In our present work, we were interested in being able to enhance the DSTD signal through two separate avenues. First, we investigated the question of how sensitivity would change if a material other than fused silica were used as the capillary. In this case, we compared stainless steel (S.S.) to fused silica tubing. Second, to what degree was the DSTD signal enhanced through the formation of an ion-pair with the surfactant analyte and detecting the ion-pair versus the analyte itself?

The material from which the capillary is constructed affects the DSTD response. Previously, fused silica capillaries had been used with much success but their relatively short lifetime became an ongoing issue, particularly in the context of using the DSTD as an analytical instrument. According to Hool and Schuchardt [31], the orifice dimensions of a capillary are very critical in droplet formation and subsequent detachment, with the surface area available to the drop for wetting a major point of consideration. More exactly, the outside diameter (o.d.) of a capillary in comparison with its inside diameter (i.d.) determines the "effective" diameter of the capillary. Machining the capillary o.d. as close as possible to the i.d. was found to minimize the front facial surface area and give superior performance. An investigation into the performance of a S.S. capillary was undertaken with its results being compared with that of the fused silica.

The primary focus of this paper is to report our observations that the DSTD response to ionic surfactants could be enhanced through the formation of an ion-pair between an analyte and an appropriate ion-pairing agent prior to detection. Obviously, the ability to increase the sensitivity of the DSTD would be quite advantageous and with that in mind several experiments were designed and carried out in order to more fully understand the enhancement effect. Answers to two specific questions were sought. First and foremost, to what degree was the DSTD sensitivity actually enhanced through ion-pair formation? Second, what ratio of ion pairing agent to analyte is needed to optimize the enhancement? Meyers [32] indicates that the packing density of adsorbed surfactants is altered when ion-pairs are formed and that the altered packing increases the efficiency of surface tension lowering. Efficiency is defined as the bulk concentration necessary to reduce the surface tension by a given amount. Higher efficiency manifests itself as an increase in

the surface binding constant [32,33], K_2, of the surfactant or the ion-pair in Eq. (2), which increases $S(t)$ and consequently $\Delta r_{1,2}$ via Eq. (4), as described in the Theory section. The model system used in this study consisted of sodium dodecyl sulfate (SDS) and tetrabutylammonium hydroxide (TBA). The end goal of this work is to apply the advantageous ion-pairing effect to the rapid analysis of surfactants using the DSTD.

Also of interest was how the DSTD signal varied with drop time (inversely proportional to flow rate) and analyte concentration. Delahay and Fike [34] examined through computer simulations the kinetics of the adsorption of a hypothetical analyte on an expanding mercury sphere. Their results with regard to how the surface layer concentration depends upon initial concentration and growth rate were compared with our observations on the behavior for the DSTD. They state that the kinetics are strongly dictated by the quantity C^0/α, where C^0 is the bulk analyte concentration and α is the parameter defining a Langmuir isotherm. By solving the boundary value problem, Delahay and Fike plotted the ratio Γ_t/Γ_e of the surface concentration Γ_t at time t to the equilibrium surface concentration Γ_e. Increasing the C^0/α ratio resulted in lowering the time required to reach equilibrium, where equilibrium is defined by a constant Γ_t/Γ_e value. Furthermore, the equilibrium surface layer concentration increases with the bulk concentration. Instead of Γ_t/Γ_e, we rely on the change in drop volume, or drop radius, Δr, as an indicator for surface coverage since, as will be shown, Δr is proportional to the relative change in surface tension, $\Delta \gamma / \gamma$, and $\Delta \gamma / \gamma$ is proportional to analyte surface coverage, Γ_t/Γ_e. Increasing the surface layer concentration results in a lowering of the surface tension which on the DSTD is seen by a decrease in Δr. When the surface layer concentration has reached a maximum, Δr should become constant.

2. Theory

A complete derivation of the theory describing the operation of the optical-based DSTD has been published previously [15,16]. The main results are

given here to provide adequate background information. The DSTD probes a length dimension of a continuously growing drop surrounded by air, and the measured data provide a direct relation of changes in drop volume to changes in surface tension. From a fundamental point of view, changes in surface tension, $\Delta \gamma_{1,2}$, relative to some baseline surface tension, as caused by the presence of a surface-active species, manifests itself as a change in drop volume, $\Delta V_{1,2}$, relative to some baseline volume, V_1. Mathematically,

$$\frac{\Delta \gamma_{1,2}}{\gamma_1} = \frac{\Delta V_{1,2}}{V_1} \tag{1}$$

where the bulk solvent is labeled with a subscript 1, the analyte with a subscript 2, and a mixture of the two with the subscript 1,2.

We will now consider the signal, $S(t)$, of the optical-based DSTD as a function of time, t. A change in surface tension, and thus $S(t)$, comes from three contributions: (1) relative change in surface tension; (2) relative degree of surface activity of the analyte; and (3) transport of the surface-active species to the air–liquid interface. $S(t)$ was derived [15] from a combination of the treatment of surface tension of a two-phase system [35] and the classical drop weight method of surface tension as reported by Adamson [21] and, in terms of Eq. (1) is given by

$$S(t) = \frac{\Delta V_{1,2}}{V_1}(t)$$

$$= C_2 \left(\frac{t_1}{t_{eq}}\right) \frac{M_1}{10^6 M_2} \beta K_2 \left(\frac{\gamma_2}{\gamma_1} - 1\right) \tag{2}$$

where t_1 is the baseline drop time interval for the solvent, C_2 is the concentration of the analyte near the surface as observed at the detector, t_{eq} is defined as the time required for the solution to reach equilibrium under static conditions, M_1 and M_2 are the molecular masses of the solvent and analyte respectively, K_2 is a thermodynamic constant determining the surface binding constant for the analyte, β describes the relative geometry of the analyte, and γ_1 and γ_2 are the coefficients of surface tension for the solvent and analyte respectively.

As with RI detection, the DSTD requires an absolute change in the probed physical property, in this case surface tension, and this is given by the $(\gamma_2/\gamma_1 - 1)$ term. Selectivity and enhanced sensitivity for surfactants depends upon their ability to form and maintain a concentrated surface layer, and this is defined by the βK_2 term. Lastly, the basis of the time-dependent response comes from analyte transport to the surface by diffusion and convection. In previous work [15] the concentration of an analyte at the drop surface over time is given by the linear approximation

$$C_2(t) = \left(\frac{t_1}{t_{eq}}\right) C_2 \qquad (3)$$

where the equilibrium signal is defined when $t_1 = t_{eq}$, thus making $C_2(t) = C_2$. Eq. (3) describes the transport of an analyte to the surface, relating the determination of surface tension by static and dynamic methods, and is strictly valid only when $t_1 \ll t_{eq}$.

While Eq. (2) describes the various physical mechanisms involved in producing a response, the detection of a surface-active species comes through actually measuring the physical change in a repeating drop volume. In practice, however, the change in drop radius, $\Delta r_{1,2}$, is actually measured and further analysis can show that $S(t)$ in Eq. (2) is approximately equal to three times the relative change in drop radius as a function of time [16]:

$$S(t) = \frac{\Delta \gamma_{1,2}}{\gamma_1}(t) = \frac{\Delta V_{1,2}}{V_1}(t)$$

$$= 3\left(\frac{\Delta r_{1,2}}{r_1}\right)(t) \qquad (4)$$

The last term gives the instrumental-based limit-of-detection (LOD) when $\Delta r_{1,2}$ is taken as three times the standard deviation of successive drops. Currently, the smallest change in drop radius detectable is 0.5 μm. The DSTD is designed to detect small changes in drop radius with optimal operation in the range of 120 μm change in drop radius, or 10% of the baseline drop radius. Since the $\Delta r_{1,2}$ measurement is recorded just prior to detachment of a given drop (maximum drop vol-

ume), then the time dependence of Eq. (4) can take on the additional meaning of the recording time of successive drops in a FIA experiment. Then, it is understood that the time dependence for a drop growth is involved as well.

3. Experimental

The experimental apparatus is shown in Fig. 1. Degassed water was used as the primary carrier solvent for all FIA analyses and was purchased as 100% HPLC-grade (J.T. Baker, Phillipsburg, NJ). An Isco SFC-500 Micro Flow Syringe Pump was used throughout (ISCO, Lincoln, NE). Analytes consisted of reagent-grade SDS and the quaternary amine TBA and were used without further purification (Aldrich Chemical Co., Milwaukee, WI).

Analytes were introduced into the system using an injection valve (Rheodyne 7125, Cotati, CA) fitted with either a 20 μl or 85 μl injection loop (sample loop in Fig. 1), depending on the experiment conducted. An ion-pairing agent was mixed with analyte either in volumetric glassware or combined using a precision microliter pipette (Rainin, Pipetman, Woburn, CA) before injection; alternatively, the ion-pairing agent could be introduced into the carrier solvent as an additive via a second injection valve (ion-pair reagent loop in Fig. 1) located immediately upstream from the sample loop. In-situ mixing of 20 μl injected

Fig. 1. Schematic of the DSTD: DL, diode laser with attached focusing lens; PH, 0.25 in pin hole aperture; PD, photodiode; AD, data acquisition board; PC, personal computer; SP, syringe pump; IP, 1 ml ion-pair reagent loop; SL, sample loop, 20 or 85 μl; MX, 70 μl mixing coil.

analyte solution with the ion-pairing agent in this manner occurs in a 70 μl mixing coil. When this latter approach is desired, a 1 ml loop is placed on the ion-pair reagent valve (Valco C10U. Houston, TX) allowing for 5 min of temporary change to the carrier solvent at 200 μl min^{-1}. All tubing consisted of 1/16 in o.d. × 0.007 in i.d. poly(etheretherketone) (PEEK) tubing (Upchurch, Oak Harbor, WA).

For analyte detection purposes, liquid would flow into a capillary from which drops approximately 8 μl in volume would form at the capillary tip. Capillaries of two different materials were studied. The fused silica capillaries had dimensions of 0.33 mm o.d. × 0.20 mm i.d. with the ends flush and manually polished before use with sandpaper containing 1 μm aluminum oxide particles to minimize surface roughness. Because the o.d. of the capillary is smaller than conventional 1/16 in i.d. chromatography fittings, it was first inserted into a piece of 0.010 in PEEK tubing and then secured with epoxy. This piece of PEEK tubing could then be coupled to the carrier solvent line with the fittings used.

S.S. capillaries were also examined. To prepare these, a 5 cm length of 1/16 in o.d. × 0.007 in i.d. S.S. tubing was cut with one end tapered to a cone such that the o.d. was approximately 50% larger than the i.d. at the tip. The capillary assembly was mounted using a clamp on a vertical post and connected to an X–Y–Z stage micrometer (Newport, 460 X–Y–Z, Fountain Valley, CA).

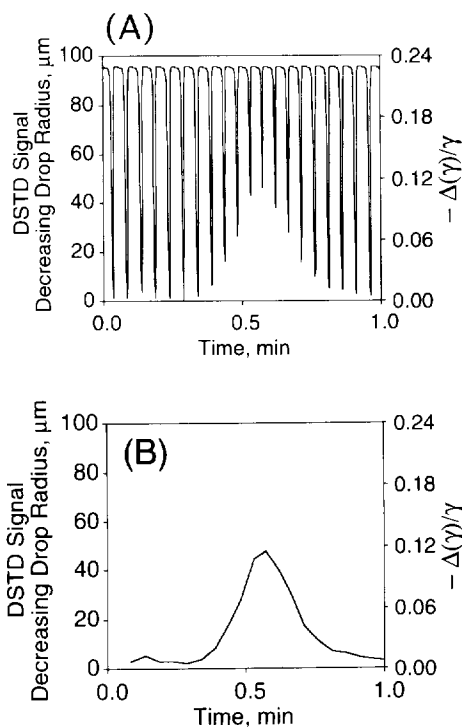
A photodiode placed behind the capillary and in-line with the diode laser is interfaced to an amplifier/voltage offset box and then to a personal computer (Delphi 80486-33, Seattle, WA) via a data acquisition board. A chart recorder is also connected to provide immediate hard copy output. Raw data were collected at a rate of 20 data points per second with each data point the average of 200 A/D reads. Processed data consisted of a measure of the final radius growth of the drop, represented as an intensity voltage, which could then be converted to $S(t)$ using Eq. (4) and the detector calibration curve. To obtain a calibration curve, the X–Y–Z translational stage upon which the capillary is mounted is used to


Fig. 2. (A) Raw data for FIA analysis of 500 ppm SDS as seen by the DSTD. Baseline drop growth is indicated by a 0 μm change in drop radius. Detection of the analyte is seen as a decrease in the final drop radius, or an increase in observed light intensity. The $\Delta\gamma/\gamma$ scale was calculated using Eq. (4) with $r_1 = 1240$ μm. (B) Raw data are processed such that only the data point corresponding to maximum drop growth is kept with the collection of these points forming the FIAgram. The data are offset vertically from zero for clarity.

position the drop in the laser beam path and relate change in drop radius, Δr, to an intensity voltage. As a drop grows at the tip of the capillary, it will significantly block out light from the diode laser. When a surfactant is present in a drop, the surface tension decreases, forcing the drop to detach at a smaller final volume, or smaller final radius, relative to a baseline solvent response. Detection of an analyte is seen as a decrease in final drop radius, or, as an increase in laser light intensity.

The raw signal, as collected by the computer before processing, is shown in Fig. 2A for a 500 ppm SDS sample. Two separate scales are used on

the dependent axes; the decrease in drop radius, $\Delta r_{1,2}$, is given on the left side with the relative change in surface tension, $\Delta\gamma/\gamma$, on the right. The conversion between $\Delta r_{1,2}$ and $\Delta\gamma/\gamma$ is given by Eq. (4). Baseline drop growth is indicated by a 0 μm decrease in drop radius, offset to about 4 μm in fig. 2A for clarity. To convert from a voltage as given by the detector to a $\Delta\gamma/\gamma$ value, the following steps are done. The maximum Δr occurs at the point of drop detachment. The numerical value of the maximum Δr is found by converting the intensity voltage at the detachment point to Δr with the detector calibration curve. The $\Delta\gamma/\gamma$ value is then calculated using Eq. (4), where Δr is divided by the baseline drop radius, r, and then multiplied by three. The final processed data consist of the data points at maximum Δr which form the FIA response curve, as shown in fig. 2B. The baseline drop radius is found by counting the number of drops formed over a given period of time at a given flow rate and then dividing this number into the flow rate to get the volume per drop. Assuming a spherical drop, its radius is found through the formula for volume of a sphere.

At a flow rate of 60 μl min^{-1} and below, the drop volume remains constant at 8 μl for both capillary materials tested but then steadily decreases with increasing flow rate. Table 1 shows how the baseline drop radius changes with flow rate using the S.S. capillary, where baseline response is for pure water. At a flow rate of 250 μl min^{-1}, for example, baseline drop radius decreases by 18 μm, a 1.5% change. The slight decrease in baseline radius with increasing flow

Table 1
Change in baseline drop radius with flow rate. The maximum baseline drop radius is 1240 μm, an 8 μl drop

Flow rate (μl min^{-1})	Drop radius (μm)	Percent decrease in drop radius
30	1240	0.0
60	1240	0.0
120	1237	0.2
200	1228	1.0
250	1222	1.5
300	1214	2.1
350	1204	3.0

rate was insignificant in the calculations reported in this paper.

For those experiments in which an ion-pairing agent is used, the contribution of the ion-pairing agent to the total DSTD signal needs to be subtracted if the ion-pairing effect on the analyte response is to be accurately determined. If the ion-pairing agent itself is surface active, then its presence will cause the baseline drop radius r_1 to decrease which would need to be taken into account when using Eq. (4). TBA, however, is only weakly surface active with a 500 ppm sample producing a Δr value of only 20 μm out of a total drop radius of 1240 μm. With SDS as the ion-pairing agent, however, a 500 ppm sample causes the drop radius to lower by approximately 70 μm.

4. Results and discussion

4.1. Flow rate and capillary material dependence

To investigate the performance of the S.S. capillary and compare it with the fused silica at constant drop volume, the change in drop radius, Δr, as a function of flow rate for an analyte mixture of SDS and ion-pairing agent TBA was examined. The results are shown in Fig. 3. The change in drop radius is actually negative (decreasing final drop volume) but for clarity the absolute value of Δr is plotted. For the fused silica capillary, the response to an injected analyte concentration of 50 ppm SDS mixed with 250 ppm TBA was measured over a flow rate range of 20-200 μl min^{-1}. For the S.S. capillary, 15 ppm SDS with 250 ppm TBA was measured over a range 30-400 μl min^{-1}. The injected volume of 85 μl was large enough to ensure that the concentration at the peak maximum remained undiluted. The flow rate dependence of the DSTD for both capillaries can be divided into two regions. At lower flow rates Δr for each data set is approximately the same and remains constant while approaching 60 μl min^{-1}. Then, the data sets branch off such that at any given flow rate, Δr for the S.S. capillary always remains greater than that for fused silica. Since Δr for each capillary is not the same over the flow rate range examined this
Fig. 3. A comparison of a fused silica and a S.S. capillary as a function of volumetric flow rate. (A) The response is for 85 μl of 15 ppm SDS, in 250 ppm TBA, injected concentration using the S.S. capillary. (B) The response is for 85 μl of 50 ppm SDS, in 250 ppm TBA, using the fused silica capillary. At flow rates below 60 μl min^{-1}, the DSTD response is essentially identical with either capillary but, due to difference in analyte concentrations, the DSTD signal with S.S. is 3.3 times more sensitive. Above a 100 μl min^{-1} flow rate the advantage for S.S. is six-fold.

implies that the capillary material does play a role in determining DSTD sensitivity and that perhaps the response can be maximized by choosing an appropriate material in which to construct the capillary.

The difference in sensitivity for the two capillaries will now be quantified (Fig. 3). While in the lower flow rate region, Δr for each capillary is approximately the same, the SDS analyte concentration at the detector with the S.S. capillary is 3.3 times less when compared to fused silica (15 ppm vs. 50 ppm). In other words, at flow rates below 60 μl min^{-1} a 3.3-fold increase in sensitivity is observed through the use of the S.S. capillary. At higher flow rates, however, sensitivity increases even further over the fused silica capillary. Looking at a flow rate of 200 μl min^{-1}, for instance, the change in drop radius is approximately 1.8 times larger with S.S. than with fused silica; coupling this with the 3.3.-fold difference in analyte concentration gives nearly a six-fold increase in sensitivity for the S.S. capillary. By switching to a S.S. capillary a two-pronged advantage is obtained. First, the S.S. capillary allowed for analysis of analytes at lower concentrations than previously obtained [15,16]. Second, the ability to

work at higher flow rates and still maintain the same signal is possible. Essentially, the flow rate dependence curve for fused silica has been shifted toward higher flow rates with the use of S.S., pointing towards a difference in the kinetic dependence of these materials with the surface tension measurement.

To better understand the behavior of the DSTD with the S.S. capillary, a series of flow rate curves were obtained at varying analyte concentrations. Fig. 4 depicts Δr vs. drop time (inversely proportional to flow rate) for a series of SDS–TBA mixtures, with the TBA concentration kept constant at 250 ppm. The curves were collected utilizing the S.S. capillary. In the shorter drop time regime—higher flow rate—the slope increases with the concentration of SDS injected and is described by Eqs. (2) and (3). The DSTD signal appears to reach a plateau when the surface layer concentration has reached a maximum for the drop time allowed and additional analyte cannot effect a change in surface tension. Also, the time required to reach equilibrium shifts towards lower drop times as the concentration of SDS increases; moreover, the equilibrium Δr value of each curve also increases with SDS concentra-
Fig. 4. DSTD signal as a function of drop time, obtained by changing flow rate for different SDS concentrations injected. Curves A, B, C, and D are for injected concentrations of 50, 25, 15 and 10 ppm SDS respectively. All samples were 85 μl in volume and contained 250 ppm TBA. The time required to reach equilibrium, as defined by approaching a constant Δr value, shifts towards shorter drop times with increasing SDS concentration. The DSTD signal linearly decreases with decreasing drop time in the kinetically-limited short drop time regime.
Fig. 5. DSTD response as a function of SDS concentration at different TBA concentrations. Curve A is for SDS without TBA present. Curve B has the TBA concentration held equal to the SDS concentration. Curve C has the TBA concentration at 10 ppt. TBA and SDS were mixed prior to injection with an injected volume of 85 μl. The flow rate was 60 μl min^{-1}. Enhancement of the DSTD signal through ion-pair formation is seen by comparing the data set with only SDS present with the other two data sets for SDS which also contain TBA. No signal advantage is obtained by increasing the TBA concentration beyond that of SDS.

tion. Consistent with the results of Delahay and Fike [34], the time required to reach equilibrium decreases with increasing bulk SDS concentration. For example, equilibrium for 15 ppm SDS is reached with a drop time of approximately 4 s: raising the concentration to 50 ppm SDS lowers the equilibrium drop time even further to 2 s.

4.2. Ion-pair formation

We have observed that the DSTD response to ionic surfactants could be enhanced through the formation of ion-pairs between the analyte and an appropriate ion-pairing agent prior to detection. The model system used in this study consisted of the analyte SDS and the ion-pairing agent TBA. Two questions were of interest. To what degree was the DSTD signal actually enhanced through ion-pair formation? Secondly, what ratio of ion-pairing agent to analyte is needed to optimize the enhancement?

To answer the first question, three calibration curves with SDS as the analyte and TBA acting as the ion-pairing agent are shown in Fig. 5. The curve of lowest slope, labeled (A), is of SDS

without TBA present. The second curve, labeled (B), has the TBA concentration always kept equal to the SDS concentration. Lastly, the third curve, labeled (C), has the TBA concentration at 10 ppt, much larger than the SDS concentration range. A sample volume of 85 μl was used throughout with the SDS and TBA mixed prior to injection. Looking at Fig. 5 it becomes obvious that TBA greatly enhances the response for SDS while TBA itself exhibits a very small response. Taking the ratio of the slope of curve B to the slope of curve A, a 50-fold enhancement is seen.

The second question of what ratio of ion-pairing agent to analyte is needed to optimize the enhancement is answered in part with Fig. 5. The calibration curves where TBA is present but in different concentrations nearly match one another (Fig. 5, curves B and C). It should also be noted that at no point did the concentration of ion-pairing agent fall below the concentration of the analyte. These two facts led us to conclude that to maximize the sensitivity for SDS detection, the concentration of the ion-pairing agent must be at least equal to the maximum concentration of the analyte intended to be analyzed and that increasing the ion-pair concentration beyond the analyte concentration provides no additional enhancement. If such an advantage did exist, then the

Fig. 6. DSTD response to TBA with 100 ppm SDS present. Injection volume was 85 μl with a flow rate of 60 μl min^{-1}. Up to 100 ppm TBA, enough SDS is present to completely ion-pair the TBA. Above 100 ppm TBA, the SDS becomes a limiting reagent and the DSTD response quickly levels off. TBA itself is weakly surface active, with very little inherent response.
Fig. 7. FIA and DSTD detection of SDS via in-situ ion-pair formation with TBA. (A) Duplicate injections of 500 ppm SDS in water. (B) Injection of 500 ppm of the ion-pairing agent TBA into carrier solvent. This was done via the ion-pair reagent injection valve containing a 1 ml sample loop, thus providing approximately 5 min of altered background. (C) Duplicate injections of 20 ppm SDS mixed in situ with TBA. Flow rate was 200 μl min^{-1} with an analyte sample volume of 20 μl. The ion-pairing agent and analyte were combined in a 70 μl mixing coil prior to detection. Listed concentrations are the amounts injected.

curve with 10 ppt TBA should have yielded a more sensitive response than when TBA was kept equal to the SDS concentration.

Fig. 6 is a calibration curve for TBA with a constant SDS concentration of 100 ppm. TBA is not surface active enough to provide much of a response but in the presence of 100 ppm SDS, the signal is observed by an indirect detection mechanism, since the baseline signal (SDS alone) is subtracted. What should be noticed in Fig. 6 is that up to approximately 100 ppm TBA, the SDS concentration is always in excess, allowing all available TBA to be ion-paired and the signal maximized. Beyond the 100 ppm mark, however, SDS is a limiting reagent and some TBA will not be ion-paired causing the DSTD signal to level off. Beyond a concentration of 100 ppm TBA, it is predicted that Δr should become constant since the maximum number of ion-pairs have formed. The point at which Δr does level off is approximately where the TBA and SDS concentrations are equal, in this case 100 ppm. In fact, looking at Fig. 6, it is observed that the calibration curve does level off sharply past the 100 ppm TBA mark. We conclude that DSTD signal enhancement through ion-pair formation only occurs up

to the point where the ion-pairing agent and analyte are present in equal amounts for the SDS-TBA system. Increasing the ion-pairing agent concentration beyond the analyte concentration does not provide any additional advantage, though at the same time it does not harm the analysis either.

4.3. FIA of surfactants through in-situ ion-pair formation

The end goal of this work is to apply the advantageous ion-pairing effect to the rapid analysis of surfactants using FIA and the DSTD. To this end, it was concluded that the ion-pairing agent would need to be present in the carrier solvent and the ion-pairs formed in situ for real-time analysis to occur. The in-situ formation was facilitated with a mixing coil placed between the sample loop injection valve and the capillary (see Fig. 1). By introduction of an ion-pairing agent such as TBA into the carrier solvent upstream from where analytes are injected, the requisite ion-pairs can form before entering the detector.

Fig. 7 depicts the data from the FIA experiment. First, 20 μl of 500 ppm SDS was injected in duplicate into a pure water carrier solvent (200 μl min^{-1}) and the detector response recorded. The signal plotted in this case is the true DSTD re-

Fig. 8. Detection of TBA via in-situ ion-pair formation with SDS. Flow rates and volumes injected are the same as in Fig. 7 except SDS becomes the ion-pairing agent and TBA the analyte. (A) Injection of 500 ppm TBA into carrier solvent water. (B) Injection of 500 ppm SDS into the carrier solvent. (C) Reset capillary position. (D) Duplicate injections of 25 ppm TBA mixed in situ with SDS.

sponse, that is, the relative change in surface tension, $\Delta\gamma/\gamma$, as defined in Eq. (4) and converted as in Fig. 2AB. Once the signal returned to baseline after the second injection, 500 ppm TBA was injected into the carrier solvent from the ion-pair reagent loop and the new, slightly altered, baseline was allowed to equilibrate. As stated previously, TBA itself is only slightly surface active and as such the change in baseline is not significant in the data conversion to $\Delta\gamma/\gamma$. With the TBA present in the carrier solvent, a 20 μl sample of 20 ppm SDS was injected, allowed to mix with the TBA in the mixing coil and the response recorded. As is evident, even with a 25-fold less concentrated sample the relative change in surface tension of SDS is approximately twice as great when TBA is present than when TBA is absent. In short, this means a 50-fold increase in sensitivity for SDS is possible through the formation of an ion-pair with TBA prior to detection by the DSTD. The LOD for SDS as a DS–TBA ion pair, where DS is the dodecyl sulfate ion, was determined to be 400 ppb (LOD $= 3 \times$ standard deviation of the baseline noise). Note that these analyses were conducted at a flow rate of 200 μl min^{-1} which, prior to the use of the S.S. capillary and the ion-pairing agents, was not possible.

Fig. 8 is the role reversal of the chemical species used in Fig. 7. TBA is the analyte and SDS acts as the ion-pairing agent present in the carrier solvent. This situation has an added importance in that it shows how non- or weakly-surface active molecules, such as TBA, can be detected with the DSTD by having an appropriate ion-pairing agent present in the carrier solvent. The relative change in surface tension, $\Delta\gamma/\gamma$, for the TBA–DS complex is roughly four-fold greater than that for TBA alone while the TBA–DS concentration was 20-fold lower, meaning the overall sensitivity has been increased 80-fold. The 1 ml plug of 500 ppm SDS injected into the carrier solvent yields a constant DSTD response as seen in Fig. 8 at about the 2 min mark. To keep the two subsequent injections on scale, the baseline light intensity was readjusted. To do this, the position of the capillary was moved further into the path of the laser beam by an amount equal to the decrease in baseline drop radius caused by the SDS.

5. Conclusion

We found that the DSTD is a more sensitive detector by switching from a fused silica capillary to one made of S.S. This allowed for operation of the DSTD at significantly higher flow rates than previous with a six-fold increase in sensitivity. Furthermore, the detection of SDS was enhanced 50-fold by the formation of an ion-pair between SDS and the quaternary amine TBA giving a final LOD of 400 ppb. The methodology reported here should be ideally suited for process analysis and biomedical applications. For purposes of environmental monitoring, however, the LOD for this method would have to be lowered further [36]. The formation of drops for the purposes of analytical measurements is not restricted to the detection of surfactants. Dasgupta et al. has recently shown that a droplet formed at the end of a capillary is capable of acting as a sampling device for gas soluble analytes such as NH_3, SO_2 and NO_2 [37,38]. Also, the feasibility of using a fiber drop analyzer (FDA) for viscosity, spectral absorbance and RI measurements has been recently reported in the literature [39]. Future work will tend towards applying the DSTD as a detector in liquid chromatography and developing FIA methodologies for analyzing mixtures of surfactants where the ion-pairing agent is present in the carrier solvent so that the enhancement effects can be realized.

Gas chromatographic sensing on an optical fiber by mode-filtered light detection[1]

Carsten A. Bruckner, Robert E. Synovec*

Department of Chemistry, Box 351700, University of Washington, Seattle, WA 98195, USA

Abstract

A chemical sensor for gas phase measurements is reported which combines the principles of chemical separation and fiber optic detection. The analyzer incorporates an annular column chromatographic sensor, constructed by inserting a polymer-clad optical fiber into a silica capillary. Light from a helium–neon laser is launched down the fiber, producing a steady intensity distribution within the fiber, but a low background of scattered light. When sample vapor is introduced to the sensor, and an analyte-rich volume interacts with the polymer cladding, chromatographic retention is observed *simultaneously* with a change in the local refractive index of the cladding. An increase in cladding refractive index (RI) causes light to be coupled out of the fiber, with detection at a right-angle to the annular column length to provide optimum S/N ratio. This detection mechanism is called mode-filtered light detection. We report a gas chromatographic separation on a 3.1 m annular column (320 μm i.d. silica tube, 228 μm o.d. fiber with a 12 μm fluorinated silicone clad) of methane, benzene, butanone and chlorobenzene in 6 min. The annular column length was reduced to 22 cm to function as a sensor, with selected organic vapors exhibiting unique retention times and detection selectivity. The detection selectivity is determined by the analyte RI and the partition coefficient into the cladding. The calculated limit of detection (LOD) for benzene vapor is 0.03% by volume in nitrogen, and several chlorinated species had LOD values less than 1%. For binary mixtures of organic vapors, the detected response appears to be the linear combination of the two organic standards, suggesting that the annular column may be useful as a general approach for designing chemical sensors that incorporate separation and optical detection principles simultaneously.

Keywords: Chemical sensor; Chemical separation; Fiber optic; Gas chromatography; Mode-filtered light detection

1. Introduction

There is continued interest in the development of fiber optic-based chemical analyzers for use in on-line monitoring systems for process analysis, as well as in environmental and clinical applications. Optical methods for gas sensing have several advantages over conventional chemical

methods, which include the possibility of fast, remote, selective, nondestructive, and safe detection [1]. Much of the work in this field is aimed towards taking advantage of optical fibers as the intrinsic sensing element. Fiber optics are able to act as sensors because their light-carrying ability is dependent on the physical nature of the fiber core and the surrounding cladding. If the core or cladding is altered by analyte interaction, the modulation of the guided light can be used for analyte detection. A large portion of the fiber optic sensors in the literature are evanescent wave sensors [1–6]. Evanescent wave sensors rely on the analyte modulation of the evanescent field, which is that portion of the guided wave power distribution residing outside the fiber core. An absorbing species will interact with the evanescent field, and the transmitted light at the fiber exit will show a decrease in intensity for the wavelengths absorbed. Many evanescent field sensors are commonly used for liquid phase detection [2–4]. Sensitivity improves with increased analyte/evanescent field interaction, which is why lengths of exposed fiber up to several meters have been used [2]. Fewer examples exist for evanescent field detection in the gas phase [1,5,6]. The sparseness is mainly due to the gas medium being a thousand-fold more dilute, making trace component detection that much more difficult. Efforts have been made to improve sensitivity by tapering the exposed fiber section [13], or by preconcentrating analytes into the polymeric cladding [5].

An alternative mode of detection involves monitoring the refractive index (RI) of the cladding. The number of paths, or modes, that light can propagate along an optical fiber are constrained by the relative RIs of the core and cladding. Changes in RI of the cladding after the allowable modes of propagation, and thus the transmission properties of the fiber. If analyte partitioning changes the cladding RI, the change in transmitted light allows for analyte detection. In a conventional sensing configuration, changes in the intensity of transmitted light are monitored [7–11]. As with evanescent wave detection, a drawback of this detection method is that small changes in a large background need to be discerned. We have been investigating the use of

optical fibers with the RI detection mechanism as intrinsic sensors in small volume systems, for which extended lengths of exposed fiber are unsuited [12,13]. Our work takes advantage of the idea that, instead of monitoring transmitted light, it is better to collect the mode-filtered light that is scattered normal to the fiber axis. The background is substantially lower than transmitted intensity measurements, and the S/N advantage allows a shorter length of fiber to be used as the sensing element.

Detecting from the side of the fiber can give the fiber additional selectivity [12,13]. By inserting a fiber into a transparent capillary tube, we have produced a configuration which provides chromatographic information as well as detection

A

B
Fig. 1. (A) Schematic of annular column sensor: HeNe laser light focused with 5× lens and launched at an angle of 25° into an optical fiber; this fiber goes into the capillary tube to form the annular column; headspace vapor is introduced to the column via the vapor injector; gas flow controlled with a needle valve; a second optical fiber carries light scattered from the annular column to a PMT. (B) Close-up of annular column: an optical fiber is inserted in a fused silica capillary tube, and gas samples flow in the channel between the fiber and the tube. Separation efficiency is improved by reducing the cladding thickness, d_c, and the distance between the fiber and the tube, $r_2 - r_1$.

(Fig. 1A). The fiber cladding functions as the stationary phase, allowing components in a sample to migrate at different rates down the length of what we term an "annular column" (Fig. 1B). After a certain degree of separation has been achieved, the components pass the detection section of the fiber. The light that is mode-filtered and scattered at this point passes through the capillary tube and is monitored (Fig. 1A). This technique has been applied by us to speciate organics, primarily in aqueous phase samples [12,13]. This paper presents the rationale for mode-filtered light detection, and expands upon the application of the annular column sensor to gas phase analysis. First, we briefly describe the theory of mode-filtered light detection in the context of gas phase measurements. Second, the first report of a gas chromatographic separation on an annular column is presented. Third, the reproducibility of the gas sensor is considered. Finally, the simultaneous separation and detection of gas phase samples are reported, and a two component mixture deconvoluted using vapor standards.

2. Theory

Consider the two cases of measuring the change in transmitted beam intensity as shown in Fig. 2, along with a third case to be discussed shortly. With an incident beam intensity I_0 coupled into a fiber optic at a wavelength of negligible absorbance, conservation of energy requires that I_0 will be either transmitted as I_T, or mode-filtered as I_F due to the natural mode-filtering processes in the fiber optic as a result of the numerical aperture (NA) condition and scattering centers. This relationship is simply

$$I_0 = I_T + I_F \tag{1}$$

where I_T is the transmitted beam background, and I_F is the mode-filtered light background. The mode-filtered light signal, ΔI_F, due to an induced change in the local NA along the fiber optic, is equivalent for both measurements shown in Fig. 2, transferring from I_T to I_F, as I_0 remains constant:

A

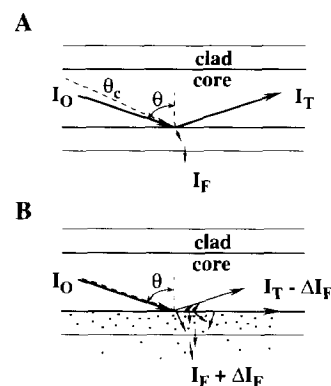
B


Fig. 2. Mode-filtered light detection mechanism: light propagates in a fiber if the critical angle θ_c is less than the propagated angle θ. (A) A small fraction of light is filtered out of the side, I_F. (B) A partitioning analyte with a RI greater than the cladding RI increases θ_c, resulting in $\theta_c \geqslant \theta$. Under this condition more light is filtered out. Monitoring mode-filtered light, I_F, has an S/N advantage over the traditional method of monitoring transmitted light, I_T. See text for details.

$$I_0 = (I_T - \Delta I_F) + (I_F + \Delta I_F) \tag{2}$$

The noise in the transmission measurement is proportional to I_T, while in the direct mode-filtered light measurement, the noise is proportional to I_F, assuming one is not shot-noise-limited in either case. If the ratio of the backgrounds is given as β, the ratio of noise levels is

$$\beta = I_T/I_F \tag{3}$$

Thus, the S/N ratio of the direct mode-filtered light measurement relative to the conventional transmission measurement at the end of the fiber is equal to β, since the signal is ΔI_F for both. As β values are around 10–100, there is a S/N advantage in measuring mode-filtered light directly.

While Eqs. (1–3) were derived with the entire fiber length in mind, a third case also warrants consideration. If one directly measures the mode-filtered light over a small fraction of the fiber surface area, ϕI_F, it follows from Eqs. (1) and (2) that both I_F and ΔI_F will be reduced by the same fraction, ϕ. Thus the S/N ratio for the case of measuring ϕI_F should be equivalent to the second case, measuring all of I_F, and will also be β times better than the conventional transmission mea-

surement case. Again, this assumes that one is not shot-noise-limited. Use of a typical helium–neon or diode laser of 5 mW is generally sufficient to avoid a shot-noise-limited measurement. Now, the small area measurement, while providing optimum S/N ratio, also affords unique advantages to small volume chemical analysis which we are taking advantage of in our design by monitoring light in only a narrow section of the annular column (Fig. 1A).

The critical angle θ_c is defined as the minimum angle at which a light ray will be totally internally reflected at the core–clad interface (see Fig. 2). Light can propagate in a fiber for extended distances only if the rays reflect at angles of $\theta > \theta_c$. Since θ_c is dependent on the relative RIs of the core and cladding through the equation

$$\sin \theta_c = n_{clad}/n_{core} \tag{4}$$

where n is the RI of the core or clad, changes in n_{clad} will affect the critical angle. Analyte partitioning into the cladding may change n_{clad}, and the resulting critical angle change results in the mode-filtered light signal ΔI_F. For a small concentration of extracted analyte

$$\Delta I_F = \alpha \Delta \theta_c \tag{5}$$

where α is a proportionality constant that takes into account the light collection efficiency and the conversion of the light flux to the detected current [12]. The change in critical angle (Fig. 2) is quantitatively related to experimental conditions, as given by

$$\Delta \theta_c = (n_{clad}/n_{core})\{(n - n_{clad})/NA\}K_d C_{v,m} \tag{6}$$

where n is the RI of the interacting chemical species, and NA is the numerical aperture of the fiber optic. The partition coefficient K_d describes the relative chemical affinity of a given chemical species between the solvent phase and the fiber clad, i.e. the relative concentration of a given species between these two phases. Essentially, K_d describes the enrichment one observes for the analyte concentration in the cladding over the initial concentration in the bulk solvent, given as $C_{v,m}$, with units of volume fraction. Thus, the mode-filtered light signal to the first order is given by Eqs. (5) and (6) and is linear with respect to

analyte RI, analyte concentration and K_d [12]. This paper presents data for analytes with appreciable sensitivity. Sensor response to analytes like pentane, which due to a low K_d value have a negligible sensitivity, are not shown, but the added selectivity for analytes with large K_d value should be recognized.

3. Experimental

The feasibility of performing chromatography with an annular column was demonstrated with a 3.1 m section of 228 μm o.d fiber with a 12 μm fluorinated silicone cladding (removable jacket, fiber type HCR-H200B, Ensign-Bickford, Avon, CT) inserted into an equal length of 320 μm i.d. undeactivated silica tubing (Polymicro Technologies, Phoenix, AZ). Attached to the end of the column was a pressure restrictor, 20 cm of 50 μm i.d. silica tubing (Polymicro Technologies). The column was run at 120°C and 20 psi in a Hewlett-Packard 5890 gas chromatograph with splite injection and flame ionization detection.

The remainder of the data was collected using a set-up incorporating optical detection (Fig. 1). The annular column consisted of the same optical fiber, inserted into a 530 μm i.d. fused silica capillary (J&W Scientific, Folsom, CA). Helium–neon laser light at 633 nm was focused with a 5 × objective into 3.5 m of the polymer clad fiber, the last 20 cm of which was inserted into the capillary tube for exposure to vapor. Focusing the light into the fiber ensured that the limiting source of noise was due to intensity fluctuations of the laser and not shot noise. Care was taken to prevent damaging the fiber, as faults in the fiber could scatter light, which would interfere with light that scattered as a result of analyte partitioning. The fiber was sealed to the tee end of the column (Fig. 1A) by gently clamping a ferrule down onto a piece of 0.010 in. i.d. PEEK tubing through which the fiber was inserted. A micropositionable fiber chuck mounted on a rotational stage (Newport, Fountain Valley, CA) was used to control the angles at which light was coupled into the optical fiber. Light propagating near the critical angle θ_c is more susceptible to mode filter-

ing upon perturbation of the cladding. The optimum S/N ratio was obtained when light was launched at 25° normal to the fiber face, so that condition was used. This launch angle is just within the acceptance angle of 26°, resulting in a large portion of the light propagating close to the critical angle. Nitrogen as the carrier gas was introduced at 20 psi at the opposite end of the column, with a flow of 0.4 ml min^{-1}, measured at the column outlet. Since the sensitivity of the device is dependent on analyte affinity with the cladding (K_d, Eqs. (5) and (6)), which in gas phase studies can be varied with temperature, a temperature-controlled heating strip was placed along the annular column, and both were wrapped in fiberglass insulation. The signal was recorded by measuring the light emitted from the side of the fiber through the capillary tube (polyimide coating removed) with a photomultiplier tube (PMT; type 1P28, Hamamatsu). The elevated temperatures prevented the use of the PMT next to the column, so 1 m of a 500 μm diameter core optical fiber from the PMT was butted perpendicular to the column with a tee, 7 cm from the column exit, to collect the mode-filtered light. The proximity of the collection and emission fibers allowed light from no more than a 1.5 mm length of the emission fiber to be monitored, despite the large 60° acceptance angle of the collection fiber. A power supply operated the PMT at 700 V, and the signal was sent to a chart recorder or computer via a current-to-voltage converter (model 3A14, Pacific Instruments, Concord, CA). Figs. 4–6 represent the signal after a 3 s moving average was applied to the raw data.

Sample vapor was injected with a 300 μl injection loop using a 10-port electrically actuated valve with computer control (model EQ36, Valco, Houston, TX). An in-house system continuously fed headspace samples through the injection loop from organic liquids slowly purged at ambient temperature with nitrogen. Injected vapor concentrations were estimated by comparing the partial pressures of the samples to the total pressure in the purging vessel.

4. Results and discussion

An optical fiber inserted in a capillary tube allows the fiber cladding to function as a stationary phase, providing a gas chromatographic separation in the annular column. As shown in Fig. 3, the annular column separates compounds based on their relative affinities to the fiber cladding. Earlier experiments without the inserted fiber showed no measurable retention of these compounds on the capillary wall at this temperature. As can be seen, the later eluting compounds are broadened considerably relative to methane. This phenomenon is not unexpected, given the thickness of the stationary phase. The polymer cladding is 12 μm thick, much thicker than traditional GC stationary phases, which are of the order of 1 μm or less. As a result, the large resistance to mass transfer in the stationary phase slows the exchange rate of analytes between the stationary and mobile phases. In subsequent experiments, the inserted fiber provided detection as well as chromatographic modulation of compounds (Fig. 1A). The emphasis for these experiments was not on the optimization of the chromatography per se, but instead on the development of the sensing aspect of the annular column. As a result, the column length was shortened to both simplify column preparation and reduce run times.

Reproducibility of the gas phase sensor was then considered. Fig. 4 shows multiple headspace injections of benzene at 90°C, which provides a measure of the system reproducibility. These data
Fig. 3. Separation of methane (A), benzene (B), butanone (C), and chlorobenzene (D) on a 3.1 m annular column with flame ionization detection, run at 120°C. This Figure highlights the chromatographic ability of the annular column configuration. Band broadening of peaks is the result of the thick 12 μm cladding.

Fig. 4. Annular column sensor response to seven benzene headspace injections, at 5% (v/v) in nitrogen at 20 psi. Responses normalized by dividing analyte response into background response. Intergrated area precision is 4.3% RSD.

Fig. 5. The annular column sensor provides selective temporal information for various species. Shown are responses to separate vapor injections of 23% (v/v) methylene chloride (M), 11% chloroform (C), and 4% trichloroethylene (T).

were corrected for light source intensity drifts by dividing the analyte response into the background response. The benzene concentration is 5% (v/v) in nitrogen, so the limit of detection is 0.03% (3σ) for the given run conditions. The relative standard deviation of the integrated response was 4.3%, which includes sample introduction error. The thickness of the cladding required a lengthened period of analyte exposure to the fiber before the sensor response equilibrated. The data therefore bear a stronger resemblance to steady-state sensor experiments than to chromatographic data. Note the low amount of background light relative to the analyte signal, which was collected by monitoring the filtered light emitted from a small section of the exposed fiber. It is this feature of mode-filtered light detection that makes it possible for the sensor to monitor its chromatographic capability. The traditional fiber optic detection mechanism, monitoring the transmitted light, is not sufficiently sensitive to measure analyte partitioning on such a small surface area, due to the high background. For transmission-type measurements, an extended length of exposed fiber is required to increase the analyte signal relative to the background. However, transmission-type measurements integrate the sensor response along the entire length of the fiber, which inhibits their use as chromatographic sensors. Operating the system at lower temperatures increased the partitioning into the cladding, which improved the detector sensitivity (Eq. (6)). However, at temperatures approaching ambient, the sensor response

became erratic. This behavior may result from hardening of the cladding at lower temperatures, or from vapor condensation on the fiber surface, which would scatter light unpredictably. The chosen operating temperature was therefore a compromise between detection sensitivity and sensor reliability.

The separation and detection of analytes by the same device is demonstrated in Figs. 5 and 6. Fig. 5 shows the superposition of three chlorinated compounds, and highlights the temporal selectivity of the sensor. Detection limits are based on calculated injection concentrations of 23% methylene chloride (v/v), 11% chloroform, and 4% trichloroethylene. Detection limits at three times the baseline noise level for methylene chloride, chloroform, and trichloroethylene are there-
Fig. 6. Sensor response to headspace of a 1:1 mixture of methylene chloride (M) and chloroform (C). Pure headspace injections of the two components were fit to this mixture, and the best fit using classical least-squares (CLS) also predicted a 1:1 mixture. Pure component responses are scaled so their sum is the best fit line. CLS required all the baselines to be centered at zero.

fore 0.5% (v/v), 0.2%, and 0.06% respectively. The varying detection limits of these compounds result from differing degrees of cladding preconcentration (K_d, Eq. (6), combined with the magnitude of the RI difference between the compounds and the cladding ($n - n_{clad}$, Eq. (6)). These detection limits highlight the fact that, for analytes with RIs different from the cladding RI, the annular column sensor is generally more sensitive to compounds with higher boiling points, which tend to preconcentrate in the non-polar cladding to a greater extent. This is because analyte boiling point is often correlated with the size of the non-polar group on the analyte. Fig. 6 shows how well the sensor responds to the headspace of a 1:1 mixture of methylene chloride and chloroform, relative to the sensor's response to the pure components. Since the components in the mixture are not fully resolved in a chromatographic sense, quantitation of the mixture required fitting the pure component responses to the mixture response using classical least-squares. The best fit mixture is also shown in Fig. 6 as a superimposed line on the actual response. The best fit also predicts a 1:1 concentration of the two components, implying that the signals are additive. Note that good quantitation does not require complete component resolution as long as the individual responses are distinct and reproducible [14].

5. Conclusion

It has been demonstrated that the annular column fiber sensor configuration can provide chromatographic information in addition to just sensitive detection. This additional information endows the annular column sensor with more selectivity in the identification of analytes. Detecting mode-filtered light directly from the side of the fiber holds promise for obtaining improved detectability. Future developments of the annular column sensor include the replacement of the fiber cladding with different coatings more suited to analyte partitioning. Reducing the thickness of the cladding will shorten the response time of the sensor and improve the chromatographic efficiency. The modified surface layer must still allow the fiber to conduct light efficiently, and it must be robust enough for extended use.

Electroinjection analysis. The introduction of a new variant of flow-injection analysis and comparison with electrophoretically-mediated microanalysis[1]

V.P. Andreev*, A.G. Kamenev, N.S. Popov

Institute for Analytical Instrumentation, Russian Academy of Sciences, 26 pr. Rigsky, 198103 St. Petersburg, Russian Federation

Abstract

A new method of mixing sample and reagent due to the difference in their electrophoretic mobilities is introduced. Unlike electrophoretically-mediated microanalysis, sample and reagent are injected from the opposite ends of a capillary tube. This method is compared with electrophoretically-mediated microanalysis. Experiments are performed showing the possibilities of this new method.

1. Introduction

Improvement of sample and reagent mixing without an increase in the product dispersion is very important for the maximization of flow-injection analysis (FIA) sensitivity, especially in the case of rapid kinetic analysis. Mathematical modeling of FIA with a fast second-order reaction [1] showed that if sample and reagent were initially premixed then a shorter reaction tube will minimize product dispersion and maximize sensitivity of the analysis. Longer reaction tubes cause expansion of the product dispersion due to the non-uniform flow profile.

The imperfections of sample and reagent mixing in the mixing tees has been shown [2] and a much better way to mix sample and reagent with the help of a coaxial jet mixer was proposed [3].

A new method of sample and reagent mixing called electrophoretically-mediated microanalysis (EMMA) was proposed and developed [4–7]. In the EMMA method, sample and reagent are mixed in the capillary electrophoretic system due to the difference in their electrophoretic mobilities.

The objective of this paper is to present another variant of sample and reagent mixing based on the same idea as EMMA and to introduce a new

---

* Corresponding author.

variant of FIA. We have called this technique electroinjection analysis (EIA), and have compared its properties with EMMA.

2. Idea of the method

In both methods (EMMA and EIA) mixing of sample and reagent takes place in the capillary with the longitudinal electric field applied. In fact both methods were realized with the help of capillary electrophoresis systems built in the laboratory. Mixing of sample and reagent in both methods is due to the difference in their electrophoretic mobilities. However, in EMMA, sample and reagent are injected from the same end of the capillary while in our method sample and reagent are injected from opposite ends of the capillary. The principles of both methods are presented in Fig. 1. In EMMA the slower reactant is injected first followed by injection of the faster one. As the faster one passes through the slower one, they will react and the product is then detected photometrically. In our method both reactants are injected simultaneously from opposite

Fig. 1. Principles of the methods of EIA and EMMA.

ends of the capillary. They meet in the capillary, pass through one another and react. As can be seen from Fig. 1, in EMMA there is some critical minimum length needed to mix sample and reagent. This is determined by w_{min}, which is equal to sample length, and by the difference in the electrophoretic mobilities of the reactants:

$$l_{mix} = t_{mix} \cdot \mu_s E = \frac{w_{min}}{\Delta\mu_{ep} E} \cdot \mu_s E = \frac{w_{min}}{\Delta\mu_{ep}} (\mu_{ep.s} + \mu_{osm})$$

where l_{mix} is the mixing length, t_{mix} is the mixing time, $\mu_s = \mu_{ep.s} + \mu_{osm}$ is the sample mobility, $\Delta\mu_{ep} = \mu_{ep.s} - \mu_{ep.r}$ is the difference in electrophoretic mobilities of sample and reagent, μ_{osm} is the electroosmotic mobility and E is the electric field strength. So, the smaller the difference in electrophoretic mobilities of the reactants the longer the mixing tube must be. According to EIA one can mix sample and reagent in very short tubes. In fact tube length is limited only by the sum of the initial sample and reagent lengths. When comparing EIA and EMMA, the question of analytical capabilities naturally arises. What are the possible samples and reagents for both methods? Are there any restrictions? In both cases, the capillary must be filled with some liquid with non-zero conductivity. In both cases, at least one of the reactants must be charged. In both cases, total velocity of the reactant is equal to the sum of its electrophoretic velocity and the electroosmotic velocity of the liquid in the capillary. Due to the presence of electroosmotic flow during EIA one can mix not only oppositely charged reactants but also neutral and charged reactants. Even reactants with the same charge can be mixed if one of them has low molecular weight and the other has high molecular weight.

Let us assume that the zeta potential of the capillary wall is negative ($\zeta < 0$), then the eletroosmotic flow is in the same direction as the electric field. In order to mix positive sample ions ($z_s > 0$) with negative reagent ions ($z_r < 0$) having total velocities equal to

$$v_s = (|\mu_{ep.s}| + |\mu_{osm}|)E \qquad (1)$$

$$v_r = (|\mu_{ep.r}| - |\mu_{osm}|)E \qquad (2)$$

then one must satisfy the condition $v_r > 0$, i.e.
$$|\mu_{ep.r}| > |\mu_{osm}| \tag{3}$$

and this condition is quite natural for low molecular weight reactants. The same condition must be fulfilled if one of the reactants is neutral ($z_s = 0$) and the other is negatively charged ($z_r < 0$), then the first one is carried by the electoosmotic flow

$$v_s = |\mu_{osm}|E \tag{4}$$

and the second one must have an electrophoretic mobility larger than the electroosmotic mobility. If both reactants are negatively charged ($z_s < 0$, $z_r < 0$) then:

$$v_s = (|\mu_{osm}| - |\mu_{ep.s}|)E \tag{5}$$

$$v_r = (|\mu_{ep.r}| - |\mu_{osm}|)E \tag{6}$$

and in order to mix reactants one must have:

$$|\mu_{ep.s}| < |\mu_{osm}| \tag{7}$$

$$|\mu_{ep.r}| > |\mu_{osm}| \tag{8}$$

Condition (7) is natural for high molecular weight reactants while condition (8) is natural for low molecular weight reactants. Sample and reagent are quite interchangeable, so one can mix with the help of EIA not only high molecular weight samples and low molecular weight reagents, but also low molecular weight samples and high molecular weight reagents. The rule is simple: the reactant that is injected in the direction opposite to the direction of the electroosmotic flow must have a high eletrophoretic mobility.

If the zeta potential of the capillary wall is positive then the same conditions must be fulfilled, but the signs of the charges of the reactants must be reversed and so positively charged reactants can be mixed if one of them has a low molecular weight and the other has a high molecular weight. If the zeta potential of the capillary wall is equal to zero then the reactants must have opposite charges in order to be mixed.

When using EMMA one can easily mix reactants with electrophoretic mobilities having the same sign as μ_{osm}. However, if the sign of electrophoretic mobility of one of the reactants is different from the sign of electroosmotic mobility, then the electrophoretic mobility must be smaller than the electroosmotic mobility of the liquid in

the capillary, and this is natural for high molecular weight reactants. This is probably the reason why EMMA was proposed and realized for biochemical reactions. EIA can be used for low molecular weight objects as well.

As can be seen, both EIA and EMMA have some limitations so far as the values and signs of the electrophoretic mobilities of the reactants are concerned. However, virtually any pair of reactants can be mixed either by EIA or EMMA, except in the case where both reactants have zero charge. In fact, these are not conflicting methods at all. They can be combined, as is shown in the following section of the paper, or realized with the same instrument — a capillary electrophoresis system with two samplers, designed so as to be capable of injecting reactants from both ends of the capillary simultaneously. However, in the case where electrophoretic mobilities of the reactants have values that permit the use of either method, it seems that EIA has some advantages over EMMA. Firstly, the possibility to use very short capillaries for EIA, and consequently to use lower electric fields, was previously mentioned. Secondly, in EMMA cross contamination of sample and reagent is possible at the introduction end of the capillary. During EIA this is impossible because sample and reagent are injected through opposite ends of the capillary. Thirdly, in the case of sorption of the reactants on the capillary wall during EMMA, there might be chemical interaction between moving and sorbed ions which might lead to the tailing of the product peak. However, in EIA, sample and reagent move in different paths and such interaction is impossible. Finally, during EMMA reactants are injected one after another, in comparison to EIA where they can be injected simultaneously electrokinetically. This seems to be an advantage not only in so far as the time of analysis is concerned. This simple type of injection seems to be the optimal one at least for the fast chemical reactions with neutral product. Let us assume the ideal situation where the reaction rate is much higher than the rate of electrophoretic transport, concentrations of both reactants are equal, and neutral product is produced. Then this situation may be described by the simplistic model presented in Fig. 2. Ideally an
Fig. 2. Simplistic model of sample and reagent mixing in EIA.

infinitely thin product zone will be formed when point b meets point c at the same place where point a meets point d. Coordinates of these points are determined by the following simple equations:

$$x_{ad}/v_1 = (l - x_{ad})/v_2 \tag{9}$$

$$(x_{bc} - l_1)/v_1 = (l - l_2 - x_{bc})/v_2 \tag{10}$$

where l is the length of the capillary, v_1 and v_2 are the velocities of reactant transport and l_1 and l_2 are the initial lengths of the reactant zones. Then from $x_{ad} = x_{bc}$, it follows that the simple condition

$$l_2/l_1 = v_2/v_1 = (\mu_{ep2} + \mu_{osm})/(\mu_{ep1} + \mu_{osm}) \tag{11}$$

can easily be satisfied if the reactants are injected electrokinetically and simultaneously by simply putting the ends of the capillary to the sample and reagent bottles and applying a high voltage to them.

3. Experimental

Preliminary experiments to demonstrate the experimental realization of EIA were performed with the help of a capillary electrophoretic system made in the laboratory. The system is presented in Fig. 3. The main difference from the usual capillary electrophoresis system is that we have included two samplers and the potential to inject reactants from both ends of the capillary simultaneously. The inner diameter of the quartz capillary was 100 μm. The potential difference applied to the capillary in most of the experiments was 15 kV. Most of the capillary, with the exception of the sample and reagent zones, was filled with distilled water. As a result very low electrical current was observed (it was never larger than 10 μA), and thus no problems with Joule heating occurred. Fig. 4 presents the typical peak for the well-known analytical reaction between Fe^{3+} ions and sulfosalicylic acid. The sample, standard
Fig. 3. Capillary electrophoresis system used for EIA experiments: (1) quartz capillary; (2) lamp; (3) filter; (4) photodetector; (5) analog recorder; (6) power source; (7) air pump; (8,9) samplers.

aqueous solution of Fe^{3+} ions, and the reagent, 0.5% solution of sulfosalicylic acid, were electrokinetically injected simultaneously through opposite ends of the capillary. The injection time was 40 s. Approximately 10 min after the injection the product peak was detected photometrically at $\lambda = 430$ nm. The experiments were performed for sample concentrations varying from 10^{-5} g
Fig. 4. Typical peak of the product of the analytical reaction of determination of Fe^{3+} with the aid of sulfosalicylic acid.
Fig. 5. Logarithm of the detector output vs. sample concentration for determination of Fe^{3+} and Ti^{4+}: (∗) Fe^{3+}; (○) Ti^{4+}.

ml^{-1}–10^{-4} g ml^{-1} and the resulting calibration curve (dependence of the logarithmic detector output vs. concentration) was practically linear (see Fig. 5).

The analytical reaction in the determination of Ti^{4+} ions using hydrogen peroxide and sulfuric acid was also realized. Actually, it was a combination of EIA and EMMA because two reactants, Ti^{4+} and hydrogen peroxide, were sequentially injected from one end of the capillary and sulfuric acid was injected from the opposite end of the capillary. The product of the reaction was detected photometrically at $\lambda = 580$ nm. A series of three injections is presented in Fig. 6. The same range of sample concentrations as in the case of the determination of Fe^{3+} ions was studied. Results of the experiments are presented in Fig. 5. The detection limit for both reactions appeared to be nearly the same and equal to 10^{-5} g ml^{-1} with the signal-to-noise ratio equal to 3. This detection limit is rather close to the detection limit reported in Ref. [7] for EMMA of ethanol and could be significantly improved by well-known methods used to enhance the sensitivity of absorbance detectors, such as using z-cells [8] or multireflec-

tion cells [9].

Of course the results presented are preliminary ones and much more experimental work must be done. The objective of presenting these experimental results is to show the possibility of the experimental realization of EIA and the possibility of combining EIA and EMMA. Either of these methods or their combination can be realized with the help of a simple capillary electrophoretic system designed in such a way as to be capable of injecting reactants from both ends of the capillary simultaneously.

4. Conclusion

The new EIA method shares the advantages of EMMA: minimal volumes of analyte and reagent (nanoliters), minimal dispersion of the product and the possibility to separate analyte from the matrix components due to the intrinsic separative capacity of electrophoresis. EIA and EMMA can be combined to realize chemical reactions with several reagents. There are also some advantages of EIA when compared with EMMA, among them the possibility to prevent cross contamination of sample and reagent since they are injected from opposite ends of the capillary. EIA has a lot
Fig. 6. Series of three experiments for the determination of Ti^{4+} with the aid of hydrogen peroxide and sulfuric acid.

of potential as far as micromachining is concerned, because to realize EIA on a microchip one need not have moving parts for sample injection, or even an injection cross that was used in the microchip variant of CE [10]. The simplest EIA could be realized on a microchip with just the help of one microgroove with a micro reservoir at each end.

Abstract

There has been a rapid growth in the development of field-portable analytical instrumentation capable of in-situ and real-time feedback of data from remote sites. Advances have been made in applications for many technologies aided by developments in electronics, computing and telecommunications systems. This report presents a brief review of these developments and particularly of portable flow-injection systems applied in both the liquid and gas phase modes of operation with potentiometric sensors and gas sensors of the tin-oxide semiconductor types.

Keywords: Air pollution; Portable flow-injection systems; Water pollution

1. Introduction

The aim of this paper is to present a range of applications of portable monitors for the analysis of various aqueous and gas samples. For the analysis of aqueous samples, a multi-cell consisting of potentiometric sensors has been investigated in the flow-injection mode. Multiple sensors have been employed in flowthrough cells in which the cells-in-series concept has been applied to measure various anions with improved sensitivity over conventional single-cell systems. A portable multi-sensor monitor has also been developed using tin-oxide semiconductor sensors to monitor various gases and vapours.

The emergence of monitoring portability is contingent on recent advances in the development of chemical sensors, biosensors, gas sensors and disposable test strip sensors. Combinations of sensors with electronic transducers allows conversion of molecular or ion recognition response into an electrical signal which is then used to determine the analyte concentration. Chemical sensors have the potential to form the basis of low-cost, long-term monitoring devices as shown in Table 1 which lists the types of sensor configurations re-

ported previously [1,2]. In addition, there are now available many options based on miniature versions of conventional laboratory instruments, such as gas chromatography [3].

The ideal type of monitor is one which has automated sample introduction and calibration, self-cleaning capabilities, in-built algorithms for sample analysis, and provides data storage, data plotting and telecommunications options. Table 1 indicates the various components used in sensor configurations to produce portable monitors. The possibilities for remote site monitoring depend on the weight and power requirements of the monitor, as listed in Table 2. Classifications may be arbitrarily assigned as being fixed-site, transportable, portable, submersible, or hand-held analysers. The monitor types developed particularly of portable operation and applications are summarised in Table 2. Power consumption is a most important parameter to be considered.

1.1. Transportables

Advances have occurred with regard to development of transportable instruments in many areas including mass spectrometry, gas chromatography, ion mobility spectrometry, infrared and UV spectroscopy, X-ray fluorescence and laser radar spectroscopy. A review has recently been published [3] on these techniques which remain highly costly. However, the relatively low

cost person-portable and hand-held types of monitors have undergone remarkable advances in the last 10 years due to the improvements in sensor design and miniaturised electronics and computing mentioned above. The main advances have been made in molecular and ion analysers, and gas and vapour analysers. These are applicable in many of the areas of technology mentioned below.

1.2. Chemical ion sensors

Relatively low cost portable monitoring techniques have been produced and are based on flow-injection analysis, electrochemistry, chemical sensors, gas sensors, biosensors, and filed test kits. Portable devices have been developed for a range of applications such as medical, automotive, industrial, food processing and production, domestic water production, mining, forensic and legislative, oceanographic and environmental areas, particularly for monitoring of water quality and air pollution. Reviews mentioned above on flow-injection techniques for water monitoring and air pollution monitoring have been published [1–3].

Many application areas are in environmental chemistry. User-friendly, field-portable instruments of low cost are now available so that on-the-spot testing can be performed at suspected sites of pollution and also for other quality assur-

Table 2
Classification of remote-site and portable monitors

Type	Weight	Applications
Fixed-site	> 100 kg	Bench top instruments in remote-site housing
Transportable	> 10 kg	Mobility in cars, boats, aircraft
Portable	< 10 kg	Man-portable in backpacks or shoulder packs
Hand-held	< 0.5 kg	Pocket-sized instruments
Submersible	Variable	Designed according to depth requirements

ance tests which may need to be carried out at sites remote from chemical laboratories [4]. The advent of portable notebook computers interfaced to appropriate electronic data acquisition systems has made this possible. Data loggers are alternatives to using notebook computers for long-term operation in remote sites. Communication systems have also decreased in price to such an extent that it has become feasible for field operation with direct transmission of data back to central laboratory computers by use of cellular telephones which can be operated at acceptable costs. The use of portable chemical monitors has therefore taken on a new dimension whereby many non-technical personnel can have access to such systems for monitoring and surveillance purposes. Table 3 shows the types of species detectable with low-cost ion sensors applicable in portable flow-injection analysis (FIA) monitors [5–7] and in ion chromatography [8] in place of the large conventional ion-selective electrodes.

The portability is based on low-cost miniature flowthrough cells containing potentiometric metallic electrode sensors which can be coated with polymer membranes for ion selectivity. The design of a single cell is shown in Fig. 2. The metallic copper electrode responded to various anionic and cationic species shown in Table 3.

1.3. Multi-sensor arrays in FIA

Combinations of these cells in a single FIA system have been used for improved sensitivity in

potentiometric detection of chloride and cyanide [10–12], and have been applied in portable FIA systems [13] with up to three ion sensors for potassium, sodium and nitrate [14]. A four-sensor cell has been reported [15] with ion-selective membrane electrodes for potassium, calcium, nitrate, and chloride, as well as screen printing technology for batch fabrication of integrated chemical sensor arrays [16] for potassium, ammonium, calcium and pH.

1.4. Test kits, disposable test strips and submersible probes

Portable field kits based on colorimetric analysers [17] are available for a wide range of pollutants and nutrients. These require reagent solutions specific for the analyte, and a field-portable photometer equipped with a data-logging facility. Metal cations, inorganic anions and some types of organic and bio-pollutants can be determined. Up to 120 preprogrammed calibrations are possible. Immunoassays and enzyme assays have also been reported based on colour-forming reagents. Pesticides and coliform testing are examples of applications.

Field-portable and submersible electrochemical probes and other electrochemical methods such as anodic stripping voltammetry for trace toxic metals have been described. Test kits are also available based on submersible electrochemical probes for dissolved oxygen, pH, chloride, conductivity, and temperature. Hand-held pH meters, conductivity, and oxidation–reduction potentials have become commonly used, and compact ion

meters based on planar membrane ion-selective electrodes are available for pH, nitrate, chloride, calcium, potassium and sodium. Portable digital voltammeters have been produced for anodic stripping determinations of trace metals.

Disposable test strip methods have also become available based on the early work on blood glucose sensors [18]. Reflectance spectroscopy has been used with test strips coated with immobilised reagents which react to produce a colour change [18]. Reflectance meters are available as small as pocket size for a wide range of analytes including glucose, ammonium ions, ascorbic acid, copper, iron, lead, phosphate, and sulfite. Amperometric methods and anodic stripping voltammetry have also been used as portable methods for test strip sensors. The amperometric blood glucose test strip analyser has been developed [19] in the shape and size of a ball-point pen, and has become highly successful. Hand-held anodic stripping voltammeters have been produced [20] based on disposable test strips containing the electrode sensors for copper and lead in water samples. These developments are proving of immense value in many fields of technology, allowing for rapid tests to be performed in the field.

1.5. Gas sensors

Gas sensors have been developed for many applications, and a number of types of sensor are available [21]. Portable and hand-held monitors are available for many toxic gases including carbon monoxide, sulfur dioxide, nitrogen oxides, hydrogen sulfide, and volatile organic compounds. The sensors are of numerous types including electrochemical, tin-oxide semiconductors, piezoelectric, surface acoustic wave, infrared, photoionization, and thermal conductivity devices [21].

In the present paper, we review developments of portable analysers and report on new flow-injection monitors for liquids which can also be operated in the gas phase mode. The portable liquid FIA systems developed are based on both single-cell and multi-cell potentiometric sensors applied for the detection of potassium, chloride, nitrate and cyanide. For gas analysis, methods for detection of various gases such as carbon monoxide and total hydrocarbons from car exhaust, and volatile alcohols such as ethanol in beverages, are also reported using tin-oxide semiconductor gas sensors in portable monitors. Diamond [22] has published a review on electrochemical sensor arrays for the analysis of aqueous samples based on

potentiometric, amperometric and voltammetric modes as well as recent advances of gas analysis based on the development of the electronic nose.

2. Experimental

2.1. Design of the portable liquid monitors

The data presented in this paper were recorded using portable FIA instrumentation previously developed [13,14]. Both the liquid and gas analysers were designed in a similar way, as shown in Fig. 1. The electronic circuit, pump and flowthrough sensor cells were constructed in a carry case. For liquid analysis, cells containing ion-selective electrodes (ISEs) were used with a two-channel peristaltic pump (Alitea, OEM-S2) to introduce liquid samples into the flow cell. Flow rates could be varied in the range of 1–8 ml min^{-1}. Manual injections were performed using a Rheodyne-type 5020 rotary injection valve with replaceable sample loops varying in volume from 20–200 μl.

Numerous types of flow cells have been designed and employed for the analysis of liquids. Two types of flowthrough cells were employed in this study. Firstly, a flowthrough perspex block using wire indicator electrodes (< 0.5 mm id) has

Fig. 3. Top and side views of a flow cell housing a planar design liquid-polymer-membrane-based potassium ISE.

been employed with our portable flow-injection monitor which has been described previously [9], and combinations of these cells have been made for studying multi-sensor response [14]. A six-cell system has also been constructed containing six-sensor electrodes and six-reference electrodes and has also been described previously [11] and is shown in Fig. 2. The total volume of the flowthrough cell was approximately 120 μl, the flow rates used were typically 1–2 ml min^{-1} and the carrier stream was seawater. The second flow cell design employed a commercial potassium planar-type ISE obtained from Horiba Ltd. (Japan) that was assembled in a flowthrough cell for flow-injection analysis, as shown in Fig. 3. The potassium planar ISE employed was a liquid-polymer-membrane-based electrode, and the cell volume was approximately 500 μl. Much higher flow rates of up to 6.8 ml min^{-1} were used with this cell due to the larger dead volume and the carrier stream employed was 10 mM lithium acetate.

2.2. Gas analyser design

The hand-held monitor was designed and constructed in-house and is the subject of a provi-

Fig. 2. Multi-sensor potentiometric cell for flow-injection analysis with up to six metallic sensor electrodes (S1...) and six Ag/AgCl reference electrodes (R1...), constructed of perspex, length 120 mm, width 50 mm, internal flow path 1.0 mm diameter.
Fig. 4. Peak height response observed for cyanide using six metallic copper electrodes: (A) 5 ppm; (B) 10 ppm; (C) 20 ppm; (D) 40 ppm; (E) 60 ppm; (F) 80 ppm; (G) 100 ppm cyanide in FIA mode.

sional patent [27]. The analyser was fitted with two Taguchi-type sensors (TGS812 and TGS824) obtained from Figaro Inc. (Osaka, Japan) and built into a flowthrough compartment. The gases were pumped through the compartment using a diaphragm pump at a flow rate of 1 l min^{-1}. The sensors and pump were controlled by an electrical

circuit described previously and operated with a rechargeable Ni–Cd battery pack of 7.2 V and 1.4 A h output.

The data from both the liquid and gas analysers were acquired using an eight-channel, 12-bit analog-to-digital converter (ADC) with a serial output at 9600 baud rate with RS-232C serial output to a notebook computer (Macintosh Powerbook 150). The ADC, the pump and the control circuit were powered with a 7.2 V rechargeable Ni–Cd battery pack. The total weight of the system was about 2 kg.

The acquired data from either the liquid or gas analyses were displayed in real time millivolt readings plotted as a function of time using a data acquisition program titled Satod$^\copyright$ (Ver. 1.37) and were saved as text files. The software package IGOR PRO (AD Instruments, Sydney, N.S.W.) was used for data analysis and graphical representation of the data.

3. Results and discussion

3.1. Results for the flow-injection potentiometric analysers

As an example, the portable system described in Section 2 has been successfully used for ISE analysis [13,14] with both conventional ISEs in flowthrough cells and with a three-sensor array of planar electrodes. The FIA output for a cyanide six-cell monitor with metallic copper sensor electrodes is shown in Fig. 4, illustrating the well-defined peaks obtained with a response slope of -370 mV decade^{-1} change in concentration.

Table 4
Single and multi-cell response characteristics for several anions and cations

Ion	Sensor	No. of cells	Slope (mV decade^{-1})	Det. limit (ppm)	Interferences
Cyanide	Copper	6	-370	0.04	S^{2-}, I^-SCN
Chloride	Ag/AgCl	6	-360	0.01	S^{2-}, I^-SCN^-, CN^-
Nitrate	Polypyrroledoped	3	-153	0.02	S^{2-}, ClO_4^-, $Cr_2O_7^{2-}$
Potassium	Valinomycin	1	51	0.02	Na^+, Ca^{2+}, Mg^{2+}
Fig. 5. FIA peaks for the planar-designed potassium ISE in the flow-injection mode. The carrier was 0.01 M lithium acetate, the flow rate was 6.8 ml min^{-1} and the injection volume was 100 μl.

The data show the very high peaks obtained by use of the cells-in-series approach with an array of sensor electrodes. Various other sensor arrays have been employed in FIA techniques as mentioned above. Batch injection analysis (BIA) has been introduced by Wang and Chen [23] and by Diamond et al. [24]. Wang et al. [25] have also developed a remote sensor electrode for potentiometric stripping analysis.

Similar results have been obtained with chloride and nitrate using six-cell and three-cell systems respectively, as reported recently [26]. Table 4 summarises the data obtained for these cells. Clearly, the electrode responses for cyanide, chloride and nitrate were enhanced in a multi-cell arrangement and improved sensitivity and detection limits were observed.

With a new approach, a planar electrode for potassium has been successfully employed for FIA. The data show excellent peak formation, as shown in Fig. 5, giving a response slope of 50.7 mV decade^{-1} using a 0.01 M lithium acetate background in FIA mode. In this case the injection volume was 100 μl. The observed slow return to baseline for the higher potassium ion concentration was the result of the dispersion of the injected sample zone, due to the relatively large surface area of the electrode used in this arrange-

ment. The calibration data are shown in Table 4. The possibility of using the planar design in a serial array of sensor electrodes has been recently reported [14]. Thus, many possible combinations of sensor electrodes should be possible with the portable monitoring system reported here.

3.2. Results for gas sensors

Tin-oxide semiconductor sensors are widely used in gas vapour monitors [21]. These devices are limited by lack of selectivity, sensitivity, and reproducibility. However, recent developments have led to much improved performance in hand-held monitors employing the Figaro-type gas sensors [27,28]. Fig. 6 shows some data for the response of hydrocarbons using a portable gas sensor device recently developed [27] with dual semiconductor sensors. The peak heights recorded in Fig. 6 are dependent on the concentration of total hydrocarbons in a sample, and vary linearly with the log concentration of hydrocarbons with only a limited working range.

3.3. Monitoring car exhaust emissions

Carbon monoxide (CO) and total hydrocarbons (THC) can be monitored using the dual tin-oxide
Fig. 6. Peaks recorded with the portable gas analyser for various concentrations of a C1–C6 hydrocarbon mixture. The sensors used were: sensor 1, TGS824; sensor 2, TGS812.
Fig. 7. The response of two types of Figaro gas sensor in the portable monitor observed for the following conditions: (a) peaks during the acceleration of the motor; (b) during idling of a 1983 Toyota Corolla.

semiconductor gas sensors [27], and clearly show that the Figaro-type sensors respond well to CO and hydrocarbons and could be used for continuous on-the-spot measurements for pollutants released in the atmosphere. These results show that the tin-oxide type of sensor is useful in a flowthrough configuration for monitoring air quality in situations where these gases occur due to pollution from automobile engines and other sources.

Continuous monitoring was also possible with the hand-held monitor using the dual tin-oxide semiconductor gas sensors. Fig. 7 shows the car exhaust profile of an 1983 Toyota Corolla. The initial peak response shows a burst of car exhaust expelled upon starting the motor, then decaying as it idles and the second and third peak responses were the result of acceleration. Turning the motor off resulted in a decrease in the response shown in Fig. 7 back to ambient readings.

A comparison between exhaust emissions from a 1987 Toyota Celica and a 1983 Toyota Corolla was performed with the same hand-held monitor described above. The car exhaust profiles for the

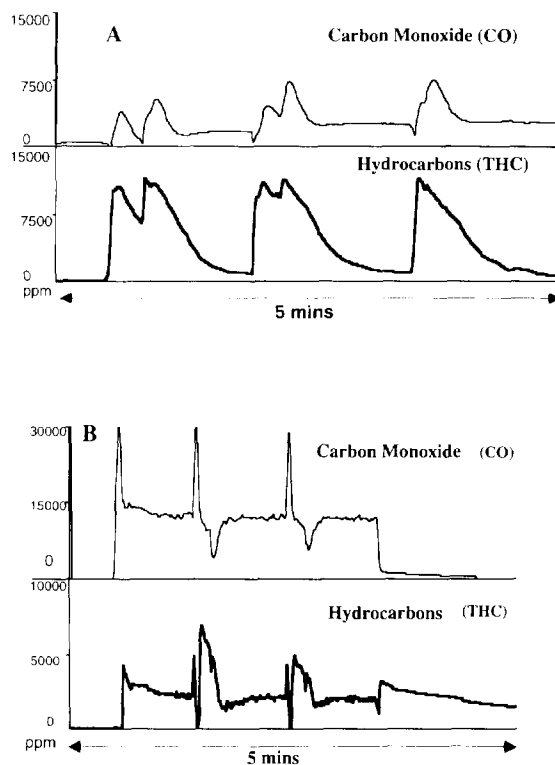
Celica and the Corolla are given in Fig. 8, the former being fitted with a catalytic converter to reduce emissions. These profiles show the calculated CO and THC concentrations expelled from these cars. Clearly Figs. 8A and 8B show that the CO and THC concentrations are the lowest when idling (plateau region), but acceleration caused a peak response for both cars. Fig. 8 shows that both the CO and THC levels are much higher for the Corolla than for the Celica when idling, but the THC levels are similar for both cars when accelerating. The performance of the hand-held monitor therefore offers a simple, low-cost method for real-time monitoring of car emissions by government authorities and hence a means to help reduce the pollution problem from vehicular exhausts.


Fig. 8. The car exhaust emissions calculated for carbon monoxide and total hydrocarbon observed for (A) 1987 Toyota Celica and (B) 1983 Toyota Corolla from the data recorded in Fig. 7.
Fig. 9. Monitoring of response of a single gas sensor (TGS812) to hydrocarbon emissions for vehicles travelling over a speed hump situated on a busy road close to an apartment building.

3.4. Air pollution in residential homes

The hand-held monitor was used for testing hydrocarbons from car exhausts in homes situated near traffic speed humps on a busy road. The data in Fig. 9 show the problem in a particular house, indicating consecutive measurements recorded over 10 min periods while traffic flowed across the speed hump on the road outside the house. A single sensor, the TGS812, sensitive to total hydrocarbon emissions, was used to detect pollution problems inside the house. The data shown in Fig. 9 were for a single sensor showing voltage readings using the TGS812 sensor in comparison with the baseline readings in the back lane.

The sensor was independently calibrated for total hydrocarbons and carbon monoxide, as described previously [27]. The calibration plot for

this sensor towards total hydrocarbons is shown in Fig. 6. The single sensor used here is most sensitive to hydrocarbons and much less sensitive to carbon monoxide [27]. The traffic speed hump was situated on the road about 30 m from the front of the house. Measurements were made in the street next to the hump, in the house with the front windows open, and in the back lane which was about 130 m from the road and protected by trees and plants from the traffic emissions. The readings in each location were taken consecutively, since only one monitor was available. The data show a flat baseline reading for the back lane. In the street, peaks were observed each time a vehicle slowed down and then accelerated over the hump. The readings inside the house were higher than in the street and indicate peaks as vehicles passed over the traffic hump outside. The evidence is clear that the vehicular emission gases
Fig. 10. Peaks for ethanol standards and various diluted alcoholic beverages recorded using two different Figaro-type gas sensors in the portable monitor.

are being trapped inside the house, and showed increases due to the traffic hump. This type of measurement is therefore valuable for rapid testing of pollution problems in urban areas.

3.5. Determination of ethanol in alcoholic beverages

The response characteristics of the dual-sensor monitor have also been used to evaluate alcohol levels in beverages. The detection method was based on the head space analysis of vapour above aqueous samples containing ethanol reported previously [29]. Relative standard deviations of better than 5% were obtained with the Figaro-type sensors, depending on the ethanol concentration, as shown in Fig. 10. The port and Drambuie samples were analysed after a 10-fold dilution and these samples were bracketed by the ethanol standard solutions as shown in Fig. 10. The accuracy of this method gave a correlation coefficient of 0.9999 in comparison with gas chromatographic analysis [29].

4. Conclusions

The use of these mobile sensor devices is a radical departure from traditional methods of chemical analysis involving sampling and transport of the samples back to laboratories for chemical and biochemical testing. Examples of tests for safety and quality control in food technology, mining, chemical industries, environmental, and medical areas are numerous, and further rapid development of portable sensing technology can be expected.

Potentiometric and voltammetric detection using a two-channel fountain cell[1]

M. Wasberg*, K. Stenlund, A. Ivaska

Åbo Akademi, Laboratory of Analytical Chemistry, Biskopsgatan 8, FIN-20500 Åbo, Finland

Abstract

The design and use of a two-channel fountain cell in potentiometric and voltammetric detection is described. The two flows produced two distinct sectors inside the thin layer region and one of the sectors was used as the internal electrolyte of a reference electrode built into the cell body and the other as the indicator/counter electrode section. The behavior of the flowthrough $Ag/AgCl$ reference electrode was first investigated and found satisfactory and it was then employed as the reference electrode in the subsequent experiments. Continuous and flow-injection measurements were made using the Fe^{III}/Fe^{II} redox couple in potentiometry and the reduction of Fe^{III} in voltammetry.

Keywords: Iron; Potentiometric detection; Two-channel fountain cell; Voltammetric detection

1. Introduction

Electrochemical detection in flowing systems has been done using flow cells of various designs and two very widely used types are *wall-jet* and *thin layer* cells [1–4]. In the former the incoming electrolyte is directed perpendicularly towards the working electrode and in the latter the electrolyte is passed through a thin layer created using a spacer in which the working electrode is placed. The so-called fountain cell was developed for use in optical measurements [5] and is basically a combination of the wall-jet and the thin layer electrode. In the fountain cell the incoming electrolyte is directed perpendicularly towards one of the walls which confines a circular thin layer region so as to create a radial flow from the entrance orifice towards a circular "well" of larger volume at the perimeter of the thin layer. The geometry and properties of the fountain cell are such that the incoming flow spreads out equally in all directions from the center, and if the cell is equipped with two or three entrance orifices close to the center of the thin layer, the flows will establish themselves in very well-defined parts of this region. Depending on the ratio of the flow rates in a two-channel flow cell the sectors occupied by the two flows will vary, so that the flow with higher flow rate will occupy a larger sector of

[1] Presented at the Seventh International Conference on Flow Injection Analysis (ICFIA '95), held in Seattle, WA, USA, August 13–17. 1995.

the circular thin layer area than the flow with the lower flow rate. There is also a thin layer cell commercially available with radial flow pattern which is intended for chromatographic detection [6]. This cell, which is made for amperometric measurements, is only a single-channel two-electrode cell for small currents and is thus not intended for general use. It is, however, of the fountain cell type and needs to be mentioned here.

The fountain cell has been evaluated in a perfusion study of living cells in which it was connected to a flow-injection system and a fluorescence microscope was used as detector [7]. It is the aim of this work to investigate the possibilities of the fountain cell as an electrochemical detector using voltammetric and potentiometric methods of detection. The special properties of this detector, which include the possiblility of using multiple flows as well as the radial flow pattern [7] in the thin layer region, make it attractive for this purpose. Its ability to let two or more independent flows meet in the detector region [8] should allow differential measurements to be made in a novel way and the circular symmetry of the thin layer region allows convenient placement of working/indicator, counter and reference electrodes. The use of two flows was examined in this work. One of the flows contained a reference electrolyte solution which together with the built-in Ag/AgCl electrode comprised a reference electrode in one half of the thin layer region. This part of the cell is referred to as the "in-cell" reference electrode. The other flow contained the components to be detected and passed by a working/indicator electrode and a counter electrode. This section of the cell is referred to as the "detection side".

2. Experimental

All chemicals used were of analytical grade and the solutions were prepared by using distilled, deionized water (MilliQ). Teflon tubing was used to transport electrolytes and PVC tubing was used in the peristaltic pump. Before use the block containing the electrodes was ground by hand with emery papers of successively finer grit ending

with size 1000 after which it was polished first with coarse and later with fine alumina powder. The electrodes were polished with alumina before each deposition of Ag/AgCl. The in-cell reference electrode was prepared by oxidizing the silver disk electrode (3 mm diameter) galvanostatically in a solution containing 1 mol dm^{-3} KCl for 12 min at a current of 100 μA to produce a very smooth layer of AgCl. The counter electrode for AgCl deposition was of circular shape and made of 0.5 mm diameter platinum wire. After deposition of AgCl and before assembling the cell the electrode was stored in the same solution at open circuit. When not in use the cell was filled with 1 mol dm^{-3} KCl, by pumping this solution through both channels, or opened and the electrode block placed in the same solution. All KCl solutions used were saturated with AgCl. The potentiometric measurements were made with a pH meter (Metrohm 691) equipped with an analog recorder output. The resolution of this output was 1 mV and the signal was recorded using a 12 bit A/D converter (ADC1000, Pico Instruments) connected to the parallel port of an IBM AT-compatible computer. Voltammetric and amperometric measurements were made using computer-interfaced laboratory-built instrumentation. Solution flow through the cell was achieved by a peristaltic pump or by means of hydrostatic pressure. The peristaltic pump (Desaga STA) enabled the use of variable pumping speeds and by using 0.8 mm i.d. PVC tubing in the pump flow rates from 0.004 to 0.04 ml s^{-1} were obtained. In some measurements hydrostatic pressure from a height of 30–40 cm was used. Selection of different flows and flow injection was made using a computer-controlled eight-channel valve (Pharmacia MV8), the use of which has been described earlier [9].

3. Results and discussion

3.1. Flow cell details and investigation of flow pattern

The cell which is sketched in Fig. 1 was made of Plexiglass and consisted of three parts: a cell top

B, center "flow introduction block" A and an electrode block E at the bottom. The blocks were held together by four corner-positioned 6 mm diameter screws fitting into threads in the electrode block. The cell top and the flow introduction block were sealed by a gasket D when the cell was in use and with a similar 0.25 mm thick gasket/spacer the center block and electrode block were sealed and separated so as to create a thin layer region of spacer thickness between the blocks. This thin layer region was circular in shape (diameter 20 mm) and extended from the center of the cell where the inlet orifices were positioned out to the inner perimeter of the well indicated in A. The position of the thin layer region is also indicated by a dashed circle on the electrode block marked E in Fig. 1. The volume of the thin layer region was thus $\approx 80\ \mu l$ using the 0.25 mm thick spacer. In detail the cell thus consisted of the followng parts:
Fig. 1. Sketch of the fountain cell in assembled form from the side (C) and separated into parts: (A), inlet block; (B), cell top; (D), gasket/spacer; (E), electrode block.

- an electrode block at the bottom (E in Fig. 1) into which the electrodes were molded using a polyester resin. The electrodes were placed in holes drilled in the proper positions all the way through the bottom of a cylindrical molding cavity machined in the center of the electrode block. The width of the cavity was somewhat larger than the diameter of the circular well (see part A in Fig. 1). The reference electrode consisted of a silver cylinder (99.98% purity), 3 mm diameter and 5 mm in length, and the working/ indicator electrode consisted of a gold cylinder (99.98% purity) of the same size. Both these electrodes were soldered to brass holders which protruded through the positioning holes. The counter electrode was made of glassy carbon and had the same shape and size as the other electrodes. This electrode was fixed to the brass holder by pressing it by force into an oval hole at the top of the brass holder. The brass gave way to accept the electrode and no electrical contact problems were encountered when using the counter electrode.

- a central flow introduction block (A in Fig. 1) where the two electrolyte flows entered the cell. The flows first passed through 1 mm diameter channels which narrowed to 0.5 mm at a 90° turning point. A circular "well" with a width of 3 mm and a depth of 4 mm was milled in the block (see Fig. 1) to disrupt the thin layer region and to reduce flow velocity. A similar, somewhat deeper well, was milled from the opposite side of the block and the two wells were connected by eight 1.6 mm diameter holes. The Teflon tubing for electrolyte flow (0.5 mm i.d.) was widended at the contact point with the flow introduction block to produce a flange which was pressed to the cell body by means of hollow nuts made of plastic.

- the cell top (B in Fig. 1) which is used to collect the electrolyte from the well has a collection chamber shaped like a cone which narrows at the upper end and connects to a fitting for the outlet tube.

A series of experiments were made in order to make sure that the two incoming flows really
Fig. 2. Effect of flow rate ratio on flow profiles in the fountain cell. Two dyed solutions were used and at equal rates the flows each occupied half of the cell (A). Photographs B-D show the results of using various unequal flow rates.

behaved as expected, i.e. that they occupied two well-defined sectors of the circular thin layer region. Especially, it was of importance that the thin layer region was divided into two equal parts at equal flow rates, so that the electrodes were exposed correctly to the incoming flows. Photographs showing the thin layer region occupied by two differently-dyed solution flows at four different flow rate ratios are displayed in Fig. 2.

To design and construct a two-channel fountain cell was somewhat more demanding than to make a thin layer or wall-jet cell. However, once the acrylic parts were machined and the electrodes molded in place and polished a remarkable well behaved cell was obtained. The two flows, i.e. the in-cell reference electrode electrolyte flow and the analyte flow, stayed well separated and even when the reference electrode side was contaminated by mistake e.g. by a ferric/ferrous solution, it recovered quite rapidly. The fast recovery may have been due to the very smooth finish of the AgCl layer obtained in the electrolytic deposition. The pores of the AgCl layer could not therefore have been very deep and the contaminants were washed rapidly away. The reproducibility and stability of the flow patterns in Fig. 2 are also remarkable,

even when the flows were propelled by peristaltic pump. Especially, the border region displayed a sharp change between the solutions indicating little or no mixing of the flows. This fact is a prerequisite for a multiple channel fountain cell and one of the reasons why it works in electrochemical measurements. All potentiometric measurements are inherently differential measurements, involving measurement of the difference of potentials of two half cells which are in contact through a liquid junction. In a two-channel fountain cell this liquid junction consists of the sharp dividing line(s) between the two flows, but here no glass frits or asbestos fibres are needed to separate the electrodes.

The effective dead volume of the cell used was also small. Using a 0.25 mm spacer the dead volume was only ≈ 80 μl, not counting the in-cell reference electrode side. By decreasing the spacer thickness it should be possible to decrease the volume further. Being a thin layer cell the thin layer area is quite large and can accommodate a number of electrodes, a fact which could be useful for detectors equipped with multiple sensors.

In the initial experiments with the cell, silicon tubing was used in the peristaltic pump and this introduced problems in the form of gas bubbles appearing in this section. Once created these bubbles were transported into the cell and often clung to the walls of the cell in the thin-layer region. The tendency of the bubbles to do this might have been due to the properties of the polyester polymer which was used to mold the electrode in place. After changing to PVC tubing the problems with the bubbles were essentially eliminated. It is also likely that an improvement in the sensitivity to bubble retainment could be achieved by designing the input channels so that the flow is upwards, and it is our aim to do this in the next generation of fountain cells.

3.2. Stability of in-cell reference electrode and potentiometric measurements with the Fe^{III}/Fe^{II} couple

One of the basic ideas of this investigation was to use one half of the thin layer region of the fountain cell as a reference electrode. Thus, all

potentials measured would be made with reference to this in-cell reference electrode and the quality of all potential measurements would rely on the stability and reproducibility of its potential. The reference electrode part of the cell was comprised of the left-hand side of the thin layer region indicated by a dashed circle on part E of Fig. 1. In order to determine the potential behaviour of this in-cell reference electrode an SCE (saturated calomel electrode) was placed in a beaker (containing electrolyte up to a level of ≈ 2 cm) into which the cell outlet tube was also placed, and the potential difference between these two electrodes was recorded under different conditions. The solution level in the beaker was kept constant by pumping out excess electrolyte by means of and aspiration pump. During these measurements both channels of the fountain cell were fed with the reference electrode solution, i.e. 1 mol dm^{-3} KCl.

In Fig. 3 potential data are shown for a long time stability experiment extending over 4 days. The potential of the in-cell Ag/AgCl reference electrode vs. the SCE was recorded for a flow of a 1 mol dm^{-3} KCl solution (saturated with AgCl). The flow rate was 0.02 ml s^{-1} and a freshly prepared Ag/AgCl electrode was used. In the beginning there is a rather sharp 4 mV increase in the potential difference which takes place during
Fig. 3. Data from potential stability experiment for an in-cell Ag/AgCl reference electrode in which the potential was measured against an SCE placed in the outlet stream. The measurement started with a freshly made Ag/AgCl surface.
Fig. 4. Potential of in-cell Ag/AgCl electrode measured against an SCE for KCl solutions of different concentrations and different flow rates. The flow rate was initially 0.004 ml s^{-1} and finally 0.04 ml s^{-1}. The flow rate was increased in ten steps every 5 min and the pump was stopped at $t = 50$ min.

the first 6 h and after this the variation is of the order of ± 1 mV. During the last 1.5 days the potential difference is stable at 9 mV. The spikes seen in the curve occurred while filling up the KCl container, during which the pump was also stopped. The broken line at 8.7 mV indicates the potential value obtained from theory and the tabulated chloride ion activity coefficient [10] for the concentration used.

Another shorter stability test was made using different pumping speeds and different KCl concentrations and the results are summarized in Fig. 4. During the measurements the pumping speed was increased in ten steps from 0.004 to 0.04 ml s^{-1} and the pump was stopped at $t = 50$ min. For the 1 mol dm^{-3} KCl solution stable potential readings were obtained ≈ 1 mV below the calculated value. No effect of flow rate could be detected and the signal was fairly free of noise. This is also the case for the flow of 0.1 mol dm^{-3} KCl, except that the noise level has increased somewhat. For the 0.01 and 0.001 mol dm^{-3} solutions the noise level increased further and a flow rate dependence could also be seen. For the 0.01 mol dm^{-3} solution a difference of ≈ 10 mV is obtained between slow flow rate and flow at full pumping speed.

In order to investigate the behavior of the fountain cell in potentiometric detection, using

the in-cell reference electrode, the potential of the Au indicator electrode was measured in solutions containing Fe^{II} and Fe^{III} in different concentration ratios. Two solutions flows were thus used: one of 1 mol dm^{-3} KCl (saturated with AgCl) for the reference electrode and the other one containing the iron species. The flows were produced by the peristaltic pump and in this case the solution flow was changed manually after stopping the pump. In the measurement solution flow the concentration of Fe^{III} was kept constant at 0.2 mol dm^{-3} and the concentration of Fe^{II} was varied: 0.2, 0.02, 0.002, 2×10^{-4} and 2×10^{-5} mol dm^{-3}. The measurement solutions were passed through the cell in succession in two duplicate measurements starting with the 0.2 mol dm^{-3} Fe^{II} solution. Data from this experiment are shown in Fig. 5.

A series of potentiometric flow-injection experiments were also done. The carrier used was a solution of 0.1 mol dm^{-3} NaOH containing 0.2 mol dm^{-3} $Fe(CN)_6^{3-}$ and 2×10^{-5} mol dm^{-3} $Fe(CN)_6^{4-}$. The solutions injected were of the same salts with $c_{Fe(III)} = 0.2$ mol dm^{-3}, $c_{Fe(II)} = 2 \times 10^{-3}$ mol dm^{-3} Fe^{II} and $c_{Fe(III)} = 0.2$ mol dm^{-3}, $c_{Fe(II)} = 0.2$ mol dm^{-3} Fe^{II}. The two solutions were injected using the peristaltic pump at a flow rate of 0.02 ml s^{-1} and the eight-channel computer-controlled valve. The valve and flows were
Fig. 5. Potential of Au electrode measured against in-cell Ag/AgCl reference electrode (1 mol dm^{-1} KCl, sat. AgCl) for 0.1 mol dm^{-1} NaOH solutions having different concentration ratios of $K_4Fe^{II}(CN)_6$ and $K_3Fe^{III}(CN)_6$.
Fig. 6. Data from potentiometric flow-injection experiment with varying injection times using an in-cell reference electrode and two different Fe^{III}/Fe^{II} solutions. Carrier solution: 0.1 mol dm^{-3} NaOH with $c_{Fe(III)} = 0.2$ mol dm^{-3} and $c_{FF(II)} = 0.0002$ mol dm^{-3}. The solutions injected were also prepared in a base electrolyte of 0.1 mol dm^{-3} NaOH and are described in the Fig.

set up so that the carrier occupied one of the channels and the solutions to be injected the adjacent channels. The injection time was then the time for which the valve was kept in the position at the adjacent channels. The injection volume was thus varied by varying the time of injection. Results obtained with injection times from 1 to 20 s are shown in Fig. 6. In order to investigate the reproducibility of the FIA (flow-injection analysis) 20 peaks were recorded and the trace is shown in Fig. 7. The r.s.d. was 0.7%.

The in-cell reference electrode shows a stability which is adequate for FIA, i.e. after the initial 5–6 mV change the potential was stable. The pH meter used had a recorder output with a resolution of 1 mV, which made the measurement of smaller changes in potential by computer impossible. However, it can be concluded from the data in Fig. 3 that once the potential has stabilized the long-term change in potential is at the most 1 mV, and this is certainly adequate for most analytical measurements, especially those involving FIA in which the background signal is recorded immediately before injection.

The flow rate of the reference electrode solution had little effect on the potential as long as c_{KCl}

was 10 mmol dm^{-3} or higher. For this concentration there is a difference in potential of only about 2 mV between stationary solution and flowing solution at maximum pump speed (0.04 ml s^{-1}). For the 1 mmol dm^{-3} KCl solution the same difference is 9 mV. The reason for the change in measured cell potential as the flow rate and ion strength are varied is the streaming potential, the value of which is also higher the more dilute the electrolyte is and the higher the flow rate is. There was also a noticeable increase in the noise level at lower concentrations and the data in Fig. 4 clearly show that the noise successively increases as the concentration decreases. One reason for the noise increase is the streaming potential itself which fluctuates as the flow pulsates with the frequency of the pump rollers. Potential data were acquired once a second and this rate was too low compared to the roller frequency to enable us to distinguish any signals due to flow pulsation. This was checked by Fourier analysis of the signals at different pumping speeds. The potential signal could thus have been sampled at any point on the pump pulsation cycle, which also varied during the experiment. The electrical properties of the KCl electrolyte change with dilution and the decreased conductivity (higher impedance) in the medium between the two electrodes used makes the measurement more susceptible to noise pickup
Fig. 7. Measurement of peak height repeatability in potentiometric flow-injection experiment. An r.s.d. of 0.7% was obtained for 20 injections of 40 μl.

from the surroundings. Although most of the noise at $c_{KCl} = 1$ mmol dm^{-3} is due to pumping a clearly increased noise level was observed for the static electrolyte too.

The ferric/ferrous redox system was chosen for the potentiometric evaluation because of the simplicity of the indicator electrode arrangement and because it is widely used as a test system. However, there were some drawbacks to this choice, e.g. no data on the activity coefficients for ferric and ferrous hexacyanides were found for the electrolyte used and this in turn made the calcuation of the potential responses inexact. Also, the electrode potential response to changes in solution redox potential could sometimes be slow, especially if one of the redox components were present in low concentration. However, reproducible peaks were obtained for the solutions used in FIA. It must be kept in mind that variations in injection volume in this case depend on the precision with which the multichannel valve is manipulated. For shorter injection times a larger relative variation is obtained. A special source of variation is the peristaltic flow pulsation which also has a larger influence for shorter injection times. The r.s.d. of 0.7% obtained for an injection time of 2 s must be considered satisfactory considering the simplicity of the injection system used.

3.3. Voltammetric detection of Fe^{III} on gold electrode

The fountain cell was equipped with two electrodes (gold and glassy carbon) on the detection side and these, together with the in-cell reference electrode, comprise a three-electrode electrochemical cell suitable for voltammetric and amperometric measurements. The glassy carbon electrode was placed downstream with respect to the gold electrode and for this reason the gold electrode was chosen as working electrode and the glassy carbon as counter electrode. In this configuration the reaction products produced at the counter electrode could not end up on the working electrode.

The behavior of the cell in the reduction of Fe^{III} in 0.1 mol dm^{-3} NaOH was studied in a cyclic voltammetric experiment. The cyclic voltam-
Fig. 8. Cyclic voltammetric curves at a scan rate of 50 mV s^{-1} obtained using the fountain cell equipped with a gold working electrode. The solid line is for the supporting electrolyte (0.1 mol dm^{-3} NaOH) showing surface oxidation and reduction peaks typical for gold. The broken line is for a solution of 1 mmol dm^{-3} K$_3$Fe(CN)$_6$ in supporting electrolyte.

mograms recorded in the fountain cell, both for the supporting electrolyte (solid line) and for 1 mmol dm^{-3} K$_3$Fe(CN)$_6$ (broken line), are shown in Fig. 8. The scan rate was 50 mV s^{-1} and the solution flow of 0.02 ml s^{-1} was hydrostatically produced in order to avoid limiting current oscillations due to the pulsating flow caused by the peristaltic pump. Oxidation of the gold surface in pure electrolyte gives rise to a peak at 0.32 V and the reduction of the layer produced gives a corresponding reduction peak at 0.09 V. Below a potential of about −1.25 V reduction of the electrolyte starts to take place to a significant degree. When the 1 mmol dm^{-3} ferric solution was introduced a reduction current was obtained in the cyclic voltammetric scan (broken line) at potentials on the negative side of the oxide reduction peak.

FIA with amperometric detection was investigated by selecting a potential of −0.75 V and injecting ferric solutions of different concentrations into a carrier consisting of 0.1 mol dm^{-3} NaOH supporting electrolyte. Data for five different concentrations are shown in Fig. 9. The flow rate was 0.02 ml s^{-1}. With the intention of determining the repeatability of the amperometric FIA 18 injections of 40 μl of 2 mmol dm^{-3} fe^{III} were recorded and the results are shown in Fig. 10. An r.s.d. of 1.3% was obtained.
Fig. 9. FIA peaks obtained for the amperometric reduction of different concentrations of Fe(CN)$_6^{3-}$ in 0.1 mol dm^{-3} NaOH. The flow rate was 0.02 ml s^{-1} and the flow was produced by hydrostatic pressure. Potential: −0.5 V.

Reduction of Fe(CN)$_6^{3-}$ was chosen for the experiments on voltammetric detection because of its well-known character and because the reaction product (Fe^{II}) is soluble in the electrolyte phase, an aspect which is of importance in avoiding surface fouling and changes on solid electrodes. In Fig. 8 the typical surface processes of a gold electrode are shown with clear, sharp oxidation and reduction peaks. The steep changes in current for these peaks are an indication of negligible iR drop in the cell, a result which indicates good
Fig. 10. Amperometric FIA repeatability measurement. An r.s.d. of 1.3% was obtained for a ferric ion concentration of 2 mmol dm^{-3} and an injection volume of 40 μl.

potential control despite the thin layer configuration. The contact area between the reference electrode "internal" electrolyte and the cell supporting electrolyte is large in the fountain cell and extends over the whole width of the thin layer section. This is in contrast to conventional cells in which the potential of the electrolyte is measured at only one point, at the tip of the reference electrode. In some flow detectors this point may even be outside the cell. The good potential control apparent here may be due to the special design of this cell with its in-cell reference electrode, but conclusive evidence will be pursued in a separate study. As 1 mmol dm^{-3} Fe(CN)$_6^{3-}$ is introduced on the detection side (Fig. 8, broken line) a reduction current appears due to reduction of this ion. This process starts immediately the oxide layer is removed, even when it is only partially removed. This is analogous to the case with oxidation of Fe^{III} on the same electrode in which the oxide film also inhibits the bulk process [11].

The injection of different concentrations of Fe(CN)$_6^{3-}$ produced the peaks shown in Fig. 9, and in this case the lower concentrations produced more reproducible peaks. Especially at the highest concentration of 10 mmol dm^{-3} Fe^{III} a continuous decrease in peak height is observed as the injections are repeated. It is not clear what the reason for this behavior is. However, a concentration of 10 mmol dm^{-3} is rather high and at this level the concentration of electroactive contaminants present in the reagents may be high enough

to produce surface compounds affecting the state and properties of the solid working electrode. The r.s.d. for amperometric detection of 2 mmol dm^{-3} Fe^{III} was higher than for the potentiometric detection (1.3% compared to 0.7%). This must in part be due to the linear concentration dependence of the amperometric signal compared with the logarithmic dependence for the potentiometric signal. Mass transport phenomena are also more important in amperometry than in potentiometry, which in turn makes the stability of the signal from the former more dependent on flow variations.

Flow-injection analysis systems with immobilized enzymes. Improvement of applicability by integration of coupled reactions, separation steps and background correction[1]

Abstract

The specificity of enzymes is often not sufficient to simultaneously determine two parent substrates in a given matrix. Approaches to enhance the selectivity by applying the principle of an array arrangement to flow-injection analysis (FIA) systems based on several immobilized isoenzymes are successful. Immobilized enzymes and detectors in FIA systems often suffer from interferences from impurities of the matrix. Examples are given which prove that this problem can be overcome by an integrated preseparation of the analyte (pervaporation, electrodialysis) or by correction of the matrix signal based on background subtraction using computerized data accumulation and processing.

Keywords: Flow-injection analysis; Bioprocess control; Fuzzy logic; Sample pretreatment; Enzyme selectivity

1. Introduction

Routine food quality analysis and on-line fermentation control demand specific, fast and reliable substrate determination. In this context the simultaneous determination of two or more substances is often needed. In principle this can either be performed by enzymatic analysis or by means of an efficient separation method (GC or HPLC). However, in the case of very similar substrates the specificity of available enzymes may not be sufficient, or the separation system needed must be very sophisticated. Both alternatives may be laborious and time-consuming, and hence slow and not suitable for on-line application. Flow-injection analysis (FIA) with integrated immobilized enzymes, supplemented by fast and continuous modules for clean-up and preseparation of analytes, or with integrated background correction, may combine the advantages of enzymatic analysis and efficient separation. In addition, for the

---

determination of very similar substrates with non-specific enzymes it should be possible to combine the response of different FIA lines in the manner of an array for the enhancement of specificity. The present contribution will demonstrate the advantages and limits of this principle using various examples, most of which are based on commercially available enzymes.

2. Results and discussion

2.1. FIA systems with integrated clean-up or separation modules

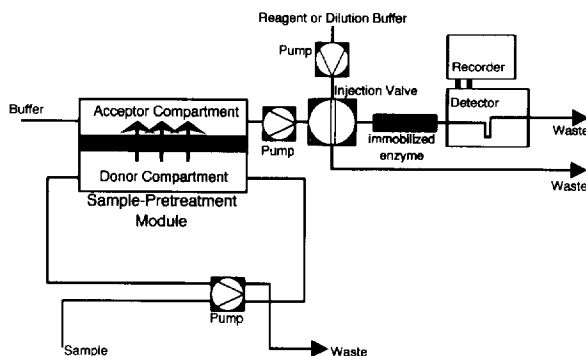
The continuous monitoring of a given amino acid out of a mixture in a FIA system with an oxidase or dehydrogenase can easily be performed, providing a specific enzyme is available. Sometimes the problem is restricted to the task of determining a given amino acid in the presence of a limited amount of a few others. The corresponding analysis system should also imply a certain versatility in that it could be used for the determination of different amino acids. In this respect, we have connected a continuously working electrodialysis module to a FIA system [1], schematically shown in Fig. 1, in which amino acids are determined by the unspecific amino acid oxidase reaction and the monitoring of the enzymatically formed H_2O_2 is by means of an amperometric electrode. The buffer in the central chamber of the electrodialysis unit was adjusted to the pH value


Fig. 1. FIA system with integrated sample-pretreatment module.

of the isoelectric point of the amino acid to be monitored, with the expectation that this one would pass the chamber, while other amino acids were eliminated by migration in the electric field. In practice, with complex mixtures of amino acids, it turned out that this separation procedure was not sufficient to quantitatively remove interfering amino acids. The analytical error was dependent on the type and concentration of the foreign amino acids. However, as proved for the analysis of arginine in the millimolar-range, satisfactory results were obtained when not more than three foreign amino acids were present and their total concentration did not exceed that of the analyte in question by a factor of four. Therefore, the device will be of advantage for the continous monitoring of a given amino acid in the presence of impurities of others. Its selectivity may be changed by shifting the pH value of the carrier buffer in the central chamber of the electrodialysis unit to that of the isoelectric point of the amino acid in question.

In the case of monitoring volatile analytes we proved that it would be advantageous to separate the analyte from the sample liquid through a pervaporation module [2], and use the secondary circuit of this device as the input to the enzyme-based FIA system, generally with an integrated dehydrogenase and NADH monitoring system [3] (for principal FIA set-up see Fig. 1). With this arrangement enzyme and detector are protected from interfering impurities, and hence show prolonged lifetime and reduced noise respectively. In addition, the substrate concentration in the secondary circuit can be adjusted to the linear detection range of the biosensor either by varying the relative flows of the primary and secondary liquid streams or the temperature of the donor chamber in the pervaporation module. This principle worked very well in the case of routine assay of ethanol in beer or with the monitoring of acetic acid in a fermentation broth [4]. The related reaction pathways are shown in Scheme 1.

It is useful to vary the relative concentrations of mixtures of homologue substrates and hence to support the selectivity of the enzymes. An extraordinary challenge for the application of the pervaporation principle was the analysis of diacetyl

Ethanol + NAD$^+$	Alcohol dehydrogenase $\underset{\longleftarrow}{\longrightarrow}$	Acetaldehyde + NADH + H$^+$
Acetate + ATP	Acetate kinase $\underset{\longleftarrow}{\longrightarrow}$	Acetylphosphate + ADP
Phosphoenolpyruvate + ADP	Pyruvate kinase $\underset{\longleftarrow}{\longrightarrow}$	Pyruvate + ATP
Pyruvate + NADH + H$^+$	Lactate dehydrogenase $\underset{\longleftarrow}{\longrightarrow}$	Lactate + NAD$^+$
Diacetyl + 2 NADH + 2 H$^+$	Diacetylreductase $\underset{\longleftarrow}{\longrightarrow}$	Butanediol + 2 NAD$^+$
Pentanedione + 2 NADH + 2 H$^+$	Diacetylreductase $\underset{\longleftarrow}{\longrightarrow}$	Pentanediol + 2 NAD$^+$
Acetoin + NADH + H$^+$	Diacetylreductase $\underset{\longleftarrow}{\longrightarrow}$	Butanediol + NAD$^+$

Scheme 1.

(butane-2,3-dion) in beer [5] (see Scheme 1). This compound seriously impairs the flavour of beer, and the control of its reduction to acetoin and butanediol in the course of the maturation process of beer is of great importance. At the beginning of the process beer contains approximately 0.01 ppm of this compound, and in addition about the same concentration of pentanedione-1,2 and 20 times more acetoin (butane-2-ol-3-on). There is no enzyme available which is specific for diacetyl, all dehydrogenases in question having similar affinities to pentanedione-1,2 and acetoin. We could, by pervaporation, attain a shift of the relative concentrations of the three substrates, in that the excess of acetoin was drastically reduced. However, we have still obtained an integral response which could only be corrected using acetoin concentrations independently determined by GC. Hence, in this case, because of the extreme ratio of the competing substrates, the integrated pervaporation could not completely compensate for inadequate specificity of the enzyme.

2.2. FIA systems with coupled enzyme reactions

A mixture of similar substrates is often analyzed in an enzyme-based FIA system by a common indicator enzyme reaction supported by a suitable auxiliary reaction. For example, the determination of maltose or sucrose and glucose is possible by means of the glucose oxidase reaction before and after hydrolysis of the disaccharides

with a glucosidase (integral measurement). Xylose can be measured with the unspecific glucose dehydrogenase reaction using NAD$^+$ as oxidant; however, in the presence of glucose this substrate has to be eliminated by means of the (specific) glucokinase reaction (differential measurement). The reaction sequence is shown in Scheme 2.

The differential principle has been used as a reference method in a study of the applicability of two unspecific enzymes (glucose oxidase, glucose dehydrogenase) for the parallel determination of xylose and glucose in mixtures [6]. In a FIA system (Fig. 2) the two substrates either passed only the dehydrogenase "channel" (immobilized enzyme) or a subsequent oxidase and dehydrogenase "channel". The activity of the immobilized oxidase was chosen such that the substrates were only partially converted. The two fluorimetrically obtained NADH signals for the mixture in the two "channels" allowed calculation of the individual concentrations of the two compounds using a partial least-squares algorithm. Encouraging results were obtained providing the enzymes had slightly different affinities for the substrates and the ratio of xylose/glucose was not below the value of 25. The same principle, although with the use of four "channels", namely two with individual dehydrogenases and two with subsequent oxidases/dehydrogenases, was used for the monitoring of mixtures of the three lipophilic amino acids valine, leucine and isoleucine. Only slight affinity differences existed for these sub-

Scheme 2.

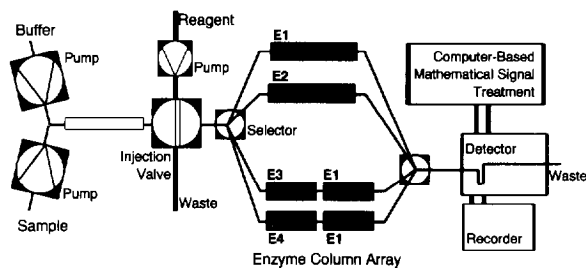
strates with the oxidases or dehydrogenases available. It turned out, that by a mathematical treatment of the NADH signals in the different FIA lines ("channels") not only one individual amino acid out of the three could be identified, but also a quantitative analysis of all of them was possible, when they occurred in the millimolar-range in comparable concentrations [6]. In any of the following systems the so-called "nested-loop" injection of the sample into a plug of NAD$^+$ carrier was used instead of a continous flow of NAD$^+$-containing buffer, in order to save this expensive coenzyme [7] (Fig. 3). The determination of glucose and fructose in different technical syrups was


Fig. 2. FIA system with integrated enzyme-column array and mathematical signal treatment.

performed as a reference with a classical FIA system using specific enzymes, namely glucose dehydrogenase/NAD$^+$ for glucose and mannit dehydrogenase/NADH for fructose [8] (Scheme 3). The inconvenience of this system was that in one case the production, and in the other the consumption, of NADH had to be determined. Therefore, we conceived a new alternative in which we used just one dehydrogenase and the formation of NADH only. We determined glucose before and after equilibration of the two isomers with hexose isomerase, and from the two values and the known equilibrium constant the fructose concentration could be calculated. The results found for both carbohydrates were in excellent agreement with those measured by the classical FIA method and by an independent HPLC analysis. We believe that this principle will be of general importance.

2.3. Mathematical background corrections

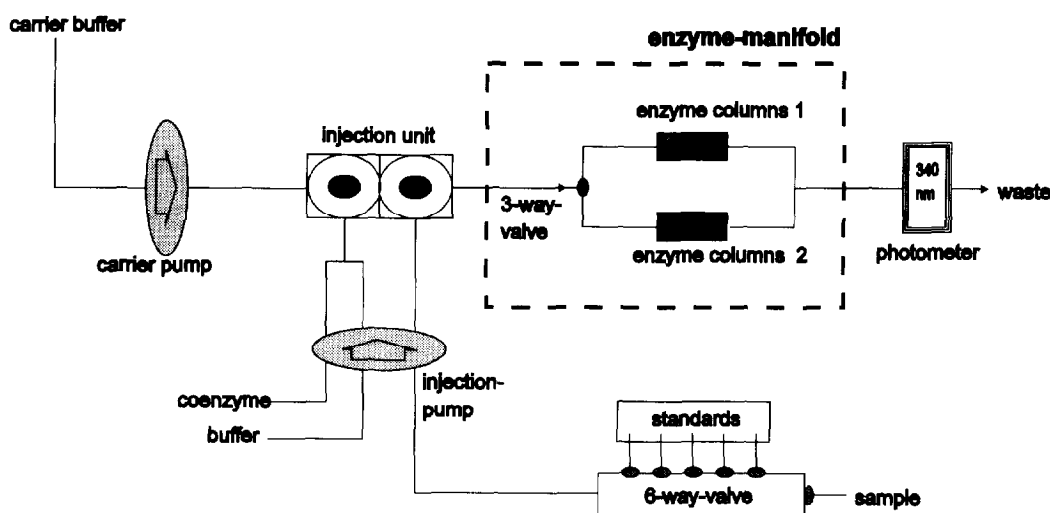
Photometric or fluorimetric NADH determinations in untreated real samples often suffer interferences from unknown background signals of variable intensity. In classical enzymatic analysis a correction for this background is made by using a


Fig. 3. Schematic representation of a FIA system with nested-loop injection, variable enzyme manifold and mathematical signal treatment.

"reference cuvette" for compensation. The analog procedure in FIA would be the individual injection of a sample with and without NAD$^+$ and the storage and subtraction of the signals, preferably in the form of the whole absorption peaks, leading to a corrected signal peak. This procedure will be successful in cases where the absolute response for the signal background is relatively low and the signal-to-noise ratio is high. In order to meet this condition we developed a FIA system which worked with very small injection volumes on the basis of a special conformation of the injection valves used. Thus, the absolute response for interfering compounds was low. An additional effect was the enhancement of the stability and lifetime of the immobilized enzyme.

One application dealt with the on-line parallel determination of D- and L-lactate in the course of a 100 h fermentation with a mixed culture of *lactobacilli* for the acidification of beer [8]. The results were in excellent accordance with those obtained by classical off-line analysis. An additional drawback occurred when ethanol was determined in untreated beer. The first results obtained were not satisfactory, probably because the samples contained—in addition to impurities

interfering with the measurement—ingredients which seemed to partially inhibit the enzyme. Correct results could be obtained only after a five fold dilution of the samples. As this would cause an additional treatment and hence would imply errors, we have conceived, based on parameters typical for an ideal shape of the response curve (NADH absorption peak observed for ethanol in water), a program for the correction of "realistic" curves using fuzzy logic [8]. With the use of this program correct and reproducible ethanol values were obtained even after injection of undiluted samples of beer. Again, we are convinced that these principles of mathematical background and matrix compensation are of general value and importance for future developments.

3. Conclusions

The versatility, selectivity and reliability of FIA systems with integrated immobilized enzymes can readily be enhanced by the integration of physical sample pretreatment modules, the combination of (not necessarily specific) enzyme reactions and by mathematical treatment of the response signals. In cases where neither specific

Abstract

A rapid and highly sensitive potentiometric flow-injection method for the determination of trace hydrogen peroxide was developed by use of an Fe(III)–Fe(II) potential buffer solution containing bromide and Mo(VI). The analytical method was based on a linear relationship between a concentration of hydrogen peroxide and a largely transient potential change of an oxidation–reduction potential electrode due to bromine generated by the reaction of hydrogen peroxide with the potential buffer solution. The oxidation of bromide to bromine by hydrogen peroxide occurred very rapidly with the assistance of Mo(VI) when Fe(II) existed in the potential buffer solution. It was estimated by batchwise experiments that hydroxyl radical, OH·, was generated by the reaction of hydrogen peroxide with Fe(II) as an intermediate, and subsequently oxidized bromide to bromine. In a flow system, analytical sensitivities to hydrogen peroxide obtained by the detection of the transient change of potential were enhanced about 75 fold compared with those obtained by using the potential change caused by the reaction of hydrogen peroxide with the potential buffer solution without bromide and Mo(VI). Sensitivities increased with decreasing concentration of the Fe(III)–Fe(II) buffer in the reagent solution. The detection limit ($S/N = 3$) of 4×10^{-7} M (13.6 ppb) was achieved by using the 1×10^{-4} M Fe(III)–Fe(II) buffer containing 0.4 M NaBr, 1.0 M H_2SO_4 and 0.5% $(NH_4)_6Mo_7O_{24}$. Analytical throughput was ≈ 40 h^{-1} and the RSD ($n = 6$) was 0.6% for measurement of 4×10^{-6} M hydrogen peroxide. The proposed method was applied to the determination of hydrogen peroxide in real rainwater samples, and was found to provide a good recovery for H_2O_2 added to rainwater samples.

1. Introduction

Hydrogen peroxide in the atmosphere is known to be formed by a reaction of two HO_2 radicals, which are produced in photochemical oxidation processes of hydrocarbon compounds [1]. The amount of hydrogen peroxide existing in photochemical smog is said to be increased in summer due to an increase in the intensity of ultraviolet light. Sulfur oxides (SOx) and nitrogen oxides (NOx) which are discharged at industrial areas, are major causes of acid rain as they are oxidized to sulfate ion and nitrate ion by hydrogen peroxide in the atmosphere. The oxidation process of these oxides in the liquid phase is different from that in the gas phase. In the liquid phase, hydrogen peroxide is said to be a dominant source of oxidant for SOx and NOx [2]. Therefore, hydrogen peroxide in rainwater also plays a part in the formation processes of acid rain, so that the development of an analytical method for hydrogen peroxide is important in atmospheric environmental analysis.

An analytical method for trace hydrogen peroxide in rainwater is required to be highly sensitive and accurate. Furthermore, since trace hydrogen peroxide is unstable and is rapidly decomposed by many substances, a rapid analytical method which can be operated in a substantially closed system, is desirable for measuring hydrogen peroxide. Flow-injection analysis (FIA) [3] has been shown to be a versatile and valuable tool that can analyze many samples automatically and quickly and is therefore suitable for analyzing unstable analytes such as hydrogen peroxide in rainwater. There have been many reports on the determination of hydrogen peroxide using FIA. Spectrophotometric [4–7], fluorophotometric [10–13] and chemiluminescence methods [14–19] using peroxidase, and a spectrophotometric method using titanium(IV)–2-((5-bromopyridyl)azo)-5-(N-propyl-N-sulfopropylamino) phenol (Ti–PAPS) reagent [8,9] have been reported and applied to rainwater samples [7–9,12,13,18,19]. An ultra-highly sensitive flow analysis that detected a concentration as low as 10^{-11} M by applying a sensitized chemi-

luminescence method [20,21] has also been reported. Electrochemical methods based on amperometry for determination of hydrogen peroxide have been reported where a preoxidase immobilized column or oxidation reaction of iodide were employed [22–25]. However, few reports on the potentiometric determination of trace hydrogen peroxide have appeared [26].

Recently, we have reported on the potentiometric FIA of redox components utilizing reactions with potential buffer solutions consisting of a redox pair such as Fe(III)–Fe(II), $Fe(CN)_6^{3-}$–$Fe(CN)_6^{4-}$ and Ce(IV)–Ce(III) [27–30]. In a previous paper [29], a highly sensitive potentiometric method for determination of various oxidizing components such as bromate ion, chlorite ion, Cr(VI) and hydrogen peroxide has been proposed by detecting the largely transient potential change of an oxidation–reduction potential (ORP) electrode which appears for a short period after mixing a sample with a Fe(III)–Fe(II) potential buffer containing bromide. Our method has been applied to the determination of Cr(VI) in seawater and sufficient sensitivity was obtained to meet the Japan standards level for Cr(VI) in effluent water (≈ 500 ppb) [30]. In this method, bromine generated by the reaction of Cr(VI) with bromide was proved to cause the large potential change by spectrophotometric studies of the reaction. Furthermore, from the spectrophotometric studies, it was clarified that Fe(II) induced the oxidation of bromide and Cr(V) generated as an intermediate during the reaction of Cr(VI) with Fe(II) oxidized bromide to bromine.

In this paper, the potentiometric analytical method for hydrogen peroxide, reported in Ref. [29], was examined in detail to improve the sensitivity, and was applied to rainwater. Furthermore, in order to elucidate the reaction mechanism involved in the present method, bromine generated by the reaction of hydrogen peroxide with the Fe(III)–Fe(II) potential buffer containing bromide was determined by batchwise experiments.

2. Experimental

2.1. Reagents and solutions

Standard aqueous solutions of hydrogen peroxide were prepared by diluting analytical grade hydrogen peroxide (purity 30%); (Katayama Ltd.) with deionized water. Stock solutions (0.1 M) of Fe(III) and Fe(II) in 0.1 M H_2SO_4 were prepared according to the procedure described previously [29]. The stock solution (2%) of Mo(VI) was prepared by dissolving ammonium molybdate (Katayama) with hot deionized water. An Fe(III)–Fe(II) potential buffer solution containing 0.4 M NaBr, 0.5% Mo(VI) and 1.0 M H_2SO_4 (Solution A) was prepared by mixing the above stock solutions mentioned above. An Fe(III)–Fe(II) buffer solution without bromide and Mo(VI) (Solution B) was prepared in the same manner as solution A. Solutions A and B were used as the reagent solutions of the flow system as well as for the batchwise experiments.

2.2 Procedure for flow-injection determination of hydrogen peroxide

A schematic diagram of the flow-injection system is given in Fig. 1a. The flow-injection apparatus consisted of a peristaltic pump, a sample injection valve, a flowthrough ORP electrode detector, which consists of a gold-plated ORP electrode and a silver/silver chloride reference electrode, a potentiometer and a recorder as described previously [29]. PTFE tubing of 0.5 mm i.d. was used for the manifold.

Solution A was pumped through the reagent channel (R.S.) at a flow rate of 1 ml min^{-1}, while water was pumped through the carrier channel (C.S.) at the same flow rate. The reagent and carrier channels are maintained at 25°C. The sample solution (200 μl) was injected into the carrier stream and merged with the reagent stream at confluence point C. Hydrogen peroxide in the sample reacted with the components in the reagent stream in the 100 cm long reaction coil (R.C.). The mean residence time of the sample zone in the R.C. was about 6 s. The change of potential of the ORP electrode detector (D) was measured with the potentiometer and its signal was recorded as a peak.

2.3. Procedure for batchwise experiment and determination of bromine generated by the reaction of hydrogen peroxide with the reagent solution

The relationship between the potential change of the ORP electrode and the reaction time was examined by the same batchwise experiments as described previously [29]. 10 ml of a H_2O_2 sample solution was added quickly to 10 ml of solution A or solution B in which the ORP electrode and the reference electrode used for the detector were immersed. The potential change of the ORP electrode was measured as a function of time and recorded.

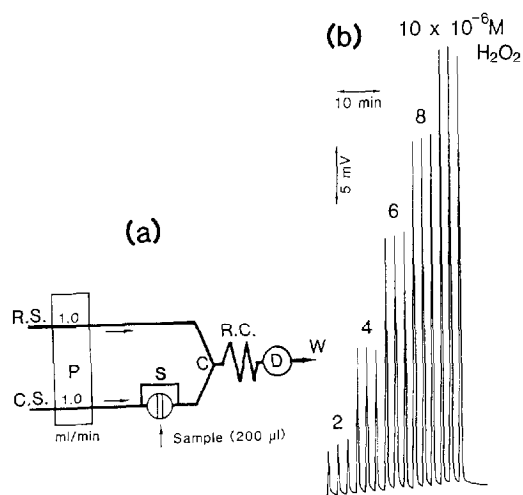
A schematic diagram of the experimental apparatus for determinations of free bromine generated by the reaction of hydrogen peroxide with the reagent solutions used for the flow system is given in Fig. 2. Solution A (45 ml) was placed in a reaction vessel (a) at 25°C and bubbled vigorously


Fig. 1. Schematic FIA diagram for H_2O_2 (a) and calibration peaks (b). R.S., reagent stream (solution A); C.S., carrier stream (H_2O); R.C., reaction coil (100 cm × 0.5 mm i.d.); P, peristaltic pump; S, sample injector (200 μl); C, confluence point; D, flowthrough type ORP electrode detector; W, waste. The temperature of R.S. and C.S. was maintained at 25°C.
Fig. 2. Schematic diagram of the experimental apparatus for determination of bromine evolved by the reaction between H_2O_2 and reagent solution: (a) reaction vessel, solution A (45 ml); (b) syringe, H_2O_2 solution (5 ml); (c) KI solution (100 ml); (d) N_2 gas bomb; (e) gas scrubber; (f) manometer.

with N_2 carrier gas. 5 ml of H_2O_2 solution (b) was quickly added to solution A. The total volume of the mixed solution in the vessel was 50 ml. The reaction was allowed to take place for 30 s and then free bromine generated in vessel (a) was transferred by N_2 gas to a vessel (c) filled with a KI solution (100 ml), pH 7.4–7.6. Bromine was absorbed by the KI solution and iodine oxidized by bromine was determined spectrophotometrically at a wavelentgh of 352 nm ($\varepsilon = 2.76 \times 10^4$).

3. Results and discussion

3.1. Potential change of ORP electrode for reaction of hydrogen peroxide with reagent solutions in batch system

The reaction between H_2O_2 and Fe(II) in sulfuric acid solution is expressed as follows:

$$H_2O_2 + 2Fe^{2+} + 2H^+ \rightarrow 2Fe^{3+} + 2H_2O \qquad (1)$$
Fig. 3 shows the potential response of the ORP electrode arising from the reaction between H_2O_2 and solution A or B in the batchwise experiment. Curve (a) shows the potential change when a 1×10^{-4} M H_2O_2 solution was added to solution B. The response potential increased gradually with time and finally reached a constant equilibrium potential after reaction for 1 min. The observed potential change between the initial potential and the equilibrium potential agreed well with the value (10.38 mV) calculated from the

Nernst equation based on reaction (1). When the 1×10^{-4} M H_2O_2 solution was added to solution B containing 0.5% Mo(VI), the potential quickly increased from the same initial potential to the same equilibrium potential as those for the above solution. However, the time for the potential to reach the equilibrium potential was as short as 15 s. This means that Mo(VI) acts as a catalyst of reaction (1). Curve (b) shows the response potential change when solution B containing bromide was used. The potential increased quickly within 6 s, decreased gradually with time after passing through a maximum, and finally reached a constant equilibrium potential which is almost the same as that of curve (a). The potential change of the maximum point at a reaction time of 6 s, was ≈ 5 times larger than that of curve (a) at the same time. This mountain-shaped transient potential may be due to bromine generated as an intermediate by the reaction between hydrogen peroxide, bromide and Fe(II) in sulfuric acid solution. That is, the electrode reaction seems to be shifted from the standard potential of the Fe(III)–Fe(II) couple (0.77 V vs. NHE) to that of the Br_2–Br^- couple (1.06 V vs. NHE). Curve (c) shows the
Fig. 3. Potential change of the ORP electrode by addition of the H_2O_2 solution to the Fe(III)–Fe(II) buffer solution: (a) 1×10^{-4} M H_2O_2 solution + solution B; (b) 1×10^{-4} M H_2O_2 solution + solution B containing 0.4 M NaBr; (c) 5×10^{-5} M H_2O_2 solution + solution A. ΔE is the potential difference between the initial potential and the equilibrium potential of the ORP electrode after addition of the H_2O_2 solution to the Fe(III)–Fe(II) buffer solution.
Fig. 4. Amount of bromine generated by the reaction between H_2O_2 and bromide solution containing Fe(II) and Mo(VII) or ethanol: (a) 5 ml of 2×10^{-3} M H_2O_2 was added to 45 ml of the solution A; (b) 5 ml of H_2O_2 was added to 45 ml of solution A containing 20 (v v%) ethanol. The reaction time is 30 s.

response potential when solution A was used. In this case, in spite of the lower concentration of H_2O_2, half of the concentration in curves (a) and (b), the potential change is steep and its maximum potential is much larger than that of curve (b). This indicates that the reaction rate for generation of bromine is accelerated by the addition of Mo(VI) to the reagent solution if the potential maximum comes from bromine. Sensitivity (mV/ mM^{-1}), based on the potential change normalized by the concentration of H_2O_2 at the maximum of the curve (c), was $\approx 1.2 \times 10^3$ and was enhanced by ≈ 40 fold compared to the transient potential change at the same time for curve (a). The potential change at the maximum was almost proportional to the H_2O_2 concentration down to 1×10^{-5} M. The decrease in the potential with increasing reaction time after passing through the maximum may be due to consumption of bromine. The potential change was increased $\approx$ 1.2 times when the concentration of Fe(III)– Fe(II) in solution A was decreased from 1×10^{-3} M to 1×10^{-4} M, keeping the concentrations of Mo(VI) and bromide the same. This may be due to a decrease in the reduction rate of bromine by

Fe(II). Therefore, a highly sensitive determination of hydrogen peroxide is expected if the potential change around the maximum obtained by lowering the concentration of Fe(III)–Fe(II) in solution A can be detected by a flow-injection system which is capable of using a transient reaction.

3.2. Reaction mechanism of transient potential change by reaction between hydrogen peroxide and reagent solutions containing bromide, Fe(II) and Mo(VI)

In order to elucidate the large potential change described above, the elementary reactions which possibly occur between H_2O_2, Br^-, Fe(II) and Mo(VI) in an acidic solution were examined experimentally and theoretically. Reaction (2) is expected to occur spontaneously, judging from the following facts:

(1) From the results of the batchwise experiments, the large transient potential change, believed to be due to bromine generation, was observed when solution A was used.

(2) The value of the Gibbs' free energy of the reaction between H_2O_2 and bromide in the acidic solution is negative [31]:

$$H_2O_2 + 2Br^- + 2H^+ \rightarrow Br_2 + 2H_2O$$

$$\Delta G = -32.5 \text{ kcal mol}^{-1} \qquad (2)$$

This suggests that the amount of bromine generated by reaction (2) is dependent on the concentration of bromide, but it was not true experimentally for solution A containing different concentrations of bromide. Therefore, the effect of the concentration of Fe(II) on the amount of bromine generated by the reaction of hydrogen peroxide with solution A was examined using the apparatus shown in Fig. 2. In this apparatus, the residence time of bromine generated in the reaction vessel is very short, and bromine is transported quickly to vessel (c) filled with the KI solution. The reaction time in the vessel was set at 30 s, because the time at the maximum of the transient potential described above was very short. The results are shown in Fig. 4. As can be seen from curve (a), the amount of bromine generated was very small when the reagent solution

contained bromide and Mo(VI) without Fe(II), but the amount of bromine increased markedly with increasing concentration of Fe(II) up to 2 × 10^{-3} M in the reagent solution. Therefore, this indicates that the presence of Fe(II) in the reagent solution contributes greatly to the generation of bromine. This may be because Fe(II) induces the oxidation of bromide in a similar manner to when bromide is oxidized by Cr(V) in the presence of Fe(II) as reported previously [30]. The decrease in the amount of bromine with increasing concentration of Fe(II) above 2 × 10^{-3} M may be due to the consumption of bromine by reaction with Fe(II).

Kolthoff and Medalia [32] reported that the rate equation of reaction (1) can be expressed by a first-order reaction with respect to H_2O_2 and Fe(II) and measured the rate constant for the reaction. They pointed out that reaction (3), where hydroxyl radical (OH·) is produced as an intermediate, is a rate-limiting step of reaction (1). This radical is known to oxidize organic compounds such as alcohols, acetone, acetic acid, etc. Curve (b) in Fig. 4 shows the case where solution A containing 20% (v/v) ethanol was used. The amount of bromine is less than one-third that of curve (a). This result suggests that the hydroxyl radical generated as an intermediate of reaction (1) reacts with bromide to generate bromine as expressed by reaction (4). The lower amount of bromine in the presence of ethanol may be because hydroxyl radical reacts preferably with ethanol than with bromide. It is possible to believe that this side-reaction of hydroxy radical

with ethanol suppressed the reaction with bromide. Therefore, the generation of bromine by addition of H_2O_2 to the solution containing Br$^-$ and Fe(II) in sulfuric acid can be explained by considering the elementary reactions (3)–(5). The contribution of reaction (2) to the generation of bromine seems to be very small, as can be seen from Fig. 4 at the concentration of Fe(II) = 0.

$$H_2O_2 + Fe^{2+} + H^+ \rightarrow Fe^{3+} + OH· + H_2O \quad (3)$$

$$OH· + Br^- + H^+ \rightarrow 1/2Br_2 + H_2O \quad (4)$$

$$OH· + Fe^{2+} + H^+ \rightarrow Fe^{3+} + H_2O \quad (5)$$
H_2O_2 reacts with Fe^{2+} to produce hydroxyl radical and the hydroxyl radical produced simultaneously oxidizes Br$^-$ and Fe^{2+}. The abrupt potential increase shown in Figs. 3b and 3c can be explained by the bromine generated from the elementary reaction above. The presence of Mo(VI) in the solution may accelerate reactions (3) and (4). The overall reaction of H_2O_2 with the solution containing Br$^-$ and Fe^{2+} is expressed by reaction (6) (sum of reactions (3) and (4))

$$H_2O_2 + Fe^{2+} + Br^- + 2H^+$$
$$\rightarrow 1/2Br_2 + Fe^{3+} + 2H_2O \quad (6)$$
As shown in Figs. 3b and 3c, the potential decreases after passing through the maximum. This decrease in the potential can be explained by consumption of bromine:

$$1/2Br_2 + Fe^{2+} \rightarrow Fe^{3+} + Br^- \quad (7)$$
Reaction (1) is the sum of the elementary reactions (3) and (5). The reactions of H_2O_2 with solutions A and B are expressed by the same overall reaction (1), but the former reaction consists of the elementary reactions (3), (4) and (7), while the latter reaction consists of reactions (3) and (5). That is, the presence of bromide in solution A may act as an homogeneous catalyst for the formation and reduction of bromine.

3.3. Flow-injection analysis of trace hydrogen peroxide

The flow system utilizing the detection of the large transient potential change described in the

Table 1
Effect of concentrations of Fe(III)–Fe(II) buffer in solutions A and B on sensitivity (the flow system is the same as that of Fig. 1a)

Fe(III)–Fe(II) concentration[a]	Sensitivity (mV mM^{-1})		Enhancement factor[b]
	Solution A	Solution B	
1 × 10^{-2}	5.6 × 10^2	10	56
1 × 10^{-3}	2.5 × 10^3	42	60
1 × 10^{-4}	3.3 × 10^3	44	75

[a] Both Fe(III) and Fe(II) are dissolved in the same concentration in the buffer.
[b] Defined as the ratio sensitivity obtained by solution A to that obtained by solution B.

Table 2
Recovery of H_2O_2 added to rainwater (samples A and B were collected at Kyushu Sangyo University and the pHs were 4.22 and 4.17 respectively)

Sample (Date)	H_2O_2 added ($\times 10^{-6}$ M)	H_2O_2 found ($\times 10^{-6}$ M)	Recovery (%)
A	0	0	
(30/10/93)	2.50	2.41	96.4
	5.00	4.79	95.8
	7.50	7.41	98.8
B	0	0	
(8/11/93)	2.50	2.58	103.5
	5.00	5.20	104.1
	7.50	7.41	98.8

previous section was designed as shown in Fig. 1a. The concentration of the potential buffer solution and the reaction time were important factors for the sensitive determination of H_2O_2 based on the detection of the transient potential change. The sensitivity to hydrogen peroxide increased with increasing concentrations of sulfuric acid and sodium bromide in the potential buffer solution, and became almost constant at about 0.5–1.0 M sulfuric acid and ≈ 0.4 M sodium bromide. Since the reaction time which gave the maximum potential was 6 s from the batchwise experiments shown in Fig. 3c, a 100 cm long reaction coil and a pumping rate of 1 ml min^{-1} for the carrier and reagent streams were set for the flow system to maintain the reaction time at 6 s. The calibration peaks for the standard H_2O_2 sample are shown in Fig. 1b. The relative standard deviation (RSD) for peak heights was 0.6% for determinations of six samples of 4×10^{-6} M hydrogen peroxide. A sampling rate of 40 H^{-1} was possible with the present manifold. The detection limit at a signal-to-noise ratio of 3 was 4×10^{-7} M (13.6 ppb). In this case, sensitivity, peak heights normalized by concentrations of H_2O_2, was 3.3×10^3 mV/ mM^{-1} and was 75 times larger than that using the reagent solution without bromide and Mo(VI) i.e. solution B. The sensitivity was also dependent on the concentration of Fe(III)–Fe(II) in solution A. The sensitivities to H_2O_2 obtained for solution A at different Fe(III)–Fe(II) concentrations are

listed in Table 1 together with those for solution B. The sensitivity increases with decreasing concentration of Fe(III)–Fe(II) for the solutions A and B in the same way as for the batchwise experiments. The enhancement factor, defined as the sensitivity ratio, for solutions A and B increased slightly with decreasing concentration of Fe(III)–Fe(II). The sensitivities obtained for solution A with the flow system were about twice those obtained for the same solution with the batch system. The lower sensitivity with the batch experiment may be due to escape of the generated bromine into the atmosphere because of the open system [29].

The effects of several coexisting ions for the determination of hydrogen peroxide were examined. Coexisting 100 fold amounts of Cl^-, SO_4^{2-}, NO_3^-, Na^+, K^-, Mg^{2+}, Ca^{2+} and NH_4^+ which are usually contained in rainwater were tolerated for the determination of 4×10^{-6} M hydrogen peroxide.

3.4. Application to hydrogen peroxide in rainwater

It is generally said that hydrogen peroxide content in rainwater is greatly influenced by the season of the year. For example, Matsubara et al. [9] have reported that the concentration of hydrogen peroxide in rainwater was $(7-9) \times 10^{-6}$ M in summer and $(0.5-1.5) \times 10^{-6}$ M in winter in the Kanto district of Japan. These results were obtained with theri FIA method using the Ti–PPAS reagent. Our proposed method was applied to two rainwater samples collected at our university in November. The results are shown in Table 2. Hydrogen peroxide in two samples could not be detected either by our proposed method or by the method of Matsubara et al., using the Ti–PPAS reagent. This means that H_2O_2 in the rainwater sample must be less than 13.6 ppb, the detection limit of our method, or 1.36 ppb ($S/N = 2$), that of the method of Matsubara et al. Our method was than applied to the rainwater sample to which a known amount of the standard H_2O_2 solution was added. The proposed method provided a a good recovery within 95–104% for samples containing hydrogen peroxide at the 10^{-6} M level.

4. Conclusion

In conclusion, the proposed flow-injection analysis method for hydrogen peroxide was improved in sensitivity compared to the previous method [29] and applied to the determination of hydrogen peroxide in a rainwater sample. It was realized that hydroxyl radical, OH·, produced by the induced reaction of hydrogen peroxide with Fe(II), contributes to the generation of bromine which causes the large transient potential. The proposed method could be useful for the determination of concentrated hydrogen peroxide in the bleaching process of dyeing.

Abstract

An automated flow-injection method for determination of primary aromatic amines based on the Bratton–Marshall reaction is described. This method is used for analysis quality control of three different X-ray contrast media (Omnipaque[®], Imagopaque[®] and Visipaque[®] which are viscous solutions. In flow-injection analysis, such samples cause refractive index effects and low, broad peaks due to prolonged residence time. hese interferences are minimized by the use of a carrier solution (7 w/v % NaCl in 1 M HCl) with same refractive index as the samples, careful pH adjustment, use of knotted coils, and a specially designed detector. Validation of the method in the concentration range 4–40 μg ml^{-1} (injected samples) shows a repeatability ($n = 6$) and day-to-day reproducibility ($n = 9$) of 0.4–9.2 and 2.3–17.5% RSD respectively. The accuracy is 81(near the lower limit of detection)–101%, with a limit of detection of 1 μg ml^{-1}. Linearity was shown in the concentration range tested. The method is well suited for in-process analysis, release control and stability testing of both drug substance and drug product. The cost of analysis is reduced compared to the manual method.

Keywords: Aromatic amine; Flow-injection analysis; Quality control; X-ray contrast media

1. Introduction

Nycomed Imaging AS, acknowledged as a world leader in contrast agents for X-ray, magnetic reso-

nance imaging (MRI) and ultrasound techniques, develop, manufacture, and promote contrast agents within these modalities. The company is, in common with other pharmaceutical companies, interested in reduction of production time and costs; here we include analytical costs. Thus, simple, rapid and precise analytical methods are continuously developed and flow-injection analysis (FIA) is one of the promising techniques evaluated.

[1] Presented at the Seventh International Conference on Flow Injection Analysis (ICFIA '95), held in Seattle, WA, USA, August 13–17, 1995.

Omnipaque®, Imagopaque® and Visipaque® are non-ionic, iodinated X-ray contrast media supplied as ready-for-use aqueous injection solutions with different iodine concentrations. A primary aromatic amine—5-amino-N,N'-bis(2,3-dihydroxypropyl)-2,4,6-triiodo-1,3-benzenedicarboxamide (Cpd 5400)—is an intermediate in the chemical manufacturing process of these contrast media and hence is a possible impurity in the products. The primary aromatic amine concentration is controlled in-process, for release and during stability studies of both drug substance and drug product. The current analytical method is a manual, time-consuming spectrophotometric technique based on the Bratton–Marshall [1] reaction. The number of papers on FIA determination of primary aromatic amines [2–7] published, and the fact that the samples are aqueous with a well-defined sample matrix, made FIA an attractive technique.

This paper presents an FIA method developed for the quantification of Cpd 5400 in the contrast media. As these media are concentrated and viscous samples, refractive index (RI) effects [8] and broad peaks with prolonged retention time [9] were expected. Optimisation steps are thus presented, as well as validation results.

2. Experimental

2.1. Reagents

Sodium chloride, sodium nitrite and hydrochloric acid of p.a. grade were prepared in degassed deionized water to the concentrations given in Fig. 1. The carrier solution consisted of 7% w/v NaCl in 1 M HCl. Solutions of 0.1% w/v N-(1-naphthyl)-ethylenediamine-dihydrochloride (NEDD) (Merck, Darmstadt), and 0.6 mM NaNO$_2$ were freshly prepared. 5-Amino-N,N'- bis(2,3-dihydroxypropyl)-2,4,6-triiodo-1,3-benzenedicarboxamide (Cpd 5400), the X-ray contrast media drug substances (iohexol, iopentol, and iodixanol), and the corresponding drug products (Omnipaque®, Imagopaque®, and Visipaque®) were all manufactured by Nycomed Imaging AS.

2.2. Instruments

Two commercial FIA systems were used for development, optimization and validation of the method: a Tecator 5010 Flow-Injection Analyzer equipped with Tecator 5017 Sampler, Tecator 5023 Spectrophotometer and Tecator V100 Injector (Tecator AB, Sweden), and a Lachat QuickChem AE Ion Analyzer (Lachat Instruments, Milwaukee, WI) equipped with a spectrophotometric detector designed by Lachat for samples with high matrix concentration. The analytical manifold designed for this analysis, reagents, flow rates and detection wavelength are shown in Fig. 1.

2.3. Procedure

Six calibration aqueous standards (4, 8, 12, 20, 40, and 50 μg Cpd 5400 ml^{-1}) were prepared by first diluting the standard stock solution (1000 μg Cpd 5400 ml^{-1}) with carrier solution to 100 μg Cpd 5400 ml^{-1} and then by taking aliquots (1.0–12.0 ml) of the latter, further diluted to 25.0 ml with carrier solution. Samples of drug substance (1.22 g weighed accurately) were dissolved in 10 ml of water. Concentrated HCl was added (3.0 ml), and the mixture was then diluted to 20.0 ml with water. Drug product samples were prepared by adding 3.0 ml HCl, and diluting to a concentration equivalent to 60 g drug substance ml^{-1}. Samples for the validation were prepared by spiking the X-ray drug substances with various amounts of Cpd 5400 prior to dilution with water. Final concentrations are given in Table 1.
Fig. 1. Flow-injection manifold for primary aromatic amine analysis: I, injector, 40 μl loop; C$_1$, reaction coil knotted, 40 cm × 0.8 mm; C$_2$, reaction coil, knotted, 200 cm × 0.8 mm; C$_3$, reaction coil, knotted, 50 cm × 0.8 mm; C, carrier, 7% w/v NaCl in 1 M HCl; R$_1$, 1 M HCl; R$_2$, 0.6 mM NaNO$_2$; R$_3$, 0.1% w/v NEDD.

Table 1
Validation data for FIA method for determination of primary aromatic amine (Cpd. 5400) in X-ray contrast media. Samples of spiked drug substance

Added Cpd 5400 (μg g^{-1})	Accuracy (% recovery)	Linearity[a]	Precision		Sensitivity	
			Repeatability (%RSD) ($N = 6$)	Reproducibility (%RSD) ($N = 12$)	LOD (μg g^{-1})	LOQ (μg g^{-1})
Iohexol (51.4–308)	98.2–100	$r = 0.998$ $n = 0.96$	0.4–1.8	2.4–3.0	20	65
Iopentol (51.3–513)	97.0–97.3	$r = 0.998$ $n = 0.98$	0.7–2.5	2.3–4.0	27	90
Iodixanol (51.3–819)	81.3–101.2	$r = 0.9997$ $n = 0.99$	1.1–9.2	2.8–17.5	24	81

[a] r = regression coefficient; n = factor of curvature, in $Y = a + bx^n$; zero within 95% confidence limits for all methods.

Standards and sample solutions are injected into the manifold. The concentration of the samples is calculated by using peak area and standard curve.

3. Results and discussion

3.1. Manual method

The manual procedure for determination of primary aromatic amines is based on the Bratton–Marshall reaction. The amine is diazotized with nitrous acid giving a diazonium ion which is coupled to NEDD. The reaction product, an azo dye, is measured spectrophotometrically at 495 nm. This procedure involves a cumbersome reaction, which requires low temperature (ice bath) for stabilization of the diazonium ion, and addition of nitrous acid at an exact given time interval. Excess nitrous acid must be removed by adding sulphamic acid, with subsequent debubbling of the nitrogen formed, as nitrous acid decomposes the chromogen and azo dye. The produced azo dye must be measured within a specific time interval.

3.2. FIA method

The FIA method is based on a paper presented by Koupparis and Anagnostopoulou [2]. With a

combination of low nitrous acid concentration and the advantageous kinetic nature of FIA, they were able to eliminate the removal of excess nitrous acid. The method was fast, sensitive, linear and worked well with aqueous solutions of Cpd 5400.

3.3. Optimisation

To optimize the system for Cpd 5400, a 2^4 factorial design with reaction time (flow rates), acid, nitrite, and NEDD concentrations as variables was performed. It was shown that the main effects were caused by the reaction time and the acid and nitrate concentrations. Further univariate optimisation of reaction time (flow rates, reaction coil dimensions), concentration of HCl and nitrous acid, and wavelength, resulted in the manifold described in Fig. 1.

To make analysis as simple and fast as possible, injection of undiluted samples would be advantageous. However, the contrast media are highly concentrated, and have high viscosities (22–27 cP). Fig. 2 shows injection of undiluted Visipaque[R] (320 mg I ml^{-1}) and aqueous standard (4 Cpd 5400 μg ml^{-1}). Here, two major effects of FIA of viscous and concentrated samples are demonstrated. Firstly, an RI effect occurs when the sample matrix of samples with low analyte concentration is more concentrated than the car-

rier, and vice versa. The RI effect, characterized by a positive and a negative peak, is superimposed upon the analytical signal, making determination of low analyte concentrations impossible. Secondly, the sample viscosity causes prolonged residence time in the coils resulting in lower and broader peaks (Fig. 2).

With a combination of several simple steps, these problems were minimized: sample dilution and reduction of injection volume is the easiest way to eliminate problems caused by concentrated sample matrix. However, the low analyte concentration prevents dilution of the samples by more than 5–10 fold. Thus, to minimize the RI effect, a carrier with the same RI as the diluted samples was introduced. It consisted of a high concentration of an inert compound—7% w/v NaCl in 1 m HCl. Aqueous standards were also diluted with the carrier. Finally, to make the method more rugged, a detector designed by Lachat to minimize RI effects was used. In this detector, the light aperture is reduced in size and placed slightly off center, the surface area of the photodiode is increased, and the flow cell has a flat, highly polished surface.

Injection of analyte-free sample in the manifold results in a negative peak. This peak, which is another effect of sample viscosity, is superimposed upon the analytical signal, causing an analytical error. This is explained by a slow, pH-dependent reaction between NEDD and nitrous acid which causes an absorbing background. The reaction time available for this reaction is short (coil 3, Fig. 1). When a viscous sample is injected, the background absorption is

Fig. 2. Maximized FIA signals of undiluted Visipaque® 320 mg I ml⁻¹ (a), and aqueous standard 4μg Cpd 5400 ml⁻¹ (b).

lower compared to normal conditions. This is caused by incomplete mixing and hindered molecular transport, and the result is a negative peak. The diazotation of the amine is not hindered by the sample viscosity, because the reaction time is longer (coil 2, Fig. 1), nor is the fast coupling reaction with NEDD in coil 3.

The samples were adjusted with acid to compensate for this loss of background absorption. The amount of acid added was chosen carefully, since the diazotation reaction is also pH-dependent. The accuracies and the linearity given in Table 1 show that the amount of acid added is just sufficient to compensate for the loss of background absorption. For further minimization of sample viscosity effects, knotted coils were used to optimize mixing. Under these conditions, the use of peak area instead of peak height was adequate to compensate for the broader sample peaks compared to aqueous standard peaks.

Fig. 3 shows FIA signals obtained when the physical interferences were minimized.

3.4. Validation

Linearity and accuracy (given as the recovery of added amounts of Cpd 5400) were tested at six and three concentration levels respectively. Precision was tested at three levels: as repeatability with six sample replicates, and as reproducibility over three days with a total of 12 sample replicates. The specificity was studied by analyzing blank samples of the injection solutions without drug substance addition: i.e. excipients only. Lower limit of detection (LOD) and lower limit of quantitation (LOQ) were determined by use of the variation around the calibration curve ($S_{y,x}$), and its slope (b): ($3xS_{y,x})/b$ and ($10xS_{y,x})/b$ respectively. The validation results are shown in Table 1. The linearity is given as absorbance versus added amount of Cpd 5400 in the concentration range from the LOQ—corresponding to 4–40 μg Cpd 5400 ml⁻¹ in injected samples. The detection limit is approximately 1 μg ml⁻¹. As the chemistry is specific for primary aromatic amines, and no
Fig. 3. FIA signals of calibration standards (4. 8. 12, 20 μg Cpd 5400 ml⁻¹). blank samples and samples of Visipaque* 320 mg I ml⁻¹.

matrix interferences were observed when analyzing blank samples, the method is selective for primary amine in X-ray contrast media.

viscous samples, each application has to be "tailored".

4. Conclusions

FIA is an excellent tool for automation of the Bratton–Marshall reaction. The method described in this paper is well suited for the analysis of Cpd 5400 in in-process control, for product release and instability testing. The validation results are equal to, or better than, the current manual method. Because the FIA method is so simple and fast, the analytical costs can be reduced significantly, depending on the amount of samples analyzed in a series. The method is currently being evaluated for other applications.

FIA can be used for the analysis of concentrated, moderately viscous samples, but to overcome the physical interferences caused by highly

Abstract

An electron transfer mediator, 8-dimethylamino-2,3-benzophenoxazine (Meldola Blue), dissolved in the carrier solution in a flow-injection system, was found to reduce the oxidation potential for hydrogen peroxide from 600–1200 mV without mediator to -100 mV vs. Ag/AgCl with the mediator present. The very low background current of reticulated vitreous carbon (RVC) at this potential makes it possible to detect very low levels of hydrogen peroxide or glucose. Glucose oxidase was covalently coupled with carbodiimide to RVC, and the RVC was formed into a column inserted in a flow-injection system. The calibration curve was linear from 30 nM to 10 μM glucose with 5 μM mediator. At higher mediator concentrations, the linear range was extended to 1000 μM, but with a much higher background current. The sample throughput was about 60 h^{-1}. The current response decreased to 50% of the original response after 20 days. The coulometric yield was high because the sample was pumped through the pores of the RVC. It was 16% and 55% at a flow rate of 1 ml min^{-1} at mediator concentrations of 5 and 50 μM respectively.

1. Introduction

A great number of biosensors for glucose determination have been described in the literature over the last two decades [1–3]. The major goal has been to develop sensors for determining glucose in blood. Some work has also been devoted

[1] Presented at the Seventh International Conference on Flow Injection Analysis (ICFIA '95), held in Seattle, WA, USA, August 13–17, 1995.

to determination of glucose in biotechnological processes. Very little emphasis has been put on developing glucose sensors for the submicromolar range.

Hydrogen peroxide is a reaction product in a number of enzymatic reactions used in substrate determinations. It can be determined spectrophotometrically using peroxidase-catalyzed color reactions of the Trinder type [4]. It can also be determined electrochemically by oxidation at about + 1200 mV vs. SCE on glassy carbon [5] or at lower potentials on platinum or by using chemically-modified electrodes, e.g. + 400 mV at palladium sputtered on carbon [6]. With catalysts such as peroxidases on the electrode surface reduction starts at + 600 mV and reaches a constant value at − 200 mV [7]. A number of soluble or immobilized mediators have been used for lowering the necessary electrode potentials for detection of hydrogen peroxide produced by oxidases. Mediators

for glucose determination include N-methylphenazinium salts [8] and Meldola Blue. Both mediator and enzymes were incorporated into carbon paste electrodes [9].

The superior electrochemical properties of reticulated vitreous carbon (RVC) [10] have prompted a study of this material for use as a sensor at very low concentration levels. Previously glucose oxidase has been coupled covalently to RVC and the production of hydrogen peroxide was determined by oxidation at + 900 mV vs. SCE [11].

In this paper we report on the use of a soluble electron transfer mediator, Meldola Blue, which can detect hydrogen peroxide or glucose down to − 100 mV vs. Ag/AgCl. Glucose oxidase was used in this study because this enzyme is very stable and has been comprehensively studied previously. It is thus a good model system although the use of other oxidases may provide even higher sensitivity from a practical point of view. The ability to select a potential at which the background currents are extremely low should be of great importance in making sensors for low substrate levels.

2. Experimental

2.1. Chemicals

Glucose oxidase (GOx) type S-X (*Aspergillus niger*), Meldola Blue, 8-dimethylamino-2,3-benzophenoxazine and 1-cyclohexyl-3-(2-morpholinoethyl)-carbodiimide metho-p-toluenesulfonate were obtained from Sigma. The RVC, porosity grade 100-S (pore size nominally 0.25 mm), was from Energy Research and Generation Inc. (Oakland, CA).

The potentiostat (model MA 5410, Chemel AB, Lund, Sweden) was set at a voltage of − 100 mV vs. Ag/AgCl. The carrier buffer was 0.1 M sodium phosphate, pH 7.0, containing 1.9 mg Meldola Blue 1^{-1} (5.0 μM). Meldola Blue is unstable at higher pH, the half-life time at pH 7.0 is 100 h [12], and new buffer solutions were therefore prepared every day. The peristaltic pump was from Alitea AB (model C-4v). Sample injection was through a 100 μl loop.

Fig. 1. Cell configuration for determination of glucose or hydrogen peroxide.

Table 1

Peak currents at various applied voltages (vs. Ag/AgCl) observed when injecting 100 μl of 1 μM glucose samples into a phosphate buffer, pH 7.0, containing 5 μM Meldola Blue. Flow rate 1 ml min^{-1}

Applied voltage	(mV)	−150	−100	−50	0	50	100	150
Peak current	(nA)	270	230	230	230	250	250	280

2.2. Preparation of the column

RVC cylinders (1.5 × 0.5 cm^2) were cut (using eye and dust inhalation protection devices) from a block of material and left in 6 M HCl for 1 h. They were washed with distilled water until the solution reached pH 5, and then left in dry methanol for 2 h. Finally, the cylinders were dried in an oven at 110°C overnight. A cylinder was fixed in a glass tube as shown in Fig. 1 with a counter electrode of the same material. The reference electrode was mounted downstream, which should be acceptable due to the low currents.

2.3. Immobilization

A 0.05 M acetate buffer (pH 5.1) containing carbodiimide (40 mg ml^{-1}) was pumped through the system at a flow rate of 0.2 ml min^{-1} for 150 min in order to activate the RVC surface. Then acetate buffer was circulated under an ice bath at a flow rate of 1.2 ml min^{-1} for 30 min. For immobilization of GOx, an enzyme solution (60 mg per 10 ml) in buffer was circulated in the column under an ice bath at a flow rate of 0.2 ml min^{-1} for 3 h. The final rinsing procedure consisted of pumping a cold phosphate buffer (0.1 M, pH 7.5) for 5 min.

3. Results and discussion

The RVC material is porous and can be shaped in the form of a column permitting a liquid to be pumped through, thus giving efficient mass transfer to the surface. The surface area will be very large but the background current will still be low because of the favourable properties of RVC. A large surface area is necessary in order to immobilize a sufficient amount of enzyme but it is also necessary to obtain a high coulometric yield. The

electrode was made in the form of a cylinder and inserted into a flow-injection system.

3.1. Reaction properties

Injection of 10 μM glucose samples produced oxidation peaks which were almost independent of the applied voltage, see Table 1. The redox potential of adsorbed Meldola Blue is −175 mV at pH 7.0 [12]. The applied voltage should therefore be sufficient to keep the mediator in the oxidized form. The potential was set to −100 mV for all subsequent experiments.

The mediator concentration has a pronounced effect on both the background current (Table 2) and the response factor and linearity of the calibration curve, Fig. 2. The lowest background was obtained with a mediator concentration of only 5 μM. The current at 10 μM glucose for example was much lower than that at the higher mediator concentrations; compare the current scale in the inset of Fig. 2 with that of the main graph. A low mediator concentration decreased the linear range (not shown in Fig. 2) because the amount present in the sample zone becomes less than that of the hydrogen peroxide or glucose. The coulometric yield at a flow rate of 1 ml min^{-1} was 16, 45 and 55% at mediator concentrations of 5, 20 and 50 μM respectively.

The current due to glucose oxidation at −100 mV in the presence of mediator decreased when the flow rate increased, see Fig. 3. For compari-

Table 2

Observed background currents of the enzyme-covered RVC electrode in a phosphate buffer, pH 7.0, containing various concentrations of mediator. Applied voltage, −100 mV vs. Ag/AgCl; flow rate, 1 ml min^{-1}

Mediator concentration	(nM)	5	20	50
Background current	(nA)	10	200	6000
Fig. 2. Influence of mediator concentration on the response to glucose injections (100 μl) with various concentrations of Meldola Blue: (▲) 50 μM; (●) 20 μM. The inset shows the low range response with 5 μM mediator. Phosphate buffer containing mediator, pH 7.0; applied potential, – 100 mV; flow rate, 1 ml min⁻¹.

son, Fig. 3 also gives the currents for hydrogen peroxide oxidation at + 600 mV in the absence of mediator. This is the potential where the oxidation of hydrogen peroxide begins. The curves for hydrogen peroxide and glucose follow each other closely, indicating that similar rate-limiting steps are involved. The fast decrease in response with flow rate is due to a reduced residence time at the RVC electrode giving more time for the reactions.
Fig. 3. Response variation with flow rate for injections (100 μl) of 10 μM glucose (●). Phosphate buffer, pH 7.0, containing 5 μM Meldola Blue; applied potential, – 100 mV vs. Ag/AgCl. The Figure also shows the response to hydrogen peroxide at + 600 mV in a buffer without any added mediator (▲).
Fig. 4. Peak currents for hydrogen peroxide (△) and glucose (●) injections (100 μl) with a carrier of phosphate buffer, pH 7.0, containing 5 μM Meldola Blue. The non-enzymatic oxidation of glucose (■) is also shown. Flow rate, 1.0 ml min⁻¹; applied potential, – 100 mV vs. Ag/AgCl.

