon$ value as high as $10^5$ has been reported. Thiocyanate methods have been mostly used for the determination of Mo in steel samples. However, it has also been used for other types of samples ranging from sea-water to rocks, ores and minerals. Thiocyanate methods, though more than 100 years old, will continue to be used for the determination of molybdenum in a wide variety of samples.

## REVIEW

# ALTERNATIVE METHODS FOR TITRATABLE ACIDITY DETERMINATION

O. YU. BEREZIN, YA. I. TUR'YAN, I. KUSELMAN* and A. SHENHAR

The National Physical Laboratory of Israel, Danciger A Build., The Hebrew University, Jerusalem 91904, Israel

(*Received* 20 *April* 1994. *Accepted* 30 *September* 1994)

**Summary**—Methods for determination of titratable acidity, other than traditional titration, *i.e.* methods without titration, are considered. A number of them use analytical acid–base reagents which quickly convert a mixture of strong and weak acids into a new system. This conversion makes it possible to obtain directly the analytical signal (pH, optical density, *etc.*) for titratable acidity calculation. These methods in stationary conditions and in flow injection analysis are discussed. Methods not using acid–base reagent (iodide–iodate, chromatographic, spectroscopic and others) are also described. The advantages of the alternative methods such as the decrease labour-consumption and analysis time, simplicity of automation and others are shown.

Titratable acidity (or acid value) corresponds to the total concentration of titratable acids in a sample. Titratable acidity (TA) is an important characteristic of the quality of numerous products such as vegetable oils, juices, wines, petroleum, motor oils, polyesteric resins, plasticizers and others.

The national and international standards for TA determination are based on acid–base titration techniques.[1] These techniques are time- and labour-consuming, have relatively high detection limits and are difficult for automation, including the Gran technique.[2] These drawbacks are aggravated when TA-control is carried out in non-aqueous solutions and particularly when preliminary acids extraction is necessary.[1]

This review is concerned with alternative methods for TA determination, *i.e.* methods without titration which are free from the drawbacks indicated above. A number of these methods are based on the use of analytical acid–base reagents. After the reagent addition, the measured analytical signal (pH, optical density, *etc.*) permits one to obtain the unknown TA value.

Owing to the reagent, acid extraction from the insoluble material is accelerated. The reagent increases functional capacities of the pH-meter in the case where the pH-analytical signal is used for TA determination, and allows flow injection analysis (FIA) to be used for TA determination without titration.

The methods for TA determination without titration are frequently called 'single point titration'.[3,4] However, as these methods do not actually imply titration of any kind, we have named them 'methods for TA determination without titration'.

The methods using acid–base reagents can be classified on the basis of the type of reagent at the initial state as follows:

(i) one-component acid–base reagent method (OCABR method),
(ii) multi-component acid–base reagent method (MCABR method).

Methods that do not require the use of acid–base reagents for TA determination without titration (such as chromatography, spectroscopy, *etc.*) are also described in the review. These methods are considered in less detail because some of them (for example, chromatographic) have already been analyzed in reviews and others are in the initial stage of being studied.

*Author to whom correspondence should be addressed.

## 1. ONE-COMPONENT ACID–BASE REAGENT METHOD

The OCABR method[5–17] is based on the use of a weak inorganic or organic base as a reagent. In some applications indifferent salt is added into the reagent solution to support the ionic strength ($I$). In spite of this addition the indifferent salt does not become a new component in the solution of the one-component reagent.

### 1.1. *Aqueous systems*

The theory of application of OCABR method in aqueous solutions was suggested by Tur'yan *et al.*.[14] A charged reagent $R^-$ (the anion of the weak acid, for example AcO− from sodium acetate or MR generally)[7,8,12–14] and an uncharged reagent B, for example hexamethylenetetramine[9,11,14] are used. The analytical reactions between the reagent and the sum of the analyzed acids may be expressed by:

$$\Sigma H_z An + \Sigma z R^- \leftrightarrow \Sigma An^{z-} + \Sigma z HR \quad (1)$$

$$\Sigma H_z An + \Sigma z B \leftrightarrow \Sigma An^{z-} + \Sigma z BH^+, \quad (2)$$

where $An^{z-}$ is an anion, $z$ is a stoichiometric coefficient.

The OCABR method is based on the following conditions:

(i) Equilibria (1) and (2) are practically shifted to the right hand side.

(ii) The reagent is in high excess relative to the sum of analyzed acids. In accordance with these conditions the following equations may be obtained for a charged reagent:[7,8,12–14]

$$\lg N_{TA} = -\lg \frac{K_W^\circ}{K_{R^-}^\circ \cdot C_{MR} \cdot f_{R^-}} - pH \quad (3)$$

and for an uncharged reagent[9,11,14]

$$\lg N_{TA} = -\lg \frac{K_W^\circ \cdot f_{BH^+}}{K_B^\circ \cdot C_B} - pH, \quad (4)$$

where $f$ is the activity coefficient (for uncharged particles equal to 1), $K_W^\circ$ is thermodynamic autoprotolysis constant for water, $K_{R^-}^\circ$ and $K_B^\circ$ are thermodynamic constants for the basic dissociation of the reagent (Table 1); $C$ is the total (analytical) reagent concentration.

As can be seen from relations (3) and (4), the dependence $\lg N_{TA}$ *vs.* pH may be expressed in linear form with a slope equal to 1 when $I = \text{const}$ and $C_{MR}$ or $C_B = \text{const}$.[14] In this case the first right hand side item in equations (3) and (4) is a constant value.

The OCABR method is applicable to a great number of both strong and sufficiently weak acids.[14] When $I = 1$ for more complete proceeding of the analytical reaction, hexamethylenetetramine is more preferable than NaOAc as a reagent. But a relative excess of NaOAc ($\gamma = C_{MR}/N_{TA} \approx 200$) provides sufficient completeness of the analytical reaction. Tribasic acids may be analyzed when $I = 1$ and the constant of the third dissociation stage is not below $4 \times 10^{-7}$, which corresponds to citric acid. The dibasic acids may be analyzed when $I = 1$ and the constant of the second dissociation stage is not below $2 \times 10^{-6}$, for example succinic acid.

The upper limit of the acids being determined in the linear interval $\lg N_{TA}$ *vs.* pH is obtained from $(N_{TA})_{max} = C_{MR}/\gamma$ or $(N_{TA})_{max} = C_B/\gamma$. The values $\gamma \geqslant 100$[14] or $\gamma \geqslant 200$[8] are most often chosen and at $C_{MR}$ or $C_B = 1M$, $(N_{TA})_{max} \leqslant 10^{-2}$ eq/l.

The principles of obtaining $(N_{TA})_{min}$ presume[14] that the concentration $(N_{TA})_{min}$ corresponding to the linear plot $\lg N_{TA}$ *vs.* pH must be at least 10-fold greater than the concentration of the hydrolysis products HR (reagent MR) or $BH^+$ (reagent B) in the pure solvents. Hence at $C_{MR}$ or $C_B = 1M$ and $I = 1$ one can observe a linear plot $\lg N_{TA}$ *vs.* pH for NaOAc for $N_{TA} = 2.4 \times 10^{-4} - 1.0 \times 10^{-2}$ eq/l

Table 1. Thermodynamic autoprotolysis constants $K_s^\circ$ for solvents and constants of basic dissociation $K_{R^-}^\circ$ and $K_B^\circ$ for charged and uncharged reagents, accordingly (OCABR method, 25°C)

| Solvents | $H_2O$ | | Complex solvent* |
|---|---|---|---|
| $pK_s^\circ$ | 14.00[18] | | 22.79[15]† |
| Reagents | $pK_B^\circ$ | $pK_{R^-}^\circ$ | $pK_B^\circ$ |
| Triethanolamine | 6.23[19] | — | 11.50[15]† |
| Hexamethylenetetramine | 8.87[18] | — | — |
| Acetate anion | — | 9.24[18] | — |

*Solvent: 80% $Et_2O$ + 19% $C_2H_5OH$ + 1% $H_2O$

†Constants were determined at 20°C.

and for hexamethylenetetramine in the range $N_{TA} = 5.8 \times 10^{-4} - 1.0 \times 10^{-2}$ eq/l.

The decrease of the reagent concentration up to $C_{MR} = 0.01M$ (NaOAc) permits a decrease in the value of $(N_{TA})_{min}$ which allows the reduction of the detection limit, for example in the determination of volatile acids.[13]

The choice of the reagent is determined by its basic properties, that is by its base dissociation constant. From the point of view of completeness of the analytical reaction proceeding, the value of the constant must not be too small. However, an increase in $K^{\circ}_{R^-}$ or $K^{\circ}_{B}$ leads to an undesirable increase in $(N_{TA})_{min}$. The values equal to constant $K^{\circ}_{R^-}$ for NaOAc and to $K^{\circ}_{B}$ for hexamethylenetetramine are optimal.

### 1.2. *Non-aqueous systems*

The theory of the method was developed in detail by Lapshina *et al.*[15]

Uncharged reagent only (triethanolamine) was used in non-aqueous systems.[5,6,10,15–17] Values of $K^{\circ}_{B}$ and the thermodynamic autoprotolysis constant of the non-aqueous solvent $K^{\circ}_{s}$ were established[15] (Table 1). The equation for analytical applications, under conditions similar to those used for aqueous systems, is in principle analogous to equation (4):

$$\lg N_{TA} = A^{\circ}_{s} - \lg \frac{K_s \cdot f_{BH^+}}{K^{\circ}_{B} \cdot C_B} - pH', \qquad (5)$$

where $A^{\circ}_{s}$ is constant at $I = \text{const}$. The value $A^{\circ}_{s}$ follows the change of the glass electrode standard potential (when non-aqueous solvents are used instead of water) and also the value of the interfacial potential on the boundary with the aqueous reference electrode (Ag, AgCl, $KCl_{satd}$). The value pH′ in equation (5) is the conventional pH value. At $I = \text{const}$, one can observe the linear plot $\lg N_{TA}$ *vs.* pH′ with a slope equal to 1.[5,6,10,15]

The OCABR method was theoretically and practically tested for the non-aqueous system:[15] 80% $Et_2O$ + 19%EtOH + 1% $H_2O$ (%V), and for system:[6,16,17] 75% $CHCl_3$ + 24% EtOH + 1% $H_2O$ (%V).

Equation (5) is confirmed in the wide interval of $N_{TA}$.[15] This interval ($4.0 \times 10^{-5}$–$2.0 \times 10^{-2}$ eq/l.) is essentially larger than the one that may be obtained for aqueous solutions. The increase of the linearity interval $\lg N_{TA}$ *vs.* pH′ for the non-aqueous systems in comparison with aqueous systems is a result of the small solvolysis degree of triethanolamine in comparison with the hydrolysis degree of $AcO^-$ or/and hexamethylenetetramine.

### 1.3. *Practical application of the method*

To determine $N_{TA}$ both the calibration plot and the standard addition methods have been used.[5–17] The second method is preferable since it implies a lower probability of changes in the first right hand side item in equations (3) and (4) in the course of the analysis, as well as of changes in the analogous value from equation (5) for non-aqueous systems.

The equation for the final analytical calculation with the use of the standard addition method[14,15,17] is

$$N_{TA} = \frac{N_{st}}{(10^{\Delta pH} - 1)}, \qquad (6)$$

where $N_{st}$ is the concentration of the standard acid in reactive mixture; $\Delta pH = pH_1 - pH_2$; $pH_1$ is the pH of the reagent solution to which the sample was added and $pH_2$ is the pH of the previous (reagent + sample) solution after the addition of the standard acid. For non-aqueous systems the value ΔpH in equation (6) is substituted by ΔpH′.

Equation (6) does not differ in principle from the basic equations of the standard addition method in the ionometric technique which was shown by Tur'yan *et al.*[20] for the glass electrode in the presence of the above OCABR.

Although the precision and the accuracy of titrimetric methods may theoretically be higher than for OCABR method, especially at pH-meter accuracy not higher than pH ±0.01, the possibilities of the OCABR method are sufficient for industrial purposes. At the same time there are a number of advantages of the OCABR method: low labour- and time-consumption, especially in the case of oil-seeds;[6,10,15] simplicity of analysis automation and low detection limit (for example, for volatile acids in wines).[13]

*Aqueous systems.* The method was applied for determination of TA in several materials and products of the wine-making industry. Both total acidity[7,8,11,12] and volatile acidity[13] were determined with the use of pH-meter with accuracy pH ±0.01. Sodium acetate (2.0 *M*) or hexamethylenetetramine (0.2 *M*) were used as the initial reagents for determination of the total acidity. In the first case the calibrated plot was applied; in the second, the standard addition (of oxalic acid) method. The interval of the TA analyzed values, expressed as tartaric

acid, is 0.3–30 g/l. The relative standard deviation is $\leqslant$3.2%. The duration of the analytical determination is 2–3 min. For determination of volatile acids in wines[13] 0.1$M$ NaOAc was used as the initial reagent. Its concentration was 0.01$M$ after water and volatile acids were distilled. For the $N_{TA}$ determination the standard addition method was used. The interval of the determined $N_{TA}$ values, expressed as acetic acid, is 0.22–1.93 g/l. The relative standard deviation is $\leqslant$4–11%. The duration of the analysis is 18–20 min instead of 40–60 min in the standard titrimetric method.

*Non-aqueous systems.* This method was used for determination of TA in vegetable oils[5,6,10,15–17] and in oilseeds.[6,10,15] As the reagent 0.15–0.20$M$ triethanolamine in solvent (80% $Et_2O$ + 19% EtOH + 1% $H_2O$, %V) was used. This reagent accelerates considerably the extraction of acids from solid oilseeds: the extraction time was up to 1 min instead of 4 h in the standard method of oil extraction with pure solvent. The use of the standard addition method appears to be the most efficient one.[15,17] The $N_{TA}$ determination interval in vegetable oils is 0.2–19 mg KOH/g oil and in oilseeds, 0.2–17 mg KOH/g oil.[15] The relative standard deviation is $\leqslant$6% (obtained with the use of a pH-meter with accuracy pH $\pm$0.01). The duration of oil analysis is 2–3 min; of oilseeds, 10–12 min.

## 2. MULTI-COMPONENT ACID–BASE REAGENT METHOD

The MCABR method is often known as the linear buffer method or the linear-response method because of the existence of the simple linear plot $N_{TA}$ *vs.* pH, in contrast to the logarithmic linear plot lg $N_{TA}$ *vs.* pH in the OCABR method. If linearity of $N_{TA}$ *vs.* pH is observed then buffer capacity $\beta = -dN_{TA}/dpH$ is independent from pH.

The MCABR may consist at the initial state of two or more components.[21–23] As in the case of the OCABR method, an indifferent salt added to the system for creation of $I$ = const is not a new component of the reagent. The higher the number of the components in the reagent, the wider the linearity interval of the plot $N_{TA}$ *vs.* pH is.

The MCABR method was first used by Ghosh and Schild,[24] as far as we know, and later by other workers.[25,26] The theoretical analysis of the MCABR method in stationary conditions

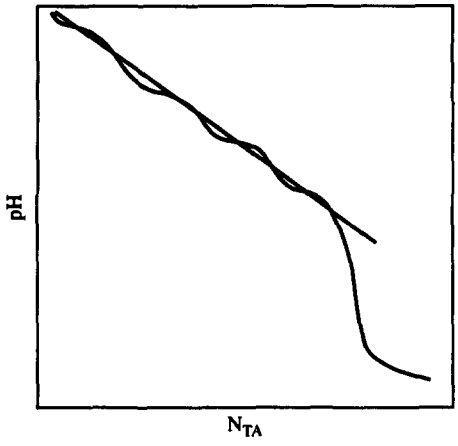

Fig. 1. The titration curve for multi-component acid–base reagent with strong acid (free hand drawing).

was suggested by various authors[21,27,28,30–42] and by others for FIA techniques.[22,23,29,43–48]

In contrast to the OCABR method where only potentiometric detection was used (pH, glass electrode), the MCABR method also utilizes spectrophotometric detection. The MCABR method is usually used in aqueous solutions and only in one case[22] was 10% EtOH 90% $H_2O$ (%v) solvent applied.

### 2.1. *Analysis in stationary conditions*

The most general theory of the MCABR method with the pH-metric detection for bases analysis was suggested by Johansson and Backen.[27] These authors[27] and also Astrom[28] have experimentally confirmed the theory. Astrom[23] applied the MCABR method theory to acid determination.

The titration of a multi-component reagent by a strong acid leads to only one pH break (Fig. 1) because of the proximity of the dissociation constant values for corresponding components. The upper plot of the titration curve is close to the linearity $N_{TA}$ *vs.* pH (Fig. 1). This plot may be expressed by the equation:

$$N_{TA} = L - \beta \,.\, pH, \qquad (7)$$

where $L$ is constant and $\beta$ is buffer capacity. The relation (7) is the basis of the MCABR method.

Johansson and Backen[27] obtained relationships for the description of the above upper plot of the titration curve. In various papers[21,27,28] this relationship was used to describe the reagent consisting of components with two dissociation stages, but it may be easily generalized for components with higher basicity. Determination of the concentration $C_i$

for component $i$ of the reagent was carried out for components of known nature and definite $\beta$ and $L$ values (equation 7). In this case the maximum proximity of the experimental curve to the linear plot $N_{TA}$ *vs.* pH (the upper part, Fig. 1) was to be reached. The following solution was suggested by Olson:[48] firstly, correction is made for the thermodynamic dissociation constants on the basis of the Debye–Hückel equation. Next, the $C_i$ values are calculated by the Johansson and Backen[27] regression method, the obtained dependence $N_{TA}$ *vs.* pH being compared to the experimental titrametric data. The second approximation again involves the calculation of the corrected dissociation constants and a new regression until the linearity dependence $N_{TA}$ *vs.* pH is obtained with the best accuracy. The final results of the determination of the component concentrations in the reagent, as well as the pH range for the linear part of $N_{TA}$ *vs.* pH dependence were suggested by Olson[48] for the FIA, but they may also be used in stationary conditions.

The pH interval of the linear part of the dependence $N_{TA}$ *vs.* pH is sufficiently large and increases with the decrease of the buffer capacity. Therefore, it is possible to determine both strong and relatively weak acids.

The limit of detection for determined acids is approximately the same for strong and weak acids and reaches 0.01–0.02 eq/l.[23] Apparently this limit is affected by the increase of the uncertainty while the $N_{TA}$ value decreases. The decrease of the $\beta$ value leads to reduction of the uncertainty and permits a decrease in the lower limit of the $N_{TA}$ determination up to $N_{TA} = 1 \times 10^{-4}$ eq/l.[48]

Simpler reagents were suggested by Havas,[30] and Damokos and Havas.[36,37,42] These reagents consist of two components: mixtures like phosphate buffer,[30] citric acid and $KH_2PO_4$[36,37,42] *etc.* The intervals of the determined acids are $10^{-2}$–$10^{-1}$ eq/l.[42] and $10^{-3}$–$10^{-1}$ eq/l.[36]

To choose the simplest two-component acid–base reagent (the buffer) it is reasonable to consider the dependence of the buffer capacity *vs.* pH. For buffer MR + HR this dependence may be expressed as[49]

$$\beta = 2.303\left(\frac{K_{H_2O}}{[H^+]} + [H^+] + \frac{C_b \cdot K_a \cdot [H^+]}{(K_a + [H^+])^2}\right), \quad (8)$$

where $K_a$ is the dissociation constant of HR; $C_b$ is the total buffer concentration.

The analysis of relation (8) shows that in the range of pH close to $pK_a$ and under usual conditions ($C_b \cdot K_a \gg K_{H_2O}$ and $C_b \gg K_a$) the buffer capacity is practically independent from the pH-values. The $\beta$ value in this range of pH becomes equal to $\beta_{max} = 0.576 \cdot C_b$ ($pH = pK_a$) and changes slightly when pH values are not far from $pK_a$. This leads to the appearance of a linear plot of $N_{TA}$ *vs.* pH (equation 7). However, the linearity interval of the plot of $N_{TA}$ *vs.* pH for a two-component reagent is usually small: 0.5–1 unit pH.[22,42,43] In spite of this drawback the reagent may be applicable for acid determination.[22,42,43]

It is of interest to compare the OCABR and MCABR methods under stationary conditions for potentiometric detection (pH, glass electrode). Equations (3) or (4) for the OCABR method and equation (7) for the MCABR method yield the following conclusions:

(1) The maximum relative uncertainty of the $N_A$ determination in the OCABR and MCABR methods is approximately the same. But in the MCABR method, in contrast to the OCABR method the uncertainty depends upon the value of $N_{TA}$, and an increase in $N_{TA}$ leads to a decrease in the relative uncertainty.

(2) The detection limit of TA determination is considerably lower in the OCABR method.

(3) The buffer capacity of the reagent in the OCABR method depends upon $N_{TA}$ and may be considerably smaller than for reagents in the MCABR method, but this does not affect the rate of dynamic response of the glass electrode.[14,15]

(4) The sensitivity of the OCABR method depends upon $N_{TA}$ and may be higher or lower than in the MCABR method.[14]

### 2.2. *Flow injection analysis*

The MCABR method was applied to two applications of the FIA technique: (i) the tested sample containing acids reacts with the reagent;[23,29,46] (ii) the tested sample containing the substrate produces an acid or a base as the result of an enzymatic reaction between the immobilized ferment and the substrate in the flow conditions. Finally, products (acid or base) react with the reagent.[21,43–46,48]

In FIA both potentiometric (pH, glass electrode)[22,29,43,45,48] and spectrophotometric[23,44,46,47] detections were used to obtain the analytical signal.

*Potentiometric detection.* For potentiometric detection the following relation may be

obtained on the basis of equation (7) and the known dependence of the glass electrode potential:[21]

$$N_{TA} = (F\beta/2.3RT)\delta E_p, \quad (9)$$

where $\delta E_p$ is the difference between the glass electrode potential for the analytical signal peak and for the flow of the carrier buffer solution (the multi-component reagent); $F$, $R$ and $T$ have their usual meanings.

Paparello *et al.*[21] used immobilized penicillinase to produce penicilloic acid ($H_2$Pen) from penicillin (Pen) under FIA conditions:

$$\text{Pen} \xrightarrow{H_2O,\ \text{penicillinase}} H_2\text{Pen}. \quad (10)$$

The penicilloic acid afterwards reacted with a special multi-component reagent. The reagent consists of $4.0 \times 10^{-4}M$ $K_2HPO_4 + HCl$ (pH 7).[21]

The application of the Michaelis–Menten equation to FIA with enzymatic reaction gives:

$$S = \frac{F}{2.3 \cdot RT} \cdot \frac{K_m \cdot \beta}{V_m \cdot \delta t}\delta E_p, \quad (11)$$

where $S$ is the substrate (penicillin) concentration; $K_m$ is the Michaelis constant ($K_m \gg S$); $V_m$ is the maximum rate of the enzymatic reaction; $\delta t$ is the sample residence time in the reactor (the column).

One can observe from equation (11) that there is a linear plot between the substrate concentration and changes in the glass electrode potential. It was shown[21] that the linear plot may be observed in the interval $S = 8 \times 10^{-5}$–$5 \times 10^{-4}M$.

An analogous determination of the penicillin was made by Gnanasekaran and Mottola,[45] but in contrast to the work[21] they used a more concentrated phosphate buffer ($1 \times 10^{-3}M$) with constant ionic strength and pH 6.4. The interval of the determined penicillin (G and V) concentration is $S = 5 \times 10^{-5}$–$5 \times 10^{-4}M$.

Olsson[48] also investigated the application of FIA with potentiometric detection for penicillin determination based on reaction (10). It should be noted that the author[48] also studied the application of the Michaelis–Mention equation when the condition $K_m \gg S$ is not fulfilled. An interesting point of the work[48] was the research on the influence of the buffer capacity of the reactor upon the analytical signal.

Ruzicka *et al.*[43] elaborated enzymatic determination of urea in serum in FIA conditions. In this case urease was used as the immobilized ferment. The analytical reaction is

$$CO(NH_2)_2 + H_2O + H^+ \xrightarrow{\text{urease}} 2NH_4^+ + HCO_3^-. \quad (12)$$

The multi-component reagent was suggested to detect the product. In this case the base ($HCO_3^-$) but not acid was determined.

For individual acid determinations the multi-component reagent was used by Astrom.[29] The applicability of equation (9) for HCl, formic and acetic acid determination was shown.[29] The interval of the determined acids or bases is 0.01–0.1$M$, which is approximately the same as the one for stationary conditions.[23,28]

*Spectrophotometric detection.* The theoretical and practical approaches to acid determination by FIA with spectrophotometric detection were elaborated by Hansen *et al.*,[44] by Ishilashi and Imato[46] and by Israel.[22] It is common for these approaches to use the acid–base indicators in addition to the above components of MCABR.

The complex reagents approach was suggested by Hansen *et al.*[44] As in the case of pH-metric detection, it is of interest to consider the linear part of the dependence $N_{TA}$ *vs.* $A_p$, where $A_p$ is the absorbance at the peak of the analytical signal. Hansen *et al.*[44] formulated the following conditions for the application of acid–base reagent with indicators:

(1) The dissociation constants of the acid–base components of the reagent must not be far from one another including the acid–base indicators.

(2) The absorptivities of acid–base forms of indicators must be near to one another.

In the mentioned conditions the authors[44] used an equation analogous to (11) to spectrophotometrically indicate the products of the urea enzymatic reaction:[43]

$$S = k\frac{K_m \cdot \beta}{V_m \cdot \delta t}\delta A_p, \quad (13)$$

where $k$ is a constant.

In contrast to the complex reagent,[44] Ishibashi and Imato[46] suggested a simple reagent: $HR + MR + HInd + Ind^-$, consisting of one acid–base buffer pair and one pair of acid–base component indicators. This approach allows one to obtain the simple relation expressing the linear plot $N_{TA}$ *vs.* $A_p$ for acid control by FIA (without sample dilution):

$$N_{TA} = k'\delta A_p, \quad (14)$$

where

$$k' = C_b/C_{Ind} \cdot l \cdot (\epsilon_{HInd} - \epsilon_{Ind^-}), \quad (15)$$

$C_b$ is the total concentration of the buffer components (MR + HR); $C_{Ind}$ is the total concentration of the indicator (HId + $Ind^-$); $l$ is the length of the cell, $\epsilon$ is the absorptivity. It should be noted that equation (14) is true only under the conditions of Hansen *et al.*,[44] *i.e.* when $K_{HR} \approx K_{HInd}$.

Israel[22] used a very simple reagent for acid and base determination by FIA with spectrophotometric detection. The reagent for acid determination is $R^-$ + HInd + $Ind^-$. Under the same conditions[44,46] ($K_{HR} \approx K_{HInd}$) and when $\epsilon\ Ind^- = 0$, $l = 1$ cm an expression analogous to (14) was obtained:[22]

$$N_{TA} = \frac{D \cdot C_R}{C_{Ind} \cdot \epsilon_{HInd}} \delta A_p, \quad (16)$$

where $D$ is the sample dispersion coefficient.

The reagent suggested by Israel[22] is similar to the one-component reagent (NaOAc) considered in Section 1. However, there is a considerable difference between these reagents because the reagent[22] is not used in excess relative to determined acids. Besides, in this reagent an acid–base indicator (a second component) is also present. It should be noted that a one-component base reagent in contrast to this reagent[22] gives a lower detection limit $N_{TA}$: $2 \times 10^{-5}$–$2 \times 10^{-4}$ eq/l.

Ruzicka *et al.*[50–52] suggested the application of FIA for individual strong acid determination by the peak width measured in time units. The authors[51] used Bromothymol Blue as indicator added to the alkaline carrier stream. This interesting idea was developed by Koupparis *et al.*[53] for determination of individual weak acids. Woods *et al.*[54] have shown that in this technique both the peak width and the peak height in the same solution carrier may be used.

*Other kinds of detection.* Polta *et al.*[55] determined strong acids and bases by detecting the time change of the anodic current on the Pt-electrode, *i.e.* by FIA without performing any chemical reaction. Fucsko *et al.*[56] with the same aim used a simpler pH-detector. Weak acids were not considered in these works.[55,56]

### 2.3. *Practical application of the method*

Usually for acid determination by the MCABR method a calibration plot is used. The multi-component reagent was suggested for determination of $N_{TA}$ in gastric juices;[24,42] for determination of sulphuric acid in anodizing electrolytes for aluminium;[26] for determination of metal ions and ligands (complexonometry) without titration;[34,37,57] for determination of ion-exchange capacity[38,40] and also for linearization of the potentiometric acid–base titration curves.[58]

The MCABR method was used for analysis of penicillins after their enzymatic hydrolysis up to penicilloic acid[22,45,48] by FIA. The relative standard deviation was $\leqslant 2\%$[22] in the penicillin concentration interval of $8 \times 10^{-5}$–$5 \times 10^{-4} M$. By the data[48] the relative standard deviation was $\leqslant 1\%$. The sample throughputs were 60 and 150 $h^{-1}$.[45,48]

In previous work[43,44] the MCABR method was used for urea determination in serum after enzymatic conversion of urea into $NH_4HCO_3$. The relative standard deviation was 0.52%. The sample throughput was 60 $h^{-1}$.

## 3. METHODS NOT USING ACID–BASE REAGENTS

### 3.1. *Iodide–iodate method*

The iodide–iodate method has been used for a long time for determination of strong and relatively weak acids generally, owing to its low detection limit.[59] The known reaction

$$IO_3^- + 8I^- + 6H^+ \leftrightarrow 3I_3^- + 3H_2O \quad (17)$$

is the basis of the method. The reaction (17) equilibrium is shifted to the right hand side in analogy to the protolytic reactions considered above. However, in contrast to the latter, reaction (17) proceeds quite slowly when the $H^+$ value is relatively small. The use of excess $Na_2S_2O_3$ leads to acceleration of reaction (17) and shifts its equilibrium to the right hand side. This factor is very important for analytical applications.[59] Both direct and indirect titration are usually used for acid determination by the iodide–iodate method with instrument detection.[60–64] Since this review considers mainly the TA determination alternative to titration, we refer to works[65–67] based on the measurement of the analytical signal connected with produced $I_3^-$, without titration. For this purpose the spectrophotometric absorbance[65,66] or biamperometric indication[67] were used.

Hoppe *et al.*[65] used 1% KI + 0.05% $KIO_3$ under stationary conditions. The concentration of the analyzed acids was: $10^{-5} \div 10^{-3}$ eq/l. The absorbance of $I_3^-$ was measured at wavelength 420 nm. Two intervals of the linear plot $N_{TA}$ *vs.*

$A_p$ with different slope were estimated for $10^{-5} \div 10^{-4}$ and $10^{-4} \div 10^{-3}$ eq/l., respectively. The first interval gives the relative uncertainty of acid determination (HCl, benzoic, salicylic and propionic acids) which is $\leqslant 30\%$ and the second interval $\leqslant 6\%$. But for each of the determined acids it is necessary to obtain the calibrated curve.

Kamson[66] also elaborated spectrophotometric detection for the iodide–iodate method but with the use of the FIA technique. The reagent is $5 \times 10^{-3}M$ KI + $1 \times 10^{-3}M$ $KIO_3$. The absorbance of the $I_3^-$ is measured at wavelength 350 nm, which differs from the one used in the work.[65] Only strong acids ($H_2SO_4$, $HNO_3$, HCl) were determined. The linear calibration plot $N_{TA}$ *vs.* $A_p$ in the concentration interval $4 \times 10^{-4}$–$8 \times 10^{-4}M$ for $H_2SO_4$ and $3 \times 10^{-4}$–$5 \times 10^{-3}M$ for $NHO_3$ and HCl was obtained. Even for strong acids the slopes of the calibration curve were different, probably because of the small concentration of KI.

Matuszewski *et al.*[67] also used FIA for acid determination by the iodide–iodate method. The applied reagent was $2M$ KI + $5.0 \times 10^{-3}M$ $KIO_3$. Biamperometric indication on the polarized Pt electrodes was used for $I_3^-$ determination. For $H_2SO_4$, monochloracetic, formic and acetic acids, the linear interval $N_{TA}$ *vs.* $i_p$ ($i_p$ is the current corresponding to the peak of the analytical signal) was obtained with a slope decreasing with the decrease of the acid strength. Therefore, reaction (17) proceeds incompletely and it is impossible to analyze the sum of acids. Individual acids are determined in the intervals $1 \times 10^{-3}$–$8 \times 10^{-4}$ eq/l. (for $H_2SO_4$) and $2 \times 10^{-3}$–$2 \times 10^{-2}$ eq/l. (for $HNO_3$ and HCl). The relative standard deviation is 0.2%.

The efficiency of potentiometric detection for the system $I_3^-/3I^-$ was shown for $Cu^{2+}$ determination.[68] This detection at the excess of iodide ions permits the control of $I_3^-$ up to $C_{I_3^-} \approx 10^{-7}M$ and may be used under stationary conditions as well as FIA for acid determination.

It should be noted that the iodide–iodate method has been used only for separate acid determination.

### 3.2. *Chromatographic methods*

The chromatographic methods for fatty acids determination have been described recently in Ackman's review[69] and in AOAC book.[70] Below we consider recent publications only (1992–1993). The GC method was used for fatty acids determination in fats and soaps,[71] oilseeds,[72] and fats and oils.[73–76] For analytical purposes the acids were transformed into Me esters[73,75,76] or into acyl pyrolidides as was done by Dasgupta *et al.*[74] In this case[74] the reactions were accelerated by microwave irradiation. FID[72] and MS[72,74,76] were used for detection. The relative standard deviation is 1–8%.[75]

The capillary LC method implying the reversed-phase and laser-induced fluorescence detection was used by Yoo *et al.*[77] for fatty acids determination in fish oil. The accuracy was better than 0.46%.

Jen *et al.*[78] used the HPLC method with UV detection for volatile fatty acids determination in landfill leachates. Olalla Herrera *et al.*[79] used this method for non-volatile acid (non–TA) determination in wines. The relative standard deviation is 1.0–1.1%.[79] Akasaka *et al.*[80] suggested the use of highly sensitive fluorescence reagent for acid detection in HPLC.

May *et al.*[81] automated the GLC method for fatty acids determination in oilseeds. The linear correlation between the results obtained by this method and those obtained by standard titrimetric method was shown.

Chem *et al.*[82] used the ion chromatographic method for determination of organic and inorganic acids in precipitation samples. For more complete determination the gradient and the ion-exclusion techniques were combined.

It should be noted that the chromatographic methods are more suitable for determination of separate acid groups than for TA determination. For example, in some cases,[83,84] the HPLC recovery was only 85–90%.

### 3.3. *Spectroscopic methods*

Sato *et al.*[85] optimized the conditions for the near-IR spectroscopic determination of fatty acids in fats and oils. For these compounds, Fourier transform IR spectroscopy was also successfully applied.[76,86] Ismail *et al.*[86] suggested an indirect method for oxidized oils. Acids were extracted by 1% KOH in MeOH, and carboxylate anions that were formed were determined at 1570 $cm^{-1}$. Determination takes <2 min and the authors believe that method to be suitable for routine TA control.

Sadeghi-Jorabch *et al.*[87] used Fourier transform Raman spectroscopy for determination of fatty acids in oils, margarines and butters. They recommend this method for the food industry

as the most rapid one for TA determination in comparison with conventional methods.

Lin *et al.*[88] suggested the use of atomic absorption spectrometry for free fatty acids determination in biological samples. The method is based on the acid extraction with the help of $CHCl_3$–n–hexane–MeOH in the presence of copper ion which forms copper soaps.

Walde[89] worked out a colorimetric method for free fatty acids determination in oils. The coloured compounds are formed from acids reacting with phenol red in isooctane.

Among the spectroscopic methods Fourier transform IR[86] and Raman[87] spectroscopy are of greatest practical interest. However, unlike the OCABR pH-method (see section 1) the spectroscopic methods were applied only for non-aqueous systems and are considerably more expensive.

### 3.4. *Amperometric methods*

The amperometric monitoring for acid determination in milk was suggested by Baldo *et al.*.[90] In this technique a hydrogen ion discharge current on a Pt-microelectrode was used, value of the current depending on the pH of the milk. However, the correlation of current with the TA was not investigated.

Albery *et al.*[91] studied an amperometric method for bile acids determination. They used an enzyme (3-α-hydroxysteroid dehydrogenase) electrode. Bile acids take part in the electrode reaction as reducers. The method allows only the determination of free bile acids. A detection limit of 1 μM was achieved.

### 3.5. *Gel techniques*

For determination of acidity and alkalinity, Tsionsky and Lev[92] used a capillary detector containing a sol-gel glass doped with acid–base indicators. The concentration of the acid corresponded to the length of the coloured section of the capillary. The method is simple and rapid, but only hydrochloric acid was studied.