Diffusion within the pores also plays an important role in the mass transfer because less substrate reaches the pore walls at shorter residence times.

Kulys et al. [9] suggest that Meldola Blue (MB) shuttles electrons from the redox center of glucose oxidase (GOx) to the graphite surface according to the following scheme (corrected by us):

glucose + GOx(FAD)

$\rightarrow$ GOx(FADH₂) + gluconolactone　　　　(1)

GOx(FADH₂) + MB⁺

$\rightarrow$ GOx(FAD) + MBH + H⁺　　　　(2)

MBH $\rightarrow$ MB⁺ + H⁺ + 2e⁻　　　　(3)
In our studies, we observed that the response to hydrogen peroxide closely followed that of glucose. The following observations have to be accounted for in a complete description of the reaction mechanism. Hydrogen peroxide injections into a system with an RVC electrode without enzyme but with mediator produced only negligible responses at – 100 mV. This proves that the enzyme is necessary for the hydrogen peroxide reaction. A mixture of equal concentrations of mediator and hydrogen peroxide (5 μM) was put in a spectrophotometer cuvette and monitored at 568 nm. The absorbance decreased linearly with time from 0.81 to 0.75 AU in 15 min and continued to decrease after 2 h. Oxygen will react with

the reduced mediator until it is finally colorless and no quantitative data can be drawn from the experiment. The mean residence time in the flow system is 28 s at 1 ml min^{-1}, i.e. the direct reaction between mediator and hydrogen peroxide is far too slow to explain the observation that hydrogen peroxide produces peaks at -100 mV. The peak heights for glucose injections decreased substantially when the carrier was deoxygenated. Although the oxygen was not completely removed the experiment nonetheless proves that oxygen is important. This indicates that the glucose first reacts with oxygen to produce hydrogen peroxide which is then oxidized enzymatically. This path does not exclude a parallel reaction according to Eq. (2). The mediator is reduced and reoxidized electrochemically. The reaction scheme will then be

$$\text{glucose} + O_2 \xrightarrow{\text{GOx}} H_2O_2 + \text{gluconolactone} \quad (4)$$

$$H_2O_2 + MB^+ \xrightarrow{\text{GOx}} MBH + O_2 + H^+ \quad (5)$$
followed by Eq. (3). The proposed scheme is tentative and has to be supported by a mechanistic study.

Fig. 4 shows calibration curves for three decades. The current reached a plateau at 100 μM and did not increase when the glucose or hydrogen peroxide concentration was increased to 1

or 10 mM (not shown). The plateau is due to small amounts of mediator in comparison with the concentrations of glucose or hydrogen peroxide. The two curves are almost identical (even at 1 and 10 mM) which indicates that Eq. (5) is the rate-limiting step. Thus the rate is highly dependent on the mediator concentration (see Fig. 2).

The current observed with glucose as a sample decreased only slightly over the pH range 6–8. Hydrogen peroxide generated by the enzymatic reaction of glucose is produced at the pore walls within the diffusion layer. It reacts with the enzyme and mediator which are also present within the diffusion layer. The mediator is regenerated electrochemically and immediately available for a new oxidation cycle. The fact that the calibration curves for glucose fall very close to those for hydrogen peroxide demonstrates that very little hydrogen peroxide is lost to the bulk solution during glucose oxidation.

A blank electrode without enzyme was also prepared and its response to various levels of glucose is shown in Fig. 4. The oxidation current is concentration dependent and 1–3 orders of magnitude lower than the currents in the presence of enzyme. It is, however, much higher than the background current obtained in the absence of glucose. A possible explanation for this non-enzymatic reaction is a direct oxidation of some of the six tautomers of glucose. The aldehyde, and possibly also the gem-diol, which are present at 0.0024% and 0.0077% respectively (27°C) [13], could be oxidized by the mediator or directly at the electrode.

The electrode stability can be seen in Fig. 5. It can be seen that the response remains almost constant initially because the enzyme is in excess and some deactivation can occur without affecting the results. Subsequently, enzyme or electrode degradation reduces the response.
Fig. 5. Stability tests made by injecting 100 μl of 1 μM glucose. Phosphate buffer, pH 7.0, containing 5 μM Meldola Blue; applied potential, -100 mV; flow rate, 1 ml min^{-1}.

4. Conclusions

The low level calibration curve is linear up to about 10 μM and the detection limit is at present around 30 nM glucose but could perhaps be

lowered with further optimization. The electrode performs well in a flow-injection system and a throughput of 60 samples h^{-1} was readily obtained. The detection system is very attractive for low level measurements. The porous electrode material results in a high coulometric yield combined with a low inherent background current. Another advantage is the possibility of covalently immobilizing enzymes directly onto the RVC electrode.

Flow-injection systems for determination of trace manganese in various salts by catalytic photometric detection[1]

Takeshi Yamane*, Kazuo Koshino

Department of Chemistry, Faculty of Education, Yamanashi University, Takeda-4, Kofu 400, Japan

Received 13 November 1995; revised 11 December 1995; accepted 11 December 1995

Abstract

Two flow-injection analysis (FIA) systems for the determination of trace manganese in salts are presented using highly sensitive catalytic detection based on the oxidation of 3,4-dihydroxybenzoic acid by hydrogen peroxide. Two different approaches, the use of a large sample volume injection in a usual FIA mode (system A) and on-line coupling of a cation-exchange separation column with detection in a continuous flow system (system B), have proved very effective for eliminating the blank peak problem and thus affording direct injection of a sample solution containing a large concentration of salt. The limits of determinations are 0.04 ppm and 0.01 ppm for systems A and B respectively, when a 5 g sample is used for preparing the 100 ml sample solution. The proposed FIA systems were satisfactorily applied to the determination of manganese at 0.03–1.59 ppm in solar salts (salts made by exposing brine to the sun) with good precision.

Keywords: Catalytic photometric detection; Flow-injection systems; Manganese

1. Introduction

The determination of some metals, e.g. calcium, magnesium, iron, manganese, vanadium, etc., in sodium chloride is of considerable interest particularly in the chemical industry for quality checks of salts as raw materials and for monitoring such metals during the electrolysis process. A photometric method [1] with oxidation of mangan-

ese(II) to permanganate, and atomic absorption spectrometry (AAS) [2–4] have been used for this purpose. The former lacks the necessary sensitivity for most solar salts (made by exposing brine to the sun) and the latter requires the time-consuming and laborious separation and/or preconcentration of manganese from the matrix salt since AAS is subject to interference from a large background absorption by the matrix.

Flow-injection analysis (FIA) with catalytic photometric detection has proved to be a powerful method for rapid, simple and reproducible determination of trace metals. Recently, a FIA method has been reported with catalytic detection

* Corresponding author. Fax: (+81) 552-20-8183.

based on the malachite Green–periodate reaction for trace manganese in salts [5]. However, off-line batch procedures for preseparation of manganese using a minicolumn packed with chelating resin (Dowex A-1) were still needed, because the method suffered severely from a refractive index problem which occurred when the sample solution containing salt was injected into the carrier stream. In addition, the indicator reaction used required a long reaction time to achieve high sensitivity, which resulted in a long analysis time. Therefore, this method does not make use of the characteristic advantages of FIA, namely simplicity and rapidity. A blank peak effect is one of the great problems in FIA for determining trace constituents and is due to refractive index perturbation which occurs when samples containing a large excess of salts are injected into the carrier stream. One of the authors [6] has proposed a simple way to eliminate this blank peak effect based on the provision of a non-dispersed zone for analytical measurements in the sample plug. Ion-exchange separation, coupled directly with detection in a continuous flow system, described previously for determining manganese in river water [7], seems to be another possible way to remove the matrix effect. In the present work, we have studied these two approaches in the FIA determination of trace manganese in salts in order to allow direct injection of sample solutions into the FIA system. Manganese-catalysed oxidation of 3,4-dihydroxybenzoic acid (DHBA) by hydrogen peroxide [8] has also been examined as a means for detecting trace manganese especially if the catalytic reaction rate detection can be used to eliminate the blank peak effect, even in the presence of large amounts of sodium chloride.

2. Experimental

2.1. Solutions

All reagents were of analytical-reagent grade, unless otherwise noted.

The DHBA solution was prepared by dissolving 2.00 g of reagent in 30 ml of ethanol and diluting to 100 ml with water. Before use, 20 ml of this

solution was diluted to 50 ml with water and the resulting solution was mixed with a 1.5% hydrogen peroxide solution in a 1:1 ratio.

Sodium carbonate solution (1.0 M) was prepared by dissolving the reagent in water.

The eluent was prepared by mixing 0.15 M sodium tartrate, 0.0045 M tartaric acid and 0.3 M sodium chloride.

2.2. Apparatus and general procedure

Fig. 1 shows a schematic diagram of the manifold used. In the determination by FIA without on-line separation (system A), the cation-exchange column (SC) should be omitted in accordance with replacing eluent (C) by distilled water as carrier. All components in contact with solution (tubing, valves, and connectors) were made of Teflon, Daiflon, ceramics or glass. The separation column (SC) was prepared by slurry packing the strong cation-exchange resin (Hitachi Custom Resin No. 2611, 15.5 μm) into a borosilicate glass column (4 mm i.d., 7 cm long). A Tokyo Rikakikai Model LP-1000 pump (metal-free type) and a Sanuki Kogyo Model DM2M-1024 pump were used. The sample solution was injected into the carrier stream (or eluent stream) with a six-way valve with a 5 m sample loop (0.5 mm i.d.), and the absorbance was measured at 480 nm with a Jasco model UVIDEC-100VI spectrophotometric detector. The peak height or the height of
Fig. 1. Flow-injection manifold for determination of manganese in salts: C, carrier (water for a large sample volume injection; 0.15 M sodium tartrate–0.0045 M tartaric acid–0.3 M sodium chloride as eluent in the case of introducing SC); R₁, indicator mixture (2.6 × 10⁻² M DHBA and 0.75% hydrogen peroxide); R₂, 1.0 M sodium carbonate solution; S, sample injection with loop (0.5 mm i.d., 5 m long); SC, separation column (cation-exchange resin, 4 mm i.d., 7 cm long); RC, reaction coil (0.5 mm i.d., 5 m long); D, spectrophotometric detection at 480 nm; BC, back-pressure coil; TB, temperature-controlled bath (40°C); W, waste.

signal response from the baseline is rectilinearly related to the manganese concentration. The calibration graphs were made with standard manganese solution to which sodium chloride was added in the same concentration as in the sample solution.

2.3. Sample preparation

2.3.1. For soluble manganese

A salt sample (2–3 g for normal solar salt) was accurately weighed and dissolved in $\approx$ 60 ml water. The resultant solution was filtered through a membrane filter (0.45 μm) and then diluted to 100 ml with water. The sample weight can be increased within 5 g of the upper limit so that the manganese level determined in the sample solution by peak height measurements should fall into linear ranges of 2–12 ppb for system A and 0.5–15 ppb for system B.

2.3.2. For total manganese

The salt sample was dissolved in $\approx$ 5 ml of water together with 3.6 ml of 2.0 M hydrochloric acid and 3 ml of 1.5% hydrogen peroxide solution by heating for 5–10 min on a hotplate. After cooling, the resultant solution was treated as for soluble manganese.

3. Results and discussion

3.1. Catalytic determination of manganese in a continuous flow system

Manganese-catalyzed oxidation of DHBA by hydrogen peroxide was successfully used in the sensitive determination of manganese. Basically, the reaction conditions and the FIA manifold were almost the same as those described previously [7, 8]. A minor modification was made to the present study such that a mixed solution of DHBA and hydrogen peroxide was used as the indicator mixture to simplify the flow system. The increase in absorbance at 480 nm, recorded as the peak shape signal in this FIA system, due to the catalyzed reaction is the measure of the manganese concentration.
Fig. 2. Dependence of the shape of signal response on the sample loop length for injection of a sample solution containing a mixture of 4.0 ppb manganese and 0.85 M sodium chloride. Sample loop length: (a) 1 m; (b) 2 m; (c) 3 m; (d) 4 m; (e) 5 m; (f) 6 m.

3.2. FIA system with large sample volume injection (system A)

The concept for eliminating the blank peak effect presented by one of the authors can be realized by the use of a larger sample injection. Fig. 2 shows the dependence of the shape of the signal response on the sample loop length when the sample solution containing 4.0 ppb manganese plus 0.85 M sodium chloride was injected. In the signal response, a plateau on the upper side of the ascending signal was observed with a sample loop longer than 300 cm, although a blank peak appears as a set of sharp negative and positive peaks. The increase in the sample loop length from 3 m to 6 m did not show any effect on the height of this plateau from the baseline at constant manganese concentration. This shows that there is a portion of the sample plug which is unaffected by the carrier stream. By using a 5 m sample loop, the effect of sodium chloride concentration on the sample solution was studied for the catalytic detection of 8.0 ppb manganese. As shown in Fig. 3, the height of the plateau initially increased with increasing sodium chloride concentration and then reached an almost constant value in the range 0.51–1.3 M. An initial increase in the height may be attributed to a rate-enhancing effect of sodium chloride on the manganese-catalyzed reaction as described later. Based on these results it is clear that the real signal of manganese

can be recognized and measured at this plateau portion of the overall signal response even in the presence of excessive sodium chloride. It is noted that there was found to be a slight drop in the signal response for blank solution (no manganese) from the baseline level when the sodium chloride concentration was increased too much (> 0.86 M). The reason is not clear. Although this seems to be the limitation of catalytic detection in the media containing a higher concentration of salt, it is evident that the blank peak has little effect on the trace manganese determination using the large sample volume injection.

Calibration graphs obtained by plotting the height of the plateau (H in Fig. 2) against the manganese concentration were rectilinear in the range 2–15 ppb manganese both in the presence and absence of 0.85 M sodium chloride, although the graph became steeper in the presence of sodium chloride, as shown in Fig. 4. The increased slope of the graph is probably due to the rate-enhancing effect of sodium chloride on the catalytic reaction, as was observed in another catalytic reaction [9]. This increased slope, however, was found to be almost unchanged by increasing the sodium chloride concentration from 0.51 to 1.5 M. Although manganese in concentrations as low as 0.2 ppb can of course be detected, the limit of determination was defined here as the lowest concentration of linear response, thus

Fig. 4. Calibration graphs for system A with a 5 m sample loop for (a) manganese standard solution and (b) manganese standard solution containing 0.85 M sodium chloride.

taken as 2 ppb. This value corresponds to 0.04 ppm based on a solid sample if a 5 g sample is used for preparing the 100 ml sample solution. The relative standard deviation for 8.0 ppb manganese was 0.9% ($n = 5$). An injection rate of 20 h^{-1} is estimated.

3.3. FIA system with on-line cation-exchange separation (system B)

In order to achieve the separation and/or preconcentration of manganese from a sodium chloride matrix, a strong cation-exchange column with tartrate solution as eluent was introduced and coupled on-line with the catalytic detection system. The elution conditions entail some modifications to the procedure proposed earlier [7], because the sample solution in the present study contains large amounts of sodium chloride which cause a lowering of the distribution coefficient of manganese [10] and may impair the separation efficiency. Different ratios of the concentrations of tartaric acid, tartrate and sodium chloride in the eluent were examined for obtaining a baseline separation of the manganese peak from the sodium chloride matrix. An eluent of 0.15 M tartrate, 0.0045 M tartaric acid and 0.3 M sodium chloride (pH 5.1) was found to be best to provide good resolution of manganese from a large blank peak which appeared at void volume as a set of negative and positive peaks. Typical signal traces

Fig. 3. Dependence of peak height (H) on sodium chloride concentration in sample solution containing 8.0 ppb manganese with use of a 5 m sample loop.

for manganese are shown in Fig. 5. It is notable that repetitive sample injections can be performed because the eluent works as carrier solution and also regenerates and washes the column. In this FIA system it is evident that the blank peak effect on the signal response from trace manganese by the catalytic reaction can no longer exist. The peak height increased on decreasing the flow rate of the carrier solution; an increase in the peak height by about 1.3 times was observed when the flow rate was decreased from 0.8 to 0.4 ml min⁻¹ keeping the flow rate of other solutions constant at 0.5 ml min⁻¹. This should be attributed to an increase in the residence time, and hence the reaction time, at a constant reaction coil length.

Fig. 6 shows the dependence of peak height on the concentration of sodium chloride added for the sample solution of 10 ppb manganese. The peak height gradually decreased with increasing sodium chloride concentration despite the well-resolved peak shape which remained. A similar peak height dependence was also observed in the case of cation-exchange separation of magnesium and calcium [11]. A decrease in the peak height at higher sodium concentration suggests that there is a limitation on improving the limit of determination by taking a larger sample weight for preparation of the sample solution. An attempt to improve sensitivity was made by on-line preconcentration using the same separation column from the solution prepared with a limited lower sodium

Fig. 6. Effect of sodium chloride concentration on peak height for 10 ppb manganese solution in the FIA system with separation column (system B).

chloride concentration. The peak height for 10 ppb manganese increased linearly with increase in the sample loop length up to 8 m even in the presence of 0.85 M sodium chloride. This indicates that the sensitivity of manganese determination can be improved by using a large sample volume. However, the use of a sample loop longer than 8 m resulted in a tendency towards deviation from the linear relationship and poorer peak resolution, probably due to partial elution (leakage) of manganese. Therefore, a 0.85 M sample solution and an 8 m sample loop were considered the limits for achieving sensitive determination of manganese in salt.

Calibration graphs were rectilinear for manganese in the range 0–15 ppb in the presence of 0.85 M sodium chloride. The slopes of the graphs have a tendency to gradually decrease with increasing sodium chloride concentration above 0.51 M; for instance, equations of the calibration graph in the presence of 0.51 M and 0.68 M sodium chloride are $Y = 1.17X$ with a correlation coefficient of 0.999 and $Y = 1.07X$ with a correlation coefficient of 0.998 (Y, peak height in cm; X, manganese concentration in ppb) respectively. Thus it is recommended to prepare the calibration graph using the same concentration of sodium chloride as in the sample solution. For the sample injection with a 5 m sample loop, the relative standard deviation for 7.0 ppb manganese is 1.4% ($n = 5$) and the limit of determination (defined as

Fig. 5. Typical signal traces for manganese in solar salt for the FIA system with separation column (system B).

five times the limit of detection) is 0.5 ppb, which corresponds to 0.01 ppm based on a solid sample when a 100 ml sample solution is prepared by dissolving 5 g of sample. This limit of determination is lowered to one-quarter that of the FIA system A. The sensitivity of this FIA method is sufficient for analysis of most solar salts to judge from the manganese contents reported in the literature [3–5]. An analysis rate of 8 h^{-1} is estimated.

3.4. Interference study

The effect of foreign ions on the determination of 5.0 ppb manganese with the two FIA systems A and B was studied. No significant interference was observed in either FIA system with the following ions (μg ml^{-1}): Ni(II) (10), Cu(II) (10), Pb(II) (20), Fe(III) (0.5), Al(III) (10), V(V) (10), Cr(III) (0.3), Mg(II) (20), Ca(II) (20), Cd(II) (5), Mo(VI) (5), F$^-$ (100), Br$^-$ (100), I$^-$ (20), H$_2$PO$_4^-$ (100). Cobalt showed a positive interference at the same level as manganese in FIA system A. The concentrations of ions mentioned above in most salt samples are usually lower than the levels examined in this study. It is noted that FIA system B is recommended for use when samples are suspected to contain metal ions in high concentration, because metals with a rela-

tively stronger tendency to form complexes with tartrate [10], such as copper, iron, cobalt, cadmium, nickel, lead, and zinc, should be easily separated by elution before manganese. Experiments showed that these ions did not affect manganese determination in system B at 50 ppm levels. In addition calcium and magnesium, which form relatively weaker complexes with tartrate, did not show any effect even at 100 ppm.

3.5. Analysis of salt samples

Manganese was determined in solar salts using the present FIA systems; the preparation of the sample solution was, in principle, based on the method described in the literature. Soluble and total manganese are defined here as manganese determined in the sample solutions prepared by treatment with distilled water, and with a mixture of hydrochloric acid and hydrogen peroxide respectively. The results obtained with the two FIA systems are summarized in Table 1, and show good agreement with each other. Such agreement for soluble manganese indicates that FIA system A has good selectivity and is applicable to the usual solar salts. Satisfactory precision, less than 3% relative standard deviation, was obtained with the exception of the results for the Australian sample 2 which were close to the limit of determination. It is a characteristic advantage of FIA system B that the determination of total manganese can be made conveniently because the sample solution containing hydrochloric acid and hydrogen peroxide can be directly injected without any perturbation of the catalytic reaction detection.

Table 1
Analysis of solar salts by the proposed FIA systems

Sample	Manganese determined in sample (ppm)[a]		
	Soluble Mn		Total Mn
	FIA (A)	FIA (B)	FIA (B)
Mexican	0.31 (3.0)[b]	0.30 (3.3)[b]	0.40 (2.5)[b]
Australian			
(1)	0.47 (2.1)	0.49 (2.3)	0.98 (1.2)
(2)	0.04$_4$ (10)		0.03$_5$ (11)
(3)	0.51 (2.5)	0.53 (2.1)	0.84 (1.7)
(4)	0.85 (0.9)	0.84 (1.1)	1.59 (0.9)

[a] Sample solutions were prepared by dissolving 2–3 g of solid salt in 100 ml of solution. A 5 m sample loop was used.
[b] Parentheses denote the relative standard deviations for 3–5 determinations.

4. Conclusions

Two approaches to FIA, the use of a large sample volume injection and the introduction of on-line cation exchange separation, both coupled with catalytic detection by the DHBA–hydrogen peroxide reaction, have proved to be very effective to determine trace manganese in the presence of excessive levels of salts by eliminating the blank

peak refractive index problem, consequently allowing the direct injection of sample solutions. The main advantage of the present FIA systems over conventional photometric and AAS methods is that the analysis is achieved in a continuous and nearly closed system without instrumental and operational complexity. A short analysis time of 3–7 min is an additional important merit of the FIA systems. Moreover, the present FIA systems provide 2–10 times higher sensitivity than that of AAS. It can be said that FIA system B is more applicable than system A to a wide variety of salt samples as the former is superior to the latter with respect to the limit of determination and the tolerance level of co-existing metal ions. However, system A enables more rapid and simpler analysis than system B. The difference in the optimal salt concentration in the sample solution between the two systems is not so significant.

Flow-injection spectrophotometric determination of ascorbic acid in pharmaceutical products with the Prussian Blue reaction [1]

Joaquim A. Nóbrega *, Gisele S. Lopes

Grupo de Química Analítica, Departamento de Química, Universidade Federal de São Carlos, Caixa Postal 676, CEP 13565-905, São Carlos, SP, Brazil

Abstract

A lot of modern analytical strategies for exploiting chemistries have been developed by using flow-injection analysis. However, even after 20 years of flow-injection evolution, there still are new quantitative procedures being established using old qualitative assays. The formation of Prussian Blue is a classical test to detect Fe^{2+} using hexacyanoferrate(III) as a precipitating reagent. This reaction was evaluated for spectrophotometric determination of ascorbic acid employing Fe^{3+} and hexacyanoferrate(III) as chromogenic reagents. An excess of the complexing anion avoids the formation of precipitate and forms a deep blue solution when Fe^{3+} is reduced to Fe^{2+} by ascorbic acid. The maximum absorbance of the colored complex occurs at 700 nm and the molar absorptivity is 3.0×10^4 l mol^{-1} cm^{-1}. Under flow-injection conditions the Prussian Blue reaction was employed with an intermittent flow of an oxalate alkaline solution for removing the colored product adsorbed on tube and flow-cell walls. Reference solutions containing 5.0×10^{-6}–1.0×10^{-4} M of ascorbic acid were employed to obtain the analytical curve ($r = 0.9999$). For all solutions the relative standard deviation was lower than 1.0% ($n = 10$). Results obtained for ascorbic acid determination in pharmaceutical products (Cewin, Redoxon and Cebion) are in good agreement with those obtained by using a flow-injection procedure involving the reaction between triiodide and ascorbic acid. The sampling frequency is 140 h^{-1} and only 430 μl of reagents is consumed in each determination.

1. Introduction

Ascorbic acid (Vitamin C) is essential for the development and regeneration of muscles, bones, teeth and skin. Vitamin C has also been used for the treatment of the common cold, mental illness, infertility, cancer and AIDS [1]. Many analytical methodologies have been proposed for the deter-

* Corresponding author. Fax: +55 162 74 8350; e-mail: djan@power.ufscar.br
[1] Presented at the Seventh International Conference on Flow Injection Analysis (ICFIA '95), held in Seattle, WA, USA, August 13–17, 1995.

mination of ascorbic acid taking into account its chemical role. Redox processes are generally involved in these determinations and it is possible to minimize air oxidation by using techniques such as flow injection (FI). The FI systems proposed are mainly based on electroanalytical detectors due to inherent redox chemistry of the analyte and reagents. Optical FI methods also involve redox reactions with ascorbic acid in which a colored compound is formed or decomposed. Thus, the formation of ferroin complex from the reduction of Fe(III)–phenanthroline [2] and a method using chloramine T in the presence of starch–KI solution [3] were adapted to flow systems. Descolorimetry was also employed by reduction of cerium(IV) [4] and by reduction of triiodide [5]. This last paper involves the on-line formation of iodine and the measurement of the inverse peaks caused by the excess of triiodide at 350 nm or the triiodide/starch complex at 580 nm.

The objective of the present work was to adapt the Prussian Blue reaction for the determination of ascorbic acid. The formation of Prussian Blue is a classical qualitative test to detect Fe(II) using hexacyanoferrate(III) as reagent [6]. The first step is the oxidation of iron(II):

$$Fe^{2+} + [Fe(CN)_6]^{3-} \rightarrow Fe^{3+} + [Fe(CN)_6]^{4-} \qquad (1)$$
The second step is the formation of hexacyanoferrate(II) ferric complex (Prussian Blue):

$$4Fe^{3+} + 3[Fe(CN)_6]^{4-} \rightarrow Fe_4[Fe(CN)_6]_{3(s)} \qquad (2)$$
The complex formed is highly insoluble ($K_s = 3.0 \times 10^{-41}$; Ref. [7]). Employing an excess of the complexing anion and Fe(III) as colorimetric reagents, a deep blue soluble compound is formed when Fe(III) is reduced to Fe(II) by ascorbic acid:

$$2Fe^{3+} + C_6H_8O_6 \rightarrow 2Fe^{2+} + C_6H_6O_6 + 2H^+ \qquad (3)$$
The excess of hexacyanoferrate(III) avoids the occurrence of precipitation [6]. The procedure was successfully applied for the determination of ascorbic acid in pharmaceutical products.

2. Experimental

2.1. Apparatus

An eight-channel Ismatec peristaltic pump (model 7618-40, Switzerland) fitted with Tygon pump tubing was used for propulsion of fluids. The manifolds were constructed with polyethylene tubing (0.8 mm i.d.). Sample injection was done by using a laboratory-constructed three-piece manual commutator [8] made of Perspex, with two side bars and a sliding central bar which is moved for sampling and injection.

The UV-visible absorption spectra were obtained with a diode array spectrophotometer (Hewlett-Packard, model 8452A, USA) using a quartz cuvette with an optical path of 1.0 cm. All flow measurements were carried out using a Femto spectrophotometer (model 435, Brazil) with a glass flow-cell (optical path 1.0 cm). This equipment was connected to a two-channel strip-chart recorder (Cole–Parmer model 12020000, USA).

2.2. Reagents, analytical solutions and sample preparation

All reagents were of analytical-reagent grade and all solutions were prepared using distilled-deionized water.

Reference solutions containing from 5.0×10^{-6} to 1.0×10^{-4} M ascorbic acid were prepared immediately before use by dilution of a 1.0×10^{-2} M stock solution in a 0.014 M nitric acid medium with deaerated water, because ascorbic acid oxidation is slower in acidic medium. The effect of acidity on sensitivity was evaluated using 0.014 and 0.14 M nitric acid solutions.

The Fe(III) reagent was prepared by dissolving iron(III) nitrate salt in 0.014 M nitric acid in the following concentrations: 1.0×10^{-4}, 5.0×10^{-3}, 1.0×10^{-3}, and 1.0×10^{-2} M, for the evaluation of the effect of Fe(III) concentration on sensitivity. The hexacyanoferrate(III) solutions (5.0×10^{-2} and 5.0×10^{-3} M) were prepared by dissolving the potassium salt in water.

A complexing solution containing 0.5% w/v oxalic acid in 0.1 M sodium hydroxide was em-

ployed for removing the blue complex adsorbed on the tube and flow-cell walls.

The triiodide procedure was implemented by using solutions containing 8.0×10^{-2} M potassium iodide and 5.0×10^{-5} potassium iodate. A 1.0×10^{-3} M sulfuric acid solution was employed as carrier.

Three solutions of pharmaceutical products (Cewin, Redoxon, and Cebion) were prepared by dissolving suitable amounts of the commercial liquid samples in 0.014 M nitric acid solution and diluting the resulting solution to adjust the concentration to that required by the experimental conditions adopted. A solid product (Supradyn) was also analysed after grinding and dissolution in 0.014 M nitric acid solution.

2.3. Procedure

Fig. 1 shows a schematic flow diagram in which chromogenic reagents (R_1: 1.0×10^{-3} M Fe^{3+} and R_2: 5.0×10^{-3} M $[Fe(CN)_6]^{3-}$) were introduced by confluence and the carrier stream is a 0.014 M nitric acid solution. As can be seen in Fig. 1, during the sampling state, i.e. while the sample loop is filled, the intermittent flow of alkaline oxalate solution is introduced and the
Fig. 1. Flow diagram with colorimetric reagents (R_1 and R_2) introduced by confluence (x and y points). B_1 and B_2 are reactors of 150 and 100 cm respectively. L is a sample loop of 100 cm. C, carrier stream; W, waste; S, sample or reference solution. R_3 is an intermittent flow of an alkaline oxalate solution. Numbers between parentheses represent the flow rates.
Fig. 2. Flow diagram adapted from Hernández-Méndez et al. [5]. C is a 1.0×10^{-3} M sulfuric acid solution flowing at 3.0 ml min^{-1}, R_1 is a potassium iodide solution and R_2 is a potassium iodate solution, both flowing at 1.5 ml min^{-1}. B_1 and B_2 are reactors of 300 and 150 cm respectively. E, spectrophotometer; W, waste; S, sample or reference solution. L is a sample loop of 100 cm.

adsorbed complex on the flow-cell walls is removed. After commutation, ascorbic acid solution is injected and the alkaline oxalate solution remained recycled. The blue compound formed was measured at a wavelength of 700 nm.

For comparison of results the triiodide procedure proposed by Hernández-Méndez et al. [5] was adapted. Iodine is generated in the flow system (Fig. 2) as triiodide ion by reaction between iodide and iodate in a long reactor (B_1) and a steady spectrophotometric signal is measured at 350 nm. After injecting ascorbic acid, the excess of triiodide is measured by inverse peaks that reflect consumption of triiodide by the redox reaction between ascorbate and triiodide.

3. Results and discussion

Considering that the Prussian Blue reaction had been employed only in qualitative tests, a first experiment was made to obtain the UV–visible absorption spectrum of this compound. Fig. 3a shows the absorption spectrum for chromogenic reagents, i.e., Fe(III) mixed with hexacyanoferrate(III), and a strong absorption band can be observed in the UV region and a weaker band with wavelength peak at 420 nm, which is related to the formation of the brown complex hexacyanoferrate(III) ferric [6]. After adding ascorbic

(a)

(b)
Fig. 3. UV–visible absorption spectra. (a) Chromatogenic reagents: Fe(III) plus hexacyanoferrate(III). (b) Chromatogenic reagents as for (a) plus ascorbic acid.

acid to this mixture, the absorption spectrum changed as can be seen in Fig. 3b due to the formation of Prussian Blue ($Fe_4[Fe(CN)_6]_3$), with an absorbance peak at 700 nm. The experimentally determined molar absorptivity of the complex compound formed is 3.0×10^4 l mol^{-1} cm^{-1}. Taking into account this value of molar absorptivity, it can be estimated [9] that if the minimum absorbance to be measured is 0.010 and the optical path is 1.0 cm, the lowest concentration of ascorbic acid that can be spectrophotomet-

rically determined is approximately 3×10^{-7} M.

The first flow diagram projected involved the transport of the injected solution of ascorbic acid by a carrier stream and the introduction of chromogenic reagents at confluence points, such as that shown in Fig. 1. After less than 1 h of measurements, the extension tubes and the glass flow-cell walls were strongly impregnated by the blue compound and a gradual increment in the baseline was observed. This problem was aggravated when relatively concentrated ascorbic acid

solutions were introduced, e.g. after injecting a 1.0×10^{-4} M solution the absorbance of the baseline was increased by 10%. Thus, accumulation of the blue complex on the tube and flow-cell walls should be avoided. The hexacyanoferrate(III) ferric complex is soluble in an alkaline oxalate solution [6] and this solution was evaluated to circumvent complex adsorption. When this solution was introduced as a confluent reagent, the formation of the blue complex did not occur. This effect can be explained by considering the complexing capacity of oxalate for both iron redox forms and the fact that oxalate concentration was higher than hexacyanoferrate(III) concentration. In subsequent experiments, oxalate solution was introduced as an intermittent flow after the measurement of the signal maximum (Fig. 1). It was observed that the sensitivity was critically dependent on the location of the confluence point. When the intermittent flow was introduced immediately after the injection point a strong decrease in sensitivity was observed and this can be explained by considering the merging caused by dispersion between the rear zone of the oxalate solution and the front zone of the sample. To avoid this deleterious effect, the penetration between oxalate and sample zones should be minimized, and this can be attained by changing the location of the confluence point. An increase in sensitivity was experimentally observed by increasing the reactor length between the sample injection point and the oxalate introduction point. Best sensitivity was achieved when the confluence point was put 10

Table 1
Ascorbic acid concentrations in pharmaceutical products and standard deviations ($n = 5$) as determined by the proposed procedure and the triiodide procedure [5]

Sample	Proposed procedure (% w/v)	Triiodide procedure (% w v)
Cewin	21.8 ± 0.10	22.6 ± 0.20
Redoxon	22.4 ± 0.10	21.6 ± 0.20
Cebion	23.4 ± 0.20	24.2 ± 0.10

cm before the flow cell. Using this flow diagram, sensitivity was not affected and baseline stability was accomplished. It should be mentioned that desorption processes of the blue complex adsorbed on the B_2 reactor caused loss of precision in experiments with concentrated ascorbic acid solutions. However, for ascorbic acid concentrations in the range 10^{-4}–10^{-5} mol l^{-1} this effect did not happen.

The effect of Fe(III) concentration was also evaluated. In the proposed methodology, Fe(III) concentration should be higher than ascorbic acid concentration. Additionally, the sensitivity and reproducibility should not be negatively affected. Low concentrations of Fe(III), such as 1.0×10^{-4} M, caused a strong decrease in sensitivity. However, higher concentrations of Fe(III), such as 5.0×10^{-3} M, caused a loss of linearity, probably due to bad reproducibility caused by desorption processes, which are more critical when the formation of the blue compound is increased. Considering the compromise between sensitivity and linearity, all further measurements were made employing a 1.0×10^{-3} M Fe(III) solution. Taking into account these same effects, hexacyanoferrate(III) concentration was fixed at 5.0×10^{-3} M, which is five-fold higher than the Fe(III) concentration, to avoid the precipitation of the blue compound formed [6].

The acidity effect was evaluated by changing the composition of the carrier stream. When 0.14 M nitric acid was used as carrier the sensitivity decreased, and this effect can be related to higher protonation of ascorbic acid in this medium, since the reducing agent is the ascorbate anion [10]. Best results were attained by using a solution containing 0.14 M nitric acid as carrier stream. This is also suitable for sample preparation because ascorbic acid oxidation is slow in acid medium.

Using the established conditions, the sampling frequency is 140 h^{-1} and the relative standard deviation was 0.65% for a solution containing 6.0×10^{-5} M ascorbic acid ($n = 10$). This compound was determined in three samples of pharmaceutical products (Table 1). Results obtained by the proposed procedure are in good agreement with those established us-

ing a previously proposed procedure [5] and with label values. For Supradyn, which is a polyvitaminic compound, positive errors were observed in ascorbic acid determination and this can be explained by considering the presence of Vitamin E which is also a reducing agent [11] and acted as interferent. Some preliminary results obtained for determining ascorbic acid in natural and artificial tropical fruit juices also showed positive errors, probably caused by citric acid. These interference effects are being critically assessed for evaluating other samples that could be analyzed by the Prussian Blue procedure.

Lead preconcentration onto C-18 minicolumn in continuous flow and its determination in biological and vegetable samples by flame atomic absorption spectrometry[1]

Rosimar Lima, Katia Christina Leandro, Ricardo Erthal Santelli*

Geochemistry Department, Federal Fluminense University, Niteroi, Rio de Janeiro 24020-007, Brazil

Abstract

A procedure for the preconcentration and determination of lead in vegetable and biological samples was developed in the continuous mode coupled to a flame atomic absorption spectrometer. Lead is quantitatively preconcentrated in acetic buffer as its diethyldithiocarbamate chelate onto a C-18 minicolumn, placed in the loop of a proportional injector, eluted by a stream of methyl isobutyl ketone and introduced directly into the nebuliser. A detection limit of $3 \ \mu g \ l^{-1}$ is obtained using a time-based technique for 2 min preconcentration and an RSD of 3.8% was readily achieved for three measurements of $25 \ \mu g \ Pb \ l^{-1}$. The sample throughput is $24 \ h^{-1}$. Using preconcentration times of 10 min an enrichment factor of 189 can be obtained. The continuous flow system was used for some reference sample analysis and the obtained results reveal that the methodology can be easily applied for vegetable and biological sample analysis.

1. Introduction

Solid phase extraction (SPE) has long been used in chromatography for separations and, more recently, in continuous flow analysis for both separation and preconcentration. Since its introduction in analytical chemistry several years ago [1], modified silica with hydrocarbon chains has been employed for trace metal preconcentra-

tion, after on-line chelation with a suitable reagent. Rapid extraction is generally ensured because the coating is very thin (typically in the range $10–100 \ \mu m$) and therefore the sample flow rate can be higher. As the neutral forms of analytes are more efficiently extracted by non-ionic polymeric coatings, the pH of the aqueous sample must be adjusted to prevent analyte ionization [2]. SPE has a number of attractive features compared with the traditional extraction technique. It is fairly simple, inexpensive, can be used in the field, needs relatively little toxic solvents, and can be easily automated [2]. Notwithstanding these ad-

---

vantages, for trace metal analysis in flow systems it was used primarily for water samples and its application to other matrices has not been widely reported.

Lead, even at very low concentrations, is a well-known toxic element for animals and humans. For humans, the main lead sources are water and food, and therefore rapid and sensitive methods must be accessible for its determination in these samples [3].

The advantage of continuous automatic techniques such as flow analysis are particularly attractive when extensive manipulation is involved in a given determination, as is the case in preconcentration procedures [4,5]. Flow systems have also been successfully proposed for metal preconcentration, employing several techniques, e.g. solvent extraction [6], precipitation–dissolution [7], activated carbon [5,8], activated alumina [9], ion-exchange [10], cellulose sorbent [11] and fullerenes [12,13]. Regarding lead determination, bonded silica was used for the establishment of several analytical methods. Ruzicka and Arndal [14] were the first to explore the analytical potential of C-18 for lead preconcentration in the continuous mode employing two flow systems. In the first flow system a fixed volume of 4.0 ml of sample solution containing 1 mg l^{-1} lead was introduced, giving a preconcentration factor of 5.6 with a detection limit of only 0.1 mg l^{-1}. In another flow system based on sample time loading a preconcentration factor of 60 was obtained using a 40 ml sample volume. In this way a detection limit of 0.01 mg l^{-1} was attained. Fang et al. [15] proposed a flow system coupled to a graphite furnace atomic absorption spectrometer (GFAAS) using a microcolumn containing only 15 μl of sorbent. A preconcentration factor of 26 was obtained using 2.1 ml of sample solution and the methodology was tested in spiked sea water. Similarly, Porta et al. [16], employing a C-18 microcolumn, obtained recoveries of 92 ± 10% for lead from spiked sea water, but a double elution was necessary to obtain these results. In other studies, Sperling et al. [17] and Welz et al. [18], improving lead preconcentration from real sea water, obtained an enhancement factor of 20. In another paper, the research group of Welz et al. [19] obtained a

preconcentration factor of 64 using a microcolumn containing 9 μl of C-18 connected to a GFAAS. Berndt et al. [20], using high-performance flow atomic spectrometry, obtained a detection improvement of 48 times when coupling a C-18 minicolumn for the analysis of drinking water. All of these workers used diethyldithiocarbamates as chelating reagents.

The aim of this work was the development of a preconcentration flow system methodology for lead determination by flame atomic absorption spectrometry for vegetable and biological sample analysis. Diethylammonium N,N-diethyldithiocarbamate (DDTC) was selected as the lead chelation agent in acetic medium and C-18 as the solid phase extractor.

2. Experimental

2.1. Apparatus

A Perkin-Elmer 3100 atomic absorption spectrometer equipped with a hollow cathode lead lamp and a deuterium background corrector was used. The instrument was set at a wavelength of 217 nm and the air–acetylene flame was adjusted according to the manufacturer's recommendations. An Ismatec MP-13R peristaltic pump was used with Tygon tubes for the propelling system. A proportional injector–commutator made of PTFE was operated for selecting both the preconcentration and elution steps. The sorption minicolumn was made by packing a PTFE tube (3 cm long × 2 mm i.d.) with about 100 mg of C-18 and small glass wool beads at the ends to prevent material losses. This minicolumn was initially flushed with methanol and subsequently with methyl isobutyl ketone before use. After each elution cycle it was ready for re-use without further treatment. The transient signals were measured with a single pen record (RB-201, Equipamentos Cientificos do Brasil).

2.2. Reagents

Analytical-reagent grade reagents were always used as well as distilled, deionized water.

A 1000 μg ml^{-1} lead stock solution was prepared by dissolving 1.598 g of lead nitrate in water containing 30 ml of 65% HNO$_3$ and making up the volume to 1000 ml. The lead calibration solutions, containing 10% v/v of the buffer solution, were prepared daily by appropriate dilution of the stock solution.

Diethylammonium N,N-diethyldithiocarbamate was prepared daily at a concentration of 0.1% w/v.

Acetic acid buffer solution, pH 4.6, was prepared by adding 60 ml of glacial acetic acid to 800 ml of water, adjusting the pH to 4.6 with 57% ammonium hydroxide and making up the volume to 1000 ml with water.

Modified silica C-18 from commercially available Sep-Pak cartridges (Waters) was used to prepare the minicolumn.

Methyl isobutyl ketone and acetylene (atomic absorption grade) were also used.

2.3. Flow system

A flow system was built to perform the lead preconcentration and determination steps, as shown in Fig. 1. In the preconcentration step, the sample (S) merges with the reagent stream (R) and the lead–diethyldithiocarbamate complex formed in the reaction coil (RC) is retained by the C-18 while it passes through the minicolumn. At the same time, methyl isobutyl ketone (MIBK) fills the loop (L) and water (C) flows through the atomic absorption nebulizer (AAS). By switching the commutator (I), a small volume (20 μl) of
Fig. 1. Flow system for preconcentration and determination of lead. S, sample solution in acetic acid buffer (4.0 ml min^{-1}); R, reagent (0.27 ml min^{-1}); L, loop of MIBK (380 μl); C, carrier (water, 3.0 ml min^{-1}); RC, reactor coil (200 cm); C-18, minicolumn; W, waste; AAS, flame atomic absorption spectrometer.

water washes the minicolumn and water (C) displaces the MIBK from the loop (L) and flows through the C-18 minicolumn. The lead complex goes through the AAS nebulizer producing a transient signal. Peak height was always used as the measurement parameter.

3. Results and discussion

3.1. Chemical and flow optimizations

The system depicted in Fig. 1 was studied in relation to chemical and flow variables (univariate method) in order to obtain the best analytical conditions. The sample pH was tested within the range 2.8–8.1. Best results were obtained at pH 4.6 in acetic acid buffer medium. The reagent concentration was investigated between 0.0001 and 0.2% (w/v), and the highest signals were found at concentrations higher than 0.01%. In order to prevent some interferences due to the presence of other metallic species the reagent concentration was chosen to be 0.1%. The sample flow rate was studied in the range 2–7.5 ml min^{-1}. Flow rates of $\leqslant$ 4 ml min^{-1} revealed maximum absorbance signals, but analyte losses were observed at flow rates higher than 4 ml min^{-1}, owing to short residence times which entail incomplete retention. Therefore, this parameter was adjusted to 4 ml min^{-1} for future optimization. The reagent flow rate was tested in the range 0.07–0.6 ml min^{-1}. For flow rates lower than 0.27 ml min^{-1} incomplete retention was observed due to the lack of the reagent. With flow rates higher than 0.27 ml min^{-1} the system shows higher and reproducible signals. We do not recommend higher flow rates due to the possibility of reducing the sample flow rate and lowering the sample throughput. Therefore a reagent flow rate of 0.27 ml min^{-1} was selected. The carrier flow rate was adjusted to 3 ml min^{-1} to give better nebulization of the organic phase. The reactor coil length was investigated in the range 14–250 cm and the best complex formation was observed with a 200 cm coil length. A reactor coil length < 200 cm did not ensure sufficient residence time which is required for lead complexation by di-
Fig. 2. Selection of the eluent. Blank and net absorbance signals obtained when eluting the lead chelate after a preconcentration time of 2 min (8.0 ml sample volume) for 100 μg Pb^{2-} l^{-1}: A, methanol; B, butanol; C, ethanol; D, dichloroethane; E, N,N-dimethylformamide; F, acetylacetone; G, methyl ethyl ketone; H, carbon tetrachloride; I, methyl isobutyl ketone.

ethyldithiocarbamate. With a reaction coil length of > 200 cm the absorbance signals remained higher and constant. A study for the choice of the best eluent was done using several organic solvents. Methanol, butanol, ethanol, dichloroethane, N,N-dimethylformamide, acetylacetone, methyl ethyl ketone, carbon tetrachloride and methyl isobutyl ketone were assayed. The results can be seen in Fig. 2. Water-miscible solvents give bad results, probably because they mix with the water carrier. For the immiscible organic solvents studied (with the exception of MIBK) the blank signals were so high that these solvents were useless for this purpose. Best conditions were obtained with MIBK (low blank with high analytical signals). Also, the minimum volume of MIBK necessary to displace the complex from the C-18 minicolumn was evaluated to be within the range 250–500 μl. The highest absorbance signal was obtained with 380 μl of MIBK which gives better recoveries without any peak carryover. In order to use a less toxic organic solvent 380 μl of MIBK was chosen for the lead complex elution.

3.2. Interference study

The effect of the concomitants was studied with analytical lead solutions prepared with and with-

out each interferent species. Co(II), Ni(II) and Cr(VI) did not interfere up to an interferent/analyte ratio of 100. Cu(II) did not affect the lead signal if the interferent/analyte ratio was not higher than 10. These ratios are never obtained with real samples such as those analyzed in this work.

Interference studies were also done using real samples. For this test, two vegetable samples (almond leaves) and one biological sample (fish tissue) were prepared. The almond leaves were collected from two different areas: an urban area with heavy traffic and a rural area. The leaves were washed with water, dried at air temperature and ground using a knife grinder. The fish tissue was lyophilized and ground using the same knife grinder. These samples were homogenized and stored in plastic bottles inside a dessicator. With solutions of these samples, prepared as described in Section 3.3, addition curves were constructed using the flow system depicted in Fig. 1. The ratios of the slopes of the addition curves and the analytical curves (aqueous standards) varied from 0.994 to 1.01, showing that trace metals present at their normal concentration levels in these samples do not influence the lead signals, and corroborating the fact that there is no influence from these matrices in the lead preconcentration and determination steps.

3.3. Sample preparation

The samples used for the interference study and the reference sample materials analyzed with the developed methodology were decomposed by wet ashing with acid treatment, based on the study of Icbinoki and Yamazaki [21]. Before analysis all samples were dried at 120°C for 24 h. The weighed samples (the weights depend on the lead content) were placed in a Pyrex beaker and after the addition of 15 ml of 65% nitric acid, the covered beaker was allowed to stand for one night. Then, the samples were heated slowly on a hotplate until they became transparent (colorless or pale yellow). Then 5 ml of 72% perchloric acid was added and the heating was continued until the liquor became colorless (until complete wet ashing of the organic mater). The solution was

then heated almost to dryness. After cooling, the residue was extracted with the buffer solution, filtered, and the volume made up with water, maintaining the 10% v/v buffer solution concentration. These samples were analyzed immediately after dissolution. A blank solution was prepared for each sample batch dissolution and was used to prepare the analytical lead solutions for calibrations.

During the sample preparation step it was noted that if any organic matter remains, a big interference occurs because lead remains bonded to the original organic matter and therefore is not able to react with the diethyldithiocarbamate. However, the minicolumn is also able to retain neutral organic matter, competing with the Pb–DDTC complex in the sorption processes. This results in a very small recovery of lead from the samples. Therefore, the implementation of a sample preparation step involving $HClO_4$ was needed and according to Gorsuch [22] this treatment is the best way to oxidise all traces of organic matter from real samples.

3.4. Analytical features

Using the flow system of Fig. 1, lead can be determined in the range 20–100 $\mu g\ l^{-1}$ with time-based sampling for only 2 min, equivalent to a sample volume of 8 ml (sample flow rate of 4.0 ml min^{-1}). The calibration equations are typically $A = -0.001 + 3.005 \times 10^{-3}$ [Pb($\mu g\ l^{-1}$)] with $r^2 = 0.998$. The detection limit calculated as three times the standard deviation of the peak absorbance was 3 μg Pb l^{-1}. The RSD at the 25 μg l^{-1} level was 3.8% for all three measurements. The sample throughput was 24 h^{-1}. Fig. 3 shows some typical peaks obtained using the flow system and a manual flame AAS signal. The flame transparency in the working wavelength region is uniquely responsible for the blank signal.

An enrichment factor of 60, calculated as the ratio between the slopes of the calibration graphs obtained by this flow method and the manual direct aspirations, was readily achieved. By using a 10 min preconcentration time, enrichment factors as high as 189 can be obtained, which ensure the lowering of the detection limit by a factor of
Fig. 3. Typical absorbance signals (FIA peaks) obtained with the flow system in Fig. 1 using a preconcentration time of 2 min (8.0 ml of sample volume loading): A, signal obtained when aqueous solution containing 4 μg Pb^{2+} ml^{-1} was introduced into the FAAS using direct aspiration; B, blank; C, 20 μg Pb^{2+} l^{-1}; D, 100 μg Pb^{2+} l^{-1}.

three. These values are bigger than those obtained by comparing only volumes of sample and eluent (≈ 20) due to the faster complex elution and due to the very low dispersion of the organic phase (380 μl of MIBK pumped at 3.0 ml min^{-1} by a water stream crossing only 25 cm × 0.5 mm i.d. tubing to get ahead of the AAS nebulizer).

3.5. Determination of trace amounts of lead in vegetable and biological samples

The developed methodology was used for lead determination in almond leaves, fish tissue and for some reference sample analysis. For this purpose, each sample was mineralized in duplicate as described in Section 3.3 together with similar blanks which allowed for the contribution of the lead present in the reagents for the digestion procedure. Each dissolved sample was analyzed in triplicate (except for the fish flesh sample). These

Table 1
Results obtained for lead determination in the analysis of almond leaves and fish tissue. Results in $\mu g\ g^{-1}$ for dry samples

Sample	Analytical curve	Standard addition
Almond leaves 1	1.72 ± 0.03	1.61 ± 0.03
Almond leaves 2	1.15 ± 0.02	1.18 ± 0.02
Fish tissue	3.45 ± 0.06	3.22 ± 0.06

Table 2
Results obtained for the analysis of reference sample materials. Results in $\mu g\ g^{-1}$ for dry sample

Reference sample	Obtained values	Certified values
Citrus leaves (NIST)	$13.2 \pm 0.3\ (n = 3)$	13.3
Fish tissue MA-B-3/TM (IAEA)	$4.74 \pm 0.03\ (n = 3)$	4.62 $(3.85–5.13)^a$
Copepoda MA-A-1/TM (IAEA)	$2.1 \pm 0.1\ (n = 3)$	2.1 $(1.8–2.4)^a$
Fish flesh MA-A-2/TM (IAEA)	$0.80 \pm 0.02\ (n = 2)$	0.58 $(0.51–0.65)^a$

^{a} Confidence interval.

results can be seen in Table 1 and Table 2. The results found for the almond leaf samples and for the fish tissue, when compared with the standard addition methods, are consistent and acceptable in all instances. The two samples of almond leaves (collected at different sites) had the same lead content, probably due to the fact that this species is not a good pathfinder for lead (not recommended for biogeochemistry prospecting) or owing to a large lead scattering. However, the results obtained for the reference samples agreed very well with the certified values, corroborating the fact that the developed methodology can be applied for lead preconcentration and determination in vegetable and biological analysis. The concomitants did not influence the analytical signal due to their very low concentrations in the real samples analyzed.

Our methodology, when compared to another published previously, shows some similarities and differences. In the work of Peña et al. [8] the performance of the activated carbon minicolumn was similar to that in this work. The analytical range was extended but the detection limit was worst than that obtained by us, assuming the same preconcentration time. Peña et al. found similarities when they compared their results with results obtained by C-18 sorbent extraction. Naghmush et al. [11], using different cellulose

sorbents, detected some interferences due to the presence of Fe(III), Cu(II), Ca, Mg, K and Na. Their method was applied successfully for water samples and showed very low detection limits $(0.17\ \mu g\ l^{-1})$ when employing 50 ml of sample (six times more than that used in this work). Yebra Biurrum et al. [10] found a similar detection limit $(3.1\ \mu g\ l^{-1})$ using only 2 ml sample volume when employing a new chelating resin (containing polyaminophosphonic acid as chelating group) synthesized by their research group.

4. Conclusion

In conclusion, the developed methodology can be easily applied for vegetable and biological sample analysis for lead determination with good selectivity, reproducibility and accuracy. Our methodology is also comparable with techniques such as GFAAS, especially in terms of time and detection limit, and is advantageous for laboratories seeking cheaper analysis methods.

Abstract

The objective of the present work was the evaluation and characterization of a glassy carbon (GC) electrode modified by a bilayer lipid membrane (BLM) with incorporated single-stranded deoxyribonucleic acid (ss DNA). Various procedures were developed and tested for the incorporation of ss DNA at the electrode modified by the lipidic membrane:

1. formation of self-assembled BLMs over ss DNA adsorbed on the electrode surface;
2. direct adsorption of ss DNA into a BLM modified GC electrode;
3. formation of a BLM with incorporated ss DNA at the electrode surface using the monolayer folding technique.

Differential pulse voltammetry (i.e. oxidation of guanine and adenine residues) was used to monitor the incorporation of ss DNA at the GC electrode modified by the BLM. The results have shown that the lipid membrane enhances the stability of ss DNA during a "medium-exchange" of the electrode and prohibits its diffusion from the electrode surface. The third scheme was proven to be the most appropriate as both electrode modification by the BLM and DNA adsorption occur in one stage and much faster (as no BLM thinning process is required) as compared to the former two techniques; furthermore, maximized loading of DNA in BLMs is achieved which reduces by ca. 10-fold the DNA amounts that can be detected electrochemically. Conventional planar "free-suspended" and self-assembled metal supported BLMs were used to monitor in situ the incorporation of ss DNA in these membranes. The results have shown that the adsorption of ss DNA at lipid membranes (as a medium for DNA incorporation on an electrode surface) can occur much faster, using milder conditions and smaller amounts of DNA than by previously described techniques.

Keywords: Bilayer lipid membranes; Chemically modified electrode; DNA; Glassy carbon electrode

1. Introduction

A growing interest has recently arisen in the development of DNA sensors which are expected

* Corresponding author.

eventually to replace conventional methods in gene diagnoses using nucleic acid hybridization techniques for infectious diseases. DNA biosensors that are being developed presently are based largely on piezoelectric, electrochemical, or opti-

cal transducers. Brabec and Palecek have pioneered the electrochemistry of nucleic acids and their adsorption/oxidation at different types of carbon electrodes [1] and this type of transduction scheme has gained popularity with substantial achievements in the field of biosensing. Such achievements include sequence-specific gene detection with DNA modified electrodes [2,3], selective detection of cystic fibrosis using modified carbon electrodes to which DNA was covalently bound [4,5] and differential pulse voltammetric determination of traces (picomole range) of RNA in the presence of DNA and nucleic acid components [6]; the detection limit was recently improved to the femtomole range by using constant current potentiometric analysis at carbon paste electrodes; this may open doors for investigating structural transitions and interactions of RNA [7]. A number of studies have been reported in the literature concerning the adsorption of single-stranded DNA (ss DNA) at bare (unmodified) carbon electrodes [2,8]. This type of DNA adsorption results in the use of long adsorption times (more than 30 min) under vigorous conditions (i.e. high temperatures [2] or potentials [8]), whereas great concerns have arisen on the stability of adsorbed DNA during "medium-exchange" experiments.

The goal of our work is to investigate the use of lipid membranes either for the modification of carbon electrodes for improved incorporation of DNA or as transducers to monitor directly DNA hybridization, since lipids are known to associate with DNA with high affinity [9] and therefore create a biosensor for rapid nucleic acid detection. The work herein reports the evaluation and characterization of a glassy carbon (GC) electrode modified by a bilayer lipid membrane (BLM) with incorporated ss DNA. Several procedures were used in the present studies to modify the glassy carbon electrode with lipid membranes for ss DNA incorporation. Results from direct ss DNA adsorption from solution on a GC modified electrode and the stability of adsorbed DNA during a medium-exchange of the electrode are described herein. Examples of the use of BLM systems to monitor directly the incorporation of ss DNA in membranes are provided.

2. Experimental

2.1. Materials and apparatus

The lipid used throughout this study was egg phosphatidylcholine (egg PC; lyophilized, Avanti Biochemicals, Birmingham, AL, USA). Gramicidin D was supplied from Sigma Chemical Co. (St. Louis, MO, USA). Calf thymus DNA (sodium salt, type I) was also obtained from Sigma Chemical Co. and was used without further purification. Silver wires (diameters 0.5 and 1.0 mm) were obtained from Aldrich Chemical Co., Inc. (Milwaukee, WI, USA). All other reagents were of analytical-reagent grade. Water was purified using a Milli-Q cartridge filtration system (Millipore, El Paso, TX, USA) and had a minimum resistivity of 18 MΩ cm.

Single-stranded DNA (ss DNA) was prepared by the following procedure. An accurately weighed sample of approximately 3 mg of calf thymus DNA was treated with 0.5 ml of pure perchloric acid and stirred to dissolve for 10 min. A volume of 0.5 ml of 9 M NaOH was then added to neutralize the solution, followed by the addition of 0.1 M KCl electrolyte solution such that the final volume was 10 ml and the pH value 5.5. The resulting solution of ss DNA was scanned from 220 to 300 nm (using a Hitachi U-2000 spectrophotometer) and the absorbance at 260 nm was found to be 0.219, whereas the absorbance of a solution containing 3 mg native DNA (not denatured) was found to be 0.040. These data can not be used to calculate the concentration of ss DNA in solution; however, they indicate that denaturation has occurred [10].

The differential pulse voltammograms were recorded using a μAutolab potentiostat/galvanostat running with model GPES version 3 software, from Eco-Chemie, The Netherlands. The potential range studied was from +0.025 to +1.4 V vs. SCE, and the differential pulse voltammetry conditions were pulse amplitude, 50 mV; pulse width, 70 ms; interval time, 400 ms; and scan rate, 5 mV s^{-1}. A one-compartment cell contained a GC electrode (Tokai, GC, area 0.07 cm^2), a platinum gauze counter electrode and a SCE reference

electrode. The working electrode was polished with diamond paste down to 1 μm particle size on a polishing table before use and thoroughly cleaned; it was repolished as necessary, and always between adsorption experiments.

The equipment for the formation of conventional planar "free-suspended" solventless BLMs have been described in detail elsewhere [11]. BLMs were formed in an aperture of 0.32 mm diameter in a Saran-Wrap (PVDC; DowBrands, L. P., Indianapolis, IN, USA) partition of thickness ca. 10 μm that separated two identical Plexiglas chambers (each with volume of 10 ml and an air/water interface of 3 cm^2) and were supported in a 0.1 M KCl electrolyte solution. A two-electrode configuration was used throughout the experiments using self-assembled BLMs (s-BLMs) and consisted of a sensing electrode (i.e. silver wire of 0.5 or 1.0 mm diameter with a s-BLM) and a Ag/AgCl electrode acting as a reference. A 25 mV dc voltage was applied across the membrane between two Ag/AgCl reference electrodes when using the former technique of free-suspended BLMs, whereas a 25 mV dc potential was applied between the sensing and reference electrode when using the metal-supported s-BLMs (above and beyond the open circuit potential of this electrode system). A digital electrometer (Model 614, Keithley Instruments, Cleveland, OH, USA) was used to measure the ionic current through the BLMs and as a current-to-voltage converter. The electrochemical cell and electronic equipment were isolated in a grounded Faraday cage.

2.2. Procedures

A stock solution of PC (2.5 mg ml^{-1}) in n-hexane was used for the preparation of a dilute PC solution (0.2 mg ml^{-1}) in the same organic solvent on a daily basis; this stock lipid solution was stored in a nitrogen atmosphere at $-4°C$. Planar free-suspended BLMs were prepared by the application of a 10 μl volume of dilute lipid solution onto the electrolyte surface in the one cell compartment, and then over a period of a few seconds, the water level in one solution compartment was brought below the aperture

and then raised again with a disposable syringe [11]. When the ion current stabilized (over a period of about 5 min), the ss DNA solution was injected in one solution compartment using continuous gentle stirring. s-BLMs were constructed according to established techniques [12,13]. The stock PC solution (2.5 mg ml^{-1}) was used for the formation of metal supported s-BLMs. A lipid layer was deposited onto a nascent metallic surface cut with a scalpel just before or while immersing the metal wire into the lipid solution. The wire coated with the lipid solution was subsequently immersed into a 0.1 M KCl aqueous solution, and the ionic current was stabilized over a period of 25 or 40 min for diameters of silver wire of 0.5 or 1.0 mm, respectively. Ionic current stabilization was followed by injection of ss DNA solution while stirring continuously. All experiments were done at $25 \pm 1°C$.

3. Results and discussion

3.1. Characterization of BLM structure and the stability of lipid membranes on the solid electrodes

The Langmuir-Blodgett technique has previously been used to deposit a controlled number of lipid layers on glassy carbon electrodes [14,15]. However, the method of formation of stabilized metal supported s-BLMs as reported by Tien et al. [12,13] was chosen from various techniques owing to the simplicity and low cost of BLM preparation. The diameter of the wires that were used was found to play an important role in the time for BLM stabilization, and on the magnitude and noise of the background ion current. An increase in the diameter of the silver wires from 0.5 to 1.0 mm resulted in a decrease in the time for BLM stabilization from 40 to 25 min, respectively; furthermore, this increase resulted in an increase in the background ion currents and decrease in the noise levels. The impedance of BLM assemblies on metals is directly related to the noise levels and the stabilization time due to the packing effects of the BLMs, which depend on the diameter and the

degree of surface roughness of the wire used to support BLMs [13,16,17]. Any BLMs used for electroanalytical experimentation must be characterized to demonstrate the existence of the BLM structure. Specific capacitance is often used as the primary criterion for membrane characterization (i.e. to estimate the apparent thickness of the lipid bilayer and whether there is any solvent retained in the hydrocarbon region of the BLMs) [11]. The electrical capacitance of s-BLMs was measured as previously described [11] over time until a steady-state value was obtained. The steady-state value of membrane specific capacitance was found 4 mF cm^{-2} (for silver wire of 0.5 mm diameter) which is in agreement with previous reports [13,17]; however, this value can not be used to estimate the hydrocarbon thickness of the s-BLM, since the actual area of the bilayer is not known.

Chemical characterization of the bimolecular thickness of s-BLMs can be derived from the addition of gramicidin as this peptide transports monovalent cations through the membrane by the formation of ion-channels and the conductance increases many fold [11]. Gramicidin does not induce conductance alterations if the membrane is thicker than one bilayer [18,19]. The ion selectivity of BLMs containing gramicidin D for the transport of monovalent ions is greatest for ammonium and potassium ions relative to sodium and lithium [19]. Experiments using s-BLMs were done using 0.1 M NaCl as the electrolyte solution which provided a background ion current value of ca. 100 pA, whereas in the presence of 4 μM gramicidin the ion current increased to 166 nA. Similar experiments using KCl as the electrolyte have provided larger ion current increases. The bilayer structure of the lipid film on the glassy carbon electrodes was also verified by using gramicidin and 0.1 M KCl as the electrolyte; the ion current values were ca. 100 nA in the absence of gramicidin and increased to 1 μA in the presence of 1 μM gramicidin.

Cholesterol has been used extensively in lipid mixtures to prepare metal supported BLMs and it acts as a stabilizing agent [20]. The use of cholesterol to stabilize BLMs on solid electrodes was found to be unnecessary in our experiments as the lipid membranes prepared herein were stable for

long periods of time (routinely over 48 h) and were not prone to collapse in response to a mechanical or electrical shock. This is an advantage as compared to planar free-suspended BLMs which are normally stable for periods of time of ca. 6 h and suffer from mechanical or electrical instability [11].

3.2. BLM formation over ss DNA adsorbed on the electrode surface

The glassy carbon electrode was modified with ss DNA adsorbed at + 1.4 V [8]. The electrode with adsorbed ss DNA was then immersed in a solution containing PC (2.5 mg ml^{-1}) in n-hexane and the lipid layer was thinned into a bilayer by subsequent immersion in 0.1 M KCl for ca. 30 min. It was assumed that the ss DNA that was adsorbed on the electrode surface was covered by this bilayer. By scanning from 0.025 to 1.4 V, peaks corresponding to guanine and adenine were observed (Fig. 1).

These peaks continued to appear and were not reduced in magnitude when the BLM modified electrode with incorporated ss DNA was transferred to another 0.1 M KCl supporting electrolyte solution (medium-exchange procedure). These results show that the lipid membrane can strongly hold DNA molecules on the electrode
Fig. 1. Differential pulse voltammograms obtained in 0.1 M KCl supporting electrolyte: (a) two successive scans of a glassy carbon electrode modified by a lipid membrane on which ss DNA was adsorbed prior to BLM formation; (b) glassy carbon electrode without ss DNA.
Fig. 2. Differential pulse voltammograms obtained in 0.1 M KCl supporting electrolyte plus 27 μg ml^{-1} ss DNA: (a) glassy carbon electrode modified by a BLM, formed on the electrode surface in 0.1 M KCl solution prior to DNA addition to the electrolyte solution: (b) clean glassy carbon electrode.

surface [9,21] during medium-exchange procedures. Previous voltammetric studies of ss DNA adsorption at a GC electrode have shown that there is significant loss of DNA during medium-exchange of the electrode in a solution not containing ss DNA [8]. Recent studies have reported that electrochemical treatment of carbon electrodes may improve ss DNA adsorption [7].

3.3. Direct adsorption of ss DNA into a BLM modified GC electrode

The GC electrode was immersed in a solution containing PC (2.5 mg ml^{-1}) in n-hexane and the lipid layer was thinned into a bilayer by subsequent immersion in 0.1 M KCl for ca. 30 min. Small aliquots of ss DNA (6.5, 12, 14, 20, 25 and 27 μg ml^{-1}) were added to the KCl solution and the potential was scanned from 0.025 to 1.4 V. The results are shown in Fig. 2. Note that the solutions were gently stirred for 20 s after DNA addition and prior to potential scanning; this time was found to be sufficient to obtain maximized signal magnitude which is in agreement with the time of DNA incorporation obtained when using s-BLMs (vide infra).

The guanine (1.46 μA) and adenine (0.97 μA) peaks observed in Fig. 2(a) exhibit the direct

adsorption of ss DNA at the BLM modified GC electrode; no peaks were observed using a bare electrode dipped in a 0.1 M KCl solution containing 27 μg ml^{-1} ss DNA (Fig. 2(b)). The peak magnitude was decreased with a decrease of ss DNA concentration in solution, i.e. a peak magnitude of ca. 97 nA was observed when using a solution of ss DNA with a concentration of 6.5 μg ml^{-1}. These peaks continued to appear and were not reduced in magnitude during medium-exchange procedure.

3.4. Incorporation of ss DNA into BLM at a GC electrode using the monolayer folding technique

The monolayer folding technique [11] was used in order to maximise DNA loading in BLMs while the latter are deposited on the GC electrode. This was attempted in order to use smaller amounts of ss DNA for electrode modification than those previously described (vide supra) or reported [8]. ss DNA solution was co-deposited with the lipid film on the electrolyte surface and a subsequent film casting on the GC electrode surface was followed. The results have provided a detectable guanine peak of 125 nA using 0.6 μg of ss DNA; smaller amounts of ss DNA did not provide a measurable signal. Present research is focused on estimating the surface coverage of the electrode with lipid films containing DNA using scanning electron microscopy, and exploiting the stability of lipid modified GC electrodes with incorporated DNA.

3.5. Incorporation of ss DNA in free-suspended BLMs

Measurements of ion conductivity changes (i.e. recordings of ion current vs. time) through conventional free-suspended BLMs [11] were used to monitor in situ ss DNA incorporation in lipid membranes and therefore to estimate the time required for association of ss DNA with lipid membranes. The use of liposomes as agents for DNA transfer was previouly described [9] and recent research using vesicles has been focused on exploiting DNA–lipid interactions [21]. However, no studies have been reported in the literature to

date to study these interactions using lipid membranes with a bilayer structure. Various volumes of the solution containing ss DNA were injected into the electrolyte solution after BLM formation and current stabilization. Fig. 3 shows a typical recording obtained after ss DNA injection in bulk electrolyte solution. A minimum volume of 4 μl of ss DNA solution (270 μg ml^{-1}) was required to induce increases in ion current values larger than the background (residual) ion current values; the concentration of ss DNA in bulk solution was 0.108 μg ml^{-1} and the ion current increased by 15.8 pA. The ion current increase was correlated to ss DNA concentration in bulk solution by the equation: ΔI (pA) = 277.5 C (μg ml^{-1}) – 14.6 (r^2 = 0.9995). Concentrations of ss DNA in bulk solution larger than ca. 0.27 μg ml^{-1} caused membrane rupturing. Control experiments involving the use of double-stranded DNA (ds DNA) were performed as well to demonstrate that the ion current increases were due to ss DNA/membrane interactions. It is therefore presumed that no alteration of the DNA conformation from ss to ds occurs in BLMs. These results suggest the potential of BLMs to act as a medium for DNA hybridization and offer a route to monitor this phenomenon.

The results in Fig. 3 show that the incorporation of ss DNA in BLMs occurs within 1.3 to 2.5 min. These data also indicate that for all ss DNA concentrations that were tested, it takes about the same delay time for the current increases to be observed. The relative invariable delay time
Fig. 4. Typical recordings obtained with s-BLMs. The ss DNA concentration in the bulk electrolyte solution was (a) 54 ng ml^{-1} and (b) 148 ng ml^{-1}. The arrow shows the injection of ss DNA in solution.

(much longer than mixing or diffusion times) does not appear to be related to ss DNA concentration, and suggests a mechanism of response in pertinent analogy to the function of a protein in BLMs. The electrochemical results indicate that a critical concentration of ss DNA exists beyond which increases of ion conductivity occur. These increases were noticed either in response to stepwise increases of DNA in the bulk solution or injections of DNA to a bulk solution containing no DNA (the regression equations correlating ion current to DNA concentration practically coincided). There were no discernible threshold transients observed during our experiments, suggesting that critical events due to changes of the surface potential of the BLMs were absent [22]. The results presented herein indicate that ss DNA spans the membrane to form a conductive pore. It is also possible that the increases of ion current values are likely to be due to concurrent DNA–lipid interactions which tend to disrupt the continuum of lipid interactions on one side of a BLM. However, the present results indicate that the incorporation of ss DNA in BLMs can be studied in situ by monitoring ion permeability changes and that the time required for the incorporation is less that 2.5 min.

3.6. Incorporation of ss DNA in BLMs

Stabilized s-BLMs on metal electrodes were used to monitor ss DNA incorporation in BLMs. Fig.

Fig. 3. Typical recordings obtained with planar free-suspended BLMs. The ss DNA concentration in the bulk electrolyte solution was (a) 108 ng ml^{-1} and (b) 162 ng ml^{-1}. The arrow shows the injection of ss DNA in solution.

4 shows the typical recordings obtained with increases in ss DNA concentration in the bulk solution. The required time for ss DNA incorporation in membranes is of the order of ca. 10 s (for all concentrations of DNA). This time is less than that obtained using free-suspended BLMs (vide supra); note that the reproducibility of the required time for DNA incorporation in s-BLMs is of the order of ± 14%. The shorter time delay for DNA incorporation can be correlated to the structure of s-BLMs. One side of the metal supported BLMs is in contact with the aqueous electrolyte solution, whereas the second monolayer touches the metal surface with some regions (depending on the metal roughness) covered with the electrolyte solution. Any ion rearrangement at these regions will occur more rapidly than in a homogeneous membrane such as those with a planar bilayer structure as a direct result of packing effects. An increase in ss DNA concentration in the bulk electrolyte solution results in increased ion current values obtained with s-BLMs (Fig. 5). The minimum detectable ion current increase (as set by the signal to noise ratio of 3) is ca. 10 nA, which is caused by an amount of ss DNA in bulk solution of about 30 ng ml^{-1}. This amount is far smaller that those previously used to incorporate ss DNA on metal electrodes [8], a substantial advantage of the present method. Reproducibility of the response was found to be of the order of ± 4 to 7% ($N = 5$, 95% confidence limit).
Fig. 5. Ion current dependence on ss DNA concentration in the bulk electrolyte solution using s-BLMs.

4. Conclusions

Various procedures were developed for the incorporation of ss DNA at a GC electrode modified by BLMs. Results using differential pulse voltammetry (i.e. oxidation of guanine and adenine residues) have shown that the lipid membrane enhances the stability of ss DNA towards a medium-exchange transfer of the electrode and prohibits diffusion of ss DNA from the electrode surface. The monolayer folding technique is preferred to the dip-casting methods for electrode modification by BLMs for DNA incorporation. Both phenomena can be achieved by the former technique in one stage, without a BLM thinning process which results in a substantially reduced time for electrode modification with incorporated DNA. Furthermore, maximized loading of DNA in BLMs can be achieved with the monolayer folding technique which reduces by ca. 10-fold the DNA amounts that can be detected electrochemically. Conventional planar BLMs and s-BLM systems results have shown that the adsorption of ss DNA at lipid membranes acting as a medium to incorporate ss DNA on an electrode surface can occur much faster using milder conditions and smaller amounts of ss DNA than by previously established protocols. Present research is focused on the potential of the GC electrode modified by BLM and/or using stabilized systems of BLMs for DNA hybridization and preparation of DNA sensors.

Abstract

A new ligand capable of producing calcium-selective electrodes with excellent characteristics is presented. The ligand (1) is a calix[4]arene bearing phosphine oxide ligating groups on the lower rim and this is the first report that such ligands can discriminate in favour of calcium ions against magnesium ions and the alkali metal ions. This calcium selectivity is in complete contrast to the behaviour of the well-known calix[4]arene tetraester derivatives (such as 2) which are selective for sodium against other alkali metal ions and group II ions. Electrodes based on PVC membranes incorporating ligand 1 display almost nernstian slopes and excellent selectivity against common interferents, including magnesium (log $K_{Ca,Mg}^{pot}$). The electrodes have demonstrated effective lifetimes of at least 7 weeks (duration of the study) and very fast response times.

Keywords: Calcium-selective electrode; Calix[4]arene; PVC membrane; Tetraphosphine oxide

1. Introduction

A new series of calixarene derivatives with lower rim phosphine oxide ligating groups have recently been synthesised and shown to exhibit interesting metal complexation behaviour with certain lanthanides and actinides [1]. In this study, selective extraction was demonstrated even under very highly acidic conditions (e.g. 4 M HNO_3) and in the presence of a large excess of sodium. We recently reported the properties of a Eu^{3+}-se-

lective PVC membrane electrode based on ligand 1 which showed excellent selectivity against a wide range of common ions [2]. The lack of response to alkali metal ions was particularly interesting given the well documented selective complexation of sodium ions by tetraester calixarene derivatives such as 2 [3]. During screening experiments for determining the characteristics of the Eu^{3+}-selective electrode based on 1, a relatively large response to Ca^{2+} was noted. This prompted us to investigate the possibility of making a calcium-selective sensor based on ligand 1.

In this paper, we report on a calcium(II)-selective electrode incorporating 1 as the sensing

Ligand 2

ionophore in a PVC membrane. The results are compared to those of an electrode based on the tetramethylester calix[4]arene (2).

2. Experimental

All membrane components except the ligands were obtained from Fluka and used as received. Other reagents including metal chlorides were purum grade obtained from Reidel-de-Haen. Ligands 1 [1] and 2[4] were synthesised as described previously. PVC membranes were prepared by a standard procedure [5] using the following composition: ligand, 10.0 mg; potassium tetrakis p-chlorophenylborate (KTpClPB), 1.0 mg; nitrophenyloctylether (2-NPOE), 1.0 g; PVC, 500 mg. The membrane components were dissolved in tetrahydrofuran (THF) and the resulting solution poured into a glass mould. Upon evaporation (overnight), transparent PVC membranes about 0.2 mm thick were obtained from which electrode membranes were cut using a cork borer. The membranes were clipped into the tip of an electrode body which was then filled with 0.1 M $CaCl_2$ as internal reference electrolyte. Cell potentials were measured relative to a calomel electrode using a Hewlett Packard μV meter (Model 34401A). Transient responses were captured using an MIO-6 I/O card and virtual instrument software developed in-house using LabView (ver 3.0).

Calibration solutions were prepared by serial dilution of 0.1 M $CaCl_2$ stock solution to 10^{-6} M

with deionised water. All activity values were calculated using the Davies equation. Selectivity coefficients were estimated by the separate solutions method at 0.1 M concentrations of primary and interfering ions. Injection experiments were carried out in an electrolyte that was 10^{-2} M LiCl and 10^{-4} M $CaCl_2$. This involved injecting 250 μl aliquots of a 0.1 M solution of a metal ion chloride into a stirred 50 ml portion of the background electrolyte to give an approximate six-fold concentration excess of the injected ion over the initial calcium concentration. The high background of LiCl ensured that the ionic strength remained relatively unchanged. LiCl was chosen as ionic strength adjuster following initial screening experiments which demonstrated no response by the electrode to lithium ions. Electrodes were conditioned in 0.1 M $CaCl_2$ solution between experiments. In each case, the initial injection was followed by two 250 μl injections of 0.1 M $CaCl_2$ to investigate whether the presence of the interfering ion had any effect on the calcium response. These injections cause approximate six-fold and two-fold increases in the calcium ion activity, which in turn should generate electrode responses of the order of $+20$ mV and 5–6 mV respectively. It should be stressed that these injection experiments are used as quick screening experiments, and not precision measurements, as the change in potential depends on the electrode slope, the exact amount of electrolyte added and the initial concentrations of the ions. Nevertheless, they do provide convincing evidence of selectivity and a useful indication of the dynamic respone behaviour of the sensors.
Fig. 1. Typical calibration curve obtained with $CaCl_2$ solutions. The solid line is the average of $n = 4$ measurements with one electrode, with the standard deviations are shown as error bars. The slope is 26.35 mV decade^{-1} measured over the activity range 10^{-4}–10^{-2} M $CaCl_2$ (no correction for residual junction potential).

3. Results and discussion

The electrodes generated very stable potentials with little drift. Fig. 1 shows a typical calibration curve, with the electrode slope being 26.3 mV decade^{-1} (0.1 M to 10^{-4} M Ca Cl_2). In order to assess the electrode lifetime, the slope over the above range was measured each week over a period of 6 weeks, while the electrode was in continual use (Fig. 2). After a small initial decline in slope, the electrode continued to function in a reproducible manner for the rest of the assessment period, and in no case did the slope fall below 22 mV decade^{-1} ($n = 5$ electrodes).

Selectivity was investigated by the separate solutions method and by injection experiments. The calculated selectivity coefficients for electrodes based on both ligands are summarised in Table 1. Clearly, there is a striking change in the selectivity, with the tetraester (2) being very selective for sodium against all ions tested, and the tetraphosphine oxide (1) being very selective for calcium ions against all other ions tested. In order to

Table 1
Selectivity coefficients for the tetraphosphine oxide (1) and tetraester (2) calix[4]arenes measured by the separate solutions method with 0.01 M chlorides of the metals

Ligand	Log K_{ij}^{Pot}	
	1	2 [3]
Na^+	−2.2	0.0
K^+	−2.7	−2.7
NH_4^+	−2.0	−3.5
Li^+	−1.6	−2.9
Mg^{2+}	−2.6	−3.7
Ca^{2+}	0.0	−3.5

verify the selectivity, injection experiments were performed as described in the experimental section (Fig. 3). The results clearly demonstrate the almost total lack of response to the interfering ions injected, despite an approximate six-fold excess of the injected ion over that of the initial calcium concentration. Furthermore, in every case, there was little or no apparent effect on the subsequent injection of two similar aliquots of calcium, which led to responses which were effectively nernstian within the limits of reproducibility of the experiment.

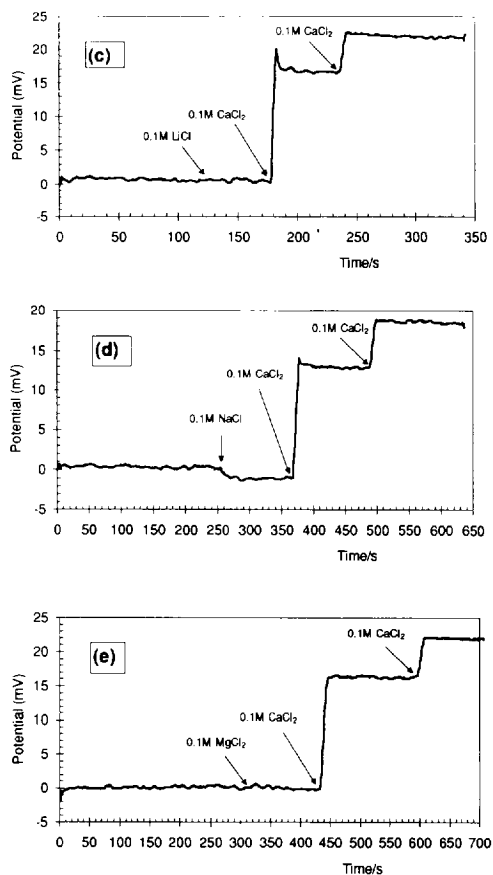

Fig. 3. Transient responses to injection of 250 μl aliquots of various metal chlorides followed by two further injections of 250 μl aliquots of 0.1 M CaCl₂. Injection points indicated by arrows.

Previously, calcium-selective electrodes have been fabricated with varying degrees of success using a number of different ligand types, including lipophilic diamide derivatives [6], macrocyclic polyethers [7] and a polymerisable benzo-15-crown-5 [8]. A water hardness electrode (which

responds to both Ca^{2+} and Mg^{2+}) has also been reported [9]. However, to our knowledge, this is the first report of a selective electrode for calcium based on phosphine oxide ligating groups and, as such, offers the possibility of a new series of calcium-selective ligands based on the well-known ease of modification of the calixarene building block.

Physicochemical measurements and modelling experiments based on energy minimisation calculations are underway to probe the structural basis for the affinity between the phosphine oxide ligand and the calcium ion.

Short communication

Laser-induced breakdown spectroscopy of silicate, vanadate and sulfide rocks

J.M. Vadillo, J.J. Laserna*

Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, 29071-Málaga, Spain

Abstract

Laser-induced breakdown spectroscopy (LIBS) in air at atmospheric pressure has been used to study four geological samples belonging to different structural families. Atomic emission spectra of vanadinite, pyrite, garnet and a type of quartz (compostela's quartz) are shown. The 532 nm line of a Nd:YAG laser at an irradiance of 18×10^{11} W cm^{-2} was used. The precise focus of the beam allowed microanalysis of a 0.02 mm^2 surface area working in single-laser shot mode. The use of an intensified gateable charge-coupled-device (CCD) detector permitted time-resolved studies. The spectral lines have been assigned to transitions in the neutral charge state of the corresponding atom of the material under investigation. The behavior of different transitions with time delay are shown. In experiments, minor components contained in several minerals have been detected. This fact has been used to demonstrate the applicability of the technique to characterize and identify similar minerals.

Keywords: Geochemical analysis; Laser-induced breakdown spectroscopy; Laser-induced plasmas; LIBS

1. Introduction

The effect of a short pulse of laser radiation focused on a sample produces an irradiance sufficient to vaporize a small spot of a solid on the surface, resulting in a high-temperature and electron-density plasma that can be spectrally analyzed by optical emission spectroscopy. This technique is called laser-induced breakdown spectroscopy (LIBS) [1].

The physics of laser/surface interaction is a well-known process. The surface reflects some of the energy and the remaining part is absorbed by the surface. Due to the short laser pulse duration, there is not enough time for thermal diffusion into the surface material outside the focal spot. This fact explains the quick heating of the surface, resulting in a rapid vaporization. The vapor moves outward from the surface and by a multi-photon absorption process; some of the material is ionized creating an appreciable ionic population. When a sufficient density of ions and electrons is created, an inverse Bremstrahlung process

---

* Corresponding author.

causes the incident laser light to be absorbed minimizing the laser light reaching the sample surface. The electrons are heated causing an increase in temperature, and rapid energy transference and electron–ion collisions which result in neutral species. Subsequent spectral analysis has been successfully used for elemental analysis in solids [2], gases [3], liquids [4] and aerosols [5]. Applications of LIBS for the analysis of solids include the detection of contaminants on electronic microcircuits [6], on-line process control [7] and analysis of noble and alloyed jewelry metals [8]. The advantages of improving the technique by working under high vacuum have been also described [9].

LIBS allows direct analysis of a wide range of solids, including minerals and rocks and shows great capabilities to perform routinely non-destructive identification of microscopic inclusions in their material hosts [10]. The simple requirements in sample-preparing-and-handling provide several advantages with respect to other widely used techniques including electron and ion microprobes [11]. LIBS can be used to identify, map out the distribution and determine the quantity of elemental constituents of the sample. The main advantage is the possibility of simultaneous multi-element analysis over a wide spectral range without pre-treatment or transport of the sample to the excitation source (inductively coupled plasma atomic emission spectrometry (ICP-AES)). Although the coupling of laser ablation to ICP-AES or ICP-MS (inductively coupled plasma mass spectrometry) systems is becoming a powerful tool in geochemical analysis, it can be said that LIBS is the right choice when the number of elements to be found is large or the composition of the sample is unknown [12].

The high performance of charge-coupled-device (CCD) detectors in terms of spectral range, quantum efficiency, integration time and gating, allows resolution of the complex spectra of geological samples better than using scanning spectrometers with photomultipliers tubes detectors [13]. Furthermore, because of the two-dimensional character of the CCD detector, spatial and spectral information can be achieved simultaneously. When combined with intensifier devices, extremely

low light levels can be recorded without increasing acquisition times.

In this paper, time-resolved LIBS is used to obtain the spectra of minerals from different families including sulfides, vanadates and silicates. No sample preparation is required. In addition, time-resolved LIBS is used to improve the signal-to-noise ratio (SNR) as well as to reduce the Stark effect and continuum background often found in LIBS spectra. Examples are shown to demonstrate the capability to conduct geological taxonomy and to analyze a field sample.

2. Experimental

2.1. Apparatus

The experimental setup for time-resolved LIBS is shown schematically in Fig. 1. The second harmonic of a pulsed Nd:YAG laser ($\lambda = 532$ nm, pulse width 5 ns, 170 mJ pulse^{-1}, Continuum, Surelite SLI-20) was used to irradiate the samples. The beam was focused at normal incidence onto the sample surface with a glass planoconvex lens with a focal length of 100 mm and f-number of 4. The spot area was 0.012 mm^2, which resulted in an irradiance of 18×10^{11} W cm^{-2}.

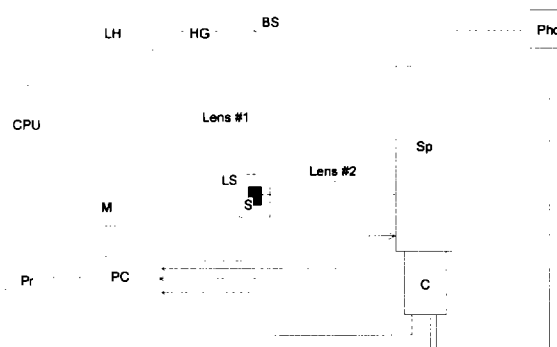
A 1:1 image of the plasma was focused using a planoconvex quartz lens with focal length of 100


Fig. 1. Schematic setup used in this paper. LH, laser head; CPU, cooling power unit; HG, second harmonic generator; BS, beam splitter; Phd, trigger photodiode; Sp, spectrograph; C, CCD detector; LS, linear stage; S, sample; PC, personal computer; M, monitor; Pr, printer; Lens #1, glass lens; Lens #2, quartz lens.
Fig. 2. Variation of peak intensity as a function of time delay. Sample: vanadinite; wavelength: 291 nm; gate width: 100 ns; laser energy: 170 mJ; MCP gain: 700 V.

mm and f-number of 4 into the entrance slit of a 0.5 m focal-length Czerny–Turner spectrograph (Chromex, 500 IS). Light was dispersed using a 2400 grooves mm^{-1} holographic grating (250 nm blaze). The entrance slit width was 10–200 μm, and the height was 10 mm. The spectrograph was computer controlled using specific software (Chromex Host Control Software 2.21).

The dispersed plasma light is detected using a solid-state two-dimensional CCD (Stanford Computer Optics, 4 Quik 05). The CCD consists of 752(h) × 582(v) elements. The photoactive area is 6 × 4.5 mm^2. The device is equipped with an S 20 Q photocatode (spectral response from 180 to 820 nm) and an intensifier system (microchannel plate, MCP). The intensifier system allows a high photonic gain, better than 10^6 electrons/photon. Extremely high system responses are achieved (50–500 000 ASA) with a 12 bit dynamic range. Operation of the detector was controlled by 4 Spec 1.20 Software. Shutter and delay times can be selected in 50 ns steps. A fast photodiode was used as the external trigger for exact synchroniza-

tion of the incident laser pulse and opening of the camera shutter.

The experimental conditions were optimized in order to obtain the best SNR. A gate width of 100 ns was used in all experiments, while the time delay was varied when required. The MCP gain was fixed in 700 V when single-shot experiments were run. When different shots were accumulated in order to improve the SNR, the gain was reduced.

Video image capture, processing and display were made using a PC-compatible monochrome frame grabber (Data Translation, DT2855). As images are captured, they can be displayed with 768 × 512 square pixels resolution and 256 gray levels. This number of pixels and gray levels produced a high-definition display with continuous tones to match real images. Later on, they can be output for real-time images processing and pseudo-color display into a VESA-ISA Local Bus PC specially equipped for fast capture and processing images.
Fig. 3. Pyrite single-shot LIBS spectrum. Time delay: 500 ns. Other conditions as in Fig. 2.

2.2. Samples

Samples were directly taken from the field and analyzed without other treatment than washing the surface with deionized water to remove dust and mud. Four mineral species were analyzed: garnet, vanadinite, compostela's quartz and pyrite. Details on chemical structures and atomic cells implants will be discussed in the results and discussion section.

Table 1

3. Results and discussion

3.1. Time-resolved analysis

Spectral analysis of geological samples obtained using LIBS involves complex spectra in the presence of a noisy background with many overlapped peaks due to band broadening (Stark effect). Spectral lines corresponding to high populated energy levels are the result of the elevated plasma temperature. Spectra can be drastically simplified and the SNR greatly improved by delaying observation of the plasma. Time-resolved LIBS is useful since three benefits are achieved. First, there is a considerable decrease of the continuum emission due to Bremstrahlung radiation occurring immediately after plasma formation. Second, it is possible to avoid spectral interferences between species that emit at different times during plasma decay allowing characterization of different species. Third, spectral resolution improves because the Stark effect contribution is minimized.

The temporal behavior of different atomic species of the plasma is illustrated in Fig. 2. As

shown, the 279.5 nm transition corresponding to Mn[(1)] shows a different temporal behavior reaching its maximum intensity at 50 ns of delay while the rest of the lines decay immediately after plasma formation.

3.2. Spectral analysis

Fig. 3 shows a pyrite (FeS$_2$) emission spectrum. The selected window does not allow the observation of sulfur lines and only Fe[(1)] lines are plotted. Although the laser is a powerful mean of inducing plasmas and it is able to produce ionization states as high as other continuum plasma sources (ICP, microwave-induced plasma and other), these are often not visible. The explanation must be found in the pulsed nature of the laser-induced plasma that determines many secondary processes of recombination (with oxygen mainly involved). These processes reduce the lifetime of many ionic lines in the spectrum and can be minimized working under vacuum conditions. Table 1 summarizes the results and spectroscopical parameters of the most relevant lines [14].

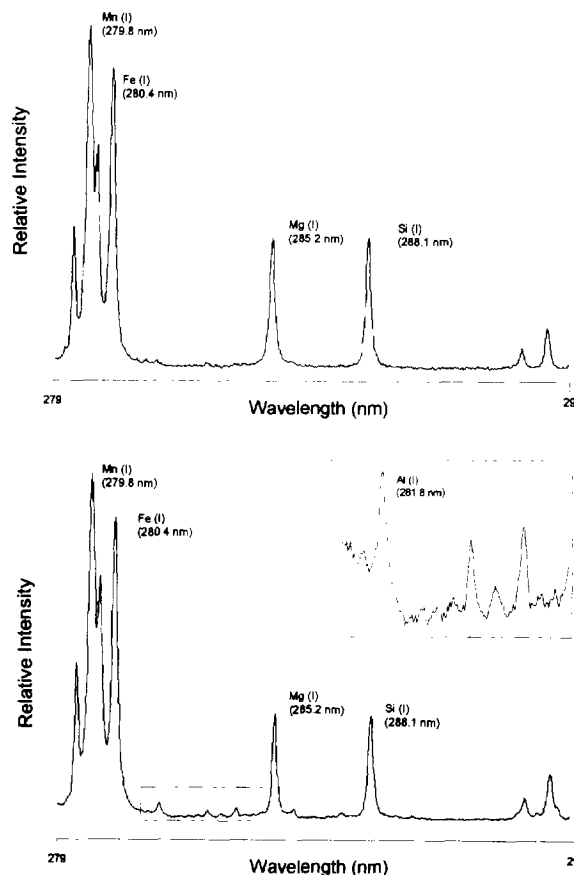
In order to show the applicability of the method in the determination of mineral species, LIBS spectra of compostela's quartz and garnet were obtained. Fig. 4 shows line emission of quartz (top) and garnet (bottom). Both minerals contain the same silicate matrix with differences due to their three-dimensional structure. Garnet involves a large group of nesosilicates with many isostructural minerals. The general formula is $A_3B_2(SiO_4)_3$, where A refers to large divalent cations, mainly Mg^{2+}, Fe^{2+} and Mn^{2-}, and B alludes to trivalent cations a few smaller in size, Al^{3+}, Fe^{3+} and Cr^{3+}. On the other hand, compostela's quartz is a very typical quartz variety from northern Spain, characterized by a light-red color due to iron insertions. Cr^{2+}, Mn^{2+} and Mg^{2+} can also be found [15]. Large similarities in spectral behavior of both samples are expected and only the analysis of insertions in the atomic cell can be fruitful to discriminate the samples. As Fe, Cr, Mn and Mg insertions can be found in both garnet and quartz, the presence of Al emission lines in the garnet spectrum provides information required to discriminate the minerals. For


Fig. 4. Comparison of LIBS spectra of Compostela's quartz (top) and garnet (bottom). Time delay: 500 ns; accumulated shots: 10; MCP gain: 600 V. Other conditions as in Fig. 2.

this purpose, experimental data were obtained by accumulating ten shots in order to avoid surface interferences and to improve the SNR. Fig. 4 shows lines corresponding to Fe[(1)], Mn[(1)], Mg[(1)] and Si[(1)] in both garnet and quartz as expected. However, a detailed comparison reveals an aluminum line at 281.8 nm in garnet, which is not found in the LIBS spectrum of compostela's quartz.

4. Conclusions

In the present paper, the laser-induced plasma emission phenomenon described can be used to detect and identify atomic constituents on the

surface of inorganic minerals. Analysis can be performed quickly in air at atmospheric pressure with a comparatively simple experimental setup. Furthermore, the laser plasma light is collected and directed to the detection system using a lens or a fiber optic cable which allows direct field measurements from samples located in difficult sites.

Enhancement of spectral lines with respect to the plasma continuum has been achieved by time-resolved spectroscopy. The quick decay of continuum emission in the first 100 ns suggests that laser-induced plasma emission of neutrals is the dominant process. The development of similar experiments under vacuum conditions would be useful to enhance the lifetimes of the ionic lines. The applicability of the method has been illustrated in the characterization of two very similar mineral species. In a second study, quantitative results will be reported.

Selectivity enhancement for glutamate with a Nafion/glutamate oxidase biosensor

Shengtian Pan[a], Mark A. Arnold*

Department of Chemistry, University of Iowa, Iowa City, IA 52242, USA

Abstract

Response properties and selectivity are reported for glutamate biosensors constructed with a film of Nafion between the platinum anode and a layer of immobilized glutamate oxidase. The effects of enzyme loading, sample pH and temperature are established. Operation at pH 7.8 and 37°C results in linearity up to 800 μM and a limit of detection of 0.3 μM. Nafion enhances selectivity for glutamate over test species that include ascorbic acid, uric acid and acetaminophen. Selectivity enhancement was greater over the anionic interferences because of electrostatic repulsion and the extent of this enhancement depends on the thickness of the Nafion layer. Even under ideal conditions, some interfering signal is observed when glutamate levels are ten-times less than ascorbate.

Keywords: Glutamate; Nafion/glutamate oxidase biosensor; Selectivity enhancement

1. Introduction

Numerous reports have described work to develop a functioning biosensor for glutamate [1–5]. Typically, glutamate oxidase is immobilized at the surface of an anodic electrode and the enzymatic generation of hydrogen peroxide is monitored amperometrically. The two major applications for such glutamate biosensors are as monitors for bioreactors [6] and as real-time sensors during neurochemical experiments [7]. In both cases, selectivity for glutamate over easily oxidized endogenous species is critical for acceptable accuracy.

Ascorbate represents a major potential interference, especially in neurochemical systems where high and varying levels of ascorbate can be present. Ascorbate interference is caused by direct oxidation at the electrode surface. One strategy to enhance sensor selectivity is to add a layer of Nafion which electrostatically repels anions, such as ascorbate, while freely passing hydrogen peroxide. This strategy has been used effectively with electrochemical sensors for dopamine [8,9] and blood glucose [10,11]. In both cases, Nafion coated electrodes provide sufficient selectivity enhancement for accurate measurement under conditions where the analyte concentration is greater than or equal to that of ascorbate. In some neuro-

[a] Present address: College of Engineering, University of California, Riverside, CA 92521, USA.

chemical situations, however, glutamate levels can be orders of magnitude lower than ascorbate levels, which places further demands on sensor selectivity.

In this paper, Nafion is evaluated as a means to enhance selectivity of glutamate measurements performed with the glutamate oxidase based biosensor. Selectivity for glutamate over ascorbate is characterized with and without a thin layer of Nafion positioned between the immobilized enzyme and a platinum anode. Although the response to ascorbate is attenuated significantly in the presence of the Nafion layer, this response is not completely eliminated. Even with the Nafion layer, measurement inaccuracies can be substantial depending on the relative concentrations of glutamate and ascorbate. As a result, the utility of this glutamate biosensor in neurochemical experiments will be restricted to situations where the relative amounts of ascorbate and glutamate permit accurate measurements. Besides our characterization of the Nafion membrane, the effects of enzyme loading, pH and temperature are evaluated, and conditions for the optimal glutamate response are identified.

2. Experimental

2.1. Apparatus

Amperometric measurements were made with a Model DCV-5 Voltammetry Controller from Bioanalytical Systems, (West Laffayette, IN, USA) and recorded on a Sargent-Welch Model XKR strip chart recorder. All pH measurements were made with a Ross-type combination pH electrode (Orion Model H4100-12) in conjunction with a Model ϕ72 meter. Solution temperatures were controlled with VWR model 1140 water bath (Polyscience Corp., Niles, IL, USA).

2.2. Reagents and supplies

Platinum electrodes were disk shaped with a diameter of 1.6 mm (MF-2013). These electrodes were purchased, along with the silver–silver chloride reference electrodes (MF-2020), from

Bioanalytical Systems. Glutamate oxidase (8 U mg^{-1}) was generously donated from Hitoshi Kusakabe from Yamasa Shoyu Co. Ltd. (Choshi, Chiba 288, Japan). Nafion was purchased from Aldrich Chemical Co. (Milwaukee, WI, USA) as a 5% (w/w) suspension of the perfluorinated ion-exchange powder in a mixture of low molecular weight aliphatic alcohols and 10% water. L-Glutamic acid (monosodium salt, 99–100%), bovine serum albumin (BSA, 98–99%) and glutaraldehyde (Grade II, 25% aqueous solution) were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Concentrated hydrogen peroxide (30%) was purchased from Fisher (Chicago, IL, USA) and was standardized periodically by titration with sodium thiosulfate. All other chemicals were obtained from common suppliers as reagent grade materials.

All solutions were prepared with distilled–deionized water by passing the house distilled water through a three-house Milli-Q water purification unit. The working buffer had a pH of 7.4 and contained the following salt concentrations: 50 mM NaCl, 10 mM KH$_2$PO$_4$ and 40 mM Na$_2$HPO$_4$. Solutions of L-glutamate were prepared by dissolving L-glutamic acid (dried at 104°C for 2 h) in working buffer.

2.3. Procedures

2.3.1. Electrode preparation

Platinum electrodes were polished sequentially with 3, 1 and 0.3 μm aluminum oxide lapping films and washed in a sequence of acetone, distilled–deionized water, nitric acid (1:1) and distilled–deionized water in an ultrasonic cleaner. Polished electrodes were electrochemically pretreated in 0.5 M sulfuric acid by cycling the applied voltage between −0.4 to 1.3 V versus Ag/AgCl at a scan rate of 50 mV s^{-1} for 10 min.

Nafion layers were constructed by placing a 10 μL aliquot of a 1% Nafion suspension on the surface of a treated platinum electrode. Films were formed by allowing the solvent to evaporate at room temperature for 20 min. Different film thicknesses were generated by either using a different concentration of Nafion or applying a different volume.

Glutamate oxidase was immobilized by crosslinking with BSA and glutaraldehyde. First the platinum electrode was polished, washed and electrochemicaly pretreated. A Nafion film was prepared by placing one 10 μL aliquot and, subsequently, four individual 3 μL aliquots of 1% Nafion on the surface of the platinum electrode. In each case, the previous layer was allowed to dry before the next aliquot was administered. An enzyme solution was prepared by dissolving 0.5 mg of glutamate oxidase in 5 μL phosphate buffer (pH 6.86). This glutamate oxidase solution was mixed well with 2.5 μL of 10% (w/w) BSA and 1.25 μL of 2.5% glutaraldehyde. A 2 μL aliquot of this final mixture was placed on the Nafion film. Approximately 0.91 units of glutamate oxidase were immobilized on a surface area of 0.2 mm^2. After drying at room temperature for 30 min, the electrode was washed thoroughly with phosphate buffer to remove any unretained enzyme. Different enzyme loadings were obtained by adjusting the concentration of the glutamate oxidase stock solution.

2.3.2. Sensor response measurements

Sensor responses were measured by recording anodic currents as a function of time. Unless stated otherwise, the working electrode potential was maintained at 0.65 V versus a Ag/AgCl reference electrode. Data for the response curves were collected by first immersing the sensing tip in a blank solution of working buffer to determine the background current. Microliter additions of a glutamate standard were then added sequentially and the corresponding steady-state currents were noted. In most cases, the sample solution was stirred with a magnetic stir bar. Stirring was stopped, however, to reduce noise when solutions with low glutamate concentrations were measured. Response times were measured as the time required to achieve 95% of the final steady-state response after a step change in glutamate concentration.

3. Results and discussion

Response properties for the glutamate biosen-

sor have been measured as a function of enzyme loading, solution pH and operating temperature. In addition, the effect of Nafion on electrode selectivity has been established with particular interest in the effect of Nafion layer thickness.

3.1. Operational parameters

The amount of glutamate oxidase required to saturate the sensing tip was determined by comparing the response curves obtained from a series of sensors constructed with different amounts of immobilized glutamate oxidase. The results are presented in Fig. 1. As the amount of immobilized glutamate oxidase approaches 0.91 units, the sensor response becomes independent of the amount of enzyme. Below this saturation point, however, the response is strongly affected by the amount of glutamate oxidase. The slope of the calibration curve increases with increasing glutamate oxidase concentrations, until a saturating amount is reached. Unless noted otherwise 0.91 units of glutamate oxidase were used for the construction of all subsequent sensors.
Fig. 1. Sensor response curves with enzyme loadings (U per membrane) of 0.001 (open squares); 0.01 (closed squares); 0.23 (open triangles); 0.91 (closed triangles); and 1.37 (circles).
Fig. 2. pH profile for response to glutamate.

The magnitude of the sensor response depends strongly on solution pH. The sensor response was monitored at different solution pH values for a step in glutamate concentration from zero to 0.7844 mM at room temperature. Fig. 2 shows how the response depends on solution pH. The maximum response is obtained at pH 8.0 and over 95% of this maximum response is obtained over the pH range from 6.5 to 9.5. This pH profile is similar to that reported for the free enzyme [12] where the optimum pH is 7–8.

Temperature also strongly influences the sensor response as expected because of the well known effects of temperature on reaction kinetics, enzyme activity and mass transport [13]. The effect of temperature was evaluated by measuring the sensor response to 0.37 mM glutamate over a temperature range from 5.6 to 63.0°C. Enzyme loading was reduced in this experiment to 0.23 U at the electrode surface in order to amplify the temperture effects. The magnitude of the response increases dramatically as the temperature increases from 5.6 to 48°C. The temperature coefficient over this range is approximately 8.5 nA °C^{-1}. A maximum response is observed at 48°C and the response drops at a rate of 2.8 nA °C^{-1} as the temperature increases beyond 48°C. Glutamate oxidase is a thermally stable enzyme [14]

which accounts for large responses at temperatures above 40°C. Thermal degradation of the enzyme does become a factor, however, above 48°C.

Ideal sensor response properties are obtained with at least 0.91 units of immobilized enzyme operating at pH 8.0 and 48°C. More importantly, these results demonstrate that the sensor can operate well over a wide range of pH and temperature values. Finally, the influences of pH and temperature are sufficiently strong that precautions to control these parameters are required for accurate measurements.

3.2. Nafion and selectivity

As expected, easily oxidized species, such as ascorbic acid, uric acid and acetaminophen, are positive interferences when biosensors are prepared without Nafion. The magnitude of this type of interference is illustrated by comparing the sensor responses in solutions containing only 0.369 mM glutamate and those containing 0.369 mM glutamate plus 0.369 mM of the interfering compound. Direct oxidation of the added compound increases the measured current which results in systematic errors corresponding to apparent glutamate levels of 191.9, 186.5 and 197.0%, the actual values in the presence of ascorbic acid, uric acid and acetaminophen, respectively.

Such interfering responses are reduced in the presence of Nafion and the extent of this reduction depends on the thickness of the Nafion layer.

Table 1
Ascorbate oxidation with different Nafion layer thicknesses

Thickness (μm)	Electrode response (μA)[a]	
	$E_{app} = 0.4V$[b]	$E_{app} = 0.6V$[b]
0	0.98 (100%)	1.08 (100%)
2.2	0.12 (12%)	0.48 (44%)
4.5	0.085 (8.7%)	0.22 (20%)
6.7	0.021 (2.1%)	0.06 (5.6%)
9.0	0.012 (1.2%)	0.03 (2.8%)
11	0.004 (0.4%)	0.014 (1.3%)

[a]Per cent response with no Nafion given in parenthesis.
[b]Measured relative to Ag/AgCl.

Table 1 summarizes steady-state currents measured for 1.0 mM ascorbate solutions with different Nafion layer thicknesses for two applied potentials (0.4 and 0.6 V versus Ag/AgCl). At both potentials, the response drops significantly as the Nafion layer thickness grows from 0 to 11 μm. At 11 μm, the relative response decreased to 0.4 and 1.3% of the original values at applied potentials of 0.4 and 0.6 V, respectively.

Nafion also reduces the electrode response to hydrogen peroxide. The Nafion layer adds an additional diffusion barrier which lowers the flux of hydrogen peroxide to the electrode surface, thereby lowering the monitored current. Of course the extent of signal reduction is greater for ascorbate and the other anionic species, because both electrostatic repulsion and diffusion barrier effects are combined to reduce responses from these interferences. Relative to no Nafion, a 6.7 μm layer of Nafion results in a 35% reduction in the steady-state current for hydrogen peroxide. Under the same conditions, nearly 95% of the response to ascorbate is removed. Without Nafion, currents for ascorbate are approximately 41% of those for the same concentration of hydrogen peroxide. This percentage drops to less than 3% when the Nafion layer thickness reaches 6.7 μm. No further reduction in the relative response to ascorbate was obtained with thicker layers. It is important to stress that some response was observed for ascorbate at all Nafion layer thicknesses which suggests absolute selectivity for hydrogen peroxide is not possible with this approach.

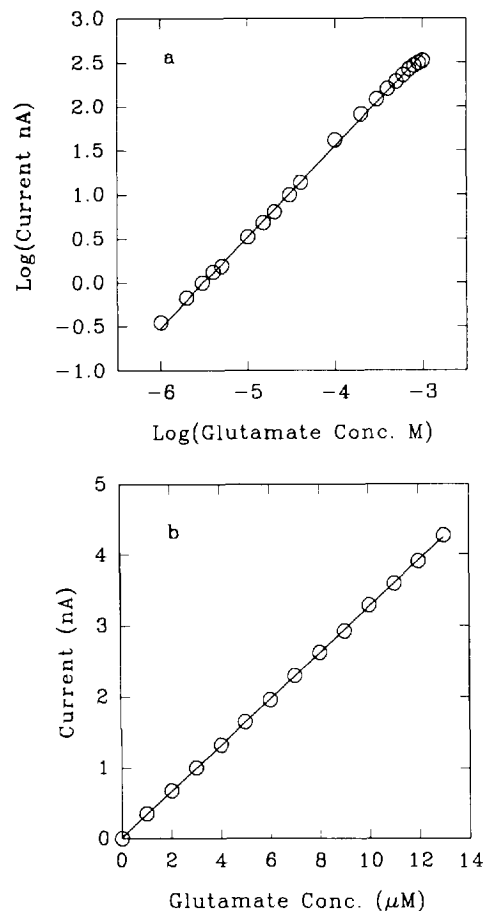
By altering the response to hydrogen peroxide, the Nafion layer also affects the response to glutamate. Without Nafion, the mean response (± 95% confidence interval) for 10 consecutive measurements of 0.5 mM glutamate was 446 (± 10) nA and the corresponding response time was 7 (± 1.5) s. With a 5 μm thick Nafion film, the mean current and response time are 195 (± 10) nA and 14 (± 1) s, respectively, for seven consecutive measurements at the same glutamate concentration. Nafion causes a 2.3-fold decrease in magnitude of response and 2-fold increase in response time. Still, linear calibration curves are achieved with Nafion. Example curves are presented in Fig. 3 over wide and narrow ranges of glutamate


Fig. 3. Calibration lines for glutamate showing (a) log-log plot for a wide dynamic range and (b) normal plot for the micromolar concentration range.

concentrations. Fig. 3a illustrates linearity over a wide range of glutamate levels. Regression analysis of these data reveal a slope of 1.022 (± 0.008), a y-intercept of 5.64 (± 0.03) and a correlation coefficient of 99.90% for this log-log plot. Fig. 3b presents a calibration line for 1 to 13 μM glutamate. Regression analysis indicates a slope of 0.3253 (± 0.0009) nA μM^{-1}, a y-intercept of 0.018 (± 0.013) nA and a correlation coefficient of 99.99%. The calculated limit of detection (S N = 3) from Fig. 3b is 0.3 μM and the response times are approximately 14 s at all concentrations. Data for both curves were collected at 37°C.

Selectivity for glutamate over anionic species is enhanced with the Nafion layer. No differences in sensor response were observed when the electrode was exposed to solutions of 0.369 mM glutamate and 0.369 mM glutamate plus 0.369 mM ascorbate or urate. This lack of response is strikingly different than that noted above in the absence of the Nafion film. Some effect of ascorbate was observed, however, when the ascorbate concentration was 10 times greater than glutamate. In this experiment, the sensor tip was immersed in an air saturated solution composed of 0.369 mM glutamate and no ascorbate. After the steady-state current was noted, solid ascorbic acid was added to give a final ascorbate concentration of 3 mM. The average relative difference in the response caused by the addition of ascorbic acid was 2.08% for six repeated trials. Ascorbate was added in this way to minimize the production of hydrogen peroxide via anaerobic oxidation [15]. The Nafion layer was much less effective in reducing interference from acetaminophen. The electrode response increased by 29.9% when comparing the responses to solutions with 0.369 mM glutamate alone and 0.369 mM glutamate plus 0.369 mM acetaminophen. Although the interfernce by acetaminophen is sizable with the Nafion layer, the magnitude of interference is reduced considerably compared to sensors without Nafion (see above for specific values). Enhancement in selectivity over the neutral acetaminophen is presumably caused by differential diffusion barrier effects by Nafion between acetaminophen and hydrogen peroxide.

4. Conclusion

Selectivity for glutamate can be enhanced by incorporating a thin layer of Nafion between the electrode surface and the immobilized layer of glutamate oxidase. The extent of selectivity enhancement depends on the thickness of the Nafion film. Even with the maximum thickness, however, response to interferences cannot be completely eliminated. Inaccurate measurements can result from oxidizable anionic species, such as ascorbate, when the glutamate concentration is ten-

times less than the interfering species. As a result, this electrode configuration does not provide the selectivity needed for many neurochemical experiments where ascorbate levels are known to be two orders of magnitude greater than glutamate. Under such demanding conditions, alternative selectivity enhancement strategies, such as Wilson's dual enzyme system [7] or our hydrogen peroxide gas-sensing scheme [15], are needed to ensure accuracy. Nevertheless, the Nafion/glutamate oxidase system described here offers the key advantages of being easy to construct and simple to operate, which makes it a viable alternative when the selectivity demands permit.

Abstract

A glucose sensitive enzymatic thermal sensor based on a pair of commercial microthermal probes was fabricated by cross-linking of the corresponding enzymes (glucose oxidase and catalase) with bovine serum albumin onto the chip surfaces. The characteristics of this sensor were optimised by testing it in different conditions. To find the maximal sensitivity, the calibration curves of this sensor were measured in different buffer solutions with and without the addition of H_2O_2 to the analysed samples at various rates of sample flow stream. Different buffer solutions and hydrogen peroxide concentraions were used to realise the principles of a chemical and biochemical amplification of the biosensor response. It was shown that the level of the biosensor response and its dynamic range increase if hydrogen peroxide is added to the analysed samples and depend on the type of buffer solutions tested and the rate of the sample flow stream.

1. Introduction

Thermal biosensors based on either thermocouples or thermopiles [1–5] have been applied successfully in biochemical analysis. The recent developments in this field were mainly focused on miniaturisation and multi-analytes capabilities offered by the micromachining and microelectronics technologies. Another approach in the design of new low-cost biosensors is to use a commercial probe and to modify it in order to obtain new properties. By this way it is possible to combine the well stated advantages of the original sensor with the new properties of the modified one to obtain a simple multisensor with the reliability of

Fig. 1. Experimental set-up. 1, glass reaction cell; 2, plexiglas homemade cork with a pair of thermistors; 3, thermistors; 4, heat exchanger; 5, metallic tube to be used to heat the solution injected into the reaction cell; 6, thermostatic bath; 7, peristaltic pump.

a commercial transducer and the simplicity of a single type of signal treatment.

With this aim, in the present work, we have modified classical microprobes used for minimally invasive measurement of temperature, thermal conductivity and tissue blood flow [6,7] with enzymatic membranes. Consequently it has been possible to add biochemical sensing capabilities to a probe previously designed for the physical measurement of physiological parameters. Before using these two types of microprobes simultaneously it was necessary to optimise the measurement conditions of the enzymatically modified classical thermal probe, by altering the buffer type and increasing the sensitivity by the addition of specific chemical reagents.

2. Experimental

2.1. Materials

Glucose oxidase (EC 1.1.3.4) from *Aspergillus niger* with an activity of 180 U mg^{-1}, catalase (EC 1.11.1.6) from bovine liver with an activity of 13 000 U mg^{-1} and bovine serum albumin (BSA) were purchased from Sigma. A 25% aqueous solu-

tion of glutaraldehyde (GA) was obtained from Merck. All other reagents were of purum analytical grade. Bidistilled or deionized water was used throughout for the preparation of samples, buffer and other solutions.

2.2. Enzyme immobilisation

Glucose oxidase and catalase were immobilised using a modified procedure described earlier [8]. Solutions of glucose oxidase, catalase and BSA (10% w/w) were prepared in a 10 mM phosphate buffer (KH$_2$PO$_4$-NaOH), pH 7.4. Prior to their deposition on the sensor chip these solutions were mixed in defined proportions and then glycerol and GA were added. The mixture composition used was 5% glucose oxidase, 1% catalase, 5% BSA, 10% glycerol and 2.5% GA. As a differential experimental set-up was used, a drop of the enzyme-containing mixture was deposited on the sensitive area of one of the thermistors, whilst a mixture containing 11% BSA, 10% glycerol and 2.5% GA was deposited on the reference thermistor. The membranes were dried for 15–20 min at room temperature. Before use the membranes were soaked in a 10 mM phosphate buffer, pH 7.4, for at least 15–20 min to equilibrate the membrane system.
Fig. 2. Calibration curves of the glucose sensor in different buffer solutions: curve 1, 100 mM phosphate buffer, pH 7.4; curve 2, 100 mM TRIS buffer, pH 7.4; curve 3, 100 mM HEPES buffer, pH 7.4.

2.3. Apparatus

Two matched thermistors "Betatherm" 10 K3MCD2 (10 000 Ω at 25°C, temperature coefficient of -4% °C^{-1} (25°C)) connected to a Wheatstone bridge have been used. These thermistors were fabricated using microtechnology techniques by ASLEC (France). The active parts of the thermistors were covered by a polyimide layer for an efficient electrical insulation. The biomembrane containing the enzymes was applied to the surface of one of the thermistors and the membrane without enzyme was applied to the surface of the other thermistor. As a result of the enzyme reaction the temperature increases near the enzyme thermistor surface whilst the temperature near the other thermistor does not change. The temperature difference between the two thermistors leads to the thermistor resistance difference being converted into the voltage signal by means of an electrical scheme. This signal is directly proportional to the concentration of the substrate in the buffer solution. After amplification, the differential signal of the two thermistors

was registered with a recorder.

The pair of thermistors was placed within a thermostated glass cell (volume of 80 ml) (Fig. 1). Buffer solution was constantly pumped through the cell at flow rate of 0.80 ml min^{-1} by means of a homemade peristaltic pump. The temperature of the solution inside the cell and the solution flowing into the cell was held at 28°C by means of thermostated bath. Temperature oscillations of the cell solution were 5×10^{-3}°C; thus the thermistor differential reduced the noise of the temperature changes to 10^{-4}°C for oscillations of low frequencies (period $= 1$ mn) and 10^{-5}°C for oscillations of high frequencies (period < 1 min). The measurements were carried out using a potentiometric recorder at a sensitivity of 5×10^{-3}°C for a full-scale deflection in the 50 mV range. Glucose solutions at different concentrations were injected through the cell, and the measurements were carried out in a steady-state situation. The total time required for a determination depends on the cell geometry and the flow rate; for the experimental conditions used it usually takes 2–3 min.
Fig. 3. Calibration curves of the glucose biosensor in TRIS buffer, pH 7.4, at different concentrations of buffer: curve 1, 20 mM; curve 2, 50 mM; curve 3, 100 mM.

3. Results and discussion

When glucose is injected into the cell, the following reactions occur close to the thermistor covered by the membrane containing the enzymes glucose oxidase and catalase:

$$\beta\text{-D-glucose} + O_2 \xrightarrow{\text{GOD}} \text{D-glucono-}\delta\text{-lactone} + H_2O_2 \ (79 \text{ kJ mol}^{-1}) \tag{1}$$
$$\downarrow$$
$$\text{D-gluconate} + H^+$$

$$H^- + \text{buffer} \rightleftharpoons \text{buffer} - H \ (X \text{ kJ mol}^{-1}) \tag{2}$$

$$\overset{\text{Catalase}}{H_2O_2 \longrightarrow H_2O + 1/2O_2} \ (100 \text{ kJ mol}^{-1}) \tag{3}$$
Glucose oxidase oxidises glucose with a heat production of about 80 kJ mol^{-1}. The differential pair of glucose sensitive thermistors can register this heat production, which is proportional to the concentration of glucose in the sample; nevertheless the sensitivity of such a process can be not very high. There is a possibility of increasing the total amount of heat produced in the actual oxidation of glucose by using the heat produced in the second and third reactions (buffer protonation (2) and hydrogen peroxide decomposition by

catalase (3)) and, thus, realising an effective chemical and biochemical amplification of the biosensor response to the glucose concentration.

For effective chemical amplification of the biosensor responses different types of buffer solutions were used. As can be seen in Fig. 2, the biosensor responses depend on the type of buffer, and the calibration curves show different shapes and various dynamic ranges. The biosensor response is higher in HEPES (N-(2-hydroxy-ethylpiperazine-N'-(2-ethane – sulphonic acid)) and TRIS (tris(hydroxymethyl(aminomethane)) buffers compared to the one obtained in a phosphate buffer (pH for each buffer solution was the same and was equal to 7.4). Comparison of the calibration curves of the biosensor obtained in HEPES and TRIS buffers shows that the sensor
Fig. 4. Calibration curves of the glucose biosensor in 100 mM TRIS buffer, pH 7.4, at different concentrations of hydrogen peroxide: curve 1, 0 mM; curve 2, 1 mM; curve 3, 3 mM.

response in HEPES buffer is higher in the range from 2 to 8 mM glucose concentration, but a larger linear dynamic range of the glucose sensor is obtained in TRIS buffer. Further, TRIS buffer was chosen and the dependence of the glucose biosensor response on the buffer concentrations was studied. These results are presented in Fig. 3. As one can see, a buffer concentration of 20 mM is not sufficient for a complete binding of all the protons generated by reaction (1). In 50 and 100 mM buffer solutions the sensor response is higher and almost the same; thus a buffer concentration of 50 mM is sufficient to obtain a maximum signal. But the effect obtained by changing from phosphate buffer to TRIS or HEPES buffer cannot be explained only by the higher protonization enthalpy of these buffers. It is probable that the buffer effects of an enzyme conformation more favourable to the molecular recognition occur, inducing a better enzymatic turn-over. So it is well known that HEPES constitutes a good tissue culture medium; the growing ability of the cells is related to their metabolism which is governed mainly by enzymatic reactions. On the other

hand, phosphate based buffers present poor long term stability and such polluted aged buffers could induce enzyme inhibition.

The possibility of biochemical amplification of the biosensor response by the use of reaction (3) was studied. The results are presented in Fig. 4. Hydrogen peroxide was added in the solutions of buffer and glucose. Catalase decomposes H_2O_2 and therefore the concentration of oxygen increases in the cell solution. From Fig. 4 it is seen that increasing the concentration of hydrogen peroxide only up to 1 mM induces a significant increase in the sensor response value and the sensor linear range; such low H_2O_2 concentrations do not affect the enzyme activity. This effect of biochemical amplification by using the catalase reaction was investigated earlier and reported by Tran-Minh and Vallin [9]. But in our case the combination of chemical and biochemical amplification of the sensor responses is much more efficient.

All the results presented were obtained with a flow rate of 0.8 ml min^{-1} in the cell. Therefore in further experiments the influence of the flow rate in the cell on the sensor characteristics was stud-
Fig. 5. Calibration curves of the glucose biosensor in 100 mM TRIS buffer, pH 7.4 with different sample flow rates in the cell: curve 1, 0.08 ml min^{-1}; curve 2, 0.8 ml min^{-1}.

ied. It was shown (Fig. 5) that when the flow rate in the cell decreases from 0.8 to 0.08 ml min^{-1} the sensor demonstrates a more narrow linear dynamic range. This effect can be explained by the differences between the diffusion rates for glucose and oxygen in the enzyme membrane. For high glucose concentrations nearly the same maximum sensor response corresponding to the maximum rate of the enzymatic reaction V_m is reached. At low flow rates the reaction is limited by oxygen diffusion which is not at a sufficient concentration near the enzymatic membrane; thus a low value of the Michaelis constant K_m is observed. K_m values correspond approximately to the substrate concentration giving the $V_m/2$ rate and reach about 1.5 mM. For higher flow rates the renewal of oxygen is sufficient and a value for K_m of around 4 mM is observed, which is closer to the values (4.5 mM) usually given for the immobilized GOD/catalase system [10].

4. Conclusions

A glucose sensitive enzymatic thermal sensor based on a pair of commercial microthermal probes was prepared by cross-linking the corresponding enzymes (glucose oxidase and catalase) with bovine serum albumin on the sensor surfaces. Characteristics of the obtained sensor were tested in different conditions. To find the maximal sensitivity, the calibration curves of this sensor were measured in different buffer solutions, with and without the addition of H_2O_2 to the samples at various sample flow rates in the cell. Different buffer solutions and hydrogen peroxide concentrations were used to realise the principles of a chemical and biochemical amplification of the biosensor response. It was shown that the value of the biosensor response and its dynamic range increase in the presence of hydrogen peroxide and depend on the type of buffer solutions tested and the rate of the sample flow stream.

In the future such a sensor could be integrated into multimicrosensing devices for the simultaneous measurements of physical and chemical parameters.

Abstract

A liquid membrane electrode prepared with moclobemide–dipicrylamine ion-pair complex, dissolved in nitrobenzene as solvent, was studied for analytical performance. The linear response covers the range 10^{-3}–10^{-6} M moclobemide solution, with a slope of 50.7 mV decade^{-1} (pH range 3.5–8). The detection limit is 3×10^{-7} M. The electrode shows stability, good reproducibility and fast response. The selectivity of the electrode is good. There are two important interfering ions: mianserin and thiamine (Vitamin B_1). The compression excipients (such as Mg^{2+}, starch, talcum powder) do not interfere. These characteristics of the electrode enabled it to be used for the determination of moclobemide in drugs and as an active substance, via indirect and direct potentiometric methods. Via an indirect potentiometric method moclobemide, as an active substance, can be determined with an average recovery of 99.96% and a relative standard deviation of 0.85%, and this method can also be used for its determination in drugs with a relative standard deviation of < 2%. The electrode is useful for the determination of the dissolution rate of moclobemide tablets. The physical processes are numerically simulated by typical equations. The apparent first-order rate constants for disintegration and dissolution were calculated.

Keywords: Moclobemide-selective membrane sensor; Pharmaceutical analysis; Potentiometric methods; Dissolution rate; Content uniformity

1. Introduction

The development of ion-selective membrane electrodes has been quickly followed by applications not only in inorganic analysis but also in the pharmaceutical field [1–4]. From the analytical point of view they represent a favorable means for

determining various ions owing to their ability to monitor selectively and continuously the activity of a particular ion in a solution. They can be used in kinetic studies [5], resolution of reaction mechanisms, biochemical and biomedical research, and flow-injection analysis.

Moclobemide (MB), p-chloro-N-(2-morpholinoethyl)benzamide, is widely used in the treatment of depression.

* Corresponding author.
Moclobemide

The pharmacokinetics of moclobemide were studied [6–8]. The structure of moclobemide was confirmed by Wonters et al. [9]. The official standard method for the assay of moclobemide is based on non-aqueous titration [10]. In this paper, a method for the determination of moclobemide in pharmaceutical preparations is proposed. The method is fast and shows good reproducibility.

2. Experimental

2.1. Electrode design

The membrane electrode, based on a moclobemide–dipicrylamine (DPA) ion-pair complex, was prepared by impregnating the support material (a graphite rod) as described elsewhere [11] with a solution of 10^{-3} M ion-pair complex in nitrobenzene and attaching it to the end of a Teflon tube. When not in use, the electrode was kept in a 10^{-3} M MB^+DPA^- solution.

2.2. Apparatus

A Cole Parmer pH/mV meter was used for all direct potentiometric measurements. The electrode was used in conjunction with a Radiometer K401 calomel electrode. The titration curves were obtained by using an automatic titration assembly consisting of an ABU 12 autoburette, a TTT2 titrator, and a SBR 2c recorder (Radiometer, Copenhagen, Denmark). The pH measurements were performed with a Radiometer G202 B glass electrode in combination with a Radiometer K401 calomel electrode. The dissolution test was performed in a basket-stirrer USP-type apparatus [10].

2.3. Reagents and materials

Moclobemide and its pharmaceutical preparations were supplied by the Institute of Chemical and Pharmaceutical Research, Bucharest. Other materials and the reagents DPA and nitrobenzene (NB) were obtained from Fluka (Buchs, Switzerland).

Solutions of moclobemide were prepared by serial dilution while keeping the pH constant (citrate buffer pH 4.5, 71.9 ml of 0.1 M sodium citrate solution and 29.1 ml of 0.1 M HCl solution). A solution of DPA (10^{-2} M) was prepared by dissolving 0.4390 g DPA and diluting it in 100 ml of 5% Na_2CO_3 solution. The standard solution of sodium tetraphenylborate (NaTPB), of concentration 5×10^{-2} M, was prepared by dissolving 17.1220 g of the compound in distilled water and diluting it to 1 l, which dilution factor was determined using a chloroquine diphosphate standard substance.

2.4. Recommended procedures

2.4.1. Direct potentiometry

Standard solutions of 10^{-2}–10^{-6} M of pH 4.5 (citrate buffer) were prepared by serial dilutions of a 10^{-2} M solution of moclobemide. The electrode was placed in the stirred standard solutions and graphs of E (mV) vs. pMB were plotted. The unknown concentration is determined from the calibration graph.

2.4.2. Potentiometric titration

The electrode was placed in the sample solution (30–40 ml, concentration approximately 10^{-2} M, containing 2 ml of 5 M HCl solution) and the solution was titrated with 5×10^{-2} M NaTPB. The end point corresponds to the maximum slope on the E (mV) vs. volume of titrant curve (1 ml of 5×10^{-2} M NaTPB is equivalent to 13.4 mg of moclobemide).

2.4.3. Content uniformity assay of moclobemide tablets

One tablet was placed in each of 10 separate 100 ml beakers and dissolved by shaking with about 30–40 ml distilled water, in the presence of

2 ml of 5 M HCl solution. The solutions were titrated potentiometrically, as described above.

2.4.4. Dissolution test

The test was carried out according to the USP XXII method [10], with the use of the equipment described elsewhere [12]. One tablet was placed in the basket, and the dissolution medium (250 ml of 0.1 M HCl) was maintained at $37.0 \pm 0.5°C$. The basket was rotated at 50 rev min^{-1}. For the potentiometric determination, after an appropriate time interval (1 min) the potential values are recorded, and the amount of moclobemide is calculated from the calibration graph. In order to investigate all the important physical processes during the dissolution period, the release profiles were numerically simulated by typical equations [13].

3. Results and discussion

3.1. Electrode response

The equation of the calibration graph is $E = E° + 50.7 \times \log[MB]$ with a correlation coefficient of 0.9997.

The response characteristics of the electrode are shown in Table 1. The stability of the electrode response was checked over a period of 8 months. The response time of the electrode depends on the

E(mV) vs SCE
Fig. 1. Effect of pH on the response of the moclobemide electrode (10^{-3} M moclobemide solution).

Table 1

Response characteristics for moclobemide-selective electrode (all values are the average of 20 determinations; all measurements made at 25°C)

Parameter	Response
Slope (mV pMB^{-1})	50.7 ± 0.8
Intercept, $E°$ (mV)	329.91 ± 2.12
Linear range (M)	10^{-3}–10^{-6}
Detection limit (M)	3×10^{-7}

concentration of moclobemide (less than 1 min for 10^{-3}–10^{-4} M moclobemide solutions and 1–2 min for 10^{-5}–10^{-6} M moclobemide solutions). The electrode response displayed good stability and reproducibility over the test, as shown by the relative standard deviation values.

3.2. Effect of pH on the response of the electrode

The effect of pH on the response of the potential readings of the moclobemide was checked by recording the emf of a cell which contained 10^{-3} M moclobemide solution at various pH values, which were obtained by the addition of very small volumes of HCl and/or NaOH solution (10^{-1} M or 1 M of each). The E (mV) vs. pH graph presented in Fig. 1 shows the pH independence in the range 3.5–8.

At higher pH values, free base precipitates in the test solutions and consequently the concentration of unprotonated species gradually increases. As a result, lower emf readings are recorded. At low values, the concentration of protonated species gradually increases and the emf is a function of pH.

3.3. Selectivity of the electrode

Moclobemide has to be determined in pharmaceutical dosage forms which contain various inorganic and organic substances. The effect of some of these matrices on the response of the electrodes was studied by the mixed solution method. The concentrations of interfering ions and moclobemide were 10^{-2} M and 10^{-4} M respectively.

The selectivity coefficients, presented in Table 2, indicated that the response of the proposed mem-

Table 2

brane electrode is highly affected by mianserin and thiamine (vitamin B1). Excipients such as Mg^{2+}, starch and talcum powder do not interfere.

3.4. Analytical applications

The electrode proved to be useful for the assay of the moclobemide content of pharmaceutical formulations using the potentiometric titration method. The results obtained are given in Table 3. As can be seen, a high precision was obtained (RSD < 2%).

Table 3

Determination of moclobemide with a moclobemide-selective membrane electrode

Product	Sample	Recovery (% of nominal value)[a]	RSD (%)[b]
Moclobemide	1	100.00	0.85
raw material	2	99.69	
	3	99.89	
Moclobemide A[c]	1	99.21	1.05
100 mg per tablet	2	98.20	
	3	98.76	
Moclobemide B[c]	1	99.98	1.03
100 mg per tablet	2	99.41	
	3	99.58	

[a] All values are the average of four determinations.
[b] RSD (%) refers to all 12 determinations.
[c] Moclobemide A represents a batch obtained with high pressure pastillation.
[d] Moclobemide B represents a batch of talcum powder-coated tablets obtained with low pressure pastillation.
Fig. 2. Dissolution profiles of moclobemide A and moclobemide B. All values are the average of six determinations.

The results obtained by potentiometric titration of moclobemide raw material and moclobemide A and moclobemide B tablets were in good accordance with those obtained by potentiometric titration in non-aqueous media [10] with 0.1 N $HClO_4$: 99.20%, 99.25% and 99.40% respectively.

The desirability of an in-vitro test that adequately reflects the physiological availability of solid dosage forms of drugs is now recognized. The measurement of a parameter that is related to the rate of dissolution of a solid has been suggested as a more realistic variable and this has led to numerous papers describing different methods and equipment for monitoring dissolution tests [13–15].

The dissolution test was performed with a basket-stirrer USP-type apparatus operated at 50 rev min^{-1} in 250 ml of 0.1 M hydrochloric acid (simulated gastric fluid) by the direct potentiometric moclobemide membrane electrode method. The simulated gastric fluid was kept at $37.0 \pm 0.5°C$. The equation of the new calibration graph is $E = 24.37 + 79\,016.2 \times c$ with a correlation coefficient of 0.9078 (c is the moclobemide concentration in mole l^{-1}).

Fig. 2 shows the dissolution profiles of moclobemide tablets. Taking into account the S shape of the curves, there are some possibilities for the simulation of physical processes involved in the dissolution steps. The release of the active principle of the uncoated tablets (moclobemide A)

in simulated gastric fluids follows the Langenbucher model [16] (for high pressure pastillation, 6 kgf cm^{-2}) i.e. the dissolution process involves two main steps: an initial step of about 3 min during which there is a disintegration process followed by a rapid process of active principle dissolution. The Fick–Higuchi model is followed for talcum powder-coated tablets (moclobemide B) (low pressure pastillation, 3 kgf cm^{-2}): i.e. the dissolution process involves a rapid release of the active principle. All other simulation possibilities tested were found to be inadequate for the moclobemide tablets. A graphical method was proposed for the disintegration–dissolution analysis of cumulative percent dissolved vs. time data [5]. With the aid of this method, we can determine the pharmacokinetics of moclobemide tablets. The apparent first-order rate constants for disintegration (k_d) and dissolution (k_s) respectively were: $k_d = 0.156$ min^{-1}, $k_s = 0.394$ min^{-1} for moclobemide A and $k_d = 0.778$ min^{-1}, $k_s = 0.940$ min^{-1}, for moclobemide B. In both cases, the dissolution process is more rapid than the disintegration process. There are no degradation products detected in the in-vitro test. The differences between the dissolution and disintegration rates are due to the different values of pressure utilized for manufacturing the tablets. The compression excipients do not interfere.

4. Conclusions

The moclobemide-selective membrane electrode, based on the MB$^+$DPA$^-$ ion-pair complex, exhibits useful analytical characteristics for the determination of moclobemide in pharmaceutical formulations. This is due to its good and reproducible response characteristics. These character-istics enable the electrode to be used in the quantitative analysis and determination of the dissolution profiles of moclobemide in its pharmaceutical formulations. The advantage of the electrode technique for carrying out such a test is that the selective electrode can monitor continuously the concentration of the active ingredient in the standardized dissolution cells.

Amperometric determination of lactate dehydrogenase based on a carbon fiber microcylinder electrode modified covalently with Toluidine Blue O by acylation

H.X. Ju *, L. Dong, H.Y. Chen

Department of Chemistry, Nanjing University, Nanjing 210093, People's Republic of China

Abstract

A method has been developed for the modification of a carbon fiber microcylinder electrode with acylation. The stability and surface coverage of the Toluidine Blue O-modified microelectrode were studied by cyclic voltammetry. The modified electrode showed significant activity for the electrocatalytic oxidation of NADH in pH 6.8–7.8 solution. The catalytic current increased linearly with increasing concentration of NADH from 4.0×10^{-5} to 1.5×10^{-3} M. A simple amperometric determination based on electrochemical detection of NADH produced from the enzymatic reaction of lactate with NAD^+ under the catalysic effect of lactate dehydrogenase (LDH) is reported. The experimental factors which had primary influence on the analytical performance were studied. The sensor had a linear response over a range of LDH concentrations from 5.0 U l^{-1} to 200 U l^{-1} at -0.2 V vs. SCE under optimum conditions. A satisfactory result was obtained for the determination of LDH in clinical blood samples.

Keywords: Acylation; Amperometric determination; Carbon fiber microcylinder electrode; Lactate dehydrogenase; Toluidine Blue O

1. Introduction

Many current works in the analytical field are devoted to chemically-modified electrodes and biosensors [1,2]. Some mediators have been fixed on the electrode surface by adsorption, electrochemical polymerization or polymer coating to efficiently facilitate electron transfer and to determine some biomolecules [1–4]. The irreversible adsorption of commercial dyes on a

graphite electrode is a simple method for preparing modified electrodes [2,5]. In order to increase the stability of the modifying layer, Persson and co-workers [2,6,7] synthesized derivatives of Toluidine Blue O by introducing several aromatic rings to enhance π-electron overlapping with the carbonaceous surface. However, at a microelectrode modified by irreversible adsorption, no matter what the mediator is, even if it has a few aromatic rings, the stability of the modified microelectrode is very poor because of the high mass transport rate of

* Corresponding author.

the microelectrode [8,9], which makes the mediator, and its product, diffuse rapidly away from the surface during the process of electrochemical reaction. Thus, the catalytic efficiency declines greatly.

The application of carbon fiber microelectrodes (CFMEs) for electrochemical determinations has attracted great interest [8,9–13]. The preparation of modified CFMEs is usually done by using noble metal deposition [12], polymer coating [13,14] or covalent modification [15]. On the surface of a carbon electrode, the process of covalent modification is usually done by acylation [16–18]. Hajizadeh et al. [18] have used a crosslinking agent — triisocyanate — to fix thionin on a graphite electrode by acylation. The method has also been used to immobilize enzyme at a CFME by using carbodiimide [19,20]. However, to our knowledge, there has been no report until now of covalent modification by direct amidation with thionyl chloride at a CFME. In this work, Toluidine Blue O (TBO) was covalently bonded to the surface of a CFME for the first time. The stability of TBO-modified CFME is very good. The modified electrode can effectively catalyze the oxidation of NADH at a carbon fiber microelectrode.

The coenzyme NAD⁻ and its reduced form NADH are used by over 250 dehydrogenases, and play a major role in many biological redox reactions. The direct electrochemical determination of NADH, particularly in a small system, is very important in clinical medicine. The electrochemical oxidation of NADH, whose normal formal potential is −0.56 V vs. SCE at pH 7.0 and 25°C, has been extensively studied at various modified electrodes [2,5,6,18,21–28]. Willner and Riklin [27] developed the amperometric sensors for NADH and malic acid by covalently linking pyrroloquinolinequione (PQQ) or PQQ and malic enzyme with 1-ethyl-3[3-(dimethylamino)propyl]-carbodiimide (EDC) and N-hydroxysulfosuceinimide sodium salt at a self-assembled cyteamine monolayer-modified Au electrode. Katz et al. [28] used cystamine and cysteamine to functionalize both Au and Pt electrodes and to covalently link PQQ with EDC; the modified electrodes can also catalyze the oxidation of NADH. However, little study of the direct electrochemical determination of NADH at

a CFME has been reported. The electrocatalytic oxidation of NADH at a TBO- (and its derivatives) modified graphite electrode has been presented by Persson and co-workers previously [2,6]. However, if the TBO-modified carbon fiber microelectrode was prepared with their method, its stability was very poor [29]. Moreover, the determination of lactate dehydrogenase (LDH) with a TBO-modified CFME has never been studied. Here we report on the use of a TBO-modified microelectrode in biosensors for the monitoring of LDH based on the determination of NADH. The results will be very significant for the monitoring of enzyme in a small clinical system and the development of microbiosensors.

2. Experimental

2.1. Materials and reagents

TBO (B.S. grade) was obtained from the Chroma Chemical Reagent Company (UK), the reduced form of nicotinamide–adenine dinucleotide (NADH, >95%) and LDH (EC 1.1.1.27, Type XI, from rabbit muscle, 700 U mg⁻¹) were from Sigma (USA). These reagents were directly used as received without further purification. The reagents used for making up 0.2 M pH 2–12 phosphate buffer solutions, thionyl chloride (SOCl₂), and other reagents, obtained from chemical companies in The People's Republic of China, were of analytical-reagent grade. Pyridine was redistilled with P₂O₅ (8 g per 100 ml) and was stored over a 4 Å molecular sieve activated at 550°C. Water used in the experiment was doubly-quartz-distilled. Carbon fibers (PAN-type) with 6–7 μm diameter were obtained from the Shanghai Synthetic Fiber Research Institute. Epon 812 epoxy resin (New York, USA) was used to seal the electrodes.

2.2. Preparation of TBO-modified CFME

The method of fabrication of the CFME was similar to that given in a previous paper [9]. Briefly, a single carbon fiber was sealed in a glass capillary tube with epoxy resin. First, a CFME of

length 6-10 mm was washed thoroughly with acetone and distilled water in an ultrasonic bath, and pretreated electrochemically in 1.0 M H_2SO_4 solution with a triangular-wave potential sweep from -1.0 V to $+2.0$ V at a scan rate of 200 mV s^{-1} for 50 min. Next, the treated electrode was washed with doubly-distilled water and dried in air, and immersed in $SOCl_2$ for 30 min. Then the electrode was rinsed with tetrahydrofuran (THF) to remove $SOCl_2$ remaining on its surface, and dipped in anhydrous pyridine solution containing 1.0×10^{-3} M TBO for 15 min. During this process pyridine, as proton acceptor, deprotonated the oxidized TBO and gradually converted it into the imino form which reacted with the $-COCl$ group on the electrode surface. Finally, the modified electrode was rinsed with phosphate buffer (pH 7.0) and stored in the same buffer solution.

2.3. Procedures

Electrochemical measurements were carried out with a Model BAS-100B Electrochemical Analyzer with a PA-1 Preamplifier (Bioanalytical Systems (BAS), West Lafayette, IN) to amplify current and filter out noise and an FPG-310 Color Plotter (Fujitsu Company, Japan) to record the voltammograms. A type 501 thermostat (Shanghai, People's Republic of China) was used to control the experimental temperature at $20 \pm 0.1°C$.

A three-electrode configuration with a saturated calomel electrode (SCE) as reference, Pt wire as counter and the above-modified electrode as working electrode was employed. After deaerating with pure N_2 for 10 min, the electrochemical measurements were carried out under a nitrogen atmosphere.

3. Results and discussion

3.1. Cyclic voltammogram of TBO-modified CFME

The cyclic voltammograms of the TBO-covalently-modified electrode in pH 7.0 buffer solution at a scan rate of 100 mV s^{-1} showed a couple of cathodic and anodic peaks (Fig. 1). Their peak

potentials were at -276 mV and -228 mV ($E^{o'} = -252$ mV, $\Delta E_p = 48$ mV) respectively. The peak potentials shifted slightly in a positive direction in comparison with those of soluble TBO at a bare carbon fiber microelectrode [29] and the change in the normal formal potential was about 29 mV. The small change was similar to that resulting from acylation found in the literature [16,30], indicating that TBO on the electrode surface had been acylated.

At the beginning of the cyclic voltammetric sweep of the TBO-covalently-modified electrode, the cathodic and anodic peak currents decreased rapidly, then dropped gradually to a constant value and remained at this value for a very long time (see Fig. 1). Furthermore, no change in peak current appeared after the modified microelectrode had been dipped in pH 7.0 buffer solution for several weeks, indicating that the stability of the TBO-covalently-modified CFME was very good. However, the half life of TBO adsorbed on the CFME is only 55 min [29]. The better stability indicated that TBO was firmly fixed on the surface of the carbon fiber by a covalent bond. The decrease in peak current at the beginning of the sweep was due to the desorption of some adsorbed TBO. Because the differences in peak potentials of acylated TBO and adsorbed TBO,
Fig. 1. Cyclic voltammograms of TBO-modified microelectrode in pH 7.0 phosphate buffer solution at 100 mV s^{-1}.

about 25 mV for the cathodic and 32 mV for the anodic peak, were small, only a single pair of peaks occurred, as shown in Fig. 1.

The reactions in the process of TBO covalent modification can be described as follows. First of all, a lot of carboxyl groups were formed on the surface of the carbon fiber during electrochemical pretreatment [15,20], they were then acylated by the reaction between –COOH and $SOCl_2$ to form –COCl groups under the usual conditions. Finally, these –COCl groups were amidated with TBO in the presence of excess organic base pyridine, as a proton acceptor, which removed the positive charge of TBO and converted it to the imino form, to form the amido link and to covalently bond TBO to the surface of the carbon fiber. Thus, this method of preparing a modified carbon fiber electrode can greatly enhance the stability.

3.2. Surface concentration of TBO at modified microelectrode

The surface concentration Γ of TBO can be calculated according to $\Gamma = Q/nFA = S/nFAv$, where Q is the charge consumed during complete reduction of TBO, S is the peak area of the cyclic voltammogram, and the other symbols have their usual meanings. At a microcylinder electrode with a geometric area A of 2.0×10^{-3} cm^{-2}, the surface concentration Γ_{exp} was 3.4×10^{-10} mol cm^{-2} ($n = 2$), which was determined from the steady cyclic voltammogram at 100 mV s^{-1} in pH 7.0 buffer solution.

Given that the horizontal section area of methylene blue, which is of similar structure to TBO, is 0.75 nm^2 [31], the theoretical mono-layer adsorbance Γ_{theory} of MB at an electrode is 2.2×10^{-10} mol cm^{-2}. Comparing $\Gamma_{exp,TBO}$ with $\Gamma_{theory,MB}$, TBO fixed on a carbon fiber surface was a monolayer due to the roughness of the pretreated carbon fiber surface, and almost the whole electrode surface was activated by electrochemical oxidation and acylation.

3.3. Electrocatalytic oxidation of NADH at TBO-modified carbon fiber electrode

This work showed that the TBO-modified electrode was able to catalyze the oxidation of NADH in pH 7.0 phosphate buffer solution via an electron transfer reaction between acylated TBO and NADH at the heterogeneous boundary layer. The experimental results are shown in Fig. 2. When the buffer solution included 1.0×10^{-3} M NADH, the anodic peak current of the cyclic voltammogram increased, the cathodic peak current decreased, and the anodic peak potential shifted in a positive direction by about 60 mV, which is very characteristic of an electrocatalytic oxidation process. The shift resulted from the catalytic reaction between acylated TBO and NADH, which possibly changed the ratio of surface concentrations of oxidized and reduced forms of TBO and the electron transfer rate between the electrode and the TBO at the same potential. The catalytic mechanism can be expressed as follows:

$$TBO_{red} - 2e \rightleftarrows TBO_{ox}$$

$$NADH + TBO_{ox} \rightarrow TBO_{red} + NAD^+$$
The catalytic current i_{cat} ($= i_2 - i_1$, where i_1 and i_2 are the anodic peak currents of the modified electrode in buffer without and with NADH respectively) of NADH increased linearly with increasing concentration of NADH from 4.0×10^{-5} to 1.5×10^{-3} M (inset to Fig. 2) with a correlation coefficient of 0.992 and a relative standard deviation of 1.5% for six determinations with 1.0×10^{-3} M NADH.

3.4. Effects of experimental conditions on catalytic peak current

Fig. 3 shows the dependence of catalytic peak current on scan rate. At a high scan rate the catalytic peak current was proportional to $v^{1/2}$; however, at a lower scan rate the plots deviated from linearity. The catalytic current curve (broken line in Fig. 2) tended to a sigmoidal shape with the decrease of the scan rate. These are the characteristics of diffusion mass transport at a microelectrode. Considering that the peak potential was independent of v, the electrode process was controlled by the diffusion of NADH in solution [13,32]. Thus, the interfacial chemical reaction rate between bonded TBO and NADH was large, and the electrode process is similar to
Fig. 4. Scheme of electrochemical response for LDH at a TBO-modified electrode.

the direct electrochemical oxidation of NADH at the electrode.

The catalytic peak current also depended greatly on the pH of the solution (Fig. 3). When the pH was low, the catalytic current was very small, and it increased with increase of pH. However, when the pH was >7.8, the current decreased with increase in pH. This phenomenon is similar to those described in Refs. [2] and [18], which resulted from both decomposition of NADH in acid solution and the rate of reaction between the TBO and NADH. With increasing pH the reaction rate and catalytic current decreased [2]. However, when the pH was <7, because the experiment was carried out after NADH was added to background for about 1 min in order to stir and deaerate, part of the NADH would decompose, which resulted in the decrease of the catalytic peak current. NADH is stable in neutral and basic pH solutions and the concentration of NADH did not change with time. Therefore, the catalytic peak current was a maximum between pH 6.8 and 7.8. A pH of 7.0 was used for the subsequent work [18].

3.5. Response of the modified microelectrode to LDH

When the pH 7.0 phosphate buffer solution included 1.0×10^{-3} M NAD^+, or 1.0×10^{-3} M NAD^+ and L-lactate, both the anodic and cathodic peak currents of the cyclic voltammogram of the TBO-modified microelectrode did not change. This result indicated that NAD^+ and L-lactate did not interfere with the electrode process of the TBO electrode. However, when the solution of 1×10^{-3} M NAD^+ and lactate included 100 U l⁻¹ LDH, the cyclic voltammogram of the TBO-modified electrode showed the same change as in Fig. 2, indicating that LDH cata-

Fig. 3. Plots of catalytic peak current vs. $v^{1/2}$ at pH 7.0 (○) and vs. pH of solution at 100 mV s⁻¹ (●).

lyzed the oxidation of lactate with a simultaneous reduction of NAD^+ to produce NADH. The formed NADH diffused to the electrode surface and catalyzed the electrode reaction of TBO. With increasing LDH concentration, the catalytic peak current increased, which is the basis for the determination of LDH. The overall reaction process can be seen in Fig. 4.

3.6. Effect of experimental conditions on the amperometric response to LDH

In amperometric measurements, the potential dependence of LDH response (hydrodynamic voltammogram) in the range $-0.6-+0.1$ V indicated that the amperometric response of the modified electrode to LDH started at -0.35 V. With the positive shift of applied potential, the response rose sharply up to -0.2 V, and then exhibited almost a constant value. An applied potential of -0.2 V was chosen for subsequent work.

The effect of pH on the LDH response was very obvious. In the pH range 4–6.8, the amperometric response to LDH increased with increasing pH. The response remained constant at pH 6.8–8.5, and then decreased when pH was >8.5. A wider pH range of stable response to LDH than to NADH occurs because the reaction of lactate and NAD^+ under the catalysis of LDH is a process of releasing H^+, and therefore a high pH is advantageous to the positive reaction. However, too high a pH would result in both the decomposition of NAD^+ and the decrease of the reaction rate between NADH and mediator. Therefore, the amperometric determination was performed at pH 8.0.

NAD^+ concentration also affected the response of the modified electrode to LDH. At various LDH concentrations, all responses increased with increasing NAD^+ concentration, and remained constant when the NAD^+ concentration was larger than 1.0×10^{-3} M, which was selected as an optimum condition. In order to quicken the catalytic reaction of LDH, an excess lactate concentration of 5.0×10^{-3} M was selected.

3.7. Application of TBO-modified electrode in the measurement of LDH

Fig. 5 shows a typical trace of the steady state current–time response of the TBO-modified electrode at -0.2 V with successive injections of LDH (in 50 U l^{-1} steps). With the injection of LDH the response increased, and the time to reach constant response was very short (<10 s). The calibration plots of amperometric response vs. the concentration of LDH (inset to Fig. 5) showed a linear relationship. The linear response range was from 5.0–200 U l^{-1} with a correlation coefficient of 0.990. The relative standard deviation of results was 3.2% for five successive determinations at 100 U l^{-1}.

After a clinical human blood serum sample of 200 μl was injected into 1.8 ml pH 8.0 buffer solution including 1.1×10^{-3} M NAD^+ and 5.5×10^{-5} M lactate for 30 s, the amperometric response of the TBO-modified microelectrode was used to assay the LDH content without any interference. The average value of three determinations with an interval of 8 h was 23 U l^{-1} (SD = 0.5) in the diluted solution. Thus, the content of LDH in the human blood serum sample was 230 U l^{-1}. The result was close to the value of 225 U l^{-1} obtained by spectrophotometry (LDH–L method) at 340 nm wavelength. The advantages of the biosensor are that it has a
Fig. 5. Amperometric response to successive addition of 50 U l^{-1} LDH in pH 8.0 buffer including 1.0×10^{-3} M NADH and 5.0×10^{-3} M lactate with an interval of 1 min at -0.2 V. Inset: calibration curve of LDH at TBO-modified carbon fiber electrode.

shorter response time to LDH, it can detect LDH by a direct electrochemical method in a smaller system and it could potentially be used for in vivo and clinical analysis.

Review

Basic aspects and applications of tristimulus colorimetry

K.M.M. Krishna Prasad*, S. Raheem, P. Vijayalekshmi, C. Kamala Sastri

Physical Chemistry Research Laboratories, School of Chemistry, Andhra University, Visakhapatnam 530003, Andhra Pradesh, India

Abstract

A detailed account of the specification of colour using the 1931 Commission International de L'Eclairage tristimulus coordinates and subsequent colour spaces for the measurement of small differences in colour is provided along with a review of the application of quantitative parameters for the evaluation of colour changes of acid–base and complexometric indicators. The development of screened indicators to improve the quality of colour changes at the equivalence point is discussed. Various computer programs proposed to calculate the different parameters by different algorithms are reviewed.

Keywords: Colour specification; Computer programs; Indicators; Tristimulus colorimetry

1. Introduction

Colour is what we see [1]. The sensation that results when one looks at a coloured object depends upon the nature of the surrounding field and the nature of the field to which the observer has been previously exposed. Therefore, the fundamental specification of colour must consider it as an inherent property of an object and must be based on objective measurements [2]. This specification of colour enables one to define it in terms of a set of physical operations. Consequently, the set of physical operations carried out to arrive at a physical quantity is considered as the definition of colour [3].

The visual stimulation that results when one looks at a coloured surface depends upon the character of the light by which the surface is illuminated. If a source of light is radiating energy confined within a narrow band of wavelengths such as the violet region of the spectrum, the surface will reflect only violet light. In other words, if a source is illuminated by light of substantially a single wavelength it will reflect light of this wavelength, except in the case of materials that exhibit fluorescence. Even though it is known that green paint reflects green light more effectively than light of other wavelengths, it is possible to make the green paint take on any hue of the spectrum, if suitably illuminated. However, when light of daylight quality, which is a mixture of all the components of the visible spectrum in

---

* Corresponding author.

nearly equal proportions, falls upon the surface of the green paint, blue–greenish light is reflected into the eye of the observer. In the case of an individual colour, the wavelength of the spectral region with which that particular colour is most closely identified, when illuminated by daylight, is known as its dominant wavelength [4]. However, in the case of purple it is impossible to find a single region of the spectrum that simulates this colour and the observed dominant wavelength (from the spectral reflectance curve) is that of the green colour which is complementary to purple, where the complement of a colour is the colour that produces a neutral grey in an additive mixture of the two colours.

Extensive investigations have been carried out to study the distrubution of energy (E_0) in daylight [5] by dispersing it into a spectrum by means of a prism. Each spectral region is then isolated and the amount of energy present in each region is determined from the reading of a sensitive temperature-measuring device, the surface of which has been blackened so as to convert the light energy into heat. From these studies a filter has been prepared which, when used with a tungsten lamp operated at the proper temperature, provides a source that is a close approximation to the average daylight (which is considered as a mixture of sunlight and blue light from the sky on a clear day). A source having this distribution of energy was adopted as an international standard of illumination at a meeting of the International Commission of Illumination (Commission International de L'Eclairage; CIE) in 1931 [6]. This standard source is usually denoted I.C.I. illuminant C. Two other standards, designated illuminant A and illuminant B, were also adopted at the same meeting. Illuminant A represents a source having an energy distrubution similar to that of a gas-filled tungsten lamp, whereas illuminant B is an approximate representation of mean noon sunlight. Illuminant B is slightly yellower than illuminant C and has an energy distribution intermediate between those of illuminants A and C. The characteristics of these three standard illuminants are given below [7,8].

1.1. Illuminant A

Illuminant A is a tungsten lamp operated at a temperature of 2800 K.

1.2. Illuminant B

Illuminant B utilises a lamp having the spectral quality of illuminant A in combination with a filter. The filter consists of 1 cm thick layers of each of the solutions B_1 and B_2. These solutions are in a double cell constructed of optical glass. The composition of each solution is as follows.

Solution B_1: copper sulphate ($CuSO_4 \cdot 5H_2O$), 2.452 g; mannite [$C_6H_8(OH)_6$], 2.452 g; pyridine (C_2H_5N), 30.00 ml, distilled water to make up to 1000.0 ml.

Solution B_2: cobalt ammonium sulphate [$CoSO_4(NH_4)_2SO_4 \cdot 6H_2O$], 21.71 g; copper sulphate ($CuSO_4 \cdot 5H_2O$), 16.11 g; sulphuric acid (density 1.835 g cm^{-3}), 10.00 ml, distilled water to make up to 1000.0 ml.

1.3. Illuminant C

Illuminant C consists of a source having the spectral quality of illuminant A in combination with a filter. An identical cell is used but the solutions C_1 and C_2 have the following compositions.

Solution C_1: copper sulphate ($CuSO_4 \cdot 5H_2O$), 3.412 g; mannite [$C_6H_8(OH)_6$], 3.412 g; pyridine (C_2H_5N), 30.00 ml, distilled water to make up to 1000.0 ml.

Solution C_2: cobalt ammonium sulphate [$CoSO_4(NH_4)_2SO_4 \cdot 6H_2O$], 30.580 g; copper sulphate ($CuSO_4 \cdot 5H_2O$), 22.520 g; sulphuric acid (density 1.835 g cm^{-3}), 10.00 ml, distilled water to make up to 1000.0 ml.

The spectral energy distributions of the three standard illuminants A, B and C, as adopted by the C.I.E., are taken from the consolidated study of Judd [3,4].

The question to be considered now is how light with a known distribution of energy will stimulate the eye of an observer. Even though no two observers respond in the same manner to a stimulus, the differences are very small except in the

case of observers with colour blindness [9]. Normally, an observer exposed to light of a known spectral quality cannot describe the sensation that it produces in absolute terms but only in terms of reference to some other visual sensation. Such a reply is not a description of the sensation but it does provide information that another stimulus evokes the same sensation. The analogy suggests the possibility of evaluating a colour in terms of certain standard or primary stimuli. However, it is already known that the sensation of any colour stimulus on the observer's eye can be duplicated by mixing light from three primary sources in the correct proportions. This can be achieved with the help of an optical instrument containing a suitable photometric field of view [6]. The light whose colour is to be matched is introduced into one half of the field and the light from the three sources is introduced in controlled amounts into the other half. By manipulation of the controls. a setting can be found where an exact colour match between the two halves of the field is obtained. For any given colour there is one setting for each of these controls that will produce a match. By calibrating the controls, the amount of each primary can be recorded. The unknown colour can then be specified by three numbers X, Y and Z. These numbers are known as the tristimulus values and each number represents the amount of one of the primary stimuli. The tristimulus values for any colour can then be obtained by the experimental work of an observer on a properly designated optical instrument [5]. When the same experiment is carried out by another observer for the same colour, the tristimulus values obtained are slightly different from the values reported by the earlier observer even though neither of the observers can be classed as colour blind. The two specifications may differ slightly because of the individual characteristic nature of the observers in obtaining the exact colour match by mixing the three primaries. This has led to the comparison of inter-laboratory experimental data of different groups of observers. However, the combination of the basic colour mixture data from a large group of carefully selected observers and spectrophotometric data resulted in a method to compute the average tristimulus values for any test sample.

Since the readings obtained with a spectrophotometer are independent of the peculiarities of an observer's eye, this procedure provides a basis for the specification of colour in terms of the average chromatic properties of an internationally accepted group of observers.

Initially, it is essential to determine the chromaticity values of radiation of different wavelengths with standard observers using a simple optical instrument (colorimeter). One half of the photometric field of the colorimeter is illuminated by a measured quantity of light of approximately a single wavelength, for example 400 nm. Then the observer determines the amount of each of the three primaries required to colour-match both halves of the field. These amounts of the primaries are the tristimulus values for this quantity of light of this wavelength [6]. The wavelength of light is then changed to 410 nm. Again a colour match is made and the tristimulus values are recorded. This process is continued until the entire visible spectrum has been examined. Experiments of this sort were carried out by a number of researchers and the results obtained by them were summarized and published in a convenient form by the Colorimetry Committee of the Optical Society of America [2]. After the publication of these data, it became feasible to base tristimulus specifications on spectrophotometric data. In this way the uncertainties associated with the colorimeter can be avoided and the spectrophotometer can be used to determine the tristimulus values. However, Wright [10] and Guild [11] independently redetermined the fundamental data employing a number of carefully selected observers. The primaries employed in the experimental study of Wright [10] are spectrum colours and their wavelengths are 650, 530 and 460 nm. However, Guild [11] chose red, blue and green primaries in his investigations. When the results of these two investigators were reduced to a comparable basis, it was discovered that their data were in extraordinary good agreement with each other and also in good agreement with Optical Society of American data [2]. In 1931, the CIE undertook the task of bringing out an international standard procedure for the evaluation of tristimulus values for the pure spectrum colours. The tristimulus values that were adapted

by the CIE using good experimental techniques and a number of observers for various spectrum colours are presented at intervals of 10 nm [2].

The tristimulus values ($\bar{x}$, $\bar{y}$, $\bar{z}$) of the pure spectrum colours indicate the amount of each of the primaries that is required to colour-match a unit quantity of radiant energy of the various wavelengths. The value of $\bar{x}$ represents the amount of a primary which is a reddish purple of higher saturation than any obtainable colour having this hue. The value of $\bar{y}$ represents the amount of a green primary considerably more saturated than the spectrum colour whose wavelength is 520 nm. The value of $\bar{z}$ represents the amount of blue primary that is considerably more saturated than the spectrum colour whose wavelength is 477 nm.

The tristimulus values of the spectrum colours at different wavelengths, with 10 nm intervals, that were adapted by the International Commission on Illumination are presented in Table 1. This provides the necessary data for evaluating a stimulus that is equivalent to the given sample when the latter is illuminated by light having the spectral quality of illuminant C and is viewed by the standard observer.

2. Determination of tristimulus values

The tristimulus values of a test sample can be determined by adopting two equivalent procedures which are denoted "weighted ordinate method" and "selected ordinate method".

2.1. Tristimulus values obtained by the weighted ordinate method

The tristimulus values of the test sample can be determined by multiplying the transmittance at a particular wavelength by the product of the energy and tristimulus value of that wavelength followed by the summation of these values corresponding to each primary. Once the spectrum of the sample whose chromaticity values are to be determined is available, the procedure tends to be the multiplication of the transmittance at a particular wavelength by the $E_0\bar{x}$, $E_0\bar{y}$ and $E_0\bar{z}$ values at that wavelength and the same procedure is also

repeated at other wavelengths. The summation of the product values for each of the three primaries results in three chromaticity values (X, Y, Z) for that colour and can be represented mathematically as follows [12]:

$$X = \sum_{380\ \text{nm}}^{700\ \text{nm}} E_0 \bar{x} T \Delta\lambda \tag{1}$$

$$Y = \sum_{380\ \text{nm}}^{700\ \text{nm}} E_0 \bar{y} T \Delta\lambda \tag{2}$$

$$Z = \sum_{380\ \text{nm}}^{700\ \text{nm}} E_0 \bar{z} T \Delta\lambda \tag{3}$$

Table 1
Tristimulus values of pure spectrum colours

2.2. Tristimulus values obtained by the selected ordinate method

In the weighted ordinate method a summation is made of the values of $E_0\bar{x}T$, $E_0\bar{y}T$ and $E_0\bar{z}T$ at wavelengths equally spaced throughout the visible region, i.e. $\Delta\lambda$ is constant. However, in the selected ordinate method, the wavelength intervals are unequal and are chosen so as to give constant $E_0x\Delta\lambda$, $E_0y\Delta\lambda$ and $E_0z\Delta\lambda$ values. The integration process in this procedure is effected by making a summation of transmittance values at median wavelengths of each of these wavelength intervals. The three sums are multiplied by factors which are proportional to the constants, $E_0x\Delta\lambda$, $E_0y\Delta\lambda$ and $E_0z\Delta\lambda$. The values of the wavelengths at which the transmittance values are measured are known as selected ordinates. The mode of calculation using 100, 30 and 10 selected ordinate methods has been described by Hardy [2]. The values of the ordinates (median wavelenghts) for the three standard illuminants A, B and C are tabulated [2]. In addition, the factor values used to multiply the summation of the transmittance values to obtain tristimulus values are mentioned. The selected ordinate method reduces the process of determining the tristimulus values to mere addition of transmittance values, whereas the weighted ordinate method involves many multiplications followed by summation.

In the present investigation the weighted ordinate method is adopted for the evaluation of chromaticity coordinates.

2.3. Chromaticity diagram

In order to understand the relationship between the various colours a graphical representation of the tristimulus values has been proposed. It was found that this would require a three-dimensional coordinate system which is not practicable. Therefore the coordinates denoted by trichromatic coefficients as

$$x = \frac{X}{X + Y + Z} \tag{4}$$

$$y = \frac{Y}{X + Y + Z} \tag{5}$$
Fig. 1. Chromaticity diagram showing that the green (G) may be regarded as a mixture of illuminant (C) and a spectrum colour having a wavelength of 506 nm and (R) is the colour point of a red colourant.

and

$$z = \frac{Z}{X + Y + Z} \tag{6}$$

are used for convenient representation of chromaticity in a two-dimensional diagram as shown in Fig. 1. Among the coordinates z is dependent on x and y and so only x and y need to be considered for the description of the sample colour. However, the trichromatic coefficients (coordinates), used to denote true colour points on the chromaticity diagram are

$$x = \frac{\sum E_0\bar{x}T\Delta\lambda}{\sum E_0\bar{x}T\Delta\lambda + \sum E_0\bar{y}T\Delta\lambda + \sum E_0\bar{z}T\Delta\lambda} \tag{7}$$

$$y = \frac{\sum E_0\bar{y}T\Delta\lambda}{\sum E_0\bar{x}T\Delta\lambda + \sum E_0\bar{y}T\Delta\lambda + \sum E_0\bar{z}T\Delta\lambda} \tag{8}$$

$$z = \frac{\sum E_0\bar{z}T\Delta\lambda}{\sum E_0\bar{x}T\Delta\lambda + \sum E_0\bar{y}T\Delta\lambda + \sum E_0\bar{z}T\Delta\lambda} \tag{9}$$

The curve (Fig. 1) represents the locus of all the spectrum colours and the points on this curve are

trichromatic coefficients which are calculated from the trichromatic values of pure spectrum colours. The trichromatic coefficients for standard illuminant C are $x = 0.3101$ and $y = 0.3163$ (Fig. 1).

A chromaticity diagram is of immense value especially when more than one colour exists in the form of a mixture. If R and G represent red and green on the chromaticity diagram, then the point corresponding to an additive mixture of these two colours will always lie on the line joining R and G, regardless of the proportion in which these colours are mixed.

All real colours lie within the area enclosed by the solid line, since every real colour can be considered to be a mixture of its spectral components in various proportions. All the real colours lying both within the solid line and above the broken lines in Fig. 1 can be considered as a mixture of standard illuminant C and spectrum light of a certain wavelength. Consequently the colour point G can be treated as a mixture of standard illuminant C and spectrum light having a wavelength of 506 nm. This wavelength is known as the dominant wavelength. Since the green lies on a line which terminates as a pure spectrum colour at one end and at the illuminant point at the other end, the sample is not so pure a green as the corresponding spectrum colour. The ratio of the distances of the sample point and the pure spectrum point from the illuminant point is denoted as the purity of the sample. The numerical procedure proposed by Judd [13] for the calculation of the dominant wavelength is adopted in the present investigation.

As the three-dimensional coordinate system of representation of chromaticity is reduced to a two-dimensional system, the colour space is non-uniform. Judd [14] suggested the possibility of constructing chromaticity diagrams in which approximately equal distances separate points representing all pairs of equally bright colours which are just noticeably different under certain specified conditions of observation. Methods for the transformation of CIE coordinates into other coordinate systems were pursued by MacAdam [15,16]. Breckenridge and Schaub [17] proposed a coordinate system called the rectangular uniform

chromaticity scale (RUCS) in which the first quadrant contains only greens, the second blues, the third purples and the fourth reds and yellows. General transformation equations for changing coefficients into RUCS (U, V) coordinates are given by

$$U = 0.075 - \frac{0.832(x + y - 1)}{1.0x - 7.05336y - 1.64023} \qquad (10)$$

$$V = \frac{3.6970x - 5.07713y - 1.36896}{1.0x - 7.05336y - 1.64023} - 0.5 \qquad (11)$$

The reverse transformation equation, i.e. conversion of RUCS coordinates into CIE coordinates, was also proposed by these authors.

Measurement of the colour difference represented by two points on the chromaticity diagram is not feasible because equal distances between two points do not represent the same amount of colour difference at different locations in the chromaticity diagram. MacAdam [18] studied this factor and represented the experimental results in the form of 25 ellipses in the chromaticity diagram. In each for these ellipses every line from the centre to any point on the periphery of the ellipse represents approximately 100 chromaticity steps just noticeable by the eye of an observer. The determination of a unit standard deviation for colour matching (ΔS), was suggested by MacAdam [19] using the emperical relation

$$\Delta S = [g_{11}(\Delta x)^2 + 2g_{12}(\Delta x)(\Delta y) + g_{22}(\Delta y)^2]^{1/2} \qquad (12)$$

in which g_{11}, $2g_{12}$ and g_{22} were determined from the contour diagrams and Δx and Δy indicated the numerical differences between the coordinates of two neighbouring colour points whose colour difference is being measured.

The CIE recommended a colour space denoted as CIE Lu^*v^* to promote uniformity of practice in the evaluation of colour differences [20]. This colour space is produced by plotting the quantities L, u^*, v^* in rectangular coordinates and which were defined as

$$L = 116(Y/Y_n)^{1/3} - 16 \qquad (13)$$

$$u^* = 13L(u - u_0) \qquad (14)$$

$$v^* = 13L(v - v_0) \qquad (15)$$

where the values of u, v, u_0 and v_0 were given as

$$u = \frac{4X}{X + 15Y + 3Z} \quad \text{and} \quad v = \frac{9Y}{X + 15Y + 3Z} \quad (16)$$

$$u_0 = \frac{4X_n}{X_n + 15Y_n + 3Z_n} \quad \text{and}$$

$$v_0 = \frac{9Y_n}{X_n + 15Y_n + 3Z_n} \quad (17)$$

In the expressions for u_0 and v_0, the values of X_n, Y_n and Z_n are tristimulus values of the standard illuminant C ($X_n = 98$, $Y_n = 100$ and $Z_n = 118$) and the coordinates (u, v) are the simplified transformation to the perceptually more uniform chromaticity spacing (PMUCS) as recommended by CIE [5,21]. The total colour difference ΔE^*(CIE Lu^*v^*) between two colours, each given in terms of L, u^*, v^*, is calculated from

$$\Delta E^* \text{CIE}(Lu^*v^*) = [(\Delta L)^2 + (\Delta u^*)^2 + (\Delta v^*)^2]^{1/2} \quad (18)$$

Another uniform colour space (CIE La^*b^* 1976) [22,23] recommended by the *CIE Colorimentry Committee Working Program on Colour Differences* is produced by plotting the quantities L, a^*, b^* in rectangular coordinates which are defined as

$$L = 116(Y/Y_n)^{1/3} - 16 \quad (13)$$

$$a^* = 500[(X/X_n)^{1/3} - (Y/Y_n)^{1/3}] \quad (19)$$

$$b^* = 200[(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}] \quad (20)$$

The total colour difference ΔE^* CIE La^*b between two colours each given in terms of L, a^*, b^* is calculated from

$$\Delta E^* \text{CIE}(La^*b^*) = [(\Delta L)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2} \quad (21)$$

Richter [24] suggested a new uniform colour space LABHNU 1977 whose coordinates were obtained from the expressions:

$$L = 116(Y/Y_n)^{1/3} - 16 \quad (13)$$

$$A^* = 500(A' - A'_n)Y^{1/3} \quad (22)$$

$$B^* = 500(B' - B'_n)Y^{1/3} \quad (23)$$

where

$$A' = 1/4(x/y + 1/6)^{1/3} \quad (24)$$

and

$$B' = -1/12(z/y + 1/6)^{1/3} \quad (25)$$

2.4. Complementary tristimulus colorimetry

The procedure described for specifying colours by tristimulus colorimetry is applicable for characterisation of additive colours only. However, in the case of chemical indicators, subtractive colours are involved. Moreover, the concentration of the indicator and the presence of other colorants influences the final colour of a solution in a complicated way. This difficulty arises because the intensity of the light leaving the titration vessel is related to the concentration in an exponential manner in accordance with Beer's law. Consequently, the simple treatment of additive colours is no longer applicable to evaluating the quality of colour change of indicators.

In view of the above, Reilley et al. [25] resorted to the application of complementary tristimulus colorimetry for the characterisation of the color quality of indicator transitions. The "complementary tristimulus coordinates" (Q_x, Q_y, Q_z) are calculated by following essentially the same procedure adopted in the case of tristimulus coefficients (coordinates), but the transmittance value is replaced by the absorbance value (A) in these calculations. The complementary tristimulus coordinates can be represented as

$$Q_x = \frac{\sum E_0 \bar{x} A \Delta\lambda}{\sum E_0 \bar{x} A \Delta\lambda + \sum E_0 \bar{y} A \Delta\lambda + \sum E_0 \bar{z} A \Delta\lambda} \quad (26)$$

$$Q_y = \frac{\sum E_0 \bar{y} A \Delta\lambda}{\sum E_0 \bar{x} A \Delta\lambda + \sum E_0 \bar{y} A \Delta\lambda + \sum E_0 \bar{z} A \Delta\lambda} \quad (27)$$

$$Q_z = \frac{\sum E_0 \bar{z} A \Delta\lambda}{\sum E_0 \bar{x} A \Delta\lambda + \sum E_0 \bar{y} A \Delta\lambda + \sum E_0 \bar{z} A \Delta\lambda} \quad (28)$$

The relationship between the tristimulus coordinates and the complementary tristimulus coordinates is derived and presented as follows:

$$P_r = G_r - J(Q_r - G_r) - J^2(Q_r - G_r + Q_r^d) \quad (29)$$

where P_r (where $r = 1, 2$ and 3 implies x, y and z) is the true colour point and Q_r is the complementary colour point, G_r is the illuminant point, Q_r^d is a measure of the dichromatistic tendency of the colour system and J is the optical concentration which is a product of the concentration (c) and the total absorptivity of the colour system (E).

The complementary colour point Q_r specifies the colour of a subtractive colour system in a concentration-independent way, whereas the true colour point is concentration-dependent and moves from the grey point to the periphery of the chromaticity diagram as the concentration increases. Since the complementary colour point is related to the light absorbed by the solution, this point will be located in the chromaticity diagram at a place corresponding to the complementary colour of the true colour point. However, the coordinates of the illuminant point (grey light) are the same and are independent of the colour system.

Eq. (29) was further simplified by introducing two other quantities, namely V_r and W_r, which are sufficient to describe a dilute colour system fully and are given by

$$V_r = Q_r - G_r \tag{30}$$

$$W_r = V_r - Q_r^d \tag{31}$$

The expression for the true colour point in terms of these quantities can be written as

$$P_r = G_r - JV_r - J^2 W_r \tag{32}$$

This equation is used as a unified basis for the interpretation and calculation of colour phenomena, such as designation of colour change, quality of the end points and screening of the indicators.

2.5. Determination of quality of colour change

The overall quality of colour change of an indicator at the end point is a composite function of two factors, namely (1) the chemistry of reaction which governs the colour change and (2) the colour phenomena in the solution and their relation to the observing eye. The latter problem is much more complex because it involves physiological and psychological parameters.

In order to solve this problem Reilley et al. [25] took advantage of the numerical characterisation of the colour of the indicator by complementary tristimulus colorimetry to evaluate the quality of colour change of the indicator. Since any colorant has fixed complementary tristimulus coordinates on the chromaticity diagram, the distance between the two points of the titrant solution before and after the end point is considered as a quantitative measure of the quality of colour change of the indicator used in this titration. The longer the distance between the two points, the better will be the quality of colour change at the end point. However, the distance alone is not adequate, as the location of the points in the diagram is also important. Besides these two factors, the greyness should also be considered.

Let $Q_{r,b}$ and $Q_{r,a}$ represent the complementary colour coordinates of an indicator before and after the end point. The quality of the colour change at the end point is considered to be good if the distance between the points is considerable. Also, if the line traverses through the grey point and extends beyond it, the quality of colour change is better still, because a grey (colourless) region appears during the transition of the indicator from one colour to another at the end point and provides a better memory factor.

For a set of indicators the quality of their colour change at the end point can be compared on a quantitative basis from the measured value of the distance between complementary colour coordinates before and after the colour change of the respective indicators. Such comparison is worthwhile only when all the corresponding lines joining the $Q_{r,b}$ and $Q_{r,a}$ coordinates of the set of indicators are lying in the same location of the chromaticity diagram. Only when the length, location and direction of the line joining $Q_{r,b}$ and $Q_{r,a}$ are the same for two different indicators is the quality of colour change for these two indicators considered to be equal. Therefore, the point to be made in the study of chromatic differences is that equal distances do not represent the same quality of colour change at different locations in the chromaticity diagram.

Bhuchar et al. [26] studied this factor and utilised the RUCS coordinates (U, V) in accor-

dance with the transformation recommended by Breckenridge and Schaub [17] (Eqs. (10) and (11)), to calculate a parameter called the specific colour discrimination (SCD), which is defined as the average number of colour discrimination steps for an acid–base indicator for one pH unit. It can be obtained from the relationship

$$SCD = \frac{1}{3} \times 1000 \frac{[(U_2 - U_1)^2 + (V_2 - V_1)^2]^{1/2}}{pH_2 - pH_1} \quad (33)$$

in which (U_1, V_1) and (U_2, V_2) are the RUCS coordinates at the pH values pH_1 and pH_2. This relationship can be expressed in a simplified way as

$$SCD = \frac{1}{3} \times 1000 \times \frac{\Delta\sigma}{\Delta pH} \quad (34)$$

The parameter SCD is correlated with the unit standard deviation for colour matching (ΔS) values of MacAdam [19] ellipses (Eq. (12)), using the data of several phthalein and sulphonephthalein indicators, (phenolphthalein, cresolphthalein, thymolphthalein, Phenol Red, Cresol Red, Thymol Blue and Congo Red), by plotting SCD vs. ΔS. The slopes of the straight lines obtained for all the studied indicators are found to be unity, indicating a correlation between these two parameters. Therefore the numerical value of SCD at the pH of maximum colour change (pH_{mcc}) is taken as the quantitative measure of the quality of colour change. The half bandwidth of the SCD vs. pH peak is inversely proportional to the rapidity of the colour change. This study of Bhuchar et al. [26] enabled comparison of the quality of colour change of a series of acid–base indicators and the rapidity of colour change at the end point. Bhuchar and Agarwal [27] synthesised two sulphamphthalein indicators, namely phenol sulphamphthalein and o-cresol sulphamphthalein, to evaluate the colour change in terms of SCD, which is determined from RUCS coordinates and PMUCS coordinates (Eq. (16)), in order to compare this parameter with the CIE La^*b^* 1976 parameter. From the results, it was concluded that ΔE^* CIE La^*b^* (Eq. (21)) appears to have the same significance as ΔS, the unit standard deviation for colour matching (Eq. (12)). It is further stated that CIE La^*b^* recommendations

are preferred over the RUCS or PMUCS modes of calculation. No matter how the numerical values of the pH of maximum colour change, the half bandwidth of the change of SCD in pH units and the SCD value would hold true. The graphs drawn between a^* and b^* (Eqs. (19), (20)) are presented to clearly visualise the transition of the indicators, since the origin in this plot is the illuminant point (grey).

Cacho et al. [28] proposed another parameter, based on the optical concentration J, to evaluate the equality of colour change of indicators in aqueous medium. The progress of optical concentration values of acid–base indicators, such as o-cresolphthalein, thymolphthalein, phenolphthalein, phenol red, crespol red, thymol blue and congo red, with change of pH is shown by plotting $\Delta J/\Delta pH$ vs. pH. From the value of $\Delta J/\Delta pH$ at the pH of the maximum colour change, the quality scale of these indicators in the alkaline region is proposed in descending order as cresolphthalein > thymolphthalein > cresol red > thymol blue > phenol red > congo red > phenolphthalein. This order of quality of colour change is the same as the one proposed by Bhuchar et al. [26], indicating that the behaviour of the parameter $\Delta J/\Delta pH$ is similar to that of SCD. A similar parameter has been utilised for evaluation of colour changes of complexometric indicators in the titration of calcium with EDTA [28].

Martinez Calatayud et al. [29] ignored this parameter because in most cases two peaks are obtained in the graphs $\Delta J/\Delta pH$ vs. pH, causing gross errors in calculating the pH of maximum colour change. It is also concluded that the total colour difference ΔE^* is the most uniform parameter because of its linear behaviour with respect to the standard deviation of colour matching (ΔS). Fernandez and Guzman Chozas [30] stated that the total colour difference ΔE^* CIE La^*b^* and the parameters of SCD are adequate for describing a colour change because the CIE La^*b^* parameters are linearly related to the LABHNU parameters.

Kotrly and Vytras [31] proposed a method for the calculation of the optimum concentration of an indicator in a particular titration by plotting

the parameter $\Delta\text{pH}/\Delta E^*$ (index of colour change perceptibility) against log C/C_0, where C is the indicator concentration used for the calculation of the particular chromaticity transition and C_0 is the experimental value of the indicator concentration. The value of the concentration C at the minimum of this curve is taken as the optimum concentration of the indicator in the titration. Reilley and Smith [32] proposed an expression for the determination of the equilibrium constant of the indicator $\text{p}K_a$ using complementary tristimulus coordinates, which is expressed as

$$\text{p}K_a = \text{pH} - \log \frac{(Q_r)_\text{A} J_\text{A} - Q_r J}{Q_r J - (Q_r)_\text{B} J_\text{B}}$$

where Q_r is the complementary colour point, and $(Q_r)_\text{A}$ and $(Q_r)_\text{B}$ are the chromaticity coordinates of the indicator at the pH mentioned in the above equation in acidic and base media respectively. Flaschka [33] also reported a similar equation for the determination of $\text{p}K_a$ which includes the optical concentration (J) term also.

2.6. Specification of colour changes of complexometric indicators

The parameters described for specifying the colours and colour differences in accordance with tristimulus colorimentry are determined at different C_L/C_M (ratio of the concentrations of ligand to metal ion) values for the evaluation of quality of colour change of indicators, in order to give an objective basis for indicator selection in complexometric titrations.

The 1931 CIE parameters (x, y), the RUCS coordinates (U, V), the dominant wavelength (λ_d) and the purity (p_e) were used to evaluate the quality of colour change of indicators such as xylenol orange, methyl thymol blue, pyrocatechol violet, pyrogallol red and bromopyrogallol red, in the titration of lead (II) with ethylene diaminetetraacetic acid (EDTA) by Kotrly and Vytras [34]. Methyl thymol blue is recommended as the most suitable indicator for this titration, since its colour transition curve passes very close to the grey point. A study with the involvement of the CIE Lu^*v^* parameters also supported the same conclusion [35]. However, a study by Martinez

Calatayud et al. [36] on the specification of colour changes of these indicators with the help of coordinates (x, y), RUCS coordinates (U, V), PMUCS coordinates (u, v), CIE La^*b^* and $\Delta J/\Delta(C_\text{L}/C_\text{M})$ vs. C_L/C_M revealed that bromopyrogallol red is the most suitable indicator, followed by methyl thymol blue. However, Arsenazo III is reported to be superior in terms of its colour change over all the other indicators studied in this titration, as the plot of $\Delta E^*/\Delta(C_\text{L}/C_\text{M})$ vs. C_L/C_M exhibited a higher peak for this indicator [37]. The quality of this indicator is assessed in the complexometric titration of calcium(II), bismuth(III), iron(III) and lanthanum(III) by specifying the colour changes with the coordinates (x, y), CIE La^*b^* parameters and the plot a^* vs. b^*. Arsenazo II and sulphosalicylic acid acid indicators are recommended over salicylic acid and potassium thiocyanate in the titration of iron(III) with EDTA from a study of the trichromatic parameters (x, y), (U, V) and CIE La^*b^* [38].

The quality of colour change of indicators such as Arsenazo III, calcein, calcon, eriochrome blue black B, methyl thymol blue, murexide, phthalein complexone and thymolphthalein complexone in the titration of calcium(II) with EDTA is specified from the parameters (x, y), (Q_x, Q_y), colour concentration (J), dominant wavelength (λ_d) and purity of the colour (p_e) determined at different values of C_L/C_M near the end point and from a plot of $\Delta J/\Delta(C_\text{L}/C_\text{M})$ vs. C_L/C_M [39]. The following order of indicator quality of colour change has been mentioned: thymolphthalein complexone > phthalein complexone > Arsenazo III > calcon = murexide > calcein > methyl thymol blue = eriochrome blue black B. However, arsenazo (2-(4-arsonophyl)-(azo-7-(antipyril)azo-1,8-dihydroxy-3,6-naphthalene disulphonic acid) is considered a superior indicator in this titration because the trajectory of the (x, y) curve is almost perpendicular to the major axis of the MacAdam ellipse situated in that region [40]. A sharp peak observed in the plot of $\Delta E^*/\Delta(C_\text{L}/C_\text{M})$ vs. C_L/C_M for this indicator further confirmed its superior quality of colour change.

Vytras et al. [41] studied the trichromatic parameters, namely (x, y), (Q_x, Q_y), PMUCS (u, v), the colour concentration (J), dominant wave-

length (λ_d), purity of the colour (p_e) and CIE Lu^*v^* parameters for the specification of colour changes of the metallochromic indicators eriochrome blue SE, eriochrome red B, naphthylazoxine 6S, SNAZOXS (disodium salt of 8-hydroxy-7-[(4-sulphonaphthyl) azo]-5-quinoline sulphonic acid) and zincon[2-(2-(α-(2-hydroxy-5-sulphonphenyl azo) benzylidene) hydrazino) benzoic acid] in the titration zinc(II) with EDTA and claimed that zincon gives the best colour quality of transition, since the colour change is from blue to orange–yellow and passes close to the point of achromatic colour. Cacho et al. [28] determined the values of the optical concentration (J) via the titration of copper(II) with EDTA using indicators such as PAN(1-(pyridyl(-2′-azo-2-naphthol))), MeTDAN(2-(5-methyl-1,3,4-thiadiazolyl azo-1)-2-naphthol), murexide, MeTDAΔMF(2-(5-methyl-1,3,4-thiadiazolylazo-6)-3,4-dimethyl phenol) and TeADMF(5-(1,2,3,4-tetrazolylazo-6)-2,4-dimethyl phenol), and the order of the quality of colour change is ascertained from a plot of $\Delta J/\Delta(C_L/C_M)$ vs. C_L/C_M. However, Martinez Calatayud et al. [29] in their critical search for an ideal chromatic parameter stated that the colour concentration (J) showed a non-uniform behaviour and hence it is not recommended for the measurement of quality of colour change. The parameter ΔE^* is preferred in this regard, as it is more uniform against the standard deviation of colour matching, ΔS.

Cacho et al. [42] used arsenazo [2-(2-arseno phenyl) azo-7-(4-azo-1,8-dihydroxy-3,6 naphthalein disulphonic acid] as metallochromic indicator in the titration of calcium(II) with EDTA and its colour quality was studied using CIE chromaticity diagrams.

Cacho et al. [43] investigated the performance of five metallochromic indicators in the determination of barium using tristimulus chromaticity theory and concluded that metolphthalein and thymolphthalein complexone were the most suitable out of the indcators studied. Further to this, Cacho et al. [44] carried out a comparative study of metallochromic indicators for the titrimetric determination of magnesium with EDTA and observed that eriochrome black T and antipyrl-o-arsenazo I were the most suitable indicators for this titration.

The quality of colour changes at the end point in the complexometric titration of bismuth (III) with EDTA, using the indicators hematoxylin, PAN [1-(2-pyridyl azo)-naphthol-2], PAR [4-(2-pyridyl azo)-resorcinol], xylenol orange and thoron, was studied by means of the 1931 CIE trichromatic system, using SCD and colour difference (ΔE^*) and hematoxylin was recommended as the most suitable indicator for this titration [45]. Krishna Prasad and Raheem [46] applied trichromatic colorimetry for the specification of colour changes of metallochromic indicators, namely PAR, eriochrome black T, bromopyrogallol red, solochrome blue black B, pyrocatechol violet and PAN, in the complexometric titration of cadmium(II) to assess the quality of colour change at the equivalence point using the CIE La^*b^* 1976 system and the value of the SCD parameter. Prasad and Raheem [47] measured the quality of colour change of the complexometric indicators eriochrome black T, bromopyrogallol red, solochrome blue black B, pyrocatechol violet, methyl thymol blue, chromeazurol S and solochrome dark blue in the titration of magnesium(II) with EDTA with the help of tristimulus colorimetry. Studies on the specification of colour changes of the complexometric indicators in the titration of metal ions, namely copper(II) [48], nickel(II) [49] and cobalt(II) [50], with EDTA were carried out recently.

2.7. Specification of colour changes of acid–base indicators in aqueous medium

Fortune and Mellon [51] carried out a spectrophotometric study of a number of neutralisation indicators and specified the colour of the indicators before and after the equivalence point with the help of trichromatic evaluation. These authors also mentioned the trichromatic values of the mixed indicators, namely methyl red and bromocresol green. Kotrly et al. [52] characterised the specification of colour changes of the indicators phenolphthalein, phenol red, thymol blue, bromothymol blue, methyl red and congo red with the help of the CIE colorimetric system. The colour quality of the studied indicators was specified by a curve on the chromaticity diagram.

The authors tabulated the true colour coordinates, dominant wavelength, purity of colour and RUCS coordinates at different pH values for all the studied indicators. Vytras and Kotrly [53] developed procedures for the calculation of all absorbance curves for the colour transition of an acid–base indicator when three consecutive dissociation equilibria are involved. ALGOL computer programs were developed by these authors to calculate the true colour coordinates from the absorbance values. The evaluation of the dominant wavelength and the excitation purity was also discussed. The mathematical treatment of the colour transitions of acid–base indicators has been applied to compute the colour changes of bromothymol blue and phenol red. Bhuchar and co-workers [26,27] proposed a quantitative measure of the quality of colour change, namely specific colour discrimination, to evaluate the colour changes of phthalein and sulphonephthalein indicators, phenolphthalein, cresolphthalein, thymol phthalein, phenol red, cresol red, thymol blue and congo red. Barbosa et al. [54] carried out a comparative study of some hydroxyanthraquinones, namely alizarin, alizarin S, quinalizarin and quinizarin with bromocresol green and methyl orange as reference indicators. The numerical values of the chromaticity coordinates, complementary chromaticity coordinates, pK_a values, pH of maximum colour change and the quality of colour change indicated that these hydroxyanthraquinones have a colour change quality similar to that of bromocresol green. The semicarbazones and thiosemicarbazones derived from 1,2-naphthoquinone, namely 1,2-naphthoquinone-2-semicarbazone (NQS), and its 4-sulphonic derivatives (NQS4S) and 1,2-naphthaquinone-2-thiosemicarbazone 4-sulphonic acid (NQT4S)], are reported as acid–base indicators by the evaluation of their transition limits via tristimulus chromaticity coordinates [55]. In this study the true colour coordinates, the PMUCS coordinates, RUCS and CIE $La*b*$ 1976 parameters are evaluated for the specification of the colour changes of these acid–base indicators and it is stated that NQS4S exhibit similar sharpness to that shown by methyl red. Fernandez and Guzman Chozas [30] utilised a new colour space denoted as LABHNU 1977 [24] with

the object of attaining uniformity for the CIE $Lu*v*$ and CIE $La*b*$ 1976 systems. These authors studied the specification of the colour change of the indicators pyridine-2-aldehyde-p-nitrophenyl hydrazone and 6-methylpyridine-2-aldehyde-p-nitrophenyl hydrazone with the help of the LABHNU colour space and observed that the $\Delta E*$ values evaluated by this method linearly relate to those obtained by the application of the CIE $La*b*$ colour space. Gulati et al. [56] studied the colour transition of 2-(2′-lepidylazo-)-1-naphthol-4-ammoniumsulphonate as an acid–base indicator with the help of the true colour coordinates and RUCS coordinates along with the SCD parameter and found that the sensitivity of the indicator is comparable to that of thymol blue. Bhaskare et al. [57] studied the use of the azo dye α-(2-hydroxy-4-sulpho-phenylazo)-p-(nitrobenzyl cyanide) as an acid–base indicator by evaluating the sensitivity of the indicator in terms of the indicator in terms of specific colour discrimination steps and the half bandwidth of the change of specific colour discrimination in pH units. Kotoucek and Lemr [58] carried out investigations for satisfactory functioning of celestine blue as an acid–base indicator for visual titrations of strong and moderately strong protolytes. On the basis of the tristimulus coordinates the CIE $La*b*$ 1976 parameters were calculated with the help of the TRICHROM program on an EC 1033 computer. Kotoucek and Lemr [59] studied the characterisation of the colour change of some acid–base indicators of the phenoxazine dye group and disodium 2,8-dihydroxy 1,4-naphthaquinone-3,6 disulphonate using tristimulus chromaticity coordinates, CIE $La*b*$ parameter, dominant wavelength and purity of colour. Dissociation constants of indicators were calculated from the values of trichromatic complementary coordinates and are compared with the published values.

2.8. Specification of colour changes of indicators in non-aqueous acid–base titrimetry

Non-aqueous acid–base titrimetry has gained considerable importance for the ease with which the quantitative analysis of pharmaceutically im-

portant compounds can be carried out in non-aqueous media. A number of non-aqueous titrimetric procedures have been developed in this way involving visual indicators.

The use of 1,4-dihydroxy anthraquinone as an acid–base indicator in isopropyl alcohol medium is studied by the evaluation of colour change limits via complementary chromaticity coordinates at different pH values in the titration of benzoic acid and veronal with 0.1 M tetrabutyl ammonium hydroxide [60]. The dissociation constants pK_1 and pK_2 are evaluated in accordance with the method of Reilley etal. [25] and it was shown that these values coincide with those determined by the standard methods. This new indicator is used in the titration of aromatic acids, aliphatic acids, amino acids, aromatic heterocycles and phenols in isopropyl alcohol with tetra butyl ammonium hydroxide with a relative error of less than 0.8%. Barbosa et al. [61] studied a series of commercial indicators—cresol red, thymol blue, bromophenol blue, bromocresol green, bromocresol purple, bromothymol blue, methyl orange, methyl red and neutral red—in order to establish them over the whole useful pH range in propan-2-ol medium. These authors evaluated the complementary chromaticity coordinates, specific colour discrimination, pH of maximum colour change, half band width of specific colour discrimination peak, pK_{in} and optimum indicator concentration together with the CIE $La*b*$ 1976 parameters. To illustrate the usefulness of the work, a mixture of picric acid and benzoic acid was titrated with tetrabutyl ammonium hydroxide using thymol blue as indicator and also a relationship between pK_{in} in aqueous and propan-2-ol medium was proposed. Barbosa et al. [62] carried out similar studies with 2-methyl propan-2-ol medium to establish the above-mentioned commercial indicators over the whole useful pH range. The chromatic parameters, the chromaticity coordinates, complementary chromaticity coordinates, optical concentration, specific colour discrimination, pH of maximum colour change, half bandwidth, $\Delta E*$ value of CIE $La*b*$ 1976, and CIE $Lu*v*$, together with the optimum indicator concentration, are evaluated utilising the indicator transition in the titration of trichloroacetic acid

with tetrabutyl ammonium hydroxide. A linear relationship between pK_{in} values in 2-methyl propan-2-ol and in aqueous medium is also proposed. Mixtures of dithio uracil and 2,4-dichlorophenol were titrated with tetrabutyl ammonium hydroxide using methyl red and thymo blue as indicators. Barbosa et al. [63] studied a series of acid–base indicators, namely p-naphthol benzein, neutral red, tropaeolin 00, quinalidine red, brilliant green, malachite green and bromocresol green, in acetonitrile medium and determined the chromaticity coordinates, pK_a values, transition pH ranges, pH of maximum colour change, optimum concentration for titration and quality of colour change for each of these studied indicators together with the effect of ionic strength on their properties. These authors recommended neutral red or a mixture of bromocresol green and tropaeolin 00 as indicators in the titration of a binary mixture of tetramethyl guanidine and pyridine. The indicator transition ranges at zero ionic strength are presented for all the studied indicators. These authors further reported that the studied indicators provided very sharp end points in titrations of bases with the dissociation constants of the order of 10^{-10} or lower. Bosch and Roses [64] proposed 1,2-naphthoquinone-2-thiosemicarbazone as an acid–base indicator for use in isopropyl and t-butyl alcohol media and evaluated the quality of colour change by determining the parameters specific colour discrimination, pH of maximum colour change, half bandwidth of specific colour discrimination peak, true and complementary colour coordinates together with the parameters of CIE $La*b*$ 1976, and CIE $Lu*v*$. This indicator is found to yield results of very good accuracy and precision in titrations of trichloroacetic, dichloro acetic and chloro acetic acids. Martinez Calatayud et al. [65] carried out studies using tristimulus colorimetry theory on several recommended indicators (crystal violet, methyl violet, tropaeolin 00, bromocresol purple and malachite green) for the titration of metformine with perchloric acid and in acetic acid medium and found that crystal violet and methyl violet were most suitable. With the help of CIE $La*b*$ 1976 parameters these authors were able to develop screened indicators of crystal violet and methyl violet by mixing them with appropriate

inert colorants such as neozapan yellow and thymol blue. Barboza et al. [66] extended their studies on the chromatic characterisation of several commercial indicators (metanil yellow, quinalidine red, 4'-dimethyl aminobenzal rhodamine, tropaeolin 00, brilliant green, crystal violet, malachite green, p-naphtholbenzein, nile blue and sudan red) in anhydrous acetic acid medium and evaluated the chromatic parameters in the titration of either urea or sodium acetate in anhydrous acetic acid medium with perchloric acid. The colour sequence of these indicators, described with the widely-used chromaticity coordinates, complementary chromaticity coordinates, the specific colour discrimination parameter and the parameters CIE $La*b*$ 1976, and CIE $Lu*v*$, enabled these authors to determine the formation constants of the indicators and also the optimum concentration of the indicator. These authors also determined the indicator transition range, in terms of pC_{HClO_4} of indicators in acetic acid medium. An objective study on the comparison of the colour changes of the indicators crystal violet and methyl violet in acetic acid medium for the determination of a number of pharmaceutically important compounds revealed that the trichromatic parameters and the transition curves of both these indicators coincide with each other, indicating that these two dyes are identical in their behaviour [67]. Barbosa et al. [68] carried out investigations to determine the optimum concentrations of the indicators crystal violet, alizarin-9-imine and quinalizarin-9-imine in anhydrous acetic medium with the help of tristimulus coordinates and observed that the first two are good indicators. Barbosa et al. [69] further carried out a comparative study of colour change quality of the indicators crystal violet, p-naphthol benzein, tropaeolin 00, malachite green and nile blue in acetic medium. Barbosa and Bosch [70] carried out similar studies with N,N-dimethyl formamide medium to test the properties of the indicators thymol blue, bromocresol green, bromothymol blue, meta cresol purple, phenol red and azoviolet with the help of the chromatic parameters, complementary colour coordinates, specific colour discrimination parameter and the parameters of the CIE $La*b*$

and CIE $Lu*v*$. It is also stated that a binary mixture of 2,6-dihydroxy benzoic and benzoic acids was titrated in the presence of azoviolet with an error of less than 2%.

2.9. Screening

A screened indicator is an indicator which changes from one colour to its complementary colour through greyness at the equivalence point of the titration. Such a screened indicator is obtained by mixing the indicator with one or more inert dyes in a definite proportion. Reilley and co-workers [25,32] and Flaschka [33] derived an expression for the volume of the inert dye solutions which should be added to 1 ml of the indicator solution, so that the resulting mixture, the screened indicator, exhibits greyness at the end point.

Since the coordinates of the grey point (0,0) in the chromaticity diagram with V_r coordinates $(V_r = Q_r - G_r)$, a mixture of "i" colorants will exhibit greyness if

$$\sum_{i=0}^{i} V_{ri} \cdot J_i = 0$$

If two inert dyes are used to achieve this condition, the above equation can be written as

$$V_{r,e} \cdot J_e m_e + V_{r,b} \cdot J_b \cdot m_b + V_{r,v} \cdot J_v \cdot m_v = 0$$

where $V_{r,e}$ represents the coordinates of the pure indicator at the equivalence point and $V_{r,b}$ and $V_{r,v}$ are the coordinates of the two inert dyes, J is the optical concentration, "m" represents the volume of solution, and the subscripts e, b and v correspond to the indicator, a blue inert dye and a violet inert dye respectively. Since $V_{r,e}$ (calculated from the coordinates of the limiting forms of the indicator), $V_{r,b}$, $V_{r,v}$ and the corresponding J values are known, the volumes m_b and m_v to be added to 1 ml of the dye can be calculated by solving the simultaneous equations which result on incorporating $r = 1$, 2, since $V_{1,e}$ is $V_{x,e}$ and $V_{2,e}$ is $V_{y,e}$. Flaschka [33], following the procedure described, prepared a screened acid-base indicator of methyl orange with the inert colorants blue CI 671 and violet CI 697 and the colour coordinates of this mixture at the equiva-

lence point are found to be the same as those of the illuminant point. Reilley and Smith [32] reported the screening of methyl red with kiton yellow and brilliant blue and they preferred inert colorants whose V_r points are located near the periphery of the chromaticity diagram. Bosch et al. [71] studied the colour changes of different screened indicators and reported that all the screened indicators which can be prepared from the same pure indicator and different screening dyes show colour changes that, when plotted on the complementary chromaticity diagram, are on the same straight line. These authors calculated the slope of this straight line from the colour parameters of the pure indicator and consequently determined the parameters relating to the colour changes of all the possible screened indicators prepared from this pure indicator. These authors employed a parameter known as relative greyness (g), which is a measure of the amount of grey proportion in a colour and is given by the expression

$$g = \frac{G_r(Q_r^0 - Q_r)}{Q_r^0(Q_r - G_r)}$$

where Q_r, G_r and Q_r^0 correspond to the complementary "r" coordinate of the colour, the illuminant and the pure spectrum colour of that wavelength respectively, for the comparison of the quality of colour change of the screened indicators prepared from the same or different indicators.

These authors equalised the relative greyness equations of both the limiting forms of the screened indicator to obtain the conditions for best colour change. By applying these theoretical considerations, two screened indicators, mixtures of NQT4S–sandolan turquoise EAS–picric acid and NQT–sandolan turquoise EAS–picric acid, are proposed. It is shown that these two indicators exhibit a colour change between the complementary colours through colourlessness with the same amount of relative greyness for both the limiting forms of the indicators.

The method of caluclation of the composition of screened indicators, as described by Reilley and Smith [32], has been applied for the screening of eriochrome blue SE in the titration of

zinc(II) and SNAZOXS in the titration of copper(II) with EDTA [72]. Eriochrome blue SE is screened with methyl blue and alizarin pure blue to obtain an achromatic hue at the end point. Martinez Calatayud and Pascual Marti [38] reported methylene blue as an inert colorant to screen sulphosalicylic acid indicator in the titration of iron(III) with EDTA to improve the quality of colour change which is measured from the $\Delta J/\Delta(C_L/C_M)$ vs. C_L/C_M plot. In the titration of lead(II) with EDTA, two screened indicators in powder form with the following compositions were proposed [73]:

(1) Eriochrome black T–methyl red (7.4 + 1)– NaCl (1 + 100)
(2) Bromopyrogallol red–naphthol green B–thymol blue (2.5 + 21 + 1)–NaCl (1 + 100)

From the values of percent standard deviation of the result, it has been shown that the screening of the indicator improved the accuracy of the determination. The (a^*, b^*) curves of both the screened indicators pass through the origin, indicating occurrence of achromatic colour at the end point. Cacho et al. [74] proposed five screened indicators to improve the quality of colour change for the complexometric titration of calcium(II) with EDTA, using tristimulus colorimentry. The studied indicators are calcon–tartrazine–orange-II   (6.8 + 1 + 4.6), thymolphthalein   complexone–orange-II–tartrazine (14.22 + 1.22 + 1), Arsenazo III–renazol brilliant blue–tartrazine (25.2 + 8.9 + 1), phthaein complexone–tartrazine–renazol brilliant blue (2.47 + 1 + 1.1) and methylthymol blue–orange II-tartrazine (13 + 2.9 + 1).

Bhuchar and Das [75] screened phenol red, an acid–base indicator, with methylene blue and compared the quality of the colour change with that of another screened indicator, phenol red screened with copper oxalato complex, with the help of the SCD parameter and concluded that the former screened indicator is superior in its quality of colour change.

Vytras et al. [76] proposed the screening of the acid–base indicators phenol red, bromothymol blue and methyl red by mixing with appropriate inert colorants as mentioned below:

Indicator	Inert colorants
Phenol red	Methylene blue – picric acid
Phenol red	Methylene blue – tartrazine
Methyl red	Methylene blue – picric acid
Methyl red	Methylene blue – tartrazine
Bromothymol blue	Phenosafranine – orange II
Bromothymol blue	Phenosafranine – Eg acid orange GG

Vytras and Kotrly [53] determined the tristimulus coordinates of the screened indicators phenol red (with methylene blue and tartrazine) and bromothymol blue (with phenosafranine and orange II) at different pH values using a computer program for the simulation of absorbance curves. Zahradnicek [77] recommended screened indicators such as ethyl orange–nile blue A and phenol red–methylene blue for improving the sharpness of colour change at the end point in acid–base titrations. The stability of the mixed indicator is demonstrated by the position of the complementary colour points in the chromaticity diagram [78]. Zahradnicek and Subert [79] reported that the colour transition curve of the screened indicator methyl orange–methylene blue passes through the grey point whereas that of the screened indicator dimethyl yellow–nile blue A deviates slightly from the grey point, possibly due to slight decomposition in the latter case. These indicators are used in the determination of medical substances.

Martinez Calatayud et al. [65] proposed screened indicators in acetic acid medium for the titration of metformine with perchloric acid. The screened indicators crystal violet–neozapan yellow and methyl violet–thymol blue exhibited very low values of percent relative standard deviation in comparison with the unscreened indicators, indicating the higher accuracy of the screened indicators. It has also been shown that (a^*, b^*) graphs of both the screened indicators have curves passing through the origin. Barbosa et al. [80] proposed three efficient indicators consisting of malachite

green and a screening dye for use in anhydrous acetic acid media utilising the concepts of tristimulus colorimetry. Krishna Prasad and Raheem [81] proposed the following screened indicators for acid–base titrations and reported a single colour transition curve for screened indicators formed by mixing with different inert colorants:

Methyl red + methylene blue (3:1)
Methyl red + indigo carmine (3:2)
Methyl red + malachide green (2.5:2)
Ethyl red + methylene blue (6:1)
Ethyl red + indigo carmine (3:2)
Dimethyl yellow + methylene blue (3:1)
Dimethyl yellow + indigo carmine (2:1)

Lemr and Kotoucek [82] have written a computer program for the peparation of screened indicators for acid–base titrations. These authors [83] prepared six screened acid–base indicators and their colour characteristics are studied with the help of the 1931 CIE parameters.

2.10. Other applications of tristimulus colorimetry

Reilley and Smith [32] developed mathematical equations for the analysis of binary and ternary mixtures of dyes with the help of complementary chromaticity coordinates. Flaschka [84] simplified the procedure by reducing the number of wavelengths at which the absorbances are measured for calculating the complementary coordinates and proposed a mathematical procedure for the determination of the concentrations of individual components in binary and ternary mixtures. This procedure is further improved by adopting a least-squares approach for solving this problem and it is claimed that this method is superior compared to the earlier methods [85]. With the help of complementary tristimulus colorimetry, a mixture consisting of plutonium in four different oxidation states ($+3$, $+4$, $+5$, $+6$) is analysed by representing the data points of the individual pure components as the vertices of a pyramid and the data points corresponding to a mixture of these four components lie within the pyramid [86].

Reilley et al. [25] determined the stability constant of the complex formed between copper ion and (7-4(sulpho-1-naphthyl azo)-8-hydroxy quinoline-5-sulphonic acid) using the complementary tristimulus coordinates by drawing a plot of

Q_xJ vs. Q_yJ at different ratios of ligand to metal ion concentrations. The pH range of existence of mixed complex formed between copper(II), aluminium(III) and tartrate ion is determined with the help of complementary tristimulus colorimetry [87]. Trichromatic colorimetry has recently been applied to the determination of the colour of transition metal complexes [88]. The chromaticity coordinates of the transition metal compounds $Cr(NO_3)_3$, $CrCl_3$, $Cr_2(SO_4)_3$, $COCl_2$, $NiCl_2$ and $CuSO_4$ in aqueous solutions are determined at varying concentrations and it is stated that the trichromatic parameters link colour properties of a substance with those of spectroscopic origin, which depend on d electrons, crystal field symmetry and the nature of the bond. Tawa and Hirose [89] applied simplified tristimulus colorimetry for the determination of primary and secondary amines in the presence of tertiary amines by enabling their complexes with copper(II) ion to be extracted into chloroform. The unreacted copper(II) is estimated because of its catalytic effect on the reaction between hydrogen peroxide and pyrocatechol by determining the pseudo-first order rate constants with the help of simplified tristimulus colorimetry. Tawa and Hirose [90] determined mixtures of aniline and its derivatives by a differential reaction using a mixture of potassium hexacyanoferrate(III) and potassium dichromate as oxidant. Necessary rate proportionality constraints for application of the differential rate method are determined by simplified complementary tristimulus colorimetry and from the slope of the straight line portion of the plots of concentration of semiquinone vs. time. Application of simplified tristimulus colorimetry has been proposed by Tawa and Hirose [91], in a method aimed at determining uric acid in serum without the removal of proteins. The method requires calculations of absorbance at 290 nm as a function of time by simplified tristimulus colorimetry and computation of initial and final absorbances based on the kinetics of first order reactions and using multiple linear regression analysis. The chemical detector system uses uricase catalysis for the conversion of uric acid to allantoin.

Simplified complementary tristimulus colorimetry [92] has been applied for the identification of

the reactive species involved in the oxidation of oxalate ion with permanganate and catalytic decomposition of hydrogen peroxide by mixed catalysts (sodium tungstate and copper(II)). The expression derived for the mole fraction of the light-absorbing species in terms of complementary tristimulus coordinates is utilised for the calculation of the pseudo-first order rate constant of the oxidation reaction of the sulphonephthalein dyes, cresol red and cresol purple, by potassium periodate. It has also been shown that the presence of the coloured impurity, bromocresol green, has no effect on the value of the pseudo-first order rate constant determined by this procedure. This study has been applied for the determination of the rate constants of consecutive irreversible first-order reactions and is illustrated by the assay of xanthine oxidase which catalyses the oxidation of hypoxanthine to uric acid [93].

The tristimulus coordinates are utilised for the quantitative analysis of dyes [94] and the identification of drugs [95] by high performance liquid chromatography.

2.11. Computer program for tristimulus calculations

Because of the numerous multiplications and additions involved in obtaining tristimulus values and the associated parameters, the necessity of the development of computer programs was appreciated even in the early stages of application of tristimulus colorimetry for the measurement of quality of colour change of indicators.

In 1960 Reilley and Smith [32] developed an analogue computer by considering various computer circuits available for multiplying and summing operations. The algorithm adapted for this analogue tristimulus computer for the calculation of chromaticity coordinates is the weighted ordinate method at the selected wavelengths.

Vytras and Kotrly [52], considering the relationship between the absorbance value and the equilibrium system of an acid-base indicator, wrote programs in ALGOL to simulate the absorbance curve of a given indicator at a given pH. From the simulated absorbance curve, the chromaticity coordinates can be calculated by another

program, which is also written in ALGOL. The genreal program developed by these authors is capable of calculating the chromaticity coordinates of an indicator at different values of delta (the fraction of the indicator in the unprotonated form) by taking the individual dissociation constants as input data. This simulation program has been applied to evaluate the results for the colour changes of the indicator phenolphthalein, the screened indicator phenol red in combination with tartrazine and methylene blue, and another screened indicator bromothymol blue in combination with orange II and phenosafranine.

Martinez Calatayud et al. [96] proposed a computer program for the determination of the chromaticity coordinates, the RUCS coordinates, the CIE La*b* 1976 parameters and the values of the optical concentrations. An output consisting of all these parameters for 34 different indicator solutions has been presented.

Bosch et al. [71] developed the computer program COLOR on a Hewlett-Packard series 200 microcomputer system for the computation of tristimulus values, tristimulus coordinates, complementary tristimulus coordinates, RUCS coordinates, CIE La*b* 1976 and CIE Lu*v* paramaters, total colour difference and the index of greyness. This program is capable of displaying a graphical output (on screen, printer or plotter) of all the chromaticity bidimensional systems evaluated in this program. Other facilities included in this program are calculation of the dissociation constant of the indicator from complementary chromaticity coordinates, computation of the optimum indicator concentration, graphical output of ΔE^* vs. pH and SCD vs. pH curve. Two other programs, GRIS 1 and GRIS 2, are capable of calculating the chromaticity coordinates of the screened indicators which are screened with one and two inert colorants respectively.

Roses [97] reported the program SUPER COLOR written in BASIC for the evaluation of the colour changes of indicators, which has the capabilities of COLOR, GRIS 1 and GRIS 2 as well as simulating the colour change of an indicator.

The chromaticity parameters on the indicators methyl orange, bromocresol green and 1,2-naphthaquinone-2-thiosemicarbazone-4-sulphonic acid have been determined by the application of the SUPER COLOR program.

Cacho et al. [28] proposed a program RI-CANER, written in BASIC, for the evaluation of the chromaticity parameters and colour concentration. Recently, another program for the determination of tristimulus coordinates was proposed [88].

Kotrly and Vytras [98] carried out a comparative study of the results obtained by the weighted ordinate method and the selected ordinate method (10 and 30 selected ordinates) and concluded that the former procedure is more reliable at $\Delta\lambda = 10$ nm. These authors claimed that there is a higher propability of introducing gross personal error whilst reading the transmittance values from the graphs at 90 different non-integral wavelengths while adapting the 30 selected ordinate method and so discarded the application of this selected ordinate method.

Zahradnicek and Subert [99] also concluded that the selected ordinate method is inferior in terms of accuracy to the weighted ordinate method. Kotrly and Vytras [98] preferred the weighted ordinate method for the evaluation of chromaticity coordinates not only for the accuracy of the results obtained but also for ease of development of the computer program. However, a computer program has been written for the selected ordinate method algorithm using the Lagrange interpolation technique for reading the absorbance at the non-integral wavelengths [100].

Review

Microwave-assisted sample preparation in analytical chemistry

Frank E. Smith*, Edward A. Arsenault

Department of Chemistry and Biochemistry, Laurentian University, Sudbury, Ontario, P3E 2C6, Canada

Abstract

The speed and efficiency of instrumentation for chemical analysis has improved dramatically over the past twenty years. Until recently, however, methods of sample preparation had not changed to keep pace, so this had become the slowest step in analytical chemistry methodology. The widespread adoption of domestic microwave ovens during the past twenty-five years has eventually led to their usage in chemical laboratories. Microwave technology has now advanced to the point where it is revolutionizing chemical sample preparation and chemical synthesis. Since the first application of a microwave oven for sample preparation in 1975, many microwave-assisted dissolution methods have been developed— these are applicable to virtually any kind of sample type. This review attempts to summarize all the microwave-assisted dissolution and digestion methods reported up to and including 1994. In addition, some very recent developments in continuous-flow automated dissolution systems are discussed, as is the emergence of databases and software packages related to the application of microwave technology to sample dissolution.

There are 344 references.

Keywords: Analytical chemistry; Microwave-assisted sample preparation

1. Introduction

Microwave-assisted sample preparation techniques are becoming widely used in analytical laboratories all over the world. This review is an attempt to describe the most significant advances made, and to summarize the available literature up to the beginning of 1995. For the convenience of readers, methods have been divided according to sample type (e.g. geological, environmental, etc.). This inevitably leads to overlap, as some samples fall within more than one category, but it also makes for faster information retrieval. This review includes microwave techniques applied to atmospheric pressure dissolutions, fusions, Kjeldahl determinations and ashing procedures but focuses on the major application of microwave heating in this field, which is high-pressure dissolutions in sealed vessels/systems, where the elevated temperatures attained lead to faster sample breakdown and analyte dissolution.

Microwave ovens have been used in chemical laboratories for the sintering of ceramic mixtures [316], moisture analysis [311] and the wet ashing of biological and geological materials [31,32,81] for many years. The pressure dissolution of geological specimens in Parr bombs heated in water baths has also been exploited for a long time [11]. However, it is only within the last decade that the two techniques have been combined to provide rapid pressure dissolutions of analytical samples prior to AA or ICP analysis (10,132,148,270,319–321].

It is interesting to review briefly the circumstances which have led up to the development and adoption of this new pressure-dissolution technique. Since many of the first studies were carried out by researchers from the minerals sector, it is appropriate to trace the story from this perspective–however, the very significant contributions of researchers in other fields, notably Abu-Samra [31,32], Brown [81] and Kingston and Jassie [270] and all their co-workers must be acknowledged.

Efficient exploitation of minerals in the earth's crust requires extensive knowledge of the detailed geology, mineralogy and geochemistry of the various deposits, as well as a comprehensive understanding of the behavior of the various ores and minerals at different stages of the mining, milling, smelting and refining processes. Analytical chemistry is fundamental to the acquisition of this knowledge. Over the past decade, the mining and smelting industry has come under increasing pressure on two main fronts–economic and enviromental. On the economic front, inflation along with weak metal prices, increasing competition and lower quality ore bodies have forced companies to improve efficiency and productivity. At the same time, society has become increasingly concerned with the environmental effects of the industry. This has led to a demand for more stringent controls on emissions and effluents, and for the monitoring and revegetation of previously devasted areas. These influences have in turn made efficient management more and more dependent on reliable chemical analysis at all stages of the mining and smelting process. Analytical chemistry has never had a more important role to play. Similar trends are evident in other indus-

tries, and the signs are that the role of analytical chemistry will become even more crucial in the future. These pressures have favored the trend for analytical chemistry instrumentation to become more and more sophisticated. Improved instruments with the capability to detect ever-smaller quantities of more and more elements and compounds, more rapidly than before, are constantly being developed and usually incorporate powerful computational capabilities. However, many of these advanced techniques require the sample to be in solution form prior to analysis and yet few innovations had been made to sample dissolution methods. Conventional wet ashing dissolution techniques are very slow, and involve heating samples in various acids or mixtures of acids in an oven or on a hot plate for extended periods of time. Often the sample–acid mixture must be brought down to dryness, cooled, and then re-reheated with more acid in order to ensure dissolution. Also, these techniques are susceptible to loss of volatile analytes and cross-contamination. Other problems often associated with conventional sample preparation techniques include, tedium, danger due to the use of strong oxidizers, incomplete digestion and the need for large amounts of reagents, constant supervision and special fume hoods. For those samples containing intractable matrices such as refractory minerals, closed vessels such as steel-jacketed Teflon™ PTFE bombs or glass Carius tubes heated in a conventional oven have traditionally been used– again, lengthy heating times are required. Thus sample preparation became the slow step in the analytical process, providing the impetus for the development of fast and reliable alternative methods to those traditionally employed.

In 1975 Abu-Samra and his co-workers reported the use of microwave ovens for the purpose of wet ashing biological samples prior to elemental analysis [31,32]. These authors used a domestic microwave oven equipped with a spray fume scrubber to wet ash a range of biological samples. The only previously recorded laboratory uses of microwave ovens were for the drying of wet cake and paste in an inorganic chemical manufacturing plant [311] and for the sintering of silica and alumina mixtures [316]. The inspiration

for pressure-dissolution studies came from a US Bureau of Mines report [16], which described how a rapid dissolution of some mineral samples had been achieved by using a microwave oven to heat samples and an acid mixture contained in polycarbonate bottles. When this experiment was repeated [10], the method showed great potential, but the vessels proved unsuitable for more rigorous conditions—the vessels needed to be transparent to microwave radiation, chemically inert and resistant to acid attack, able to withstand high temperatures and pressures, and yet be reasonably cheap. Vessels should also be small enough to allow up to a dozen inside the oven at the same time, yet be readily sealed and opened to enable routine use by laboratory staff. A range of commerically available Teflon™ bottles was tried, but these deformed or burst during the heating process. Some test vessels were machined out of solid Teflon™ blocks, but it was found that the screw threads in the cap deformed during the heating, allowing the cap to explode off. Finally, a vessel was constructed from 4 cm diameter Teflon™–PFA tubing and end caps and this proved successful. Arrangements were then made with the manufacturer [337] to make vessels from the tubing. These were marketed and eventually became the vessel of choice for microwave experimentation. The identification and development of this more suitable vessel was a very important step forward and led to the development of a variety of digestion protocols [10,20,132,270,319–321], and also to a range of organic and organometallic syntheses [315,322–326], all extremely fast compared to the traditional methods they were intended to replace. Since then, both oven and vessel design have improved markedly. Dramatic reductions in sample preparation times, containment of volatiles and sample type versatility are evident advantages for closed vessel dissolutions when compared to classical wet digestion methods. Closed vessels result in the development of high temperatures and pressures which make dissolutions much more vigorous and rapid; hence the greater speed of the technique. The increased acceptance of the microwave pressure-dissolution technique is reflected by the dramatic rise in the number of publications appearing over the past

few years. These report dissolution methods involving geological, botanical, zoological, environmental, food, sludge, coal and ash, metallic material and synthetic material samples. Other papers focus on drying, on-line/flow-injection/continuous-flow systems, extraction/desorptions, distillations, total nitrogen determinations (Kjeldahl), reviews, general reports and databases, automated/robotic systems, oven modifications, special dissolution techniques and equipment, safety and moisture content determinations.

In many analytical laboratories, the microwave pressure-dissolution technique is already the method of choice for sample preparation. The new protocols reported have been, in most instances, verified exhaustively against standard reference materials. Microwave pressure-dissolution must now be considered an accepted technique. Other microwave-assisted processes for sample preparation are being constantly developed and put into practice. This is an extraordinarily dynamic and rapidly changing area of chemistry.

2. Microwave-assisted dissolution procedures

2.1. Geological samples

Geological materials often contain immutable matrices resistant to acid attack. Many of these matrices consist of refractory minerals (e.g. chromite) with high melting points or other compounds which may require several hours of heating in acids, or a fusion process, for satisfactory dissolution. The introduction of microwave-assisted pressure dissolution techniques has been a major advance in geochemical analysis. Since the introduction of this new technique [10], many other reports have been published involving the use of microwave energy for the dissolution of geological samples [1–30,129]. Table 1 is a summary of these references (see also Table 5 on environmental samples).

Some researchers used modified ovens [7,13,16,22,28] for their dissolutions. The most common modification involved systems for purging the oven's cavity of fumes to a fume hood either with compressed air, CO_2 gas or fan forced

Table 1
Geological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Bastnaesite ore: containing limonite, baryte and quartz	Closed 150 mL Teflon™ vessels compared with open-air methods	HCl, HF–HCl, HCl–H_2O_2	Ce, Eu, Gd, La, Nd, Pr, Sm, Y	ICP-ES	1
Ores	Domestic oven; open corundum crucibles; 70% electrical saving compared to muffle furnace/alkali fusion	NaOH	U, Th		2
V–Ti–Fe ore	Closed Teflon™ vessels; compared to classical methods	HCl–HF	Si, Al, Ca, Co, Cu, Fe, Mg, Mn, Ni, Ti, V	ICP, AAS	3
Geological	PTFE beakers surrounded by solid MgO inside tightly sealed PTFE containers	HNO_3–HF–$HClO_4$, MgO	(1) Ba, Be, Ca, Ce, Co, Cu, Fe, La, Mn, Ni, Sr, Ti, Vi, Zr (2) K, Li, Na	(1) ICP–AES (2) FAAS	4
Cu concentrates	The heating process and digestion system are discussed; compared with international standard methods	HNO_3–HCl	As, Ag, Hg, Pb, Sb, Zn	AAS	5
Geological: Cu/Ni sulfide–enriched	CEM MDS–81 oven; closed 150 mL Savillex Teflon™–PFA vessels; compared with two other classical methods; three-step dissolution	HNO_3–HCl then HF, EDTA, H_3BO_3	Major, minor and trace elements, oxides	ICP–ES	6
Thirty-three standard reference materials of rock, soil and sediment, and 18 standard reference materials of ores and minerals	Modified domestic oven with a turntable placed inside a fume hood purged with compressed air via tubing; closed 250 mL polycarbonate vessels and threads wrapped with Teflon™ tape inside a polyethylene food container sealed with a top to hold 12 vessels; all metal parts covered with plastic tape; safety discussed; 100 samples/day prepared; refractory minerals such as quartz, chromite, corundum, rutile and zircon are only paritally dissolved; all elements except Cr, P, Mg and Ti can be completely recovered; two-step dissolution	HNO_3, then HCl–HF, then H_3BO_3	Ag, Al, As, Au, B, Ba, Be, Bi, Fe, Ca, Cd, Ce, Co, Cr, Cu, Ga, Ge, In, K, La, Li, Mg, Mo, Mn, Na, Nb, Ni, P, Pb, Sc, Si, Sn, Sr, Ti, Tl, V, W, Y, Yb, Zn, Zr	ICP–OES, dc arc spectrography	7

Table 1 (continued)
Geological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Powdered carbonate rock samples, i.e. GFSs: 400 (dolomite), 401 and 402 (limestones) and 403 (limestones–dolomite blend); NIST SRM 88a (dolomite)	CEM MDS-81D oven; (1) open 120 mL Teflon™–PFA vessels with ethanoic acid on a hot plate then (2) closed with pressure release valves in microwave; heating process discussed; compared with two other author's work (classical methods) and certified values	(1) ethanoic acid, then (2) HF–HNO_3, then H_3BO_3 in microwave oven again	SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO, Na_2O, K_2O	AAS	8
NBS SRMs: 613 & 615 glass wafers, 278 obsidian rock and 603 K-feldspar; US geological survery whole rock standards: BCR-1 basalt, GSP-1 granodiorite, G-2 granite and zircon	CEM MDS-81 oven; closed 60 mL Savillex Teflon™ vessels surrounded by a 300 mL Teflon™ jar; discussion of the action of microwaves with sample–acid mixture	HNO_3–HF–$HClO_4$, HCl	Pb and some isotopes of Pb and U	Isotope dilution technique	9
Sulfide minerals: feeds, tailings and concentrates (Ni, Cu, pyrrhotite)	Toshiba model ER-800BTC domestic oven; closed 150 mL Savillex Teflon™–PFA vessels; compared with classical open beaker method; incomplete digestion for some samples especially high silica ones such as tailings; eight-fold reduction in digestion time	K–chlorate–HF–HNO_3 mixture	Cu, Ni	AAS	10
G-2 granite and MESS-1 marine sediment, silicate and quartz standard reference materials	Panasonic model NE-7970C domestic oven; lab.-designed, 1/2 in. thick walls and base, Lorran 20 mL Teflon™–TFE bombs (Lorran Int., Porters Lake, Nova Scotia, Can., B0J 2S0) which do not require annealing, machined from molded, stress-relieved Teflon™–TFE rods; with pressure release seals (250 psi); vessels are hand-tightened; domestic microwave pressure cooker with a pressure indicating stem used to contain leaking fumes; compared with same vessels in boiling water	Aqua regia HF, then boric acid upon dilution	SiO_2, Al_2O_3, Cr, Zn	GF-AAS	11

Table 1 (continued)
Geological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Standard rock sample andesite JA-1	A Koizumisango NDR-0500 oven; closed 23 mL PTFE Parr 4781 bomb with a pressure release mechanism (Teflon™ screw, max. pressure 100 Kg cm^{-2})	HNO$_3$ or aqua regia, then HF, then H$_3$BO$_3$ for Si determination	Fe, K, Mg, Mn, Na, Si	AAS	12
Ga and Ge ores: goethite, jarosite, hematite and some secondary Cu minerals; Zn processing waste: sphalerite, gypsum, quartz and anglesite	Modified Sears Kenmore Model 88861 domestic oven with an exhaust duct vented to a fume hood: closed Savillex 50 mL Teflon™ vessels; inhibition of volatile chlorides being formed; 20 samples/h; two-step dissolution; discussion of volatilization: GaCl$_3$ and (201°C) GeCl$_4$ (84°C)	HF–HNO$_3$, then H$_3$BO$_3$ HNO$_3$	Ga, Ge	nitrous oxide–acetylene FAAS or EAAS	13
Geological: Au and Ag bearing ores	microwave dissolution compared to fire assay technique		Au, Ag		14
Two fractions of Au and Pt group bearing rocks i.e. metallic and non-metallic parts	A dry chlorination method and wet microwave dissolution method	HF HNO$_3$–HCl	Platinum group elements and Au	ICP-MS	15
Slag, feldspar and Ni–Cu alloy	Modified conventional oven; fumes expelled to a fume hood using a CO$_2$ gas flow through pre-drilled holes; turntable used: two-stage dissolution; close polycarbonate bottles; in agreement with certified values (rel. std. dev. was 1%);	HF–HClO$_4$–HNO$_3$, then boric acid	Al, Ca, Cu, Fe, K, Mg, Mn, Na, Ni, Si	AAS, ICP-OES, XRS	16
Geological and metallurgical materials	Recommendations for the development of methods: in Russian with only the title translated				17
Minerals	Closed vessels; manual and robotic control; in Russian with only the title translated				18
Na$_2$SO$_4$, Cu–Pb–Zn ores	Microwave heating as an alternative in gravimetry; also Na$_2$O$_2$–ZnO fusion using microwave energy		S	Gravimetry	19

Table 1 (continued)
Geological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
(1) Ores (2) blister Cu	Closed Teflon™–PFA vessels; advantages over conventional methods; new technology such as lined vessels, temperature and pressure probes, and flow-through systems	HNO_3–HCl	(1) As, Cu, Se, Zn (2) Ni	(1) ZE–FAAS (2) AAS	20, 21
A U-rich sandstone (DL-la), a granite (BOE), a river sediment (SRM 1645) and a nearshore, marine sediment (RIID)	Modified Hitachi MR-6750 domestic oven inside a fume hood; closed Teflon™ bombs in a sealed box which is flushed with compressed air; how to digest obdurate minerals using Parr bombs	HNO_3–HCl HF	U, Th, some isotopes (^{238}U, ^{234}U, ^{232}Th, ^{230}Th)	Radio-chemical separation and alphaspectrometry	22
Free silica in a K–feldspar matrix, quartz, respirable dust samples	Closed vessels; procedure for determining the quantity of free silica in respirable dust samples, quartz recovery was 97%	Pyrophosphoric acid	Free silica		23
Fe ores and slags; representative CRMs; Fe, C and low-alloy steels	Commercial lab. oven; selection of acid mixtures and vessels; study of variables; establishment of operating procedures				24
Au-bearing ores	PATENT: pulsed microwave energy technique where the Au-bearing ore is exposed to pulses for 1–30 s with 10 s–2 min intervals between pulses for a total treatment of about 1 h; then leached by cyanidation to recover Au; Pb and Zn can be recovered as well	Cyanide	Au, Pb, Zn		25
Stone cutting waste	Closed PTFE vessels; filtered then residue ashed in a clay crucible at 1000°C; weight of fired material $\times 400 = \%$ SiC	HCl HF	SiC	Gravimetric	26
NBS: 278 obsidian rock, 688 basalt rock, 1633 and 1633a coal fly ash, 1645 river sediment and 1646 estuarine sediment	CEM MDS-81 commercial oven; closed 120 mL PTFE vessels; compared with high-temperature $Li_2B_4O_7$ fusion and PTFE bomb method using HF, HNO_3 or $HClO_4$	HF, HNO_3 or $HClO_4$, or HF–aqua regia	Al, Ba, Ca, Co, Cr, Cu, Fe, K, Mg, Mn, Na, Ni, Sc, Si, Ti, V, Zr	ICP-ES	27

Table 1 (continued)
Geological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Buddingtonite	Domestic oven modified by fitting tubing through the ventilation holes for cavity purging with compressed air and all exposed interior metal parts covered with plastic tape; 12 closed polycarbonate vessels capped with polypropylene screw caps inside a PE food container; ammonium determinations compared with those from Kjeldahl method; safety discussed	HF HCl	Ammonium K, Na	IC, potentiometric-measurements using an ammonia-specific electrode	28
US Geological Survey diabase W-1 and basalt BCR-1; NBS SRM 1632, 1632a and 1635 coals, 1633 and 1633a fly ash, 1645 sediment; IAEA SRM SL-1 sediment, polymers	Domestic Sears Kenmore oven; open Teflon™ or polycarbonate beakers inside a Pyrex vacuum desiccator	aqua regia–HF	Al, As, Ba, Be, Ca, Co, Cr, Cu, Fe, K, Li, Mg Mn, Na, Ni, P, Pb, Si, Sr, Ti, V, Zn	ICP-AES	29
Geological	Field instrumentation for a microwave digestion method followed by portable AAS		Metals, semi- and volatile organics	AAS, XRF for higher levels or inorganics	30

air. Most of the microwave dissolutions were performed using sealed vessels but some studies involved the use of pressure release mechanisms [8,11,12] and pressure and/or temperature monitors [11,20,21]. Three of these papers discussed the use of specialty dissolution vessels [11,20,21] while only two discussed the safety aspects of using closed vessels and microwave energy [7,28]. Some of the closed vessel dissolutions made use of containers which enclosed the vessels to prevent leaked fumes from destroying oven cavities [7,9,11,22,28]. Two dissolution methods used open vessels such as corundum crucibles [2] and Teflon™ or polycarbonate beakers [29]. Fusion procedures using microwave ovens are being developed [19] and a handbook describing them is to be published early in 1996 [332].

Despite the widespread use of certified reference materials, comparisons were also made with other non-microwave-assisted techniques to test the reliability, accuracy and precision of microwave methods [1–3,5,6,8,10,11,14,15,19,27, 129]. Discussions of the practicality of the technique for automation and robotics [18], flow-through systems [20,21] and field instrumentation for microwave digestions followed by portable AAS [30] have been reported. One report describes a pulsed microwave energy technique, followed by cyanide leaching, to recover Au, Pb and Zn [25].

By judicial adjustment of the various parameters (choice of acid mixture, power setting, time of irradiation) it has been found possible to dissolve most geological samples using the microwave-assisted pressure-dissolution technique. Precision and accuracy are generally as good as or better than those attained through conventional dissolution protocols.

2.2 Biological samples

It has become increasingly apparent that trace elements play an important role in biological systems, sometimes as nutrients and sometimes as toxins. There are even reports that they are responsible for causing diseases, such as urolithiasis [33]. One of the major problems in the determination of trace metals in biological materials is the dissolution 'of organic matter. The numerous problems associated with the destruction of organic matter have been described by Gorsuch [314]. When dealing with botanical and food samples, similar problems are encountered—the paragraphs that follow should be taken to include samples of these types as well.

The high pressure generated using closed vessels raises the boiling point of the acid(s) used and substantially increases the dissolution rate of these organic matrices. For example, nitric acid normally boils at 120°C, but at 5 atm in a closed container, it boils at 176°C when heated by microwaves [270]. This is 56°C above its normal boiling point and this results in an increase of its oxidation potential and speeds up its reactions. Under classical hot-plate conditions, the organic matrices of biological samples would remain intact due to the low boiling point of nitric acid. Under these circumstances, reagents such as perchloric acid would have to be used for the complete destruction of the organic matter.

The closed vessel microwave approach makes it possible to avoid the use of perchloric acid which is potentially explosive when in contact with easily oxidized inorganic or organic materials, expecially at elevated temperatures. Great care should be taken when heating percholoric acid under pressure, even by itself—one report [270] has shown that closed vessels heated with only 5 mL of perchloric acid remain pressurized even after cooling with liquid nitrogen. Instead of vaporizing and condensing like other acids, perchloric acid generates chlorine gas via an irreversible decomposition reaction when high temperatures are reached. The chlorine gas is not easily frozen and maintains a high pressure within the vessels. Despite the hazard, some authors do report the use of perchloric acid mixtures under pressure for

decomposition of biological samples (see Tables 2, 3, and 4).

Fortunately, pressure dissolutions involving other acid mixtures can usually be substituted with acceptable results. However, even when other acids are used, the considerable change in internal pressure generated by the production of CO_2 and NO_2 as the organic matrices are decomposed must be anticipated and controlled to prevent vessel rupture, microwave oven damage and possible personal injury. As a safety precaution, vessels with some kind of pressure release mechanism are recommended. Biological, botanical and food samples are primarily composed of three basic constituents: carbohydrates, proteins and lipids. Carbohydrates are the first constituent to decompose at approximately 140°C. Next, proteins decompose at about 150°C, followed by the lipids at around 160°C [193,270]. At each of these temperatures, significant increases in pressure are recorded with virtually no increase in temperature. Thus, for safety reasons and for determining the most efficient temperature for decomposition, the analyst should have some knowledge of the constituents of a sample matrix.

Abu-Samra et al. [31,32] were the first to report the use of a microwave oven for sample dissolution, vide supra. They used a nitric–perchloric acid mixture to oxidize biological samples in open 125 mL Erlenmeyer flasks using a domestic microwave oven. Since then, numerous articles have been published involving the use of microwave energy for the dissolution of biological samples [31–93,121,122,125]. Table 2 summarizes these reports. (See also Table 3 on botanical samples and Table 4 on food samples). Some reports describe interesting oven modifications [31–33,41,87,122]. Small holes can be drilled through an oven's side and liner in order to accommodate an exhaust port to remove fumes to a scrubber [31,32]. A water-jet aspirator can be used to remove fumes to a fume scrubber [87,122]. The cavity of an oven can also be sprayed with a silicone spray as a form of protection [87]. Two dissolution systems involved the use of focused microwaves in order to increase efficiency and to decrease digestion time [36,65].

Table 2
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
NBS CRMs: 1577a bovine Liver and 1571 orchard leaves, hair, fingernail and *Drosophila*	Modified domestic oven; open 125 mL flasks; fume scrubber using solid CaO, $CaCO_3$, liquid NaOH and water spray trap materials were tried; water aspirator, vacuum cleaner and a drum fan also tried for oven venting; Plexiglas box to protect oven from fumes	HNO_3-$HClO_4$	As, Co, Cr, Cu, Pb, Se, Ni, Zn	AAS, NAA	31, 32
Urinary calculi	Sharp (Model R6950 E) domestic oven; 50 mL flasks covered with small beakers all inside a dessicator connected to a fume scrubber using NaOH; no loss of any elements; excellent agreement with hot-plate method	HNO_3–$HClO_4$	Al, Ca, Cu, Fe, K, Li, Mg, Mo, Mn, Na, P, Pb, S, Sr, Zn	ICP-AES, XRD	33
NBS CRM 1577a bovine liver	CEM MDS-81D oven; closed 60 mL Teflon™–PFA with high-pressure release valves compared to open glass 30 mL beakers; powered fixed-torque capping station; fumes vented to a fume hood via a flexible duct; drying	HNO_3–H_2O_2	Fe	AAS	34
NIES CRMs: #5 human hair, #1 pepperbrush, #6 mussel, #7 tea leaves; NIST SRM 1566 oyster tissue	Mitsubishi RO-2500 domestic oven; closed PFA Tuf-Tainer vials in PTFE vessels enclosed in a jacket of polypropylene to protect oven from the fumes	HCl–$HClO_4$–HNO_3–HF, NAOH in the outer PTFE vessel	Al, Cu, Fe, Mn, Zn	ICAP	35
NIST SRM 1577a bovine liver	Special continuous power output, focused microwave system (via a waveguide); close stainless steel jacketed 28 mL tetrafluoro-metoxil–PTFE vessels (m.p. 350–380°C) in a ceramic vessel liner; rupture discs; fluid cooling system for pre- and post-digesting cooling of vessels; internal and external antennas provide coupling of microwave energy between a magnetron and the sample and acid(s)	HNO_3, can also use H_2SO_4 due to the higher melting point of the TFM–PTFE polymer vessel	residual C	Microcoulo-meter, Knobloch apparatus, elemental analyzer	36
BCR CRMs: 186 pig kidney, 184 bovine muscle, 062 olive leaves, 060 and 061 aquatic plants; NRCC CRMs: DORM-1 and DOLT-1 fish tissues and TORT-1 lobster hepatopancreas; NIST SRMs: 2670 freeze-dried urine and 1572 citrus leaves	Panasonic (Model NN-8507/8557) domestic oven with a rotating antenna for homogeneous microwave distribution; used closed PTFE Parr 478 bombs and results in agreement with certified values	HNO_3–HCl, then NaOH for pH adjustment, $NaClO_4$ and buffer	Ni	ICP-AES	37
NBS: oyster tissue and bovine liver; SRMs: 1643a and 1643b water samples	Domestic oven; 23 mL Parr Teflon™ bombs (maximum pressure 1200 psi); 30 s dissolutions	HNO_3	Cd, Cu, Fe, Pb, Zn	AAS	38

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
NBS SRM 1577 bovine liver; NIES CRM # 6 mussel, # 1 pepperbush and # 7 tea leaves	Mitsubishi R0-2500 domestic oven; capped 7 mL Tuf-Tainer PFA vials inside closed 50 mL Teflon™–PFA vessel all enclosed inside a polypropylene jacket; can digest 500 mg samples	HNO_3–HCl– $HClO_3$–HF mixture	Ca, Cu, Fe, K, Mg, Mn, Na, Zn	AAS	39
Fish muscle, IAEA MA-M-2/TM lyophilized muscle tissue	Prolabo Microdigest 300 oven; borosilicate glass flasks; 5 min, two-step dissolutions; optimum amount of HF required for best recovery was found to be 1 mL for a 1 g sample	HNO_3, or HNO_3–H_2SO_4 or HNO_3– H_2SO_4–H_2O_2	Hg	CV-AAS	40
Serum, NIST SRM 1577a bovine liver	Modified domestic oven with a plastic turntable and fumes directed to a fume hood; closed 50 mL PTFE centrifuge tubes; annealing method for vessels (200°C for 96 h)	HNO_3–H_2SO_4, then H_2O_2	As, Se	HG-AAS	41
Human plasma, NIST CRMs: 1572 citrus leaves, 1567a wheat flour	CEM MDS-81D oven; closed 120 mL PFA Teflon™ vessels with pressure release valves, collection vessel, tubing and powered fixed-torque capping station; multi-stage dissolutions	HNO_3–HCl	B	ICAP	42
Mussel, tobacco, peat, pine bark, ryegrass, apple, rice, vine leaves, cotton, hay, lettuce, flour, skim milk powder—spiked, BCR # 61, BCR # 60, pepperbush, NIST SRM 1548 and SRM 1573a, baby food	Moulinex 430 commercial oven and a Milestone microwave system (MLS-1200 MEGA); four digestion procedures using 25 mL Parr bombs (max. pressure 8×10^6 Pa) and MRD 1000/6/100/110 Teflon™ vessels (max. pressure 11×10^6 Pa)	HNO_3, HF, H_2O_2, $HClO_4$ and mixtures of these depending on the sample type	B, Cu, Fe, Mn, P, Pb, Zn	ICP-ES, FAAS, GF-AAS, ET-AAS	43
Hemodialysis water			Al	DPP, GF-AAS	44
Pig liver	Closed vessels	HNO_3–H_2O_2	Fe, Mn, Se	FAAS, HG-AFS	45
Biological, food, botanical	Open vessels				46
Pig liver	Closed PTFE vessels; cooled in an ice bath	HNO_3–H_2O_2	Mn, Fe	FAAS	47
CRMs: 1577a bovine liver, 1572 citrus leaves, 1575 pine needles, NIST 1648 urban particulate and 1576a flour, BCR CRMs: 186 pig kidney, 184 bovine muscle, 62 olea europae, 60 lagarosiphoumajur, 150 milk powder, 141 soil and 185 sediment	Semi-closed 3 mL Teflon™ tubes sealed only by Teflon™ tape mounted on a tray inside a Sterilite box, which was covered inside with a transparent plastic film; two-step dissolution	HNO_3–H_2O_2, then aqua regia–HF, boric acid	Cu, Cd, Fe, Mn, Pb	Ze-GF-AAS	48
Biological and some SRMs	Closed Teflon™ vessels		Ni	ETA-AAS, ICP-AES	49

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Human vertebrae, NIST SRMs: 1577 bovine liver and 1573 tomato leaves	All Teflon™ coated microwave digestion system		Ba, Bi, Cd, Co, Cs, Cu, Mo, Mn, Pb, Sr, Th, Tl, U, Zn	ICP-MS	50
Biological, and 5 NBS standard reference materials	Compared with conventional procedures		Al, Ca, Cu, Fe, K, Mg, Mn, Na, P, Sr, Zn	ICP-AES	51
Feces, urine	Sharp R-9280 oven; open crucibles; testing of the chelating effect of 1,2-dimethyl-3-hydroxy-pyrid-4-one for Fe overloaded rates	HNO₃	Fe	GF-AAS	52
Human semen, NIST 1577a bovine liver	Compared with conventional method		Cd, Cu, Cr, Pb, Zn	GF-AAS	53
Biological, NIST SRMs: 1570 spinach, 1571 orchard leaves, 1572 citrus leaves, 1573 tomato leaves, 1575 pine needles and 1577a bovine liver; BCR 63 milk powder; IAEA H4 animal muscle	Amana RS 560A domestic oven with rotating antenna for homogeneous microwave distribution; closed 60 mL Teflon™ vessels (Model 561R2, Savillex Corp., Minnetonka, MI, USA); safety vessels of 7.5 mL of vegetable oil/100 mL sample for excess microwave absorption; essentially the same accuracy and precision with only slightly higher detection limits as compared to the regular oven Teflon™ bomb method	HNO₃ with 9ppm Y as an internal standard	As, Ba, Br, Ca, Cr, Cu, Fe, K, Mn, Mo, Ni, Pb, Rb, Se, Sr, Ti, V, Zn	PIXE	54
Marine organisms, RMs: soils, sediments, wheat flour, citrus leaves, copepod homogenate, fish flesh homogenate, mussel tissue, olive leaves	Programmable Milestone MLS 1200 microwave oven; closed 120 mL PTFE bombs with pressure release valves (100 psi) and reflux system; recovery 104% and precision 1%	HNO₃–HCl, then H₂O₂, and HNO₃ for reflux system	As, B, Ba, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Sb, Se, Sr, Zn	ICP-AES, GF-AAS	55
SRMs: oyster tissue, bovine liver, milk powder, flour	Radarange domestic oven with a rotating antenna placed in a fume hood; lidded plastic box inside; closed 60 mL Teflon™–PFA vessels, three-step dissolution	HNO₃	Hg	CV-AAS	56
SRMs: cod muscle, muscle tissue, orchard leaves, fish flesh, lobster hepatopancreas, bovine liver and muscle, bread, milk powder and spruce needles; red cabbage, blood, urine, cooking oil, human breast milk	Buchi MLS 1200 domestic oven and a CEM MDS 81D oven; with PMD (Pressurized Microwave Digestion) quartz vessels with Teflon™ caps (by Paar, Graz, Austria); vessels have cooling unit, a piston indicating pressure and a sensor that shuts off power to the oven when 85 bar is attained until pressure is reduced; cooling unit; 10 samples at a time	HNO₃–HClO₄–H₂SO₄	As, Cd, Co, Cu, Ni, Pb	HG-AAS, DPASV	57
Biological	Teflon™ autoclaves		Twenty-four trace elements	ICP-AES, ET-AAS	58

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
SRMs: oyster tissue, rice flour, wheat flour, bovine liver, human urine	Modified CEM MDS 81 oven (a 360° reversing turntable, 12-position carousel, variable speed exhaust fan to remove fumes to a fume hood via a PVC hose mounted at the back wall of the cavity and a flexible and a rigid stainless stell waveguide attenuator cutoff grounded and mounted at the cavity wall to proved access for temperature and pressure lines); closed 60 mL Teflon™–PFA vessels (Savillex) with temperature (thermocouple) and pressure (transducer) probes; annealation of vessels; computer monitored system; reaction control techniques and safety precautions	HNO_3, H_2SO_4, HCl	Power absorption tests		59
CRMs: bovine liver, pine needles			Trace elements		60
SRMs: feces, citrus leaves, wheat flour and mixed diet	CEM MDS-81D oven with a rotating turntable and variable-speed exhaust fan; closed 120 mL Teflon™–PFA vessels (CEM Corp.); compared with traditional HNO_3–$HClO_4$ method	HNO_3–HCl. with and without HF, $HClO_4$ or H_2O_2	Ca, Cu, Fe, K, Mg, Mn, P, Zn	ICP-ES	61
NBS bovine liver; several hundred fish tissue samples (liver, muscle and kidney), plant, soil and plasma samples	Domestic oven; closed 60 mL Savillex Teflon™–PFA vessels (Savillex) placed inside a wide-mouth plastic container closed with a screw cap	HNO_3–H_2SO_4	Ca, Cd, Cr, Cu, Fe, Pb, Zn and l in Plasma	FAAS	62
Bone and teeth	Moulinex (Model Micro-chef FM 2515) domestic oven; closed 23 mL Parr 4781 Teflon™ bombs; cleaning of vessels; the first time that Ba and Cd levels in teeth have been reported	HNO_3	(1) Ce, Fe, K, Mg, Na, Zn (2) Ba, Cd, Pb	(1) AAS (2) GF-AAS	63
NRCC lobster hepatopancreas, marine biological reference material TORT-1	Commercial CEM MDS-81 oven: (1) closed 120 mL Teflon™–PFA vessels with pressure release valves; (2) closed 23 mL Parr Teflon™ bombs and (3) closed 100 mL Berghof PTFE vessels with rupture foil; 11 mL sample cups and an all PTFE microsampling device	HNO_3–H_2O_2	As, Cd. Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb, Se, Sr, V, Zn	FAAS, ZE-GF-AAS, carbon analyzer, CO_2 Coulometer	64
Alfalfa, hevea leaves, mixed feed, tuna fish, SRMs: mussel and fish flesh homogenate, animal muscle, milk powder, bovine liver and wheat flour	Automated focused microwave Prolabo A-300 digestion system equipped with two pumps for the addition of reagents; digestion and extraction using 150 mL Kjeldahl flask topped with a 50 mL reservoir and vertical condenser; compared with conventional method	HNO_3, $HClO_4$	Se	ET-AAS	65
Biological NBS and CBR samples			As, Na, Ca, Cd, Cu, Fe, K, Mg, Mn, Pb, Zn	FP-ICP	66

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Freeze-dried mussel, tea leaves, lotus-seed flour, SRMs: tea leaves and mussel	Closed PTFE vessels	HNO_3, $HClO_4$, HF, H_2O_2; mixtures	Multi-elements	ICP-AES	67
Haemodialysis water	Commercially available CEM MDS-81D oven; comparison of closed 7 mL Parr-type PTFE bombs and closed Teflon™–PFA vessels with pressure release valves	HNO_3–H_2O_2	Al	GF-AAS, DPP	68
NIST SRMs: liver and oyster; IAEA-CRM: human animal muscle	Panasonic NE-6660C conventional oven with a rotating turntable; closed 23 mL Teflon™ PFA Parr bombs	HNO_3, H_2O_2	Al, As, Ba, Ca, Cd, Ce, Cr, Cs, Cu, Fe, La, Li, Mg, Mn, Ni, Rb, Sb, Se, Sr, Mo, Tl, V, Y, Zn	ICP-MS	69
Eight octocoral species	Panasonic NE-7660/6660 domestic oven with a rotary tray; drying of samples; closed 200 mL thick-walled Pyrex glass test tubes with screw caps; compared with conventional sample drying and dissolution	HNO_3	Cd, Cu, Ni, Pb, Zn, total organic C	GF-AAS	70
Three NIST SRM bovine livers and one of orchard leaves and IAEA animal muscle	CEM MDS-81D oven; closed Teflon™ Parr bombs and 120 mL Teflon™ vessels with pressure release valves; two-step dissolution; problem in determining Al due to the detection limits of the methods	HNO_3	Al, B, Ca, Co, Cr, Cu, Fe, K, Mg, Mn, Na, Ni, P, Pb, S, Zn	ICP-AES, NAA	71
Human bone	CEM MDS-81D oven; closed 7 mL machined, and PTFE vessels with pressure release valves	HNO_3–H_2O_2	Al	DPP, GF-AAS	72
NIST SRM 1577a bovine liver; BCR CRMs: milk powders 150 and 151, olive leaves 62, sewage sludge 146, bovine muscle 184; SRMs: 1575 pine needles and 1566 oyster tissue; fiish muscle, pig kidney, peas, kale, lettuce	Domestic oven; closed 25 mL PTFE vessels (max. pressure 10 bar, supplied by Valtech Plastics, Thirsk); study of the stabilizing effects of Ru and Pd modifiers for retaining volatile analyte species during the charring step and for removal of interfering matrices; Ru better and retains volatiles 200–500°C higher than normal	HNO_3	Ag, Cd, Cu, Fe, Ga, Hg, Mn, Pb, Sb, Se	ZE-GF-AAS, ET-AAS, FANES	73
NIES CRMs: No. 6 mussel and fish tissue	Delonghi MW-155 domestic oven; closed PTFE vessels in a lidded plastic box to protect the oven from fumes	HNO_3–H_2SO_4, then H_2O_2; Na_2SO_3, KIO_3, H_2O_2	Se	DPP compared with HG-AAS	74
CBR CRM 278 mussel tissure, fish	Moulinex FM-460 oven; closed PTFE Parr bombs (model 4782); 90 s dissolution	HNO_3	Hg	CV-AAS, HG-AAS	75
Mussel products, NIST SRM 1556a oyster tissue; CBR CRM 278 mussel tissue	Bauknecht (Model MWT-732) domestic oven; closed 120 mL PTFE vessels compared with dry mineralization; moisture determination (drying) compared with conventional method	HNO_3–H_2O_2	As	GF-AAS	76

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
NIST SRMs: bovine liver 1577a and citrus leaves 1572; breakfast cereal mix	Prolabo Microdigest A-300 digestion apparatus (Rhone Poulenc, Prolabo Division Paris, France); oven vessels; programs for sample type; compared with hot plate method	$HNO_3-H_2O_2$ and sometimes H_2SO_4 as well; no need for $HClO_4$	Ca, Cu, Fe, K, Mg, Mn, Na, Zn	FAAS	77
NBSs: oyster tissue 1566, bovine liver 1577, spinach 1570, citrus leaves 1572, tomato leaves 1573, pine needles 1575, what flour 1567, rice flour 1568; apple leaves	CEM MDS-81 oven; closed 100 mL volumetric flasks	HNO_3, then H_2O_2	Ba, Ca, Cr, Cu, Fe, K, Mg, Mn, Na, Ni, P, S, Zn	ICAP-ES	78
NBS SRM 1577a bovine liver	CEM microwave digestion system; closed 60 or 120 mL PFA–Teflon™ vessels by Savillex; temperature measurement via a fibreoptic thermometer and pressure via a pressure sensor; vessels cooled in a dry ice–ethanol bath; residual organic species in a nitric acid digest identified which are destroyed if perchloric acid used (atmospheric pressure)	HNO_3 alone or with $HClO_4$	Residual organic species, Cu, Zn	UV/vis spectrophoto-meter, voltammetry, HPLC	79
Femur and parietal (skull) bones from 48 female rats, food	Domestic oven; open 125 mL flasks; rats given various concentrations of Pb in their drinking water	HNO_3	Pb	FAAS	80
Archaeological bone (ancient skeletal remains)	Open 25 mL conical flasks; samples cleaned ultrasonically	HNO_3 followed by $HClO_4$	Sr	FAAS	81
Pig liver	Closed 30 mL PTFE vessels; vessels cooled in an ice bath	$HNO_3-H_2O_2$	Mn, Fe	FAAS	82
Bone and brain tissue	1 h predigestion at 200°C then 6 min with HNO_3 in closed PFA vessels; improvement in detection limits for Al; digestion time, blank levels of Al (10 to 1 ppb) and amount of acid required (reduced 70%) were decreased	HNO_3	Al	GF-AAS	83
NRCC: (1) lobster hepatopancreas (TORT-1) and (2) marine sediment (MESS-1)	CEM MDS-81 commercial oven; closed 120 mL Teflon™–PFA vessels (CEM) with and without pressure release valves (75–85 psi); pressure measurements via a CEM PM pressure transducer attached to one of the digestion vessels with a pressure sensor designed to open if internal pressure within the line reached 100 psi; capping station; all vessels annealed; one or two stage dissolutions and subsequent evaporation on a hot plate (1) compared with hot-plate method (2); safety discussed	(1) HNO_3-HClO_4 or (2) HNO_3-HClO_4- HF	(1) As, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Se, Zn (2) same as above; total carbon in TORT-1	FAAS, GF-AAS, ICP-AES, total carbon analyzer, ICP-MS, ASV (using two-stage digests)	84

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
NBS SRM 1577 bovine liver	Domestic Philips AKB 100 oven; open conical flasks heated to near dryness; criteria for sample preparation and suitability of sample solution for ICP analysis discussed; compared with conventional extraction with HNO_3, solubilization in tetramethylammonium hydroxide, digestion with H_2O_2 and $HClO_4$, digestion in Teflon™-lined steel bombs, low-temperature ashing and muffle furnace ashing; safety discussed	HNO_3–$HClO_4$	Cd, Cu, Fe, Mn, Pb, Zn	ICAP-AES	85
Human blood	Domestic oven; stable tracer ^{58}Fe technique for iron utilization studies in man; open 250 mL Erlenmeyer flasks heated to dryness then dissolved with HCl, buffered with Na citrate, reduced with hydroquinone and complexed with 1, 10-phenanthroline	HNO_3–$HClO_4$	^{58}Fe	NAA, UV/vis spectrophotometer for complexed Fe	86
(1) Human teeth (2) Swordfish and Tunafish	Modified domestic oven with its cavity sprayed with silicon, a Pyrex jar used as an interior cavity and a Nalgene #6140 aspirator used to remove fumes from the cavity to a fume trap and a KOH scrubber; (1) 30 open ASV cells (Pyrex 20 × 85 test tubes) taken to dryness (2) open 125 mL Erlenmeyer flasks with a small funnel; blank Pb levels lowered from 9 ng (hot plate) to 5 ng	(1) HNO_3–$HClO_4$–H_2SO_4 (2) HNO_3–H_2SO_4	(1) Pb (2) Hg	(1) ASV (2) CV-AAS	87
Human blood (plasma and red cells)	Domestic oven, open 125 mL flasks; measurement of the extent of ^{70}Zn enrichment in plasma samples in man	HNO_3–H_2O_2	^{68}Zn and ^{70}Zn	NAA	88
NIST SRMs: 1577 bovine liver, 1566 oyster tissue, 1571 orchard leaves, 1570 spinach, 1572 citrus leaves, 1549 non-fat milk powder; IAEA: H-4 animal muscle, A-11 milk powder, V-10 hay, H-9 mixed human diet, total diet samples; NIES CRM-3 chlorella; RM-127 potato powder, RM-8 wheat flour, RM-115 animal muscle, RM-121 milk powder; whole egg and milk powder, wheat gluten, bovine muscle powder, corn bran, durum wheat flour; USDIET-I and II; DBW-9a and -11a swedish diets	Domestic Admiral oven; closed Parr bomb equipped with pressure release valves; cooled in a refrigerator; safety discussed	HNO_3	I	PNAA	89

Table 2 (continued)
Biological samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
NIST 1577a bovine liver		HNO_3	Se	ZE-AAS	90
Human head hair of 53 gas station workers and an equal number of controls	Domestic Philips AKB 100 oven; microwave dissolution (NaOH scrubber) in open test tubes before flow-injection/ASS Pb determination; hair washed first with EtOH and water; effects of washing, sample digestion of procedures, head sampling site, hair color, age, smoking habits and duration of exposure to Pb discussed; Pb content of gas station workers almost three times higher than normal controls	HNO_3–$HClO_4$	Pb	FI-AAS	91
NBS SRM 1577 bovine liver; NIES CRMs: #6 mussel, #1 pepperbush, #7 tea leaves	Domestic Mitsubishi RO – 2500; closed 7 mL Teflon™–PFA vessels	HNO_3–$HClO_4$–HCl–HF	Ca, Cu, Fe, K, Mg, Mn, Na, Zn	FAAS	92
Protein samples	Evaluation of microwave-assisted protein hydrolysis protocol	HCl	Amino acids		341
Protein samples	Comparison of the recovery of amino acids after vapor phase hydrolysis of proteins in a Pico Tag apparatus and a microwave hydrolysis system	HCl	Amino acids		342
Biological tissue containing seleno-amino acids	Direct detection of seleno-amino acids following microwave-assisted hydrolysis	HCl	Seleno-amino acids	Anion exchange electrochemical detection	344
Non-defatted lobster hepatopancreas tissue LUTS-1		HNO_3–H_2O_2	Seven trace elements, Hg	ICP-MS	93

Three papers discussed vessel annealation methods [41,59,84] which is important for decreased vessel porosity and increased strength. Gil et al. report the first simultaneous determinations of both barium and cadmium levels in teeth—they used a domestic oven and 23 mL Parr Teflon™ bombs [63]. Closed vessels were sometimes cooled using an ice bath [82], a refrigerator [89] or a dry ice–ethanol bath [79]. This allowed for the opening of vessels sooner than normal due to reduced vapor pressures. Safety concerns when using closed vessels were discussed in only three papers [59,85,89]. Open vessels were used less often but can provide complete dissolutions fairly quickly depending on the sample type [31–33,40,46,48,52,65,77, 80,81,85–88,91,122].

Sometimes special equipment was required and installed, such as fume scrubbers [31–33,87,91,122], vessels with pressure release mechanisms [34,36,42,55,64,71,72,84,89] and pressure and temperature monitors [57,59,79,84]. Other equipment included containers which enclose dissolution vessels to protect the microwave oven's cavity from leaking fumes [35,39,56,74,87], dissolution vessel cooling systems [36,57] and automatic capping modules [84,201]. One particularly noteworthy report [36] describes the design, construction and testing of a special vessel which incorporates a microwave source inside a stain-

Table 3
Botanical samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Oilseed rape stems, maize, wheat, barley	Teflon™-lined microwave bombs (Scientific & Medical Products, Manchester, UK; max. pressure 7.6×10^5 Pa and 180°C); compared with conventional method	NaOH, then HCl for pH adjustment; extracted with ethyl acetate	Total phenolic acids	Extraction	94
Barley straw, carnations, oak leaves, pine needles and rye grass	Microwave dissolution compared to classical method		Four major and six trace elements	ICP, ICP-MS	95
Standard reference materials; plant materials	Commercial lab. microwave–acid digestion system; closed Teflon™–PFA vessels with pressure release valves; compared with a dry ashing procedure; did not result in complete mineralization of samples although good results were obtained for the metals studied	HNO_3–HCl	Ca, Cu, Fe, Mg, Mn, Zn	FAAS	96
Plant material and standard reference materials	Open vessels; effects of acidic digestion mixtures upon dissolution; reaction vessels and power levels; procedure optimized	Various acids			97
Algae, seagrasses, fresh water and terrestrial plants, spermatophyta leaves, wood, rhizomes, roots and bark, NBS SRMs: pine needles and citrus leaves, *Pinus radiata* leaves	Modified Sanyo EM-840 domestic oven placed inside a fume hood; 50 mL Nalgene FEP (fluorinated ethylene propylene) Teflon™ vessels buried to half their height in a Pyrex container and sand; a glass water vacuum pump attached to Teflon™ tubing to vent off fumes from the container; instrument availability, purchase price, operating costs, acid volume and number of samples per hour compared to classical methods; safety aspects	HNO_3–$HClO_4$	Ca, K, Mg, P, S	ICP-ES	98
Plant tissues—BCRs: #279, #62 and #60; IAEA V-10 hay; halophyte *Aster tripolium*	CEM MDS-81D oven; closed 120 mL Teflon™–PFA vessels with pressure release valves (max. pressure 120 psi)	HNO_3–HCl, or HNO_3 alone	Ca, Cd, Cu, Fe, K, Mg, Mn, Na, Pb, Zn	FAAS, GF-AAS	99
NIST SRM citrus leaves #1572; agricultural crops: ryegrass, alfalfa, stargrass, bahiagrass, leucaena	CEM MDS-81D oven; 13 different power levels and times of exposure; closed 120 mL Teflon™–PFA vessels (exhaust ports in the centre of the lids) with pressure rupture release discs; compared with dry ashing and H_2SO_4–H_2O_2 wet digestion; diagrams of microwave vessels and system	HNO_3–HCl	Ca, Cu, Fe, K, Mg, Mn, P, Zn	ICP	100

Table 3 (continued)
Botanical samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
NIST SRMs: 1572 citrus leaves, 1575 pine needles, 1573 tomato leaves and 1567 wheat flour	CEM MDS – 81D oven; semi-closed 120 mL Teflon™ vessels with an exhaust port which allow the addition of H_2O_2 and HCl without removing the screw cap lids; Teflon™ coated oven cavity; compared with an open and closed (bomb) microwave method; three-step dissolution; 36–48 samples person/day	HNO_3, then H_2O_2, then HCl	Al, Ca, Fe, K, Mg, Mn, Na, P, S	ICP-AES	101
High organic content sample: sweet bay	CEM MDS-81D oven; semi-closed 120 mL Teflon™–PFA vessels covered with a predigestion reflux condenser or a cold finger assembly cooled using chilled heptane for preventing excessive pressure when samples are later digested under pressure; entering and leaving temperatures of coolant heptane measured by a Technosyn temperature probe; pressure monitoring via an external transducer (Sensym SX150DN); diagrams of both condenser and finger assemblies	HNO_3, heptane (chilled in a cardice with a CO_2-methanol slurry)	Mn	FAAS	102
Plant materials: six different reference materials	Closed Teflon™ · PFA vessels; method is dependent on the sample type and elements to be determined	HNO_3–HCl, or HNO_3– HF-H_2O_2	Al, Ca, Cr, Cu, Fe, K, Mg, Mn, Si, Ti, Zn	FAAS, DCP-AES	103
Plant tissue and CRMs	A dissolution method was developed without the use of H_2SO_4 and/or $HClO_4$ which create various molecular species which overlap with several important isotopes	HNO_3	Cr, Ni and other elements	ICP-MS	104
Plant material, reference materials: NIES rice flour 10c; IAEA V-10 hay and NBS wheat flour	CEM MDS-81D oven; closed 120 mL Teflon™–PFA vessels; four-step dissolution; precision and accuracy good enough for the application to long-term tracer studies with stable isotopes of Mo	HNO_3 then perhydrol, spiked solution (^{97}Mo-enriched aqua regia)	Mo and Mo isotopes	ID-MS	105
NBS SRM plant samples: citrus leaves and peach leaves; $(NH_4)_2SO_4$	CEM MDS – 81D oven; closed 120 mL Teflon™–PFA vessels with pressure venting system; special cap with two ports for pressure and temperature (fibre-optic-fluoroptic thermometry system) monitoring; fumes vented to a fume hood via PVC piping; capping machine; comparison with wet ash digestion	HNO_3–HCl, and HNO_3 H_2O_2	S	ICP	106

Table 3 (continued)
Botanical samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Plant materials: citrus leaf standard, peach and tomato leaves: $(NH_4)_2B_4O_7 \cdot H_2O$	CEM MDS – 81D oven; closed vessels compared with dry ash digestion	HNO_3, then H_2O_2	B, S	ICP-ES	107
Wood and wood-based materials (plywood and particleboards)	Non-destructive method based on measuring microwave attenuation		Moisture		108
Plants, food	Comparison with other decomposition techniques such as acid-oven, pressure, plasma and UV dissolutions	Mineral acids	Heavy metals		109
Plants and biological fluids	Open 125 mL vessels	$HNO_3 - HClO_4$	Se	INAA	110
Eight peat samples	CEM MDS-81 commercial oven; four closed 60 mL Savillex PTFE–PFA vessels, two to a set of Nalgene 16-500 polypropylene bottles with loosely closed lids; sample heated with HNO_3 on a hot plate at 130°C then inside nalgene bottles in a microwave oven with $HClO_4$, cooled, then again in the oven with HF, then brought to dryness on a hot plate, compared with conventional hot-plate and dry ashing methods; caution advised; new method requires only 2 h compared to 30 h on a hot-plate with 45 mL of acid	HNO_3 then $HClO_4$ then HF (the greater the silicate content, the greater the amount of HF used)	Al, Ca, Cu, Fe, K, Li, Mg, Mn, Na, Zu	FAAS	111
NBS SRM 1571 orchard leaves	Open vessels; digests analyzed using a CRA and Woodriff furnace; acid fumes exhausted to a fume hood	HNO_3, $HClO_4$ and a few drops of HF	Cr, Cu, Pb, Zn	CRA and Woodriff furnace GF-AASs	112

less steel jacketed vessel lined with TFM–PTFE™. Inside the vessel, a steel waveguide focuses the microwave energy directly onto the sample. Operating temperatures of up to 350°C are attainable.

Much of the research has included results from standard reference materials for verification purposes. In addition, much of the development work was carried out in paralled with a more traditional method, and the results of the two methods compared [33,51,53,61,65,70,76,77,84,85,121,122]. In addition, there are reports of studies on biological materials involving drying [34,70,76], automation [65], a Kjeldahl apparatus/technique [249] and reflux/extraction systems [55,65]. The use of

microwave-transparent, inert, closed vessels for sample dissolution appears to be the method of choice for the destruction of organic matter. Loss of analyte by volatilization or adsorption onto the walls of the vessel is negligible despite the generation of the high pressures and temperatures associated with the technique. In most instances, the high pressures and temperatures result in complete dissolution of the organic matter which often remains after dissolution by conventional techniques. There are some reports of the use of microwave ovens for protein hydrolysis (particularly vapor phase) prior to amino acid analysis [341–344]. In view of the long reaction times required for conventional protein hydrolysis, this

Table 4
Food samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Brine shrimp (adult *Artemia* sp.)	Modified Penney RE-705TC domestic oven; open polyethylene and polypropylene cups and vials inside a closed polypropylene or pyrex container attached to a water aspirator and KOH scrubber for time removal. No loss of volatile trace elements	HNO_3	Cu, Cd, Fe	HG-AAS	113
Meat, oatmeal	Domestic oven; moisture determination by weighing samples before and after treatment, error < 0.01%		Moisture	None	114
Food	Domestic oven; closed 50 mL PTFE vessels cooled afterwards at −25°	HNO_3–H_2O_2	Ca, Cu, Fe, Mg, Mn, Zn	ICP-AES	115
SRM IAEA A-11 full-cream milk powder; soyabean flour, chocolate cream, milk chocolate, peanut butter, sunflower oil, linseed	(1) MWS 700 (Bacuknecht) and (2) Prolabo Microdigest 300M domestic ovens; (1) closed 50 mL low-pressure PTFE vessels with pressure release blast discs (1 MPa) connected to an acid container via PTFE tubing — a three-step dissolution; compared with: (1) high-pressure 23 mL polyimide bombs with PTFE sample vessels; (2) open quartz Kjeldahl flasks with a Vigreux colomn—three or four-step dissolution; (3) cool plasma ashing with microwave excitation and wet pressure digestion with conductive heat in an autoclave (Tolg); reproducibility, completion of digestion, contamination problems and loss of analytes discussed	HNO_3 then after the second stage of dissolution H_2O_2, or HNO_3–H_2SO_4, or HNO_3 alone	(1) Cu, Fe, Zu (2) Ni and other low concentration elements (3) Hg, Se	(1) FAAS (2) GF-AAS (3)HG-AAS	116
Food	PATENT: food material that had been sterilized and/or bleached is irradiated (1000–3000 MHz) to decompose H_2O_2 residues	H_2O_2			117
Grapefruit juice	Domestic General Electric JET 212 oven; closed 60 mL Teflon™–FEP bottles; advantages and possibility of automation discussed	Aqua regia	B, Ba, Ca, Cu, Fe, K, Li, Mg, Mn, Na, P, Rb, Sn, Sr, Zn	ICP-AES	119
Brine shrimp	Penny RE-705TC domestic oven modified with a water aspirator and KOH scrubber; open polyethylene autosampler cups; compared with dry ashing, hot block and high-pressure techniques	HNO_3	Cd, Cu, Fe	GF-AAS	120

Table 4 (continued)
Food samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Shellfish, SRM lobster hepatopancreas	Closed vessels; compared with wet and dry ash procedures		Cd, Cr, Cu, Pb, Zn	FAAS	121
Roasted soyabean flour (kinakao), cabbage, seaweed, hog liver, NBS SRM 1566 oyster tissue	Domestic Toshiba ER-500 oven modified using a water-jet aspirator to draw fumes to an NaOH scrubber, open Erlenmeyer flasks; compared with conventional wet digestion method	HNO_3–H_2SO_4	As, Cd, Cu, Mn, Pb, Zn	AAS, GF-AAS	122
Food: rice, maize and red beans	Domestic oven Model WBL-823 (Jinan Quanli); four covered 30 mL PTFE vessels; Fe(III) later complexed	$HClO_4$–HNO_3	Fe	Adsorption chronopotentiometric determination	123
Wheat flour, mixed diet, pig liver	Closed 44 mL custom PTFE vessels; vessels cooled in a −25°C refrigerator	HNO_3–H_2O_2	Ca, Cu, Fe, Mg, Mn, Zn	ICP-AES	124
Food	Comparative study of conventional and microwave-assisted protein hydrolysis protocols	HCL	Amino acids		343
Thirty-two different fish species; CRM 278 mussel tissue	Domestic Moulinex FM-460 oven; closed Parr 4782 vessels	HNO_3 with a few micrograms of VO_5 as catalyst	Pb	ET-AAS	125

would appear to be an area where microwave-assisted techniques will become very important.

2.3. Botanical samples

Elemental analysis of botanical tissues is an essential requirement of soil fertility programs, nutrient budget and cycling investigations, environmental monitoring and elemental uptake studies. Botanical samples have the same dissolution problems encountered for biological samples described about–the destruction of organic matrices comprising carbohydrates, proteins and lipids.

Many articles have been published describing the use of microwaves for the dissolution of botanical samples [31,32,35,37,39,42,43,46,48,50,54, 55,57,60–62,65,67,71,73,77,78,89,92,94–112,147]. Tables 2, 3 and 5 contain these references, detailing the use of microwaves to various botanical samples.

Oven modifications included the use of forced air to purge fumes to fume scrubbers [31, 32] and the use of a glass water vacuum pump attached to Teflon™ tubing to vent fumes [98]. Many of the closed vessels used were equipped with some form of pressure release mechanism [45,55,71,89,96,99,100,106] such as pressure release valves, rupture discs and exhaust ports. One type of closed vessel was equipped with a cooling unit [57] while others were simply cooled in a refrigerator [89] before opening. Internal vessel temperature measurements were monitored via fibre-optic fluoroptic thermometry [106]. Pressure measurements were made via a real-time monitor [106], one with a piston which protrudes as the pressure increases [57] and one with an external transducer [102]. Often, the vessels were enclosed in containers such as a plexiglas box [31,32], polypropylene jackets [35,39], a Pyrex vacuum desiccator [98] and polyethylene bottles [111] to protect the oven's cavity. The reliability, precision

and accuracy of the technique has been tested by comparison with conventional techniques [61,65,77,94–96,98,100,101,106,107,109,111]. Safety however, has only been discussed in three papers [89,98,111]. Reports of particular interest involved a focused microwave system with the possibility of automation [65], special reflux systems [55,65] including one using either a condenser or a cold finger assembly cooled with microwave-transparent heptane [102] and a non-destructive method for determining moisture [108].

2.4. Food samples

Food samples present the same general problems as discussed for biological samples. Foods which are higher in lipids generally require higher dissolution temperatures and/or other acid mixtures than foods comprised mostly of proteins. High-protein foods generally require higher dissolution temperature and/or other acid mixtures than high carbohydrate foods.

Although the use of nitric acid alone for the treatment of food samples commonly results in the incomplete digestion of organic material, the method appears to provide reproducible results [79,270]. No significant traces of carbohydrates, proteins and lipids were detected chromatographically after using this method. Only a few organic molecules remained intact and they have been identified. For example, chromatographically separated liver digestate sequestered only o-, m- and p-nitrobenzoic acids. These are assumed to be of aromatic amino acid origin through their nitration and subsequent oxidation from the original protein.

Many articles have been published concerning the use of microwaves for the dissolution of foods [43,46,48,54–57,59,61,65,67,73,75,77,78, 80,87,89,94,100,101,109,113–125,145]. Two papers do not involve dissolution techniques but rather moisture determination by drying [114] and a patent for the decomposition of peroxide residues [117]. Tables 2, 3, 4 and 5 contain these references, detailing the use of microwaves to various food samples. Of particular interest, one technique used vanadium pentoxide as a dissolu-

tion catalyst [125]. Some reports describe oven modifications: several of these involved the use of a water aspirator and scrubber for fume removal and disposal [87,113,118,120,122]. The interior of one microwave oven was coated with a silicone spray to protect the cavity from corrosive fumes [87]. One oven was modified by making use of a flexible and rigid stainless steel waveguid attenuator cutoff, grounded and mounted at the cavity wall, with a 360° reversing turntable, a variable speed exhaust for removal of fumes via a PVC hose mounted at the back of the cavity, and a 12-position carousel, all with computer control [59]. Containers used to enclose dissolution vessels were a lidded plastic box [56] and a closed polypropylene or Pyrex™ container [113], all of which were later vented off in a fume hood. Refluxing and/or extractions have also been reported [55,57,59, 61,65,77,78,100,101,116]. Dissolutions, refluxing and extractions could also be performed using a focused, automated microwave system [65]. One method describes a microwave-assisted procedure for the hydrolysis of food protein prior to amino acid analysis [343].

Specialty vessels described included pressurized microwave digestion quartz vessels with cooling units [57], Teflon™-lined microwave bombs [94] and custom-made 44 mL PTFE vessels [124]. A method for vessel annealation was presented only once [59]. Safety aspects of using closed vessels under pressure were discussed only twice [59,89]. Some vessels were equipped with pressure release mechanisms such as pressure release valves [55,89] and discs [100,116]. The pressure was monitored via transducer probes and the temperature via a thermocouple [59]. The pressure was also measured using quartz vessels equipped with pistons monitored by sensors which shut off the oven power at 85 bar, until the pressure had dropped [57]. A refrigerator was used to cool dissolution vessels [89] in order to shorten sample preparation time. Open vessels were used less often to perform food dissolutions [46,48,65,77,80,87,113,118,120,122, 123].

Comparisons were sometimes made with other conventional techniques for validation and re-

producibility of microwave-assisted dissolutions [61,65,77,94,100,101,109,116,120–122].

2.5. Environmental samples

Many environmental samples are sediments. Sediments are highly variable and complex matrices, considered to be the ultimate sink of heavy metals released into the environment [143] and also reserviors for other environmental pollutants such as organochlorine insecticides [237]. The relative ease with which metals are released from, or bound to sediments is poorly understood. With increasing environmental and health regulations, the demand for environmental analysis and the range of sample types has grown enormously over the past decade. Environmental samples may be inorganic, organic or biological in nature, or a mixture of all three. Circumstances may dictate that rapid results are needed—this category therefore includes a very wide variety of sample types and analytical methods, but microwave-assisted pressure dissolution is gaining wide acceptance as the method of choice for sample preparation in this field [7,11,22,23,27,29,38,48,55,62,84,98,118,126–152]. Table 5 lists the applications of microwave techniques to various environmental samples (see also Tables 1, 3, and 6). Three reports describe the purging of oven cavities for fume removal either with compressed air [7,22] or via a glass water vacuum pump [98].

Safety measures and cautionary notes when using closed vessels were expressed in only four papers [7,98,128,132]. However, some of these vessels were equipped with pressure release mechanisms such as valves [55,84,118,141, 144,147] and seals [11,136]. Techniques of annealing vessels were presented in two papers [84,151]. One author monitored pressure via a stem which protruded from a domestic microwave pressure cooker enclosing the dissolution vessels [11] while three others used pressure transducers [84,118,136]. Containers used to enclose dissolution vessels in case of fume leakage were polyethylene containers [7,128], a domestic microwave oven pressure cooker [11], a sealed box [22] and Pyrex™ vacuum desiccators

[29,98]. Special dissolution vessels are described such as one-half inch thick 20 mL Teflon™–TFE bombs which do not require annealing [11], fluorinated ethylene propylene–Teflon™ vessels [98] and double-walled, lined Teflon™–PFA vessels [142]. One author mentioned that double-walled 200 psi dissolution vessels are now available which may be useful for better recoveries of Sb when digesting soils [138]. Only five researchers used open vessels to perform dissolutions [29,48,98,130,143].

Comparisons were made with conventional techniques for the validation of elemental recoveries in terms of precision and accuracy [11,27, 84,98,126,128,129,133,137–142,147,150,151]. Mention has been made of possible automation and advanced computer control [137], the use of a uranium salt for the neutralization of the electrical charges within oven cavities [142], software for finding the best dissolution method [144] and a reflux apparatus [55].

2.6. Sludge samples

Perhaps the most important type of sludge is that which comes from the treatment of sewage. This sludge is produced in large quantities all over the world and is often deposited at specific sites. Although there are appreciable benefits in the application of this sludge to farmland [154,313], there is also the risk of toxic elements and bacteria accumulating in the soil due to improperly treated sewage. This accumulation can lead to the contamination of soils, ground water, lakes and streams etc. and eventually to contamination of the food chain, e.g. fish, crops and livestock.

A few articles have been published involving the use of microwave techniques for the dissolution of sludge samples [73,137–141,152–155]. Table 6 summarizes these reports (see also Table 2 and 5). All the articles involve the dissolution of sludges with the exception of one article which discussed a microwave oven/electronic balance system for the determination of total solids content [153]. Three articles concern the loss of antimony when sludge samples

Table 5
Environmental samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Lake sediments and mine tailings along with CRMs	CEM oven, Savillex vessels. Acid mixture digestion. Pressure limited to reduce loss of volatiles—improved recovery of As and Se compared to hot-plate digestion	HCl HNO₃ HF	As, Se	HG-AAS	118
Standard reference sediment and soil; suitable for anthropogenically contaminated soils and sediments	Compared with hot-plate digestion method; faster, more routine and less subject to technician error	HNO₃	Ag, As, Ba, Cd, Cr, Cu, Hg, Ni, Pb, Se, Tl, Zn		126
Four reference soils from the CCRMP: SO-1, SO-2, SO-3 and SO-4; mineral soil and clay samples	Commercial oven; closed 60 mL Savillex Teflon™–PFA vessels; freezer used to cool vessels; addition of boric acid prevents loss of Si	HNO₃–HF, then H₃BO₃	Al, Ca, Fe, K, Mg, Mn, Na, Si, Ti	ICP-AES	127
Three reference soils and nine other randomly selected soils	Sears Kenmore (Model 87751) oven; closed 60 mL Savillex Teflon™–PFA (fully fluorinated alkoxy-side chain) vessels inside a 4 L polyethylene container; effect of power level; compared to an open vessel method with HNO₃–HF-HClO₄; safety	HNO₃–HF	Cu, Zn	AAS	128
Venezuelan red mud, NBS SRMs; phosphate rock and flint clay	National Panasonic (Model NE6660) domestic oven; closed 100 mL PTFE vessels; polyethylene and polycarbonate vessels tried as well; compared with conventional and soild sampling techniques	HNO₃–HF–HCl (9:5:6 best), then H₃BO₃	Ag, Au, Cd, Cr, Pb	GF-AAS	129
Aqueous heat transfer agent of power stations	Elektronika SP-01 oven; open glass beakers, porcelain, PTFE and PET vessels; shapes of and effect of vessel material investigated (glass, porcelain, PTFE and PE)	Mineral acids, NaOH for Si	Fe, Cu, Ni, Pb, Si, Zn		130
SRMs: pond sediment, soil-1, soil 83401 and other silicate samples	Domestic oven; closed PTFE vessels; vessels cooled in a refrigerator; combination of HNO₃ and H₂O₂ greatly increases reaction rate and accelerates digestion process of organic matrices	HNO₃–HF H₂O₂	Ba, Ca, Cr, Cu, Fe, Mg, Mn, Sr, Zn		131
Soils	A procedure developed using closed vessels to minimize loss of As	Various acid mixtures	As		132
Aged (<80 years) Zn-contaminated soils from a location subject to airborne contamination from a smelter site	Evaluation of the technique for routine lab. use, compared with block digester and hot-plate techniques; significantly more complete metal release, greater metal concentration values and replication uniformity with microwave digestion method		Zn		133

SO-1 regosolic C horizon soil, SO-2 podzolic B horizon soil, SO-3 calcareous C horizon soil and SO-4 black chernozemic A horizon soil	Domestic Toshiba model ER 855BTC oven: closed 150 mL Teflon™-PFA vessels, four-step dissolution; safety precautions: compared with CANMET values of each soil type	HNO_3, then HNO_3-$HClO_4$-H_2SO_4	As	FAAS	132
Industrial wastewater	Detection limits were 1.9 ppb for Ni and 0.40 ppb for Cr		Cr, Ni	GF-AAS	149
Airborne particulates	Compared with conventional extraction and digestion with HNO_3	HNO_3-$HClO_4$	Cd, Cu, Pb, Zn	DPASV	150
NRCC MESS-1 and BCSS-1 marine sediments	Closed Teflon™-PFA vessels: annealing of vessels; results comparable or superior to those obtained using conventional methods: significant precision improvements especially for those elements with poor conventional precision	HNO_3-HCl	Environmentally significant elements	ICP-AES GF-AAS	151

were digested using closed vessels [138,139,140]. One report of the use of automated procedure is of particular interest [137].

Some comparisons of dissolution efficiency were made with conventional techniques [137–141].

2.7. Coal and ash samples

Using conventional procedures, coals and other samples such as ashes, require heating periods of about 12 h for total dissolution. Microwave procedures have reduced this heating period to a matter of a few minutes [27,29,142,157,160–162,167–169]. Besides being useful in performing dissolutions, microwaves have found use in moisture content determinations [156,158,163,165,166], desulfurization [164] and in the determination of the unburnt carbon content of coals [159]. Table 7 lists and summarizes these references (see also Tables 1 and 5). In one report concerning coal fly ash, a uranium salt was used for the neutralization of the electrical charges within an oven cavity [142]. A technique for the determination of unburnt car-

bon based on microwave attenuation and phase shift differences [159], and a mositure determination technique based on input and output 10 GHz microwave energy differences [163] have been patented. Moisture has been determined using a microwave meter while the sample was being simultaneously heated and weighed [165,166], and from projecting final weights from a weight loss curve after a fraction of the time required for complete drying [156].

Many microwave-assisted determinations were compared with the results from conventional methods [27,142,158,161,162,166,167,169].

2.8. Metallic samples

The determination of metal purity and the elemental composition of alloys is of utmost importance in the metallurgical industry. Companies have the responsibility of providing metals and alloys of particular elemental composition as specified by their customers. Samples are often analyzed as solids following fire assay or directly from metal castings using XRF and

Table 6
Sludge samples

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Sludge and waste water samples	Closed vessels; 110 mL liquid and 1 g soil samples; sample preparation and processing time was reduced by 5–50 times with ashing done at 180°C using HNO₃; microwave unit has a Teflon™-coated inner chamber equipped with a 2.8 m³ min⁻¹ aspirator exhaust system and a Teflon™ carousel 12-sample holder	HNO₃ or HNO₃, HNIO₃ mixtures to avoid the use of HClO₄	Concentration and isolation of various metals for subsequent analysis		152
Dewatered activated sludge	Microwave oven electronic balance system		Determination of total solid content		153
BCR 144, 145 and 146 sewage sludge standards; sewage sludges	CEM MDS-81 oven; six closed 120 mL PTFE vessels in a carousel	HF aqua regia, or aqua regia alone, then boric acid	Al, As, Be, Ca, Cd, Co, Cr, Cu, Fe, K, Mg, Mn, Mo, Na Ni, Pb, Sb, Sc, Se, Sn, Ti, Tl, V, W, Zn, Zr	ICP-AES, FAAS	154
Sewage sludges and CRM sludge samples	Closed vessels	HNO₃ and 2-ethyl-hexan-1-ol	Cd, Cu, Fe, Mn, Pb, Zn	FAAS	155

OES. Solution samples may be prepared for analysis by fusion followed by wet ashing or by straight wet ashing techniques. However, these sample preparation methods are time consuming and labor intensive and often result in incomplete elemental digestions. An example is the problem of completely digesting Al in steels without having spectroscopic interference from salt matrices (from fusions) [176]. Other problems include the hydrolyzation of refractory elements (e.g. Ta and W) when hydrofluoric acid is not used, the low solubility of fluoride salts of Y [172], Pb, Ca, U and Th, and the loss of volatile fluorides of Si, As and Se [270].

Microwave techniques are often well suited for the dissolution of metallic samples. For example, hydrofluoric acid can be used in closed vessel dissolutions to digest silicate matrices and to stop the hydrolyzation of refractory elements without the loss of volatile fluorides. After cooling, boric acid can be added to complex unreacted hydrofluoric acid. This allows for the use of conventional glassware, acts as a matrix

modifier for AAS and more importantly redissolves precipitated fluorides [270]. The solid sample itself may absorb microwave radiation, creating a heated surface on which the acid(s) can react. Microwave muffle furnaces are now commerically available [332] based on oven linings made out of the highly efficient microwave absorber silicon carbide. This microwave absorber rapidly heats up the oven's cavity to ashing or fusion temperatures. Other solid samples may reflect microwaves, creating high sample–acid interface microwave densities. This can result in very rapid heating of the acid(s) used and create turbulence and sample agitation both of which sweep sample surfaces clean of acid-resistant coatings, exposing fresh, unexposed sample surfaces which are open to acid attack.

Under some circumstances, the use of microwave energy in the presence of metallic materials is not recommended. Specifically, interaction of certain metals with microwave energy can result in uncontrolled sparking and electrical arcing, possibly leading to electrical

Table 7
Coal and ash samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
8-Mesh coal	Open vessels; final weight predicted by projecting the weight loss curve to its end point after a fraction of the time required for complete drying		Determination of water content		156
Certified coal reference standard AR-1800, NBS 1632a; petroleum coke samples	Domestic oven; closed, modified Pyrex glass test tubes; microwave treatment the most efficient method for V extraction	HNO_3–HF	V	GF-AAS, XRF	157
Coal, esp. sub-bituminous western coal (USA)	Open vessels; no coal degradation; compared to conventional methods		Moisture content		158
Fly ash	PATENT: generation and transmission of microwaves through fly ash; receiver of a microwave signal passed through the sample, and a means to determine the attenuation and phase shift differences of the transmitted signal to produce a measure of the unburnt C content; can be used to control a coal-fired boiler		C	Attenuation phase shift differences of the signal	159
Particulates, ashes and oil fuels	Closed vessel; wet and dry digestion of waste samples before elemental analysis; effect of preparation conditions: acid matrix, heating time and pressure	Different acid matrices	Fifteen toxic or hazardous elements	ICP-AES	160
Coal ash samples	Alternative to the $Li_2B_4O_7$ fusion process; requires the use of HCl for P determination	HNO_3–HF–HCl	P and others		161
Coals and coke containing 43–88.8% fixed C	Proportional relationship was observed between time for complete digestion and fixed C content for both acid mixtures; compared with PTFE bomb method	HNO_3–H_2SO_4 or HNO_3–$HClO_4$	Cu, Mn, Ni, Pb and Zn	AAS	162
Crude lignite	PATENT: 10 GHz microwaves passed through brown coal; sieved (<2 mm) coal is sampled by means of compressed air into a quartz tube inclined 15° to the microwave source; measure the difference between input and output energies as it passes through the sample	None	Water content	Microwave meter	163

Table 7 (continued)
Coal and ash samples

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Bitumite coal	Samples irradiated at 2.45 GHz for various lengths of time to determine the coal desulfurization effect			[57]Moessbauer measurements	164
Coals with a moisture content between 0–15%	Use of a microwave meter to determine the moisture content in coals; use 1.5 kg samples; determination error was 0.8%		Moisture content	A microwave meter	165
Coals	A measuring device was developed for a rapid moisture determination in samples which are continuously weighed when heated by microwaves; integrated gas sensors prevent samples from overheating; thus preventing gas evolution; comparable to the drying cabinet method (DIN 59718)		Moisture analysis	Moisture is monitored by a computer in response to weight changes	166
Alpha Resources reference standards: AR-1800, 1803 and 2777 coals; NBS SRM 1632a coal; Venezuelan coal samples	Domestic National Panasonic NE-6660; closed 200 mL thick-walled Pyrex glass test tubes; compared with conventional method; decomposition efficiencies compared; effects of acid mixtures, heating power and time settings investigated to optimize dissolution	HNO_3–$HClO_4$	Fe, Ni, V	ETA-AAS	167
Coal fly ash	Closed PTFE vessels; four different decomposition procedures investigated; microwave decomposition with HNO_3–HF–$HClO_4$ was applicable for all the elements and gave results in agreement with the certified values	HNO_3–HF–$HClO_4$	As, Cd, Pb, Sb, Se, Tl	Stabilized temp. platform furnance technique with ZE-AAS, NAA for As, Sb, Se	168
Twenty-two coals	Six closed autoclavable 25 mL polypropylene bottles (Cat. # 2006-0004) placed in a sealed plastic container; later centrifuged or filtered; P complexed; compared with the Australian standard method (dry oxidation procedure); safety discussed; two step dissolution	HCl HF then boric acid	P	UV-vis spectrophotometer	169

component and magnetron damage. This can be a problem and is a safey hazard when performing closed vessel dissolutions. Several metallic materials, especially iron-based alloys, spark when subjected to microwave energy. This sparking can ignite the hydrogen gas generated

from the dissolution of metals [270,176]. Fernando et al. recommend that dissolution vessels be sealed under an inert atmosphere to eliminate the presence of oxygen in the gas volume generated when digesting metals [176]. Matthes et al. were the first to use a microwave oven for the dissolution of metals [16]. Since then, several articles have been published outlining microwave dissolution procedures for metallic materials [16,17,20,21,24,170–178,189,190]. Table 8 summarizes these reports (see also Tables 1 and 9). Closed vessels were almost exclusively used to digest metallic materials [16,20,21,172,175–177] as opposed to open vessels which were used only once [173]. None of the closed vessels were equipped with any sort of pressure release mechanism, and safety was discussed in only two papers [174,176]. Comparisons of results were made with those obtained using conventional techniques [170,171,174–177].

2.9. Synthetic material samples

Microwave-assisted dissolution techniques show their versatility through their application to a variety of synthetic materials. Reports have been made concerning the dissolution of polymers [29], $(NH_4)_2SO_4$ [106] and $(NH_4)_2B_4O_7\cdot4H_2O$ [107], activated carbon [188] and other inorganic samples [184], inks [182], resins [188] and other organic materials [184], oils [137,146,160,179], wear metals in lubricating oils [190], carbon fibre–epoxy materials [180], automotive [181] and petroleum industry catalysts [192] and glass samples [191]. In addition, a number of patents have been issued concerning microwave techniques and devices for the dissolution of radioactive and medical wastes [183], ZnO-based samples [185], man-made wastes [186] and spent nuclear fuels [189]. Microwave techniques have also been used for moisture determinations of asphalt [187], plywoods and particleboards [108]. Table 9 summarizes these reports and lists the references (see also Tables 1, 3, 5 and 7). Microwave dissolution efficiencies were sometimes compared with conventional efficiencies in terms of elemental recoveries [106,107,137,146,182,192].

2.10. Mixed samples

Some articles describe research involving the microwave dissolution of more than one sample type. For this reason, these articles have been grouped together into a separate category—Table 10.

Geological [193,201], specifically diabase, oil shales and rocks [194], basalt [194,200], minerals [194,199], ores [194,198], refractory samples [199] and obsidian rock [200] have been digested. Dissoluton methods have been described involving biological samples [196,197,199,201], carbohydrates, proteins and lipids [193], oyster tissue and animal materials [194], bovine liver [194,200], lobster hepatopancreas [195] and marine tissue [202]. Botanical samples [193], orchard leaves [194], tomato leaves and pine needles [194,200], peat [195] and dry plant leaves [197] have been digested. Food samples [197], spinach and vegetable samples [194] and flour [203], and environmental samples such as sediments [194,200,202], soils [194,196], muds [195,203] and dusts [204] have been digested. Sludges [198,200] and coals/ashes [194,197,200,204] have been digested. Metallic materials [193] such as alloys [194], automobile shredder wastes [198], steels [201] and metals on filter media [204] as well as other synthetic materials such as glass [193], polymers like polypropylene [194,203], butyl rubber[194], polyethylene, and polyurethane [203], catalysts, industrial pipe deposits and scales [194], petroleum, heavy oil fertilizers and activated carbon [197], medical and toxic wates [198], gas [200], fibreglass and paper [203], air sampling filters, powdered lead-based, powdered and liquid paints and paint scrapings [204] have all been digested using microwave-assisted techniques.

3. Microwave-assisted sample drying

A common problem associated with the process of assaying in analytical laboratories is obtaining precise and reproducible methods of sample drying. Drying is defined as the removal

Table 8
Metallic samples

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Steel reference samples	Effects of temperature of digestion and Si level in samples are described; compared with conventional dissolution techniques		Si	AAS, ICP	170
Metal alloy samples (e.g. steel samples containing <0.5% W, Ti and Nb, or Cu)	Comparison of pressurized sample preparation devices (High pressure Asher and Pressurized Microwave Decomposition Device)	(1) HNO_3–HCl or (2) HNO_3–HCl–H_2SO_4–H_3PO_4	(1) Cr, Cu, Mn, Ni, P, S, V (2) Nb, Ti, W	ICP	171
NBS 899 (Tracealloy C); Ni-based superalloys (Ni–Cr–Al–Y)	Whirlpool (Model MW-8750) domestic oven; 12 closed 250 mL polycarbonate, flat bottomed centrifuge bottles with polypropylene screw caps placed inside a polycarbonate container; wind-up mechanical carousel	HNO_3, HCl, HF and mixtures of them, H_3BO_3	(2000 ppm). Al, Co, Cr, Hf, Mo, Ni, Ta, Ti, W	ICP-OES	172
Czechoslovakian, British and German ferrochromium and ferromanganese CRMs: CSAN 4-2-01, 4-2-02, 4-2-03, 4-2-04, 4-3-01, 4-3-02, BCS 203 2, 204 1, 208 1, 280; BAM ECRM 530-1, 533-1	Philips M 704 domestic oven; open PTFE beakers; found that only H_2SO_4 and H_3PO_4 were required for dissolution (including Si), and so HF is not needed	HNO_3, HCl, H_2SO_4, H_3PO_2, and various mixtures of them	Al, Co, Cr, Cu, Mo, Mn, Ni, Si, Ti, V	ICP-AES FAAS	173
Inorganic samples: e.g. Cr_3C_2–Ni–Cr and Ni alloy samples	CEM MDS 81D oven; closed PTFE 4782 Parr bombs with a pressure-indicating screw which protrudes from the cap; advantages and disadvantages are given; compared with other methods; diagram of bomb; safety precautions	Various acid mixtures depending on the sample type and or required elemental analysis	Various elements	Can be applied to various instrumentation	174
Tool steels, SKD 61 and 11, MBH 34C and 37B	Closed vessels; compared with hot plate method	HNO_3 HCl–HF	Various elements	ICP-AES	175
NBS SRM 365 electrolytic iron and 179 (steel with a nominal Si content of 3%); BCS 452 (a mild steel) and 317 (3.49% Si); Spex Hi Pure iron (for calibration blank)	Domestic Sears Kenmore oven; closed 60 mL Savillex Teflon™ vessels; use of a carousel; caution advised for metallic materials (should be present in an inert atmosphere to prevent ignition); compared with Parr bomb method	HNO_3 HCl–HF	As, Al, Cr, Cu, Mo, Mn, P, Ni, Si, Sn, Ti, V	DCP-ES	176
Twenty-four high-alloy steel CRMs: NBS 892, 890, 346, 168, 73B, 161, 343, 133A, 160B and 101F; BAM 228-1, 278-1, 328-1, CrNiSiMn1, 277-1 and CrMnMoNiTi1; IRSID 204-1; BCS 339, 211 1, 342, 340, 338 & 341; JK 8F	CEM commercial oven; closed Teflon™-PFA vessels; all steels completely dissolved except NBS 892 which required more HNO_3 and reheating under pressure in the oven followed by fuming on a hot plate with H_2SO_4–H_3PO_4; compared with two hot-plate fuming and a fusion procedure and dissolution with H_2SO_4 then H_2O_2 (hot plate)	HNO_3 HCl–HF	Cr	Titration with dichromite solution	177
BCS 346 (Ni-based alloy)	System found to have a detection limit of 1.3 ng		As	Continuous flow HG-AAS	178

of volatiles from a sample [207]. It should result in identical sample compositions despite differences in starting volatile content and sample history. Usually, the major volatile component required to be removed from a sample is water. Different sample types absorb varying amounts of water and therefore must be dried to an equilibrium weight. When a plot of weight loss versus time reaches a plateau, equilibrium weight has been achieved. Many samples are hygroscopic and must be kept in a moisture-free environment after drying, such as that provided by a desiccator. Variation in water content is one of the most common sources of non-reproducible sample weights. This can result in lower assay precision and accuracy, and possibly give biased analytical data. In order to eliminate, or at least minimize the problem, samples are usually dried before weighing. Classical or conventional methods of drying include the use of convection ovens, vacuum ovens and desiccators. All three methods are effective and can result in samples with reproducible composition. However, some samples may contain different temperature-dependent volatile components or degrees of hydration. This can lead to varying equilibrium weights and should be of concern to the analyst. Generally, the least aggressive method yielding reproducible and stable sample composition is the recommended pretreatment. The least aggressive method minimizes the risk of chemical alteration of the sample.

Microwave-assisted drying provides a rapid and simple alternative to conventional methods of drying. Specialty microwave ovens are now commerically available for this purpose [331–333,335,339]. Since solvent molecules are directly heated by the microwave radiation, they can be volatilized without heating the container they are in. This reduces the cooling time required in a desiccator before accurate weight measurements can be made. (Heat from sample containers can cause inaccurate and fluctuating balance readings due to rising warm air). In concert with drying samples, moisture determinations can be made. Table 11 summarizes the use of microwave methods for

the drying of a variety of sample types [205–212].

4. Continuous flow digestion systems and on-line applications

The microwave-assisted pressure dissolutions described in previous sections of this review have been essentially batch processes, with separate digestions for each sample. Several continuous flow systems have been described [213–224,340], and some are now available as commerical packages [331–334,337]. The development of these flow-through and stopped-flow (or "discrete-flow" [331]) microwave pressure dissolution systems which may be connected to flow-injection manifolds for a variety of instruments is a further step towards total automation. These systems are of particular interest in the determination of toxic and volatile elements such as mercury. Table 12 contains summaries of these on-line systems. They generally involve the introduction of the sample in the form of a slurry via an autosampler. Slurries are usually made by the pretreatment of samples with an appropriate acid or acid mixture while being stirred in an open vessel. The slurry is then aspirated into the closed system by a peristaltic pump to the microwave oven. The slurry is digested as it passes through a coil made out of a microwave-transparent material located inside the oven's cavity. After the pressure dissolution stage, some sytems have incorporated filters, cooling steps and gas trap chambers to condense and to remove gas vapors generated from the dissolution step. Finally, the digestate may be injected into a carrier stream via an injection valve where it is carried to the appropriate instrument for analysis, or collected in an autosampler tray. These systems have great potential for handling situations with a high throughput of relatively easy-to-treat samples, but operators should be prepared for breakdowns and malfunctions—even the commerical models are only just out of the development stage. Within a few years,

Table 9
Synthetic materials

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Cold rolling oil (of emulsion type used in mills during manufacture of steel and stainless steel sheets — usually called "coolant")	Open 200 mL beakers; samples (coolant) were digested using one of several organic acids whereby the surfactants are not destroyed but the Fe fines are dissolved; all organic acids successful except succinic acid	NaOH, oxalic acid, maleic acid, citric acid, DL-malic acid, succinic acid, CCl_4 or $HCCl_3$	Determination of non-ionic surfactants (82–98% recovery)	HPLC	179
Ciba-Geigy T800/924, T800/922 and T800/914 carbon fibre–epoxy materials	Domestic oven; closed Parr 4782 bombs; determination of fibre volume fraction (volume of resin holding fibres together)	HNO_3			180
Monolithic ceramic automotive catalysts	CEM MDS-81D oven; closed 120 mL PFA-Teflon™ vessels with pressure release valves (120 psi)	HCl–HF, or HNO_3–HCl–HF, then $HClO_4$ on a hot plate or H_3BO_3	Ba, Ca, Ce, Fe, La, Mn, Ni, P, Pb, Pd, Pt, Rh, S, Zn	ICP-MS, WD-XRF	181
Inks: polyamide, nitrocellulose and aqueous acrylic-based ink samples, packaging inks	CEM MDS-81D or a Floyd RMS-15 OPCM oven; closed 120 mL PFA-Teflon™ vessels (CEM); compared with open vessel hot plate method	HNO_3	Ag, As, Ba, Cd, Co, Cr, Cu, Hg, Ni, Pb, Sb, Se, Sr	ICP-AES, CV-AAS, GF-AAS, PIXE, NAA	182
Radioactive waste liquids and medical diagnostic wastes (e.g. containing ^{125}I)	PATENT: a microwave oven connected to a microwave source via a waveguide tube and an insulator; used for concentrating waste materials				183
Inorganic and organic materials	Closed vessels with an excess pressure security system for dissolving materials with volatile components; written in German, only the summary is translated	HCl, HF, HNO_3, KOH			184
ZnO-based samples	PATENT: closed vessels; analysis of ZnO-based devices	HF–HCL or HF–HNO_3			185
Man-made wastes	PATENT: open vessels; recovery of Hg from crushed wastes (such as Hg battery); heated by microwaves to 100–700°, then gas carried off by flowing air and collected in a condenser at −5°C	None	Hg		186
Hot-mix asphalt concentrate	Use of 12.4–18.0 GHz sweep of radiation to detect moisture by measurement of dielectric constant and the loss factor	None	Moisture		187
Activated C and resin	Teflon™ bottles	Acid mixtures	Au, Ag and base metals	ICP-AES and others	188
Spent nuclear fuel	PATENT: a device consisting of a microwave heater under a barrel containing a sample basket which is connected via a pipe to a solvent dispenser, for the dissolution of spent nuclear fuel				189

Glass samples		$HF-HNO_3-HCl$ then B_3BO_3	Non-radioactive elements	ICP-AES, AAS	191
Three types of heterogeneous petroleum industry catalysts (Ketjen, Catal and Laterite)	Domestic Balay Bahm-100 oven, closed 125 mL vessels; compared with conventional techniques	HNO_3-isoamyl alcohol then H_3PO_4, also aqua regia	Co, Fe, Mo, Ni	FAAS, XRF	192

reliability problems should have been dealt with, and the instruments should be adaptable to the more rigorous digestion conditions required for difficult samples.

5. Solvent extraction and desorption systems

Several conventional techniques are available for the extraction and/or desorption of analytes from particulate matter. Although these techniques are widely accepted, each has inherent limitations and problems. Solvent extraction methods, such as Soxhlet extraction, tend to be inefficient and can lead to the generation of chemical artifacts due to the harsh sample treatment. The shake flask method is tedious and is also inefficient in that it is primarily superficial in function and requires several large amounts of solvent(s). Thermal desorption procedures are superficial in function as well since they make use of infrared radiation (IR) to heat a sample. This frequency of radiation is considered to be surface heating radiation since it only penetrates matter to a depth of less than one micron. Particles become non-uniformly heated through this mechanism since the interiors can only be heated by conduction. Another problem is that chemical artifact generation is possible using IR since energies lie in the range of 0.3 to 30 kcal mol^{-1}, which lies very close to the 30 to 225 kcal mol^{-1} energy range required for bond dissociation (microwave radiation at 2.45 GHz has an energy of about 0.23 cal mol^{-1}).

Microwave extractions are proving to be efficient and are even suitable for the extraction of labile components from various complex matrices. Particles are heated uniformly by microwaves since they are able to penetrate them to a depth of several thousand microns. Also, the degradative effects of high temperatures can be avoided by adjusting power levels, exposure times and number of repeats of irradiation. It has been demonstrated that the high temperatures which can be generated using microwave energy are not required in order to facilitate rapid desorption from matrices [238].

Table 13 summarizes microwave extraction and desorption techniques [229–242]. Patents have been issued for an extraction system which may be automated [239] and for a microwave vacuum oven which can quickly extract volatiles without causing overheating [241]. Microwave extraction/desorption techniques have also been compared to steam distillation [232–234], Soxhlet [235,237,238,242], chloroform fumigation [236], reflux [237,240], polytron [237] and shake flask methods [238].

6. Microwave Kjeldahl systems

Distillation has been used to separate volatile chemical components since about AD 100 when the method was used to separate ethanol for the production of brandy [243]. The technique is still widely used today in a variety of industries and for a range of separations. Whereas conven-

Mud, flour, fibreglass, paper, polyethylene, polypropylene and polyurethane	Features, advantages and applications of a microwave oven for dissolutions; compared with conventional methods				203
SRMs: 1633a coal fly ash and 1579 powdered lead-based paint; NIST SRM 2676b metals on filter media; air sampling filters, dusts and ashes, paint scrapings, powdered and liquid paints (cellulose and isophthalic acid polyester-based industrial), mixed metal dust/ash internal QC sample	CEM Model MDS 81D microwave digestion system; closed vessels; method does not decompose the polymers in paints allowing for their removal, thus reducing possible matrix effects	HF–aqua regia, HNO_3 for paints	Ag, Al, As, B, Ba, Be, Ca, Cd, Co, Cr, Cu, Fe, Mg, Mn, Mo, Ni, P, Pb, Sb, S, Sn, Ti, V, W, Zn	ICP-AES, NAA	204

tional distillation techniques rely on conduction for heating, microwave heating results from direct interaction of the energy with the sample. This allows energy transfer to the entire sample as opposed to this taking place via convection currents as with conductive heating. This advantage makes microwave heating an excellent candidate for replacing distillations and reflux procedures limited by long heating periods. For example, a major limitation of Kjeldahl procedures is the extended period of digestion needed for complete nitrogen recovery—this is commonly from 3–6 h. Microwave heating can re-

duce this time to a matter of several minutes since the sulfuric acid used in the Kjeldahl method is a strong microwave absorber. Microwave heating can raise a Kjeldahl digestion mixture to 360°C in 2 min and to 400°C in 4 min, compared to the same temperatures in 15 and 45 min respectively, using a block digestor [270]. Once the optimum temperature is attained, the microwave power can be stopped, ending heating and stopping the temperature from rising due to the absence of an external hot mass. Research has shown that microwave Kjeldahl digestions can be as much as 20 times

Table 11
Microwave-assisted drying of various sample types

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Rice leaves	DRYING: Sharp R-4K53 commercial oven: comparison of classical methods with microwave oven techniques for determination of dry weight and N concentration	None	None		205
Water samples	DRYING: open vessels; drying of water samples: compared to the standard method	None	Total solids		206
Non-fat milk powder (SRM 1549), bituminous coal (SRM 1632b), clays, copper ore, wheat flour (SRM 1567a), rice flour (SRM 1568a), buffalo river sediment (SRM 2704), $Na_2HPO_4·7H_2O$ and $CuSO_4·5H_2O$ (for loss of hydrated water)	DRYING: CEM AVC-80 drying oven equipped with a top loading electronic balance stem and a pan protruding through the oven cavity floor; a Thermopad if needed: compared with conventional oven and thermal drying techniques	None	Moisture	Electronic balance	207
Treated and untreated wastewaters, mixed liquor suspended solids, recycle solids and primary, thickened and dewatered sludges	DRYING: household microwave oven used to dry the samples: open vessels; comparable to conventional oven technique		Determination of suspended and total solids		208
Various wastewater treatment sludges	DRYING: open vessels; drying of samples; comparable to conventional oven technique: decreases drying time by 96%		Determination of suspended and total solids		209
Precipitates: $AgCl_2$, $BaSO_4$ and $CaC_2O_4·H_2O$	DRYING: open crucibles for thermogravimetric determinations; Mettler AE200 analytical balance: water molecules directly heated leaving the crucible relatively cool: allows for faster weighing: compared with conventional drying; water of hydration of the oxalate is not lost		Drying of precipitates	Mettler AE200 analytical balance	210
$BaSO_4$ precipitate	DRYING: open sintered glass filter crucible: compared with a traditional technique		Drying of precipitates	Analytical balance	211
Various samples of different geometry and size	DRYING: measurements of moisture profiles compared with convective drying; several methods for determining local moisture profiles are presented and discussed	None	Moisture profiles		212

faster and yet show comparable accuracy and precision to that of a conventional digestion.

Table 14 summarizes microwave Kjeldahl methods for the determination of total nitrogen content [243–251]. Alvarado et al. used a domestic microwave oven and a commerical laboratory Kjeldahl apparatus and compared the results obtained from both [249]. All other researchers used specialty microwave Kjeldahl systems. Comparisons were made with conventional techniques in terms of recoveries and time required [243 247,249,250]. Two patents have been issued for microwave Kjeldahl apparatuses [245,251].

7. Databases and software packages

A wide range of different microwave-assisted dissolution protocols have been developed to treat the enormous variety of samples requiring dissolution prior to chemical analysis. Many of these methods are becoming standardized and are replacing some of the conventional standard methods. Currently, the development, testing and certification of new standard methods is slowed down by the lack of skilled manpower to perform these tasks, so there is a delay in making this new technology readily available to all potential users. As the number of methods increases, so does the task of making these methods available to analysts. To help remedy this situation, new standard methods are now being encapsulated in database formats capable of electronic inter-laboratory transfer. As well, software has been developed to create, format and transfer protocols for microwave-assisted dissolutions.

With ready access to a database of validated methods, an analyst may be able to find an appropriate dissolution method by entering relevant information about the sample, analyte(s), instrumentation etc. (i.e. analytical descriptors). Once a method has been selected by the software, which best matches the analytical descriptors, the database can yield not only details of the required procedure, but also other imporant

information such as safety advice and recommendations based on research experience. Systems like these have the capability of "learning" additional procedures as other new and successful methods are developed.

Table 15 summarizes four published software systems for microwave dissolution databases [225–228]. Of special interest, Walter et al. discuss a database/software system capable of retrieving dissolution parameters and controlling sample preparation and dissolution through automation [227]. Feinberg et al. have prepared a database of nearly 780 different outlines of microwave dissolution procedures [228].

8. Reviews

Numerous reviews have been published these are summarized in Table 16 [252–282]. These reviews discuss microwave techniques, equipment, applications, theoretical microwave principles and mechanisms, various dissolutions, drying and moisture determinations, history, advantages, safety guidelines, economy, automation and robotics, sample preparation characteristics, prediction of dissolution parameters and data handling.

9. General reports

A number of general reports have been published. These are summarized in Table 17 [283–294]. These papers are more specific and focused than the reviews. One report compared microwave bomb methods with EPA method 3050 [284] and another described a specialty microwave digestion system (Q Wave-1000). New areas of microwave technology application were discussed in another report [293]. One publication discusses non-microwave-assisted methods of acid pressure decompositions, but was included in this review [294] since much of the information presented is relevant to microwave pressure dissolutions, such as advantages, problems, PTFE vessel material characteristics and decomposition efficiencies.

Table 12
Continuous-flow digestions and on-line applications

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Whole blood	FLOW-INJECTION: modified Panasonic (Model NE-7660 6660) domestic oven with a coiled Pyrex tube is used for dissolutions; peristaltic pump; Solvaflex tubing	Triton X-100 (anti-clogging agent), HNO_3, HCl	Cu, Fe, Zn	AAS	213
Biological	FLOW-INJECTION: a review with 41 references about the use of microwave ovens for the decomposition of biological samples and its combination with flow-injection AAS			FI-AAS	214
Solid samples such as a slurry, e.g. sewage sludge, CRM 144 and 146	ON-LINE DIGESTION: closed flow-injection analysis system; slurries passed through a PTFE coil located in a domestic Balay Bahm 100 microwave oven for digestion, then injected into a carrier stream and transported to an AAS flame using a peristaltic pump; 12 samples h	HNO_3	Pb	FAAS	215
Sewage sludge, two ECB reference samples	Direct introduction of slurries from batch digestions using a single-channel manifold; influence of flow-injection parameters on the sensitivity and accuracy of the procedure was established		Cu, Mn, Pb	FI-AAS	216
Hg compounds used to determine Hg recovery, lake, river and rain water, urine samples: (Lanonorm metals 1 and 2, control urine for metals, lyphochek urine metals level II, seronorm trace elements urine and toxic metals in freeze-dried urine - NIST SRM 2670)	ON-LINE SAMPLE PRE-TREATMENT: flow-injection system; Prolabo Maxidigest MX 350 oven with a TX 31 Maxidigest programmer; focused microwave digestor; PTFE reaction coil; peristaltic pump; filters; antifoaming agents for urine analysis; CEM MDS-81D oven for off-line digestions	HCl, $KBrO_3$, $NaBH_4$, KBr, $K_2S_2O_8$, $KMnO_4$, H_2SO_4, HNO_3, $K_2Cr_2O_7$, NaOH	Hg	AAS, HG-AAS, FI-CV-AAS compatible for Hg	217
Biological and environmental samples	ON-LINE SAMPLE PRE-TREATMENT: flow-injection system; Prolabo Maxidigest MX 350 oven; focused microwave digestor; PTFE reaction coil; peristaltic pump	HCl, $KBrO_3$, $NaBH_4$, KBr, $(NH_4)_2S_2O_8$, HNO_3, CH_3COOH, H_2SO_4, NaOH	As, Bi, Hg, Pb, Sb, Se, Sn, Te	HG-AAS, CV-AAS, AAS	218
Urine and environmental waters	ON-LINE DIGESTION: for flow-injection manifold; testing for the determination of the most successful oxidation mixtures; optimization of chemical reagents and analytical conditions; 13 30 samples h	$K_2S_2O_8$, NaOH, KBr, HCl, $KBrO_3$, $(NH_4)_2S_2O_8$, HNO_3, CH_3COOH, H_2SO_4, Tartaric acid	As, Bi, Hg, Pb, Sn	CV-AAS, HG-AAS	219

Table 12 (continued)
Continuous-flow digestions and on-line applications

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Bovine whole blood, human whole blood and concentrated blood, recoveries of five Hg compounds	ON-LINE: Prolabo Maxidigest MX 350 oven with a TX3 1 Maxidigest programmer; focused microwave digestor; 10 m × 0.9 mm long PFA digestion coil knitted around a PTFE backbone tube, then coiled again to be water cooled; system maintenance discussed; compared with off-line autoclave digestion using open PTFE vessels, various reagents added at different stages of the system	Triton X-100, $NaBH_4$, NaOH, HCl, Dow Corning DB 110A: Si anti foaming agent, KBr, $KBrO_3$, $KMnO_4$, HNO_3, $HClO_4$, $K_2S_2O_8$	Hg	FI-CV-AAS	220
Artichoke, dietary products, sewage sludge, certified tomato leaves and sewage sludge samples	ON-LINE DIGESTION: Balay Bahm 100 domestic oven; using 100 cm of 0.8 mm Teflon™ digestion coil; peristaltic pump for sample transport; ice water cooling bath then injection into an AAS	HNO_3 H_2O_2	Cu, Mn	AAS	221
	FLOW-INJECTION: a patent for an apparatus including a continuous-flow digestion system				222
Bovine liver (SRM 1577), orchard leaves (SRM 1571), other botanical standards (e.g. MOE V85-1)	STOPPED-FLOW DIGESTION SYSTEM: slightly modified domestic Toshiba (model EXP-1690C) oven; Teflon™–PFA tube serves as a sample container and a digestion vessel; closed-vessel approach minimizes the risk of sample cross contamination; compared with hot-plate digestion method	HCl, HNO_3 or aqua regia or HNO_3-H_2O_2	Al, Ba, Cd, Cu, Fe, Mg, Mn, Zn	ICP-OES	223
CRMs: mussel, chlorella, sargasso, pepperbrush, bovine liver (SRM 1577a)	Continuous-flow microwave digestion on-line with AAS; samples introduced as slurries with 5% HNO_3; comparison of flow-injection with direct determination results—no loss in sensitivity	HNO_3	Fe, Ca, Mg, Zn	AAS	340
Horse kidney reference material, bituminous coal (NIST 1632b), Hershey's cocoa powder, pine needles (SRM 1575), bovine liver (SRM 1577a), oyster tissue (SRM 1577a)	ON-LINE SAMPLE PRE-TREATMENT: stopped-flow-injection system; CEM MDS-81 oven; glass reaction vessel inside microwave cavity attached to PTFE tubing; pressure transducer, compared with microwave and hot-plate-ash methods; certain degree of maintenance required	Triton X-100 HNO_3	Fe, Ca, Cd, Mg, Zn	FAAS, ICP-AES	224

10. Automation and robotics

The simplicity and efficacy of microwave dissolution techniques easily lends itself to the ad-vantages of automation and robotics. Systems have been developed which are capable of weighing-out samples, adding acids, capping and uncapping vessels, carrying out microwave disso-

Table 13
Microwave extraction and desorption systems

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Lean lateritic Ni ores leached with H_2SO_4	EXTRACTION: separation extraction process for immiscible liquids; gravity separation of mixed liquids is accelerated by microwave irradiation by heating over 10°C in 15–20 s; compared with conventional gravity separation; suitable for Ni extraction from ores leached with H_2SO_4	H_2SO_4, alamine (C_{8-14} primary alkyl amine) 20, isodecanol 10 and kerosine 70. vol.%.	Ni		229
	EXTRACTION: design, operational safety and applicatons of a microwave digester system with rotor technology; pressure extraction (yields of 99% for pesticides), accuracy and recovery rates presented	Solvents	Various elements, pesticides		230
Hedera helix L. leaves	EXTRACTION METHOD: National Panasonic (Model NE 1330) domestic oven; all but the summary written in French	MeOH	Hedera-saponin C and alpha-hederin	HPLC	231
Lippia sidoides leaves	EXTRACTION: essential oil extracted by a current of air as sample heated for 5 min was identical when compared to steam distillation		Essential oils		232
Lemon	EXTRACTION: of aroma compounds compared to steam distillation		Aroma compounds	GC	233
Plant	EXTRACTION: of essential oils (1 min) compared to steam distillation (2 h)		Essential oils		234
Plants: raw and processed broad bean, cottonseed meal	EXTRACTION: of antinutritive compounds compared to the Soxhlet extraction technique; microwave extraction found to be more effective with respect to yields and protection of compounds; method suitable for the rapid extraction of large sample series		Various anti-nutritive compounds: (pyrimidine-glu-cosides and gossypol)		235
Soils, sand, silt and clay	EXTRACTION: domestic Sharp (Model R-6740) oven; for C and N, microwave biocide potential compared with chloroform fumigation method; microwave method not as effective as $CHCl_3$ fumigation for microbial biomass estimates in soils due to inactivation of enzymes normally active during the 24 h of fumigation	Water	C, N	Extraction with 0.5 M K_2SO_4 and ninhydrin method for N, oxidation diffusion for C	236

Table 13 (continued)
Microwave extraction and desorption systems

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Sediments	EXTRACTION: domestic Kenmore (Model 85962) oven; extraction of pesticides using open 5 mL Reacti-Vials; microwave extraction (30 s × 5 repeats) compared with other conventional techniques such as Sohxlet (8 h of Soxhlet extraction), polytron and reflux—better recoveries; evaluation of sediment moisture, microwave effects, extraction time and solvent, pesticide concentration and type	Various solvents and solvent mixtures	Pesicides	GC	237
Yeast, lupine, maize, soya bean, baby food, walnut, meat flour, Fava bean, cottonseed and soils	EXTRACTION: domestic Toshiba ER 638 ETD type oven; closed screw-cap vials; compared with Soxhlet and shake-flask method; almost 100 times faster than traditional methods; more efficient than Soxhlet extraction for polar compounds with water-containing solvents; recoveries of non-polar compounds were only slightly less with a non-polar water-free solvent; higher recoveries for sensitive molecules due to lower temperatures and shorter extraction times	MeOH H$_2$O. or methanol or hexane	Crude fat. vicine, convicine, gossypol, pesticides	HPLC, chrom- atographic column	238
Food	EXTRACTION: a patent for an analytical apparatus for drying of a preweighed sample, reweighing to determine volatile loss, followed by solvent extraction, and final measurement of residual solids, may be automated		Fats, oils . . .		239
Aromatized products: candies, chewing gum, coffee	EXTRACTION: of aromatic fraction (essential oils); compared with conventional methods such as refluxing, simultaneous distillation solvent extraction, hydrodistillation		Aromatics	GC- MS	240

lutions, diluting digestates, transferring vessels, and even cleaning and reusing the vessels. Once such a system is operational, the only things the analyst has to do is supply and place the representative sample(s) in locations recognized by the system and then initiate the controlling pro-

Table 13 (continued)

Various samples	EXTRACTION: a patent for a microwave vacuum oven; quickly removes volatile material from samples without overheating them; oven has a vacuum chamber for receiving samples in a closed vessel and a vacuum source for expelling volatiles; object is to accelerate removal of volatiles, eliminate weight determinations and reduce problems from overheating	None	Determination of volatile material content		241
Organic compounds, coconut charcoal	DESORPTION: use of a microwave desorption apparatus for releasing compounds from the surface of particulate matter collected on a filter; low MW species recovery more efficient than the Soxhlet extraction; > 130 Watts required to desorb high MW compounds; microwave basics; both polar and non-polar species may be desorbed	Cyclo-hexane, water, standards containing polycyclic aromatic hydro-carbons, pesticides and PCBs in acetone	Isolation of chemical components	GC-MS	242

gram. Automation and robotics not only work around the clock they also free analysts of often tedious and potentially dangerous work, allowing them to perform other, more intellectually challenging tasks. Table 18 summarizes primarily the application and functioning of these systems. One of these automated systems has been patented [298].