Blumenthal *et al.*[93] suggested the determination of TA in oils on the basis of a changing colour indicator in a liquid gel. It is a simple technique of solventless analysis with a non-toxic reagent. The analysis is relatively time-consuming in comparison with the technique,[92] but more studied. Recently a collaborative study of this technique was carried out by AOAC International.[94]

## CONCLUSIONS

For determination of titratable acidity without titration one- or multi-component acid–base reagent can be used.

After reagent addition, potentiometry (with pH-glass electrode) and spectrophotometry were used for detection purposes. The determinations can be carried out both in stationary conditions and by flow injection analysis.

The method of the one-component acid–base reagent is characterized by a lower detection limit. The multi-component reagent may provide higher accuracy, but to control complex acids mixtures over a wide range of strength and concentration the one-component reagent is more efficient. The latter also considerably accelerates acid extraction from insoluble materials, which makes the analysis more rapid.

Determination of titratable acidity may be performed without the use of acid–base reagents, by Fourier transform infrared spectroscopy as well as Raman spectroscopy. Unlike acid–base reagent methods these spectroscopic methods are applied only for non-aqueous systems and are considerably more expensive.

The alternative methods of analysis (without titration) appear to be applicable for standardization and practical usage at the same time as titration methods or instead of them.

*Acknowledgement*—The authors would like to express their gratitude to Prof. E. Schoenberger for his valuable advice.

(*Received* 20 *May* 1994. *Revised* 29 *August* 1994. *Accepted* 29 *August* 1994)

**Summary**—A trifluoroacetic anhydride–sodium iodide mixture (TFAA-I) reacts with nitroxide radicals with liberation of iodine. Since stoichiometric amounts of iodine are formed from nitroxides, the TFAA-I reagent can be applied to their analytical determination. Two procedures for the determination of nitroxides (titrimetric on μmol and spectrometric on nmol levels) are described.

Nitroxide radicals belong to the most common classes of stable free radicals. Owing to their EPR activity, nitroxides play a crucial role in the investigations of many chemical, especially bio-organically[1] oriented problems, and are also involved in various industrial applications.[2–4] In spite of such a broad spectrum of applications, their determination still belongs to the problems of analytical chemistry of *N*-oxy compounds,[5] as only a very few reports on this subject are published in the available literature. Nitroxide radicals have been determined iodometrically, after their redox reaction with hydroiodic acid solution.[6] A direct method has been developed for an amperometric titration of free iminoxyl radicals with cerium (IV) sulphate solution by the anodic current of their oxidation.[7] The possibility of the determination of nitroxide radicals by means of their prereduction with ascorbic acid, and subsequent back titration of excess reductant, has also been suggested.[8]

Recently we have published analytical applications of the trifluoracetic anhydride–sodium iodide (TFAA-I) reagent for detection[9–12] and determination[13–16] of various *S*-oxy and *N*-oxy compounds. Among them, we have presented preliminary results on the reaction of the TFAA-I reagent with nitroxide radicals.[15] We have established that this reaction is fast, even under mild conditions (2- to 4-fold excess of TFAA and NaI, room temperature), affording hydroxylamine-*O*-trifluoracetates (**2A**) with simultaneous formation of stoichiometric amounts of iodine according to equation (1).

Since the release of iodine is quantitative in respect to nitroxide radicals **1** in a very broad range of their concentration, the TFAA-I reagent can be considered a prime reagent for iodometric procedures for determination of nitroxide radicals.

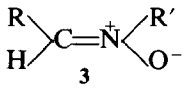
*Author to whom correspondence should be addressed.

In this paper we present our results on the application of the TFAA-I reagent for the determination and microdetermination of nitroxide free radicals (**1**) and also their differentiation from nitrones (**3**).



3

## EXPERIMENTAL

### *Materials*

Trifluoracetic anhydride, acetic anhydride, acetyl chloride, benzoyl chloride, methanesulphonyl chloride and *p*-toluenesulphonyl chloride were purchased from Aldrich (Milwaukee, U.S.A.)

Acetone was distilled over phosphorus pentoxide, redistilled over anhydrous potassium carbonate and stored over molecular sieves 3 Å. Sodium iodide (Aldrich) was dried *in vacuo* over phosphorus pentoxide before use.

Nitroxide radicals **1a–d**: 2,2,6,6-tetramethylpiperidinyloxy (TEMPO, **1a**), 4-hydroxy-2,2,6,6-tetramethylpiperidinyloxy (4-hydroxy-TEMPO, **1b**), 4-oxo-2,2,6,6-tetramethylpiperidinyloxy (4-oxo-TEMPO, **1c**) and 3-carbamoyl-2,2,5,5-tetramethylpyrrolidin-1-yloxy (3-carbamoyl-PROXYL, **1d**) free radicals were purchased from Aldrich and purified by two to three crystallizations from pentane. Nitrones: *N*-methyl-α-phenylnitrone (**3a**) and *N*-phenyl-α-phenylnitrone (**3b**) were synthesized according to Refs 18 and 19, respectively. 2,2,6,6-Tetramethylpiperidine (**2a**) and *N*-hydroxy-2,2,6,6-tetramethylpiperidine (**2b**) were synthesized according to Ref. 8.

### *Solutions*

NaI, a 0.5*M* solution of sodium iodide in anhydrous acetone. TFAA, a 0.8*M* solution of trifluoracetic anhydride in anhydrous acetone (the solution was prepared immediately before use). Acetic anhydride (and acid chlorides), 0.8*M* solutions in anhydrous acetone, prepared immediately before use. Nitroxide radicals, 0.1*M* solutions of nitroxide radicals **1a–d** in anhydrous acetone. Working solutions of nitroxide radicals for spectrophotometric determinations had the concentration $1 \times 10^{-3}M$ and were prepared immediately before use by dilution of a 0.1*M* solution with anhydrous acetone. Nitrones, 0.1*M* solutions of nitrones (**3a** and **b**) in anhydrous acetone. Hydroxylamines, 0.1*M* solutions of hydroxylamines (**2a** and **b**) in anhydrous acetone. KI, an aqueous 0.1*M* solution of potassium iodide. Sodium thiosulphate solution, 0.02*M*, standardized by coulometric titration with iodine. Starch, a 0.5% aqueous solution.

### *Instruments*

The absorption spectra were scanned on a Specord UV-VIS instrument, the absorbances were measured on a VSU-2P spectrophotometer (both Zeiss, Jena). EPR spectra were recorded on a SEX-2543 Radiopan Spectrometer at X-band frequencies (*ca.* $9.25 \times 10^9$ Hz) using a 100 kHz modulation unit and 0.1 mT modulation amplitude.

Mass spectra were obtained on a LKB-2091 spectrometer at 70 eV ionization energy. Samples were introduced via a chromatographic column system (OV-17 oil, 3%, 2.7 m of column, at program temperature 100°–260°C, 10°C/min).

### *Procedures*

*Iodometric titration.* A known amount of nitroxide radical (40–200 μmol contained in 0.4–2 ml of 0.1*M* solution) was placed in a 100 ml Erlenmeyer flask and 1 ml of 0.5*M* NaI in acetone added, followed by addition of 1 ml of 0.8*M* TFAA in acetone. The reaction solution was gently mixed for 0.5 min and allowed to stand in a dark place for the time indicated in Table 5, it was then diluted with 20 ml of 0.1*M* KI and titrated at once with sodium thiosulphate. At the end of the titration, starch was added.

| 8 | **2b** | — | | 0.8 | 60 | **2Ab** |

*1 ml of a 0.1*M* solution of **1** or **2** (0.1 mmol) in acetone. †*ca.* 75 mg of NaI. ‡*ca.* 0.11 ml of TFAA.

*Spectrophotometric determination.* A known amount of nitroxide radical (20–1000 nmol in 20–1000 $\mu$l of an acetone stock solution) was taken in a 10 ml volumetric flask and 1 ml of 0.5*M* NaI in acetone, followed by 100 $\mu$l of 0.8*M* TFAA in acetone added. The reaction mixture was mixed well and diluted with acetone to 10 ml. Part of this solution was placed in a quartz cuvette (for amounts of nitroxide radical 20–100 nmol, - cuvettes with 50 mm light path and for 100–1000 nmol, - cuvettes with 10 mm light path were used) and the absorbance ($A$) was measured after 2 min (after addition of TFAA) against acetone as a reference ($\lambda = 362$ nm). The blank correction measurement ($A_0$) was also performed after 2 min for the reaction mixture of 1 ml of 0.5*M* NaI and 100 $\mu$l of 0.8*M* TFAA, diluted to 10 ml with anhydrous acetone, against acetone as a reference. The relation $A' = A - A_0$ as a function of nitroxide radical quantity constituted the calibration line, which was established from nitroxide **1b** determinations (in the range of 20–1000 nmol of **1b**, linear course) and was applied for determination of other nitroxide radicals.

*Iodometric titration–reverse mode procedure.* A known amount of nitrone or nitroxide radical (100 $\mu$mol contained in a 0.1*M* acetone solution) was taken into a 100 ml Erlenmeyer flask and 1 ml of a 0.8*M* TFAA acetone solution added. After the time indicated in Table 7, 1 ml of 0.5*M* NaI in acetone was added. After gentle mixing for 1 min the contents were diluted with 20 ml of 0.1*M* KI and titrated at once with sodium thiosulphate. At the end of the titration, starch was added.

*Mass spectrometric investigations.* Nitroxide radicals **1** or hydroxylamines **2** (0.1 mmol in 1 ml of a 0.1*M* solution) were placed into a Wheaton 2 ml micro product V-vials, equipped with a spin vane and treated with corresponding components of the TFAA-I reagent (Table 2). The reaction mixtures were stirred at ambient temperature for the time indicated in Table 2 and analyzed by means of GC/EIMS.

These reaction mixtures according to the mass spectrometric analysis exhibited corresponded to 1-trifluoroacetoxy-2,2,6,6-tetramethylpiperidines (**2A**). 1-Trifluoroacetoxy-2,2,6,6-tetramethylpiperidine (**2Aa**, R = R′ = H) was detected in the reaction mixtures in experiments (1), (2) and (7). 1-Trifluoroacetoxy-4-oxo-2,2,6,6-tetramethylpiperidine (**2Ac**, R = R′ = 0) was found in the reaction mixtures of the experiments (5) and (6). 1,4-Di(trifluoroacetoxy)-2,2,6,6-tetramethylpiperidine [**2Ab**, R = H, R′ = $CF_3C(O)O$] was found in the reaction mixtures of the experiments (3), (4) and (8). The partial mass spectra (EIMS) of derivatives **2Aa–c** are presented in Table 1.

Nitroxide radicals **1** (100 μmol) were treated with: (a) 800 μmol of acylating agent and 500 μmol of sodium iodide, or (b) 1 ml (17.5 mmol) of glacial acetic acid and 500 μmol of sodium iodide (as above), respectively, and iodine was determined after the indicated exposure time.

## RESULTS AND DISCUSSION

The reaction of the TFAA-I reagent with nitroxide radicals **1** occurs with the formation of *N*-trifluoroacetyloxy-2,2,6,6-tetramethylpiperidines (**2A**) (confirmed by GC-MS measurements of the reaction mixture, see Experimental) and simultaneous release of elemental iodine (equation 1). The results of the titrimetric investigations on the reaction of nitroxide radicals with the TFAA-I reagent and the related systems are presented in Table 4. These results reveal that the rate of iodine formation is strongly influenced by nitroxide radical structure. Thus, the reactivity of TEMPO radical (**1a**) appears to be higher than that 4-oxy-TEMPO (**1c**) which in turn is more reactive than 3-carbamoyl-PROXYL radical (**1d**). The comparison of the activities of various reagents towards nitroxide radicals reveals the distinct differences in the application of the acyl reagent-NaI systems, suggesting the dominating role of the acylation stage on the general course of the reaction.

Consequently, the nitroxide radicals are not reduced by the $Ac_2O$–NaI reagent. The similar 'acylation powers' of acetyl chloride and trifluoroacetic anhydride are reflected by the similar results of nitroxide radicals reductions by means of the TFAA-I and AcCl–NaI systems. The nitroxides reductions occur also when they are carried out in AcOH–NaI acetone solution. In this case the reduction is slower in spite of *ca.* 20-fold excess of acetic acid in comparison with trifluoroacetic anhydride (TFAA) used. The lower reaction rate is also observed for the reagents based on benzoyl chloride, *p*-toluenesulphonyl chloride and methanesulphonyl chloride and sodium iodide. This effect can be explained by the stabilization of the intermediate radical cation **1A** formed, caused by the benzoyl and also the sulphonyl substituents.

These results illustrate superiority of the TFAA-I in comparison with other presented reagents in analytical application, especially that the alternative AcCl-NaI system cannot be applied for the spectrophotometric determination of nitroxide radicals owing to a high blank level (Fig. 1). For reasons analogous to these discussed in our former paper on application of the TFAA-I reagent (Ref. 16), we have used a minimum of a 4-fold molar excess of TFAA and a 2.5-fold molar excess of NaI for the determination of nitroxide radicals on a μmol scale (iodometric titration procedure). The results of the iodometric and spectrophotometric determination of nitroxide radicals **1** are summarized in Tables 2, 5 and 6.

The iodometric titration of the iodine released permits one to determine nitroxide radicals at

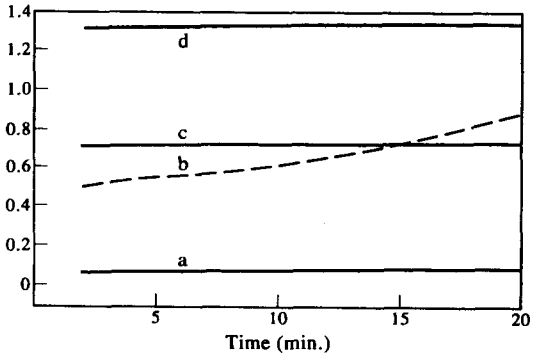

Fig. 1. The dependence of released iodine quantity as a function of time: (a) standard solution of TFAA-I (without nitroxide radical), (b) solution of 1 ml of a 0.5 ml solution of sodium iodide and 0.1 ml of a 0.5*M* solution of acetyl chloride in 10 ml of acetone, (c, d) standard reaction mixtures containing 500 nmol (c) or 1000 nmol (d) of nitroxide radical **1a** in 10 ml of acetonic solutions.

| | 1 | 100.0 | 98.0‡ | −2.5 | 0.0067 |
| | 1 | 200.0 | 195.0‡ | −2.5 | 0.0050 |

The determinations of iodine were performed after addition to the nitroxide radical solutions the following amounts of reagents:
*0.8 mmol of TFAA and 0.5 mmol of NaI,
†1.6 mmol of TFAA and 2.0 mmol of NaI,
‡0.8 mmol of AcCl and 0.5 mmol of NaI.

the 40–1000 μmol level with an average deviation up to ±2.8% (RSD 0.0018–0.0094). This method is especially recommended for the fast and accurate determination of nitroxide radicals (*e.g.* determination of purity of **1**, see Table 6).

For kinetic reasons, a 100-fold molar excess of TFAA-I has been applied for the determination of nitroxide radicals on a nmol scale (spectrophotometric procedure). Consequently, the blank correction is only required in the spectrophotometric procedure since the iodine from air oxidation constitutes, in this case, a substantial part of the total released iodine. In fact, examination of the course of iodine release as a function of time (Fig. 1), reveals that the reaction is complete in a short time (dependent on the structure of the nitroxide radical) after mixing of the solutions, with gradual subsequent increase of the iodine level caused by a side oxidation ($A = 0.02$–$0.03$ in 20 min). For this reason the blank reaction is run separately and its absorbance ($A_0$) is subtracted from that for the nitroxide radical determination ($A$). The very low molecular absorbances of nitroxides **1** and hydroxylamine-*O*-trifluoroacetates (**2A**) in the analytical wavelength region (Fig. 2) practically eliminates the requirement of additional correction of absorbance. The results of the spectrophotometric determinations of nitroxide radicals **1** are given in Table 3. This spectrophotometric method permits the determination of nitroxide radicals (equivalent to released iodine) at the 100–1000 nmol level in standard ($l = 1$ cm) and at the 20–100 nmol level using cuvettes with light path $l = 5$ cm. The average deviation of these determinations is ±3% (for the level 20 nmol, 4.5%) and RSD 0.018–0.092. The sensitivity of this method seems comparable with the sensitivities offered by EPR techniques (Fig. 2), additionally presenting better versatility and simplicity of measurements.

Table 6. Determination of purity of nitroxide radicals **1a–c**

| Nitroxide radical **1** (100 *μmol*) | | Number of crystallization I | II | III | Literature[1] m.p. (°C) |
|---|---|---|---|---|---|
| **1a** | m.p. (°C) | 33.5–35.0 | 35.0–36.5 | 36.0–37.0 | 36–38 |

| | purity (%) | 97.5 | 99.0 | 99.5 | |

*According to the iodometric titration procedure

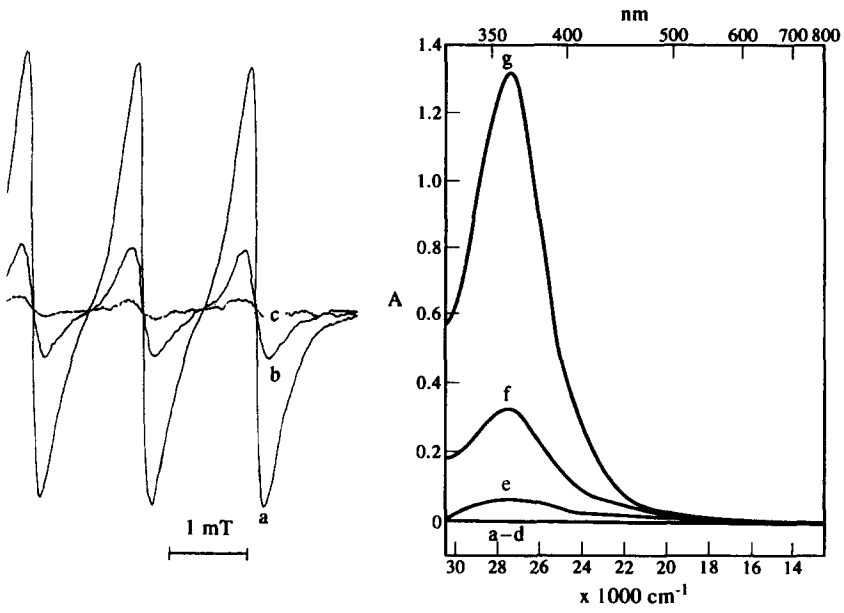

Fig. 2. UV and EPR spectra: (a–c) solutions of nitroxide radical **1a** containing 1000 nmol (a), 200 nmol (b), and/or 8 nmol (c) of **1a** in 10 ml of acetone, (d) $1 \times 10^{-4}M$ solution of *N*-trifluoroacetyloxy-2,2,6,6-tetramethylpiperidine (1000 nmol of hydroxylamine **2a** and 0.1 ml of a $0.5M$ solution of TFAA in 10 ml of acetone). (e) standard solution of TFAA-I (without nitroxide radical), (f, g) standard reaction mixtures containing 200 nmol (f) or 1000 nmol (g) of nitroxide radical **1a** (in 10 ml of acetone), respectively.

This reaction has also been examined in respect to the addition order of sub-components of TFAA-I. Thus, if trifluoroacetic anhydride was added first (reverse mode), and after the exposure time (indicated in Table 7) followed by addition of sodium iodide, the quantities of iodine determined decreased with prolongation of the exposure time (see Table 7).

This effect is in accordance with the mechanism of disproportion of protonated free nitroxide radicals (Ref. 17) and was also confirmed by GC-MS measurements of the reaction mixtures of **1** and TFAA (see Experimental). This slow rearrangement of derivatives **1A** creates a possibility for the differentiation of nitroxide radicals **1** and nitrones **3** (Table 7). Thus, in the reverse

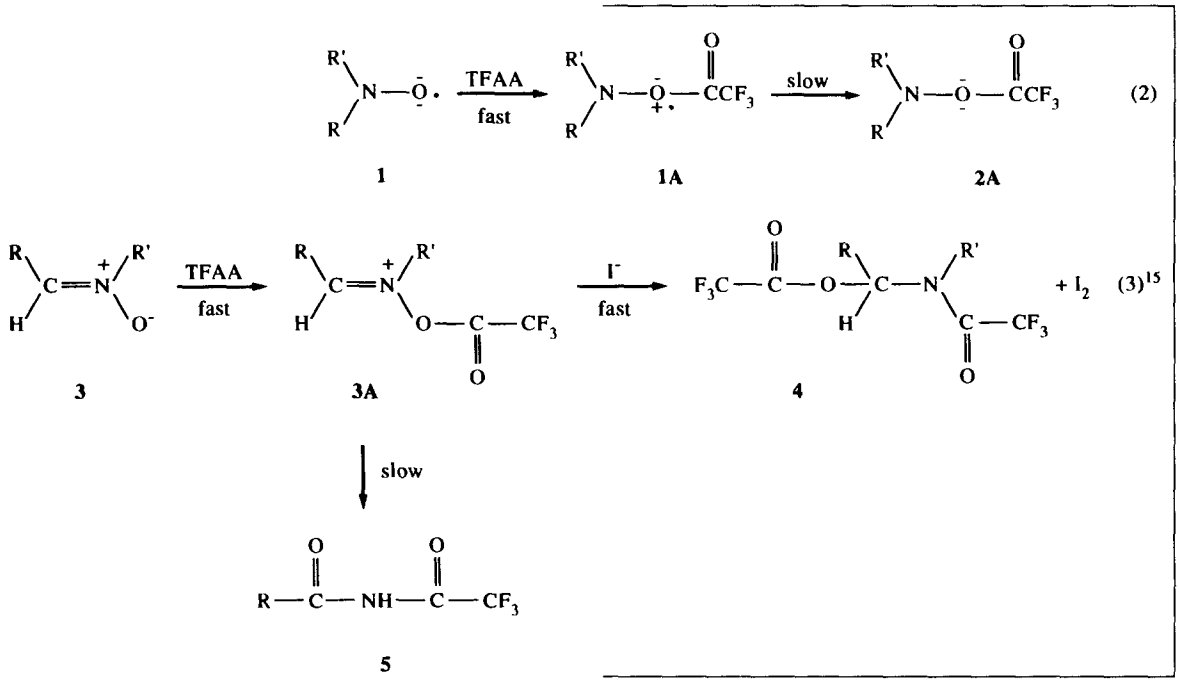
|  | 100 | 98.7 | 97.2 | 94 | 90 | 82 |

*According to the iodometric titration–reverse order procedure

Table 8. Comparison with other methods of nitroxide radicals **1** determination

| Method | Time (*min*) | Range (*mmol*) | Range (*nmol*) | Accuracy (%) | Standard used |
|---|---|---|---|---|---|
| A. Reduction of **1** with KI in glacial acetic acid. Titration of iodine with 0.1*M* $Na_2S_2O_3$.[6] | 30–45 | 1.6–0.7 | | 0.2–0.9 | **1b** and PhC(O)O-TEMPO |
| B. Amperometric titration of **1** with 0.01–0.1*M* cerium (IV) sulphate[7] | | 0.22–0.001 | | 1.1–4.5 | TEMPO and PROXYL radicals |
| C. Prereduction of **1** with ascorbic acid. Redox back titration with standardized solution of iodine[8] | | | | | |
| D. Acylation-reduction of **1** with the TFAA-I or AcCl-I. Iodometric titration with 0.02*M* $Na_2S_2O_3$ (Table 6) | 1–10 | 1.0–0.040 | | 0.1–2.5 | **1a–d** |
| E. Acylation–reduction of **1** with the TFAA-I. Spectrophotometric determination of iodine (Table 2) | 2 | | 1000–20 | 0.1–4.5 | **1a–c** |

mode of the TFAA-I procedure (TFAA is used in the first stage, followed by addition of NaI) (equations 2 and 3), the corresponding *N-O*-trifluoroacetyl derivatives **1A** and **3A**, formed during the treatment of **1** and **3** by means of TFAA, rearrange at different rates to **2A** and **5**, respectively, which are not able to oxidize the iodide anion.[15,16] (The mechanism of the reaction of nitroxide radicals **1** with the TFAA-I and related reagents is under investigation.)



As the reaction **3A** → **5** proceeds much faster than the reaction **1A** → **2A**, the application of this reverse order procedure permits at least the differentiation of these types of *N*-oxy compounds (Ref 12 and Table 7).

A comparison of these methods with other published procedures of determination of nitroxides is presented in Table 8.

# SLURRY-ELECTROTHERMAL ATOMIC ABSORPTION SPECTROMETRIC DETERMINATION OF ALUMINIUM AND CHROMIUM IN VEGETABLES USING HYDROGEN PEROXIDE AS A MATRIX MODIFIER

P. VIÑAS, N. CAMPILLO, I. LOPEZ GARCIA and M. HERNANDEZ CORDOBA*

Department of Analytical Chemistry, Faculty of Chemistry, University of Murcia, E-30071 Murcia, Spain

(*Received* 14 *June* 1994. *Revised* 30 *September* 1994. *Accepted* 30 *September* 1994)

**Summary**—Fast heating programmes for determining aluminium and chromium in vegetables using electrothermal atomic absorption spectrometry with slurry sampling are developed using wall atomization. The build-up of carbonaceous residues inside the atomizer is avoided by adding 4% hydrogen peroxide and 1% nitric acid to the slurries instead of using an air-ashing stage. In accordance with fast-programme methodology, the conventional drying and charring steps are replaced by a modified drying stage, simplifying the heating programmes. For suspensions containing 0.1% m/V of ground vegetables, the relative standard deviation (RSD) is about ±5% for aluminium. For chromium determination, the use of 0.5–1% m/V suspensions leads to RSDs close to ±4%. Calibration is carried out using aqueous standards. The aluminium and chromium contents of a number of vegetable samples obtained by using the slurry approach agree with those obtained by means of a conventional procedure based on the total dissolution of the samples. The reliability of the procedures is also confirmed by analysing two certified reference materials.

Aluminium is one of the most common elements in the earth and relatively high levels are found in vegetables which could have a potential impact on the environment, animals and man. Chromium is present at low levels and may be toxic if certain limits are exceeded. The dissolution of chromium from stainless steel which is widely used in the food industry, is probably the main source of chromium contamination of food.[1] Electrothermal atomization atomic absorption spectrometry (ETAAS) can be used to determine both elements and a number of papers concerning the determination of aluminium[2–12] and chromium[12–18] in foods and biological samples by ETAAS have been published.

However, the dissolution of samples for analysis in the conventional ETAAS practice is a long and tedious process. When a suitable particle size for solid samples can be attained,[19,20] the use of suspensions has proved useful for ETAAS purpose because, in addition to a considerable saving of time and effort, there is a smaller risk of contamination and loss of analyte. One practical problem associated with the atomization of suspensions prepared from biological materials is the build-up of carbonaceous residues inside the tube, which, in some instances, can even block the light beam. This can be avoided by using an air-ashing step,[17,21,22] although old electrothermal atomizers do not permit this. As has been recently reported,[23–25] the addition to the slurry of a chemical oxidant can also alleviate this problem since the action of the chemical during the heating cycle has a similar effect to that exercised by the air-ashing step. This method of decreasing the accumulation of organic residues can be of practical interest, since it allows a number of low-cost or old instruments to be used in slurry-ETAAS analyses of materials with a high organic content.

This simple approach together with heating programmes based on fast-programme methodology[26–28] are used in this study to develop procedures for the rapid determination of aluminium and chromium in vegetables. The reproducibility and accuracy of the results in a wide variety of vegetable matrices are studied and two reference materials are analysed to confirm the reliability of the proposed methods.

## EXPERIMENTAL

### *Instrumentation*

A Perkin-Elmer Model 1100B atomic-absorption spectrometer equipped with deuterium-arc background correction and an HGA-400 electrothermal atomizer were used. The measurements were made using hollow cathode lamps operated at 15 and 10 mA lamp currents, 0.7 nm slits and 309.3 and 357.9 nm wavelengths for aluminium and chromium, respectively. Wall-atomization was used for both elements using Perkin-Elmer pyrolytic graphite coated tubes (Part number B013-5653). Background-corrected integrated absorbance was used as the analytical signal. Argon (purity higher than 99.999% SEO, Spain) was used as the inert gas, the flow-rate being 300 ml/min during all stages except during atomization, when the flow was stopped for chromium. In some instances, a miniflow of 30 or 100 ml/min was maintained during aluminium atomization to decrease sensitivity. A Branson ultrasonic bath of 14 W constant power was used. A Fritsch ball-mill of 80 ml capacity with 20 agate-balls of 1 cm diameter was also used.

### *Reagents*

High quality water obtained using a Milli-Q system (Millipore) was used throughout. All glassware, plasticware, storage bottles and pipette tips used were previously immersed for several hours in a 20% v/v nitric acid solution and then rinsed with water. Aluminium-free paper was used for cleaning pipette tips. Stock solutions of aluminium and chromium (1000 $\mu$g/ml) were obtained from Panreac (Spain) and diluted as necessary to obtain working standards. High quality ethanol (Riedel-deHaër), concentrated (65% m/V) nitric acid (Merck), perchloric acid (Probus, Spain) and 30% m/V hydrogen peroxide (Fluka) were used as received.

### *Analytical procedures*

The vegetables were obtained from a local supermarket, washed repeatedly with pure water, chopped and oven-dried at 90°C. The dried samples were first ground in a domestic grinder for 15 sec and then in a ball mill for 15 min. No sieving was carried out.

Suspensions were prepared by adding 2 ml ethanol, 1 ml hydrogen peroxide and 0.25 ml concentrated nitric acid to the ground sample (typical amounts ranged between 10 and 500 mg, depending on the metal and its level in the sample), the solution being finally diluted up to 25 ml. The use of a high speed tissue homogenizer was discarded because of the high contamination observed for both elements. The suspensions were submitted to ultrasounds for 5 min and then magnetically stirred for another 10 min. The same practical results were obtained by using a manual homogenizer with teflon pestle and glass tube. While the suspensions were being continuously stirred, 20 $\mu$l aliquots were taken and injected into the furnace. The heating programmes given in Table 1 (where the quoted temperatures are values set on the HGA-400 power supply) were run and the background corrected peak areas due to the analytes obtained. Calibration was performed by injecting aqueous standards under the same experimental conditions. Certified reference materials were analysed in the same way.

The samples were previously analysed for comparison purposes. Fractions of 0.2–1 g of the dried, ground vegetables were calcined at 500°C for 8 hr. The ashes were treated with 5 ml nitric acid, heated to dryness and then again treated with 2 ml nitric acid and 2 ml perchloric acid before heating to almost dryness; 2 ml hydrogen peroxide was then added and, after the digestion was complete, the solution was diluted with water and evaporated to reduce acidity, and finally diluted up to 50 or 100 ml with water. Aliquots of 20 $\mu$l were directly injected into the furnace to obtain signals within the linear response range.

## RESULTS AND DISCUSSION

The use of STPF conditions for aluminium determination is widely recommended,[4,11,29] although this is far from being a general rule.[5,30,31] This is not surprising since in those cases where the analyte requires a high atomization temperature, as occurs with aluminium, and depending on the type of sample, the same

*Aluminium, argon flow, 30 ml/min.
†Chromium, the gas flow was stopped.

practical results can be obtained by using wall atomization or platform atomization.[32,33] For this reason and because of the saving which can be made by using pyrolytic tubes instead of the more expensive platforms for routine purposes, the procedure here studied was optimized by comparing the results obtained with both atomization modes.

Since some of the samples analyzed had too high an aluminium content, it was necessary to reduce the sensitivity. For this purpose, alternative lines or a low-flow of the purge gas during the atomization stage were tried.[34] Wavelengths below 300 nm produced a sufficient decrease in sensitivity; however, the radiation intensity was very low and showed poor signal/background ratios, thus diminishing the reproducibility. The 396.2 nm line permits the calibration range to be extended[31] but the reduction in sensitivity[35] is only about 20%. The sensitivity could also be decreased[34] by about 50% by using the 394.4 nm line, but this was still insufficient for the purpose desired. On the other hand, better results were obtained when, operating at 309.3 nm, the argon flow was not fully stopped at the atomization step. Figure 1 shows the results obtained using alternative lines and the effect of the purge gas flow for a vegetable slurry. A flow ranging from 30 to 300 ml/min was selected. This permitted the analysis of all the samples with their very different aluminium contents without the necessity of preparing extremely diluted suspensions with their inherent problem of poor reproducibility.

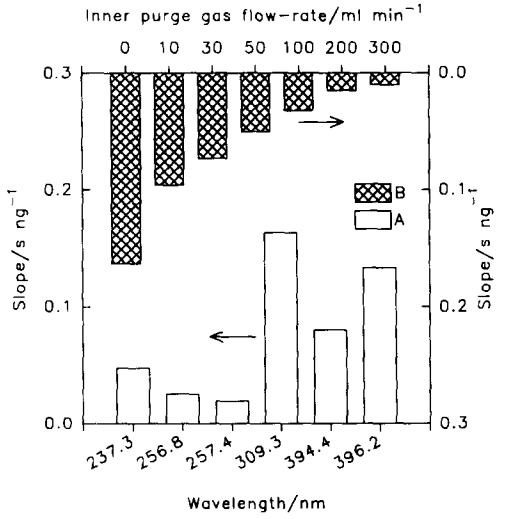

Fig. 1. Effect of different wavelengths (A) and argon flow rate (B) during the atomization step on the slope of aluminium calibration graphs.

*Composition of the suspension medium*

Preliminary experiments concerning aluminium quantification in different samples and reference materials using water as the suspending medium led to standard additions graphs with no reproducible slopes, most of the results being too high for the aluminium content. In addition, the slopes of calibration addition graphs (additions of suspension to a reference solution) were different to those shown by standard additions lines, confirming the unreliability of the results obtained. Similar results were obtained when either wall or platform atomization were used. To overcome these difficulties, the use of several chemical modifiers [$Mg(NO_3)_2$, $Pd(NO_3)_2$, $NH_4H_2PO_4$, $K_2Cr_2O_7$, $NH_4NO_3$] was tried, and again, the results obtained when using both atomization modes differed from the true values and an increase in the absorption background, as has been previously reported,[33] was observed. A number of additional experiments showed that sulphate and halides could be discarded as the cause of the poor results. The non-reproducible slopes are possibly a result of the formation of colloidal aluminium compounds,[31] as is suggested by the fact that only the addition of nitric acid to the suspension medium[2,4,5,30,36,37] led to the correct results being obtained. Apparently, in addition to extracting a fraction of the analyte into the supernatant, nitric acid plays an important role in reproducibility.[36] A detailed study was carried out using a 0.5–5% concentration range of nitric acid in the suspension medium. With concentrations at or above 1% the slopes of standard additions calibration graphs obtained using either of the atomization modes were reproducible and practically identical to those obtained for aqueous standards, leading to correct results for the aluminium content. Other authors[4] used higher percentages of acid (5% of $HNO_3$), which also led to exact results. In our opinion, to enlarge the useful lifetime of the pyrolytic material, it is preferable to maintain the nitric acid concentration as low as possible and so a 1% acid in the suspension medium was selected as adequate.

The direct atomization of suspensions prepared from the ground vegetable samples produced an accumulation of carbonaceous residues inside the atomizer. Thus, a periodic cleaning of the tube was necessary.[2,3] This effect was more marked for concentrated suspensions. Since the only electrothermal atomizer available

did not permit an air-ashing stage to be included in the programme, a recently reported[23–25] simple approach based on the addition of hydrogen peroxide to the suspension medium was used. The combination $H_2O_2$–$HNO_3$ proved an adequate suspension medium for biological materials, thus acting as a true chemical modifier during the drying step. When 4% $H_2O_2$ and 1% $HNO_3$ were used, the carbonaceous residues remaining after the atomization step practically disappeared, the background signals obtained were very low and a mechanical cleaning of the inside of the graphite tube was only needed occasionally. It must be noted that most of the experiments were performed using percentages of solid matter below 1% in the suspension medium. Thus, after 50 injections of 20 $\mu$l of a 0.5% suspension, no carbonaceous residue was observed. When the suspension concentration was higher than 1%, the optimal oxidant concentration had to be reconsidered. Ethanol (8%) was added to the suspensions to aid dispersion of particles, although aliquots were hand-pipetted while solutions were magnetically stirred.[24]

For the determination of chromium, the same suspension medium as was used for aluminium is recommended, thus standardizing both procedures.