11. Other relevant articles

The few articles remaining are quite specific and do not readily fit into any of the other categories. They include a discussion of a vessel cooling technique [303], special equipment [304], microwave oven modifications [305], fundamental relationships and prediction methods [306], safety [307], temperature control [308],

temperature measurement [309] and super-heating effects [310]. These are summarized in Table 19.

12. General considerations

12.1. Safety

Great care should be taken when using the pressure-digestion methods outlined above. This is particularly true when new protocols are being developed. Many of the references given describe methods in which oxidizing and reducing agents which react to form gaseous products are heated together in sealed vessels. There are few reports of accidents in the literature, but most of those involved in development work have encountered explosions.

Table 14
Microwave Kjeldahl systems

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Limonene (Citrus oil)	KJELDAHL METHOD: open 1 L Pyrex boiling flask for distillation connected to a collection apparatus outside oven; compared with steam distillation	$CuSO_4-H_2SO_4-K_2SO_4$, then $(NH_4)_2SO_4$	Total N	Modified Kjeldahl method	243
Seven soils, wheat leaf, corn grain, rice straw	KJELDAHL METHOD: CEM MDS-81D oven; (1) closed Teflon™-PFA vessels; and; (2) 50 mL Kimax or Pyrex Erlenmeyer flasks for microwave Kjeldahl method; compared with conventional method	(1) HCl, HF, H_3BO_4 (2) H_2SO_4, K_2SO_4	Total N	Modified Kjeldahl method	244
Succinimide oil C 5935	KJELDAHL METHOD: a patent; a receiver with retention capacity extended by a cylindrical neck and a microwave cavity whose height is almost the same as the receiver; new microwave oven compared with using an IR and conventional microwave ovens	H_2SO_4–Kjeldahl catalyst	Total N in 1 h	Modified Kjeldahl method	245
Food: milk, wheat flour, powdered egg, casein, meat and grass hay	KJELDAHL METHOD: collaborative study involving 11 labs. as an alternative Kjeldahl method	$H_2SO_4-H_2O_2$ and no catalyst	N	Modified Kjeldahl method	246
Eight A1 horizons of italian soils	KJELDAHL METHOD: CEM MDS-81D oven; closed Teflon™ vessels; compared with three other conventional methods	$HF-HCl$, then H_3BO_3, then H_2O_2	Total N	Micro-Kjeldahl apparatus	247
Food	KJELDAHL METHOD: Maxidigest MX-350 focused microwave digester; a prototype application of an expert system for a fully automated, open vessel, focused microwave digestion system; based on selection of reagents, reagent volume, digestion time, average power and analytical method	Reagents are provided by the expert system based on the input of analysis criteria	Strictly adapted to the Kjeldahl N determination in food samples	KJELTEC 1026 (PERSTORP)	248
Amino acids: Val. Ser, Leu, Phe, Tyr, Trp, Cys, cassaba and gamelte leaves, fractional corn germ, ocumo, white broad beans, precooked corn flour, milk powder and whey, squid and octopus flour, canned ham	KJELDAHL METHOD: National Panasonic (Model NE-6660) domestic oven; closed 200 mL thick-walled Pyrex glass test tubes fitted with polypropylene screw caps on a Petri dish inside a sealed 2 L plastic jar; Labconco micro-Kjeldahl apparatus, Model 60/300 coupled to a Pregel-Parnas-Wagner distillation unit, Model 7051-G10	H_2SO_4 K_2SO_4 HgO	Total N	Kjeldahl method	249

Table 14 (continued)
Microwave Kjeldahl systems

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Meat	KJELDAHL METHOD: Prolabo Maxidigest oven; three-step 11 minute digestion program; 19 minute digest for tryptophan; compared with conventional hot-plate method using Cu as a catalyst		Total N	Kjeldahl method	250
Organic samples	KJELDAHL METHOD: a patent for a microwave-based apparatus; reactive vessel extends via a hollow tubular body outside the oven; air cooled; scrubber for digestion gas evolution removal		Total N	Modified Kjeldahl method	251

Oven modifications should be carried out with caution, since leaked microwave radiation poses a health hazard. An excellent summary of this aspect is given by Kingston and Jassie [270].

12.2. Economy and efficiency

The conversion of electrical energy into microwave energy by a magnetron is an inefficient process [263]. However, since a microwave oven heats internally yet does not become heated itself, and may not heat the vessel containing the sample, microwave ovens are more economical than conventional electric ovens for some applications [263,317,318].

12.3. Superheating

The effect of pressure on the boiling point of a solvent is well known and widely understood, but it has recently been reported that many organic solvents, when heated in a microwave oven at atmospheric pressure, may boil at temperatures 13–26°C above their normal boiling points [327]. The explanation for this probably lies in the fact that conventional boiling occurs via heat transfer from the walls of a vessel, where there are large numbers of nucleation sites. In microwave heating however, heat transfer takes place far from the walls, where the number of nucleation sites around which bubbles may readily form is very limited, leading to superheating effects.

12.4. Specific "microwave" or athermal effects

A few reports have appeared which suggest that, in certain instances, reactions carried out by microwave heating give different products from those carried out by conventional heating [328, 329]. This question is of great concern to the food industry, in view of the widespread use of domestic microwave ovens, and so Unilever and Nestlé sponsored a special meeting on this issue during the summer of 1993, in Switzerland [338]. It was generally agreed that all the anomalous results reported could be explained on the basis of localized superheating effects at different hotspots in the reaction mixtures, and that there were no athermal effects. This conclusion is not surprising in view of the energy considerations. Microwave radiation is of low energy, about 1 J mol^{-1} of photons. When this is compared to bond energies (H-bonds approxi-

Reviews covering microwave applications

Sample types	Review details	Ref.
Various sample types	REVIEW: 69 references covering the application of microwave techniques in analytical chemistry with respect to sample dissolution, moisture determination, AES and chromatography	252
Various sample types	REVIEW: 37 references dealing with application of microwave ovens for drying, dissolution of samples, acceleration of reactions and preparation of new materials in the laboratory	253
Various sample types	REVIEW: 54 references dealing with applications of microwaves and their application for sample dissolution	254
Various sample types	REVIEW: Eight-references covering the history and applications of microwave heating for acid digestion of samples; commercial application	255
Various sample types	REVIEW: 40 references concerning the applications of microwave heating for dissolution and decomposition of organic and inorganic materials for elemental and isotopic analysis; principles, advantages and instrumental equipment discussed	256
Various sample types	REVIEW: 38 references dealing with the techniques of microwave heating and their uses covering four sections: mechanism of sample decomposition, general applications, areas of attention and conclusion	257
Various sample types	REVIEW: 19 references covering the theoretical concepts, equipment and their applications in microwave heating for acid dissolution, two mechanisms discussed: ionic conduction and dipole rotation	258
Various sample types	REVIEW: 17 references concerned with the working principle, equipment and applications of microwave digestion	259
Various sample types	REVIEW: without references discussing the advantages of high-pressure degradation compared with conventional high-pressure methods; requirements for vessel materials employed	260
Various sample types	REVIEW: 14 references covering theory, instruments (AAS and ICP-AES), applications, methods and advantages of microwave digestion extraction technique	261
Various sample types: plant leaves, nickel alloy, silicate material, coal flyash, organics, geological (Fe ore, dolomite), copper nickel ore, wool, aluminum, bronze	REVIEW: 28 references giving options for the use of domestic microwave ovens and PTFE vessels for sample dissolution; various lab. practices and examples of successful dissolution recipes; safety; vessel and microwave oven limits and specifications; Kjeldahl determinations	262
Inorganic materials	REVIEW: 36 references concerning densifying and strengthening ceramic components; economy of using microwave ovens; dielectric measurements; rates of heating; equipment; reaction kinetic enhancement	263
Blood, ores, food, cement, quartz, silicate fibres	REVIEW: six references covering the principles of microwave energy and instrumentations and advantages of microwave decomposition	264
Animal, plant, ore and alloy samples	REVIEW: 25 references outlining the characteristics of microwave heating; acids and vessels used	265
Samples with complex biological matrices	REVIEW: ten references describing microwave-assisted high-temperature and pressure wet ashing systems for sample preparation of complex biological matrices; automated control of pressure and temperature	266
Many sample types	REVIEW: 72 references relating to the digestion mechanism; open and closed vessel systems; efficiency; commercial microwave digestion systems; applications	267
Biological, food, plant, blood, geological, soil, sediment, environmental materials, waste water, sewage sludge, coal, oil, metallic materials, fly ashes and other samples	REVIEW: 181 references covering the applications of microwave dissolution	268

Table 16 (continued)
Reviews covering microwave applications

Sample types	Review details	Ref.
Various samples	REVIEW: 51 references discussing the characteristics of sample preparation, factors affecting microwave absorption, equipment and uses for the technique	269
Geological (phosphate rock, tin ore, sulfide ore, Au ore, Ni an Cu ores, feeds, concentrates and tails, Pb or Ag fire assay beads and chromite), metallic, botanical, biological (blood), pharmaceutical (vitamins, aztreonam), metallurgical (NBS 121C steel, Cu slag, superalloys, NBS 127 Pb–Sn solder and TiO_2); and food samples	REVIEW: a book covering dissolution methods, monitoring and prediction of digestion parameters, guidelines for developing dissolution methods, Kjeldahl N determination, manual and remote operation of microwave systems, remote operation for dissolutions in highly radioactive environments, robotic systems and safey guidelines, theoretical concepts of microwave heating and equipment design; flow-injection-ICP	270
Organic and geological	REVIEW: 39 references outlining microwave oven systems and dissolution techniques	271
Metal contaminated soils	REVIEW: 50 references covering the benefits, ovens, soil digestion methods, organic bound metals and engineering applications	272
Food and feeds	REVIEW: no listed references discussing the interest in microwaves for rapid analysis of agrofood products and preparation for analysis	273
Food	REVIEW: no listed references discussing the interest in microwaves for mineralization of food products; discussion of recently developed automated systems	274
Paper	REVIEW: two references describing the advances in paper moisture measurement by microwave loss	275
Biological, geological, and other samples	REVIEW: 21 references covering the working principle of microwave sample dissolution; applications to sample dissolution	276
Minerals, rocks, ceramics and other related materials	REVIEW: direct heating of minerals showing how they heat; explanation as to why based on the mineral's chemical composition and physical properties	277
Samples amenable to ICP-AES analysis	REVIEW: ten references concerning advances in plasma emission transport processes (for ICP-AES) with an emphasis on direct injection nebulization techniques	278
	REVIEW: without references discussing the advantages of using microwaves during the high-pressure degradation for trace analysis; compared to conventional high-pressure methods; special requirements and materials employed; MWS 1200 system described	279
Soil and plant material	REVIEW: 11 references; development and application of new equipment for sample preparation, robotics, instrument control and data handling, for soil testing and plant analysis	280
MACSP: two sediments, three biological tissues and three seawater CRMs	REVIEW: 21 references; an overview of the Marine Analytical Chemical Standards Program (MACSP) including rapid dissolution techniques using microwave heating	281
	REVIEW: 14 references concerned with the theory, instruments, applications, methods and advantages of microwave techniques for dissolution	282

mately 20 kJ mol⁻¹, the C–H bond energy about 350 kJ mol⁻¹), it seems unlikely that microwave energy could preferentially rupture any chemical bonds.

12.5. Radioisotope studies—microwave syntheses of radioactively labelled compounds for tracer studies in medicine

The isotope of carbon, ¹¹C, which is a positron emitter, has a half-life of just 20 min. This means that if ¹¹C-labelled compounds are used in PET studies, at the end of the testing period, residual radiation will quickly decay, reducing the risk of radiation damage to the patient. But, as the half-life is so short, speedy synthesis of labelled compounds is essential. This is an area where microwave synetheses can be used very effectively [330].

12.6. Lined reaction vessels

The latest reaction vessels available for digestions or syntheses incorporate a Teflon™–PFA liner, cover and rupture membrane enclosed in a casing and cap of Ultem™–polyetherimide. These are safe at pressures of up to 200 psig (1380 kPa) and temperatures up to 250°C. Special vessels that can operate at up to 600 psig (4140 kPa), or even 1600 psig (11 040 kPa) are also available. The vessels are also available fitted with ports to accommodate temperature and pressure probes [331–335].

12.7. Temperature probes

Temperature is a crucial factor in all chemical reactions and digestions, but some difficulties arise if conventional thermocouples are used in the reaction mixture inside the microwave cavity—the microwave radiation may interact directly with the probe. This problem has been resolved by the use of fibre optic probes. Several types are used, depending on the manufacturer [331–334].

12.8. Digestion systems with both temperature and pressure monitors and settings

Four systems are now commercially available which incorporate simultaneous pressure and temperature monitoring [331–334]. The reaction/digestion may be pre-set to run at either a given temperature, or a given pressure. The temperature or pressure may be programmed to vary in a step-wise fashion over a pre-determined time period. The systems are microprocessor-controlled, and printouts of reaction conditions may be obtained.

13. Conclusions

Though only relatively recently developed, the microwave-assisted dissolution technique is rapidly becoming the method of choice for the routine handling of large numbers of analytical samples. Although the approach does not so far provide a universal sample preparation technique, it does offer certain advantages over conventional dissolution techniques. For example, the rate-determining step for sample throughput is usually sample preparation. Microwave-assisted dissolution techniques offer a reasonably economical solution to this problem. As the result of saving time, these techniques are generally more economical in the long run as well, through savings due to reduced labor costs. Also, these techniques often require smaller amounts of sometimes expensive reagents, can contain corrosive fumes thereby preventing contamination and loss of volatile elements, require less supervision, are simpler and more efficient, and have proven to be reliable. Another major advantage of the speed with which microwave-assisted dissolutions occur, is that this can lead to rapid availability of results. Modern process control often requires constant monitoring of analytical parameters—these are sometimes available via on-line XRF analyses, but often AAS or ICP results are needed, so that a rapid sample dissolution method becomes a necessity for efficient plant operation.

Table 17
General reports concerning microwave applications

Sample(s)	Digestion mode and special information/equipment	Required reagents	Analyte	Method of analysis	Ref.
Foods, biological, botanical, man-made oils, environmental, sludge, geological, coal, metallic and ash samples	GENERAL REPORT: general guidelines for microwave sample preparation; advantages and disadvantages of classical and microwave dissolution techniques, extractions; Kjeldahl analysis; safety	Depends on the sample type	Whatever is required by the analyst	Appropriate for determination	283
	GENERAL REPORT: comparison of high-pressure microwavable bomb method with EPA method 3050			AAS, ICP-ES	284
	GENERAL REPORT: Proceedings of an International Conference on Millimeter and Submillimeter Waves and Applications				285
	GENERAL REPORT: Microwave dissolution: development of a new sample preparation technique				286
Various samples	GENERAL REPORT: comparison of the use of polycarbonate and Teflon™ vessels; discussion of sample types not amenable to microwave-assisted digestion; compared with Na_2O_2 fusion method				287
Various samples	GENERAL REPORT: reviews (11 references) a selection of the available techniques and the results obtained from the analysis of several types of samples				288
Ceramics, dried fish tissue, Fe oxide, minerals, foods, lipstick, paint, paper pulp, peanut butter, oils, alumina catalyst, alloys, coca, fly ash, silicon glue, sediment, solid waste, paints: practically all types	GENERAL REPORT: describes the Q Wave-1000 microwave digestion system (Questron Corp.): power readout, microwave-transparent internal temperature and pressure probes, automatic load adjustment, computer integration and on-line applications directory, efficiency, safety mechanisms and full graphics	Depends on the sample type		AAS, ICP, ICP-MS	289
SRMs: serpentite, limestone, dolomite, andesite, hawaiian basalt, granite, marine mud, cody shale and nepheline syenite	GENERAL REPORT: CEM MDS-81D oven: critically evaluates results obtained from using closed 120 mL PTFE–PFA vessels, compared with alkali fusions using a muffle furnace and open Teflon™ PTFE beakers on a hot plate ($HClO_4$–HF)	HF–HNO_3–HCl_4	Seven mineral oxides and nine other elements by ICP-AES, 38 elements by ICP-MS	ICP-AES, ICP-MS	290

General reports concerning microwave applications

Sample(s)	Digestion mode and special information equipment	Required reagents	Analyte	Method of analysis	Ref.
Non-specific	GENERAL REPORT: a focus outlining the problems with conventional techniques and the advantages of using microwave dissolution techniques	None	None	None	291
Non-specific	GENERAL REPORT: a focus outlining NBS-CEM Corporation's developments in microwave dissolution technology and techniques: closed vessels, replacing conventional methods, pressure and temperature measurements, microwave muffle furnace	Various acids and acid mixtures	Non-specific	Non-specific	292
Synthetic polymers, inorganic and organic acids, water and organic solvents	GENERAL REPORT: discussion of new areas of microwave technology application in labs. and process engineering; material properties and absorption coefficients given	None	None		293
Inorganic and organic samples	GENERAL REPORT: non-microwave methods of acid pressure decompositions in trace element analysis; advantages of pressure decompositions, problems, PTFE vessel material, safety, pressure casings, heating systems, decomposition efficiency and conditions and sample types discussed	Various acids and acid mixtures	Whatever is required by the analyst	Whatever is suitable for the determination	294

Techniques involving microwaves are not without faults albeit they can be minimized. One disadvantage when compared with the use of open digestion vessels is that dissolution variables such as sample weight and type, acid volume, microwave power, microwave distribution homogeneity and duration of exposure must be collectively acknowledged and controlled with all due respect to the possible explosive nature of the method. However, such control itself is advantageous since dissolution conditions are accurately reproduced without surpassing vessel limitations. As well, analyte accuracy and precision limits within batches of samples should be reduced due to this reproducibility.

Microwave-assisted dissolutions, though relatively rapid, do themselves have one disconcertingly slow step. This is the necessary delay in opening closed vessels with high internal pressures. These must be cooled to room temperature in order for this pressure to be reduced to a safe level. Several methods of shortening cooling times have been investigated such as internal vessel cooling systems, refrigeration or use of a freezer, cooling in ice, water or some other cold material such as liquid nitrogen. However, the time required for cooling of vessels by whatever method is only a minor inconvenience when considering how much time can be saved in performing dissolutions. For example, it takes 24 h

	AUTOMATION: microwave systems with remote control		295
Various sample types	AUTOMATION: focused microwave source to decrease dissolution time; open vessels; compared with classical techniques		296
	AUTOMATION: Microdigest A 300 using open and closed sytems	AAS, ICP	297
Mineral, organic or organometallic compounds	AUTOMATION: a patent, for an oven capable of receiving sample containers, means of placing samples at a fixed place inside its cavity, means of transporting samples to and from the oven and an automated command module; application selects the method, temperature and duration of exposure depending on the sample type		298
Organic and inorganic samples	AUTOMATION: Microdigest A301 system; description and applications		299
Titanium dioxide	AUTOMATION: CEM MDS-81D oven; 140 mL Milestone 140-10 digestion vessels equipped with pressure regulating valves; robotic system weighs out samples, adds acids, torques on caps, carries out microwave dissolution, dilutes and transfers the solutions to beakers and cleans the digestion vessels; 60 samples/16.5 h; reliability; software written in MODULA-2; sample identification data and operating parameters; closed 140 mL vessels with pressure regulating valves	ICP-AES	300
Environmental	AUTOMATION: integrated system of independent computer programs to encapsulate and transfer standard methods which involve automated equipment		301
Refractory tantalum metal powder	ROBOTICS: a robotic system in a quality control laboratory environment for trace element analysis for the control of a manufacturing process; closed Teflon™ vessels. After cooling the digestate is diluted robotically. Better precision and accuracy for some volatile elements using the robotic system	DCP	302

for the complete dissolution of wool using classical methods whereas only eight minutes are required using microwave digestion [227]. This is 180 times faster!

The usefulness of microwaves in analytical chemistry is increasingly evident. From a meager start in the 70s represented by only seven references, publication has increased to 132 references in the 80s and to 166 references in only the first four years of the 90s! This review has not only shown that microwaves can be used in the dissolution of a wide variety of sample types but also in other analytical areas as well. Microwave energy has proven to be useful in shortening drying, extraction, Kjeldahl determination, ashing and fu-

sion times as well as in increasing efficiency. Microwave techniques are also exceptionally applicable to continuous flow and on-line systems due to their simplicity and ease of use. These systems are now commerically available although essentially still in the prototype stage, but within the next year or so they will most likely replace the closed-vessel methods described above in high-throughput situations.

A new method for the determination of residual piperazine in pharmaceuticals by capillary gas chromatography

K.N. Ramachandran*, G.S. Kumar

Shriram Institute for Industrial Research, 14, 15, Sadararmangala Industrial Area, Whitefield Road, Bangalore 560 048, India

Abstract

A new selective open tubular capillary gas chromatographic method is developed for the determination of trace amounts of piperazine. Piperazine is extracted from pharmaceuticals into cyclohexane and is partitioned with water. The aqueous solution is then injected into a 5% crosslinked Ph–Me silicone column programmed at 50–180 °C for 10 min. Piperazine is eluted after 3.18 min under isothermal conditions. The lower limit of determination is 0.4 ppm. This method has been successfully applied for the assay of piperazine in pharmaceutical formulations and its trace determination in fluoroquinolone drugs such as norfloxacin and ciprofloxacin. The method is reproducible and the standard and relative standard deviation for 10 repeated injections of 2 μg piperazine are 0.7 and ±2.1% respectively.

1. Introduction

Piperazine is one of the most potent drugs used as anthelmintics. It is also one of the raw materials used in the synthesis of fluoroquinolone drugs such as norfloxacin, ciprofloxacin, etc. [1]. The pharmocological significance of piperazine has led to the development of several methods for its determination in pharmaceutical formulations. Nonaqueous titration [2] and gravimetric methods [3] are the most popular. In addition several colorimetric methods [4–20] have been reported for

its determination. However, these methods are not applicable for the determination of residual piperazine in fluoroquinolone drugs. A survey of the literature failed to indicate a suitable method for the trace analysis of this compound. Methods such as high performance liquid chromatography (HPLC) and potentiometry, reported for the determination of norfloxacin or ciprofloxacin, cannot be used for piperazine. This necessitates the development of a suitable method for the determination of residual piperazine in pharmaceutical formulations and their standards.

In this paper a new, sensitive and selective capillary gas chromatographic method is pro-

---

*Corresponding author. Fax: (+80) 845-2734.

posed for the determination of piperazine. Piperazine is extracted into water and injected into a pre-conditioned column of 5% Ph–Me silicone. The column is programmed at 50–180°C for 10 min. The lower limit of determination is 0.4 ppm. This method has been applied for the determination of residual piperazine in norfloxacin, ciprofloxacin, etc. The results have been compared with those from other established methods and found to be satisfactory.

2. Experimental

2.1. Reagents

All reagents used were of AnalaR grade and solvents were supplied by Merck. Piperazine was obtained from Aldrich. Doubly–distilled deionised water was used.

2.2. Equipment

A Hewlett Packard Series II 5890 gas chromatograph with a flame ionization detector and a 30 m × 0.3 mm i.d fused silica column coated with a 3.0 μm film of 5% cross linked Ph–Me silicone was used. The carrier gas was nitrogen, at a flow rate of 1 ml min^{-1}, measured with a bubbler flow meter at a column temperature of 50°C. The injector and detector temperatures were kept at 200°C and 225°C respectively. The column temperature was programmed at 50°C for 5 min, then
Concentration of piperazine is 0.4 ppm

Fig. 1. Chromatogram of piperazine.

increased by 15°C min^{-1} to 180°C and held at that temperature for 10 min. The injection volume was 1 μl on the column. Standard and sample solutions were injected in five replicates. Data analyses were performed on a HP 3395 integrator system. Calibrated glassware was used for all volumetric purposes. Millipore 0.45 μm filters were used for filtration of samples.

2.3. Analytical standard preparation

Stock solution (1000 ppm): 100 mg of anhydrous piperazine was accurately weighed in to a 100 ml calibrated volumetric flask and made up to the mark with distilled water.

Working standard: working standards were prepared by appropriate dilution of the stock solution.

2.4. Procedures

2.4.1. Preparation of calibration graph

1 μl of an aliquot of standard piperazine solution (0.4–10 ppm) was injected into a pre-condi-

Fig. 2. Calibration graph for piperazine.

Table 1
Retention times of solvents and piperazine

Compound	Retention time (min)	Compound	Retention time (min)
Piperazine	3.21	DMF	21.3
Methanol	2.21	Benzyl alcohol	27.5
Ethanol	2.73	Ethyl acetate	5.6
Acetone	3.15	DMSO	23.4
Diethyl ether	2.85	Carbon tetrachloride	6.95
Isooctane	3.17	Benzene	7.6
Dochloromethane	3.69	Hexane	4.41
Chloroform	4.95		

tioned column programmed at 50–180°C under programmed conditions. Instrumental and integrator parameters such as attenuation, range and chart speed were set at their optimum values. A calibration graph of peak area vs. concentration was prepared.

2.4.2. Determination of piperazine in norfloxacin and ciprofloxacin

1 g of norfloxacin was transferred into a 25 ml separatory funnel along with 10 ml (2 × 5 ml) of cyclohexane. The mixture was shaken thoroughly for 10 min and filtered under suction with a 0.45 μm filter. The cyclohexane filtrate was partitioned with 10 ml water in another separatory funnel for 10 min. The organic phase was discarded and the aqueous phase was thermostatted at 45°C for 10 min. 1 μl of this solution was injected on to the column as described above.

Table 2
Percentage recovery/extraction efficiency of piperazine from real samples

Sample	Piperazine added (μg)	Piperazine found (μg)	% Recovery
Norfloxacin USP	-	3.5 ($\pm$0.4)	-
	5	8.4 ($\pm$0.1)	98.8
	10	13.4 ($\pm$0.2)	98.8
Ciprofloxacin HCl	–	2.6 ($\pm$0.2)	–
	5	7.5 ($\pm$0.3)	98.1
	10	12.4 ($\pm$0.1)	98.4

2.4.3. Determination of piperazine in piperazine citrate

1 mg of piperazine citrate was taken in a 100 ml volumetric flask and diluted to 100 ml. 1 μl aliquots of the sample were injected on to the column as described above.

3. Results and discussion

A composite chromatogram showing the retention time of piperazine is given in Fig. 1. Under optimum conditions piperazine was eluted as a singlet. The mean peak area and retention time are 77 214 (AU) and 3.18 min respectively. The attenuation and range of the instrument were set according to the concentration of the sample. The lower limit of detection is the concentration which would give a peak height equal to three times the baseline noise. This value for piperazine was 0.4 mg. A monovariant calibration graph was made with the integrator for assay. A linear relationship between the peak area and concentration is shown in Fig. 2. The slope, intercept of the best fit line and coefficient of correlation are 5.876, −0.0063 and 1.000 respectively.

The compatibility of various solvents for extraction of piperazine from fluoroquinolone drugs was studied. Although piperazine is highly soluble in water, water is not the preferred solvent since most of the pharmaceuticals used in the present study were also soluble in water. The performance of the column is affected in such cases. Among several solvents studied such as acetone, ethanol, methanol, isooctane, dichloromethane, chloro-

Table 3
Comparison between the results obtained from the proposed method and the USP method[a]

Sample	Piperazine added (μg)	Piperazine found (μg)	
		Proposed method	USP method
Norfloxacin USP	-	4.1	16.3
	5	8.0	16.3
	10	13.9	16.5
	25	29.0	21.5
Ciprofloxacin HCl	–	1.8	24.2
	5	6.4	24.4
	10	11.2	24.5
	25	26.1	29.8

[a]Means of three replicate analyses are given.

form and cyclohexane, cyclohexane was found to be the best for extraction of piperazine. After the extraction of piperazine into cyclohexane, piperazine was partitioned into the aqueous phase prior to injection. Retention times of piperazine and general solvents are given in Table 1.

The efficiency of the extraction procedure was studied by replicate injections of extracted piperazine on to the column. The results are given in Table 2.

3.1. Effect of temperature

The effect of temperature on elution of piperazine was studied. A column temperature of 50°C was sufficient for piperazine elution. Injector and-detector temperatures of 200 and 225°C were found to be the most suitable for the precise determination of piperazine. An increase in tem-

perature does not have any adverse effect on performance. While analysing pharmaceutical materials such as norfloxacin and ciprofloxacin, the column temperatue was raised to 180°C. This helps to avoid the interference of non-volatile residues and enables reproducible performance of the column. Under optimum conditions the column was programmed at 50°C for 5 min, then increased at 15°C min^{-1} to 180°C and held at that temperature for 10 min.

3.2. Linearity and precision studies

Solutions for the linearity studies were prepared by suitable dilution of the stock. Reproducibility was assessed by performing 10 replicate injections of a solution containing 2 μg of piperazine. The mean, standard and relative standard deviations were 1.974 μg, 0.041 μg and ± 2.1% respectively.

Table 4
Results of analysis[a]

Sample No.	Norfloxacin USP (μg)		Ciprofloxacin USP (μg)		Piperazine citrate (%)	
	I[b]	II[c]	I[b]	II[c]	I[b]	II[c]
1	4.1	3.9	1.8	1.5	96.85	96.9
2	3.7	3.55	1.6	1.42	96.1	96.0
3	3.2	3.21	1.65	1.42	96.3	96.3

[a]Means of three replicate analyses are given; analyses were carried out after extraction by the proposed method.
[b]Proposed method.
[c]USP method after extraction.

3.3. Applications

The proposed method has been successfully applied for the determination of residual piperazine in norfloxacin and ciprofloxacin and their reference standards (Table 3). Piperazine was also estimated by the potentiometric titration method of the USP [2]. The values obtained by the USP procedure were very high, due to interferences. Hence piperazine was extracted as proposed here and analysed. Results of analyses are given in Table 4.

3.3.1. Piperazine in reference materials

The proposed method has been applied for the determination of trace impurities of piperazine in reference materials of norfloxacin and ciprofloxacin. About 1 mg of these substances was dissolved in 100 ml of water, filtered through a 0.45 μm filter, injected on to a pre-programmed column and analysed as described earlier.

4. Conclusion

The capillary gas chromotographic method described above is novel, selective and sensitive to trace levels. The method has been successfully applied for the determination of residual piperazine in norfloxacin and ciprofloxacin and for the assay of piperazine samples. The method is reproducible and free from interferences such as amino compounds and ammonia. The method is superior to non-aqueous titration and gravimetric methods.

Amperometric flow-injection method for the assay of L-ascorbic acid based on the photochemical reduction of Methylene Blue

Luis E. León*

Departamento de Química, Universidad Simón Bolívar, Apartado 89000, Caracas 1080-A, Venezuela

Abstract

Ascorbic acid (AA) is determined by amperometric detection based on the photochemical reduction of Methylene Blue (MB^+) in 0.1 M phthalate buffer at pH 3.8. In this medium, MB^+ using flow-injection analysis. The carrier stream is 1 mM MB^+ is reduced quasi-reversibly at a glassy carbon electrode at -0.34 V vs. Ag/AgCl, while AA is oxidized irreversibly at about 0.3 V. The reactor is irradiated with a 500 W halogen lamp to facilitate the development of the photochemical reaction. A laboratory-built wall-jet electrode system was used. The Leucomethylene Blue formed in the reaction is detected at $+0.050$ V. At 2.2 ml min^{-1} and using a sample loop of 43 μl, the method allows the determination of AA in the range $5.0-90.0$ μg ml^{-1}, with a relative standard deviation of $1.3-4.8\%$, a detection limit of 1.9 μg ml^{-1} and a sampling frequency of $45-50$ h^{-1}.

Keywords: Amperometry; L-Ascorbic acid; Flow injection; Methylene Blue; Photochemical reduction

1. Introduction

The determination of ascorbic acid (AA) has received great attention in analytical chemistry due to its wide use in soft drinks, human and animal food, and drugs. It is also important clinically to determine its concentration in blood, urine and some tissues [1]. Numerous conventional methods have been described for the determination of AA [2,3]. Several flow-injection (FI) methods with electrochemical detection have also been proposed for its determination [4,8]. Strohl

and Curran [4] used a reticulated glassy carbon electrode to carry out the coulometric and amperometric determination of AA, achieving detection limits of a few nanograms. Almuaibed and Townshend [5] used a miniamperometric detector for individual and simultaneous determination of uric acid and AA. Fogg et al., [6] used a sessile mercury drop electrode for determination of AA and dopamine without deoxygenation. Two amperometric methods using immobilized enzyme (ascorbic acid oxidase) reactors have also been proposed [7,8].

The electrochemical characterization of Methylene Blue (MB +) in aqueous solution has been reported [9–11] and it is known that MB^+ is re-

duced to Leucomethylene Blue (LMB) by a reversible two-electron process [12].

In a previous paper [13], AA was determined indirectly by spectrophotometry at 666 nm based on the photobleaching of MB^+ in a FI system. Samples of AA were injected into a buffered MB^+ carrier stream. The peaks recorded were of decreasing absorbance owing to the reduction of MB^+ with AA. Although the method was shown to be very simple and accurate, it only allowed determination of AA in the range 0.18–6.12 μg ml^{-1}. In this paper, luminous light is again used for determination of AA by photobleaching of MB^+ in a FI system. The determination is based on the measurement of the current due to the oxidation of LMB formed during the photobleaching process. The present method allows direct, amperometric determination of AA in the range 5.0–90.0 μg ml^{-1}. This is a more acceptable linear range to work in particularly for the kind of samples being considered.

2. Experimental

2.1. Reagents

All reagents used were of analytical-reagent grade purity. AA and 2,6-dichloroindophenol were purchased from Merck and MB^+ was purchased from Aldrich (basic blue 9, C.l. 52015).
Fig. 1. Schematic diagram of the FI configuration used: A, thermostated water bath; B, reactor; C, tungsten lamp; D, mechanical shutter; E, light intensity regulator; F, detector; G, injection valve; H, light-tight protection; W, waste; Q, peristaltic pump; AA, ascorbic acid; MB, Methylene Blue.

Fig. 2. Laboratory-built electrochemical flow cell: A, working electrode; B, Teflon body; C, Teflon tubing (inlet); D, auxiliary electrode; E, glass holder; F, reference electrode; G, glass tubing (outlet).

2.2. Manifold

Fig. 1 shows the scheme of the FI configuration used. The sample is injected into a MB^+ carrier stream (0.1 M phthalate buffer at pH 3.8) by means of an Omnifit 1106 sample injection valve (G). The reactor B (Teflon, 150 cm long, 0.5 mm i.d.) is irradiated with a 500 W halogen lamp (C) to facilitate the development of the photochemical reaction. The reactor is wrapped around a Pyrex test tube and placed in a thermostatically-controlled water bath (A) 5 cm below the water level and 15 cm from the radiation source. The tubing connecting the reactor and the electrochemical detector (F) was protected from light with black PVC tubing of 1 mm i.d. Flow rates were maintained using a Gilson Minipuls 3 peristaltic pump (Q).

2.3. Apparatus

A three-electrode potentiostat (Tacussel PGS201T) with electrochemistry software (Tacussel ELCOM201) was used for the cyclic voltammetry experiments. Amperometric measurements were made by means of a PAR 173 potentiostat/galvanostat equipped with a Houston Instruments Omnigraphic 2000 X–Y recorder [14]. Fig. 2 shows the laboratory-built electrochemical flow

cell. It was equipped with a glassy carbon electrode (0.071 cm²) (A), a platinum wire auxillary electrode (D), and a 3 M KCl. Ag/AgCl reference electrode (F).

2.4. Procedure

Samples and standards were examined using the flow system shown in Fig. 1. Samples of vitamin C tablets were dissolved in 50 ml 0.1 M HClO₄. The final solution was filtered and diluted to volume with 0.1 M HClO₄. Dilute samples were prepared by appropriate dilution in 0.1 M phthalate buffer. The final pH was 3.8. The resulting solutions were protected from light during all experiments and kept in a refrigerator prior to use.

3. Results and discussion

Fig. 3 illustrates the cyclic voltammogram of 1 mM MB⁺ (curve A) and 1 mM AA (curve B) in 0.1 M potassium hydrogen phthalate at 5 mV s⁻¹. MB⁺ is reduced at a glassy carbon electrode at − 0.34 V giving LMB, which is oxidized at − 0.27 V, while AA is oxidized irreversibly at about + 0.3 V. The LMB formed in the reaction between MB⁺ and AA can be detected at + 0.050 V.

Fig. 3. Cyclic voltammograms of 1 mM MB (A) and 1 mM AA (B) in 0.1 M potassium hydrogen phthalate, 0.1 M KCl, 10 μM TX; pH 3.8; scan rate, 5 mVs⁻¹.

Fig. 4. Amperometric response to 30.0 μg ml⁻¹ of AA. A, without TX; B, after adding TX.

3.1. FI variables

The reactor was irradiated with a 500 W halogen lamp to facilitate the developement of the photochemical reaction. The variation of the FI peak with light intensity was similar to previous results [13]. It increases almost linearly up to 90% of applied power, after which the peak height becomes independent of intensity. All the experiments were done at 90% of maximum power. The signal increases linearly with pumping rate between 1.0 and 3.0 ml min⁻¹. The experiments were done at 2.2 ml min⁻¹ with a loop of 43 μl. These conditions give a residence time of 20 s and a sampling rate of 45–50 h⁻¹. The increase in the signal with the temperature was not significant. However, the heat produced by the lamp increases the water temperature up to 32°C; therefore, this temperature was chosen for further experiments. Fig. 4 shows the response of the detector when a sample of 30.0 μg ml⁻¹ of AA is injected in the FI system. Fig. 4A shows the poor reproducibility of the signal after each injection. This effect can be suppressed if each injection is made after

Table 1
Determination of AA in vitamin C tablets

Sample[a]	AA content[b]	Amperometry[c]	AOAC[c]	F-test	t-test
A	1000	997.0 (0.87)	997.2 (0.29)	9.00	−0.05
B	500	498.3 (0.92)	497.4 (0.31)	8.84	0.42
C	500	498.6 (0.89)	498.8 (0.39)	5.19	−0.09
D	500	497.1 (0.61)	496.2 (0.47)	1.69	0.19
E	500	498.2 (0.96)	498.9 (0.34)	7.91	−0.11

[a] All samples gave on dilution a white suspension of starch, which is used as a "vehicle" in these preparations. They also contain fructose (A–D) and artificial fruit flavor compounds (E). In addition, sample A contains sodium carbonate. A, Redoxon[R] (effervescent), Merck, S.A.; B. Lilly Co. of Venezuela; C. Roche Products, S.A.; D, Roche Products, S.A. (generic); E, Cebión[R] (chewable), Merck, S.A.

[b] In milligrams per tablet

[c] Average of five determinations: milligrams per tablet; (RSD)

reaching the baseline, but this takes at least 2 min. This behavior was suppressed by adding Triton X-100 (TX) to the carrier solution [12]. The result is illustrated in Fig. 4B. It seems that LMB, which is less soluble than MB +, tends to be adsorbed on the FI manifold. Furthermore, LMB tends to form compact and conductive layers with MB$^+$ which is already adsorbed on the electrode. The presence of TX seems to decrease the adsorption phenomena of LMB, thus decreasing the time needed to reach the baseline after each injection. The influence of TX concentration on the signals was not studied.

3.2. Determination of standard AA samples

The standard solutions of AA injected yielded a linear peak current–AA concentration response in the range 5.0–90.0 μg ml^{-1} which obeyed the equation

$$i_p = 0.03194c - 0.1207 \ (r = 0.999)$$

where i_p is the peak current (μA) and c is the concentration of AA (μg ml^{-1}). The precision of the method expressed as the relative standard deviation for $n = 9$ was 4.8% and 1.3% for 5.0 and 90.0 μg ml^{-1} of AA respectively. The detection limit was 1.9 μg ml^{-1} (three times the baseline noise).

A study of potential interferents that may be present in most vitamin C tablets [13] was performed with samples containing 10.0 μg ml^{-1} of AA and 100-fold amounts of the following compounds: glucose, fructose, sacchrose, sodium tartrate, citric acid, sodium benzoate and maleic acid. There is no major interference from these species. Sodium benzoate may give the strongest interference. However, benzoate is oxidized at about +0.150 V. Potential interference by this compound could be reduced by detecting LMB at more negative potentials, e.g. 0.0 or −0.050 V.

Table 1 lists five commercial AA samples. All samples gave a white suspension on dilution. This was found to be particles of starch, which is used as a "vehicle" in these preparations. Other general constituents of these drugs are fructose and citric acid. In addition, sample A contains sodium carbonate and sample E contains articificial flavor compounds. The method was not applied to assay AA in biological fluids; further studies with these kinds of samples may require additional information on matrix composition.

3.3. Analysis of vitamin C tablets

Table 1 lists the results obtained on application of the proposed method to vitamin C tablets. These results are compared with those obtained by the AOAC standard method [15]. Column five shows the results obtained on application of the F test. There are no significant differences between the standard deviations of both methods since the critical value of F for a

two-tailed test at the 5% level of probability is 9.605. Column six shows the respective results obtained on application of the t test. Since the critical value of t ($P = 0.05$) is about 2.31, it may be concluded that both methods give similar results [16].

The conventional, titration method employs simpler, economical materials, and it is probably the method of choice for the analysis of few samples. However, the proposed method can be readily implemented on a very simple configuration and it is the best choice for the analysis of large amounts of samples. There is a further advantage of the FI system: the carrier solution once prepared can stand for a long period of time without losing its titer. In the titration method, solutions of 2,6-dichloroindophenol must be filtered and then kept out of direct sunlight and stored in a refrigerator; furthermore, their titer must be checked regularly [15].

The results indicate that the proposed method can be implemented on a very simple FI configuration with the typical advantages of continuous analysis over the conventional, time-consuming, titration method. The method described is adequate for measurements of AA in purified materials, specifically vitamin C tablets. However, compared to other amperometric determinations, the proposed method effectively lowers the applied potential and the presence of other reducing agents with ascorbic acid may not interfere in the electrode reaction. Also, the inherent selectivity of

the photobleaching process increases the potential of the method.

Use of 4-chloro-7-nitrobenzofurazane as a derivative reagent for the determination of amino acids by cathodic stripping square wave voltammetry in biological fluids

Oscar Nieto*, Pedro Hernández, Lucas Hernández

Department of Analytical Chemistry and Instrumental Analysis, Universidad Autónoma de Madrid, E-28049 Madrid, Spain

Abstract

The rapid and simple reaction of 4-chloro-7-nitrobenzofurazane with amino acids allows the determination of amino acids in urine using cathodic stripping square wave voltammetry. The obtained compounds are adsorbed on a hanging mercury drop electrode for determination by voltammetric methods using phosphate buffer at pH 2.0 as supporting electrolyte. The proposed method allows determination with an error of $\leq 5.68\%$. A limit of detection (3σ) of 3.64 nM (0.766 ng ml^{-1}) and a limit of determination (10σ) of 12.12 nM (2.55 ng ml^{-1}) are obtained for arginine determination. The proposed method has been applied to the determination of amino acids in urine.

Keywords: Amino acid determination; 7-Chloro-4-nitrobenzofurazane; Square wave voltammetry

1. Introduction

The problem of the determination of amino acids for applications in the fields of medicine, biology, etc., can be solved with the use of voltammetric techniques. Several methods for determination of amino acids using electrochemical techniques have been proposed, depending on the concentration level and on the selectivity. For instance, a sample containing amino acids is decomposed by dry ashing and the amount of NH_3, formed as a product of reaction, is determined using a selective electrode for NH_3 [1]. Several proposed methods are based on potentiometric or conductimetric titration, either of the amino acid [2–4] or its basic nitrogen in non-aqueous media [5]. These methods are very common in the determination of arginine in the presence of aztreonam [6,7].

Amino acids are able to form complexes with cupric ions [8] as well as charge-rate complexes with p-benzoquinone [9]. These properties have been applied to the colorimetric determination of amino acids in urine.

The direct determination of amino acids by voltammetric techniques is usually performed with metallic electrodes such as Cu [10] and Au [11]. The amino acids are determined either by amperometric metal–amino acid complexation or by electrocatalytic oxidation to form metallic ox-

* Corresponding author. Tel.: (+32) 14-571-252; fax: (+32) 14-584-273; e-mail: palmeiro@davinci.irmm.jrc.be

ides in the presence of the amino acid. Hui and Huber [12] used a nickel oxide working electrode for the direct determination of the amino acid by flow-injection analysis. A high oxidation state of Ni, maintaining the potential at $+0.49$ V versus SCE, is involved in the reaction mechanism. The disadvantages of these methods are the lack of sensitivity and selectivity.

The determination of amino acids by voltammetric techniques is possible via a derivatization reaction. Nussbaum et al. [13] derivatized the amino acids with naphthalene-2,3-dicarboxyaldehyde to give cyanobenzo (f) isoindole-amino acid. Using cyclic voltammetry, an anodic peak appears due to the oxidation of the indole group. In this way, the problem of the quenching effect, produced in the determination of these compounds by fluorescence, is avoided [14]. Li et al. [15] determined the amino acids by cyclic voltammetry and differential pulse polarography in borax and acetaldehyde buffer. A Schiff's base is formed and the determination is carried out by the reduction of the imido group. Moreira et al. [16] derivatized the amino acids with phenylisothiocyanate to form phenylthioidantoin amino acids. The determination was carried out by differential pulse cathodic stripping voltammetry in the presence of Cu(II) salts.

There are many publications concerning methods of determination of amino acids using biosensors. These biosensors are based either on the response of different kinds of electrodes to the decomposition of amino acids to L-aminoacidoxidase [17–19] or on measurement of the difference of potential generated by two biosensors [20]. In the case of arginine, either electrodes with immobilized arginase and urease using Tris–EDTA buffer as supporting electrolyte [21] or electrodes with immobilized *Streptococcus faecium* bacteria, selective for arginine [22], have been used.

The derivative reagents which are used for determination of amino acids are common to every type of amino acid and, as a result, each derivatized amino acid exhibits the same response at the detector. Therefore, separation methods must be used for the determination of each of the amino acids. The separation technique most often used is high performance liquid chromatography

(HPLC). The direct determination of the amino acid by HPLC with electrochemical detection is carried out with metallic working electrodes such as Cu [10,23,24], Pt [25], or Ni using an alkaline eluent in the case of arginine and other compounds with a guanidine group [26]. In all cases, the detection is performed throughout the electrocatalytic oxidation of the metallic electrode in the presence of the amino acid.

In most of the methods proposed for the determination of amino acids by HPLC, a derivatization reaction is carried out. Typical reagents for the derivatization reaction are 4-fluoro-7-nitrobenzooxadiazole [27–30], o-phthalaldehyde/2-mercaptoethanol [31–34], ninhydrin [34], o-phthalaldehyde-t-butylthiol [35], phenylisothiocyanate [31,36,37] naphthalene-2,3-dicarboxyaldehyde [38, 39], perinaphthindantrione [40] or Sanger's reagent (2,4-dinitrofluorobenzene) [41], using electrochemical detection or other methods. There are few methods for determining amino acids by gas chromatography [42].

Another separation method frequently used for amino acid determinations is capillary electrophoresis with fluorimetric detection [43–47]. Olefirowicz and Ewing [47] added 3,4-dihydroxybenzylamine to the buffer for the indirect determination of amino acids by capillary electrophoresis with electrochemical detection.

In this work the use of 4-chloro-7-nitrobenzofurazane (CNBD) as derivative reagent in the determination of amino acids by voltammetric methods has been proposed. CNBD is a nonfluorescent reagent introduced by Ghosh and Whitehouse [48] in 1968. This reagent is converted into a highly fluorescent compound on reacting with compounds containing thiol and amine groups. Glycine reacts rapidly with this reagent in methanol or in aqueous solutions in the presence of potassium acetate. Cysteine methyl ester and glutathione react in aqueous solutions of phosphate buffer at pH 7.0.

Fager et al. [49] used CNBD as a derivative reagent for the determination of amino acids. The procedure for the derivatization reaction is described in Ref. [50]. The characteristic fluorescence of the NBD–amines is best observed in solvents with low polarity at an excitation wave-

length in the visible range (464 nm). Therefore, the use of quartz cells is not necessary for quantitative determination. The nitro and benzofurazane groups are electroactive and both electrochemical reaction mechanisms are widely known [51,52]. Imai and co-workers [27–30] used this derivative reagent for the determination of amino acids by chromatographic techniques with electrochemical detection [27–29] and others, but they did not study in detail the mechanism of reaction of both electroactive groups.

The study of the electrochemical behaviour as well as the optimization of the experimental parameters for the quantitative determination of NBD–amino acids is discussed in this paper. The aim of this study is to improve the sensitivity of analytical techniques with the use of electrochemical methods. In addition, the electrochemical techniques allow selective determinations and can be applied to complex matrices such as urine.

2. Experimental

2.1. Reagents

A standard solution of arginine (clorohydrate) from Sigma (St. Louis, MO) at a concentration of 1.00×10^{-2} M dissolved in water was used without further purification and preserved at 4°C. A standard solution of CNBD from Fluka at a concentration of 1.00×10^{-2} M dissolved in methanol was used without further purification, preserved at 4°C and protected from light. C_{18} Sep-Pak cartridges (Millipore) were used for the separation of amino acids from the urine. Amberlite IR-120 cationic resin from Carlo Erba was used for the separation of the amino acid mixture. Tridistilled metallic mercury was used. All the reagents used were of analytical grade quality, and the water was deionized using a Milliro-Milli Q system (Waters).

2.2. Apparatus

A PAR Model 384B potentiostat with a PAR Model 303A polarographic stand, equipped with a hanging mercury drop electrode, a Ag/AgCl/KCl (3 M) reference electrode and a platinum counter electrode was used. A PAR Model 305 magnetic stirrer is coupled to the polarographic stand.

A Bioanalytical System BAS-100 potentiostat equipped with a mercury pool working electrode, a saturated calomel reference electrode and a platinum counter electrode was used. The reference electrode and the counter electrode were isolated from the working solution with agar/electrolyte plug bridges. They were used for the coulometric experiments.

A Hewlett-Packard 5890 Series II gas chromatograph, equipped with a 5971A mass spectrometric detector, was used for identification of the reaction products.

2.3. Procedure

The conditions used for the reaction of amino acids with CNBD are the following: to a test tube are added 2 ml of methanol, 100 μl of a saturated solution of sodium acetate in methanol, 20 μl of a solution of 1.00×10^{-2} M CNBD and 5 μl of a solution of 10^{-2} M arginine in water. The mixture is heated in a water bath at 75°C for 20 min.

First, an aliquot of the above-mentioned solution is added to the supporting electrolyte. The pH is adjusted, if necessary, with a suitable amount of NaOH or $HClO_4$. A purge of nitrogen is applied for 5 min at the beginning of the work and for 1 min between each measurement. Each measurement is performed with a new mercury drop. The square wave voltammograms are recorded with the following parameters: square wave frequency, $f = 50$ Hz; scan increment, $\Delta E = 2$ mV; square wave amplitude, $a = 20$ mV. In the study of each parameter, in order to establish the most suitable conditions, the other parameters were kept as the values detailed above.

The studies of the influence of pH and accumulation potential were carried out using the following buffers: 0.04 M phosphate buffer in the pH ranges 2.0–3.0, 6.0–8.0 and 11.0–12.0; 0.04 M acetate buffer in the range pH 4.0–5.0; and 0.04 M borate buffer in the range pH 9.0–10.0. The equilibration time after accumulation was 5 s and the rest of the instrumental conditions were as mentioned above.

The coulometric study was carried out as follows. The reaction of CNBD with arginine is performed, using a ratio of [CNBD]:[Arg] = 8:1, under the experimental conditions for the derivatization reaction described above. The products of the reaction are dissolved in 0.04 M phosphoric acid at pH 2.0 and the NBD–Arg is extracted in ethyl acetate. Once the solvent has been removed with a stream of nitrogen in a water bath at 50°C, 10.0 ml of 0.08 M phosphoric acid at pH 2.0 is added and the final concentration of NBD–Arg was 1.0×10^{-4} M. The applied potential on the working electrode was -300 mV vs. SCE.

The procedure for separation of interferences, in order to achieve easy sample manipulation, is as follows. The original urine sample was collected 24 h before use and stored at 4°C in order to precipitate proteins. Then, the solutions were centrifuged at 2500 rev min^{-1} for 3 min. The supernatants were adjusted at pH 2.0 and passed over a C_{18} Sep-Pak cartridge previously activated by passing the following solvents through the cartridge: ethanol, ethyl acetate, 0.1 M ammonium acetate and water. The hydrophobic compounds are adsorbed on the silica but the amino acids remain in the solution. Afterwards, the amino acids are separated in a cationic resin IR-120 column (30 mm × 5.2 mm i.d.) previously equilibrated with 1.0 M HCl. The elution is carried out with solutions of 0.04 M citrate buffer at different pH values: 2.00, 2.50, 2.65, 2.80, 3.20, 4.00 and 4.90 with a flow rate of 0.5 ml min^{-1}. An aliquot of each collected fraction is added to a mixture of sodium acetate, CNBD and methanol and then the derivatization reaction is carried out as described above. The product is diluted in 0.08 M phosphate buffer at pH 2.0. Then the voltammograms are recorded under the most suitable conditions as determined from the calibration curve.

3. Results and discussion

Fig. 1 shows the square wave voltammogram of CNBD in 0.04 M phosphate buffer at pH 7.0 (voltammogram a). The peak at -380 mV (peak I) is due to the electrochemical reduction of the

nitro group and the peak at -1094 mV (peak III) is due to the electrochemical reduction of the benzofurazane (benzo-2-oxa-1,3-diazole) group. The voltammogram of CNBD which has reacted with arginine (voltammogram b) shows a decrease in current of the peak due to the reduction of the nitro group and the appearance of a new peak at -496 mV (peak II) which corresponds to the compound NBD–Arg.

When an accumulation potential is applied for 60 s there is no variation in the voltammogram of CNBD without amino acid (Fig. 2, voltammogram a). However, when CNBD has reacted with arginine, the current of the peak at -496 mV increases (Fig. 2, voltammogram b) after the application of an accumulation potential for 60 s. This indicates that the NBD–Arg complex is adsorbed on the surface of the mercury electrode and that peak I, due to CNBD, does not interfere with peak II.

In the voltammograms corresponding to both solutions, another peak appears at -650 mV. The origin of this peak has not been identified. The peak current is bigger in the voltammogram of CNBD with Arg than in the voltammogram with solely CNBD. When CNBD and Arg are present

Fig. 1. Square wave voltammograms of CNBD (a) and NBD–Arg in a [CNBD]:[Arg] ratio of 4:1 (b) without applying an accumulation step. Conditions: supporting electrolyte, 0.04 M phosphate buffer at pH 7.0: SW amplitude, 20 mV: SW frequency, 50 Hz: scan increment, 2 mV.
Fig. 2. Square wave voltammograms of CNBD (a) and NBD–Arg in a [CNBD]:[Arg] ratio of 4:1 (b) after the application of an accumulation potential of − 100 mV for 60 s. Other conditions, as in Fig. 1.

in the solution at pH 7.0 and have not reacted, this adsorption peak is already observed. In fact, the efficiency of the reaction is not quantitative under the given experimental conditions ([CNBD]:[Arg] = 4:1). Otherwise, there is no interference with this peak when arginine has reacted quantitatively with CNBD under the most suitable experimental conditions for the determination (a ratio of [CNBD]:[Arg] = 8:1 and the supporting electrolyte at pH 2.0 as detailed below).

It should be noted that no further purification is necessary after the derivatization reaction has been carried out.

A study of the accumulation potential at each value of pH studied was carried out. Fig. 3 shows a three-dimensional plot of the peak current, i_{pII}, vs. pH and vs. accumulation potential, E_{ac}. The optimum peak current is obtained at pH 2.0 ($i_{\mathrm{p}} = 2.90$ μA), when the applied accumulation potential is − 100 mV. Another maximum value is obtained at pH 8.0 when the applied accumulation potential is − 410 mV ($i_{\mathrm{p}} = 2.25$ μA). However, at basic pH the stability of the compound is low and the measurements are not reproducible.

There is a linear relationship between peak potential and pH according to the equation:

$$E_{\mathrm{p}}(\mathrm{mV}) = -154 - 51.4 \ \mathrm{pH}$$

A study of pH was also carried out by cyclic voltammetry, using a scan rate of $v = 100$ mV s^{-1}. The best accumulation potential obtained at each pH by square wave voltammetry was applied previously for 60 s, and the equilibration time was 5 s. The peak potential shifts with pH according to the equation:

$$E_{\mathrm{p}}(\mathrm{mV}) = -162 - 51.5 \ \mathrm{pH}$$

which value of the slope is very similar to the one obtained by square wave voltammetry. The value of the slope in both experiments suggests that the same number of electrons and protons are involved in the electrochemical reaction.

The most suitable supporting electrolyte is 0.08 M phosphate buffer at pH 2.0.

The study of the derivative reagent:amino acid ratio was carried out by preparing several solutions with the same amino acid concentration and varying the proportion of derivative reagent. The results obtained are shown in Fig. 4 where i_{p} vs. ratio of derivative reagent:amino acid, expressed as mol CNBD: mol Arg, is represented. The maximum value of i_{p} is obtained for a proportion of 8:1 and for higher ratios of CNBD to Arg the peak current does not increase. Hence, a CNBD to Arg ratio of 8:1 was used as the optimum for

Fig. 3. Variation of i_{p} with pH and accumulation potential. Accumulation time, 60 s. Other conditions, as in Fig. 1.
Fig. 4. Variation of i_p with molar ratio of [CNBD]:[Arg]. Supporting electrolyte. 0.04 M phosphate buffer at pH 2.0: accumulation time, 60 s at − 100 mV; other conditions, as in Fig. 1.

the final experiments. By mass spectrometry, the estimated stoichiometry for the compound NBD–Arg is 2:1, assuming that the molecular weight of the molecular ion is 499. From the results plotted in Fig. 4, a formation constant of $K_f = (1.4 + 0.4)10^{11}$ M^{-2} [53] has been evaluated.

The variation of the accumulation time was performed with different concentrations of arginine, maintaining the ratio of Arg to CNBD at 1:4 (mol/mol). The results are shown in Fig. 5. At high NBD–Arg concentrations the adsorption is rapid, decreasing i_p values are observed while the accumulation time increases once a maximum value has been reached. A maximum value for i_p for smaller concentrations of amino acid is observed and once the maximum i_p has been reached, i_p decreases for longer accumulation times. Therefore the same tendency is maintained but in a less pronounced way. From these results. an accumulation time of 120 s for the final studies has been chosen.

With the study of the influence of square wave frequency on the electrochemical response, several kinetic aspects, as well as the optimization of this parameter for the analytical application, can be deduced. The variation of i_p with square wave

frequency has a linear relationship according to the equation:

$$i_p(\mu A) = 0.77 + 4.26 \times 10^{-2} f(Hz) \quad r^2 = 0.995$$

These data show that the process of electrochemical reduction of the nitrobenzene group in NBD–Arg is regulated by a diffusion-controlled adsorption [54–57]. A square wave frequency of 120 Hz was chosen as optimum for the final experiments.

The variation of E_p with the logarithm of the square wave frequency is adjusted to a linear equation:

$$E_p(mV) = -192.8 - 46.9 \log f(Hz) \quad r^2 = 0.996$$

From the value of the slope, which corresponds to the expression $\Delta E_p / \Delta \log f = - RT/Fn\alpha$ [54], the charge rate coefficient can be evaluated. From a coulometric experiment performed using the conditions described in Section 2, the total charge exchanged on the electrode surface was 0.77 C, after blank subtraction, for 10.0 ml of a solution of 1.0×10^{-4} M NBD–Arg. We have taken into account that the electroactive group studied (peak II, Fig. 1) is due to the reduction of nitrobenzene

Fig. 5. Variation of i_p with accumulation time. Supporting electrolyte, 0.04 M phosphate buffer at pH 2.0; accumulation potential − 100 mV for 60 s; other conditions as in Fig. 1. Concentrations of NBD–Arg: ($\bigtriangledown$) 2.5×10^{-6} M; ($\Diamond$) 5.0×10^{-7} M; ($\bigcirc$) 2.5×10^{-7} M; ($\bigcirc$) 5.0×10^{-8} M.
Fig. 6. Cyclic voltammogram of CNBD–Arg with a [CNBD]:[Arg] ratio of 4:1. Conditions: accumulation time. 60 s at 100 MV; supporting electrolyte. 0.04 M phosphate buffer at pH 2.0; scan rate. 100 mV s^{-1}.

group (Ph–NO$_2$ → Ph–NHOH), and that two NBD groups are bound to the molecule of arginine. Then, the number of electrons involved in the electrochemical process, $n = 4$, is obtained. Therefore, a charge rate transfer coefficient of $\alpha = 0.31$ is obtained.

These data can be confirmed by cyclic voltammetry. The voltammograms recorded (as shown in Fig. 6) have the characteristic shape of a totally irreversible electrochemical process and correspond to the electrochemical reduction of a nitrobenzene group. There is a shoulder at a potential more anodic than the peak of NBD–Arg and this is due to the excess of CNBD that has not reacted with arginine. The NBD–Arg complex is strongly adsorbed on the electrode surface and hence the CNBD peak (peak I) is overlapped by the NBD–Arg peak (peak II). The variation of i_p with scan rate is linear, according to the equation:

$$i_p(\mu A) = 1.45 \times 10^{-2} - 1.53 \times 10^{-2}v \quad r^2 = 0.987$$

where v is expressed in millivolts per second. The representation of peak current vs. scan rate indicates that it is a diffusion-controlled adsorption

process. The variation of the logarithm of peak current with peak potential obtained for each applied scan rate is linear, according to the equation:

$$\log(i_p) = -4.48 - 1.73 \times 10^{-2}E_p(mV)$$

$$r^2 = 0.979$$

where i_p is expressed in microamperes. The value of the slope, which corresponds to the expression $\Delta \log i_p/\Delta E_p = -\alpha nF/RT$ [57], allows one to evaluate the charge rate coefficient. A charge rate coefficient of $\alpha = 0.29$ is obtained by cyclic voltammetry, which is very close to the value obtained by square wave voltammetry.

Up to a square wave amplitude (SWa) of 50 mV, the peak current increases with the SWa, and for higher values of SWa the peak current remains constant. Hence. a SWa of 50 mV is applied for the final studies. Up to a SWa of 10 mV, the representation of i_p vs. SWa is adjusted to a straight line according to the equation:

$$i_p(\mu A) = 0.122 + 174.0 \, SWa(V) \quad r^2 = 0.990$$

The electrode surface concentration on the mercury drop can be calculated from the value of the slope of this equation [57]. The electrode area is 0.0278 cm^2 and hence a value of $\Gamma = 4.3 \, 10^{-9}$ mol cm^{-2} is obtained.

There is an increase in i_p with the scan increment range studied, from 1 to 10 mV; there is also an increase in half peak width from 65 to 155 mV with scan increment from 1 to 10 mV respectively as well. Therefore, with an agreement between selectivity and sensitivity in order to get the best optimization of the method, a scan increment of $\Delta E = 4$ mV is applied for the final studies.

Once all the parameters that can affect the determination of arginine with CNBD have been studied, the variation of the peak current with concentration of NBD–arginine is performed. The most suitable conditions obtained from the previous studies of the experimental parameters have been applied.

A series of arginine solutions of different concentrations reacted with the CNBD in a ratio of CNBD:Arg = 8:1 using the method described in Section 2. An aliquot of each reaction product is

added to a solution of 0.08 M phosphate buffer at pH 2.0 as the supporting electrolyte. An accumulation potential of -100 mV was applied for 120 s followed by an equilibration time of 2 s at -100 mV. The voltammograms were recorded with a square wave frequency of 120 Hz, a scan increment of 4 mV and a square wave amplitude of 50 mV.

A linear relationship between the peak current and the concentration of arginine in the concentration range 5.0–85.0 nM (1.05–17.9 ng ml^{-1} or arginine) is obtained according to the equations, adjusted by least-squares:

$$i_p(\mu A) = -0.0852 + 0.0256C$$

where C is the concentration of arginine expressed in nanomolar and

$$i_p(\mu A) = -0.0852 + 0.122C$$

where C is the concentration of arginine expressed in nanograms per milliliter. The correlation coefficient in both cases is $r^2 = 0.999$.

From the corresponding statistical study, the proposed method allows one to perform the determination of arginine with a relative error of $\leqslant$ 2.0% and a relative standard deviation of $\leqslant 5.7\%$. From the standard deviation of the blank, a limit of detection (3σ) of 3.64 nM (0.766 ng ml^{-1}) and a limit of determination (10σ) of 12.12 nM (2.55 ng ml^{-1}) are obtained.

Using the same experimental conditions for other NBD amino acid complexes, similar results are obtained, as expected. In fact, CNBD is not a specific reagent for arginine but it is for general use with primary and secondary amines. Different calibration plots for each amino acid, with small variations in sensitivity, are obtained. These variations depend on the stoichiometry of each NBD– amino acid and on the amount of NBD–amino acid adsorbed on the mercury electrode. Fig. 7 shows the corresponding standard additions of several NBD–amino acids in a 25 nM solution of NBD–Arg. Hence, the proposed method can be used as a general method for the determination of amino acids. It is necessary to apply a separation method for the determination of a single amino acid in urine samples following the method described above.

The quantification of the levels of amino acids in urine, once the separation method has been applied, can be performed using the calibration plot. The recovery in this procedure is $79 \pm 3\%$ for all samples. The recovery was monitored in each part of the separation method using both spectrophotometry with ninhydrin [58] and the proposed voltammetric method and similar results were obtained in all cases. The levels of amino acids found in urine samples taken from ten different individuals were in the range 3.5–4.8 nM.

The following list gives some representative values of individual amino acid concentrations (mM) found in urine. The pH values of the collected fractions are shown in parenthesis.

| Arginine	0.02–0.04	(4.87)
Aspartic acid	0.05–0.08	(2.62)
Lysine	0.10–0.16	(4.53)
Glycine	1.20–1.60	(3.33)
Aspargine	0.03–0.06	(4.18)
Cysteine	0.08–0.12	(3.48)
Tryptophan	Absence	(3.23)
α-NH$_2$-butyric acid	Absence	(3.07)

Fig. 7. Standard additions of NBD–amino acids in 35.0 nM solutions of NBD–Arg. Conditions: supporting electrolyte, 0.08 M phosphate buffer at pH 2.0; accumulation potential, -100 mV for 120 s; SW amplitude, 50 mV; SW frequency, 120 Hz; scan increment, 4 mV. (○) NBD–Aspartic acid; (◇) NBD–lysine; (▽) NBD—aspargine; (○) NBD–serine.

Similar results have been obtained using spectrophotometry with ninhydrin as well. The relative standard deviations for the amino acid determinations are ≤ 6.2%. These values are in the range of normal levels of amino acids in urine for healthy humans [59].

Spectrophotometric determinations of some phenothiazine drugs

H.D. Revanasiddappa*, P.G. Ramappa

Department of Studies in Chemistry, University of Mysore, Manasagangotri, Mysore-570 006, India

Abstract

A rapid and sensitive spectrophotometric method has been developed for the quantitative determination of some phenothiazine derivatives as the pure substances and in different dosage forms. The method is based on the formation of red coloured products with 1% iodic acid in sulphuric or phosphoric acid medium. The reaction involves oxidation of the phenothiazine nucleus into a semiquinonoid radical. The optimum reaction conditions and other analytical parameters are evaluated. The influence of the substrates commonly employed as excipients with phenothiazine drugs has been studied. Statistical comparison of the results with those of an official method shows excellent agreement and indicates no significant difference in precision.

1. Introduction

Phenothiazine drugs are now widely used as tranquillizers, antihistaminics, antiemetics, analgesics and sedatives. In view of their importance considerable work has been done on their detection and quantification. Methods used for the determination of these drugs include titrimetry [1,2], spectrophotometry [3–8], fluorimetry [9], coulometry [10], gas liquid chromatography [11] and high performance liquid chromatography [12,13]. The official methods normally involve non-aqueous titrimetry or ultraviolet spectrophotometry [14–16]. The widespread use of these drugs has necessitated the development of a rapid, simple and precise method for their quality control.

In the present paper, a study of the spectrophotometric determination of seven phenothiazine drugs is described. The proposed method is based on interaction of phenothiazines with iodic acid in the presence of sulphuric or phosphoric acid medium to yield a red coloured product. The proposed method has been applied to the assay of these drugs in tablets, injection solutions, syrups and elixirs.

Experimental

2.1. Apparatus

Jasco model UVIDEC-610 and Elico model CL-27 spectrophotometers with 1 cm matched quartz cells were used for all absorbance measurements.

[a] Average recovery from six experiments.

2.2. Reagents

All chemicals were of analytical-reagent grade. 1% iodic acid was prepared in distilled water.

2.3. Standard solutions of phenothiazines

Aqueous solutions of promethazine hydrochloride (PMH; Rhone-Poulenc Ltd., India), isothipendyl hydrochloride (IPH; German Remedies Ltd., India), thioproperazine mesylate (TPPM; Rhone-Poulenc), trifluoperazine hydrochloride (TFPH; SKF Ltd., India), fluphenazine dihydrochloride (FPH; Sarabhai Chemicals, India), trifluopromazine hydrochloride (TPH; Sarabhai Chemicals) and prochlorperazine maleate (PCPM; Rhone-Poulenc) were prepared by dissolving the requisite amount of the samples in distilled water. Insoluble PCPM was dissolved by the addition of a few drops of dilute hydrochloric acid. Working solutions were prepared as required by dilution.

2.4. Standard procedure for the determination of phenothiazines

An aliquot of the sample solution containing 12.5–800 μg of PMH, 5–900 μg of IPH, 7.5–800 μg of TPH, 5–1000 μg of TPPM, 10–1000 μg of FPH, 2.5–625 μg of TFPH or 10–1250 μg of PCPM was transferred into a series of 25 ml standard flasks. The acid concentration was adjusted to 3 M for PMH, 1.5 M for IPH and TPPM, and 1 M for FPH and TFPH with orthophosphoric acid and to 1 M for TPH and PCPM with sulphuric acid. 2 ml of 1% iodic acid was added to each flask, the contents were diluted to the mark with distilled water and mixed well. The absorbance was measured at 515 nm for PMH, at 510 nm for IPH and TPPM, at 500 nm for TPH, FPH and TFPH and at 525 nm for PCPM against the corresponding reagent blank. A calibration graph was drawn or regression equation calculated.

2.5. Analysis of synthetic mixtures containing phenothiazines

Synthetic mixtures with the compositions given in Table 1 were prepared. A portion of the mixture containing about 25 mg of PMH, IPH, TPPM, TFPH, FPH, TPH and PCPM was accurately weighed. The phenothiazine was extracted from the mixture, filtered and washed with distilled water. The filtrate and washings were then combined in a 100 ml calibrated flask and the volume was made up with distilled water. An aliquot of this solution was treated as described in Section 2.4, the drug content was evaluated and the results are presented in Table 1.

2.6. Procedure for pharmaceutical formulations

A quantity of the sample (a mixture of 20 powdered tablets) equivalent to 25 mg of the drug

was weighed accurately and transferred into a 100 ml standard flask and the volume made up with distilled water and filtered. Appropriate aliquots of the drug solution were taken and the standard procedure was followed for the analysis of drug content.

For the analysis of injection solution, syrup and elixir, the requisite volume was transferred to a 100 ml calibrated flask and diluted to the mark with distilled water. The phenothiazine content in the diluted solution was determined as described above. The results of the analysis are given in Table 2.

3. Results and discussion

Phenothiazines undergo one-electron reversible oxidation in acid medium to form a red intermediate which is believed to be a radical cation [17]. This was confirmed by the ion-exchange technique. The red species was retained by cation-exchange resin but not retained on an anion-exchange resin column.

3.1. Effect of acids

The stability of the coloured species depends on the nature of the acid medium. The red species is unstable in hydrochloric acid medium, and does not give maximum colour intensity in acetic acid medium. The maximum colour development is obtained in the range 1.0–2.0, 3.0–5.0, 0.75–3.0, 0.5–2.5 and 0.5–3.0 M orthophosphoric acid for IPH, PMH, TPPM, FPH and TFPH respectively. The maximum absorbance is obtained immediately and remained constant for a period of 12, 15, 14, 12 and 13 min for IPH, PMH, TPPM, FPH and TFPH respectively. The maximum colour intensity is obtained in the range 0.5–2.0 and 0.5–2.5 M sulphuric acid for TPH and PCPM respectively. The maximum absorbance is obtained instantaneously and is stable for a period of 13 and 15 min for TPH and PCPM respectively. Attempts to increase the stability of the coloured species were not successful. The intensity and stability observed are in the order $H_3PO_4 > H_2SO_4 \gg HCl \ggg CH_3COOH$ for PMH, TPPM, FPH and TFPH; $H_3PO_4 > H_2SO_4 > HCl$

Table 3
Optical characteristics and precision data

Parameter	PMH	IPH	TPH	PCPM	TPPM	FPH	TFPH
Beer's law limit (μg ml^{-1})	0.5–32	0.2–36	0.3–32	0.4–50	0.2–40	0.4–40	0.5–25

Sandell's sensitivity (mg cm^{-2} per 0.001 abs. unit)	0.063	0.0875	0.099	0.1273	0.114	0.0835	0.072
Correlation coefficient (r) Regression equation (Y)[a]	0.99	0.995	0.999	0.99	0.995	0.999	0.9999
Slope (b)	0.01295	0.00749	0.0093	0.00693	0.00894	0.00966	0.0105
Intercept (a)	0.05803	0.0099	0.0116	−0.007	−0.0021	0.02358	0.0177
% Relative standard deviation	0.95	1.2	1.1	1.25	1.1	1.3	0.99

[a] $Y = a + bx$, where x is the concentration in μg ml^{-1}.

for IPH; and $H_2SO_4 \approx H_3PO_4 \gg HCl \ggg CH_3$-COOH for TPH and PCPM. The colour is not obtained in acetic acid medium for IPH. Hence, 1.5 M and 1.0 M H_3PO_4 for IPH, TPPM and FPH, TFPH and PMH respectively, 1.0 M H_2SO_4 concentrations for TPH and PCPM were maintained in subsequent studies.

3.2. Effect of iodic acid concentration

The effect of the concentration of iodic acid was studied by measuring the absorbances at the specified wavelengths in the standard procedures for solutions containing a fixed concentration of phenothiazine and varying amounts of iodic acid. The constant absorbance readings were obtained in the range 1.0–5.0, 0.5–5.0, 1.0–7.0, 1.5–7.0, 1.0–5.0, 1.0–7.0 and 1.5–8.0 ml of 1% iodic acid solution for PMH, IPH, TPH, PCPM, TPPM, FPH and TFPH respectively. A volume of 2 ml of 1% iodic acid in a total volume of 25 ml was used in all subsequent work.

The maximum colour intensity remained constant in the temperature range 3–35°C. The order of addition of reagents had no effect. Beer's law range, molar absorptivity, slope, intercept and correlation coefficients obtained by linear least-squares treatment of the results are presented in Table 3.

3.3. Effect of diverse ions

The extent of interference by common anions and substances was determined by measuring the absorbance of a solution containing 20 ppm of phenothiazines and various amounts of diverse ions. An error of ± 2.5% in the absorbance readings was considered tolerable. The substances tested and the tolerance limits found are presented in Table 4. The proposed method is free from interferences by various ions and concomitant substances.

To test the accuracy of the method, recovery experiments were performed on synthetic mixtures prepared in the laboratory. The usual tablet diluents and excipients were found not to interfere with the analysis by the proposed method (Table 1).

The proposed method was successfully applied to the analysis of phenothiazine drugs in various pharmaceutical preparations. The contents of the phenothiazine drug were calculated using the formula

$$\text{mg phenothiazines} = \frac{A_t \times D \times C}{A_s \times 1000}$$

where A_t and A_s are the absorbances of the test and standard solutions respectively, D is the dilution factor and C is the concentration of phenothiazines in μg ml^{-1}. The samples were also determined by the regression equation method. The results of the assay of the tablets, injection

solutions and syrup presented in Table 2 compare favourably with the official methods of the British Pharmacopoeia and the United States Pharmacopoeia [14–16]. The proposed method, which is simple and rapid, offers the advantages of sensitivity and a wide range of determination without the need for extraction or heating. The assay method does not involve any critical reaction conditions or tedious sample preparation. The method is unaffected by slight variations in experimental conditions such as acidity, reagent concentration and temperature. The wide applicability of the new procedure for routine quality control is well established by the assay of the phenothiazines in pharmaceutical preparations.

A conductance sensor for dissolved sulphur dioxide using a series piezoelectric crystal device

Yuanjin Xu, Changyin Lu[1], Kang Chen, Lihua Nie, Shouzhuo Yao*

Department of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, People's Republic of China

Abstract

A new piezoelectric crystal impedance sensor for the determination of sulphur dioxide in aqueous solution is presented. It is realized using a series piezoelectric crystal device which is constructed by connecting an AT-cut piezoelectric crystal to a probe in series. The probe is filled with an internal electrolyte solution that is separated from sample solutions by a gas-permeable membrane. The present sensor exhibits a favourable frequency response to 1×10^{-7}–1×10^{-3} M sulphur dioxide. The detection limit is 1×10^{-8} M. The effects of the sensor preparation are considered. Dynamic range, reproducibility, response time and selectivity of the sensor are also discussed. The proposed sensor has been used successfully for lamp sulphur determinations in petroleum samples.

1. Introduction

By using selective absorbent coatings, piezoelectric crystal sensors have been developed into highly sensitive devices for the detection of traces of atmospheric pollutants [1]. For the detection of sulphur dioxide in air, several coated piezoelectric crystal sensors have been developed [2–4]. However, the coated piezoelectric crystal sensor cannot be used directly in the determination of sulphur dioxide in aqueous solution because it is very sensitive to interference from water vapour.

In order to overcome the water vapour response of the coated piezoelectric crystal sensor, we report a new piezoelectric crystal impedance sensor for dissolved sulphur dioxide. In contrast to the coated piezoelectric crystal sensor based on the mass effect of a piezoelectric crystal, this sensor is based on the high sensitivity to solution conductivity of the series piezoelectric crystal device [5, 6].

The series piezoelectric crystal, which is constructed by connecting an AT-cut piezoelectric crystal and a conductive electrode in series, possesses a high sensitivity to solution conductivity and a good frequency stability [5, 6]. The oscillation frequency, *F*, is expressed as

* Corresponding author.
[1] On leave from: Hengyang Medical College, Hunan 421001, People's Republic of China.

$$F = F_0 \left[1 + \frac{\pi F_0 C_m (2\pi F_0 C_s - YG)}{4\pi^2 F_0 C_s (C_0 + C_s) - 2\pi F_0 C_0 YG + G^2} \right. $$

$$\left. - \pi F_0 C_m R_m Y \right] \tag{1}$$

where F_0, C_m, R_m and C_0 are the resonance frequency, motional capacitance, motional resistance and static capacitance of the piezoelectric crystal respectively. G and C_s are the conductance and capacitance of solution respectively. $Y = \tan(\theta)$, where θ is the oscillator phase angle.

The sensitivity to conductivity, i.e. the slope of the plot of frequency F vs. conductivity χ, can be calculated by differentiating eq. (1) with respect to χ. The theoretical response sensitivity to conductivity with various cell constants is illustrated in Fig. 1 for typical values. It can be seen that the series piezoelectric crystal device still has a highly sensitive response even in solutions of rather high conductivity. Compared with the direct conductivity measurement method [7], the series piezoelectric crystal device can be used in samples which contain large amounts of unreacted foreign electrolytes. Hence, it can be used as a new type of practical sensor, just like the potentiometric pH sensor and fibre optical pH sensor, to develop gas sensors and enzyme sensors using additional membranes.
Fig. 1. Theoretical response sensitivity of the series piezoelectric crystal device to conductivity with various cell constants.

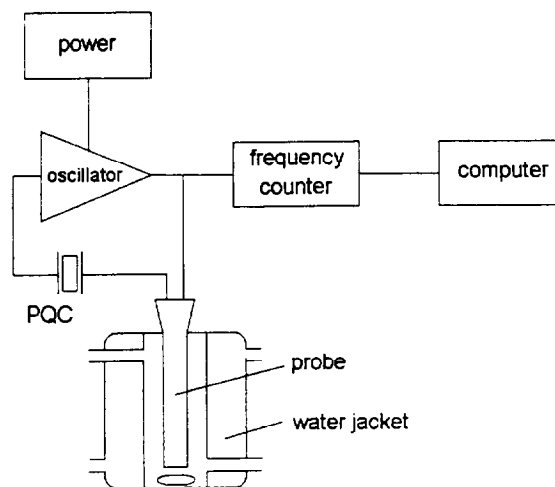

Fig. 2. Schematic diagram of the experimental system.

In this work, a novel impedance sensor for the determination of sulphur dioxide in aqueous solution was developed using a series piezoelectric crystal device. Unlike a potentiometric sensor [8–10], the proposed sensor requires neither a reference electrode nor a fragile internal glass pH electrode and thus it is simple to construct and easy to miniaturize. Compared with the sensor based on the conventional measurement of ionic conductivity with a mixed-bed ion exchanger used inside the sensing probe [11], the proposed sensor is very simple in design. Its high selectivity, utilizing an additional gas-permeable membrane, makes it suitable to be used directly in analytical determination of species in natural media. The use of the proposed sensor for lamp sulphur determination in petroleum samples was investigated. The accuracy of the sensor was also evaluated by comparing the results with those obtained by the conventional lamp sulphur determination method [12].

2. Experimental

2.1. Apparatus and reagents

The experimental apparatus was assembled as shown in Fig. 2. The IC-TTL oscillator was described previously [13]. The frequency output

from the oscillator was monitored by an Iwatsu Model SC7201 universal frequency counter and was recorded by a computer (Hewlett-Packard 300) which was interfaced to the frequency counter. The piezoelectric crystal was a 9 MHz AT-cut 12.5 mm disk with a gold electrode (6 mm in diameter) on both sides. The temperature of the test cell was thermostated at $25 \pm 0.1°C$ with a water jacket and a temperature controller. Teflon membranes with an average pore size of 0.02 μm were purchased commercially from Jiangsu Electroanalytical Instrument Co. An impedance analyzer (Hewlett-Packard 4192A) was used to measure the parameters of the sensor.

The probe is shown schematically in Fig. 3. The dimensions of the probe were about $15 \times 6 \times 0.3$ mm^3. Two finely ground platinum foils were used as electrodes. The thin layer between the electrodes was filled with an internal electrolyte solution (≈ 5 μl) which was separated from the sample solutions by two pieces of gas-permeable membrane mounted firmly on both sides of the probe. The cell constant of the probe was determined by measuring the conductance when the probe was filled with a standard KCl solution whose conductivity is accurately known.

The buffer solution used to acidify samples was made by adding 19 g Na_2SO_4 to about 800 ml of water in a 1 l volumetric flask, adding 5.3 ml of concentrated H_2SO_4 and diluting to the mark. The pH of the buffer was about 1.2. All other reagents used were of analytical grade. Doubly-distilled deionized water was used for all solutions.

Fig. 3. Schematic diagram of the probe: (1). (6) gas-permeable membranes; (2) thin layer of internal electrolyte solution; (3) insulation substrate; (4,5) platinum electrodes.

2.2. Procedures

Sensor calibration was performed by immersing the probe in 3 ml of buffer solution and making an addition of $NaHSO_3$ standard solution.

Petroleum samples were burnt by the lamp combustion method [12]. The absorption solution contained 10.86 g $HgCl_2$, 5.9 g KCl, 0.06 g Na_2 EDTA, 3.42 g $NaH_2PO_4 \cdot H_2O$, 3.52 g Na_2HPO_4, and 20 ml glycerine per liter. Before acidifying the absorption solution, 0.5 g of sulfamic acid was added to destroy absorbed nitrogen oxides [9]. Then, the sulphur dioxide in the absorption solution was measured with the proposed sensor. For comparison, the sulphur in the petroleum samples was also determined by the conventional lamp combustion–titrimetric method [12].

3. Results and discussion

3.1. Theoretical background

When the probe is in contact with a sample, gaseous sulphur dioxide diffuses across the gas-permeable membrane until its partial pressure is equal on both sides. The sulphur dioxide that diffuses into the internal electrolyte solution will dissolve in water and come to equilibrium with bisulphite [10]:
$$SO_2 + H_2O \rightleftharpoons HSO_3^- + 2H^- \qquad (2)$$
For the general case, the effect of sulphite must also be considered. The pertinent equilibrium equations are:

$$[SO_2] = K_p[H^+][HSO_3^-] \qquad (3)$$

$$[HSO_3^-] = K_1[H^+][SO_3^{2-}] \qquad (4)$$

$$[H^+][OH^-] = K_w \qquad (5)$$
where $\log K_p = 1.9$ and $\log K_1 = 6.8$.

With N as the $NaHSO_3$ concentration of the internal electrolyte solution, the electroneutrality condition leads to the following relationship:

$$N + [H^+] = [HSO_3^-] + 2[SO_3^{2-}] + [OH^-] \qquad (6)$$
When the sample is acidified in an air-tight test cell:

Fig. 4. Frequency response of the sensor: (——) simulated; (○) experimental data; (– – –) regression results of experimental data. Cell constant, 0.0120 m. Internal electrolyte solutions: 5×10^{-4} M $NaHSO_3 + 1\%$ glycerine.

$$[SO_2] = K_p[H^+]_s[HSO_3^-]_s \qquad (7)$$

$$[SO_2] + [HSO_3^-]_s = C \qquad (8)$$

where C is the $NaHSO_3$ concentration of the sample solution. The subscript "s" denotes the sample solution phase.

From eqs. (3)–(8), the concentrations of $[H^+]$, $[HSO_3^-]$ and $[SO_3^{2-}]$ can be given as a function of C using a computer. The conductance, G, of the internal electrolyte solution can be calculated as

$$G = k\{\lambda_{H^+}[H^+] + \lambda_{OH^-}K_w/[H^+] + \lambda_{Na^+}N$$

$$+ \lambda_{HSO_3^-}[HSO_3^-] + \lambda_{SO_3^{2-}}[SO_3^{2-}]\} \qquad (9)$$

where k is the cell constant of the probe. The limiting molar ionic conductance, λ, used is (10^{-4} m^2 S mol^{-1}): H^+, 350; OH^-, 198; Na^+, 50.1; HSO_3^-, 50.0; SO_3^{2-}, 159.8.

From eqs. (1) and (9), the frequency response of the sensor as a function of sample concentration C can be calculated. The plot of this function and the experimental data are shown in Fig. 4. The correlation between the simulated curve and the experimental results is quite good in low concentration of sample.

3.2. Choice of buffer composition

The influence of the $NaHSO_3$ concentration in the internal electrolyte solution on the sensitivity was investigated. The frequency responses of the sensor filled with various concentrations of $NaHSO_3$ solution are shown in Fig. 5. It is evident that for the sensor filled with lower $NaHSO_3$ concentrations the sensitivity is higher for low sample concentrations. However, the sensor filled with high $NaHSO_3$ concentrations produces curves with a steady, continuous response for high sample concentrations. In the following experiments, the probe was filled with 5×10^{-4} M $NaHSO_3$ solution.

The influence of unreacted foreign electrolytes which exist in the internal electrolyte solution on the sensor sensitivity was also investigated. The sensitivity of the sensor with various concentrations of added foreign electrolyte, KCl, is shown in Fig. 6. When the KCl concentration is less than 1×10^{-3} M, the influence of the unreacted foreign electrolytes on the sensitivity is slight.

The osmotic effect is inherent in the design of the probes where a semi-permeable membrane separates two solutions, the sample and the internal electrolyte film [8]. If the total concentrations of dissolved species on the two sides of the mem-

Fig. 5. Effect of $NaHSO_3$ concentration in internal electrolyte solution on sensor sensitivity. Cell constant, 0.0120 m. $NaHSO_3$ concentrations (M): (1), 0; (2), 1×10^{-4}; (3), 5×10^{-4}; (4), 1×10^{-3}.
Fig. 6. Effect of foreign electrolyte concentration in internal electrolyte solution on sensor sensitivity. Cell constant, 0.0120 m. KCl concentrations (M): (1), 0; (2), 1×10^{-4}; (3), 5×10^{-4}; (4), 1×10^{-3}; (5), 3×10^{-3}.

brane are different, then an osmotic pressure difference results and water vapour diffuses across the membrane until the water activity is the same on each side. Transfer of water across the membrane results in dilution or concentration of the internal electrolyte solution, which causes the sensor response to drift. In contrast to a potentiometric sulphur dioxide sensor which responds to the concentration of H^+ of the internal solution, this sensor responds to the amount of ionic species exiting the internal solution. The osmotic effect of the sensor can be neglected for short term measurements. However, for long term applications and in storage the osmotic effect must be considered. To reduce the osmotic effect, some non-electrolyte can be added to the internal solution according to the concentrations of dissolved species of the sample solutions. In this work, the sensor is stored in a dilute solution of Na_2SO_3. Therefore, 1% glycerine is used in the internal electrolyte solution to reduce the osmotic effect and to inhibit the chain reaction mechanism by which free sulphur dioxide is oxidized [9].

3.3. Effect of cell constant

The cell constant of the probe, k, is an important parameter for design of a series piezoelectric

crystal impedance sensor. Various values of k result in quite different sensitivities to the solution conductivity (χ), and alter the solution capacitance (C_s) of the probe since $G = k\chi$ and $C_s = k\varepsilon + C_p$, where ε is the dielectric constant of the solution and C_p is the parasitic capacitance between the leading wires of the probe. As k increases, the sensitivity to conductivity increases; meanwhile, the solution capacitance also increases which reduces the sensitivity of the sensor's frequency response to solution conductance. The frequency response sensitivity of the sensor is determined by these two opposing factors. As shown in Fig. 7, the sensitivity of the sensor reaches a maximum around $k = 0.01$ m and decreases significantly when k is 0.0247 m. In this experiment, the cell constant of the probe is 0.0120 m.

3.4. Response properties

The sensor filled with 5×10^{-4} M $NaHSO_3 +$ 1% glycerine solution exhibits a favourable response to 1×10^{-7}–1×10^{-3} M sulphur dioxide, with a detection limit of 1×10^{-8} M. For 13 calibration samples in the range 1×10^{-7}–1×10^{-4} M sulphur dioxide the regression equation is given by

Fig. 7. Effect of the cell constant on sensitivity. Internal electrolyte solutions: 5×10^{-4} M $NaHSO_3 +$ 1% glycerine; cell constants (m): (1), 0.0043; (2), 0.0094; (3), 0.0120; (4), 0.0154; (5), 0.0247.

Table 1
Interferences in the sensor detection of sulphur dioxide

Interferent	Interferent concentration (M)	Sulphur dioxide concentration (M)	
		Added	Found
CH_3COOH	1×10^{-5}	1×10^{-5}	1.02×10^{-5}
	5×10^{-5}	1×10^{-5}	1.08×10^{-5}
HF	1×10^{-5}	1×10^{-5}	1.03×10^{-5}
	5×10^{-5}	1×10^{-5}	1.13×10^{-5}
CO_2	1×10^{-4}	1×10^{-5}	1.03×10^{-5}

$$\Delta F = -720\,175C^{0.603} \tag{10}$$

where C is the concentration of the sample. As shown in Fig. 4, the curve tends to slope downwards at higher concentrations.

The recovery of sulphur dioxide added to 2×10^{-5} M sulphur dioxide samples was $98.6 \pm 4.2\%$ ($n = 5$).

The response time (to 95% of the steady state) of the sensor is ≈ 3.5 min for sulphur dioxide concentration change from 1×10^{-5} to 1×10^{-4} M.

To test the short time reproducibility of the sensor, the frequency response was measured when the sensor was exposed to repeated concentration step changes between 1×10^{-5} and 5×10^{-5} M for sulphur dioxide samples. For five concentration step changes, the standard deviations in frequency were 5.6 Hz and 8.3 Hz for 1×10^{-5} and 5×10^{-5} M sulphur dioxide, which correspond to standard deviations of sulphur dioxide concentration of 0.8% and 1.2% respectively.

The sensor was used for 4 weeks without replacing the internal electrolyte solution. There is no significant loss in sensitivity with the probe being kept in a dilute Na_2SO_3 solution when not in use.

3.5. Interferences

The samples were prepared in strongly acidic solutions and so interference from ammonium and volatile amines can be ignored. Several potential interferences were tested and the results are listed in Table 1. The probe used was filled with 5×10^{-4} M $NaHSO_3 + 1\%$ glycerine as internal electrolyte solution. The interference from dissolved carbon dioxide is negligible.

3.6. Sample analysis

The proposed sensor has been used to determine sulphur in petroleum samples. For comparison, the samples were also analyzed by the lamp combustion–titrimetric method [12]. The results are shown in Table 2. It can be seen that the results obtained from the proposed sensor agree well with those obtained by the titrimetric method.

3.7. Comparison with potentiometric sulphur dioxide sensor

As summarized in Table 3, the proposed sensor has advantages over conventional sulphur dioxide sensors in terms of high sensitivity and rapid response. In addition, the proposed sensor is simple to construct and easy to miniaturize as it requires neither the reference electrode and fragile glass pH electrode which are used in the potentiometric sulphur dioxide sensor nor the mixed-bed ion exchanger which is used in the conventional conductivity sensor. Compared with the coated piezoelectric crystal gas sensor, the proposed sensor can be applied to aqueous samples directly. The advantages of this sensor should make it an attractive alternative to the sensors currently in use.

Table 2
Determination of sulphur in petroleum samples

Sample	Sulphur (wt.%)[a]	
	Proposed sensor	Titrimetric method
1	0.038 ± 0.0019	0.039 ± 0.0015

Extraction of ternary complexes of thorium(IV) with 3-phenyl-4-benzoyl-5-isoxazolone and neutral donors from nitric acid medium

P. Thakur[1], R. Veeraraghavan, P.K. Mohapatra, V.K. Manchanda*, K.C. Dash[1]

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400085, India

Abstract

The extraction behaviour of thorium(IV) from aqueous nitric acid employing 3-phenyl-4-benzoyl-5-isoxazolone (HPBI) in the presence of tri-n-octyl phosphine oxide (TOPO) as well as tri-n-butyl phosphate (TBP) in xylene medium was investigated. The extraction constant ($\log k_{ex}$) for the binary organic phase species Th(PBI)$_4$ was determined to be 8.26 which is by far the largest amongst the corresponding values known for other β-diketones. The overall extraction constant ($\log K$) for the ternary species Th(PBI)$_4$·TBP and Th(PBI)$_4$·2TOPO were estimated to be 14.96 and 20.96 respectively. An inverse correlation of the adduct formation constant ($\log K_s$) with the pK_a of the β-diketones, 2-thenoyltrifluoroacetone, 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone and HPBI, was observed. The steric as well as the electronic effects of adduct formation have been discussed. Analytical application of HPBI for the separation of ^{234}Th radiotracer from natural uranium (99.3% ^{238}U) has been suggested.

Keywords: Extraction; HPBI; Thorium(IV)

1. Introduction

The extraction behaviour of metal ions using β-diketones has been studied extensively [1]. This class of ligands is fascinating because of their unique property of extracting metal ions over a wide range of acidities with the proper choice of substituents. Employing dioxouranium(VI) as a typical metal ion, it has been shown by Batzar et

al. [2] that the lower the pK_a value of the β-diketone, the higher is the two-phase equilibrium constant of the binary extraction system as well as that of the ternary (synergistic) extraction system. Actinide ions, due to their large coordination number, invariably form coordinatively unsaturated β-diketonates which partition as hydrates towards the organic phase. The substitution of the inner-sphere water molecules by a neutral donor leads to higher distribution ratio values due to the enhanced organophilicity of the ternary complex.

In view of its modest pK_a value, favourable partition coefficient towards the organic phase

and easy commercial availability, 2-thenoyltri-fluoroacetone (HTTA; Fig. 1, **I**) is the most extensively used β-diketone for analytical applications. However, it has a few limitations such as slow kinetics, poor loading characteristics, photo-sensitive decomposition, hydrolysis under conditions of high pH (> 7.0) and above all its inability to extract metal ions from strong acidic and complexing media. Pyrazolones and isoxazolones, however, have been found to be particularly effective analytical extractants for actinide ions from strong acidic as well as complexing media [3,4] encountered at different stages of the nuclear fuel cycle. The much lower pK_a values of these ligands arise due to the participation of the heterocyclic ring in electron delocalization, imparting additional resonance stabilization. Some recent reports explain the better extractability of these ligands based on the O–O distance [5].

We have been investigating the extraction behaviour of actinide ions such as UO_2^{2+}, Pu^{4+}, Np^{4+}, Am^{3+} etc. with pyrazolones and isoxazolones [6–10]. It was observed that whereas neutral donors such as tri-n-butyl phosphate (TBP) and tri-n-octyl phosphine oxide (TOPO) significantly enhance the extraction of bivalent uranyl ion and trivalent americium ion by the chelating extractants, such enhancement was marginal for tetravalent plutonium. This was attributed to the relatively small ionic radius of Pu^{4+} which offers large steric hindrance to the coordination of the neutral oxo donor when it is surrounded by four β-diketone moieties. It is envisaged that the larger size of Th^{4+} would help in reducing the steric hindrance offered to the incoming organophilic oxo donor, thereby increasing the extractability of the metal ion significantly. TBP and TOPO have widely differing basicities and are well known extractants employed in the nuclear industry. 3-Phenyl-4-benzoyl-5-isoxazolone (HPBI; Fig. 1, **III**) is known to have a much lower pK_a value than either HTTA or 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (HPMBP; Fig. 1, **II**). Therefore it was of interest to investigate the extraction behaviour of Th(IV) using HPBI as the chelating extractant and TOPO and TBP as the auxiliary ligands. Xylene was employed as the organic diluent. An attempt has also been made to compare

the extraction constant data obtained in the present work with those for similar systems involving either **I** or **II** reported in the literature.
2. Experimental

2.1. Reagents

HPBI was prepared by the method reported in the literature [11] and recrystallized from benzene –hexane medium. The purity was checked by elemental analysis: %C = 72.50 (72.45); %H = 4.00 (4.15); and %N = 5.60 (5.28); m.p. = 146°C. The stock solution (2.00 × 10^{-2} M) was prepared by weighing the desired quantity of HPBI in xylene and was pre-equilibrated for 24 h using 1 M HClO$_4$. A stock solution of Th^{4+} (1.0 × 10^{-2} M) was prepared in 1 M nitric acid using the metal nitrate (Th(NO$_3$)$_4$·6H$_2$O) and was diluted to the desired concentration for the extraction studies.
Arsenazo III solution was prepared by dissolving 25 mg of the reagent procured from Merck

[b] $[HNO_3] = 1.00$ M

(Germany) in 25 ml of distilled water. Analar grade TBP from BDH, proanalysi grade TOPO and extra pure grade xylene from E. Merck were used as received.

2.2. Procedure

2.2.1. Distribution studies

The aqueous phase (usually 1 ml) containing Th(IV) at the desired concentration of HNO$_3$ was equilibrated with the required organic phase (1 ml) containing the extractant. The equilibration was usually carried out for 1 h in a thermostated water bath at $25 \pm 0.1°C$. Subsequently the equilibration tubes were centrifuged, phases were separated and aliquots from the aqueous phase (200–500 μl) were assayed by spectrophotometry using a Beckmann DU-7 single beam spectrophotometer.

The equilibrium concentration of Th(IV) in the organic phase was determined by the difference between the initial and final Th concentrations in the aqueous phase. Occasionally the organic phase containing thorium was stripped by 10 M HNO$_3$ and the metal concentration was estimated by the above method. Excellent agreement ($\pm 2\%$) was observed between the Th concentrations determined by these two methods. Details of the experimental conditions employed for the present studies are listed in Table 1. The distribution ratio D was defined as the ratio of the

concentration of Th in the organic phase to that in the aqueous phase. The experiments were carried out in duplicate and the precision was found to be within $\pm 5\%$.

2.2.2. Estimation of Th

Thorium was assayed spectrophotometrically using Arsenazo III which forms a stable chelate compound with the former [12]. Fig. 2 shows the visible spectra of Arsenazo III and its complex with Th(IV). To arrive at the optimum HNO$_3$

Fig. 2. Visible spectra of (a) 2.8×10^{-5}M Arsenazo III; (b) 3.2×10^{-6}M Th(IV) in 2.8×10^{-5}M Arsenazo III.

concentration for absorbance measurements, experiments were carried out in the acidity range 2.4–7.2 M. It was observed that the sensitivity of the measurement increases with acidity up to 4.8 M, remains constant in the range 4.8–6.5 M and decreases thereafter at higher acidity. All the measurements in the present studies were therfore carried out with 6 M HNO_3. Th(IV)–Arsenazo III complex was developed in 10 ml of solution containing 1 ml of 0.1% Arsenazo III solution and varying concentrations of thorium followed by the addition of 5 ml of 12 M HNO_3 and 1 ml of sulfamic acid (1 M). The absorbance of the solution against a suitable blank was measured at 660 nm. Beer's law was obeyed in the Th^{4+} concentration range 1.1×10^{-6} M–6.5×10^{-6} M. The molar extinction coefficient was determined to be 1.0×10^5 M^{-1} cm^{-1}.

3. Calculations

The extraction of Th(IV) by a β-diketone (HA) is represented by

$$Th^{4+} + 4HA_{(o)} \rightleftharpoons ThA_{4(o)} + 4H^+ \tag{1}$$
The subscript "o" refers to the species in the organic phase and those species without a subscript are in the aqueous phase. Charges of the species are omitted henceforth for the sake of simplicity. Applying the law of mass action, the extraction equilibrium constant (k_{ex}) can be expressed as

$$k_{ex} = \frac{[ThA_4]_o[H]^4}{[Th][HA]_o^4} \tag{2}$$

Neglecting the complexation by the isoxazolonate anion (A^-) in the aqueous phase [13], the distribution ratio for the binary extraction system Th(IV)–HA from nitric acid medium is given as

$$D_o = \frac{[ThA_4]_o}{[Th]\{1 + \sum \beta_i[NO_3]^i\}} \tag{3}$$

where β_i are the complex formation constants of Th^{4+} with nitrate ion in the aqueous phase ($\log \beta_1 = 0.1$; $\log \beta_2 = 0.8$) [14]. For the calculation of k_{ex}, the corrections for the aqueous com-

plexation of nitrate ion have been incorporated. On rearrangement Eq. (2) becomes:

$$\log k_{ex} = \log D_o + 4\log[H] - 4\log[HA]_o + \log(1 + X) \tag{4}$$

where $X = \sum \beta_i[NO_3]^i$. For a synergistic extraction system employing a neutral donor S the extraction equilibrium may be represented as

$$Th + 4HA_{(o)} + nS_{(o)} \overset{K}{\rightleftharpoons} ThA_4S_{n(o)} + 4H \tag{5}$$
The overall extraction constant (K) is given as

$$K = \frac{[ThA_4S_n]_o[H]^4}{[Th][HA]_o^4[S]_o^n} \tag{6}$$

The distribution ratio for the synergistic extraction system (D) is given by

$$D = \frac{[ThA_4]_o + [ThA_4S]_o + [ThA_4S_2]_o + \cdots + [ThA_4S_n]_o}{[Th]\{1 + X\}} \tag{7}$$

From Eqs. (2), (6) and (7):

$$K = \frac{(D - D_o)[H]^4(1 + X)}{[HA]_o^4[S]_o^n} \tag{8}$$

Taking the logarithm:

$$\log K = \log(D - D_o) - 4\log[HA]_o - n\log[S]_o + 4\log[H] + \log[1 + X] \tag{9}$$

In the case where S = TOPO, K is referred to as K' for $n = 1$ and as K'' for $n = 2$. Determination of K' and K'' was done graphically by following the method reported earlier [7]. The organic phase adduct formation reaction is represented as

$$ThA_{4(o)} + nS_{(o)} \overset{K_S}{\rightleftharpoons} ThA_4S_{n(o)} \tag{10}$$

where K_S, the organic phase adduct formation constant, is given as

$$K_S = \frac{[ThA_4S_n]_o}{[ThA_4]_o[S]_o^n} \tag{11}$$

From Eqs. (2), (6) and (11):

$$K_S = K/k_{ex} \tag{12}$$

or

Table 2
Parameters of the equations for the best fit linear regression lines

Variable	Fixed parameter	Slope	Intercept	r^2
[PBI]	[H$^+$]	3.89 ± 0.08	9.37 ± 0.18	0.999
[H$^+$]	[PBI]	-3.78 ± 0.04	-1.55 ± 0.02	0.999
[TBP]	[PBI], [H$^+$]	0.97 ± 0.02	3.49 ± 0.07	0.999
[TOPO]	[PBI], [H$^+$]	1.29 ± 0.10	6.31 ± 0.41	0.991
[PBI]	[TBP], [H$^+$]	4.05 ± 0.10	10.41 ± 0.27	0.999
[PBI]	[TOPO], [H$^+$]	3.81 ± 0.15	11.74 ± 0.43	0.997

$$\log K_S = \log K - \log k_{ex} \qquad (13)$$

The interaction of TOPO with HNO$_3$ was considered to compute the concentration of the free ligand at equilibrium. It was unnecessary to follow this step in the case of TBP due to its lower basicity. Equilibrium constants for the acid uptake by TOPO are expressed as

$$H + NO_3 + TOPO \overset{K_H}{\rightleftharpoons} HNO_3.TOPO \qquad (14)$$

Total TOPO, [TOPO]$_t$, present in a distribution experiment is distributed as

$$[TOPO]_t = 2 \times [Th(NO_3)_4 \cdot 2TOPO]$$

$$+ [Th(PBI)_4 \cdot TOPO]$$

$$+ 2[Th(PBI)_4 \cdot 2TOPO]$$

$$+ [HNO_3 \cdot TOPO] + [TOPO]_f \qquad (15)$$

where [TOPO]$_f$ is the free concentration of TOPO at equilibrium. In the present experiments where the thorium concentration varies in the range $2.0 \times 10^{-5} - 2.8 \times 10^{-5}$ M and [TOPO]$_t$ varies in the range $2.5 \times 10^{-4} - 2.0 \times 10^{-3}$ M, TOPO bound to Th(IV) was found to be negligible (< 3%). However, TOPO bound with HNO$_3$ as HNO$_3 \cdot$TOPO is a large proportion of [TOPO]$_t$:

$$[TOPO]_f = \frac{[TOPO]_t}{1 + K_H} \qquad (16)$$

where K_H for TOPO is 8.9 [10]. [TOPO]$_f$ was employed throughout for the equilibrium constant data calculations as well as for the determination of the stoichiometry of the extracted species.

4. Results and discussion

4.1. Extraction of Th(IV) by HPBI alone

The variation of $\log D$ with $\log[HPBI]$ is linear with a slope of 3.89 ± 0.08 (Table 2) indicating that four moieties of the β-diketone are associated with the extracted species. The dependence of $\log D$ on log(hydrogen ion activity) is found to be -3.78 ± 0.04 (Table 2), thereby suggesting the validity of Eq. (4). These observations are consistent with the organic phase species Th(PBI)$_4$. Table 3 gives the extraction constant values obtained graphically as well as algebraically after incorporating nitrate complexation correction factors. The difference in the $\log k_{ex}$ values obtained by the two methods is due to the small variations in the observed slopes as compared to the expected values (Table 2), although it is within the statistical variation limit (95% confidence level). It is fascinating to note that the extraction constant for the Th(IV)–HPBI system is much larger than those for the Th(IV)–HPMBP [15] and Th(IV)–HTTA systems [16]. The $\log k_{ex}$ value obtained in the present work is larger than that reported by Jyothi and Rao [13], probably due to the use of diluents of different polarities in the two studies. The $\log k_{ex}$ values increase in the order Th(IV) < Np(IV) < Pu(IV) which follows their ionic potentials [6,8,9].

4.2. Synergistic extraction studies

Synergistic extraction of Th(IV) by HPBI and neutral donors has been carried out from 1 M HNO$_3$. Table 2 indicates the linear nature of the plots of $\log(D - D_o)$ vs. $\log[HPBI]$ at a fixed

Table 3
Extraction constants of Th(IV) in binary and ternary systems

Extraction constant (binary/ternary)	Variable	Graphical method	Algebraic method	Mean
$\log k_{ex}$	HPBI	7.95 ± 0.18	8.22 ± 0.04	
				8.26 ± 0.04
	H$^+$	8.37 ± 0.01	8.29 ± 0.04	
$\log K$ (TBP)	HPBI	15.06 ± 0.27	14.88 ± 0.04	
				14.96 ± 0.04
	TBP	14.93 ± 0.07	15.03 ± 0.02

$\log K''$ (TOPO)	TOPO	20.96 ± 0.47	–	

concentration of nitric acid as well as neutral oxo donor. Slope values of 3.81 ± 0.15 ([TOPO] = 2.5×10^{-4} M) and 4.05 ± 0.10 ([TBP] = 1.0×10^{-3} M) indicate that four HPBI moieties are attached to the ternary complexed species. The plots of $\log(D - D_o)$ vs. $\log[S]$ at fixed concentrations of HPBI and HNO$_3$ suggest that only one unit (slope = 0.97 ± 0.02) of the neutral donor is present in the ternary extracted complex of TBP. In the case of TOPO, apart from binary Th(PBI)$_4$ species, Th(PBI)$_4$·TOPO and Th(PBI)$_4$·2TOPO appeared to coexist (slope = 1.29 ± 0.10). A graphical method was therefore employed for computing the adduct formation constants [7]. Table 3 summarizes the extraction constant data obtained by graphical as well as algebraical methods after incorporating aqueous nitrate complexation correction.

It is clear from the data summarized in Table 4 that the equilibrium constant values for the formation of the adduct increase with increasing basicity. The $\log K_S$ values clearly show that TOPO is a more effective synergist than TBP. This observation is in line with our earlier report for trivalent, tetravalent and hexavalent metal ions [7,8,10].

Adduct formation constant data (Table 4) could be explained on the basis that the β-diketone with lower pK_a has less tendency to orient its electron cloud towards the ketonic oxygen atoms. This leads to a residual positive charge over the metal ion which is responsible for the greater interaction with the incoming neutral donor. Data in Table 4 suggest that the steric factors do not disturb the trend expected from the electronic effects.

The β-diketonate chelate is hydrated partially in the inner coordination sphere and more extensively in the outer coordination sphere [17]. The stronger M–L bond suggests greater polarizability of the donor electron cloud over the "O" atom, resulting in more extensive outer-sphere hydration (through H-bonding) and hence less partitioning towards the organic phase [18]. In the case of symmetrical complexes a greater number of water molecules can be accommodated in the secondary coordination shell, leading to lower distribution ratio values. In contrast, for sterically hindered complexes the number of water molecules associated in the secondary coordination shell is restricted due to the staggered geometry of the complex thereby rendering greater organophilicity.

It is interesting to note that the extracted species in the present work do not contain any nitrate ion as earlier reported by Irving and Edgington [16] for the HTTA extraction system. This is indicated by the slope analysis of plots of $\log D$ vs. both $\log[PBI]$ and $\log[H^+]$. It may be due to the better availability of the isoxazoloante anion (pK_a = 1.12) for complex formation, even at moderately high nitric acid concentrations, which eventually forms more organophilic ternary extractable species such as Th(PBI)$_4$·S.

4.3. Nature of the metal ion

We have reported earlier the extraction constants of Pu(IV) with HPMBP as well as HPBI [19]. It was observed that in spite of the significantly lower pK_a value of HPBI as compared to

Table 4
Comparison of the extraction constants of the Th(IV)–HPBI and Th(IV)–HTTA systems

β-Diketone	log k_{ex}	log K_S (TBP)	log K_S (TOPO)	Ref.
HPBI	8.26 ± 0.04	6.70 ± 0.04	8.56 ± 0.28[a]	Present work
			4.14 ± 0.55[a]	
HTTA	2.25	4.63	7.50	16

[a] In the case of TOPO, two adduct formation constants for Th(PBI)$_4$·TOPO and Th(PBI)$_4$·2TOPO respectively are reported

HPMBP, the k_{ex} value decreases slightly for the former (Fig. 3). This was attributed to the prominent role of steric factors in the case of HPBI (O–O distance 2.9 Å). Fig. 3 also shows the extraction constant data of Th(IV) with the three β-diketones which follow a linear inverse relation with the pK_a values of the ligands. This is similar to the trend reported earlier for the UO$_2$(VI)–β-diketone system [10]. In spite of the presence of four bulky PBI moieties around the Th(IV) ion, steric factors do not influence the trend expected on the basis of electronic effects. This is in sharp contrast to the behaviour of a similar extraction system involving Pu(IV), which can be explained on the basis of the larger size of Th(IV) (ionic radius = 1.05 Å) compared to Pu(IV) (0.96 Å) [20].

Fig. 3. Dependence of log k_{ex} on pK_a of β-diketones: (○), Pu(IV); (●), Th(IV).

In the Pu(IV) synergistic systems involving TOPO as the oxo donor, species of the type Pu(PBI)$_3$X·TOPO as well as Pu(PBI)$_3$X·2TOPO are co-extracted (where X = NO$_3^-$). It is interesting to note that in the present work with Th(IV), species of the type Th(PBI)$_4$·TOPO and Th(PBI)$_4$·2TOPO were predominant, indicating that there is no steric hindrance to the adduct formation. The adduct formation constant of Th(PBI)$_4$ with TOPO is larger by two orders of magnitude compared to the corresponding value for Pu(PBI)$_4$ [8,21].

4.4. Analytical significance

^{234}Th, the daughter product of naturally occurring ^{238}U, can be obtained from the latter when the two nuclides are in secular equilibrium. It is desirable to develop efficient methods for the chemical separation of trace concentrations of Th from kilogram quantities of U which enable the use of ^{234}Th as a radioactive tracer. The existing methods are based on the preferential extraction or adsorption of U(VI) as UO$_2$Cl$_4^{2-}$ using quarternary amines as liquid anion exchangers and Dowex 1X4 as the anion exchange resin material. In view of the presence of a large excess of U these methods have limitations for the recovery and purification of Th.

It is desirable to develop alternative methods based on the preferential transfer of trace concentrations of Th(IV) towards the organic phase leaving the bulk U in the raffinate. Due to the large difference in the extraction constants of HPBI with Th(IV) (log k_{ex} = 8.3) and UO$_2$(VI) (log k_{ex} = 1.4), this reagent offers promise for the recovery and purification of ^{234}Th from bulk ^{238}U. Preliminary experiments carried out in our

laboratory on depleted U solution using HPBI gave satisfactory results as revealed by α-spectrometry (^{233}U was used as a labelling tracer) and γ-spectrometry (γ peaks of ^{234}Th at 63 and 93 keV). Brief details of the analytical procedure are as follows.

30% Aliquat 336 in chloroform was saturated with uranium by contacting with a 8 M HCl solution of UO_3. The organic phase was stored for about 3 months to allow ^{234}Th ($t_{1/2} = 24.1$ days) activity to grow and attain secular equilibrium with ^{238}U ($t_{1/2} = 4.47 \times 10^9$ years). ^{234}Th thus produced was transferred to the aqueous phase by contacting the uranium-loaded organic phase with 8 M HCl. Th(IV) at the picomolar concentration level is associated with a millimolar concentration of uranium at this stage. The aqueous medium was subsequently changed to 0.5 M HNO_3. 0.01 M HPBI in xylene was used for the preferential extraction of Th(IV) followed by two cycles of scrubbing with 0.5 M HNO_3. A separation factor (D_{Th}/D_U) of approximately 2000 was achieved at every step. Th from the uranium-free organic phase was stripped by 8 M HNO_3 and the aqueous phase was freed from any dissolved ligand by contacting it twice with xylene.

5. Conclusions

Formation of adducts of the stoichiometry Th(PBI)$_4$·S and Th(PBI)$_4$·2S suggests the possibility of coordination numbers of nine and ten for Th^{4+} in these complexes. Adduct formation constants are noticeably larger (by about two log units) for the thorium (IV) ternary complexes as compared to the corresponding values for Pu(IV) complexes, conforming to the reduced role of steric factors in the case of Th^{4+}. Extraction constants of Th–HPBI are larger by about six log units and those of Th(IV) – HPBI–TBP by about eight log units than the corresponding values with HTTA. Consequently, thorium can be recovered from stronger acidic and complexing solutions. HPBI has been found to be a promising extractant

for the separation of ^{234}Th from natural uranium.

The determination of lead, nickel and vanadium in Saudi Arabian crude oil by sequential injection analysis/inductively-coupled plasma mass spectrometry

Hassan M. Al-Swaidan

Chemistry Department, College of Science, King Saud University, P.O. Box 2455, Riyadh 11451, Saudi Arabia

Abstract

The coupling of sequential injection with inductively-coupled plasma mass spectrometry as an analytical tool for trace element detection is described. The technique is applied for determining the concentrations of lead, nickel and vanadium at part per billion levels in sample solutions of Saudi arabian crude oils. A microemulsion crude oil sampling procedure and a standard addition method using oil-soluble organo metallic salts of trace elements were used. A reference oil sample (NBS 1634b) was analyzed to obtain the accuracy and precision of the method. Results showed percentage recovery values of 98.2%, 95.7% and 101.4% and standard deviations of 2.9%, 1.5% and 2.0% for lead, nickel and vanadium respectively. The method is sensitive, requires only small sample volumes and is quick.

Keywords: Crude oil; Lead; Nickel; SIA/ICP-MS; Vanadium

1. Introduction

The determination of trace elements in petroleum is important in the oil industry because it provides information to the geologist about crude oil origins, migration and types. The determination of vanadium and nickel have been made for geological surveys. These elements are the source of environmental pollution, catalytic poisoning in the petroleum cracking process and corrosion of equipment, especially in the refinery. Crude oil containing lead as an organometallic compound is a very important source of pollutants especially if it is not replaced during the refining process of unleaded gasoline by methyl-tert-butylether (MTBE) [1].

Inductively-coupled plasma mass spectrometry (ICP-MS) exhibits high sensitivity and accuracy, with high sample throughput. ICP-MS also allows simultaneous multielement determination with rapid and easy operation for determination of trace metals in petroleum samples [2–4].

The direct dilution of petroleum-based materials with an organic solvent is an attractive sample preparation procedure because it is rapid and simple. The problems of carbon build-up on the mass spectrometer interface and excessive deterioration of the metal interface cones, which are associated with the direct analysis of organic solutions by ICP-MS, have been the major difficulties. The direct method of analysis causes instrumental errors and possible loss of volatile elements by

ICP-MS [5–7]. An acidified microemulsion technique simplifies the sample preparation procedure and the determination of trace metals in petroleum by ICP-MS [8,9].

A simple reduction of the organo matrix is accomplished by minimizing the use of organic solvents in the sample stream. The coupling [10] of flow injection (FI) to ICP-MS is an attractive approach for the analysis of solutions of high salt content. Advantages of the FI method over the conventional solution introduction method have been discussed in previous papers [11–14]. Sequential injection analysis (SIA) is based on a different approach, using a selector valve by which sample zone and reagent zones are sequentially injected into a channel [15], while in conventional FI the sample zone is injected into a flowing carrier stream and auxiliary reagents are merged with it on the way to the detector [16]. The benefits of the SIA technique include minimization of reagent consumption and waste disposal because flow is not continuous during the sequencing and measurement steps, and the handling of corrosive liquids in a closed system. The SIA technique requires only a single pump and a single valve in a single line system, and is capable of accommodating diverse reagents and sample concentrations by reconfiguration of the zone sequencing from a computer keyboard [17,18].

A previously investigated technique used an optimized acidified microemulsion as a sample pretreatment for the determination of trace elements in crude oil by ICP-MS [19]. We couple SIA with ICP-MS (SIA/ICP-MS) to optimize the accuracy and precision and increase the sensitivity of the analysis.

2. Experimental

2.1. Apparatus

A MIS-1 modular injection system (Alitea, USA) configured for SIA with a multiposition selection valve, reactor modules and a peristaltic pump was used as the sample introduction system. Teflon tubings used for the MIS were 30 cm of 0.8 mm i.d. for carrier solution, 15 cm for pump, 160 cm of 0.8 mm i.d. for holding coil, 5 cm of 0.5 mm i.d. connected to port 2 of sample, 10 cm of 0.8 mm id. for auxiliary waste (port 10) and 45 cm of 0.8 mm i.d. connected from port 1 directly to the concentric nebulizer into the ICP-MS system (all tubings were supplied by Upchurch Scientific, Inc.). The MIS is operated by Alitea's FIA lab software and an IBM-compatible PC and the operating instructions in the MIS manual are followed for SIA [20]. Table 1 includes FIA lab software method entries used for Alitea MIS-1 SIA. Flow rates are 60 μl s^{-1}. In step 1, 300 μl of carrier is pumped through the detector. Then 120 μl of sample is aspirated into the holding coil and then to waste, to wash the sampling tube with sample. Finally, 60 μl of sample is aspirated into the holding coil and is then propelled to the detector in step 5.

An Elan inductively-coupled plasma mass spectrometer model 250 with a standard addition program (Sciex) is used with a 15 BCO 12B computer (Matrix Electronic System Ltd.) and a plotter (Houston). A schematic diagram of the MIS-1 coupled to the ICP-MS instrument is given in Fig. 1 and the ICP-MS operating conditions are listed in Table 2. An Edmund Buhler vortex mixer model 25 was used for crude oil sample agitation.

2.2. Reagents

Chemicals used were of analytical-reagent-grade and include lead and nickel cyclohexane butyrate, bis[1-phenyl butanedionato-(1,3)] oxo vanadium (IV) (Eastman Organic Chemicals, Rochester, NY), indium oxide (Spex Industries, Inc., NJ) and analar nitric acid (sp.gr. 1.42, 69–71%, BDH Chemicals Ltd., Poole, UK). Tetralin (1,2,3,4 tetrahydronaphthalene, Fluka AG, Bucks, Switzerland) as a co-solvent and a nonionic surfactant Triton X-100 (BDH) as emulsifying agent were chosen.

Deionized distilled water was obtained by a Corning Mega-pure water distillation apparatus model MP3.

Solutions of 40% (v/v) nitric acid were prepared by dilution of concentrated nitric acid. Stock solutions (100 ppm) of nickel, lead and vanadium were prepared by dissolving the weighed organometallic salts in 40% (v/v) nitric acid solution. Multi-element standard solutions of lead (2.5 ppm), nickel (25 ppm) and vanadium (50 ppm) were prepared by dilution from the stock solutions. A stock solution of indium oxide (100 ppm) was prepared by dissolving its weighed oxide in 1% (v/v) nitric acid solution.

2.3. Samples

Saudi Arabian heavy, medium and light crude oil samples supplied by Aramco (Saudi Arabia) were analyzed for lead, nickel and vanadium content. Some general properties of these samples are shown in Table 3. Standard Reference Material NBS1634b (Residual Fuel Oil, National Institute of Standards) was tested to determine the accuracy and precision of the method.

2.4. Procedure

Into three different stoppered glass bottles (200 ml), a 0.50 g aliquot of NBS oil sample was weighed. Portions of 1.5 ml of tetralin as a co-solvent, 0.5 ml of Triton X-100 as emulsifying agent, 5 ml of 40% (v/v) nitric acid solution and 0.5 ml

[a] n.c. = not certified.

ments programs (Sciex). Replicates of the sample were analyzed to obtain the accuracy and precision of the method. The procedure was applied similarly for the determination of Pb, Ni and V in the different crude oil samples.

3. Results and discussion

SIA/ICP-MS will reduce the organic matrix by minimizing the use of organic solvents in the sample stream. The previous optimized acidified microemulsion procedure was chosen for crude oil sampling [19]. The sequential injection system easily introduces the sample by connecting the Teflon tube out of the multi-position valve directly to the concentric nebulizer of the ICP-MS instrument, as shown in Fig. 1. Plasma extinguishing problems

due to carbon build-up on the torch walls were solved by using an acidified microemulsion as the sample pretreatment technique.

The peaks of different solutions are plotted for Pb, Ni and V concentrations. Typical peaks of Standard Reference samples (NBS) solution obtained for Pb, Ni and V are shown in Fig. 2. Peak heights in centimeters for the sample only and for the sample with added concentrations of elements are constructed as standard addition graphs. These standard addition graphs of Pb, Ni and V for heavy, medium, light and NBS oil samples appear in Fig. 3. The NBS sample is analyzed three times for Pb, Ni and V concentrations and compared to standard values [21,22]. Recovery values calculated are 98.2% for Pb, 96% for Ni and 101.5% for V. Recovery data for NBS 16346 oil samples are listed in Table 4.

Calculations for different sample contents resulted in concentration ranges of 0.30–0.81 μg g^{-1} for Pb, 3.13–9.4 μg g^{-1} for Ni and 8.8–13.8 μg g^{-1} for V in the different analyzed Saudi oil samples. Each sample is analyzed 3–5 times to obtain the standard deviation values which are found to be less than 4% for all the analyzed elements. Table 5 includes concentrations, standard deviations and correlation coefficients for Pb, Ni and V in crude oil samples and a compari-

	L	11.3 ± 0.2	13.4 ± 0.4

son made between the results obtained by the proposed method and other published methods is shown in Table 6 for the same sample.

It is found that concentrations of Pb and Ni obtained by the proposed SIA/ICP-MS method are higher than those found with the continuous ICP-MS method. Vanadium concentrations are lower with the SIA/ICP-MS method. This may be due to its high background signal (as shown in Fig. 2), especially in crude oil samples where solution concentrations are low.

4. Conclusions

The interfacing of sequential injection and inductively-coupled plasma mass spectrometry provides a new automated technique for trace elements analysis which is easy to handle, requires only small sample volumes and is sensitive. The results are reproducible and this technique can be used for the determination of other trace elements in crude oil samples.

Determination of copper by electrothermal AAS after electrodeposition on a graphite disk electrode

J. Komárek[a],*, P. Stavinoha[a], S. Gomišček[b], L. Sommer[a]

Abstract

The electrodeposition of copper on a graphite electrode at a constant potential with subsequent atomization in the graphite atomizer HGA-400 has been studied. A special graphite disk electrode is suitable for electrochemical enrichment at $E = -0.7$ V vs. SCE and the determination of copper by electrothermal-atomic absorption spectrometry (ET-AAS) if atomized at 2300°C. In this way copper was determined in potable water and free Cu^{2+} could be distinguished from that bound in chelate speciations after using a suitable deposition potential of the working electrode. This approach seems to be an alternative to the commonly used anodic stripping voltammetry (ASV) for the preconcentration and determination of free metal ions.

1. Introduction

Previous separation and preconcentration techniques are frequently used in connection with AAS as a means of removing interferences and increasing sensitivity. The electrochemical deposition of minor concentrations of metals on suitable electrodes is one of the methods used prior to determination by electrothermal AAS. Wires from refractory metals especially tungsten [1–3], graphite [4,5] or a hanging mercury-drop [6,7] were suitable for electrodeposition. The atomization resulted from electrically heated tungsten wire being placed in the tube [1,2] or after shifting into a CRA-90 graphite atomizer [3]. Common graphite electrodes were pulverized prior to sampling in the graphite tube [4] or the electrode was part of the atomizer [8]. An electrode disk, properly cut and covered by the metal deposit was also inserted into the atomizer [9] or the electrode in a suitable form which was tightly led into the atomizer [5]. Recently a special graphite disk electrode was developed as a probe to be inserted into the atomizer without touching the wall of the tube. The electrodeposition of the metal took place on the disk, which was situated on a thin stem [10].

* Corresponding author.

Although metals can also be conveniently analyzed by anodic stripping voltammetry (ASV) [11,12], there are a number of elements, notably cobalt, nickel, manganese and chromium for which the deposition is irreversible. In the presence of other metals, intermetallic compounds may be formed and their redissolution by ASV is difficult [11]. Moreover, a broadened stripping peak or two peaks may be observed, the first one due to the voltammetric oxidation of metal, and the second one due to the adsorption in the presence of species in environmental samples [13]. ET-AAS may serve as a selective element detector of electrochemically deposited metals on the electrode and the electrothermal atomization simply replaces the ASV stripping step.

In this paper the electrodeposition of copper under a controlled potential was studied as a model on a graphite disk electrode in connection with the subsequent determination by ET-AAS and in the presence of complexing agents.

2. Experimental

2.1. Chemicals

Cu^{2+} standard solution containing 0.993 g l^{-1} Cu^{2+} was prepared by dissolving metallic copper (99.96%) in 10 ml of concentrated HNO_3 and diluting to 1:1 with bidistilled water. The solution was standardized by EDTA titration on murexide indicator.

Ethylenediaminetetraacetic acid disodium salt (EDTA) p.a., nitrilotriacetic acid (NTA) p.a. and dinitrilocyclohexylentetraacetic acid (DCTA) p.a. were obtained from Lachema Brno and N-(2-hydroxyethyl)ethylenediamine N',N,N''' triacetic acid trisodium salt hydrate (HEDTA) p.a. was obtained from Fluka-Chemika.

All other chemicals were of analytical grade purity.

2.2. Instruments

An AA spectrometer (Perkin-Elmer 3030) with a graphite atomizer HGA-400, a copper hollow cathode lamp Intensitron heated for 20 mA (324.8

nm) and a mercury electrodeless discharge lamp operated at 5 W (253.7 nm) were used. The atomization followed in argon.

A Radelkis OH 405 potentiostate for the metal deposition and an analogous precision potentiometer OP-205 for deposition potential adjustment on the developed disk graphite electrode were used. The potential was measured against a SCE, platinum served as the counter electrode, and electrodeposition followed during vigorous stirring of the solution containing the metal ion (50 ml). The electrolysis was carried out in the system with a single or four working electrodes. The single electrode was inserted into the graphite rod (5 mm diameter with the hole 3 mm in diameter). The contact to the potentiostate was connected to the upper part of the rod. In the four-electrode arrangement the four graphite disk electrodes were inserted into holes of 3 mm diameter in a graphite cube of size 30 × 30 × 10 mm located in a quadrangle position. The connection to the potentiostate was led from the upper part of the cube. The platinum electrode was isolated in the middle and the electrolysis took place on the four electrodes simultaneously. The arrangement with the four electrodes was used for practical application.

The graphite disk electrode was prepared from graphite rods (3 mm diameter, SU Elektrokarbon Topolčany and RW III Ringsdorffwerke Bonn) and the final disk was turned to 0.6 mm thickness, ground by a fine emery paper and polished by a dense filter paper. The resulting thickness of the disk was 0.5 mm (Fig. 1).

The prepared electrode was double ignited in a graphite tube at 2300°C for 6 s in argon; the stem of the electrode was protected by a tightly wound Teflon strip (10 × 40 mm) and the electrode was fixed up into the graphite contact of the electrolyzer. After the electrodeposition the electrode was rinsed with bidistilled water, the Teflon strip was removed and the electrode was rinsed with water and inserted by the use of an applicator into the enlarged sampling hole in the atomizer tube (3.5 mm diameter) horizontally through the orifice in the contact. The insertion of the electrode into the atomizer was realized by a graphite applicator of diameter 5 mm and length 11 cm

with an orifice of diameter 3 mm and depth of 10 mm (Fig. 1). The graphite applicator with the electrode was then slid into a glass tube in a holder. The correct positioning of the disk electrode in the graphite tube was indicated by a non-selective absorbance of 0.004–0.008.

The drying of the disk and stem of the electrode took 15 s at 160°C with a 5 s ramp, the pyrolysis stage took 15 s at 600°C with the same ramp and the atomization of copper took 5 s at 2300°C with no flow of argon and temperature-controlled maximal power heating. The cleaning of tubes followed at 2300°C for 3 s.

A scanning electron microscope (Philips SEM 500) was used for preparing photographs of the electrode surfaces.

The sensitivity of the determination corresponds to the slope of the calibration plots and the relative standard deviation (RSD) is calculated from six measurements.

2.3. Determination of copper in potable water

A 50 ml volume of the water sample, acidified with concentrated HNO_3 to pH 2, was electrolyzed for 1–5 min at $E = -0.7$ V (against SCE) and the copper was determined by ET-AAS under the conditions given above. The results were evaluated by the method of standard additions (1–10 μg l^{-1} Cu^{2+}). The RSD was 5.4–6.4% ($n = 6$) for 1,5–8 μg l^{-1} Cu. The results

Fig. 1. Graphite disk electrode (A, data in mm) and its applicator for the atomizer HGA-400 (B). 1, Electrode; 2, holder; 3, tube.

were in good agreement with those observed by ASV.

3. Results and discussion

3.1. Conditions for electrodeposition

According to experimental $i = f(E)$ plots, the limiting current for copper was observed from $E = -0.15$ V for solutions containing 5 mg l^{-1} Cu^{2+} in 0.01 mol l^{-1} HNO$_3$, 0.005 mol l^{-1} H$_2$SO$_4$ or 0.01 mol l^{-1} HCl. The results of the ET-AAS for the amount of copper deposited on the disk electrode from solutions with 10 μg l^{-1} Cu^{2+} during a 2 min period continuously increased for the interval of $E = (-0.2$ V$)-(-1.2$ V$)$ with some delay at $(-0.6$ V$)-(-0.8$ V$)$. A potential $E = -0.7$ V vs. SCE was found to be optimal.

3.2. Effect of the electrode material

Cu^{2+} was sorbed in part from the solution on the graphite electrode surface even in a currentless state in an open electric circuit and could not be removed by rinsing with water. Comparing electrodes from graphite SU and RW III, the interaction of Cu^{2+} with the surface in diluted HNO$_3$ and HCl is considerably lower for graphite RW III and does not depend on the number of firings when less than ten. At pH 2 the sorption was independent of the acids used (HCl, HNO$_3$, H$_2$SO$_4$).

The dependence of the absorbance of the sorbed copper against the Cu^{2+} concentration in solution for various dipping times is shown in Fig. 2. The sorption of Cu^{2+} is not sufficiently reproducible and the RSD is often worse than 30%. The copper amounts deposited after an electrolysis of 2 min is by the order larger than that which was spontaneously sorbed. Thus, this copper does not influence expressly the determination of copper, especially during longer electrolysis times.

Burning of the electrodes from the periphery to the centre of the electrode disk was observed by the scanning microscope. Graphite RW III was more resistant to firing and was used for further measurements.
Fig. 2. Relationship between the absorbance of the sorbed copper against Cu^{2+} concentration in solution for various dipping times (RW III graphite). Curve 1, 10 s; curve 2, 2 min; curve 3, 10 min (0.005 mol l^{-1} H_2SO_4). Each point of the plot corresponds to the average of 16 measurements.

3.3. Selected conditions for ET atomization

The pyrolysis plot showed a constant course until a temperature of 1200°C was reached. The pyrolysis temperature used for the measurements was 600°C. Since the graphite disk electrode contained largely metallic copper deposits, this pyrolysis step partially corresponds to the completion of drying. Temperatures higher than 2300°C caused faster burning-off of the disk which negatively influenced the precision of the determination. The disk endured 10–11 firings without damage and the need for polishing. For larger numbers of firings the surface of the electrode increased and thus the amount of copper; consequently polishing with a dense filter paper is necessary after ten firings. After 40–50 firings polishing was unsuccessful and the RSD of the determination increases to more than 10% (for $A = 0.2$). High temperature gradients of heating led to a slight split of the absorbance signals (Fig. 3). Uniform peaks were obtained for temperature gradients of 3 s but the precision decreased. Thus, atomization by temperature-controlled maximum power heating was only used. The reason for peak splitting during fast heating may be caused by expansion of the gases but also by the temperature decrease at the increased sampling orifice. The sensitivity of the determination expressed with the slope of calibration plots $A = f(Cu, \mu g$

l^{-1}) was 0.012, 0.023, 0.048 and 0.072 $(\mu g \, l^{-1})^{-1}$ for electrodeposition times of 1, 2, 4 and 6 min, respectively.

3.4. Co-deposition of copper with mercury

Copper was deposited from solutions containing Cu^{2+} in the presence of 2.5×10^{-5} mol l^{-1} Hg^{2+}. Selected working parameters on the HGA-400 were 110°C (drying), 800°C (pyrolysis) and 2300°C (atomization) in this case. At 550°C two forms of mercury indicated by the absorbance minimum for mercury at 253.7 nm, i.e. free mercury atoms and the decomposition of the copper amalgam at this temperature. The signal for copper at 324.8 nm increases by 39% after the complete decomposition of the amalgam at 800°C in comparison to the results for copper without amalgamation. The RSD for copper was 2.2% in the presence of mercury. Reproducible signals were, however, obtained only during three firings on the disk electrode without polishing. The disadvantage of such procedure is the toxicity of released mercury vapors.

3.5. Effect of acids and NaCl

The electrodeposition of copper was studied from solutions containing HCl, H_2SO_4 or HNO_3 only and with a pH of 1–2 (adjusted with H_2SO_4 or HNO_3) (Fig. 4). The decrease of signal with the decrease of acid concentration could arise from

Fig. 3. Absorbance signals of copper after electrodeposition on the graphite disk electrode. peak 1, $t_R = 0$ s; peak 2, $t_R = 3$ s (10 $\mu g \, l^{-1}$ Cu^{2+}, 0.01 mol l^{-1} HNO_3).
Fig. 4. Relationship between the copper absorbance on the logarithm of the acid concentration (in mol l^{-1}). Curve 1, HCl; curve 2, HNO_3; curve 3, H_2SO_4 (10 μg l^{-1} Cu^{2+}, $E = -0.7$ V).

the lower conductivity of solution. An increased concentration of hydrochloric acid interferes due to the formation of chlorine at the counter electrode.

If 10 μg l^{-1} Cu^{2+} solution was electrolyzed in 0.005 mol l^{-1} H_2SO_4 the amount of copper deposited decreased if more than 0.1 g l^{-1} of NaCl was present. This decrease reaches 36% with 0.4 g l^{-1} NaCl. The effect of more than 0.1 g l^{-1} NaCl is however negligible if the counter electrode was protected from the electrolyte by a glass tube with an agar sintered disk. The electrode separation eliminates the effect of chlorine formed by the oxidation of chlorides on the counter electrode.

3.6. Deposition of copper from solutions containing complexing reagents

For the determination of free Cu^{2+} in the presence of copper complexed in various stable chelates a suitable deposition potential must be selected, if free metal is deposited and no metal chelate decomposition takes place, or if the reagent is not reduced on the negatively charged electrode. As followed from studies of polarization plots in the system, $E = -0.19$ V against SCE was suitable in the presence of most of the studied chelating ligands. Thus, Cu–EDTA begins to decompose electrolytically at $E = -0.23$ V against SCE.

The concentration of free Cu^{2+} in solution was evaluated from calibration plots prepared under the same conditions, pH, potential and electrolysis time for Cu^{2+} solutions without ligand. The experimental results were compared with those calculated according to the modified SQUAD [14,15] program from the corresponding stability, protonation constants of the Cu–chelates or ligands and the stability constants of particular Cu–hydroxocomplexes [16] (cf. Table 1). The differences between the determined and calculated concentration of free copper in the presence of chelons such as EDTA, NTA, HEDTA and DCTA were no larger than 25%. Thus, such a way is suitable for the determination of free Cu^{2+} in the presence of metals bound in Cu–chelates.

Variable-angle synchronous fluorescence spectrometry and rank annihilation methods for mixture resolution

F. García Sánchez*, M. Cedazo, J. Lovillo, A. Navas Díaz

Departamento de Química Analítica, Facultad de Ciencias, Universidad de Málaga, 29071-Málaga, Spain

Abstract

The potential of variable angle synchronous spectroscopy (VASS) for fluorescent mixtures resolution was assessed and compared with the rank annihilation method (RAM). For this purpose, a set of excitation–emission matrices from three standard cyclodextrin fluorescence-enhanced solutions of the pesticides aminocarb, carbendazim and coumatetralyl and a mixture of them was obtained. Careful selection of the spectral routes to be scanned provides analyte signals that are free of interferences. Application of the rank annihilation method to excitation–emission matrices (EEMs) obtained by conventional scanning spectrofluorimetry gives quantitative results that show poor precision and accuracy when compared to those of VASS. The recoveries from ternary mixtures by VASS are within 99–104% and by RAM within 84–130%.

1. Introduction

Although spectrofluorimetry has great sensitivity and moderate selectivity as an analytical technique, these performances in multicomponent analysis fall considerably because overlapping spectra give rise to energy-transfer processes and inner filter effects that produce spurious analyte signals. At present there are two fundamental ways to avoid this problem: modifications in analytical sampling and signal processing by mathematical algorithms after the raw data are obtained.

Simultaneous multicomponent analysis can be performed by mathematical treatment of the data such as realized by principal components regression (PCR), partial least squares regression (PLS), rank annihilation method (RAM), etc. Alternatively it is possible to act over experimental data acquisition in such a way that the contribution to the analytical signal from interfering components can be eliminated, or at least minimized. Variable angle scanning spectrometry [1–3] gives a useful approach to data acquisition for the simultaneous

analysis of fluorescent multicomponent samples because of the reduction of the interferences associated with the design of the technique.

Mixture resolution by fluorescence spectrometry performed by mathematical procedures normally gives good results, when there are no strongly overlapped spectral profiles that would facilitate energy transfer processes between donor molecules (emission spectra) and acceptor molecules (excitation spectra). This effect produces quenching of donor and enhancement of acceptor that changes the spectral profiles of the mixtures compared with those of the standard solutions. This aspect is not a problem in VASS in which the selected routes can circumvent spectral zones subject to these energy transfer processes. The results obtained in this paper can be interpreted in this context.

Three different types of synchronous scanning have been developed: constant wavelengths (CW), constant energy (CE) and variable angle (VA). CE and CW scans maintain a constant separation (in cm^{-1} and nm, respectively) between excitation and emission beams [4]. An alternative approach, denoted variable-angle synchronous scanning (VASS) varies the separation in a controlled way. The continuous variation of the wavelength separation between the monochromators can be achieved either mechanically, by varying the scan speeds of the two monochromators, or digitally, by processing the stored data. Because mechanical control of the monochromator's speed only produces linear scan paths [5] and the generation of VASS from stored data [6] is very time consuming, a commercial digital instrument has been modified [7] to generate the variable-angle synchronous scan directly from the spectrofluorimeter output. This permits the VASS scan to be obtained in a few minutes by following a path previously selected by inspecting the contour lines.

The reduced peak-half-widths is often cited as the most important attribute of synchronous techniques for the resolution in multicomponent analysis. Recently, the theory of variable-angle synchronous spectrofluorimetry has been described in detail [8] and it has been deduced that the resolution in synchronous techniques is more

related to the maximal peak intensity than with minimal peak width. Thus, the true advantage of VASS with respect to CWS is not the band narrowing effect but the capacity to go throughout maximal intensity peaks (circumvents overlapping spectral areas). This confirms the superior advantage of VASS in multicomponent analysis against CE, CW or derivative synchronous techniques due to the added flexibility in the choice of a scan path nearest to maxima.

Synchronous scanning methods have potential for multicomponent analysis that has not been fully realized, particularly for the automatization of sampling data. We report the simultaneous analysis of the agrochemicals aminocarb, carbendazim and coumatetralyl by VASS. The studied compounds display a low fluorescence quantum yield which is enhanced by using one of the almost universal features of cyclodextrin complexes such as fluorescence enhancement [9–11] by the inclusion of an organic fluorophore in the cyclodextrin (CD) cavity.

The technique of rank annihilation, described by Ho et al. [12] utilizes the excitation–emission matrix M, to determine quantitatively the concentration of a component in the presence of a mixture. The excitation–emission matrix of a standard solution of each analyte yields a series of standard reference matrices S_1, S_2, etc. Then, successive fractions β of S are subtracted from the mixture matrix M. When the fraction of S subtracted from M equals the amount of S originally present in M, the rank of the resulting difference matrix $M - \beta S$ is one less than the rank of M and the nth eigenvalue of the difference matrix goes to a minimum. The concentration of the analyte in the mixture is then given by β times the concentration of the analyte in the standard solution used to measure S. These operations are accomplished by performing a singular value decomposition (SVD) of the difference matrix:

$$v = \mathrm{svd}(M - \beta^* S)$$

and adjusting the scalar fraction β until the nth singular value $v(n)$ is a minimum.

In this paper we try to evaluate the performances of a technique based on the more precise acquisition of the signal from the sample (VASS)

so as to compare it with the results obtained by a chemometric technique (RAM) based on signal processing. The critical comparison of the results obtained by both methods is also an objective of this paper.

2. Experimental

Fluorescence spectra were obtained with a Perkin-Elmer LS-5 luminescence spectrophotometer equipped with a xenon lamp (9.9 W) pulsed at line frequency. The spectrometer was interfaced to an IBM-PC/AT computer via the RS232C serial interface. The software package FLUOROPACK [7] controlled the instrument, data acquisition and data processing. The software used for the data analysis was PC-MATLAB (MAt-Works Inc., Sherborn, MA, USA).

The solvents used were pro analysis (Merck). Water was distilled and deionized. The pesticide carbendazim (99%) was purchased from Riedel-de Haen; aminocarb (99%) and coumatetralyl (96%) were supplied by Dr. Ehrenstorfer (Augsburg, Germany); β-cyclodextrin was kindly supplied by Amaizo, Co. (USA).

The stock standard solutions of aminocarb, and coumatetralyl 1 g L^{-1} and carbendazim 0.25 g L^{-1} were prepared by dissolving the pesticide in methanol, and were stored in the dark at 4°C. Working solutions of coumatetralyl and carbendazim were prepared weekly and that of aminocarb each two days, by dilution with methanol. β-cyclodextrin was purified by recrystallization once from boiling water and 10^{-2} M aqueous solutions were prepared. A buffer solution of pH 4.5 was prepared from 0.2 M acetic acid/sodium acetate.

2.1. Sample preparation

Aliquots of sample solution to give a final concentration between 1.5–4.0 μg mL^{-1} of aminocarb, 6.7–300 ng mL^{-1} of coumatetralyl and 2.3–5 μg mL^{-1} of carbendazim were placed in a 10 mL standard flask. The contents were slowly evaporated to dryness by a nitrogen stream, and after adding 1 mL of pH 4.5 acetate

buffer, the volume was adjusted to 10 mL with 10^{-2} M β-cyclodextrin solution. The solution was sonicated for 20 min and the variable angle scanning spectra (VASS) was scanned. Finally, fluorescence intensity was measured in the VASS plots at 235/390 nm, 310/380 nm and 290/335 nm, respectively, and plotted against the concentration of each pesticide.

3. Results and discussion

Separate experiments were conducted to study the behavior of aminocarb, carbendazim and coumatetralyl in water and β-cyclodextrin solutions. In Table 1 the excitation and emission wavelengths and relative fluorescence intensities (RFI) in these media are presented. An emission enhancement in cyclodextrin media compared to water is observed. The weaker complexes produce faint emission signals. The formation constants of the β-CD complexes ([aminocarb] = 2 μg mL^{-1}, [coumatetralyl] = [carbendazim] = 1 μg mL^{-1}), obtained by the Benessi–Hildebrand methods [13] were 267 L mol^{-1}, 21 L mol^{-1} and 669 L mol^{-1} for the β-CD–aminocarb, –carbendazim and – coumatetralyl complexes, respectively. The maximum RFI is achieved in 10^{-2} M solutions of β-CD, a slight modification in this concentration has little effect on fluorescence intensity. Ethanol has also a little effect on the fluorescence; low proportions of this solvent are admitted but absence gives maximum sensitivity. A pH of 4.5 is adequate for sensitivity because it permits greater emission signals to be obtained.

Table 1
Excitation and emission wavelength and relative fluorescence intensity (RFI) for aminocarb, carbendazim and coumatetralyl in water and β-CD.

Compound	λ_{exc} (nm)	λ_{em} (nm)	RFI
Aminocarb (water)	237	383	185

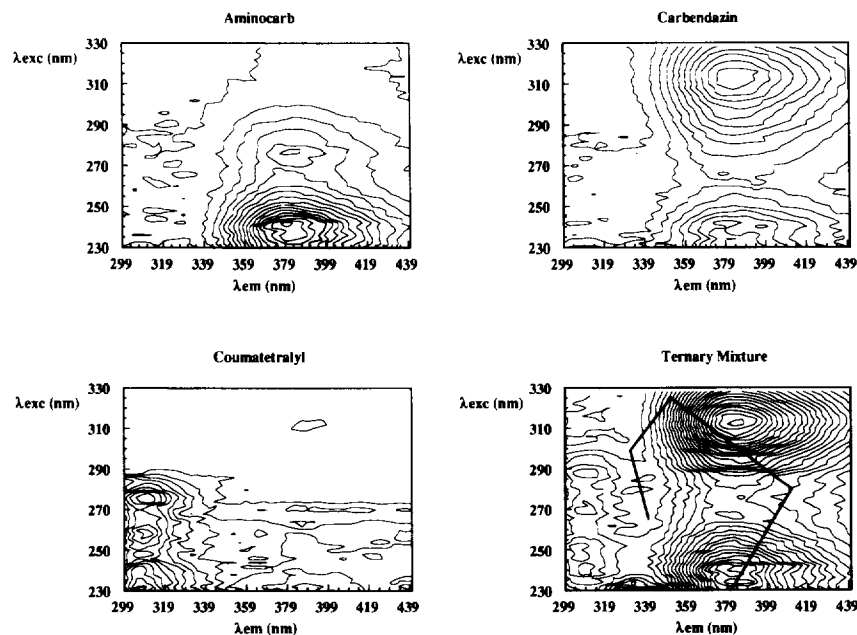
Coumatetralyl (β-CD)	311	387	785


Fig. 1. Contour plots of aminocarb (3 µg mL⁻¹), carbendazim (5 µg mL⁻¹), coumatetralyl (0.5 µg mL⁻¹), and a mixture of them (approximately isoemissive, same concentrations as standards) showing the selected VASS route.

An EEM of the mixture (Fig. 1) was obtained and maxima of analytes were identified. The excitation and emission maxima pairs for β-CD complexes with aminocarb, coumatetralyl and carbendazim are 238–375 nm, 315–387 nm and 280–307 nm, respectively. This type of mixture cannot be resolved either by conventional fluorimetry (there are no excitation–emission pairs for selective excitation) nor synchronous scanning fluorimetry because the almost complete overlap of the spectral shapes impedes the detection of an interference-free signal. Moreover, using VASS, we can find those regions with minimum overlap and reduced cross interference between analytes.

The variable-angle scanning route was carefully determined by trial and error to traverse those parts of the three-dimensional (3-D) spectral zones with the least overlap. The scan was selected to transverse those parts of the 3-D data matrix with the least overlap and the nearest of the maximum peaks. In spite of the fact that losses in sensitivity occur because no maximum peaks are traversed, interference-free signals of the three components may be obtained from the

chosen routes that scan the three-dimensional zones by skirting the slopes of the peak and avoiding the areas of interference between the three compounds. Fig. 2 shows a 3-D variable angle scanning spectrum for a ternary mixture.

The superior advantage of VASS in multicomponent analysis against CE, CW or derivative synchronous technique is due to the added flexibility in the choice of a scan path nearest to

(B) [coumatetralyl] = 0.05 μg mL⁻¹; [carbendazim] = 5 μg mL⁻¹; [aminocarb] = 0, 1 > 1.5, 2.5, 3 and 5 μg mL⁻¹. (C) [carbendazim] = 5 μg mL⁻¹; [aminocarb] = 1 μg mL⁻¹; [coumatetralyl] = 0, 0.025, 0.05, 0.1, 0.2 and 0.3 μg mL⁻¹.

maxima. So, as expected the generation of VASS by following rigid routes, or by introducing a circular, elliptical or other function into the software routine, did not improve the method. The 2-D profiles of the optimized routes were less pronounced when rigid geometric functions were introduced.

Several 3-D variable angle spectra of a three-component mixture of the pesticides are shown in Fig. 3 to illustrate the potential utility of this technique for mixture analysis. The software program produces and displays the required data in 4–5 min. The fact that both monochromators of the spectrofluorimeter cannot be set to difficult

Table 2
Analytical parameters

Compound	Linear dynamic range (mg L⁻¹)	Limit of detection (ng mL⁻¹)	RSD (%)
Aminocarb	0.29–5.0	89	4.32

RSD, relative standard deviation.

scan speeds does not matter because the program signals override and differentially vary the excitation and emission monochromator drive motors of the spectrofluorimeter by pulsing their power input.

Once the VASS spectra were obtained, fluorescence intensity readings at the maximum of VASS spectra and setting of the excitation and emission monochromators at the adequate wavelengths were performed.

Linear calibration graphs were obtained by plotting the fluorescence intensity against standard concentrations of aminocarb, carbendazim and coumatetralyl. Table 2 gives the linear dynamic range, detection limits and precision of the method. The accuracy was evaluated through a interferences study; the effect of some pesticides (fenitrotion, chlorpiryfos, dicofol and tetradifon) on the determination of a synthetic sample of composition 2 μg mL⁻¹ aminocarb, 2 μg mL⁻¹ carbendazim and 0.12 μg mL⁻¹ coumatetralyl was evaluated. Various volumes of stock solutions of the different potential interferents were added to the standard solution in order to obtain different interferent-to-analyte ratios in the final solution. The results obtained are given in Table 3. Acceptable recoveries of coumatetralyl are obtained. Recoveries are low and high for

Table 3
Recoveries in the ternary mixture by VASS

| Compound	Taken (mg L⁻¹)	Found (mg L⁻¹)	Recovery (%)	RSD (%)
Aminocarb	2.0	1.99	99.5	4.56
Carbendazim	2.0	2.067	103.8	8.25
Coumatetralyl	0.11	0.115	106	3.09

Fig. 4. First (■), second (●), and third (▽) singular values as a function of β. (A) Aminocarb, 3 mg L^{-1}; (B) Carbendazim, 5 mg L^{-1}; (C) Coumatetralyl, 0.3 mg L^{-1}.

aminocarb and carbendazim, respectively, when the interferent is twice or higher than the analyte concentration.

To apply the RAM method to the three-component mixture under study, we used four data sets, each composed of an EEM of the single standard component and a mixture of the three standards. The EEM were smoothed and blank-subtracted to remove scattered light. The resulting 48 × 48 matrices were then analyzed. Although blank substraction does not totally eliminate high scattered light, the regions of analytical interest are situated far away from the scatter emission; thus, this event will not affect the estimated concentrations of the analytes.

Performing a singular value decomposition of the difference matrix $(M - \beta S)$ and adjusting the scalar fraction β until the nth singular value $v(n)$ is a minimum, we can obtain the optimum β value that multiplied by the standard matrix S (or the concentration of standard equivalent) gives the concentration of each standard in the mixture.

Fig. 4 shows the plot of the logarithm of the singular values (v) against the β parameter, showing the minimum value that gives the correct β value. It must be stressed that adequate selection of the svd values is critical to obtain good results.

The results of the rank annihilation method are summarized in Table 4. It can be observed from Table 3 that the recovery values are closest to 100% in the case of VASS indicating that interferences are avoided, while RAM suffers the interference of the other components in the mixture to a considerable extent. This result can be assigned to the incapacity of RAM, a method that uses all the

spectral data to calculate the individual concentrations in the mixture, to eliminate the interferences arising from energy transfer or inner filter effects.

Finally, it must be pointed out that chromatographic resolution of this type of mixtures with severe spectral overlap, may be better and faster provided that no degradation of the products, during the chromatographic elution occurs. Moreover, in this case the use of cyclodextrin may be troublesome in the chromatographic elution.

4. Conclusions

Cyclodextrin-enhanced fluorescence determination of the pesticides aminocarb, carbendazim and coumatetralyl was performed by VASS and RAM. Fluorescence spectral distribution show great overlap that precludes the direct determination of this type of mixture. VAS shows better analytical performances than RAM due to the resolution of mixtures of overlapping fluorescence compounds.

Spectrofluorimetric determination of iron(III) with 2-pyridinecarbaldhyde-5-nitro-pyridylhydrazone in the presence of hexadecyltrimethylammonium bromide surfactant

Ki-Won Cha*, Chan-Il Park

Department of Chemistry, Inha University, Incheon 402-751, South Korea

Abstract

2-pyridinecarbaldehyde-5-nitro-pyridylhydrazone (2PC-5NPH) was synthesized and its application in the spectrofluorimetric determination of Fe(III) ions in the presence of surfactants was examined. An emission peak of 2PC-5NPH, which increased remarkably by the addition of Fe(III), occurs at 420 nm upon excitation at 300 nm, and allows for the sensitive, selective determination of the ferric ion in the 0.20–1.45 μg ml^{-1} range. The detection limit is 0.028 μg ml^{-1} in the presence of hexadecyltrimethylammonium bromide (CTMAB).

Keywords: Hexadecyltrimethylammonium bromide surfactant; Iron(III); 2-Pryidinecarbaldehyde-5-nitro-pyridylhydrazone; Spectrofluorimetric determination

1. Introduction

Because of the ever-increasing interest in the determination of trace elements in industrial, biological and environmental materials at low concentrations, there is a need for the development of more sensitive analytical methods. The spectrophotometric method involving the use of organic reagents is one of the inexpensive and reliable methods.

Fluorescence complexes of iron have received a great deal of attention. Few spectrofluorimetric methods for the determination of iron have been reported and most of them are based on the fluorescence quenching of indicators, owing to the inherent strong paramagnetism of iron cation [1]. Mori et al. [2] recently proposed a sensitive and convenient fluorimetric procedure for the determination of iron using o-hydroxyhydroquinonephthalein as the fluorgenic reagent in the presence of Brij-58.

Hydrazones, in particular, nitrogen-containing heterocyclic hydrazones have attracted much attention as analytical reagents, because of high sensitivity and selectivity, easy synthesis and good yield. Their applications have been reviewed by Katyal and Dutt [3] and later by Jain and Singh [4].

In recent years, surfactants have become of great interest because they provide a reaction medium in which the sensitivity and selectivity of numerous reactions are improved. For example, the metal complexes formed in micellar media are generally more stable than those formed in the absence of micelles [5,6]. Most prior work has focussed on spectrophotometric determinations, but surfactants are now also being applied successfully in fluorimetry [7–12], giving even higher sensitivity and lower detection limits. This first of such applications was the determination of aluminium with lumogallion in the presecnce of the non-ionic surfactant polyethylene glycol monolauryl ether. Recently, Sanz Medel [13] and Garcia Alonso [14,15] and Hinze et al. [16], have reviewed the topic of micellar media in fluorimetric analysis.
In this work, a new hydrazone, in which a nitro group was introduced in the 5-position of the pyridine ring moiety of 2-pyridinecarbaldehyde-pyridylhydrazone (2PC-5NPH), was synthesized and applied as a reagent for the determination of micro amounts of Fe(III). In addition, a study of the effect of surfactants on the fluorescence phenomena of the Fe(III)–2PC-5NPH complex was conducted.

The described, developed fluroscence method for ferric ion is sensitive, simple and very selective.

2. Experimental

2.1. Synthesis of 5-nitro-2-pyridylhydrazine

2PC-5NPH was synthesized according to Scheme 1 as follows: 1.58 g of 2-chloro-5-nitro-

pyridine was dissolved in 100 ml ethanol (0.01 M) at room temperature. To this solution was added dropwise, a solution of hydrazine monohydrate (7.5 g) with stirring. The mixture was stirred for an additional 60 min at room temperature, allowed to stand overnight in a refrigerator, filtered and dried at 50°C under reduced pressure to yield a red precipitate, which was used without purification in the next step, the synthesis of 2PC-5-NPH.

2.2. Synthesis of 2-pyridinecarbaldehyde-5-nitro-pyrdylhydrazone

2PC-5-NPH was synthesized by refluxing equimolar amounts of 2-pyridinecarbaldehyde and 5-nitro-2-pyridylhydrazine in ethanol–water (4:1, V/V) for 3 h. The product, a yellow crystal, was recrystallized from ethanol and dried at 110°C for 10 h under reduced pressure.

2.3. Reagent

Analytical-reagent grade chemicals and distilled, deionized water were used throughout. A iron(III) stock solution $(1 \times 10^{-3}$ M) was prepared by dissolving appropriate amounts of analytical grade $FeCl_3$ in doubly distilled water and this was standardized with EDTA [17]. Working solution were prepared by suitable dilutions of the stock solution with deionized water. The hexamethylenetetramine (HTM) was dissolved in deionized water.

Surfactant solutions were prepared by dissolving suitable amounts of surfactants in deionized water with gentle heating.

2.4. Apparatus

All fluorescence measurements were made with a Shimadzu RF-5000 spectrofluorophotometer using 1 cm quartz cells. The band passes were set at 5 nm for both the excitation and emission monochromators.

A Hitachi IR 435 infrared spectrophotometer, NOVA-310 pH meter and Yamato model MP-1 melting point apparatus were used. The surface tension of the soluble solutions were measured at 25°C $\pm$ 0.1 with a Fisher tensiometer equipped with a glass plate.

Scheme 1. Synthesis of 2PC-5NPH.

Table 1
Data of melting point, yields and infrared sprctra of synthesised hydrazone

Hydrazone	M.P. (°C)	Yield (%)	IR spectra (cm^{-1})		
			$\nu_{C=N}$	$\nu_{C=N}$	ν_{N-H}
5N-2PH	200	92.5	–	1420	1290
2PC-5NPH	236	71.8	1600	1423	1292

2.5. General procedure for the detemination of Fe(III) in the presence of surfactant

A 5 ml sample solution containing 1×10^{-4} M Fe(III) was placed in a 50 ml calibrated flask; 5.0 ml of 1×10^{-3} M 2PC-5NPH in methanol, 2.5 ml of 0.5 M hexamethylenetetramine and 10 ml of 1.0×10^{-3} M surfactant solution were added, then the contents were diluted to the mark with methanol and mixed thoroughly.