*Optimization of furnace programmes*

Since the preliminary experiments showed that the action of hydrogen peroxide together with the use of diluted suspensions led to low background signals, the heating cycles were optimized by means of fast-programme methodology.[26–28] For aluminium, the conventional drying and ashing steps were replaced by a modified drying stage performed at 200°C during 20 sec for wall atomization and 400°C during 30 sec for platform atomization. The atomization temperature was studied in the 1800–2650°C range (Fig. 2). The maximum signal was reached at 2300 and 2600°C for wall (curve A) and platform (curve B) atomization, respectively. Using these temperatures, the appearance time of the signals were 1.4 and 2.6 sec, respectively. Our experience has shown that when using platform atomization at temperatures higher than 2500°C, the useful lifetime of the atomizers was about 200 and 300 firings for standard and fork platforms, respectively, whereas the lifetime of tubes operating at the same temperature was much higher. Since the results obtained were similar as regards sensitivity and precision when

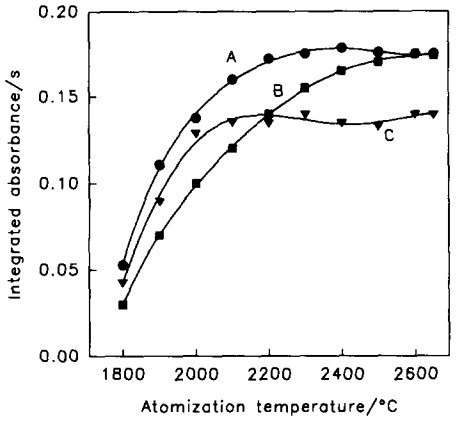

Fig. 2. Influence of the atomization temperature on the peak area signals for Al using wall (A) and platform (B) atomization and Cr using wall atomization (C).

either atomization mode was used, wall atomization was finally selected to cut costs. Although the gas flow was not stopped during atomization, a partial condensation of the analyte in the cold zones of the atomizer might have produced cross-contamination.[38] To avoid this problem, a temperature of 2500°C was selected. By means of a second firing it was verified that the amount of aluminium remaining inside the atomizer was negligible. A cleaning stage at 2650°C was also included in the programme.

In a similar way, the programme for chromium was optimized. In this case, when using a platform, the holding time during the atomization stage had to be at least 7 sec, which shortens the lifetime of the atomizer. In addition, the signal showed a tail, which became more marked with the aging of the platform. Consequently, wall atomization was again selected. Maintaining a drying temperature of 200°C for 20 sec, the atomization temperature was varied from 1800 to 2650°C (Fig. 2, curve C). The peak area increased up to 2100°C and a 2300°C value was selected since higher temperatures distorted the peak profiles. In this case, the argon flow was stopped during the atomization step owing to the lower sensitivity for chromium and the lower content of this element in the samples. A cleaning stage was also included to avoid the carryover of chromium. The final furnace programmes are given in Table 1.

*Extraction of the analyte into the aqueous phase*

As previously described[5,23,24] when dealing with slurries there is generally a partial

Table 2. Extraction of aluminium and chromium from a bean leaves slurry by addition of nitric acid

| Nitric acid (%) | % Extraction | |
|---|---|---|
| | Aluminium | Chromium |
| 0.0 | 34.7 | 45.0 |
| 0.4 | 79.9 | 61.8 |
| 1.0 | 78.0 | 76.0 |
| 2.5 | 81.9 | 81.4 |
| 5.0 | 84.8 | 82.2 |
| 10.0 | 84.6 | 84.7 |

extraction of the analytes into the aqueous phase of the suspension. Table 2 shows the extraction percentages obtained from bean leaves suspensions containing 4% hydrogen peroxide in a 0–10% nitric acid range. The samples were magnetically stirred for 15 min at room temperature and aliquots were centrifuged to allow all the solids to settle out. The supernatant liquid fraction was then injected into the furnace. Values significantly increased in the presence of nitric acid. The high extraction percentage (approximately 75% of the Al and Cr were in the liquid phase for 1% acid) meant that the reproducibility was less dependent on the number of particles sampled in each injection and, consequently, led to a better precision.

Although analyte extraction was also possible with other acids (HCl, HF, $HClO_4$, $H_2SO_4$), interferent effects appeared in the determination of aluminium.[28,38] Chloride and fluoride produced a decrease in the analyte signal in both the suspension and the supernatant due to the formation of volatile halides, which decreased the atomic density in the atomization stage.

*Influence of the slurry concentration*

The precision of the procedure was studied using different slurry concentrations ranging between 0.007 and 0.16% for aluminium and 0.04–2.0% for chromium in cauliflower (80 and 1.9 $\mu$g/g of Al and Cr, respectively). Figure 3 shows the concentration ranges in which a linear response for the Al (Fig. 3a) and Cr signals (Fig. 3b) were obtained. In each case, the mean value and the standard deviation calculated for 10 replicate determinations for each slurry concentration are given. In addition, a bar graph showing the relative standard deviations is also presented. Two successive atomization steps were performed to check that aluminium was

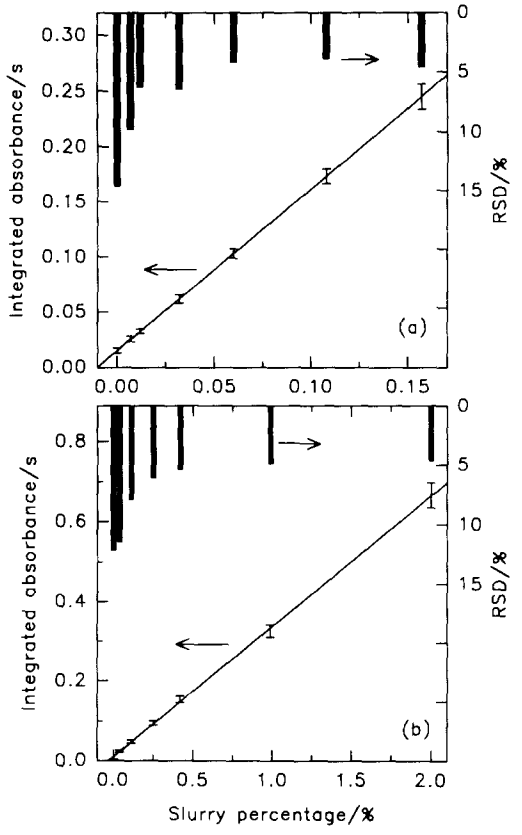

Fig. 3. Effect of the suspension concentration on the signal obtained for (a) Al and (b) Cr. Bar graphs indicate RSD values.

not retained in the tube. RSD values were below ±7%, except for very diluted suspensions, which gave peak area signals lower than 0.05 sec. Optimal slurry percentages ranged from 0.03 to 0.15 and 0.3–2.0% for Al and Cr, respectively.

*Calibration and results*

Figure 4 shows absorbance–time profiles (solid lines) for aluminium and chromium resulting from the analysis of vegetable slurries. These plots were similar to those observed for simple aqueous standards, indicating that the effect of chemical interferences due to the matrix was negligible. The background signals were very low (dotted lines). The standard additions method was also used to investigate the possibility of interference by the matrix. Each graph was constructed from five points and each point was measured three times. The slopes of the aqueous standards and standard additions graphs were similar, confirming the absence of interference from the matrix and showing that the method permitted

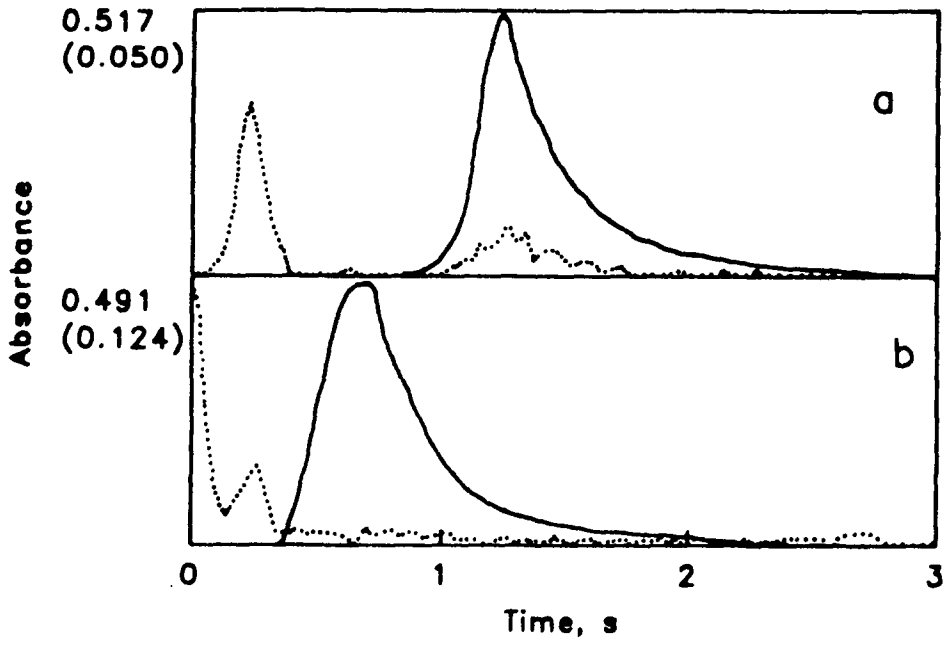

Fig. 4. Atomization profiles (solid lines) of Al obtained from a 0.1% bean leaves slurry (a) and Cr obtained from a 0.92% cauliflower slurry (b). The dotted lines give the background absorbance.

aqueous standards to be used for calibration. The proposed slurry procedures were applied to a wide range of vegetable materials. Results for aluminium and chromium are included in Table 3, showing the comparative results obtained by the slurry methods and those obtained with a conventional procedure based on dry-ashing and acid dissolution. All values are in good statistical agreement. The methods were validated using two certified reference materials and good concordance with the certified values was obtained. To discard the possible effect of contamination due to grinding, these certified materials were analysed both as received and after a grinding stage identical to that applied to the samples, no differences being noted.

A graphic comparison of the results obtained by the proposed procedures and those certified or obtained by mineralization led to correlation graphs which parameters showed no significant differences with the hypothetical values. Results of ordinate $\pm$ confidence interval (CI, 95%) for Al and Cr were $0.015 \pm 1.125$ and $0.037 \pm 0.072$ $\mu$g/g, respectively. Slope $\pm$ CI (95%), were $1.0023 \pm 0.0298$ and $1.0090 \pm 0.0809$ for Al and Cr, respectively.

Table 3. Aluminium and chromium contents in vegetables

| | Aluminium ($\mu g/g$) (mean $\pm$ SD) | | Chromium ($\mu g/g$) (mean $\pm$ SD) | |

## CONCLUSION

The determination of aluminium and chromium was carried out using the slurry technique for the direct analysis of vegetables, and proved an alternative method to the introduction of solutions in ETAAS for routine analysis. Sample preparation was very simple, thus avoiding any risk of contamination. The use of fast-programme methodology led to a considerable saving of time. No advantages were noted for platform atomization and so, wall atomization was used. Addition of both hydrogen peroxide and nitric acid to the slurry eliminated the build-up of carbonaceous residues inside the tube, and there was no need of an air-ashing step.

# THERMODYNAMICS OF FORMATION OF UREA COMPLEXES WITH MANGANESE(II), NICKEL(II) AND ZINC(II) IONS IN *N,N*-DIMETHYLFORMAMIDE

KAZUHIKO OZUTSUMI*, YOKO TAGUCHI and TAKUJI KAWASHIMA

Laboratory of Analytical Chemistry, Department of Chemistry, University of Tsukuba, Tsukuba 305, Japan

(*Received* 28 *April* 1994. *Revised* 28 *July* 1994. *Accepted* 5 *October* 1994)

**Summary**—The complexation of urea (ur) with manganese(II), nickel(II) and zinc(II) ions has been studied by titration calorimetry in *N,N*-dimethylformamide (DMF) containing 0.4*M* $(C_2H_5)_4NBF_4$ as a constant ionic medium at 25°C. The calorimetric data were well explained in terms of the formation of $[Mn(ur)]^{2+}$, $[Mn(ur)_2]^{2+}$ and $[Mn(ur)_4]^{2+}$ for manganese(II), $[Ni(ur)]^{2+}$ for nickel(II) and $[Zn(ur)]^{2+}$ and $[Zn(ur)_2]^{2+}$ for zinc(II), and their formation constants, reaction enthalpies and entropies were determined. The complexation of the nickel(II)-urea system in DMF has also been studied by means of spectrophotometric titration and electronic spectra of individual nickel(II) complexes were determined. On the basis of the stepwise thermodynamic quantities and the individual electronic spectra of the complexes, it is revealed that the $[Mn(ur)]^{2+}$, $[Mn(ur)_2]^{2+}$, $[Ni(ur)]^{2+}$, $[Zn(ur)]^{2+}$ and $[Zn(ur)_2]^{2+}$ complexes have a six-coordinate octahedral structure, while the $[Mn(ur)_4]^{2+}$ complex has a four-coordinate tetrahedral structure.

Complexation of metal ions with anions is more enhanced in aprotic solvents such as *N,N*-dimethylformamide (DMF), dimethyl sulfoxide, pyridine and acetonitrile than in water, regardless of their different electron-pair donating abilities.[1–4] Large and positive entropies are usually associated with the complexation in the aprotic solvents. These are a result of the enhanced solvation of anions in water, *i.e.* hydrogen bonding of the ions with water molecules, compared with that in aprotic solvents, and also of the hydrogen-bonded water structure in the bulk, *i.e.* entropies of reactions in nonaqueous solvents are closely related with structures of solvents. However, studies on complexation of metal ions with neutral ligands are rather limited in nonaqueous solution. Extended works including various neutral ligands are necessary to elucidate thermodynamics of complexation in aprotic solvent.

First row divalent transition metal ions are relatively hard acceptors and prefer a relatively hard donor atom. Relative affinities among halide ions to these metal(II) ions have been studied in aprotic solvent.[5–13] The affinity decreases in the sequence Cl > Br > I and the metal(II) ions really behave as a hard acceptor in aprotic solvent. Knowledge on affinities of various donor atoms to the metal(II) ions must be important in view of hard and soft acids and bases. However, donor atoms other than halide ions have scarcely been examined in nonaqueous media. In this study we focused our attention on urea (ur) and thiourea (tu) and investigated their complexation with manganese(II), nickel(II) and zinc(II) ions in DMF containing 0.4*M* $(C_2H_5)_4NBF_4$ as a constant ionic medium by precise calorimetry at 25°C. The formation of the nickel(II) complexes was also investigated by spectrophotometry.

## EXPERIMENTAL

### *Reagents*

All chemicals used were of reagent grade. DMF solvates of metal(II) tetrafluoroborate were prepared from relevant hydrates of metal(II) tetrafluoroborate and dried *in vacuo* over $P_2O_5$. Urea and thiourea were used without further purification and dried *in vacuo* at room temperature. Tetraethylammonium tetrafluoroborate was recrystallized once from water and dried in a vacuum oven at 100°C. DMF was purified as described elsewhere.[10] All DMF solutions were prepared and treated under a dry nitrogen atmosphere.

*Author to whom correspondence should be addressed.

*Measurements*

Calorimetric measurements were performed at 25°C on a twin-type calorimeter (Tokyo Riko, Japan) and a PC-9801VM computer (NEC, Japan) was used for the calorimeter control and data acquisition.[14] Two Teflon-coated stainless steel vessels were inserted in an aluminium block thermostated at 25°C within ±0.0001°C. A test solution (40 $cm^3$) containing metal(II) tetrafluoroborate in the vessel was titrated with either 0.2 or 0.4*M* urea DMF solution by using an APB-118 autoburete (Kyoto Electronics, Japan) under a dry nitrogen atmosphere. All test solutions contained 0.4*M* $(C_2H_5)_4NBF_4$ as a constant ionic medium. Heats of complexation ranging from 0.4 to 1.0 J at each titration point were measured with an error of ±0.02 J (three standard deviations). Heats of dilution of titrants were measured by titrating a 0.4*M* $(C_2H_5)_4NBF_4$ DMF solution with either 0.2 or 0.4*M* urea DMF solution.

Spectral changes with varying ligand concentrations for nickel(II) urea DMF solutions were measured on a UV-2100 spectrophotometer (Shimadzu, Japan). The spectrophotometer was controlled with a PC-9801VM computer, which also stored absorbance data in 1 nm interval over the wavelength range 300–850 nm. A nickel(II) tetrafluoroborate DMF solution was placed in a reaction vessel with a thermostated water jacket and titrated with 1*M* urea solution by using an autoburet under a dry nitrogen atmosphere. The reaction vessel was connected to a flow cell with a light path length of 1 cm through Teflon and glass tubes. Absorbances were measured with an error of ±0.006 (three standard deviations). Spectrophotometric data at selected 50 wavelengths were used for a subsequent least-squares calculations.

*Data analysis*

The overall formation of complexes between the divalent metal ion ($M^{2+}$) and ligand (L) can be defined as equations (1) and (2), considering the formation of only mononuclear species.

$$M^{2+} + nL = [ML_n]^{2+} \quad (1)$$

$$\beta_n = [ML_n^{2+}]/[M^{2+}][L]^n. \quad (2)$$

The concentrations of free $M^{2+}$ and L are related to their total concentrations, $C_{M,i}$ and $C_{L,i}$, in a solution $i$ by the following mass-balance equations.

$$C_{M,i} = [M^{2+}]_i + \Sigma\beta_n[M^{2+}]_i[L]_i^n \quad (3)$$

$$C_{L,i} = [L]_i + \Sigma n\beta_n[M^{2+}]_i[L]_i^n. \quad (4)$$

A heat $q_i$ measured at a titration point $i$ is represented by the overall formation constant $\beta_n$ and the enthalpy $\Delta H^0_{\beta n}$ of $[ML_n]^{2+}$ as equation (5),

$$q_i = -(V_i\Sigma\beta_n(\Delta H^0_{\beta n})[M^{2+}]_i[L]_i^n - V_{i-1}\Sigma\beta_n(\Delta H^0_{\beta n})[M^{2+}]_{i-1}[L]_{i-1}^n), \quad (5)$$

where $V_i$ denotes the volume of the test solution.

Similarly, an absorbance $A_{ij}$ measured in a solution $i$ at a given wavelength $\lambda_j$ is expressed by the formation constant $\beta_n$ and the molar absorption coefficient $\epsilon_n(\lambda_j)$ as equation (6).

$$A_{ij} = \Sigma\epsilon_n(\lambda_j)\beta_n[M^{2+}]_i[L]_i^n + \epsilon_M(\lambda_j)[M^{2+}]_i + \epsilon_L(\lambda_j)[L]_i. \quad (6)$$

Formation constants and enthalpies were obtained simultaneously by minimizing the error-square sums $\Sigma(q_{i,obsd} - q_{i,calcd})^2$, and formation constants and molar absorption coefficients by $\Sigma\Sigma(A_{ij,obsd} - A_{ij,calcd})^2$ using nonlinear least-squares programs MQCAL and MQSPEC,[15] respectively, which are based on an algorithm proposed by Marquardt.[16]

## RESULTS AND DISCUSSION

Very small heat of complexation other than heat of dilution of titrant was evolved in the course of the titration of the manganese(II), nickel(II) and zinc(II) ions with thiourea in DMF and thus reliable values of the formation constant and enthalpy were not determined. Also, spectrophotometric titration data for the colored nickel(II) thiourea system slightly changed with varying the $C_{tu}/C_{Ni}$ mole ratios, revealing that the formation constants of nickel(II) thiourea complexes are very small. In the following, we describe the equilibria of the urea system.

*Self-association of urea*

Heats of dilution of urea solutions measured by titrating a 0.4*M* $(C_2H_5)_4NBF_4$ solution are endothermic and relatively large (0.5–1 J) as shown in Fig. 1, where the heat of dilution $q$ measured at each titration point is normalized with the volume of the titrant added $\delta v$ and the concentration of urea in the titrant $C_{L,tit}$, and the term $-q/(\delta v C_{L,tit})$ is plotted against $C_L$, where $C_L$ denotes the total concentration of urea in the test solution. Also, the endothermicity appreciably increases with increasing the concentration of the titrant. The major part of heats

§Standard deviation of the observed heats.

of dilution (0.2–0.4 J) may usually be a result of the partial self-association of solute molecules in the titrant. The titrant solution is diluted to cause the dissociation of the self-associated molecules to monomers when the formation constants of the self-associated molecules are small and/or the concentration of the solute in the test solution is kept low throughout measurements. Since the concentration of urea in the test solution was low enough (less than 0.2*M*) in the present case, the large and concentration-dependent heats of dilution suggest that the self-associated urea molecules do not completely dissociate to monomers by dilution.

Urea molecules three-dimensionally connect each other by forming hydrogen bonds in crystal[17-20] and thus it is plausible that urea molecules associate by hydrogen bonds to form polymeric species in DMF. The calorimetric data in Fig. 1 were then analyzed by considering the formation of sets of polymeric species and the Hamilton *R* factor and standard deviation of the observed heats $\sigma$ were compared (see Table 1). The data were well explained in terms of the dimer formation but the curves calculated with the best-fit parameters obtained by an assumption of the trimer formation considerably deviate from the experimental points. No significant improvement of the *R* and $\sigma$ values resulted by assuming the formation of both dimer and trimer. The least-squares calculation thus leads to a conclusion that urea associates to form dimers in DMF. The solid lines in Fig. 1, calculated using the parameters under dimer in Table 1, well reproduced the experimental points. The $\Delta G^0$, $\Delta H^0$ and $\Delta S^0$ values for the reaction

*Manganese(II) complexes*

Calorimetric titration curves for manganese(II)-urea solutions are shown in Fig. 2(a). In the figure, the term $-q/(\delta v C_{L,tit})$ is plotted against $C_L/C_M$, where $q$ is the heat of reaction uncorrected for the heat of dilution of titrant and $C_M$ denotes the total concentration of the metal ion in the test solution.

The calorimetric titration curves were analyzed by assuming the formation of various sets of mononuclear complexes. The dimer formation of urea was taken into account and the formation constant and enthalpy were fixed at the values described above during the least-squares calculations. The results are compared in Table 2. The calorimetric titration curves were not reproducible by an assumption of the formation of two complexes, $[Mn(ur)]^{2+}$ and $[Mn(ur)_2]^{2+}$, owing to large $R$ and $\sigma$ values [see set (1, 2) in Table 2]. Sets (1, 2, 3), (1, 2, 3, 4) and (1, 2, 4), which assume the formation of $[Mn(ur)_3]^{2+}$ and/or $[Mn(ur)_4]^{2+}$ in addition to $[Mn(ur)]^{2+}$ and $[Mn(ur)_2]^{2+}$, gave appreciably smaller $R$ and $\sigma$ values than the set (1, 2). The $R$ and $\sigma$ values for the set (1, 2, 4) are slightly larger than those for the sets (1, 2, 3) and (1, 2, 3, 4), but the difference among the three sets is marginal. Furthermore, the standard deviations of the formation constants for the set (1, 2, 4) are remarkably smaller than those for the sets (1, 2, 3) and (1, 2, 3, 4). This indicates that the formation of $[Mn(ur)_3]^{2+}$ is very much suppressed. We thus propose the formation of the $[Mn(ur)]^{2+}$, $[Mn(ur)_2]^{2+}$ and $[Mn(ur)_4]^{2+}$ complexes in DMF.

*Nickel(II) complexes*

Calorimetric and spectrophotometric titration data of the nickel(II)-urea system are depicted in Figs. 2(b) and 3(a), respectively. The electronic spectra show a monotonous shift with increasing $C_L/C_M$ in solution. Both calorimetric

and spectrophotometric data were well explained in terms of the formation of $[Ni(ur)]^{2+}$ only (see Table 3). We further considered the formation of $[Ni(ur)_2]^{2+}$. However, no significant decrease in the *R* and $\sigma$ values achieved, suggesting that the formation of $[Ni(ur)_2]^{2+}$ is practically negligible under the experimental conditions examined. Very similar values of the formation constant of $[Ni(ur)]^{2+}$ are obtained by calorimetry and spectrophotometry. The electronic spectrum of $[Ni(ur)]^{2+}$ in Fig. 3(b) shows a very similar pattern to that of the nickel(II) ion having an octahedral $[Ni(dmf)_6]^{2+}$ structure,[21] indicating the same octahedral geometry of $[Ni(ur)(dmf)_5]^{2+}$.

*Zinc(II) complexes*

Calorimetric curves for the zinc(II)-urea system shown in Fig. 2(c) were analyzed by a similar manner to that employed for the manganese(II)– and nickel(II)–urea systems. The results are summarized in Table 4. The calorimetric data were well explained in terms of the formation of $[Zn(ur)]^{2+}$ and $[Zn(ur)_2]^{2+}$ with appreciably small *R* and $\sigma$ values [see set (1, 2) in Table 4]. Slightly smaller *R* and $\sigma$ values were obtained for sets (1, 2, 3), (1, 2, 3, 4) and (1, 2, 4) considering the formation of $[Zn(ur)_3]^{2+}$ and/or $[Zn(ur)_4]^{2+}$ along with $[Zn(ur)]^{2+}$ and $[Zn(ur)_2]^{2+}$, but the difference is not significant. Thus, complexes higher than $[Zn(ur)_2]^{2+}$ are hardly formed under the experimental conditions examined. It is concluded that the zinc(II) ion forms the $[Zn(ur)]^{2+}$ and $[Zn(ur)_2]^{2+}$ complexes in DMF.

*Stepwise thermodynamic parameters and coordination structure*

The thermodynamic parameters for the stepwise formation of the complexes are summarized in Table 5. The species distribution

calculated by using the formation constants is depicted in Fig. 4.

The manganese(II), nickel(II) and zinc(II) ions are present as the hexasolvate $[M(dmf)_6]^{2+}$ in DMF.[21] In the nickel(II)-urea system, the $[Ni(ur)]^{2+}$ complex has an octahedral structure because the electronic spectrum of the complex shown in Fig. 3(b) is very similar to that of octahedral $[Ni(dmf)_6]^{2+}$. The $[Mn(ur)]^{2+}$ and $[Zn(ur)]^{2+}$ complexes also have an octahedral structure because of their similar $\Delta H_1^0$ and $\Delta S_1^0$ values to those of nickel(II), although there is no direct spectrophotometric evidence. Both $\Delta H_2^0$ and $\Delta S_2^0$ values for manganese(II) and zinc(II) are more negative than the $\Delta H_1^0$ and $\Delta S_1^0$ values and this is a normal trend when no change in the coordination structure around metal(II) ion occurs. Thus, it is expected that the six-coordination around the manganese(II) and zinc(II) ions is kept in the $[Mn(ur)_2]$ and $[Zn(ur)_2]^+$ complexes. On the other hand, the $(\Delta H_3^0 + \Delta H_4^0)$ and $(\Delta S_3^0 + \Delta S_4^0)$ values for manganese(II) is more positive than the $\Delta H_2^0$ and $\Delta S_2^0$) values. This indicates that the number of solvent molecules liberated on the formation of $[Mn(ur)_4]^{2+}$ is large. The coordination structure around the manganese(II) ion changes from octahedral to tetrahedral at this step. Thus, we conclude that octahedral $[Mn(ur)(dmf)_5]^{2+}$, $[Mn(ur)_2\text{-}(dmf)_4]^{2+}$, $[Ni(ur)(dmf)_5]^{2+}$, $[Zn(ur)(dmf)_5]^{2+}$ and $[Zn(ur)_2(dmf)_4]^{2+}$ and tetrahedral $[Mn(ur)_4]^{2+}$ are formed in DMF.

The enthalpy changes for the formation of $[M(ur)(dmf)_5]^{2+}$ (M = Mn, Ni, Zn) are all negative in DMF (see Table 5). On the other hand, the heats ascribed to the complexation of the metal(II) ions with thiourea were small but evidently endothermic. Although reliable thermodynamic parameters of complexation have not been determined for the thiourea system, it is thus demonstrated that the manganese(II), nickel(II) and zinc(II) ions prefer oxygen atom to sulfur one and behave as a hard acceptor in DMF.

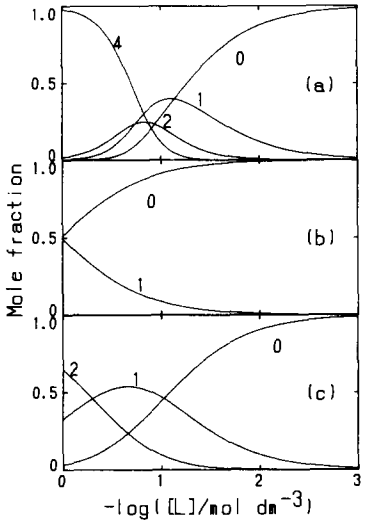

Fig. 4. Species distribution of (a) manganese(II), (b) nickel(II) and (c) zinc(II) urea complexes in DMF. *n* represents $[M(ur)_n]^{2+}$.

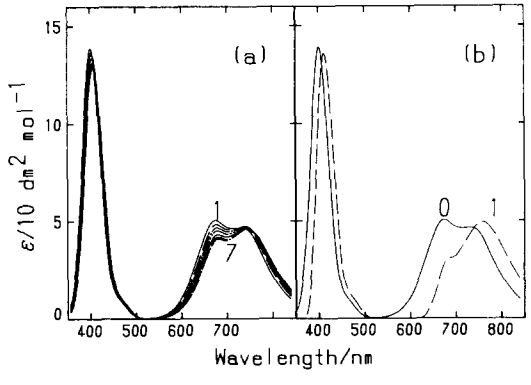

Fig. 3. (a) Typical variation of electronic spectra of nickel(II) urea DMF solutions with varying molar ratios ($C_L/C_{Ni}$) in the range 350–850 nm at 25°C. The total concentrations of nickel(II) and urea, $C_{Ni}$ and $C_L/mM$, in measured solutions are (1) 150.4 and 0, (2) 125.3 and 167.2, (3) 107.4 and 286.6, (4) 93.98 and 376.1, (5) 75.19 and 501.5, (6) 60.15 and 601.8, and (7) 50.12 and 668.7. (b) Electronic spectra of individual nickel(II) urea complexes in DMF. *n* represents $[Ni(ur)_n]^{2+}$.

The entropy changes for the formation of $[M(ur)(dmf)_5]^{2+}$ (M = Mn, Ni, Zn) are nearly zero as seen in Table 5. The DMF molecules in the first coordination sphere within $[M(dmf)_6]^{2+}$ are expected to lose freedom of motion to a considerable extent. The solvating molecules are released from the solvation sphere of the metal(II) ions upon complexation and then enter a structureless bulk solvent to lead to a large entropy gain. In fact, the halogeno complexation of the manganese(II), nickel(II) and zinc(II) ions in DMF is accompanied by a large and positive entropy change,[10–13] as generally seen in aprotic solvent.[1,2] Desolvation of anions also contributes to the positive entropy value of the reaction. Solvation of non-charged molecules is expected to be weaker than that of anions, *i.e.* non-charged molecules may have enough freedom of motion in bulk DMF, and the ligand molecules appreciably lose their freedom of motion upon complexation. Thus, the entropy changes are expected to become a value close to zero as found in the case of the 2,2′-bipyridine complexes with divalent transition metal ions.[22–24]

(*Received* 23 *May* 1994. *Revised* 13 *September* 1994. *Accepted* 30 *September* 1994)

**Summary**—An efficient, real-time chemiluminescence detector for hydrazine vapor, $N_2H_4(g)$, is described, capable of monitoring sub part-per-billion levels of hydrazine in air. The catalytic oxidation of hydrazine by colloidal platinum forms an intermediate, oxidizing agent (*e.g.* ·OH or ·OOH) which subsequently oxidizes luminol, generating a chemiluminescence signal that is proportional to the hydrazine concentration. Major components of the instrument include a photomultiplier tube (PMT), a short length of glass tubing coiled directly in front of the PMT cathode surface, a vacuum pump for sampling the air, and a peristaltic pump for circulating the liquid reagent. The liquid reagent, a basic solution (pH 13) of luminol and colloidal platinum, is continuously recycled. The detection sequence is initiated by pumping the hydrazine vapor through a short length of teflon tubing that is concurrently transporting the liquid reagent. The liquid is separated from the gas stream in an impinger and quickly pumped to the PMT. We have evaluated the effect of solution pH, luminol and platinum concentrations, and air and liquid flow rates on the analytical characteristics of this system. A linear, dynamic detection range for hydrazine has been obtained from 1 to 2000 ppb in air, with an instrument response that is fully reversible and achieves plateau response in less than 2 min.

Hydrazine is a widely used propellant and a common precursor in the synthesis of a number of polymers, plasticizers, and pesticides. Owing to the toxic nature of hydrazine, there is a growing need in both industrial and government laboratories for the development of a highly sensitive, on-line monitor for low levels of hydrazine in air. This need is spurred by the American Conference of Governmental Hygienists' (ACGIH) proposal to lower the threshold limit value (TLV) for hydrazine from 100 ppb to 10 ppb in air.[1] While other analytical techniques have shown success for the detection of hydrazine, none combines the necessary qualities of an inexpensive, on-line, sensitive and selective monitor for hydrazine that is necessary for protecting the safety of workers in hazardous workplace environments. Examples of other techniques which have been used for the detection of hydrazine include coulometry,[2] potentiometry,[3] mass spectrometry,[4] fluorescence,[5] flow injection analysis,[6] and dosimetry.[7]

Chemiluminescence techniques have been successfully applied to the detection of numerous analytes.[8] These methods typically rely upon the oxidation of a chemically reactive species, *e.g.* luminol or lucigenin, and the subsequent emission of a photon from an electronic, excited-state intermediate. Chemiluminescence sensors are free of Raman and Rayleigh scattering, interferences typically associated with fluorescence techniques, thus permitting the operation of a photomultiplier tube at maximum sensitivity. One of the most widely investigated chemiluminescence reagents is 3-aminophthalhydrazide, or luminol. Luminol has been effectively used for the detection of many different metals and oxidants, due to the catalytic behavior these metals have on the chemiluminescent oxidation of luminol. Examples include the detection of Cr(III),[9] Co(II),[10] Fe(II),[11] $H_2O_2$,[12] $NO_2$,[13] and $ClO^-$.[14]

There have been no reports of chemiluminescence methods for the detection of hydrazine vapor, although Faizullah and Townshend report a flow injection analysis scheme based upon hypochlorite for the chemiluminescence detection of hydrazine in solution.[15] Pilipenko and Terletskaya demonstrated that the detection of trace amounts of platinum (0.02 $\mu$g/ml) is possible in a basic solution of lucigenin and hydrazine.[16] They proposed that hydrazine is

*Author to whom correspondence should be addressed.

catalytically oxidized at the surface of colloidal platinum to form a radical, peroxo intermediate. This reactive intermediate subsequently oxidizes lucigenin, allowing for the detection of platinum. Discussion here will center about the analytical feasibility of employing a basic solution of luminol and colloidal platinum for the detection of hydrazine. Chemiluminescence presents the possibility for the development of an inexpensive, on-line monitor of hydrazine that is rapid, sensitive and reversible over a wide dynamic range.

## EXPERIMENTAL

### *Apparatus*

Initial characterization of the hydrazine/Pt/luminol system was performed using an SLM 8000 spectrofluorometer operating in the chemiluminescence mode of measurement. The injection port consisted of a lid with a septum permitting injection of different levels of hydrazine to a 4 $cm^3$ cuvette, while maintaining complete darkness within the sample compartment. A magnetic stirring bar allowed continuous mixing of the reagents. An EMI (PT9635QA) UV/VIS selected photomultiplier tube was used for these experiments, at a potential of 900–1200 V.

The hydrazine vapor detection system (see Fig. 1) consisted of an Anspec 3-Channel peristaltic pump, a vacuum pump (MSA Flow-Lite Turbo) for controlling the air flow from 0 to 5 l./min, and a photomultiplier tube (PMT). A 1000 V power supply was used to drive the PMT, and a Keithley 485 picoammeter was used to monitor the anodic current. National Instruments' LABView for Windows software was used to control the data acquisition from the analog output of the picoammeter to a National Instruments' analog/digital board (Lab-Pc+). Pharmed tubing (a polypropylene-based material with a plasticizer) was used within the peristaltic pump, while all other tubing within the system was teflon PFTE. Tubing distances used were 60 cm for the gas/liquid sampling line leading to the impinger (1/16″ i.d. PFTE), 40 cm for the tubing leading to the PMT (1/8″ i.d. Pharmed), and 480 cm (3/16″ i.d. PFTE) from the PMT back to the air sampling tee.

The hydrazine vapor generation system, which has been described elsewhere, was used to generate hydrazine concentrations from 0 to 2000 ppb in air.[17] This system consisted of a small ampule containing anhydrous hydrazine (Olin Chemicals), immersed in a temperature controlled, water bath (Neslab exacal). The ampule was plugged with a piece of capillary tubing, around which a continuous flow of nitrogen (0.1 l./min) carried away the hydrazine vapor. The final concentration was adjusted by diluting the hydrazine vapor in a stream of air (0.5–10 l./min). The air stream consisted of house air scrubbed to remove water, $CO_2$, $NO_2$ and organic impurities. All flow rates were controlled using Matheson 8200 mass flow

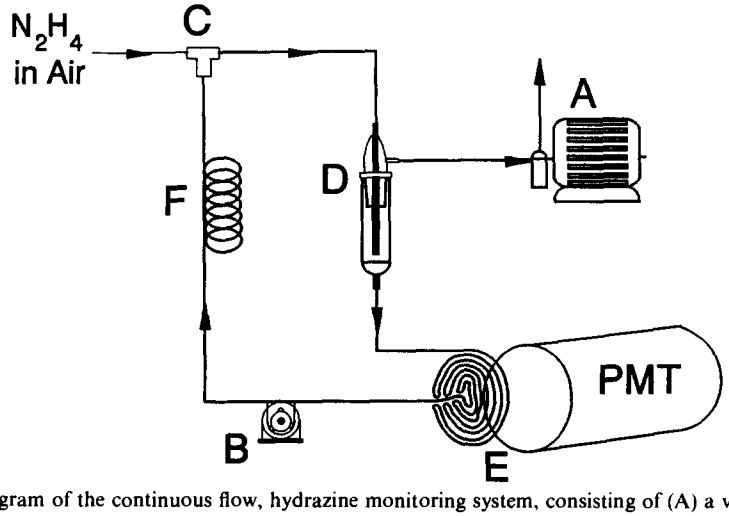

Fig. 1. Diagram of the continuous flow, hydrazine monitoring system, consisting of (A) a vacuum pump for sampling hydrazine in the atmosphere; (B) a peristaltic pump for circulating the luminol/platinum reagent; (C) a sampling tee leading to the liquid/vapor sampling line; (D) an impinger for collecting the liquid prior to transport to (E) a coil of glass tubing positioned in front of a photomultiplier tube; and (F) excess PFTE tubing in order to delay the recycling of the chemiluminescent reagent until the background chemiluminescence has returned to its baseline value.

controllers. Humidity was controlled through the use of bubblers and line mixers, with the humidity being quantitated with a Hygrodynamics hygrometer. The hydrazine concentration was determined using a coulometric method described earlier.[2]

Mixing of all the test gases was obtained within a baffled chamber, containing a port for connection to the vacuum pump of the hydrazine monitoring system. The flow rate to the MSA vacuum pump was determined using an American Meter Model 802.

*Chemicals and stock solutions*

All chemicals were used as received from the suppliers. 3-Aminophthalhydrazide (luminol) (97%) was obtained from Aldrich and a $5 \times 10^{-3}M$ stock solution was prepared in $0.1M$ KOH and stored under dark conditions for a period of several weeks. The stock solution of colloidal platinum was prepared by chemically reducing a $10^{-3}M$ solution of hydrogen hexachloroplatinate (IV) with ascorbic acid at a pH of 3.5, with subsequent dilution to give a $10^{-4}M$ solution of platinum. The chemiluminescent solutions studied were prepared and examined daily by the appropriate dilution of the stock solutions into a buffer solution. Phosphate buffers ($0.1M$) were prepared for all pH studies, using KOH and a calibrated pH meter in order to adjust the pH. The aqueous hydrazine standard solutions were prepared daily by diluting anhydrous hydrazine (Olin Chemicals) in purified water (Millipore) to give the following concentrations: 1, 10, 100 $\mu$g/l., 1, 10, 100 and 1000 mg/l. Stock solutions ($10^{-3}M$) were also prepared for several metal ion catalysts, including $MnSO_4$, $CuCl_2 . 6H_2O$, $FeSO_4 . 7H_2O$, $Fe(NO_3)_3 . 9H_2O$ and $CoSO_4$.

A number of interference gases were tested for chemiluminescence using the hydrazine monitoring system. Gas mixtures were obtained from Matheson and Scott Specialty Gases, and diluted with air to give varying concentration levels. The standards employed include: 99 ppm $NO_2$ in $N_2$; 110 ppm NO in $N_2$; 99.8 ppm $SO_2$ in $N_2$; 10% HCl in Ne; 7.2% $H_2$ in $N_2$; 450 ppm $NH_3$ in $N_2$; 99.99% $CO_2$; Freon 12; multi-component mixture #1 [51.2 ppm Freon 12, 50.7 ppm Freon 11, 49.3 ppm Freon 114, 20.4 ppm $CH_4$, and 9.96 ppm hexane in He]; and, mixture #2 [1.004% CO, 1.098% $CO_2$, 0.9640% $CH_4$, 0.9996% ethane, 1.014% ethylene, and 1.014 acetylene in He].

*Procedure*

For those experiments employing the SLM 8000 spectrofluorometer 2 ml of the appropriate buffer solution was pipetted into a quartz cuvette, along with 10–100 $\mu$l (Eppendorf microburette) of the platinum and luminol stock solutions. The optimal concentrations of luminol and platinum were determined to be $10^{-4}$ and $10^{-6}M$, respectively. Subsequent spiking of these solutions with varying levels of hydrazine was accomplished by injecting 1–100 $\mu$l of solution from the appropriate dilution standard via the injection port of the sample compartment. The final concentration of hydrazine in solution varied from 50 ng/l. to 500 $\mu$g/l. The flow injection analysis experiments were conducted by using a multichannel peristaltic pump in conjunction with a cuvette (Starna Cells) containing three ports: one for injection of the basic, Pt/luminol reagent, one for the hydrazine solution, and one for the exit of the solution from the cuvette.

For those experiments using the continuous flow, hydrazine monitoring system, 150 ml of operating solution were prepared at concentrations of platinum and luminol similar to that described above. Quantitation of the hydrazine vapor concentrations was determined by coulometry, and then sampled by connection of the vacuum pump to the mixing chamber.

## RESULTS AND DISCUSSION

*Chemiluminescence reaction characteristics*

The addition of colloidal platinum to a basic solution of luminol permits the indirect quantitation of hydrazine via a two step process (steps 1 and 2 shown below):

$$2O_2(g) + N_2H_4(aq) \rightleftarrows 2H_2O_2(aq) + N_2(g) \quad (1)$$

$$\text{luminol(aq)} + 2H_2O_2(aq) + 2OH^- \rightleftarrows \text{3-aminophthalate(aq)} + 4H_2O + N_2 + h\nu \quad (2)$$

$$N_2H_4(aq) + 2H_2O_2(aq) \rightleftarrows N_2(g) + 4H_2O \quad \text{(side reaction)}. \quad (3)$$

Both reactions (1) and (2) are catalyzed by colloidal platinum.[16,18] Reaction (1) is the first step in the oxidation of hydrazine at the platinum surface. An important side reaction is

the reaction of hydrogen peroxide with a second molecule of hydrazine, which completes the oxidation of hydrazine to nitrogen and water (reaction 3). Pilipenko *et al.* have indicated that, although hydrogen peroxide is formed in the net reaction of hydrazine with oxygen, it is likely an intermediate, radical peroxo species (and not $H_2O_2$) which is actually responsible for the oxidation and subsequent chemiluminescence of lucigenin.[16] The presence of a radical species was inferred from the immediate inhibition of chemiluminescence following the addition of methyl methacrylate, a free radical acceptor. Regardless of the exact nature of the oxidant formed at the platinum surface, the net result is the oxidation and chemiluminescent response of luminol. Reaction step (2) is a multi-step process giving rise to chemiluminescence, and has been discussed in detail elsewhere.[19]

Initial evaluation of the analytical potential of this system was accomplished by observing the complete, chemiluminescent response obtained following the introduction of 49 $\mu$g/l. of hydrazine to a basic solution (pH 13, NaOH) of platinum (0.25–2.9 $\mu M$) and luminol ($7.4 \times 10^{-5} M$). The concentration of colloidal platinum plays an important role in determining the shape and size of the response curve (see Fig. 2). Note the difference in response obtained for solutions containing 0.25 and 1.0 $\mu M$ colloidal platinum. For the lowest concentration of platinum examined, 0.25 $\mu M$, the time necessary to reach a maximum in signal intensity is longer, the peak height is substantially lower, and the chemiluminescence persists for up to an hour following the injection of hydrazine. As the concentration of colloidal platinum increases

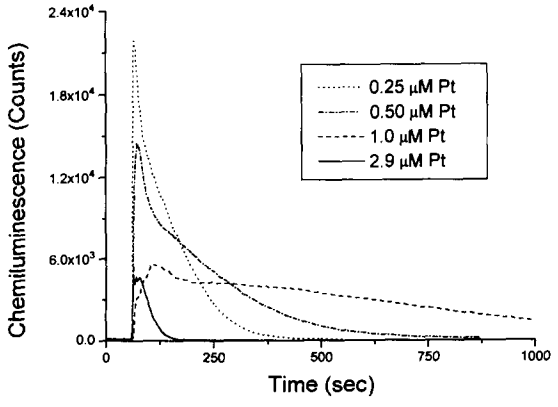

Fig. 2. Time dependence of the chemiluminescence signal following the introduction of 49 $\mu$g/l. hydrazine to a pH 13, $7.4 \times 10^{-5} M$ luminol solution containing 0.25, 0.50, 1.0, and 2.9 $\mu M$ colloidal platinum.

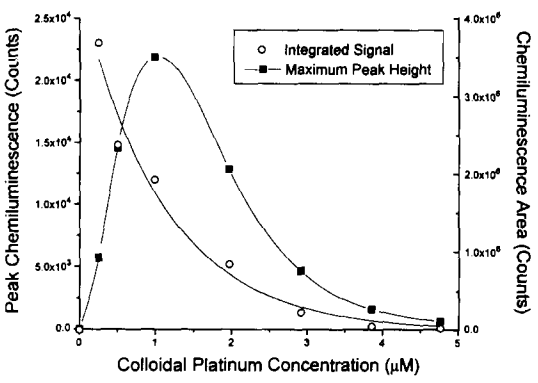

Fig. 3. Peak and integrated chemiluminescence intensities as a function of colloidal platinum concentration.

(up to 1.0 $\mu M$), the decay of the chemiluminescent signal becomes much faster, the maximum in signal intensity is attained in seconds, and the intensity of the chemiluminescent signal is more than four times that obtained for the 0.25 $\mu M$ platinum solution.

These results are summarized in Fig. 3, which is a plot of both the maximum signal intensity and the integrated chemiluminescence acquired for varying concentrations of colloidal platinum. It is evident from Figs 2 and 3 that as the concentration of platinum is increased, the total integrated chemiluminescence signal decreases dramatically. This result is attributed to the catalytic effect platinum has upon the oxidation of hydrazine to water and nitrogen (reactions 1 and 3), a side reaction decreasing the total luminol oxidation possible. Referring to Fig. 3, a maximum in the instantaneous, chemiluminescent intensity is observed for 1.0 $\mu M$ platinum. The signal intensity decreases for either higher or lower concentrations of platinum. The optimal concentration of colloidal platinum requires a compromise between having sufficient metal to promptly catalyze the oxidation of luminol (reaction steps 1 and 2), and having an excess of platinum which catalyzes the oxidation of hydrazine to water and nitrogen (reaction 3). As we shall see in the discussions pertaining to the continuous flow system, the concentration of platinum, the liquid flow rate, and the distance from the vapor/liquid interface to the photomultiplier tube are all important parameters influencing the overall sensitivity of the system.

### *Optimization of parameters in solution*

The pH is an important parameter in determining the magnitude of the chemiluminescence response. A basic solution is required to initiate the reaction sequence. Typically, luminol systems

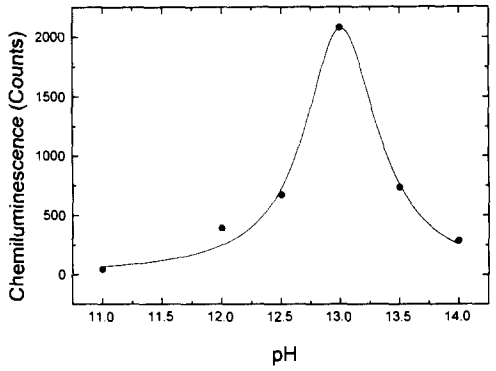

Fig. 4. Effect of pH on the chemiluminescence signal intensity for the introduction of 4.6 $\mu$g/l. of hydrazine to a solution containing $6.1 \times 10^{-5}M$ luminol and $1.2 \times 10^{-6}M$ colloidal platinum.

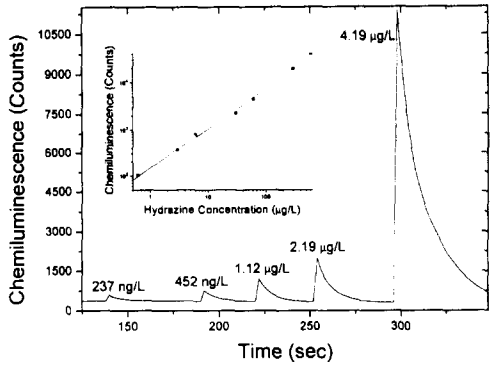

Fig. 6. Chemiluminescent signal intensity following sequential additions of increasing concentrations of hydrazine to a pH 13 (NaOH) solution containing $6.1 \times 10^{-5}M$ luminol and $1.2 \times 10^{-6}M$ platinum. Inset plot is an example of the linear dynamic range obtained for hydrazine detection from the flow injection analysis scheme.

used in the detection of metals or hydrogen peroxide operate optimally at a pH of 10–11.[8] It has been suggested that this is necessary in order to form a reactive diazine by abstraction of the second amino proton from luminol.[20] Figure 4 shows the integrated chemiluminescent response seen with varying pH conditions to the introduction of 4.6 $\mu$g/l. of hydrazine to a luminol/Pt reagent. The optimal pH in the detection of hydrazine is pH 13. Several factors in the reaction sequence are known to be pH dependent. The autoxidation of hydrazine is maximized at a pH of 12–12.5,[18] while the production and lifetime of the intermediate product (peroxide) is highest at a pH of 13–13.5.[16]

Increasing the concentration of luminol results in an increase in the integrated chemiluminescence obtained for a given concentration of hydrazine. Figure 5 demonstrates that the response is non-linear with respect to the concentration of luminol. This may be due to self-absorbance of the chemiluminescence by luminol, or to luminol acting as a bidentate chelate, complexing with platinum, and perhaps

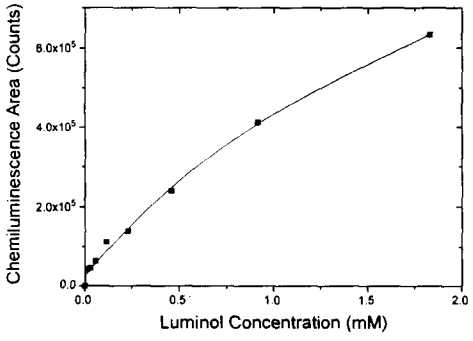

Fig. 5. Integrated chemiluminescence signal dependence on luminol concentration using a pH 13 solution containing $2.3 \times 10^{-6}M$ colloidal platinum and 50 $\mu$g/l. hydrazine.

rendering it inactive. The latter effect has been seen for the cobalt-catalyzed reaction with luminol.[21] The possibility remains, though, that a high concentration of luminol may be used in the hydrazine vapor detection system to improve the lifetime characteristics of the system.

*Analytical characterization of hydrazine detection in solution*

To determine the quantitative potential of the platinum/luminol system for hydrazine detection, a series of increasing concentrations of hydrazine were injected into a cuvette containing the optimum reagent concentrations, while measuring the chemiluminescence. An example of the addition of 0.24, 0.45, 1.1, 2.2 and 4.2 $\mu$g/l. of hydrazine is shown in Fig. 6. A plot of the integrated chemiluminescent response as a function of the hydrazine concentration exhibited excellent linearity over the concentration region examined (50 ng/l.–35 $\mu$g/l.). With the voltage gain on the photomultiplier tube increased to 1275 V, the sensitivity ($m$) was calculated to be $1.05 \times 10^5$ counts/($\mu$g/l.). with an intercept (b) of $1.96 \times 10^4$ counts and a correlation coefficient of $r > 0.9999$ (other regression data include: $n = 5$, $\sigma_m = 4.95 \times 10^3$ counts/($\mu$g/l.), $\sigma_b = 1.07 \times 10^5$ counts, and $\sigma = 2.07 \times 10^5$).

A flow injection analysis scheme for the detection of hydrazine was examined using a modified 4 cm$^3$ cuvette containing three inlet ports. The reagent solution containing luminol and colloidal platinum at pH 13 was mixed directly and continuously with varying concentrations of hydrazine in solution (see the Experimental). The speed of the chemiluminescent reaction makes it feasible to mix the reagents

directly in front of the photomultiplier tube within the cuvette. For this experiment, the chemiluminescent signal came to a plateau response (as opposed to decaying back to the baseline) in less than a minute while using a flow rate of 0.11 ml/min hydrazine solution and 1.8 ml/min platinum/luminol solution. The inset plot in Fig. 6 shows the change in the chemiluminescence response with the concentration of hydrazine in solution ($r > 0.999$). The linear regression data collected for this line are as follows: $n = 8$, $m = 65.0$ counts/($\mu$g/l.), $\sigma_m =$ 0.475 counts/($\mu$g/l.), $b = 189$ counts, $\sigma_b = 115$ counts, and $\sigma = 276$. The detection limit, assuming a signal-to-noise ratio of 3:1, was calculated to be 0.40 ng/l. The limit of detection is ultimately limited by the noise inherent to the PMT, in addition to pumping variability associated with the peristaltic pump.

In addition to colloidal platinum, other metal and metal cation catalysts were evaluated for the detection of hydrazine, *e.g.* $MnSO_4$, $CuCl_2 . 6H_2O$, $FeSO_4 . 7H_2O$, $Fe(NO_3)_3 . 9H_2O$, $CoSO_4$, Pd (colloid) and Ag(colloid). In each case, the sensitivity for hydrazine detection was substantially lower than the response obtained using colloidal platinum. In addition, these other metal catalysts examined resulted in a much higher baseline signal, and a slower return to baseline following the cessation of hydrazine flow. These results are likely due to the catalytic effect these metals have upon the oxidation of luminol by $O_2$.[22] Although there is some oxidation of luminol by $O_2$ in the presence of colloidal platinum, it is not as severe.

*Hydrazine vapor monitor*

The development of a hydrazine vapor monitor employing the Pt/luminol system requires first a means for concentrating hydrazine vapor into solution. A simple method for accomplishing this task is diagrammed in Fig. 1. A peristaltic pump delivers the luminol/platinum/KOH reagent through a short length of teflon tubing which concurrently transports sampled vapor. It is this gas/liquid interface which initiates the oxidation of hydrazine at the Pt surface, and ultimately, the oxidation of luminol. The liquid is efficiently separated in a modified, teflon impinger, and pumped through a short section of glass tubing coiled directly in front of the PMT. The rapid decay of the chemiluminescent signal back to the background level following the addition of hydrazine to the line, allows the reagent to be recirculated.

As demonstrated earlier, the concentration of active platinum in solution determines the magnitude of the chemiluminescence signal seen

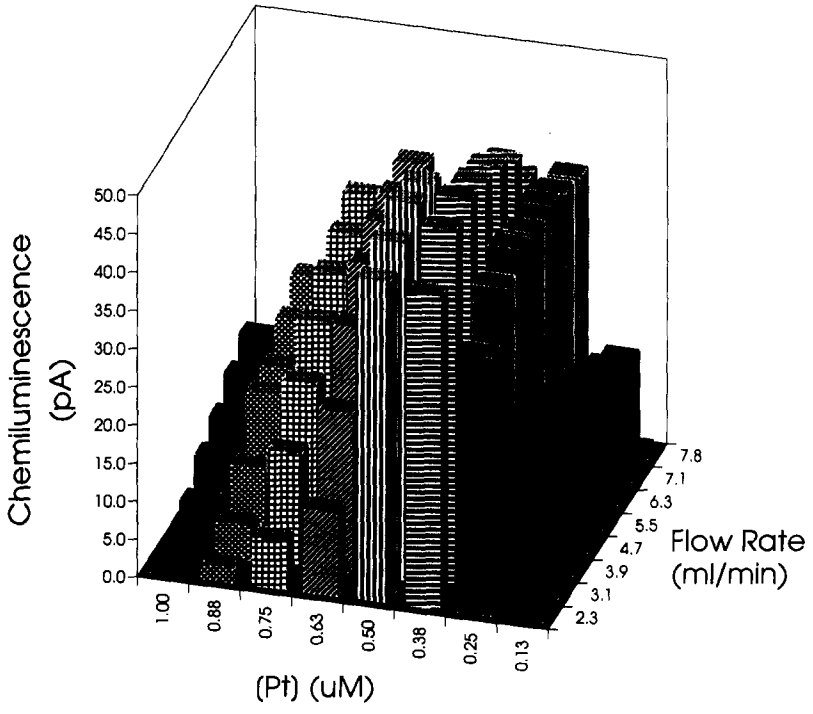

Fig. 7. Plot of the chemiluminescent signal obtained from a $4.9 \times 10^{-5} M$ luminol solution at pH 13, as a function of the concentration of colloidal platinum and the liquid flow rate.

at the photomultiplier tube. The optimum concentration of platinum used for the continuous flow system is closely linked to the liquid flow rate and the length of tubing from the sampling point to the photomultiplier tube. A three-dimensional plot of the chemiluminescence response with respect to the liquid flow rate and the concentration of platinum, while maintaining a constant air pumping rate and luminol, KOH, and hydrazine concentrations is shown in Fig. 7. For the tubing distance used in our experimental setup, low concentrations of platinum ($10^{-7}M$) resulted in a weak, chemiluminescent signal which decreased with increasing liquid flow rate. An examination of Fig. 3 indicates that at these concentrations of platinum, while the signal has a long lifetime, its maximum peak intensity is not very high. The slower the flow rate, then, the longer the liquid remains in view of the PMT, and the larger the chemiluminescent signal will be. In addition, at a constant air flow rate, decreasing the liquid flow rate concentrates more hydrazine vapor into solution, thereby, giving a larger signal at the PMT.

As the concentration of platinum in solution is increased ($5 \times 10^{-7}M$), the chemiluminescent signal becomes larger, and the maximum in peak intensity occurs at higher flow rates. Referring again to Fig. 3, at these platinum concentrations the instantaneous chemiluminescent signal obtained is higher, therefore, giving a larger signal at the PMT. This is providing, of course, that the liquid flow rate is rapid enough to transport the solution to the PMT before the signal decays. If the flow rate is too high, though, the signal will decrease for two reasons: (1) less hydrazine vapor is concentrated into solution; and (2) the solution remains in view of the PMT for a shorter period of time. Ultimately, as the platinum concentration is increased to even higher concentrations ($10^{-6}M$), the signal intensity drops substantially for low flow rates. At these concentration levels, the chemiluminescence signal decays extremely rapidly—long before the solution reaches the PMT. In order to effectively use these higher concentrations of platinum, it is necessary to use extremely rapid flow rates so that the signal is sampled before the chemiluminescence decays away.

Just as the liquid flow rate controls the concentration factor for bringing hydrazine vapor into solution, so too does the air flow rate. As the air flow increases at a constant liquid flow rate, the amount of hydrazine concentrated into solution increases. This is demonstrated in Fig. 8, which is a plot of chemiluminescence intensity *vs.* air flow rate for a pH 13 NaOH solution containing $5 \times 10^{-5}M$ luminol and $10^{-6}M$ platinum (the concentration of hydrazine sampled was 13 ppb in each case). There are several problems associated with operating at high flow rates. Firstly, there is difficulty in preventing air bubbles from entering the tubing leading to the PMT, a result which leads to excessive noise. In addition, at the higher air flow rates, our vacuum pump rate was very uneven, and the level of liquid in the impinger was difficult to maintain constant, both factors leading to inconsistent results. Finally, the efficiency for concentrating hydrazine vapor into solution is expected to decrease at very high flow rates; the hydrazine has less time to interact with the solution within the liquid/gas sampling line. An optimum pumping rate can be determined for a particular platinum concentration that maximizes the trapping efficiency without sacrificing the stability of the measurement.

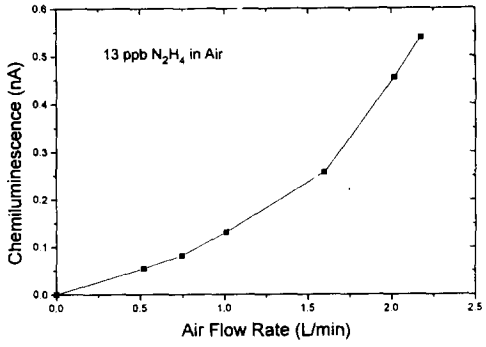

Fig. 8. Effect of air flow rate on the observed chemiluminescence signal intensity to the introduction of 13 ppb hydrazine in air.

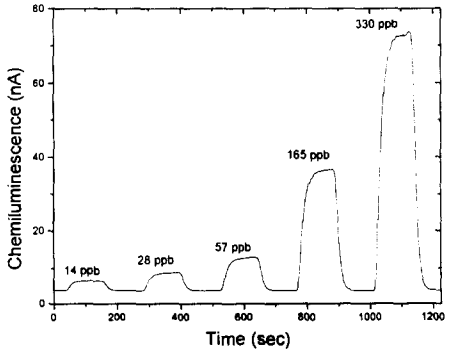

Fig. 9. Time responses obtained using the hydrazine vapor detection system for 14, 28, 57, 165, and 330 ppb hydrazine in air.

Our studies have established the following optimum experimental parameters for the detection of hydrazine: $10^{-6}M$ platinum, $10^{-4}M$ luminol, $0.1M$ KOH, 7 ml/min liquid flow rate, 2 l./min air flow rate. In order to test the analytical response of this system, the chemiluminescent response was monitored for successively higher concentrations of hydrazine in air. An example of the time responses obtained following the introduction and cessation of 14, 28, 57, 165 and 330 ppb hydrazine in air is shown in Fig. 9. A linear relationship was obtained for hydrazine concentrations measured from 10 to 2000 ppb ($r = 0.997$). The linear regression data collected over this concentration regime were as follows: $n = 9$, $m = 1.77$ counts/($\mu$g/l.), $\sigma_m = 0.0516$ counts/($\mu$g/l.), $b = 40.4$ counts, $\sigma_b = 40.6$ counts, and $\sigma = 103$. The time necessary to reach 90% of a plateau response is 1.3 min, and the return to background requires 1.2 min. The detection limit was calculated to be 1.4 ppb, based upon a signal-to-noise ratio of 3:1. The reproducibility of the data is within 5%. The primary disadvantage found for recirculating the chemiluminescent reagent is that the stability of the system will drift slightly over the course of hours of operation (1%/hr). The lifetime of the reagent is ultimately dependent upon the concentration of luminol in solution, and the lifetime of the catalyst. Because of problems associated with the slow oxidation of luminol by $O_2$(g) and/or the gradual change in pH from absorbed $CO_2$(g) in the airstream, it is necessary to change the solution daily to prevent shifts in the sensitivity.

Interference effects were studied by sampling various gases at concentration levels 1 at least twice their regulated exposure levels. A solution of luminol/platinum was prepared at pH 12.6 and exposed to the gases listed in Table 1. For interferents resulting in a measurable chemiluminescence, Table 1 indicates the concentration which gives the same signal intensity as 10 ppb hydrazine in air. The majority of gases examined, with the exception of $NH_3$, $NO_2$, $SO_2$, and HCl, either gave no signal, or actually produced a slight decrease in the baseline signal. This latter effect likely arises from a decrease in the concentration of oxygen. Oxygen results in a small, baseline chemiluminescence signal due to the direct oxidation of luminol. Positive interferences were seen for $NO_2$, $SO_2$, and HCl, but the sensitivities were much lower than for hydrazine. A concentration of 9 ppm $NO_2$ gives a signal comparable to 10 ppb hydrazine in air. Considering that the regulated exposure levels for $NO_2$, $SO_2$, and HCl are 1 ppm (STEL), 2 ppm (TLV), and 5 ppm (TLV), respectively, these interferents are not expected to be a problem for hydrazine vapor detection. The presence of $NH_3$ can give a false positive signal if the sampling line is not constructed correctly. Hydrazine will stick to any portions of tubing on the end of the sampling tee that are not being continually washed by the reagent. Ammonia, a strong Lewis base, competes very well with hydrazine for adsorption to the sides of the tubing leading to the impinger. Any hydrazine which is dislodged will react to give a measurable chemiluminescent response. The signal is spurious, returning to the baseline again after all of the hydrazine coating the tubing has been eliminated. This effect can be mollified by shortening the vapor side of the sampling tee to the point that there are minimal portions which are not continuously being exposed to the reagent. A smaller diameter tubing on the liquid/vapor sampling side (1/16″ i.d. or less) will also help ensure that the tubing does not have trace amounts of hydrazine adsorbed to the sidewalls.

Reports in the literature have demonstrated that the chemiluminescence of luminol systems can be enhanced by the introduction of a high concentration of halide ions.[23] We corroborated

Table 1. Interference vapors tested using the hydrazine vapor monitor, and the concentration required to give an intensity comparable to 10 ppb hydrazine in air

| Interference vapor | Concentration giving a response similar to 10 *ppb* Hydrazine in air |
|---|---|
| $NO_2$ | 9 *ppm* |
| $SO_2$ | 124 *ppm* |
| HCl | 210 *ppm* |
| $NH_3$ (50 *ppm*) | spurious false positive |
| NO, $H_2$, $CO_2$, CO, $CH_4$, $C_2H_6$, $C_2H_5OH$, $(CH_3)_2CHOH$, $C_2H_4$, $C_2H_2$, $C_6H_{14}$, Freon 11, Freon 12, Freon 114 | no effect or a slight decrease in the baseline chemiluminescent signal (see text) |

See text for more detail on the interferents listed in the final section which gave little or no change in the baseline chemiluminescence.

this effect in the detection of hydrazine, via the addition of 0.56*M* KBr to a $5 \times 10^{-5}M$ luminol, and $1 \times 10^{-6}M$ platinum in pH 12.6 solution. These experiments established that the sensitivity to hydrazine can be more than doubled via the introduction of a large concentration of the bromide salt. It is thought that the halide facilitates electron transfer from luminol to the active peroxide.[23]

## CONCLUSIONS

In this paper, we demonstrate the efficacy of colloidal platinum/luminol for detecting trace hydrazine vapor in real-time. The real-time detection limit is 1 ppb hydrazine in air; further improvements in the sensitivity can be accomplished by adding KBr salts, increasing the rate of air flow, or increasing the number of coils in front of the photomultiplier surface. A linear dynamic range was obtained from 10 to 2000 ppb hydrazine, with response times for the detection and return to baseline of less than two minutes. The response time of the system can be improved substantially by increasing the liquid flow rate, although the platinum concentration must also be adjusted to ensure a comparable sensitivity. Selectivity is the biggest potential disadvantage of this system. Our tests indicate that of the gases examined, only $NO_2$ and $NH_3$ gave a positive response, the ammonia response being spurious and the nitrogen dioxide sensitivity being low enough that at the TLV level or below it is undetectable.

We are currently investigating solid-phase chemiluminescence in order to further simplify and improve upon this detection scheme. Some success has been seen in incorporating the colloidal platinum and luminol within a polymer matrix possessing Lewis acid properties. The polymer film itself helps to concentrate the hydrazine within the polymer matrix. Current efforts involve examining different polymer substrates and metal catalysts to obtain optimum response characteristics.

# ESTIMATION OF CHROMIUM IN ORES AND BENEFICIATED PRODUCTS: AN ULTRASONIC APPROACH

USHARANI PATNAIK and J. MURALIDHAR*

Regional Research Laboratory, Council of Scientific & Industrial Research, Bhubaneswar-751 013, India

(*Received* 24 *June* 1994. *Revised* 13 *September* 1994. *Accepted* 30 *September* 1994)

**Summary**—Cr(III) slowly forms a violet complex with EDTA at pH 3.5 ± 0.2 under normal conditions. The complex formation can be catalyzed by irradiating the reacting mixture with ultrasonic waves. Quantitative formation of the complex was possible with ultrasonic waves of 15 W/cm$^2$ intensity within 7.5 min of sonication. This method may be successfully applied to the determination of chromium in ores and beneficiated products containing 20–60% $Cr_2O_3$ without separating the analyte from the matrix elements.

Colorimetric analysis of chromium involves oxidation of Cr(III) to Cr(VI) followed by complexation.[1–3] Even the methods based on atomic absorption spectrophotometry or ICP also focus on Cr(VI).[4,5] However, colorimetric methods based on Cr(III) are of less importance because of its sluggishness towards any substitution reaction. The reaction between polycarboxylic acids (DCTA, NTA, EDTA) and Cr(III) is very slow.[6] Cr(III) slowly forms a violet complex H[Cr(EDTA)–($H_2O$)] with ethylenediaminetetraacetic acid (EDTA) in the pH range 3–5.2. However, the rate of complexation can be accelerated by the addition of bicarbonate ion,[8] manganese salt[9] or by boiling the solution for 30 min.

The effect of ultrasonic waves on chemical reactions has recently become the focus of research activity.[10–12] High intensity ultrasonic waves may accelerate a chemical reaction which occurs under normal conditions or initiate a reaction which does not take place under ordinary conditions.[13,14] Irving[9] reported that the complexation of Cr(III) with EDTA can be catalysed by the *in situ* generation of chromous ions by the addition of Zn dust to the solution containing an excess of EDTA. However, it has been observed that in the presence of high concentrations of sulphates and phosphates, complexation is not quantitative by the addition of bicarbonate or Zn dust. Hence an attempt has been made to catalyze the complexation of Cr(III) with EDTA by irradiating the reaction mixture with ultrasonic waves and to extend its application to the estimation of chromium in ores and beneficiated products.

## EXPERIMENTAL

A Varian DMS-100S UV-Vis Spectrophotometer equipped with an Epson LX printer and 1.00 cm quartz cells was used for the optical density measurements.

A high intensity ultrasonic liquid processor (Sonics Materials, USA) capable of producing ultrasonic intensity of 50 W/cm$^2$ at 20 KHz frequency was used in these studies. A horn made up of titanium with a tapered micro tip of 3.64 mm diameter was used to sonicate the solutions.

All the chemicals used were of analytical grade. Solutions were prepared in doubly distilled water.

Three chromite ore samples, *viz.* BCS-No. 308 (Grecian chrome ore), CHR-Pt and CHR-Bkg (chromites of CRPT, France, standard) and two beneficiated products, *viz.* SKP-D2 and HG-3 were analysed for chromium content.

### *Procedure*

To 0.5 g of finely ground chromite sample in a 250 ml beaker was added 20 ml each of 50% (v/v) $H_2SO_4$ and 50% (v/v) $H_3PO_4$. The

*Author to whom correspondence should be addressed.

solution was heated on a hot plate at 200°C until the complete disappearance of dark coloured particles. It was cooled, diluted and filtered through a G-4 crucible under suction and made up to 250 ml. A 10 ml aliquot was pipetted into a 100 ml beaker and adjusted to pH 3.5 with 5% (w/v) NaOH solution. A 10 ml 0.3*M* EDTA solution was added and irradiated with ultrasonic waves of 15 W/cm$^2$ intensity for 7.5 min. It was cooled and made up to 100 ml. The solution was taken in a 1.00 cm cell to measure the optical density at 547 nm against reagent blank, drawing the calibration curve using appropriate standards.

*Appropriate standard preparation*

A 0.5 g $K_2Cr_2O_7$ sample was reduced to $Cr_2(SO_4)_3$ in the presence of a 1:1 mixture of $H_2SO_4$ and $H_3PO_4$ (20 ml) and a pinch of $Na_2SO_3$. The volume was made up to 250 ml and diluted to give 1 mg/ml $Cr_2O_3$ solution. A 1 mg/ml $Fe_2O_3$ solution was prepared from $Fe_2(SO_4)_3$ and $Cr_2O_3$ solution taken in 50 ml beakers in quantities equivalent to 10–100 ppm of $Cr_2O_3$. A 3 ml quantity of 1 mg/ml $Fe_2O_3$ was added and boiled for 5 min, cooled and the pH of the solution adjusted to 3.5.