With excitation at 300 nm, fluorescence spectra and the fluorescence intensity at 420 nm were measured.

3. Results and discussion

3.1. Identification of the hydrazones

2PC-5NPH is yellowish solid which is slightly soluble in water but can be easily dissolved in methanol. Identification of the synthesized hydrazones was carried out by infrared (IR) spectra. IR spectra (potassium bromide pellet) of the synthesized hydrazones were measured in order to confirm their structures.

The spectra exhibited absorption peaks assigned to the stretching vibration of an azomethine bond ($-N=C<$) around 1600 cm^{-1}. The melting point, yield and IR spectral data of the synthesized hydrazones are summarized in Table 1.

3.2. Study of Fe(III)-2PC-5NPH complex

The 2PC-5NPH ligand reacted with Fe(III) to yield a yellow colored solution at pH 7.0. Fig. 1

Fig. 1. Excitation (Ex) and emission (Em) spectra of 2PC-5NPH and its Fe(III) complex in 35% water and 65% methanol medium. (1) absence of Fe(III); (2) 2.6×10^{-7} M Fe(III); (3) 5.0×10^{-5} M Fe(III); (4) 1.0×10^{-4} M Fe(III): 1.0×10^{-4} M 2PC-5NPH.

shows the excitation and emission spectra of the reagent and its complex with Fe(III) at pH 7.0. The excitation and emission peak of the ligand were found to be 300 nm and 425 nm, respectively. As shown in Fig. 1, a remarkable increase in fluorescence intensity and absorbance of the ligand at each wavelength was observed in the presence of Fe(III). The excitation peak of the 2PC-5NPH in the precence of Fe(III) is also at 300 nm, but the emission peak shifts from 425 to 410–420 nm.

The pH effect on the fluorescence intensity of the Fe(III)-2PC-5NPH complex at 420 nm was made in the pH range 4.0–11.2 (Fig. 2). The

Fig. 2. Effect of pH on the fluorescence intensity of Fe(III)-2PC-5NPH in 35% water and 65% methanol medium. 2.0×10^{-5} M Fe(III): 1.0×10^{-4} M 2PC-5NPH.
Fig. 3. Plot of the continuous variation method for formation of the Fe(III)–2PC-5NPH complex in 35% water and 65% methanol medium. [Fe^{3+}] and [2PC-5NPH]: 1.0 × 10^{-4} M.

results indicate that maximum fluorescence intensity was obtained at pH 7.0. Thus, pH 7.0 was selected as the optimum pH in further investigations. The solution pH was adjusted with hexamethylenetetramine solution and hydrochloric acid or sodium hydroxide.

In order to study the composition of Fe(III) and 2PC-5NPH, the mole ratio of Fe(III) and 2PC-5NPH in the Fe(III)-2PC-5NPH complex was determined using the continuous variation method.

The fluorescence intensity of each solution containing a different volume fraction of Fe(III) and 2PC-5NPH at the same concentration was measured. The results (Fig. 3) indicate that the mole ratio of Fe(III) and 2PC-5NPH in the complex was 1:2.

The composition of 2PC-5NPH and Fe(III) can be considered with the formation of the Fe(2PC-5NPH)$_2$ complex as follows:

$$Fe^{3+} + 2HL = FeL_2^- + 2H^+ \ (HL = 2PC\text{-}5NPH)$$
3.3. Effect of surfactant on the fluorescence intensity of the Fe(III)–2PC-5NPH complex

The effects of various surfactants were studied. As shown in Table 2 and Fig. 4, a remarkable increase of the absorbance and fluorescence intensity of the Fe(III)–2PC-5NPH complex was observed in the solution of cationic and non-ionic surfactants. The order of increase in absorbance and fluorescence intensity was hexadecyltrimethy-

Table 2
Fluorescent characteristics of Fe(III)–2PC-5NPH in the different surfactants

Surfactant	Concentration (M)	Fluorescence intensity λ_{em} (420 nm)	EF Em
None		21.8	1.0
CTMAB	1.0 × 10^{-4}	89.4	4.1
CPC	1.0 × 10^{-4}	32.7	1.5
DTMAB	1.0 × 10^{-4}	53.1	2.4
Triton X-100	1.0 × 10^{-4}	46.5	2.1
SDS	1.0 × 10^{-4}	20.6	0.9

Fe(III):1.8 × 10^{-5}; 2PC-5NPH: 1.0 × 10^{-4} M.
EF, enhancement factor.

lammonium bromide (CTMAB) > dodecyltrimethylammonium bromide (DTMAB) > Triton X-100 > cetylpridinium chloride (CPC). However, in a solution of the anionic surfactant, sodium dodecyl sulphate (SDS), a somewhat diminished fluorescence was observed.

3.4. Effect of CTMAB concentration

The greatest fluorescence intensity for the Fe(III)–2PC-5NPH complex was observed in the CTMAB surfactant. The influence of the CTMAB concentration on the fluorescence intensity of Fe(III)–2PC-5NPH complex is shown in Fig. 5.

The maximum fluorescence intensity of Fe(III)–2PC-5NPH was obtained at a CTMAB concentration of 2.0 × 10^{-4} M. Hence, 2.0 × 10^{-4}

Fig. 4. Surfactant effects on the excitation and emission spectra of the Fe(III)–2PC-5NPH complex at pH 7.0. 1.8 × 10^{-5} M Fe(III); 1.0 × 10^{-4} 2PC-5NPH; 1 × 10^{-4} M surfactant.
Fig. 5. CTMAB concentration effects on fluorescence intensity of Fe(III)–2PC-5NPH complex at pH 7.0. 1.8×10^{-5} M Fe(III); 1.0×10^{-4} M 2PC-5NPH.

M CTMAB was chosen as the optimum concentration in further studies.

The critical micellar concentration (CMC) of CTMAB in the water medium was determined as 5×10^{-4} M. When CTMAB was dissolved in the water above the CMC, the molecules of CTMAB exist mainly as a micelle state. The phenomenon of the increase of fluorescence intensity below 2×10^{-4} M can be considered as the solubility increase of Fe(III)–2PC–5NPH by the surfactant, but in a concentration higher than 2×10^{-4} M CTMAB, the bromide ion liberated from CTMAB reduced the fluorescence intensity of the complex.

The mole ratio of the Fe(III)–2PC-5NPH complex was also determined in the presence of 1×10^{-3} M CTMAB using the continuous variation method.

The mole ratio of Fe(III) and 2PC-5NPH in the presence of CTMAB was also 1:2.

3.5. Calibration curve

The conditions for determining Fe(III) with 2PC-5NPH were optimized. The most suitable concentration of 2PC-5NPH was found to be 1.0×10^{-4} M (for 1.0 μg ml^{-1} iron).

A linear relationship between fluorescence intensity and Fe(III) concentration was obtained in the 0.20–1.45 μg ml^{-1} range (Fig. 6). The calibration equation, obtained by the least-squares method, is: $Y = 1.496x - 0.04$ ($r = 0.997$, $n = 7$),

Fig. 6. Calibration curve of Fe(III)–2PC-5NPH at pH 7.0 using optimized procedure.

where Y is the relative fluorescence intensity, and x the concentration of Fe(III) in μg ml^{-1}. The detection limit ($S/N = 2$) was 0.028 μg ml^{-1} and the relative standard deviation at the 0.3 μg ml^{-1} iron level was 2.9% ($n = 7$).

3.6. Effect of foreign ions

The influence of common cations and anions on the determination of 1.0 μg ml^{-1} of Fe(III) was examined. The results are summarized in Table 3. The tolerated amounts of each ion were calcul-

Table 3
Effect of interfering ions on the determination of iron(III) (1 μg ml^{-1})

ated as the concentration values which resulted in less than 5% deviation in the fluorescence intensity.

4. Conclusion

2PC-5NPH is a new fluorimetric reagent for the determination of Fe(III). The method described is very sensitive and selective for the direct determination of iron(III) over the range 0.20–1.45 μg ml^{-1} Fe(III). It was found that the fluorescence intensity of the Fe(III)–2PC-5NPH complex in the presence CTMAB was strongly enhanced. The excitation and emission peak of Fe(III)–2PC-5NPH are 300 nm and 420 nm, respectively, in both the presence and absence of CTMAB. The detection limit of the method is 0.028 μg ml^{-1}.

HPLC–Electrochemical detection with graphite–poly(tetrafluoroethylene) electrode Determination of the fungicides thiram and disulfiram

C. Fernández, A.J. Reviejo, L.M. Polo, J.M. Pingarrón*

Department of Analytical Chemistry, Faculty of Chemistry, Complutense University of Madrid, 28040 Madrid, Spain

Abstract

The suitability of composite graphite–poly(tetrafluoroethylene) (Teflon) electrodes as amperometric indicator electrodes in HPLC detection is demonstrated. The determination of the fungicides thiram and disulfiram in the presence of ziram has been chosen as an analytical problem. The optimization of working conditions, such as the choice of the organic solvent used in the mobile phase as well as its percentage, the potential applied to the composite electrode, and the time elapsed between mixing the carbamates and the injection, has been accomplished by using the wall-jet flow-cell configuration. The effect of the acetonitrile percentage used in the mobile phase on the retention of thiram, disulfiram, ziram and phenol was evaluated. Resolution up to the baseline can be achieved with 45% acetonitrile. The sensitivity of the determination of thiram and disulfiram in the presence of a constant concentration of ziram is slightly better when using a wall-jet cell; however, the background current is higher, as well as the baseline noise and the time necessary to achieve stabilization of the baseline before the injection. Lower limits of detection for both fungicides, as well as a better repeatability, were obtained when using a thin-layer flow cell configuration. As an application, the determination of thiram in spiked apple samples, at a level of 0.5 mg thiram kg^{-1} apple, has been carried out with a mean recovery of 97 $\pm$ 3% for a significance level of 0.05.

Keywords: Composite electrodes; Disulfiram; Graphite–Teflon; HPLC; Thiram

1. Introduction

The use of composite matrices, consisting of at least one conductor phase mixed with at least one insulator phase, for the fabrication of high performance indicator electrodes in flowing systems such as flow-injection analysis (FIA) and liquid chromatography (LC) is an area of increasing practical interest in modern electroanalysis. The main objective is, obviously, to improve the performance of conventional electrode materials such as glassy carbon (GC), essentially with regard to sensitivity and fouling of the electrode surface, which involves tedious chemical or electrochemical pretreatment of such a surface. An outstanding approach to achieve this is the use of carbon paste electrodes whose use in LC detection has

---

* Corresponding author.

been reviewed by Baldwin and Thomsen [1]. Nevertheless, some authors [2–4] have claimed that these electrodes show a lack of long-term stability in flowing streams mainly because of swelling phenomena. Several interesting strategies have been proposed to improve the mechanical stability of carbon electrode matrices, including the use of conductive carbon cement [5], or of several insulator materials such as Kel-F [6], epoxy [7], solid parafin [8], and Teflon (poly(tetrafluoroethylene)) [9].

Regarding Teflon–graphite electrodes, although Shah and Honigberg demonstrated in 1983 that these electrodes are useful for the electrochemical detection of phenolic compounds, separated by liquid chromatography [10], surprisingly, no further work on the use of this composite material for electrochemical detection (ED) in flowing systems was made until very recently, when our group reported flow-injection methods with amperometric detection based on the electrochemical oxidation of the N,N-dialkyldithiocarbamate fungicides thiram (tetramethylthiuram disulfide) and disulfiram (tetraethylthiuram disulfide) on these electrodes [11]. We showed that usual FIA methodologies used with conventional electrodes can also be applied to graphite–Teflon composite electrodes, which offer very advantageous properties from a practical point of view, in particular their compatibility with non-aqueous solvents and the very easy regeneration of the electrode when necessary.

In this paper, graphite–Teflon electrodes have been used as electrochemical detectors in HPLC. Because of the strong interference that the presence of thiram caused on the disulfiram amperometric signal, as well as the interference from other species previously tested [11] such as the fungicide zinc N,N-dimethyldithiocarbamate (ziram) and phenol, we have chosen the determination of both thiram and disulfiram in the presence of ziram as an analytical problem for evaluating graphite–Teflon composite electrodes as amperometric indicator electrodes in HPLC detection.

2. Experimental

2.1. Apparatus

Chromatographic separations were carried out using a Waters Model 510 (Millipore) solvent-delivery pump connected to a 10 cm × 0.46 cm i.d. C_{18} column packed with Lichrosorb RP18 with a particle size of 5 μm (Technokroma). Samples were injected by means of a Valco (Metrohm) injection valve with a sample loop of 10 μl. The column was thermostatted at 25°C.

Electrochemical detection was accomplished by using a Metrohm 656 detector provided with a Metrohm EA-1096 wall-jet cell. Detection with a thin-layer configuration was carried out with a Model MP-1305 EG&G PARC LC thin-layer cell. Electrode potentials were controlled by means of an Eco Chemie Autolab PSTAT 10 potentiostat equipped with the module ECD and using the software package GPES 3.1.

A P-Selecta Ultrasons ultrasonic bath, a P-Selecta Meditronic centrifuge, a W-2000 Heidolph rotary vacuum evaporator, and a Waring blender with glass container were also used.

2.2. Electrodes

Graphite–40% Teflon pellets were fabricated as described in a previous paper [9]. When working with the wall-jet cell, 3.0 mm diameter disk portions of the pellets were bored, and each disk was press-fitted into a Teflon holder. Electrical contact was made through a stainless-steel screw. A Metrohm Model 6.0727.000 Ag/AgCl/3 M KCl reference electrode and Metrohm Model 6.0333.010 gold counter electrode were also used.

When working with the thin-layer configuration, a cell body similar to that of the MP-1305 commercial cell was made from Teflon, leaving a 3.0 mm diameter hole in place of the conventional glassy carbon disk. This hole was partially refilled with carbon paste (Metrohm 6.2801.00) in order to allow electrical contact and finally, the 3.0 mm diameter graphite–40% Teflon disk was press-fitted into the cavity. The reference electrode used was an EG&G PARC Model P/N 219054 Ag/AgCl electrode.

2.3. Reagents and solutions

Thiram, disulfiram, ziram and phenol (Aldrich) stock solutions (2500 μg ml^{-1} in the case of thiram, disulfiram and phenol, and 750 μg ml^{-1} in the case of ziram) in acetonitrile (Panreac) were prepared weekly by weighing. More dilute standards were obtained by suitable dilution with acetonitrile. All stock solutions were stored at 4°C in the refrigerator.

The mobile phases used were mixtures of acetonitrile and 0.01 M phosphate buffer pH 7.4, and they were filtered through Whatman nylon membrane filters (0.45 μm pore size). All chemicals were of analytical-reagent grade, and the water used was obtained from a Millipore Milli-Q purification system.

2.4. Procedures

The graphite–Teflon electrode was polished daily for 5 s on a 150 grit SiC paper. No chemical or electrochemical regeneration of the electrode surface was then necessary during the whole working day.

Calibration graphs for both thiram and disulfiram were constructed with and without the presence of ziram as interference. They were obtained by injecting 10 μl aliquots of the appropriate stock solution of a mixture of the three herbicides in pure acetonitrile into the mobile phase (55:45 v/v mixture of 0.01 M phosphate buffer pH 7.4 and acetonitrile) at a flow rate of 2.0 ml min^{-1} (pressure = 1400 p.s.i.). Injections were carried out immediately after the preparation of the mixture solution of ziram, thiram and disulfiram, in that order. The oxidation signals were recorded at + 1.0 V vs. Ag/AgCl.

2.5. Determination of thiram in spiked apple samples

About 50 g of cut apple sample was weighed accurately and transferred to a blender. Then 50 μl of a 500 μg ml^{-1} thiram stock solution and 125 ml of chloroform were added. The mixture was homogenized at 18 500 rev min^{-1} for 1 min and transferred into six 35 ml centrifuge tubes.

The blender was rinsed several times with water and the rinsings were added to the tubes. After centrifugation at 4000 rev min^{-1} for 10 min, the organic phase was filtered through a Buchner funnel fitted with a No. 4 glass frit (10–16 μm diameter), transferred to a 250 ml vessel of the rotary vacuum evaporator, and evaporated to dryness at room temperature. The residues were dissolved in 4.5 ml of acetonitrile with the aid of ultrasonic stirring, filtered through nylon membrane filters of 0.2 μm pore size (Lida), and collected in a 5 ml volumetric flask, diluting to the mark with acetonitrile. A 10 μl portion of this solution was injected into the HPLC column, and chromatographed at a flow rate of 2 ml min^{-1}. The determination of thiram was carried out using a calibration graph, in the range 5.0–25.0 μg ml^{-1}, obtained by adding aliquots of fungicide stock solution to a blank apple sample subjected to the above treatment.

3. Results and discussion

The optimization of working conditions, such as the choice of the organic solvent used in the mobile phase as well as its percentage, the potential to be applied to the composite electrode, and the time elapsed between mixing the carbamates and the injection, was accomplished by using the wall-jet flow-cell configuration. The composite electrode composition, i.e. a mixture of graphite–40% Teflon, as well as the aqueous component of the mobile phase (phosphate buffer pH 7.4), were the same as those used in previous works [9,11].

3.1. Choice of the mobile phase

Prior to the coupling of the chromatographic column to the system, some assays were carried out in order to estimate the amperometric response of a graphite–40% Teflon electrode to the decrease in the polarity of 0.01 mol l^{-1} phosphate buffer (pH 7.4) carrier solution, due to the addition of different methanol or acetonitrile ratios. In order to do this, 60 μg ml^{-1} aliquots of thiram solutions prepared in the same medium as the carrier were injected into the flowing system with

no chromatographic column. The flow rate was 2.0 ml min^{-1}, and the applied potential + 1.0 V [11].

As the organic solvent percentage increased, a sharp decrease in the peak current as well as an increase in the background current were observed. The amperometric signal decreased by 80% if 25% methanol was used in the mobile phase, and by 95% if 50% was employed. If 75% methanol was used, the analytical signal was lower than the baseline noise.

When using acetonitrile, the signal decrease was somewhat lower. If the mobile phase contained 25% acetonitrile, i_p was 70% lower than in 0.01 M phosphate buffer medium, but the noise level and the background current were lower than when using methanol. For 75% acetonitrile, precipitation of phosphate was observed. Taking into account these results, acetonitrile was chosen as mobile phase modifier.

In previous work [11], amperometric flow-injection measurements of thiram and disulfiram in aqueous carrier solutions, using graphite–Teflon composite electrodes, were made by applying a potential of + 1.0 V to the electrodes. Nevertheless, in order to ascertain if the use of an acetonitrile:phosphate buffer mixture as mobile phase could affect this potential value for amperometric detection, the peak current values measured at different applied electrode potentials within the

Fig. 1. Influence of the applied potential on the thiram peak current for a graphite–40% Teflon composite electrode. Carrier: (●) 0.01 M phosphate buffer (pH 7.4); (■) 40:60 v/v acetonitrile: 0.01 M phosphate buffer (pH 7.4). Flow rate 2.0 ml min^{-1}.

range 0.50–1.20 V were examined. Fig. 1 shows data obtained from 10 μl injections of 180 μg ml^{-1} thiram in a medium consisting of 40:60 v/v mixture of acetonitrile and 0.01 M phosphate buffer pH 7.4, used as mobile phase. Data obtained in 0.01 M phosphate buffer with no acetonitrile added are also displayed for comparison purposes. As can be seen, the shape of these plots is similar in both cases showing well-defined plateau zones between + 0.90 and + 1.1 V, and consequently, the same potential value of + 1.0 V was chosen to be applied to the graphite–Teflon electrode in subsequent experiments.

A very important aspect of the practical use of graphite–Teflon composite electrodes is to show how this material improves the performance of conventional electrodes, in particular of GC electrodes, in flowing conditions. Fig. 2 shows successive injections of 2.25 μg disulfiram, using the same carrier solution mentioned above, at both graphite–Teflon (A) and glassy carbon (B) amperometric indicator electrodes. As can be clearly seen, successive responses are highly reproducible when using the composite electrodes, whereas dramatic fouling of the electrode surface, leading to disappearance of the disulfiram peak, becomes evident in the case with a GC electrode. Furthermore, the magnitude of the peak current is very much larger at the graphite–Teflon electrode. Another important difference is the time needed to attain a stable baseline. As can also be observed in Fig. 2, a constant background current is reached after approximately 400 s in the case of the composite electrode, whereas at least 1500 s is needed when GC is used. All these practical aspects confirm the potentiality of graphite–Teflon composite electrodes as suitable indicator electrodes in flowing systems.

3.2. Separation of thiram, disulfiram, ziram and phenol

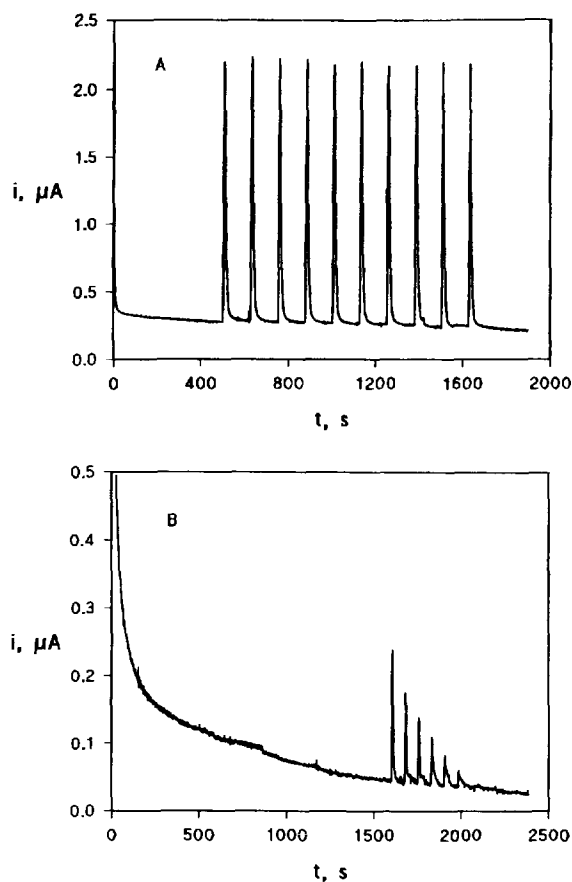
The effect of the acetonitrile percentage used in the mobile phase on the retention characteristics of thiram, disulfiram, ziram and phenol was evaluated. The respective capacity factors, when 0.6 μg of each substance was injected individually in mobile phases of different acetonitrile:phosphate


Fig. 2. Successive injection of 2.25 μg disulfiram in a 40:60 v/v mixture of acetonitrile and 0.1 M phosphate buffer pH 7.4 using (A) a graphite–40% Teflon electrode, (B) a GC electrode, as amperometric detector. Flow rate: 2.0 ml min⁻¹.

buffer ratios, are shown in Table 1. As can be deduced, ziram does not interact with the column, and its retention time practically coincides with the value of t_0 calculated from the quality control data of the column. However, no baseline perturbation at t_0 was detected when pure acetonitrile was injected and, consequently, the determination of ziram would also be possible. The k' values in Table 1 were calculated by taking the ziram retention time as t_0.

When acetonitrile percentages of 40% or lower were used, disulfiram exhibited retention times higher than 30 min and, therefore, its signal became broader and the analysis time increased considerably. However, as expected, when the acetonitrile content in the mobile phase increased,

the peak areas for both thiram and disulfiram decreased remarkably due to a lowering of the diffusion coefficient with changing ionic strength and viscosity of the medium. Resolution up to the baseline of the three fungicides can be achieved when an acetonitrile percentage of 45% is used.

When a solution containing a binary mixture of thiram and disulfiram was chromatographed, two peaks were obtained if the injection was made immediately after preparing the mixture. However, if a few minutes elapsed before the injection, a third peak appeared, probably corresponding to N,N-diethyl-N',N'-dimethylthiuram disulfide, with an intermediate retention ($k' = 6.9$ for 50% acetonitrile in the mobile phase). This effect has been described previously in the literature [12]. Fig. 3 shows chromatograms corresponding to a mixture of 60 μg ml⁻¹ thiram and 60 μg ml⁻¹ disulfiram when the injection (10 μl) was accomplished just after the preparation of the mixture, and after different elapsed times. As the time elapsed between preparation of the mixture and injection increased, the peak areas for thiram and disulfiram decreased and that of the compound with an intermediate retention increased up to approximately 90 min.

The above-mentioned third peak was not observed if a mixture of thiram and ziram was chromatographed, even though the injection was carried out 90 min after the preparation of the binary mixture solution. On the contrary, if a mixture of ziram with disulfiram was analysed, four peaks appeared in the chromatogram regis-

Table 1
Capacity factors for thiram, disulfiram, ziram and phenol in acetonitrile:phosphate buffer mobile phases. 0.6 μg of each substance injected. Flow rate: 2.0 ml min⁻¹

Fungicide	Mobile phase Acetonitrile: 0.01 M phosphate buffer (pH 7.4)			
	40:60	45:55	50:50	60:40

Mobile phase. 50:50 v/v acetonitrile: 0.01 M phosphate buffer (pH 7.4); flow rate. 2.0 ml min^{-1}; E_{app} = + 1.0 V; volume injected, 10 μl.

Fig. 5. HPLC-ED response for a sample containing 30 μg ml^{-1} ziram (1), 30 μg ml^{-1} phenol (2), 30 μg ml^{-1} thiram (3), and 60 μg ml^{-1} disulfiram (4) injected immediately after preparing the mixture. Mobile phase, 38:62 v/v acetonitrile:0.01 M phosphate buffer (pH 7.4). Flow rate: 1.5 ml min^{-1} from (a) to (b), and 5.0 ml min^{-1} after (b).

tered some minutes after the injection, with capacity factors of 0, 3.0, 6.4 and 15.7, when 50% acetonitrile in the mobile phase was used (Fig. 4). The retention time of the second eluate was coincident with the retention time of thiram under the same conditions, and so it can be deduced that ziram, thiram, disulfiram and the aforementioned N,N-diethyl-N',N'-dimethylthiuram disulfide co-
existed in solution.

Resolution up to the baseline of the peaks corresponding to the above-mentioned four compounds can be achieved with 45% of acetonitrile in the mobile phase and a flow rate of 2.0 ml min^{-1}. Consequently, these working conditions were chosen for all subsequent studies (calibration graphs and determination of thiram in apple samples), except those in which phenol was involved. However, if phenol was also present in the test solution, its peak overlapped with that of ziram, although this did not prevent the determination of thiram and disulfiram. If a complete separation of all these compounds was desired, a lower acetonitrile percentage had to be used, as well as a modification of the flow rate when running the chromatogram in order to avoid an excessive retention of disulfiram. This increase in the flow rate produced a baseline drift, as would happen if this problem was solved by using a mobile phase gradient. Fig. 5 shows a chromatogram obtained from a mixture containing ziram, phenol and thiram, each of them at 30 μg ml^{-1} level, and 60 μg ml^{-1} disulfiram using 38% acetonitrile in the mobile phase, and a flow rate of 1.5 ml min^{-1} between the points marked (a) and (b) in the chromatogram, and a flow rate of 5.0 ml min^{-1}

from (b). A 10 μl aliquot was injected immediately after the preparation of the mixture.

3.3. Calibration graphs. Comparison of wall-jet and thin-layer flow-cell configurations

Calibration graphs for both thiram and disulfiram in the presence of a constant concentration of ziram (45 and 4.5 μg ml⁻¹ for the upper and lower concentration ranges considered respectively) were constructed. For comparison purposes, both wall-jet and thin-layer flow-cell configurations were employed to obtain these calibration graphs. Ranges of linearity appear in Table 2. Sensitivity is always slightly better when using the wall-jet cell. However, background current is higher, as well as baseline noise and the time necessary to achieve stabilization of the baseline before the injection (35–40 min in the case of a wall-jet cell configuration vs. 10 min with a thin layer cell).

The analytical characteristics calculated from the respective calibration graphs are listed in Table 2. Relative standard deviations were calculated from 10 different solutions containing 2.0 μg ml⁻¹ thiram, 6.0 μg ml⁻¹ disulfiram and 4.5 μg ml⁻¹ ziram in the case of the wall-jet configuration, and 1.0 μg ml⁻¹ thiram, 4.0 μg ml⁻¹ disulfiram and 4.5 μg ml⁻¹ ziram for the thin-

layer configuration. The limits of determination and detection were calculated according to the 10 × standard deviation and the 3s criteria respectively, where s is the standard deviation of the signals from the above-mentioned solutions. As can be deduced, lower limits of determination and detection were obtained, as well as a better repeatability, for both thiram and disulfiram when using a thin-layer flow-cell configuration.

3.4. Determination of thiram in spiked apple samples

As an application of the HPLC with amperometric detection method using the graphite–PTFE composite electrode, the determination of thiram in spiked apple samples, at a level of 0.5 mg thiram kg⁻¹ apple, was carried out by applying the procedure described in Section 2. Thiram is widely used as an active fungicide, having been found in apples, and the amounts allowed in agricultural applications are 0.03–0.01 g kg⁻¹ [13]. In the European Union regulations tolerances for dithiocarbamates are drafted as 2–7 mg kg⁻¹ (expressed as carbon disulfide). The proposed procedure was first applied to a blank apple sample to which no thiram was added. The signals obtained when an aliquot of the blank sample extract was injected (1), as well as those corre-

sponding to succesive additions of 5 μg ml⁻¹ thiram to different aliquots of this extract (2–6). are shown in Fig. 6. The slope and intercept of the calibration plot constructed in this way were 0.120 ± 0.006 μA s 1 mg⁻¹ and 0.1 ± 0.1 μA s respectively ($r = 0.9995$). As can be observed, a chromatographic peak due to an unknown endogenous compound present in the apple appeared before the peak of thiram. This endogenous peak did not interfere with the thiram analytical signal, thus allowing thiram determination under the chosen working conditions.

For three determinations of apple samples spiked with thiram at a concentration level of 0.5 μg g⁻¹ (which implies a final thiram concentration in the analytical solution of 5.0 μg ml⁻¹). an experimental mean concentration of 4.8 ± 0.2 μg ml⁻¹ (0.48 ± 0.02 μg g⁻¹) was obtained with a mean recovery of 97 ± 3% for a significance level of 0.05. This recovery is better than that obtained by other authors in the same type of sample and at the same pesticide concentration level, using different HPLC with UV detection methodologies [14–16], indicating that the method proposed here is suitable for the determination of thiram in apple samples.

Fig. 6. HPLC–ED response with a graphite–Teflon electrode for an apple sample extract: (1) blank sample extract; (2)–(6) successive additions of 5 μg ml⁻¹ thiram to different aliquots of this extract. Mobile phase. 45:55 v/v acetonitrile: 0.01 M phosphate buffer (pH 7.4); flow rate, 2.0 ml min⁻¹; $E_{app} = +$ 1.0 V; volume injected, 10 μl.

4. Conclusions

All the aforementioned results demonstrate the suitability of graphite–Teflon composite electrodes for use as electrochemical detection systems in HPLC. The methodologies employed with conventional electrodes can also be used with these consolidated segregated composites which offer very advantageous practical properties, such as their compatibility with non-aqueous solvents, resistance to fouling, and the very easy regeneration of the electrode surface when necessary.

Synchronous fluorimetric determination of salicylic acid and diflunisal in human serum using partial least-squares calibration

A. Muñoz de la Peña*, M.D. Moreno, I. Durán-Merás, F. Salinas

Department of Analytical Chemistry, University of Extremadura, 06071 Badajoz, Spain

Abstract

The simultaneous determination of salicylic acid and diflunisal in human serum has been accomplished by synchronous fluorimetry, in combination with partial least-squares multivariate calibration. The total luminescence information of the analytes has been used to optimize the spectral data set for the calibration, by analysis of the three-dimensional excitation–emission matrices. The synchronous spectrum, maintaining a constant difference of $\Delta\lambda = 128$ nm between the emission and excitation wavelengths, has been selected as optimum to perform the determination. The method is based on the fluorescence of these compounds in chloroform containing 1% (v/v) acetic acid. Serum samples are treated with trichloroacetic acid to remove the proteins, and both analytes are extracted into chloroform–1% (v/v) acetic acid prior to the determination. For concentrations ranging from 60–240 μg ml^{-1} of each drug, analytical recoveries range from 96% to 103% for salicylic acid and from 97% to 105% for diflunisal.

Keywords: Diflunisal; Partial least-squares; Salicylic acid; Synchronous Fluorimetry

1. Introduction

Diflunisal [2-hydroxy-5-(2,4-difluorophenyl) benzoic acid] is a ring-substituted salicylic acid derivative with analgesic and anti-inflammatory properties which make the drug useful for the treatment of osteoarthritis [1]. A comparison of the pharmacological profile of diflunisal with those of some well-known anti-inflammatory agents, such as aspirin, ibuprofen and indomethacin, showed that diflunisal is more potent and less toxic than these drugs [2].

Two reports [3,4] have appeared demonstrating that diflunisal significantly interferes with salicylate measurements in most methods used in the routine analysis of this drug: photometry, fluorimetry and fluorescence polarimetry. This interference is a problem if the salicylate concentration determined by these methods is used for therapeutic monitoring, or in emergency toxicology screening of salicylate [3].

To analyze mixtures of salicylic acid and diflunisal in serum samples, gas chromatography [5] or high performance liquid chromatography [6] have been used.

Recently, a non-chromatographic method has been proposed for the simultaneous determination

of diflunisal and salicylic acid in human serum by second-derivative synchronous fluorimetry [7].

Multivariate statistical methods, such as principal component regression (PCR) and partial least-squares (PLS), have been applied in the analysis of mixtures, using mainly infrared or UV/visible absorption spectroscopy. Only a small number of methods have been described in which fluorescence data are used for multicomponent analysis, by multivariate calibration methods [8]. Lindberg et al. [9] applied PLS calibration, for the first time, to emission fluorescence data, analyzing mixtures of humic acid and ligninsulfonate. Martens and co-workers [10–12] quantified three botanical components, pericarp, aleurone and endosperm, in several wheat varieties, to analyse the cereal composition, by applying PLS calibration. To perform the determination, a combination of several emission scans, recorded at different excitation wavelengths, characteristics of each of the mixture components, was used as the spectral data set.

Jones et al. [13] reported the use of excitation, emission and synchronous spectra for the determination of acyclovir and guanine, applying several multivariate calibration methods. In addition, they investigated the utilization of second-derivative synchronous spectra in the multivariate calibration methods. They found that the use of synchronous spectral data was the best choice for the determination of acyclovir, whereas the use of second-derivative synchronous spectra was the best choice for the determination of guanine.

Sánchez Peña et al. [14] applied PLS to the analysis of binary mixtures of sulfonamides by photochemically-induced fluorimetry. Recently [15], we reported on the optimization of the spectral data set for the resolution of ternary mixtures of salicylic acid and two of its main urinary metabolites, salicyluric acid and gentisic acid. The excitation spectrum was found to be the best spectral data set to determine salicylic and salicyluric acids, while the emission spectrum was the optimum for gentisic acid determination by PLS or PCR methods. Later on [16], the PLS method was applied to the determination of the three compounds in urine samples, using a data set composed of the excitation plus the emission spectra as the analytical signal.

In the present study, a method is reported for the simultaneous determination of salicylic acid and diflunisal in serum samples, by combination of synchronous fluorimetry and PLS multivariate calibration.

2. Experimental

2.1. Reagents

Stock solutions of salicylic acid (Merck) and diflunisal (Sigma), containing 500 μg ml^{-1}, were prepared in chloroform containing 1% (v/v) acetic acid. Working standard solutions were prepared by appropriate dilution. A 160 g l^{-1} solution of trichloroacetic acid in chloroform and a 0.5 M buffer solution of glycine/sodium hydroxide pH 9.4 were also used.

2.2. Apparatus

Fluorescence measurements were made on an SLM Aminco Bowman Series 2 luminescence instrument, equipped with a 150 W continuous xenon lamp, interfaced with a PC 386 microcomputer. Data acquisition and data analysis were performed with the use of AB2 software version 1.40, running under OS/2 2.0. The excitation and emission slits were both maintained at 8 nm. The scan rate of the monochromators was maintained at 4 nm s^{-1} for recording conventional spectra, and at 30 nm s^{-1} for the acquisition of three-dimensional excitation–emission spectra. All measurements were performed in 10 mm quartz cells, at 20°C, by use of a thermostatic cell holder and a Selecta model Frigiterm thermostatic bath.

2.3. Software

The GRAMS-386 Level I version 2.0 software package, with the PLS plus version 2.1G application software [17], was used for the statistical treatment of the data and the application of the PLS multivariate calibration method. The digitized spectra acquired with the Series 2 luminescence instrument were converted to ASCII XY format with the converter included in the AB2

software, and imported to the GRAMS-386 program through the included ASCII XY converter. A converter program running in BASIC, developed by us, was used to transform the bidimensional files, in ASCII XY format, to the software package SURFER for Windows [18], to obtain the three-dimensional excitation–emission matrices presented as contour plots. The contour plots in the two dimensions of excitation and emission are generated by linking points of equal fluorescence intensity to form the contour map.

2.4. Optimization of the procedure

In the literature, several methods have been proposed for determining salicylic acid or diflunisal in biological samples. Some of the procedures described for the determination of salicylic acid in biological fluids used a preliminary step of extraction in chloroform in acid medium and re-extraction of salicylic acid to aqueous solution in basic medium [15,19–21]. We performed several experiments to examine if this method was appropriate for the determination of salicylic acid and diflunisal in mixtures. Aliquots of serum were spiked with different quantities of salicylic acid or diflunisal and extraction with chloroform in hydrochloric acid medium was performed. An aliquot of the organic phase was taken and glycine/NaOH buffer solution pH 9.4 was used for the re-extraction. The fluorescence of the aqueous phase was measured. The obtained recoveries for salicylic acid were always higher than 95%; however, the recoveries found for diflunisal were between 80% and 90%. In consequence, this method was not adequate for the determination of both drugs in mixtures.

An alternative procedure, recently described in the literature [7], was investigated. The method used trichloroacetic acid to remove proteins, and extraction of salicylic acid and diflunisal into chloroform–1% (v/v) acetic acid solution prior to instrumental determination. Chloroform containing 1% (v/v) acetic acid has also been previously reported as a solvent mixture for the fluorimetric determination of salicylic acid in the presence of aspirin [22]. Using this approach, the recoveries were satisfactory for both drugs.

2.5. Procedure

Place 0.4 ml of serum containing 25–250 μg ml^{-1} of salicylic acid and 25–250 μg ml^{-1} of diflunisal into a test tube. Add 0.12 ml of trichloroacetic acid solution in chloroform and 1.6 ml of the chloroform–1% v/v acetic acid solution. Sonicate for 5 min and centrifuge for 3 min at 1500g. Take a 0.3 ml aliquot of the organic layer and dilute to 6 ml with chloroform–1% v/v acetic acid solution, for the measurements. Record the synchronous fluorescence spectra, maintaining a constant difference $\Delta\lambda = \lambda_{em} - \lambda_{ex} = 128$ nm, in the excitation range 231–364 nm. Use the synchronous spectra as the analytical signal to make the calibration. Perform the PLS-1 calibration with a calibration set of 16 samples following a two-factor, four-level design, in the final concentration ranges varying from 0.25–2.5 μg ml^{-1} and 0.25–2.5 μg ml^{-1} for salicylic acid and diflunisal respectively. Apply the optimized calibration matrix, calculated by application of the PLS-1 method, to analyze the synchronous spectra of the problem samples, and determine the concentrations of salicylic acid and diflunisal in the serum samples.

3. Results and discussion

3.1. Optimization of chemical variables

The excitation and emission spectra of both analytes were recorded in a solution of chloroform–1% (v/v) acetic acid. In this solvent mixture, salicylic acid shows an excitation maximum at 312 nm and an emission maximum at 444 nm, while diflunisal shows two excitation maxima, at 262 nm and 324 nm, and two emission maxima, at 402 nm and 448 nm.

Serum samples were treated as described in Section 2.5, and the fluorescence intensity was measured at the corresponding excitation and emission maxima of salicylic acid and diflunisal respectively. In both cases, recoveries higher than 95% were obtained and, in consequence, this procedure was selected for the analysis.

3.2. Contour plots

When using fluorescence data for calibration, two variables, the excitation and emission wavelengths, are available for optimization. When using fluorescence data, the prior optimization of the spectral data set, before the application of a multivariate calibration procedure, has been previously suggested and exploited [13,15,16].

The selection of the optimum spectral data set to perform the determination is best examined by collecting the total luminescence spectrum of each of the analytes, in the form of an excitation–emission matrix (EEM). The EEMs were collected by scanning the emission spectra, between 300 and 540 nm, at increments of the excitation wavelength of 4 nm, between 200 and 440 nm, and displayed as contour plots. Fig. 1 shows the contour plots corresponding to salicylic acid and diflunisal in chloroform–1% (v/v) acetic acid solution. The spectral data sets selected are represented in the contour plots as solid lines slicing the data matrix. To make the selection of the corresponding scanning conditions to obtain the

Fig. 1. Contour plots of the total fluorescence spectra of (—) salicylic acid and (- - -) diflunisal in chloroform–1% v:v acetic acid. The selected paths for scanning the excitation $(\lambda_{em} = 466$ nm), emission $(\lambda_{ex} = 318$ nm) and synchronous $(\Delta\lambda = 128$ nm) spectra are shown by the solid lines slicing the data matrix. [DF] = 0.62 μg ml^{-1}, [SA] = 0.62 μg ml^{-1}.

corresponding spectra, we considered the longer wavelength maxima of both compounds. They were selected, as compromise values, to pass as clse as possible to the maxima of the components of the mixture. Taking into account that the excitation maxima of salycilic acid and diflunisal are located at 312 and 324 nm respectively, the emission spectrum was recorded at 318 nm. Similarly, as the corresponding emission maxima are located at 444 nm and 448 nm, the excitation spectrum was recorded at an emission wavelength of 446 nm. For the selection of the optimum $\Delta\lambda$ value in the synchronous spectra for the resolution of the mixture, the following considerations were taken into account. The optimum $\Delta\lambda$ value for the individual determination of salycilic acid, without losing sensitivity, would be $\Delta\lambda = \lambda_{em\,(max)} - \lambda_{ex\,(max)} = 444 - 312$ nm = 132 nm. Similarly, for diflunisal determination: $\Delta\lambda = 448 - 324$ nm = 124 nm. The $\Delta\lambda$ value chosen (128 nm) is intermediate between 132 nm and 124 nm. This selection agrees very well with the optimum value $\Delta\lambda = 130$ nm chosen by other authors for the simultaneous determination of salycilic acid and diflunisal by second-derivative synchronous fluorescence spectroscopy [7]. The corresponding excitation, emission and synchronous spectra are presented in Fig. 2.

3.3. Matrix of calibration and selection of the spectral zones for the analysis by PLS

The three different data sets selected—the excitation spectra, the emission spectra and the synchronous spectra—were evaluated to perform the determination. Because full-spectrum methods, such as PLS, can use many wavelengths it seems that wavelength selection is unnecessary, and all available wavelengths are often used. However, measurements from spectral wavelengths that are non-informative in a model degrade performance. Correlation plots that search for wavelength ranges exhibiting good selectivity and sensitivity, for the analytes of interest, over the calibration set, were used for the wavelength range selections. The spectral regions between 228 and 366 nm for excitation, between 340 and 540 nm for emission and between $\lambda_{ex}/\lambda_{em} = 231/359$ and 364/492 nm
Fig. 2. (a) Excitation (λ_{em} = 466 nm), (b) emission (λ_{ex} = 318 nm) and (c) synchronous ($\Delta\lambda$ = 128 nm) spectral data sets for the determination of SA and DF using PLS-1 multivariate calibration. [DF] = 0.62 μg ml^{-1}, [SA] = 0.62 μg ml^{-1}.

for the synchronous path were selected for the analysis, because these are the zones with the maximum spectral information from the mixture components. This implies working with 139, 201 and 134 experimental points per spectra, as the spectra were digitized each nanometer.

Recent studies of multivariate calibration techniques for the multicomponent resolution of UV/visible data [23–25] or fluorescence data [14–16] revealed no significant difference between the predictions made by PCR and PLS. However, if one considers its theoretical advantages and optimal performance over a wide range of conditions, PLS is considered to be the method of choice [26]. The PLS-1 algorithm, that performs the PLS analysis one component at a time, has been selected to perform the determination.

A two-factor, four-level design with a calibration set of 16 samples was used to statistically maximize the information content in the spectra. The calibration set for the application of the PLS-1 calibration method is represented in Fig. 3. Each concentration was varied between 0.25 and 2.5 μg ml^{-1}, through the calibration matrix, and the run order of the experiments was randomized to avoid overfitting of the data by modeling spectrometer drift.

3.4. Selection of the optimum number of factors

An appropriate choice of the number of principal components, or factors, is necessary for a correct performance of PLS. The number of factors should account as much as possible for the experimental data without resulting in overfitting, and several criteria have been recommended for selecting the optimum number [27]. To perform that selection in the PLS-1 algorithm, cross-validation, leaving out one sample at a time, was used. The predicted concentrations were compared with the known concentrations of the compounds in each calibration sample, and the predicted error sum of squares (PRESS) was calculated [28]. The PRESS was calculated in the same manner each time a new factor was added to the PLS-1 model.

To select the optimum number of factors, the criterion proposed by Haaland and Thomas [28]
Fig. 3. Mixture design for the two-component mixtures used in the data set (△), for the PLS-1 calibration method. and composition of the synthetic mixtures assayed (□), for the evaluation of the predictive ability of the method.

was used. The model selected is that with the fewest number of factors such that PRESS for that model is not significantly greater than PRESS from the mode which yielded the minimum PRESS. The significance level is attributed by using an F test ($x = 0.25$). The optimum number of factors was two for salicylic acid and diflunisal determination, with the three spectral data sets employed.

3.5. Statistical parameters

Known concentrtions of all tested samples included in the calibration matrix were compared with the predicted concentrations, by cross-valida-

tion, for the three spectral data sets employed. The values of the root mean squared error, RMSE (RSD) [29], which is an estimate of the absolute error of prediction, by cross-validation, for each component in the calibration matrix, are summarized in Table 1. The correlation coefficients, R, obtained when plots of actual versus predicted concentrations were constructed, are also included in Table 1. In addition, to evaluate the predictive ability of the method, for each compound, PLS-1 was applied to the three spectral data sets of a series of problem mixtures, selected in the same concentration ranges as those used in the calibration set (Fig. 3). The prediction set of samples was run at the same time as the calibration set of samples. To quantify the predictive performance, the standard error of prediction (SEP) [29] and the relative error of prediction (REP) were calculated. The REP is the standard error of prediction, expressed as a percentage of the mean of the true concentrations on the prediction set [23].

In Table 2, the SEP and REP values obtained for salicylic acid and diflunisal prediction, by the three data sets used, are summarized. In accordance with the statistical data obtained by the internal cross-validation, the values found for the SEP and REP show that slightly better results for the prediction of salicylic acid and diflunisal were obtained when using the synchronous spectral data set as analytical signal and, in consequence, this spectral data set was selected for the application of the method to serum samples.

3.6. Application of the method to serum samples

For the application of the method, pooled serum samples were spiked with different quanti-

Table 1
Statistical parameters of the PLS-1 method. using the three spectral data sets

Component	Excitation spectrum		Emission spectrum		Synchronous spectrum	
	RMSE (RSD)[a]	R	RMSE (RSD)[a]	R	RMSE (RSD)[a]	R
Salicylic acid	0.030 (2)	0.9992	0.041 (2)	0.9986	0.028 (2)	0.9993
Diflunisal	0.039 (2)	0.9987	0.040 (2)	0.9987	0.038 (2)	0.9988

[a] Values in parentheses correspond to the number of factors used in prediction.

Table 2
SEP and REP (%) values for salicylic acid and diflunisal determination using the excitation, emission and synchronous spectral dat by PLS-1 calibration

Compound	Excitation spectrum		Emission spectrum		Synchronous spectrum	
	SEP	REP (%)	SEP	REP (%)	SEP	REP (%)
Salicylic acid	0.044	3.0	0.050	3.4	0.036	2.4
Diflunisal	0.056	3.8	0.059	4.0	0.047	3.2

ties of salicylic acid and diflunisal, in such a form that their concentrations were in the range 25–250 μg ml^{-1}. The selected concentrations for the binary mixtures are typical for salicylic acid and diflunisal levels in serum during the first 24 h from a typical subject following an oral dose of 650 mg of aspirin [30] and 500 mg of diflunisal [31].

The proposed method was then applied as described in Section 2.5. The percentage recoveries found by application of the PLS-1 calibration method are shown in Table 3. Three spectra of three different samples at the same concentration were used for each concentration level included in the Table. Analytical recoveries range from 95% to 103% for salicylic acid and from 97% to 105% for diflunisal. for concentrations ranging from 60 to 240 μg ml^{-1}.

The method is an alternative to that proposed

by Konstantianos and Ioannou [7], for the determination of salicylic acid and diflunisal in serum samples, by second-derivative synchronous fluorimetry. In that method, diflunisal is directly monitored by measuring the second-derivative synchronous fluourimetric signal from the maximum of excitation at 248 nm, to the minimum at 272 nm, where the contribution of the salicylic acid is negligible. However, no specific signal for salicylic acid is found in the second-derivative synchronous spectrum, and the signal from the minimum at 314 nm to the maximum at 334 nm is used to obtain the contributions of both analytes. In consequence, salicylic acid concentration is calculated by difference. In our case. the PLS calibration simplifies the method, allowing the determination of both analytes using the whole synchronous spectrum as the analytical signal, instead of measuring at a single wavelength.

Table 3
Recovery of salicylic acid (SA) and diflunisal (DF) in serum samples by combination of synchronous fluorimetry and PLS calibration

Serum concentration (μg ml^{-1})		Concentration found[a] (μg ml^{-1})		Recovery ± SD (%)	
SA	DF	SA	DF	SA	DF
60	130	59	126	98 ± 1	97 ± 3
90	210	86	220	96 ± 1	105 ± 2
130	60	134	62	103 ± 2	103 ± 2
160	160	163	165	102 ± 1	103 ± 1
210	240	216	250	103 ± 2	104 ± 3
240	90	237	88	99 ± 2	98 ± 2

[a] Average of three measurements.

4. Conclusions

The results obtained in this work allow us to conclude that the two components of the binary mixture are accurately determined by synchronous fluorimetry in combination with PLS calibration.

The total luminescence information contained in the three-dimensional excitation–emission matrices allows the selection of the most suitable spectral data set to perform the multivariate calibration. The narrowing of the emission band produced by the synchronous scanning slightly improved the resolution of the overlapping spectra of the analytes investigated.

The investigation of the combination of the different fluorimetric techniques [32]—conventional synchronous, variable-angle synchronous and constant-energy synchronous fluorimetry with PLS calibration—seems interesting for broader applications in drug analysis as a rapid alternative to chromatography.

Characterization of the ionization and spectral properties of mercapto-carboxylic acids
Correlation with substituents and structural features

M. Carla Aragoni, Massimiliano Arca, Guido Crisponi*, Franco Cristiani, Francesco Isaia, Valeria M. Nurchi

Dipartimento di Chimica e Tecnologie Inorganiche e Metallorganiche, Via Ospedale 72, 09124 Cagliari, Italy

Abstract

The ionization constants in aqueous solutions of meso- and DL-dimercaptosuccinic acid and of monomethyl and dimethyl meso-succinates were carefully determined by potentiometric and spectrophotometric methods as a result of the increasing interest in these molecules as heavy metal chelators. In order to explain the influence of various substituents on ionization and ^{13}C NMR properties, the study was extended to the related oxygen derivatives of succinic acid and to simpler ethanoic derivatives. With the Swain–Lupton dual substituent treatment it was possible to clarify the influence of substituents on both spectral and equilibrium parameters. The differences in pK due to conformation are also discussed.

Keywords: Ionization constants; Mercapto-carboxylic acids; Potentiometric measurements

1. Introduction

meso-Dimercapto succinic acid (DMSA) has been proposed as a very powerful ligand for the treatment of heavy metal poisoning [1–4]. A number of studies have appeared concerning both the in-vivo behaviour of this drug [5,6] and the chemical characterization of its metal complexes and related solution equilibria [7–15]. The involvement of both carboxylic and sulfhydryl bonding is well established, although some disagreement on the bonding schemes as well as the numerical values of equilibrium constants exists. The aim of the present work is to contribute to the knowledge of DMSA equilibria via a thorough study on the ionizations of DMSA and related molecules, to explain how their acid behaviour and consequently their binding properties towards metal ions [16,17], can be affected by substituents and conformations. In order to obtain reliable results accurate potentiometric and spectrophotometric measurements were used. Table 1 shows all compounds and nomenclature used in the paper.

2. Experimental

2.1. Materials and methods

The compounds were all Aldrich products, with the exception of DL-tartaric and meso-tartaric acids which were purchased from Fluka, and DL-mercapto succinic acid, monomethyl and dimethyl dimercapto succinates which were synthesized by us according to Gerecke et al. [18]. The commercial compounds were used without further purification; the others were checked by ^{13}C NMR, IR spectra and elemental analysis with a CHN-S Fisons instrument. The following elemental analysis results were obtained:

Compound	15	18	19
Calculated (%)	C 26.4, H 3.3, S 35.2	C 30.6, H 4.1, S 32.7	C 34.3, H 4.8, S 30.5
Found (%)	C 26.7, H 3.4, S 35.1	C 30.5, H 4.3, S 32.0	C 33.9, H 4.9, S 30.8

Solutions of reagents were always freshly prepared by dissolving a weighed amount of reagent in freshly bidistilled water saturated with argon, in view of their aptitude for decomposition, and stored in a refrigerator. Taking into account the possibility of decomposition, the solutions were degassed with argon during the experimental work and periodically tested by recording UV spectra in solutions with a fixed addition of 0.1 M KOH.

2.2. IR

The IR spectra were recorded with a Perkin-Elmer 983 instrument in the range 4000–200 cm^{-1} using KBr pellets for solid compounds and CsI disks for neat liquids.

2.3. Potentiometric studies

Titrations were performed on a Dosimat 655 Metrohm automatic titrator connected to a Metrohm 654 pH meter, in a thermostatted glass cell equipped with a magnetic stirring system, a Metrohm glass electrode for highly alkaline solutions, a thermometric probe, a microburet delivery tube, an inlet–outlet ar-

gon tube and a salt bridge connected to the reference cell. This was filled with 0.1 M KCl solution, in which a saturated calomel electrode was dipped. The solutions (25 cm^3, at an ionic strength of 0.1 M KCl) were titrated at 25°C with carbonate-free 0.1 M KOH whose titre was controlled daily.

The electrode was calibrated for hydrogen ion concentration by titration with HCl; the resulting potentiometric data were analyzed with the Gran [19] procedure using our GRANPLOT program. The ionization constants were calculated with the PSEQUAD [20] program operating on the experimental data (ml, $log[H^+]$), as in Fig. 1A for dimethyl dimercapto succinate.

2.4. Spectrophotometric measurements

Absorption spectra were recorded on a Hewlett-Packard 8452 diode array spectrophotometer; a flow cell joined to a titration vessel with a peristaltic pump was used; the whole apparatus was thermostatted at 25°C and kept under an argon atmosphere. In order to make reliable spectrophotometric determinations of the ionization constants, 15–20 spectra (such as those presented in Fig. 1B for dimethyl dimercapto succinate) were collected at pH values in the range ±2 pH units around the pK value to be determined, by titrating the solutions with 0.1 M KOH (at an ionic strength of 0.1 M KCl). The spectra were then recorded by transferring the solution to the flow cell at a fixed time interval after each KOH addition. The concentrations of the acid solutions were chosen on the basis of their absorptivities estimated from previous measurements.

2.5. NMR measurements

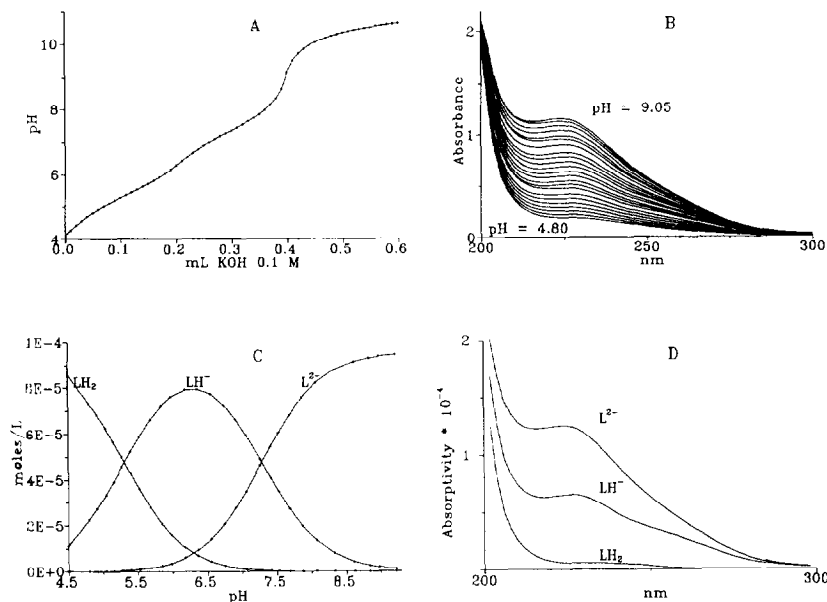
Natural abundance ^{13}C NMR spectra were recorded on a Varian VXR-300 spectrometer at 75.43 MHz using 10 mm diameter tubes. The ^{13}C spectra were ^1H-decoupled by means of square


Fig. 1. Experimental data and calculated results for dimethyl dimercapto succinate (19): (A) potentiometric titration of 25 ml of 1×10^{-3} M 19 with 0.1 M KOH (points are experimental data, solid line is calculated); (B) UV spectra of 1×10^{-4} M solution of 19 at different H^+ concentrations; (C) distribution plots of a 1×10^{-4} M solution of 19 using the pK values in Table 2; (D) absorptivity spectra of the variously protonated forms of 19 obtained by SPECFIT least-squares calculations.

wave modulation of the decoupler carrier centered on the proton field. The carbon chemical shifts were measured at 21°C in $CDCl_3$ solutions ($\delta = 77.0$). The substances were first dissolved in the smallest possible amount of CD_3OD whenever their dissolution in pure $CDCl_3$ was not possible.

2.6. Calculation of ionization constants from spectrophotometric data

Matrix A of absorbance data for each substance collected at N_W wavelengths on N_S solutions of different pH was analyzed by the SPECFIT program [21]. SPECFIT performs evolving factor analysis which allows one to calculate the concentration profiles and spectra of all absorbing species without using the law of mass action or defining the stoichiometric composition of the species. As a second step, constants and spectra of all absorbing species can be calculated with the usual least-squares analysis; the results of such calculations on the experimental data for 19 are shown in Figs. 1C and 1D.

Matrix A was also analyzed with our SPECPEAK program [22] which performs a decomposition of spectra into the component gaussian peaks. The peak heights thus calculated give a further evaluation of ionization constants and of the reliability of the data.

3. Results and discussion

Before analyzing 14, 15, 16, 18 and 19 as chelating molecules, we carried out a preliminary study of their acid behaviour. In order to evaluate how structure and substituents affect acidity, the broader set of molecules presented in Table 1 was examined. Besides the above-mentioned compounds, the basic compound 10 and the analogous hydroxy compounds 11, 12, 13 and 17 were chosen to obtain a deeper insight into the effects of substituent on both chemical and spectral features. The simpler bifunctional 0–9 compounds were also considered, both to observe the influence of each substituent in a simpler structure and to compare the trends.

Table 2
Measured values of ionization constants (pK_{C1}, pK_{C2} refer to first and second ionization of COOH; pK_{S1}, pK_{S2} refer to first and second ionization of SH), ^{13}C NMR chemical shifts in ppm (δ_{C1}, δ_{C2} refer to the two COOH groups and δ_2 and δ_3 to carbon atoms in the chain) and IR frequencies in cm^{-1} of SH and CO stretchings (ν_{SH} and ν_{CO}).

[c] The Aldrich Library of Infrared Spectra.

The pK values of the carboxylic groups were measured potentiometrically; those of the sulfhydrylic groups were measured potentiometrically and spectrophotometrically. The ^{13}C NMR and IR spectra of all these molecules were recorded to assess their strong dependence on substituents and for their prospective use in characterizing metal complexes. The collected data are summarized in Table 2. Values from the literature are specified.

In order to overcome the uncertainty inherent in potentiometry at a high pH, we resolved to resort to spectral measurements. Despite the scepticism of Rivera-Laos [23] on the reliability of the UV results of Egorova [1], it is possible to make correct measurements of ionization constants with this technique when operating in a controlled atmosphere. In a preliminary survey of these systems, large spectral variations in the 200–300 nm spectral range due to ionization of the SH groups were observed, while UV spectra appear completely insensitive to COOH deprotonation. The

pK values of ionization constants for SH, obtained both by SPECFIT and graphically from peak heights obtained by SPECPEAK, are in perfect agreement with potentiometric results.

The spectrophotometrically determined values of pK_{S2} for compounds 15 and 16 present uncertainties due to: (i) large amounts of base which alter in an assessable amount the ionic strength of the solution; (ii) changes in substances due to oxidation at high pH values. The pK values for compounds 18 and 19 are new. In fact only the values in 50% (v/v) water/methanol are reported in the dissertation of Rivera-Laos [23]. We easily prepared $\approx 10^{-3}$ M solutions of 18 and 19 in water by dissolving correct amounts of compounds in an ultrasonic bath, while Rivera-Laos reported that 18 and 19 were not water-soluble. Our results in water are ≈ 0.9 pK units lower than those in water/methanol, but they exhibit an analogous trend. The NMR and IR data agree perfectly with the previous results [23].

The ionization constants of DMSA, as studied by a large number of workers with pH metric measurements, present a large variability, above all in the first ionization at acidic pH and in the last ionization at high pH values. Our data for DMSA are comparable with those of Harris et al. [14] at the same temperature and ionic strength, and with those of Kiss et al. [15] considering that pK_1 increases and pK_2 and pK_3 decrease on increasing the ionic strength as pointed out by Vukicevic et al. [13]. The data published by Lenz and Martell [8] present a much higher pK_1 and a lower pK_3, while pK_2 is almost equal to our value. The data obtained at 20°C present a lower dispersion and as expected they are higher than those at 25°C.

Our results for **15** are comparable with those of Egorova and co-workers [1–4] at 20°C, the differences being similar to those for **16**.

As far as the last deprotonation is concerned, our comment is similar to that of Jones et al. [9] who state that "..the value 11.82 indicates the second sulfhydryl group only deprotonates at very high pH and thus is beyond the scope of the glass electrode. In view of this an estimated value of 12 is assumed". This was also confirmed by Harris et al. [14].

The ^{13}C NMR chemical shifts in $CDCl_3$ of all the compounds present typical values for the carboxylic group between 170 and 180 ppm, with the exception of compound **4** which has a 160.1 ppm shift; the values for the carbon atoms in the chain range from 10–80 ppm according to the substituent groups.

The IR bands for C=O stretching fall in the typical 1677–1744 cm^{-1} range, which is indicative of hydrogen bond association in related compounds. **10, 15, 17** and **18** show a splitting of ν_{CO}: it is reasonable to explain the presence of these two peaks as due to steric effects, as already proposed by Duncanson [24] for some derivatives of succinic acid. The values of ν_{SH} vibrations confirm that all the molecules carrying this group are involved in self-association; in the case of **14, 15, 16** and **18** a splitting of this band is also detectable.

In order to explain the numerical values of ionization constants as a function of structure and

substituents we analyzed first the trend of simple linear bicarboxylic acids as a function of the bonds between the two carboxylic groups; the data at 25°C and 0.1 μ reported in Fig. 2 are taken from Refs. [25–28]. Despite some disagreement among literature data, the trends are highly significant. The trend of the first ionization depends on inductive factors, which cause an increase in acidity with respect to unsubstituted monocarboxylic acids. This inductive effect vanishes almost completely for succininc acid (three bonds). The joint influence of inductive and resonance effects can rationalise the more complex trend of the second ionization: in this case a constant value is reached only for glutaric acid. It should be remarked that the limiting pK_1 and pK_2 values are respectively lower and higher than those obtained for linear carboxylic acids ≈ 4.6 at the same temperature and ionic strength. Furthermore, we wish to explain how the substituents in the basic structures of succinic acid affect the ionization of both carboxylic and proximal SH groups. To do this the next two sets of compounds were examined by Swain–Lupton (SL) dual substituent analysis [29,30] in the form $Y = Y_0 + r_1\mathscr{F} + r_2\mathscr{R}$. In set 1, which included compounds **0, 1, 2, 3** and **4**, we studied the influence of CH_3, CH_2OH, CH_2SH, COOH and COO$^-$ on COOH ionization, while in set 2 (**5, 6, 7, 8** and **9**) the effect of CH_3, CH_2OH, CH_2SH, COO$^-$ and COOCH$_3$ (which can be considered as COOH) on SH ion-

[a] Without $\mathscr{F}$ and $\mathscr{R}$ for CH_2SH.
[b] With $\mathscr{F}$ and $\mathscr{R}$ for CH_2SH.
[c] Calculated on **10–18** compounds.
[d] Calculated on **10–16**.

ization was examined. In these sets bivariate regression parameters were calculated by using $\mathscr{F}$ and $\mathscr{R}$ taken from Ref. [30]. Although no value for the CH_2SH group was available, $\mathscr{F} = 0.05$ and $\mathscr{R} = -0.05$ were estimated from the values for CH_2SMe in Table IV of Ref. [30]. The pK values of compounds **3** and **7** can thus be taken into account. The SL analysis performed on set 1 and set 2 data both with and without $\mathscr{F}$ and $\mathscr{R}$ for CH_2SH (cases b and a) gave almost similar
results, thus substantiating the above estimates. The values reported in Table 3 show a dependence of pK_{COOH} and pK_{SH} on both inductive and resonance factors.

The pK for COO^- is an outlier in the plot of pK_{SH} vs. pK_{COOH} for analogous substituents (see Fig. 3). This can be clearly explained by the different contributions of resonance in determining the ionization of the carboxylic group. The

Fig. 3. pK_{SH} for set 1 compounds vs. pK_{COOH} for analogous compounds in set 2.

Fig. 4. Regression line of ^{13}C NMR chemical shifts of CH_2X carbon atoms in sets 1 and 2 vs. corresponding values of resonance SL parameters.
Fig. 5. Regression line of ^{13}C NMR chemical shifts of CHX CHY carbon atoms in set 3 vs. corresponding values of resonance SL parameters, where (*), ($\triangle$) and ($\bigcirc$) refer to Y–H, OH and SH respectively.

Fig. 6. Trends of pK_{SH} vs. number of methylated carboxylic groups. ($\bigcirc$) and ($\star$) refer to pK_{s1} and pK_{s2} respectively.

values of ^{13}C NMR chemical shifts of carboxylic groups can be analyzed in the same way. In this case a greater influence of the inductive effect is observed even if lack of data variability lowers the quality of the results. The ^{13}C NMR chemical shifts of carbon atoms close to COOH and SH groups of both sets 1 and 2 were treated together on the basis of SL parameters for the X substituent on CH_2X. In this way a clear influence of the effects of resonance is shown. A linear regression on the resonance parameters alone (see Fig. 4) does not give a significant variation in either standard error (S.E.) or correlation coefficient with respect to the bivariate regression, and this implies that chemical shifts for these molecules do not depend on inductive effects.

For the succinic acid derivatives (set 3) we calculated the SL parameters as the sum of the tabulated parameters for X and Y in the central part of COOH–CHX–CHY–COOH; this is a simplified assumption which does not take into account the distances of X and Y from the ionizable COOH group. As expected on the basis of SL parameters for COOH and $COOCH_3$, there is no appreciable difference between the results of cases c (which includes compounds **17** and **18**) and d. A very strong dominance of the field effect is evident here, unlike in set 1. A very similar behaviour is shown by the second ionization constant. A strong increase in correlation coefficient
is evident when the $p\beta_2$ values are used instead of pK_2. This is probably because of some averaging of distance contributions. Also, in this case the chemical shifts depend strongly on the resonance parameter, but a second-order dependence on the substituent Y is evident, as clearly shown in Fig. 5. If a bivariate regression of the resonance parameter of X and the field parameter of Y is made, the S.E. and correlation coefficients are improved.

Regarding the deprotonations of the SH groups, each methylation of the carboxylic groups increases the acidity of both SH groups by about two pH units, as shown in Fig. 6. This can be ascribed to a large extent to the difference in electrical charge in the ionizable molecules. The results of the SL analysis show that this treatment

Fig. 7. pK_1 ($\bigcirc$), pK_2 ($\triangle$) and the melting point ($\star$) are reported vs. the X (upper) and Y (lower) substituents in the COOH–CHX–CHY–COOH molecules.

Form 1

Form 2

can thoroughly rationalize both the ionization and spectral features of sets 1 and 2 relating to simpler structures. In the third set, relating to the succinic acid derivatives, only the spectral parameters are explained satisfactorily, and the pK values are explained only in general terms. Intrinsically, an SL treatment cannot take into account those structural effects arising from conformation differences which largely affect acid behaviour. These marked differences between meso and DL forms are clearly depicted in Fig. 7, and are furthermore substantiated by the large variability of some solid-state properties, such as the frequencies and shapes of the v_{CO} band and, above all, the melting points.

The differences in acid behaviour between meso and optically active forms of tartaric acids were clearly discussed by Pettit and Swash [31] who stated that "...Provided that the interactions between the groups are purely steric in origin, the most stable conformation is the centrosymmetric anti conformer (see form a in the above scheme), in which all the similar groups are fully staggered about the central C–C axis. This conformation can only be adopted by meso form; the optically active forms necessarily contain sterically unfavourable gauche interactions (form b)". If in solution, as in the solid state, meso-tartaric acid assumes the conformation c to maximize hydrogen bonding, than the repulsion between the charged carboxylated groups is particularly unfavourable and this explains the pK_2 value of the meso form being higher than that of DL forms. The difference in the first deprotonation is smaller because the electrostatic repulsion in form c is eliminated. The intramolecular hydrogen bonding with SH groups is negligible in the case of the mercapto-succinic acids and therefore the meso compound 16 assumes the centrosymmetric anti conformation a, which is more stable than the

gauche form b assumed by optically active compounds. These latter considerations allow one to explain the fact that the pK_2 value of 16 is lower than those of both DL-mercapto succinic and meso-tartaric acids.

The very low pK_1 value of DL-mercapto succinic acid cannot be easily explained by the above arguments, and we should resort to some sort of hydrogen bonding stabilization of the fully protonated form of 15.

These considerations are basically in accordance with those on chelating properties of DMSA made by Arnold et al. [10] who suggest that "chelation is not present in the 1:1 complex of DMSA, despite the adjacent sulfhydryl groups, because of the resultant unfavourable proximity of the two deprotonated carboxylate groups which would result in this case".

Short communication

Anion-exchange enrichment of thallium and cadmium prior to their flame atomic absorption spectrometric determination in soils

E. Ivanova*, S. Tsakovski, G. Gentscheva, I. Havezov

Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, BG-1113 Sofia, Bulgaria

1. Introduction

Thallium and cadmium are among the most toxic environmental pollutants. This makes their determination in soils and other environmental samples a problem of acute importance [1,2]. The reported natural cadmium content in cultivated Bulgarian soils is $0.1-0.5\ \mu g\ g^{-1}$ [3]. There are no official data for the thallium content but it is assumed to be of the same order.

Since standard reference materials for soils and related samples, especially ones with a certified thallium content, are hard to obtain, the accuracy of methods for trace pollutant determination in such materials is often checked by comparison with the results obtained by independent methods.

Conventional flame atomic absorption spectrometry (AAS) is still widely used despite developments with electrothermal AAS. There are less matrix interferences and related systematic errors with the flame technique. The major limitation of flame AAS is poor sensitivity in comparison with electrothermal AAS. Methods for improving the sensitivity of flame AAS using preconcentration and/or special sample introduction have been described [2]. For example, the use of a slotted quartz tube provides 2.6- and 2.3-fold increases in sensitivity for thallium and cadmium respectively [4]. This sample introduction technique cannot, however, be directly applied to soil digests since the matrix components present severely etch the quartz tube [4]. Therefore a preliminary separation of the analytes from the matrix soil components is necessary.

In our former work [5] the chlorocomplexes of Tl(III) were selectively sorbed on an anion-exchange resin from the soil digest in 0.1 M HCl. Since cadmium is also sorbed on anion exchangers from HCl solutions of relatively low acidity [6], it was of interest to study the possibilities for the simultaneous anion-exchange separation of Tl(III) and Cd(II) from the soil digest with a view to their subsequent flame AAS determination in the corresponding eluate.

* Corresponding author.

2. Experimental

Reagents of AR grade and redistilled water were used throughout. The stock solutions of the elements (1 mg ml^{-1}) were prepared from Merck titrisols. The flame atomic absorption spectrometer model SP 192 (Pye Unicam) equipped with a slotted quartz tube according to Ref. [4] was used. To prolong the lifetime of the quartz tube, it was coated prior to each run with a 1% (w/v) aqueous solution of LaCl$_3$ by aspirating for 3 min in the burner flame [5]. Calibration was performed by means of acidified aqueous standards comparable to the corresponding eluates of the analytes.

2.1. Procedures

2.1.1. Sample digestion

Grind the air-dried soil samples in an agate mortar to pass a 100-mesh sieve. Add 10 ml of aqua regia to 0.5 g of the soil sample in a glass beaker. Cover the beaker and allow to stand overnight. Heat the covered beaker on a water bath for 1 h at 90°C, then evaporate to a wet residue. Add 2 ml of concentrated HCl, dilute with water and filter into a 25 ml measuring flask. Add some drops of aqueous bromine to maintain thallium as Tl(III) and make up to volume with water. The final solution has an acidity of ≈ 1 M HCl.

2.1.2. Preconcentration of thallium and cadmium and separation from the matrix

Use a column of 5 mm i.d. the lower part of which (between the bottom and the outflow) is hydrophobised so that no liquid adheres to the column walls. Fill the column with the anion-exchange resin Dowex 1X8 (200–400 mesh, Cl$^-$ form) to a height of ≈ 10 mm (100 mg of resin). Pass the soil digest solution through the column at a rate of ≈ 0.5 ml min^{-1}. Wash the residual solution from the column with 0.5 ml of 1 M HCl. Pass five consecutive 0.5 ml aliquots of 2 M HNO$_3$. Collect the first 2.0 ml of the eluate and analyse for cadmium. Subsequently, pass three 0.5 ml aliquots of 2% (w/v) ascorbic acid and collect 1.0 ml of this eluate for thallium determination. The use of a new column filling for each run is

recommended since a layer of organic soil constituents settles on the top of the resin when the digest passes through the column. This layer cannot be removed from the resin and lowers the sorption efficiency in the subsequent runs. The effect is particularly manifested when soils rich in organic matter are analysed.

3. Results and discussion

The anion-exchange procedure [5] recently developed for thallium separation was modified in order to provide the simultaneous sorption of thallium and cadmium on the resin. The optimization experiments revealed that 1 M HCl was the suitable acid with the right chloride concentration for the simultaneous quantitative sorption of Tl(III) and Cd(II) as chlorocomplexes on the anion-exchange resin. Quantitative elution of Tl was achieved with 2% ascorbic acid [5] and that of Cd with 2 M HNO$_3$. The advantages of the batch technique used in Ref. [5] could not be utilized in the present work since different eluents were needed for the elution of thallium and cadmium from the resin and their use in a mixture did not yield quantitative recovery of the analytes. Therefore the column technique was employed. It was found that both the use of a very short layer (1 cm) of a fine-grained resin (200–400 mesh) and the addition of the eluents in small (0.5 ml) consecutive aliquots yielded extremely sharp elution curves of the analytes, which permitted the achievement of quantitative elution with minimum eluent volumes: 2.0 and 1.0 ml for cadmium and thallium respectively (see Fig. 1). It should be stressed that the elution of Cd should precede that of Tl, otherwise losses of Cd were registered due to its partial elution with Tl.

The behaviour of the major soil components accompanying the analytes in the aqua regia soil digest [Fe(III), Ca, Mg, Na, K and Al] during the anion-exchange enrichment was studied. That of Fe(III) was of particular interest, since, in contrast to alkali metals, alkaline earth metals and aluminium, the chlorocomplexes of Fe(III) were expected to be retained on the anion exchanger in 1 M HCl [6]. A model solution simulating the

aqua regia soil digest was used for this purpose. It contained 25 mg of Fe(III), 5 mg each of Ca, Mg, Al, Na and K, 1.0 μg of Tl (III) and 0.5 μg of Cd in 25 ml of 1 M HCl. The solution was passed through the separation procedure and elution was performed as described in Section 2. A subsequent 1.0 ml aliquot of the ascorbic acid solution was collected separately. In a second experiment the elution was performed in the following way: after washing out the column with 1 M HCl, alternating 0.5 ml aliquots of the solution of nitric acid and ascorbic acid were passed and a common 2.0 ml eluate for Cd and Tl was collected. A subsequent 1.0 ml aliquot of the nitric acid solution was collected separately. The concentrations of the elements in the washing solution and in the separate eluates were determined by flame AAS (pulse aspiration). The results obtained for Cd, Tl, Fe, and Mg are shown in Table 1. The concentrations of Ca, Na and K were at the same level as that of Mg. The concentration of Al was below the limit of detection.

It follows from the data presented in Table 1 that:

(i) Cd and Tl are quantitatively recovered from the simulated aqua regia soil digest by both elution procedures. Procedure 1 was preferred in the final version since it provided a higher extent of preconcentration for Tl;

(ii) the quantitative elution of Tl, especially in the case of alternating nitric and ascorbic acid solutions (procedure 2), is evidence for the successful course of the redox reaction between $TlCl_4^-$ and ascorbic acid under the dynamic conditions in the column, yielding the Tl(I) species

Fig. 1. Elution curves of cadmium and thallium.

Table 1
Recovered amounts of Cd, Tl, Fe and Mg in the separated eluates. Added to the model solution: 0.5 μg Cd, 1.0 μg Tl, 25 mg Fe(III) and 5 mg Mg

Solution	Volume	Element μg			
	(ml)	Cd	Tl	Fe	Mg
Elution procedure 1[a]					
1 M HCl	0.5	0	0	100	20
2 M HNO$_3$	2.0	0.5	0	5	0.5
2% ascorbic acid	1.0	0	1.0	0.5	0
2% ascorbic acid	1.0	0	0	0	0
Elution procedure 2[b]					
1 M HCl	0.5	0	0	100	20
2 M HNO$_3$ + 2% ascorbic acid	2.0	0.5	1.0	5	0.5
2 M HNO$_3$	1.0	0	0	0.5	0

[a] According to Section 2.
[b] A common eluate for Cd and Tl consisting of alternating aliquots of 2 M HNO$_3$ and 2% ascorbic acid.

which is not retained on the anion exchanger;

(iii) appreciable amounts of Fe(III) and other major soil components were detected only in the 1 M HCl washing solution, which implies that these were residues from the initial solution. Thus the negligible concentration of Fe(III) in the separate eluates can be related to insignificant sorption rather than to incomplete elution.

Table 2
Thallium and cadmium contents in Bulgarian cultivated soils digested with aqua regia. The average of five digestions is presented.

Soil sample	Thallium (μg g^{-1})		Cadmium (μg g^{-1})	
	Present work	Ref. [7]	Present work	Ref. [7]
Calcarous chernozem	0.68 $\pm$ 0.04	0.62	0.55 $\pm$ 0.03	0.49
Leached chernozem	0.49 $\pm$ 0.04	0.45	0.60 $\pm$ 0.03	0.56
Leached cinnamonic forest soil	0.52 $\pm$ 0.04	0.55	0.81 $\pm$ 0.03	0.77
Alluvial meadow soil	0.51 $\pm$ 0.04	0.50	0.70 $\pm$ 0.03	0.67
Grey forest soil	0.34 $\pm$ 0.04	0.38	0.35 $\pm$ 0.03	0.40

The method was applied to the determination of thallium and cadmium in some typical representatives of Bulgarian cultivated soils digested with aqua regia. The soil samples were taken from the top layer (0–20 cm) of several experimental fields of the Institute for Soil Research "N. Pushkarov", Sofia. The accuracy of the method was checked by comparing the results to those obtained by solvent extraction of the analytes from the aqua regia soil digest acidified with sulphuric acid, followed by flame AAS determination in the organic extract [7] (see Table 2).

The limits of detection of the flame AAS determination using the slotted quartz tube were 0.002 μg ml^{-1} amd 0.02 μg ml^{-1} for cadmium and thallium respectively. The limits of detection of the whole procedure were 0.01 μg g^{-1} and 0.04 μg g^{-1} for cadmium and thallium, respectively.

The relative deviation at the 0.5 μg/g^{-1} level was about 7%. The approach is amenable to flow-injection analysis.

Abstract

A solid state potentiometric biosensor for urea determination was assembled coupling a nonactin-based ISE without an internal solution with immobilized urease. The system proved to be useful for continuous monitoring of urea during dialysis treatment using the ultrafiltrate of blood as sample. A noticeable shift of potential occurred during the dialysis (probably due to continuous extraction of ionophore by the ultrafiltrate). Therefore a flow injection analysis assembly was necessary to control the shift of electrode potential.

Keywords: Dialysis; Solid-state biosensor; Urea

1. Introduction

The problem of monitoring the course of dialysis treatment in order to allow a personalized treatment (length and frequency) is still a challenge even though several suitable approaches have been recently published [1–8]. During dialysis treatment the concentration of urea in blood decreases from 50 mM to below 10 mM [9]. Nowadays no on-line monitoring of the dialysis performance is available and of course the treatment is rarely interrupted at the optimal point.

This paper reports the realization of a solid-state pontentiometric biosensor (a nonactin-based ion-selective electrode without an internal liquid solution coupled with immobilized urease) which is very practical and easy to change after every dialysis treatment and a procedure based on flow-injection analysis (FIA) which is proven to be necessary for continuous monitoring of the ultrafiltrate of blood. The FIA procedure permits the continuous control of the shift occurring at the potentiometric urea sensor which is probably due to a continuous extraction of the ionophore (nonactin) by the ultrafiltrate of lipophilic character.

We specifically refer to dialysis treatment where the ultrafiltration of blood realized in a suitable filter precedes the true dialysis process realized by a second filter where the dialysis liquid re-equilibrates the blood (Multimat system from Bellco,

* Corresponding author.

Italy). The ultrafiltrate of blood obtained in the first filter consists of a proteinaceous pale yellow liquid which contrains all low-molecular weight compounds and is wasted in the dialysis treatment. This liquid was considered the most suitable for continuous monitoring of urea because the urea concentration in this liquid corresponds perfectly to the blood concentration [10].

2. Experimental

2.1. Materials and apparatus

Urease (EC 3.5.1.5 from jack beans type VII, 400–800 U mg^{-1}) was obtained from Sigma. Nonactin was an ionophore from Fluka. All chemicals used were of analytical grade. All potentiometric measurements were made vs. the SCE with an Amel 336 potentiometer and an Amel 866 recording apparatus (Amel, Milan, Italy). A Rheodyne valve 7010 with pneumatic actuator 5701 (Rheodyne, Cotati, CA) and an air-controlled solenoid valve 7163 (Rheodyne) was used in conjunction with a Crouzet type TOP 948 programmable timer (Crouzet Componenti SpA, Milan, Italy) for automatic sampling. A flow cell of wall-jet type was obtained from Metrohm (cat. no. 656 (electrochemical detector); Metrohm, Herisau, Switzerland) where the urea sensor was adjusted instead of the working electrode. A Gilson (Gilson, Villiers-le-Bel, France) Minipuls peristaltic pump was used at a flow rate of 0.8 ml min^{-1} as the flowing apparatus.

2.2. Instrumentation

The sensor was obtained by immobilizing over a graphite electrode a layer of PVC–nonactin solution in tetrahydrofuran and over it a layer of urease immobilized with the use of bovine serum albumin and glutaraldehyde. The sensor has been used in a flow cell (preliminary experiments) or in a wall-jet provided with a sampling valve in the FIA procedure. The valve was actuated automatically with a pneumatic actuator and an electronic timer to obtain a peak every 4 min. The diagram of the instrumentation is presented in Fig. 1 with the scheme of the urea potentiometric sensor.

2.3. Procedures

2.3.1. Preparation of graphite electrode

Graphite powder (3.5 g) was thoroughly mixed with epoxy glue. As epoxy were mixed Araldite M (1 g), Araldite H 964 hardener (1 g) and Araldite Y960 (DY060) (0.5 g) as accelerator obtained from Fluka. After mixing the graphite with epoxy, it was introduced in a plastic syringe and to eliminate air bubbles pressure was applied with the piston of the syringe. The syringe was left for 24 h. The barrel of hardened graphite was then taken out of the syringe and cut into 5–10 mm long pieces. Each was fixed in a PVC tube with an external diameter of 7 mm and an internal diameter of 3.5 mm. A copper wire was glued from one side with the aid of conductive epoxy.

2.3.2. Immobilization of nonactin

5 mg of nonactin, 100 mg of PVC (high molecular weight), 200 mg of BBPA (bisbutylpentyladipate) and 1.5 ml of tetrahydrofuran were mixed and stirred in a closed flask (5 ml) for about 2 h, to allow complete solubilization of the compounds.

Fig. 3. Experiment with the ultrafiltrate. Two standard solutions, 10 and 100 mM, were prepared and flowed at the beginning and end of a 40 min experiment during when the ultrafiltrate (urea content 200 mM) flowed.

100 μl of this solution was layered over the graphite electrode (3.5 mm of graphite in a PVC tube with an external diameter of 7 mm). After 2–3 h the ammonia electrode was ready to be used [6].

2.3.3. Immobilization of urease

Over the nonactin-based layer was spread 2 mg of solid urease (type VII from Sigma), 10 μl of BSA (bovine serum albumin solution, 10 mg in 500 μl of phosphate buffer 0.02 M, pH 7.0) and 5 μl of glutaraldehyde solution (2.5%). The mixture was mixed carefully and allowed to dry for 1–2 h. Then the electrode was left in stirred glycine solution (0.5 M) for 30 min; during this period the free aldehyde groups react with the amino group of glycine [11]. The electrode was found to be stable for several months if kept dry in a refrigerator. When the sensor was fixed in the flow cell or in the wall-jet cell an additional membrane of cellulose acetate was mounted and fixed with an O-ring in order to protect all the layers and push them against the graphite sensor.

2.3.4. Ultrafiltrate samples

Samples were obtained by ultrafiltration of heparinized (50 U ml^{-1}) bovine blood (adjusted to

Fig. 4. Successive calibration curves obtained with a continuous flow of ultrafiltrate during a 5 h period. Each calibration curve was recoreded every hour. Curve A was measured at the start of the experiment, curve B after 1 h of continuous flow of ultrafiltrate, curve C after 2 h, etc. The slopes are reported in Table 1.

40% v/v for hematocrit value), through a filter cartridge with a surface of 0.07 m² (Cod. 621) and with a surface area of 1.3 m² (Cod. N. BL627; commercially available from Sorin (Saluggia, Italy)). The hematocrit value was adjusted with phosphate buffer (sodium salts) in 0.1 M sodium chloride (about 250 ml of buffer per 1 l blood). The hematocrit value was adjusted to simulate human values in order to obtain similar flowing conditions in the filter cartridge. The concentration of urea in the ultrafiltrate was evaluated in the range 1–2 mmol l [-1].

3. Results and discussion

Fig. 2 shows the calibration curve obtained in the flow system with standard solutions of urea

and ammonium in buffer phosphate. Different solid-state sensors (more than 20 sensors were tried) show nerstian behavior in the range 1–100 mM; they have E_0 values which differ by up to ± 200 mV for unknown reasons and this value can shift from day to day. However, the potential value is very stable for several hours and permits easy determination in flow systems.

Fig. 3 reports the shift observed in an experiment where ultrafiltrate of constant urea concentration (obtained from heparinized bovine blood and adjusted to 40% v/v for the hematocrit value) flowed in the continuous mode. We can see how the signal shifted during the 40 min of continuous flow and that the signals obtained with two standard solutions (10 and 100 mM) of urea were shifted in the same period by about 25 mV.

Fig. 4 gives several calibration curves obtained in continuous flow in another experiment during a 5 h period, showing a continuous shift, while the slope was maintained almost constant. The slopes of the curves are given in Table 1.

Fig. 5. Calibration curves of urea standard solutions (1, 10 and 100 mM of urea) realised in buffer (without potassium ion) (SS) and in ultrafiltrate (UF) recorded with the FIA procedure.

Fig. 6. Continuous recording over a 5 h period of calibration curves of standard solutions (SS) and ultrafiltrate spiked with a standard urea concentration (UF). UF 10, UF 30 and UF 100 are the signals obtained from ultrafiltrate spiked with 10, 30 and 100 mM urea respectively. 10 Urea and 100 Urea are the signals obtained with standard solutions of 10 urea and 100 nM respectively.

After assembling a FIA system (sampling valve 50 μl) we obtained the results reported in Fig. 5 with standard solutions in phosphate buffer and prepared in ulttrafiltrate. Fig. 6 shows results obtained over a long period (5 h) with consecutive injections of sampling probe standard solutions of urea, ultrafiltrate and ultrafiltrate with added urea in suitable concentrations (10, 30, 100 mmol l^{-1}), simulating the concentration values obtained during a real dialysis process. The baseline obtained in the last experiment is very stable and the sensitivity of the probe is not impaired by contact with the ultrafiltrate and the long duration of the experiment. Therefore we can conclude that this sensor preparation and this analytical procedure are very suitable for the continuous monitoring of urea in such applications.

In Figs. 5 and 6 it can be seen that in the low range of urea concentrations the peaks obtained in ultrafiltrate are higher than the same urea concentrations in buffer. This result was expected and is due to the well-known interference of potassium ions at the nonactin-based ammonium sensors. However, the low range of urea is the least important part of the calibration curve for clinical purposes.

The drift observed in the continuous flow experiment (Figs. 3 and 4) can be ascribed to the lipophilic nature of the ultrafiltrate which probably extracts the constituents of the PVC membrane (ionophore or softener) from it. This was reported with other ISEs with neutral carriers when in contact with blood or proteinaceous fluids [12]. However, the FIA procedure eliminates the problem, at least for up to 5 h. It is logical that the small period of contact between the ultrafiltrate and the sensor membrane permits one to obtain a very reproducible signal, but does not alter the composition and structure of the membrane. We think that this approach solves the problem of continuous monitoring of urea during the dialysis treatment with a cheap, disposable and easily fabricated sensor. For mass production the sensor can even be printed in a printing process (preliminary experiments in this laboratory proved it to be feasible) and therefore it can be considered to be a real disposable sensor.

Measurement/data-processing method to improve the ruggedness of membrane-based sensors: Application to amperometric oxygen sensor

Sheldon Williams, Harry L. Pardue*, Christopher E. Uhegbu[1], Aaron M. Smith, Joanna Studley

Department of Chemistry, 1393 BRWN Bldg., Purdue University, West Lafayette, IN 47907-1393, USA

Abstract

This paper describes alternative measurement and data-processing approaches that can reduce effects of experimental variables on results obtained with a membrane-based sensor for oxygen. In the new approaches, the membrane-based sensor is first equilibrated with the sample solution, after which a polarizing voltage is applied and current vs. time data are recorded as the response decays toward a steady-state condition. Current vs. time data are then processed by a fixed-time option and an integration option designed to determine the charge corresponding to the total amount of oxygen inside the membrane when a polarizing voltage is applied. The current measured at a fixed time and the total charge varied linearly with oxygen concentration between 0.05 and 0.26 mmol l^{-1}. Pooled relative standard deviations ($N = 35$) for the measurement/data-processing step were near 0.4% for the new pre-equilibrium options compared to a value of 0.3% for the steady-state option. Dependencies of the pre-equilibrium options on membrane thickness and stirring rate in the most sensitive regions were at least two orders of magnitude smaller than for the steady-state option.

Keywords: Amperometric oxygen sensor; Data-processing method; Membrane-based sensors; Ruggedness

1. Introduction

Membrane-based devices are used for a variety of selective measurements in analytical chemistry [1–5]. One very popular membrane-based detector system is the so-called oxygen electrode which involves an amperometric electrode isolated from the sample solution by a membrane that is selective for small molecules, including oxygen [1,6]. Like most such devices, this one is usually used in the steady-state mode. It has been shown that results obtained with the "oxygen electrode" used in the steady-state mode are very sensitive to changes in stirring rates and properties of the membrane such as thickness and permeability [6–8]. Accordingly, to obtain reliable results by using

[1] Present address: Diametrics Medical, Inc., 2658 Patton Road, Roseville, MN 55113, USA.

the steady-state mode, it is necessary to control variables within narrow tolerances.

A general approach to resolving such problems is to make measurements that depend on equilibrium conditions rather than rate processes. One such approach evaluated for the "oxygen electrode" is to first pre-equilibrate the solution inside the membrane with each sample solution with no polarizing voltage applied and then to apply the polarizing voltage and measure the initial rate of change of the resulting current [6,7]. An alternative approach is to use the same pre-equilibration procedure, then apply the polarization voltage, digitize and store current vs. time data, and use a curve-fitting procedure to extrapolate the transient data to the current at time zero [8].

The present study was undertaken to evaluate other data-processing approaches that can be used to extract the desired information from the transient data resulting from the pre-equilibration approach. The rationale for this extended study is based on the belated realization that if the rate of the mass transfer process to and across the membrane is slow relative to the rate of equilibration of the measurement process inside the membrane, then virtually all features of the measured signal will be related to the bulk concentration of analyte in the sample solution and independent of variables that affect the rates of mass transfer across the membrane. Two alternative data-processing approaches were used to test this hypothesis by using the membrane-based "oxygen electrode" as a model system.

The simpler of the two approaches is an analog of the conventional fixed-time kinetic option [9–12]; it involves measurement of the signal amplitude at a fixed point in time for each response. The more complex of the two approaches is a hybrid of the integration and predictive curve-fitting options [12–14]; it involves integration of the time-dependent current and use of curve-fitting methods to extrapolate the resulting charge vs. time data to the value of charge at $t = 0$ (Q_0) and as $t \to \infty$ (Q_∞). These extrapolated values are used to compute the total charge ($\Delta Q_\infty = Q_\infty - Q_0$) corresponding to electrolysis of all the analyte (oxygen) inside the membrane when a polarizing voltage is applied.

The latter option was complicated by the facts that current–time responses included charging currents near zero time and did not decay to zero at longer times but rather to finite steady-state values. Two approaches similar to those described earlier [15] were used to extract the charge corresponding to analyte inside the membrane when a polarizing voltage was applied. One option involved integration of the unmodified signal including the component approaching steady state and use of a model for simultaneous zero-order and first-order processes [16] to extract the desired component of the charge. The other approach involved subtraction of the steady-state current from all time-dependent currents before integration of the transient response; this is called the background-correction option herein.

2. Experimental

The same data reported in an earlier paper [8] were used for this study. Accordingly, an abbreviated procedure is presented here.

Samples were prepared by adding aliquots of an air-saturated solution (≈ 0.26 mmol l^{-1} oxygen) to a fixed volume of deaerated water. For linearity and reproducibility studies, five runs were made at each of eight different oxygen concentrations between 0 and 0.26 mmol l^{-1}. For studies of effects of variables, five runs were made at each of three different membrane thicknesses and four different stirring rates at a fixed oxygen concentration (0.26 mmol l^{-1}).

The "oxygen electrode" was equilibrated with each test solution by immersion in the solution for 30 s before the polarizing voltage was applied. When the polarizing voltage was applied, 250 data points were collected at intervals of 0.0006 s per point for the first 100 points and 0.027 s per point for the last 150 points.

For the fixed-time approach, current amplitude was measured at the same time after the polarizing voltage was applied for each sample. Fixed-time measurements were taken near the peak (0.17 s), on the steep part of the decay curve (1.2 s) and in the region approaching steady state where the

rate of change of signal was sufficiently small that timing errors would not have unusually large effects (3.92 s, the average of ten data points between 3.75 and 4.1 s). For the integration option without background subtraction, unmodified current vs. time data were integrated between 0.33 and 4.1 s and a model for simultaneous zero-order and first-order processes [16] was fit to the data to resolve the charges resulting from the transient and steady-state components. For the integration option with background subtraction, the average of the last ten data points (3.75–4.1 s) was subtracted from each signal value and the resulting data between 0.33 and 4.1 s were integrated. A first-order model [14] was then fit to charge vs. time data to extrapolate to $t = 0$ and $t \rightarrow \infty$.

3. Results and discussion

Unless stated otherwise, random uncertainties are reported at the level of one standard deviation based on five runs per sample.

3.1. Response curves

Fig. 1 shows typical plots of current vs. time without (plot a) and with (plot b) background correction. Zero time corresponds to the point at which the polarizing voltage was applied. The initial rise represents charging current and the gradual decrease after the peak is caused by depletion of oxygen inside the membrane at a rate faster than it is replaced by mass transfer across the membrane.

It is apparent from the plots that the currents did not reach true steady-state values during the 4 s measurement period. Accordingly, use of currents from the latter parts of these responses for background correction tend to overcompensate for the steady-state current.

Fig. 2 includes charge vs. time data without and with background correction. The open circles in the upper plot (without background correction) represent experimental data and the solid curve through the points represents a fit of a model for simultaneous zero- and first-order processes to the

Fig. 1. Current vs. time response after pre-equilibrium with air-saturated solution (0.26 mmol l^{-1} O_2) without (a) and with (b) background correction.

data. The curvature reflects the decaying current after the polarizing voltage is applied and the nearly linear extension at longer times represents the approach to steady state. Clearly, the model for combined zero- and first-order processes fits the data very well. The lower plots (curves b and c) represent the first-order component of the charge vs. time data obtained by the fitting process. The open triangles represent the first-order component from the fit of the model for combined zero- and first-order processes to data without background correction and the open squares represent charge vs. time data obtained from background-corrected data (plot b in Fig. 1). The

solid curve is a fit of a first-order model to the latter data. The darker area near zero time represents the higher data rate at shorter times. This is the difference between the change at $t = 0$ and $t \to \infty$ ($\Delta Q_x = Q_x - Q_0$) that is used to quantify oxygen concentration.

The negative values of extrapolated charges in Fig. 2 merit comment. Because the integration process was begun at 0.3 s, the apparent charge at that point is zero. Accordingly, extrapolation to $t = 0$ is expected to give negative values. It is the total difference between values at $t = 0$ and $t \to \infty$ that is used to quantify oxygen concentration.

3.2. Linearity

Each of the three data-processing options yielded linear plots of the measurement objective (current at fixed time or extrapolated charge) vs. concentration. Results for linear least-squares fits of measurement objectives vs. concentration are given in Table 1. In each case, intercepts and standard errors of the estimates are divided by slopes to normalize results to concentration units for easy comparison. Intercepts are similar for the two integration options and about five-fold smaller than for the fixed-time option. Standard errors of the estimates and correlation coefficients are about the same for all three options.

Fixed-time results were also obtained near the peak (0.17 s) and on the steep portion of the decay curve (1.2 s). In each case, calibration plots

were linear. Slopes for the three measurement times (0.17, 1.2 and 3.92 s) were 16.8, 3.5 and 0.92 μA mmol^{-1} l^{-1} respectively; intercepts were 0.02, −0.009 and 0.004 mmol l^{-1} respectively; standard errors of the estimates were 0.015, 0.009 and 0.01 μA respectively; and correlation coefficients were 0.964, 0.986 and 0.988 respectively. All statistics were slightly improved for the two measurements at longer times after the peak than at the peak.

If the time-dependent data behaved ideally, then we would expect the same results from both integration options. However, this is not the case; data without background correction do not follow combined zero-order/first-order behavior exactly and data with background correction do not follow first-order behavior exactly. Accordingly, identical results are not expected or obtained for the two integration options. This is reflected primarily by the different slopes in Table 1.

3.3. Imprecision

The uncertainty associated with sample preparation and handling is much larger than that associated with the measurement and data-processing steps. Because our primary focus was on features of different measurement/data-processing options, imprecision is reported here for repeat runs on air-saturated samples. For seven data sets of five runs each on air-saturated samples (0.26 mmol l^{-1} oxygen), pooled standard deviations for

the fixed-time option, and the integration option without and with background correction were 0.0012 μA, 0.0042 μC and 0.0044 μC respectively, corresponding to relative standard deviations (RSDs) of 0.34%, 0.30% and 0.31% respectively. For the same data sets, pooled RSDs for the steady-state option and the predicted signal at $t = 0$ [8] were 0.2% and 2.6% respectively. The imprecisions for the three options included in this study are only slightly degraded relative to the steady-state option and are almost 10-fold less than that for the extrapolation option described earlier [8].

3.4. Variable dependencies

The principal advantage expected for the options described herein is low sensitivity to changes in experimental variables. Results in Figs. 3A and 3B illustrate effects of membrane thickness and stirring rate on the three new options described herein along with results obtained with the conventional steady-state option. All results are normalized to the value at one extreme of the range of variables studied to facilitate comparisons. Whereas results obtained with each of the three pre-equilibrium options are virtually independent of both membrane thickness and stirring rate throughout the ranges examined, steady-state results decrease by about 50% when the membrane thickness is increased three-fold and increase by about 25% from no stirring to a moderate level of stirring.

These sensitivities to membrane thickness and stirring rate can be quantified by using error coefficients (ECs), defined as the change in concentration per unit change in the variable of interest. ECs for the different options computed as described earlier (Eq. (2) in Ref. [8]) are summarized in the first two data columns of Table 2.

Ratios of ECs for the steady-state option divided by values for the other options (EC_{ss}/EC_{opt}) are included as the last two columns in the Table. In the most sensitive regions, the pre-equilibrium options are all at least two orders of magnitude more rugged than the steady-state option. Improvement factors approach unity at greater membrane thicknesses and higher stirring rates.

4. Conclusions

With the exception of the procedure involving extrapolation of current to zero time, the precision of the pre-equilibrium procedures is similar to that of the steady-state approach. Accordingly, it is possible to exploit the improved ruggedness of the pre-equilibrium approaches described herein without sacrificing precision.

The different pre-equilibrium options evaluated in this and the previous study [8] have similar degrees of ruggedness for the conditions studied. However, it is important to note that there are some fundamental differences among them. The initial-rate option described earlier [6,7] and the

fixed-time option reported herein both replace one group of kinetic processes with another, and consequently can be expected to depend on variables such as temperature that could affect these processes. The procedure involving extrapolation to the current at zero time [8] should, in principle, eliminate kinetic aspects of mass-transfer processes but is expected to depend upon variables that affect electrode kinetics. Moreover, that approach is complicated by the charging current when a polarizing voltage is applied and is subject to large uncertainties associated with extrapolated intercepts. Because the integration options produce a charge corresponding to the total amount of analyte in the fixed volume inside the membrane, they have the best chance of eliminating effects of all kinetic processes so long s the rate of the electrolysis process inside the membrane is sufficiently fast relative to the rates of mass transfer to and across the membrane. In this regard, this approach probably will be most effective with thick membranes and little or no stirring.

The principles illustrated here for the "oxygen electrode" should be applicable to other membrane-based "sensors" such as an amperometric sensor for carbon monoxide [5] and other gases [18]. These principles should also be applicable to other types of applications of membranes such as those cited earlier [1–4] as well as to separations or preconcentrations based on combinations of membranes with flow systems [19]. Furthermore,

whereas it was convenient to use a pre-equilibrium procedure in this example, this is just one option for the general concept. In the most general sense, the primary goal is to obtain an equilibrium-based result. If it is not feasible to establish an equilibrium condition experimentally, then another option is to extrapolate transient responses to equilibrium values [14]. For example, an alternative approach with the "oxygen electrode" would be to completely deplete the analyte inside the membrane and then to follow the approach to equilibrium as the concentration of oxygen inside the membrane approaches that in the sample solution. This would require an intermittent measurement approach that would minimize depletion of oxygen concentration inside the membrane.

Received 15 January 1996; accepted 5 February 1996

Abstract

A remote electrochemical sensor for field monitoring of hydrazine compounds is described. The new submersible probe relies on the coupling of an effective electrocatalytic modified electrode to a 50 ft long shielded cable. The catalytic surface, based on an electorpolymerized film of 3,4-dihydroxybenzaldehyde, offers low-potential detection of hydrazine compounds. Such catalytic activity results in high sensitivity and selectivity, and hence offers convenient measurements of micromolar hydrazine concentrations in untreated groundwater, river water or lake water samples. Coexisting sample constituents do not contrubute to the response. Operational conditions have been optimized to meet the spacific requirements of remote operation. The concept seems suited for the remote monitoring of other contaminants via the judicious choice of the surface modifier.

Keywords: 3,4-Dihydroxybenzaldehyde; Electrocatalytic modified electrode; Field monitoring; Hydrazines

1. Introduction

Because of the toxicological significance of hydrazine compounds, a reliable method is required for their environmental and industrial monitoring. Continuous measurement of hydrazines, affected in the natural media, is preferable, since it affords the option of an in-situ warning system and avoids the errors and delays inherent in laboratory-based analyses. Controlled-potential electrochemical techniques, particularly those relying on electrocatalytic modified electrodes, have been de-

veloped for the detection of hydrazine compounds [1-4]. The adaptation of these schemes for field measurements of hydrazines is thus a logical extension of their capabilities.

In this paper we describe a remote modified electode for in-situ monitoring of hydrazine contaminants. The new remote sensor (Fig. 1) couples the strong electrocatalytic action of electropolymerized films of 3,4-dihydroxybenzaldehyde (3,4-DHB) [5] towards hydrazine compounds [2] with the attractive features of our new remote electrode configuration [6,7]. Such a configuration was employed recently for stripping-based monitoring of toxic metals [6,7]. While such stripping work has relied on the use of a bare gold fiber electrode, the present sensor employs, for the first time, an

Fig. 1. Schematic diagram of the remote electrochemical sensor for monitoring hydrazines. The right-hand displays the electrocatalytic action of the polymer-modified working electrode.

electrocatalytic modified electrode for facilitating the detection of contaminants. The electrocatalytic considerations are thus coupled with the requirements for remote operation, including large instrument–sample distances, sealed electrical contacts, a rugged and compact electrode assembly and the ability for rapid maintenance. Although the new concept of remote modified electrodes is presented within the framework of hydrazine sensing, it could be extended to other relevant polllutants (via a judicious choice of the modifier). The challenges, obstacles and solutions for a submersible operation of catalytic electrodes in untreated water samples are explored below in connection with our novel remote electrode assembly.

2. Experimental

2.1. Apparatus

Chronoamperometric and voltammetric experiments were performed with the BAS Model CV-27 voltammetric analyzer (Bioanalytical Systems, West Lafayette, IN), in connection with a BAS X–Y–t recorder. Experiments were performed in a 40 ml plastic (PVC) beaker. A schematic diagram of the remote modified electrode is shown in

Fig. 1. The probe design is similar to that of our previously reported remote metal sensor [5,6], with the exception that a modified glassy carbon electrode (3 mm diameter, Model MF-2012) replaces the gold fiber. The working electrode is cut to a 2.5 cm length for compatibility with the PVC-based sensor tip. The electrode assembly, housed in a PVC housing tube, was connected to the 50 ft long shielded cable via a three-pin environmentally-sealed rubber connector. A Ag/AgCl electrode (BAS, Model RE-4) served as reference. Details of the probe design are given in Refs. [6] and [7].

2.2. Surface activation and modification

The glassy carbon was first polished with a 0.25 μm alumina slurry, and then thoroughly rinsed with double-distilled water. Subsequently, the surface was activated for 5 min in a 1 M NaOH solution, while holding the potential at + 1.2 V. The electrode was then treated for an additional 5 min by scanning the potential between − 0.2 and + 1.0 V while dipping in a phosphate buffer solution. The activated electrode was subsequently modified by immersion in a 1 mM 3,4 DBH/phosphate buffer solution while holding the potential at + 3.0 V for 3 min. Subsequently, the surface was rinsed with the buffer solution.

2.3. Reagents and procedure

All solutions were prepared with deionized water. Hydrazine sulfate was obtained from J.T. Baker (Phillipsburg, NJ), while 1,2-dimethylhydrazine dihydrochloride, methylhydrazine, and 3,4-DBH were purchased from Aldrich. **Caution: in view of their toxicity, special attention is required in the handling of hydrazine compounds.** The river water and lake water samples were collected from the Rio Grande river (at Las Cruces, NM) and Lake Ontario (at Rochester, NY). The groundwater sample was obtained at the Hanford Site (Richland, WA).

Chronoamperometric and cyclic-voltammetric experiments were conducted at room temperature, while placing the sample ≈ 50 ft from the voltammetric analyzer. The chronoamperometric experiments relied upon stepping the potential from open circuit to $+0.2$ V; the steady-state current (after ≈ 45 s) was used for the quantitation.

3. Results and discussion

The use of the 3,4-DHB-coated remote electrode for the mediated detection of hydrazine compounds in natural water samples is illustrated in Fig. 2b. This figure shows typical cyclic voltammograms for hydrazine (A), methylhydrazine (B) and dimethylhydrazine (C) in an untreated groundwater sample. The 3,4-DBH-modified electrode displays a well-behaved redox process ($E^0 = +0.15$ V) in the unspiked natural water sample (a). Such peaks are attributed to the redox reaction of the surface-confined quinone moiety. A similar response was observed in a phosphate buffer blank solution, indicating that none of the groundwater sample constituents is contributing to the response. A substantial increase of the anodic peak, characteristic of an electrocatalytic process, is observed upon addtion of the different hydrazine compounds. Consistent with a strong catalytic action, no current is observed upon scanning in the cathodic direction. As will be illustrated below, such a defined low-potential catalytic response greatly faciltates the direct monitoring of hydrazine compounds at large in-

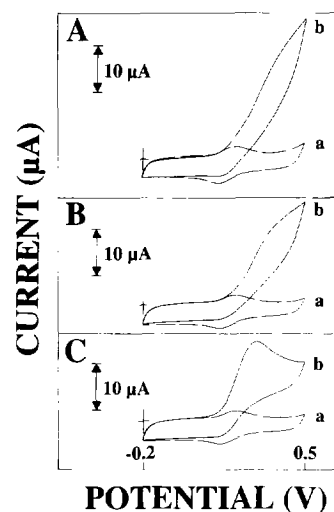

Fig. 2. Cyclic voltammograms for 1×10^{-3} M hydrazine (A;b), methylhydrazine (B;b) and dinethylhydrazine (C;b) in groundwater, along with the corresponding blank groundwater response (A–C;a). Scan rate: 100 mV s^{-1}.

strument/sample distances. The challenges of such measurements in untreated samples are explored below.

The quantitation of hydrazine compounds at the remote sensor is best carried out using the chronoamperometric operation mode. Fig. 3A displays chronoamperograms for successive 5×10^{-6} M increments in the hydrazine concentra-

Fig. 3. (A) Chronoamperometric response of the remote electrode to successive 5×10^{-6} M increments in the hydrazine concentration (a–o). Also shown is the corresponding background response (blk) and the resulting calibration plot (B). Potential step to $+0.2$ V; phosphate buffer solution (0.05 M, pH 7.4).
Fig. 4. Effect of the solution pH (A), buffer concentration (B), and measurement potential (C) upon the response to 8×10^{-6} M hydrazine. Other conditions as in Fig. 3.

tion (a–o). The remote electrode offers convenient quantitation of these micromolar concentrations. The current decays rapidly (20 s) to a steady-state value. The latter depends upon the analyte concentration over the entire (5–80 μM) concentration range examined. Linearity prevails over the 5–40 μM range (slope: 1.56 nA μM^{-1}; correlation coefficient: 0.998); a slight curvature is observed for higher levels.

The adaptation of modified electrodes for in-situ monitoring poses several challenges. Unlike laboratory-based sensing applications, where the solution conditions can be adjusted for optimal performance, submersible probes rely on the use of the natural conditions (i.e. untreated samples). Fig. 4 examines the influence of solution variables, relevant to field operation. The catalytic response is nearly independent of the pH over a broad range (between 7 and 11). A sharp decrease of the signal is observed in acidic solutions, with disappearance of the response below pH 5 (A). Such a profile reduces the applicability of the probe. Yet, as will be illustrated below, the probe operates well in numerous relevant natural water matrices (of sufficiently high pH, i.e. above 6). Programmable pH compensation, common with various water profilers, may be useful for addressing the pH dependence between 5 and 7. Field

calibrations, using the target sample [6], should also be useful for this task. Unlike its pH profile, the hydrazine sensor displays a very broad ionic-strength independence (B). Less than 20% signal changes are observed for buffer concentrations ranging from 10^{-6} to 10^{-1} M.

Fig. 4C displays the dependence of the hydrazine response upon the operating potential. The anodic detection of the hydroquinone form of the catalyst (i.e. the product of the catalytic reaction) starts at $+0.1$ V; the response rises sharply up to $+0.3$ V and levels off at higher potentials. Potential steps to $+0.2$ V were employed in all subsequent work, as a compromise between sensitivity and selectivity. Such an operational potential minimizes possible contributions from coexisting electroacitve constituents.

The remote modified electrode displays a remarkably stable response. The long-term stability, shown in Fig. 5, was monitored by measuring the chronoamperometric steady-state current for 1 $\times$ 10^{-5} M hydrazine (in a river water sample) over a 10 day period using the same electrode surface. The coated electrode functioned in a normal fashion throughout. While a slight (about 10%) decrease in the response was observed over the first 5 h, the catalytic activity remained constant thereafter. A relative standard deviation of 3.0% was calculated for this prolonged series of experiments. Another shorter (5 h) experiment, involving repetitive measurements of 5×10^{-6} M dimethylhydrazine in a river water sample, yielded a highly stable response (with a relative standard deviation of 3.7%; $n = 30$). Such behaviour is consistent with the high stability of redox-active

Fig. 5. Stability of the response of the remote electrode to 1×10^{-5} M hydrazine in an untreated river sample. Potential step to $+0.2$ V.
TIME (min)

Fig. 6. Chronoamperometric response to untreated groundwater (A) and lake water (B) samples containing increasing levels of hydrazine and dimethylhydrazine respectively, in 2×10^{-6} M steps (a–j). The corresponding sample response is also shown (s). Other conditions as in Fig. 5.

3,4-DHB electropolymerized films [5]. The electropreparation approach also assures good control of the surface coverage and thus reproducibility between different surfaces.

The performance of the sensor in untreated natural water samples is demonstrated in Fig. 6. This Figure demonstrates the chronoamperetric response of the submersible probe to groundwater (A) and lake water (B) samples with increasing levels of hydrazine and dimethylhydrazine respectively (a–j). This probe responds to these 2×10^{-6} M concentration changes. Detection limits of around 5×10^{-7} M can thus be estimated for both compounds ($S/N = 3$). Notice also the negligible response of the unspiked sample (amperogram s), indicating the absence of electroactive interferences (at low potential accrued form the catalytic action). A nearly linear response is observed for both compounds. Such response characteristics (including the sensitivity) are similar to those observed in "synthetic" samples (e.g. Fig. 2), reflecting the minimal matrix effects (including pH ones). Similar response characteristics were observed for all three hydrazine compounds in these lake water and groundwater samples (not shown).

4. Conclusion

In conclusion this paper demonstrates that hydrazine compounds can be monitored at large sample/instrument distances by coupling the surface modification technology with our recently developed submersible probe design. The remote monitoring capablility is coupled to a sensitive, selective and reversible response. While the new concept of a remote modified electrode is presented within the context of hydrazine detection, it could be extended to other relevant contaminants (via a judicious choice of the modifier). The rich and diverse chemistry—accrued from the deliberate tailoring of electrode surfaces—should greatly benefit the remote monitoring of pollutants, and environmental electrocatalytic in general. Work in this laboratory is thus progressing towards the development and testing of new remote probes based on electrocatalytic and preconcentration surfaces.

Phase inversion cellulose acetate membranes for suppression of protein interferences in anodic stripping voltammetry 2[1]. Improvement of the membrane preparation procedure

Boy Hoyer*, Nina Jensen

Department of Chemistry, Aarhus University, Langelandsgade 140, 8000 Aarhus C, Denmark

Abstract

Phase inversion (PI) cellulose acetate membranes were cast on glassy carbon electrodes from a solution containing acetone as solvent and aqueous magnesium perchlorate as pore former. It is shown that a significant improvement of the reproducibility and permselective properties of the membrane is obtained by allowing complete evaporation of the solvent in a controlled humidity environment before the membrane is gelated. By using cadmium and lead as test analytes and differential pulse anodic stripping voltammetry as the detection method, it was found that the modification of the electrode greatly reduces the interference from albumin, lysozyme, gelatin and polyethylene glycol (MW 6000). The permselectivity of the PI membrane can be controlled by varying the amount of magnesium perchlorate in the casting solution and the relative humidity during the pre-gelation conditioning of the membrane.

Keywords: Anodic stripping voltammetry; Phase inversion cellulose acetate membranes; Protein interferences

1. Introduction

One of the most serious limitations of the applicability of electroanalytical methods is fouling of the electrode surface due to adsorption of macromolecular constituents of the sample [1]. Usually, the symptom of this interference is a gradual decrease in the response towards the analyte [2], which introduces accuracy risks and necessitates frequent regeneration of the electrodes. Recent

[1] For Part 1 see Ref. [21].

research (reviewed in Refs. [3–5]) has shown that coating the electrode surface with a permselective membrane is one of the most promising strategies for suppressing or eliminating adsorption interferences. However, the design of such membranes is not trivial because a compromise must be sought between protection of the electrode and the inevitable loss of sensitivity caused by the diffusional resistance of the membrane. The protective membranes should be as thin as possible, and this favours an approach in which the membrane is cast in situ on the electrode surface because the membrane need not be mechanically self-supporting.

Cellulose acetate (CA) has proven to be one of the most useful materials for the preparation of protective membranes on electrodes. In particular, Wang and co-workers [6–9] have demonstrated that in-situ-formed CA membranes are useful for suppression of adsorption interferences and selective detection of low molecular weight species. In their work, the permselectivity of the CA coating is controlled by base hydrolysis. However, this approach also has disadvantages because the polymer backbone is partly broken down by the treatment, and poor stability and reproducibility of the resulting modified electrodes has been reported [10]. The phase inversion (PI) method for preparation of permselective CA membranes has been widely used for the manufacture of reverse osmosis, ultrafiltration and dialysis membranes for more than 30 years [11,12] but the potential of this technology for coating electrodes with protective membranes has only recently been explored by Kuhn and co-workers [13,14] and by us [15]. In the wet PI method, the permselectivity of the CA membrane is controlled by adding a pore former or swelling agent to the casting solution [12]. After evaporation of the solvent, the polymer is precipitated by immersion in a non-solvent gelation bath. The formation of the membrane structure takes place during this step, and anisotropic membranes with a dense skin layer and a more porous sublayer are generally obtained [12].

We have previously shown [15] that CA membranes prepared by the PI method give better protection against interference from albumin in anodic stripping voltammetry (ASV) than those prepared by the base hydrolysis method. Equally importantly, the permeability characteristics of the PI membranes are more reproducible. Most likely, these differences can be ascribed to the fact that the PI method does not involve any degra-dation of the membrane polymer. The PI membranes were cast from the "classical" four-component system of Loeb and Sourirajan [11] in which acetone serves as solvent for CA and aqueous magnesium perchlorate is the pore former.

In the present work, significant improvements in the preparation of the PI membranes are presented which increase the permselectivity further and reduce the variation in the properties of individual membrane preparations. Also, the study of the capability of the membranes to suppress adsorption interferences has been extended with more proteins as well as a surfactant. It is also shown that the permeability of the membrane can be controlled via the amount of pore former added to the casting solution and by varying the relative humidity during the pre-gelation drying step.

2. Experimental

2.1. Apparatus

Voltammetric measurements were performed with a programmable electrochemical analyser [16]. The electrochemical cell comprised a Metrohm 628-50 rotating disk electrode unit with a 3 mm diameter glassy carbon electrode. The reference electrode was a Radiometer K401 saturated calomel electrode (SCE), while the counter electrode was a glass-fitted platinum wire (1 cm long, 0.5 mm thick).

The constant humidity environment needed for the pre-gelation drying of the PI membranes was established in 500 ml soft plastic bottles in which the air was in equilibrium with an aqueous solution of lithium chloride. Each bottle contained the appropriate amount of the salt dissolved in 50 g of water. In this manner, a relative humidity from 13% to 100% (25°C) can be obtained [17]. For example, the 21% relative humidity environment was established by dissolving 30.4 g lithium chloride in 50 g of water. The electrode tip was inserted into the bottle through a hole cut in the side.

2.2. Reagents

Buffers and supporting electrolyte media were prepared from Merck Suprapur reagents and triply-distilled water, while other reagents were of analytical grade. The acetone was a special, dry grade (Merck, max. 0.01% (w/w) water). CA (39.8% acetyl content, MW 30 000) was obtained from Aldrich. Bovine albumin (fraction V, essentially globulin-free, lyophilized, MW 66 000) and

lysozyme (from chicken egg white, lyophilized, MW 15 000) were obtained from Sigma. A 0.1% (w/v) solution of the surface-active compounds was prepared daily. Unless stated otherwise, the composition of the casting solution for the PI membranes was: 20 g acetone, 0.250 ml 0.9 M Mg $(ClO_4)_2$ in water and 0.05 g CA. The concentration of CA in this solution is 0.25% (w/v). Note that magnesium perchlorate is extremely hydroscopic, and therefore the actual concentration of solutions prepared by weighing out and dissolving the salt is uncertain and must be measured. The standard method for the determination of hardness of water by titration with EDTA was used for this purpose.

2.3. Procedure for preparation of modified electrodes

Prior to coating, the glassy carbon electrode was polished with 0.25 μm diamond paste, rinsed with ethanol and dried with lens paper. Coating with CA was done by inverting the rotating disk electrode and applying 2.5 μl of the casting solution to the glassy carbon surface while the electrode was spinning at 1500 rev min $^{-1}$. When the acetone had evaporated, the electrode tip was placed in a bottle with controlled humidity for 10 min. The relative humidity was 21% unless stated otherwise. Hereafter, the electrode was quickly withdrawn from the bottle and immersed in an ice-water gelation bath (0°C) for 30 min. This transfer was done in less than 1 s. Unless stated otherwise, mercury was deposited on the glassy carbon/CA substrate by electrolysis for 10 min at -1 V vs. SCE in deaerated acetate buffer spiked with 2.5 × 10 $^{-5}$ M mercury(II). A conventional thin mercury film electrode (TMFE) was prepared in the same manner, but minus the polymer coating. In the following, a TMFE coated with CA by the PI process is abbreviated as PI-TMFE.

2.4. Procedure for differential pulse (DP) ASV measurements

All measurements were performed in 0.1 M acetate buffer spiked with 2.0 × 10 $^{-7}$ M Cd(II)

and 2.0 × 10 $^{-7}$ M Pb(II). Solutions were deaerated with argon for 5 min prior to DPASV measurements. The working electrode was rotated at 750 rev min $^{-1}$ during deposition, while stripping was carried out in a quiescent solution following a 15 s rest period. The stripping signals were recorded in differential pulse mode with the following instrumental settings: deposition potential, -1000 mV vs. SCE; deposition time, 2 min; scan range, -1000 to -50 mV vs. SCE; pulse height, 50 mV; pulse width, 20 ms; sampling time, 2 ms; pulse repetition time, 0.24 s; effective scan rate, 12.3 mV s $^{-1}$. Signals were smoothed with a seven-point Savitsky–Golay algorithm, and the background signal was corrected for by subtraction of an interpolated linear baseline. A freshly prepared electrode was preconditioned by performing two deposition/stripping cycles in the acetate buffer.

In the interference experiments, the surfactant concentration in the test solution was raised incrementally in the following sequence: 1, 2, 5, 10 and 20 ppm. Two stripping measurements were carried out after each addition. In this manner, the dependence of the DPASV peak current on the surfactant concentration could be studied, and the adsorption of surfactant onto the working electrode was closer to equilibrium.

3. Results and discussion

Several improvements in the preparation of the PI-TMFE have been introduced in the present study, including better control of the water content in the casting solution by use of dried acetone, application of the casting solution to the electrode whilst spinning, and pre-gelation drying of the coating in a controlled humidity environment. However, the experiments left no doubt that the last-mentioned improvement is by far the most important. When bulk membranes are produced by the wet PI process, it is common practice to allow a partial evaporation of the solvent prior to gelation [12], however, this drying step becomes a source of poor reproducibility with thin films because the zone in which the solvent is depleted extends throughout the polymer layer.

[c] Data from Ref. [15].

Moreover, the fraction of the solvent which evaporates prior to the gelation step depends on experimental parameters such as the duration of the drying step, temperature, and convection in the drying environment, which also lower the reproducibility. It is therefore preferable to allow complete evaporation of the solvent, and the number of components in the polymer film is reduced from four to three (CA/magnesium perchlorate/water) before it is immersed in the gelation bath. Equally importantly, the water content is also under control due to the constant humidity drying environment.

As can be seen from Table 1, the new scheme

for preparation of the PI-TMFE (type II) offers considerably better protection against the albumin interference than the previous method (type I) described in Ref. [15]. A t-test (assuming unequal variances of the populations) showed that the peak depression observed with the two electrode modifications is different at a 99.9% confidence level for cadmium as well as lead. Also, control experiments were carried out in which no surfactant was added, and the "natural" fall-off in the signals for the PI-TMFE II is no different to that observed when albumin is added (cf. Table 1). This means that the PI-TMFE II is insensitive to

Table 2
DPASV peak currents of cadmium and lead obtained with the PI-TMFE and the TMFE

PI-TMFE II	2.0	0.4	3.4	0.5	8
PI-TMFE III	1.6	0.3	2.4	0.6	8

[a] No. of individual electrode preparations.
[b] Data from Ref. [15].

the albumin interference within the concentration range tested. Furthermore, the variability of individual electrode preparations with respect to the suppression of the albumin interference is much smaller for the new electrode modification procedure. These improvements can be attributed to the introduction of the drying step as discussed above.

Next, the suppression of the interference from lysozyme was tested. This protein has a much lower molecular weight than albumin (15 000 and 66 000 respectively), and it therefore poses a greater challenge for the permselectivity of the PI membrane. Lysozyme also causes a dramatic decrease in the DPASV signals at the conventional TMFE (cf. Table 1). The PI-TMFE II offers a substantial reduction of the interference from lysozyme, but does not eliminate it. Therefore, a PI membrane with a denser skin layer (type III) was produced by lowering the concentration of magnesium perchlorate in the pore former from 0.9 to 0.7 M. In order to maintain a suitable mercury loading on the electrode, the concentration of mercury in the plating solution was tripled. In this manner, the interference from lysozyme could also be eliminated (cf. Table 1). The PI-TMFE III also offers good protection towards interference from gelatin, but some suppression of the cadmium peak remains. However, the interpretation of this result is complicated by the fact that gelatin is a product of the structural and chemical degradation of collagen and shows a wide molecular weight distribution [18], including a significant fraction with MW below 10 000.

Polyethylene glycol (PEG; MW 6000) caused suppression of the cadmium signal at the PI-TMFE III. Assuming that the permselectivity of the CA membranes is primarily based on molecular weight [8], it can therefore be concluded that the molecular weight cut-off of the PI-TMFE III is in the range 6000–14 000. This result must be viewed in relation to the requirements for protection of the electrode set by the sample type and the electroanalytical method applied. An important potential application of the PI membranes lies in clinical chemistry, and it is interesting to note that ultrafiltration of human serum samples with a 5 kDa filter was found to be necessary in order to obtain undistorted voltammograms of redox probes added to the serum [19]. With respect to clinical analysis it would therefore be desirable to achieve a somewhat lower molecular weight cut-off of the PI membranes. Work to this aim is currently in progress in our laboratory.

As shown in Table 2, the DPASV peak currents obtained with the conventional TMFE are reduced by factors of approximately three for the PI-TMFE II and four for the PI-TMFE III. This order is in agreement with the general rule that a decrease in the molecular weight cut-off of a size-exclusion membrane is accompanied by loss of sensitivity owing to the increased diffusional resistance. In comparison, a reduction of the sensitivity in ASV by a factor as high as 18 has been reported when bulk CA membranes are applied for protection of the electrode [20]. It has also been reported that the response of an amperometric detector was reduced between 10 and 20 times

when a base-hydrolyzed CA film was applied to the working electrode [8].

Voltammograms obtained with the conventional TMFE and the three types of PI-TMFE are shown in Fig. 1. The peak potentials for cadmium and lead were the same at the TMFE and the PI-TMFE I and II (− 715 and − 545 mV vs. SCE respectively), while the peak positions at the PI-TMFE III were 10–15 mV more positive for cadmium as well as for lead. The reason for this difference is not known. For all electrode types, the peak width at half wave height was close to 45 mV for both metals. The moderate effect of the coating on the DPASV peak characteristics (apart from the peak height) indicates that the polymer layer is a passive membrane without specific interaction with the analyte. Also, the shape and size of the background signal were not affected noticeably by the polymer coating (cf. Fig. 1). At the conventional TMFE, all surfactants tested shifted the peak potentials for cadmium and lead in the positive direction. Addition of 20 ppm surfactant was accompanied by the following shifts in peak potentials for cadmium and lead respectively: albumin, + 30 and + 20 mV; lysozyme, + 23 and + 11 mV; gelatin, + 19 and + 8 mV; PEG 6000, + 14 and + 4 mV. For the combinations of surfactant and PI-TMFE type listed in Table 1, the addition of 20 ppm surfactant caused peak shifts in only two cases, namely lysozyme/PI-TMFE-II (+ 4 and + 3 mV for cadmium and lead respectively) and PEG 6000/PI-TMFE III (+ 8 and + 3 mV). The addition of the surfactant also

Fig. 1. DPASV signals of cadmium and lead obtained with (A) TMFE, (B) PI-TMFE I, (C) PI-TMFE II and (D) PI-TMFE III. The measurement conditions are given in Section 2.

Fig. 2. Effect of the concentration of magnesium perchlorate in the pore former on the DPASV peak currents of cadmium (▲) and lead (■) obtained with the PI-TMFE. Apart from the parameter varied, the standard formulation of the casting solution was used (see Section 2). No surfactant has been added. Each point represents the average of not less than two electrode preparations.

caused significant signal suppression for both combinations (cf. Table 1), and the analyte signal which was most suppressed by the surfactant also exhibited the largest peak shift. These observations are not surprising because signal suppression and peak shift at the PI-TMFE both indicate that the surfactant has penetrated the membrane and caused interference at the electrode/electrolyte interface. However, it was also found that addition of albumin to the PI-TMFE I caused suppression of the cadmium and lead signals (cf. Table 1) without any concomitant peak shift.

As shown in Fig. 2, the DPASV peak currents for cadmium and lead depend strongly on the amount of magnesium perchlorate in the pore former. Since this salt is a powerful desiccant and the polymer coating is dried under constant humidity conditions, it is reasonable to assume that the molar quantities of magnesium perchlorate and water in the film are proportional at the moment when the electrode is immersed in the gelation bath. The porosity of the PI membrane can therefore be controlled via the amount of magnesium perchlorate in the casting solution. Fig. 3 shows the decrease in the DPASV peak current caused by albumin addition as a function of the magnesium perchlorate content in the pore former. The apparent increase in the sensitivity of

the PI-TMFE towards the albumin interference seen with the most dense PI membrane ([Mg(-$ClO_4)_2$] = 0.53 M) is an artifact related to insufficient mercury loading of the electrode. Control experiments, in which no albumin was added, showed decreases in the DPASV peak currents comparable to those given in Fig. 3. However, when the concentration of Hg(II) in the plating solution was tripled, the fall-off in the signals was similar to that obtained with 0.7 M and 0.9 M $Mg(ClO_4)_2$ as pore former (see Fig. 3). Apparently, the signal stability of the PI-TMFE deteriorates when the amount of mercury deposited becomes too low, and the increased diffusional resistance of PI membranes with dense skin layers should therefore be compensated for in the mercury deposition step.

As expected, some increase in the sensitivity of the PI-TMFE towards albumin is seen at the highest concentrations of $Mg(ClO_4)_2$ in the pore former (1.13 M and 1.44 M). Still, the extent of the albumin interference is much smaller than at the bare TMFE, while the DPASV peak currents for cadmium and lead obtained with the PI-TMFE (using 1.44 M $Mg(ClO_4)_2$ as pore former) are reduced by 28% and 21% respectively relative to those obtained with the TMFE. Thus,

Fig. 4. Effect of the relative humidity during the drying step on the DPASV peak current for cadmium (▲) and lead (■) obtained with the PI-TMFE. No surfactant has been added. Each point represents the average of not less than four electrode preparations.

it is also possible to produce PI membranes which only reduce the sensitivity moderately and yet offer good protection against interference from albumin.

The effects of the relative humidity in the pre-gelation drying step on the characteristics of the PI-TMFE are shown in Figs. 4 and 5. The DPASV peak current only displays minor variations when the relative humidity is 35% or higher

Fig. 3. Effect of the concentration of magnesium perchlorate in the pore former on the discriminative power of the PI-TMFE towards albumin: (▲) cadmium; (■) lead. Apart from the parameter varied, the standard formulation of the casting solution was used (see Section 2). The ordinate shows the decrease in the DPASV peak current after incremental addition of 20 ppm albumin. Each point represents the average of not less than two electrode preparations.

Fig. 5. Effect of the relative humidity during the drying step on the discriminative power of the PI-TMFE towards albumin: (▲) cadmium; (■) lead. The ordinate shows the decrease in the DPASV peak current after incremental addition of 20 ppm albumin. Each point represents the average of not less than four electrode preparations.

(cf. Fig. 4), whereas the peak depression caused by albumin increases monotonically with the relative humidity in this range. Consequently, the pre-gelation conditioning of the membrane should be done at a relative humidity of 35% or lower. The increase in the sensitivity of the electrode towards the albumin interference at the lowest humidity tested (13% relative humidity, cf. Fig. 5) is probably an artifact related to reduced signal stability owing to insufficient mercury deposition on the electrode as discussed above.

As previously mentioned [15], the spin-coated PI membranes have diffuse, concentric refraction rings, which is evidence of a non-uniform thickness of the polymer layer. The rings develop during the evaporation of the casting solvent. It is believed that further progress in the preparation of the PI membranes is linked to the achievement of a uniform polymer layer, which means that alternative coating methods must be found. At present, the feasibility of applying the casting solution to the electrode surface by electro-spraying is being explored.

There is no reason to expect that the attractive properties of PI membranes for suppression of electrode fouling should be limited to ASV. Protective membranes are an integral part of most electrochemical (e.g. amperometric) sensors for analysis of biological fluids owing to the complex nature of the matrix [4,5], and the PI process for preparation of CA membranes could also prove to be useful for such applications.

Second-derivative constant-wavelength synchronous scan spectrofluorimetry for determination of benzo[b]fluoranthene, benzo[a]pyrene and indeno[1,2,3-cd]pyrene in drinking water

M.J. López de Alda Villaizán*, M.S. García Falcón, S. González Amigo, J. Simal Lozano, M.A. Lage Yusty

Department of Analytical Chemistry, Nutrition and Bromatology, Area of Nutrition and Bromatology, Faculty of Pharmacy, University of Santiago de Compostela, E-15706 Santiago de Compostela, La Coruña, Spain

Abstract

The use of derivative constant-wavelength synchronous scan fluorimetry is reported for the determination of three polycyclic aromatic hydrocarbon pollutants in drinking water (linearity range 0.4–4 μg l^{-1}). The limits of detection (LD) and quantification (LQ) (μg l^{-1}) are 0.01 and 0.07 for benzo[b]fluoranthene, 0.03 and 0.12 for benzo[a]pyrene and 0.19 and 0.57 for indeno[1,2,3-cd]pyrene in the presence of three other pollutants, benzo[k]fluoranthene, benzo[ghi]perylene and fluoranthene. The precision (RSD ≤ 10.6%) and recovery (≥ 85%) were satisfactory.

Keywords: Benzo[a]pyrene; Benzo[b]fluoranthene; Indeno[1,2,3-cd]pyrene; Synchronous scan spectro fluorimetry

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) are a group of essentially man-made organic compounds which are now widely distributed in the environment. Since some of these compounds, e.g. benzo[b]fluoranthene, benzo[a]pyrene and indeno[1,2,3-cd]pyrene, are known carcinogens [1], monitoring of their levels is considered necessary. However, owing largely to the complexity of the matrices in which they occur and the often low

concentrations to be measured, no standardized official method for the quantification of PAHs has yet been developed. For drinking water, the WHO nevertheless suggested a joint recommended limit of 200 ng l^{-1} for the six PAHs designated as indicators (benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[ghi]perylene, benzo[a]pyrene, fluoranthene and indeno[1,2,3-cd]pyrene), and the same limit has been adopted as an official maximum allowable concentration by the European Union (EU), formerly the European Community (EC) [2], while EC-Council Directive 75/440/EEC on the quality required of surface waters destined

for the production of drinking water [3] stipulates the same allowable maximum of 200 ng l^{-1} for class A1 and A2 waters and 1000 ng l^{-1} for class A3 waters.

There have been a number of different approaches to the quantification of PAHs. The EC proposed, as a reference method for surface waters destined for the production of drinking water [4], measurement of UV fluorescence after thin-layer chromatography in comparison with measurements of standard mixtures of the six indicator substances mentioned above, and for drinking water itself [2].

For surface water, tap water and wastewater, the American Society for Testing and Materials subsequently published a liquid chromatograpic (LC) method with UV and/or fluorescence detection [5], and for urban and industrial wastewaters

the US Environmental Protection Agency [6] later recommended a gas chromatographic–mass spectrometric (GC–MS) method. However, a number of authors [7–12] have proposed the use of synchronous spectrofluorimetry (first developed by Lloyd [13] in 1971), which offers several advantages over the others: analysis is rapid and so allows a high throughput of samples; the solvent consumption is limited to that required for the preparation of the sample; the detection and quantification limits are low; and the sensitivity is much better than that of UV–visible absorption methods. The selectivity of the technique is enhancable not only by the virtual absence of non-fluorescent interferents in the sample, but also by the simultaneous scanning of both the excitation and emission monochromators, which affords narrower bands than in conventional spec-

Inset: magnification of boxed area.

trofluorimetry and virtually eliminates interference from Rayleigh scattering [7,14–21]. As with other spectroscopic techniques, analysis of multi-component samples whose spectra have overlapping bands can be further improved by using the derivative modes [17,22].

Synchronous spectrofluorimetry has been adopted for the global determination of total amounts of the six named PAHs, officially designated as indicators of drinking water quality [23,24].

This paper describes a second-derivative constant-wavelength sychronous scan spectrofluorimetric method for the individual determination of the six carcinogenic PAHs, namely benzo[b]fluoranthene, benzo[a]pyrene and indeno[1,2,3-cd]pyrene in the presence of benzo[k]fluoranthene, benzo[ghi]perylene and fluoranthene.

2. Experimental

2.1. Materials

2.1.1. PAH standards

Benzo[a]pyrene and fluoranthene were obtained from Aldrich and benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[ghi]perylene and indeno[1,2,3-cd]pyrene from Sugelabor. (Caution: all these compounds, except benzo[ghi]perylene, are suspected carcinogens and all are toxic; they

should be handled only in a hood, using safety glasses and other appropriate approved safety measures, to avoid contact with skin, eyes and clothing.) Solutions of benzo[b]fluoranthene, benzo[a]pyrene and indeno[1,2,3-cd]pyrene in hexane were prepared at concentrations of 0.4, 1.0, 2.0 and 4.0 μg l^{-1}. Four stock solutions containing the following mixtures (all in hexane) were likewise prepared: 0.04, 0.1, 0.2 and 0.4 μg l^{-1} benzo[k]fluoranthene + 10-fold masses (μg l^{-1}) of each of the other five indicator PAHs.

2.1.2. Extractant/solvent

n-Hexane for residue analysis (Merck) was used.

2.2. Apparatus

The spectrofluorimeter was a Perkin-Elmer LS-50 luminescence spectrometer equipped with a xenon

discharge lamp, Monk–Gillieson mono-chromators and 1 cm quartz cuvettes. For acquisition and processing of spectral data by Fluorescence Data Manager software, the instrument was serially interfaced (RS232C) to a PC.

2.3. Working conditions

For each of the above solutions, three scans with excitation – emission wavelength differences of 110, 160 or 185 nm were run at a scan rate of 240 nm min^{-1} between 200 and 500 nm (excitation slit width 2.5 nm and emission slit width 20 nm).

3. Results and discussion

The optimum excitation – emission wavelength difference for each PAH was obtained by scanning
(A)

Fig. 3(A)
(B)

Fig. 3. (A) Normal and (B) second-derivative synchronous fluorescence spectra of 2.0 μg l^{-1} solutions of indeno[1,2,3-cd]pyrene in hexane (—) or hexane containing 0.2 μg l^{-1} of benzo[k]fluoranthene and 2.0 μg l^{-1} of each of the other PAHs (•), $\Delta\lambda$ = 185 nm. Inset: magnification of boxed area.

its solutions between 200 and 500 nm with the difference set at 10 nm (scan 1) and increasing this difference by 5 nm for each of 49 successive scans. Comparison of the scans with the narrowest, best defined bands with the corresponding spectra of mixtures with the other admixed five indicator PAHs showed overwhelming interference (Fig. 1(A)–3(A)). However, in the second-derivative spectra there were wavelength intervals allowing the detection and quantification of the target PAHs in the presence of the others, coincidence between the single- and multiple-PAH spectra at these wavelengths showing that the multiple-PAH peak was due solely to the target PAH (Fig. 1(B)–3(B), Table 1).

For quantification, the calibration lines listed in Table 2 were constructed by regressing the

peak-to-trough heights of these second-derivative peaks against the concentrations of the working solutions specified in the Experimental section. Following the recommendations of the American Chemical Society's Subcommittee on Environmental Analytical Chemistry [25], limits

Benzo[a]pyrene	78.34	2.68	0.9991	2.45	0.95	0.03	0.12
Indeno[1,2,3-cd]pyrene	24.77	1.81	0.9967	2.55	1.34	0.19	0.57

[a] x = Concentration in μg 1^{-1}.
[b] Second-derivative signal.

of detection (LD) and quantitation (LQ) were calculated as the concentrations corresponding to the mean blank signal + three and ten standard deviations, respectively.

In previous experiments [23] using constant-wavelength synchronous scan fluorescence spectrometry, the suitability of hexane for analyses of this type (for which it is recommended by the EU [2]) was evaluated and it was found to have both excellent extractive capacity and spectrofluorimetric properties [26].

There were no signs of interference from the aqueous matrix in the determination of these PAHs (no significant differences were observed between the spectrum of hexane and that of hexane extracts of PAH-free water), and any signal distortion due to drift of background noise was automatically corrected by using the second-derivative method. The method precision and recovery were calculated by spiking six replicate distilled PAH-free water samples [23] with 0.2 μg 1^{-1} of benzo[k]fluoranthene and 2 μg 1^{-1} of each of the other PAHs (Table 3).

This technique is rapid, easy to apply and offers limits of detection and quantification which can-

Table 3
Precision and recoveries obtained for six replicate distilled PAH-free water samples each spiked with 0.2 μg 1^{-1} of benzo[k]fluoranthene and 2 μg 1^{-1} of each of the other PAHs

Compounds	Recovery (%)	Precision (RSD, %)
Benzo[a]pyrene	91.3	8.9
Benzo[b]fluoranthene	99.5	8.5
Indeno[1,2,3-cd]pyrene	85.0	10.6

not be matched by some chromatographic methods. For these reasons, it is ideally suited to the regular monitoring of PAH levels in large numbers of water samples.

4. Conclusions

The described technique allows the determination of three of the six carcinogenic polycyclic aromatic hydrocarbons whose presence in drinking water is officially recognized as indicative of pollution, namely benzo[b]fluoranthene, benzo[a]pyrene, and indeno[1,2,3-cd]pyrene, in the presence of the other three. For benzo[b]fluoranthene, a working emission – excitation wavelength difference of 160 nm affords limits of detection and quantification in hexane of 0.01 and 0.07 μg 1^{-1}, respectively, for the second-derivative peak at 300–305 nm. In the case of benzo[a]pyrene, a working emission – excitation wavelength difference of 110 nm affords limits of detection and quantification in hexane of 0.03 and 0.12 μg 1^{-1}, respectively, for the second derivative peak at 290–296 nm. However, for indeno[1,2,3-cd]pyrene, a working emission – excitation wavelength difference of 185 nm affords limits of detection and quantification in hexane of 0.19 and 0.57 μg 1^{-1}, respectively, for the second derivative peak at 314–319 nm.

Long-wavelength stopped-flow fluorimetric determination of lysozyme

B. Gala, A. Gómez-Hens, D. Pérez-Bendito*

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

Abstract

The use of Cresyl Violet and sodium dodecyl sulphate for the kinetic fluorimetric determination of lysozyme from dynamic fluorescence measurements at a long wavelength in the range near 600 nm was explored. The high initial rate of this system allows analytical measurements to be made within ca. 2 s after the reactants are mixed, by using the stopped-flow mixing technique, which makes the method applicable to automatic routine analysis. The calibration graph is linear over the range 0.5–40 μg ml^{-1} lysozyme hydrochloride and the detection limit of 0.19 μg ml^{-1}. The precision is less than 2% (relative standard deviation). The results obtained by applying the proposed method to the analysis of pharmaceutical samples with no pretreatment shown how readily it can be adapted for routine analyses. Analytical recoveries ranged between 94.0 and 104.0%.

Keywords: Cresyl Violet; Fluorimetry; Kinetic method; Lysozyme; Pharmaceuticals; Stopped-flow

1. Introduction

Long-wavelength fluorescent dyes in analytical applications have attracted considerable attention in recent years on account of their advantages over conventional fluorescent dyes, such as reduced background interferences and sample photodecomposition [1]. Among others, long-wavelength fluorescent dyes have been used as labels in immunoassay [2] and as reagents in chromatography [3] and capillary electrophoresis [4]. Diode lasers are frequently used as light sources in near-infrared fluorescence spectroscopy

because their high irradiance and very narrow bandwidth afford very low detection limits and good selectivity. However, most lasers only emit a few discrete wavelengths, so optimum excitation can only be achieved if the output matches the fluorophore excitation wavelengths. In addition, the current practical limit for a commercial diode laser is 660 nm [5].

In this work, the scope of the analytical application of long-wavelength fluorescence dyes was extended to the simple, fast kinetic determination of proteins in the presence of an anionic surfactant, sodium dodecyl sulphate (SDS). For this purpose, several azine dyes with fluorescent properties in the spectral region near 600 nm were tested and a kinetic fluorimetric method for

* Corresponding author.

lysozyme determination was developed. Experiments were carried out with a 450 W xenon arc lamp as the light source because the excitation wavelengths for these compounds are shorter than the above-stated limit for diode lasers (660 nm). The high initial rates obtained for these systems cannot be measured by using the batch technique, requiring the use of the stopped-flow mixing technique to obtain kinetic measurements. In addition, this technique facilitates automation through automatic mixing of sample and reagent solutions and kinetic data from the mixed solution can be acquired for immediate processing in order to obtain the analytical information.

Lysozyme is a proteolytic enzyme present in numerous pharmaceutical preparations of antibiotics such as tetracyclines, penicillins and aminoglycosides because it is claimed to enhance their antimicrobial activity when given concomitantly. This protein has been determined in pharmaceutical preparations by measuring the fluorescence intensity of 4-methylumbelliferone released by lysozyme from 4-methylumbelliferyl tetra-N-acetyl-β-chitotetraoside, which acts as the substrate [6]. Since the enzyme also appears to catalyse the hydrolysis of the substrate to the saccharide, without release of the fluorescent moiety, the sensitivity of the assay was increased by adding β-N-acetylhexaminidase, obtaining a rectilinear calibration graph from 10 to 70 μg ml^{-1} lysozyme. A chromatographic method using a similar substrate (4-methylumbelliferyl tri-N-acetyl-β-chitotrioside) has been described for the determination of lysozyme in food [7]. Other fluorimetric methods for lysozyme determination by using other substrates such as fluorescein isothiocyanate-labelled peptidoglycan [8] and fluorescamine-labelled peptidoglycan [9] have been described. Also, 4-nitrophenyl penta-N-acetyl-β-chitopentaoside has been proposed as substrate for the photometric determination of lysozyme [10], which liberates 4-nitrophenol. Turbidimetry has been also used for the determination of lysozyme involving *Micrococcus luteus* as substrate [11,12]. The method, with a rectilinear calibration graph from 0.5 to 15 μg ml^{-1} lysozyme, has recently been adapted to commercial analyser [13], but data on throughput have not been given.

The methods involving a lysozyme-substrate reaction require an incubation time close to 30 min at 37°C. However, the alternative method described in this paper avoids the use of a substrate and allows the fast and simple determination of lysozyme by using the stopped-flow mixing technique. Its usefulness was assessed by analysing various pharmaceutical samples.

2. Experimental

2.1. Instrumentation

A Model 8000C photon counting spectrofluorimeter from SLM-Aminco (Urbana, IL, USA), equipped with a 450 W xenon arc source and an R928 photomultiplier tube, was used. The instrument was furnished with an SLM-Aminco Milliflow stopped-flow reactor, a TWC computer and a Roland plotter. The stopped-flow module, fitted with an observation cell of 0.2 cm pathlength, was controlled by the associated electronics, the computer and a pneumatic syringe drive system. The solutions in the stopped-flow module were kept at a constant temperature of 20°C by circulating water from a thermostated tank.

2.2. Reagents

A 200 μg ml^{-1} stock aqueous solution of lysozyme hydrochloride (grade VI, Sigma) was prepared. Aqueous solutions of Cresyl Violet acetate (9.3 $\times$ 10^{-5} M, Sigma) and SDS (1.5 $\times$ 10^{-2} M, Merck) were also prepared. A 0.1 M borate buffer solution was made from boric acid and adjusted to pH 10.0 with sodium hydroxide.

2.3. Procedure

Two aqueous solutions (A and B) were used to fill the 2 ml drive syringes of the stopped-flow reactor. Solution A contained lysozyme hydrochloride at a final concentration between 3.6 $\times$ 10^{-8} and 2.9 $\times$ 10^{-6} M, borate buffer (1.7 $\times$ 10^{-2} M) and SDS (1.5 $\times$ 10^{-3} M). Solution B contained SDS (1.5 $\times$ 10^{-3} M), borate buffer (1.7 $\times$ 10^{-2} M) and Cresyl Violet acetate (1.4 $\times$

10^{-5} M). In each run, 0.04 ml of each solution was mixed at a flow-rate of 20 ml s^{-1} in the mixing chamber. The increase in the fluorescence intensity with time throughout the reaction was monitored at λ_{ex} 585 nm and λ_{em} 627 nm using the slow kinetic acquisition mode of the instrument. All measurements were carried out at 20°C. Fluorescence values were obtained for 10 s and processed by the computer, running a linear-regression program for application of the initial-rate method. The reaction rate was determined in ca. 2 s and each standard or sample was assayed in triplicate. The blank signal was found to be negligible at 20°C.

2.4. Determination of lysozyme in pharmaceutical samples

Analyses for lysozyme were carried out similarly to the above-described procedure. Each sample was analysed by weighing and powdering a tablet, transferring the powder into an appropriate volumetric flask (50 or 250 ml) and diluting to volume with distilled water. The suspension was shaken for 5 min in an ultrasonic bath (50 W) and then filtered. Finally, an aliquot of the filtrate was treated as described above.

3. Results and discussion

3.1. Spectral studies

Three fluorescent azine dyes [Cresyl Violet (λ_{ex} 585, λ_{em} 627 nm), Nile Blue (λ_{ex} 624, λ_{em} 675 nm) and Azure B (λ_{ex} 647, λ_{em} 673 nm)], were assayed for use as reagents for lysozyme. These compounds exhibit an intense fluorescence in aqueous solutions that is not affected by the presence of lysozyme, as shown in Fig. 1 for Cresyl Violet. However, SDS completely quenches the fluorescence of the dye at a concentration below the critical micelle concentration (c.m.c.). The c.m.c. for SDS in this system was measured with a stalagmometer, and found to be 1.7 × 10^{-3} M, which is approximately five times lower than that reported in pure aqueous solutions (8.1 × 10^{-3} M) [14]. Under these conditions, the presence of

lysozyme caused an increase in the fluorescence intensity (Fig. 1) proportional to the concentration of the protein (Fig. 2). These results were obtained at a pH lower than the isoelectric point of lysozyme (11.0).

On the other hand, the fluorescence of the dyes was not quenched but rather increased at an SDS concentration above its c.m.c. This can be attributed to the fact that the interaction between Cresyl Violet and SDS changes when micelles are formed and dye molecules are sheltered from non-radiative processes by the micellar environment. Under these conditions, the presence of lysozyme does not affect the fluorescence of these systems. Also, placing SDS with a non-ionic (Triton X-100) or cationic surfactant (cetyltrimethylammonium bromide) results in no difference between the sample and blank. Two other anionic surfactants assayed (Tergitol 7 and sodium dodecylbenzenesulphonate) provided poorer results than SDS.

A possible explanation for the behaviour of SDS in this system is the following: the surfactant

Fig. 1. Emission spectra for Cresyl Violet (1) in the absence and presence of lysozyme, (2) in the presence of SDS and (3) in the presence of SDS and lysozyme. [Cresyl Violet] = 1.4 × 10^{-5} M; [lysozyme] = 25 μg ml^{-1}; [SDS] = 1.5 × 10^{-3} M.
Fig. 2. Kinetic curves obtained for Cresyl Violet–SDS–lysozyme system at different lysozyme concentrations (1) 10, (2) 20, (3) 30 and (4) 40 μg ml^{-1}. [Cresyl Violet] = 1.4 × 10^{-5} M; [SDS] = 1.5 × 10^{-3} M.

monomers, which are negatively charged, interact with Cresyl Violet, which is positively charged, causing a change in the electronic distribution of this dye and a loss of fluorescence. Lysozyme, a bulky molecule with numerous positive charges, can partially react with SDS to release Cresyl Violet and restore the original fluorescence signal. The interaction between SDS and lysozyme can be ascribed to the fact that SDS is a protein denaturant [15].

The kinetic curves for these systems were obtained by using the stopped-flow mixing technique. Although the three dyes behaved similarly, the best initial rate values were obtained with Cresyl Violet. Thus, the initial rates obtained for 20 μg ml^{-1} lysozyme by using Cresyl Violet, Nile Blue and Azure B were 49, 3.5 and 2.8 s^{-1}, respectively. Fig. 2 shows the kinetic curve obtained using Cresyl Violet; as can be seen, the initial rate could be obtained within only 2 s.

3.2. Effect of reaction variables

Experimental variables were optimized using the univariate method. All reported concentra-

tions are initial concentrations in the syringes (twice the actual concentrations in the reaction mixture at time zero after mixing). Each kinetic result was the average of three measurements. The optimum values taken were those for which the relative standard deviation of the initial rate measurements was minimal, under conditions where the reaction order concerning the variable studied was zero or as close to it as possible.

One of the most critical variables of this system was the SDS concentration because, as noted above, no interaction between lysozyme and Cresyl Violet was observed in the absence of the surfactant or in the presence of a concentration above its c.m.c.; also, the fluorescence intensity of the dye was strongly dependent on the SDS concentration. Fig. 3 (A) shows the variation of the initial rate of the system with the concentration of SDS in the range 8 × 10^{-4}–3 × 10^{-3} M. As can be seen, the maximum initial rate was obtained near the c.m.c. of SDS and decreased above it. The blank signal was negligible up to the c.m.c. but increased above that level, so no difference between the sample and blank was observed at an SDS concentration close to 3 × 10^{-3} M.

The effect of pH was studied over the range 4.4–12.0 by using different amounts of sodium hydroxide and hydrochloride acid (Fig. 3(B)). The reaction rate of the system increased slightly up to pH 10.7, which is very close to the isoelectric point of lysozyme, and decreased sharply at higher pH values. Consequently, no interaction between lysozyme and SDS exists when the protein is negatively charged. pH 10 was chosen as optimal and a borate buffer was used to adjust it in the samples. The study of the effect of the buffer concentration showed that the initial rate was independent of this variable over the range 2 × 10^{-2}–4.5 × 10^{-2} M, outside which the initial rate was lower. Fig. 3(C) shows the effect of the Cresyl Violet concentration; as can be seen, the initial rate increased sharply up to a 1.2 × 10^{-5} M reagent concentration, remained constant from this concentration up to 1.7 × 10^{-5} M and decreased slightly beyond that point.

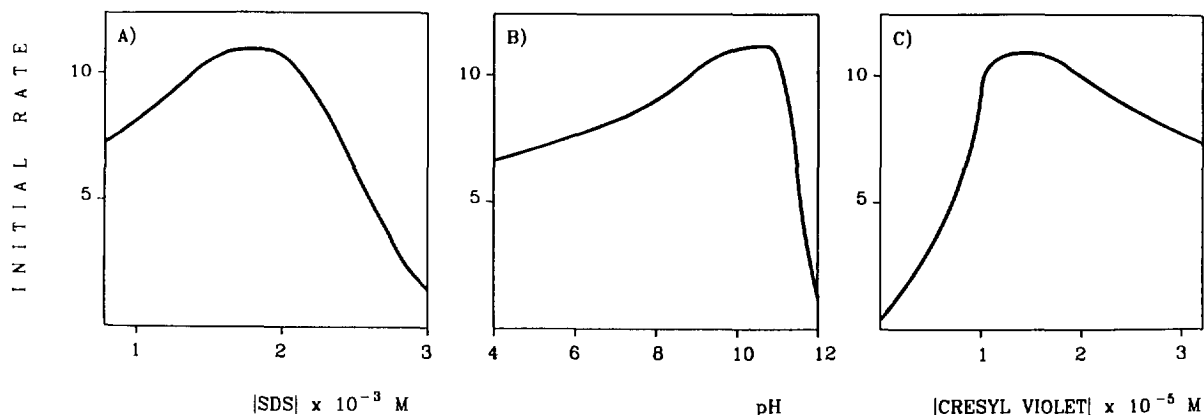
The initial rate of the system was found to be independent of the temperature in the range 15–35°C and to increase slightly above it, increasing


Fig. 3. Effects of (A) SDS concentration, (B) pH and (C) Cresyl Violet concentration on Cresyl Violet–SDS–lysozyme system. [lysozyme] = 20 μg ml^{-1}; [Cresyl Violet] = 1.4 $\times$ 10^{-5} M (A) and (B) and SDS 1.5 $\times$ 10^{-3} M in (B) and (C); 10^{-2} M borate buffer (pH 11.3) in (A) and (C).

also the blank signal. A temperature of 20°C was chosen to avoid working under high-temperature conditions where, in addition, the blank signal must be subtracted.

Based on the slopes of the fluorescence vs. time curves obtained for solutions containing different amounts of lysozyme, the reaction is first order with respect to the analyte. Under the working conditions used, the reagents exhibited a pseudo-zero-order dependence, so the following kinetic equation is proposed: $v = k$[lysozyme], where v is the reaction rate and k is the conditional rate constant.

3.3. Figures of merit of the proposed method

The fluorescence–time curves obtained for different amounts of lysozyme under the optimum conditions were processed by the initial-rate method. The calibration graph was linear over the concentration range 0.5–40.0 μg ml^{-1} and conformed to the equation $v = 2.56C + 1.25$, where v is the initial rate (s^{-1}) and C the lysozyme hydrochloride concentration (μg ml^{-1}). The Pearson correlation coefficient (r) was 0.998 ($n = 11$). The detection limit, calculated according to IUPAC recommendations [16], was 0.19 μg ml^{-1}. The blank standard deviation was determined by assaying 30 samples, each containing a very low analyte concentration (0.25 μg ml^{-1}), enough to yield an adequate signal. This procedure is usually

used to determine the detection limit when the blank does not give an appreciable signal. The sampling rate was 60 h^{-1}, calculated from the time taken to perform three replicate analyses including changeover in the stopped-flow module (about 30 s). The precision was studied at two concentrations of lysozyme hydrochloride, 5 and 25 μg ml^{-1}; the relative standard deviations obtained by measuring the initial rate ($n = 11$) were 1.2 and 1.8%, respectively.

Equilibrium measurements can also be carried out by using this approach. However, the detection limit obtained was 0.79 μg ml^{-1}, which was much higher than that obtained by kinetic methodology. Also, the relative standard deviations for 5 and 25 μg ml^{-1} lysozyme hydrochloride were higher (2.8 and 7.5%, respectively).

The selectivity of the proposed method was assessed by assaying several potentially interfering compounds that frequently accompany lysozyme in pharmaceutical preparations. A substance was considered not to interfere at a given concentration if the reaction rate obtained in its presence was within one standard deviation of the value obtained with the analyte alone. All the compounds assayed (tetracycline, ampicillin, tyrothricin, bacitracin, benzocaine, sodium cyclamate, saccharin and sucrose) were tolerated up to at least a 100-fold excess relative to the analyte. One of the most salient features of the proposed method is speed; since the time required

to obtain analytical data is only ca. 2 s, the method is a useful, simple alternative to automatic routine procedures for the determination of lysozyme.

3.4. Applications

In order to validate the proposed stopped-flow method of lysozyme, it was applied to various pharmaceutical samples by direct analysis (with no sample pretreatment), using initial-rate measurements. The results obtained from the average of six determinations of six different tablets of each sample are summarized in Table 1. Recoveries were determined by adding three different amounts of lysozyme hydrochloride standard to each sample and subtracting the results obtained for similarly prepared pharmaceuticals to which no analyte was added. Table 1 lists the analytical recoveries obtained, which ranged from 94.0 to 104.0% (mean 98.9%).

4. Conclusions

The proposed method is the first reported application of kinetic methodology in conjunction with the stopped-flow mixing technique for the development of a rapid method for the determination of lysozyme by using initial rate measurements at long wavelengths. The results obtained show that the method can readily be adapted to automatic quality control of the analyte in pharmaceutical preparations. Therefore, it extends the scope of application of long-wavelength fluorescence dyes to fast kinetic determinations with improved analytical features relative to equilibrium measurements.

The method can be considered universal for protein determinations (a prior separation will be required for determining lysozyme in the presence of other proteins). However, when selectivity is not a limitation (e.g. in the quality control of

lysozyme in pharmacuetical formulations), the main aim is to develop a fast, simple, sensitive method of use for routine analyses. Despite the reliability of the methods previously described for lysozyme determination, which are based on its reaction with different substrates, they are time-consuming as they require a previous incubation step. However, the proposed stopped-flow method allows measurements to be made shortly after mixing and analytical data to be acquired in only a few seconds.

Abstract

The best reproducible technology of pH measurement for precise pH buffer solutions regulated by Japanese Industrial Standards (JIS) was studied. A pH meter was devised with a high resolution of ± 0.0001 pH. An 18-bit analog-to-digital converter is used, one-bit resolution corresponding to 0.0019 mV (ca. 0.000032 pH) against an input electrode potential ± 500 mV. Digital data were treated smoothly for some types of noise, a reproducibility of ± 0.0002 pH being obtained with a potentiometer. A flow cell was devised to attain temperature control within $\pm 0.03°C$ and air-tight measurement prevented contamination with carbon dioxide. Also, the flow cell has a structure such that potassium chloride (KCl) inner solution effused from a ceramic junction of the reference electrode designed so as not to touch the glass membrane. A combination pH electrode (a glass electrode and a reference electrode) was assembled to minimize the dead volume of sample solution. This highly sensitive pH measuring system, consisting of a pH meter, a flow cell, a combination pH electrode, a circulating water thermostat and a peristaltic pump, was used for the certification of pH standard solutions in Japanese metrological law. The performance of this system was within ± 0.0006 pH reproducibility and 20–30 min response time (5 min within ± 0.0002 pH) at a sample flow rate of 3 ml min^{-1}.