## RESULTS AND DISCUSSION

*Effect of pH*

Owing to protolysis, the absorption spectrum of the Cr(III)–EDTA complex is greatly influenced by the pH of the solution. The pH of the acid decomposed chromite solutions was adjusted at different values starting from 2.5 to 7. A pH of 3.5 $\pm$ 0.2 has been found to be suitable for quantitative formation of complex as well as negligible interference of Fe(III). Beyond pH 5.5, the violet complex transforms into blue Cr(OH)–EDTA$^{2-}$ and $Cr(OH)_2EDTA^{3-}$ hydroxo complexes.[15]

*Effect of ultrasound intensity and sonication time*

The effect of intensity of ultrasound waves and time of sonication on complex formation was investigated and the results are represented graphically in Figs 1 and 2. The reaction mixture containing 100 ppm of $Cr_2O_3$ and 10 ml of 0.3*M* EDTA was irradiated continuously with ultrasonic waves at varying intensities within the range 5–20 W/cm$^2$ for 2 min. Complexation was insignificant at lower intensities, but was maximum at 15 W/cm$^2$. A further increase in the intensity was not beneficial. After sonication, a

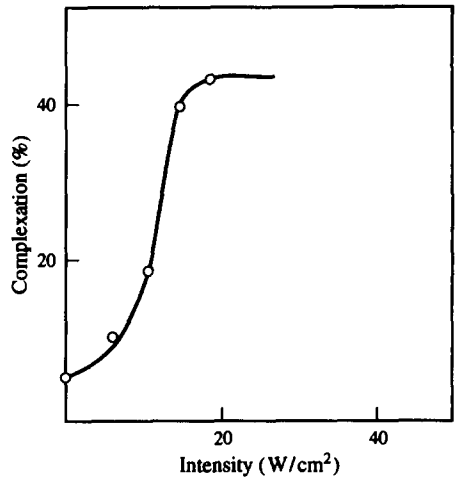

Fig. 1. Effect of intensity of ultrasound waves on rate of complexation.

20°C increase in temperature of the reacting solution from the ambient temperature was observed. The reason may be a result of the rapid generation and collapse of microbubbles within the reacting medium irradiated with ultrasonic waves. This leads to significant pressure and thermal differentials on a microscopic scale resulting in the enhancement of energy transfer and accelerated mass transport.[15]

A comparison of percentage of complexation with respect to time both in the presence and absence of ultrasound waves at 15 W/cm$^2$ intensity reveals that initially a sharp increase in complexation rate was observed in both cases. In the absence of ultrasound where the reacting mixture was heated on a water bath at 60°C for 8.0 min, only 60% complexation was observed with 100% complexaton being achieved after 30 min of further boiling. However, in the presence of ultrasound, quantitative complexation was possible after 7.5 min of sonication.

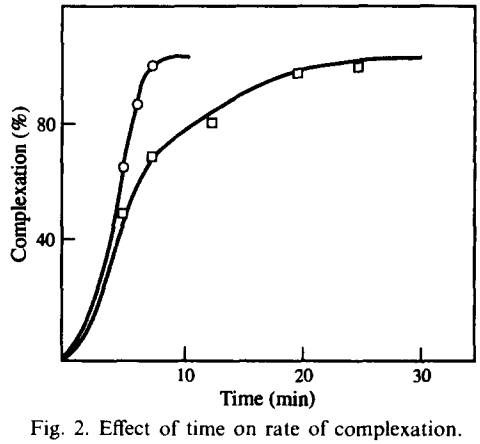

Fig. 2. Effect of time on rate of complexation.

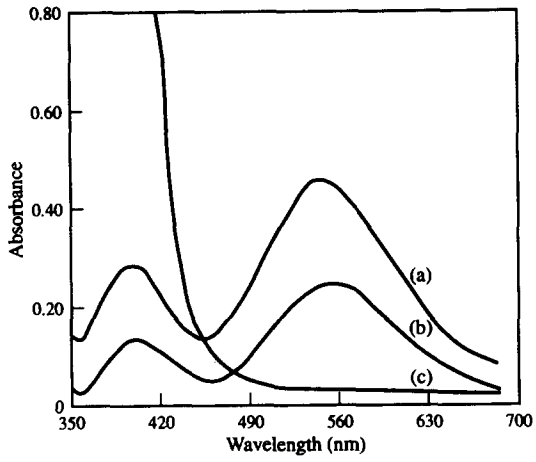

Fig. 3. Absorption spectra of Cr(III)–EDTA in $Cl^-$, $SO_4^{2-}$, $PO_4^{3-}$ and spectra of Fe(III)–EDTA.

*Effect of diverse ions*

In order to assess quantitative determination of chromium by this method, the effect of diverse ions must be taken into consideration. The possible interfering ions in the spectrophotometric determination of Cr(III)–EDTA are $Fe^{3+}$, $Mg^{2+}$, $Al^{3+}$, $Mn^{2+}$, $SO_4^{2-}$ and $PO_4^{3-}$. Spectral interferences owing to colourless cations like $Mg^{2+}$, $Al^{3+}$ and $Mn^{2+}$ in equivalent amounts can be eliminated in the presence of excess EDTA. $Fe^{3+}$ forms a yellow coloured complex with EDTA soon after its addition. The extinction value of Fe(III)–EDTA solution does not change on heating the solution. The molar absorption coefficient of this complex is 4 compared to 180 for Cr(III)–EDTA solution at the measured wavelength (Fig. 3). Therefore, no interference from iron(III) is to be expected during the analysis of Cr(III). However, a calculated amount of $Fe^{3+}$ solution may be added during the standard preparation. Of the anions, the molar absorption coefficient of Cr(III)–EDTA complex in chloride environment ($\epsilon = 202$) decreases significantly in phosphate and sulphate environment ($\epsilon = 180$) (Fig. 3). Hence the use of an appropriate standard is advocated. The absorbance of Cr(III)–EDTA in the presence of these diverse ions is presented in Table 1.

The calibration curve was drawn using the appropriate standards. Beer's law is valid within 5–100 ppm of $Cr_2O_3$ with the correlation coefficient 0.9998.

This method was applied to the determination of chromium in three standard ore samples and two beneficiated products. The results are presented in Table 2. $Cr_2O_3$ values determined by this method are in acceptably close agreement with the certified values. This method has been found to be less time consuming and can be used without separating the analyte from the matrix elements prior to analysis. This method can be conveniently applied to ores and beneficiated products containing 20–60% $Cr_2O_3$.

*Acknowledgements*—The authors thank Dr K. Lakshminarayana for his assistance in conducting the ultrasonic experiments. Thanks are also due to The Director, R.R.L., Bhubaneswar for giving permission to publish the work.

# DETERMINATION OF LEAD IN PRESERVED EGG BY FLAME ATOMIC ABSORPTION SPECTROMETRY AFTER CHEMICALLY MODIFIED PRECONCENTRATION

LU GUANGHAN, XIA WANG, WAN JIALIANG, SHONG FON and XU HAN YING
Department of Chemistry, Central China Normal University, 430070, Wuhan, People's Republic of China

(*Received* 11 *August* 1993. *Revised* 3 *October* 1994. *Accepted* 10 *October* 1994)

**Summary**—A sensitive method for the determination of lead in preserved egg by flame absorption spectrometry using ammonium pyrrolidine dithiocarbamate–polystyrene chemically modified platinum wire matrix is presented. The modified platinum wire matrix, after preconcentrating the lead, is placed in a flame burner for direct atomization and measurement. The concentration range is linear between 5 and 500 ng/ml lead in solution and the detection limit is 0.65 ng/ml. This new technique is sensitive and convenient.

Atomic absorption spectrometry (AAS), characterized by high sensitivity and considerable accuracy, is an ideal method to determine trace metals. Flame atomic absorption spectrometry is in routine use for the determination of trace amounts of lead. However, this method, like other methods, sometimes requires the metals determined to be accumulated beforehand so that interference can be avoided and the level of analysis and sensitivity raised. In order to increase the detectability of flame atomic absorption spectrometry, lead is often preconcentrated from samples using chelating ion exchange resins,[1] or chelate solvent extraction.[2–6] For example, Chau[7] extracted lead into methyl isobutyl ketone (MIBK) using ammonium pyrrolidine dithiocarbamate (APDC). Belchev *et al.*[8] used APDC–polystyrene as the extraction system in the determination of lead in high purity salts. However, these methods are often time-consuming in the analytic procedure and complicated in application. The aim of the present work is to offer a simple and sensitive method for the analysis of lead.

A new technique for determination of trace lead with a chemically modified platinum wire matrix preconcentration–flame atomic absorption spectrometry was developed. Trace lead was preconcentrated on the ammonium pyrrolidine dithiocarbamate (APDC)–polystyrene modified platinum wire matrix, the platinum wire matrix was then put onto a flame atomizer, and the absorbance measured. The time and labor needed for the analysis is decreased and contamination by impurities contained in the reagent reduced.

## EXPERIMENTAL

### *Apparatus*

A Model WXY-402 atomic absorption spectrophotometer equipped with an air/acetylene flame burner was used. The wavelength was set to 2833 Å and the slit width to 4 nm. A hollow cathode lamp for lead was operated at 4 mA.

### *Reagents*

All reagents used were of analytical reagent grade. A 0.1000 g/ml stock solution of lead was prepared by dissolving metal lead (spectral purity) in a small amount of nitric acid and diluting to 100 ml with water. The standard solutions were obtained by diluting the stock solution. 1.0% APDC and a 1.0% solution of polystyrene in MIBK were prepared for the preconcentrated lead. The solutions were prepared from triply distilled water.

### *Preparation of the modified platinum wire matrix*

The platinum wire (diameter 0.2 mm) was wound into a spiral coil (diameter 0.5 mm) and 10 $\mu$l APDC and MIBK–polystyrene added onto the platinum wire spiral coil (Fig. 1) with a micro-syringe. The modified platinum wire matrix was then dried under an IR lamp, a

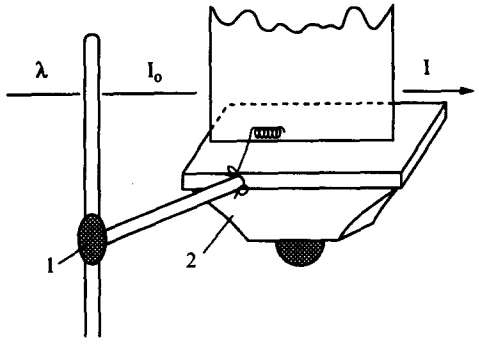

Fig. 1. Position of platinum wire coil in flame. (1) Holder; (2) platinum wire coil.

thin APDC-polymeric film was formed on the platinum wire matrix.

*Procedure*

*Preconcentration and measurement.* The modified platinum wire spiral coil was immersed in a Britton-Robinson (BR) buffer solution (pH 3.0) containing lead[11] (50 ng/ml), which was stirred by a magnetic stirrer, after a given period of time (5 min), the modified platinum wire spiral coil was removed from the preconcentration cell and blotted with filter paper. The modified platinum wire spiral coil was then transferred to the air/acetylene flame burner, positioning the platinum wire spiral coil below the light path (Fig. 1) to measure the absorbance (peak height).

*Effect of pH.* The pH of the solution had a considerable effect on the absorbance. If the pH was higher than 4, the modified reagent fell off from the platinum wire. If the pH was lower than 2, the preconcentration efficiency decreased. Therefore, the optimum is 3, in subsequent experiment, pH was used (Fig. 2).

*Effect of amount of modified reagent.* Polystyrene can adsorb lead, as a result, there is an absorbance from the polystyrene itself. However, the signal was low (Table 1) APDC, when within the range of pH 2 – 4, can form a complex with Pb(II) which can then be extracted. However, APDC cannot be adsorbed

Table 1. Effect of amount of polystyrene

| Polystyrene (1%) (*μl*) | Peak height (*cm*) |
|---|---|
| 0 | 0 |
| 5 | 2.0 |
| 10 | 2.1 |
| 20 | 2.4 |
| 30 | 2.2 |

50 *ng/ml* Pb(II). Preconcentration time: 5 *min.*

Table 2. Effect of amount of APDC

| APDC (1%) (*μl*) | Peak height (*cm*) |
|---|---|
| 0 | 0 |
| 5 | 0.48 |
| 10 | 0.50 |
| 20 | 0.49 |
| 30 | 0.48 |

50 *ng/ml* Pb(II). Preconcentration time: 5 *min.*

very well by the platinum wire as it is slightly soluble in water. Therefore, the absorbance from the APDC is very small (Table 2). The $\pi$ electron of the benzene ring in polystyrene can connect to and share the surface of the platinum wire. Polystyrene, because of its characteristics as a macroporous resins, can function as a carrier of APDC and the fixation APDC–Pb(II) complex is accumulated on the platinum wire (Fig. 3). If both polystyrene and APDC are present at the platinum coil, the absorbance will be significantly enhanced (Table 3).

When the modified platinum wire is put into the solution containing Pb(II), the platinum wire will extract and adsorb the complex formed by Pb(II) and APDC. If there is no modified reagent, Pb(II) cannot be accumulated onto the platinum wire (Table 3). After the modified reagent was applied to the platinum wire, the absorbance gradually increased. Our experiment shows that the absorbance reached a maximum value when 1.0% of APDC and 1.0% of polystyrene were 10 *μl* each (Table 3).

*Effect of preconcentration time.* The dependence of the absorbance on preconcentration time is shown in Fig. 4. The absorbance increased rapidly at first, but after 6 min the quantity of modified platinum wire spiral coil

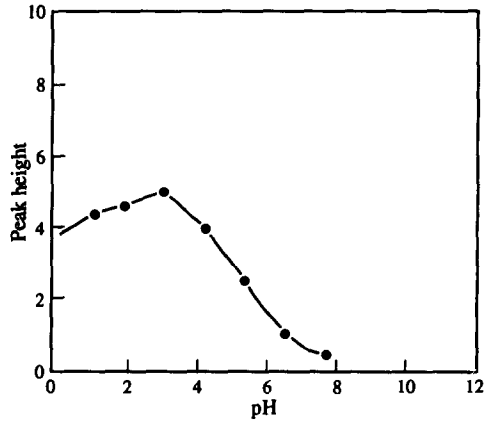

Fig. 2. Effect of pH on the absorbance. 50 ng/ml Pb(II). Preconcentration time, 5 min.

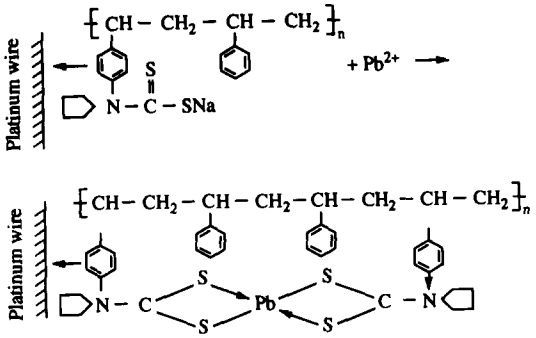

Fig. 3. Adsorption of Pb(II)–APDC complex at platinum wire coil.

surface tended to saturation in the presence of a certain amount of lead, so the absorbance varied little with preconcentration time. It took only 5 min to preconcentrate, because the preconcentration requirements were met.

*Interferences*

The tolerance for various foreign ions was studied for the determination of 50 ng/ml Pb(II). The results show that $SO_4^{2-}$, $Cl^-$ and $NO_3^-$ had no effect, and at least 200-fold amounts of $K^+$, $Na^+$, Ca(II), Mg(II), 100-fold Co(II), Ni(II), Fe(II) Cd(II), Cr(VI), Mo(IV), Zn(II), 50-fold Cr(III). 20-fold Cu(II) and Fe(III) had little effect on the determination. When the contents of Cu(II) and Fe(III) were much higher, the harmful action of those ions were easily removed by addition of 8-hydroxyquinoline.

*Calibration graph, limit of detection and precision*

Under the optimal conditions described above, the absorbance is directly proportional to the lead(II) concentration over the range 5–500 ng/ml. The relative standard deviation was 5.3% ($n = 20$). The detection limit calculated as the concentration corresponding to three times the standard deviation of the blank signal was found to be 0.65 ng/ml. As each amount of the modified reagent is the same, only the modified reagent can adsorb Pb(II), whereas unmodified platinum wire cannot adsorb Pb(II). This accumulation results in a similar amount of Pb(II), and when the absorbance of Pb(II) is determined, the position of the platinum wire in the burner is reproducible. Therefore, the determination can be quite precise.

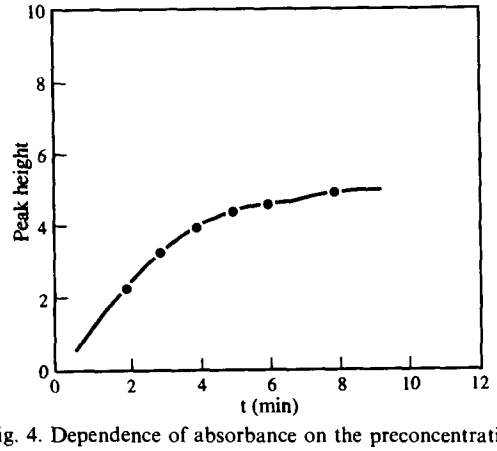

Fig. 4. Dependence of absorbance on the preconcentration time 50 ng/ml Pb(II), pH 3.

Table 3. Effect of amount of modified reagent

| Polystyrene (1%) ($\mu l$) | APDC (1%) ($\mu l$) | Peak height ($cm$) |

| 5 | 5 | 3.8 |
| 10 | 5 | 4.0 |
| 5 | 10 | 3.9 |
| 10 | 10 | 4.5 |
| 20 | 10 | 4.5 |
| 10 | 20 | 4.4 |

50 *ng/ml* Pb(II). Preconcentration time: 5 *min*.

Table 4. Determination of lead in preserved egg ($n = 6$)

| Sample | Pb(II) added ($\mu g$) | Pb(II) found ($\mu g$) | Recovery (%) | RSD (%) |
|---|---|---|---|---|
| 1 | 0 | 1.68 | 95 | 2.2 |
| | 4.0 | 5.49 | | |
| 2 | 0 | 0.92 | 97 | 2.4 |
| | 4.0 | 4.82 | | |

*Determination of lead in preserved egg*

An appropriate amount of preserved egg was ground. A 0.5000 g sample was put into a beaker (250 ml), 5 ml $H_2SO_4$ and 15 ml $HNO_3$ were added and carefully heated under a cover on a hotplate, and then treated with 1*M* hydrochloric acid evaporated to near dryness. The digested sample was diluted to 100 ml (flask) with R-B buffer solution for analysis. Lead was determined by the above procedure. Table 4 summarizes the results obtained for the determination of lead and recovery studies on preserved eggs. The recovery of lead in preserved eggs was good.

# NON-LINEAR CURVE FITTING USING MICROSOFT EXCEL *SOLVER*

S. WALSH and D. DIAMOND*

School of Chemical Sciences, Dublin City University, Dublin 9, Ireland

(*Received* 8 *September* 1994; *Revised* 12 *October* 1994. *Accepted* 12 *October* 1994)

**Summary**—*Solver*, an analysis tool incorporated into Microsoft Excel V 5.0 for Windows, has been evaluated for solving non-linear equations. Test and experimental data sets have been processed, and the results suggest that *solver* can be successfully used for modelling data obtained in many analytical situations (*e.g.* chromatography and FIA peaks, fluorescence decays and ISE response characteristics). The relatively simple user interface, and the fact that Excel is commonly bundled free with new PCs makes it an ideal tool for those wishing to experiment with solving non-linear equations without having to purchase and learn a completely new package. The dynamic display of the iterative search process enables the user to monitor location of the optimum solution by the search algorithm. This, together with the almost universal availability of Excel, makes *solver* an ideal vehicle for teaching the principles of iterative non-linear curve fitting techniques. In addition, complete control of the modelling process lies with the user, who must present the raw data and enter the equation of the model, in contrast to many commercial packages bundled with instruments which perform these operations with a 'black-box' approach.

Recent trends in data generation, owing in part to the computerization of instrumentation, have led to larger and more complex data sets. Traditional approaches to experimental data processing are largely based on linearization and/or graphical methods. However, this can lead to problems where the model describing the data is inherently non-linear, or where the linearization process introduces data distortion (*e.g.* in standard deviations of data which are logarithmically related to the analyte concentration as with ion-selective electrodes). Hence, with the ready availability of the PCs in laboratories, there is increasing interest in applying non-linear curve fitting techniques to experimental data.

Computers provide an ideal tool to overcome such problems. Although statistical programs have been available for large main-frame computers for many years, these were often cumbersome to use and the computers were not readily available. Many of these statistical packages have now been converted for PCs, but their application to solving analytical data processing problems is still relatively rare as, although scientifically correct and effective, these packages tend to be engineer-orientated, not especially user-friendly and expensive.

In contrast, many analysts are very familiar with spreadsheets such as Microsoft Excel and Lotus 1-2-3, and several books have appeared recently describing their use as sophisticated calculators for processing, displaying and interpreting scientific data, and as tools for teaching calculations in chemistry.[1,2] The familiar Windows user interface, ready availability (often bundled free with new machines or on site-wide licence) and access to desk-top publishing for integrating text and graphics were the main attractions. However, like Lotus 1-2-3, Excel was primarily targeted at the business market, and was frustratingly under-developed for scientific applications, particularly in terms of display and data processing tools (*e.g.* non-linear regression). The balance has been somewhat addressed in recent years, and the appearance of powerful analysis tools such as *solver* makes Excel an important addition to the analyst's armoury for processing experimental data.

Central to the successful application of *solver* is the user's depth of understanding of the problem, in contrast to many analytical data processing packages, in particular those bundled with instruments which often employ a 'black-box' approach. With *solver*, the user

*Author to whom correspondence should be addressed.

must present the raw data in a spreadsheet, enter the model and model parameters correctly, and finally initiate the model building process. Graphical windows enable the dynamics of the model building process to be observed, a feature which can be used to great effect in teaching the principles of data modelling.

## USING *SOLVER*

The following steps describe the general principles of using *solver* which were used in all of the theoretical and practical examples described later. The data set to be modelled must first be obtained. In the case of theoretical studies, the data are generated by means of the equation of interest. A suitable range of values can be quickly obtained by means of the 'edit-fill-down' command. Figures 1 and 2 show the various procedures involved in finding the solution to a Gaussian peak generated using the well known equation;

$$f(X) = H \exp\left[\frac{-(X-\bar{x})^2}{\sigma^2}\right] + B, \qquad (1)$$

where $H$ = peak height above baseline, $X$ = point on $x$-axis, $\bar{x}$ = distance along $x$-axis to peak maximum, $\sigma$ = standard deviation of the peak, $B$ = baseline offset from zero.

Figure 1 shows the layout of a typical Excel spreadsheet prior to using *Solver* using data generated with equation 1. Column A contains the $x$-axis data, and column C Gaussian data generated via equation (1) using column A data and known values for the parameters $H$, $\bar{x}$, $\sigma$ and $B$, which have to be found by *solver*. Column B shows data generated using equation (1) with the initial starting values of $H$, $\bar{x}$, $\sigma$ and $B$ shown in cells G3 to G6. For convenience, these parameters should be entered as named variables in Excel using the 'insert-name' command.

In order to find the solution to the best-fit values of the Gaussian parameters, the user must present a target cell which contains the sum of squared residuals (SSR) between the known data (column C) and the estimated data (column B). The residuals are listed in column D and are obtained by subtracting equivalent cells in columns B and C. Column E contains

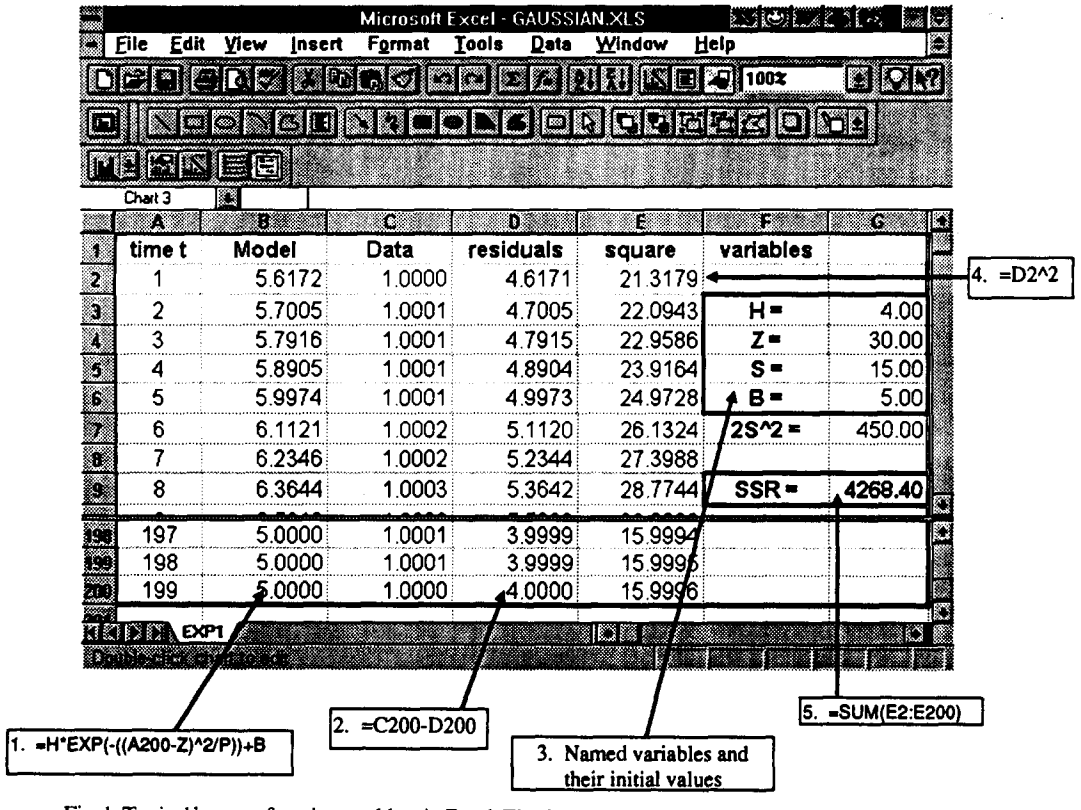

Fig. 1. Typical layout of a *solver* problem in Excel. The data in column C are for the Gaussian peak (generated via equation 1), and the model is entered in column B. Residual errors are in column D and their squares are in column E. The named variables used by *solver* are in cells G3–G6 and the sum of squared residuals (SSR) is in cell G9. Note that $\bar{x}$ is represented by $z$ and $\sigma$ by S in the named variables list.

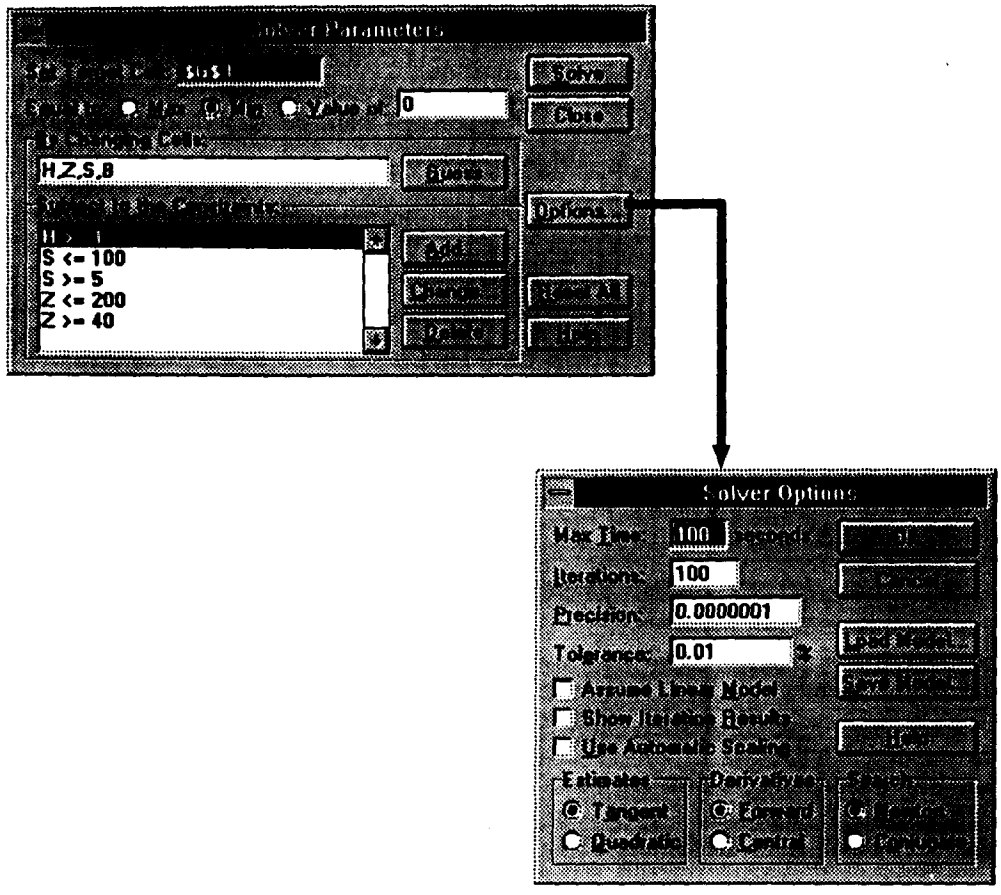

Fig. 2. (a) Initial panel presented to the user when *solver* is activated via the 'tools' menu. (b) The 'options' dialog box which opens when activated by the user. See text for further details.

the squared residuals, and cell G9 the sum of the squared residuals (*i.e.* the sum of cells E2 to E200). This is the quantity which will be minimized by *solver*.

*Solver* is activated via the *tools* menu. On activation, the user is presented with the panel shown in Fig. 2a, which in this case, is set up to solve the Gaussian problem described above. The user options available are:

*Set target cell* specifies the target cell which can be maximized, minimized or set to a certain value. In this case the target cell is *G*9 and it is set to be minimised.

*By changing cells* specifies the cells which will be varied by the search algorithm in order to minimise the number in cell *G*9, *i.e.* cells *G*3 to *G*6 in this example.

*Subject to the constraints*: constraints can be applied by the user to limit the search space explored by the optimization algorithm. As is usual in iterative search procedures based on gradient-type algorithms, efficiency is best if the search is initiated as near the global solution of the problem, and the unknown variables are restricted in value to realistic ranges. This of course implies that the user has considerable knowledge of the problem prior to initiating the search.

*Options* displays the solver options dialogue box (Fig. 2b) in which the user can vary more features of the solution process. These are:

*Max. time* limits the time allowed for the search process.

*Iterations* limits the number of iterations during the search process.

*Precision* sets the precision of the search process. This will determine the minimum change in the target cell which will cause the search process to stop. The best value for precision varies according to how far from the global optimum the initial search position is, and how smooth the error surface is.

*Tolerance* represents a percentage of error allowed in the optimal solution. A higher tolerance would tend to speed up the solution process but at the expense of accuracy in the final solution.

*Assume linear model* will speed up the solution process but obviously should be used only if the relationship is linear.
*Estimates* specifies the approach used to obtain initial estimates of the variables. Briefly, these are

*Tangent* uses linear extrapolation from a tangent vector. That is from a tangent, *solver* extrapolates in different directions to identify which gives a minimum for the target cell. This identifies the next direction of the search process.
*Quadratic* uses quadratic (*i.e.* non-linear) extrapolation which can greatly improve results in very non-linear problems at the expense of speed at arriving at an answer.

*Derivatives* forward and central differentiation options exist for estimates of partial derivatives which give the gradient of the search at that point.
*Search* determines which search algorithm (Newton and Conjugate) is used at each iteration. Both methods are dependent on the calculation of gradient values in the error surface at each stage in the iteration.[3,4]

The Newton method typically requires more memory than the conjugate search but requires fewer iterations. The conjugate search is useful if you have a complex problem (multiple model parameters, large data sets) and memory usage is a concern. We have found little difference in using either algorithm to date.

*Load/save model* is used when more than one solver model is to be used with the worksheet.
*Show iteration results* gives the user a complete update of all data after each complete iteration. If the estimated and known data are graphed, the user can observe a dynamic display of the search process as it proceeds through each iteration. This is very useful in observing visually the progress of the algorithm, but can obviously greatly slow down the process where a large number of iterations are involved. If this option is not exercised, the search process proceeds automatically, reporting only the value of the target cell after each iteration.
*Use automatic scaling* is useful in situations where data may be distorted through gross differences in the magnitude of various parameters in the search algorithm.

Figure 3 shows the results obtained with *solver* for the Gaussian problem. Figure 3a shows the initial position of the search, with the estimated data being well displaced from the required Gaussian curve. Figure 3b shows the final positions of the known and estimated data, illustrating the excellent fit obtained. The values returned by *solver* for the model parameters ($H = 10$, $\bar{x} = 100$, $\sigma = 20$ and $B = 1$) are equal to the values used to generate the test Gaussian curve.

*Modelling two overlapping Gaussian peaks*

A more difficult task is to model two overlapping Gaussian peaks, particularly where one of the peaks appears only as a shoulder on a more dominant peak, a situation which often occurs in spectroscopy and chromatography. Figure 4 illustrates such a situation which has been successfully modelled using *solver*. In this example, both the test data and the model data were generated using the equation;

$$f(x) = H_1 \exp\left[\frac{-(X-\bar{x}_1)^2}{2\sigma_1^2}\right] + H_2 \exp\left[\frac{-(X-\bar{x}_2)^2}{2\sigma_2^2}\right] + B, \qquad (2)$$

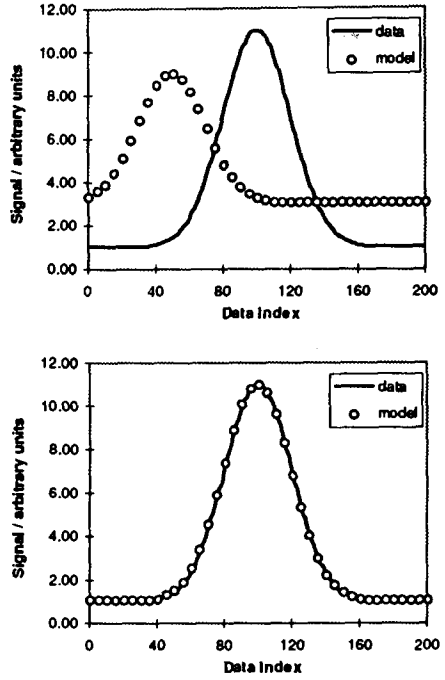

Fig. 3. Results returned by *solver* for the fit to the Gaussian data shown in Fig. 1. (a) The initial positions of the *solver* data and the Gaussian peak. (b) The final fit to the Gaussian peak obtained using *solver*.

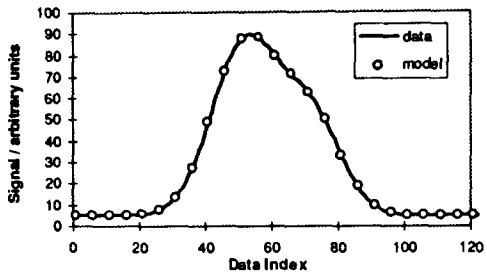

Fig. 4. Fit obtained with *solver* to two overlapping Gaussian peaks where one of the peaks appears only as a shoulder on a more dominant peak.

where $H_1$ = height of peak 1 above baseline, $H_2$ = height of peak 2 above baseline, $\bar{x}_1$ = position of peak 1 maximum along $x$-axis, $\bar{x}_2$ = position of peak 2 maximum along $x$-axis, $\sigma_1$ = standard deviation of peak 1, $\sigma_2$ = standard deviation of peak 2, $B$ = baseline offset from zero on $y$-axis.

Once again, the search returns an exact solution to the problems, with all parameters being successfully returned with the correct values ($H_1 = 80$, $\bar{x}_1 = 52$, $\sigma_1 = 10$, $H_2 = 45$, $\bar{x}_2 = 72$, $\sigma_2 = 9$ and $B = 5$).

Examples like these are very useful for teaching the principles of optimization and non-linear least squares fitting to graduate students, and in particular, in highlighting the need for direction by the user of the process, as initial conditions can easily be set which do not allow the algorithm to locate the desired minimum.

## MODELLING EXPERIMENTAL DATA

In this section, we demonstrate the application of *solver* to modelling experimental data sets which, unlike the theoretical tests discussed previously, will not have exact solutions. However, the validity of the results can be inferred by comparison with results obtained with other optimization algorithms, through knowledge of the system being studied or through examination of the error of the fit.

### *Example (1). Modelling chromatography peaks*

Chromatography (and flow-injection) peaks are characterized by a Gaussian-type shape distorted by tailing which occurs on the falling portion of the peak. Models such as the exponentially modified Gaussian[5-8] and the tanks-in-series[9,10] have been developed in order to allow this distortion of the standard Gaussian peak shape to be described mathematically. This has important applications in the area of data storage (results can be described mathematically rather than stored as relatively large ASCII files), and in the analysis of peak purity (*e.g.* by comparing the shape parameters of experimental peaks to that of a typical peak obtained with the analyte under normal conditions).

*Exponentially modified Gaussian model.*[5-8] The exponentially modified Gaussian function (EMG) is the result of the convolution of a Gaussian function and an exponential decay. In Excel, this is achieved as follows. $Y(n)$ represents an unconvoluted Gaussian data array of $n$ points calculated according to equation (1) above. The difference $\Delta Y(m)$ between a point $Y(m)$ and the previous point $Y(m-1)$ is easily obtained by subtracting the appropriate cells. The convoluted set of points, EMG($m$) is derived from the $Y(m)$ array as follows:

$$\mathrm{EMG}(m) = \mathrm{EMG}(m-1) + \left[\frac{Y(m) - \mathrm{EMG}(m-1)}{A}\right], \quad (3)$$

where

$$A = \left[\frac{1}{1 - \exp(-W_2/\tau)}\right] W_1, \quad (4)$$

where $\tau$ = time constant of the exponential decay (where a time dependent function is being modelled), $W_1$, $W_2$ = weighting factors, with $W_2$ normally set at unity and $m$ is the data index in the array.

On the spreadsheet, the Gaussian equation (1) is first used to create a Gaussian data array over the range of interest. The first point on this array is then set equal to the first convoluted point (EMG(1)). The second EMG point (EMG(2)) can then be calculated via equations (3) and (4) above. This procedure is repeated for the entire Gaussian array using the 'edit-fill-down' command in Excel.

*Tanks-in-series model.*[9,10] In this approach, the flow system is regarded as behaving as a series of mixing chambers which serve to distort the initial ideal square-wave concentration profile of the sample plug as it travels to the detector. The equation used in this instance is;

$$f(t) = H\left[\left(\frac{1}{T_i(t/T_i)^{N-1}}\right) \times \left(\frac{1}{(N-1)!}\right)\exp(-t/T_i)\right], \quad (5)$$

where $T_i$ = mean residence time of an element of fluid in any one mixing tank ($i$). $N$ = number of tanks, $t$ = time ($x$-axis index), $H$ = scaling factor.

Figure 5a–d illustrates the superior performance of the EMG model in describing an experimental HPLC peak. Figure 5a shows the best-fit obtained with the Gaussian model using solver while Fig. 5b and c shows the equivalent best-fit obtained with the EMG and tanks-in-series models, respectively. Figure 5d compares the residual errors obtained with each model expressed as a percentage of the response maximum, and while there is some structure in the

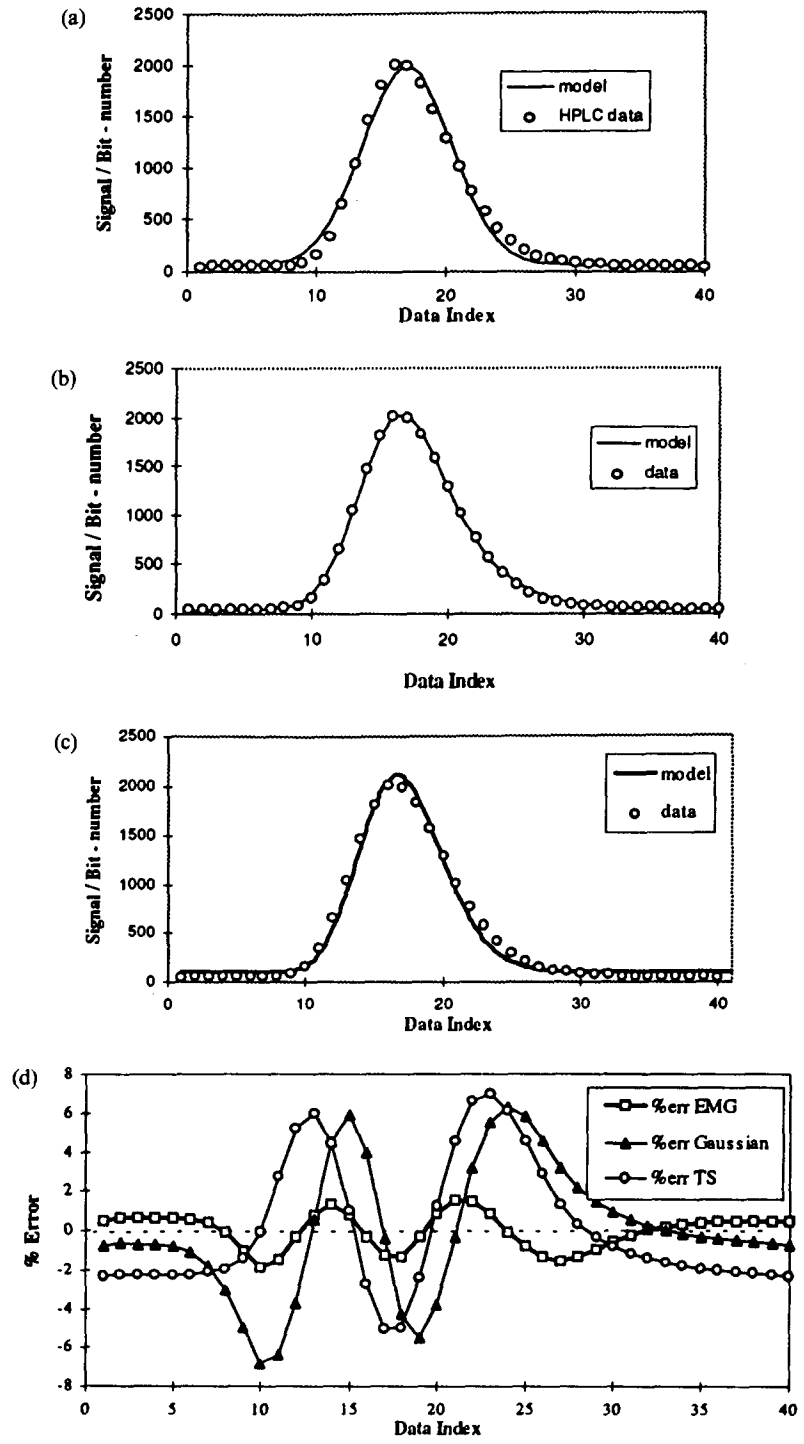

Fig. 5. Comparison of (a) Gaussian, (b) exponentially modified Gaussian (EMG), (c) tanks-in-series models to an experimental HPLC peak and (d) the residuals obtained for each fit (expressed as a % of the peak maximum). The unit 'Bit-number' refers to the number returned by the I/O card on digitization of the detector signal.

EMG residuals, the error is clearly much smaller than that obtained with the other models. The inability of the Gaussian model to cope with the peak tail is demonstrated by the comparatively large residual error for points 22–30 which is much reduced in the EMG residuals.

*Example (2). Modelling fluorescence decay processes*

The data set for the single exponential modelled in this equation refers to fluorescent emission decay lifetime measurements of the compound: ruthenium-bis(2,2′-bipyridyl)(5-isothiocyanate-1,10-phenanthroline) $[Ru(bpy)_2(NCSphen)]^{2+}$ using a Q-switched ND-YAG laser. The samples were aerated and measurements were carried out in 0.1*M* carbonate buffer (pH 9.6). The compound absorbs at 455 nm and is characterized by a fluorescence decay with a single time constant.

The double exponential model has been applied to fluorescent emission decay lifetime measurements of the same compound after attachment of bovine serum albumin via a thio-urea linkage.[11] Once again the samples were aerated and measurements carried out in 0.1*M* carbonate buffer (pH 9.6). Binding of the protein has little effect on the excitation and absorbance wavelengths but lifetimes of fluorescent centres near the binding sites are affected, leading to differing sets of fluorescent emissions emanating from species bound in different environments. The models used in this investigation were general single and double exponential equations of the form:

$$f(t) = [A(1 - \exp(-kt)] + B, \qquad (6)$$

where $A$ = pre-exponential factor, $k$ = rate constant, ($1/k$ = decay lifetime), $t$ = time, $B$ = baseline offset and for the double exponential

$$f(t) = [A_1(1 - \exp(-k_1 t)] + [A_2(1 - \exp(-k_2 t)] + B, \qquad (7)$$

where $A_1$, $A_2$ = pre-exponential factors, $k_1$, $k_2$ = rate constants, $t$ = time, $B$ = baseline offset.

Data obtained from the instrumentation are transformed to suit the above exponential models via in-house software prior to modelling.

Figure 6a and b illustrates the fit obtained using the single exponential model (equation 6) with the NCS compound, and the residuals of the fit, respectively. Clearly the model parameters returned by *solver* fit the data well, with the error (expressed as a percentage of the maximum response) never being greater than ±2%, which is quite acceptable given the noise on the original signal, and the time base of the experiment. The time constant obtained from the fit ($\tau = 450$ nsec) is typical of this material.

Figure 6c and c shows fits obtained with the protein bound ruthenium compound using the double exponential model (equation 7). Again, *solver* returns a good fit to the data, ($\tau_1 = 286$ nsec, $\tau_2 = 833$ nsec) with the error being within about ±3% outside the initial 200 ns of the curve. While, fitting two exponentials to data obtained in these experiments is almost certainly an approximation such an approach can yield important information on the environment of the fluorescent centre through examination of the time constants obtained, while the pre-exponential factors may yield information on the relative populations of centres in the different environments.[11] However, this is a matter of considerable debate amongst specialists in the area. For example, in these experiments it is likely that the fluorescent centres exist in a number of different environments which modify the emission characteristics (*e.g.* the time constants). The fit with the double exponential model is reasonably good, and the time constants obtained are in the range expected. However, the curvature in the residuals suggests that there is some additional structure in the data. This in turn indicates that the fluorescent centres exist in two main environments but this is probably not the complete picture. In addition, careful examination of the residuals suggests an oscillating structure above 1500 nsec, which can also be seen in the original data. It is likely that this is instrumental rather than chemical in origin (*e.g.* environmental noise).

*Example 3. Modelling ion-selective electrode characteristics*

ISEs can be characterized in terms of the well known Nikolskii–Eisenman equation (8) below in terms of the cell constant ($E^\circ$), the slope ($S$), and selectivity coefficients ($K_{ij}^{pot}$) which describe the effect of various interfering ions ($j$) on the response of the electrode to the primary ion ($i$):

$$E = E^\circ + S \log\left(a_i + \sum_j K_{ij}^{pot} a_j^{z_i/z_j}\right), \qquad (8)$$

where $a_i$ and $a_j$ are the activity of the primary and interfering ions, respectively, and $z_i$ and $z_j$ are their charges. We have used a simplified version of the above equation (neglecting the

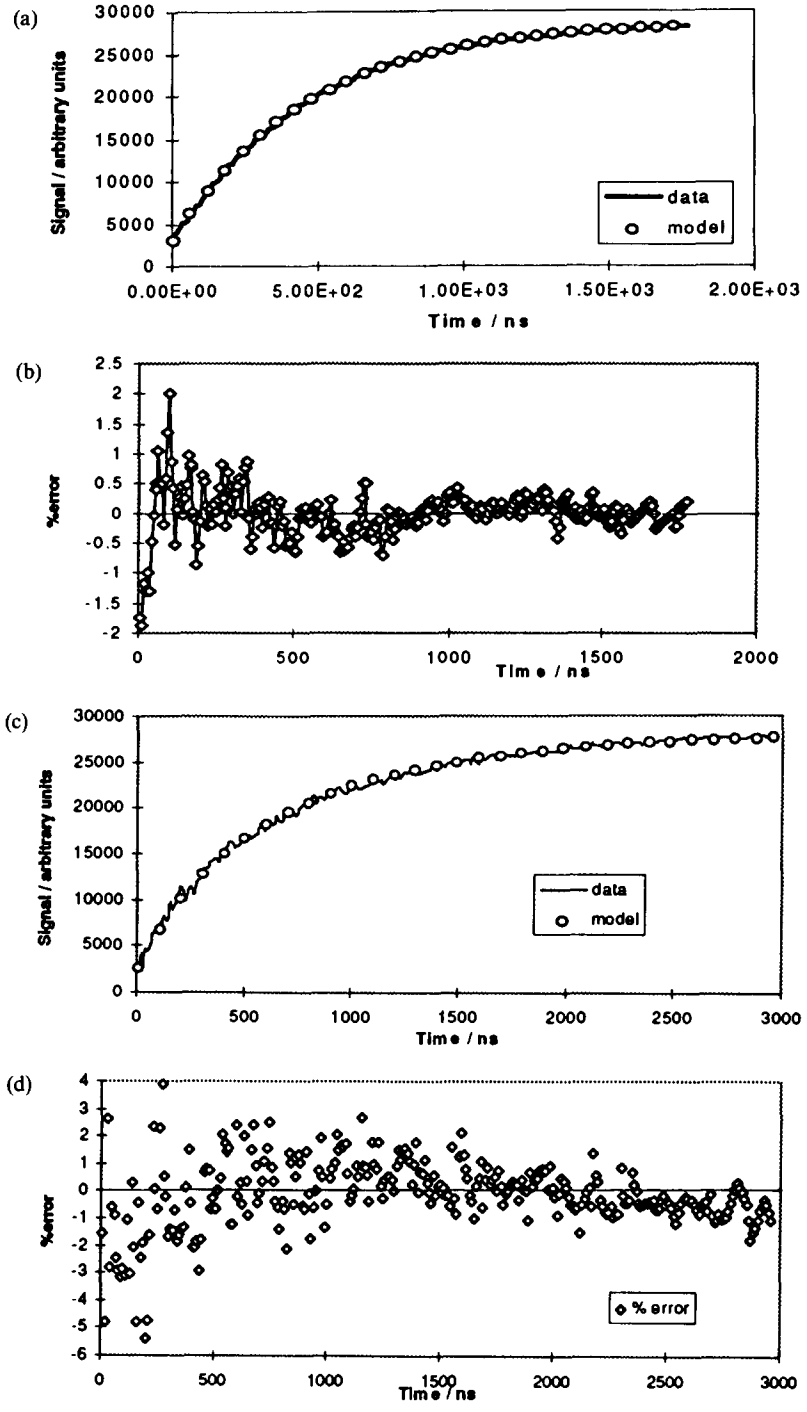

Fig. 6. (a) Fit obtained using a single exponential model for fluorescence decay obtained with ruthenium bipyridyl isothiocyanate phenanthroline using a Q-switched ND-YAG laser,[11] (b) residual errors obtained with the single exponential model. (c) Fit obtained using the double exponential model for the protein bound ruthenium bipyridyl isothiocyanate phenanthroline[11] and (d) the residual errors obtained with the double exponential model.

charge factors on $a_j$) extensively to enable errors on analytical signals arising from interferents to be decoupled and corrected.[12] Approaches such as simplex optimization and genetic algorithms[12,13] have been investigated for estimating the electrode characteristics (selectivity coefficients, slopes, cell constants), which involved extensive programme development. The methodology basically involves generating a matrix of electrode responses to a series of calibration

solutions containing the ions of interest at activity levels set according to a fractional factorial calibration design (see Tables 1 and 2). Thus for a four electrode array, 32 solutions are required, eight of which are targeted at each electrode (*e.g.* solutions 1–8, Table 1 are for the ammonium electrode, solutions 9–16 for the sodium electrode, solutions 17–24 for the potassium electrode and solutions 25–32 for the calcium electrode). We typically model the Nikolskii–Eisenman parameters for a particular electrode using the matrix of potentials obtained from the electrode array with the eight calibration solutions for that electrode, and then estimate the validity of the model by examining the residuals between the predicted array potentials (calculated via the model parameters and the known activities in Table 1) and the observed array potentials (Table 2).

Table 3 show a comparison of fits obtained for the potassium and sodium ISEs by three different approaches, *genetic algorithm with simplex optimization* (uses a genetic algorithm to locate the approximate position of the minimum of the error surface, and then switches to a simplex to fine-tune the position of the minimum), *simplex* (uses the simplex only) and *solver*, results obtained with *solver*.

Table 1. Matrix of ion-activities in calibration solutions[12,13]

| | Activities (*molar*) | | | |
|---|---|---|---|---|
| Solution | $NH_4^+$ | $Na^+$ | $K^+$ | $Ca^{2+}$ |
| 1 | 7.89E-03 | 7.10E-03 | 2.37E-03 | 3.18E-03 |

| 19 | 3.38E-03 | 6.76E-04 | 8.54E-03 | 3.61E-04 |
| 20 | 6.80E-04 | 2.55E-03 | 8.50E-03 | 2.11E-04 |
| 21 | 1.63E-03 | 7.34E-04 | 8.16E-05 | 4.07E-03 |
| 22 | 2.56E-04 | 3.42E-03 | 8.54E-05 | 1.61E-03 |
| 23 | 8.68E-04 | 4.34E-03 | 8.68E-05 | 5.15E-04 |
| 24 | 1.79E-04 | 3.58E-04 | 3.95E-05 | 1.93E-04 |
| 25 | 6.31E-03 | 5.52E-03 | 6.31E-04 | 3.98E-03 |
| 26 | 3.96E-03 | 5.55E-04 | 6.34E-03 | 4.05E-03 |
| 27 | 2.44E-04 | 8.13E-04 | 3.25E-04 | 4.46E-03 |
| 28 | 5.69E-04 | 8.12E-05 | 8.12E-04 | 4.45E-03 |
| 29 | 5.13E-03 | 5.13E-03 | 5.98E-04 | 5.41E-05 |
| 30 | 2.62E-03 | 6.99E-04 | 2.62E-03 | 5.87E-05 |
| 31 | 7.04E-04 | 1.76E-03 | 1.76E-03 | 6.05E-05 |
| 32 | 5.37E-04 | 4.48E-04 | 8.95E-05 | 6.46E-05 |

The results show good agreement on the values of the cell potential and slope for both electrodes with all three approaches. Furthermore, the values for selectivity coefficient for the main interferent are very close for both electrodes (*i.e.* around 0.18 for potassium interference on the ammonium electrode and 0.14 for the value of ammonium interference on the potassium electrode). Even the low-valued selectivity coefficients are modelled to around the same value in each case, which is surprising given their relatively minor effect on the fit. The worst case is for the sodium interference on the potassium electrode ($K^{pot}_{K^+,Na^+}$), for which a value could not be obtained with *solver*. However, examination of the values obtained with the other methods show this to be the smallest coefficient with least effect on the fit. These results show that *solver* can obtain good estimates of electrode parameters using the array-FIA calibration design. However, the genetic algorithm performs better and has the added advantage of being an unsupervised search technique (*i.e.* requires no prior knowledge of the problem). Nevertheless, considering the ease with which *solver* can be used, we feel it performed creditably well in this particular task.

*Example (4). Modelling of ion-selective electrode (ISE) dynamic response in flow-injection analysis*

We have also used *solver* to look at the dynamic responses obtained with PVC membrane electrodes in a flow-injection analysis set-up similar to that used in the calibration experiments.[12] One approach is to use a logistic/sigmoid model to characterize the rising portion of the ISE response peak. The equation used is:

$$E(t) = \left[\frac{a}{(1 + \exp[b(t - c)])^e}\right] + d, \qquad (9)$$

where a = peak height (mV), $b$ = slope coefficient (mV per decade change in $[K^+]$, $c$ = time from beginning of the peak to the inflexion on the rise (sec), $d$ = baseline offset (mV), $e$ = symmetry parameter for the sigmoid, $E(t)$ = electrode response at time $t$ (mV), $t$ = time (sec).

This model can give some indication of the rate of ion-uptake at the membrane surface as the sample plug passes and enable comparisons to be made for different experimental situations (varying concentration of the primary ion, effect

Table 2. Matrix of electrodes responses to calibration solutions[12,13]

| $K^{pot}_{K^+,Ca^{2+}}$ | $5.36 \times 10^{-3}$ | $5.32 \times 10^{-3}$ | $7.33 \times 10^{-3}$ |
| SSR (8) | 29.17 | 30.04 | 28.97 |
| SSR (32) | 497.7 | 496.3 | 481.8 |

The sum of the squared residuals (SSR) for each method is also shown. SSR (8) refers to the squared residuals for the eight calibration solutions and SSR (32) refers to the squared residuals over the whole situation set.

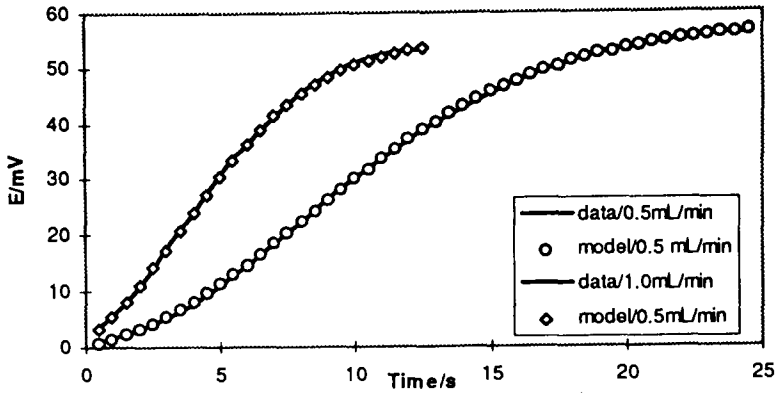

Fig. 7. Fit obtained with sigmoid model for the rising portion of FIA peaks obtained with a potassium PVC membrane electrode at 1.0 and 0.5 mL/min flow rates (see Table 4); Carrier composition: $5 \times 10^{-2}M$ $MgCl_2$, $10^{-6}M$ KCl. Sample composition: $5 \times 10^{-2}M$ $MgCl_2$, $10^{-4}M$ KCl; injection volume: 150 $\mu$l.

(1.0 and 0.5 ml/min). The model parameters returned by *solver* for each flow rate are compared in Table 4.

From these results we can deduce that increasing the flow rate causes a slight reduction in the peak height ($a$), an increase in the slope of the rise (given by the increased magnitude of $b$), a reduced time to the rise inflexion ($c$), and a less symmetrical rise in terms of the sigmoid model (larger value for $e$). Characterizing peaks in this manner can be very useful for instrumental optimization purposes as mentioned above, and for describing peak shapes in terms of a few simple parameters. This characterization can be useful for processing large numbers of peaks and for identifying the possible presence of impurities through the definition of a 'typical' analyte peak as possessing these parameters within certain limits.

## CONCLUSIONS

Using examples from chromatography, spectroscopy and electrochemistry, we have demonstrated the usefulness of *solver* as a tool for mathematical modelling of experimental data.

Table 4. Model parameters for sigmoid model of FIA peak rise obtained with valinomycin ISE in an FIA system at two different flow rates (see Fig. 7)

| Model parameters | 1.0 *ml/min* | 0.5 *ml/min* |
|---|---|---|
| $a$ (mV) | 5.70E + 01 | 5.93E + 01 |
| $b$ (mV per decade change in $[K^+]$) | −1.78E − 01 | −1.03E − 01 |
| $c$ (sec) | 4.84E + 00 | 9.59E + 00 |
| $d$ (mV) | −9.62E + 01 | −1.14E + 00 |
| $e$ | 7.49E + 00 | 4.16E + 00 |

Carrier composition: $5 \times 10^{-2}M$ $MgCl_2$, $10^{-6}M$ KCl. Sample composition: $5 \times 10^{-2}M$ $MgCl_2$, $10^{-4}M$ KCl. Injection volume: 150 $\mu$l.

While it is not on a par with custom-written software packages for this purpose such as Mathlab or Mathcad, or with more complex search methods such as genetic algorithms, it is nevertheless, quite a useful aid to data interpretation and an excellent means for introducing non-linear curve fitting into research and teaching. Given the fact that Excel is readily available, and familiar to most research and undergraduate students, it can be expected to be quickly adopted by many workers for such applications. However, the existence of *solver* appears to be not widely known, a situation which we hope this publication will redress in analytical circles. The fact that the user must import the experimental data, and arrange the spreadsheet in a suitable manner for each problem implies a complete understanding of the mathematics of the model. The ease with which named variables may be varied in Excel enables the user to experiment with equations and become familiarized with their effect on the curve obtained.

In conclusion, we hope the few examples presented in this paper will stimulate other workers unfamiliar with non-linear optimization to experiment with this very useful Excel add-on.

*Acknowledgements*—We wish to thank Maurice Burke (DCU) for providing the chromatography data, Johannes Vos (DCU) for the fluorescence data and useful discussions, and F. J. Sáez de Viteri and Margaret Hartnett (DCU) for the ISE data and useful discussions.

# SELECTIVE SPECTROPHOTOMETRIC DETERMINATION OF ASCORBIC ACID IN DRUGS AND FOODS

OSAMA H. ABDELMAGEED, PAKINAZ Y. KHASHABA, HASSAN F. ASKAL, GAMAL A. SALEH and IBRAHIM H. REFAAT

Department of Pharmaceutical Analytical Chemistry, Faculty of Pharmacy, Assiut University, Assiut, Egypt

(*Received* 31 *August* 1994. *Revised* 14 *October* 1994. *Accepted* 14 *October* 1994)

**Summary**—A new analytical method was developed for the determination of ascorbic acid. The method is based on the reaction of ascorbic acid with 4-chloro-7-nitrobenzofurazane (NBD-Cl) in the presence of 0.2*M* sodium hydroxide, where a bluish green colour ($\lambda_{max}$ 582 nm) is developed after dilution with 50% (v/v) aqueous acetone solution. Beer's law was obeyed in a concentration range of 5–20 $\mu$g ascorbic acid/ml with a good correlation coefficient ($r = 0.9990$). The method was found to be highly specific for the determination of ascorbic acid in the presence of dehydro-ascorbic acid, all other vitamins and minerals possibly present in multivitamin preparations, rutin, salicylamide, acetyl salicylic acid, paracetamol, caffeine, phenylephrine hydrochloride and dipyrone. Moreover, the proposed procedure was also successfully applied for the determination of ascorbic acid in some canned and fresh fruit juices, some vegetables and infant milk products without interference from coloured and other substances present in the plant extracts.

Ascorbic acid is an essential vitamin with recommended daily intake of about 70 mg. Continuing interest in the benefits of a well-balanced vitamin intake has resulted in the fortification of many food products with a variety of vitamins, including vitamin C or ascorbic acid. In the case of insufficient uptake the symptoms of scurvy appear.[1] Ascorbic acid occurs naturally in most fresh fruits, fruit juices and is often added during the manufacture of juices or soft drinks. Vitamin C degrades quickly and, therefore, there is special concern regarding the shelf-life of these fortified foods. Consequently, there has been considerable interest in alternative methods of determining the ascorbic acid content of food products.

Since spectrophotometric methods are the instrumental methods of choice commonly used in industrial laboratories; a great number of colourimetric methods have been proposed for the determination of ascorbic acid.[2–11] The majority of these methods are based on its oxidation–reduction properties or its ability to couple with diazotized aniline derivatives. Some of these methods are time consuming and suffer from lack of specificity or good sensitivity especially if they are used for the analysis of beverages, fruits or even some pharmaceutical preparations where colouring matter can interfere with the determination. Tedious pretreatment is often needed to remove possible interferents.[12,13] Therefore, the need for a fast, low cost and selective method is obvious, especially for routine quality control analysis of ascorbic acid-containing products.

In the present work, a facile, sensitive and selective method for the determination of ascorbic acid, based on its reaction with 4-chloro-7-nitrobenzofurazane in alkaline medium, is described.

## EXPERIMENTAL

### *Instrument*

Perkin-Elmer, Lambda 3 B UV/Vis (U.S.A.) and Uvidec-320 (Japan) spectrophotometers with two matched 1-cm quartz cells were used.

### *Reagents and materials*

4-Chloro-7-nitrobenzofurazane (NBD-Cl), (Fluka AG, Switzerland): a 0.1% (w/v) fresh solution in acetone was prepared daily. A 0.2*M* aqueous solution of sodium hydroxide and 25% (w/v) aqueous solution of trichloroacetic acid were prepared, each in distilled water. Ascorbic acid (Sigma, Germany), was used as working standard without further treatment. A stock solution was prepared immediately before use in

cold aqueous solution of 0.5% (w/v) citric acid. This solution was diluted quantitatively with 0.5% citric acid solution in order to obtain 50–200 $\mu$g/ml final concentrations. All other chemicals, reagents and solvents were of analytical grade.

*Dosage forms and food products*

The following commercial ascorbic acid formulations were subjected to analysis by the proposed procedure. Tablets containing only ascorbic acid: vitamin C tablets (Alex. Co., Egypt) and vitacid C effervescent tablets (CID Co., Egypt). Tablets containing ascorbic acid in combination with salicylamide: Cidal C tablets (CID Co., Egypt); in combination with rutin: Ruta C 60 (Kahira Co., Egypt); in combination with paracetamol, caffeine, phenylephrine hydrochloride: Rhino C (CID Co., Egypt). Tablets containing ascorbic acid with vitamins A, B complex, $D_2$, E, nicotinamide and calcium pantothenate together with minerals: Theregran Hematic (Squibb Co., Egypt). Effervescent tablets containing ascorbic acid and calcium carbonate: Vitacal forte and Vitacid Calcium. Tablets containing ascorbic acid and acetylsalicylic acid: Aspocid C. Tablets containing ascorbic acid and multivitamins: Gericid (CID Co., Egypt). Multivitamin capsules containing ascorbic acid and vitamins A, B complex, $D_2$ and E with minerals: Viterra plus (Pfizer, Egypt). Syrups containing ascorbic acid and vitamins A, B complex, $D_2$, E, nicotinamide and calcium pantothenate: Beco C (Misr Co., Egypt), Fruital (CID Co., Egypt) and phosphoplex C (Kahira Co., Egypt). Ampoules containing ascorbic acid only: Cevarol; ascorbic acid in combination with dipyrone: Cevagine (Memphis Co., Egypt). Drops containing ascorbic acid as a single component: Ceviline drops (Kahira Co., Egypt). Canned fruit juices: orange juice (Edfina Co., Egypt), orange juice (Kaha Co., Egypt); apple juice (Foodico Co., Egypt). Fresh fruits and vegetables such as parsley, green pepper, lemon and tomato were purchased from the local market and subjected to the described extraction procedure. Infant milk formula: Dialac-m (N.V. Nutricia, Holland), Neslac® (Nestlé, Holland) and Bebelac® No. 1 (B.V. Lijempf, Holland).

*General procedure*

Into a 10-ml volumetric flask, 1.0 ml of standard or sample preparation was pipetted followed by 1.0 ml of 0.2*M* sodium hydroxide and 1.0 ml of 0.1% (W/V) NBD-Cl solution. The contents of the flask were mixed well and diluted to volume with 50% (v/v) aqueous acetone. The absorbance of the resulting solution was measured at about 582 nm against reagent blank prepared similarly.

*Tablets*

An accurately weighed amount of powder, obtained from 20 tablets, equivalent to about 50 mg of ascorbic acid, was transferred into a 100-ml volumetric flask. 0.5% (w/v) citric acid solution was added to volume and the content of the flask was shaken for about 5 min, filtered and the first portion of the filtrate was rejected. This solution was further diluted with 0.5% (w/v) citric acid to obtain 100 $\mu$g/ml. Then 1.0 ml of this sample preparation was analysed as described under general procedure.

*Capsules*

The contents of 10 capsules were mixed and weighted. Then an amount of the mixed powder equivalent to 50 mg vitamin C was transferred into a 100-ml volumetric flask. The volume was completed with 0.5% (w/v) citric acid solution. The procedure was completed as described for tablet preparation.

*Ampoules, syrups and drops*

An accurately measured volume, equivalent to about 50 mg of ascorbic acid was transferred into a 100-ml volumetric flask. 0.5% (w/v) citric acid solution was added to volume and the contents were mixed well. This solution was further diluted with the same solvent to obtain a sample preparation containing 100 $\mu$g/ml. The procedure was completed as described under general procedure.

*Canned juices*

An accurately weighed amount equivalent to 1.0 g from canned fruit juice was transferred into a 10-ml volumetric flask and diluted to volume with 0.5% (w/v) citric acid. The contents of the flask were mixed well, filtered if necessary and 1.0 ml from this solution was used for the analysis of ascorbic acid as described under general procedure.

*Fruit extracts*

About 50 g portions of each sample was squeezed or homogenized mechanically for about 5 min and then extracted separately with

about 75 ml of 0.5% (w/v) citric acid in divided portions. The extracts obtained were filtered into a 100-ml volumetric flask and the filtrate was made up to volume with the same solution. These solutions were used for the analysis or diluted quantitatively, if necessary, with 0.5% (w/v) citric acid solution to obtain suitable concentrations for the assay. For parsley and green pepper samples a pretreatment step was done before dilution where the extracts were shaken with petroleum ether several times followed by filtration into a 100-ml volumetric flask.

*Infant milk*

About 15 g of the powder milk was accurately weighed in a 250-ml beaker, 80 ml of 0.5% (w/v) citric acid solution was added and the contents were mixed well with continuous stirring in order to obtain a homogenized preparation. A 25% (w/v) aqueous solution of trichloroacetic acid was added dropwise until coagulation of milk started to occur. The mixture was allowed to stand for about 5 min, followed by filtration into a 100-ml volumetric flask. The residue was washed with citric acid solution and the filtrate as well as washing solution, after mixing, was completed to about 95 ml and was treated with 1*N* sodium hydroxide dropwise so as to bring the solution to a final pH of about 6.5. The solution was made up to volume using 0.5% (w/v) citric acid solution and 1.0 ml of this solution was used for the determination of vitamin C content as described under general procedure.

## RESULTS AND DISCUSSION

*Features of the reaction*

4-Chloro-7-nitrobenzofurazane (NBD-Cl), as an activated halide derivative, was first introduced as an analytical fluorigenic reagent for the determination of some amines and amino acids.[14] In a recent report NBD-Cl was further used, for the first time, as a colourimetric reagent for the determination of D-penicillamine in its bulk form and in the presence of other degradation products of penicillin and other possible ingredients that may be present in tablet formulation such as ascorbic acid.[15] Ascorbic acid was found to interfere with the suggested method.[15] Therefore, owing to the fact that no reports could be found in the available literature regarding the use of the cited reagent for the analysis of ascorbic acid in any available dosage forms or in food products, it was decided to extend our previous study to develop a novel approach for the determination of ascorbic acid in bulk drug, dosage forms and some food products.

*Optimization of conditions and absorption spectrum of the reaction product*

Conditions under which the reaction of ascorbic acid with NBD-Cl fulfills the essential analytical requirements were investigated. All conditions studied were optimized at room temperature (25 ± 5°C) and away from direct sun or artificial day light. Because an aqueous solution of ascorbic acid is known to be unstable, 0.5% (w/v) citric acid, was used as an aqueous medium for the cited drug throughout this work as an efficient stabilizer.[16] To generate the nucleophile from ascorbic acid different inorganic aqueous bases were used, such as borax, sodium hydroxide, sodium carbonate or bicarbonate, sodium acetate and sodium dihydrogen phosphate, all 0.1–0.5*M*. The best results were observed with about 1 ml of 0.2*M* sodium hydroxide. The solvents used for NBD-Cl as well as for dilution of the colour formed were carefully studied. A marked red shift was observed with acetone rather than other polar solvents such as alcohols. These results are in good agreement with our previous report.[15] For this reason 0.1% NBD-Cl (w/v), in acetone was recommended and about 1 ml was found to be satisfactory. Because dilution of the colour formed with pure acetone resulted in colloidal solution, probably owing to separation of the excess base, 50% (v/v) aqueous acetone is recommended to avoid any precipitation. Under these conditions the reaction between NBD-Cl and ascorbic acid was found to be instantaneous

*Average of five determinations.

@B.P., 1988, p. 47. (Ref. 23); for other dosage forms, Ref. 10 was used as the reported method.

and stable for at least 30 min as long as it was kept from direct sun or artificial light. Figure 1 represents the bluish-green coloured product with two maxima at about 458 and 582 nm. At 582 nm both the reagent and ascorbic acid have no absorption. In addition, being the more red-shifted one it is expected that measurement at 582 nm should eliminate any interferences which may arise from the presence of colouring matter present in fruits, vegetables or added to liquid pharmaceutical preparations. In our previous report[15] it was proved that reagent blank, prepared under similar conditions, has absorption values in the region of 285–485 nm, with minimum or neglected absorption at 558–612 nm.[15] Therefore, the maximum at about 458 nm probably represents the absorption of the NBD moiety in the reaction product.

Table 2. Determination of ascorbic acid in some canned fruit juices

| Juice | Found* ($\mu g/g \pm$ SD) | Reported† ($\mu g/g$) |
|---|---|---|
| Apple (Foodico) | 8 ± 0.31 | 2–36 |
| Orange (Kaha) | 300 ± 0.50 | 97–700 |
| Orange (Edvina) | 350 ± 0.28 | 97–700 |

*Average of three determinations per sample.