Keywords: Legal traceability; pH measurement; pH standard solutions

1. Introduction

The pH value is given by the electromotive force (e.m.f.) of a cell with a hydrogen gas electrode and a reference electrode [1]. The practical pH value of a sample solution is determined by adding the pH value of a standard buffer solution to the value of the difference between the e.m.f. of the former cell against the sample solution and the e.m.f. against the standard buffer solution divided by the Nernstian slope for monocations (59.16 mV at 25°C) (a single standard method). In another definition of pH value by use of the linear

---

relationship between pH and the e.m.f. of the former cell, the operational pH value of the sample solution is determined by the e.m.f. against two types of standard buffer solution and against the sample solution (a multi-standard method). For a practical scale of pH a series of standard buffer solutions were defined in the literatures [2–5].

One of the most important areas where accurate values of pH measurement are required is in environmental water pollution control. The pH value of industrial waste water is regulated between pH 6.5 and 8.5 by the Basic Environment Law in Japan [6]. Therefore, the correct calibration of pH meters is very important to monitor environmental pollution by the industrial waste water, referring to precise pH standard solutions. In metrological law, a series of standard buffer solutions are provided as certified reference materials (CRMs) that are traceable to reference materials (RMs) [7]. In 1983, the Japanese government defined a precise pH standard solution, the reproducibility of which is ± 0.002 pH, to maintain a clean environment in the presence of industrial waste water. Therefore, a practical pH measuring system for the purpose of referring the sample buffer solutions to the primary pH standard solution was required. The standards of reproducibility of pH buffer solutions in Japanese Industrial Standards (JIS) are within ± 0.002 pH. Therefore, the development of a pH meter with a measurement ability of ± 0.0001 pH unit resolution was required to determine pH values of buffer solutions correctly. For the purpose mentioned above, we have developed a high-performance pH measuring system for Japanese pH standard solutions using a flow system, and developed an airtight flow cell system which has good stability to temperature changes and pH changes in pH buffer solutions.

A cell consisting of a hydrogen gas electrode and a silver–silver chloride electrode was reported as a pH measuring cell [8,9]. However, electrode preparation just before use, such as platinum black plating of a platinum electrode and silver chloride plating of a silver electrode, is indispensable for reproducible measurements. Therefore, this method is not very practical. As the most

practical method, we studied a cell with a glass electrode and a silver–silver chloride reference electrode. In comparison with the hydrogen gas electrode, the glass electrode has a high impedance of the glass membrane and a long response time. In the reference electrode, an appropriate and constant outflow of KCl from the liquid junction should be supplied for a stable liquid junction potential. However, the KCl might change the original pH value of the sample soltution slightly when it reaches the glass electrode. During the measurement, the pH standard solution should be kept away from ambient air to prevent a change in pH value due to dissolved carbon dioxide.

However, up to now, no pH measurement system has a ± 0.0001 pH unit resolution. In this work, we constructed a precise pH measurement system by developing a flow cell system with a glass electrode and a reference electrode in response to a request from the National Chemical Laboratory for Industry and studied the effects of temperature control, sample flow rate, response time and reproducibility on pH.

2. Outline of certification system for pH standard solutions in Japan

Fig. 1 shows the scheme for the traceability of pH standard solutions regulated by the Japanese government in 1984. In this traceability system, the pH standard materials made into a stock standard solution and primary pH standard solutions are prepared from it at the National Chemical Laboratory for Industry. The Chemical Inspection and Testing Institute, Japan (CITI), was founded as the certifying organization to supply pH standard solutions for practical use. Secondary pH standard solutions are prepared there using chemicals of pH measurement grade and certified by using the primary standard solutions. After all the pH standard solutions for practical use have been inspected and certified by the secondary pH standard solutions, they are distributed to the users of pH meters.

3. Experimental

3.1. Apparatus and reagents

A DKK Model EL6157 combination glass electrode was used. A Yamato Model BH-51 thermostat was used for temperature control of the sample solution. An Alitea Model U4-XV peristaltic pump was used to send the sample solution into the flow cell. A Yokogawa Model LR4110 analog recorder and an IBM Model N27 personal computer with software written in Microsoft Visual Basic were used to record and collect the data.

Potassium tetraoxalate, potassium hydrogenphthalate, potassium dihydrogenphosphate, disodium hydrogenphosphate, sodium tetraborate decahydrate, sodium hydrogencarbonate and sodium carbonate were obtained from Kanto Kagaku (Tokyo, Japan), Wako Chemicals (Osaka, Japan) and Merck (Darmstadt, Germany). All chemicals were of pH measurement grade or analytical-reagent grade. Pure water obtained with a Milli-Q SP Reagent Water System was used throughout. A Model F10 porous ceramic used as the ceramic junction was purchased from Kyocera (Kyoto, Japan). Z-7 chelating resin was purchased from Miyosi Oil and Fat (Tokyo, Japan).

Fig. 1. Traceability scheme for pH standard solutions in Japan.

3.2. Preparation of pH standard solution

Six kinds of pH standard solution were prepared as follows. A 0.05 mol (kg H_2O)$^{-1}$ potassium tetroxalate dihydrate solution was prepared as a pH 1.679 standard solution at 25°C according to JIS K 0018 [10]. A 0.05 mol (kg H_2O)$^{-1}$ potassium hydrogenphthalate solution was prepared as a pH 4.008 standard solution at 25°C according to JIS K 0019 [11]. A 0.025 mol (kg H_2O)$^{-1}$ $KH_2PO_4 + 0.025$ mol (kg H_2O)$^{-1}$ Na_2HPO_4 solution was prepared as a pH 6.865 standard solution at 25°C according to JIS K 0020 [12]. A 0.008695 mol (kg H_2O)$^{-1}$ $KH_2PO_4 + 0.03043$ mol (kg H_2O)$^{-1}$ Na_2HPO_4 solution was prepared as a pH 7.415 standard solution at 25°C according to JIS K 0023 [13]. A 0.01 mol (kg H_2O)$^{-1}$ $Na_2B_4O_7 \cdot 2H_2O$ solution was prepared as a pH 9.180 standard solution at 25°C according to JIS K 0021 [14]. A 0.025 mol (kg H_2O)$^{-1}$ $NaHCO_3 + 0.025$ mol (kg H_2O)$^{-1}$ Na_2CO_3 solution was prepared as a pH 10.012 standard solution at 25°C according to JIS K 0022 [15]. The primary standard pH solutions were obtained from the National Chemical Laboratory for Industry.

3.3. Preparation of pH electrode

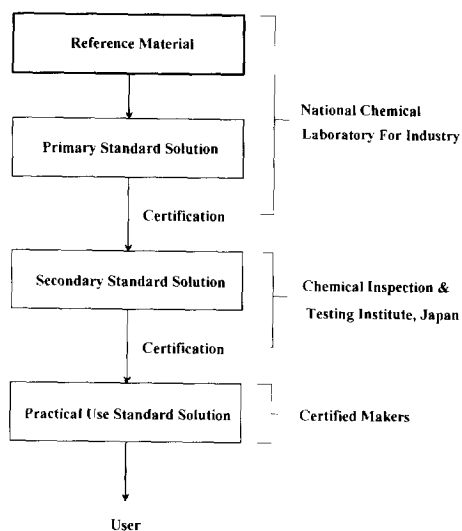
The pH electrode used is shown in Fig. 2. The Model EL6157 is a combination-type pH electrode with a long-term stable reference electrode, which can eliminate silver chloride complex ions in the potassium chloride (KCl) inner solution by the use of chelating resins [16]. To stabilize the liquid junction potential thoroughly, a remodelled Model EL6157 pH electrode was used. The chelating resin was changed from MX-8 to Z-7, which was more effective in adsorbing silver chloride complex ions dissolved from the silver–silver chloride inner electrode. The ceramic junction was changed from Model F11 to Model F10, with which the outflow rate of the KCl inner solution was about five times that with the Model F11. Furthermore, the numer of ceramic junctions was changed from one to two by adding one at the opposite side of the electrode body. The diameter of the glass membrane is 6 mm and that of


Fig. 2. Structure of stable pH combination electrode.

the electrode body with ceramic junctions is 12 mm.

3.4. Manufacture of pH flow cell

The pH flow cell developed is shown in Fig. 3. The flow cell consisted of an acrylic resin body and

pH flow cell

Fig. 3. Structure of flow cell for pH.

a spiral glass tube to keep the temperature constant. The sample from the sample inlet was kept at a constant temperature (25°C) in the spiral glass tube, passing by way of the glass membrane and the ceramic liquid junction and being exhausted from the sample outlet. The length of the glass spiral tube was about 60 cm. The distance passed by the sample from the sample vessel to the glass membrane was about 1 m. The diameter throughout the sample route was 1 mm and the volume of the sample passage was about 0.8 ml. The dead volume around the glass membrane was about 0.6 ml. The flow cell has two narrow gaps, with a width of 2 mm and a depth of 0.5 mm, to separate the glass membrane from the liquid junction, because if KCl diffused from the liquid junction and contact with the glass membrane some errors would occur in pH measurements. The diameter of the flow cell was 66 mm and the height was 140 mm.

3.5. Development of high-resolution pH meter

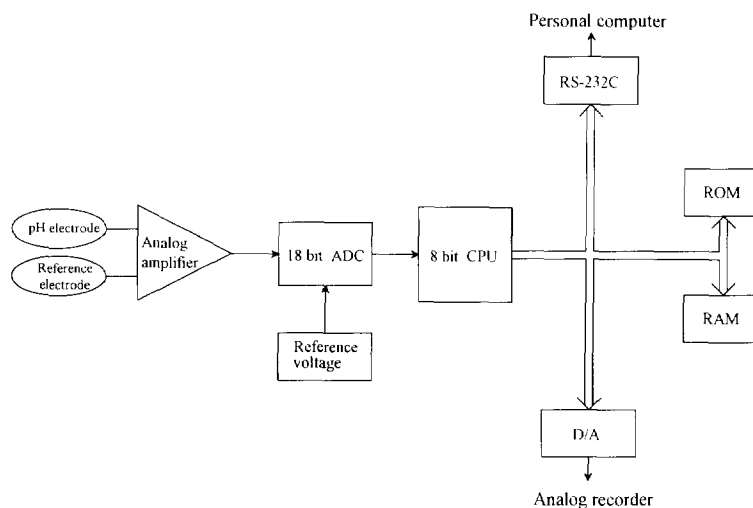
A block diagram of the pH meter developed is shown in Fig. 4. The operational amplifier for conversion from the high-impedance e.m.f. of the glass membrane to the low-impedance output voltage was used as an analog amplifier. An analog-to-digital converter (ADC) of double integral type was used as an 18-bit ADC; 18 bits of the digital signal corresponded to $\pm$ 500 mV of e.m.f. The sampling time of the ADC was about 1 s. One-bit resolution was corresponded to 0.0019 mV. The e.m.f. was always referred to the reference voltage (0 and 500 mV). The pH meter has a function of two-point calibration operated by the 8-bit central processor unit (CPU) by means of operational software written in Intel PLM Compiler. The unknown pH(X) value was determined by the multi-standard method from two standard solutions of pH(X$_1$) and pH(X$_2$). Furthermore, as the pH(X) value was very close to the pH(X$_1$) value, the difference between these values was determined very precisely. The pH(X) value was calculated against E mV of the e.m.f. as shown in Eqs. (1), (2) and (3), where X_1 and E_1 correspond to the pH and the mV of the e.m.f. in the first-point calibration, respectively, and X_2 and E_2 to those of the e.m.f. in the second-point calibration, respectively.


Fig. 4. Block diagram of precise pH meter.

$$X = [(X_2 - X_1)/(E_2 - E_1)](E - E_1) + X_1 \qquad (1)$$

When E_1 was changed to $E_1{}'$ by a repeated first-point calibration, the offset potential of the calibration curve was changed as follows:

$$X = [(X_2 - X_1)/(E_2 - E_1{}')](E - E_1{}') + X_1 \qquad (2)$$

Further, when E_2 was changed to $E_2{}'$ by a repeated second-point calibration, the offset potential and the sensitivity (electrode slope) of the calibration curve were changed as follows:

$$X = [(X_2 - X_1)/(E_2{}' - E_1{}')](E - E_1{}') + X_1 \qquad (3)$$

All measurements were made at 25°C. The data on the e.m.f. and pH were sent to the personal computer through the RS-232C interface, and at the same time were recorded on the analog recorder through the 14-bit digital-to-analog converter. All operations of calibration and the measurement were made through the personal computer.

3.6. pH-measuring flow system

Fig. 5 shows the pH-measuring flow system. The sample was sucked and carried into the flow cell by the peristaltic pump located downstream. Water was circulated at 2 l min^{-1} between the thermostat and the water-jacket of the flow cell and was maintained at 25 ± 0.03°C. The flow cell

body and the sample vessel were situated in an air-conditioned room. The relationship between the sample flow rate and the ambient tempreature was studied. The sample flow rate was examined between 0.5 and 6 ml min^{-1}. The characteristics of the thermal exchange in the flow cell were examined against the change in the ambient temperature. The sample vessel was purged with nitrogen to prevent contamination by atmospheric carbon dioxide. The e.m.f. of the pH electrode measured by the pH meter was recorded and collected by the analog recorder and the personal computer.

3.7. Verification procedure for pH standard solution

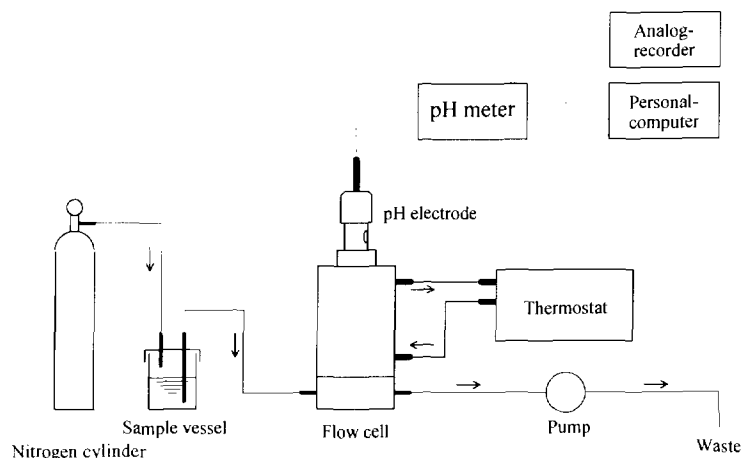
The procedure for verification of the prepared pH standard solution with the primary pH standard solution is as follows. First, the pH meter is calibrated by two kinds of primary pH standard solutions, the first-point calibration using one with same pH value and the second-point calibration with one with another pH value, which is usually different by several pH units. For example, if the prepared phosphate pH standard equimolal solution (pH 6.865) is verified, the first-point calibration of the pH meter is executed beforehand using the phosphate primary pH stan-


Fig. 5. Precise pH-measuring flow system for pH standard solutions.

dard equimolal solution (pH 6.865) and the second-point calibration is executed with the phthalate primary pH standard solution (pH 4.008). These calibrations were repeated several times until the measured value corresponded to the value of the standard solution within ± 0.0002 pH. Subsequently, a prepared pH standard solution was measured. When many samples were measured, the first-pont calibration was repeated after every few measurements and each set of data was corrected by interpolation from the difference between two of the first-point calibrations. The measurement was considered to have reached the final value when the e.m.f. remained constant within ± 0.0002 pH for 5 min.

4. Results and discussion

4.1. Effect of sample flow rate

Each pH standard solution has a temperature coefficient. Near 25°C, the temperature coefficients of the oxalate pH standard solution (pH 1.679), the phthalate pH standard solution (pH 4.008), the phosphate pH standard equimolal solution (pH 6.865), the phosphate pH standard solution (pH 7.413), the tetraborate pH standard solution (pH 9.180) and the carbonate pH standard solution (pH 10.012) are 0.001, 0.0012, — 0.0028, — 0.0028, — 0.0082 and — 0.0096 pH

$°C^{-1}$, respectively [2]. The calculated temperature values which give a 0.0001 pH error are 0.100, 0.083, — 0.036, — 0.036, — 0.012 and — 0.010°C, respectively. Therefore, the tempreature of the sample solution needed to be precisely controlled within ± 0.01°C.

The relationship between the sample flow rate and the ambient temperature is shown in Fig. 6. The water in the water-jacket of the flow cell was controlled at 25 ± 0.03°C. Lines 1, 2, 3, 4, 5, 6, 7 and 8 represent ambient temperatures of 26, 24, 27, 23, 28, 22, 29 and 21°C, respectively. When the sample flow rate was faster than 5 ml min^{-1},

Fig. 6. Relationship between flow rate and temperature of sample.

Fig. 7. Response time of pH flow system under different conditions.

the temperature control became worse owing to the inadequate temperature exchange capacity of the spiral glass tube. When the sample flow rate was lower than 2 ml min^{-1}, temperature control was lost because of the effect of the temperature change due to the flow cell body. The temperature of the sample remained constant in the flow rate range 2–5 ml min^{-1} when the ambient temperature was controlled at $25 \pm 1.5°C$ and the circulating water in the flow cell was controlled at $25 \pm 0.03°C$.

4.2. Response time

Fig. 7 shows the typical response time during measurement of the pH buffer solution using the present system. The response time was almost independent of the type of pH standard solution. The response time to the same type of pH standard solution is usually 10–15 min (A), e.g. from the secondary phthalate pH standard solution (pH 4.008) to the primary phthalate pH standard solution (pH 4.008). The response time in the case of the second-point calibration is usually 20–30 min (B), e.g. the primary oxalate pH standard solution (pH 1.679) to the primary phthalate pH standard solution (pH 4.008).

4.3. Reproducibility

In each of the six types of pH standard solution, after the pH system had been calibrated by the primary pH standard solution, the secondary pH standard solution was measured. Ten replicate measurements were made and the standard deviations of the final values were claculated. The standard deviations of the oxalate pH standard solution (pH 1.679), the phthalate pH standard solution (pH 4.008), the phosphate pH standard equimolal solution (pH 6,865), the phosphate pH standard solution (pH 7.413), the tetraborate pH standard solution (pH 9.180) and the carbonate pH standard solution (pH 10.012) were ± 0.0005, ± 0.0005, ± 0.0006, ± 0.0006, ± 0.0004 and ± 0.0004 pH, respectively. Although it seems that the phosphate standard solution is slightly inferior to the others, it can be concluded that overall reproducibility was ± 0.001 pH.

4.4. Other factors influencing precision

The pH standard solutions as CRMs are required to have a certified value of ± 0.002 pH. The specification of a pH meter to verify them inevitably requires a reproducibility of ± 0.001 pH. There are some factors to be considered with regard to precise pH measurement. First, temperature control is the most important. Not only the sample temperature but also the ambient temperature should be controlled precisely because the pH electrode is affected by the ambient temperature in the electrode cap. Second, the maintenance of a smooth KCl outflow and a clean liquid junction in the reference electrode is important, too. Third, the glass electrode should be renewed at least every 6 months because the response of the glass membrane gradually decreases with time. Fourth, small air bubbles on the surface of the glass membrane can affect the stability of the e.m.f. and also, the formation of air bubbles is not desirable for stable pH measurements because the dead volume from the sample vessel to the flow cell increases and a smooth KCl outflow might no longer apply. The formation of air bubbles on the glass membrane

can be effectively prevented by degassing the sample with an aspirator before measurements. In comparison with the classical cell of the hydrogen gas electrode and the silver–silver chloride electrode, the present pH measurement system seems to show improved reproducibility and response times in practical use.

5. Conclusion

We have constructed a precise pH measurement system for supporting the traceability of pH standard solutions in Japan, with the development of an improved pH meter, a pH glass electrode and a flow cell. This system was applied to the measurement of pH standard solutions regulated by JIS and a reproducibility (standard deviation) of ± 0.0006 pH was attained. We conclude that the present flow system for pH measurement is very useful for the certification of pH standard solutions in traceability systems.

Room-temperature phosphorimetry studies of some addictive drugs following dansyl chloride labelling

Ai-Jun Tong*, Ying-Guang Wu, Long-Di Li

Department of Chemistry, Tsinghua University, Beijing 100084, China

Received 8 November 1995; revised 14 February 1996; accepted 16 February 1996

Abstract

A room-temperature phosphorimetric (RTP) method for the analysis of barbital, codeine, morphine and practolol after labelling with dansyl chloride (DNS-Cl) is described. The drug–DNS derivatives were obtained by refluxing with drug–ethyl acetate solutions and solid DNS-Cl in the presence of anhydrous potassium carbonate. The reaction conditions were investigated in detail. The fluorescence emission of drug–DNS derivatives shifted to longer wavelengths compared with that of DNS-Cl. The RTP phenomena observed for these derivatives by using a micellar stabilized room-temperature phosphorescence technique were examined and optimum conditions for their RTP emission were studied using an orthogonal array design. Derivative RTP spectra were obtained and successfully used to determine practolol by the established method without further separation.

Keywords: Addictive drugs; Dansyl chloride labelling; Room-temperature phosphorimetry

1. Introduction

Banned substances include narcotic and mental drugs and are sometimes abused by athletes to improve their physical performance in sport games and by drug addicts. On the other hand, some addictive drugs are very useful and essential in medical treatment. It is therefore very important to establish rapid, accurate and sensitive analytical methods for such drugs for the effective control of their illegal use in sport, for the confirmation of drug addicts, for their monitoring during drug rehabilitation programmes and for therapeutic drug monitoring.

Numerous methods have been established for addictive drug control. Gas chromatography (GC) [1], gas chromatography–mass spectrometry (GC–MS) [2], liquid chromatography (LC) [3] and radioimmunoassay [4] are some approved methods for drug screening. Alternative methods, including fluorimetric [5] and phosphorimetric [6,7] detection, chemiluminescence methods [8] and enzyme and fluorescence immunoassay [9,10], have also been developed.

Room-temperature phosphorimetry (RTP), especially the MS–RTP technique, is a recently developed method [11,12]. Phosphorescence emission usually appears at longer wavelengths than fluorescence, permitting selective detection in the presence of other fluorophores. The RTP tech-

---

nique also has the advantages of simplicity, good sensitivity and the possibility of automation. Further, MS-RTP is a fluid system, which has prompted its widespread application to various samples. RTP determinations of trace organic components [13,14] and proteins [15], which show suitable phosphorescence emission, have been reported. Although there has been a report of RTP studies of amino acids with fluorescamine labelling [16], there has been little research work concerning phosphorescence labelling. The aim of this work was to apply the MS-RTP method to the determination of barbital, codeine, morphine and practolol with dansyl chloride (DNS-Cl) as a phosphorescence labelling reagent.

Dansyl chloride is a well known fluorescence labelling reagent, reacting with amino phenolic and active hydroxyl groups under suitable experimental conditions. The RTP properties and the possibility of using DNS-Cl as a phosphorescence probe for amino acids have been reported [17]. In this work, an MS-RTP method for the analysis of addictive drugs with DNS-Cl labelling was established. The labelling conditions were studied in detail and some factors which affect the RTP emission of the drug DNS derivatives were studied by an orthogonal array design. Derivative RTP spectra were used to determine the addictive drugs without further separation.

2. Experimental

2.1. Apparatus

RTP spectra and fluorescence spectra were measured with a Perkin-Elmer LS-50B luminescence spectrometer. When scanning phosphorescence spectra, the delay time and the gate time were set at 0.1 and 2.0 ms, respectively; the excitation and the emission slit widths were set at 15 and 20 nm respectively. When fluorescence spectra were recorded, both slit widths were set at 4 nm. Derivative spectra were obtained automatically on the instrument.

Phosphorescence lifetimes were obtained with phosphorescence short decay application of the instrument and the data were obtained automatically with an Enzfitter program.

2.2. Reagents and solutions

Barbital, codeine phosphate, morphine and practolol were reference chemicals, obtained from the National Laboratory of Narcotic Drugs, National Institute for the Control of Pharmaceutical and Biological Products (China). Stock solutions of 10^{-3} M of the above drugs in ethyl acetate were prepared. DNS-Cl (Fluka) product was purchased from Baitai Biochemicals (China) and was used as received. Sodium dodecyl sulphate (SDS) was obtained from Beijing Chemical Factory (China) and was recrystallized twice with hot ethanol before use. Other chemicals were of analytical-reagent grade.

Deionized water was redistilled in a sub-boiling quartz distillation system and was used throughout the experiments.

2.3. Labelling procedure

In a carefully dried 50 ml reaction vessel, 5 ml of 10^{-3} M drug in solution ethyl acetate, certain amounts of DNS-Cl solid and finely ground and dried K_2CO_3 were mixed. The reaction mixture was heated with an air bath with continuous stirring for slow refluxing of the ethyl acetate. The labelling time was about 20 min for morphine and practolol and 60 min for baribtal and codeine. After the solid had been separated, ethyl acetate solutions of drug–DNS derivatives were analysed immediately or placed in a refrigerator at 4°C to prevent thermal or light decomposition. A labelling blank was prepared at the same time by reaction with ethyl acetate solvent and DNS-Cl under the same experimental conditions.

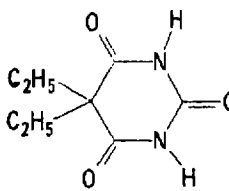
2.4. MS-RTP measurements

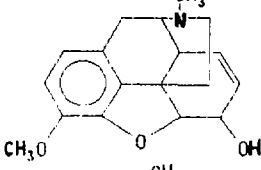
A 0.5 ml volume of about 1.9×10^{-3} M drug–DNS derivative solution was transferred into a bottle placed in a thermostat. The solution was heated at 60°C to evaporate the solvent. The same amount of 0.2 M SDS solution was added and the mixture was shaken vigorously to dissolve the derivative.

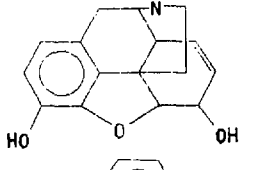
A 0.4 ml volume of the above solution was transferred into a 10 ml colorimetric tube, then 2

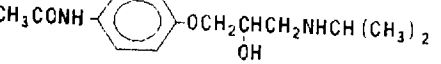
ml of 0.2 M SDS solution, 2.5 ml of 0.1 M TlNO$_3$ solution (caution: thallium(I) salts are very toxic) and 2 ml of 0.1 M Na$_2$SO$_3$ solution were added. The mixture was diluted to a final volume of 8 ml with water, heated in a water bath at 30°C for 30 min and the phosphorescence spectrum was recorded. The RTP spectrum of a DNS-Cl blank was also recorded for comparison.

2.5. Quantitative analysis of practolol

A series of 1.0, 1.5, 2.0 and 3.0 ml of 1.57 × 10^{-3} M practolol–ethyl acetate solution were reacted with 3.0 mg of DNS-Cl in the presence of 200 mg of solid K$_2$CO$_3$, and 0.2 and 0.4 ml of the above practolol solutions were reacted with 1.6 and 1.8 mg of DNS-Cl, respectively, in the presence of 200 mg of solid K$_2$CO$_3$, then the reaction








mixture was diluted to 10 ml with ethyl acetate. Two reaction blanks were prepared by reaction of 3.0 and 1.7 mg of DNS-Cl with 10 ml of ethyl acetate under the same labelling conditions as stated above. Certain amounts of the supernants were placed in colorimetric tubes and the RTP intensities were measured as stated above under the otpimum experimental conditions.

3. Results and discussion

3.1. Luminescence properties of barbital, codeine, morphine and practolol

The structures of the drugs studied and their luminescence properties are listed in Table 1. Except for practolol, the drugs show weak or

stronger fluorescence emission, but no RTP emission was observed, so phosphorescence labelling is necessary for RTP studies of these drugs. Active groups (amino, phenolic and hydroxyl groups conjugated with double bonds) are present in these molecules, so derivatization with DNS-Cl is possible.

3.2. Derativatization conditions

The reaction of DNS-Cl with active groups (e.g. amino groups) and the hydrolysis of DNS-Cl could be expressed as shown in Scheme 1.

It is clear that a basic medium is preferred in the labelling reaction to neutralize the hydrochloric acid product. Further, the hydrolysis of DNS-Cl will also proceed in basic conditions. It is therefore important to control the acidity of the reaction mixture. Several systems have been developed for the derivatization of various compounds with DNS-Cl. In this work, four derivatization systems were tested, namely the $Na_2CO_3-NaHCO_3$ buffer system [18], Na_2CO_3 medium with benzene extraction [19], pyridine non-aqueous medium and ethyl acetate medium in the presence of solid K_2CO_3 [20]. Except for the last system, these labelling methods either gave no DNS-Cl derivatives or the labelling reproducibility was not satisfactory. Therefore, the last system was selected and its reaction conditions were investigated in detail.

First, the particle size, degree of drying and amount of K_2CO_3 greatly affect the labelling pro-

cedure. Only when finely ground, carefully dried K_2CO_3 was used with continuous stirring and its amount exceeded the amount of DNS-Cl by 40–60-fold could all four drugs be labelled successfully. This could be explained by phase-transfer catalysis of the labelling reaction. Adsorption–desorption equilibria for the drug and for DNS-Cl between the solid K_2CO_3 and the ethyl acetate solvent existed. Derivatization occured only when both the drug and DNS-Cl were adsorbed on K_2CO_3 to obtain a base medium. Hence the ability of phase transfer would be weak when the amount of K_2CO_3 was not sufficient or the agitation was not thorough. A larger particle size of K_2CO_3 resulted in a small specific surface area and thus a low phase-transfer ability. The degree of drying of K_2CO_3 also greatly affected the labelling reaction because of the hydrolysis of DNS-Cl. Dansyl acid is the main by product of the labelling reaction, and even small amounts of water will affect the derivatization. All vessels and chemicals should therefore be dried carefully before the labelling process. An air bath was used instead of a water bath in our investigations.

Second, the temperature of reaction, reaction time and amount of DNS-Cl also affect the labelling. A high temperature would induce thermal decomposition of the product and a low temperature would increase the labelling time. An adequate temperature was 80°C to allow ethyl acetate to reflux slowly. In spite of drying of all the vessels and chemicals, trace amounts of water still existed
Scheme 1

and could not be neglected compared with the amounts of DNS-Cl and the drug. To prevent hydrolysis of DNS-Cl, the shorter the reaction time, the more complete is the derivatization. Our results showed that 20 min is needed for derivatization of the highly reactive drugs morphine and practolol and 60 min for the less reactive drugs barbital and codeine. Although an excess of DNS-Cl will be beneficial for quatitative derivatization of the drugs and decrease the effect of hydrolysis, an excess of drug instead of DNS-Cl is used to prevent separation in the subsequent RTP measurements. Solid DNS-Cl was used directly because of the restricted dissolution of DNS-Cl in ethyl acetate.

3.3. Fluorescence spectra of drug–DNS derivatives

Fluorescence spectra of the derivatives and DNS-Cl solutions in ethyl acetate were measured to confirm the labelling products. The results are summarized in Table 2. The emission wavelengths of the four derivatives were red shifted by 9–32 nm compared with that of DNS-Cl, indicating the formation of drug–DNS derivatives. It should be noted that the low-reactive codeine was successfully labelled under our experimental conditions, whereas its labelling was impossible in earlier study [18].

3.4. Room-temperature phosphorescence phenomena of drug–DNS derivatives

The RTP properties of the four drug–DNS derivatives were investigated using an MS–RTP

method. No RTP emission was obtained when the ethyl acetate solutions of the derivatives were treated with SDS micelles, $TlNO_3$ heavy atom perturber and Na_2SO_3 oxygen scavenger. It is considered that the existence of the organic solvent ethyl acetate would compete with the derivative for the protecting hydrophobic area and would increase the distance between the derivative and the heavy atom. These adverse effects of ethyl acetate resulted in no RTP emission. However, RTP emission was successfully observed for barbital–codeine– and practolol–DNS derivatives when the ethyl acetate was evaporated and the derivatives were redissolved in SDS micelles. RTP emission of morphine–DNS derivative was not observed under the same experimental conditions, and also no fluorescence of the SDS solution of its derivative after evaporation of the ethyl acetate was observed. The reason may be the thermal decomposition of morphine–DNS during the evaporation process or its poor solubility in SDS solution. Investigations of this aspect are in progress.

The RTP spectra and their first-derivative spectra of barbital–, codeine– and practolol–DNS are compared in Fig. 1. RTP determinations of the three drugs without separation of the reagent are possible using their first-derivative RTP intensities at fixed wavelengths at which the first-derivative RTP intensity of DNS-Cl was zero. The phosphorescence lifetimes for barbital–, codeine– and practolol–DNS are 0.543, 0.311 and 0.791 ms, respectively.

3.5. Optimum conditions for the RTP of drug–DNS derivatives

Developed by Cline-Love and Shaver [11], the MS–RTP method is one of the most important techniques for the RTP analysis of solutions. Several factors, such as concentrations and amounts of SDS, $TlNO_3$ and Na_2SO_3, deoxygenation time and temperature, are stated to be important factors which strongly affect the RTP intensities of phosphors. In this work, an orthogonal array design [21] was employed to evaluate the optimum values of these factors. Sixteen experiments were performed with a five-factor, four-level orthogonal array design (Table 3; the deoxygenation time

was fixed at 30 min). The results of these experiments were analysed by graphic interpretation. Thus, average RTP intensities for a certain factor at different levels were separately calculated; such average RTP intensities were taken as functions of the factors and the results were expressed as graphs. The following comments can be made.

The effects of SDS concentration are shown in Fig. 2. It can be seen that when the concentration of SDS was higher than 0.04 M, the RTP intensities of the three drug derivatives reached maxima. It is essential that the concentration of SDS be much higher than its critical micellar concentration (CMD) to give enough micelles to provide a protecting microenvironment for the RTP emission of phosphors. In subsequent experiments, 0.08 M SDS in the final solution was used.

Fig. 2. Effects of SDS concentration on the RTP intensities of drug–DNS derivatives. Abbreviations as in Fig. 1.

Fig. 3. Effects of Tl/Na on the RTP intensities of drug–DNS derivatives. Tl/Na = molar ratio of Tl to the sum of Tl and Na; other abbreviations as in Fig. 1.

Thallium(I) nitrate is an external heavy atom perturber; it enhances the intersystem crossing from singlet to triplet and thus increases the phosphorescence emission. When the concentration of $TlNO_3$ was higher than 0.075 M in the measuring solution, the RTP intensities remained maxima. Another important factor is the concentration and amount of Na_2SO_3. Oxygen is a strong phosphorescence quenching agent, and its removal is always necessary in RTP measurements. Sodium sulphite is an effective oxygen scavenger [12], but its deoxygenation efficiency depends on the concentration of Na_2SO_3 and on the Tl/Na ratio (the molar ratio of Tl to the sum of Tl and Na) in the solution. The deoxygenation effect was not good when its concentration was too low or was too high for the replacement of the Tl^+ ions on the surface of the micelles by the Na^+ ions. Fig. 3 shows the effects of Tl/Na on the RTP intensities of the drug derivatives. Suitable molar ratios were 26% for barbital–DNS 30% for codeine–DNS and 29% for practolol–DNS.

The effects of temperature were also studied. The RTP intensities decreased as the temperature increased because of the increase in radiationless transitions at higher temperatures. In this study, 30°C was chosen as the measuring temperature for easy temperature control even in the hot summer season. On the other hand, it is an important advantage of the proposed method that strong
enough RTP intensities for the drug–DNS derivatives were obtained at such a high temperature.

3.6. Quantitative analysis

From Fig. 1, it can be seen that the phosphorescence emission of the drug–DNS derivatives was red-shifted by 14–26 nm compared with that of the DNS-Cl blank. If the wavelength at which the derivative RTP intensity of DNS-Cl was zero was chosen as the detection wavelength, the first-derivative RTP intensity at the wavelength was due only to the drug derivative. Hence the first-derivative spectra can be used for quantitation without prior separation of the excess reagent. Fig. 1(2) shows that all three drugs could be analysed using this method.

In this paper, quantitation of practolol was chosen as an example. A 2–20-fold excess of DNS-Cl was used and the reagent blanks were prepared correspondingly. Our results show that in the practolol concentration range 1.9×10^{-5}–2.8×10^{-4} M, the calibration graph was a straight line passing through the origin. The correlation coefficient was 0.993. The detection limit of practolol calculated as three times the standard deviation of the blank (five repeated labelling reactions and RTP detection experiments) divided by the slope of the calibration graph was 0.19 ppm.

An indirect method for the spectrofluorimetric determination of trace amounts of germanium after extraction as an ion association complex with rhodamine B in the presence of chromotropic acid

S. Nalini, T.V. Ramakrishna*

Department of Chemistry, Indian Institute of Technology, Madras 600036, India

Abstract

A highly sensitive and selective spectrofluorimetric method for the determination of 0.05–2.00 μg germanium is described. Germanium is treated with chromotropic acid at pH 2.5 and the resultant anionic complex is extracted as an ion pair with rhodamine B into toluene. Addition of butanol to the organic extract releases the fluorescent dye and facilitates its measurement at 570 nm after exciting at 540 nm. The method provides a detection limit of 0.003 μg ml^{-1} and is virtually free from interference from extraneous ions. The relative standard deviaiton is 2.9% for ten determinations of 1.0 μg germanium. The method has been applied to the determination of germanium in various ores, minerals and rock samples.

Keywords: Chromotropic acid; Germanium; Ion association complex; Rhodamine B; Spectrofluorimetry

1. Introduction

The determination of germanium by generation as its hydride and subsequent measurement by atomic absorption spectrometry [1–3] or direct current plasma atomic emission spectrometry [4,5] is potentially advantageous as the methods are rapid, require minimum sample pretreatment and are sensitive at the nanogram level. Unfortunately, the presence of heavy metals such as Fe, Pb, Cd, Zn and Cu proved troublesome as they

were found to affect the evolution of germane [3]. An added disadvantage of atomic absorption spectrometry is the loss of part of the germanium as volatile GeO, which affects the reproducibility [6]. Addition of certain amino acids, however, has been shown to improve the performance of the d.c. plasma technique [4,7]. The spectrophotometric method using phenylfluorone, although useful for determining concentrations of germanium as low as 0.01 μg ml^{-1} [8], lacks selectivity and hence necessitates prior separation of germanium either by distillation or extraction [9].

Spectrofluorimetric methods based on the reaction of germanium with resacetophenone [10],

benzoin [11], quercetin [12], 3,7-dihydroxy flavone [13] and resarzon [14] have been reported. The reaction with 3,7-dihydroxy flavone is perhaps the most sensitive (detection limit 0.002 μg ml^{-1}) but, like other reactions, it is unselective and necessitates separation as a tetrachloride by extraction prior to determination. The quenching effect of Ge(IV) on the fluorescence intensity of *o*-chlorophenylfluorone has also been evaluated for its determination [15]. This method is slow and subject to a wide range of interferences.

The ability of germanium to react with hydroxy compounds to form anionic complexes is well known [16]. The reaction of germanium with chromotropic acid [17] appeared to offer analytical advantages as the resulting anionic complex was selectively extracted as an ion pair with rhodamine B into toluene. This finding, coupled with the fact that the addition of oxygen-containing solvents such as butanol resulted in complete dissociation of the ion association complex to release the fluorescent dye, suggested that the reaction could form the basis for the fluorimetric determination of germanium. This paper summarises the results of the evaluation of such a possibility. It was found that as little as 50 ng of germanium can be determined in the presence of many extraneous ions and the method can be applied directly to determination of germanium in minerals, rocks, and other geological materials.

2. Experimental

2.1. Apparatus

An Aminco Bowman spectrofluorimeter provided with a 250 VA xenon arc lamp was used for all fluorescence measurements. Slit widths of 5 mm for the excitation monochromator and 0.5 mm for the emission monochromator were employed for fluorescence measurements using a 1 cm quartz cell with polished sides and bottom. A standard 10 μg ml^{-1} quinine sulphate solution in 0.1 N H_2SO_4 was used to standardise the source intensity daily.

2.2. Reagents

2.2.1. Standard germanium(IV) solution (100 μg ml^{-1})

Dissolve 0.1441 g of germanium dioxide by heating gently with 20 ml of 2% NaOH. Transfer the solution to a 1 l standard flask and dilute to volume with distilled water. A suitable volume of this solution is diluted to obtain working standrds.

2.2.2. Glycine buffer (pH 2.5)

Dissolve 5 g of glycine and 3.896 g of NaCl in 666 ml of distilled water. Transfer the solution to a 1 l standard flask and dilute to volume with 0.1 N HCl.

Chromotropic acid (0.01%; aqueous solution), Rhodamine B (0.02%; aqueous solution), toluene and *n*-butanol (both analytical grade) were used.

2.3. Procedure

Transfer the sample solution (< 15 ml) containing up to 2 μg of Ge(IV) into a 60 ml separatory funnel. Add 1 ml each of 0.01% chromotropic acid, 0.02% rhodamine B and 3 ml glycine buffer. After a reaction time of 5 min, equilibrate the aqueous phase with 5 ml of toluene for 1 min. Allow the phases to separate and discard the aqueous phase. Wash the organic phase twice with 5 ml of glycine buffer and discard the washings. Mix 2.5 ml of the organic extract with 2.5 ml of butanol and measure the fluorescence intensity at 570 nm after exciting at 540 nm. Subtract the blank reading and establish the concentration of germanium by reference to a calibration graph prepared by applying the procedure to 0.05–2.00 μg of Ge(IV) in aqueous solution.

3. Spectral characteristics and reaction conditions

The excitation and emission spectra of the reagent blank and the ion associate in the presence of various concentrations of germanium are shown in Fig. 1. It is evident that the emission is a maximum at 570 nm and that there are three excitation maxima at 540 nm, 310 nm and 360 nm
Fig. 1. Excitation (A) and emission (B-E) spectra. (A) 1.0 μg of Ge(IV), 1 ml, 0.01% chromotropic acid, pH 2.5, 1 ml, 0.02% Rhodamine B treated as in Section 2.3. (B) 0, (C) 0.5, (D) 0.75 and (E) 1.0 μg of Ge(IV), 1 ml, 0.01% chromotropic acid, 1 ml, 0.02% Rhodamine B, pH 2.5, treated as in Section 2.3.

(in order of decreasing prominence). As the fluorescence intensity was a maximum with excitation at 540 nm, it was decided to use this wavelength for excitation purposes.

Systematic study revealed that the fluorescence intensity is unaffected in the pH range 2.0–3.0. The influence of chromotropic acid and rhodamine B concentration is shown in Figs. 2 and 3 respectively. On the basis of these studies, 1 ml each of a 0.01% solution of chromotropic acid and a 0.02% solution of rhodamine B were chosen as optimal.

Fig. 2. Effect of chromotropic acid concentration: 1.0 μg of Ge(IV), 1.0 ml 0.02% Rhodamine B, 0.25-2.5 ml 0.02% chromotropic acid pH 2.5, treated as in Section 2.3.

Fig. 3. Effect of Rhodamine B concentration: 1.0 μg of Ge(IV), 1 ml of 0.01% chromotropic acid, 0.25–2.5 ml of 0.02% Rhodamine B, treated as in Section 2.3.

The fluorescence intensity reached a maximum only when the ion pair was extracted after a reaction time of at least 5 min. Under the reaction conditions, a significant amount of the dye was found to coextract into toluene, which resulted in a high blank. However, washing the organic extract twice with the glycine buffer was found to be effective for stripping the free dye selectively from the toluene layer.

Of the solvents examined—benzene, toluene, cyclohexane, hexane, carbon tetrachloride and chloroform—extraction of the ion pair was quantitative only into benzene and toluene. 1 min equilibration was sufficient for complete extraction, which remained unaffected up to an aqueous volume of 20 ml. The addition of acetone, methanol, isobutyl methyl ketone and methyl ethyl ketone to the toluene layer was found to be as effective as the addition of butanol to break the ion pair and release the fluorescent dye. The fluorescence intensity of the liberated rhodamine B was stable for 4 h and varied linearly with germanium concentration in the range 0.05–2.00 μg in 20 ml of the aqueous phase.

The precision of the proposed method was checked by establishing the concentration of ten samples containing 1.0 μg Ge(IV). The mean recovery was found to be 97.1% with a relative standard deviation of 2.9%.

Both mole ratio and continuous variation methods indicated that the molar ratios of ger-

manium to chromotropic acid and germanium to rhodamine B were 1:1 and 1:2 respectively. This suggested that in the presence of excess chromotropic acid (CA) germanium forms $[GeO(CA)]^{2-}$, which then associates with two molecules of rhodamine B to extract as an ion pair into toluene.

3.1. Effect of diverse ions

A systematic study of the influence of 1 mg amounts of several ions in the determination of 1.0 μg germanium was carried out. Table 1 lists the effects of various ions on the analytical reaction.

The interference of Fe^{3+} was overcome by the addition of 1 ml of a 1% solution of ascorbic acid prior to the determination. Molybdate and borate, when present in excess of tolerance amounts, were overcome by the addition of 1 ml of 0.1% solution of fluoride.

4. Applications

The determination of the germanium content of a variety of geological and ore samples was carried out using the proposed method and the results are listed in Table 2.

Samples were brought into solution following the procedure described elsewhere [18]. Appropriate amounts of the samples (1.0–2.0 g) were initially heated for 10 min with 10 ml each of 16 N H_2SO_4 and concentrated HNO_3 in a platinum crucible. The contents were allowed to cool treated with 10 ml of HF and then heated to SO_3 fumes. The residue, after cooling, was treated with 10 ml of distilled water, heated to dissolve the soluble salts and made up to a known volume. The determination was completed by treating suitable aliquots with 1 ml each of a 0.1% solution of sodium fluoride and a 1.0% solution of ascorbic acid. The results, and those obtained by spectrophotometry using the phenylfluorone method after extractive separation of germanium as $GeCl_4$ [9], are given in Table 2. The data clearly show that the method is reliable for the determination of germanium in these samples.

5. Conclusion

The method described provides a simple, rapid and reliable means of determining trace amounts of germanium by spectrofluorimetry. Unlike most methods, including the one based on the reaction with morin [19] which required prior separation of germanium by extraction, the method evolved is virtually free from interferences as the deleterious effect of a few ions could be conveniently overcome by the addition of appropriate reagent solutions prior to determination. The application of the method to a variety of geological and mineral samples clearly demonstrates its usefulness for the determination of germanium at trace levels in complex matrices.

Monitoring of molecular transformations in acid–base reactions by evolving factor analysis of Fourier transform infrared spectral data

Joaquim C.G. Esteves da Silva, Adélio A.S.C. Machado*, César J.S. Oliveira

LAQUIPAI, Chemistry Department, Faculdade de Ciências, P4050 Porto, Portugal

Received 26 September 1995; revised 5 February 1996; accepted 13 February 1996

Abstract

An evolving factor analysis procedure with concentration constraints (gradient concentration window) was applied to the analysis of data sets of aqueous Fourier transform infrared (FT-IR) spectra of carboxylic acids (acetic, malonic and succinic acids) collected in experiments with varying pH. Besides the calculation of the number of acid–base systems, this procedure allowed the calculation of the FT-IR spectra of the acid–base species present in equilibrium as well as the corresponding pK_a values.

Keywords: Acid–base properties; Aqueous FT-IR; Carboxylic acids; Evolving factor analysis

1. Introduction

The qualitative or quantitative analysis of species in aqueous solutions by Fourier transform infrared spectroscopy (FT-IR) with a suitable accessory, either a transmittance or an ATR-based cell, has received increased interest in recent years [1–14]. One of the most important aspects of FT-IR is that it allows the determination of the molecular status of the substances under examination [15–19]. Structural transformations can be easily investigated because a lot of information exists concerning infrared band assignment [19]. In contrast, quantitative aqueous FT-IR analysis

has been less frequently applied, probably because it usually implies complex situations involving one or more spectral sets, with each spectrum constituted of a large number of bands, some of which are often overlapping. Moreover, only in rare instances have chemometric techniques such as multivariate calibration and self-modeling curve resolution been applied to quantitative aqueous FT-IR analysis [4,20].

A previous study [13] showed the potential of FT-IR for the analysis of the molecular transformations that occur in acid–base aqueous reactions, when coupled to chemometric methods of principal component analysis (PCA) to treat sets of spectra obtained at variable pH. However, the spectral information was not fully explored and

only the number of components was calculated by PCA. Indeed, the IR spectra of the detected components contain the most useful information about the structural transformation induced by the experimental factor variation, in this case the pH, and thus deserve further exploration.

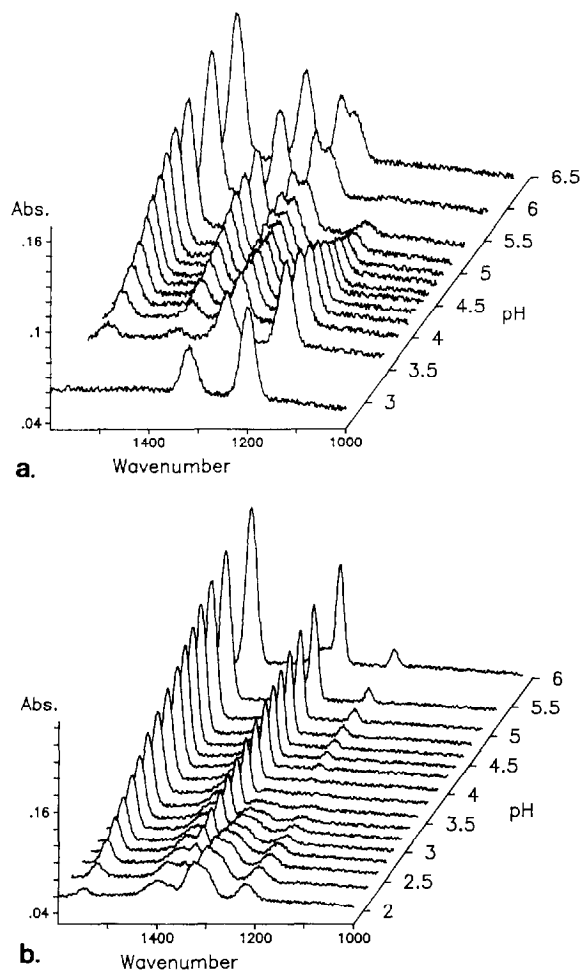
A procedure for the transformation of the abstract information obtained from the PCA of synchronous fluorescence (SyF) spectral data collected as a function of the pH was developed recently [21]. It is based on evolving factor analysis (EFA) with concentration constraints (EFA with a gradient concentration window, GCW) and allows the characterization (spectral data and acid–base properties) of the acid–base systems in the data set under analysis. Contrary to IR spectroscopy, little information exists about band assignment in SyF spectroscopy, due to both the restricted application of this technique and the more complex correlation of fluorescence spectra characteristics with molecular parameters. This limitation reduces the utility of the calculated SyF spectra in absolute terms, al-


Fig. 1. Simulated FT-IR spectra as function of pH: (a) Sim1; (b) Sim2.

though they proved to be very adequate for comparative studies [21–24].

This paper reports further studies of the spectroscopic analysis of systems in chemical equilibrium, more precisely the application of EFA with a GCW to sets of FT-IR spectra of aqueous solutions of carboxylic acids, collected at varying pH. The objectives of the present study were: (i) to evaluate the application of relatively simple chemometric data analysis (PCA and EFA) to quantitative FT-IR; (ii) to study the application of EFA with a GCW for the analysis of aqueous FT-IR data, particularly for the calculation of the spectral data of the components of mixtures; and (iii) to develop in

Sim1, monoprotic acid; Sim2, diprotic acid. Different spectral characteristics were considered in the design of these sets: in Sim1, a monoprotic acid model, different sets of bands correspond to the acid and conjugated species; in Sim2, a diprotic acid model, besides different bands, the species AH^- and A^{2-} show two superimposed bands, at 1.55 and 1.37, although with different intensities. Moreover, both sets are constituted of some bands that do not vary with pH ("constant" in Table 1). These characteristics have been observed in experimental data sets, as discussed below.

2.2. Reagents

Analytical-grade reagents were used for the preparation of 0.2 M solutions of the acids in 1.0 M sodium chloride.

2.3. Experimental titrations

Potentiometric titrations with pH measurement were conducted with a PC-controlled system assembled from a Crison MicropH 2002 pHmeter, a Crison MicroBU 2030 microburette, an Ingold U262-S7/120 pH electrode and an Ingold 373-90-WTE-ISE-S7/105-120 reference electrode. The experiments were made under
Fig. 3 (A)

Fig. 3 (B)

Fig. 3. EFA solution for the simulated data sets: (A) FT-IR spectra of the varying components (positive and negative bands correspond respectively, to the conjugated base and acid species); (B) acid–base distribution diagrams (triangles and squares represent the first and second acid–base systems respectively; filled and open symbols represent the conjugated base and acid species respectively).

nitrogen at $25.0 \pm 0.2°C$. The cell was calibrated by titrating 25.00 ml of 1.0 M sodium chloride with a standard solution of 0.1 M nitric acid (Titrisol Merck).

FT-IR spectra were recorded on a Nicolet Model 550 Magna operating in the mid-infrared range with a DTGS detector. The spectra were recorded in the 3000–800 cm^{-1} range with a 4 cm^{-1} resolution. 200 scans were accumulated.

A Spectra-Tech micro-flow circle cell with a ZnSe crystal was used as sampling accessory, with a Gilson Minipuls 2 peristaltic pump to force the displacement of the sample to the flow cell.

All the spectra were obtained using a solution of 1.0 M sodium chloride as background. Spectral data were stored on disk and converted to ASCII format with LABCALC software (Galactic

Industries Co., USA). In the data analysis, reduced spectra in the range 1600–1000 cm^{-1}, constituted of 312 points, were used.

2.4. Programs and data treatment

Titrations were simulated with a generic program for the simulation of potentiometric titrations in which the Newton–Raphson method is used for solving mass balance equations. At each pH value, the FT-IR spectrum was obtained by addition of the contributions of the acid and conjugated base species present. Simulated spectra were constituted of 312 points in the 1600–1000 cm^{-1} range.

For PCA and EFA, the covariance about the origin and the corresponding error functions [13,21,25] were used: RE, real error; IE, imbedded error; XE, extracted error; and Ind, factor indicator.

All software developed in this laboratory was written and compiled with Turbo Pascal 5.0 (Borland International, USA). An IBM AT-compatible computer with math coprocessor was used for calculations.

3. Theory

The calculation procedure for the EFA with a GCW has already been described previously [21] and only a brief summary will be given here.

3.1. PCA and EFA plots

The number of components (nc) is calculated by PCA [13,21,25] or its graphical representation as EFA plots (logarithm of the eigenvalues as a function of the number of spectra included in the calculations) [13,21,25,26] or from the analysis of the abstract spectra sets resulting from PCA. The first component corresponds to a constant spectrum and each of the others corresponds to an acid–base system. The number of components is equal to one, corresponding to a constant section of the spectral data (the constant component), plus the number of components that show no linear relation (the varying components).

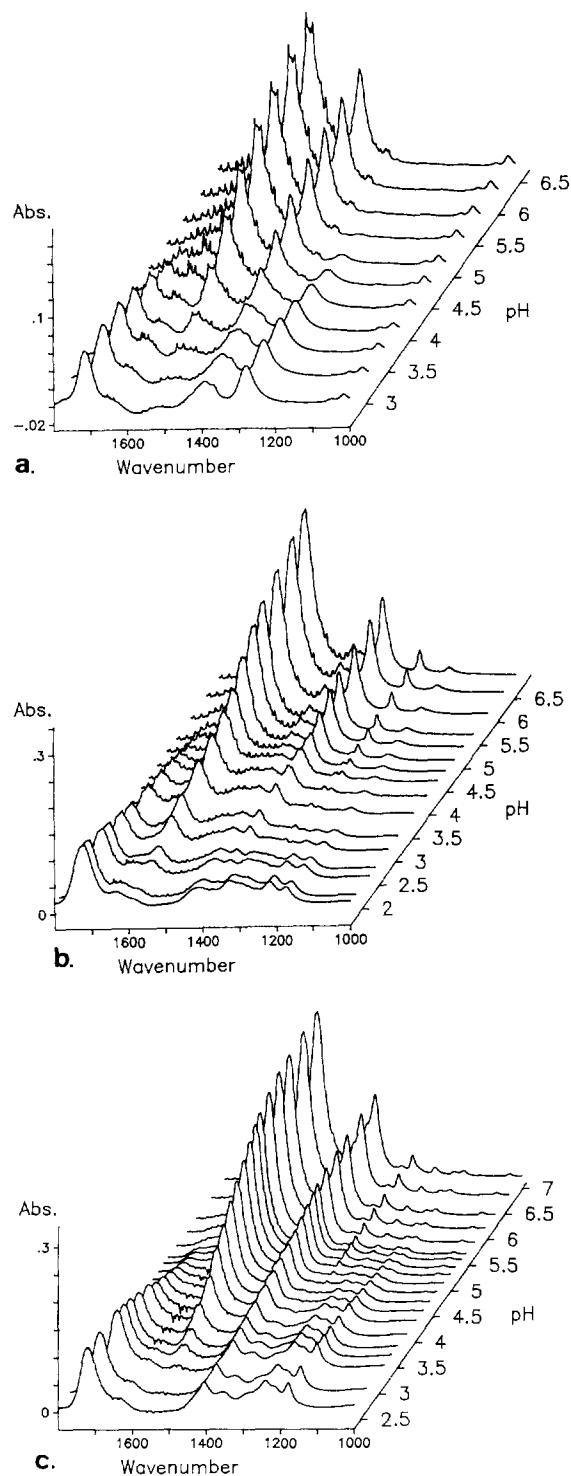

Fig. 4. Experimental FT-IR spectra as function of pH: (a) acetic acid; (b) malonic acid; (c) succinic acid.

The GCWs for the second to the nc components are determined from the analysis of the forward and backward EFA plots. Two discriminating matrices Ds and Dz (ns × nc, where ns is the number of spectra and nc is the number of components in the data matrix) with the GCW information are defined by a two-model design: model "S", the coefficients before the GCW are zero and those after the GCW are one; model "Z", the coefficients before the GCW are one and those after the GCW are zero; in both matrices, the elements of the first column are equal to one (this column corresponds to the constant component) and the value of the coefficient in the GCW is 0.5. The "S" model follows the increase in concentration of the conjugated base as the pH is raised and the "Z" model the corresponding decrease in concentration of the acid.

3.2. Evolving factor analysis (Secondary EFA)

The discriminating matrices Ds and Dz, defined above, are used as a first guess for the concentration matrix C (ns × nc). The calculation of the spectra of the components, or matrix S (nc × np), and their concentrations, consists of the following iterative procedure [21,26,27].

$$S = (C^T C)^{-1} C^T F \tag{1}$$

$$C = F S^T (S S^T)^{-1} \tag{2}$$

where F (ns × np) is the data matrix. The matrix C recalculated by this procedure is subjected to the following constraints:

$$\text{if} \quad D_{i,j} = 0 \text{ then } C_{i,j} = 0 \tag{3a}$$

$$D_{i,j} = 1 \text{ then } C_{i,j} = 1 \tag{3b}$$

$$C_{i,j} > 1 \text{ then } C_{i,j} = 1 \tag{3c}$$

$$C_{i,j} < 0 \text{ then } C_{i,j} = 0 \tag{3d}$$

with $i = 1...$nc and $j = 1...$ns. With the new C matrix, the procedure is repeated until convergence is achieved.

The quality of the iterative process is followed by the analysis of the sum of the squares of the residuals function (SSR):

$$\text{SSR} = \sum_{i=1,\text{ns}} \sum_{j=1,\text{np}} (F_{i,j} - F'_{i,j})^2 \tag{4}$$

where $F_{i,j}$ and $F'_{i,j}$ are the experimental and estimated data respectively.

Table 4

[a] See footnotes in Table 2.

The two sets of spectra, as well as the concentration profiles calculated with models "S" and "Z", are analyzed as discussed in Ref. [21].

4. Results and discussion

4.1. Simulated data sets

Figs. 1(a) and 1(b) show the two simulated FT-IR spectra sets. Different variations and the

appearance and disappearance of bands are observed. The following procedure shows how the intrinsic underlying model of each data set can be calculated.

4.1.1. PCA, EFA plots and abstract spectra

The first objective in the spectral data analysis is the calculation of the number of components. In this study three methods were used: eigenvalues analysis, abstract spectra and EFA plots. Table 2 shows the results of the eigenvalues

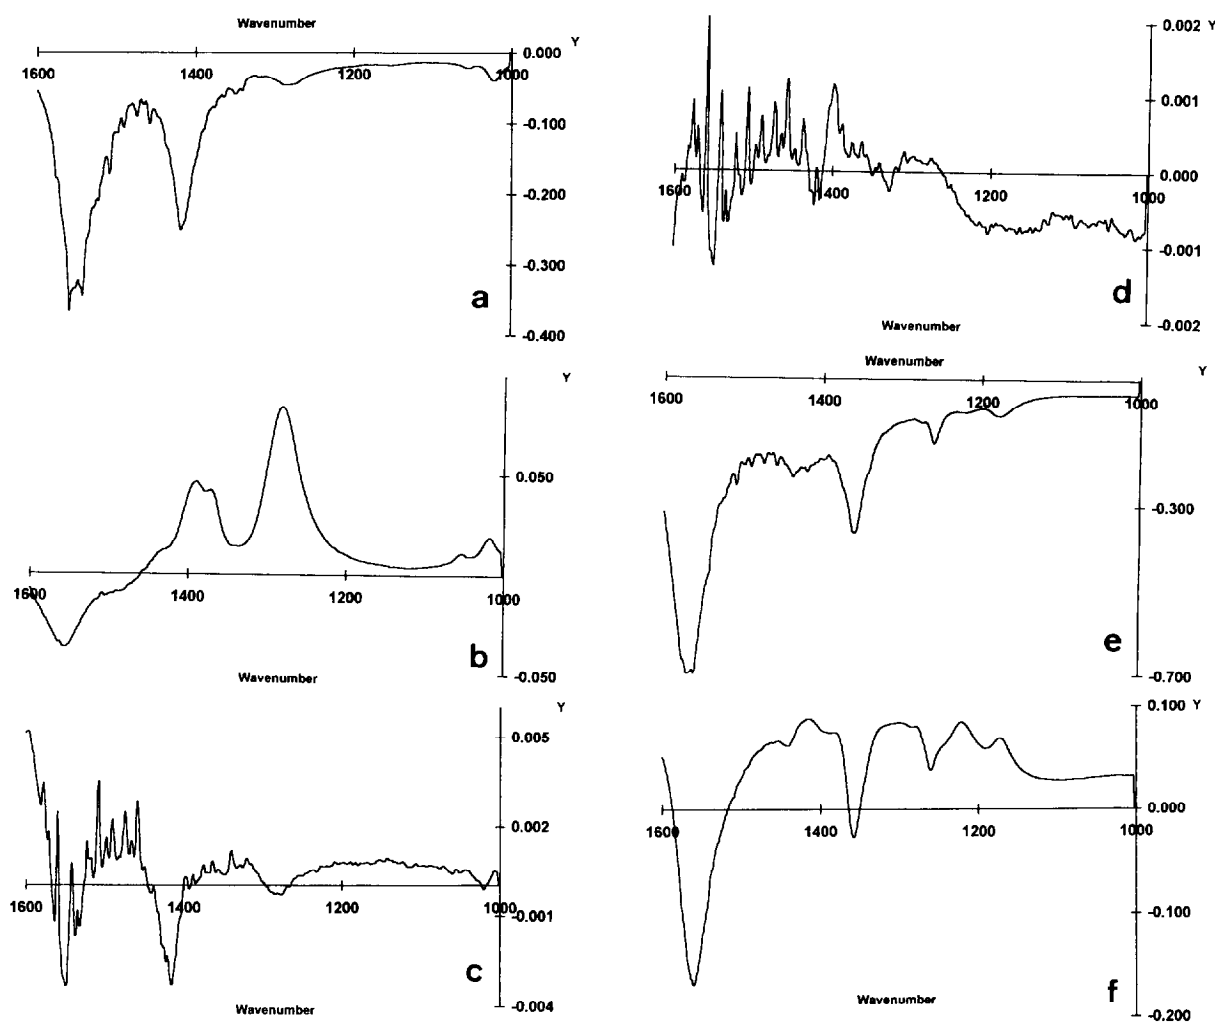

Fig. 5. Calculated FT-IR abstract spectra for (a–d) acetic acid and (e–i) malonic acid.
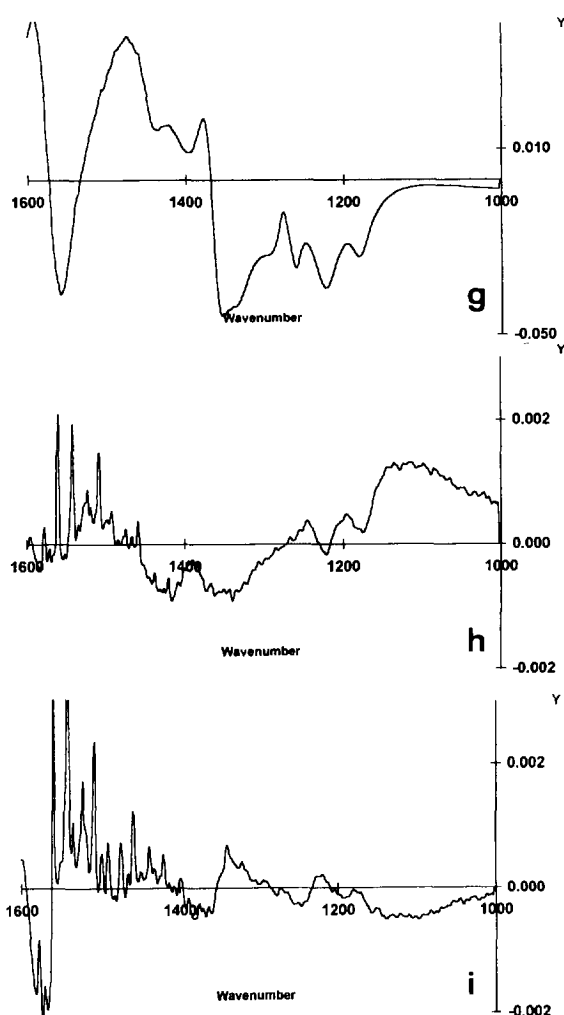

Fig. 5. (continued)

analysis and Fig. 2 shows the abstract spectra for the two simulated data sets. The shapes of the EFA plots are similar to those reported in Ref. [13].

From the values in Table 2, two and three components are found for the Sim1 and Sim2 data sets respectively, from the minima of the IE and Ind error functions and the stabilization of the RE and XE error functions. The EFA plots and the analysis of the abstract spectra of Fig. 2 gave the same information. Only the first two abstract spectra of Sim1 (Figs. 2(a) and 2(b)) and the first three abstract spectra of Sim2

(Figs. 2(d)–2(f)) contain signals. The next abstract spectra of both Sim1 (Fig. 2(c)) and Sim2 (Fig. 2(g)) contain only noise. The analysis of these noise spectra reveals that the random noise level is similar over the whole wavenumber range, as expected from the design of the simulations.

The number of components found for the two simulated data sets agrees with those expected [13]. Indeed, the number of components is equal to the number of acid–base systems plus one, corresponding to a constant background spectrum.

4.1.2. Secondary EFA

The information contained in the EFA plots was used to build the discrimination matrices [21] and the secondary EFA was performed. The iterative procedure converged quite rapidly (less than 20 iterations were required), as shown in Table 3.

The calculated spectra (using model "S") and concentration profiles for the varying components of the simulated data sets are shown in Fig. 3. The calculated spectrum for the constant component is not included because it contains no useful information about the bands that show variations upon change of pH.

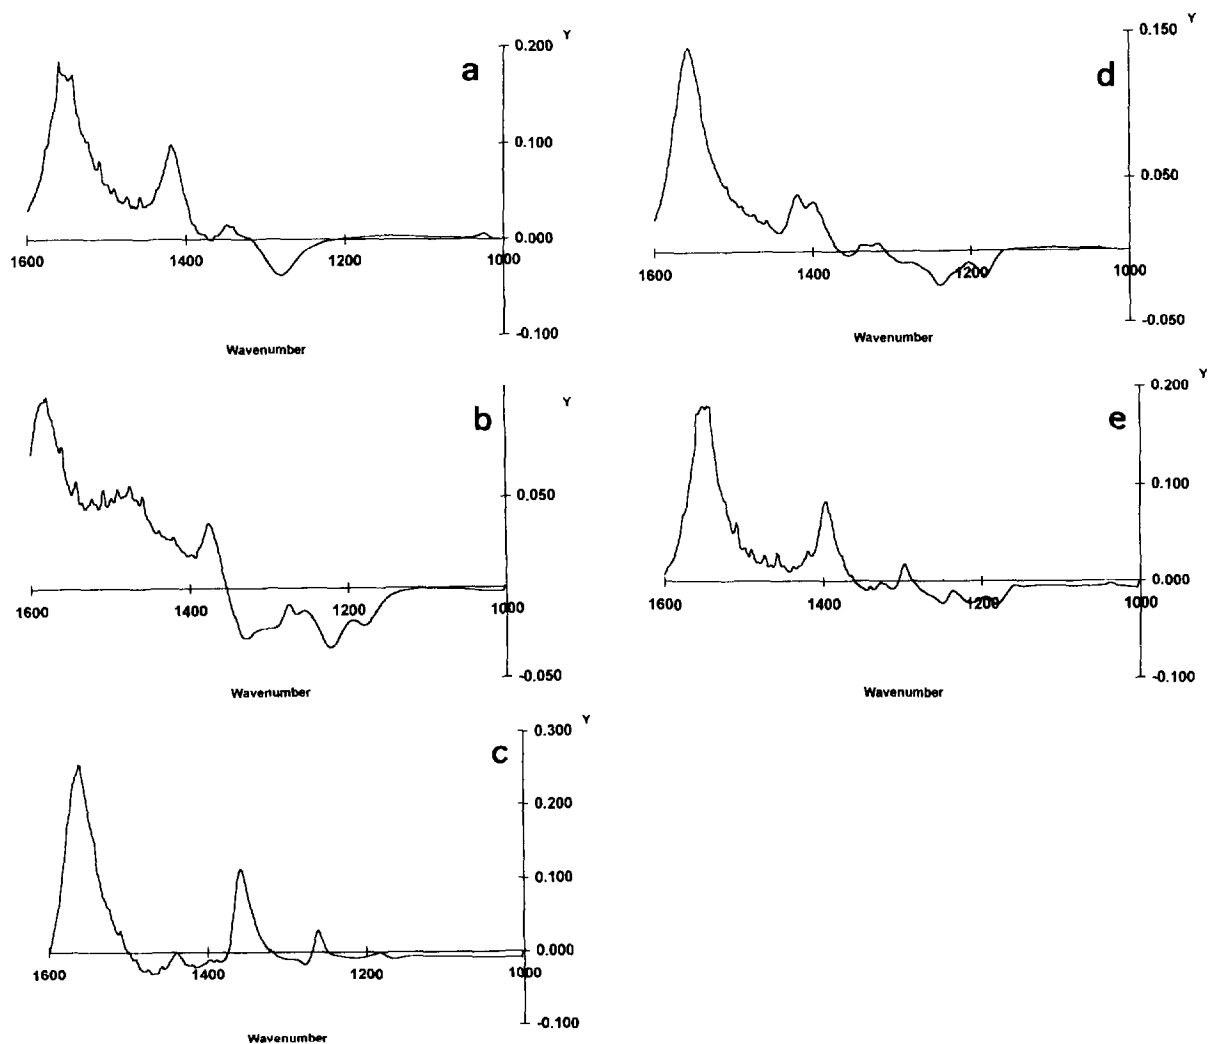
The calculation spectrum for the Sim1 simulation (Fig. 3(A)a) is composed of three positive bands and one negative band. The positive bands correspond to the conjugated base (its concentration increases with pH) and the negative band to the acid. This result, as well as the positions and intensities of the bands, show perfect agreement with the data used to generate Sim1 (Table 1). The analysis of the calculated first spectrum of Sim2 (Fig. 3(A)b) allows the identification of both positive and negative bands, explained as for the corresponding spectrum of Sim1 (Fig. 3(A)a). In contrast, the calculated second spectrum of Sim2 (Fig. 3(A)c) shows only positive bands, namely those corresponding to the A^{2-} species, while the two bands of the AH^- species, which should be negative (similar to the positive bands of the first spectrum, Fig. 3(A)b), are not present. This is due to superposition of bands of AH^- and


Fig. 6. Calculated FT-IR spectra of the varying components: (a) acetic acid; (b), (c) malonic acid; (d), (e) succinic acid. Positive and negative bands correspond to the conjugated base and acid species respectively.

A^2. Indeed, only the overall variation resulting from the two opposite variations (increase in the A^{2-} and decrease in the AH^- concentration) is recorded in the calculated spectrum.

The analysis of the spectra shown in Fig. 3(A), which correspond to the varying components, also reveals that the non-varying bands are not accounted for. This is expected, because these bands fall in the constant spectrum that corresponds to the first (constant) component. Indeed, the absence of contributions of non-varying bands is an important property of the

EFA, because it allows an easier identification of the spectral variations.

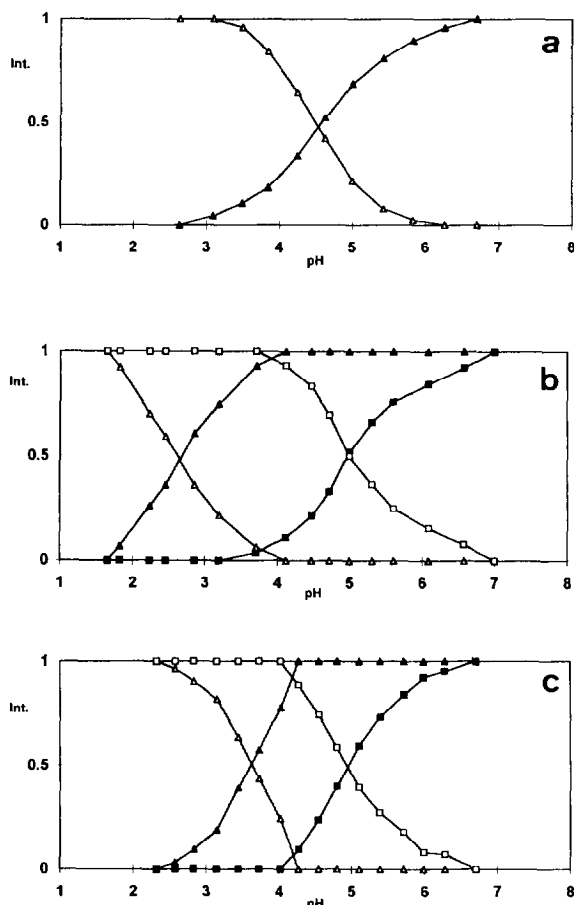
The analysis of the calculated concentration profiles, which correspond to the acid–base distribution diagrams, allows the calculation of the pK_a s values at the crossover points of the two curves corresponding to each acid–base system (at 50% ionization). Fig. 3(B)a,b shows that the calculated pK_a s values reproduce exactly those used to generate the simulated data, namely $pK_a = 4.5$ for Sim1 and $pK_{a1} = 2.8$ and $pK_{a2} = 4.5$ for Sim2.


Fig. 7. Calculated acid–base distribution diagrams: (a) acetic acid; (b) malonic acid; (c) succinic acid. Triangles and squares represent the first and second acid–base systems respectively; filled and open symbols represent the conjugated base and acid species respectively.

In conclusion, the solution of the EFA with a GCW described rigorously the spectral variations of the two simulated data sets. The position and shape of the varying bands, as well as the type of variation with the changing factor, pH in the present case, were properly recovered. The concentration profiles of the species were also rigorously determined, which allowed the calculation of the pK_as values of the intrinsic acid–base systems.

4.2. Experimental data sets

Fig. 4 shows the FT-IR spectra of acetic, malonic and succinic acids as a function of pH in the 1800–1000 cm^{-1} range. Besides the existence of several bands displaying different variations with pH, a particularly high noise level is detectable around 1640 cm^{-1}. This is the position of the maximum of the FT-IR water spectrum and, because this noise causes variations in the data which are difficult to model, the 1800–1600 cm^{-1} wavenumber region was removed from all the spectra before data analysis.

4.2.1. PCA, EFA plots and abstract spectra

Table 4 shows typical results obtained from the eigenvalue analysis of the experimental data sets. The determination of the number of components is not as straightforward as that for the simulated data sets, particularly because the IE and Ind error functions show no minima. Nevertheless, from the analysis of the RE and XE error functions and from the variations of eigenvalue magnitude, the number of components is found to be two for acetic acid and three for the other two acids. Indeed, at these numbers of components, the RE and IE error functions stabilize their magnitudes and the eigenvalue that corresponds to the next component is much smaller than the previous one. These results are compatible with the EFA plots, as discussed previously [13], and with those found for the simulated data sets: the number of components in these data sets is also equal to the number of acid–base systems plus one.

The analysis of the abstract spectra, shown in Fig. 5 for acetic and malonic acids as examples, supports these conclusions about the number of components. Indeed, for the acetic acid only the first two abstract spectra (Figs. 5(a) and 5(b)) clearly contain signals, while the third and fourth (Figs. 5(c) and 5(d)) correspond to noise. For malonic acid, the first three abstract spectra (Figs. 5(e)–5(g)) contain information, but the following (Figs. 5(h) and 5(i)) correspond to noise. However, the type of noise present in the experimental sets is markedly different from that

Table 5
Characteristics of the calculated FT-IR spectra of the acid–base species calculated with model "S"[a]

Acid	N	Sp	Positive bands			Sp	Negative bands				
			1	2	3		1	2	3	4	5
Acetic	1	A⁻	1553	1419		AH	1280				
Malonic	1	AH⁻	1581	1480	1374	AH₂	1330	1299	1264	1220	1177
	2	A²⁻	1561	1357	1259	AH⁻	1470				
Succinic	1	AH⁻	1560	1420	1410	AH₂	1239	1180			
	2	A²⁻	1552	1397	1297	AH⁻	1248	1212	1179		

[a] Position of the bands in cm^{-1}; number of the acid-base systems; Sp, acid-base species.

in the simulated sets. Indeed, Figs. 5(c), 5(d), 5(h) and 5(i) reveal a higher level of noise in the 1600–1300 cm^{-1} range than for lower wavenumbers. This is due to the effect of the water band in these spectra.

4.2.2. Secondary EFA

The iterative procedure for the experimental data sets shows a pattern similar to that observed for the simulated data sets (see SRR function evolution as a function of the number of iterations in Table 3). The results of the secondary EFA, namely the spectra (calculated with model "S") and concentration profiles of the components, are shown in Figs. 6 and 7

Table 6
Comparison of the calculated pK_a s values with literature values[a]

Acid	Number of systems	pK_a	
		This work[b]	Literature
Acetic	1	4.5	4.55
Malonic	2	2.7	2.74
		5.0	5.11
Succinic	2	3.8	3.95
		5.0	5.05

[a] Literature values of 25°C and $I = 1.0$ M with the exception of acetic acid (20°C) and succiric acid ($I = 0.5$ M) [28,29]
[b] Precision of graphical estimate: ±0.1.

respectively. The main characteristics of the calculated FT-IR spectra are shown in Table 5.

The calculated spectra of the varying components show the following characteristics: (i) the existence of clear positive and negative bands (the positive are stronger than the negative) in the spectrum of the first varying component (which corresponds to the first acid–base system); and (ii) for malonic and succinic acids, the spectrum of the second varying component (second acid–base system) shows no clear negative bands. The existence of positive and negative bands is due to opposite concentration variations when the pH is increased, and consequent opposite variations for the bands corresponding to acid and conjugated base. The existence of closely spaced bands in narrow acid–base reaction, in the present case to the carboxylic and carboxylate groups. Constant bands, i.e. those corresponding to structures not involved in the reaction that is being monitored, are accounted for in the calculated constant component.

The calculated spectra of the AH (acetic acid) and AH₂ (malonic and succinic acids) acid species are composed of a main band in the range 1220–1280 cm^{-1}. This is due to the C–O stretching of the carboxylic structures, because its intensity decreases with the increase in pH for the three acids. Other neighboring bands, which are only clearly detected for malonic acid, are probably due to the C–O or C–C stretching vibrations.

The calculated spectra of the A⁻ (acetic acid) and A²⁻ (malonic and succinic acids) species

are composed of the following bands: a band in the range 1552–1561 cm^{-1} due to asymmetric COO$^-$ stretching; a band in the range 1357–1419 cm^{-1} due to symmetric COO$^-$ stretching; and, for the case of the diprotic acids, a third band in the range 1259–1297 cm^{-1}, which is probably due to $-CH_2-$ deformation. The comparison of these calculated infrared frequencies for the carboxylate stretchings with literature values, also obtained in aqueous solution [19], shows good agreement.

For the AH$^-$ species of malonic and succinic acids the analysis of the calculated spectra is complex and, as far as the authors know, there is no literature information available to allow a comparison.

The calculated concentration profiles shown in Fig. 7 are similar to those for the simulated data sets and allow the calculation of the pK_as values of the corresponding acid–base systems. These are presented in Table 6 together with literature values. An overall good agreement between calculated and literature values was found.

5. Conclusions

The results of the present study show that the application of EFA with a GCW to aqueous FT-IR spectroscopy can be a very useful technique because it provides data for elucidation of molecular transformations during chemical reactions and for calculation of equilibrium constants. Considering the vast amount of information contained in the literature about the assignment of IR bands and their correlation with molecular structure, the procedure is expected to be far-reaching for resolution of this type of problem.

The technique has the potential to be incorporated in software already available for instrument control. However, the analysis with EFA of FT-IR spectral sets collected during a chemical transformation requires specific constrictions (in the concentrations and/or spectra) adequate to the transformation that is being experimentally provoked.

Simultaneous determination of quinoline yellow and brilliant blue FCF in cosmetics by solid-phase spectrophotometry

L.F. Capitán-Vallvey, N. Navas Iglesias, I. de Orbe Payá, R. Avidad Castañeda*

Department of Analytical Chemistry, University of Granada, E-18071 Granada, Spain

Abstract

A method for the simultaneous determination of quinoline yellow (QY) and brilliant blue FCF (BB) in mixtures by solid-phase spectrophotometry has been developed. Both colorants were isolated in Sephadex DEAE A-25 gel showing maximum absorbances at 632 nm and 415 nm for BB and QY respectively. The applicable concentration ranges were between 25.0 and 500.0 μg l^{-1} for BB and between 50.0 and 750.0 μg l^{-1} for QY. The detection limits were 6.1 and 13.4 μg l^{-1} for BB and QY respectively. Application of the method to real samples (colognes, after shave lotions and shampoo gels) involves a previous extraction process of the colorants before their isolation on the gel.

Keywords: Cosmetics analysis; Quinoline yellow–brilliant blue FCF determination; Solid-phase spectrophotometry

1. Introduction

Quinoline yellow (CI 47005) and brilliant blue FCF (CI 42090) are two synthetic colorants widely used as additives in cosmetic products. In Spain, the use of quinoline yellow (QY) has been authorized provisionally without stating the maximum limit of concentration, while brilliant blue FCF (BB) can only be used up to 1% (w/w) in lipstick and up to 25 μg ml^{-1} in other cosmetics [1,2]. As the synthetic colorants can produce discomfort in susceptible individuals [3], quantitative analysis of these chemicals would be appreciated.

Traditionally, spectrophotometric methods have been used for these purpose if the sample only contains one colorant. When the sample contains two or more colorants (usually two or three), a previous separation step is needed. The separation can be carried out by thin layer chromatography (TLC) [4].

Electroanalytical techniques have been also proposed for the detection and determination of these compounds [5,6] and more recently derivative spectrophotometry and ratio spectra derivative [7] have also been suggested. However, the analysis of synthetic colorants in cosmetics is not very easy because the complex composition of most of the cosmetic products is often not pro-

* Corresponding author.

vided by the majority of manufacturers since they do not feel obliged to reveal what they consider as trade secrets.

We propose in this paper a sensitive method for the simultaneous determination of QY and BB either single or as a mixture in cosmetics by conventional and/or first-derivative spectrophotometry. In the case of real samples of shampoo gel a previous separation step of the colorants using methylene chloride is needed. Thus, the method is simple, sensitive, inexpensive and does not show the possible interferences caused by other additives usually present in cosmetics because of the previous extraction.

2. Experimental

2.1. Apparatus and software

A Perkin-Elmer Lambda-2 spectrophotometer (with 1 mm cell) connected to an IE 486 computer fitted with PECSS software and a Hewlett-Packard Laser III printer were used for all measurements. Statgraphics software package [8] was used for the statistical analysis of the calibration graphs. Smoothed and derivative spectra were calculated by the Savitzky and Golay method [9,10].

Further, we used a Crison 501 digital pH meter with a combined glass–saturated calomel electrode and an Agitaser 2000 rotating bottles agitator.

2.2. Reagents

All reagents were of analytical reagent grade. Reverse osmosis quality water was used throughout.

Quinoline yellow stock solution (10.0 mg l^{-1}) (Aldrich Chemical Company Inc.) was prepared by exact weighing of the standard product and dissolution in water. This solution remains stable for at least one month. Solutions of lower concentration were obtained by dilution with water.

Brilliant blue FCF stock solution (10.0 mg l^{-1}) (Aldrich Chemical Company Inc.) was prepared in water by exact weighing of the standard, and

working solutions were obtained by dilution with water. The stock solution was stable for at least one month.

Buffer solutions of pH 4.0 were prepared from 0.1 M sodium acetate solution (Merck) and 0.1 M acetic acid (Merck).

Sephadex DEAE A-25 anion exchanger (Pharmacia Fine Chemicals) in the chloride form and without pretreatment was used as solid support.

2.3. Absorbance measurements

The absorbance spectra of the colorant–gel systems packed in a 1 mm cell were recorded against the blank between 400 and 800 nm at 20.0 ± 0.5°C and stored in a disk file. These spectra were smoothed with 13 experimental points and the first-derivative of the QY spectrum was calculated and recorded using 4 nm intervals. If the sample contained only one of the colorants the absorbance measurements of the gel beads containing the colorant were carried out (in a 1 mm cell) at 415 nm and 800 nm in the absorption spectrum for QY and at 632 nm and 800 nm for BB. The latter measurement (800 nm) is the range where only the gel absorb radiation. The net absorbance for the colorant–gel systems was obtained from $A_n = A_\lambda - A_{800}$ where A_λ is the absorbance at 415 nm or at 632 nm [11]. If the sample contained QY and BB, the first-derivative spectrum was used to determine QY and the zero-order spectrum was used for the determination of BB and then the measurements were carried out at 453 nm for QY, applying the "zero crossing" technique [12,13], and at 632 nm for BB.

2.4. Extraction process

In the analysis of real samples, a extraction process of the colorants must be carried out before doing the absorbance measurements. Namely, the sample amount was shaken after mixing it with an appropriate volume of methylene chloride. In accordance with Holló and Wieg [14], if the proportion of ethanol/water in the sample is smaller than 80/20 (v/v) and the methylene chloride volume is equal or higher that

4/5 parts of the volume of the sample, two phases are formed. Otherwise, only one-phase ethanol/water/methylene chloride is obtained. Working at the proportion of ethanol/water/methylene chloride above suggested, the hydroalcoholic phase formed contains the colorants while the organic phase contains the other additives present in the commercial products.

2.5. Procedure

Standards containing between 25.0 and 500.0 μg l^{-1} of BB and between 50.0 and 750.0 μg l^{-1} of QY were prepared as follows: in a 100 ml calibrated flask, an appropriate volume of standard solution and 5.0 ml 0.1 M acetic/acetate buffer solution (pH 4.0) was placed and made to the mark with water. The mixture was transferred into a 250 ml glass bottle and 50 mg of Sephadex DEAE A-25 gel was then added. After mechanical shaking for 10 min the gel beads were collected by filtration under suction and packed into a 1 mm cell together with a small volume of solution (0.2 ml) with the aid of a pipette. Blank solution containing all the reagents except the analyte was prepared in the same way as the sample. The absorbances (at $^1D_{453}$ and $^0D_{632}$) were measured against a 1 mm cell of reference packed with gel equilibrated with blank solution and the net absorbance was obtained as described under Section 2.3.

2.6. Procedure for real samples

To 10.0 ml of eau de cologne or 5.0 ml of after shave lotion in a 100 ml calibrated flask, 5.0 ml of 0.1 M acetic/acetate buffer solution (pH 4.0) was added and the solution was made to the mark with water. This solution was then transferred into a 250 ml glass bottle and treated as described under Section 2.5.

To analyze shampoo gel the following procedure was carried out: 50 ml of ethanol was added to 1 g of shampoo gel in a 100 ml calibrated flask, and water was added to make the solution to the mark. This solution was then transferred into a 250 ml separatory funnel and 80 ml of methylene chloride were added. The mixture was shaken for

1 min and the hydroalcoholic phase (containing the colorants) was then transferred into a 100 ml calibrated flask. A volume of 5.0 ml of 0.1 M acetic/acetate buffer solution (pH 4.0) were then added and made to the mark with water. The resulting solution was transferred into a 250 ml glass bottle and then treated as described under section 2.5. Previous to the determination of the colorants in commercial cosmetic samples, identification by TLC [4] was carried out.

3. Results and discussion

3.1. Spectral characteristics

Fig. 1 shows the absorption spectra of BB and QY isolated in Sephadex DEAE A-25 gel. As can be seen the absorption spectrum of BB shows two absorption bands between 400 and 440 nm and between 502 and 694 nm, whereas QY only shows an absorption band between 400 and 460 nm. This fact allows the determination of BB in the presence of QY at $\lambda = 632$ nm using the absorption spectra of the mixture, but does not allow the determination of QY in the presence of BB because at $\lambda = 415$ nm the absorption spectra of both colorants overlap considerably hindering the

Fig. 1. Absorption spectra of (A) QY (500.0 μg l^{-1}); (B) BB (200.0 μg l^{-1}) and (C) a mixture of both compounds, in the same concentration levels, isolated in Sephadex DEAE A-25 gel in all cases.

Fig. 2. First-derivative absorption spectra of (A) QY (500.0 μg l^{-1}); (B) BB (200.0 μg l^{-1}) and (C) a mixture of both compounds, in the same concentration levels, isolated in Sephadex DEAE A-25 gel in all cases.

resolution of their mixtures by conventional spectrophotometry.

However, QY can be determined in the presence of BB using the first-derivative spectrum of the mixture of both chemicals and applying the above-mentioned "zero crossing" technique. It is assumed that the derivative of the spectral band is equivalent to the sum of the derivatives of its component bands. Therefore, the total derivative spectrum is only a function of the concentration of the other component when the first-derivative spectrum of one of the two components is zero. Fig. 2 shows that the height h_1 ($\lambda = 453$ nm) is only proportional to the QY concentration allowing its determination.

The two-phase extraction process allows not only the separation of the colorants but also avoids the interferences produced by other additives (fragrances, emulsifiers, etc.) usually present in cosmetic products. These additives show absorption bands in the same region as QY, which often hinders the use of conventional and derivative spectrophotometry for the determination of this colorant.

3.2. Experimental and instrumental parameters
The absorbance measurements were practically

not affected by the experimental parameters, percentages of ethanol and/or amount of methylene chloride, but the extraction process was indeed affected by these parameters. Fig. 3 shows that for values of the percentage of ethanol/water higher that 70/30 (v/v) the absorbance of the system decreases noticeably. This fact can be attributed to the formation of one single-phase ethanol/water/methylene chloride as explained above. We

		400.0	$1.53 \cdot 10^{-5}$	$2.61 \cdot 10^{-4}$

have selected 50/50 (v/v) ethanol/water as the working proportion. On the other hand, we found that the proportion CH_2Cl_2 (ethanol–water) must be 4/5 for the optimum extraction. One min was selected as a shaking time for the extraction process because we found that for times above 30 s the process was not influenced by this parameter.

In order to test the pH influence on the fixation of the colorants in the Sephadex DEAE A-25 gel different values of pH were studied using hydrochloric acid (1.0 M and 0.1 M) and sodium hydroxide (1.0 M and 0.1 M) solutions. At pH values lower than 2.9 the absorbance of the gel system (colorant–Sephadex DEAE A-25) decreases, probably due to the protonation of the sulfonic groups that hindered the fixation of QY and BB. For pH values between 2.9 and 10.0 the measurements of absorbance remained practically constant showing a maximum absorption at pH = 4.0. In this range of pH (between 2.9 and 10.0) the sulfonic groups remain unprotonated

allowing fixation on the anionic gel. At pH values higher than 10.0 the OH$^-$ ions present in the solution compete with QY and BB reducing the absorbance of the solid phase. A pH 4.0 was selected as an optimum value for the fixation of the colorants on the Sephadex gel. Buffer solutions of acetate, monochloroacetate and hydrogen phthalate were tested for adjustment of the pH. Sodium acetate/acetic acid buffer solution (pH 4.0) was found to yield the best results.

Other experimental variables were the amount of gel (Sephadex) used, equilibration time, percentage of ethanol, ionic strength of the solution, scan speed, sample volume and speed of shaking. These variables could influence the fixation of the colorants on the solid support (Sephadex gel) and hence could affect the absorbance measurements. Ten min was selected as the equilibration time because longer times did not provided any improvement. The speed of shaking did not influence the results. We selected 80 rev min^{-1}. The ionic strength only influenced the results when the NaCl concentration was higher than 1.5 M.

The amount of solid support and sample volume of solution for the equilibration process with the Sephadex gel are however more critical. A mass of 50 mg was selected as the optimum amount of Sephadex gel because a large amount of the gel lowered the absorbance measurements. Consequently, only the amount required to fill the cell and facilitate handling (50 mg) was used in all the measurements. Increasing the sample volume of solution for equilibration with the Sephadex gel increases the sensitivity of the method. This effect can be assessed by measuring the absorbance of

Sephadex gel equilibrated with different volumes of solution containing the same concentration of colorants and proportional amounts of the other reagents. The experimental data show a linear dependence of the absorbance measurements on sample volume below 500 ml. However, we have taken a 100 ml sample volume because the sensitivity of the method in this case is high enough for the determination of the BB and QY in real samples.

3.3. Analytical parameters

The calibration graphs for standard samples treated according to the procedure above were linear for the concentration ranges between 50.0 and 750.0 μg l^{-1} for 100 ml of sample volume in the case of QY and between 25.0 and 500.0 μg l^{-1} for the same sample volume in the case of BB. The adjustment of these calibration graphs was carried out by the linear regression model. The lack-of-fit test [8], for three replicates, was applied to probe its linearity as suggested by the Analytical Methods Committee [15].

The repeatability of the method was determined as the relative standard deviation (RSD) for two series (one for QY and the other for BB) of ten independent determinations containing in the first, 500.0 μg l^{-1} of QY, and in the second, 300.0 μg l^{-1} of BB. In both cases 100 ml of sample volume were equilibrated with the solid support. The IUPAC detection limits [16,17] and the quantification limits [18] were also calculated in accordance with the equation:

$$L = \frac{ns_{b}}{m}$$

where L is the detection or quantification limit, s_{b} is the blank standard deviation, m is the slope of the calibration graph and $n = 3$ or $n = 10$ when the detection limit or quantification limit are calculated. These and other analytical parameters are summarized in Table 1.

4. Applications of the method

4.1. Synthetic mixtures

A recovery study was carried out in synthetic samples containing several amounts of BB and QY

in order to check the accuracy of the proposed method. Calibration graphs of one colorant with and without different amounts of the other colorant were constructed. The results obtained show that the slopes of these calibration graphs are similar and that the intercepts have no influence on the measurement of the analytical signals. The null hypothesis test (student's t-test, $p = 0.01$) was applied to the experimental data to prove these facts. We can conclude that the accuracy of the method is acceptable in all instances. The results obtained are summarized in Table 2.

4.2. Determination of QY and BB in real samples

Two colognes, one after shave lotion and one shampoo gel were selected as appropriate commercial products to apply the method in real samples. The cologne labeled 1 contains BB and QY, cologne, 2 only contains only QY, the shampoo gel contains QY and BB and the after shave lotion contains only BB. Samples were prepared and treated as described under Section 2.6. A previous identification by TLC of the colorants present in the samples was carried out.

For 100 ml sample volumes the average values found for three independent determinations agrees with the results obtained by the reference methods [19]. Table 3 shows the results obtained.

In conclusion, this method provides a practical application of first-derivative spectrophotometry in combination with solid-phase spectrophotometry to multi-component colorant analysis without the need of a previous separation.

Separation studies of molybdenum(VI) and rhenium(VII) using TPPO as an extractant

Santosh V. Vartak, Vijay M. Shinde*

Analytical Laboratory, Department of Chemistry. The Institute of Science, 15, Madam Cama Road, Bombay 400 032, India

Abstract

A simple, rapid and reproducible method for the extractive separation of molybdenum(VI) and rhenium(VII) is proposed using triphenylphosphine oxide (TPPO) dissolved in toluene as an extractant. The extractions are carried out from the hydrochloric and hydrobromic acid medium. The extraction of molybdenum is quantitative from 2.54–3.10 M hydrochloric acid and from 3.76–3.98 M hydrobromic acid, and that of rhenium is from 6.78 7.91 M hydrochloric acid. The probable nature of the extractable species is established using log distribution ratio–log concentration plots. The method permits mutual separation of molybdenum(VI) and rhenium(VII) and is applicable for the analysis of alloys and pharmaceutical sample. The detection limits for molybdenum(VI) and rhenium(VII) are 0.8 ppm and 4 ppm respectively.

1. Introduction

Molybdenum is an important trace element in nature, required by both plants and animals in very small amounts. It has a large number of applications in various fields. It is used in radios, thermocouples, anticathodes of X-ray tubes and in the production of special steels. Molybdenum is a major product of uranium fission. Rhenium is a trace metal and used largely in high temperature filaments and in petroleum refineries as a catalyst. A Re–Mo alloy is reported to be superconducting

at 10 K. In view of these applications both elements are required in pure form. In this communication we propose a simple method for extractive separation and determination of molybdenum(VI) and rhenium(VII), using triphenylphosphine oxide (TPPO) as an extractant.

Potassium ethyl xanthate [1], diethyldithio carbamate [2,3], 1-10 phenanthroline [4], mesityloxide [5], diisopropylether [6], bis(2-ethylhexyl)phosphate [7], bis(2-ethylhexyl)hydrogenphosphate [8], tributylphosphate [9,10], tris(2-ethylhexyl) phosphate [11], OOS-tripropylphosphorodithioate [12], cyanex 301 [13,14], and alamine 310 [15] are the reported extractants for molybdenum while

Table 1
Optimum extraction conditions for molybdenum(VI) and rhenium(VII)

Metal ion	Halide concentration/ total volume	[TPPO]/diluent	Extraction period (s)	Stripping solution	Estimation procedure
Mo(VI), 20 μg	2.54–3.10 M HCl and 3.76–3.98 M HBr/10 ml	5 ml of 6% TPPO/toluene	60	2 × 5 ml water	Thiocyanate [28]
Re(VII), 100 μg	6.78–7.91 M HCl/10 ml	5 ml of 6% TPPO/tolune	120	2 × 5 ml water	Thiocyanate [29]

α-benzoin oxime [16], tri-n-octylamine [17,18], cyclohexanone [19], ethylxanthate [20], mesityl oxide [21], tributylphosphate [22,23], trioctylphosphine oxide [24] and aliquat 336 [25] are the reported extractants for rhenium. These methods, however, have limitations such as interference by other ions [1,3–5,7,12], longer extraction periods [2,5,13–16,22], use of salting out agents [5,10,19,21], multiple extraction [3,4,23], critical pH [8,18,25], higher acidic conditions [11,12], milligram amounts of metal used [9], visual comparison for determination [6] and highly acidic stripping agents [17]. The proposed method is free from all these drawbacks and has the following advantages.

1. Extraction occurs in a single step and recoveries of the elements are > 99.0%.
2. It provides mutual separation of molybdenum(VI) and rhenium(VII).
3. The method is applicable for the analysis of alloys and pharmaceutical samples.
4. The method is rapid, reproducible, accurate and free from interference due to commonly associated elements.

2. Experimental

2.1. Apparatus

The absorbance measurements were taken on a Shimadzu UV-VIS 160A spectrophotometer (Shimadzu Corporation, Japan).

2.2. Reagents and chemicals

The stock solutions of molybdenum(VI) and rhenium(VII) were prepared by dissolving 0.046 g of ammonium molybdate in 250 ml distilled water and 0.155 g of potassium perrhenate in 100 ml of distilled water (containing 5 ml of 6 N H_2SO_4), respectively. Solutions of lower concentrations were obtained by dilution and were standardised by standard methods [26,27]. TPPO (Fluka grade) dissolved in toluene was used for extraction and separation of molybdenum(VI) and rhenium(VII).

All other chemicals used were of analytical reagent grade.

2.3. General extraction procedure for molybdenum(VI) and rhenium(VII)

To an aliquot of a solution containing 20 μg of molybdenum(VI) and 100 μg of rhenium(VII), hydrochloric acid was added to obtain 2.54 M and 6.78 M solutions, respectively, in a total volume of 10 ml. The aqueous solution was then equilibrated for 60 s with 5 ml of 6% TPPO dissolved in toluene for molybdenum(VI). For rhenium(VII), the acqueous solution was equilibrated with 5 ml of 6% TPPO dissolved in toluene for 120 s. After stripping with 2 × 5 ml of water both of the elements were determined spectrophotometrically with the thiocyanate method [28,29] as follows. For rhenium(VII), 2 ml of concentrated hydrochloric acid, 1 ml of 20% potassium thiocyanate solution and 2 ml of 35% stannous chloride solution were mixed together and allowed to stand for 5 min. The absorbance at 430 nm was measured against a reagent blank prepared analogously. For molybdenum(VI), 2 ml of concentrated hydrochloric acid, 1 ml of 10% ferrous ammonium sulfate solution, 3 ml of 10% potassium thiocyanate solution and 3 ml of 10%
Fig. 1. Extraction of Mo(VI) and Re(VII) as a function of HCl and HBr concentration.

stannous chloride solution were mixed together and the absorbance was measured after 5 min at 465 nm against a reagent blank prepared analogously. The molybdenum and rhenium contents were computed from earlier drawn calibration plots. The optimum extraction conditions are given in Table 1.

3. Results and discussion

In order to ascertain the optimum concentra-

Fig. 2. Extraction of Mo(VI) ane Re(VII) in HCl as a function of TPPO concentration.

tion of acid (HCl/HBr) and TPPO (using toluene as diluent) for the quantitative extraction of molybdenum(VI) and rhenium(VII), the extraction studies were carried out at various concentrations of hydrochloric acid (1.13–7.91 M) and hydrobromic acid (1.77–6.2 M) with different concentrations of TPPO (0.5–6.0%). The quantitative extraction of rhenium(VII) occurred with 5 ml of 6% TPPO dissolved in toluene at 6.78–7.91 M hydrochloric acid solution whereas from hydrobromic acid solution its extraction was incomplete. The quantitative extraction of molybdenum(VI) from 2.54–3.10 M hydrochloric acid and

3.76–3.98 M hydrobromic acid was feasible with 5 ml of 6% TPPO in toulene.

The effect of various diluents such as toluene, xylene, benzene, chloroform and carbon tetrachloride on the extraction of both molybdenum(VI) and rhenium(VII) was investigated using the proposed method. A 6% solution of TPPO in toluene provided quantitative extraction of molybdenum and rhenium. The extraction, however, was incomplete with other diluents.

While prolonged shaking had no adverse effect on the extraction of molybdenum(VI) and rhenium(VII), a shaking period of 60 s for molybdenun(VI) and of 120 s for rhenium(VII) was adequate for the quantitative extraction.

3.1. Nature of extracted species

The nature of the extracted species was established using log–log plots of the distribution ratio versus TPPO concentration and hydrochloric acid concentration. The plot of the log of the distribution ratio versus the log of the hydrochloric acid concentration (at 6% TPPO in toluene) for molybdenum(VI) and rhenium(VII), gave slopes of 2.3 and 3.2, respectively. Similarly, a plot of the log

of the distribution ratio versus the log of the TPPO concentration at 2.54 M HCl for molybdenum(VI) and 6.78 M HCl for rhenium(VII), gave slopes of 2.1 and 3.3 for molybdenum(VI) and rhenium(VII), respectively. It indicates a metal to TPPO ratio of 1:3 for rhenium(VII). For molybdenum(VI), at lower TPPO concentration it was 1:1 and at higher TPPO concentration it was 1:2. Hence the probable extracted species were solvated salts of the type $MoO_2Cl_2 \cdot 2TPPO$ and $ReO_2Cl_3 \cdot 3TPPO$. TPPO, being more basic, supplanted the water molecules and rendered the species hydrophobic (Figs. 1 and 2).

3.2. Effect of foreign ions

To an aliquot of the solution containing a fixed amount of molybdenum (20 μg) and rhenium (100 μg), varying amounts of foreign ions were added to study their interference in the recommended procedure. The tolerance limit of the foreign ion was set at the amount required to cause $\pm 2\%$ error in the extraction and subsequent determination of molybdenum(VI) and rhenium(VII) by the proposed method. The results are reported in Table 2.

3.3. Binary separation of molybdenum(VI) from rhenium(VII), copper(II), manganese(II), vanadium(V), titanium(IV) and uranium(VI)

Molybdenum(VI) and rhenium(VII) were separated by extracting molybdenum(VI) from 2.54 M hydrochloric acid solution with 5 ml of 6% TPPO dissolved in toulene. It was then stripped with water and determined by the thiocyanate method [28]. Rhenium (VII), under this condition, remained in the aqueous phase which was then determined by the thiocyanate method [29]. Copper (II), manganese(II), vanadium(V), titanium(IV) and uranium(VI) remained quantitatively in the aqueous phase at the optimum extraction conditions of molybdenum(VI) and were determined spectrophotometrically using 4-(2-pyridlazo)resorcinol [30], formaldoxime [31], 4-(2-pyridylazo) resorcinol [32], hydrogen peroxide [31] and 4-(2-pyridylazo) resorcinol [33]. The recoveries of molybdenum and that of the added ions were ≥ 99.0%. The results are reported in Table 3.

3.4. Binary separation of rhenium(VII) from molybdenum(VI), copper(II), manganese(II) and titanium(IV)

Separation of molybdenum(VI) and rhenium(VII) was discussed above. Rhenium(VII) was separated from titanium(IV) copper(II), and man-

ganese(II) as these ions remained quantitatively in the aqueous phase at the optimum extraction conditions of rhenium(VII). Copper(II), manganese(II) and titanium(IV) were then spectrophotometrically determined by 4-(2-pyridylazo)resorcinol [30], formaldoxime [31] and hydrogen peroxide [31], respectively. The results are reported in Table 3.

3.5. Analysis of alloys and pharmaceutical sample

A 100 mg alloy sample, Mn–Mo steel (BCS 214/2), was dissolved in aqua regia, followed by the addition of 5 ml perchloric acid. The solution was evaporated to dryness and diluted to 25 ml with distilled water after leaching up with distilled water. A mass of 25 mg of alloy Nimonic 901 (BCS 387) was dissolved in aqua regia, evaporated to dryness and diluted to 25 ml with distilled water. A mass of 100 mg of alloy Ce–Zn–Zr (BCS 307) was dissolved in concentrated hydrochloric acid and diluted to 25 ml with distilled water. Since we could not procure samples containing rhenium, a known quantity of rhenium was added to the standard alloy solutions BCS 214/2 and BCS 307. An aliquot from each alloy solution was than analysed by the proposed method. Rediplex tablet manufactured by ESPI chemicals, India, was dissolved in 10 ml of perchloric acid. The solution was evaporated to dryness and then the residue was leached up with distilled water, the solution was filtered and diluted to 100 ml with distilled water. An aliquot of Rediplex solution was then taken for the extraction and determination of molybdenum by the proposed method. The results are reported in Table 4.

High sensitivity flow-based analysis system using a semiconductor laser and thin long flow-through cell for the determination of total phosphorus in water

Takashi Korenaga*[1], Fusheng Sun[2]

Toyama National College of Technology, 13, Hongo-machi, Toyama 939, Japan

Received 11 September 1995; revised 26 February 1996; accepted 28 February 1996

Abstract

A highly sensitive detection system using a semiconductor laser (SCL) and a thin long flow-through cell (TLFCT) to match flow-based analysis, such as flow injection analysis (FIA), has been developed. The SCL was a GaAlAs semiconductor laser emitting at 780 nm (5 mW), and the TLFTC, which has a 100 mm thin long light path, was made of a poly(tetrafluoroethylene) (PTFE) rod. The sensitivity was essentially improved about 10-fold in comparison to usual FIA-spectrophotometry using a 10 mm conventional flow cell. When this detection system was applied to the determination of total phosphorus (P) in water by molybdenum-blue spectrophotometry, the relative standard deviation, detection limit and linear range were 1.0% ($n = 10$ at 20 μg P l^{-1}), 0.6 (3 σ) and 1.0–50 μg P l^{-1}, respectively, and the results for the samples were fairly consistent with those by the official method. It may also be possible to apply the present detection system to other flow-based analytical methods such as the liquid chromatography family.

Keywords: Eutrophication; Flow injection analysis; Semiconductor laser; Spectrophotometry; Thin long flow-through cell; Total phosphorus; Trace analysis; Water

1. Introduction

As a large number of samples must be analyzed daily and the concentrations of most components in the samples are usually low, more sensitive and rapid flow-based analytical methods are needed in many fields, such as environmental chemistry, clinical chemistry, etc. Many ways have been studied for solving this problem.

According to the Lambert–Beer's law increasing the light path length is one of the ways to improve the sensitivity of spectrophotometry. However this would be difficult when the light path length is very long because the intensity of the transmitted light, emitted from an ordinary light source such as tungsten lamp, may become too low to be measured, and a large amount of sample solution is needed. One of the possible ways to solve this problem is to use a light source, which can emit light with very strong intensity, excellent monochromaticity and coherence, and a cell with a thin light path. Several attempts on this topic have been reported [1,2]. However, it was indicated that the multireflection–multipass system for the elongation of the light path length is effective only for gas samples not liquid as this system requires a rather large amount of sample, and the adjustment of optical configuration is difficult when a cell filled with liquid is inserted between the mirrors. Wei et al. have used a powerful light source, such as a xenon discharge lamp, a tungsten incandescent lamp and a helium–neon laser, and a long capillary cell for increasing the sensitivity for determination of phosphorus [1].

Although the sensitivity was improved from several hundred fold to thousand fold times higher than normal spectrophotometry, it was reported that the source light hits the wall of the long capillary cell and as a result, the apparent sensitivity deviates from the ideal Lambert–Beer's law. Another test using a total-reflection long capillary cell [2] also has some troubles because the solvent had a refractive index higher than that of the cell material, and the linear range of the calibration curve for the analyte was narrow. As a SCL has more advantages (see Section 3) than other conventional lasers [3,4], it could be more suitable as a light source to match the thin long light path cell for increasing the sensitivity.

Application of FIA to automatic analysis yields a fast, precise, accurate and extremely versatile system that is simple to operate. Although photometry is currently the most important detection technique in FIA, the design of

photometric cells has not received attention in working laboratories [5]. Only a few papers on the subject have been reported [6–8], and the detection limits for these designs were not good enough for the determination of lower concentrations of analytes in samples. A photometric detector having higher sensitivity for practical trace analysis by FIA has not been reported.

Improving the sensitivity for the determination of phosphorus is very important in environmental analysis as phosphorus is one of the major nutrients besides nitrogen. The heavy growth of algae in lake and stream waters is sometimes caused by phosphorus, and this results in the eutrophication of the water. This concentration of phosphorus is often less than that detectable by an ordinary spectrophotometry. In order to explain the mechanism of phosphorus circulation in environmental waters, the development of a continuously and highly sensitive method for detecting phosphorus should be indispensable. FIA was first used to determine phosphorus by Ruzicka and Hansen [9] and since then some other papers for the determination of phosphorus in water by FIA have been published [10–13]. Most of the methods described in these papers were based on the method of molybdophosphate blue (MPB), but the sensitivities of these methods were not very high and the detection limits were generally around 2–10 μg P l^{-1}. Some modifications have been made to improve the sensitivity of the determination of phosphorus by FIA [14,15], but they were rather complicated.

In the present paper, a highly sensitive detection system, which had a SCL and TLFTC, compatible with FIA for continuous trace analysis and its application in the determination of total phosphorus in water were reported. This new detection system was more sensitive than usual FIA with an ordinary photometric detector, and it was inexpensive and convenient to operate. It could be suitable for the continuous analysis of multiple components in samples, and for use in other flow-based techniques, such as liquid chromatograph and capillary electrophoresis [16,17].

2. Experimental

2.1. Reagents

All reagents were analytical reagent grade manufactured by Wako pure Chemical Industries Ltd, Osaka, Japan. Distilled water was used for all solutions and dilutions. Potassium dihydrogen phosphate was taken as a standard material for phosphorus, and it was dried for about 3 h at 110°C and then cooled to room temperature. It was used to prepare 50 mg P l^{-1} of stock standard solution with water. The oxidant, which was used for the oxidation of all phosphorus in samples to orthosphate, was prepared by dissolving 3 g of potassium persulfate in 1 liter of water. The developing reagent was composed of two parts, solutions A and B. Solution A was prepared by dissolving 6 g of ammonium molybdate tetrahydrate [$((NH_4)_6Mo_7O_{24}\cdot4H_2O)$] and 0.24 g of potassium antimonyl semihydrate tartrate $(K(SbO)C_4H_4O_6\cdot1/2H_2O)$ in about 300 ml of water, then adding 120 ml of 2 + 1 H_2SO_4 to the solution and diluting to 500 ml with water. Solu-

tion B was made by dissolving 7.2 g of L-ascorbic acid with water, and then diluting to 100 ml. Before delivering the developing reagent, solutions A and B were mixed by 5 + 1 and further diluted five times with water [18].

2.2. Apparatus

Fig. 1 shows the new detection system, which was essentially composed of three sections: semiconductor laser radiation, thin long light path absorption and logarithmic conversion-amplification and recording. A Model LN9805 K GaAlAs semiconductor laser (Semiconductor Selling Division, Matsushita Denshi Co. Ltd., Nagaokakyo, Kyoto, Japan) was used for the light source of the detector. The operation parameters of the laser are listed in Table 1. A light emitting diode (LED) (Model TLS143, Toshiba Co. Ltd., Japan) was used as a light source for the reference light beam of the detector. Two identical silicon photodiodes (PD) (Model S1087-01, Hamamatsu Photonics Co. Ltd., Japan) were arranged as receivers for the light beams of sample and reference, respec-

tively. A Model 757 N logarithmic ratio module and a Model LM308 three amplifying size differential OP amplifier (Analog Devices Co Ltd., USA), and a Model U-228 chart recorder ranged 0–10 V (Nihon Denshi Kagaku Co. Ltd., Tokyo, Japan) were used for the logarithmic conversion amplification and recordation, respectively.

A schematic diagram of the FIA is shown in Fig. 2. This part should be made of materials which are resistant to oxidation and reduction reagents, acids and bases. There were three reactions, the oxidation of total phosphorus to orthophosphate, the formation of MPA and the reduction of MPA to MPB, in the FIA system. Because the reactions were carried out at higher temperature (140°C) for increasing the reaction rate and improving the sensitivity, higher back pressure would exist. The double-plunger micropump, with a linear cam mechanism and short/fast reciprocation, can provide a continuous pulse-free flow. In addition, the micropump was sutable for operations against a higher than normal pressure, and for handling aggressive liquid [19]. Therefore, a pair of double-plunger micropumps (Model SR-3000, Sanuki Industry Co. Ltd., Japan) was used for pumping the reagents (600 μl min^{-1}). The standard solution of phosphorus or water sample (300 μl) were injected by an automatic injector (Model SJ-1700 ASI, Atto Co. Ltd., Japan). An oil bath (O_b, 140°C) was used,
in which PTFE coils C_1 and C_2 (10 m × 1.0 mm i.d.) were immersed. C_1, C_2 and the path for the developing reagent were connected by a T-shaped PTFE connector. A PTFE back pressure coil (Bpc) (3 m × 0.25 mm i.d.) was put behind the TLFTC to decrease pulsations in the propelling system and prevent the formation of bubbles in the streams.

2.3. Design of TLFTC

Usually, the light path length of a commerically available flow-through cells for the application of photometry in FIA is 10 mm with 8 μl inner volume. In order to improve the detection sensitivity and decrease the reagent and sample consumption in the FIA laser spectrophotometry, the TLFTC was designed. The schematic of the TLFTC is shown in Fig. 3. It was made of PTFE rod, and the smoothness and linearity of the central thin and long hole (1.4 mm i.d.) must be very good to prevent the light emitted from the SCL from hitting the wall of the hole. TLFTCs with different lengths (10, 20, 50 and 100 mm) of light path were made for this study.

2.4. Detection system matching FIA

The reacted solution, leaving from coil C_2, flows into the TLFTC through the inlet hole

(9.7 mm × 1.0 mm i.d.) and shallow gap at one side of the TLFTC, and then flows out of the TLFTC through the other shallow gap and outlet hole (9.7 mm × 1.0 mm i.d.) at the other side of the TLFTC into the Bpc. The position of the SCL should be finely adjusted by moving the SCL so that the light beam emitted from the SCL can exactly pass the center of the thin long light path in the TLFTC, without hitting the wall of the thin long light path. The distance between the TLFTC and the SCL was not considered critical as the effect of the different distances (0–150 mm) on the absorbance for the determination of total phosphorus was not obvious. The light transmitted through the sample solution is received by the PD and converted to an electrical signal for the sample. The other light beam emitted from the LED is also received simultaneously by the other PD and converted to an electricial signal for the reference. Both of the signals are compared, logarithmically modulated and amplified in the logarithmic ratio module, and the final detection signal is recorded on the chart recorder.

2.5. Analytical procedure for determination of total phosphorus in water

The oxidation and developing reagents were pumped by a pair of double-plunger micropumps

Fig. 5. Results of the determination for standard solution of phosphorus using different light path lengths of the TLFTC.

at a flow rate of 600 μl min^{-1}. The standard solution of phosphorus or sample (300 μl) were injected by the automatic injector at a rate of 12 samples per hour and merged into the stream of oxidation reagent, flowing into coil C_1. All of the phosphorus in the sample was oxidized to orthophosphate. The solution merged with the developing reagent in coil C_2, and was converted to MPA by reacting with ammonium molybdate and potassium antimonyl tartrate. Finally, the MPA was reduced to MPB by L-ascorbic acid in coil C_2, and the absorbance of the MPB solution flowing into the TLFTC was measured at 780 nm. The concentrations of phosphorus in the samples were calculated using a standard curve for phosphorus.

3. Results and discussion

3.1. Light source

A light source, that can emit intensive, coherent and monochromatic radiation is very important for spectrophotometry with a thin long light path cell. The He–Ne laser was used as the light source in long-capillary-cell absorption sectrophotometry because the laser can emit intensive light with good coherency and monochromaticity. The SCL has even more advantages than the He–Ne and other conventional lasers in conjunction with thin long light path spectrophotometry. The materials of the SCL are very sensitive to operation conditions, and the function of the SCL could be adjusted in many variables, such as temperature, pressure, radiation, different impurities and so on. The SCL has a very high conversion efficiency from electricity to light (theoretically it can reach 100%), quite large power output, very small dimension (several decimal μm are available) and excellent beam coherency and monochromaticity. It has a long life-time (10^5 h), low cost (one chip is about 10 US $) and wide range of wavelength (from near UV to IR). The GaAlAs has an alloplasm form, and it is very convenient for use as it can be continuously oscillated at room temperature [3,4,20]. Hereby, the GaAlAs was selected as the most suitable light source of the detector in thin long light path spectrophotometry and for

improving the sensitivity in FIA spectrophotometry.

The distance between the cell and the light source can be adjusted by moving the light source. Considering the light stability and the cheap price of LEDs, and the simplicity of light circuit system, the LED was selected as the light source of the reference light beam.

3.2. Concentration of oxidant and temperature of oxidation

The absorbencies for the determination of total phosphorus, using sodium triphosphate as a testing sample, were very similar using a range of concentrations of oxidant solution of 0.1–0.8% (w/v). Considering ecomony, 0.3% of oxidant solution was used in this study.

The oxidation of phosphorus to orthophosphate in the samples was not complete when the oxidation temperature was lower than 100°C. When the temperature was in a range of 120–160°C, the oxidation was complete and the results of the determination was almost identical. In the standard method of the Environmental Agency, Government of Japan, oxidation is carried out at 120°C, and the reaction time is 30 min [16]. In our work 13 min was sufficient when the reaction was carried out at 140°C in coil C_1 immersed in the O_b and the flow rate of the oxidant solution was 600 μl min^{-1}. Therefore, 140°C was used as the oxidation temperature.

3.3. Developing temperature

According to the standard method issued by the Environment Agency, Government of Japan, the developing temperature for phosphorus using a MPB method is 20–40°C (water bath), and the developing time is 15 min [18]. It was found that the sensitivity of the method for the determination of phosphorus was lower when developing was carried out at that temperature. Different temperatures from 20 to 160°C were tested and the sensitivity was highest when the temperature was in a range of 95–160°C and the flow rate of the developing reagent was 600 μl min^{-1}. With these considerations the temperature of the oxidation

for phosphorus was chosen to be 140°C and the coils C_1 and C_2 could be immersed in the same bath.

3.4. Analytical rate, precision and detection limit

Considering that the oxidation of phosphorus to orthophosphate in the coil C_1 took 13 min and a good separation between two peaks of neighboring samples (Fig. 4) was needed, the automatically continuous analysis rate for samples was set to 12 per hour. When 100 mm TLFTC was used, 10 measurements of 20 μg P l^{-1} standard solution gave an average absorbance of 0.0616 with a standard deviation (SD) of ± 0.0006. The relative standard deviation (RSD) and the detection limit (3 σ) were calculated to be 1.0% and 0.6 μg P l^{-1}, respectively.

3.5. Light path length of TLFTC and linear range for the determination of phosphorus

The effect of TLFTCs with different lengths (10, 20, 50 and 100 mm) of light path on the determination of phosphorus was tested, and the results are shown in Fig. 5. The sensitivity for the

	R	0.15	0.12	0.03	25

determination of phosphorus by a 100 mm TLFTC was enhanced by about 10-fold when compared to usual FIA sectrophotometry using a 10 mm absorption cell. The longer the length of the TLFTC, the higher the detection sensitivity. The linear ranges for the determination of phosphorus, using 10, 20, 50 and 100 mm light path lengths, were 10–200, 5–100, 2–50 and 1–50 μg P l^{-1}, respectively.

3.6. Recovery of phosphorus in some phosphorus compounds and the determination of total phosphorus in water

The recoveries of phosphorus in some phosphorus compounds are listed in Table 2. From Table 2 it was known that the recoveries were between 94–107% when potassium dihydrogen phosphate was considered as the standard of phosphorus.

Some wastewater and treated wastewater were determined by this method and the official method. The results of the determination are shown in Table 3. The RDs, which were obtained by comparison with the results analyzed by the official method, for the concentrations of total phosphorus in the wastewater and treated wastewater, were 3.4–14 and -3×10–2×10^2%, respectively. Most of the results analyzed by the two methods showed little difference, except for a few results in the treated wastewater. The correlation between the results analyzed by both of the methods is shown in Fig. 6. It shows that the correlation was quite good.

Traces of total phosphorus in some natural waters, sea water, hot-spring water and snow, were determined to evaluate the applicability of the present method. The results are listed in Table
Fig. 6. Correlation between the results analyzed by the present and official methods.

technique was successfully applied to the automatically continuous monitoring of them in water.

The technique utilizes the merits of FIA, TLFTC and SCL, i.e. high speed, good reproducibility and automatically continuous analysis of FIA, thin long light path with low reagent and sample consumption, samples, high sensitivity of TLFTC, and excellent radiation intensity, monochromaticity and coherency of SCL. This technique could be used for the determination of other trace analytes in samples, and it may also be useful to other flow-based analytical techniques, such as liquid chromatograph, capillary electrophoresis, etc.

4. The RSD stated as above in these samples were in a range of − 7–12%. The results were similar except for the river water in which concentrations of total phosphorus were too low to be detected by the official method.

4. Conclusions

The application of laser spectrophotometry FIA with the new detection system, composed of the TLFTC and SCL, to the determination of total phosphorus and dissolved silica [21] in water have clearly illustrated that, by comparison with a normal 10 mm flow cell, the detection sensitivities were improved by about 10-fold. The analytical

Abstract

The extraction of gallium(III) with newly prepared 5-alkyloxymethyl-8-quinolinol derivatives with alkyl substituent at the 2-position in 8-quinolinol moiety has been studied. The Ga(III)-5-octyloxymethyl-8-quinolinol (HO_8Q), Ga(III)-2-methyl-5-octyloxymethyl-8-quinolinol (HMO_8Q), Ga(III)-2-methyl-5-hexyloxymethyl-8-quinolinol (HMO_6Q), and Ga(III)-2-n-butyl-5-hexyloxymethyl-8-quinolinol ($HNBO_6Q$) complexes extracted in heptane from a perchloric acid medium were $Ga(O_8Q)_3$, $Ga(OH)(H_2O)(MO_8Q)_2$, $Ga(OH)(H_2O)(MO_6Q)_2$ and $Ga(OH)H_2O)(NBO_6Q)_2$, respectively. The 2-$tert$-butyl-5-hexyloxymethyl-8-quinolinol did not exhibit any reactivity toward gallium(III). The extraction constants for $Ga(O_8Q)_3$ ($K_{ex} = [Ga(O_8Q)_3]_{org} [H^+]^3/[Ga^{3+}][HO_8Q]_{org}^3$), $Ga(OH)(H_2O)(MO_8Q)_2$ ($K_{ex} = [Ga(OH)(H_2O)(MO_8Q)_2]_{org} [H^+]^3/[Ga^{3+}][HMO_8Q]_{org}^2$), $Ga(OH)(H_2O)_2(MO_6Q)_2$ and $Ga(OH)(H_2O)(NBO_6Q)_2$, which were extracted in heptane from an acidic solution, are $10^{3.21 \pm 0.12}$, $10^{-4.24 \pm 0.16}$, $10^{-3.84 \pm 0.16}$ and $10^{-4.07 \pm 0.07}$, respectively at $I = 0.1$ M and 25°C.

$HNBO_6Q$ exhibited very high selectivity toward gallium(III) in the presence of aluminum(III). Even in the presence of a 100 fold excess of aluminum(III) to gallium(III) (1.43×10^{-5} M), gallium(III) was completely extracted and the distribution ratio of aluminum(III) was found to be less than 2.0×10^{-3}.

Keywords: Alkyl substituents; Gallium(III) extraction; Hydrophobic 8-quinolinol

1. Introduction

Selective separation of rare metal ions has been an attractive subject in analytical chemistry and separation science. The molecular design for the highly selective chelating extractants has been extensively studied to establish the most selective separation system for metal ions.

Since 8-quinolinol provides many extractable and stable metal complexes, it has been one of typical extractants for practical purpose, despite

low selectivity [1,2]. A Kelex 100 extractant characterized by very large hydrophobicity has been known to provide high extractability for gallium(III) from a strongly alkaline solution [3,4], and for palladium(II) from a strongly acidic solution [5].

The present authors have reported that the alkylated 8-quinolinol derivatives such as 5-octyloxymethyl-8-quinolinol (HO_8Q) and 2-methyl-5-octyloxymethyl-8-quinoinol (HMO_8Q) behave as highly selective extractants for molybdenum(VI) from a strongly acidic solution [6,7]. HO_8Q and HMO_8Q gave extractable 1:2 molybdenum(VI) complexes. The extraction constant for HO_8Q was about three orders of magnitude larger than that for HMO_8Q. Such a different extraction behavior between HO_8Q and HMO_8Q was explained by the steric hindrance of the methyl group at the 2-position.

The lack of reactivity of 2-methyl-8-quinolinol with alluminum(III) has been ascribed to the difficulty in forming an extractable Al(III)-2-methyl-8-quinolinol complex due to the steric hindrance of methyl group [2]. The substitution at the 2-position of 8-quinolinol does not remarkably affect the pK_{a1} and pK_{a2} values, but it seriously decreases the stability constants of metal ions such as copper(II), nickel(II) and zinc(II) [8]. A systematic study on the extraction behaviors of metal ions with 2-methyl-8-quinolinol has been done by Motojima and Hashitani [2]. However, a few extraction constants have been determined [9–11]. In this study, the extraction behavior of gallium(III) with alkylated 8-quinolinol was investigated to get detailed information concerning the steric effect of the alkyl substituents in the hydrophobic 8-quinolinol moiety on the extractability and selectivity for the metal ion.

2. Experimental

2.1. Reagents

2.1.1. Synthesis of 2-butyl-5-hexyloxymethyl-8-quinolinol ($HNBO_6Q$) and 2-tert-butyl-5-hexyloxymethyl-8-quinolinol ($HTBO_6Q$)

A 2.6 g quantity of 5-hexyloxymethyl-8-quinolinol (HO_6Q) dried under vacuum at 100°C was dissolved in 20 ml of dry ethylether and the solution cooled to 0°C under a dry nitrogen atmosphere. Next 32 ml of n-butyl lithium (51 mmol) was dropped into a stirred reaction flask containing HO_6Q in ethylether and kept below 0°C. The solution was allowed to stand for 4 h at 0°C. The reaction product was hydrolyzed by dropping water into the reaction flask, the ethylether was separated, and the solvent was evaporated to obtain a yellowish oil. The crude product was purified by chromatography on silica gel. Hydrochloric acid was added to the purified, oily $HNBO_6Q$ in methylene chloride. The yellow crystalline product of $HNBO_6Q \cdot 2HCl$ was recrystallized from methylene chloride (yield, 33%). Analysis calculated for $C_{20}H_{29}NO_2 \cdot 2HCl_2$: C, 61.85; N, 3.61; H, 8.05% and found: C, 61.64; N, 3.63; H, 8.34%. ^{1}H-NMR (300 MHz $CDCl_3$): 0.85(t, 3H), 0.97(t, 3H), 1.25(m, 6H), 1.41(m, 2H), 1.58(m, 2H), 1.81(m, 2H), 2.97(t, 2H), 3.47(t, 2H), 4.79(s, 2H), 7.06(d, 1H), 7.26(d, 1H), 7.34(d, 1H), 8.39(d, 1H). Precise mass calculated: 315.22 for $C_{20}H_{29}NO_2$ and found: 315.22.

In a similar manner, $HTBO_6Q$ was synthesized from HO_6Q and tert-butyl lithium and purified by chromatography on silica gel. The product was oily (yield, 26%). ^{1}H-NMR (300 MHz, $CDCl_3$): 0.85(t, 3H), 1.25(m, 6H), 1.51(s, 9H), 1.62(m, 2H), 3.47(t, 2H), 4.71(s, 2H), 7.07(d, 1H), 7.34(d, 1H), 7.61(d, 1H), 8.43(d, 1H). Precise mass calculated:315.22 for $C_{20}H_{29}NO_2$ and found: 315.22.

The extractants, (HO_8Q) [12] and (HMO_8Q) [7] were synthesized by our previous method. In addition, HO_6Q and HMO_6Q were synthesized by a similar manner to HO_8Q and HMO_8Q, respectively.

The structures of the 8-quinolinols are shown in Fig. 1.

A heptane solution of HO_8Q was prepared by dissolving weighed amounts of HO_8Q into heptane just before use. A HMO_8Q heptane solution was prepared by shaking weighed amounts of $HMO_8Q \cdot HCl$ with a mixture of heptane and a dilute aqueous ammonia solution. A gallium(III) perchlorate stock solution was prepared by replacing the chlordie ion of a spectroscopic stan-

dard gallium(III) chloride solution with perchlorate ion. Heptane was purified by distillation before use. All other chemicals were of reagent grade and used without further purification.

The ionic strength was kept at 0.1 M or 0.5 M $(1\ M = 1\ mol\ dm^{-3})$ by addition of sodium perchlorate or sodium chloride. The pH of an aqueous phase containing gallium(III) was adjusted with perchloric acid or sodium hydroxide solutions.

2.2. Apparatus

An inductively coupled plasma atomic emission spectrophotometer (ICP-AES, Nippon Jurrell Ash ICAP-575) was used for the determination of gallium(III) in aqueous solutions. The pH measurements were made by a Radiometer PHM93 pH meter. A mechanical shaker (Iwaki) was used

to equilibrate the extraction vials. All the experiments were carried out at 25°C in a thermostated room.

## 2.3. Extraction equilibrium

An aqueous gallium(III) solution $(1.01 \times 10^{-5}-1.01 \times 10^{-3}\ M)$ was placed in a 50 ml extraction vial fitted with a plastic cap. To the solution, an equal volume of organic solvent containing $1.01 \times 10^{-3}-1.01 \times 10^{-2}\ M$ of extractant was added and shaken for 12 h. After centrifugation, the gallium(III) concentration in the aqueous phase was determined by ICP-AES. To determine the gallium(III) concentration in the organic phase, the $Ga(III)$-HMO_8Q and $Ga(III)$-HO_8Q complexes were stripped with 1 M hydrochloric acid and the resulting aqueous solution analyzed by ICP-AES. The distribution ratio $(D = [Ga(III)]_{org}/[Ga(III)]_{aq})$ was calculated from the gallium(III) concentration in both phases, where the subscripts of org and aq represent the organic phase and the aqueous phase, respectively.

3. Results and discussion

3.1. Extraction of Ga(III) with HO_8Q from a perchloric acid and hydrochloric acid medium

A shaking time of 12 h was found to be sufficient to establish the extraction equilibrium of gallium(III) with $1.00 \times 10^{-3}\ M\ HO_8Q$ at pH 2.04. Under the given extraction conditions $(1.00 \times 10^{-2}\ M\ HO_8Q$, pH 1.10), the distribution ratio was independent of the initial gallium(III) concentration $(1.01 \times 10^{-5}-1.01 \times 10^{-3}\ M)$, suggesting that the extracted $Ga(III)$-HO_8Q complex is a mononuclear species. Also no aggregation of the 8-quinolinol derivatives themselves in heptane was separately ascertained by studying the distribution equilibrium [14]. Assuming that the extracted $Ga(III)$-HO_8Q complex is $Ga(O_8Q)_3$, the extraction equilibrium is provided as follows:

$$Ga^{3+} + 3HO_8Q_{org} \overset{K_{ex}}{\rightleftharpoons} Ga(O_8Q)_{3,\ org} + 3H^+ \qquad (1)$$
The extraction constant K_{ex} is expressed by Eq. (2):
$$K_{ex} = \frac{[Ga(O_8Q)_3]_{org}[H^-]^3}{[Ga^{3+}][HO_8Q]_{org}^3} \qquad (2)$$

Under the acidic experimental conditions, the predominant species of gallium(III) in an aqueous phase is $Ga(H_2O)_6^{3+}$ and negligibly small amounts of $Ga(OH)(H_2O)_5^{2-}$ and $Ga(OH)_2(H_2O)_4^+$ occur. The fraction of the hydrolyzed species of gallium(III) was calculated using the following reported hydrolysis constants: $K_{h1} = 8.91 \times 10^{-4}$ ($K_{h1} = [Ga(OH)(H_2O)_5^{2+}][H^+]/[Ga(H_2O)_6^{2+}]$), $K_{h2} = 2.51 \times 10^{-7}$ ($K_{h2} = [Ga(OH)_2(H_2O)_4^+[H^+]^2/[Ga(H_2O)_6^{3+}]$) at $I = 0.1$ M and 25°C. The presence of dinuclear species can be neglected in lower gallium(III) concentration (1.08×10^{-4} M) [13]. For the calculation of the equilibrium constants, the hydrogen ion concentration was determined by using the measured pH value ($= -\log A_{H^+}$) and the activity coefficient ($\gamma = 0.83$) of the hydrogen ion at $= 0.1$ M.

If the concentrations of Ga(III)-HO_8Q complexes such as $Ga(O_8Q)_3$, $Ga(O_8Q)_2(H_2O)_2^+$, and $Ga(O_8Q)(H_2O)_4^{2+}$ in the aqueous phase are negligibly low compared with that of gallium(III), the distribution ratio of gallium(III) is represented by equation (3):

$$D = \frac{[Ga(O_8Q)_3]_{org}}{[Ga^{3+}](1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2})} \qquad (3)$$

From Eqs. (2) and (3), Eq. (4) is derived.

$$\log D + \log(1 + K_{h1}[H^-]^{-1} + K_{h2}[H^+]^{-2})$$
$$= -3 \log[H^+] + 3 \log[HO_8Q]_{org} + \log K_{ex} \qquad (4)$$

Based on calculations using literature, pK_{a1}, pK_{a2} and the distribution constant of HO_8Q between heptane and an aqueous solution at pH 1–2, the equilibrium HO_8Q concentration in an aqueous phase is negligibly low [14]. Therefore, the HO_8Q concentration in the organic phase is approximately equal to the initial HO_8Q concentration.

The plots of $\log D + \log(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2}) + 3 \log[H^+]$ versus $\log[HO_8Q]_{org}$ provided a straight line with a slope of 3.2. This indicates that three molecules of HO_8Q are participating in the extraction of gallium(III).

The relationship between $\log D + \log(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2}) - 3 \log[HO_8Q]_{org}$ and $-\log[H^+]$ gave a straight line with a slope of 2.9, implying that the extraction reaction accompanies the release of three hydrogen ions from HO_8Q molecules into the aqueous phase during the extraction reaction.

From these results, it was concluded that the molar ratio of gallium(III) to HO_8Q in the extracted Ga(III)-HO_8Q complex is 1:3 ($Ga(O_8Q)_3$). The log K_{ex} value was determined to be 3.21 ± 0.12 at $I = 0.1$ M and 25°C (Table 1). It was also ascertained that the extractability of gallium(III) with HO_8Q was independent of the chloride ion concentration (0.01–0.1 M) at $I = 0.1$ M(H, Na)(Cl, ClO_4).

3.2. Extraction of Ga(III) with HMO_8Q, HMO_6Q and $HNBO_6Q$ from perchloric acid and hydrochloric acid medium

The extraction equilibrium of gallium(III) (1.0×10^{-4} M) with HMO_8Q (1.0×10^{-2} M) at pH 1.1 was achieved by shaking for 50 h. The extracted Ga(III)-HMO_8Q complex is a mononuclear species as in the Ga(III)-HO_8Q case, as determined by the independence of the distribution ratio on the gallium(III) concentration (2.02×10^{-5}–1.01×10^{-3} M). The plots of log D versus $\log[HMO_8Q]_{org}$ at pH 3.1 gave a straight line with a slope of 2.2 (Fig. 2), suggesting that two molecules of HMO_8Q are included in the extracted gallium(III) complex. As mentioned above, three molecules of HO_8Q are included in the extracted gallium(III) complex. This difference may be ascribed to the steric hindrance of the methyl group at the 2-position of 8-quinolinol moiety. The steric hindrance of methyl group prevents the third molecule of HMO_8Q from coordinating to gallium(III). If the extracted Ga(III)-HMO_8Q complex is assumed to be $Ga(OH)(H_2O)(MO_8Q)_2$, the extraction equilibrium is represented by Eq. (5):

$$Ga^{3+} + 2HMO_8Q_{org}$$
$$+ 2H_2O \overset{K_{ex}}{\rightleftharpoons} Ga(OH)(H_2O)(MO_8Q)_{2, org} + 3H^+$$
$$(5)$$

Table 1
Extraction constants of Ga(III) with 8-quinolinol derivatives in the acidic region

Extractant	log K_{ex}	Extracted complex	Solvent
HO$_8$Q	3.21 ± 0.12[a] (0.1 M (H, Na)ClO$_4$)	Ga(O$_x$Q)$_3$	Heptane
HMO$_8$Q	−4.24 ± 0.16[a] (0.1 M (H, Na)ClO$_4$)	Ga(OH)(H$_2$O)(MO$_8$Q)$_2$	Heptane
	1.30 ± 0.02[a] (0.5 M (H, Na)Cl)	Ga(Cl)(H$_2$O)(MO$_8$Q)$_2$	Heptane
HMO$_6$Q	−3.84 0.16[a] (0.1 M (H, Na)ClO$_4$)	Ga(OH)(H$_2$O)(MO$_6$Q)$_2$	Heptane

[a] This work.
[b] From Ref. [1].
[c] From Ref. [16].
[d] 7-(1-vinyl-3,3,5,5,-tetramethylhexyl)-8-quinolinol

The extraction constant K_{ex} is represented as follows:

$$K_{ex} = \frac{[Ga(OH)(H_2O)(MO_8Q)_2]_{org}\,[H^+]^3}{[Ga^{3+}][HMO_8Q]_{org}^2} \quad (6)$$

As discussed above, under the experimental conditions (pH 2.2–3.1), gallium(III) exists as

Fig. 2. Effects of the extractant (HA) concentration in heptane on the distribution ratio of Ga(III). Ga(III) 1.43 × 10^{-5} M; ■, HMO$_8$Q (−log[H$^+$] = 3.0); ●, MO$_6$Q (−log[H$^+$] = 2.9); ○, HNBO$_6$Q (−log[H$^+$] = 2.8).

Ga(H$_2$O)$_6^{3+}$, Ga(OH)(H$_2$O)$_5^{2+}$ and Ga(OH)$_2$(H$_2$O)$_4^+$ in an aqueous solution. Accordingly, the distribution ratio of gallium(III), D is shown by Eq. (7):

$$D = \frac{[Ga(OH)(H_2O)(MO_8Q)_2]_{org}}{[Ga^{3+}](1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2})} \quad (7)$$
From eqs. (6) and (7), the following equation is derived:

Fig. 3. Effects of the hydrogen ion concentration on the distribution ratio of Ga(III) with 0.01 M HMO$_8$Q and HMO$_6$Q in heptane. Ga(III): 1.43 × 10^{-5} M.

$$\log D + \log(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2})$$

$$= -3\log[H^+] + 2\log[HMO_8Q]_{org} + \log K_{ex} \quad (8)$$

As shown in Fig. 3, the plots of $\log D + \log(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2})$ versus $-\log[H^+]$ gave a straight line with the slope of 2.9. The result was consistent with the above assumption that three hydrogen ions participate in the gallium(III) extraction. The same results were obtained for the extraction of gallium(III) with HMO_6Q and $HNBO_6Q$. However, gallium(III) was not extracted with $HTBO_6Q$ at all. The $\log K_{ex}$ values of -4.24 ± 0.16 (HMO_8Q), -3.84 ± 0.16 (HMO_6Q), and -4.07 ± 0.07 ($HNBO_6Q$) were obtained at $I = 0.1$ M and 25°C (Table 1).

As mentioned above, the extractability of HO_8Q toward gallium(III) was independent of the chloride ion concentration. However, since the extraction of gallium(III) with HMO_8Q takes place at lower pH region in the presence of chloride ion than in the absence of chloride ion, the composition of the $Ga(III)-HMO_8Q$ complex extracted in the presence of chloride ion was studied. The independence of the distribution ratio of gallium(III) ion concentration suggests the extraction of the mononuclear gallium(III) complex. If we assume $Ga(Cl)(H_2O)(MO_8Q)_2$ as the extracted species, the extraction reaction can be shown by equation (9):

$$Ga^{3+} + 2HMO_8Q_{org}$$

$$+ Cl^- \overset{K_{ex}}{\rightleftharpoons} Ga(Cl)(H_2O)(MO_8Q)_{2org} + 2H^+ \quad (9)$$

Eq. (10) represents the extraction constant.

$$K_{ex} = \frac{D(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2} + \beta_1[Cl^-])}{[H^+]^2 \quad [HMO_8Q]_{org}^2 [Cl^-]} \quad (10)$$

where β_1 is the formation constant of $GaCl^{2+}$ ($\beta_1 = 10^{-2}$ at 20°C) [15]. At constant hydrogen ion and chloride ion concentrations, the plots of $\log D$ versus $\log[HMO_8Q]_{org}$ are expected to give a straight line with a slope of two. The plots of $\log D$ versus $\log[HMO_8Q]_{org}$ gave a straight line with a slope of 2.0 and the relationship between $\log D + \log(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2} + \beta_1[Cl^-])$ and $-\log[H^+]$ yielded a straight line with a slope

Fig. 4. Effect of chloride ion concentration on the distribution ratio of 1.43×10^{-5} M Ga(III) with 0.01 M HMO_8Q. $-\log[H^+] = 2.0$; $I = 0.1$ M (H, Na)(ClO$_4$, Cl).

of 2.0. As shown in Fig. 4, we found a linear relationship with a slope of 0.9 between $\log D + \log(1 + K_{h1}[H^+]^{-1} + K_{h2}[H^+]^{-2} + \beta_1[Cl^-])$ and $\log[Cl^-]$, indicating that one chloride ion was included in the gallium(III) complex in the course of the gallium(III) extraction.

These results support the above assumption that the extracted species should be $Ga(Cl)(H_2O)(MO_8Q)_2$. The K_{ex} value was $10^{1.30 \pm 0.02}$ at $I = 0.1$ M and 25°C (Table 1). The larger extraction constant for $Ga(Cl)(H_2O)(MO_8Q)_2$ than that for $Ga(OH)(H_2O)(MO_8Q)_2$ can be ascribed to the higher hydrophobicity of Cl^- than that of OH^-.

The structures of the extracted Ga(III)-8-quinolinol [1], $Ga(III)-HO_8Q$ and Ga(III)-Kelex 100 [16] complexes are expected to show octahedal coordination. $Ga(III)-Cl-HMO_8Q$ and $Ga(III)-OH-HMO_8Q$ (HMO_6Q, $HNBO_6Q$) complexes extracted into heptane may have a octahedral configuration, although the five coordinated structure cannot be ruled out since 2-methyl-8-quinolinol (HMQ) exhibits a five coordinated $Ga(Cl)(MQ)_2$ in solid. This structure was crystallographically characterized [17].

The facts that Ga(III) is extracted with Kelex 100 and HO_8Q as 1:3 Ga(III) complexes indicates that the steric hindrance of bulky alkyl group at the 7-position in 8-quinolinol moiety is not essential. On the other hand, the steric hindrance of alkyl group at the 2-position of HMO_8Q should be critical for small metal ions such as gallium(III).

Table 2
The distribution ratio (D) of Ga(III) in the presence of Al(III)

HA	[Al(III)]/[Ga(III)]	D	
		Al(III)	Ga(III)
HO$_6$Q	1	3.6×10^{-1}	2.5×10^2
	10	3.3×10^{-2}	2.5×10^2
	100	3.4×10^{-2}	1.0×10^3
HMO$_6$Q	1	3.0×10^{-2}	2.6
	10	3.8×10^{-3}	3.5
	100	1.0×10^{-4}	4.0
HNBO$_6$Q	1	4.6×10^{-2}	2.0×10^2
	10	5.5×10^{-3}	5.0×10^2
	100	1.4×10^{-3}	1.0×10^3

[Ga(III)] = 1.43×10^{-5} M; [HA]$_{org}$ = 0.01 M; pH = 2.84–2.99.

3.3. Separation of gallium(III) from aluminum(III)

Table 2 shows the distribution ratio of gallium(III) (1.43×10^{-5} M) and aluminum(III) (1.43×10^{-5}–1.43×10^{-3} M) with HO$_6$Q, HMO$_6$Q and HNBO$_6$Q (0.01 M) at pH 2.84–2.99. The distribution ratio of gallium(III) with HO$_6$Q in the presence of aluminum(III) (1.43×10^{-5} M–1.43×10^{-3} M) was more than 2.0×10^2. On the other hand, the distribution ratio of aluminum(III) was about 3.7×10^{-1} in the solution containing equal amounts of gallium(III) and aluminum(III). In the case of 10–100 fold excess of aluminum(III) to gallium(III), the distribution ratio of aluminum(III) was approximately 1.0×10^{-3}. Based on these results, HO$_6$Q seems not to be a highly selective extractant toward gallium(III). Although the distribution ratio of aluminum(III) with HMO$_6$Q was lower than that with HO$_6$Q, gallium(III) was not completely extracted. HNBO$_6$Q exhibited very high selectivity for gallium(III) in the presence of large amounts of aluminum(III). The distribution ratio of alumium(III) decreased with increasing aluminum(III) concentrations. The bulkiness of the alkyl group at the 2-position of hydrophobic 8-quinoli-

nol derivatives may play an important role in the selective separation of gallium(III) from aluminum(III). HNBO$_6$Q can be powerful extractants for practical use in analytical chemistry and hydrometalurgy due to the high selectivity and low solubility of these compounds in acidic aqueous solutions.

Application of partial least-squares regression to the resolution of highly correlated spectra. Simultaneous spectrofluorimetric determination of Al^{3+}, Ga^{3+} and In^{3+}

M. Blanco*, J. Coello, F. González, H. Iturriaga, S. Maspoch, A.R. Puigdomènech

Departament de Química, Unitat de Química Analítica, Universitat Autònoma de Barcelona, E-08193 Bellaterra, Barcelona, Spain

Abstract

The simultaneous spectrofluorimetric determination of mixtures of aluminium, gallium and indium as their 8-hydroxyquinoline complexes following extraction into chloroform is studied. The high collinearity of the spectra hindered their resolution by multiple linear regression (MLR) methodology; therefore, experimental data were processed by partial least-squares regression (PLSR) methodology. A previous step in the study of three-dimensional fluorescence spectrum is possible to select the best information to quantify this system with high collinearity. Finally the optimal conditions for quantitation, the best data preprocessing procedure and the most suitable spectral mode for calibration were established. Using an external set allowed the three analytes to be determined simultaneously at concentrations below 1 μg ml^{-1} with errors less than 10% for aluminium and indium, and 15% for gallium.

1. Introduction

Spectrofluorimetry is a highly useful interesting analytical technique on account of its increased sensitivity and selectivity. The development of fairly selective spectrofluorimetric methods is facilitated by the fact that only a small fraction of chemical species is naturally fluorescent, and by their discriminating capabilities, which afford appropriate selection of the excitation and/or emission wavelength. In the presence of several fluorescent analytes, wavelength selection is constrained by the width of both the absorption and emission bands; this restricts the number of available specific wavelengths for each analyte.

This severe constraint on mixture resolution has been addressed in various ways including the use of synchronous fluorescence spectra and derivative spectra (of both the fluorescence and the synchronous type [1,2]), which decrease bandwidth and hence increase selectivity. The excitation, emission and synchronous paths, in combination with differentiation techniques [3], and the use of a combination of excitation and

* Corresponding author.

emission spectra by partial least squares [4], are also used for the multivariate resolution of mixtures. Phase-resolved [5] and time-resolved spectrofluorimetry [6], which rely on differences in the fluorescence lifetime between mixture components, are effective in many cases but entail using sophisticated, expensive equipment.

Greater information can be obtained from a three-dimensional spectrum where fluorescence intensities are a function of both the excitation and the emission wavelength [7,8]. Three-dimensional spectra can be used to draw a contour map with the excitation and emission wavelengths represented on two axes and contour lines connecting points of identical fluorescence intensity. The selectivity can be increased by using from the fluorescence intensities three-dimensional matrix a vector of fluorescence intensities corresponding to excitation and emission wavelengths pairs. The selection of the different vectors to assay mixture quantitation has been made by visual inspection of the contour maps of the three complexes, selecting those with the bigger differentiation.

The growing use of computers in the laboratory has fostered the development and application of mathematical algorithms for processing the vast amounts of information provided by modern analytical instruments. Multivariate calibration techniques improve on the selectivity of analytical methods and avoid the need for preliminary separations in many instances [8–10].

In this work, the potential use of the fluorescence three-dimensional matrix information in combination with linear partial least-squares regression for the resolution of ternary mixtures of species with highly correlated absorption and emission spectra was assessed. The application is demonstrated with the oxinates of aluminium, galium and indium in chloroform (oxine or 8-hydroxyquinoline is a widely used extractant for the determination of metal ions [11] which forms complexes that are both fluorescent and UV-absorbing). Resolutions of binary mixtures of the above-mentioned metals [1,8] have been reported; while using multiple linear regression poses few problems—not even with strongly overlapped spectra—tertiary mixtures result in serious errors.

2. Experimental

2.1. Reagents

A 0.01 M 8-hydroxyquinoline solution (Merck) was prepared in water-saturated chloroform (Fluka). A 1 M acetic acid/sodium acetate buffer was also used. Stock analyte solutions of Al^{3+}, Ga^{3+} and In^{3+} containing 1 g l of each ion (Merck) were made in 1 M HCl in order to avoid hydrolysis of the metal ions. The solutions were standardized by back titration with ethylenediaminetetraacetic acid (EDTA) and Zn(II) using Eriochrome Black-T as indicator. Working-strength solutions were obtained from the stocks by appropriate dilution with double-distilled water.

2.2. Apparatus

Spectrofluorimetric measurements were made on a Perkin-Elmer LS 50 instrument furnished with a xenon flash tube, Monk-Gillieson monochromators and 10×10 mm quartz cells. The instrument was connected to an Epson PC AX-2 computer via an RS232-C interface. Its bundled software allows instrumental control, parameter selection, and recording and processing of spectra. All fluorescence measurements were made at a scan rate of 200 nm min^{-1} and 0.5 nm resolution by using excitation and emission windows of 15 and 10 nm, respectively. All spectra were averaged in groups of three as they were recorded.

A Cenco rotary agitator and a Radiometer 29 pH meter furnished with an Ingold U 455-57 glass electrode were also used.

2.3. Software

Experimental data were processed with FL Data Manager® (FLDM), a software package designed for instrumental control and handling of fluorescence spectra recorded on Perkin-Elmer spectrofluorimeters.

Contour plots were constructed with the program SigmaPlot v. 2.0, from Jandel Corp. (Erkrath, Germany). Partial least-squares regres-

sion (PLSR) calibration was done with Unscrambler v. 3.54, from Camo (Norway).

A multicomponent analysis program (MC) developed by the authors in Microsoft QuickBasic v. 4.5 was used for multiple linear regression (MLR) of the sample spectrum on those for the pure components. The program calculated the concentration of the mixture components and their confidence intervals, and also provided information about the regression quality from an analysis of the residuals between real and calculated spectra.

Derivative spectra were obtained with the program FDSG, also developed by the authors, which uses the Savitsky–Golay algorithm and allows the user to chose window size (from 3 to 21 points) and the resolution with which the spectra to be derived are input (0.5–4 nm at 0.5 nm intervals).

In order to compare the quality of the results obtained with the different calibration models used, the relative standard deviations for the error of prediction (RSEP) for each analyte in the sample set were calculated.

$$RSEP(\%) = \sqrt{\frac{\sum\limits_{1}^{n} (c_{found} - c_{added})^2}{\sum\limits_{1}^{n} c_{added}^2}}$$

where c_{found} is the concentration calculated, c_{added} is the concentration present in the mixture and n is the number of samples.

2.4. Extraction and recording of spectra for the metal–oxine complexes

The optimum conditions for extraction of the metal oxinates were determined by using aluminum solutions. The conditions thus established were also used for the other two ions.

The extraction tubes were loaded with 5 ml of a slightly acid solution containing one or more of the metal ions and 10 ml of oxine in chloroform, and placed in a rotary agitator at 50 rev min^{-1} for 10 min. Then, 5 ml of the buffer solution at pH 4.7 was added and further agitation was applied for 10 min. The extraction tubes were next centrifuged at 2000 rev min^{-1} for 5 min and

allowed to stand at about 25°C for 10 min in order to equilibrate both phases. Finally, the phases were separated and the spectrum for the organic one was recorded against a blank prepared using the same procedure.

Standard spectra were recorded for five solutions of each metal ion. The above-described procedure was employed to extract the complexes with oxine. Oxinate spectra were recorded in triplicate. The UV absorption spectra for the previous solutions were standardized and then averaged at a concentration of 3, 8 and 12 μg ml^{-1} for aluminium, gallium and indium, respectively (Fig. 1) so as to obtain a maximum value of absorption as similar as possible for the three complexes. Standard fluorescence spectra were recorded similarly; however, they were stadardized at 12.5 ng ml^{-1} for aluminium, 0.1 μg ml^{-1} for gallium and 0.25 μg ml^{-1} for Indium (Fig. 2) in order to obtain as similar as possible fluorescence spectra. These standard spectra were used for multiple linear regression calculations. Single (rather than triplicate) mixed spectra for the metal ions were recorded by using the same procedure.

Fig. 1. UV absorption spectra of aluminium (3 μg ml^{-1}), gallium (8 μg ml^{-1}) and indium (12 μg ml^{-1}) oxinates at the wavelength range 300–430 nm.
Fig. 2. Standard fluorescence spectra of aluminium (12.5 ng ml^{-1}), gallium (0.1 $\mu g\ ml^{-1}$) and indium (0.25 $\mu g\ ml^{-1}$) oxinates obtained at $\lambda_{ex} = 394$ and λ_{em} from 470 to 590 nm.

3. Results and discussion

3.1. Multiple linear regression

3.1.1. UV absorption spectra

In previous work we studied the simultaneous spectrophotometric determination of aluminium, iron, copper, titanium and nickel in binary, ternary and quaternary mixtures by extracting their oxine complexes into chloroform and using MLR [12] for calibration. Application of the same procedure to mixtures of aluminium, gallium and indium provided the results given in Table 1. As can be seen, binary mixtures were resolved with good precision; however, ternary mixtures could not be resolved at all (quantitation errors exceeded 100% for indium). This can be ascribed to the highly overlapped and virtually identical profile of the absorption spectra for the three complexes (Fig. 1), with the absorption maximum at 390, 394 and 398 nm for aluminium, gallium and indium, respectively. Such strong overlap resulted in high spectral collinearity, which is one of the constraints to MLR application [13]. The

2.5. Contour map

The contour map was drawn from solutions of the metal complexes prepared by applying the above-described procedure to three solutions containing 80 ng ml^{-1} Al^{3+}, 0.59 $\mu g\ ml^{-1}$ Ga^{3+} and 1.92 $\mu g\ ml^{-1}$ In^{3+}. Their emission spectra were recorded between 440 and 620 nm at excitation wavelengths over the range 350–450 nm at 4 nm intervals. The emission spectra obtained at the different excitation wavelengths were used to construct an excitation–emission matrix for each ion, from which the contour map was obtained with the aid of the program SigmaPlot v. 2.0. Fig. 3 shows the contour map for the aluminium oxinate, with its fluorescence maximum at $\lambda_{ex} = 394$ nm and $\lambda_{em} = 508$ nm. The contour maps for the other two ions were very similar with the same λ_{ex} and only differed appreciably in the position of the emission maximum (508, 522 and 531.5 nm for the aluminium, gallium and indium complex, respectively).

Fig. 3. Fluorescence contour map of aluminium oxinate and the fluorescence maximums of aluminium, gallium and indium oxinates.

Table 1

Quantitation of aluminium, gallium and indium in mixtures by MLR from absorbance or first-derivative spectra recorded over the range 390–430 nm, and fluorescence spectra obtained at $\lambda_{ex} = 390$ and λ_{em} from 470 to 590 nm

| Mixture | n | Concentration ranges (mg l⁻¹) | | | RSEP (%) | | | | | |

n, number of samples.

spectral correlation coefficient is one measure of spectral collinearity; as can be seen in Table 2, the coefficient for our absorption spectra was always greater than 0.99. From the results in Table 1 it follows that RSEP values for the first-derivative spectra were much poorer because derivation raised the spectral resolution but also decreased signals and increased spectral noise.

3.1.2. Fluorescence spectra

The lower collinearity between fluorescence spectra (Table 2), with emission maxima at 508, 522 and 531 for aluminium, gallium and indium, respectively (Fig. 2), encouraged us to attempt their resolution by MLR from standard spectra for pure solutions of each metal ion by using the wavelength of maximum absorption for the aluminium complex as the excitation wavelength for the three ions.

Table 2

Correlation coefficients for spectra

	Al–Ga	Al–In	Ga–In
Absorbance[a]	0.9973	0.9905	0.9979
Fluorescence[b]	0.9895	0.9877	0.9998
Fluorescence[c]	0.9598	0.9372	0.9973

[a] Wavelength range 390–430 nm.
[b] $\lambda_{ex} = 390$ nm; $\lambda_{em} = 470$–590 nm.
[c] $\lambda_{ex} = 394$ nm; $\lambda_{em} = 470$–590 nm.

An overall 26 solutions containing the three metal ions at concentrations over the previous ranges were prepared and quantified from their emission and first-derivative spectra. Table 1 shows the prediction errors obtained. As can be seen, RSEP values were much lower than those resulting from the absorbance spectrum but were still too high for gallium and indium. Such errors were even higher for first-derivative spectra as the likely result of the increased spectral noise (Fig. 4). In order to minimize the effect of noise on the quantitation, spectra were derived by using the Savitsky–Golay algorithm as implemented in the program FDSG, with optimization of both the number of points included in the window and the resolution with which the spectra to be derived were input. Very large window sizes resulted in exceedingly diminished signals and the loss of spectral information. The best signal-to-noise ratio for the intended purpose was obtained with a 7-point window and 2 nm resolution; even so, the errors were too large.

The high collinearity between the emission spectra hindered resolution of the mixtures; this prompted us to explore the potential use of the fluorescence three-dimensional matrix information in combination with MLR [8] in order to select a wavelength set with a lower correlation that might improve on the previous results. The excitation–
Fig. 4. Non-smoothed first-derivative fluorescence spectra of standard fluorescence spectra showed at Fig. 2.

emission matrix contained abundant information (9000 fluorescence data points for each sample), which allowed a subset of excitation-emission wavelength pairs to be selected for calibration and sample quantitation. Such points formed vectors in the contour plot that was chosen in such a way as to maximize the differences between the analytes. The following vectors were tested (Fig. 4).

(a) Recording the emission spectrum from 450 to 600 nm using $\lambda_{ex} = 394$ nm.

(b) Recording the excitation spectrum from 360 to 430 nm using the maximum emission wavelength for each complex as its λ_{em}.

(c) Recording the fluorescence intensity at various excitation-emission wavelength pairs over the ranges 360-430 nm (λ_{ex}) and 450-600 nm (λ_{em}) conforming to the equations $\lambda_{em} = 1.8 \ \lambda_{ex}$ and $\lambda_{em} = -1.25 \ \lambda_{em} + 995$.

(d) Combinations of the previous three.

The best quantitation results (maximum discrimination between the three analytes) were obtained with the model defined by the vector including $\lambda_{ex} = 394$ nm and λ_{em} between 450 and 600 nm. However, as can be seen from Table 1, the results were not significantly better: while lower, spectral collinearity was still too high—especially between the gallium and indium spectra (Table 2).

The fluorescence spectra obtained under these conditions were used in all the subsequent calculations.

3.2. Partial least-squares regression

Since none of the vectors tested decreased spectral collinearity for the system studied to an appreciable extent—prediction errors were thus relatively high—, we assayed PLSR calibration, which minimizes collinearity between the variables and is less markedly affected by noise [13].

3.2.1. Construction of the calibration matrix

The fluorescence spectra for 40 binary and ternary mixtures of the three metal ions at concentrations over the ranges 0-83 ng ml^{-1} aluminium, 0-0.30 μg ml^{-1} gallium and 0-0.76 μg ml^{-1} indium were recorded. Of the 40 mixtures, 24 were used to construct the calibration matrix and 16 as the external validation set to determine the predictive capacity of the method.

One key to the correct performance of PLSR is an appropriate choice of the number of principal components, which should account as much as possible for the experimental data without resulting in overfitting [13]. There are various recommended criteria for selecting the optimum number of principal components [14]. We used the cross-validation method and as many cancellation groups as objects were included in the calibration matrix, as well as the number of principal components minimizing the validation variance as the optimum number of principal components.