†Ref. 18

*Quantification*

A linear correlation ($r = 0.9990$) was found between the absorbance at 582 nm and the concentration of ascorbic acid in the range of 5–20 $\mu$g/ml. Regression analysis of Beer's plot gave the following linear regression equation:

$$A_{582} = 0.02 + 0.036C \quad (n = 6),$$

where $A_{582}$ is the absorbance at 582 nm and $C$ is the concentration in $\mu$g/ml. This equation has a slope of 0.036 with an intercept of 0.02.

*Application of the proposed method to real samples*

The basic method, as described, was applied for the determination of ascorbic acid in various pharmaceutical preparations (Table 1). Good recoveries were obtained with tablets, capsules and solutions without interference from vitamins A, B complex, D and E, minerals, rutin, acetylsalicylic, salicylamide, paracetamol, caffeine, phenylephrine hydrochloride, dipyrone and tablet excepients.

Results in Tables 2 and 3 give the ascorbic acid contents of some of the seasonally available canned fruit juices or fresh vegetables analysed by the proposed method. The values were found

†Ref. 17

to be consistent with the normal concentrations of ascorbic acid reported.[17,18] No interference was observed from the presence of the very complex matrix of the fruit juices or vegetables as indicated by the good recovery of ascorbic acid added to the studied samples. The only recommended pretreatment step was the extraction of chlorophyll with petroleum ether in the case of parsley and green pepper.

Moreover, analysis of different products of dried infant milk for their ascorbic acid content were successfully carried out (Table 4). Trichloroacetic acid, used for milk protein precipitation, being a strong acid can affect the pH of the medium. Therefore, the pH of the studied solution was readjusted to its optimal value, about 6.5, using 1*M* aqueous sodium hydroxide solution, prior to the application of the suggested procedure.

*Possible mechanism*

Being an active halide derivative, NBD-Cl was considered as a likely target for good nucleophile, under basic condition, such as amines, amino acids and thio-compounds.[14,15] This nucleophilic displacement reaction mechanism (SN2) seems obvious in the case of ascorbic acid reaction with the cited reagent. Treatment of ascorbic acid solution with aqueous sodium hydroxide should produce an ascorbate anion (Scheme 1), as reported,[19–21] which in turn can act as nucleophile to displace the $Cl^-$ anion of NBD-Cl to give the corresponding 4-substituted-7-nitro-benzofurazane derivative (Scheme 2). The suggested mechanism is proved by the experimentally negative results obtained upon the interaction of dehydroascorbic acid (Scheme 1), which represents the oxidized form of the enediol group of ascorbic acid, with NBD-Cl under exactly the same described condition. No colour is produced even at concentrations several times more than that recommended for ascorbic acid. Further proof was obtained through the application of Job's method of continuous variation,[22] which revealed a 1:1 ratio of ascorbic acid to NBD-Cl. These findings indicate that the ascorbate anion is the only nucleophile formed during the reaction. Accordingly, the presence of the enediol group makes this reaction highly specific for the determination of ascorbic acid in the presence of other vitamins or/and dehydroascorbic acid.

Another mechanism based on an ion association complex between the two reactants is unlikely owing to the fact that no report(s) could be found in the literature indicating the possible use of NBD-Cl as a basic or acidic dye.

Experimentally, trials have been carried out to extract the colour formed at 582 nm, before and after dilution with 50% (v/v) aqueous acetone, using some water immiscible solvents such as chloroform or toluene. No colour was observed in the immiscible solvents which strongly disagrees with the idea of an ion associ-

## CONCLUSION

The proposed method offers several advantages over previously used procedures, as it has a high degree of specificity owing to the enediol group of ascorbic acid. With the proposed method, any reducible substances, *e.g.* sugars, should not interfere when present in quantities usually encountered in multivitamin preparations. The method holds good promise for the possible determination of ascorbic acid in biological fluids which will be our target in the future.

(*Received* 3 *June* 1994. *Revised* 14 *October* 1994. *Accepted* 14 *October* 1994)

**Summary**—It was proved that the $N_4$-oxide group included in chlordiazepoxide (CDZ) is involved in its phototoxicity. At a wavelength of 350 nm, CDZ photoisomerizes only into oxaziridine (OXA) which is not available as standard. In the course of cytotoxicity investigations, the optimal CDZ irradiation conditions were established as acetonitrile as solvent, 10°C as temperature of the irradiated solutions and 70–90 min as irradiation time for solutions in the range of 12.2–152.0 μg/ml. The kinetic parameters of the CDZ photodegradation reaction order have been calculated using an appropriate algorithm. In all cases, the first order reversible or irreversible was selected by Akaïke's criteria. The percentage of undecomposed CDZ and OXA generated after irradiation were determined by a reversed HPLC method. The latter also permitted the separation of CDZ major impurities in aqueous solutions (demoxepam and 2-amino-5-chlorobenzophenone) as well as the oxaziridine of demoxepam. In this study, the experimental irradiation conditions allowed us to produce 98% pure OXA from CDZ. This HPLC method could be easily extended to the analysis of the molecules in pharmaceutical studies.

Chlordiazepoxide (CDZ) usually used as a tranquillizer, induces undesired side-effects after its consumption and human exposure to sunlight.[1-4] The 1-4 benzodiazepine derivative contains a $N_4$-oxide function involved in the CDZ phototoxicity.[5,6] When exposed to daylight, CDZ, as well as its two major metabolites, desmethylchlordiazepoxide (DES-CDZ) and demoxepam (DEM) respectively, photoisomerize into a photolabile oxaziridine derivative[7,8] (Fig. 1). The epoxy function included in this molecule is unstable. When exposed to UV radiation, it is transformed into quinoxaline and benzoxadiazocine[9,10] and when submitted to high temperature, it is converted back to the parent drug.[7,11]

According to Cornelissen *et al.*,[10,12] 350 nm is the optimal wavelength to photoisomerize CDZ into oxaziridine and avoid its subsequent photodecomposition. In this work, we developed and validated on the one hand a reversed-phase high performance liquid chromatography method in order to quantify the CDZ degradation and the formation of its oxaziridine derivative and on the other we determined the optimal irradiation conditions to quantitatively produce pure OXA as well as to calculate the CDZ photodegradation kinetic parameters. This study is a major step in the investigation of the potential *in vitro* anticancer activity of oxaziridine (unpublished data).

## EXPERIMENTAL

### *Reagents and solutions*

Chlordiazepoxide (CDZ) was kindly supplied by Hoffman-La-Roche (Belgium). Chlordiazepoxide hydrochloride (CDZ HCL) was purchased from Federa (Belgium) and 2-amino-5-chlorobenzophenone from Sigma (Belgium). Demoxepam was synthesized according to published methods.[13,14] Disodium hydrogen phosphate . $2H_2O$ and potassium monohydrogen phosphate were of analytical grade (Merck). Acetonitrile was HPLC grade (Labscan analytical science). House-purified, HPLC grade water, was used in all mobile phases and solutions. The mobile phases were filtered through 0.2 μm membranes and sonicated before use.

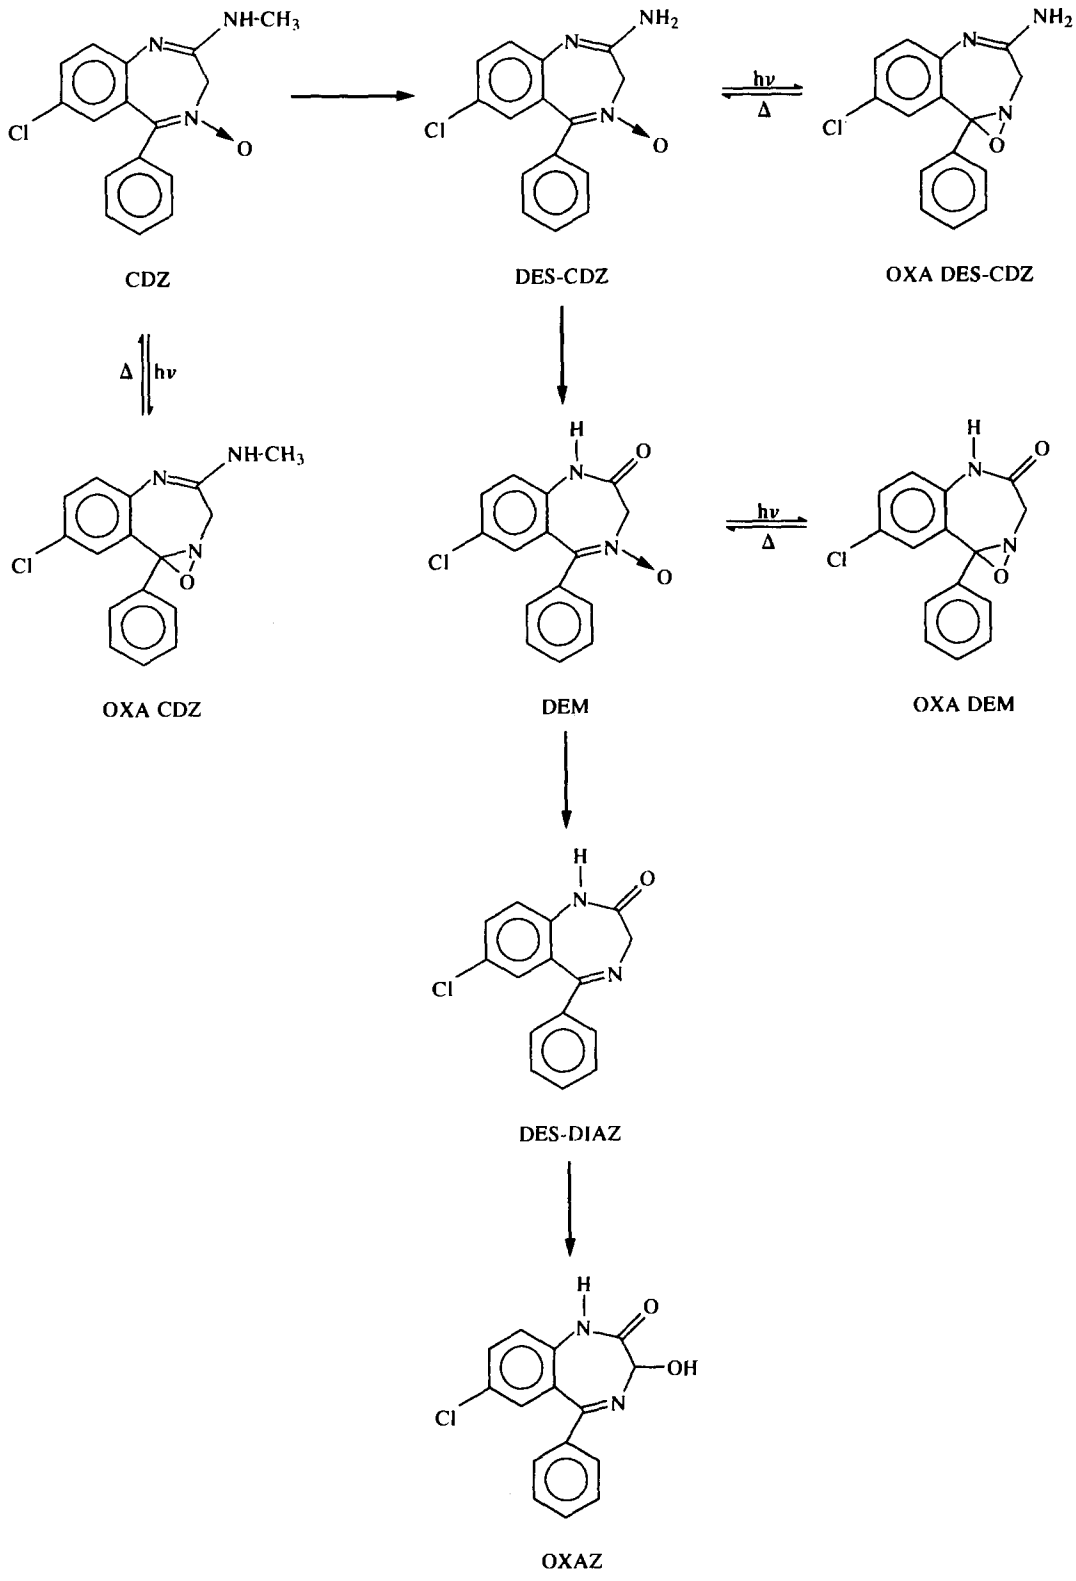

Fig. 1. Structures of chlordiazepoxide (CDZ), its metabolites (DES-CDZ, desmethylchlordiazepoxide; DEM, demoxepam; DES-DIAZ, desmethyldiazepam; OXAZ, oxazepam) and its photoproducts (OXA CDZ, oxaziridine of chlordiazepoxide; OXA DES-CDZ, oxaziridine of desmethylchlordiazepoxide; OXA DEM, oxaziridine of demoxepam).

*The HPLC system*

The HPLC system consisted of a Gilson model 305 pump (Gilson) a model 7125 loop injector (Rheodyne) and a HM holochrome UV monitor (Gilson) connected to a recorder (Kipp and Zonen). The chromatographic column (100 × 4.6 mm i.d.) was packed with 5 $\mu$m particles of $C_{18}$ Nucleosil (Chrompack) and operated at 20°C with a flow rate of 1 ml/min. The mobile phase consisted of a mixture of 0.07*M* phosphate buffer at pH 5.4 and $CH_3CN$ (70:30), 20–70 $\mu$l samples were injected and detection was performed at 280 nm.

*The irradiation system*

The irradiation system was built in our laboratory (Fig. 2). The materials (Oriel, Stratford, U.S.A.) used were: (a) an arc lamp power supply 68806 which operates with a 150 W xenon lamp; (b) a photomax lamp housing 60100 with the xenon lamp in the vertical position, a reflector provided with a demineralized water circulation cooling system, a system of mirror RAL-UV and lens; (c) a monochromator with a band pass of 6 nm and settled at 350 nm; (d) a sample vessel (1 cm i.d., 1 cm height), 0.7 ml volume and thermostatted at a fixed temperature.

*Purity and identification analysis*

The IR spectra were recorded on a Perkin-Elmer 1720 × spectrophotometer equipped with a liquid nitrogen cooled TGA detector, having a resolution of 2 $cm^{-1}$. The oxaziridine was generated after irradiation of a CDZ base solution at a concentration of *ca.* 30 $\mu$g/100 $\mu$l acetonitrile. The CDZ and oxaziridine solutions were deposited on a thallium plate and dried gently under $N_2$ stream before analysis.

The NMR spectra of oxaziridine dissolved in $CDCl_3$ was recorded on a Bruker 2.50 WM; the amount of drug used for NMR spectra was obtained by pooling solutions of six successive CDZ irradiations.

The diode-array analysis [Beckman Instruments: module 168 system gold and system gold chromatography software (ASW-2)] were used for purity determination as well as UV analysis.

*Conditions for the CDZ UV irradiation*

Irradiation was carried out at 350 nm (power supply of the lamp setting at 6.5 A for a tension of 18 V). The energy measured with a OL 730 digital radiometer (Optronic, Orlando, USA), at the surface of the sample, was 0.22 $mW/cm^2$.

Different parameters were investigated: (a) influence of the sample volume (solution volumes between 0.1 and 0.7 ml were tested); (b) influence of the nature of the solvent (organic solvent: acetonitrile and chromatographic mobile phase); (c) influence of the temperature (two different temperatures, 20° and 10°C were considered).

*Kinetic study and data analysis*

Different initial concentrations of CDZ base dissolved in acetonitrile (12.2, 38.0, 60.8, 76.0, 152.0 and 304.0 $\mu$g/ml) were irradiated at 10°C.

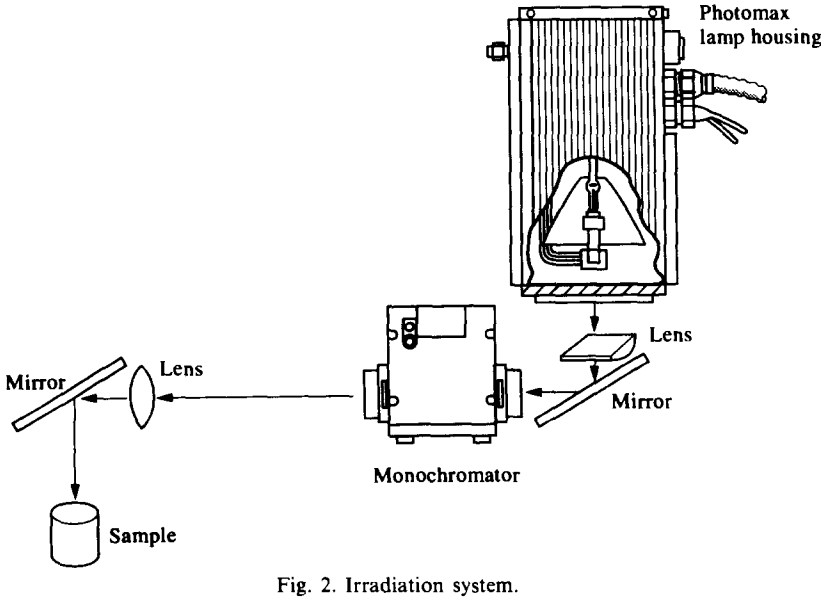

Fig. 2. Irradiation system.

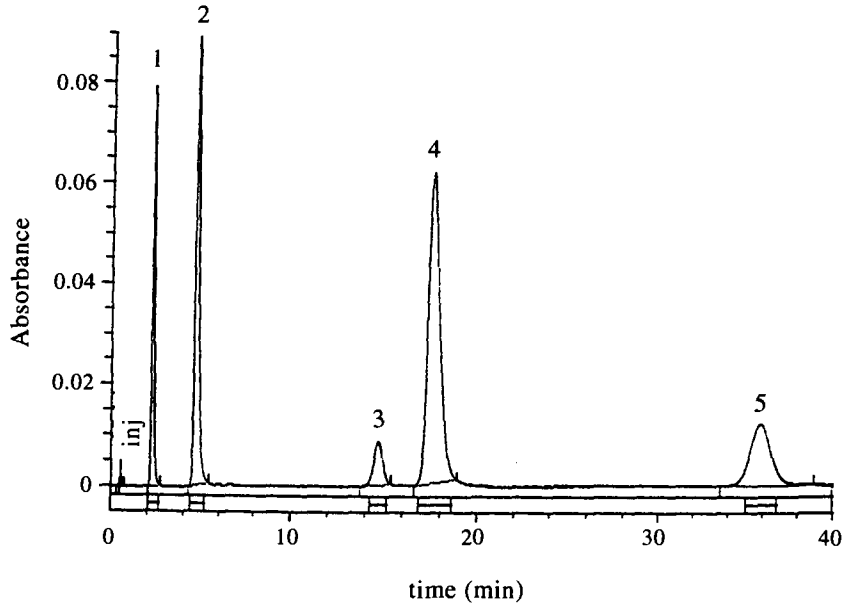

Fig. 3. HPLC separation of chlordiazepoxide (**2**), its photoproduct (**4**) and its decomposition products, namely demoxepam (**1**), as well as its oxaziridine (**3**) and 2-amino-5-chlorobenzophenone (**5**) after irradiation.

Firstly, the data were computed to classical kinetic models namely order O, order 1 reversible or not, order 2. For each concentration studied, the first order reversible or not was selected. Secondly to improve the estimation of CDZ photoizomerization kinetic parameters three software packages were compared: (a) Linreg[15] is based on a least square linear regression analysis. In this regression analysis, data were converted to provide a logarithmic linear transformation. First order reversible equation:

$$\ln(A_t - A_\infty) = \ln(A_o - A_\infty) - Kt, \qquad (1)$$

where $A_t$ is CDZ concentration at time $t$ ($\mu$g/ml), $A_\infty$ is CDZ concentration at time infinity ($\mu$g/ml), $A_o$ is initial CDZ concentration ($\mu$g/ml), $K$ is apparent rate constant ($min^{-1}$), $t$ is time (min). Here, a value for $A_\infty$ is required to allow the logarithmic transformations to $\ln(A_t - A_\infty)$. In the case of first order irreversible, $A_\infty = 0$.

Generally, $A_\infty$ is not known and the usual programs such as Linreg[15] only calculate an approximative concentration at infinity which is then used in the linear regression analysis. In this way, estimations of kinetic rate constants are often erroneous. The best value of $A_\infty$ can only be estimated after non-linear least squares regression analysis by optimization of the parameters in equation (2).

(b) Nonreg[15] and FADHA[16] are based on non-linear least squares regression analysis. Data are fitted to first reversible and irreversible ($A_\infty = 0$) equations (equation 2). First order reversible equation:

$$A_t = A_o e^{-kt} + A_\infty(1 - e^{-kt}). \qquad (2)$$

Nonreg estimations of parameters are based on matrix calculations.[15] In FADHA, we developed an algorithm based on the simplex method which minimizes a non-linear cost function by a sequence of elementary geometric transformations.[16–18]

(c) The Akaïke information criteria (AIC)[19] selected the equation describing the best fit to the data. It is viewed as the sum of a measure of the model fitting criterion and a penalty function proportional to the number of parameters $p$ in the model. In weighted least square analysis with Gaussian errors, the criteria is $AIC = N \ln F + 2p$ in which $F$ is the weighted sum of deviations squared with the $p^{th}$ set of parameters ($F$ = cost function). The lowest value of AIC selects the best model.

## RESULTS AND DISCUSSION

The main objective of this analytical section was to develop a HPLC method suitable to determine the best irradiation conditions to generate OXA-CDZ (peak 4, Fig. 3) and to study the kinetic parameters of this photoisomerization. This method was also used to

follow the photoisomerization kinetic of CDZ metabolites (DEM and DES-CDZ) into their oxaziridine derivatives, OXA-DEM and OXA-DES-CDZ (see Fig. 1) (unpublished data). The HPLC methods described in the literature determined the kinetic parameters of the CDZ hydrolysis in aqueous solutions[20,21] and quantified its impurities, namely demoxepam (DEM) and 2-amino-5-chlorobenzophenone (BENZ).[22] Our method permitted the separation of CDZ, DEM and BENZ and the photoproducts of DEM and of CDZ (Fig. 3).

However, the total analysis time is rather high because of the differences in the chromatographic behaviour between CDZ (peak 2), DEM (peak 1) and their oxaziridine derivatives (peaks 4 and 3, respectively). The latter appear to be more lipophilic drugs.

Selectivity of the method and purity of the peaks were controlled by the diode array Gold system.

The linearity of the calibration curve was checked over the range of 1.1–225.4 $\mu$g/ml of CDZ dissolved in acetonitrile. The equation of the mean calibration graphs and the mean regression coefficients as well as standard deviations are given in Table 1 (results of seven successive days). The absolute detection and quantification limits were: 4 ng (for a concentration yielding a signal-to-noise ratio of 2:1) and 20 ng (for concentration yielding a signal-to-noise ratio of 10:1), respectively. Intra- and inter-days determinations of CDZ before irradiation by this HPLC method show a good precision with a mean RSD lower than 4.0%. In order to evaluate the precision of the HPLC assay coupled with the irradiation procedure, three initial CDZ concentrations were irradiated during 70 min (12.2 and 60.8 $\mu$g/ml) or 90 min (304.0 $\mu$g/ml) in $CH_3CN$ before injection. Under these conditions intra-day precisions for CDZ and OXA results were very good since the mean percentage of RSD was below 5%. The inter-day precision for CDZ was maintained under 6% in spite of the low concentration of this drug remaining in solution (0.28 $\mu$g/ml) after a complete as possible isomerization.

This irradiation procedure involves the generation of high concentrations of oxaziridine which can then be measured with an inter-day precision lower than 9%.

Our results showed that the variances were concentration dependent after Fisher–Snedecor's $F$ test ($P < 0.05$). The overall accuracies within the concentration range determined (3.9–175 $\mu$g/ml) were 97–104% with an inter-day RSD less than 5%.

The oxaziridine of CDZ was identified by IR, UV and NMR analysis. UV and NMR spectra were previously published[7,10] and our results have confirmed these works. However, the IR spectra of this drug had not been reported (Fig. 4). The CDZ spectrum showed a characteristical peak of the symmetric stretching of the N—O bond at 1173 $cm^{-1}$, whereas the oxaziridine spectrum indicated two characteristical peaks of the epoxy function: one at 957 $cm^{-1}$ for the asymmetrical ring deformation and the other at 884 $cm^{-1}$ for the symmetrical ring deformation.

One of the main objectives of this study was to produce large amounts of very pure oxaziridine. Experimental conditions which influence CDZ photodegradation were thus particularly investigated, i.e. sample volume, solvent influence, temperature, time of irradiation, sample concentrations.

Several volumes of the sample vessel were investigated. Results showed that 41.3 $\mu$g/ml of CDZ HCl and of CDZ base dissolved in the chromatographic mobile phase (30% acetonitrile) and in pure acetonitrile, respectively, and irradiated for 10 or 34 min at 20°C produce the same percentage of oxaziridine independently of

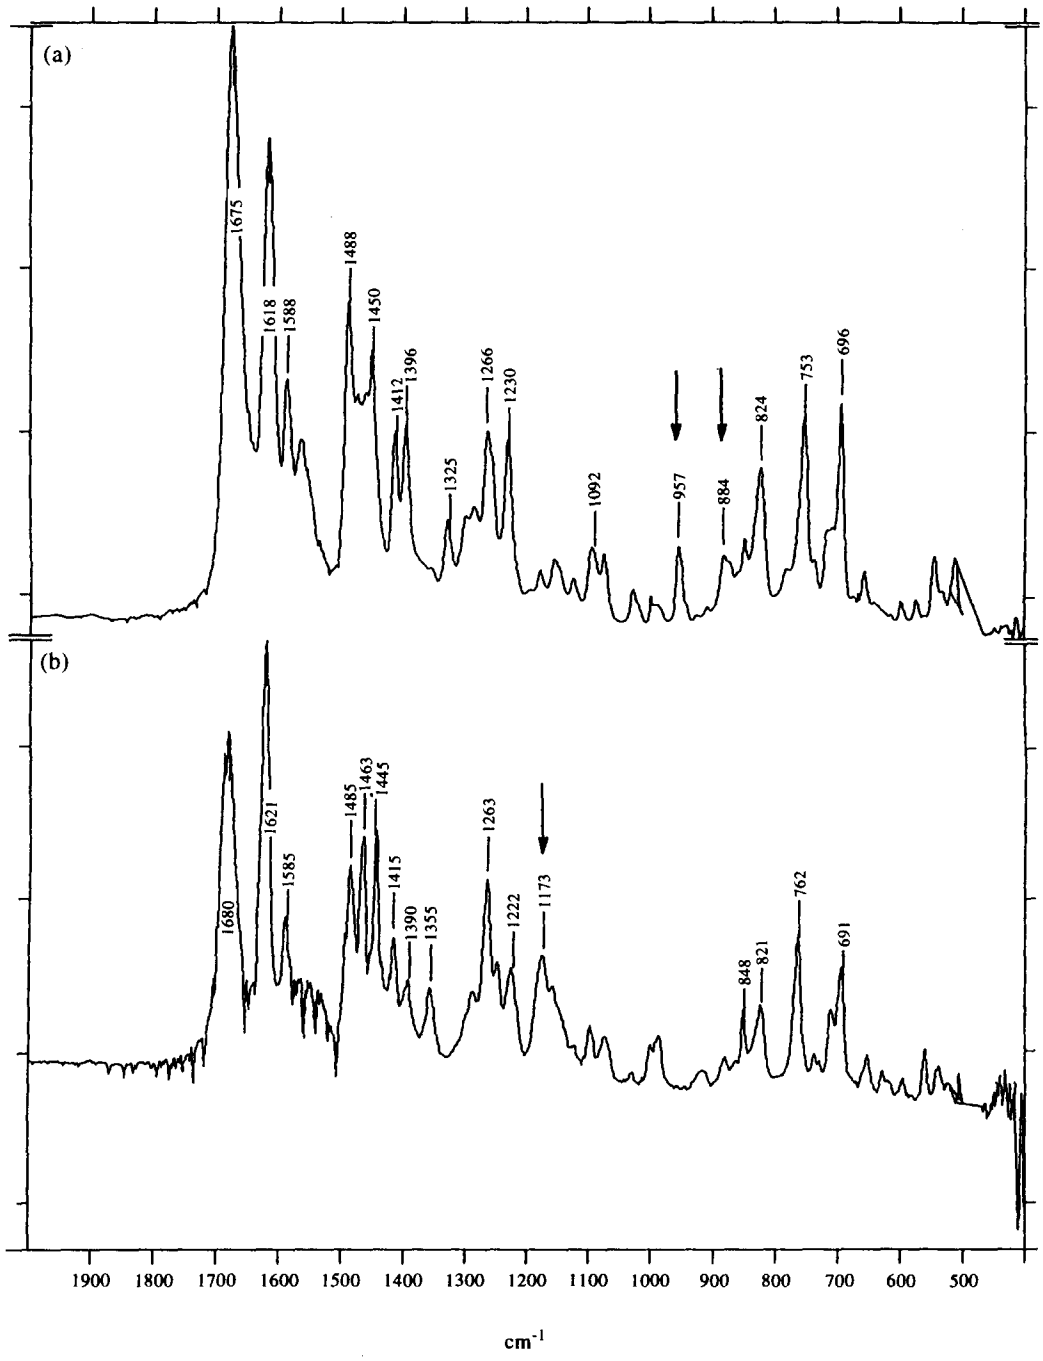

Fig. 4. IR spectra of (a) oxaziridine and (b) chlordiazepoxide in the range of 400–2000 $cm^{-1}$, at a resolution of 2 $cm^{-1}$. (a) Characteristic bands of the epoxy function at 884 and 957 $cm^{-1}$. (b) Characteristic band of the N-oxide at function 1173 $cm^{-1}$.

sample volume within the range of 0.2–0.7 ml (Student's $t$ test $P > 0.05$). Under these conditions, the larger volume was chosen (0.7 ml) and used for all experiments.

The CDZ isomerization time course curves were studied at $20 \pm 1$°C when the drug was dissolved in the chromatographic mobile phase and acetonitrile. Under these experimental conditions and at a concentration of 30.5 $\mu$g/ml, Fig. 5 shows that degradation of CDZ is faster when the drug is dissolved in acetonitrile. After 47 min of irradiation, the percentage of CDZ was still 29% in the mobile phase and only 5% in acetonitrile. The results were confirmed when a concentration 10 times higher was tested. Acetonitrile, which allowed us to obtain high

efficiency in producing oxaziridine and to avoid aqueous hydrolysis of CDZ was thus chosen for kinetic studies.

Isomerization of CDZ is faster at 20°C than at 10°C, but the temperature can also influence the stability of the generated oxaziridine and quickly displace the equilibrium to the parent molecule (CDZ) when irradiation is stopped. Therefore, a temperature of 10°C was chosen to quantitatively transform CDZ base into oxaziridine (Fig. 6).

The kinetics of CDZ isomerization was studied at five initial concentrations. Kinetic and fitting parameters were determined by the FADHA algorithm (Table 2). For each concentration, the Akaïke's criteria (AIC) selected the first order reversible or irreversible model but fitting parameters were very similar for both estimation.

At the end of the irradiation period, CDZ concentrations were very low and estimated values of $A_\infty$ in the first order reversible model were close to zero. These observations showed that UV light strongly displaces the

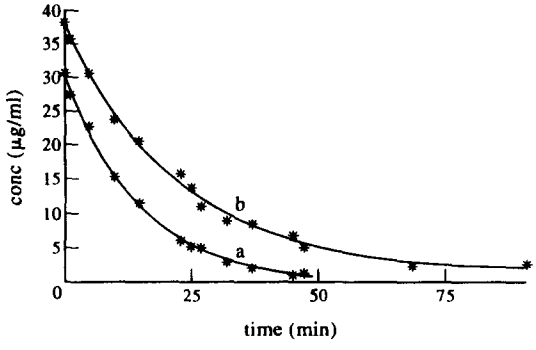

Fig. 6. Influence of irradiation temperature on CDZ photoisomerization kinetic in acetonitrile. (a) 20°C, CDZ (38.0 μg/ml); (b) 10°C, CDZ (30.5 μg/ml).

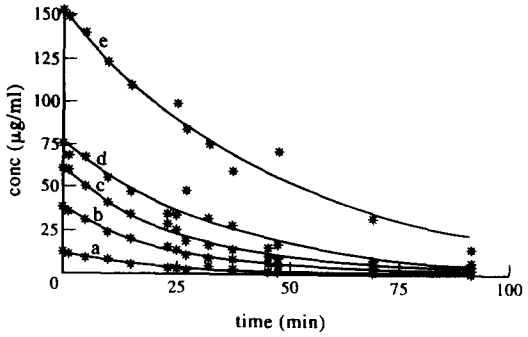

Fig. 7. Evolution of CDZ concentrations as a function of irradiation time. (a) 12.2 μg/ml, (b) 38.0 μg/ml, (c) 60.8 μg/ml (d) 76.0 μg/ml, (e) 152.0 μg/ml.

isomerization equilibrium towards the formation of oxaziridine. As indicated by Fig. 7, synthesis of rather pure oxaziridine from CDZ is thus possible.

A surprising finding is that $K$ is concentration dependent. Actually following a first order kinetic rate constant $K$ should be independent of the initial reactant concentration. Table 2 shows that the apparent kinetic rate constant decreases when CDZ concentration is raised from 12.2 to 152 μg/ml. Percentages of non-transformed CDZ are situated in the range of 2 to 15 after 90 min of irradiation. However, in all cases the first order equations are best fitting to the experimental data. Moreover, the photoisomerization of DEM and DES-CDZ was also a first order reaction (unpublished data). Variation of the rate constant could result because the photoreaction becomes limited by the number of incident quanta of energy and because in concentrated solution quenching of the excited CDZ molecules becomes more efficient.[23]

Data analysis by linear (Linreg) and non-linear (Nonreg and FADHA) least squares regression analysis were compared. Non-linear software has the advantage of estimating values for all parameters of the models. In the linear regression method precise estimation of $A_\infty$ is not possible and users have to approximate its value to calculate other parameters. However, the Nonreg software does not always lead to the absolute minimum or does not assume the convergence. This latter case is illustrated in Table 3, where one can see that appropriate initialization parameters ($K$: 0.05 $min^{-1}$ and $A_0$: 12.2 μg/ml) lead to results. Yet, by selecting 0.2 $min^{-1}$ as the increment of the initial $K$ value, no convergence is observed. Moreover, Nonreg estimations are generally dependent on the initial parameter values. Consequently, kinetic parameters were estimated by FADHA which

Table 2. Kinetic and fitting parameters determined by FADHA software

ensures convergence independently of initial estimations. It proved that the algorithm, based on successive geometric transformations to minimize a cost function, is more efficient than those using matrix calculations.

In conclusion, experimental conditions to generate 98% of pure oxaziridine from CDZ have been established. The determination of the photoisomerization reaction order has permitted us to plan and to quantify the production of OXA from the undegraded CDZ fraction for defined irradiation conditions. Indeed, it is reasonable to consider that at 350 nm each mole of oxaziridine is stoechiometrically generated from 1 mole of the parent benzodiazepine. The HPLC method developed allows the separation of CDZ from its major impurities and photoproducts. The analytical approach is particularly suited to control the synthesis efficiency and its application could be advantageously extended to other pharmaceutical fields. It is interesting to point out that photoproducts are generally not determined in quality control of CDZ. Furthermore, very few assays are suitable to quantify the unstable drugs studied here. The development of the proposed method and the optimal irradiation conditions had been a major step for the investigation of oxaziridines cytotoxicity *in vitro* (unpublished data).

*Acknowledgements*—This study was supported by the "Institut de Recherche Servier" (3 rue de la République, 92150 Suresnes, France). We thank F. Vanhorenbeke for the infrared spectra, G. Verbeeck for the loan of digital radiometer, R. Ottinger for the NMR spectra and Dr R. Collin for helpful scientific discussion. The gift of chlordiazepoxide from Hoffman-La-Roche (Basle) is gratefully acknowledged.

# PREPARATION AND ANALYTICAL PROPERTIES OF A CHELATING RESIN CONTAINING BICINE GROUPS

KAPIL DEV and G. N. RAO*

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi-110016, India

(*Received* 4 *March* 1994. *Revised* 12 *September* 1994. *Accepted* 18 *October* 1994)

**Summary**—A polystyrene divinyl benzene based resin containing bicine groups has been prepared and its analytical properties investigated. The pH dependence of sorption of metal on the resin has been determined for Cu(II), Fe(II), Ni(II), Co(II), Zn(II), Hg(II) and Pb(II). The important characteristics of the resin are fast equilibrium, high selectivity and small volume change between its hydrogen and metal forms. These enable it to be applied to the rapid concentration of trace amounts of these metal ions. It shows promise for the separation of lead from other metal ions.

Metal chelating resins have found widespread application for the concentration of trace metals from natural waters owing to their selectivity. Use of these resins has allowed field sampling and has eliminated the need for collection and storage of large sample volumes. Many different approaches have been used for the immobilization of metal chelating functional groups on natural and synthetic solid supports for the concentration and/or separation of trace metals.

Muzzarelli and co-workers chemically modified the natural polymer chitosan.[1,2] A number of chelating resins containing aminocarboxylic acid groups (*e.g.* ethylenediamine tetraacetic acid,[3] iminodiacetic acid[4–6]) have been prepared and their analytical properties investigated. Fritz and co-workers synthesized resin containing sulphonic acid, amide and hexylthioglycolate groups.[7–9] Atushi Sughi *et al.* synthesized and applied polystyrene resin containing phenylalanine groups.[10] Schlogl and Fabitschowitz have reported polystyrene resin containing glycine groups.[11]

In the present work, the macroporous resin XAD-4 (polystyrene divinyl benzene) has been functionalized with bicine [*n*,*n*-bis (2-hydroxyethyl) glycine], which contains both alcoholic and carboxylic functionalities. Higher selectivity is expected with bicine ligands over chelating resins having iminodiacetic acid ligand which has only carboxylic groups. The resin has been characterized and sorption behaviour of different metal ions on the resin studied.

## EXPERIMENTAL

### *Apparatus*

A Varian AA 475 atomic, absorption spectrometer equipped with a CRA 90 graphite furnace atomizer was used for all metal measurements. An Elico (India) digital pH-meter LI-120 was used for pH measurements. IR spectra were recorded on a Nicolet DX FTIR with KBr pellets. A mechanical shaker (Scientific Instruments, India) with a speed of 200 strokes/min was used for batch equilibration.

### *Reagents*

The stock metal ion solutions were prepared by dissolving the reagent grade nitrates and chlorides in water or the matrix acid. Polystyrene divinyl benzene resin (XAD-4) and bicine were obtained from Fluka. The following buffered solutions were prepared: hydrochloric acid–glycine (pH 1–3); acetic acid–sodium acetate (pH 3–5); disodium hydrogen phosphate–potassium dihydrogen phosphate (pH 5–8); and sodium borate–hydrochloric acid (pH 8–9).

### *Preparation of XAD-4–bicine resin*

Styrene divinyl benzene polymer (XAD-4) was functionalized through an esterification

route. XAD-4 beads (10 g) were refluxed with acetic anhydride (20 ml) and anhydrous aluminium trichloride (1 g) in petroleum ether (60–80°C) at 70°C for 30 hr. The product was filtered off and washed with 50 ml hexane. The intermediate product (II) was then stirred in 500 ml water containing 8.5 g potassium permanganate and 10 g sodium hydroxide at 40°C for 1 hr. The product was filtered off, washed with water and then treated with hydrochloric acid (1:1). It was then refluxed with 50 ml thionyl chloride at 60°C for 30 min. The intermediate resin (IV) was refluxed with bicine (2.5 g) and sodium ethoxide (11.3 m*M*) in toluene at 100°C for 6 hr. A pale yellow resin was obtained. A total of 20 g resin was prepared and the 200–250 mesh fraction of the resin was used for metal sorption studies.

*Optimum pH of metal ion uptake*

The optimum pH of metal ion uptake was determined by batch equilibration technique. Excess metal ion (50 ml, 50 $\mu$g/ml) was shaken with 100 mg of resin for 2 hr. The pH of the metal ion solution was adjusted prior to equilibration over a range of 2–9 with buffer solutions. After the equilibration, the concentration of the metal remaining in the solution was determined by atomic absorption spectrometry (AAS). Adsorption experiments were carried out in duplicate each time.

*Resin capacity*

The capacity of the resin was determined by shaking the excess metal ion (50 ml, 100 $\mu$g/ml) with 100 mg resin (50 mg for mercury and lead) for 6 hr at optimum adsorption pH. Resin was filtered off and concentration of the remaining metal ion in the solution was determined by AAS. The capacity was also checked after soaking the resin in 1*N* HCl/1*N* alkali for 24 hr.

*pH dependence of trace metal ion uptake*

A 50 ml volume of a buffered solution containing 5 $\mu$g/ml of metal ion was shaken with 100 mg of resin for 2 hr in a glass stoppered bottle. The resin was filtered off and the amount of metal ion remaining in the filtrate was determined by atomic absorption spectrometry (AAS). Concentration of the adsorbed metal ion was also determined after eluting with 1*N* hydrochloric acid (10 ml) and diluting the resultant sample solution to 50 ml with distilled water.

*Equilibrium time*

To determine the time of equilibrium for the metal under investigation, the metal ion solution (50 ml, 10 $\mu$g/ml), at a constant pH, was sampled in six bottles. The first bottle was removed from shaker after 5 min and the remaining bottles at intervals of 15 min. The last bottle was removed after 2 hr. The concentration of the metal ion was determined by AAS. The time of equilibrium for all the metal ions was determined in a similar manner. The duplicate values agreed with a precision of $\pm 2\%$.

*Effect of diverse ions*

Standard solutions of 50 ml of Pb, Cu and Ni (1–5 $\mu$g/ml each) containing sodium chloride, Mg and Ca ions as interferents were analysed.

*Concentration and separation of metal ions*

Batch equilibration study was used to concentrate the trace metal ions. Sample solution (250–500 ml) containing 0.1 $\mu$g/ml metal ion was adjusted at optimum pH of adsorption with buffer solution and then shaken with 100 mg of resin for about 10 min. Sorbed metal ions were eluted with 1*N* hydrochloric acid (10 ml) and the concentration of the metal ion in the eluent was determined with AAS.

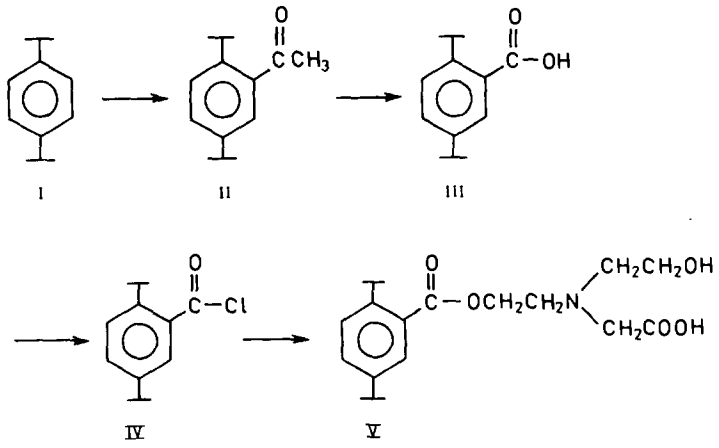
Based on the sorption behaviour of metal ions on the XAD-4–bicine resin at different pH values, separation of these metals in the binary mixtures were carried out. A 50 ml solution containing lead (5 $\mu$g/ml) and other metal ion was shaken with 100 mg resin at pH 5. Lead retained on the resin was eluted with 1*N* hydrochloric acid (10 ml). Copper, cobalt, nickel and zinc was determined in the effluent and lead in the eluate.

Separation of these metal ions was also carried out by a column method. The dry resin (0.5 g) was loaded into a glass column, immersed in the buffer solution and the metal ion solution was passed through the column at a flow rate of 2.0 ml/min$^{1}$. The adsorbed metal ion was desorbed from the resin with 1*N* HCl.

## RESULTS AND DISCUSSION

The resin was synthesized according to Scheme 1. Spherical macroreticular styrene–divinyl benzene beads were used as starting material.

In the IR spectrum of intermediate IV (Scheme 1, Fig. 1), an absorption band appears



Scheme 1

at 670 $cm^{-1}$ ($\nu_{C-Cl}$) which disappears in the spectrum of resin V. Another feature in the spectrum of IV is the absorption band at 1740–1765 $cm^{-1}$, probably resulting from Fermi resonance between the carbonyl band and the overtone of a longer wavelength band near 875 $cm^{-1}$.[12]

Both the above bands appear in the spectrum of intermediate resin IV and disappear in the final resin V. Comparison of the spectrum of

Table 1. Metal uptake capacities

| Metal | Optimum pH | Capacity (SD) *(mmol/g resin)* |
|---|---|---|
| Cu (II) | 7.06 | 0.38 (0.01) |
| Ni (II) | 8.43 | 0.39 (0.02) |
| Co (II) | 6.55 | 0.42 (0.01) |
| Fe (II) | 5.52 | 0.44 (0.01) |
| Zn (II) | 6.85 | 0.38 (0.01) |
| Pb (II) | 5.58 | 0.40 (0.02) |
| Hg (II) | 5.52 | 0.32 (0.02) |

final resin V with the spectrum of pure bicine also confirms the presence of bicine groups since all the major absorption bands in the spectrum of bicine are present in the spectrum of resin V with reduced intensities.

Nitrogen analysis of the resin gave 0.61% nitrogen. Assuming that all nitrogen is part of intact bicine groups, the capacity for metal ion should be 0.44 mmol/g of resin for the resin. The values actually obtained are reported in Table 1.

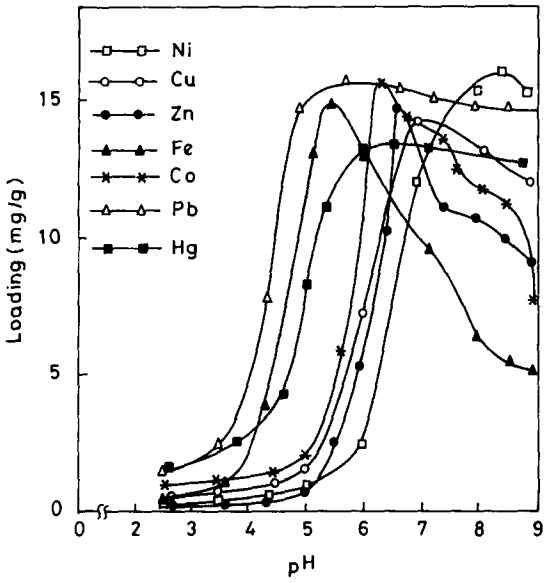

Fig. 2. Effect of pH on metal sorption with bicine resin.

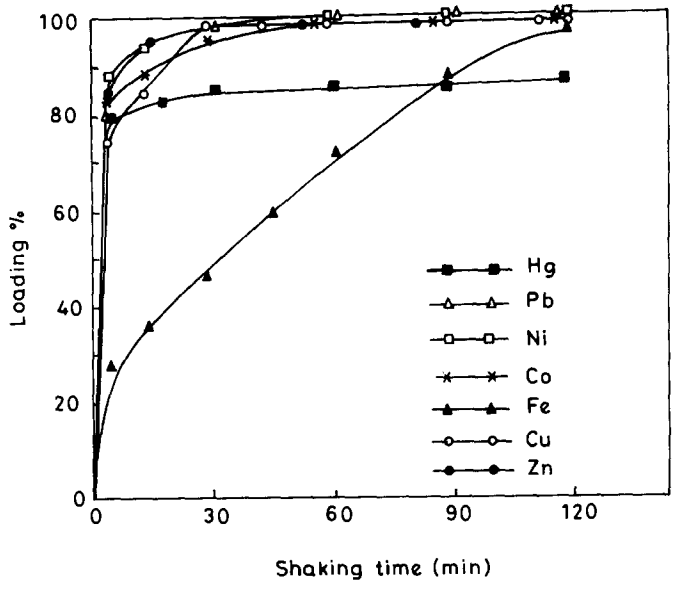

Fig. 4. Rate of uptake of metal ions.

The resin was found to be very stable on successive treatment with dilute acid and alkaline solutions. The stability was checked by change of the hydrogen–metal exchange capacity and the nitrogen content.

In a preliminary experiment, the sorption behaviour of some metal ions on XAD-4–bicine resin at different pH values has been examined by the batch method, and the results are shown in Fig. 2. In general, the adsorption of metal ions increases with increasing pH, reaching a limiting value in each instance, followed by a decrease in adsorption, beyond the limiting value.

The capacity of the resin is an important factor to determine how much resin is required to quantitatively remove a specific metal ion from the solution. The capacity of each metal ion is reported in the Table 1.

Adsorption behaviour of the trace amount of metal ion on the resin is shown in the Fig. 3. The complete adsorption for the trace metal ions are in the region of pH 6–7.5 for Cu(II); 7–8.5 for Ni(II); 6–8.5 for Co(II); 5–6 for Fe(II); 7–9 for Zn(II); 6.5–9 for Hg(II) and 5–9 for Pb(II). A special feature in these breakthrough curves is the complete adsorption of Pb(II) at lower pH, which should enable its separation from other metal ions in this pH region.

The kinetics of the resin–metal interaction are of considerable importance if the resin is to be used in a dynamic system such as a packed column and a flowing stream. If the complexation is not sufficiently rapid for certain metals, then their concentration on a packed column is unlikely owing to the short contact time between the resin and the solution. In those cases a batch extraction with a large excess of resin should be conducted over an extended period.

Kinetic experiments were performed at the optimum pH of adsorption for metal ions and the results are plotted in Fig. 4.

In most cases the kinetics are rapid; Ni(II); Co(II), Pb(II), Hg(II) and Zn(II) are at least 80–90% extracted within 5 min of interaction with the resin. At pH 7.06, Cu(II) is extracted upto 76% after 5 min equilibration with resin. Fe(II) is relatively slower requiring 90 min to reach the 90% extracted level. Considering the

slow reaction kinetics of the Fe(II), separation of small amounts of this metal ion in the presence of some other metal ion by conventional column techniques appeared promising.

Alkali and alkaline earth metals do no effect the recovery of metal ion from the solution. The results in Table 2 show the recovery rates in the presence of excess of these foreign ions. This suggests the use of this resin for trace concentration from natural samples.

Preconcentration of the metal ions on the resin was carried out and results are shown in Table 3. Metal ions could be enriched upto 40–50 times with XAD-4–bicine resin. The separation of trace amounts of lead in the presence of diverse metal ions was examined, both by batch and column methods (Tables 4 and 5). Lead is separable from copper, nickel, cobalt and zinc because they are not retained on the resin at pH 5.0. Lead retained on the resin is eluted with 1*N* hydrochloric acid. Though the elution is easier and complete with column method, but batch method was preferred for the XAD-4–bicine resin as it was found to be less time consuming.

## CONCLUSIONS

These investigations indicate that the XAD-4–bicine resin has good potential for the enrichment of trace metals and their separation from aqueous solutions. Resin can be used for the trace concentration of metal ions from seawater, which has high concentrations of alkali and alkaline earth metals. Enhanced selectivity is observed with XAD-4–bicine resin for lead as compared to Dowex A-1 resin. Equilibration is fast as 80–90% metal ions are sorbed within 5 min of interaction. Resin has high mechanical and chemical strength which makes it useful after recycling.

# BIASES IN SUMMARY STATISTICS OF SLOPES AND INTERCEPTS IN LINEAR REGRESSION WITH ERRORS IN BOTH VARIABLES

A. H. KALANTAR,[1] ROBERT I. GELB[2] and JOSEPH S. ALPER[2]*

[1]Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada T6G 2G2
[2]Department of Chemistry, University of Massachusetts—Boston, Boston, MA 02125, U.S.A.

(*Received* 15 *August* 1994. *Revised* 13 *October* 1994. *Accepted* 18 *October* 1994))

**Summary**—Monte Carlo simulations are employed to investigate the bias in linear regression parameters for cases in which both variables are subject to normally distributed errors. Both homoscedastic and heteroscedastic errors are treated. The results show that, in general, the arithmetic mean, geometric mean, and angle mean (tangent of the mean of the arctangents) of the slopes are biased and non-normally distributed. The arithmetic and geometric means of the intercepts are generally biased and non-normally distributed as well. However, for all the cases considered, the medians of the slopes and of the intercepts are found to be unbiased. In view of the non-normal distributions of the slopes and intercepts, a nonparametric method is used to determine confidence intervals for the slopes and intercepts.

As many previous authors have noted, ordinary least squares regression (OLS) cannot be used to determine slopes and intercepts if there are errors in both the dependent and independent variables.[1–9] This situation arises in a number of chemical applications. In many experiments, the values of the independent as well as the dependent variables are obtained by measurement. In experimental design, calculations performed to determine the optimal choice of the distribution and values of the independent variable must take into account the experimental uncertainties in both variables.

There are several methods for determining the regression parameters for the linear equation $Y^\circ = a^\circ + b^\circ X^\circ$ with errors in both $X^\circ$ and $Y^\circ$.[1–3,5,7,9] We use the superscript '°' in referring to the 'true' values. The Williamson[2] modification of the York[1] method is particularly convenient. Denote the data points by $(X_i, Y_i)$ and their respective uncertainties by $(\sigma_{Xi}, \sigma_{Yi})$. Next, set $x_i = X_i - \langle X \rangle$ and $y_i = Y_i - \langle Y \rangle$, where $\langle X \rangle$ and $\langle Y \rangle$ are the weighted mean values of $X_i$ and $Y_i$, respectively, The York–Williamson (YW) regression slope, $b$, is given by

$$b = \frac{\sum W_i^2 \sigma_{Yi}^2 x_i y_i + b \sum W_i^2 \sigma_{Xi}^2 y_i^2}{\sum W_i^2 \sigma_{Yi}^2 x_i^2 + b \sum W_i^2 \sigma_{Xi}^2 x_i y_i}, \quad (1)$$

where

$$W_i = (\sigma_{Yi}^2 + b^2 \sigma_{Xi}^2)^{-1}. \quad (2)$$

The intercept, $a$, of the regression is given by $a = \langle Y \rangle - b\langle X \rangle$.

In their careful study of the YW regression, Christian and Tucker (CT) used Monte Carlo simulations to study the regression parameters derived from the model equation $Y_i^\circ = X_i^\circ + 1$.[9] They set $X_i^\circ = -2, -1, 0, +1, +2$ and created simulated data sets by assuming $\sigma_{Xi}$ and $\sigma_{Yi}$ to be gaussian deviates each with mean 0 and standard deviation 0.5. They found that the difference between the arithmetic mean of the slopes obtained from 20,000 simulated data sets and the 'true' slope of 1 was statistically significant ($P < 0.01$). However, the geometric mean of the slopes did not exhibit this bias.

In this work, we extend the CT study to more general data sets. We find that for the cases studied, the arithmetic mean, geometric mean (the antilog of the mean of the logs), and angle mean (the tangent of the mean of the arctangents) of the slopes are all biased in the sense described above. To interpret the angle mean, recall that the arctangent of the slope is the angle the regression line forms with the $X$ axis. Unlike these various means, the median of the slopes is consistently unbiased. Similarly, for the general case, only the median of the intercepts is unbiased.

*Author to whom correspondence should be addressed.

The biases in the slopes and intercepts arise from the fact that when there are errors in both variables, the distributions of the slopes and of the intercepts are not normal. This non-normality has the additional consequence that the standard errors of the slopes and intercepts cannot be used to calculate confidence intervals.

## SIMULATIONS AND CALCULATIONS

Following the CT example, we set $X_i^\circ = -2, -1, 0, 1, 2$ and $Y_i^\circ = 1 + X_i^\circ$. Simulated data points, $X_i$ and $Y_i$, were generated from these exact variables by means of the equations

$$X_i = X_i^\circ + \epsilon_{Xi}\sigma_{Xi}; \quad Y_i = Y_i^\circ + \epsilon_{Yi}\sigma_{Yi},$$

where $\epsilon$ is a gaussian random deviate with mean 0 and standard deviation 1, and $\sigma_{Xi}$ and $\sigma_{Yi}$ are the uncertainties in $X_i$ and $Y_i$, respectively. The gaussian deviates were obtained using the method of Box and Muller.[10] The pseudo-random numbers required by the Box–Muller algorithm were calculated from the well established congruential multiplicative generator based on $2^{31} - 1$ and $7^5$.[11–13]

Since several hundred thousand random numbers were used in this study, it was important to check for deviations from randomness and from normality. We examined $\chi^2$, means, standard deviations, skews, run frequencies and lengths, and several autocorrelations.[14–17] These tests were conducted for the entire set of numbers as well as for the subsets added to each $X_i^\circ$ and $Y_i^\circ$. For each test, deviations from randomness or normality were statistically not significant ($P > 0.05$).

For each data set we obtained the regression slope and intercept using the YW method described above. For each group of data sets derived from the same model we calculated the following statistics of the slopes: mean and its standard deviation, skew, kurtosis, and $\chi^2$ per degree of freedom. In addition, we obtained the geometric mean and its standard deviation, the tangent of the mean arctangent and its standard deviation, the median and the nonparametric estimates[18] of its central 68.3 and 90% confidence intervals. The same statistics, with the exception of the tangent, were obtained for the intercepts. All calculations were performed in VS/APL on a mainframe Amdahl 5870, in double precision.

## RESULTS

### *The Christian–Tucker data set*

The CT data set has been described above. Table 1 gives the results of the ordinary least squares (OLS) and the York–Williamson (YW) treatment of 10,000 simulated CT data sets of five points each. These results are in excellent agreement with those reported by CT: CT report $-0.0507$ and 0.029 for the biases in the OLS and YW slopes; we obtain $-0.0498$ and 0.0288. In order to assess the precision of the results, 10 groups of 10,000 data sets were analyzed. Each of the values shown in Table 1 is an average over the 10 groups. Typically, fluctuations in the median and the various means from one group to another were less than $\pm 0.002$.

Standard deviations, $\sigma$, for the slopes and intercepts were calculated using Williamson's expressions.[2] These estimates of $\sigma$ obtained from $\sigma_{Xi}$ and $\sigma_{Yi}$ using propagation-of-variance are approximately 10% too low. For example, $\sigma_{am}$ for the slope obtained using the propagation-of-variance procedure is 0.2236; the observed value is 0.247. The difference arises because the propa-

*All values are averages over 10 runs of 10,000 data sets.

†Based on the division of each run of 10,000 data sets into 50 groups of 200 data sets each. The number of counts is the average number of estimates (out of a total of 50) that lie below the true value.

gation-of-variance procedure, which neglects contributions higher than first-order, is inaccurate when the errors in $X$ and $Y$ are large. For smaller values of the errors (0.05 rather than 0.5), the propagation-of-variance estimates agree more closely with the observed values. Additional calculations confirmed CT's observation that $\sigma$ is essentially proportional to $\sigma_X$ or $\sigma_Y$ and that the bias in the arithmetic mean of the slopes is proportional to $\sigma_X^2$ or $\sigma_Y^2$. In the present context, the bias of an estimator of a parameter is the expectation value of that estimator minus the true value of the parameter calculated from the exact data set. The values of $\sigma$ given in Table 1 are calculated from the means of the variances observed for each of the 10 groups. These values of $\sigma$ are quite stable; their range is no greater than $\pm 2\%$ of the mean.

The statistical significance of a bias is traditionally tested by means of the Student $t$-statistic, the bias divided by the standard error of the mean of the slopes or intercepts. The values of $t$ in the table are averages over the 10 groups. The observed standard deviation of each $t$ over the 10 groups was approximately 1 as expected.[16] If the absolute value of $t$ for a particular estimator is less than 1 or 2, the bias is less than 1 or 2 standard errors from the 'true' value. In this work, we consider such an estimator to be unbiased. This criterion is in accord with the usual threshold of statistical significance, *i.e.* $P = 0.05$.

On the other hand, if the absolute value of $t$ is greater than say, 10, the estimator is almost certainly biased. Assuming that the calculated slopes and intercepts are normally distributed and that the estimator were unbiased, an absolute value of $t$ as large as 10 would occur by chance with a probability of $< 10^{-23}$.[19] Even though, as will be shown below, the actual distributions of the slopes and intercepts are not normal as is required for the application of the $t$-test, we can say with confidence that this extremely small probability indicates a biased estimator.

In contrast, the mean values of the intercepts obtained from either the OLS and YW treatments are unbiased. This result is a consequence of the fact that the mean of the values of $X^\circ$ is 0, and as a result, the intercept ($\langle Y \rangle - b\langle X \rangle$) equals the mean of the values of $Y_i$. The correlation between the slopes and their respective intercepts is 0 for the exact data set. For the actual CT data sets, correlation coefficients averaged 0.006 with an observed range of 0.02. The medians of the intercepts for both regression methods are also observed to be unbiased estimators, but the geometric means are clearly biased and so are not included in the subsequent tables.

As mentioned above, tests of bias using the Student $t$-statistic assume that the parameters are normally distributed. To test this assumption, we calculated $\chi^2$/(degrees of freedom), the skew, and the kurtosis of the parameters for each group of 10,000 data sets. For a normal distribution, these statistics take on the values 1, 0, and 3. For the 10 groups, the means and standard deviations of these statistics for the YW slopes were $34 \pm 3$, $0.90 \pm 0.09$, and $47 \pm 20$, respectively, indicating a decidedly non-normal distribution that is asymmetric and heavy-tailed. However, the corresponding means and standard deviations of these statistics for the intercepts, $0.9 \pm 0.4$, $-0.009 \pm 0.028$ and $3.8 \pm 1.4$, are consistent with a normal distribution.

A more detailed characterization of the distributions of the slopes and intercepts can be obtained by numerically ordering each group of 10,000 slopes. In a normal distribution, 68.3% of the values lie within $\pm\sigma$ of the mean value. To obtain corresponding values for the actual distribution, we select the median, the 8414th and the 1587th entries, which we label $M$, $B_u$, and $B_L$, respectively. If the distribution were normal, both $(B_u - M)$ and $(M - B_L)$ would equal $\sigma$. For the 10 groups of YW slopes, we find $(M - B_L) = 0.828(\pm 0.008)\sigma$ and $(B_u - M) = 1.043(\pm 0.021)\sigma$. The corresponding differences for the 90% interval should, in a normal distribution, be $\pm 1.64\sigma$. For the actual distribution, we find the differences to be $1.30(\pm 0.019)\sigma$ and $1.90(\pm 0.032)\sigma$. Thus, the distribution of slopes is clearly non-normal. For the intercepts, $(B_u - M)$ and $(M - B_L)$ differ on average from $\sigma$ by less than $0.4(\pm 2.9)\%$, consistent with a normal distribution.

The direct examination of the distributions of slopes and intercepts provides a nonparametric method for evaluating the bias. We first partition each group of 10,000 slopes (or intercepts) into 50 bins of 200 each. For each bin, we calculate the following estimators of the slope: the mean, geometric mean, angle-averaged mean (tangent of the mean of the arctangents), and median. For the intercepts, we determine the mean, geometric mean, and median. The Central Limit Theorem states that, in the limit of large $N$, the means of samples drawn from a

population with finite $\sigma$ become normally, and thus, symmetrically distributed. Since each of the estimators obtained from a bin of 200 slopes or intercepts is either a mean, a monotonic function of a mean, or a median, the estimator will have equal probability of being either greater than or less than the mean of the entire population of calculated slopes or intercepts. Consequently, approximately 25 of the 50 values of the estimator will lie above (or below) the value of the estimator obtained from the total population of slopes or intercepts.

We test for bias by counting the number of the 50 values that lie above or below the true value of the slope or intercept. If the estimator is unbiased, this count should also be approximately 25. The values in Table 1 labeled 'counts' are the number of times (out of 50) that the estimators, averaged over the 10 groups were smaller than 1, the true value of both the slope and intercept. For example, on averaging over the 10 groups, we find that 46.5 out of the 50 arithmetic means of 200 slopes lie below the true value of 1. The variation in these 'counts' among the 10 groups ranged from 2 to 4. These results confirm the conclusion suggested by the $t$-tests that the arithmetic mean is a biased estimator of the true slope.

It is natural to ask whether these results for the CT data sets depend on the number of points in each set. To address this question, 10,000 data sets were constructed each with 17 points whose values of $X_i^\circ$ were evenly spaced between $-2$ and $+2$. Setting $\sigma_X = \sigma_Y = 0.5$, the OLS slopes were characterized by $\sigma = 0.121$ and $t = 100$ for the arithmetic mean estimator. A second group of 10,000 consisted of data sets with four points, each with its own value of $X_i$ and $Y_i$, scattered from $X^\circ = -2$, four scattered from $X^\circ = -1$, *etc.*, for a total of 20 points in each set. For OLS regression, $\sigma = 0.100$ and $t = 99$. As expected, in both cases the value of $\sigma$ was smaller than that for the 5 point data set ($\sigma \approx 0.2$, see Table 1). However, the bias of the arithmetic mean of slopes increased markedly, resulting in a much larger value of $t$. For both of these cases, the arithmetic mean OLS slope differs from the true slope by approximately $1.0\sigma$. Thus, increasing the size of the data set does not reduce the bias if an inherently incorrect regression method is used in the analysis.

These two groups of data sets were then analyzed using the YW method. The values of $\sigma$, the bias, and $t$ for each group decreased from the values obtained from the sets with five data points. However, although the magnitude of the bias was reduced, the $t$-statistic showed that the bias remained statistically significant. The median estimators of the slope and intercept of the larger data sets remained unbiased.

We can summarize the analyses of the CT data sets as follows: when there are errors in both coordinates, the arithmetic mean of the slopes obtained by OLS regression is a biased estimator. The arithmetic mean of the slopes obtained using the YW procedure is also biased although considerably less so. However, the geometric mean, angle-averaged mean and median of the YW slopes are unbiased. The arithmetic mean and median provide unbiased estimators of the intercepts. Thus, for the cases studied, only the median is an unbiased estimator for both slope and intercept.

*Other homoscedastic data sets*

We now investigate data sets for which $X_i^\circ = 1, 2, 3, 4$, and 5 and $Y_i^\circ = 1 + bX_i^\circ$, where $b = 1/4$, $1/2$, 1, 2, or 4. $\sigma_X$ and $\sigma_Y$ are chosen from the set 0.125, 0.25, and 0.5. In these examples, determining the intercept involves a short extrapolation. These types of data sets arise in numerous practical situations such as analytical calibrations or dose–response plots where the blank is not determined. In this connection, we emphasize that the present treatment, like that of CT, assumes independent errors in each value of $X_i$ and $Y_i$. This assumption implies that each value of these variables is a measured rather than a preset quantity.

The results shown in Table 2 are based on YW regressions on a single group of 10,000 data sets for each case. The results of the preceding section show that this number of simulations is sufficient. For the sake of clarity, this table includes only a selection of the many possible combinations of slope, $\sigma_X$, and $\sigma_Y$. Since the values of $\sigma$ for the various averaging methods are equal to within a few per cent, only the values of $\sigma$ based on the arithmetic mean are shown.

In general, estimators of the slope based on the arithmetic mean, geometric mean and angle-averaged mean are all biased. For the special case, $\sigma_X = \sigma_Y$, the angle-averaged mean is an unbiased estimator of the slope. If the slope is equal to $\sigma_Y/\sigma_X$, the geometric mean is an unbiased estimator. However, the estimator based on the arithmetic mean is always biased while the estimator based on the median is

‡The bias in each case is approximately equal to $t\sigma_{am}/100$ (see text).

always unbiased. Both the parametric and nonparametric methods for detecting bias agree in all cases.

As was the case with the CT data set, the median is also found to be an unbiased estimator of the intercept. However, the arithmetic mean is now significantly biased. Since the mean of the values of $X^\circ$ is no longer 0, the slopes and intercepts are correlated ($\rho = -0.915 \pm 0.001$), resulting in a biased intercept.

Direct examination of the 10,000 intercepts ranked in numerical order shows that their distribution is clearly asymmetric and thus nonnormal. The ratio $(M - B_L)/(B_u - M)$ varied between 1.2 and 1.33. $\chi^2$ per degree of freedom exceeded 25, the kurtosis exceeded 30, and the absolute value of the skew exceeded 0.7 in all cases studied.

As was the case for the CT data sets, increasing the number of points in each data set had no qualitative effect on the results. The bias decreased somewhat, but it remained statistically significant.

In summary, for data sets with homoscedastic errors, if $\sigma_X$ is not equal to $\sigma_Y$ and $\sigma_Y/\sigma_X$ is unequal to the slope, only the medians are found to be unbiased estimators of the slope and intercept.

*Heteroscedastic errors*

In view of the large number of possible combinations of slopes and values of $\sigma_X$ and $\sigma_Y$, we focus, somewhat arbitrarily, on data sets for which the slope is equal to 1, $\sigma_X$ is unequal to $\sigma_Y$, and the mean of the $X_i^\circ$ is not equal to 0. These data sets avoid the special cases in which the angle-average or the geometric means of the slopes are unbiased.

Table 3 shows the results of the analysis of three data sets illustrating heteroscedastic errors in one or both variables. In the first case, $\sigma_{Xi} = 0.5$ and $\sigma_{Yi} = 0.05i$, $i = 1, \ldots 5$. In the second case, $\sigma_{Xi} = 0.2i$ and $\sigma_{Yi} = 0.5i$. Finally, in the third case, $\sigma_{Xi} = 0.2i$ and $\sigma_{Yi} = 0.125i$. In all cases the exact slopes and intercepts were set equal to 1. The YW regression method was used throughout. Table 3 shows that, as in all previous cases, the median of the slopes and intercepts are unbiased. The arithmetic and geometric means of the intercept and the arith-

*See footnotes of Table 2.

metic, geometric, and angle-averaged means of the slopes all show significant biases. The values of $\chi^2$ per degree of freedom, the skew, kurtosis and $B_u$ and $B_L$ indicate that the distributions of the slopes and intercepts are significantly non-normal.

Calculations with data sets containing a greater number of points show similar results. The bias and the values of $t$ decreased only slightly and not uniformly. The 'count' values were not significantly changed.

To summarize, as was the case with the other types of data sets, for the data sets involving heteroscedastic errors studied here, only the medians provide unbiased estimators of the slopes and intercepts. The magnitude and statistical significance of the bias of the other estimators are not strong functions of the number of data points.

## DISCUSSION

The present results reinforce the conclusion of CT[9] that ordinary least squares regression should not be used when both $X$ and $Y$ are subject to errors because, in general, the slopes and intercepts will be significantly biased. As was shown above for the data sets with 17 and 20 points, the mean OLS values for the slope differ from the true value by approximately $1.0\sigma$. We believe that this bias is sufficiently large to necessitate the use of the YW algorithm in data analysis especially in cases where replicate measurements are used to offset the effects of low precision data. While the YW algorithm significantly reduces the biases of the slope and intercept (based on the arithmetic mean), it does not entirely eliminate the biases. Estimators based on the arithmetic mean, geometric mean and angle-averaged mean all remain biased. Only the median provides unbiased estimators of the slope and intercept for all the cases studied here.

The presence of bias indicates that the distributions of the slopes and intercepts are not normal. As shown by the various statistics discussed above, such as the skew, kurtosis, and the values of $B_u - M$, and $M - B_L$, the deviations from normality are significant. Recall that $M$ is the median, and the interval $[B_L, B_u]$ encompasses 68.3% of the total number of slopes or intercepts. This result implies that the customary parametric estimates of the errors of the slope and intercept will be incorrect. Thus, for the CT data set, the 68.3% confidence interval for the slope is given by $[M - 0.83\sigma, M + 1.04\sigma]$. The symmetric interval, $m \pm \sigma$, where $m$ is the mean, is appropriate only if the calculated slopes are normally distributed.

Although the biases in the parameters obtained by YW regressions are clearly statistically significant, their magnitudes relative to the standard deviations of the slopes and intercepts are small. In most cases, it is unlikely that these biases would lead to serious errors in the analysis of a single set of experimental data. However, these biases may become important in data analyses involving functions of the slopes and/or intercepts. Moreover, they may also become important in the calculations involved in determining the optimal design of an experiment. In such calculations, the analysis of many hypothetical data sets might be required to select the appropriate values of the independent variable. The standard errors of the parameters such as the slope and intercept may become small enough so that the bias becomes important as well as statistically significant. For these cases, the use of biased, and thus incorrect, values of parameters like the slope and intercept may lead to a non-optimal choice of the $X_i^o$'s. In addition, since the distributions of the parameters are non-normal, estimates of confidence intervals for the parameters should be based on (o. at least checked by) nonparametric methods, such as the one outlined above.

The present study is restricted to normally distributed errors in the dependent and independent coordinates and to straight line regressions. For more general situations, the question of whether any averaging procedure, including the median, provides unbiased estimators of the regression parameters remains for future investigations. However, even in these more general situations, the nonparametric method described above will continue to be applicable for the estimation of confidence intervals.