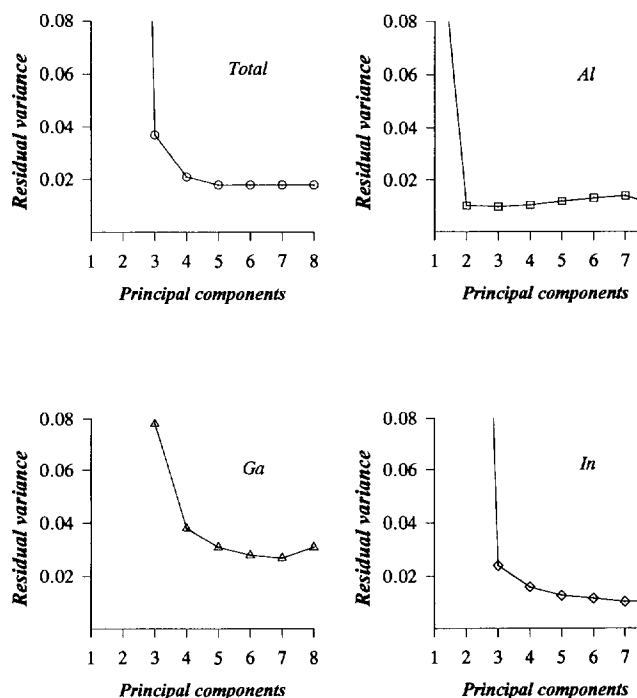
A preliminary model was constructed from fluorescence data for the previous samples over the wavelength range studied (450-600 nm). Then, the output parameters provided by the software were used to determine the objects and variables that were either outliers or contributed no significant information to the model. Such objects and variables were discarded and a calibration matrix consisting of 21 mixtures (three objects were removed to be detected like outliers, and data were recorded at 2 nm intervals over the wavelength range 470-550 nm) was constructed.


Fig. 5. Overall residual validation variance (total and for each ion) calculated with PLS2.

We assessed two data pretreatment procedures (mean-centring and autoscaling), and two PLSR calibration modes, namely PLS2, which uses all the analytes to be determined, and PLS1, which constructs the calibration model for each of the analytes. All these variants were implemented in two spectral modes: fluorescence and first derivative. The model with the maximum predictive capacity was determined from the overall error of prediction for each analyte in the validation samples.

A plot of the residual validation variance for each analyte and the overall residual validation variance against the number of principal components (Fig. 5) revealed the minimum value for the latter—the criterion used to determine the number of PCs to be included in the model—to be provided by five PCs with PLS2. On the other hand, the PLS1 calibration mode led to a different number of PCs for each ion (three for aluminium and seven for gallium and indium), also shown in Fig. 5. However, the predictive capacity was similar for the two modes.

Table 3 shows the prediction errors obtained for each analyte by applying the four models to the 16 external validation samples. The highest predictive value was that of the PLS2 model with autoscaled fluorescence intensity data (the RSEP was 7% for aluminium and indium and 15% for gallium). The errors for the three ions were substantially lower relative to the previous treatments.

The errors obtained for the three analytes with first-derivative spectra were greater than the previous ones—particularly those for gallium and in-

dium—since derivation increased spectral resolution but diminished signals, decreased the sensitivity to gallium and indium relative to aluminium, and increased noise.

In order to better illustrate the quality of the results obtained and the real significance of the RSEP values given in the previous tables, Table 4 shows the individual results for the 16 samples included in the external validation set. As can be seen, the resolution quality was highly satisfactory for all the mixtures.

4. Conclusion

Spectral collinearity is a major constraint to the simultaneous quantitation of several analytes using a multivariate calibration technique. The large amount of information supplied by spectrofluorimetry, which encompasses a three-dimensional space composed of λ_{ex}, λ_{em} and fluorescence intensity, allows an appropriate data

set to be used to reduce collinearity. Even so, high collinearity can prevent correct resolution of a mixture (e.g. the proposed mixture) by multiple linear regression. In such an event, applying partial least-squares regression to data for the best of several high correlated vectors can minimize collinearity problems and enable correct resolution of the mixtures. In this respect, we should emphasize the good resolution achieved for the mixture studied in this work despite the low concentration levels involved.

## Abstract

Considerable disparity exists in the published thermodynamic data for selected species in the $Ca^{2+}/CO_2/H_2O$ system near 25°C and 1 atm pressure. Some authors doubt the significance of $CaCO_3^0(aq)$ complexes although there is experimental evidence of their occurrence. Evaluation of all the published experimental and estimated data for aqueous calcium carbonate species confirms that the consistent set of constants given by Plummer and Busenberg in 1982 is the best available, and suggests a formation constant $\log \beta = 3.22$ for $CaCO_3^0(aq)$. This value was confirmed by additional experimental data and calculations using a specially developed computer program. The solubility s and solubility product K_s are critically evaluated for each solid polymorph (amorphous $CaCO_3$, ikaite, vaterite, aragonite and calcite) using a hydrated ion pair model and we give coherent explanations for the calcium carbonate precipitation/dissolution process and the existence of supersaturated waters. The practical cases of scale formation and its inhibition by phosphonate-type compounds are discussed and explained with the same model, taking into account the $CaCO_3^0(aq)$ species.

Keywords: Calcium carbonate; Scale formation; Scale inhibition; Phosphonates

1. Introduction

In a previous paper [1], we presented a model for the precipitation of an insoluble ionic compound MX by the initial formation of a partially hydrated uncharged soluble complex species MX_h^0 whose limiting solubility s depends on its degree of hydration. We can therefore write:
$$M_h^+ + X_h^- \Leftrightarrow MX_h^0 \Leftrightarrow MX\downarrow$$
* Corresponding author. Fax: (33) 67.63.35.96.

$$\beta = |MX_h^0|/|M_h^+||X_h^-| \quad \text{and} \quad K_s = |M_h^+||X_h^-|$$

where $|\ |$ stands for activity. At equilibrium, $|MX_h^0| = s$, therefore $\beta = s/K_s$.

The more hydrated forms are more soluble and give higher K_s values. The more stable crystalline forms are generally those with lower solubility product K_s values, and therefore lower limiting solubility s values.

Since the value for the formation constant β probably does not depend significantly on the

$$M^+_h + X^-_h \iff MX^o_{h\alpha} \iff MX^o_{h\beta}$$
$$\Updownarrow \qquad\qquad \Updownarrow \qquad\qquad \underline{s}\alpha > \underline{s}\beta$$
$$MX_\alpha \qquad\qquad MX_\beta$$

Scheme 1.

hydration degree of the MX^0 species, if we know β and K_s, it is easy to evaluate the value of s according to the simple relationship

$$\log s = \log K_s + \log \beta$$

The value of K_s depends on the experimental method used, precipitation giving higher values than redissolution. This can be easily explained if we assume that the hydrated forms are first produced during precipitation and progressively evolve towards less hydrated forms. The kinetics of such processes are very important because if equilibrium is reached rapidly, the most insoluble compound should precipitate immediately.

When a compound has several different solid forms, it is assumed that these correspond to solutions of different hydrated forms of the same uncharged ion pair complex. It is probably correctly written as Scheme 1.

According to this scheme, it is possible to proceed from MX_α to MX_β by a redissolution–precipitation process since a $MX^0_{h\alpha}$-saturated solution is also saturated in $MX^0_{h\beta}$. This temporary formation of two different compounds makes it difficult to determine the corresponding solubility products.

However, in the case of redissolution of MX_β, MX_α should not precipitate because $s_\alpha > s_\beta$. MX_α supersaturation cannot therefore occur, and

only $K_{s\beta}$ can be determined by a study of MX_β dissolution.

Scheme 1 enables us to understand both why the more soluble forms generally precipitate first, and how, if we do not immediately dry out the first crystals obtained, solid phases can evolve towards the most thermodynamically stable species.

The formation of calcium carbonate scale is a subject of great practical interest because of its consequences for industrial or drinking water supplies. Various solid polymorphs can be obtained by varying temperature and other experimental conditions, and researchers now have a good knowledge of the influence of temperature on calcium carbonate solubility products (Table 1).

In the present paper, we reconsider this well-known calco-carbonic equilibrium for, although a large body of literature exists on this subject, the situation is still somewhat confusing because no clear link has been made between the studies carried out in various fields (explanation of the phenomena in hydrogeology and soil chemistry; tap water treatment and scale formation; acid rain effects; physiological equilibria during breathing or photosynthesis, etc.). We attempt here, in light of a new analysis of its thermodynamic aspects, to explain the calcium carbonate precipitation/redissolution process, focusing on the usefulness of the $\beta = s/K_s$ relationship. We clearly show the importance of the various hydrated forms of the soluble $CaCO^0_3(aq)$ complex on calcium carbonate precipitation, and use them to explain the behaviour of phosphonate-type scale inhibitors.

Table 1
Solubility products for the various forms of calcium carbonate

Form	Structure	$-\log K_s$ (at 25°C)	Temperature law (T in K; t in °C)	Reference
amorphous	–	6.40	$-\log K_s = 6.1987 + 0.005336t + 0.0001096t^2$	21
ikaite	monoclinic	6.62	$-\log K_s = 1696/T + 0.9336$	9
vaterite	hexagonal	7.91	$-\log K_s = +172.1295 + 0.077993T - 3074.688/T - 71.595 \log T$	20
aragonite	orthorhombic	8.34	$-\log K_s = +171.9773 + 0.077993T - 2903.293/T - 71.595 \log T$	20
calcite	rhomboedric	8.48	$-\log K_s = +171.9065 + 0.077993T - 2839.319/T - 71.595 \log T$	20

2. The association constant for the calcium/carbonate ion pair

The existence of the $CaCO_3^0(aq)$ ion pair in solution was first reported by Greenwald [2] in 1941. Based on calcite solubility measurements, he gave the value $\log \beta = 3.0$ for the $CaCO_3^0(aq)$ formation constant at 25°C. In 1960, Garrels et al. [3] used this ion pair concept for calcium carbonate solubility in seawater, but in 1961 these same authors [4] privileged the part of $MgCO_3^0$ and of $NaCO_3^-$ in their discussion. Thereafter, even the concept of such a $CaCO_3^0$ species was almost systematically ignored, although one year later they gave [5] the value $\log \beta = 3.2$. However, no recent papers dealing with calcium carbonate dissolution kinetics, and only some concerning scale formation [6–9], take $CaCO_3^0(aq)$ into consideration.

These papers by Garrels and his co-authors [3–5] were poorly interpreted by other researchers, and several unfortunate events have contributed to a failure of the $CaCO_3^0(aq)$ concept. In 1968, Nakayama [10] carried out a series of experiments (whose data will be discussed below) giving $\log \beta = 4.48$, but his work was criticized in 1970 by Lafon [11] who, based on the results of Nakayama [10] and Grezes and Basset [12], gave the value $\log \beta = 3.1$. In 1968, Langmuir [13] had already concluded that Garrels' value was overestimated, and in 1974 criticized [14] Lafon's procedure and minimized the importance of $CaCO_3^0(aq)$ compared to $CaHCO_3^+$. The same year, however, Langmuir contributed significantly to the determination of the formation constants for $CaCO_3^0(aq)$ and $CaHCO_3^+$ between 0°C and 50°C in a second paper [15]. These values (with $\log \beta = 3.20$ at 25°C) are, in fact, in good agreement with those of Garrels et al. [5] and Lafon [11].

In 1976, while Larson [16] proposed a value of $\log \beta = 3.22$ similar to those above, Martynova et al. [17–19] proposed a value, $\log \beta = 4.45$, similar to that of Nakayama, and Avnimelech et al. [6] used $\log \beta = 4.48$ without indicating their source.

In 1982, Plummer and Busenberg [20] published values now used as the reference values between

0°C and 90°C, with $\log \beta = 3.22$ at 25°C. These authors did not limit themselves to computer calculations using calcite redissolution data under various CO_2 partial pressures, but obtained, independently, the formation constants for the $CaCO_3^0$ (aq) and $CaHCO_3^+$ species by measuring the pH at equilibrium in various $K_2CO_3/CaCl_2$ mixtures in the absence of precipitate. Using these values, Brecevic and Nielsen determined the solubility products for the amorphous [21] and hexahydrated (or ikaite) [22] forms of calcium carbonate.

In 1983, the whole subject of formation constants versus temperature for the various (soluble and insoluble) polymorphs of calcium carbonate was studied again by Le Guyader et al. [23,24] who carried out calculations starting from solubility measurements at different pH values, and proposed a value, $\log \beta = 4.31$, again similar to that of Nakayama.

During on-going studies in the field of water treatment, Le Guyader et al. [7] attempted unsuccessfully to improve the classic Legrand–Poirier plots [25], their values being too discordant with those of Plummer and Busenberg. Although the $\beta = s/K_s$ relationship was reported in their first paper [23], it appears that, having used not only calcite redissolution, these authors may have obtained reproducible supersaturated solutions. By choosing $-\log K_s = 8.48$ for their calculations (like Plummer and Busenberg [20]), all experimental errors made in the s measurements are probably found in their β values. It is somewhat surprising that only Le Guyader et al. and Lafon explicitly take into consideration the need to determine a constant solubility value s, if equilibrium is in fact obtained.

If we use Plummer and Busenberg's $\log \beta$ and $\log K_s$ values at 25°C for calcite, the $CaCO_3^0$ (aq) limiting solubility is 5.5×10^{-6} mol L^{-1}. The calcium balance at equilibrium would therefore be only slightly, if ever, affected by the existence of this species.

We will show here that this is not the case, however, in natural systems or in cooling towers or heat exchangers when there is supersaturation. Scale formation kinetics can be better explained if the presence of hydrated $CaCO_3^0$ species in the solution is taken into consideration. It is re-

grettable that such a large body of contradictory results have delayed our knowledge of such an economically important compound whose correct formation constant ($\log \beta = 3.15$ at 25°C) was given as early as 1976 by Smith and Martell [26].

3. Comparison of the various sets of constants

We used the experimental data of Nakayama [10] for numerous long-term calcite redissolution studies under controlled carbon dioxide partial pressures at 25°C. These data include values for CO_2 partial pressure, total dissolved calcium concentration (determined by atomic absorption), pH and pCa, and calculated values for $\log \beta$ and $CaCO_3^0$ concentrations. It is regrettable that Nakayama chose to rely on ion selective electrode data for $pCa = -\log|Ca^{2+}|$, in spite of their imprecision under his experimental conditions. He was immediately criticized for this since only 28 mV corresponds to a ten-fold variation in calcium ion activity. Although it is possible to draw an even curve from the measured pH and total calcium concentration values (which seem to indicate that all solutions are in the same state of equilibrium) the $CaCO_3^0(aq)$ solubilities calculated by Nakayama are not constant. This, we believe, explains his $\log \beta$ values.

Knowing the P_{CO_2} values and the necessary thermodynamic constants, we were able to calculate the total calcium concentrations $[Ca^{2+}]_t$ and pH values. In Figs. 1 and 2 Nakayama's experimental data are compared to our values calculated using data in Table 2 where $\log \beta_1$ is the $CaHCO_3^+$ formation constant and

$$[Ca^{2+}]_t = [Ca^{2+}] + [CaHCO_3^+] + [CaCO_3^0]$$
$$+ [CaOH^+] + [Ca(OH)_2^0]$$

where [ ] stands for concentration. The equilibrium constants for carbon dioxide solubility and acidities are those used by Plummer and Busenberg [20]. For $CaOH^+$ we used $\log \beta = 1.30$ [27], and for $Ca(OH)_2^0$ we estimated $\log \beta = 0.12$ from thermodynamic data and retained $-\log K_s = 5.19$ [26]. Activity coefficients were calculated according to Davies [28].

Fig. 1. Total calcium concentration (10^{-3} mol L^{-1}) versus pH: comparison of Nakayama's experimental results [10] □ and values calculated using constants taken from ▼, Smith and Martell [26]; ■, Lafon [11]; ○, Avnimelech and Raveh [6]; ▲, Nakayama [10]; △, Martynova et al. [17–19]; and ▨, Reardon and Langmuir [15].

The best agreement was obtained with the sets of constants from Plummer and Busenberg [20] and Le Guyader et al. [23]. This seems to validate previous studies minimizing the effect of $CaCO_3^0$ formation on calcocarbonic equilibria. Plummer and Busenberg's data give a $CaCO_3^0(aq)$ limiting solubility $s = 5.5 \times 10^{-6}$ mol L^{-1}, and those of Le Guyader et al. give $s = 6.8 \times 10^{-5}$ mol L^{-1}. This gives a more than ten-fold variation, without any modification of the total calcium solubility value, as calculated at the calcite solubility equilibrium. Solubility data alone therefore do not

Fig. 2. Total calcium concentration (10^{-3} mol L^{-1}) versus pH; comparison of Nakayama's experimental results [10] □ and values calculated using constants taken from ▨, Le Guyader et al. [23] and ●, Plummer and Busenberg [20].

Le Guyader et al. [23]	8.48	1.14	4.31	4.17

enable us to choose the best CaCO$_3^0$(aq) formation constant.
4. Supersaturated solutions

Because of its economical importance, calcium carbonate precipitation has been the subject of many studies. Heterogeneous reaction causes scaling on walls, notably of heating or cooling exchangers. Homogeneous kinetics involve precipitation in the bulk solution and have recently been better explained. By studying supersaturated solutions at various temperatures, sometimes with added inhibitors, Sawada [8], and more recently Clarkson [9], demonstrated that the ionic activity product

$$IAP = |Ca^{2+}||CO_3^{2-}|$$

remains stable for a certain length of time (which depends on temperature), equalling successively the solubility products of the amor-

phous, vaterite, aragonite and, finally, calcite forms. This clearly indicates that calcite formation involves the temorary formation of all of the other, more soluble, forms of calcium carbonate. This can be presented by Scheme 2 to which we have added, according to Clarkson [9], the hexahydrate CaCO$_3$·6H$_2$O, which is only obtained at low temperature or in the presence of inhibitors, and was characterized only recently in natural systems (in 1963 by Pauly [29] who named it ikaite, i.e. "from the Ika fjord").
If we assume that $\log \beta$ at a given temperature is similar for all hydrated calcium carbonate species, it is possible to estimate the total CaCO$_3^0$(aq) concentration, depending on the nature of the polymorph at equilibrium. Values were calculated (Table 3) using $\log \beta$ data given by both Plummer and Busenberg [20] (3.22) and Le Guyader et al. [23] (4.31). It is clear that Le Guyader et al. overestimated the CaCO$_3^0$(aq) limiting solubility. Since the total calcium con-

$$Ca^{2+} + CO_3^{2-} \Leftrightarrow CaCO_3{}^0{}_{h\alpha}$$

or (according to the pH)

$$Ca^{2+} + HCO_3^- + H_2O \Leftrightarrow CaCO_3{}^0{}_{h\alpha} + H_3O^+$$

and hereafter

$$CaCO_3{}^0{}_{h\alpha} \Leftrightarrow CaCO_3{}^0{}_{h\beta} \Leftrightarrow CaCO_3{}^0{}_{h\gamma} \Leftrightarrow CaCO_3{}^0{}_{h\delta} \Leftrightarrow CaCO_3{}^0{}_{h\epsilon}$$

$$\Updownarrow \qquad \Updownarrow \qquad \Updownarrow \qquad \Updownarrow \qquad \Updownarrow$$

CaCO$_3$(amorphous)	(ikaite)	(vaterite)	(aragonite)	(calcite)

Table 3

Limiting solubility (in 10^{-3} mol L^{-1}) at 25°C for each CaCO$_3$ polymorph, calculated from the CaCO$_3^0$(aq) formation constants given by Plummer and Busenberg [20], and by Le Guyader et al. [23].

Solid form	Ref. [20]	Ref. [23]
amorphous	0.66	8.13
ikaite	0.40	4.90
vaterite	0.02	0.25
aragonite	0.008	0.093
calcite	0.005	0.068

centration in solution during scale formation is usually about several millimoles per litre, it would not be possible to obtain the calculated values for the well-known transition through the amorphous form. Using the Plummer and Busenberg value, however, we arrive at a plausible CaCO$_3^0$(aq) concentration, which cannot be disregarded, of around one millimole at the beginning of precipitation.

In order to confirm these calculations, we measured the critical precipitation pH, as reported by Venderbosch and Overman [30] according to Feitler [31]. The pH of a sample was measured during continuous, slow addition of a sodium hydroxide solution until saturation was reached and the

solution became cloudy. The pH decreased rapidly during calcium carbonate precipitation and finally stabilized. The maximum pH value is the critical pH (pH$_c$), and the equilibrium value is the saturation pH (pH$_s$). We have developed a computer model that uses analytical data for a water sample to simulate the titration curve and enables us to directly determinate pH$_c$ and pH$_s$ values. We will show in a forthcoming paper that this computer program could be applied to nuclear power plants cooling tower management. It takes into consideration all of the complexes that can be formed, as well as the variations in ionic strength caused by reactions and dilution. Comparison of experimental and calculated titration curves can reveal the presence of a precipitation inhibitor. The software can also predict the pH$_c$ value at any temperature.

In this computer program, we used the Plummer and Busenberg value [20] for the CaCO$_3^0$ (aq) formation constant. In order to validate our choice, we used artificial solutions containing 2×10^{-3} mol L^{-1} NaHCO$_3$, 4×10^{-3} mol L^{-1} CaCl$_2$ and 2×10^{-4} mol L^{-1} HCl. With a Tacussel-Radiometer titration unit 'Titrimax TT100-TT200' equipped with its electroburette EBX-2, we titrated a 100 mL sample with 10^{-2} mol L^{-1} NaOH at a 0.38 mL min^{-1} addition rate. The pH was measured with

Fig. 3. pH variation during the addition of 10^{-2} mol L^{-1} NaOH solution to 100 mL of a solution containing 2×10^{-3} mol L^{-1} NaHCO$_3$, 4×10^{-3} mol L^{-1} CaCl$_2$ and 2×10^{-4} mol L^{-1} HCl. Comparison of experimental and calculated values.
Fig. 4. pH as a function of time during and after the addition of 5×10^{-2} mol L^{-1} NaOH to 100 mL of a solution containing 4×10^{-3} mol L^{-1} NaHCO$_3$, 4×10^{-3} mol L^{-1} CaCl$_2$ and 5×10^{-4} mol L^{-1} HCl, without inhibitor and with 1 ppm ATMP. Total duration of NaOH addition, 15 min. Experimental curves and calculated data. The theoretical precipitation limits for ikaite and amorphous CaCO$_3$ are indicated by arrows.

a Hamilton combination glass electrode of the 'Flushtrode' type, in a thermostated cell at 25°C. The titration curves were simulated with our computer program. Data before precipitation (Fig. 3) gives evidence of a very good correlation between the experimental and simulated curves. When we used the value 4.31 instead of 3.22 for the CaCO$_3^0$ formation constant, there was a pH deviation of ca. 0.75 units.

Plummer and Busenberg's data [20] for the CaCO$_3^0$(aq) and CaHCO$_3^+$ formation constants, respectively

$$\log \beta = -1228.732 - 0.299444T + 35\,512.75/T$$
$$+ 485.818 \log T$$

$$\log \beta_1 = 1209.120 + 0.31294T - 34\,765.05/T$$
$$- 478.782 \log T$$

(where T is the temperature in kelvin) are therefore the most acceptable.

Studies were also carried out with other mixtures, halting NaOH addition when the solution became cloudy. We used artificial solutions containing 4×10^{-3} mol L^{-1} NaHCO$_3$, 4×10^{-3} mol L^{-1} CaCl$_2$ and 5×10^{-4} mol L^{-1} HCl. A 100 mL sample was titrated with 5×10^{-2} mol L^{-1} NaOH

at a 0.33 mL min^{-1} addition rate. Experiments were also done with the addition of 1 ppm (3.3×10^{-6} mol L^{-1}) of aminotris-(methylenephosphonic acid) (ATMP). Fig. 4 shows typical experimental titration curves obtained with and without this scale inhibitor and, for comparison, simulated curves assuming a supersaturated medium. Initial solutions were already supersaturated with respect to vaterite, aragonite and calcite, and the theoretical saturation thresholds for ikaite and amorphous calcium carbonate are indicated on the curves.

At 25°C, there is a divergence between simulated and experimental curves without ATMP inhibitor near the ikaite precipitation point (for 2.10 mL of added NaOH). With inhibitor and under our operating conditions, a pH of ≈ 10 is obtained without any turbidity, a point that will be discussed more thoroughly below. Since NaOH addition is stopped at a volume of 5 mL, only the slight pH decrease indicates that precipitation continues very slowly, as opposed to what occurred in the preceding case.

Without inhibitor and even at ambient temperature, calcium carbonate precipitation seems to be initiated by the ikaite polymorph, which thereafter changes into vaterite. For temperatures over 30°C,
Fig. 5. The effect of temperature on the precipitation pH of the various $CaCO_3$ polymorphs, as calculated for a water sample with analytical data given in Table 4.

ikaite becomes more soluble than the amorphous form because its solubility increases with temperature (in spite of its increase in instability).

Fig. 5 gives the precipitation thresholds for calcium carbonate polymorphs in the case of a water sample from the Seine River; the analytical results are given in Table 4. (Our results for amorphous

calcium carbonate are only approximate at $T >$ 55°C due to the lack of data in Ref. [21].)

Fig. 5 also gives the threshold corresponding to 40 times the calcite solubility product. This value is often considered in water treatment as a maximum value for IAP, in order to avoid scaling phenomena. A calcite supersaturation index can therefore be defined as

$$\Omega = IAP/K_s$$

This value of 40 was originally proposed by Legrand et al. [25] without any theoretical justification, Legrand and Leroy [32] have since tentatively explained this figure by calculating the energy needed for bringing together the Ca^{2+} and CO_3^{2-} ions, but without taking into consideration $CaCO_3^0$ hydrated forms or the dissociation equilibrium of HCO_3^- into CO_3^{2-}. This limiting value of 40 has frequently been questioned. Roques and co-workers [33–36], for example, has repeatedly obtained solutions with $\Omega = 80$ to 100 during heterogeneous scale formation studies at various temperatures. At 25°C, however, the beginning of precipitation corresponds to $\Omega = 72$ for ikaite, and to $\Omega = 120$ for the amorphous form. Fig. 5 enables us to better understand what occurs in drinking water supplies: at

about 10 to 20°C there is only a slight difference between the ikaite solubility limit and the value $\Omega = 40$; for hot water, however, the amorphous form solubility is nearer this limit.

We believe this limiting saturation index value of $\Omega = 40$, as proposed by Legrand and Poirier, is well adapted to both temperature ranges of drinking waters uses, which explains its practical interest. Between 30 and 70°C it is possible to greatly exceed this value (see Fig. 5), because of the Ω value between 90 and 100 for the amorphous form. But it must be remembered that at various temperatures, this limiting value corresponds to different initially precipitating polymorphs.

Several remarks should be made at this point in our discussion.

- Pelouze [37] is erroneously given credit for the discovery of $CaCO_3 \cdot 6H_2O$. He operated at room temperature with a lime milk left in contact with the ambient atmosphere, and described only the existence of a series of hydrates. In the industrial world, only one paper [38] describes ikaite formation sometime during the winter at a water treatment plant located in northern England. We observed [39] a similar phenomenon at the Salindres Rhône-Poulenc plant near Alès, France, in 1991.

- Scheme 2 clearly shows that calcite solubility data obtained from a redissolution process are the most reliable because there is no chance of supersaturation. A thorough literature survey produced a coherent set of data whose differences come mainly from the nature of the ionic strength correction used. On the other hand, all values coming from saturated solution precipitation processes are slightly higher.

- Slack [38] explained spontaneous ikaite formation by the presence of phosphate derivatives in treated water. Starting from the same principle, Clarkson [9] obtained ikaite at ambient temperature in the presence of sodium tripolyphosphate $Na_5P_3O_{10} \cdot 6H_2O$.

- Isolating and drying the first crystals formed without added inhibitor led Tarits et al. [40] to mixtures where vaterite could be the main form.

- Although more recently obtained, and in the absence of inhibitor, we have not retained the ikaite solubility product given by Brecevic and Nielsen [22] because these authors described rhomboedric crystals whereas ikaite has always been characterized as monoclinic.

5. The role of $CaCO_3^0$ in scale formation

In an attempt to analyse scaling phenomena, taking into account formation equilibria for all of the $CaCO_3^0$ hydrated forms in solution, we see (Table 3) that saturated solutions, when near to the formation equilibria for ikaite and amorphous solid calcium carbonate, should contain high concentrations of the soluble form playing the role of the precursor. Since this concentration is approximately 10^{-3} mol L^{-1}, we are in the range sufficient for a relatively rapid solid formation rate.

If, on the other hand, we have a weakly saturated medium whose IAP is only slightly higher than the calcite solubility product, the $CaCO_3^0$ (aq) concentration in the solution is approximately 10^{-5} mol L^{-1}, and it is conceivable that, under such conditions, calcite crystal formation and growth takes place very slowly if there is successive $CaCO_3^0$(aq) element addition.

If this is, indeed, the case, we can understand why there are natural waters containing microcrystalline calcite and whose IAP is nearly ten times the calcite solubility product, without any rapid evolution towards the equilibrium state. The growth of existing seeds depends on their en- counter with species that, in the present case, are only present at concentrations of less than 10^{-4} mol L^{-1}.

But how can we explain this rapid transition from the initially precipitating to anhydrous crystalline forms, when we have supersaturated solutions? A series of successive equilibria are established beyond hydrated calcium carbonate clusters for dissolution/dehydration of the various $CaCO_3^0$ soluble species. Their respective concentrations cannot exceed the limiting values given in Table 3 but, as opposed to the case of slightly saturated solutions, their precursors are in a restricted space at the precipitate/solution interface, and any consumed species is restored through equilibria displacements starting from the redissolution of the precipitated form.
Fig. 6. Calcium soluble species distribution as a function of pH for the experiment with 1 ppm ATMP as given in Fig. 4.

For heterogeneous kinetic studies, IAP values in the bulk solution do not necessarily correspond to a transition through solid hydrated forms. Koutsoukos et al. [41], for instance, studied scale formation on various metallic walls and observed that, at 80°C, vaterite settles and progressively converts into calcite. Walls might take part in the $CaCO_3^0(aq)$ dehydration equilibria, giving out the necessary energy and contributing to a rapid renewal of the polymorphs that have been converted into vaterite and calcite crystals. Again, in the present case, the wall/solution interface would be a privileged place for the seed-growth kinetics by weakly concentrated species in solution.

Further remarks are as follows.

● The pH of natural waters is generally lower than 8.5, except during periods of high photosynthetic activity [42]. The $|HCO_3^-|/|CO_3^{2-}|$ ratio is therefore usually higher than 100. Taking into account the known values for the $CaHCO_3^+$ and $CaCO_3^0$ formation constants, it becomes evident that $CaCO_3^0(aq)$ is, in fact, often the least abundant species. Classical calculations are, however, somewhat cumbersome when using only the solubility product concept, because we must choose between different K_s values depending on the advancement of the precipitation reactions. It is of interest to introduce the concept of the ratio

$$|CaCO_3^0|/|Ca^{2+}| = \beta \times |CO_3^{2-}|$$

Indeed, it is useless to seek possible precipitation of a given calcium carbonate polymorph if we are not already in the $CaCO_3^0(aq)$ formation range. On the other hand, the higher the pH, the greater the $CaCO_3^0(aq)$ form contribution, although its percentage never, in fact, reaches 20% of total calcium in solution (Fig. 6).

● Because of a typographical error, it was thought [36] that House et al. [43] had introduced the $CaCO_3^0(aq)$ concept during their kinetic studies for $CaCO_3$ crystallization. In fact, they considered that the percentage of $CaCO_3^0$ is small enough to be neglected [44].

6. The action of scale formation inhibitors

Many authors have studied the inhibitory effect of common species such as magnesium cations or orthophosphate anions. Recently, other molecules such as sodium tripolyphosphate [9,45], ethane 1-hydroxy 1,1'-diphosphonic acid (EHDP) [41] and amino tris(methylene phosphonic acid) (ATMP) [46,47] have also been studied. Since, at pH > 6.5 to 7, the electrokinetic potential for calcite suspensions is positive [48], many authors have explained this inhibitory effect by electrostatic or adsorption phenomena, and adsorption

isotherm determination studies are in agreement with such assumptions [48–50].

From a practical point of view, polyphosphates and polyphosphonates are of major interest due to their presently increasing use as precipitating sequestrant additives in washing powders. Taking into account their very low concentrations in all applications (10^{-7} to 10^{-5} mol L^{-1}), it is evident that in spite of their complexing behaviour against Ca^{2+} cations [46,51,52], it is not by a masking effect [52] that they prevent scale formation. Nevertheless, it is not really evident that at such low concentrations they can act as crystal nuclei poisons.

Experiments by Clarkson et al. [9] with supersaturated solutions containing sodium tripoly-phosphate showed that, for concentrations of about 10^{-5} mol L^{-1}, both the amorphous and the hexahydrate forms are stabilized. These authors also showed an increase in tripolyphosphate consumption when the mixtures progress towards calcite precipitation.

During our studies with ATMP (as with 4×10^{-6} mol L^{-1} sodium tripolyphosphate) no turbidity was observed in spite of the fact that we were well beyond the respective precipitation thresholds for ikaite and amorphous forms. This enables us to reject the assumption that solid/solution interaction is the only process involved. Instead of conceiving only absorption phenomena which imply calcite existence, as soon as the critical pH is reached, we believe that the inhibitor/Ca^{2+} complexes might associate with the pre-cursors of crystalline solid species, which are present in the solution in the same concentration range. Because of their sizes and charges, these complexes will form to the detriment of crystalline growth and so will maintain $CaCO_3^0$(aq) dehydration equilibria beyond calcite solubility limits.

Operating with various polyphosphonates, Black et al. [53] totally changed the appearance of barite crystals. Instead of adsorption, they too suggested a reaction between $BaSO_4$ and the inhibitors giving rise to mixed crystals. Without clearly formulating a reaction in solution as we do here, these authors assume morphological changes in the solution order at the crystal interface.

Dalas and Koutsoukos [41] fixed EHDP onto metallic walls and thereby showed the inhibitory effect on direct formation of vaterite (and thereafter calcite) that would be obtained without such a surface treatment. While discussing their inhibitory effectiveness, Roques has also described [33] the morphological crystal changes when polyacrylates are added.

These results are in good agreement with our assumption of a solution reaction between the inhibitor and $CaCO_3^0$(aq). If inhibitors react only with $CaCO_3$ solid forms, their effects at a given concentration should be a function of the mass of seeds added to trigger crystallization, but this has never been described in the literature. On the other hand, the blending of inhibitors into the crystal lattice of the solids obtained corresponds well to Clarkson's observation [9] of a tripoly-phosphate consumption during evolution towards calcite precipitation.

In our studies, the precipitation of even the amorphous species is disturbed by the presence of inhibitor. We assume that this is due to the fact that our $CaCO_3^0$(aq)/inhibitor ratio was lower than the value in Clarkson's studies. In our case with ATMP, we calculate IAP to be 0.79×10^{-6} at pH 10 while Clarkson obtained at the mixing point pH = 11.3 and IAP = 1.38×10^{-6} (as estimated by us). Moreover, a crude mixing of both Ca^{2+} and CO_3^{2-} reactants cannot be compared with our operating conditions where a mixture is progressively raised to its precipitation pH.

Finally, we consider that calcium carbonate precipitation and its evolution towards calcite formation can be delayed using inhibitor agents if seed formation itself is altered by the presence of species associated with $CaCO_3^0$(aq). Such a model could explain why these compounds are effective at such low concentrations. Our model can also provide explanations for the mechanisms of the recently described preparation of hollow porous aragonite shells, as obtained in oil/water/surfactant microemulsions [54].

7. Conclusion

In the present paper we have given more evidence of the existence of the well-known

$CaCO_3^0$ (aq) species. Through a critical review of published data, we validate the value log $\beta = 3.22$ at 25°C, as given by Plummer and Busenberg [20], with NaOH titrations of sodium hydrogenocarbonate and calcium chloride mixtures. Always using the $\beta = s/K_s$ relationship, and assuming that β depends only slightly on the dissolved $CaCO_3^0$ species hydration state, we were able to estimate that the $CaCO_3^0$(aq) concentration should be ca. 10^{-3} mol L^{-1} in saturated solutions, a value that cannot be considered to be insignificant, particularly when calculating the calcium carbonate IAP value in a cooling tower.

Since up until now the various $CaCO_3^0$(aq) species have only rarely been taken into consideration in studies of scale formation prediction and kinetics, we would like to underline the importance of such a concept. Our model suggests the existence in solution of various $CaCO_3^0$ hydrated forms whose solubilities decrease with the number of hydration water molecules. Under such conditions, it is easier to understand the progressive change of precipitated forms towards calcite, the most insoluble crystalline species. Since these dehydration reactions are endothermic [55], we can also better explain why, when in contact with hot walls, there is a more rapid evolution towards aragonite or calcite. Finally, and without neglecting other experimental approaches concerning the part played by the inhibitor, we suggest that the assumption of an interaction between inhibitor and hydrated $CaCO_3^0$ forms can aid in our understanding of this well studied but controversial subject.

Medium effect on acidity constants of some heterocyclic nitrogen azomethines

M.A. El-Taher*, A.A. Gabr

Department of Chemistry, Faculty of Science, Aswan, Egypt

Received 15 December 1995; revised 8 March 1996; accepted 15 March 1996

Abstract

The effects of different organic solvent–water mixtures on the acidity constants of some azomethines derived from 3-amino-1,2,4-triazol; 2-amino-1,3-pyrimidine and also 2-amino-4-methyl-1,3-pyrimidine have been examined. Two pK_a values for the o-OH derivatives were determined; one is assigned to the deprotonation of the nitrogen azomethine group and the other one is ascribed to the ionization of the OH group. The p-OH derivatives give one pK_a due to the ionization of the OH group. On the other hand, it was observed that with the increase in the amount of organic solvent in the medium, the pK_a of the compound studied is decreased. This behaviour can be accounted for in terms of the high stabilization of both the non-protonated and ionic forms of these compounds by dispersion forces rather than by hydrogen bonding. Also, the effects of medium polarizability on the pK_a values and thus on the spectra of the charge transfer band observed have been discussed.

Keywords: Heterocyclic nitrogen imines; pK_a

1. Introduction

The knowledge of pK_a is considered to be of interest for organic and inorganic compounds because it has a significant role in many chemical reactions. Therefore, numerous works [1–8] have been devoted to the determination of pK_a values of the Schiff bases. Despite this, information concerning the effect of the medium on the ionization process has not been fully reported.

The aim of the present work has been to study the effect of the medium on the ionization constants of some azomethines derived from 3-

amino-1,2,4-triazol; 2-amino-1,3-pyrimidine and thus 2-amino-4-methyl-1,3-pyrimidine. A number of organic solvents of various polarities and basicities as well as of different tendencies to donate or to accept hydrogen bonds have been investigated in the present work. The azomethine derivatives under examination are

(I–III): X = o-OH(a); p-OH(b).

2. Experimental

2.1. Materials and solutions

Heterocyclic azomethines under investigation were prepared as described earlier [9]. The structures of the different synthesized compounds were confirmed by micro-chemical analysis and no impurities were detected by IR spectroscopy.

All the chemcials used in this study were obtained, as high purity materials, from Fluka. They were used without further purification. The solvents used were methanol, ethanol, acetone and dimethylformamide (DMF). They were purchased from Merck, Uvasol grade.

The concentration of the solutions prepared could not be higher than approximately 1×10^2 mol dm^{-3} because of the low solubility of some of the compounds used.

2.2. Buffer solutions [10]

The modified universal buffer solutions of pH values 1.70–11.90 were prepared in aqueous media containing varying proportions of the organic solvents used in this work. The pH values of these solutions were checked using a MV-87 digital Pracitronic pH meter, accurate to ± 0.01 pH units at 25°C.

Because of the presence of organic solvent in the aqueous media of different pH values, the acidity, basicity, dielectric constant and ion activities of these partially aqueous solutions are altered compared to those of the pure aqueous ones. The measured pH values of the former solutions must be corrected according to the following equation [11]:

$$pH^* = pH(R) - \delta$$

where pH*, is the corrected reading and pH(R), is the meter reading obtained in a partially aqueous media, the pH meter is standardized using standard aqueous buffer solutions. The values of δ, of the aqueous buffer solutions containing varying amounts of the organic solvents were determined following Douheret [11].

The electronic absorption spectra of the freshly prepared dilute solutions were recorded on a Shimadzu UV-Visible Recording Spectrophotometer UV-240, using 1.0 cm matched silica cells, at 25°C.

Infrared spectra were recorded in the region 4000–200 cm^{-1} on a Pye Unicam SP 100 Infrared Recording Spectrophotometer, using the KBr disc technique.

3. Results and discussion

The electronic absorption spectra of the compounds under investigation in pure aqueous buffer solutions and also in those containing different proportions of the orgainic solvents, namely, methanol, ethanol, acetone or DMF were recorded (Fig. 1, as a representative example).

Generally, the charge transfer (CT) band observed in the absorption spectra of all the compounds studied shows a decrease in its intensity and meanwhile exhibits also a slight red shift in its λ_{max} as the pH of the medium is increased. On further increase in the pH values (≥ 7.30), this band exhibits splitting. This behaviour is attributed to the possible existence of such compounds in the NH/OH tautomeric equilibrium [6]. The first split at the shorter wavelength is ascribed to the CT transition within the enol form (non-ionized form), while the second one at the longer wavelength is due to the CT within the keto form (ionized form). Thus, in solutions of low pH values, these compounds exist mainly in the enol form, while they occur as keto form in the alkaline solutions. On the other hand, we can deduce that the CT interaction occurring within the solute molecule of these compounds is easier under the basic conditions relative to that under neutral or acidic ones. This is owing to the high mesomeric interaction of the OH group belonging to these compounds in the alkaline media, which increases the charge density on the keto tautomer resulting in easier CT interaction. A clear isosbestic point at different positions confirms the existence of such compounds in keto⇔enol tautomeric equilibrium.

Fig. 1. Absorption spectra of 1×10^{-4} mol dm^{-3} of compound III$_b$, in solutions containing different wt% ethanol: A, 0.0%; B, 10%; C, 30%; D, 50%.

The recorded visible absorption spectra of the compounds (I–III)$_{a,b}$, in pure aqueous buffer solutions and also in those containing different proportions of organic solvents, were used in the determination of the acidity constant (pK_a) of these compounds. The absorbance–pH curves (Fig. 2), are typical dissociation curves supporting the acid–base equilibrium. The mean pK_a values were determined from the above curves using the spectrophotometric methods, namely,

the half-wave height, limiting absorbance [12] and modified colleter methods [13]. The limit of accuracy of the pK_a values was checked using the least-squares method. The results obtained are listed in Tables 1–4.

3.1. Effect of molecular structure on pK_a

The pK_a values of both the pyrimidine and triazol rings cannot be determined since the de-
Fig. 2. Absorbance–pH* curves for compound III$_b$, in universal buffer solutions containing different percentages of ethanol, by wt% ethanol: a, 0.0%; b, 10%; c, 30%; d, 50%.

protonation of the pyrimidine and the triazol rings does not show any order in the absorbance of the CT band and other bands. This makes the

evaluation of pK_a values inaccurate. Also, the inability to determine pK_a values of the deprotonation of the azomethine group in the p-OH derivatives is mainly attributed to the effect of the ionization of the OH group belonging to these compounds on the absorbance of the C=N bond, which probably takes place at a pH near the value of pK_a of the deprotonation of azomethine group.

In all the media studied, the absorption spectra of the compounds (I–III)$_{a,b}$, are characterized by a clear isosbestic points denoting the existence of an acid–base equilibrium.

and neutral forms, and another one between the neutral and the ionic forms are shown below:
According to the above representative scheme, it is noticed that the o-OH compounds give two pK_a values. pK_1, can be assigned to the deprotonation of the nitrogen azomethine group and pK_2, is ascribed to the ionization of the phenolic OH group. On the other hand, the p-OH derivatives have one pK_a, mainly due to the ionization of the phenolic OH group. In addition, the pK_a value of the o-OH group is higher than that of the p-OH group. This is most likely due to the strong intramolecular hydrogen bonding between the o-OH group and the nitrogen azomethine group, as represented above. This will result in an increase in the stability of the o-OH group, so its ionization is difficult, i.e. a high pK_a value of the molecule is observed [5–8].

3.2. Effect of medium on pK_a

Careful examination of the pK_a values of the compounds studied in different organic solvent–water media shows that the pK_a values of all the compounds are largely dependent on both the proportion and nature of organic co-solvent used. The ionization and deprotonation constant values for all the compounds studied and for the o-OH compounds, respectively, decrease by increasing the percentage of organic co-solvent in the medium.

The acidity constant in aqueous medium (K_n), may be related to that in partially aqueous medium (K_m), by means of Eqs. 1 and 2 [14],

$$K_n = K_m \gamma_{H^+} \gamma_A / \gamma_{H^+A} \tag{1}$$

$$K_n = K_m \gamma_{H^+} \gamma_{A^-} / \gamma_{HA} \tag{2}$$

where γ is the activity coefficient of the subscripted species in a partially aqueous medium relative to that in a pure one. It is known that the electrostatic effect of the solvents will operate only

on the activity coefficients of any charged species [14]. In the case of deprotonation of the o-OH compounds studied, the electrostatic effect on the activity coefficient of the proton (H$^+$) exceeds that on the acid (H$^-$A). Consequently the electrostatic effect is expected to exhibit a relatively high influence on the deprotonation constant of these compounds. So, regarding the ionization of the compounds studied, the magnitude of this effect on the proton (H$^+$) and free base (A$^-$) increases compared to that on the neutral compound (HA). Thus, the deprotonation and ionization constants (K_{a_1} and K_{a_2}) of these compounds are expected to increase with the increase in the percentage of organic solvent in the medium. These are in accordance with the results given in Tables 1–4.

Furthermore, it was previously indicated that the ionization constants of the acids are affected by solvent properties such as the dielectric constant, acidic and basic strengths [15–17]. Also, stabilization of the different species existing in equilibrium through hydrogen bonding, proton–solvent interaction and dispersion forces originating from interactions between the solvent and solute molecules, plays a significant role in the

ionization constants of acids. Accordingly, the observed decrease in the pK_a values of all the compounds under investigation, as the percentage of the organic solvent in the medium is increased, can be attributed mainly to the high stabilization of both the non-protonated and ionic forms of these compounds by dispersion forces rather than by hydrogen bonding. This stabilization may be due to the high effective density of dispersion centres of the solvents under study relative to that of water [18]. This behaviour is ascribed also to the high stabilization of the proton by its interaction with organic solvent–water mixtures rather than with water molecules alone [14]. Consequently, the activity coefficients of both the non-protonated and ionic forms and of the proton decrease by increasing the percentage of the organic co-solvent in the medium. This will result in an increase in the ionization constant (low pK_a) of these compounds.

In the different media studied, an increase in the pK_a values of the compounds under investigation is observed in the presence of the same percentage of organic co-solvent in the medium according to the following sequence:

DMF < acetone < ethanol < methanol

This behaviour is expected to occur as a result of the decrease in the medium polarizability on going from DMF–water mixtures to methanol–water mixtures within the above sequence [18]. This strongly confirms the fact that the high stabilization of both the non-protonated and ionic forms by dispersion forces and that of the proton by its interaction with solvents, are the very important factors responsible for the decrease in the pK_a values of the compounds studied as the percentage of organic solvent in the medium is increased. The low pK_a values observed in the case of DMF compared to that in alcohol or acetone under the same conditions, is attributed to the high basicity of DMF i.e. solvent with strong hydrogen bond acceptor (from the protonated compounds). The reduced pK_a values exhibited in DMF can be ascribed also to the strong dispersion interaction of the free base with DMF relative to that occurring with other solvents [16].

In the context of the present work it is also worth mentioning that the CT absorption band of the compounds under investigation shows a slightly red shift with increase in the percentage of solvent in the medium. This is attributed mainly to the increase of the free negative charge on the oxygen atom of the Schiff base by increasing the percentage of solvent in the medium [3]. This is due to the weak tendency of the solvent molecules to form donor hydrogen bonds with the oxygen atom relative to water molecules. This in turn will reflect itself in the increase of the intramolecular charge transfer within the molecule and thus a lower excitation energy is required. In addition, the visible band influenced by intramolecular CT within the solute molecule shows also a red shift in the DMF medium relative to that in alcoholic media. This can perhaps be ascribed to the protonation of the nitrogen atom of the heterocyclic

ring by alcohol molecules, whereas alcohol acts as a proton donor solvent (donor hydrogen bond). Such protonation will result in blocking of the n-electrons of the nitrogen atom; thereafter, the electron charge transfer through the solute molecule is not easy. Accordingly, high excitation energy is required and a blue shift is observed in the alcoholic media. When DMF acts as a hydrogen bond acceptor, therefore, a red shift of the CT band is observed through it [7].

Abstract

A catalytic flow-injection photometric method was developed for the determination of levels of cobalt as low as 10^{-10} mol 1^{-1}. The method is based on the catalytic action of cobalt(II) on the oxidative coupling of 3-methyl-2-benzothiazolinone hydrazone with N,N-dimethylaniline to form a colored dye ($\lambda_{max} = 590$ nm) in the presence of hydrogen peroxide. The extremely activating effect was obtained in the presence of 1,2-dihydroxybenzene-3,5-disulfonate (Tiron) and sodium hydrogencarbonate as activators. Furthermore, the sensitivity of the method was enhanced by adding sodium dodecylsulfate as a surfactant. Linear calibration graphs were obtained over the range 0.04–0.2 ng ml^{-1} and 0.1–0.5 ng ml^{-1} cobalt(II), respectively, at a sampling rate of 30 per hour. The detection limit (signal/noise = 3) was 5 pg ml^{-1} and the relative standard deviations for 0.1 and 0.04 ng ml^{-1} cobalt ($n = 10$) were 1.0 and 2.3%, respectively. The method was applied to the determination of cobalt in pepperbush.

Keywords: Catalytic flow-injection photometric method; Cobalt determination

1. Introduction

* Corresponding author. Fax: (81) 298-53-6503; e-mail: kawasima@staff.chem.tsukuba.ac.jp

Many metal ion-catalyzed reactions are utilized for the kinetic-based determinations of species [1,2]. These catalyzed reactions are known to be affected by various chemical substances, particularly the activator and sufactant. Hence, the

effects of activators and surfactants on catalyzed reactions have been increasingly exploited in the last few years to improve the features of kinetic-catalytic methods [1–3].

Since kinetic-based methods are time dependent, they need care in the mixing of reactants at regular time intervals to obtain reproducible results. The flow-injection analysis lends reproducibility to both reagent addition and reaction times; the flow-injection technique is a suitable means of extending the applicability of kinetic-based methods to routine analysis [4].

The demand for highly sensitive methods for determining ultratrace amounts of cobalt has increased in industrial and environmental analysis. Indeed, a number of kinetic-catalytic methods have been reported using batch and flow-injection mode with various monitoring systems such as photometric [5–9], chemiluminescent [10–12] and thermometric [13] detections.

The oxidative coupling of 3-methyl-2-benzothiazolinone hydrazone (MBTH) with N,N-dimethylaniline (DMA) to form a colored dye ($\lambda_{max} = 590$ nm) in the presence of hydrogen peroxide has already been employed as an indicator reaction for the catalytic determinations of copper(II) [14–16], chromium(III) [17] and manganese(II) [18,19]. It was found that cobalt(II) also acts as a catalyst on this coupling reaction. This paper describes a highly sensitive catalytic flow-injection method for the photometric determination of cobalt(II) by using this indicator reaction. The catalytic activity of cobalt(II) can be effectively enhanced by disodium 1,2-dihydroxybenzene-3,5-disulfonate (Tiron) together with sodium hydrogencarbonate as activators. In addition, the sensitivity of the proposed method can be improved by adding sodium dodecylsulfate (SDS) as a surfactant. The method can be successfully applied to the determination of cobalt in pepperbush (National Institute for Environmental Studies (NIES) certified reference material No. 1) in the presence of triethylenetetramine (trien) as a masking agent for copper.

2. Experimental

2.1. Apparatus

Fig. 1 provides a schematic diagram of the flow-injection manifold used in this study. The flow lines was connected up with Teflon tubing (0.5 mm i.d.) and three-way connectors. Reagents and carrier streams were propelled by two double plunger-type pumps (Sanuki Kogyo, DM2M-1026). Samples were injected using a six-way valve (Gasukuro Kogyo, MPV-6) into the carrier stream. Absorbances were measured at 590 nm with a Soma Kogaku S-3250 spectrophotometer fitted with a flow-through cell (8 μl volume, 10 mm path length) and recorded with a Hitachi model 561-1003 recorder. Two circulating thermostated baths (Taiyo Kagaku Co., C-630) were used to control the reaction temperature and to stabilize the base line. The pH of the solution was measured with a Horiba F-8AT pH meter.

2.2. Reagents

All reagents used were of analytical reagent grade. Water, purified with a Millipore Milli-Q PLUS system, was used to prepare the solutions.

A 100 ng ml^{-1} cobalt(II) stock solution was prepared by diluting a 1000 μg l^{-1} cobalt(II) standard solution for atomic absorption spectrometry (Kanto Chemicals) in 0.01 mol l^{-1} hydrochloric acid. Working cobalt(II) solutions of appropriate concentrations were prepared daily in

Fig. 1. Flow system for the catalytic determination of cobalt. R1, carrier solution; R2, $H_2O_2 +$ Tiron $+$ NaHCO$_3$; R3, DMA; R4, MBTH $+$ SDS $+$ tris; P, pump; V, six-way valve; RC, reaction coil; CC, cooling coil; T1, T2, thermostated baths; D, spectrophotometric detector; REC, recorder; W, waste.

the same acid. A stock solution of 0.05 mol 1^{-1} MBTH was prepared by dissolving 2.7 g of the monohydrochloride (Tokyo Kasei Co.) in water and diluting to 250 ml. A stock solution of 0.1 mol 1^{-1} DMA was prepared by dissolving 3.0 g of the compound (Wako Junyaku Co.) in 0.1 mol 1^{-1} hydrochloric acid and diluting to 250 ml with the same acid. A hydrogen peroxide stock solution of 4 mol 1^{-1} was prepared from the commercial reagent (30%, Wako Junyaku Co.). Stock solutions of 0.8 mol 1^{-1} tris(hydroxymethyl) aminomethane (tris) (Wako Junyaku Co.), 0.1 mol 1^{-1} sodium hydrogencarbonate (Kanto Chemicals), 0.1 mol 1^{-1} Tiron (Dojindo Lab.), 0.2 mol 1^{-1} SDS (Tokyo Kasei Co.) and 1.0×10^{-2} mol 1^{-1} trien (Wako Junyaku Co.) were also prepared in water. More diluted solutions were prepared from these stock solutions.

2.3. Sample decompostion

An aliquot of 200 mg of dried pepperbush (NIES certified reference material No. 1) is weighed into a Teflon vessel. Five milliliters of concentrated nitric and 1 ml of perchloric acids are added into the vessel. After fastening the cap tightly, the vessel is heated in the oven at 90°C for 2 h and 130°C for 2 h for decomposition. After cooling and removing the cap of the vessel, the sample is transferred to a 100 ml volumetric flask and the volume is adjusted with water. More dilute sample solutions for the measurements are diluted with 0.01 mol 1^{-1} hydrochloric acid [20].

2.4. Procedure

As shown in Fig. 1, the carrier solution of 1×10^{-2} mol 1^{-1} hydrochloric acid (R1), a mixture of 0.6 mol 1^{-1} hydrogen peroxide, 6.0×10^{-2} mol 1^{-1} Tiron and 7.0×10^{-2} mol 1^{-1} sodium hydrogencarbonate (R2), 3.0×10^{-2} mol 1^{-1} DMA (R3), a mixture of 2.0×10^{-2} mol 1^{-1} SDS and 2.5×10^{-3} mol 1^{-1} MBTH containing 8.0×10^{-2} mol 1^{-1} tris buffer (R4) were pumped at a flow rate of 1.0 ml min^{-1}. A 160 μl sample solution was injected into the carrier stream. The color development proceeded in the reaction coil of 5 m length at 70°C, and then the colored

solution was passed through the cooling coil of 2 m length at 25°C and then the flow-through cell. The absorbance of the dye produced was monitored continuously at 590 nm.

3. Results and discussion

In the presence of hydrogen peroxide, MBTH reacts with DMA to produce a blue-violet indamine dye, which has an absorption maximum at 590 nm. The rate of color-forming reaction is catalytically accelerated by cobalt(II). The cobalt(II)-catalyzed reaction possibly involves the oxidation of cobalt(II) to cobalt(III); the coloration is catalyzed by trace amounts of cobalt as a result of the regeneration of cobalt(III) by hydrogen peroxide. In the present system, the synergistic activating effect of Tiron and hydrogencarbonate and the micellar enhancing effect of SDS on the catalyzed reaction were observed.

3.1. Effect of reaction variables

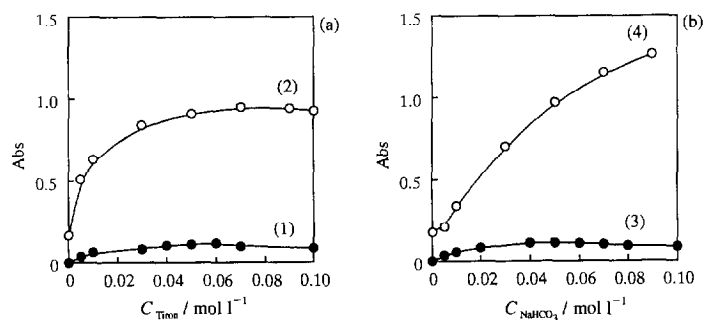
The sensitivity of kinetic-catalytic methods can be augmented by an activator. It has been defined as a substance which does not catalyze the indicator reaction but increases its rate in the presence of a catalyst. The use of activators in catalytic methods also permits an improvement in their selectivity [1,2]. Tiron is known as an activator for cobalt(II)-catalyzed reactions [7]. It was found that Tiron and hydrogencarbonate when present together greatly enhanced the catalytic activity of cobalt(II) in this reaction. Fig. 2 shows the effects of Tiron and sodium hydrogencarbonate concentrations on the catalysis of cobalt(II) at a concentration of 2 ng ml^{-1} cobalt(II). The peak heights increased with increasing Tiron or sodium hydrogencarbonate concentration. The peak height ratio between the presence of 6.0×10^{-2} mol 1^{-1} Tiron and its absence was 59. By the same way, the peak height ratio between the presence of 7.0×10^{-2} mol 1^{-1} sodium hydrogencarbonate and its absence was 56. On the other hand, the catalytic activity of cobalt(II) was strongly enhanced by using Tiron together with hydrogencar-


Fig. 2. Effects of Tiron (a) and sodium hydrogencarbonate (b) concentrations on the cobalt(II)-catalyzed reaction. (1) Tiron only; (2) in the presence of 5.0×10^{-2} mol 1^{-1} NaHCO$_3$; (3) NaHCO$_3$ only; (4) in the presence of 6.0×10^{-2} mol 1^{-1} Tiron. Other conditions as in the text.

bonate. In the presence of a 5.0×10^{-2} mol 1^{-1} hydrogencarbonate, the peak heights increased with increasing Tiron concentration up to 6.0×10^{-2} mol 1^{-1}, above which they remained almost contant (Fig. 2(a)); a Tiron concentraton of 6.0×10^{-2} mol 1^{-1} was used for the procedure. In the case of sodium hydrogencarbonate with 6.0×10^{-2} mol 1^{-1} Tiron, an increase in the hydrogencarbonate concentration substantially increased the peak heights (Fig. 2(b)). However, bubbles were observed at higher concentrations. A sodium hydrogencarbonate concentration of 7.0×10^{-2} mol 1^{-1} was thus selected. The peak height ratio between the presence of 6.0×10^{-2} mol 1^{-1} Tiron with 7.0×10^{-2} mol 1^{-1} sodium hydrogencarbonate and the absence of activators was above 1000; a synergistic effect of the two activators was observed in this catalyzed reaction.

One of the possibilities for further increasing the sensitivity of kinetic-catalytic methods is the application of micellar medium [3]. Surfactants form micelles at the concentration above the critical micellar concentration (CMC). Micelles can control reaction pathways, change reaction mechanisms, and alter the physico-chemical properties of solubilized compounds. The effects of cationic (cetylpyridinium chloride, 1-laurylpyridinium chloride, zephiramine), nonionic (brij 35, tween 80, tween 20) and anionic (sodium dodecylbenzensulfonate (SDBS), sodium dodecylsulfate (SDS)) surfactants on the cobalt(II)-catalyzed reaction were tested at their concentrations of 1.0% w/v by injecting 0.2 and 0.4 ng ml^{-1} cobalt(II) solutions.

The results are shown in Table 1. When cationic surfactants were added, precipitates were produced; the measurements of absorbance were impossible. In the case of nonionic surfactants, the absorbances increased slightly. On the other hand, significantly higher abosrbances were obtained in the presence of anionic surfactants. Thus SDS was chosen as a surfactant. The effect of the SDS concentration was examined over the range 0–4.0×10^{-2} mol 1^{-1}. The peak heights increased with increasing SDS concentration up to 2.0×10^{-2} mol 1^{-1} almost corresponding to the CMC, above which constant peak heights were obtained. A concentration of 2.0×10^{-2} mol 1^{-1} SDS was

chosen for the procedure. The peak height ratio between the presence of 2.0 ± 10^{-2} mol l^{-1} SDS and its absence was about 8 as shown in Fig. 3. In the presence of surfactant, sensitivity can be augmented as a result of the increased effective concentration of reagents on the micellar surface [3].

The effect of the reaction temperature on the peak height was examined over the range 30–80°C at a fixed cobalt(II) concentration of 0.2 ng ml^{-1}. The peak heights increased with increasing temperature up to 70°C and became constant above 70°C. The reaction temperature was therefore fixed at 70°C. The length of the reaction coil was varied in the range 1–15 m. The peak heights increased with increasing coil length; a 5 m reaction coil was chosen, taking into account reproducibility and sampling rate. The effect of pH on the peak height was examined over the pH range 6–9 by using tris buffer solutions. Since a maximum signal was obtained at a pH around 8, the catalyzed reaction was carried out at pH 8.

The effect of concentration of the reactants on the catalyzed reaction was examined at a concentration of 0.2 ng ml^{-1} of cobalt(II). The peak heights increased with MBTH concentration up to 2.0×10^{-3} mol l^{-1}, above which they changed little. Therefore, a 2.5×10^{-3} mol l^{-1} MBTH was selected as the recommended concentration for the sake of solubility of the reagent. The peak heights increased with DMA concentration up to 3.0×10^{-2} mol l^{-1} and decreased thereafter, possibly owing to the liberation of DMA in a weakly

alkaline solution. A 3.0×10^{-2} mol l^{-1} DMA concentration was chosen for the procedure. The effect of hydrogen peroxide concentration was examined over the range 0–0.8 mol l^{-1}. The peak heights increased up to a hydrogen peroxide concentration of 0.5 mol l^{-1}, above which almost constant peak heights were obtained. A hydrogen peroxide concentration of 0.6 mol l^{-1} was therefore selected for the procedure.

3.2. Analytical characteristics

Fig. 4 shows typical flow signals for cobalt(II) using the present flow system under the optimum conditions. By changing the sensitivity of the detector, linear plots were obtained for two concentration ranges 0.04–0.2 ng ml^{-1} and 0.1–0.5 ng ml^{-1}, respectively. The limit of detection for the proposed method is 5 pg ml^{-1} (signal/noise = 3). The reproducibility was satisfactory with the relative standard deviations of 1.0 and 2.3% for ten determinations of 0.1 and 0.04 ng ml^{-1} cobalt(II), respectively, and the sampling rate was 30 h^{-1}.

3.3. Interferences

The selectivity of the present method was assessed by studying the effect of foreign ions on the determination of 0.2 ng ml^{-1} cobalt(II). The results are summarized in Table 2. A relative error of less than $\pm 5\%$ was considered to be tolerable.

Fig. 4. Typical flow signals for cobalt(II). Conditions as in the text.

Table 2
Effect of foreign ions and compounds on the determination of 0.2 ng ml^{-1} of cobalt(II)

Tolerance ratio[a] [ion] or [compound]/[Co(II)]	Ion and compound added
10000	Na(I), Zn(II), Pb(II), Mo(VI), F$^-$, Cl$^-$, PO$_4^{3-}$, ClO$_4^-$, ClO$_3^-$, oxalate, tartrate, citrate
5000	K(I), Mg(II), SO$_4^{2-}$
2000	Sb(III), Ti(IV), I$^-$
1000	Al(III)
500	Ca(II), Ba(II), Cd(II), Se(IV), As(III)
200	Cr(III), Sr(II)
100	Sn(II), Ni(II)
50	Mn(II)
7	Fe(II, III)
0.2	Cu(II)

[a] A ± 5% error was considered to be tolerable.

Up to a 10 000-fold excess for most foreign ions, and a 5000-fold excess of potassium(I), magnesium(II) and sulfate did not interfere. Iron(II, III) showed positive interferences when present in seven-fold excess. A serious negative interference was observed from copper(II), although it is not fully understood at present why the copper(II) ion showed negative interference in the present method. Detailed results will be reported elsewhere. Masking with trien has been tried to eliminate its interference [21]. Fig. 5 shows the effect of trien concentration in the presence and absense
Fig. 5. Effect of trien concentration in the absence (1) and presence (2) of copper(II). (1) $C_{Co(II)}$, 0.2 ng ml^{-1}; (2) $C_{Co(II)}$, 0.2 ng ml^{-1} + $C_{Cu(II)}$, 0.2 ng ml^{-1}. Other conditions as in the text.

Table 3
Determination of cobalt in pepperbush[a]

Cobalt found[b] (μg g^{-1})	
Calibration method	Standard addition method
16.90[c]	16.14[c]
19.13[d]	23.24[d]

[a] The certified value is 23 ± 3 μg g^{-1}.
[b] Average value for three determinations: relative standard deviations were less than 2.3%.
[c] In the absence of trien.
[d] In the presence of trien.

of copper(II). The concentration of trien up to 2.0×10^{-4} mol l^{-1} did not affect the catalyzed reaction and the interference of copper(II) was effectively eliminated over the range of 5.0–8.0×10^{-5} mol l^{-1} trien. A trien concentration of 5.0×10^{-5} mol l^{-1} was therefore selected for the proposed method.

3.4. Application

The proposed method was applied to the determination of cobalt in the reference pepperbush. Analytical results were obtained by the calibration and standard addition methods. The results are shown in Table 3. Since copper(II) in pepperbush interfered in the determination of cobalt in the absence of trien, the contents of cobalt in the pepperbush were lower than the certified value as is seen in Table 3. In the presence of trien, the analytical results of cobalt obtained by the standard addition method were in good agreement with the certificate value.

4. Conclusions

The proposed flow-injection photometric method is one of the highly sensitive kinetic-catalytic methods for the determination of cobalt. In this system, extremely high catalytic activity of cobalt (II) was obtained with a synergistic activating effect of Tiron and sodium hydrogencarbonate. Moreover, the sensitivity was enhanced by the micellar effect of SDS as an anionic surfactant. Samples can be analyzed at a rate of 30 h^{-1} with

relative standard deviations of below 2.3%. The serious interference of copper(II) can be eliminated with trien. The method was applied to the analysis of pepperbush with satisfactory results.

A comparative study of the degradation of different starches using thermal analysis

Poonam Aggarwal, David Dollimore*

The Department of Chemistry and Pharmacy, The University of Toledo, Toledo. OH 43606, USA

Abstract

Four starches obtained from different sources were treated to thermal analysis and their mechanisms of degradation were deciphered using a rising temperature method of evaluation. A comparison of the solid state reactivity between the four starches was made, using a method known as the $\alpha_s-\alpha_r$ method. By this method, it was possible to differentiate between four starches of completely different plant origin. Potato starch and rice starch were found to have the highest reactivity.

Keywords: Starch degradation; Thermal analysis

1. Introduction

Starch is arguably one of the most actively investigated biopolymers [1]. The structure of starch, consisting of amylose and amylopectin units has been well characterized [2]. Amylose, the linear constituent of starch consists of α-D-glucopyranose units linked by α-(1,4)α glycosidic linkages only, while in amylopectins, there are α-(1,6)α glycosidic linkages as well, which lead to branching [3–6]. There is considerable interest in the thermal decomposition of starch, as thermal treatment of dry starch usually leads exclusively to its depolymerization if the temperature does not exceed 300°C [7]. The products of pyrolyzed starch, known as dextrins, are commerically used as industrial gums [8].

However, the ratio of amylose to amylopectin is dependent on the source from which the starch is extracted. Watson has reported the percent amylose content in starches obtained from various sources [9]. There have been several reports of studies of the degradation pattern of starch from different origins analyzed by differential thermal analysis (DTA), in the literature [10–14]. Greenwood and Muirhead have demonstrated that compounds such as alumina and sodium chloride used as reference materials, in which the starch samples were mixed, affected the thermal degradation curves of starches [15] and suggested that the acquisition of data on starches should be carried out in the absence of these materials. Nevertheless no significant differences in the thermograms were noticed between starches from different origin. In order to address this problem, we

* Corresponding author. Fax: (+1) 419 537 4033.

decided to develop a general thermal analysis technique for the comparative analysis of starches. In an attempt to compare the solid state reactivity of different starches, four starches originating from different plants were treated to thermal analysis. The starches used for the study were rice, potato, corn and wheat starch. All four starches degrade to carbon in an atmosphere of flowing nitrogen. In this study the kinetic pathway followed by these four different starches was compared, by introducing the α_s–α_r method to determine the solid state reactivity of these starches on a comparitive basis, without recourse to Arrhenius parameters.

2. Experimental

The thermal analysis equipment used in this study was a simultaneous TG–DTA (thermogravimetry–differential thermal analysis) unit from TA instruments, model number 2960, in which the TG and DTA signals are simultaneously obtained on the same sample being thermally treated. The gas flow rate was monitored with the help of an electronic flow meter. In all of the experiments a steady flow rate of 100 ml min^{-1} was maintained. Rising temperature experiments were conducted in which the heating rate was 10°C min^{-1} while considering all of the four starches. For each experiment a sample size of 5–7 mg of starch was used. Variation in sample size did not show any significant difference in either the percent weight loss or the temperature range at which the degradation could be observed. The samples were held in alumina crucibles, with empty alumina crucibles used for the reference holders, and the samples were used undiluted as suggested by Greenwood [7]. The presence of alumina crucibles did not have any effect on the degradation sequence, as was evidenced by the experiments in which the data was replicated using platinum crucibles. The starch samples were obtained from the Sigma Chemical Company. There was no residue after ignition in air for all of the four starches studied and they were all unmodified. All the starches were heated in an atmosphere of dry nitrogen from ambient to 500°C on the TG unit.

The α_s–α_r method is used here to determine the solid state reactivity of different starches on a comparative basis. In this method, the reactivity of the four starches was compared from their TG data (but any other thermal analysis data would suffice). The data obtained from the TG of rice starch was used as the reference, called α_r and the other three were designated α_s. Here both α_r and α_s refers to the fraction decomposed in a single stage decomposition. The solid state reactivity was then assessed from the plots of the extent of the reaction of the samples against that of the reference, calculated from experiments conducted under identical conditions of temperature, gas flow and heating rates.

3. Results and discussion

Solid state reactivity of the four different starches was studied and compared using the α_s–α_r method of evaluation. The reactivities of the starches was compared by noting the extent of decomposition, alpha (α) or the fraction decomposed [16]. α is determined by the following equation:

$$\alpha = \frac{w_i - w}{w_i - w_f}$$

where w is the % weight of substance; w_i is the % weight of substance at the initial time and w_f is the % weight of substance at the final time.

The TG plot of rice starch was used as the reference material, though any of the four could be selected and $\alpha_{\text{reference}}$ (α_r) was calculated from that. The other three were called α_{sample} (α_s). As can be seen from Fig. 1, the reactivity of potato starch is greater than rice used as a reference, while wheat and corn starch have lower reactivity. A plot of temperature against time and a derivative plot of the same was used also to compare the starches (Fig. 2). In all of the four cases, a plot of time against temperature appeared as a straight line, and this should indicate that there is no perturbation due to the reaction temperature of the sample, with the slope indicative of the heating rate employed. However differences in heat capacity due to the applied heating rate and due
Fig. 1. α_s–α_r plot of the starches with α_r as rice starch.

to the reaction being either exothermic or endothermic, may lead to the presence of a perturbation. In this case the perturbation is hardly noticed since probably only small perturbations are involved within a narrow temperature range. A derivative plot of time–temperature dT/dt plotted against time is clearly explicit with regard to this minute perturbation and gives much the same information as to whether an exothermic or an endothermic event is occurring (Fig. 2). Once the rate of 10°C min^{-1} has been established, the derivative plot indicates a background variation of less than 0.1°C; however in the region of the decomposition of the starch, the perturbation rises to 0.6°C.
Fig. 2. Derivative time–temperature plot of corn starch from TGA data.
Fig. 3. TG plots of the four starches in an atmosphere of dry nitrogen.

The fact that initially the perturbation dropped the heating rate below the programmed 10°C min^{-1} would indicate the occurrence of an endothermic degradation. This can also be used to give an indication of the actual heating rate of the sample under investigation. In all the cases, the conventional heating rate of 10°C min^{-1} was used but a slight variation does occur, probably due to the difference in heat capacities between the individual samples.

Starches were treated to thermal analysis in the TG unit under an atmosphere of dry nitrogen, where they undergo depolymerization and finally conversion to carbon, as can be seen from the TG plots (Fig. 3); the degradation process commences

Fig. 4. α plot of starches against temperature.

Table 1
Order of reactivity of different starches when α_r is 0.05 and 0.5

Entry number	At $\alpha_r = 0.05$ α_s/α_r	At $\alpha_r = 0.5$ α_s/α_r	Starch (α_s)
1	0.4	0.29	corn
2	0.6	0.78	wheat
3	0.9	1.27	potato

at 250°C and by 400°C there is complete weight loss in all of the four cases. The plot of the alpha values for each starch against temperature (Fig. 4) also shows the reactivity of potato and rice starch to be higher than that for wheat and corn starch. From Table 1 it can be seen that at a low α_r value (0.05) the order of the reaction is rice > potato > wheat > corn starch, while at $\alpha_r = 0.5$, the reaction is in the order, potato > rice > wheat > corn starch.

4. Conclusions

In this study a new method is utilized to provide a comparative method of assessing solid state reactivity which avoids the complexities involved in quoting the Arrhenius parameters and the reaction rate mechanism. The reactivity of rice and potato starch in the solid state was found to be higher than wheat and corn starch. This study demonstrates the applicability of the $\alpha_s–\alpha_r$ method to differentiate between the rates of degradation of starch from disparate sources. The differences in solid state reactivities between the starches are subtle by conventional TG–DTA methods. However, the use of the $\alpha_s–\alpha_r$ method

reveals a distinct difference in the reactivities of these starches. We believe that this method illustrates an example for the comparison of similar materials and can be applied to other samples.

Continuous flow system for the evaluation of the extrinsic coagulation pathway

J.M. Fernández-Romero, M.D. Luque de Castro*

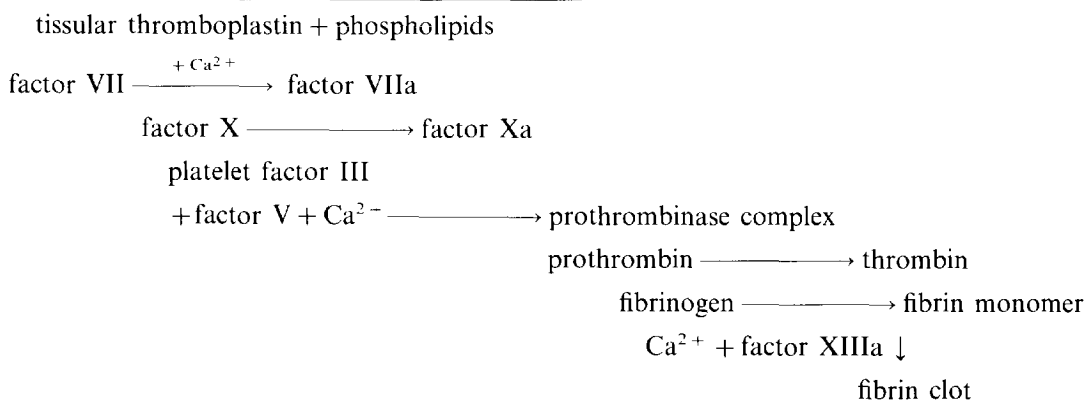
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

Abstract

A simple and reliable method for the evaluation of the extrinsic coagulation pathway is presented. The method is based on the monitoring of the last step of the coagulation pathway in which the human plasma is clotted by the presence of the coagulations factors (prothrombin, factor V, factor X, calcium and phospholipids) in an excess of thromboplastin. It has been developed using a flow injection system involving the merging-zones and stopped-flow modes. The clotting reaction rate is monitored photometrically at 340 nm. The linear range expressed as a percentage of total clottable activity was found to be between 10 and 100%, with a relative standard deviation between 0.9 and 2.8%. The usefulness of the method was tested by determining the fibrin clotting capacity in human plasma from healthy and sick individuals with excellent agreement with the conventional clotting method (automated coagulation laboratory–nephelometric method).

Keywords: Extrinsic coagulation factors; Flow injection; Haemostasy; Plasma

1. Introduction

The wide range of clinical parameters involved in the coagulation and fibrinolysis processes makes the global evaluation of the haemostasy in the clinical laboratory difficult. The analytical procedures have been focused on the elucidation of the different steps involved. Specific tests for the estimation of the primary haemostasy, plasmatic coagulation and fibrinolysis have been developed so far.


The procedures used in the clinical laboratory are mainly based on the capacity of the human plasma to in vitro clotting, induced by the presence or absence of different coagulation factors. The methods thus developed require two steps: the first is a preparative stage in which the blood sample is treated with anticoagulant substances in order to avoid the spontaneous coagulation. In a second step the plasma obtained is recalcified and mixed with the reagent containing additional coagulation factors required for the clotting step. The correlation between the clotting time and the endogenous coagulation factors is used for the diagnosis of haemostasy diseases and for the evaluation of the anticoagulant therapy.

* Corresponding author. E-mail: qa1meobj@lucano.es

The fibrin clot formed is usually monitored by the physico-chemical changes it produces in the medium (e.g. changes in the physical state, viscosity, conductivity, colour).

A number of chronometric methods with different degrees of automation and based on the above-commented changes have been described in the literature (clotting [1–4], agglutination [5–7] and precipitation [8,9]). The development of new chromogenic and fluorimetric substrates has increased the use of optical techniques with this aim in the last decade, so photometric [10–15], tur-

the sequential injection technique and a robotic method for the detemination of factor XIII have been proposed [47,48].

An automated method for the evaluation of the extrinsic coagulation pathway in human plasma is reported here. The method is an adaptation of the manual prothrombin time test to a flow injection (FI) approach. This method is used as screening of the total prothrombinase complex formed, including prothrombin, factor V, factor X_a, Ca^{2+} and phospholipids, according to the following sequence:

$$\text{tissular thromboplastin} + \text{phospholipids}$$

$$\text{factor VII} \xrightarrow{+ Ca^{2+}} \text{factor VIIa}$$

$$\text{factor X} \longrightarrow \text{factor Xa}$$

$$\text{platelet factor III}$$

$$+ \text{factor V} + Ca^{2-} \longrightarrow \text{prothrombinase complex}$$

$$\text{prothrombin} \longrightarrow \text{thrombin}$$

$$\text{fibrinogen} \longrightarrow \text{fibrin monomer}$$

$$Ca^{2+} + \text{factor XIIIa} \downarrow$$

$$\text{fibrin clot}$$

bidimetric or nephelometric [16–18] and fluorimetric [19–22] methods have been developed. Also a growing adaptation of these methods to commonplace clinical analysers has been implemented in the last few years [23–28].

The protein nature of the most abundant coagulation factors involved in the haemostasy process allowed the development of a large number of immunoassays based on the synthesis of new radioactive or enzymatic labels (radioimmunoassay [29], enzyme linked immunosorbent assay [30–33]). Immunoassay separation techniques such as immunoblotting [34], electroimmunodiffusion [35] or radioimmunodiffusion [36]) have also been used. In this area, application of other chromatographic or non-chromatographic separation techniques such as isoelectrofocusing [37], gel electrophoresis [38], affinity chromatography [39], molecular exclusion chromatography [40], high performance liquid chromatography [41–44] and gas chromatography [45,46] has been reported.

Recently, a continuous flow method based on

According to the literature [24,49] this method can be used to evaluate the extrinsic coagulation pathway. The approach designed for implementation of the method is based on the merging-zones and stopped-flow modes and the clotting reaction rate is monitored photometrically at 340 nm.

2. Materials and methods

2.1. Apparatus

A Unicam 8625 UV/VIS spectrophotometer furnished with a Hellma 176.052QS flow cell (25 μl inner volume) and equipped with a Perkin-Elmer R-100 recorder and a Neslab Exacal EX-110 recirculating thermostat was used. A Gilson Minipuls-2, four-channel peristaltic pump with a rate selector, a laboratory-made dual injection valve built using two Rheodyne 5041 injection valves and PTFE tubing of 0.5 mm i.d. were also used. A Zennitt data PC system connected via an RS-232 interface to the detector was used for

absorbance-time data acquisition, processing and delivery.

2.2. Reagents and standards

The buffer used was an aqueous solution containing 10 mmol 1^{-1} 5,5-diethylbarbituric acid sodium salt (Merck No. 500538) adjusted to pH 7.3 with hydrochloric acid. A carrier solution containing 100 mmol 1^{-1} sodium chloride (Merck No. 10.6404) and 20 mmol 1^{-1} calcium chloride (Merck No. 2382) was prepared in the above-mentioned buffer. Calcium thromboplastin (Sigma T-7280) was diluted to the appropriate extent in the carrier solution.

Coagulation control level I (Sigma C-7916) containing standardized human plasma diluted as required in the carrier solution was used for quality control of the coagulation testing according to the literature [50].

2.3. Samples

Venous blood with 129 mmol 1^{-1} trisodium citrate (1 ml per 9 ml of blood) as anticoagulant was collected with clean venipuncture and minimal stasis from healthy and sick individuals. Plasma samples were kept separate, snap frozen in small aliquots and stored at −50°C until assay (after thawing at 37°C for five minutes).
Fig. 1. Merging-zones/stopped-flow manifold. S, denotes sample; B, buffer; R, reagent; P, peristaltic pump; DIV, dual injection valve; a, merging point; L_1 open reactor; D, detector; T, thermostat; PC, personal computer; and w, waste. The boxed zone was thermostated.

Fig. 2. (A) Typical absorbance–time recordings. 1, denotes injection, Δt_1, delay time and Δt_2, stop time. (B) Detail of the coagulation curve. i_p, ΔS, and Δt denote induction period, increment of signal and time, respectively.

2.4. Flow injection manifold and procedure

The symmetrical merging-zones and stopped-flow manifold shown in Fig. 1 was used in order to minimize the reagent and sample consumption. It consists of a peristaltic pump (P) which propels the carrier (B) stream through two channels. A dual-injection valve (DIV) inserts both the calcium thromboplastin and sample solutions simultaneously into the buffer streams. Both plugs are merged at point a and then driven through the reactor L_1. When the reaction plug reaches the flow cell the peristaltic pump is halted. The clotting process is monitored during the stop time. Finally, the pump functioning is re-started and the clotting plug is wasted. A PC synchronizes the pumping periods with the injection time.

2.5. Types of measurements

Fig. 2 depicts the typical absorbance–time recordings obtained. The signal shows two parts (Fig. 2(a)). The first one, developed during Δt_1, is due to the absorption of the reaction ingredients at the selected wavelength and the second (developed in the Δt_2 interval) corresponds to the coagulation process. The latter can also be divided into two parts (see Fig. 2(B)): the first one corresponds to the induction period independent of the coagulation step, probably due to the initial adherency of the plug on the wall of the flow cell. The second part corresponds to the formation of the clot.

Table 1
Optimization of the variables

Type	Variables	Range studied	Optimum value
Instrumental	Wavelength (nm)	200–800	340

	[Calcium chloride] (mmol l^{-1})	6.0–8.0	7.3
	pH	1–10	5
	Reagent dilution	1–10	5
	Sample dilution		

The signal acquired, provides a way to establish a relationship between the initial coagulation rate and the total clotting activity in the sample. According to the common procedure followed for the estimation of the prothrombin time, by using the automated coagulation laboratory (ACL)-nephelometric method, it is also feasible to establish a relationship between the total clotting activity and the prothrombin time commonly used in the literature [49].

The measurement of the initial reaction rate was made along the linear-rising portion of the kinetic curve by using the equation $V = (A_2 - A_1)/(t_2 - t_1)$ where A_2 and A_1 are the absorbances over the linear portion of the curve defined by times t_2 and t_1, respectively.

3. Results and discussion

3.1. Study of the variables

The optimization of the process was aimed at enabling the calcium thromboplastin/sample mixture to reach the detection system as soon as possible, thus allowing a more complete monitoring of the overall process. The variables influencing the system were studied by the univariate method. Table 1 shows the ranges in which the variables were studied and the optimal values found.

3.1.1. Physical variables

The increase in temperatue had a favourable effect on the analytical signal, due to an increase in the coagulation reaction rate, up to 50°C; above this value the change was insignificant. The induction period decreased when the temperature increased above 35°C.

3.1.2. Chemical variables

The influence of the buffer concentration (5,5-diethylbarbituric acid sodium salt) on the analytical signal in the range studied was insignificant. A concentration of 10 mmol l^{-1}, enough to keep the working pH constant at 7.3, was adopted for further experiments. The carrier–buffer solution has a sodium chloride concentration of 14.54 mmol l^{-1} in order to acheive an ionic strength simialr to that of plasma.

The effect of dilution on both the calcium thromboplastin reagent and plasma solution were studied in order to minimize reagent and sample consumption. A dilution factor of five caused an acceptable clotting response with low reagent and

Table 2
Features of the method

Equation[a]	Linear range[b]	r^2	Relative standard deviation %[c]			Sampling frequency (h^{-1})
			Low	Medium	High	
ln $Y = 7.213 - 0.522$ ln X	10–100	0.9985	2.8	1.1	0.8	50

[a] Y denotes total clotting activity in %, X denotes the coagulation reaction rate.
[b] measured in % of total clotting activity.
[c] Value for 20, 50 and 80% of total clotting activity.

sample consumption. The carrier solution had a calcium concentration of 20 mM in order to avoid the dispersion of the calcium from the thromboplastin solution introduced into the dynamic system.

3.1.3. Hydrodynamic variables

High flow rates increased the analytical signal by reducing the plug dispersion along the system as the residence time of the plug was shorter, but in turn they made less precise delay time measurements. A flow rate of 1.6 ml min^{-1} was chosen as a compromise between both effects. Injection volumes of 50 μl for both calcium thromboplastin and sample provided the highest analytical signal. A length of 15 cm for reactor L$_1$ was selected as the minimum length that provided efficient mixing of the two plugs. Higher length increased the dispersion and decreased the analytical signal, i.e. a length of 60 cm caused a decrease in the peak height of 20%. Shorter reactors are not sufficient to connect the merging point a and the flow cell.

The time variables of the stopped-flow mode provided an optimal analytical signal for a delay time of 14 s for which the centre of the reacting plug was at the detector; the signal increased with the stop time but levelled off at 90 s. A plateau was obtained for longer times, which showed the stabilization of the clotting process.

3.2. Features of the method

The calibratin graph was obtained using the optimum values of the variables studied above. The human plasma calibration control was diluted to an appropriate extent in order to obtain a prothrombin activity between 5 and 100%, cal-

culated according to the conventional procedure [49]. Ten standard solutions were injected in triplicte into the FI manifold. The typical exponential relationship between the percentage of prothrombin activity and the coagulation rate obtained was represented by the following equation:

$$Y = 1357X^{-0.5422} \quad (r^2 = 0.9690)$$

where Y is the percentage of prothrombin activity and X is the reaction rate. Nevertheless, the data fit the equation below better

$$\ln Y = 7.213 - 0.5422 \ln X \quad (r^2 = 0.9985)$$

which represents the behaviour of the biochemical system between 10 and 100% of prothrombin activity; it was used in order to establish both the precision and applicability of the method.

A relationship can also be established between the coagulation reaction rate and the prothrombin time parameter (commonly use in clinical analysis), according to the mathematical expression:

$$Z = 1.403X^{-4.096} \quad (r^2 = 0.9747)$$

where Z is the prothrombin time and X is the reaction rate.

The precision afforded by the method was studied at three levels of prothrombin activity (20, 50 and 80%). Eleven samples of each level were injected in triplicate into the dynamic manifold. The repeatability, expressed as the percentage relative standard deviation, was better than 2.8% in all instances (see Table 2).

The sampling frequency was estimated at 50 per hour, due to the time required for the development of the clotting process.

3.3. Application to real samples

The performance of the method was tested by applying it to the determination of the total clotting activity in plasma, using twenty-five samples (from healthy and sick individuals) from a hospital. The samples were classified according to the procedence in normal plasma or plasma with anticoagulant therapy (courmarin or heparin treatment).

The results were compared with those obtained by using the ACL–nephelometric method [24] as shown in Fig. 3. The correlation equation and coefficient are as follows:

$$Y = 0.974X + 1.106 \quad (r = 0.9980)$$

where Y is the FI method and X is the ACL method. As can be seen, an excellent correlation exists between the proposed and the conventional method.

4. Conclusions

An automatic method based on flow injection has been used for the evaluation of the haemostasy process. This is the first time that a continuous flow system has been proposed to implement this assay.
Fig. 3. Correlation between the proposed method (FI) and the ACL–nephelometric method. Normal plasma samples (□) plasma (ten samples with similar concentration) after treatment with coumarin (■) or heparin (△).

The simplicity, repeatability and sensitivity of the method make it a valid alternative to the commercial methods for the determination of the prothrombin activity in plasma.

The sample throughput achieved by the FI approach surpasses that of the existing methods for this parameter. The results obtained by applying the continuous method to plasma samples agree well with those provided by the conventional method widely used in clinical laboratories.

The approach is a useful tool for the estimation of the extrinsic coagulation pathway (prothrombin, factor V, factor X_a, Ca^{2-} and phospholipid). It could be the basis for the development of new approaches in this area of clinical analysis.

Analysis of lead and tin in strong brine and high iron systems using the microsampling technique

T.S. Wai, H. Darus, N. Mohamed*

School of Chemical Sciences, Universiti Sains Malaysia, 11800 Penang, Malaysia

Abstract

The development of hydrometallurgical techniques such as the iron(III) chloride–sodium chloride system for the recovery of metals from scrap materials necessitates the analyses of these metals in a high salt medium during the recovery studies. An alternative method for the analysis of lead and tin in strong brine and high iron systems by flame atomic absorption spectrometry is a microsampling technique in combination with in situ standard addition. Relative standard deviations of 1.2% and 2.2% were obtained for the analysis of lead and tin respectively. The accuracy for the method is also satisfactory with recoveries ranging from 90% to 102%. The microsampling technique is rapid and simple, requires small volumes of sample and offers no clogging problems during the atomic absorption analyses.

Keywords: Lead and tin analysis; Microsampling technique

1. Introduction

The dissolution of scrap materials from which metals of interest are to be recovered is one of the basic steps in the recycling especially that of solid scrap materials. One of the most common solvent systems used in the dissolution of metal alloys is a mixture of concentrated acids. For example, a standard procedure in the dissolution of solder is by heating the alloy in a mixture of concentrated hydrochloric and nitric acids. A mixture of fluoroboric acid and hydrogen peroxide has also been used to dissolve a lead alloy containing tin and

antimony [1]. The use of hydrometallurgical processing for the recovery of metals from scrap materials offers another alternative. Kolodziej and Adamski [2] have suggested the ferric chloride hydrometallurgical process which uses acid solutions of ferrous chloride to recover silver from electronic scrap materials. Langer et al. [3] have tried the cupric chloride process for the recovery of copper from scrap materials. McDonald et al. have used cupric bromide in the recovery of copper from copper sulfide and ore concentrates [4]. An attempt has been made to use ferric chloride in a solution of sodium chloride of high concentration as a leaching reagent for solder in order to recover the tin and lead (T.S. Wai and H. Darus,

---

unpublished results). This mixture is a non-acidic solvent consisting of a mixture of iron(III) chloride–sodium chloride, which is less corrosive compared to acids. Because of the presence of a high concentration of iron(III) and sodium chloride, the analysis of lead and tin in the mixture needs further studies.

The presence of these ions may cause problems during the analysis of lead and tin using atomic absorption spectroscopy involved in the recovery studies. Many studies have been reported on the analysis of lead and tin but studies on the effects of the analysis of both elements in concentrated salt medium have been rather limited [5–10]. The interference effect of cations is usually overcome by using solvent extraction techniques or ion exchange methods. Even though the interfering elements are eliminated by these methods, these methods are tedious and problems such as the loss of the analyte during the extraction process or passage through the ion exchange column cannot be avoided. An alternative method is presented here for the analysis of lead and tin in strong brine and high iron systems by flame atomic absorption spectrometry using a microsampling technique in combination with in situ standard addition. In the microsampling technique, small volumes (< 500 µL) of solution were pipetted into a Teflon sampling cone and directly nebulized by a conventional capillary pneumatic nebulizer in a premixed flame. The transient recorder responses that result have similar precision and sensitivity to that obtained with normal larger (1–5 mL) samples by atomic absorption studies [11–13]. This sample introduction technique was found to be less susceptible to system clogging than normal steady state aspiration techniques since less sample is aspirated per analysis. The method of standard additions is used to ascertain

the elemental concentration in order to overcome sample matrix effects. Standard additions were performed on-the-spot in the Teflon sampling cone.

2. Experimental

2.1. Apparatus

A GBC Scientific Equipment Pty Ltd. (Australia) Model 903 atomic absorption spectrometer equipped with a standard nebulizer, 10 cm burner head, hollow cathode lamps and Pantos model Unicorder U-228 strip chart recorder was used for the analysis of lead. Background correction using a deuterium lamp was employed.

An IL 357 atomic absorption spectrometer equipped with a standard nebulizer, 5 cm burner head and hollow cathode lamps was used for the analysis of tin. The instrument parameters are given in Table 1.

Microliter pipettes (fixed and variable volume) were used. A Teflon sampling cone was constructed as shown in Fig. 1 with a capacity of 5 µL up to 2 mL with a 45° taper.

2.2. Reagents

All reagents were of analytical grade. All water used was deionized and distilled.

- Standard lead solutions: (1000 µg mL^{-1} Pb): a mass of 1.5985 g of analytical grade Pb(NO$_3$)$_2$ (Riedel de-Hahn) was dissolved in distilled, deionized water; 10 mL concentrated nitric acid

Table 1
Instrument parameters

| Element	Wavelength	Slit Width	Current	Flame
Pb	217.0 nm	1.0 nm	5.0 mA	Air–acetylene
Sn	235.5 nm	160 nm	6.0 mA	NO$_2$–acetylene

Fig. 1. Teflon sampling cone.

Table 2
Determination of lead in a synthetic tin–lead alloy

Sample	Concentration of Pb spike (ppm)	Concentration of Pb determined (ppm)	Percentage recovery (%)
P1	2.50	2.25	90.0
P2	2.50	2.45	98.0
P3	2.50	2.55	102.0
P4	5.00	5.20	104.0

was added and the solution was diluted to 1 liter.

● Standard tin solutions: (1000 μg mL^{-1} Sn): a mass of 1.000 g tin (99.99%) (Datuk Keramat Smelting, Pulau Pinang) was dissolved in aqua regia (HCl:HNO$_3$; 10:2), and diluted to 1 liter.

● Standard iron solutions: (1000 μg mL^{-1} Fe): ammonium iron(II) sulfate, $(NH_4)_2$ $Fe(SO_4)_2 \cdot$ (6H$_2$O), from E. Merck (Damstadt, Germany) was dissolved in 1 liter of water.

● Lead Standard 948206: Orion Research Incorp., Cambridge, Massachusetts, USA (lead as lead perchlorate, certified traceable to National Bureau of Standards SRM 928).

● Tin–lead alloy wire (60/40).

● Concentrated nitric acid (65%) from Riedel de Hahn.

● Concentrated hydrochloric acid (36%) from Ajax Chemical.

● Sodium chloride from R. M. Chemical, R & M Marketing, Essex, UK.

● Disodium salt of ethylenediaminetetraacetic acid (EDTA).

● Sodium fluoride from Fluka.

● Hexamine from BDH.

● Xylenol orange from BDH.

2.3. Procedure

2.3.1 Synthetic tin–lead alloy solution

Synthetic tin–lead alloy solutions with a 60:40 tin to lead ratio were prepared using standard tin and lead solutions. These solutions also contained 100 ppm iron(II) and 2.0 M sodium chloride to simulate samples resulting from the dissolution of the tin–lead alloy by ferric chloride hydrometallurgy.

2.3.2. Standard lead 948206

The original lead standard solution contained 0.1000 ± 0.005 mol L^{-1} lead (in the form of lead perchlorate). This is equivalent to 20720 μg mL^{-1} of lead. For the purpose of analysis, this stock solution was diluted to a range between 0 and 10 ppm.

2.3.3. Pure tin–lead alloy

The pure tin–lead alloy used in these studies is in the shape of a wire (diameter 1.2 mm, gauge 18 S.W.G.). The wires were cut with a pair of pliers to a length of 1.0 ± 0.2 cm. One alloy sample was dissolved in a mixture of 10 mL of concentrated hydrochloric acid and 2 mL of concentrated nitric acid, heated slowly on a hot plate, cooled and later filtered through some glass wool to get rid of the insoluble impurities. Another alloy sample was dissolved using ferric chloride hydrometallurgical dissolution (T.S. Wai and H. Darus, unpublished results).

2.3.4. Microsampling technique

Sample (100 μL) was pipetted into the Teflon cone using a micropipette. Water (100 μL) was added to the sample in the cone. The sample was then introduced by manually inserting the end of the plastic nebulizer tubing into the cone. A transient recorder signal resulted immediately. The concentration was estimated by comparison with the steady state signal of the appropriate standard solutions. The concentration was evaluated by the method of standard additions which was in situ in the Teflon cone. The volume of the standard added was 100 μL of an appropriate standard. At least three replicates were carried out for each sample.

2.3.5. Direct measurement

The standard solutions and the samples were aspirated directly into the flame. The concentrations of tin and lead in the samples were calculated by means of a calibration curve. These results were then compared to those obtained by the method of in situ standard additions using the microsampling technique.

Table 3
Determination of lead in standard lead samples

Sample	Concentration of Pb (certified value, ppm)	Concentration of Pb (ppm)		Percentage recovery (%)	
		DM	SA	DM	SA
LS1	20720	20800	18400	100.4	88.8
LS2	20720	18800	20000	90.7	96.5

DM, direct measurement.
SA, standard addition using the microsampling technique.
LS1 in distilled water.
LS2 in 2.0 M NaCl solution.

2.3.6. Titration method

Several solutions, 0.2 M standard EDTA solution, 0.01 M $Pb(NO_3)_2$ standard solution, 30% aqueous hexamine solution and a 0.2% xylenol orange solution were prepared. About 0.4 g of sample was weighted accurately. It was then dissolved in 10 mL concentrated hydrochloric acid and 2 mL of concentrated nitric acid with gradual heating. The mixture was then brought to the boil for 5 min. A volume of 25 mL of a 0.2 M standard EDTA solution was added and the mixture was again brought to the boil for another minute. A clear solution was obtained. This was then diluted to 250 mL with distilled water in a volumetric flask. Aliquots (25 mL) of the sample were pipetted into three separate conical flasks. Hexamine solution (15 mL), 110 mL of distilled water and four drops of xylenol orange were added to each of the conical flasks. Each mixture was then titrated with standard lead (II) nitrate solution until the color change from yellow to reddish purple was observed. Sodium fluoride (2 g) was then added to the mixture. The color of the solution then turned yellow as a result of EDTA being released from the tin(IV)–EDTA complex. This solution was then titrated until a purple color, which was stable for at least a minute, was observed.

2.3.7. Precision and accuracy of the microsampling technique

The precision and accuracy of the microsampling technique with in situ standard addition for the analysis of lead and tin in various media were evaluated.

Three samples of the synthetic tin–lead alloy solution were each spiked with 2.5 ppm of lead. The concentration of lead in these samples were then obtained by using the microsampling technique. The recoveries for the 2.5 ppm spike were then calculated.

Two solutions of the lead standard 948206 were prepared. One solution, LS1, was diluted from the stock solution with distilled water. The other, LS2, was prepared containing 2.0 M NaCl, 100 ppm iron and 100 ppm tin. The concentration of lead was determined using the microsampling technique and the direct measurement method.

A comparison between the three methods, that is, the method of standard addition using the microsampling technique, the direct measurement method and the titrimetric method was made for two alloy samples. One sample, PS1, was dissolved in a mixture of concentrated hydrochloric acid and concentrated nitric acid. The other sample, PS2, was dissolved in a mixture of $FeCl_3$–NaCl (T.S. Wai and H. Darus, unpublished results).

3. Results and discussion

3.1. Accuracy of the determination of lead using the microsampling technique

The recovery percentage for the 2.5 ppm lead spike on three samples of synthetic tin–lead alloy solutions was calculated. The recovery percentage ranged from 90.0% to 102.0%. Another sample which was spiked with 5.0 ppm lead gave a recov-

Table 4
Comparison between the three methods for the determination of lead and tin

Sample	Sample weight (g)	Weight determined (g)				Percentage (%)					
		A		B		A		B		C	
		Pb	Sn	Pb	Sn	Pb	Sn	Pb	Sn	Pb	Sn
PS1	1.0045	0.4906	0.5600	0.4746	0.5500	48.84	55.75	47.25	54.75	48.03	51.97
PS2	0.2314	0.1150	0.1330	0.1150	0.1250	49.70	54.02	49.70	54.02	49.92	50.52

B, direct measurement.
C, titrimetric method.
Note: for the titrimetric method, a different sample was used.

ery of 104.0%. The results are shown in Table 2. This showed that the microsampling technique gave accurate results for the determination of lead in samples containing 2.0 M NaCl and 100 ppm iron.

Two samples of standard lead, LS1 and LS2, were analyzed for lead using the microsampling technique and the direct measurement method.

Table 5
Precision data for the three methods in the determination of tin and lead

Method	Standard addition using the microsampling technique	Direct measurement method	Titrimetric method
Pb			
Mean (%)	49.27	48.48	48.98
Standard deviation	0.6	1.7	1.3
Relative standard deviation (%)	1.2	3.5	2.7
Sn			
Mean (%)	54.88	54.38	51.24
Standard deviation	1.2	0.5	1.0
Relative standard deviation (%)	2.2	0.9	2.0

Recoveries for the lead are shown in Table 3.

3.2. Comparison between the three methods for the determination of tin and lead

The results show good agreement for the determination of tin and lead between the three methods as shown in Tables 4 and 5. The relative standard deviation for the determination of lead using the microsampling technique, 1.2%, was the lowest among that obtained for the three methods whilst that for the titrimetric method is the highest, 2.7%. However, the relative standard deviation for the determination of tin using the microsampling technique was the highest.

4. Conclusion

The precision for the microsampling technique is satisfactory (a relative standard deviation of 1.2% for the analysis of lead and about 2.2% for the analysis of tin). The accuracy for the method is also satisfactory with recoveries of 90% to 102%. Therefore, with respect to the precision and accuracy of the microsampling technique together with its advantages, such as it being rapid and simple, requires small volumes of sample and has no clogging problems during the atomic absorption analysis, this technique was found to be suitable for the determination of the lead and tin in solder samples or solder dissolved using the iron(III) chloride hydrometallurgical process.

The separation and isolation of gold by selective extraction and transport through a polyurethane ether-type membrane

R.D. Oleschuk, A. Chow*

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada

Received 1 December 1995; revised 6 March 1996; accepted 7 March 1996

Abstract

The separation and isolation of gold(III) by selective extraction and transport through a ether-type polyurethane membrane was studied. Gold was found to be extracted into the membrane in strongly acidic solutions of HCl and HBr as the $HAuBr_4$ and $HAuCl_4$ complexes. Once extracted, the $HAuCl_4$ and $HAuBr_4$ complexes diffuse through the membrane and are recovered quantitatively in a receiving cell solution. This phenomenon was studied for the separation of a variety of binary metal solutions as well as for the separation of gold from a solution of gold ore. The preconcentration of gold was also achieved by adjusting the starting and receiving cell solution volumes.

Keywords: Gold; Isolation; Polyurethane ether-type membrane; Selective extraction; Separation; Transport

1. Introduction

In polyurethane chemistry the term "membrane" has been applied to two separate physical entities: a non-porous polymer film as used in this investigation, and foam-like films that are porous, allowing solution to percolate through them. The non-porous membranes suffer from the disadvantage of possessing a lower surface area. However, they prevent the two solutions on either side of the membrane from coming in contact with one another, ensuring the complete separation of the two phases on either side of the membrane.

Polyurethane foams were first shown by Bowen [1] to extract metals selectively from aqueous solution. Since then polyurethane foams have been extensively investigated for the sorption of both metals and organics from solution. Several reviews of the subject have been published [2–6].

When performing extractions with "foam-like" sorbents, it is often necessary to perform an additional extraction step to obtain the isolated species from the foam. Also, once the foam is saturated with a species, it is no longer an efficient sorbent. These two problems can be overcome by using polyurethane in the form of a membrane. Since the species is only in the membrane for a short period of time and is then isolated on the other side, it eliminates the additional extraction

---

step required when using the foam. The membrane can also become saturated like the foam, but will continue to perform the separation as the saturated species is transported through the membrane.

It has previously been shown that cobalt thiocyanate [7] complexes, as well as iron [8,9] and gallium [9] chloride complexes, can be extracted and transported through polyurethane membranes. The extent and rate of transport are dependent on the temperature, the affinity of the complex for the membrane and the amount of extracting species present in solution. The amount of extractable species in solution is then dependent on the individual stability constants of the metal complexes, and the relative concentrations of the complexing species present in solution. For gallium and iron the extracting species were shown to be $GaCl_4^-$ and FeX_4^- (where $X = Cl$, Br) respectively. Gold(III) is a softer acid than Ga(III) and Fe(III) in a Pearson [10] sense, so it prefers to form complexes with the larger halides at lower halide concentrations. Gold(III) forms halide complexes with chlorine, bromine and iodine. The iodide complex is less stable than the chloride and bromide, and extremely difficult to prepare in pure form [11]. The gold(III) halide complexes are analogous to those of iron(III) and gallium(III), all of which possess the formula MX_4^-.

Several researchers [12–15] have investigated the extraction of gold by polyurethane foams from aqueous media. Gold was observed to be extractable using an unloaded polyurethane ether-type foam from extremely acidic aqueous media (> 1 M HCl). The extraction was found to be due to the presence of the $AuCl_4^-$ complex formed at high HCl concentrations.

In this paper, gold is shown to be quantitatively and selectively extracted, transported and recovered, either alone or in the presence of other metals in solution. The effects of using both the chloride ($AuCl_4^-$) and bromide ($AuBr_4^-$) complexes on the transport process were investigated. The investigation into the extraction, the transport and the elution of gold from the membrane was undertaken to determine the viability of the separation as well as to obtain a better understanding of the overall extraction and transport processes.

2. Experimental

All gold analyses were performed with a Varian SpectrAA-20 atomic absorption spectrometer equipped with an Instrumentation Laboratory Visimax™ hollow cathode lamp and a Varian Mark VI burner head coupled with an air–acetylene flame. The wavelength observed was 242.8 nm with a slit width of 1.0 nm and a lamp current of 4 mA. All chemicals used were of reagent grade.

A Varian Liberty 200 ICP emission spectrometer was used for the multi-element determinations made when performing the separation of gold from gold ore. Inter-element correction was used when overlapping emission lines were present.

Stock gold solutions were prepared using $NaAuCl_4$ supplied by Johnson-Matthey. Concentrated hydrochloric acid was supplied by Fisher Scientific and concentrated hydrobromic acid from Anachemia. All water used was purified by a Barnsted Nanopure™ II system using reverse osmosis-treated feedstock. The membranes used were of the polyurethane ether-type (XPR625-FS) in two different thicknesses (0.025 mm and 0.050 mm) which were provided by Stevens Elastomerics/Urethane Products Northampton, MA, USA.

The apparatus used for membrane testing was a modified Donnan Dialysis Cell consisting of two separate cells (a starting and receiving cell). The starting cell was a Nalgene™ 125 mL PETG (polyethylene terephthalate copolyester) media bottle (cat # 2015–0125) with a 2 cm hole drilled into the screw cap. A small notch was also cut at the side of the drilled hole to prevent air bubbles being trapped at the membrane solution interface. The receiving cell consisted of a 100 mL beaker that was cut to an appropriate height for the solution volumes used. The screw caps on the media bottles allowed a quick, easy way of fastening the membrane to the bottle with an air- and water-tight seal. Experiments performed at temperatures other than ambient, used starting cells with a small hole drilled in them to prevent any

pressure build up. Membranes were cut into 5 cm × 5 cm squares and placed on the top of the open media bottle holding the sample. The screw cap was placed on the bottle and carefully tightened, yielding a membrane with an active surface area of 5.3 cm². The media bottle was then inverted and immersed in the solution held by the receiving cell. Each unit was wrapped in Parafilm™ to minimize evaporation. For each experiment a number of units were prepared and stopped after various time increments to obtain a separation profile and establish reproducibility. After the cells were stopped by removing the starting cell from the receiving cell, each cell was individually weighed and the pH measured to determine any solution losses due to evaporation or leakage through the membrane. The volume of solution in each of the cells was calculated using solution density.

All gold solutions were prepared from a 500 mg L⁻¹ standard prepared by dissolving NaAuCl₄ in water. The gold ore used in the gold ore separations is from the Kirkland Lake Mine in eastern Ontario, Canada. Gold ore solutions were prepared by first digesting the ore in aqua regia for a period of one week. The nitric acid portion of the mixture was then evaporated off while adding aliquots of concentrated HCl. The acid content of the mixture was lowered by then boling this solution while adding aliquots of deionised water. The solution was then filtered using Whatman™ No.42 filter paper to remove the silicates not dissolved in the acid. Gold standard (8 mL of 500 mg L⁻¹ gold) was added to the gold ore solution in a 250 mL volumetric flask to allow easier quantitation of the gold by both AA and ICP analysis. Finally the solution was made to 2.0 M HBr to facilitate the separation.

3. Results and discussion

3.1. Extraction and transport of HAuCl₄ and HAuBr₄

Gold in the presence of suitable HCl and HBr concentrations forms either the $AuCl_4^-$ or $AuBr_4^-$ complexes [16–18] respectively. We investigated

the use of both these complexes for the extraction and transport of gold from one cell into another. An experiment with a starting cell solution of 2.0 M HCl and 16 mg L⁻¹ gold combined with 0.5 M KCl in the receiving cell was performed with the result shown in Fig. 1. The amount of gold in the starting cell is shown to decrease to the point where it is quantitatively extracted into the membrane after 50 h. Conversely, we see the appearance of gold in the receiving cell after just 2 h, which increases to the point where quantitative recovery of the gold (> 97%) is achieved after 50 h. This experiment was also performed with 2.0 M HBr/16 mg L⁻¹ gold in the starting cell combined with 0.5 M KBr in the receiving cell. These conditions were chosen to allow direct comparison between the two gold halide complexes. The results of this experiment are also shown in Fig. 1. The quantitative extraction of gold under these conditions takes place in under 20 h, while the quantitative recovery of the gold in the receiving cell occurs in approximately 40 h. The difference in extraction and transport rates of these two complexes can be explained by the relative hydrophobicity of each of the complexes. The $AuBr_4^-$

Fig. 1. Extraction and transport of HAuCl₄ and HAuBr₄ through a polyurethane membrane. The starting cell contains 10 mL of 15 mg L⁻¹ gold in 2.0 M HCl or HBr. complex, possessing the larger bromide ligands, is more hydrophobic than the chloride analogue. Thus, the bromide complex will be more readily extracted into the hydrophobic membrane material. One would also expect that the stability constants of the gold complexes would play a factor in the extraction rate as shown by Oleschuk and Chow [8] for iron halide complexes. Pan and Wood [16,17] have performed detailed laser Raman studies on gold(III) chloride and bromide complexes in the concentration ranges in which we are working and found that the overwhelmingly predominant species present under these conditions were the $AuCl_4^-$ and $AuBr_4^-$ complexes. This explains the reason for the extraction into the membrane material but not the transport and recovery of the gold in the receiving cell solution.

Transport in the membrane material after extraction appears to follow Fick's law of diffusion and is concentration independent. The gold complex diffused through the membrane to the membrane/receiving cell interface and is then eluted into the receiving cell solution.

$$HAuCl_4 \rightleftharpoons \overline{HAuCl_4} \xrightarrow[\text{membrane}]{\text{diffusion in}} \overline{HAuCl_4} \rightleftharpoons AuCl_4^-$$

(overline indicates species in the membrane)

The conditions used in the receiving cell (0.5 M KCl and 0.5 M KBr respectively) favour the formation of the $AuCl_4^-$ and $AuBr_4^-$ complexes. This phenomena has been verified by UV/vis spectra of the receiving cell solutions. Both starting and receiving cell solutions possessed identical spectra with λ_{max} at 374 nm and 314 nm for the $AuBr_4^-$ and $AuCl_4^-$ complexes respectively.

The quantitative recovery of the gold in the receiving cell is attributable to the pH of the receiving cell solution. The pH of the receiving cell solution favours the formation of the non-protonated gold complexes (i.e. $AuCl_4^-$ and $AuBr_4^-$). The protonated neutral species are the only complexes that are extractable into the membrane material. Therefore, the protonated gold complexes diffuse through the membrane material and elute into the receiving cell solution where they form either the $AuCl_4^-$ or $AuBr_4^-$ non-protonated complexes depending on the salt used.

Fig. 2. Extraction and transport of $HAuBr_4$ using two different membrane thickness. The starting cell contains 10 mL of 15 mg L^{-1} gold in 2.0 M HBr. The receiving cell contains 0.5 M KBr. ▲, starting cell using a 0.025 mm thick membrane; ◆, receiving cell using a 0.025 mm thick membrane; ■, starting cell using a 0.05 mm thick membrane; ●, receiving cell using a 0.05 mm thick membrane.

These non-protonated gold halide complexes are not extracted by the membrane leaving the gold trapped in the receiving cell solution where it is quantitatively recovered.

3.2. Membrane thickness

To determine the effect of membrane thickness on the rate of transport, two different thicknesses of 0.025 mm and 0.05 mm were used. The solution conditions consisted of 2.0 M HBr/15 mg L^{-1} gold in the starting cell and 0.5 M KBr in the receiving cell. As expected the time required for the transport of the gold from the starting to receiving cells was faster for the thinner membrane. A transport profile for each thickness is shown in Fig. 2. The quantitative recovery of the gold in the receiving cell required approximately 20 h for the 0.025 mm membrane compared to approximately 40 h for the 0.05 mm membrane. The flux is inversely proportional to the membrane thickness and is in accordance with Fick's law of diffusion.

$$J_i = D_i \Delta c_i / x_i$$

where J is the flux of the penetrant (Au Br$_4^-$), D is the diffusivity constant of the membrane, Δc is the concentration difference within the membrane and x is the membrane thickness.

The time required for the complete extraction of the gold from solution into the membrane was the same for both thicknesses demonstrating that the rate limiting step of the overall process is the diffusion of the gold through the membrane material after it has been extracted. The increased rate of transport with the thinner membrane demonstrates that if an even thinner membrane was used, faster transport times could be obtained although this might lead to some mechanical problems such as leakage, because of the fragile nature of extremely thin films.

3.3. Effect of temperature

Experiments were carried out at four different temperatures (4, 22, 37 and 50°C) with starting cell conditions being 2.0 M HBr/16 mg L^{-1} gold and receiving cells containing 0.5 M KBr. Results depicting the sorption of the gold into the membrane material at different temperatures are shown in Fig. 3. With an increase in temperature an increase in the rate of sorption of the gold species into the
Fig. 3. Extraction of gold into a polyurethane membrane at 5, 22, 37 and 50°C. The starting cell contains 10 mL of 15 mg L^{-1} gold in 2.0 M HBr. The receiving cell contains 0.5 M KBr. ●, starting cell 5°C; ◆, starting cell 22°C; ■, starting cell 37°C; ▲, starting cell 50°C.
Fig. 4. Arrhenius plot of the gold extraction into a polyurethane membrane. The starting cell contains 10 mL of 15 mg L^{-1} gold Au in 2.0 M HBr. The receiving cell contains 0.5 M KBr.

membrane was observed. An increase in the rate of diffusion in the membrane material and rate of recovery for gold in the receiving cell was apparent. At 5°C the complete extraction of the gold species required approximately 30 h compared to 50°C where it required under 10 h. Conversely, the recovery of gold in the receiving cell at 50°C required 11 h while at 5°C the recovery of the gold was not complete even after 200 h.

The energy of activation was calculated to be 25 KJ mol^{-1} using an Arrhenius plot, as shown in Fig. 4. This value is consistent with values found for the sorption and transport of aqueous salt [19], acetic acid solution [20] and iron halides [8]. It was assumed that the gold remained in the AuBr$_4^-$ complex even though Pan and Wood [16] have shown that at higher temperatures the AuBr$_4^-$ starts to transform to the linear AuBr$_2^-$; the amount of this complex present was shown to be negligible. The linearity of the Arrhenius plot confirms that there is minimal transformation to AuBr$_2^-$.

The harsh acid and temperature conditions did not appear to alter the performance of the membrane material but changed the physical appearance of the membrane from clear and translucent to slightly opaque. After the experiment has been stopped and the membranes dried, they returned to their initial physical appearance. The change in

physical appearance is probably due to the swelling of the membrane from the absorption of water. The effects of the high acidity on the membrane were not apparent; polyether-type polyurethane is quite resistant to hydrolysis owing to the stability of the ether linkages incorporated in this polymer compared to the polyester polyurethane analogue.

3.4. Metal separations

The ability of gold to be transported under certain solution conditions using a polyether-type polyurethane membrane provides evidence that gold can be separated from other species using this process. Gold will preferentially form the extractable $HAuCl_4$ and $HAuBr_4$ complexes over other metals because of their higher stability constants. The separation of several binary metal systems has been achieved using this phenomenon. For example, in Fig. 5, data is shown for the separation of gold from a 2.0 M HBr solution containing 16 mg L^{-1} gold and 16 mg l^{-1} nickel. The receiving cell solution is 0.5 M KBr. The same transport profile is achieved for
Fig. 5. Separation of gold and nickel using a polyurethane membrane. The starting cell contains 15 mg L^{-1} gold and 15 mg L^{-1} nickel in 2.0 M HBr. The receiving cell contains 0.5 M KBr. ■, gold content in starting cell; ●, gold content in receiving cell; ▲, nickel content in starting cell; ◆, nickel content in receiving cell.
Fig. 6. Separation of gold and iron using a polyurethane membrane. The starting cell contains 15 mg L^{-1} gold and 15 mg L^{-1} iron in 2.0 M HBr. The receiving cell contains 0.5 M KBr. ■, gold content in starting cell; ●, gold content in receiving cell; ▲, iron content in starting cell; ◆, iron content in receiving cell.

gold as was demonstrated in previous figures. However, the nickel is neither extracted into nor transported through the membrane material. The extraction and transport of nickel would be evident by the decrease or increase of the nickel concentration of either the starting or receiving cells respectively. The basis of this separation is that gold forms the extractable $HAuBr_4$ at 2.0 M HBr concentrations, while the nickel does not form an extractable complex and thus remains in the starting cell. Therefore the gold is able to pass into the receiving cell where it is quantitatively recovered. This type of separation would be possible for all metals not able to form extractable complexes with the bromide ion.

There are some metals that are able to form extractable complexes with the bromide ion. It has previously been shown [8] that iron can be quantitatively transported and recovered using an analogous process. At HBr concentrations of 5.0 M, iron is present in the $HFeBr_4$ complex which is extractable into the polyurethane membrane material. A separation experiment involving gold and iron was performed with the results shown in Fig. 6. The experiment was performed with a starting

cell solution of 16 mg L⁻¹ gold and 16 mg L⁻¹ iron in 2.0 M HBr and 0.5 M KBr in the receiving cell. The extraction and transport of the gold follows the same extraction/transport profile as previously shown; however the iron is neither extracted nor transported through the membrane material. The lack of iron extraction can be explained by the iron bromide stability constants. At HBr concentrations of 2.0 M there is essentially no iron present as the FeBr₄⁻ complex; thus none of the iron is extracted and ultimately transported through the membrane material. The iron remains in the starting cell while the gold is transported through the membrane and quantitatively recovered in the receiving cell.

Several separations involving binary metal mixtures of gold and another metal have been successfully performed. These mixtures all involve gold with either nickel, zinc, iron, cadmium, tin or cobalt. In each case the extraction, transport and recovery of the gold species appears to be unaffected by the presence of the other metal in solution. The shape of the separation profiles are all virtually identical.

Although only separations using HBr to form the HAuBr₄ complex have been shown in this paper, several binary metal separations have been performed using hydrochloric acid (to form the HAuCl₄ complex) in place of hydrobromic acid and potassium chloride in place of potassium bromide. These separations were successful but were slightly slower than those for the bromide analogue. The lower rate of extraction can again be atrributed to the lower hydrophobicity of the chloride complex, HAuCl₄, relative to the bromide complex, HAuBr₄.

3.5. Preconcentration of gold

It is often valuable to concentrate as well as separate one species from another. Using a polyurethane ether-type membrane we attempted to concentrate gold by adjusting the solution volumes on either side of the membrane. Fig. 7 shows a separation and preconcentration experiment involving 30 mL of 5 mg L⁻¹ gold in 2.0 M HBr in the starting cell with 10 ml of 0.5 M KBr in the receiving cell. With these solution volumes

the quantitative transport and recovery of gold in the starting cell should produce a 15 mg L⁻¹ concentration of gold in the receiving cell, or a concentration factor of three. The concentration factor is defined as the ratio of the initial concentration to the final concentration of the particular element of interest.

This experiment clearly shows that gold can be transported and concentrated using the polyether-type polyurethane membrane material. The larger starting solution volume showed that the diffusion of the species through solution was hindering the extraction process to a significant degree. To minimize the effect of the larger solution volume the starting cell was stirred. This lead to a greatly increased rate of extraction and transport of the gold species. In all of the experiments performed in this paper the active surface area of the membrane has been kept at 5.3 cm² for the sake of comparison. If this area was increased the rate of extraction and consequently the overall concentration factor may be increased.

3.6. Separation of gold from gold ore

The ability of gold to be transported in the presence of other metals has already been shown in a previous section. Under these conditions the

[a] The gold ore solution was spiked with gold standard to 16.0 mg L⁻¹ prior to the experiment; this results in 0.168 mg of gold in each starting cell.

selective transport of gold could be achieved resulting in the quantitative separation of gold. Those separations were of relatively simple systems of a binary metal mixture. To demonstrate the ability of a polyurethane ether-type membrane to separate gold from a much more complicated medium we attempted the separation of gold from a gold ore solution. The gold ore solution was prepared as described in the experimental section. The gold ore solutions were spiked with gold standard because the small amounts of gold in the ore (fire assay 3.06 oz per ton) would be difficult to analyse and quantitate. The top cell consisted of 10 mL of gold ore solution while the bottom cell contained 30 mL of 0.5 M KBr. This experiment was performed at room temperature, carried out over a period of 48 h and was unstirred. The results of the separation are presented in Table 1. The table lists the amount of each metal in both the top and bottom cells as determined by ICP and AA analysis. The metals analysed were chosen by performing an initial scan of several metals

suspected of being in the gold ore. If a metal was present in detectable concentrations it was further analysed for in each of the cells. The gold ore from the Kirkland Lake Mine is known to possess a large concentration of pyrite. This is demonstrated by the very large iron concentrations in the samples.

Examining the metal content of the starting cells we see that the gold content of the top cell decreases as it is extracted into the membrane until it is almost quantitatively extracted after 26 h. The amounts of the other metals in the starting cells do not change drastically over a 48 h period. This indicates that very little of the other metals are being extracted and transported into the receiving cell.

The analysis of the receiving cell once again shows the trend of the gold being transported through the membrane material and into the receiving cell solution. The initial gold content of zero at the start of the experiment gradually increases to 0.155 mg, a 92.3% recovery of the

initial gold in the starting cell after 48 h. Conversely, the analysis for the other metals in the receiving cells showed that there were no detectable amounts of either cobalt or manganese in any of the cells. Also the analysis of iron, zinc and copper showed that only microgram quantities of these metals were present in the receiving cell solution after 48 h. The small amounts of copper and zinc present approached the detection limits of the instrument and the concentrations of each in the receiving cell is not significant. The results of the gold ore separation again shows that there does not appear to be a competing ion effect between the other metals and gold even though some of those metals are present in much higher concentrations than gold. The rate of extraction and transport of the gold complexes is unchanged regardless of the concentrations of the other species in solution.

By performing the separation of gold from gold ore we are not suggesting that this technique be used for this purpose as there are techniques already developed that are far more efficient for this process. We are suggesting however, that polyurethane ether-type membranes may be used for the separation of gold from complex matrices possessing a large number of species.

4. Conclusion

A polyether-type polyurethane membrane can quantitatively transport gold from hydorochloric and hydrobromic acid solutions to KCl and KBr solutions, respectively. The transport process involves the extraction of the gold species, diffusion through the membrane material, and finally the quantitative elution of the gold species from the membrane. The extraction of the gold species is due to the two protonated gold halide complexes $HAuBr_4$ and $HAuCl_4$, that predominate in high concentrations of either HCl or HBr. The diffusion through the membrane follows a Fickian diffusion model. The elution from the membrane is caused by the formation of the $AuCl_4^-$ and $AuBr_4^-$ complexes that are not extractable into the membrane.

The transport process is aided by the use of a thinner membrane and an increase in temperature. Also, with an increase in the surface area of the membrane we can expect that the overall rate of extraction and capacity of the membrane will be increased significantly where it may be used in a practical setting. The rate limiting step for the transport and recovery of the gold is the diffusion through the membrane. From an Arrhenius plot the energy of activation was shown to be 25 kJ mol^{-1}.

In this investigation all of the cells, with the exception of the preconcentration experiments, were unstirred. This allowed the direct comparison of experiments with no error associated with different rates of stirring. With the addition of stirring we see a fourfold increase in the rate of extraction into the membrane, but this does not allow direct comparison of separate experiments because of the lack of the ability for precise control of individual stirring rates. The method is inexpensive and inherently simple compared to other techniques available and so these methods may provide a useful alternative to other separation processes. Quantitative recovery of gold from the membrane into the receiving cell solution indicates that there is no permanent sorption of the complex, and further that there is no reduction of the complex to metal by the polymer.

The separation of gold from a number of other metals in binary metal systems shows that a polyurethane ether-type membrane can be used to separate gold from metals that do not form extractable complexes in the presence of either HBr or HCl. Even in cases where a metal can form extractable complexes in the presence of either of these acids (i.e. iron), the membrane can still effectively separate the two metals based on the stability constants of those metal halide complexes.

Gold ore has large amounts of other metals besides gold which are not extracted and transported through the membrane into the receiving cell solution. The separation of gold from a gold ore solution demonstrates the ability of the membrane to separate gold from very complex matrices.

Determination of fat-soluble vitamins in yogurt by HPLC with electrochemical detection

M.M. Delgado Zamarreño*, A. Sanchez Perez, M. Sanchez Rodriguez, M.C. Gomez Perez, J. Hernandez Mendez

Departmento de Quimica Analítica, Nutrición y Bromatología, Facultad de Ciencias Químicas, Universidad de Salamanca, 37008 Salamanca, Spain

Abstract

A method employing HPLC with electrochemical detection for the rapid and simultaneous determination of vitamins A, D_3 and E is described. The method uses a C-18 reverse phase column and 2.5 mM HAcO–NaAcO in methanol–water (99:1, v/v) solution as the mobile phase. The compounds are quantified using amperometric detection with a glassy carbon electrode at a potential of + 1300 mV (vs. Ag/AgCl) and the results are compared with those obtained using UV detection at a wavelength of 280 nm.

The method was successfully applied to the analysis of vitamins A, D_3 and E in yogurt samples. After saponification, fat-soluble vitamins were extracted and the methanolic solution of the extracts was injected directly into the chromatographic system, avoiding the clean-up step which is necessary when no electrochemical detection is used. Good recovery percentages were obtained.

Keywords: Electrochemical detection; High performance liquid chromatography; Vitamins A, D_3 and E; Yogurt

1. Introduction

In recent years, a great deal of research has been devoted to developing sensitive, selective, rapid and reliable methods for the analysis of fat-soluble vitamins in foods [1] because deficiencies of these vitamins cause serious nutritional diseases. The analysis of vitamins A, D_3 and E in milk is of major importance because dairy foods play a vital role in human nutrition.

Over the past few years, the consumption of yogurt has increased largely because of the nutritional and therapeutic advantages involved; it facilitates the assimilation of proteins, lactose and lipids and promotes a balanced intestinal flora [2]. Methods have been described for the analysis of fat [3], inorganic acids [4], lactose [5,6] carbohydrates [7], preservatives [8–10], ascorbic and dehydroascorbic [11] acid and α-dicarbonyl com-

* Corresponding author.

pounds [12], although currently there are no methods for the determination of liposoluble vitamins in yogurt samples.

Despite this, many research works have determined liposoluble vitamins in samples of milk and dairy products using liquid chromatography [13–28]. In some of these studies, the vitamins were extracted directly from the sample [13–18] and different extract cleaning steps were performed before quantification [19–28]. In most determinations, the classic method is used; this involves alkaline hydrolysis of the sample, followed by extraction of the vitamins from the unsaponifiable material and, finally, their injection into the chromatographic system.

In a previous paper [29] a method for the simultaneous determination of vitamins A, D_3 and E in milk samples, without the need for any clean-up step for the detection of vitamin D_3, was proposed. Recently [30] a directly-coupled sample treatment–HPLC method for on-line automatic determination of liposoluble vitamins in milk has been developed.

In this work, we report on an HPLC method with electrochemical detection for the analysis of vitamins A, D_3 and E in yogurt samples, studying extraction of the vitamins, with and without previous alkaline hydrolysis, from the fat material, for later injection into the chromatographic system.

Fig. 2. Recoveries of clean-up step: Silica cartridges; solvents used in elution are shown in the Figure.

2. Experimental

2.1. Apparatus

2.1.1. Liquid chromatograph

An SP 8800 Spectra-Physics ternary pump equipped with a Rheodyne valve with an injection loop of 10 μl was used. The detectors were a UV Spectra-Physics SP 8450 and an electrochemical EG & G PAR model 400. Peak areas were measured by an SP 4290 Spectra-Physics integrator.

2.1.2. Chromatographic columns

An RP18 15 mm × 3.2 mm, 7 μm precolumn (Brownlee Labs) and an OD-224 RP18 220 mm × 4.6 mm, 5 μm column (Brownlee Labs) were used. Sep-Pak C18 and Silica cartridges (Millipore) and a Büchi RE 121 rotavapor with Büchi 461 water bath were also used.

2.2. Reagents

2.2.1. Chemicals

The following chemicals were used: all-trans-retinol, vitamin A (Sigma); cholecalciferol, vitamin D_3 (Fluka); α-tocopherol, vitamin E (Aldrich); potassium hydroxide, acetic acid and sodium acetate (A.R. grade; Panreac). Water was purified in an Elga-Stat water purification system.

Table 1
Determination of liposoluble vitamins in different yogurt samples with the direct extraction method. Results from three replicate analyses

Sample No.	Vitamin A (μg per 100 g)	Recovery (%)	Vitamin E (μg per 100 g)	Recovery (%)
1	0.99	89	0.86	85
2	0.017	98	0.03	101
3	0.87	78	0.015	100
4	0.46	101	0.065	97
5	0.75	95	0.01	81

2.2.2. Mobile phase

A solution of 2.5 mM acetic acid–sodium acetate in methanol–water (99:1, v/v) was used.

2.2.3. Alcoholic potassium hydroxide solution

50 ml ethanol and 15 ml of aqueous KOH 80% (w/v) solution were used.

2.2.4. Solvents

Hexane, chloroform, ethanol, ether, acetonitrile and LC-grade methanol (Carlo Erba) were used.

2.2.5. Samples

Commercial yogurt was used for the samples.

2.3. Procedures

2.3.1. Liquid chromatography

The HPLC operating conditions were optimized in a previous study [29]. The mobile phase used, degassed with helium, was a 2.5 mM acetic acid–sodium acetate buffer as supporting electrolyte in a methanol–water solution (99:1, v/v). The flow rate was set at 1.0 ml min^{-1}. Standards of vitamins or extracts from the samples dissolved in methanol were injected through the Rheodyne valve. Before use, the glassy carbon electrode was treated electrochemically, polarizing at -600 mV for 10 min and $+1400$ mV for 30 min in the flow stream. The detection potential for the vitamins was $+1300$ mV (vs. Ag/AgCl). The UV detection wavelength chosen was 280 nm, a compromise wavelength for the detection of the three vitamins. The results obtained with both detection methods were similar. The different parts of Section 3 show

the results corresponding to amperometric detection with the exception of Table 4, which shows those corresponding to both types of detection.

2.3.2. Analysis without hydrolysis

Yogurt samples (40 g) were treated with 40 ml of extractant mixture (hexane–chloroform, 2:1, v/v). This was stirred at 1000 rev min^{-1} for 2 h and protected from light. Following this, it was centrifuged at 4000 rev min^{-1} and the organic phase separated. This was evaporated in a rotavapor at 50°C and the residue was treated with 6 ml of methanol. Then, a clean-up step was performed, using C18 cartridges previously treated with 2 ml of the same solvent and adjusted to a final volume of 10 ml. This was then injected into the chromatographic system.

2.3.3. Analysis with alkaline hydrolysis

Samples (20 g of yogurt) were saponified overnight at room temperature with an alcoholic solution of potassium hydroxide plus ascorbic acid to avoid oxidation. The vitamins were extracted with hexane, the solvent was evaporated off, the residue was dissolved in 5 ml of methanol and was then injected into the HPLC system after filtration (0.45 μm pore size) without any clean-up step.

3. Results and discussion

3.1. Extraction of vitamins

In the analysis of fat-soluble vitamins, different

Table 2
Influence of KOH concentration. Results from three replicate analyses

Yogurt sample	Vitamin A $10^6 \times$ area		Vitamin E $10^6 \times$ area	
	KOH 60%	KOH 80%	KOH 60%	KOH 80%
1	3.83	3.20	3.89	3.25
2	2.36	3.11	2.63	3.98
3	3.44	4.09	3.55	4.76
4	2.91	3.15	2.95	3.10
5	2.22	2.93	1.89	2.56
6	2.25	4.64	1.34	3.31
7	3.25	3.98	2.49	3.76

steps are necessary: saponification, extraction and clean-up of the samples before injection into the HPLC system. To avoid the saponification step, direct extraction of the vitamins from the yogurt samples was attempted. The samples (40 g) were treated with 40 ml of different solvents and extractant mixtures: hexane, methanol, hexane–chloroform–ethanol (6.0: 3.5: 0.5, v/v/v), hexane–chloroform (2:1, v/v) and chloroform–hexane (2:1, v/v), with constant stirring in the dark for 2 h.

According to Elton-Bolt and Stacey [31], the ideal extractant mixture for extracting different liposoluble vitamins in cod-liver oil samples is hexane–chloroform–ethanol (6.0: 3.5: 0.5, v/v/v). However, in our case, the best results were obtained with a hexane–chloroform (2:1, v/v) mixture. Accordingly, this was used in all later analyses.

After centrifugation, the organic phase was removed by evaporation in a rotavapor under vacuum at 50°C and the residue, a few milliliters, was dissolved in 6 ml of methanol and passed through a cartridge to clean the extracts before they were injected into the chromatographic system.

3.2. Cleaning of extracts

A clean-up step is necessary prior to injecting the extracts into the chromatographic system to eliminate possible interferents. Accordingly, a study was carried out on the clean-up step with

standard solutions containing the three vitamins, applying the described procedure. To do so, the extracts dissolved in different solvents were passed through a C18 cartridge, to retain impurities but not the vitamins being studied. Different solvents were tested: acetonitrile, methanol and mixtures of both of these. The best recoveries for all vitamins were obtained with 100% methanol, as can be seen in Fig. 1. The solutions thus obtained were injected directly into the chromatographic system.

A further study was carried out using Silica cartridges, previously diluting the extracts in hexane instead of methanol. In this way, the vitamins

Fig. 3. Influence of ascorbic acid. Standard: (□) vitamin A; (◆) vitamin D_3; (▣) vitamin E. Yogurt sample: (◇) vitamin A; (■) vitamin E.
Fig. 4. Influence of amount of yogurt sample on analytical signal: (□) vitamin A; (◆) vitamin E.

were retained in the cartridge but not the interfering substances. Later, the vitamins were eluted with different hexane–ether mixtures. The best results were obtained with a hexane–ether mixture of 50:50 (v/v) (Fig. 2). The solution eluted was brought to dryness and the residue dissolved in 5 ml of methanol for injection into the chromatographic system. This step was necessary because direct injection of the eluate interferes in the quantitative evaluation of vitamin A since this elutes very early on, close to the chromatographic peak corresponding to the injection.

Although the recovery values obtained are similar using both types of cartridge, the C18 cartridge was chosen for work because it avoids the evaporation step with hexane–ether and later dilution in methanol, thus simplifying the process.

3.3. Analysis of vitamins in yogurt samples: Without hydrolysis

After optimization of the vitamin extraction steps and the extract clean-up procedure, different samples of yogurt were analyzed using the procedure without hydrolysis. Vitamin levels were measured in unspiked samples and in samples spiked with standard solutions to evaluate the contents and the recovery of the method respectively. Good recoveries were obtained for vitamins A and E (Table 1). In all cases, the amounts obtained were smaller than the contents found in the tables listing the food composition for these vita-

mins [32]. Vitamin D_3 did not appear in any of the samples of yogurt analyszed with this method. The conclusion drawn was that in yogurt samples it is necessary to saponify and extract the vitamins before injection into the HPLC system.

3.4. Analysis of vitamins in yogurt samples: With hydrolysis

In view of the poor results obtained in the determination of vitamins in yogurt using direct extraction of the vitamins, the method most commonly used for analyzing liposoluble vitamins in foods was used; this consists of alkaline hydrolysis of the fatty material and later extraction of the unsaponifiable material containing the liposoluble vitamins.

Among the variables that may affect sample treatment and quantification of the vitamins are the concentration of KOH, the amount of ascorbic acid added, the amount of sample to be treated, and the injection volume. In order to

Fig. 5. Chromatogram obtained after application of the proposed method to a yogurt sample according to the scheme in the text.

Table 3
Determination of liposoluble vitamins in different yogurt samples with alkaline hydrolysis

	Amperometry (μg per 100 g)	UV (μg per 100 g)	Recovery (%)	Amperometry (mg per 100 g)	UV (mg per 100 g)	Recovery (%)
1 ($n = 8$)	23 ± 3	25 ± 3	95 ± 9	0.073 ± 0.05	0.061 ± 0.06	98 ± 4
2 ($n = 5$)	23 ± 1	23 ± 1	89 ± 4	0.057 ± 0.06	0.059 ± 0.06	93 ± 10
3 ($n = 8$)	22 ± 2	22 ± 2	91 ± 6	0.064 ± 0.05	0.058 ± 0.04	100 ± 5
4 ($n = 5$)	26 ± 2	27 ± 2	88 ± 5	0.063 ± 0.03	0.058 ± 0.02	86 ± 3
5 ($n = 6$)	31 ± 3	28 ± 1	91 ± 5	0.087 ± 0.03	0.077 ± 0.04	103 ± 5

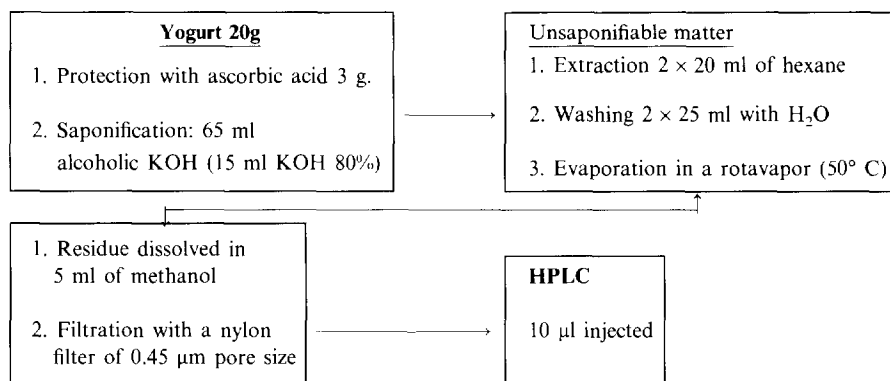
study the effects of these parameters on the determination of the vitamins, they were studied in the procedure involving hydrolysis.

3.4.1. Alcoholic potassium hydroxide solution

In samples of milk and other milk products, an alcoholic potassium hydroxide solution containing 15 ml of KOH at a concentration of 60% (w/v) and 50 ml of ethanol is generally used [29]. Since yogurt samples have different textures and it is possible that total hydrolysis of the fatty matter might not be completed, two assays were performed with KOH at 60% and at 80% following the indicated procedure with a view to checking whether there were any variations in the later evolution of the analytical signal. Table 2 shows that the best results are obtained with 80% KOH since hydrolysis is more complete.

3.4.2. Ascorbic acid

Ascorbic acid is added to the samples to be hydrolyzed as an antioxidant to protect the liposoluble vitamins, mainly vitamin E, in the alkaline medium in which hydrolysis is carried out. In order to check that the amount of ascorbic acid added is sufficient for complete protection of the vitamins, the above-described procedure was implemented both in standard solutions (containing the three vitamins under study) and in yogurt samples, in each case varying the amount of ascorbic acid added from 1–8 g. The data obtained are shown in Fig. 3. A working amount of 6 g of ascorbic acid per 40 g of yogurt was chosen—i.e. a ratio of 3/20—because the analyti-

cal signals obtained were thus reproducible and more sensitive than when lower amounts of ascorbic acid were used.


3.4.3. Sample amount

The vitamins in samples of yogurt are present at low concentrations, around the microgram per 100 g range. Although electrochemical and spectrophotometric determinations are sensitive, a minimum sample amount must be analyzed if vitamin detection is to be successful. However, the amount of sample cannot be increased too much because although with the sample preparation procedure and separation one is trying to achieve a situation in which the vitamins will be free of substances that might prevent their determination, they may be accompanied by components that gradually cause contamination of the C18 stationary phase to be used in the determination. Amounts of yogurt between 10 and 50 g were employed and the above-described method was applied, adding the corresponding amount of ascorbic acid to each sample but always maintaining the 3/20 ratio as the most suitable.

From the data thus obtained (Fig. 4) it can be deduced that 20 g of sample is sufficient for the determination of the vitamins. Larger amounts are not suitable because the extracts contain more interfering substances.

3.4.4. Analysis of Vitamins A and E

The method proposed for determination of liposoluble vitamins in yogurt samples is the following:

Yogurt 20g
1. Protection with ascorbic acid 3 g.
2. Saponification: 65 ml alcoholic KOH (15 ml KOH 80%)

→

Unsaponifiable matter
1. Extraction 2 × 20 ml of hexane
2. Washing 2 × 25 ml with H_2O
3. Evaporation in a rotavapor (50° C)

1. Residue dissolved in 5 ml of methanol
2. Filtration with a nylon filter of 0.45 μm pore size

→

HPLC
10 μl injected

Sponification of the samples with alcoholic potassium hydroxide was carried out at room temperature overnight. After extraction of the vitamins with hexane, the solvent was evaporated and the residue was dissolved in methanol and injected directly after filtration (0.45 μm filter) without the clean-up step (Fig. 5).

For the yogurt samples, the recovery percentages found were between 86% and 103% (Table 3). The amounts found for each vitamin in the different samples are summarized in Table 3. The day-to-day precision obtained (Table 4) was less than 10% in the five commercial brands of yogurt analyzed.

The result obtained in the analysis of vitamins A and E in the different samples analyzed are consistent with the contents specified by the manufacturers for those vitamins in yogurt samples, as can be seen in the tables relating to the composition of foods [32]. The day-to-day precisions obtained for the different samples of yogurt are shown in Table 4; as can be seen, the data are quite acceptable for this type of analysis.

3.4.5. Analysis of Vitamin D_3

Because of the low content of vitamin D_3 in yogurt, this vitamin is not detected using the proposed method. However, in yogurt enriched with this vitamin according to the specifications of the manufacturers it was possible to detect vitamin D_3 (Fig. 6) by modifying the procedure slightly and dissolving the extract with 2 ml of methanol instead of 5 ml and injecting 30 μl instead of 10 μl into the chromatograph. In this way, a larger amount of vitamin D_3 is injected into the system and it can be evaluated, although only in the case of enriched samples. Six samples of an enriched yogurt were analyzed; the vitamin D_3 content proved to be 0.09 ± 0.02 μg per g. The recovery of the method was $91 \pm 5\%$.

Table 4
Day-to-day precision, RSD (%), $n = 10$

| Yogurt sample	Amperometric detection		UV detection	
	Vitamin A	Vitamin E	Vitamin A	Vitamin E
1	8.33	5.55	8.00	4.92
2	4.35	8.62	4.35	5.17
3	5.00	4.68	9.09	3.51
4	3.85	1.59	8.00	1.69
5	6.45	3.45	3.57	3.90

Fig. 6. Chromatogram obtained after application of the modified method to a yogurt sample enriched with vitamin D_3.

4. Conclusion

A method is described for the determination of vitamins A, D_3 and E in samples of yogurt. The results obtained in the cases of vitamins A and E are very acceptable for the different samples analyzed. It was only possible to determine vitamin D_3 in yogurts enriched with this vitamin.

Sulphate determination after its reduction to hydrogen sulphide and volatile separation by molecular absorption spectrometry

A. Lopez Molinero*, R. Batlle, A. Villareal, J.R. Castillo

Department of Analytical Chemistry, Faculty of Sciences, University of Zaragoza, 50009 Zaragoza, Spain

Abstract

A rapid spectrophotometric method for sulphate determination in a discontinuous mode is described. The method is based on sulphate reduction to hydrogen sulphide followed by its volatilization and absorption in an alkaline solution. The reduction is obtained when a sulphate sample is heated to 287 °C for 15 min, with a mixture of $Fe°/KI$ and phosphoric acid. The resulting gas is swept by nitrogen flow into a 0.1 M sodium hydroxide solution and the absorbance of the sulphide ions is measured directly at 230 nm. The proposed method enabled us to determine 50–700 μg of total sulphate with a relative standard deviation of the order of 5%. The method has been applied for the determination of sulphates in liquid (mineral waters) and solid (gypsiferous soils) samples.

Keywords: Absorption spectrophotometry; Reduction; Sulphate determination; Volatilization

1. Introduction

There is great interest in developing new and practical methods for sulphate determination. Recently, methods have been reported in the literature which include analytical techniques such as UV–Vis molecular spectrophotometry and turbidimetry [1–3], atomic spectroscopy [4], isotopic dilution [5], X-ray difraction [6], electroanalysis [7], sensors [8,9], ion chromatography [10] or capillary ion electrophoresis [11]. The vast majority of these papers are concerned with procedures involving an important level of automatization [12].

The reduction of sulphate to hydrogen sulphide and its subsequent determination can be considered to be among the most interesting methods for sulphate determination. Ajwa and Tabatabai [13] compared some methods for sulphate determination in soils and arrived at the conclusion that the Methylene Blue colorimetric method after the reduction of SO_4^{2-} to hydrogen sulphide can be considered to be among the most accurate methods. Certain reagents have been proposed for this reduction. Steinbergs et al. [14] used magnesium for the determination of total sulphur in soil and plant material. Metallic iron has also been used. Two classical reduction mixtures have been

---

* Corresponding author.

proposed: one by Johnson and Arkley [15] composed of hydriodic acid–hypophosphorous acid–formic acid; and a second, which is similar, composed of hydriodic acid and red phosphorus proposed by Lorant and Kopetz [16]. More recently, Norwitz [16] used a mixture of hydriodic, hypophosphorous and hydrochloric acids.

In these methods the reduction step is followed by colorimetric determinations of H_2S, after its previous absorption. For this purpose an alkaline zinc acetate solution is normally used. Then, in an acid medium, sulphide reacts to yield Methylene Blue [17,18]. This is the basis of a large number of analytical procedures. Other determinations have been proposed. Norwitz [16] measured the brownish–yellow colour of the lead sulphide obtained in an ammomia collecting solution. This methodology gives excellent analytical values but is time-consuming. This seriously restricts its possibilities as a practical method.

The purpose of this paper is to develop an alternative procedure for sulphate determination based on its reduction to hydrogen sulphide. It uses common reductant reagents, takes a short reaction time and produces a high level of analytical performance.

The proposed methodology simplifies and systematizes the experimental procedure for treating samples (heating/reducing and collecting of gaseous products). The measuring step is also simplified by direct reading of sulphide absorbance in alkaline solution. It is applicable not only to liquid but also to solid samples.

2. Experimental

2.1. Apparatus

A Hewlett Packard 8452A diode array spectrophotometer equipped with 10 mm quartz cells and interfaced to a Vectra CS data station was used for absorbance measurements. A Sartorius Research R 200D balance, with a readability of 0.01 mg, was used for solid sample weights.

2.2. Hydrogen sulphide generation and collection assembly

The system for generation and collection of the hydrogen sulphide is shown in Fig. 1. It consists of a reaction flask which is placed inside a metallic cup. Its inlet tube is connected to a tank of nitrogen by rigid nylon tubing. This gas acts as a carrier gas and its pressure and flow are controlled. The outlet tube of the vessel is connected to a calibrated flask by rigid nylon tubes. The flask contains the collecting solution which is cooled by dipping it into a cold ice/water bath.

A homogeneous and reproducible manner for heating the reagents during reduction/distillation was obtained by placing the reaction vessel in a brass hot cup. The cup was then heated with a cylindrical electric heater (heater jacket; Bas-Can; 125 W). The electric heating conditions were controlled by an autotransformer to 110 V and 0.5 A. The preheating time was 20 min and the temperature was then maintained constant at 287 ± 3 °C.

2.3. Reaction flask

A schematic diagram of the home-made reaction flask, made from glass, used by us in this method is shown in Fig. 2. It consists of two pieces (head and vessel) which can easily be adapted for operation.

Fig. 1. Experimental assembly: (1) nitrogen/air supply; (2) flow regulator; (3) autotransformer AT25021IC E.BOAR; (4) cylindrical electric heater; (5) brass cup; (6) reaction flask; (7) ice/water bath (0 °C); (8) recovery solution.
Fig. 2. Reaction flask and electrical heater system: reaction flask composed of two components (head and vessel) and the heater system composed of the brass cup surrounded by a cylindrical electric heater or heater jacket.

2.4. Reagents

All chemicals used were of analytical grade. Deionized water, quality Milli Q, was used in all dilutions.

2.4.1. Standard potassium sulphate solution (5000 μg ml^{-1} sulphates)

Dissolve 0.900 g of potassium sulphate (previously dried to 120 °C) in water and dilute to 100 ml in a calibrated flask. 1 ml of solution = 1.667 mg of sulphur. Sodium sulphate and calcium sulphate solutions were prepared in a similar manner.

2.4.2. Standard sulphide solution (1000 μg ml^{-1})

Dissolve 0.7506 g of sodium sulphide in water and dilute to 100 ml in a calibrated flask. The concentration was standardized by iodometric back-titration. Working standard sulphide solution had to be used within 30 min of standardization, as the concentration of sulphide

decreased after this time owing to oxidation by air.

2.4.3. Reducing mixture

2.4.3.1. Fe^0 suspension in vaseline oil (40 g l^{-1}).
Prepared by adding 2.000 g of iron powder to 50 ml of vaseline oil in a 100 ml beaker.

2.4.3.2. Potassium iodide solution (25 g l^{-1}).
Dissolve 2.5 g of KI in 100 ml of water. Concentrated phosphoric acid (85%) and O.I.M. sodium hydroxide were used.

2.5. Procedure for hydrogen sulphide generation

Samples are placed in the glass reaction vessel and are heated at a constant temperature of 287 ± 3 °C for 15 min. If the sample is liquid, take a suitable volume of solution (of the order of 0.1–1 ml), if solid the correct weight of sample (of the order of 2–5 mg), and wash with a few microlitres of distilled water. In both cases the solvent is evaporated. When dry, add 10 μl of KI solution and evaporate the solvent (this takes no more than a few seconds). Add 0.3 ml of phosphoric acid and 0.5 ml of Fe^0/vaseline oil suspension. After stoppering the vessel, the N_2 carrier gas (at a steady flow of 70 ml min^{-1} at 1 bar pressure) is channelled through it and bubbled into a 0.1 M NaOH solution. In this way the distilled hydrogen sulphide is absorbed. The alkaline collecting solution is maintained at 0 °C for 15 min.

2.6. Determination

Hydrogen sulphide in the collecting solution is determined spectrophotometrically by measuring the solution absorbance at 230 nm. The calibration graph was prepared by treating 50 μl of standard sulphate solution (containing between 50 and 700 μg of sulphate, as sodium sulphate) and the distilled gas was collected in a 10 ml calibrated flask. A reagent blank was run throughout the entire procedure.

3. Results and discussion

3.1. Optimization of the reduction reaction

From the value of the standard potential for the SO_4^{2-}/S^{2-} couple ($E° = 0.15$ V) it can be deduced that many other couples with lower $E°$ could be used as reductant agents. However, this reaction has important limitations. In the analytical literature this reduction has only been reported with strong reductants such as metallic iron, Mg^0 [14,19] and mixtures based on hydriodic acid/hypophosphite. We have studied other reductants such as Zn^0, Devarda alloy, and $NaBH_4$, but the best results were obtained by working in acid medium (orthophosphoric acid) with a mixture of KI/Fe^0, the Fe^0 being iron powder suspended in vaseline oil. In this way the reduction can be described by the following reactions:

$$SO_4^{2-} + 8H^+ + 12I^- \rightleftharpoons S^{2-} + 4I_3^- + 4H_2O$$
in organic phase (vaseline oil):

$$I_2 + Fe^0 \rightleftharpoons 2I^- + Fe^{2+}$$
The conditions for the reduction reaction have been optimized by experimenting with the composition of the reductant ($KI/Fe^0/$vaseline oil), the acid medium and also the heating procedure.

The amount of KI added must be as small as possible, because higher quantities produce an undesirable deposition of I_2 in tubes. 2.5×10^{-4} g (10 μl of 25 g l^{-1} KI solution) was found to be best.

The vaseline oil, as an organic phase, has proved to be an optimum medium for extracting the iodine vapour, with high thermal stability during the heating step. The amount of vaseline oil is not as important as the amount of KI but an excess should be avoided in order to diminish the organic vapour distillation. Therefore 0.5 ml was chosen as the minimum volume that covers the bottom of the flask.

Iron powder has proved to be the critical reagent. It must be added in excess to ensure complete reduction. 20 mg was found to be required for the reduction of up to 1.0 mg of sulphate.

Various acids (HCl, $HClO_4$, H_3PO_4, HAc) were tested to find the best one for providing the acidic medium necessary for the reaction conditions. In this sense phosphoric acid was the best reagent. The experimental results obtained in its optimization are collected in Fig. 3. The sulphide absorbance in the collecting solution increased with increasing acid volume up to 0.3 ml, above which it decreased. Therefore 0.3 ml of concentrated phosphoric acid was chosen. If standard potassium sulphates are used, they must be previously treated with NaOH solution and then the optimum volume of acidic medium increases to 0.4 ml.

3.2. Heating and heating system

The effect of heat on reduction and distillation is very clear. The procedure is accelerated at a higher temperature. The most effective and reproducible way of heating the reaction vessel was by using an electrical power-regulator system. It consists of a cylindrical electrical heater (heater jacket) wrapped around a metallic cup made of brass. Details of the set-up are given in Fig. 1. The electrical system employed was calibrated. The power dissipated by the electrical heater jacket was varied and the temperature attained at the reaction vessel wall, and also the time taken, were measured. A thermopar, type J, connected to an electrical source type N.R-1-17 (also calibrated by a multimeter HP type 3458A) was utilized. In conclusion, it can be said that working with the power regulator at 0.455 A and 110 V, an opti-

Fig. 3. Effect of acidity on absorbance. For reduction of 900 μg of sulphates.

Fig. 4. Evolution of sulphide absorbance in the collecting solution (——) and variation of the first derivative signal of the collecting solution (—) as a function of heating time, when 700 μg of sulphate (as sodium sulphate) is reduced.

mum temperature of 287 ± 3 °C was obtained after 20 min of stabilization. The temperature was then maintained constant throughout the procedure.

3.3. The reaction heating time

When the glass reaction vessel is placed in the thermally stabilized hot cup, it attains the optimum temperature in only a few seconds. Working at 287 ± 3 °C, the heating time needed for the reduction/distillation of SO_4^{2-} was studied. 700 μg of SO_4^{2-} (as sodium sulphate) was taken and the reduction procedure given above was run. The set-up (Fig. 1) was connected to the HP diode array spectrophotometer flow cell which was filled with 0.1 M NaOH solution. The molecular absorption spectrum of the collecting solution and its first derivative spectrum were recorded every 60 s throughout the procedure. The variation of the absorbance at 230 nm (the absorption maximum wavelength of the sulphide ions in aqueous solution) with time is shown in Fig. 4. It can be observed that after 5 min the absorbance is a maximum and is stabilized. This is also seen when the variation of the first derivative spectrum signal with time was utilized. In spite of previous results we work with a heating time of 15 min, i.e. we propose an extra heating time above that determined experimentally as a security interval to ensure total sulphate reduction and also as a way of increasing the reproducibility of the procedure.

3.4. Flow of inert gas

An optimum flow of nitrogen gas of 70 ml min^{-1} at 1 bar pressure was regulated. Nitrogen can be replaced by air. In this case sensitivity is reduced, but by no more than 10%.

3.5. Recovery solution

Certain experiments were carried out using cooled ammonia solution or sodium hydroxide solution at different concentrations for hydrogen sulphide absorption. The results were more reproducible with cooled sodium hydroxide solution at 0.1 M. Under that condition (pH 13) the ratio of the species $H_2S:HS^-:S^{2-}$ is $5 \times 10^{-5}\%:50\%:50\%$ respectively.

3.6. Distilled gas identification

The chemical composition of the gaseous product of the reaction was confirmed by two tests:

(i) the characteristic yellow colour of the cadmium sulphide precipitate;

(ii) the absorption spectum of the sodium hydroxide alkaline collecting solution which after sulphate reduction is similar to the positive sulphide spectrum in alkaline solution. This is shown in Fig. 5.

This confirms hydrogen sulphide generation.

Fig. 5. Absorption spectrum for hydrogen sulphide dissolved in 0.1 M sodium hydroxide solution (——) and first derivative spectrum (—).

3.7. Spectrophotometric measurement

After sulphide absorption several colorimetric methods of sulphide determination were tested. We investigated Norwitz's spectrophotometric method [16] based on ammonia/lead citrate solution, also the Methylene Blue method [17] and the Boedeker reaction [20]. These three methods are time-consuming and can be considered very laborious. However, the sulphide ions in NaOH alkaline solution present an absorption spectrum with the absorbance maximum at 230 nm that makes a simple method for its determination possible by direct absorbance measurements at 230 nm. Also the first derivative spectrum can be used as an alternative measurement if over-heating at the reduction step produces volatilization of the organic vaseline oil which has an absorbance maximum at 195 nm.

3.8. Performance of the method: calibration graph

Calibration graphs were prepared by evaporating to dryness amounts of standard sodium sulphate solution and utilizing the reduction/distillation procedure. If potassium sulphate solution is used instead of sodium sulphate the same procedure is followed except that the experiment is performed by treating amounts of the solution with a few drops of 0.1 M sodium hydroxide solution and evaporating the solution to dryness. A reagent blank experiment without sodium or potassium sulphate is performed using the same procedure as previously. The calibration graph was linear between 50 and 700 μg of SO_4^{2-}, with a correlation coefficient of 0.999 ($n = 8$). The corresponding regression equation was:

$$A = 0.068 + 2.6 \times 10^{-3}(SO_4^{2-})$$

where the amount of sulphate (SO_4^{2-}) is expressed in micrograms and the absorbance (A) is measured at 230 nm against the reagent blank solution. The relative standard deviation for the determination of 400 μg sulphate is 5.7% ($n = 10$). The theoretical detection limit (signal/noise = 3) was 3.9 μg of sulphates. The time required to process a liquid sample was 15 min.

3.9. Interferences: effect of metals associated with sulphates

The effects of sodium, potassium and calcium, which are associated with SO_4^{2-}, have been studied. An experiment was performed with the same weight of sulphate ion (3 mg) but with three different metal salts. The degree of interference produced by the cation associates on the reduction reaction was evaluated by two parameters:

(i) the sensitivity value derived from the absorbance signal/mg ion sulphate ratio;

(ii) the time required to finish the reaction.

The results are summarized as follows:

Sulphate as sodium salt: shows a sensitivity value of 1.11. This is the highest. Therefore it can be said that this is the most sensitive salt and also the fastest to reduce.

Sulphate as potassium salt: shows a sensitivity value of 0.474. The whole reaction took more than 15 min.

Sulphate as calcium salt: shows a sensitivity value of 0.439. Its sensitivity is similar to that of potassium but lower. It takes of the of 60 min to be reduced.

3.10. Other interferences

The presence of nitrate was studied because it is a very common anion associated with sulphate in real samples and has an oxidizing effect. It was checked that the presence of nitrate at the same level as sulphate does not affect the reduction efficiency, i.e. 200 μg of nitrate did not cause reduction in the recovery of 200 μg of sulphate. However, it was noted that the addition of an excess of 0.5 ml of 6 M HNO_3 (190 mg of nitrate) drastically reduced the recovery of sulphate.

3.11. Elimination of interferences

From Section 3.9 the marked effect of potassium and calcium on sensitivity can be seen. Certain experiments were carried out in order to eliminate their influence.

It was found that the addition of NaOH solution to potassium sulphate restores the signal to the same level as that of sodium sulphate but the

Table 1

Comparison of sulphate contents of mineral water as determined by the proposed and reference methods [19]

Parameter	Reference method	Proposed method
Volume of sample (ml)	10	3
No. of determinations	5	6
Sulphate found (mg l^{-1})[a]	127.7	129.2
%Relative standard deviation	1.7	4.1

[a] Results are the average of determinations.

time required was still 15 min. The elimination of the calcium effect was attempted with sodium hydroxide and certain ligands. The addition of EDTA tetrasodium salt produced the best results and restored the signal of sulphate. In this case solid calcium sulphate and EDTA tetrasodium salt were dissolved in the minimum amount of water, according to a ratio of the order of grams sulphates/grams EDTA = 1/1. The solution was then evaporated and submitted to the reduction procedure, which required 60 min.

In contrast, the interference of nitrate was prevented by adding a sufficient quantity of Fe^0 in vaseline oil suspension (about 20 mg of Fe^0 for every 5 mg of nitrate added) to the reaction flask.

3.12. Application of the method

The proposed method was applied to the determination of sulphate in mineral water and also in solid gypsiferous soils. These two types of sample were not certified but their contents were compared with those obtained using reference methods.

The results for the determination of sulphates in mineral water samples are collected in Table 1 and were compared with a nephelometric method [17]. As can be seen, they were similar and the precision of the proposed method is poorer than that of the reference method. How-

ever, the one-tailed F-test for the comparison of precision shows that the standard deviation of the proposed method is not significantly greater than that of the reference method. Also, a statistical t-test was applied to test the means of these two determinations. So, for nine degrees of freedom the critical value of $|t|$ ($P = 0.05$) is 2.26 and since the experimental value of $|t|$ is 0.21, there were no significant differences between the two methods. The sulphate contents in gypsiferous soil samples were determined using the following procedure: solid samples were homogenized and ground to < 150 μm; between 2 and 5 mg of powdered sample was weighed into the reaction vessel; a similar weight of EDTA tetrasodium salt was also added to the reaction vessel and both sample and ligand were dissolved in a small amount of deionized water. The solution was then analyzed according to the procedure described above. The same samples were analysed by the colorimetric reference method [21]. This method is based on the displacement of chromate ions from sparingly soluble barium chromate by sulphate ions. The chromium is then determined from the colour of the chromate ions. The results are collected in Table 2. As can be seen the results were almost identical with an important, but not significant, difference in precision. In this case a paired t-test was applied to compare the difference between the three pairs of results given by the two methods. The critical value of $|t|$ ($P = 0.05$) for two degrees of freedom is 4.30 and since the experimental value of $|t|$ (1.02) is less than this, it can be said that no significant differences were found between the means of the two methods.

Preparation, characterization and metal sorption studies of a Chrome-Azurol-S-loaded anion-exchange resin

Zenovia Molodovan*, Luminiţa Vlădescu

Faculty of Chemistry, University of Bucharest, 13, Bv. Republicii, Sector 3, 70346 Bucharest, Romania

Abstract

Chrome Azurol S (CS) was imobilized on an strongly basic anion-exchange resin (Dowex 2×4, in Cl^- form) by batch equilibration. The modified resin was stable in acetate buffer solution and in 0.1 M HCl and H_2SO_4, but it was readily degraded with 2–6 M HCl and HNO_3. Retention of Ba(II), Sr(II), Ca(II), Mg(II), Al(III), Cr(III), Zn(II), Fe(III), Ti(IV), Mn(II), Co(II), Ni(II), Cu(II), Cd(II) and Pb(II) was studied using the batch equilibration method. The uptake and recovery yields were determined by using inductively-coupled plasma atomic emission spectroscopy (for Mg, Al, Cr, Ti, Fe, Mn, Ni, Zn, Cu, Cd and Pb) and atomic absorption spectrophotometry (for Ba, Sr, Ca and Co). The optimum pH value was established for performing a selective separation of Al(III) from the other metal ions. The sorption capacities of the CS-loaded resing for Al(III), Cr(III), Mg(II) (at pH 6), Fe(III) (at pH 5) and Ti(IV) (at pH 4) were 14, 2.9, 0.3, 3 and 3.9 μmoles g^{-1} respectively. On this basis a method for separating Al(III) from other cations was established.

Keywords: Anion-exchange resin; Chrome Azurol S; Metal sorption

1. Introduction

Many complexing agents have been employed for the separation of metal ions on anion-exchange resins. These reagents, which have chelating groups, have been introduced into the resins by simple loading and the modified resins have been used for the selective recovery or preconcentration of metal ions [1]. Torre and Marina [2] discussed the potential of anionic chelating agents loaded on anion-exchange resins in a thorough review. Chrome Azurol S (CS) has been used as a chromogenic agent in determinations of some metal ions using complexometric titrations or spectrophotometry [3,4].

The purpose of the present work is to explore the possibility of separating some metal ions from mixtures by use of a common anion-exchange resin loaded with CS. The sorption behaviour of Ba(II), Sr(II), Ca(II), Mg(II), Al(III), Cr(III), Zn(II), Fe(III), Ti(IV), Mn(II), Co(II), Ni(II), Cu(II), Cd(II) and Pb(II) on the chelating-agent-

* Corresponding author.

loaded resin was investigated at different pH values. The separations are based on the different affinities of these metal ions for the chelating resin as a function of pH. The proposed method was applied to the determination of Al(III) in a certified reference material sample of zinc.

2. Experimental

2.1. Apparatus

A Spectroflame (Spectro Analytical Instruments, Germany) Model P inductively-coupled plasma atomic emission spectrometer was used for determination of Mg(II), Al(III), Cr(III), Ti(IV), Fe(III), Mn(II), Ni(II), Zn(II), Cu(II), Cd(II), Pb(II), Sn(II), Sb(III) and Zr(IV). A Pye-Unicam atomic absorption spectrophotometer Model SP 192 equipped with an air–acetylene flame burner and a deuterium continuum source background corrector was used for determination of Ba(II), Sr(II), Ca(II) and Co(II). An Orion EA 920 pH meter equipped with a combined glass-calomel electrode was used for all pH measurements. A Specord M40 UV–Vis spectrophotometer was used for spectrophotometric determinations.

2.2. Reagents

All the reagents were of analytical-reagent grade.

The chloride form of the strongly basic anion-exchange resin Dowex 2 × 4 was used for the preparation of the chelating-agent-loaded resin. The exchange capacity of the resin was found to be 3.98 meq g^{-1} of air-dried resin.

The ligand employed was Chrome Azurol S (3'-sulfo-2',6'-dichloro-3,3'-dimethyl-4-hydroxy-fuchsone-5,5'-dicarboxylic acid sodium salt) produced by Merck (Darmstadt, Germany).

Working solutions of cations (10^{-3} M) were prepared by diluting Merck atomic absorption standard metal ion solutions with distilled water. Buffer solutions of pH 1–6 were prepared using a mixture of hydrochloric acid and potassium chloride (pH 1–2), tartrate buffer (pH 3) and acetate buffer (pH 4–6).

2.3. Procedure

2.3.1. Preparation of CS-loaded resin

The batch method was used for retention of CS on the resin. Thus, a weighed amount (≈ 100 mg) of dry resin (chloride form) was treated with 10 ml of reagent solution of known concentration and shaken with a mechanical shaker. Then, the loaded resin bed was filtered off in a fritted-glass funnel and washed with distilled water to remove the excess reagent. The supernatant solution and the rinsing water were collected in a 25 ml volumetric flask. The amount of CS in the supernatant solution was determined spectrophotometrically at 435 nm.

2.3.2. Procedure for the sorption of metal ions as a function of pH

Weighed amounts (100 mg) of chelating resin (0.04 mmoles CS per gram of dry resin) were equilibrated with aliquots (10 ml) of buffer solutions (pH 1–6) by shaking the mixtures with a mechanical shaker for about 1 h. Then, to these mixtures, aliquots (4 ml) of 10^{-3} M solutions of each of Ba(II), Sr(II), Ca(II), Mg(II), Al(III), Cr(III), Zn(II), Co(II), Ni(II), Cu(II), Cd(II), Pb(II) and Mn(II) and 1 ml of 10^{-3} M solutions of Fe(III) and Ti(IV) were added and shaken for 2 h. After this treatment, the resin was filtered off in a fritted-glass funnel, washed with distilled water and the excess of metal ion remaining in solution was recovered in a 25 ml volumetric flask. An appropriate volume of each filtrate was used for the determination of the metal ion.

3. Results and discussion

3.1. Retention of CS on anionic resin

The amount of CS loaded on the chelating resin was determined by the batch method. The sorption capacity was found to be 0.32 mmoles CS per gram of dry resin. In order to investigate the stability of the CS-loaded resin in the presence of other anions the most common acid solutions (HCl, HNO$_3$ and H$_2$SO$_4$) were used (Fig. 1). The effects of the anions in the sequence NO$_3^-$ > Cl$^-$

$> SO_4^{2-}$ are quite similar to their affinities for anion-exchange resin Dowex 2 × 4. It was observed that the chelating agent was quantitatively held by the resin in the presence of 0.1 M acid solutions. Some CS was still retained on the resin even in 1 M HCl or H_2SO_4 due to the π–π interaction between the benzene ring of CS and the divinylbenzene moiety of the resin matrix. The sorption of the chelating agent molecule by its chelating groups, such as the hydroxyl group, has to be taken into consideration.

3.2. Sorption of metal ions on CS resin

In order to determine the optimum conditions of the sorption of metal ions by the loaded resin, the optimum pH ranges were investigated by the batch method.

3.2.1. Sorption of Al(III)

The sorption behaviour of Al(III) on CS resin as a function of pH is shown in Fig. 2. The sorption of Al(III) increases with pH. After the sorption of Al(III), the colour of the resin changed from orange to brown. It was observed that the retention of Al(III) was complete at pH 6. The reacting ratio of Al(III) to CS was found to be approximately 1:3 under the conditions used, as shown in Fig. 3, which corresponds to the ratio in the reaction of Al(III) with CS in solution.

Fig. 2. Retention of Al(III) as a function of pH. Resin taken: 0.1 g (0.04 mmoles CS per gram of resin); volume of solution: 14 ml; concentration of Al(III): 8 ppm.

The desorption of Al(III) from the chelating resin is complete with 0.2 M HCl. The variation of the sorption of Al(III) on CS resin with pH is in good agreement with the variation of the absorbance of the metal–ligand complex in solution as a function of pH (Table 1).

3.2.2. Sorption of Fe(III) and Ti(IV)

Fe(III) and Ti(IV) also form complexes in solution. The absorbance values of these metal–ligand complexes as a function of pH are shown in Table 1. The Fe(III)–CS complex was found to show maximum absorbance at pH 6 while the Ti(IV)–CS complex presents maximum absorbance at pH 5. Owing to their tendency to hydrolyse, tests with

5	1.19	0.60	0.30
6	1.26	0.62	0.29

[a] 2 ml CS $(10^{-3}$ M) + 0.5 ml metal ion $(10^{-3}$ M) + 10 ml buffer solution (pH 1–6), diluted to 25 ml with distilled water in a calibrated flask.

small amounts of Fe(III) and Ti(IV) (5 ppm) were made. The results indicated that the sorption capacities of the loaded resin for Fe(III) and Ti(IV) increase with pH and reach a maximum of 3 μmoles g^{-1} for Fe(III) at about pH 5 and 3.9 μmoles g^{-1} for Ti(IV) at pH 4 (Fig. 4). Fe(III) at pH 6 and Ti(IV) at pH 5–6 are not retained because of their hydrolysation. It was also found that Fe(III) in the presence of 5%

Fig. 4. Retention of Fe(III) and Ti(IV) as a function of pH: (▲) Fe(III); (△) Ti(IV). Resin taken: 0.1 g (0.04 mmoles CS per gram of resin); concentration of Fe(III) and Ti(IV) solutions: 5 ppm.

$NH_2OH \cdot HCl$ solution is not retained by the CS-loaded resin because Fe(III) is reduced to Fe(II), which does not form a complex with CS.

3.2.3. Sorption of other metal ions

The sorption characteristics of the complexing resin for Ba(II), Sr(II), Ca(II), Mg(II), Co(II), Cr(III), Ni(II), Zn(II), Mn(II), Cu(II), Cd(II) and Pb(II) were also studied in the same pH range. Small retentions of Mg(II) and Cr(III) were observed at pH 6 (0.3 μmoles g^{-1} for Mg(II) and 2.9 μmoles g^{-1} for Cr(III)). The other metal ions were not retained by the chelating resin in the pH range 1–6.

The effect of possible interferents encountered in real samples has been tested: the retention of Sn(II), Sb(III) and Zr(IV) being investigated. We used 1 ppm solutions of Sn(II), Sb(III) and Zr(IV), to prevent the precipitation of their hydrolysed ions, particularly at pH 3–6. It was observed that these metal ions could be tolerated up to a level of 1 ppm.

4. Application

The results of the present study have been applied to the determination of Al(III) in a zinc sample supplied by The Institute of Rare and Nonferrous Metals (Bucharest). 2 g of zinc was completely dissolved in a minimum volume of concentrated hydrochloric acid (about 10 ml) by heating on a water bath. The solution was evaporated to a very small volume. To this a small volume of water was added. The solution was cooled, filtered and diluted to 50 ml in a calibrated flask. An aliquot (15 ml) of the sample was adjusted to pH 6 with 0.1 M NaOH and added to a mixture of 0.1 g of loaded resin and 10 ml of acetate buffer (pH 6). The mixture was shaken for about 3 h. The supernatant solution had been eliminated and the resin was then washed with distilled water. The retained Al(III) was then eluted with 25 ml of 0.2 M HCl and determined in the supernatant solution by inductively-coupled plasma atomic emission spectrometry (ICP-AES). The results are given in Table 2. These results are in good agreement

Table 2
Determination of Al(III) in a zinc sample

Sample	Composition (μg g^{-1})	Concentration of Al(III) (μg g^{-1})	
		Certified value	Found[a]
Zinc	Cd, 3.75; Cr, 0.20; Cu, 2.50; Fe, 14.75; Mg, 0.025; Mn, 0.65; Ni, 27.25; P, 0.032; Pb, 33.75; Sb, 0.025; Si, 163.75; Sn, 0.025; Ti, 0.105; Zr, 0.025	35 ± 3	33 ± 2

[a] Mean of three determinations.

with the certified values. It was observed that under optimum experimental conditions the sorption of Al(III) was quantitative and the interferences caused by low concentrations of metal ions such as Cr(III), Ti(IV) and Fe(III) were negligible.

5. Conclusion

The proposed method is able to separate and concentrate Al(III) using the reaction of Al(III) with CS supported on the anion-exchange resin. The method described above can be used for separation of an element from complex mixtures. Also, the value of the direct determination of the element from complex mixtures. Also, the value of the direct determination of the element can be controlled by introduction of an intermediary stage: preconcentration, followed by its proper determination.

A series expansion of the extended Debye–Hückel equation and application to linear prediction of stability constants

J.J. Baeza Baeza, G. Ramis-Ramos*

Departament de Química Analítica, Facultat de Química, Universitat de València, 46100 Burjassot, València, Spain

Abstract

The Debye–Hückel semiempirical extended equation is frequently used to calculate activity coefficients of chemical species and equilibrium constants at ionic strengths different from those used in their experimental evaluation. A series expansion of the extended Debye–Hückel equation is proposed here and checked with experimental data taken from the literature. The expansion is linear in the ionic parameters and yields a geometrical series which converges rapidly and that enables the accurate calculation of interpolated and extrapolated activity coefficients and equilibrium constants by simple and multiple linear regression without previous knowledge of the ionic parameters.

Keywords: Activity coefficients; Debye–Hückel equation; Ionic strength; Stability constants

1. Introduction

In the experimental evaluation of equilibrium constants an inert electrolyte is used to maintain a given ionic strength, I. Consequently, experimental values of the constants are found in the literature at only a few (frequently large) values of I. However, accurate values of equilibrium constants at low and variable ionic strengths are of great interest in calculations related to speciation and transport modelling of nutrients and pollutants in water resources, in physiological fluid studies and in other fields [1,2].

To calculate an equilibrium constant at any I value, the activity coefficients of the species involved must be evaluated. These can be calculated by the extended form of the semiempirical Debye–Hückel equation [1,3–7]:

$$\log \gamma_i = -A z_i^2 \frac{\sqrt{I}}{1 + B a_i \sqrt{I}} + c_i I \tag{1}$$

where γ_i and z_i are the activity coefficient and the charge of species i respectively, and the parameters A, B, a_i and c_i depend on the composition of the medium and on the temperature. The ionic parameters, a_i and c_i, also depend on the nature of the i species. Frequently, the term in c_i is neglected [8] and empirical values of a_i are used [3,9]. According to the Bates–Guggenheim con-

vention $Ba_i = 1.5$ for Cl^-, and this has also been extended to other ions [10]. Additional polynomial terms have been proposed, e.g. a term in $I^{3/2}$ [4].

Other more complex algorithms which relate activity coefficients to I have been developed [6,7,11–14]. The specific interaction theory (SIT) [11] relies on the Debye–Hückel equation and takes into account short-range interaction forces that are specific to each solute. The Pitzer algorithm [12] allows the accurate prediction of the properties of mixtures when the properties of the pure components are accurately known. However, this algorithm uses a great number of empirical parameters, many of which are not known. A recent study has shown that the Pitzer algorithm is very useful to fit data over wide I ranges and in mixtures of electrolytes; however, with a single electrolyte and at low ionic strengths it does not show remarkable superiority to other similar models [6].

The empirical nature of I and the ionic parameters, and the systematic errors which affect extrapolation to low values of I, have been the subject of controversy [15,16]. However, the Debye–Hückel expression is widely used [17,18]. Unfortunately, this equation and the algorithms cited above are non-linear in the ionic parameters. These should be already known or simultaneously obtained with the constants by non-linear iterative procedures. In this work, a series expansion of the extended Debye–Hückel equation is proposed and checked using literature data. The series expansion converges rapidly and is linear in the ionic parameters, which enables the accurate calculation of interpolated and extrapolated activity coefficients and equilibrium constants by single and multiple linear regression. Previous knowledge of the ionic parameters is not required.

2. Theory

2.1. A linear series expansion of the Debye–Hückel equation

The extended Debye–Hückel equation (Eq.(1)) is non-linear in a_i, but as shown next linearization

can be achieved by a series expansion. For this purpose, the non-linear term can be written as a sum of a linear term with an arbitrary constant, α, and an error, ε, giving:

$$\frac{\sqrt{I}}{1 + Ba_i\sqrt{I}} = \frac{\sqrt{I}}{1 + \alpha\sqrt{I}} + \varepsilon = F + \varepsilon \qquad (2)$$

where F is a function of I. Rearranging we have:

$$\varepsilon = F\frac{\sqrt{I}}{1 + Ba_i\sqrt{I}}(\alpha - Ba_i) \qquad (3)$$

By substituting the value of ε given by Eq. (3) into Eq. (2), we have:

$$\frac{\sqrt{I}}{1 + Ba_i\sqrt{I}} = F + F\frac{\sqrt{I}}{1 + Ba_i\sqrt{I}}(\alpha - Ba_i) \qquad (4)$$

and:

$$\frac{\sqrt{I}}{1 + Ba_i\sqrt{I}} = F + F(F + \varepsilon)(\alpha - Ba_i) \qquad (5)$$

If the process is repeated, the following geometrical series results:

$$\frac{\sqrt{I}}{1 + Ba_i\sqrt{I}} = \sum_{j=o}^{N} F^{j+1}(\alpha - Ba_i)^j \qquad (6)$$

where N is the number of terms of the series. The series reason is:

$$R = F(\alpha - Ba_i) \qquad (7)$$

The series converges in all cases when α is larger than Ba_i; further, the convergence is quicker the closer to zero is the reason, i.e. as Ba_i is closer to α. Similarly, a Taylor development [19] of the Debye–Hückel equation leads to the same series. Further, if $\alpha = 0$, the series proposed by Datta and Grzybowsky [20] results.

2.2. Evaluation of activity coefficients and ionic parameters

The equations obtained by taking only one or two terms of the series, i.e. by making $N = 1$ and $N = 2$ in Eq. (6) and substituting into Eq. (1), are given in Table 1 (Eqs. (8–11)). If at least two experimental points at two values of I are available, Eq. (8) can be used to obtain A and c_i. With three or more points simple linear regression can be used. Similarly, Eq. (9) can be used to evaluate

Table 1
Equations obtained from Eqs. (6) (upper part) and (14) (lower part) by making $N = 1$ and $N = 2$

N	Equation		Evaluated parameters	Min. no. data[a]
1	$\log \gamma_i = -Az_i^2 F + c_i I$	(8)	A, c_i	2
2	$\log \gamma_i = -Az_i^2 F - Az_i^2(\alpha - Ba_i)F^2 + c_i I$	(9)	A, Ba_i, c_i	3
1	$\log \gamma_i = +Az_i^2 F = c_i I$	(10)	c_i	1
2	$\log \gamma_i + Az_i^2 F = -Az_i^2(\alpha - Ba_i)F^2 + c_i I$	(11)	Ba_i, c_i	2
1	$\log K_c = \log K_0 + Q_1 F + CI$	(18)	$\log K_0$, Q_1, C	3
2	$\log K_c = \log K_0 + Q_1 F + Q_2 F^2 + CI$	(19)	$\log K_0$, Q_1, Q_2, C	4
1	$\log K_c - Q_1 F = \log K_0 + CI$	(20)	$\log K_0$, C	2
2	$\log K_c - Q_1 F = \log K_0 + Q_2 F^2 + CI$	(21)	$\log K_0$, Q_2, C	3

[a] Minimum number of points required to calculate the parameters; with more points, linear regression should be applied.

A, Ba_i and c_i using data at three values of I. With more than three data sets multiple linear regression can be applied.

Eqs. (8) and (9) can also be conveniently written as indicated by Eqs. (10) and (11) in Table 1. Eq. (10) is useful to obtain c_i from a single experimental point and a literature value of A. Similarly, Eq. (11) can be used to evalute Ba_i and c_i using a known value A and points measured at two values of I. With more data, the parameters can be obtained by simple linear fitting. It should be noted that F is a function of I; therefore, the regression straight lines obtained with Eqs. (8) and (11) and the regression plane given by Eq. (9) are curves on the $\log \gamma_i$ vs. I plane.

2.3. Evaluation of equilibrium constants

An equilibrium reaction in which n species are involved can be expressed as

$$\sum_{i=1}^{n} q_i[A_i] = 0 \qquad (12)$$

where q_i and $[A_i]$ are the stoichiometric coefficients, positive for reactants and negative for products, and molar concentrations respectively. The equilibrium constant at zero ionic strength, K_0, is

$$K_0 = \prod_{i=1}^{n} (A_i)^{q_i} = \prod_{i=1}^{n} [A_i]^{q_i} \prod_{i=1}^{n} \gamma_i^{q_i} = K_c K_\gamma \qquad (13)$$

where (A_i) is the activity of the i species, and K_c is

the concentration constant at any I. Taking logarithms and using Eq. (6):

$$\log K_c = \log K_0 + CI + \sum_{j=1}^{N} Q_j F^j \qquad (14)$$

where N is the number of terms of the series which are taken. The other symbols are:

$$C = \sum_{i=1}^{N} (-c_i q_i) \qquad (15)$$

$$Q_j = A \sum_{i=1}^{N} q_i z_i^2 (\alpha - Ba_i)^{j-1} \qquad (16)$$

It should be observed that Q_1 does not depend on the ionic parameters:

$$Q_1 = A \sum_{i=1}^{N} (-z_i^2 q_i) \qquad (17)$$

Eq. (14) can be used to evaluate $\log K_0$, C and Q_j, and to interpolate and extrapolate $\log K_c$ values using experimental data obtained at a few values of I. Thus, by making $N = 1$ in Eq. (6) and substituting in Eq. (14), Eq. (18) of Table 1 results. If data at three values of I are known, Eq. (18) can be used to obtain $\log K_0$, Q_1 and C. If more data are available, the parameters can be evaluated by multiple linear regression. Similarly, Eq. (19), which is obtained by making $N = 2$, can be used to evaluate $\log K_0$, Q_1, Q_2 and C if data at four or more values of I are available.

If A is known, Q_1 can be calculated from the reaction stoichiometry. Then, Eqs. (18) and (19)

can also be conveniently written as indicated in Eqs. (20) and (21) of Table 1. Data at only two values of I are enough to obtain log K_0 and C using Eq. (20). If more than two data points are available, log K_0 and C can be obtained by simple linear regression. Data points at three or more values of I and multiple linear regression are required with Eq. (21).

3. Results and discussion

3.1. Convergence of the series

The convergence of the series was checked at several values of the difference $(\alpha - Ba_i)$ and I. It should be remembered that no error is produced, even with $N = 1$, when $\alpha = Ba_i$. Fig. 1 shows the relative error obtained at increasing values of N when the logarithm of the activity coefficient of a hypothetical monovalent cation of $Ba_i = 3$ was predicted with $\alpha = 2$ at several I values. Convergence was quicker at lower values of I; however, the series converged rapidly in all cases, with errors below 1% when $N \geq 4$. Fig. 2 shows the error obtained at different I values when α was varied with $N = 2$ and $Ba_i = 2$. The error increased quickly as α moved away from Ba_i, and was also higher at larger values of I.

Fig. 1. Relative error (percent) of the predicted logarithm of the activity coefficient of a hypothetical ion of $Ba_i = 3$ at increasing values of N. Series calculated with $\alpha = 2$ and $I = 1$ (□), 0.1 (●) and 0.01 M (◇).

Fig. 2. Relative error (percent) of the predicted logarithm of the activity coefficient of a hypothetical ion when α is moved away from $\alpha = Ba_i = 2$ with $N = 2$ and $I = 1$ (□), 0.1 (◆) and 0.01 M (◇).

3.2. Fitting of experimental data

Data of the activity coefficient of proton (Table A1) and of several equilibrium constants (Tables A2, A3 and Table 5) at different values of I were taken from the literature. Eqs. (8–11) and (18–21) were used to fit the data using $\alpha = 1$.

First, the data series of Table A1 were used to obtain the regression curves with Eqs. (8–11). The average of the absolute deviations between experimental and fitted values of the logarithm of the activity coefficient of proton, log γ_H, are given in Table 2. The best fittings corresponded to Eqs. (9) and (11), where $N = 2$. A lower value of r was obtained with Eq. (8), and the lowest r corresponded to Eq. (10) in which the parameter A was maintained constant and only c_i was allowed to be fitted. The 25°C data series and the regression curves obtained with Eqs. (8) and (9) are plotted in Fig. 3. It can be observed that Eq. (9) accurately predicted all the data, and that Eq. (8) was somewhat less accurate.

Eqs. (18–21) were used to fit both pK_w data and the logarithms of the stability constants of the complexes $FeCl^{2+}$ and $FeSCN^{2+}$ at increasing I values. The data given in Tables A2 and A3 were used in the fittings. The averages of the absolute deviations between fitted and experimental values are shown in Tables 3 and 4. In both

[a] Data at temperatures other than 25°C were also taken from Ref. [4].
[b] Used to calculate the Az_i^2F term in Eqs. (10) and (11) (data taken from Ref. [4]).

cases, the deviations between experimental and fitted values were small. The best fittings were obtained with Eqs. (19) and (21), where $N = 2$, and the poorest with Eq. (20), in which $N = 1$ and only two parameters were fitted.

Next, Eq. (18) and only three experimental pK_w values taken at $I = 0.10$, 0.50 and 3.01 M were used to predict the data at intermediate values of I. The average relative error was 0.02, 0.03 and 0.07% for the LiCl, NaCl and KCl series respectively. When Eq. (20) and only two experimental points were used, i.e. $I = 0.10$ and 3.10 M, the average relative error increased to 0.03, 0.14 and 0.3% respectively. The LiCl series and the regression curve predicted by Eq. (20) are shown in Fig. 4. The curves predicted by the Pitzer, SIT and Debye–Hückel algorithms using $pK_{w,0} = 14.00$ and the ionic parameters given by Elizalde and

Fig. 3. γ_H data series of Table A1 at 25°C and regression curves obtained with Eqs. (8) (broken line) and (9) (solid line) using all the data.

Aparicio [14] are also shown in the Figure. Predictions made with these algorithms were much less accurate.

3.3. Linear extrapolation to zero ionic strength

Eqs. (18–21) and all the data given in Table A3 were used to calculate the logarithms of the stability constants of $FeCl^{2+}$ and $FeSCN^{2+}$ at $I = 0$. As shown in Table 4, Eq. (20) gave the most accurate results, and Eq. (19) lead to absurd values. The large and very large deviations in relation to the expected values were due to the presence of maxima and minima in the regression functions which caused dramatic effects in some cases when extrapolation was used to evaluate data located at large distances from the experimental values. However, the deviations found were always small when these equations were used to interpolate data.

The capability of Eq. (20) to reliably extrapolate data to $I = 0$ is also shown in Tables 5 and 6.

Table 3
Mean of the absolute values of the residues of linearly fitted pK_w values using the data of Table A2[a]

| Equation	LiCl	NaCl	KCl
18	0.0018	0.0012	0.005
19	0.0017	0.0011	0.0024
20	0.0018	0.007*	0.019*
21	0.0018	0.002	0.0021

[a] For Eqs. (20) and (21), $Q_1 = -1.018$, $r > 0.999$, except for the two cases indicated with asterisks which gave $r = 0.996$ and 0.98.

Table 4

Mean of the absolute values of the residues, d (r given between parentheses), values predicted to $I = 0$, log K_0, and deviation from the literature value, ε, for the logarithm of the stability constants of FeCl^{2+} and FeSCN^{2-} [a]

21	0.031 (0.9992)	3.15	1.77	0.0008 (0.9999)	2.95	0.14

[a] Data of Table A3; for Eqs. (20) and (21), $Q_1 = -3.054$.

In Table 5, this equation with $\alpha = 1$ and data taken at two values of I were used to extrapolate the logarithm of the protonation constant of ammonia to $I = 0$. Taking into account that the extrapolated values were obtained using only two points at very large ionic strengths, the differences from the literature value could be considered to be small. In the upper part of Table 6, the ionic product of water at $I = 0$, p$K_{w,0}$, was calculated using only two points at increasing values of I. The predicted p$K_{w,0}$ value was always in the vicinity of the expected value, 14.00 [11], even when two very close points at high I values were used. In the lower part of the Table, several points located within two rather different I ranges were used. Both low and high I ranges also lead to

Fig. 4. pK_w data series of Table A2 for LiCl: curve predicted by Eq. (20) using only the data at $I = 0.10$ and 3.01 M (solid line), and curves calculated by the Pitzer (dashed line), SIT (dotted line) and Debye–Hückel (dot-dashed line) algorithms using log K_0 and the ionic parameters given in Ref. [14].

p$K_{w,0}$ values close to 14.00.

3.4. Influence of α

The results given above were further improved by optimising α. The correlation coefficient r, was used to steer the optimisation process. The optimum value of α can be obtained by any non-linear optimization procedure; however, owing to the few data points used a simple direct search procedure was applied in this work. Thus, for the activity coefficient of proton at 10°C using Eq. (20), r improved from 0.89 to 0.997 when α increased from 1 to its optimum value which was 2.47. Also pK_w data of the LiCl and NaCl series at $I = 0.5$, 1.0 and 1.5 M were fitted using Eq. (20) with different values of α. As shown in Fig. 5, r further approached one by optimising α. Optimum values of α were found in the vicinity of 1.0 and 1.3 for the LiCl and the NaCl series respectively. The absolute differences between extrapolated p$K_{w,0}$ values and 14.00 are also plotted in
Table 5

the Figure. The minimum difference was produced at the same values of α that gave the best fittings. Analogous conclusions were obtained by modifying α in the evaluation of the protonation constant of ammonia to $I = 0$ (results not shown).

Finally, we have compared the results obtained with Eqs. (8-11) and (18-21), using an optimum value of α, with the results given by the equation of Datta and Grzybowsky [20] in which $\alpha = 0$. In all cases, Eqs. (8-11) and (18-21) gave better linearity and more accurate results. Further, when the parameter A or Q_1 was assumed to be known, i.e. taken from the literature, the Datta and Grzybowsky equation lead to much worse results.

4. Conclusions

It has been shown that the proposed series converges quickly, and that excellent fittings can be obtained using only one or two terms of the series. If experimental data at two or more values of I are available, the ionic parameters and the logarithms of the activity coefficients can be simultaneously evaluated by linear regression. Thus, the systematic errors associated with the use of previously known values of the ionic parameters are avoided, and iterative procedures are not required.

Eqs. (10) and (20) gave the worst fittings; however, they can be used to interpolate activity coefficients and equilibrium constants using

points measured at only one and two different values of I respectively, whereas more experimental points are required with the other equations. In the fittings, and provided that more experimental data than those strictly required by the equations are used, obtaining a correlation coefficient close to one means that the data are accurate and that they adequately follow the Debye-Hückel extended equation.

Finally, Eqs. (9), (11), (19) and (21), which include the term $N = 2$ of the series, are not recommended for obtaining extrapolated values. In some circumstances, deviations can be larger

Fig. 5. Correlation coefficient as 1-r (◆) and $\varepsilon = |pK_{w,0} - 14.00|$ (◇) at increasing values of α; $pK_{w,0}$ values obtained with Eq. (20) using only three pK_w values ($I = 0.5$, 1.0 and 1.5 M) taken from Table A2 for LiCl (upper part) and NaCl (lower part).

Short communication

Spectrophotometric determination of the theophylline in plasma by the apparent content curves method

M.J. Llobat-Estellés*, R.M. Marín-Saez, M.D. San-Martín Ciges

Department of Analytical Chemistry, Faculty of Chemistry, University of Valencia, Avda. Dr. Moliner 50, 46100-Burjassot, Valencia, Spain

Abstract

A direct spectrophotometric procedure for the determination of theophylline in plasma is proposed. This procedure is based on the apparent content curves method and it is not necessary to know the nature and contents of interferent substances. Bias errors introduced by plasma and metabolites are avoided. The results obtained are in agreement with those provided by an immunofluoroassay used as a reference method.

Keywords: Apparent content curves method; Plasma; Spectrophotometry; Theophylline

1. Introduction

Theophylline is a bronchodilator drug generally used in the treatment of bronchial asthma and neonatal apnea. For this purpose, plasma levels of theophylline of 10–20 μg ml^{-1} must be obtained because higher values produce undesirable secondary effects and lower values do not induce therapeutic effects. Also, differences in the individual elimination of theophylline make it necessary to monitor the plasma levels of patients treated with theophylline.

To determine theophylline in plasma, several methods have been proposed [1–3], most of them

being based on techniques such as UV–visible spectrophotometry [4–9], chromatography [2,10–14] or immunological tests [15–19]. Spectrophotometric methods are widely used but absorption measurements have low selectivity and therefore the proposed procedures include experimental steps designed to minimize the influence of the different constituents of the plasma.

In this paper, we propose the application of a mathematical model that permits the determination of an analyte in the presence of unknown interferences. This method is based on the apparent content curves approach [20–22] and it has been satisfactorily applied to the spectrophotometric determination of theophylline in pharmaceuticals [23].

* Corresponding author.

For application of this method, only the absorbance values of the sample at three wavelengths and the response coefficients of the analyte at the same wavelengths are needed. Additivity is also assumed.

2. Theoretical

Apparent content curves can be obtained, as described in previous papers [20–22], by plotting F_i values versus λ_i, F_i being calculated as

$$F_i = \left[\frac{S_T}{\alpha_A}\right]_i$$

where S_T is the analytical signal of a multicomponent sample at wavelength i and α_A is the response coefficient of the analyte at the same wavelength.

Considering that

$$(S_T)_i = (\alpha_A)_i\, C_A + \left(\sum_k^n \alpha_K\, C_K\right)_i$$

α_A and α_K being the response coefficients of the analyte (A) and each of the interferents (K) and C_A and C_K their corresponding contents, the expression for F_i becomes

$$F_i = \left[\frac{\alpha_A\, C_A + \sum_i^n \alpha_K\, C_K}{\alpha_A}\right]_i = C_A + \left[\frac{\sum_i^n \alpha_K\, C_K}{\alpha_A}\right]_i$$

$$= C_A + \Delta C_A$$

Hence, in the absence of interferent substances, the curves are straight lines with zero slopes and y-intercepts equal to C_A. However, the presence of interferences leads to different shapes for these curves, depending of the nature and contents of the interferences.

In this way, the apparent content curves show the presence of interferences, and further, they indicate the maximum contents of analyte possible (minimum of the curve in each case). In addition, the apparent content curves constitute the basis of an analytical procedure that, after identifying the total interferent present, called "apparent interferent", allows the determination of an analyte without the need for standard solu-

tions of real interferences in the sample and without the need to resort to any separation method.

For the identification of the total interferent, a computational program is used. The program looks for three signals that represent, at three established wavelengths, the spectrophotometric behaviour of the interferent present [22]. For this, the signals must obey a series of fixed conditions that imply

$$\frac{W_1}{[(\alpha)_1\, C_1]_1} = \frac{W_2}{[(\alpha)_1\, C_1]_2} = \frac{W_3}{[(\alpha)_1\, C_1]_3}$$

W_1, W_2, W_3 being the signals found and α_1 and C_1 the unknown response coefficients at the three working wavelengths and the concentration of the interferent respectively.

Once the "nature" of the interferent present has been established, determination of the analyte is carried out by the program [20–22] using F values for the sample and F^P values for the total interferent, defined as:

$$F^P_i = \frac{W_i}{\alpha_i}$$

Taking these values into account, C_A can be calculated from the expression

$$C_A = F_1 - F^P_1\left(\frac{F_1 - F_2}{F^P_1 - F^P_2}\right)$$

where $(F_1 - F_2)/(F^P_1 - F^P_2)$ is a correction factor (theoretical dilution of the signals found) that allows an interferent effect of suitable value to be obtained.

3. Experimental

3.1. Apparatus and reagents

A Perkin-Elmer Lambda 16 UV spectrophotometer was used.

The solvents propan-2-ol and dichloromethane were obtained from Panreac. An $H_2PO_4^-$ – HPO_4^{2-} HPO_4^{2-} of pH 7.4 was prepared. Stock solutions of theophylline, 1,3-dimethyluric acid, 3-methylxanthine, caffeine and 1,7-dimethylxanthine (Sigma) in suitable solvents were used to develop the experimental procedure.

1591

3.2. General procedure

For the determination of theophylline in plasma two solutions are prepared. For the first, to 0.5 ml of plasma add 0.25 ml of $(NH_4)_2SO_4$

Fig. 1. Absorption spectra in dichloromethane–propan-2-ol of theophylline and its metabolites: (1) 10 ppm of theophylline; (2) 10 ppm of (a) 1,3-dimethyluric acid, (b) 3-methylxanthine, (c) 1-methyluric acid, (d) caffeine and (e) 1,7-dimethylxanthine.

Table 1
Calibration curves for theophylline in the presence of metabolites

Metabolite	y-Intercept	Slope
None	-0.003 ± 0.01	0.0457 ± 0.0007
1,3-Dimethyluric acid	0.02 ± 0.01	0.0437 ± 0.0006
3-Methylxanthine	0.02 ± 0.02	0.044 ± 0.001
1-Methyluric acid	0.003 ± 0.004	0.0447 ± 0.0003
Caffeine	0.185 ± 0.006	0.0459 ± 0.0004
1,7-Dimethylxanthine	0.168 ± 0.003	0.043 ± 0.002

(saturated solution), distilled water to 1 ml and 2.5 ml of dichloro-methane–propan-2-ol (19:1), shake the mixture for 5 min and centrifuge at 1000 rpm. For the second solution, proceed in the same way but use a standard solution of theophylline instead of distilled water.

Absorbance values at 264, 268 and 272 nm of the organic layers of both solutions are obtained using dichloromethane–propan-2-ol (19:1) as a blank. From these values, calibration graphs for standard additions at the three working wavelengths are estimated and F_i values are obtained as the ratio of y-intercept to slope in each case. Once the F_i values and the response coefficients (slopes of the calibration graphs) have been obtained, the program calculates the content of theophylline in the sample.

4. Results and discussion

4.1. Study of the extraction procedure

Extraction of theophylline was carried out with dichloromethane–propan-2-ol (19:1) [2]. In this medium, the absorption spectra of theophylline showed a broad band with a maximum at 274 nm (Fig. 1). The responses were linear over the dynamic range of concentration studied (2–10 ppm), the equation of the straight line obtained being $A = 0.0004 + 0.544C$ ($r = 0.9994$).

After extraction of theophylline from an aqueous solution, the spectra obtained were identical, the recoveries obtained being 94.5% and 85.2% for ratios of volume of aqueous layer to organic layer of 2:10 and 2:5, respectively.

In the presence of plasma and using a ratio of volumes of 2:5, a calibration graph for theophylline was obtained with the equation $A = 0.089 + 0.0337C$ ($r = 0.998$), whereas in the ab-
Table 2

Theoretical and experimental contents of theophylline obtained by applying the proposed procedure and reference method

Sample Composition		Theophylline content (ppm)	
		Proposed method	Reference method
1	5 ppm theophylline 10 ppm 1,3-dimethyluric acid 5 ppm 3-methylxanthine 5 ppm 1-methyluric acid 5 ppm caffeine 3 ppm 1,7-dimethylxanthine	5.4 ± 0.7	5.6
2	15 ppm theophylline 20 ppm 1,3-dimethyluric acid 10 ppm 3-methylxanthine 3 ppm 1-methyluric acid 2 ppm caffeine 5 ppm 1,7-dimethylxanthine	14.9 ± 0.7	15.4
3	25 ppm theophylline 8 ppm 1,3-dimethyluric acid 4 ppm 3-methylxanthine 4 ppm 1-methyluric acid 3 ppm caffeine 2 ppm 1,7-dimethylxanthine	25.3 ± 0.7	24.9

Fig. 2. Apparent content curves for three different synthetic samples containing real plasma and various concentrations of theophylline and metabolites. Compositions of samples are given in Table 2. (1) Sample 1; (2) sample 2; (3) sample 3.

sence of plasma the equation found was $A = -0.003 + 0.0457C$ ($r = 0.9997$). Therefore, a constant error (y-intercept $\neq 0$) and a proportional error (different slopes) are introduced by the constituents of plasma.

Finally, the potential interference introduced by the principal metabolites of theophylline was studied. As can be seen in Fig. 1, the spectrophotometric behaviours of substances such as 1,3-dimethyluric acid, 3-methylxanthine, 1-methyluric acid, caffeine and 1,7-dimethyxanthine are similar to that of theophylline and so they constitute potential interferences.

The influence of such substances on the absorption spectra of the extracts was studied in the following way. A series of solutions containing various concentrations of theophylline and a fixed concentration of one of the interferents tested was prepared. These solutions were extracted and the absorption spectra of the extracts were obtained. The responses at 274 nm were plotted against

theophylline content and the equations of the straight lines and standard deviation values obtained are given in Table 1.

From these values, it can be concluded that the differences between the y-intercepts obtained are statistically significant and so a constant error for a probability level of 95% can be confirmed. However, the differences between the slopes obtained are not significant and so proportional error cannot be deduced.

In conclusion, the determination of theophylline in extracts of plasma must be carried out using experimental procedures that avoid or minimize proportional errors introduced by plasma and, therefore, constant errors introduced by plasma and metabolites.

4.2. Determination of theophylline

To verify the proposed procedure experimentally, three synthetic samples were prepared as follows. To 45 ml of plasma, various amounts of theophylline and metabolites (1,3-dimethyluric acid, 3-methylxanthine, 1-methyluric acid, caffeine and 1,7-dimethylxanthine) were added to give a total volume of 50 ml. Each sample was analysed in triplicate using the general procedure described above.

Apparent content curves for the organic layers corresponding to each sample are shown in Fig. 2. As can be seen, in all cases the lower values are clearly above the theoretical contents given in Table 2. The results obtained by application of proposed procedure agree with those provided by an immunological test used as a reference method (Table 2).

Table 3
Experimental contents of theophylline obtained by applying the proposed procedure and the reference method samples from patients

Sample	Theophylline content (ppm)	
	Proposed method	Reference method
1	10.0	10.4
2	15.0	15.9

Finally, the proposed procedure was applied to samples from patients treated with theophylline. As can be seen (Table 3), the results obtained agree with those provided by the reference method.

5. Conclusions

The determination of theophylline in plasma can be carried out using the apparent content curves method. The proposed procedure is simple, and constant and proportional bias errors introduced by other constituents of the matrix plasma are avoided.

Prussian-Blue-based amperometric biosensors in flow-injection analysis

Arkady A. Karyakin[1], Elena E. Karyakina[1], Lo Gorton*

Department of Analytical Chemistry, University of Lund, P. O. B 124, S-221 00 Lund, Sweden

Abstract

Optimisation of the electrodeposition of Prussian Blue onto mirrored glassy carbon electrodes yielded a modified electrode practically insensitive to oxygen reduction. At the same time the electrode activity towards hydrogen peroxide reduction was extremely high. This allowed the detection of hydrogen peroxide by electroreduction over a wide potential range. Flow-injection investigations of this electrode inserted into a flowthrough electrochemical cell of the confined wall-jet type showed that the response for hydrogen peroxide is limited by diffusion. Glucose and alcohol biosensors were made by immobilisation of glucose oxidase and alcohol oxidase respectively, within a Nafion layer, onto the top of the Prussian-Blue-modified electrodes. By increasing the density of Nafion and decreasing the measuring potential the glucose biosensor was made completely insensitive to both ascorbate and acetominophes.

1. Introduction

Accurate, rapid, and automatic analysis is required nowadays for clinical and industrial laboratories. Flow-injection analysis (FIA) with an enzyme electrode as the sensing element in the detector seems to accomplish this function. Operation of amperometric biosensors requires a con

jugation between the enzyme and electrochemical reactions. First generation biosensors are based on direct electrochemical detection of either the substrate or the product of the enzyme reaction. In the case of hydrogen-peroxide-producing oxidases the substrate and product refer to molecular oxygen and hydrogen peroxide respectively. Amperometric detection of these substances is usually done at platinum or platinised electrodes [1]. Electrochemical detection of hydrogen peroxide in the presence of oxygen is usually accomplished by its oxidation at anodic potentials ($> +0.6$ V, Ag/AgCl). However, all biological fluids contain a

---

series of various reductants, e.g. ascorbate, bilirubin, etc., which are easily co-oxidised at similar potentials, producing an additional current response, and this makes quantitation of the hydrogen peroxide produced and hence the enzyme substrate concentration impossible. A lot of effort has therefore been made to drastically decrease the necessary applied potential for following oxidase-based reactions. One way is to exchange the enzyme's natural reoxidation reagent (molecular oxygen) for an artificial electron acceptor [2,3]. Another is to decrease the overpotential for electrochemical conversion of hydrogen peroxide. Covering carbon electrodes with a layer of finely dispersed noble metals has proven highly catalytically efficient for both electrochemical oxidation and reduction of hydrogen peroxide [4]. However, the selectivity for hydrogen peroxide varies greatly with the metal chosen and the type of deposition [5]. Enzyme electrodes for detection of hydrogen peroxide could also be made by immobilisation of peroxidase at carbon electrodes either using a mediator or in a mediatorless approach [4,6,7]. In spite of the high enzyme activity towards hydrogen peroxide reduction the enzyme electrodes, at least in the mediatorless approach, are only seldom reported to have similar current densities as the electrodes based on noble metals [8]. The main reason for this is that not all of the immobilised peroxidase molecules are in direct electron transfer contact with the electrode [8].

Two of the current authors [9,10] and others [11] have previously reported that highly sensitive first generation amperometric-oxidase-based biosensors can be developed on the basis of Prussian-Blue-modified electrodes. One of the advantages of the first generation biosensors is that the oxidase can use its own "natural" reoxidation reagent, i.e. molecular oxygen. An absence of artificial mediators avoids the problem of competition between different electron acceptors. Prussian Blue was found to be a better electrocatalyst of hydrogen peroxide reduction than specially pretreated platinum and hydrogen peroxide could be selectively detected at the Prussian-Blue-modified electrode in the presence of molecular oxygen by both electrooxidation and electroreduction, even though at potentials below 100 mV a

slight electrocatalytic effect was also noticed for the reduction of oxygen [9,10]. This also made possible detection of hydrogen peroxide within "the optimal potential range for enzyme based amperometric biosensors" i.e. between approximately -200 and $+150$ mV (Ag/AgCl, pH 7) [4,7]. Prussian Blue is also a comparatively cheap and stable electrocatalyst compared with an enzyme (peroxidase), making it an attractive material for possible mass production of the base electrode material for biosensors.

A glucose amperometric biosensor can be constructed through immobilisation of glucose oxidase in a layer of Nafion cast directly onto the Prussian-Blue-modified electrode [4,7]. The use of an unconventional medium (Nafion, a perfluorinated polyelectrolyte) for the immobilisation of the enzyme resulted in a prolonged stability of the enzyme in this matrix. Moreover, the selectivity of the enzyme electrode was increased because the Nafion membrane also served as a barrier for negatively charged possible interfering compounds (e.g. ascorbate [12,13], paracetamol [14] etc.). The response of this biosensor exhibited a linear dependence on the analyte concentration in the range between 1×10^{-6} and 5×10^{-3} M glucose. The cathodic current density after addition of 1×10^{-6} M glucose was equal to 0.18 μA cm^{-2} [10].

The use of a further optimised method for the depostion of Prussian Blue on glassy carbon electrodes to obtain an improved selectivity for hydrogen peroxide reduction with regard to simultaneous reduction of oxygen is reported here. The electrodes were also used in biosensor configurations covered with membranes of high Nafion content and with immobilised glucose oxidase or the less stable alcohol oxidase. The applicability of these electrodes in the flow-injection mode is shown.

2. Experimental

2.1. Materials

All inorganic salts and glucose were obtained at the highest purity. Absolute ethanol was prepared

by distillation of sodium alcoholate and used immediately. Nafion (5% solution in 90% low chain aliphatic alcohols) was obtained from Aldrich (Steinheim, Germany). Glucose oxidase (EC 1.1.3.4) from *Asperigillus niger* (VII-S, 180 IU mg^{-1}) was produced by Sigma (St. Louis, MO). Alcohol oxidase (EC 1.1.3.13) from *Hansenula sp.* (Sigma) had an initial activity of 30 IU mg^{-1}.

2.2. Deposition of Prussian Blue

Glassy carbon disk electrodes (1.5 mm diameter) were used as working electrodes. Prior to use, the glassy carbon electrodes were mechanically polished with aluminium powder (Al_2O_3, 1 μm) until a mirror finish was observed. A three-compartment electrochemical cell containing a platinum net auxiliary electrode and an Ag/AgCl reference electrode in 1 M KCl was used for the deposition of Prussian Blue. The three electrodes were connected to an electrochemical analyser (bioanalytical Systems, West Lafayette, IN, model BAS-100W). The cell construction allowed deaeration of the working electrode space. Electrodeposition of Prussian Blue at the surface of the polished glassy carbon electrodes was done by immersing the electrode in a deaerated solution containing 1M KCl and 3mM HCl initially and also containing 1 mM $K_3[Fe(CN)_6]$ and 1mM $FeCl_3$ and applying a constant potential of 0.4 V for 30 or 100 s. After deposition the Prussian Blue films were activated in 0.1 M KCl by cycling the applied potential in a range between -0.05 and 0.35 V at a sweep rate of 50 mV s^{-1}. The total coverage of Prussian Blue at the electrode surface was between 2-3 and 4-5 nmol cm^{-2} after 30 s and 100 s of deposition respectively, if a transfer of four electrons per unit cell is assumed [15].

2.3. Preparation of enzyme membranes

Enzyme-containing Nafion membranes were prepared according to our recently reported method from enzyme suspensions in 90% ethanol and 10% water [16]. To this aim the lyophilised enzyme samples were dissolved in water to a final concentration for alcohol oxidase of 80 mg ml^{-1}

and for glucose oxidase of 40 mg ml^{-1}. It was shown that such concentrations caused no enzyme inactivation. Finally, the enzyme suspension was made by addition of ethanol or a water-ethanol mixture to the enzyme solution. An "enzyme-polyelectrolyte complex" was made by mixing the enzyme suspension with the Nafion solution. Enzyme-containing Nafion membranes were prepared by syringing 10 μl of the enzyme-polyelectrolyte complex to the surface of the Prussian-Blue-modified electrode and allowing the solvent to evaporate at room temperature. After deposition the enzyme-Nafion membranes were thoroughly washed with water. When not in use the electrode was stored dry in a refrigerator at 4°C.

Three different types of glucose electrodes were made using a slight variation in the immobilisation of glucose oxidase. Type I refers to the sensing electrode with a simple membrane made from the enzyme-polyelectrolyte complex with a Nafion content of 0.25%. The type II electrode was made in a similar way, but by first syringing 5 μl of glucose oxidase suspension in ethanol onto the electrode surface prior to deposition of the same enzyme-polyelectrolyte complex as above. To prepare the type III electrode the same procedure as for type I was followed except that a more concentrated (0.5%) Nafion solution was used to prepare the enzyme-polyelectrolyte complex. The total amount of immobilised glucose oxidase was almost equal for electrodes of types I and III. Alcohol oxidase was immobilised on the top of a Prussian Blue layer from an enzyme-polyelectrolyte complex with a Nafion content of 1%.

2.4. Flow-injection set-up

The flow-injection system consisted of a peristaltic pump (Gilson, Villier-le-bel, France, model Minipuls 2), A pneumatically-operated valve (Cheminert, Valco Instruments, Houston, TX, type SVA) equipped with a 50 μl injection loop, and a flowthrough amperometric cell of the confined wall-jet type [17] under three-electrode potentiostat control (Zäta Electronic, Lund, Sweden). The output of the potentiostat was connected to a strip chart recorder (Kipp & Zonen,

Delft, The Netherlands). The inlet section of the cell contained the Ag/AgCl reference electrode in a circular chamber filled with 0.1 M KCl from an external syringe. This chamber contacted the working electrode space by means of four holes (0.3 mm i.d.) concentrically surrounding the inlet (0.5 mm i.d.). The auxiliary electrode was a platinum wire encircling the outlet chamber. Glassy carbon disk electrodes (as above) were used as working electrodes. The distance between the nozzle and the working electrode was about 2 mm. The flow rates used were between 0.7 and 0.8 ml min^{-1}. A dispersion coeficient of about 1.5 was reached by injection of 50 μl of the sample. All connections in the system were made with Teflon tubing (0.5 mm i.d.). Before use all solutions were degassed to prevent microbubbles appearing in the system.

3. Results and discussion

3.1. Optimisation of Prussian Blue deposition

As already mentioned, Prussian Blue has been found to be a very efficient catalyst of hydrogen peroxide electroreduction [9,10]. However, according to the procedure followed in Refs. [9,10] it was also shown to be active for electroreduction of oxygen at potentials more negative than 100 mV. Hence there was a limited potential range where one can use Prussian-Blue-modified electrodes for the determination of hydrogen peroxide in the presence of oxygen.

The development of oxidase-based biosensors requires the electrocatalyst to be practically insensitive to oxygen and to operate at potentials from -100 mV to 100 mV (Ag/AgCl/1 M KCl). In the given potential range there is also only a minor influence of reductants on the biosensor response. It was therefore concluded to reconsider the optimisation of the deposition of Prussian Blue to obtain a catalyst even more selective for hydrogen peroxide.

As indicated in Ref. [15] the activity of Prussian-Blue-modified electrodes for the electroreduction of molecular oxygen is dependent on the conditions in which they are prepared. Thus it seemed as though

the selectivity of the catalyst layer could be controlled by the procedure of its deposition. Indeed, if molecular oxygen was not electrocatalytically reduced at the modified electrode, one could find a potential region where ascorbate, paracetamol, etc. were not oxidised and thus the response would be only to hydrogen peroxide.

Here, in contrast to the previous procedure [9,10], the electrodeposition of Prussian Blue was performed at a constant potential, where only ferric chloride was reduced. Furthermore, the initial concentrations of $K_3[Fe(CN)_6]$, KCl, HCl, and Fe^{3+} have been changed and $FeCl_3$ was used instead of $Fe(No_3)_3$. Through thorough optimisation of both the potential and the time of deposition polycrystal films were obtained with an extremely high redox activity. Fig. 1 presents a cyclic voltammogram of a Prussian-Blue-modified electrode registered in 0.1 M KCl. As seen in the case of a thin film (2 nmol cm^{-2}) the peak separation at a sweep rate of 20 mV s^{-1} was lower than 15 mV, indicating an almost electrochemically-reversible behaviour [18].

Fig. 2 illustrates the steady-state voltammograms of hydrogen peroxide and molecular oxygen reduction at the resulting electrode. To stabilise the thin layer of the electrocatalyst, the modified electrode was covered with 1% Nafion by dip-coating. The solid electrolyte was found to affect neither the redox nor the electrocatalytic properties of the deposited Prussian Blue (data not shown). In Fig.

Fig. 1. Cyclic voltammogram of Prussian-Blue-modified electrode (coverage: 2 nmol cm^{-2}) registered in 0.1 M KCl at a sweep rate of 20 mV s^{-1}.
I, μA/cm^2

Fig. 2. Steady-state voltammograms of reduction of oxygen from air-saturated solution (○) and 0.2 mM hydrogen peroxide (□) at (1%) Nafion-covered Prussian-Blue-modified electrode (2 nmol cm^{-2}) registered in 0.1 M KCl, with stirring.

2 it is seen that the current of oxygen reduction over the entire potential range was negligible and was even lower than that of O_2 reduction at a bare glassy carbon electrode (data not shown). In contrast, the modified electrode was still extremely active for hydrogen peroxide electroreduction. The half wave potential of H_2O_2 reduction (Fig. 2) coincided with the formal potential of Prussian Blue found from the cyclic voltammograms, evaluated as the mean of the anodic and cathodic peak potentials [18] (Fig. 1), indicating a very fast reaction between hydrogen peroxide and the catalyst.

One of the most useful tools for hydrodynamic voltammetric studies is the wall-jet electrode, where a jet of solution issued from a circular nozzle is allowed to impinge normally on a working disk electrode. A counter electrode is set at an appropriate position remote from the wall jet. The equation for the limiting diffusion controlled current, I_d, at the wall-jet electrode was evaluated in Ref. [19]:

$$I_d = 1.38nFC_0 D^{2/3} v^{-5/12} V^{3/4} a^{-1/2} R^{3/4}$$

where C_0 and D are the concentration and diffusion coefficient of the depolariser respectively, v is the kinematic viscosity, V is the volume flow rate of the solution, a is the diameter of the nozzle and

R is the electrode radius. From the point of view of analytical chemistry it is essential that the limiting current is proportional to the concentration of the electroactive species.

It is interesting to compare the wall-jet electrode with the most common electrochemical hydrodynamic tool, the rotating disk electrode, as the limiting current depends on the diffusion coefficient of the depolariser similarly for both systems [18]. For a disk electrode with a diameter of 3 mm (i.e. a larger one than used in this report) inserted in the current wall-jet system (having an outlet nozzle of 0.5 mm i.d. and a flow rate of 1 ml min^{-1}), the registered limiting diffusion-controlled current would be of the same order as that obtained for a corresponding rotating electrode at a rotation velocity of 240 rev min^{-1}. The kinematic viscosity is assumed to be equal to 0.01 cm^2 s^{-1} [18]. For wall-jet electrodes with a diameter less than 3 mm (as is the case in this paper) the dependence of the limiting current on the electrode radius is different from that predicted by the given equation. However, from the data presented in Ref. [18] it was possible to estimate the current that is expected for the 1.5 mm i.d. disk electrode used in this study with the present set-up (flow rate of 1 ml min^{-1} and with the 0.5 mm nozzle) and to conclude that it would correspond to a rotating electrode with a speed of between 900 and 1000 rev min^{-1}. Considering the thickness of the diffusion layer [18,20] instead of the limiting current, similar correlations could be obtained.

One of the main advantages of the flow-injection technique as an analytical tool is the possibility of using small sample volumes. Indeed a 50 μl sample is sufficient to reach a value of dispersion of 1.5 [21]. This means that the peak height reaches between 60 and 70% of the steady-state current response obtained through a continuous flow of the analyte.

Uncovered Prussian-Blue-modified electrodes were applied to the flow-injection technique as sensors for hydrogen peroxide. The thicker film (4.5 nmol cm^{-2} obtained after 100 s of deposition) showed the most stable response. Calibration curves for determination of hydrogen peroxide with this electrode showed a linear dependence of the peak current on hydrogen per-

oxide concentration in the range between 1μM and 0.2 mM. At millimolar and higher concentrations of hydrogen peroxide a slow inactivation of the electrocatalyst was noticed. The linear dependence of the current response on analyte concentration, together with the arguments above, indicate that under the present conditions the sensor response is very fast and should be virtually limited by diffusion of hydrogen peroxide. Replotting the calibration curve in logarithmic coordinates resulted in a straight line with a slope equal to 1.0, indicating the same limiting step over the entire range. Since the diffusion layer in the wall-jet system is thin, the activity of the electrocatalyst for the hydrogen peroxide reduction was extremely high. This conclusion supports the use of the optimised Prussian-Blue-modified electrodes for construction of corresponding biosensors to be used in the flow-injection mode where there is a need for a fast responding sensor and where the detection of the enzyme product should not be the limiting step.

3.2. Flow-injection glucose analysis

Glucose oxidase was immobilised on the surface of the Prussian-Blue-modified electrode in a Nafion layer as described in Section 2. We have recently reported [16] on the beneficial properties of the sensor when the enzyme is immobilised in Nafion using a high concentration of ethanol: the remaining initial activity of the enzyme, an increased long-term stability, and increased reproducibility between similarly-prepared electrodes. The concentration of Nafion in the enzyme–polyelectrolyte complex was varied so that for types I and II it was 0.25% and for type III 0.5%. The calibration curves were recorded independently at two potentials: 0 mV and −50 mV (Ag/AgCl/0.1 M KCl).

Typical FI peaks registered for the response of an electrode of type III to glucose injections are shown in Fig. 3. A stable response with sufficiently high reproducibility was observed after continuous injections (RSD < 0.5%, $n = 5$, glucose concentration 0.5 mM). It is seen that the time for one analysis was 30–40 s, depending on the glucose concentration. Calibration curves for glucose

Fig. 3. Typical response of the flow-injection glucose analysis obtained for an electrode of type III: carrier, 0.02 M phosphate buffer, pH 5.5 with 0.1 M KCl (flow rate 0.7 ml min^{-1}); applied potential, 0 mV (Ag/AgCl/0.1 M KCl).

obtained in the FI system for electrodes of types I and III are shown in Fig. 5. There is a certain concentration range where the dependence of the response on glucose concentration gives a straight line in logarithmic coordinates, with a slope of unity. However, the injection of samples with a low analyte concentration gave well recognisable responses for type III electrodes and, to some extent, also for type I electrodes (see Fig. 4), independent of the glucose content. At the same time the injection of free buffer solution caused no response from the system. No real explanation for this behaviour can be given at this time but it may be caused by a local change in pH at the electrode–polyelectrolyte interface.

Fig. 4. Calibration curves for glucose in the flow-injection system: (○), electrode type I; (△), electrode type III; applied potentials were 0 mV and −50 mV (Ag/AgCl/0.1 M KCl) respectively; carrier, 0.02 M phosphate buffer, pH 5.5 with 0.1 M KCl (flow rate 0.7 ml min^{-1}).
Fig. 5. Calibration curves for methanol (○) and ethanol (□) in the flow-injection system; applied potential, 0 mV (Ag/AgCl/0.1 M KCl); carrier, 0.02 M phosphate buffer, pH 7.5 with 0.1 M KCl (flow rate 0.8 ml min^{-1}).

Table 1 summarises some properties of the three types of glucose sensors studied in the flow-injection system. It is seen that an increase in both membrane density (type III) and the amount of immobilised enzyme (type II) caused a shift in the detection limit to higher glucose concentrations. However, it should be pointed out that the detection limits for types II and III were taken as the lowest analyte concentration, where the response started to become dependent on the glucose content. Comparing the two calibration curves in Fig. 4, it is seen that the response of type III electrodes was higher than that of type I even though the linear range is more restricted for both low (<10 μM) and high concentrations (>2 mM).

One of the most important problems to solve for any practical application of amperometric biosensors is to minimise the effect of interfering substances possibly present in a real sample. For oxidase-based systems reductants are the most severe interferences and among these ascorbate [12,13] and acetaminophen [14] are two of the most powerful ones, having upper concentration limits in biological liquids of 0.1 and 0.2 mM respectively.

The interferences of ascorbate and acetaminophen were tested in the flow-injection system with the Prussian-Blue-based biosensor as the electrochemical detector. Since the response to glucose was a cathodic current, the influence of the reductants resulted in a decrease in the response to glucose. Table 1 summarises the influ-

ence of these reductants in their limiting concentrations on the glucose response of the different types of enzyme electrodes. For each sensor the corresponding concentration of glucose is shown, which will be completely masked by the presence of the respective reductant.

The comparative influence of acetaminophen was found to be low. A signficant effect was observed only in the case of electrodes of type I at a measuring potential of 0 mV (Ag/AgCl/0.1 M KCl). In all other cases the concentration of the analyte that could be masked by this interference was lower than its detection limit. Ascorbate was found to be a more powerful interfering compound. For the type I electrode the anodic response to 0.1 mM ascorbic acid was equal to the cathodic response to 0.5 mM glucose at 0 mV. However, when the measuring potential was shifted to −50 mV the response to 0.1 mM ascorbate was decreased by a factor of 10. Even the type I electrode is possibly suitable for analytical applications for the detection of glucose, for example in a complex matrix.

Nafion membranes have already been used to decrease the ascorbate interference [12,13]. Thus a further improvement in the biosensor properties can be made either by increasing the density of the Nafion layer or by increasing the content of the immobilised enzyme. The aim of the latter approach is to improve the response towards the analyte. The influence of the interferant will obviously be decreased because the response to ascorbate is independent of the activity of glucose oxidase. Indeed it is seen in Table 1 that enzyme electrodes of types II and III are less dependent on the presence of ascorbate. The type III biosensor operating at a measuring potential of −50 mV was completely independent of ascorbate. The masking effect after addition of 0.1 mM ascorbic acid was at the level of the detection limit for glucose at this electrode.

3.3. Flow-injection ethanol analysis

Alcohol oxidase is known to exhibit a low operation stability [22], the reason being that it is inactivated by hydrogen peroxide, which is the product of the enzyme-catalysed reaction. In spite

Table 1
Flow-injection analysis of glucose

Parameter	Electrode type					
	I		II		III	
	Measuring potential (mV)		Measuring potential (mV)		Measuring potential (mV)	
	0	−50	0	−50	0	−50
Detection limit (M)	2×10^{-6}	2×10^{-6}	5×10^{-6}	5×10^{-6}	1×10^{-5}	1×10^{-5}
Response to 0.1 mM glucose (μA cm^{-2})	1.3	1.3	2.5	2.5	2.1	2.2
Response to 0.5 mM glucose (μA cm^{-2})	5.7	5.8	10	10	11.5	11.7
Response to 1 mM glucose (μA cm^{-2})	11.5	11.5	23	21	21	22
Response to 5 mM glucose (μA cm^{-2})	49	51	46	42	66	64
Glucose concentration (M) which will be masked by 0.1 mM ascorbate	5×10^{-4}	5×10^{-5}	1.5×10^{-4}	1.5×10^{-5}	1×10^{-4}	1×10^{-5}
Glucose concentration (M) which will be masked by 0.2 mM acetaminophen	5×10^{-6}	–	–	–	–	–

of using a high density of the Nafion membrane (1% Nafion in the enzyme-polyelectrolyte complex) the response of the alcohol biosensor was continuously decreased. Experiments with a lower Nafion content used for making the enzyme-polyelectrolyte complex revealed a less stable response (data not shown). However, the rate of inactivation of the final enzyme electrode was relatively low. This made possible the recording of the calibration curves shown in Fig. 5. During such an investigation (≈ 6 h) the response was reduced by less than 10%, which was controlled by repeated measurements of injected samples, maintaining a constant concentration of methanol.

It is seen in Fig. 5 for both methanol and ethanol that within certain concentration ranges (for methanol between 5 μM and 1 mM, for ethanol between 0.1 and 10 mM), the response resulted in a straight line in logarithmic coordinates. The response to methanol is much higher than that to ethanol. One reason for this is that the product formed in the reaction of methanol

with alcohol oxidase is formaldehyde, which is a good substrate for alcohol oxidase, whereas the product formed in the oxidation of ethanol, acetaldehyde, is a poor substrate. Methanol is also a smaller molecule than ethanol with an expected higher diffusion rate within the Nafion layer. The detection limit (evaluated as three times the noise level) of the system for methanol was 1 μM whereas that for ethanol was much higher, 0.05 mM. However, the addition of ethanol, even in micromolar amounts, gave a stable response independent of the analyte concentration (not shown in Fig. 5), similar to what was obtained for glucose for electrodes of type III (see Fig. 4). Since the behaviour of the biosensor in the flow-injection system with a low alcohol content was not clear, it was decided to compare the responses towards different alcohols in the millimolar region. Table 2 summarises the effectiveness of analysis of the following five different alcohols: methanol, ethanol, *n*-propanol, *i*-propanol, and *i*-butanol. The relative response is decreased as the hydrophobicity of the alcohol is increased.

Table 2

Flow-injection analysis of alcohol. The relative response towards 1 mM concentrations of different alcohols

Alcohol	Relative response (%)
Methanol	100
Ethanol	14.5
n-Propanol	2.6
i-Propanol	1.4
i-Butanol	1.4

4. Conclusion

Through the optimisation of Prussian Blue electrodepostion an electrocatalyst was produced which was almost insensitive to dissolved oxygen at an applied potential close to 0 mV, resulting in improved possibilities for using Prussian-Blue-modified electrodes in biosensors compared with our previous reports [9,10]. At the same time the activity towards hydrogen peroxide reduction was extremely high. This allowed electrochemical detection of hydrogen peroxide over a wide potential range by its electrocatalytic reduction. Given the low applied potential at which these amperometric biosensors can operate it follows that they are less sensitive to interference by ascorbate. Prussian-Blue-modified electrodes also have potential for use in flow-injection systems due to the high rate of the catalytic reaction.

The method of enzyme immobilisation into Nafion films from enzyme suspensions in a water–ethanol mixture with a high ethanol content, which was shown to give good results in steady-state measurements [16], also gave good results in flow-injection systems. Even a labile enzyme such as alcohol oxidase could be partially stabilised using this method.

. In principal it is foreseen that other hydrogen-peroxide producing oxidases could be immobilised using similar procedures as outlined here for the development of Prussian-Blue-based biosensors and applied in flow-injection systems.

Electroluminescent method for determining hydrogen peroxide and peroxydisulphate ions in aqueous solution using TiO₂ film electrodes

S.K. Poznyak, A.I. Kulak

Institute of Physico-Chemical Problems, Belarusian State University, 220080 Minsk, Belarus

Abstract

An electrochemical optical sensor system with luminescence response was proposed for the continuous determination of hydrogen peroxide or peroxydisulphate concentration in aqueous solutions. The electroluminescence (EL) of TiO₂ film electrodes, which arises under conditions of the cathodic polarization as a result of the hole injection into the TiO₂ from high-energy $OH^{\cdot}$ or $SO_4^{-\cdot}$ radicals produced by the electroreduction of H_2O_2 or $S_2O_8^{2-}$ ions on the electrode surface, was used as the analytical signal. The EL response is linearly related, in a logarithmic scale, to the hydrogen peroxide or peroxydisulphate concentration ranging from 10^{-3} to 10^{-1} M H_2O_2 and from 5×10^{-4} to 1 M $Na_2S_2O_8$. It was shown that a substantial increase in the quantum efficiency of the EL and, as a consequence, in the sensitivity of the sensor system can be achieved by doping TiO₂ films with chromium. The potential dependence of the EL spectrum for TiO₂ electrodes in $S_2O_8^{2-}$ solutions differs essentially from that in H_2O_2 solutions which allows measurement of the concentration of $S_2O_8^{2-}$ ions when they coexist with H_2O_2 in solution.

Keywords: Electroluminescent method; Hydrogen peroxide determination; Peroxydisulphate ion determination; TiO₂ film electrodes

1. Introduction

The determination of hydrogen peroxide and peroxydisulphate ions is of practical importance in chemical, biological, clinical and other fields. This motivates the growing interest in developing novel types of sensors for these substances. Several methods for the determination of H_2O_2 and $S_2O_8^{2-}$ ions in aqueous and organic solutions, such as titrimetry [1,2], spectrophotometry [3–5],

chemiluminescence [6–9], polarography [10,11], amperometry [12–16] and others, have been reported. Based on the chemiluminescence method, chemical sensors with an optical response (so-called optrodes) have been developed for H_2O_2 detection [17,18]. These sensors allow use of fibre optics [18–20]. Electrochemical methods offer an alternative way of developing sensors for H_2O_2 and $S_2O_8^{2-}$. For example, various enzyme-modified electrodes have been proposed as a basis

for amperometric sensors sensitive to H_2O_2 [13–16]. Most chemical and electrochemical sensors for H_2O_2 detection are based on using complex organic molecules (enzymes) as reagents which can deteriorate sensor characteristics such as lifetime or response time.

In the present paper, we propose an electrochemical reagentless sensor system with optical response based on semiconductor electroluminescence. It is well known [21–23] that minority carrier injection into semiconductor electrodes from some redox species in solution can cause radiative recombination between electrons and holes. Since definite species in solution take part in this process, the luminescence response of a semiconductor electrode could be used as a signal allowing detection of these species. In the previous report [24], we have shown that the change in intensity of electrochemically generated luminescence of TiO_2 electrodes can be related to the H_2O_2 concentration in aqueous solutions. In the present paper, the results of studying electroluminescence (EL) processes on TiO_2 film electrodes in solutions containing H_2O_2 or $S_2O_8^{2-}$ ions are described in view of using them in analytical purposes. We demonstrate the possibility of the increase in EL response due to doping TiO_2 films with chromium. Moreover, we show that the distinctions in the EL behaviour of TiO_2 electrodes in an H_2O_2 solution and in a solution containing $S_2O_8^{2-}$ ions can be used to detect these ions when they occur simultaneously with H_2O_2 in solution.

2. Experimental

2.1. Electrode preparation

The TiO_2 film electrodes were fabricated by hydrolysis of a solution containing 1 wt.% $Ti(OC_4H_9)_4$ in tert-butanol. In this process chemically polished titanium plates were coated by a definite dose of this solution. After evaporation of the solvent in air at room temperature, the plates were heated at 200°C for 30 min in a humid atmosphere to complete the hydrolysis of $Ti(OC_4H_9)_4$. This procedure of film deposition

followed by heating was repeated three times to give a film thickness of ca. 100 nm estimated by the interference method. Finally the TiO_2 electrodes were heated at 700°C for 1 h in a purified argon atmosphere. According to electron diffraction and Raman spectroscopy data, the TiO_2 films obtained are polycrystalline (rutile modification). To produce chromium doped TiO_2 films, a definite amount of $CrCl_3 \times 6H_2O$ was added to 1% $Ti(OC_4H_9)_4$ solution in tert-butanol.

2.2. Experimental methods and reagents

Measurements were carried out in a standard three-electrode cell with a quartz window and a platinum counter-electrode at room temperature. All potentials were determined with respect to an Ag/AgCl reference electrode (+0.201 V versus NHE) and controlled by a conventional potentiostat with a programmer. Simultaneous measurements of EL intensity and current density as a function of potential were taken under a linear potential sweep, and EL response was monitored by a photomultiplier. The output of the photomultiplier was amplified by a sensitive high-resistance voltmeter and plotted on an $X-Y$ recorder. In some cases, we used a pulsed polarization of the working electrode. The potential was pulsed between 0 V (31.5 ms) and a more negative potential (12 ms) (see the inset of Fig. 2). Such polarization allowed us to prevent some irreversible changes of the electrode properties possible under forward bias. Moreover, a lock-in technique increased markedly the sensitivity and the signal-to-noise ratio of the detection system. To obtain electroluminescence spectra, the electrochemical cell was introduced inside the sample compartment of a Spex Fluorolog spectrofluorimeter. All spectra were corrected for the spectral sensitivity of a photomultiplier.

All solutions were prepared using chemicals of analytical reagent grade and doubly distilled water. The electrolyte in the cell was stirred with a magnetic stirrer during the measurements when it was necessary. The concentration unit, mol 1^{-1}, is abbreviated as M in the present paper.

3. Results and discussion

3.1. Dependence of sensor response on the electrode potential

In order to determine the range of operating potentials for an electroluminescence sensor system based on TiO_2 film electrodes, the electroluminescence intensity (I^{EL}) and the cathodic current density (i_c) were simultaneously recorded as a function of electrode potential (E) (Fig. 1). Electrochemically generated luminescence of titanium dioxide in H_2O_2 or $S_2O_8^{2-}$ solutions was previously reported [21,25–27] to arise under forward bias according to the following mechanism. Initially, H_2O_2 or $S_2O_8^{2-}$ ions are reduced by the
Fig. 1. Electroluminescence intensity versus potential (a) and cathodic current density versus potential (b) curves for un-doped (1,2) and chromium-doped (0.1 wt.% Cr) TiO_2 film electrodes (3) in 0.1 M H_2O_2 + 0.1 M NaOH (2,3) and in 0.1 M $Na_2S_2O_8$ + 0.1 M NaOH (1). Potential was swept from 0 V with a rate of 4 mV s^{-1}.

conduction band electrons producing OH˙ or SO_4^{-}˙ radicals. Then these radicals acting as very strong oxidants inject holes into the valence band or onto intra-band-gap surface states of TiO_2. As can be seen from Fig. 1, there is an exponential increase in the cathodic current, associated with the reduction of H_2O_2 or $S_2O_8^{2-}$ ions, at potentials more positive than the flat band potential of TiO_2 ($E_{fb} \sim -1.0$ V) as determined by capacitance measurements. The EL onset potential agrees sufficiently well with the onset potential of the cathodic current. At $E < E_{fb}$, the cathodic current is saturated due to the diffusion limitation and, at $E < -1.8$ V, increases again owing to the onset of the hydrogen evolution reaction.

The potential dependences of the EL intensity are more complex as compared to i_c–E relations (Fig. 1). Two peaks of EL intensity can be distinguished on the I^{EL}–E curves, with a more negative peak occurring in the potential region of the diffusion limited current. It is noted that when the EL response is used to detect H_2O_2 or $S_2O_8^{2-}$ ions, the TiO_2 electrode should not be polarized at very negative potentials ($E < -1.7 - -2.0$ V), since this results in irreversible changes of electroluminescence and other properties of the electrode which are caused by the cathodic reduction of TiO_2.

3.2. Effect of doping TiO_2 film

Since the sensitivity of the EL sensor system based on TiO_2 electrodes could be improved by increasing the quantum efficiency of the EL process, we attempted to do this by means of doping TiO_2 films with chromium. The choice of this dopant is justified by the previously reported conclusion [26,28] that the photoluminescence intensity is considerably enhanced by the introduction of chromium in monocrystals and polycrystalline samples of rutile. Figs. 1 and 2 show the effect of the chromium doping level on the EL response obtained under potentiodynamic and pulsed polarization of the TiO_2 electrodes. Increasing the chromium concentration in the oxide film enhances markedly the EL intensity over the wide potential range. Characteristically, this doping improves only the quantum efficiency of the EL
Fig. 2. Dependence of the EL intensity on potential obtained under pulsed polarization of undoped (3) and chromium-doped TiO$_2$ film electrodes with 0.02 wt.% Cr (2) and 0.1 wt.% Cr (1) in a solution containing 0.1 M H$_2$O$_2$ and 0.1 M NaOH. The inset shows the potential pulses used to generate electroluminescence.

process and does not change the electrocatalytic activity of TiO$_2$ electrodes. The effect of chromium doping on the EL response is likely to be associated with increasing the concentration of deep recombination centres lying near the band gap centre of TiO$_2$ which are characteristic of rutile [28].

3.3. Emission spectra

Fig. 3 shows typical EL spectra for TiO$_2$ film electrodes. It should be noted that chromium doping practically does not modify the EL spectra. In H$_2$O$_2$ solution, the only band is at 850 nm in the spectrum. This band has been observed more than once in the photoluminescence and electroluminescence spectra of monocrystals and polycrystalline sintered samples of rutile both in air and in solution [25–31]. We did not reveal a noticeable effect of potential (up to − 1.7 V) on the position of this band in the EL spectrum. At more negative potentials, we failed to measure the EL spectrum reliably in H$_2$O$_2$ solution because of the low intensity of the emitted light. The EL spectrum observed in S$_2$O$_8$$^{2-}$ solution at potentials of up to − 1.1 V is similar to that in H$_2$O$_2$ solution. However, at $E < − 1.2$ V, a band lo-

cated in the visible spectral range appears (Fig. 3). The reasons of this band appearance associated with the change of the EL mechanism were previously considered in detail [31] and will not be discussed in the present paper. Here, it is important to note that the marked dependence of the EL spectrum on potential in peroxydisulphate solutions can be used to measure the concentration of S$_2$O$_8$$^{2-}$ ions in the presence of H$_2$O$_2$ in solution as will be shown below.

3.4. Time dependence of sensor response

In order to estimate the response time characteristics of the EL sensor system under consideration, we studied the transient behaviour of the I^{EL} when a pulsed polarization was applied and switched off. The I^{EL} versus time curves are shown to depend essentially on the analyte (H$_2$O$_2$ or S$_2$O$_8$$^{2-}$ ions) concentration (C) in solution. In dilute solutions, after an initial sharp drop within several minutes, the I^{EL} reaches a steady-state value or decreases slowly in conformity with the i_c–τ dependence. These transients of I^{EL} and i_c are caused by the diffusion limitation on the analyte transport to the electrode surface. The experimental fact that stirring the solution increases markedly a steady-state value of I^{EL} confirms this conclusion. In more concentrated

Fig. 3. Electroluminescence spectra for undoped TiO$_2$ film electrodes measured at − 1.0 V (1,2) and − 1.4 V (3) in 0.1 M H$_2$O$_2$ + 0.1 M NaOH (2) and in 0.1 M Na$_2$S$_2$O$_8$ + 0.1 M NaOH (1,3).
Fig. 4. Time dependence of the EL response for chromium-doped (0.1 wt.% Cr) TiO_2 film electrodes in 0.1 M $H_2O_2 + 0.2$ M KOH (2) and in 0.1 M $K_2S_2O_8 + 0.2$ M KOH (1) after starting the pulsed polarization (− 1.1 V); off denotes that the pulsed polarization has been switched off.

solutions ($C > 0.1$ M), the I^{EL} does not fall after starting the pulsed polarization and even somewhat increases before reaching a constant value. Fig. 4 represents typical transients of I^{EL} observed in alkaline solutions with 0.1 M H_2O_2 or
Fig. 5. Dependence of the steady-state EL response on the analyte concentration in a logarithmic scale for chromium-doped (0.1 wt.% Cr) TiO_2 film electrodes in H_2O_2 (1), $Na_2S_2O_8$ (2) and $Na_2S_2O_8 + 0.1$ M H_2O_2 (3) alkaline (0.1 M NaOH) solutions stirred with a magnetic stirrer. The potential was pulsed from 0 V to − 1.1 V (1,2) and −1.4 V (3). The EL emission was monitored at wavelengths longer than 700 nm (curves 1,2) and at wavelengths shorter than 700 nm (curve 3).

0.1 M $Na_2S_2O_8$ when a pulsed polarization was switched on and switched off. Characteristically, the EL rise time (10–15 min) in H_2O_2 solution is markedly longer than that (1–3 min) in $S_2O_8^{2-}$ solution. These transients may be tentatively associated with the activation of the electrode due to the electrochemical reaction. This assumption is confirmed by the fact that the EL rise time decreases considerably when applying the pulsed polarization repeatedly after reaching a steady-state value of I^{EL}. Thus, some limitation of the proposed sensor system which is associated with a relatively long rise time of the EL response can be partly overcome by preliminary training (the pulsed polarization during 15–20 min) of TiO_2 electrodes in solution just before the measurements. The EL decay time is much shorter than its rise time and lasts fractions of a second.

3.5. Relation between sensor response and analyte concentration

Fig. 5 shows the plots of steady-state EL intensity (measured on chromium-doped TiO_2 electrodes in stirring solutions) versus analyte (H_2O_2 or $S_2O_8^{2-}$ ions) concentration in a logarithmic scale. The log(I^{EL}) versus log C plot is linear in a rather wide range of H_2O_2 concentrations from 10^{-3} to 10^{-1} M. Above 10^{-1} M, there is a change in slope, the EL response levels off and even somewhat decreases at H_2O_2 concentrations above 0.5 M. Unlike the calibration plot for H_2O_2 solutions, the log(I^{EL}) versus log C curve obtained in peroxydisulphate solutions has a distinct bend at concentrations of ca. 2×10^{-2} M. Two linear parts can be distinguished on this curve, one from 5×10^{-4} to 10^{-2} M and another 5×10^{-2} to 1 M. Below 5×10^{-4} M $Na_2S_2O_8$, TiO_2 electrodes show a non-linear response in a logarithmic scale, but optical signals are still observed down to 10^{-4} M. As noted above, the characteristic dependence of the EL spectrum on potential in peroxydisulphate solutions gives the opportunity for the detection of $S_2O_8^{2-}$ ions on the background of H_2O_2. When monitored at wavelengths within the visible range of spectrum ($\lambda < 700$ nm) and at potentials negative to − 1.2 V, the EL response
Fig. 6. Electroluminescence response versus NaOH concentration curves for chromium-doped (0.1 wt.% Cr) TiO_2 film electrodes in alkaline solutions containing 0.1 M H_2O_2 (·), 0.1 M H_2O_2 + 0.25 M Na_2SO_4 (△) and 0.1 M $Na_2S_2O_8$ (✳). The potential was pulsed between 0 V and – 1.1 V.

must reflect the contribution of the $S_2O_8{}^{2-}$ ions to the electroluminescence generation process. Fig. 5 shows the plot of $\log(I^{EL})$ versus $\log(C_{Na_2S_2O_8})$ obtained at $\lambda < 700$ nm and $E = -1.4$ V (pulsed polarization) in solutions containing 0.1 M H_2O_2 and various concentrations of $Na_2S_2O_8$. This plot is linear from 10^{-2} to 10^{-1} M peroxydisulphate indicating that the presence of H_2O_2 in solution does not noticeably influence the measurement of $S_2O_8{}^{2-}$ concentration under such conditions.

3.6. Effect of pH

The EL response of TiO_2 electrodes to H_2O_2 or $S_2O_8{}^{2-}$ species depends, to some extent, on the concentration of alkali in solution. The dependences of the EL intensity on the NaOH concentration in solutions containing 0.1 M H_2O_2 or 0.1 M $Na_2S_2O_8$ are shown in Fig. 6. The EL response varies markedly in the region of relatively low concentrations of alkali ($C_{NaOH} < 0.1$ M). Moreover, in H_2O_2 solutions without an indifferent supporting electrolyte, the response falls off with decreasing NaOH concentration due to a lowering of the conductivity of the solution. The addition of 0.25 M Na_2SO_4 as a supporting electrolyte to alkaline solutions of H_2O_2 results in the opposite

effect: the EL intensity increases with decreasing pH at $C_{NaOH} < 0.1$ M. At C_{NaOH} more than 0.1 M up to 1 M, the EL intensity is slightly affected by the alkali content in H_2O_2 and $S_2O_8{}^{2-}$ solutions (Fig. 6).

Thus, the experimental results obtained show that the EL emission occurring at the TiO_2-solution interface under negative polarization can be used to determine the H_2O_2 or peroxydisulphate content in aqueous solutions within a rather wide range of concentrations. It should be noted that titanium dioxide is a semiconductor with the wide band gap (approx. 3.02 eV) and the low location of the valence band edge in the energy scale [32]. This is an advantage in using TiO_2 as a basis for the sensor development, because TiO_2 electrodes are electrochemically stable and the hole injection into the TiO_2 valence band directly from the known oxidizing redox species, which are chemically stable in aqueous solution, is negligible [21,27]. The possibility of this hole injection in hydrogen peroxide or peroxydisulphate solutions appears due to the specific two-step mechanism of H_2O_2 or $S_2O_8{}^{2-}$ electroreduction producing active intermediates (radicals) with a large positive redox potential during the first step. This peculiarity gives reasons to hope for a high selectivity of the proposed sensor system based on TiO_2 electrodes with respect to hydrogen peroxide or peroxydisulphate ions. Further study concerning the sensor characteristics (e.g. selectivity, long-term stability) is currently being conducted and the results will be reported later.

Polyphenol oxidase–catechol: an electroenzymatic model system for characterizing the performance of matrices for biosensors

J.-L. Besombes, S. Cosnier*, P. Labbé

Laboratoire d'Electrochimie Organique et de Photochimie Rédox, URA CNRS 1210, Université Joseph Fourier Grenoble 1, BP 53, 301 rue de la Chimie, 38041 Grenoble Cedex 9, France

1. Introduction

Enzyme electrodes are analytical devices based on the combination of the high specificity of biocatalytic reactions with the electrochemical (mainly amperometric) transduction of the recognition event [1]. Analysis of enzyme electrode kinetics is of importance for designing a sensor or for optimization of parameters [2–6]. Since the overall sensor response depends on the enzymatic reaction and on the mass transfer processes, the enzyme layer permeability and the efficiency of the enzymatic reaction are two crucial biosensor parameters. Their determination can give valuable information for the optimization of the biosensor configuration as well as for the development of new strategies for enzyme immobilization [5,7].

For this purpose, we present in this paper the properties of an original electroenzymatic system

based on polyphenol oxidase (PPO) and catechol for evaluating the performance of host matrices used to fabricate enzyme electrodes. PPO and catechol constitute a versatile system since the substrate (catechol) and product (*ortho*-quinone) of the enzymatic reaction can be independently determined electrochemically. Furthermore, the thermal deactivation of immobilized PPO can give additional information about the substrate diffusion through the host matrix loaded with enzymes. The utilization of this simple system to obtain criteria for optimization of sensor performance is exemplified here for enzyme electrodes fabricated by polymer entrapment [8–10]. The model of the electrode material was a polypyrrole film obtained by electropolymerization of an amphiphilic monomer, the 12-(pyrrol-1-yl)dodecyltriethylammonium tetrafluoroborate (1) [11]. The influence of the amount of enzyme immobilized within this model of electrode material on the characteristics of the resulting enzyme electrodes is investigated via the PPO–catechol system.

2. Experimental

2.1. Instrumentation

The electrochemical instrument consisted of a PAR model 362 potentiostat in conjunction with a Sefram TRP recorder. All experiments were carried out using an undivided thermostated three-electrode cell. The working electrode was a glassy carbon disk (5 mm diameter) polished with diamond paste. A saturated calomel electrode (SCE) and a platinum counter electrode were used. All measurements were carried out at 30°C.

2.2. Reagents

Polyphenol oxidase (EC 1.14.18.1, from mushroom, 123 units mg^{-1}) was purchased from Fluka and catechol was obtained from Aldrich. The synthesis of monomer 1 has been described previously [11]. Supporting electrolytes were 0.1 M LiClO$_4$ from Fluka and 0.1 M phosphate buffer (pH 6.5).

2.3. Enzyme electrode preparation

The poly 1–PPO electrodes were prepared as previously reported [8]. An aqueous dispersion of 1 (6 mM) and PPO solution (20 g l^{-1}) were mixed in water to produce several 3 mM aqueous dispersions of 1 containing 1.7, 3.3, 6.7 or 10 g l^{-1} enzyme. 30 μl portions of these mixtures were deposited at the surface of a glassy carbon electrode and dried under vacuum. The polymerization of the adsorbed monomer 1–enzyme film was carried out by controlled potential electrolysis for 30 min at +0.75 V vs. SCE in deaerated aqueous 0.1 M LiClO$_4$ solution. The irreversible inactivation of the immobilized enzyme was performed by immersion of poly 1–PPO electrode in a water-bath thermostated at 65°C for 15 min. Before electrochemical experiments, the electrode was potentiostated at −0.2 V or 0.7 V for 30 min to allow the background current to decay to a steady-state value.

3. Results and discussion

PPO catalyzes the oxidation of several monohydroxy and o-dihydroxybenzene derivatives to o-quinones involving molecular oxygen [12]. Therefore, the analytical capabilities of an amperometric PPO-based biosensor can be investigated by applying a potential of −0.2 V vs. SCE to detect the enzymatically-generated o-quinones.

In contrast, catechol can be detected amperometrically via its electrooxidation at 0.7 V and the immobilized PPO can be inactivated by thermal denaturation [13]. Thus depending on the applied potential (−0.2 or 0.7 V) and the reactive state of the enzyme (active or inactive), the immobilized PPO–catechol system can provide information about the biomaterial permeability as well as the enzymatic reaction and transduction efficiencies.

Fig. 1 illustrates the three configurations of this system used providing the following parameters: (A) the current density for the diffusion of the enzymatically-generated o-quinone; (B) the current density for the catechol diffusion through the active biomaterial; and (C) the current density for the catechol diffusion through the inactivated biomaterial. In order to keep this model simple, we assume that the diffusivity of catechol in the biomaterial is identical to that of o-quinone and that the supply of cosubstrate (O$_2$) for PPO is considered to be plentiful [14].

Fig. 1. Schematic description of the three functioning configurations of the PPO–catechol electrochemical system: (A) bioelectrode potentiostated at −0.2 V; (B) and (C) bioelectrodes potentiostated at 0.7 V, PPO being inactivated in configuration (C). S and P denote respectively the catechol substrate and the 1,2-benzoquinone enzymatically or electrochemically produced.

The ability of this system for evaluating the characteristics of polymer matrices has been investigated in the case of functionalized polypyrrole. As previously reported [8,10], the polypyrrole enzyme electrodes were fabricated by adsorption on the electrode surface of a monomer 1-enzyme mixture followed by the electropolymerization of the adsorbed amphiphilic pyrroles. Following this procedure of biosensor construction, four poly 1-PPO electrodes were prepared with different amounts of enzyme (from 0.05–0.3 mg), the amount of monomer 1 remaining constant. The voltammograms of the resulting modified electrodes exhibit, in the anodic region, the reversible oxidation of the polypyrrole matrix ($E_{\frac{1}{2}}$ = 0.48 V, with an anodic and cathodic peak potential separation (ΔE_p) equal to 0.04 V, $v = 0.1$ V s^{-1}) typical of N-substituted polypyrroles [15]. The apparent surface coverage Γ_1 can be determined from the charge recorded under the polypyrrole oxidation wave, assuming one electron per three pyrrole units [15]. It appears that the four poly 1–PPO electrodes present similar apparent surface coverages ($\Gamma_1 = (3.8 \pm 0.2) \times 10^{-8}$ mol cm^{-2}), indicating a similar film thickness for the four enzyme electrodes. The steady-state current responses of these bioelectrodes to catechol were evaluated in "air-saturated" 0.1 M phosphate buffer (pH 7) stirred at 500 rev min^{-1} by holding the bioelectrodes at -0.2 V (Fig. 1A). All bioelectrodes present the same behavior. The response currents increase linearly with increasing substrate concentration, these linear parts being followed by a curvature for catechol concentrations higher than 400 μM (see for example Fig. 2). The comparison of the S_A bioelectrode sensitivities (S_A defined as the slope of the linear part of the calibration curve) indicates that the S_A sensitivity increases with increasing enzyme loading (Table 1).

The efficiency of the enzymatic reaction was investigated by potentiostating these bioelectrodes at 0.7 V in order to detect the catechol non-enzymatically-oxidized during its diffusion through the different biomaterials (Fig. 1B). All the different resulting calibration curves for catechol exhibit two linear parts indicating a low sensitivity for low catechol concentrations (up to 400–800 μM),

Fig. 2. Calibration curve for catechol obtained at a poly 1 PPO electrode (prepared with 0.3 mg PPO). Applied potential -0.2 V vs. SCE, air-saturated 0.1 M phosphate buffer (pH 6.5) kept under vigourous stirring at 30°C.

followed by a marked increase in sensitivity for higher substrate concentrations (Fig. 3). The first part of the calibration curves corresponds to the concentration range where the enzymatic reaction rate, and hence the enzymatic catechol consumption, increase linearly with substrate concentration. The strong increase in the electrode

Table 1
Comparison of biosensor sensitivities[a], percentages of catechol consumption and detected o-quinone versus the enzyme loading

Parameter	Amount of PPO deposited for biosensor construction (mg)			
	0.05	0.1	0.2	0.3
S_A[b] (mA M^{-1} cm^{-2})	20	61	139	345
S_B[c] (mA M^{-1} cm^{-2})	221	82	39	29
S_C[d] (mA M^{-1} cm^{-2})	441	361	320	344
$(S_C - S_B)/S_C^e$ (%)	46	77	88	92
$S_A/(S_C - S_B)^f$ (%)	11	22	50	110

[a] Each sensitivity value is reported as the mean of four independent measurements recorded with two bioelectrodes.
[b] S_A = biosensor sensitivity towards catechol at -0.2 V (Fig. 1A).
[c] S_B = biosensor sensitivity towards catechol at 0.7 V before enzyme saturation (Fig. 1B).
[d] S_C = biosensor sensitivity towards catechol at 0.7 after thermal denaturation of immobilized PPO (Fig. 1C).
[e] $(S_C - S_B)/S_C$ ratio represents the percentage of catechol consumed by the enzymatic reaction.
[f] $S_A/(S_C - S_B)$ ratio represents the percentage of enzymatically-generated o-quinone detected at the electrode surface.
Fig. 3. Calibration curves for catechol obtained at poly 1–
PPO electrodes prepared with (+) 0.05, (♦) 0.1, (□) 0.2 and
(●) 0.3 mg of deposited PPO. Applied potential 0.7 V vs. SCE.
Other experimental conditions as in Fig. 2.

sensitivity observed in the second part of the calibration curves indicates that the saturation rate of the enzymatic reaction is reached. Thus, the electrode sensitivity should become independent of the enzymatic consumption of catechol, this latter being constant and independent of the catechol concentration. Effectively the catechol sensitivity of the bioelectrodes fabricated with 0.1, 0.2 and 0.3 mg PPO remains constant within experimental error $(203 \pm 5$ mA M^{-1} cm$^{-2})$ under catechol saturation conditions of the immobilized enzymes, suggesting a similar biofilm permeability. In contrast, the bioelectrode fabricated with 0.05 mg PPO exhibits a higher catechol sensitivity (360 mA M^{-1} cm^{-2}). This phenomenon can be related to the low enzyme loading, which induces an increase in the biomaterial permeability. It should be noted that the values of catechol concentration corresponding to the enzyme saturation increase with increasing enzyme loading. As expected, it is clear that the sensitivity of the amperometric electrode response to catechol before the enzyme saturation (S_B) decreases with increasing enzyme loading (Table 1). This result corroborates the relationship previously observed at -0.2 V between the S_A bioelectrode sensitivity and the enzyme loading.

In contrast, the thermal denaturation of the immobilized enzymes allows one to quantify at

0.7 V the catechol diffusion through the different biomaterials. Thus, the effect of the enzyme loading on the biomaterial permeability was investigated by comparison of catechol sensitivity (S_C) (Table 1). It appears that the increase in the amount of deposited enzyme induces a decrease in the biomaterial permeability. In particular, the bioelectrode fabricated with 0.05 mg PPO exhibits the highest S_C (411 mA M^{-1} cm^{-2}) while this sensitivity decreases down to 320 and 344 mA M^{-1} cm^{-2} for the bioelectrodes elaborated from 0.2 and 0.3 mg PPO respectively. This result is in good agreement with the variation of the catechol sensitivity of bioelectrodes previously observed at 0.7 V under substrate saturation conditions of the immobilized active enzymes.

In addition to this information, the PPO–catechol system allows one to calculate various parameters in order to evaluate the biomaterial performance. For instance, the comparison of sensitivities for the same bioelectrode measured at 0.7 V towards low concentrations of catechol after its diffusion through an enzymatically-active (S_B) or inactive (S_C) biomaterial allows one to estimate the percentage of catechol enzymatically oxidized during its permeation (Fig. 1B and 1C). This parameter could represent the efficiency of the enzymatic reaction and therefore illustrate the influence of the host matrix (permeability, denaturing microenvironment, etc.) on the enzymatic step as well as the influence of the amount of immobilized enzyme. Thus, the values of the percentate of enzymatically-oxidized catechol (defined as the ratio of sensitivities $(S_C - S_B)/S_C$) versus the enzyme loading are summarized in Table 1. As expected, this percentage increases unambiguously with increasing enzyme loading. The most efficient enzymatic conversion is obtained with the bioelectrode corresponding to 0.3 mg PPO since almost all the permeant (92%) is consumed.

The PPO–catechol system also allows us to examine the efficiency of the bioelectrochemical detection via a comparison of the amounts of o-quinone electrochemically detected and enzymatically generated. This is illustrated by the value of the $S_A/(S_C - S_B)$ ratio, S_A and $(S_C - S_B)$ being biosensor sensitivities corresponding to the

electroreduction of enzymatically-generated *o*-quinone (Fig. 1A) and the enzymatic disappearance of catechol respectively. It is clear that the efficiency of the bioelectrochemical detection increases with enzyme loading, reaching 110% for the bioelectrode fabricated with 0.3 mg PPO (Table 1). Furthermore, this value (110%) seems to indicate a signal amplification due to the well-known substrate recycling [16] (Fig. 1A). In contrast, the weak efficiency (11%) obtained with the bioelectrode fabricated with the lowest amount of PPO (0.05 mg) could indicate that much of the *o*-quinone diffused back to the solution and did not reach the electrode surface. This phenomenon could be correlated with the permeability increase previously observed for this biomaterial (Table 1), as well as with a weak efficiency of substrate recycling (Fig. 1A) due to the low enzyme loading.

In conclusion, the electroenzymatic system based on PPO and catechol constitutes a powerful means of obtaining an insight into the detailed processes that occur in amperometric enzyme-based sensors. It is expected that this system will be a useful model for comparing various types of host matrix used for bioelectrode fabrication.

Book reviews

Kirk-Othmer Encyclopedia of Chemical Technology, 4th edn., edited by J.I. Kroschwitz and M. Howe-Grant, Volume 14, Imaging Technology to Lanthanides, Wiley, New York, 1995, xxviii + 1116 pp., £195.00. ISBN 0-471-52683-5 (v.14).

Entries in the volumes of this edition of the encyclopedia are arranged in alphabetical order and with volume 14 the mid-point of the alphabet has been reached. With about 1000 + pages and about 30–40 entries per volume the coverage of topics is extensive. Some of the entries at first sight may not seem to be directly related to chemistry but closer inspection reveals that the topics are indeed of prime importance. For example, in this latest volume over 150 pages are devoted to information retrieval and information storage materials. In the former we are presented with an excellent survey of numerous modern chemical databases—some that I currently use and some which I did not know existed. Similarly in the latter, the various chemical processes involved in the production of both magnetic and optical devices for data storage are covered. A smaller entry related to these topics, Laboratory Information Management Systems, is included in this volume.

Topics related to medicinal and pharmaceutical chemistry include entries on Immunoassay, Immunotherapeutic Agents, Industrial Antimicrobial Agents and Insulin and Other Antidiabetic Agents. There is also information on Industrial Hygiene which covers hazard evaluation and control. Insect Control Technology is also well represented with 80 pages and 77 references.

Elements specifically dealt with in this volume include Indium, Iodine, Iron and the Lanthanides. Classes or groups of compounds include: Imines, Inclusion Compounds, Initiators, Inks, Inorganic High Polymers, Ionomers, Isocyanates, Ketenes, and Ketones. There are also separate entries for Indole, Isoprene and Itaconic Acid.

Techniques included are Infrared Technology and Raman Spectroscopy, Ion Exchange, Ion Implantation and Kinetic Measurements. Finally, there are entries on Insulation and Laminated Materials.

The usual high standard of supplied information is maintained with this volume of the encyclopedia. The editors are to be congratulated for their efforts in making these multi-authored volumes suitable for a wide range of readers.

Anticancer Drugs from Animals, Plants and Microorganisms, by G.R. Pettit, F.H. Pierson and C.L. Herald, Wiley, Chichester, 1994, xii + 670 pp., £78.00. ISBN 0-471-03657-9.

This book represents an update of the ongoing review by the authors of the expanding field of biosynthetic products with potential in cancer chemotherapy. The initial chapter briefly introduces the subject of cancer causing and related lethal viral diseases, with particular emphasis on the significance of HIV infection. This is followed by a chapter which seeks to illustrate the public

health hazard of environmental exposure to a variety of carcinogens, examples of which are presented in five tables; synthetic carcinogens, carcinogenic antitumor drugs, environmental and other naturally occurring carcinogens together with the effects of irradiation and tumor promoters. The main review, in tabular form however, is contained in the following chapters which spans some 450 pages. These are subdivided into three sections and the first of these "Antineoplastic and/or cell growth inhibitory agents", is arranged in nine chapters on the basis of biological origin. The second and third sections survey "Marine animal" and "Marine plant biosynthetic products" respectively, in eight chapters which are organised on the basis of chemical class.

Typically details are given of name, structure, biological origin and biological activity together with an indication of the accumulated spectral data. This information has been meticulously cross referenced to over twelve hundred published papers. The bringing together of this data provides a fascinating resource both to the molecular biologist seeking compounds to probe novel mechanisms of molecular cellular interactions or to the biosynthetic, medicinal or synthetic organic chemist in a quest for novel methodological targets. The book therefore deserves a place on the library shelf of those researchers working in the development of new anticancer drugs and will provide a ready source of new inspiration as well as hours of pleasurable "browsing". It is perhaps to be regretted that this type of publication may perish in the future to be replaced by a less stylish electronic means of information dissemination.

Good Laboratory Practice Regulations, 2nd edn., edited by A. Weinberg, Dekker, New York, 1995, x + 294 pp., US$125.00. ISBN 0-8247-9377-3.

This is Volume 69 in the Drugs & Pharmaceutical Sciences Series of Textbooks and Monographs, and is a second edition of Volume 38 which was edited by Allen F. Hirsch. The Good

Laboratory Practices prescribe standards for the conduct of studies designed to establish the safety of products regulated by the US Food & Drug Administration. Study reports are submitted to the FDA in food and colour petitions, investigational new drug applications, new drug applications, biological product licence applications, and other requests for permission to market a product. If safety and efficacy are established adequately, marketing of the product is permitted. GLPs are part of the International Market Place. The US and other members of the 24 nation Organization for Economic Cooperation and Development (OECD) have been involved in extensive international consultation in efforts to bring industrial and environmental chemical programmes into harmony. This 2nd edition of Good Laboratory Practice Regulations addresses these topics as well as discussing all aspects of the FDA's GLP regulations and techniques for implementation. These topics are presented within the contexts of an historical perspective and current laboratory automation.

Chapter 1 gives an historical perspective of the FDA focusing on problems and solutions; proposed regulations from the FDA and EPA; and GLP revisions. Chapter 2 provides a general discussion of all aspects of the FDA's GLP regulations. Chapter 3 discusses the Environmental Protection Agency (EPA), foreign GLP regulations and the EPA Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) GLPs. Chapter 4 explores the implementation of GLPs in a non-GLP analytical laboratory. Chapter 5 introduces economic behaviour as a means of evaluating and optimizing the use of automation and instrumentation technology in regulated laboratories. Chapter 6 addresses computer system validation and how it establishes the credibility of laboratory data and automated procedures. Chapter 7 presents a regulator's perspective of the laboratory inspection process. Chapter 8 presents summary commentary and ventures a forecast as to the future value and effectiveness of the GLPs as robotic laboratories become more common. An up-to-date bibliography provides useful references for GLPs.

Chapter 8 presents summary commentary and ventures a forecast as to the future value and effectiveness of the GLPs as robotic laboratories become more common. An up-to-date bibliography provides useful references for GLPs.

This book is not an easy read. One maddening aspect is the overuse of TLAs and FLAs (three and four letter abbreviations), although without them the book would be much longer. Chapter 2, as well as being the longest by far, is also the most difficult to assimilate. This is due to the nature of the subject material itself and to the thoroughness of the author, and certainly not because of any deficiency in style. Indeed, in the subsection on Testing Facilities Operation, much useful advice is given for the preparation and revision of Standard Operating Procedures (SOPs). For example, "...it is always a good idea to solicit comments from those who use the SOP manual (the workers at the bench)...". The chapter of most interest to a reader new to the subject of GLP and to those persons tasked with implementing GLPs in their laboratories will be Chapter 4. It outlines reasons for adopting GLPs, how to develop a Quality System and what it should consist of, the need for the Quality Assurance Unit to maintain a sense of humour(!), helpful hints for writing SOPs, and the need for random audits. The chapter on computer systems validation is also highly relevant and direct, pulling no punches on the subjects of poor quality control in the computer software industry, and jargon-filled non-explanations of computer professionals.

There are very few typographical errors, although on two occasions "pH" is referred to as "Ph". Although written primarily from the American viewpoint, a general interpretation will serve practitioners in almost any country. Notwithstanding the comments above, this book deserves its place on the shelf of the Quality Assurance Manager in any laboratory.

D.F. Rendle

Chromatography for Inorganic Chemistry, by M. Lederer, Wiley, Chichester, 1994, vi + 221 pp., £17.95 (softback), £39.95 (hardback). ISBN 0-471-94286-3 (softback), 0-471-94285-5 (hardback).

This book is associated with a course of lectures given by the author to advanced students at a number of Universities in Switzerland and Israel, and does not therefore aim to cover the entire literature. The author also assumes a working knowledge of the principles of chromatography, and does not survey the analytical applications of chromatography since these are already covered in other more detailed texts. Nevertheless the book provides a wide coverage of the applications of chromatography in inorganic chemistry.

The book starts with an historical introduction; following chapters deal with solvent extraction, paper and thin-layer chromatography, electrophoresis, gel filtration, ion exchange, HPLC, ion and gas chromatography, and the separation of isotopes and optical isomers. Each chapter contains many examples of the applications of each technique, liberally illustrated with clear diagrams and tables of factural information. The final chapter deals in more detail with the chromatography and electrophoresis of specific elements, including condensed phosphates, sulphur compounds and selected transition metals, lanthanides and actinides.

As might be expected from a book connected with a lecture course, the text is written in a very personal style. The examples tend to be chosen from the author's own work which of course allows him to present them with authority. Citations are given which allows the student to follow up the work from the literature. Within these confines the book is very readable and pitched at the right level for its intended readership.

Spectrophotometric determination of bio-active compounds with chloramine-T and gallocyanine

C.S.P. Sastry[a,*], K. Rama Srinivas[a], K.M.M. Krishna Prasad[b]

[a]Foods and Drugs Laboratories, Department of Organic Chemistry, Foods, Drugs and Water, Andhra University, Visakhapatnam-530 003, India
[b]Department of Physical and Nuclear Chemistry, Andhra University, Visakhapatnam-530 003, India

Abstract

A simple, sensitive and selective method for the spectrophotometric determination of drugs, viz., sulphamethoxazole, tetracycline HCl, amidopyrine, nifurtimox and isoniazid and biologically important amino acids, cysteine, aspartic acid and arginine based on their reactivity with chloramine-T (CAT) is proposed. The method involves the addition of excess CAT of a known concentration in the presence of 0.25 M HCl and the determination of the unreacted CAT by measurement of the decrease in the absorbance of the dye, gallocyanine (λ_{max}: 540 nm), the most suitable of several dyes that were tested. This method was applied to the determination of drug contents in pharmaceutical formulations and to the measurement of the aspartic acid content of some protein hydrolysates. The method is useful for the determination of the target compounds in microgram quantities from 0.4–5.6 μg mL^{-1} with the exceptions of arginine (1.0–8.0 μg mL^{-1}) and nifurtimox (0.8–5.6 μg mL^{-1}). Standard deviations were typically $\leqslant 0.5$ mg per dose (RSD 0.5–1.2%). No interferences were observed from common excipients in formulations, and detailed interference studies of other amino acids in the determination of cysteine, aspartic acid and arginine are reported. The validity of the method was tested against spectrophotometric and titrimetric reference methods. Recoveries were 99.8–102.1%.

Keywords: Chloromine-T; Gallocyanine; Spectrophotometry

1. Introduction

In recent years there has been a growing interest in the role of chloramine-T (CAT) as an analytical reagent in the determination of organic compounds [1]. CAT was developed for its disinfectant and antiseptic properties. As a result of the high yields of the products obtained in its reactions, it has been adopted for use in the determination of many orgainc compounds. CAT acts as a selective oxidizing agent in both acid and alkaline media [2,3]. When the reaction is stoichiometric and fast, the solution of CAT is useful in titrimetric determinations in which the end point is detected with either a visual indicator [4–6] or potentiometry [4]. In many instances, direct titration with CAT with a visual or poten-

---

* Corresponding author.

tiometric end point was not practicable, because the oxidation, though rapid, was not instantaneous and a back titration procedure was developed [7]. An excess of standard CAT is added to the analyte solution and is allowed to react for a given time. The excess CAT present in the acidic medium is determined by titrimetry [7,8]. However, titrimetric procedures are not suitable for the determination of compounds at microgram levels [4–8]. The aim of the present work is to provide a simple and sensitive spectrophotometric method for the determination of some typical bio-active compounds based on their reactivity with CAT.

Azine and oxazine dyes are well known for their high absorptivity, but they have not been utilized for estimating excess CAT in the indirect determinations of bio-active compounds. The present investigation proposes a selective and sensitive indirect spectrophotometric method for the determination of drugs, sulphamethoxazole (N'-(5-methylisoxazol-3-yl) sulphanilamide; SMX; CA: 723-46-6; antibacterial agent), tetracycline HCl (4-dimethylamino 1,4,4α,5,5α,6,11,12α-octahydro-3,6,10,12,12α-pentahydroxy-6-methyl-1,11,-dioxo (4S-(4α,4$\alpha\alpha$,5$\alpha\alpha$,6β, 12$\alpha\alpha$))-2-naphthacene carboxamide; TTC; CA: 60-54-8; antibacterial agent), amidopyrine (4-dimethylamine-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one; AMP; CA: 58-15-1; antiinflammatory agent), nifurtimox (3-methyl-N-((5-nitro-2-furanyl) methylene)-1,1-dioxide-4-thiomorpholinamide; NIF; CA: 23256-30-6; antitrypanocide agent) and isoniazid (4-pyridinecarboxylic acid, hydrazide; INH; CA: 54-84-3; antitubercular agent) and the amino acids, cysteine (CYS, CA: 52-90-4), aspartic acid (ASP, CA: 617-45-8) and arginine (ARG, CA: 627-75-8) in pure form and also in pharmaceutical formulations for drugs and protein hydrolysates for aspartic acid. Any one of the bio-active compounds mentioned above is made to react with an excess of CAT and the excess unreacted CAT oxidizes the oxazine dye, gallocyanine (phenoxazine-5-ium,1-carboxy-(7-dimethylamino)-3,4-dihydroxy chloride; GC; C.I. No. 51030) to a colourless form, thereby causing a decrease in the absorbance of GC. A few visible spectrophotometric methods reported for the estimation of SMX [9–12], TTC

[13–17], AMP [18–21], INH [22–26], CYS [27–30], ASP [27,31,32], ARG [33–35] and NIF [36], suffer from one or other disadvantage such as low sensitivity, lack of selectivity and simplicity. The proposed method is superior over these reported methods for its simplicity, high sensitivity and rapidity of the determination.

2. Experimental

2.1. Apparatus

A Milton Roy spectronic 1201 UV-visible spectrophotometer (USA) with 1 cm matched quartz cells was used for all the absorbance measurements. An Elico model LI-120 digital pH meter (Hyderabad, India) was used for pH measurements.

2.2. Reagents

All chemicals were of analytical grade and all solutions were prepared in triply distilled water. An aqueous solution of gallocyanine (CA: 1562-85-2, E. Gurr & Co., High Wycombe, UK, 1 mg mL^{-1}) was prepared and was further diluted to 100 μg mL^{-1}. Aqueous solutions of chloramine-T (CA: 127-65-1, Loba, Bombay, India, 1 mg mL^{-1}) were prepared and standardized iodometrically [37]. This solution was further diluted to 200 μg mL^{-1}. A 5 M aqueous solution of hydrochloric acid (CA: 7647-01-01, E. Merck, Bombay, India) was also prepared.

2.3. Preparation of standard drug or amino acid solution

Aqueous solutions containing 1 mg mL^{-1} of pharmaceutical grade sample of each drug or analytical grade sample of amino acid were prepared separately by dissolving initially in either 10 mL of dimethyl formamide (NIF, from Bayer, Germany) or 0.1 M HCl (INH, from Loba, Bombay, India) or 0.1 M NaOH (SMX, from German Remedies, Bombay, India) or hot water (ASP, from Loba, Bombay, India) or water (AMP, from Ciba-Geigy, Bombay, India; TTC, from Hoechst,

Bombay, India; CYS, from Loba, Bombay, India; ARG, from Loba, Bombay, India), followed by dilution with distilled water. Stock solutions were further diluted stepwise with distilled water to give the working standard solutions.

2.4. Analysis of pure forms

To each of 25 mL graduated test tubes containing aliquots of the standard drug solution (SMX: 0.5–4.0 mL, 10 μg mL^{-1}; TTC, AMP, INH: 0.5–4.5 mL, 20 μg mL^{-1}; NIF: 0.5–3.5 mL, 40 μg mL^{-1}) or amino acid solution (CYS, ASP: 1.0–6.0 mL, 20 μg mL^{-1}; ARG: 0.5–4.0 mL, 50 μg mL^{-1}), 1.25 mL of 5 M HCl and 2.0 mL of CAT (200 μg mL^{-1}) were added and the solutions diluted to 15 mL. After 10 min (except NIF or ASP: 30 min; ARG: 55 min), 10 mL of GC was added and mixed thoroughly and the absorbances were measured after 5 min at 540 nm against distilled water. The blank solution was prepared in a similar manner omitting bio-active compound. The decrease in absorbance corresponding to consumed CAT, which reflects the drug or amino acid concentration, was obtained by subtracting the absorbance of the blank solution from that of the test solution. Calibration graphs were prepared by plotting the decrease in the absorbance of the dye (GC), against the amount of drug or amino acid. The amount of drug or amino acid in any sample was calculated from its calibration curve.

2.5. Analysis of formulations

Since NIF formulations were not available in the Indian market, we prepared these according to the literature method [38,39]. Tablet, injection or capsule powder equivalent to 100 mg of active ingredient was treated with 10 mL of DMF, 0.1 M HCl, 0.1 M NaOH or water as given under standard stock solution preparation and the isoluble portion, if any was filtered off. The filtrate was diluted to 100 mL with water to give nominally 1 g L^{-1} concentration. The stock solutions in each case were further diluted with distilled water to obtain working solutions and were analysed as described under the procedure for pure samples.

2.6. Analysis of aspartic acid in protein hydroysates

An accurately weighed model mixture of protein hydrolysate powder equivalent to 100 mg of ASP was treated with 10 mL of hot water as given under standard stock solution preparation. It was further diluted to 100 mL with water to give nominally 1 mg mL^{-1}. This solution was further diluted to the requisite concentration and was analysed as described under the procedure for pure samples.

3. Results and discussion

In the preliminary experiments several azine and oxazine dyes such as neutral violet (NV, CA: 3562-46-7), neutral red (NR, CA: 553-24-2), wool fast blue BL (WFB, CA: 6378-88-7), azocarmine-G (AG, CA: 25641-18-3), lissamine blue BF (LBBF, CA: 6448-97-1), gallocyanine (GC, CA: 1562-85-2), gallamine blue (GB, CA: 1563-02-6), solocrome prune AS (SPAS, CA: 6416-51-9) and cresyl fast violet acetate (CFVA, CA: 10510-54-0) were tested for reaction with CAT in acidic medium. These investigations revealed that gallocyanine, neutral violet, gallamine blue and solocrome prune AS exhibit a quantitative reaction as shown by a definitive decrease in absorbance for a specific concentration of CAT even within 1 min (Fig. 1). As the difference in absorbance was found to be higher in the case of gallocyanine than for the remaining three, further studies were carried out with gallocyanine.

The similarity in the nature of the spectra recorded with GC, GC–CAT and drug or amino acid–CAT–GC in 0.25 M HCl medium indicates that the products formed by the interaction of drug or amino acid–CAT and CAT–dye do not affect the accuracy of the determination.

The method involves two steps, namely reaction of the drug with an excess of CAT giving products involving oxidation and the estimation of excess CAT using a known excess of GC. The excess dye remaining, is then measured with a spectrophotometer at 540 nm. The effect of reagent concentration, acidity and waiting period
Fig. 1. Effect of CAT on dyes in HCl (0.25 M) medium—curve A: CAT–GC system, [GC] = 0.1188 × 10⁻³M; curve B: CAT–NV system; [NV] = 0.4822 × 10⁻⁷ M; curve C: CAT–GB system, [GB] = 0.1191 × 10⁻³ M; curve D: CAT–SPAS system, [SPAS] = 0.1140 × 10⁻³ M.

in each step with respect to maximum sensitivity, blank minimum, adherence to Beer's law, reproducibility and stability of final colour were studied by means of controlled experiments varying one parmeter at a time [40].

3.1. Effect of acidity

The studies on the variation of acid concentration indicated that a constant absorbance is obtained in 0.15 to 0.4 M HCl, 0.1 to 0.25 M H₂SO₄ or 0.25 to 0.45 M CH₃COOH at a CAT concentration of 400 μg. As the difference in absorbance between the sample and the blank was found to be highest for the HCl medium, subsequent studies were carried out in 0.25 M HCl.

3.2. Effect of CAT concentration

In order to ascertain the linear relationship between the concentration of added CAT and the corresponding decrease in the absorbance of the GC (1000 μg), experiments were carried out in 0.25 M HCl medium with varying amounts of CAT. As the decrease in absorbances was found to be linear up to 400 μg of CAT (Fig. 1), subsequent studies were carried out with 1000 μg of GC and 400 μg of CAT in 0.25 M HCl medium.

3.3. Waiting period

A time span of 5 to 20 min for the reaction between the compound and CAT in first step (except ASP or NIF (25 to 40 min) and ARG (50
Fig. 2. Effect of oxidation time on drug/amino acid–CAT $(0.5680 \times 10^{-4}$ M)–GC $(0.1188 \times 10^{-3}$ M) systems. curve A: SMX–CAT–GC system, [SMX] = 3.1580×10^{-6} M; curve B: INH–CAT–GC system, [INH] = 1.1667×10^{-5} M; curve C: AMP–CAT–GC system, [AMP] = 1.3853×10^{-5} M; curve D: TTC–CAT–GC system, [TTC] = 6.6542×10^{-6} M; curve E: NIF–CAT–GC system, [NIF] = 1.3929×10^{-5} M; curve F: CYS–CAT–GC system, [CYS] = 1.6528×10^{-5} M; curve G: ASP–CAT–GC system, [ASP] = 1.2021×10^{-5} M; curve H: ARG–CAT–GC system, [ARG] = 3.7974×10^{-6} M.

to 60 min)) and 2 to 60 min between the CAT and GC in the second step, resulted in a constant and maximum difference in absorbance of the test and blank solutions (Fig. 2). Hence waiting periods of 10 min (30 min for ASP or NIF; 55 min for ARG) and 5 min were maintained in further studies of the first and second steps respectively. The above optimum conditions are incorporated in the procedure.

3.4. Analytical data

The optical characteristics such as Beer's law limits, molar absorptivity and percentage relative standard deviation for the method are given in

Table 1. Regression analysis using the method of least squares was made to evaluate the slope (b), intercept (a), correlation coefficient (r) and standard error of estimation (S_e) [41,42] for each system and the values are found to be in the following order—SMX: 0.300, 1.25×10^{-3}, 0.9999 and 1.65×10^{-3}; TTC: 0.100, 1.69×10^{-3}, 0.999 and 2.33×10^{-3}; AMP: 0.132, 0.05×10^{-3}, 0.9998 and 2.87×10^{-3}; NIF: 0.076, 1.43×10^{-3}, 0.9998 and 2.07×10^{-3}; INH: 0.139, -0.55×10^{-3}; 0.9999 and 2.45×10^{-3}; CYS: 0.182, -1.33×10^{-3}, 0.9999 and 1.62×10^{-3}; ASP: 0.174, 3.87×10^{-3}, 0.9997 and 2.82×10^{-3}; ARG: 0.050, 1.19×10^{-3}, 0.9999 and 1.45×10^{-3}.

Table 1
Optical characteristics, prescision and accuracy

3.5. Interferences

The commonly used excipients and additives in the formulations of drugs such as talc (up to 250-fold excess (w/w) compared to the drug), starch (200-fold), boric acid (150-fold), stearic acid (50-fold), cetyl alcohol (10-fold), glyceryl monostearate (30-fold), sodium lauryl sulphate (7-fold) and glycerin (10-fold) do not interfere with the determination of the mentioned drugs by the proposed method. The method was applied for the estimation of drugs in pharmaceutical formulations and the results were compared with the reference methods for SMX [12], TTC [17], AMP [19], NIF [36] and INH [43] by the application of F- and t-statistics and it is observed that the results of the proposed method compared with the reference method within the 95% confidence level.

The commonly existing amino acids in food proteins such as glycine (up to 13-fold molar excess compared to CYS or ASP); tyrosine (12-fold); alanine or leucine (11-fold); valine, isoleucine, glutamic acid, phenylalanine, tryptophan, proline or hydroxyproline (10-fold); serine, threonine, glutamine or histidine (9-fold); lysine or hydroxylysine (8-fold); and arginine (0.5-fold) do not interfere with the determination of ASP or CYS by the proposed method. However cystine or aspargine interferes in the proposed

method even if present in minor amounts. With the available information an attempt has been made to apply the present method in the determination of ASP in protein hydrolysates which do not contain CYS, cystine and aspargine. As β-lactoglobulin and chymotrypsinogen have compositions which satisfy the above conditions, model mixtures [44] of these two protein hydrolysates are prepared by mixing the amino acids as for the following compositions.

β-Lactoglobulin: alanine, 5.8 mg; arginine, 2.8 mg; aspartic acid, 11.3 mg; glutamic acid, 18.4 mg; glycine, 1.4 mg; histidine, 1.66 mg; leucine, 15.2 mg; iso-leucine, 7.3 mg; lysine, 11.2 mg; methionine, 3.12 mg; phenylalanine, 3.6 mg; proline, 5.0 mg; serine, 3.8 mg; threonine, 5.2 mg; tyrosine, 3.87 mg; and valine, 6.2 mg.

Chymotrypsinogen: alanine, 5.8 mg; arginine, 2.7 mg; aspartic acid, 10.9 mg; glutamic acid, 7.4 mg; glycine, 6.3 mg; histidine 1.16 mg; isoleucine, 4.9 mg; leucine, 8.9 mg; lysine, 7.7 mg; methionine, 1.11 mg; phenylalanine, 3.77 mg; proline, 3.8 mg; serine, 10.9 mg; threonine, 10.7 mg; tyrosine, 2.69 mg; and valine, 10.3 mg.

The results obtained in the proposed and reference [32] methods for ASP determination in protein hydrolysates are also presented in Table 2.

As an additional check of accuracy, recovery experiments were performed by adding a fixed amount of the compound (either drug or ASP) to

a pre-analysed sample of either pharmaceutical formulation or model mixture of protein hydrolysate. The results are summarized in Table 2. The statistical parameters presented in Table 2 indicate that the proposed method does not differ significantly from the reference method of each compound.

3.6. Chemistry

CAT undergoes hydrolysis in aqueous acidic medium to give sodium hypochlorite followed by hypochlorous acid [45]. This reacts with the drug or amino acid to form the relevant oxidation products, probably a mixture, which appears to be reproducible under the specified experimental conditions. The remaining hypochlorous acid may

be responsible for the bleaching of the colour of the dye. As the bio-active compounds in the present study are structurally dissimilar (possess different basic moieties and functional groups), the reactivity of CAT on each bio-active compound depends upon the vulnerable positions for its participation in oxidation. Sometimes, the oxidation under specified experimental conditions yields different products in varied proportions. So, the consumption of CAT varies from bio-active compound to bio-active compound. The mole ratios in the reaction between CAT and individual bio-active compounds under the experimental conditions for this method have been found to be 7.5, 5.0, 3.0, 2.0, 2.0, 2.0, 2.5 and 1.0 for SMX, TTC, AMP, NIF, INH, CYS, ASP and ARG, respectively.

The bio-active compounds used in this study are representative of a larger class of bio-active compounds which react with CAT. The proposed method is advantageous when compared to many of the reported visible spectrophotometric methods in having higher absorptivities. This is a decisive advantage since the interference from the associated ingredients shall be generally far less at higher wavelengths than at lower wavelengths. The method is sensitive enough to permit the determination of as little as 0.4 μg mL^{-1} of the analytes except for NIF (0.8 μg mL^{-1}) and ARG (1.0 μg mL^{-1}). The present method is superior over many of the reported spectrophotometric procedures used for the analysis of these compounds for its high sensitivity with reasonable precision and accuracy, simplicity and applicability to the intact molecule directly.

The electrochemical reduction of fullerenes, C_{60} and C_{70}

Guowang Diao, Liang Li, Zuxun Zhang*

Department of Chemistry and National Key Laboratory of Coordinational Chemistry, Nanjing University, Nanjing, 210093, People's Republic of China

Abstract

The hexaanion of fullerene, C_{60}^{6-}, was obtained in 1:5 (v/v) acetonitrile–toluene mixture with a mercury hemispherical ultramicroelectrode as a working electrode at a temperature of up to 30°C. The C_{70}^{6-} ion also can be observed under the same conditions. The differences between the redox potentials of C_{60} relative to C_{70} indicate that it is easier to add electrons to C_{70} and its anions compared to the counterparts of C_{60}. The results show that the mercury electrode is very suitable for investigation of the properties of the electrochemical reduction for the fullerenes, particularly C_{60}, at room temperature.

Keywords: Electrochemical reductions; Fullerenes

1. Introduction

Since 1990 the unusual properties of the fullerenes have caused a worldwide boom in the investigation of these systems. For example, according to the theoretical calculations, as this highly symmetrical C_{60} molecule (I_h, the Icosahedral point group symmetry) has three-fold degenerate LUMOs (the lowest unoccupied molecular orbitals) [1], it is expected that cyclic voltammetry of fullerenes would exhibit six one-electron reduction waves if sufficiently negative potentials are applied. In fact C_{60}^{6-} and C_{70}^{6-} have been generated and detected in solution by electrochemical reduction of fullerenes under special conditions. Xie et al. [2] generated and detected the C_{60}^{6-} and C_{70}^{6-} ions by electro-chemical reduction of

fullerenes in solution with a glass carbon electrode as a working electrode. They pointed out that the experimental temperature must be under 5°C in order to generate the C_{60}^{6-} ion by electrochemical reduction. Later C_{60}^{6-} was also obtained at lower temperatures by other scientists [3–7]. However, at room temperature, C_{60}^{6-} cannot be obtained in solution by the electrochemical method because of the limits of the solvent in the negative potential range.

As one would expect, the advantage of the large overpotential for hydrogen evolution makes mercury the material of choice for the cathodic process. It is expected that the sixth reduction wave of C_{60} can be observed at room temperature if a mercury electrode is selected as a working electrode. Therefore, the mercury hemispherical ultramicroelectrode served as a working electrode to investigate the behavior of the electrochemical reduction of fullerenes in this paper. The six re-

* Corresponding author.

duction waves of C_{60} have been obtained in 0.1 M Tetrabutylammonium hexafluorophosphate (TBAPF$_6$) acetonitrile–toluene (volume ratio, under 1:5) mixed solvent at a temperature of up to 30°C for the first time. Under the same conditions, the voltammograms of fullerene, C_{70}, with six reduction waves also can be observed. The results show that the reduction of C_{70} and its anions are easier than the counterparts of C_{60}.

2. Experimental

2.1. Reagents

The fullerenes were produced by a modified Krätschmer–Huffmam method [8]. From the mixture of products obtained by this technique C_{60} was extracted and purified respectively according to the references [9]. The purity was checked after separation by liquid chromatography [10]. C_{70} (> 98%) was purchased from China Yin-Han Fullerene High-Tech. Co. Ltd. (Wuhan University) and used as received. Acetonitrile (HPLC grade, Aldrich) was dried over 4Å molecular sieves for 24 h. Then under argon it was refluxed over P_2O_5 and distilled just before use. Toluene (HPLC grade, Sigma) was kept over $CaCl_2$ for a day. Then, under argon, it was refluxed over sodium for 10 h and distilled prior to use. The supporting electrolyte was TBAPF$_6$, obtained by metathesis tetrabutylammonium bromide (99%, Aldrich) with potassium hexafluorophosphate (98%, Aldrich) in water. It was recrystallized twice from a water–ethanol mixture and dried in a vacuum over at 60°C. The solution was prepared under schlenk systems in argon. All supporting electrolyte was used at a concentration of 0.1 M in toluene–acetonitrile (5:1 in volume).

2.2. Instrumentation

Electrochemical experiments were carried out using an air-tight three-electrode cell under an argon atmosphere. A platinum and a silver wire served as the counter and quasi reference electrode. The working electrode is a platinum ultra-micro-disk electrode (radius 10 μm) and mercury

hemispherical untramicroelectrode (Hg(Pt)) prepared by electroplating mercury onto the above platinum ultramicrodisk electrode [11]. Cyclic voltammetry (CV) and differential pulse voltammetry (DPV) were performed with a BAS-100B electrochemical analyzer equipped with a low current preamplifier and Faraday cage.

3. Results and discussion

From the background, shown in Fig. 1(a), a wider expansion of the available potential window down to − 3.4 V versus a ferrocenium/ferrocene (Fc$^+$/Fc) redox couple (all potential reported in this paper are relative to a Fc$^+$/Fc couple) on a mercury hemispherical ultramicroelectrode was observed at 21.3°C with the use of a mixed solvent system. Under our experimental conditions

Fig. 1. (a) At 21.3°C, the cyclic voltammogram of the acetonitrile–toluene (1:5 in volume) solvent mixture containing 0.1 M TBAPF$_6$, in the absence of fullerenes, with a 5 mV s^{-1} scan rate, and the mercury hemispherical ultramicroelectrode as a working electrode. All potentials are relative to the Fc$^+$/Fc couple. (b) The cyclic voltammogram of 0.539 mM C_{60} in above system; scan rate is 5 mV s^{-1}; other experimental conditions are the same as those described in (a). (c) The cyclic voltammogram under the same conditions except for a scan rate of 1575 mV s^{-1}. (d) The differential pulse voltammogram of C_{60} (50 mV pulse, 30 ms pulse width, 300 ms period, 25 mV s^{-1} scan rate).
Fig. 2. The plots of E against log $(i_1 - i)/i$ according to Fig. 1(b).

the ferrocenium/ferrocene redox potential is 0.41 V relative to the silver quasi reference electrode. The use of a mercury electrode allowed the first observation of the six electron reductions of C_{60} at room temperature. At 21.3°C, the cylic voltammograms of a 0.539 mM solution of C_{60} in 5:1 (v/v) toluene–acetonitrile at the mercury hemispherical ultramicroelectrode are shown in Fig. 1(b) and (c). The differential pulse voltammogram is presented in Fig. 1(d). Six reduction processes are clearly resolved and are assigned to the generation of the $-1, -2, -3, -4, -5$, and -6 anions of C_{60}. According to Fig. 1(b) the plots of E versus log $(i_1 - i)/i$ for six redox couples of C_{60} are all straight lines (Fig. 2) with slopes of 57, 60, 58, 57, 61 and 54 mV, which show that the six one-electron electrochemical reduction procedures of C_{60} are performed. The values of the half potential, $E_{1/2}$, obtained from the intercepts of these lines are $-1.03, -1.44, -1.94, -2.42, -2.91$ and -3.28 V. The values of $E_{1/2}$ are close to those previously reported in literature [12]. The minor reduction wave at -2.65 V may be due to an electroactive impurity in the C_{60} starting material [13].

According to Fig. 1(d) the peak potential differences between the anodic and cathodic processes are 33, 33, 41, 41, 41 and 56 mV successively from the first to the sixth redox couple of C_{60}. The ratio of peak cathodic current and peak anodic current are 0.95, 0.87, 0.93, 1.05, 1.19 and 1.70 respectively. It is shown that first five reductions are more reversible than the sixth one.

Under the same conditions, similar results for the reduction of C_{70} were also obtained (Fig. 3). The values of the DPV peak potentials for the six waves of the cathodic proedure of C_{70} are $-1.00, -1.40, -1.84, -2.27$ and -3.16 V, which are similar to those reported in Ref. [2], but different from the values of C_{60}. According to Fig. 1(d), the values of the DPV peak potential for the six reduction waves of C_{60} are $-1.03, -1.44, -1.93, -2.41, -2.91$ and -3.27 V respectively. The differences between the redox potentials of C_{70} relative to C_{60} indicate that it is easier to add electrons to C_{70} and its ions compard to the C_{60} counterparts, especially for higher charged ions. The further investigation of the properties of electrochemical reduction of C_{70} is currently underway.
Fig. 3. (a) The cylic voltammogram for C_{70} recorded in 0.1 M TBAPF$_6$ acetonitrile–toluene (1:5 v/v) at 21.3°C on a mercury hemispherical ultromicro-electrode. Scan rate is 10 V s^{-1}. (b) The differential pulse voltammogram of C_{70} in the above system (50 mV pulse, 30 ms pulse width, 300 ms period, 25 mV s^{-1} scan rate).

Only four reduction waves of C_{60} on a platinum ultramicrodisk electrode are shown at 21.3°C (Fig. 4). This is due to the negative potential limits for the platinum electrode in the solution. However, for the mercury electrode the six reduction waves of C_{60} can be obtained (Fig. 5) even at
Fig. 4. (a) The cyclic voltammogram of C_{60} under the same conditions as those in Fig. 1 (c) except for the use of a platinum ultramicrodisk electrode as a working electrode and a 100 mV s^{-1} scan rate. (b) The DPV curve of C_{60} at the platinum ultramicrodisk electrode. Other experimental conditions are the same as those in Fig. 1(d).
Fig. 5. (a) At 30°C, the cyclic voltammogram of C_{60} at the mercury hemispherical ultramicroelectrode (scan rate 1 V s^{-1}; other conditions are the same as those in Fig. 1(b). (b) The DPV curve of C_{60} (at 30°C; other conditions are the same as those described in Fig. 1(d)).

30°C. It is clear that the mercury electrode is suitable for studying the behavior of the electrochemical reduction of the fullerenes even at 30°C in our experimental conditions.

In conclusion, this paper presents the electrochemical formation of C_{60}^{6-} at room temperature by the use of a mercury hemispherical ultramicroelectrode. However, the current of the sixth reduction wave of C_{60} is significantly greater than that of the other five reduction waves. The reason may be a chemical follow-up process, which will return C_{60}^{6-} to C_{60}^{5-}. Normally spurious electrophilic impurities, such as trace water, trace oxygen, or even supporting electrolyte, trigger the chemical reaction of highly charged anions. The mechanism of the chemical reaction can not be confirmed at this stage. Our further investigation will focus on the mechanism of this process. In contrast, the current of the six reduction waves for C_{70}, are similar to each other, which indicate the stability of C_{70}^{6-} is better than C_{60}^{6-}. Xie et al. [2] have pointed out that the sixth reduction wave of C_{70} at 25°C can be obtained with the glass carbon electrode as the working electrode while the counterpart wave of C_{60} can not be obtained at this temperature. In this paper, with a mercury electrode as the work-

ing electrode, the six waves for both C_{60} and C_{70} were obtained at room temperature. In summary, the mercury electrode is very suitable for the study of the electrochemical properties of the fullerenes at room temperature.

Conductometric titration of thiosulfate using new-type conductivity cells

E. Forizs*, Cs. Muzsnay

Department of Chemistry, Babeş-Bolyai University, Cluj-Napoca, Romania

Abstract

The conductometric titration of thiosulfate with silver ions using non-conventional conductivity cells is described. For this purpose conductivity cells with different cell constants and electrode constructions, equipped with silver, amalgamated silver, stainless-steel and polished platinum electrodes were used. Two well-resolved break-points were observed at 1:1 and 2:1 silver/thiosulfate stoichiometries. Accurate conductometric determinations can be made, using the second break-points of the titration curves as equivalence points, in the range of thiosulfate concentrations 10^{-4}–10^{-2} M. Reverse titrations are less accurate.

Keywords: Conductivity cell; Thiosulfate; Titration

1. Introduction

The determination of sulfur-containing anions has generally been performed by argentometric or mercurimetric titration with potentiometric end-point detection, using sulfide-sensitive membrane electrodes, or mercury, silver, and carbon indicator electrodes [1–5]. The conductometric end-point detection of an argentometric titration of thiosulfate was not recommended by Kolthoff in his classical monograph [6], because during the titration irregular conductivity variations were observed. This is due to the use of conductivity cells equipped with platinized platinum electrodes. In titration systems where precipitates are formed, classical conductivity cells cannot be used. Using non-conventional conductivity cells proposed by the authors, considerable conductivity variations were observed in the course of titrations. For this purpose we studied the behavior of some new-type conductivity cells in argentometric titrations of thiosulfate equipped with silver, amalgamated silver, stainless-steel [7–10] and polished platinum electrodes. These cells were used with good results, giving particular curves in titrimetric determination of Cl^- and I^- ions [11]. In the course of the titrations the pH variations were also determined.

Fig. 2. Conductometric titration curves of 50 ml 5 mM $Na_2S_2O_3$ with 0.1 M $AgNO_3$ using conductivity cells equipped with amalgamated silver (Ag–Hg), silver (Ag) and stainless-steel electrodes.

2. Experimental

2.1. Apparatus

A Radelkis OK/102 type conductometer (Hungary) was used, equipped with two kinds of monoaxial dip-type conductivity cells. The laboratory-made cells employed in conductometric titrations had the following different electrode constructions.

Ring type. This type contains three stainless-steel rings in a polypropylene body (Fig. 1a).

Spiral type. This type was made of two silver, amalgamated silver or platinum wires of 0.4 mm diameter and different lengths ($l = 15$ mm, 10 mm) (Fig. 1b).

The amalgamation of the silver electrode was done with doubly-distilled mercury. Characteristic data for the conductivity cells are reported in Table 1.

A pH-100 Otopeni-type digital pH meter (Romania), equipped with a glass electrode and a saturated calomel electrode with a salt bridge (1 M sodium nitrate) was used for the determination of pH values in the course of titrations. The conductance and potential values were read at fixed time intervals of 60 s after each titrant portion was added.

50 ml thiosulfate samples of 10^{-2}–10^{-4} M concentration were titrated with 10^{-1}–10^{-2} M solutions of $AgNO_3$. The titrant was added in 0.5 or 0.1 ml portions with magnetic stirring.

Table 1
Characteristic data for the conductivity cells

Electrode feature	Cell constant (cm^{-1})
Polished platinum spiral, $l = 15$ mm	0.0625
Silver spiral $l = 15$mm	0.0753
$l = 10$mm	0.715
Amalgamated silver spiral, $l = 15$ mm	0.0713
Stainless-steel ring	0.132

All titrations were performed at room temperature $(23 \pm 2°C)$. During the titrations the temperature variations did not exceed $\pm 0.2°C$.

2.2. Reagents

All reagents (analytical grade) were purchased from Reactivul Chemical Co. (Bucharest, Romania). Silver nitrate solutions were standardized by

[a] Average of three determinations.

potentiometric titration with sodium chloride. Sodium thiosulfate solutions were standardized iodometrically in the usual way. 0.1 M stock solutions were used and diluted as required.

3. Results and discussion

Some examples of titration curves are shown in Fig. 2. Two distinct, sharp end-points were obtained at 1:1 and 2:1 silver/thiosulfate ratios. In the first part of the curves the conductance values decrease slightly, corresponding to the formation of thiosulfate complex ions $[Ag(S_2O_3)_x]^{1-2x}$; $x = 1-3$. These complex ions have lower mobilities than the noncomplexed thiosulfate ion.

The recoveries calculated from the first equivalence points are satisfactory only in solutions more dilute than 10^{-3} M. Some analytical results are reported in Table 2. Above concentrations of 10^{-3} M, the first equivalence point shows an error of about $+12\%$.

Fig. 3. Conductometric and potentiometric titrations of 50 ml 1 mM $Na_2S_2O_3$ with 0.1 M $AgNO_3$ using conductivity cells equipped with amalgamated silver (Ag–Hg), platinum (Pt), stainless-steel and glass (pH-GE) electrodes.
Fig. 4. Conductometric titration of 50 ml 1 mM AgNO₃ with 0.1 M Na₂S₂O₃ using conductivity cells equipped with amalgamated silver (Ag-Hg), platinum (Pt) and stainless-steel electrodes.

Following the addition of titrant after the 1:1 Ag/S₂O₃ ratio end-point, the curves show a very sharp increase of conductance values due to the formation of sulfuric acid. The formation of sulfuric acid proceeds on the basis of the following catalytic reaction [2]:

$$AgS_2O_3^- + Ag^+ + H_2O = Ag_2S + H_2SO_4$$
The catalytic effect can be attributed to the action of both Ag^+ and H_3O^+ ions.

At the 2:1 ratio of Ag/S₂O₃ end-point a well-resolved break-point is observed corresponding to the completion of the silver sulfide precipitation. An excess of titrant, increasing the concentration of silver nitrate in solution, increases the conductance values. Of the conductivity cells studied the amalgamated silver cells have the greatest sensitivity, followed by the silver cells;

the stainless-steel cells have the lowest sensitivity. The equivalence points obtained at room temperature coincide well with the theoretical ones (Table 3).

The acidity of solution increases in the course of titrations; after the 2:1 ratio of Ag/S₂O₃ end-point the pH of the solution remains practically constant (Fig. 3).

Three illustrative curves for the reverse titrations are shown in Fig. 4. The conductometric titration curves show increasing character from the start and present only one well-resolved break-point at the 1:2 S₂O₃/Ag ratio.

Some other species, e.g. halides, cyanides, thiocyanates and cyanates, may cause interference at about 10^{-5} M concentrations.

In this work we have come to the conclusion that it is possible to titrate thiosulfate ions with silver nitrate by means of a conductometric method using non-conventional conductivity cells. The recoveries listed in Table 3 in terms of amounts of thiosulfate taken and recovered are reasonably good, with an error of < 1%, with the exceptance of the conductivity cell equipped with platinum electrodes.

Spectrophotometric determination of acrivastine in urine and capsules

Heba H. Abdine*, Azza A. Gazy, Salah M. Blaih, Mohamed A. Korany

Pharmaceutical Analytical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Alexandria, 21521, Egypt

Abstract

Three sensitive and accurate spectrophotometric methods are presented for the determination of the antihistaminic acrivastine (ACR) in capsules and urine. The first method utilizes the reaction of 2-nitrophenylhydrazine hydrochloride in presence of dicyclohexylcarbodiimide and pyridine. The violet colour of the resulting acid hydrazide is measured at 550 nm. The second method is based on alkaline oxidation of the drug with potassium permanganate and subsequent measurement of the formed manganate ion at 608 nm. The third method uses derivative spectrophotometry for the determination of ACR. The last method is extended to the in vitro determination of the drug in urine. All methods gave a relative standard deviation of less than 2%.

Keywords: Acrivastine; Derivative spectrophotometry; Urine

1. Introduction

Acrivastine (ACR), (*E,E*)-3-{6-[1-(4-methyl-phenyl)-3-(1-pyrrolidinyl)-1-propenyl]-2-pyridinyl}-2-propenoic acid, is a potent competitive histamine H_1-receptor antagonist. The drug lacks significant anticholinergic effects, and has a low potential to penetrate the central nervous system [1] owing to the presence of the polar acrylic acid side-chain in the molecule. The literature reveals only one paper concerning the determination of ACR and its metabolite in human plasma using GC–MS [2].

2-Nitrophenylhydrazine hydrochloride (2-NPH · HCl) has been used for the determination of a wide range of aliphatic and aromatic acids in aqueous ethanol in the presence of pyridine and recently this method has been used for the determination of several drugs [3,4]. Alkaline $KMnO_4$ is used for the oxidation of organic compounds containing different unsaturated centres [5]. The use of derivative spectrophotometry in the analysis of pharmaceutical matrices and biological samples is well established, especially its potential for the elimination of interfering substances such as additives, excipients and endogenous substances [6,7].

The aim of this work was the development of simple and sensitive analytical methods for the

---

* Corresponding author.

assay of ACR capsules, utilizing its reaction with 2-NPH·HCl in the presence of dicyclo-hexylcarbodiimide (DDC) and pyridine and also through oxidation with alkaline $KMnO_4$. Furthermore ACR was determined both in its dosage form and in urine by using first- and second-derivative spectrophotometric measurements.

2. Experimental

2.1. Apparatus

A Perkin-Elmer Model 550S UV–VIS double-beam spectrophotometer with 1 cm quartz cuvettes and a Hitachi Model 561 recorded were used. The following operating conditions were used: scan speed, 120 mm min^{-1}; chart speed, 60 mm min^{-1}; $D_1 = (dA/d\lambda)$; $D_2 = (d^2A/d\lambda^2)$; and scan range 400–250 mm. The minimum and maximum ordinate settings were selected to record the maximum amplitude of the most concentrated standard solution at not less than 80% of the recorder full-scale deflection (25 cm).

2.2. Materials

All materials used were of analytical grade. Acrivastine (ACR) authentic sample and Semprax capsules (Amriya for Pharmaceutical Industries under license from the Wellcome Foundation, London, labelled to contain 8 mg of ACR per capsule) were used.

2.3. Reagents and solutions

The following solutions were prepared: 1% (w/v) $KMnO_4$ in distilled water; 0.24 M 2-NPH·HCl solution, by dissolving 0.456 g of 2-NPH·HCl in 100 ml of ethanol; 0.25 M DCC solution by dissolving 0.516 g of DCC in 100 ml of ethanol; 5.6% (v/v) pyriding solution, by diluting 5.6 ml of pyridine with ethanol to 100 ml; and 10% ethanolic KOH solution, by dissolving 10 g of KOH in 5 ml of distilled water and diluting to 100 ml with ethanol.

2.4. Preparation of calibration graphs

2.4.1. 2-NPH·HCl method

Dissolve 50 mg of ACR in 100 ml of ethanol. Pipette aliquot volumes ranging from 0.5 to 1.0 ml (in 0.1 ml steps) into 10 ml volumetric flasks, to each add 1 ml each of the 2-NPH·HCl, pyridine and DCC solutions and stopper the flasks. Heat at 80°C for 10 min, then add 0.5 ml of 10% ethanolic KOH solution, heat the flasks for 5 min at 60°C, then cool to room temperature and dilute to volume with ethanol. Measure the absorbance against a reagent blank at 550 nm.

2.4.2. $KMnO_4$ method

Dissolve 25 mg of ACR in 100 ml of 0.1 M H_2SO_4. Pipette aliquot volumes ranging from 0.2 to 0.6 ml (in 0.1 ml steps) into 10 ml volumetric flasks, to each add 1 ml of 1 M NaOH and 0.3 ml of 1% $KMnO_4$ and mix. Dilute to 10 ml using distilled water. Measure the absorbance in 1 cm cells against a reagent blank at 608 nm.

2.4.3. Derivative spectrophotometric method

Dissolve 25 mg of ACR in 100 ml of 0.1 M NaOH. Pipette aliquot volumes ranging from 0.1 to 0.4 ml (in 0.1 ml steps) into 50 ml volumetric flasks and dilute to volume with 0.1 M NaOH solution. Record the D_1 and D_2 values at the recorded λ (Table 1).
2.5. Procedure for capsules

2.5.1. 2-NPH·HCl method

Place an accurately weighed portion of the mixed contents of the capsules equivalent to 50 mg of ACR in a beaker, extract with ethanol, filter into a 100 ml volumetric flask and dilute to volume with ethanol. Proceed as descibed in Section 2.4.1.

2.5.2. $KMnO_4$ method

Place an accurately weighed portion of the mixed contents of the capsules equivalent to 25 mg of ACR in a beaker and extract with ca. 20 ml of chloroform. Filter into a 100 ml volumet-

Scheme 1.

2.5.3. Derivative method

Place an accurately weighed portion of the mixed contents of the capsules equivalent to 25 mg of ACR in a beaker, extract with 0.1 M NaOH, filter into a 100 ml volumetric flask and dilute to volume with 0.1 M NaOH. Proceed as described in Section 2.4.3.

2.6. In vitro determination of ACR in urine

Dissolve 25 mg of ACR in 100 ml of 0.1 M H_2SO_4. Transfer aliquot volumes ranging from 0.1 to 0.4 ml (in 0.1 ml steps) into sets of separating funnels each containing 2 ml of urine and extract with 5 ml of chloroform. Transfer the chloroform extracts into 50 ml volumetric flasks, evaporate to dryness, dissolve the residue in 0.1 M NaOH and dilute to volume with 0.1 M NaOH. Record the D_1 and D_2 values.

3. Results and discussion

3.1. 2-NPH · HCl method

Containing a carboxylic group, ACR reacts with 2-NPH · HCl in the presence of DCC and pyridine to form the corresponding acid hydrazide derivative. The reaction mechanism is illustrated in Scheme 1 [8].

The violet colour of the resulting acid hydrazide was measured at 550 nm. The experimental conditions were optimized to achieve

ric flask, dilute to volume with chloroform and mix. Transfer 0.2–0.6 ml (in 0.1 ml steps) into separate 10 ml volumetric flasks. Evaporate to dryness and dissolve the residue in 1 ml of 0.1 M H_2SO_4. Proceed as described in Section 2.4.2.

Table 1
Analytical parameters for the determination of ACR using the proposed spectrophotometric methods

Method	Concentration range (μg ml^{-1})	Wavelength, λ (nm)	Linear regression		Correlation coefficient, (r)	RSD[a] (%)	Apparent molar absorptivity, ϵ (l mol^{-1} cm^{-1})
			Intercept (a)	Slope (b)			
KMnO$_4$	5–15	608	0.032	0.0514	0.9989	1.5	17907.76

[a] Relative standard deviation ($n = 5$).

high sensitivity, a low blank reading and high colour stability, as described previously [3,4].

3.2. KMnO₄ method

Alkaline permanganate is a known reagent for the hydroxylation of alkenes. This process is thought to proceed via cyclic permanganic esters, and finally to lead to the formation of a 1,2-diol and other oxidation products [5]. Thus, ACR was oxidized, owing to the presence of unsaturated centres, by $KMnO_4$ in alkaline medium. Under the conditions used, the resulting green manganate ion (MnO_4^{2-}) was mea-

sured spectrophotometrically at its λ_{max} of 608 nm (Fig. 1).

The experimental conditions were studied and it was found that a $KMnO_4$ concentration of 30 μg per ml of the final assay solution was optimum (Fig. 2).

3.3. Derivative method

The zero-order, first-derivative and second-derivative spectra of ACR in 0.1 M NaOH are presented in Fig. 3. The two analyticl wavelengths of 315 nm (for D_1) and 268 nm (for D_2) were selected on the basis of reasonable sensitivity and reproducibility.

The sensitivity of the derivative methods allowed its application in the concentration range 0.5–2.0 μg ml^{-1}, whereas the direct A_{max} did not give satisfactory results in this concentration range. Linear plots of the measured derivatives values versus concentration in the range stated in Table 1 were obtained with negligible intercepts. Such a finding encourages the use of derivative methods for the assay of ACR in capsules (Table 2).

Regression analysis of the results obtained by the three methods using the method of least squares to calculate the slope (b), intercept (a) and correlation coefficient (r) are presented in Table 1. Replicate determinations at different concentration levels of the drug were carried out to test the precision and reproducibility of the proposed methods. The relative standard deviations were found to be less than 2% (Table 1).

Fig. 1. Absorption spectra for the coloured reaction product of 12.5 μg ml^{-1} ACR with $KMnO_4$ solid line. Dashed line, reagent blank.

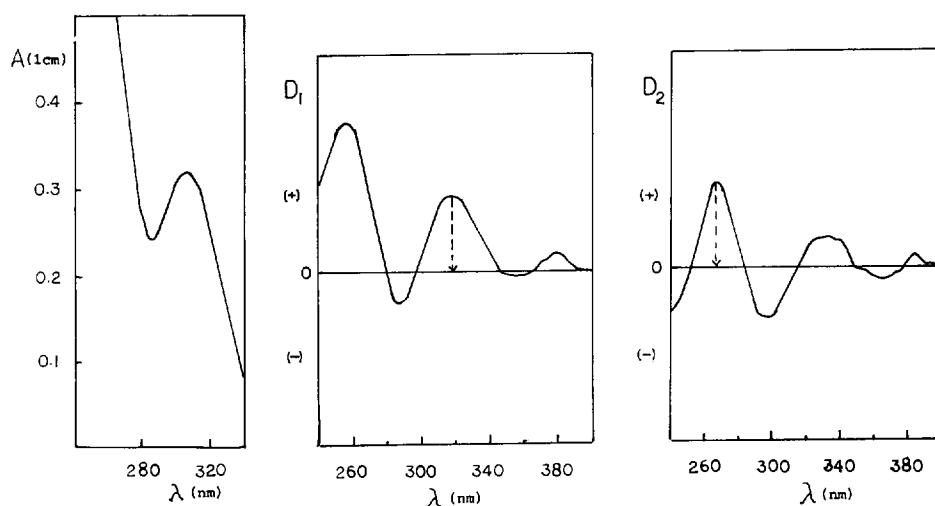
Fig. 2. Influence of $KMnO_4$ concentration on the colour intensity developed from 12.5 μg ml^{-1} ACR.


Fig. 3. (a) Zero-order (10 μg ml^{-1}) and (b) first-derivative and (c) second-derivative (2 μg ml^{-1}) spectra of ACR in 0.1 M NaOH.

The proposed methods were applied to the determination of ACR in capsules. The results obtained were both precise and accurate (Table 2).

3.4. In vitro determination of ACR in urine

It has been reported that 84% of the ACR dose was recovered in urine, predominantly in the unchanged form of the drug [9]. The above-described derivative spectrophotometric methods (D_1 and D_2) were used for the in vitro determination of ACR in urine. Direct measurements of

spiked urine gave a positive error. This error was corrected by prior extraction of the urine with chloroform. The results obtained (Table 3) indicated that the procedure was effective and reproducible.

In conclusion, the 2-NPH·HCl reaction is a specific method for the determination of the carboxylic group moiety of ACR. Hence the method may be utilized for stability studies of the drug. On the other hand, the $KMnO_4$ method is a general and simpler method for the determination of ACR through oxidation of the unsaturated centres of the drug. The derivative method was found to be more sensitive than the other two methods and was applied to the determination of ACR in urine.

Table 2
Determination of ACR in capsules using the proposed spectrophotometric methods

Method	Found[a] ± SD (%)	t[b]	F[b]

Abstract

A major problem with spectrophotometric methods for nickel is cobalt interference, because many of the reagents for nickel also react with cobalt. In this work, the interference of cobalt in the determination of nickel using 2-(5-bromo-2-pyridylaxo)-5-diethylaminophenol (Br-PADAP) was eliminated by the use of derivative spectrophotometry, using the zero-crossing method for evaluation of the derivative signal. Br-PADAP reacts with nickel(II) in the presence of Triton X-100 to form a red complex with absorption maxima at 530 and 562 nm. The reactions parameters and the conditions for the measurements of the first-derivative signal were studied and the results demonstrated that using the derivative technique, Br-PADAP can be used for nickel determination with a selectivity higher than that of ordinary spectrophotometry and with a limit of detection of 0.2 ng ml^{-1}. The pH should be in the range 5.0–6.0 using an acetate buffer. The determination of nickel in the presence of cobalt was performed with conventional and derivative procedures, and the results demonstrated that only the derivative method should be used and, of the methods used for evaluation of the derivative signal, the zero-crossing method is the best. The proposed procedure was used for nickel determination in steels standards. The results demonstrated that the procedure has satisfactory accuracy and precision. Cobalt interference can be also eliminated by using dual-wavelength spectroscopy.

Keywords: Br-PADAP; Cobalt interference; Derivative spectrophotometry; Nickel

1. Introduction

One of the major problems with spectrophotometric methods is cobalt interference during the determination of nickel, because many of the

reagents for nickel also react with cobalt. Normally [1,2] this interference is eliminated by procedures involving operations such as extraction, ion exchange and precipitation of nickel with dimethylglyoxime. In the present paper, we propose a procedure using 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (Br-PADAP) for nickel determination with derivative spectrophotometry to

* Corresponding author. Fax: (55) 71-237-4117 or (55) 71-235-5166.

increase of the selectivity. This method allowed the determination of nickel in the presence of cobalt without the need for chemical separation. The proposed method is simple, highly selective, reproducible and involves little reagent manipulation.

Br-PADAP is a good spectrophotometric reagent for nickel determination ($\varepsilon = 1.22 \times 10^5$ l mol^{-1} cm^{-1}), and has been used for nickel determination in aluminium alloys and nickel electroplating waste-water [3] and in our laboratory for the simultaneous determination of nickel and iron in copper-base alloys [4]. In both studies major cobalt interference was reported. Jarosz [5] used Br-PADAP as spectrophotometric reagent for nickel and separated it from cobalt using dimethylglyoxime.

Others procedures have been described for nickel determination by derivative techniques. Ishii et al. [6] used second-derivative spectrophotometry for the determination of micro-amounts of nickel with methylfurfural 1-phthalazinohydrazone as reagent. The procedure was proposed for nickel determination in the presence of cobalt, the cobalt interference being eliminated by formation of the cobalt(III) ammine complex or by extraction in the form of a thiocyanate complex. The surfactant Triton X-100 was used for solubilization of the reagent. Malinoswska and Kasiura [7] used 2-(2-thiazolylazo)-1-naphthol for nickel determination in the presence of several cations, the procedure being based on extraction of the resultant complex with chloroform. Murillo et al. [8] proposed the simultaneous determination of nickel and cobalt by first-derivative spectrophotometry using 1-hydroxy-2-carboxyanthraquinone as reagent; the derivative technique (zero-crossing method) allowed higher selectivity. Another procedure [9] was proposed for the simultaneous determination of nickel, zinc and copper by second-derivative spectrophotometry using 1-(2-pyridylazo)-2-naphthol as reagent. A procedure for the simultaneous determination of nickel and copper by third-derivative spectrophotometry using sodium cyanide [10] was proposed. These methods all have sensitivity lower than that with Br-PADAP.

2. Experimental

2.1. Reagents

All reagents were of analytical-reagent grade unless stated otherwise.

Nickel(II) solution (1000 μg ml^{-1}) was prepared by dissolving pure nickel (99.99%) in dilute nitric acid with heating and dilution to 1 l with demineralized water.

Br-PADAP solution (0.025%) was prepared by dissolving 0.0625 g of the compound (Aldrich) in 10 ml of ethanol and 100 ml of Triton X-100 solution (8%) and diluting to 250 ml with demineralized water.

Buffer solution (pH 5.25) was prepared by mixing 103.3 g of sodium acetate trihydrate and 14.1 ml of glacial acetic acid in 1 l of demineralized water.

Sodium thiosulfate solution (10%) was prepared by dissolution of 10.0 g of sodium thiosulfate pentahydrate in and dilution to 100 ml with demineralized water.

EGTA solution (0.001 M) was prepared by dissolving ethylene glycol-2-(2-aminoethyl)tetraacetic acid (Merck) in water.

2.2. Apparatus

Absorption spectra, first-derivative spectra and absorbences were measured with a Varian DMS-100 spectrophotometer and a Grafix FX-100 printer and a Perkin-Elmer Lambda 19 UV–VIS/NIR spectrometer with an Okidata Microline 320 printer, using a 1.0 cm cells.

A 300 Analyser pH meter was used to measure pH values.

2.3. Procedure

Transfer a portion of solution containing 1.00 μg of nickel(II) into a 25 ml standard flask and add 2.5 ml of acetate buffer (pH 5.25) and 1.0 ml of Br-PADAP solution. Mix and dilute to the mark with water. After 50 min, record the first-derivative spectrum from 800 to 400 nm against an appropriate blank at a scan speed of 400 nm min^{-1} and a slit width of 4 nm. Determine the
Fig. 1. Effect of pH on the Ni(II)-Br-PADAP system. Reference, reagent blank. [Ni(II)] = 0.08 μg ml^{-1}.

nickel content from the first-derivative spectrum by measuring first-derivative signal at 573 nm (zero-peak method) or at 563 nm (zero-crossing point for cobalt) and comparing the value obtained with an appropriate calibration curve. The wavelengths of the zero-peak and zero-crossing points quoted are those obtained in this work, and these values should be established independently for other instruments as part of the calibration procedure.

3. Results and discussion

3.1. Characteristics of the reagent and the complex

The reaction of Br-PADAP with nickel(II) cation in the presence of Triton X-100 forms a red complex with absorption maxima at 530 and 562 nm and a composition of 1:2 nickel(II)-Br-PADAP. The absorbance of the complex reaches a maximum 50 min after mixing the reagents and is stable for at least 24 h. The Br-PADAP reagent has an absorption maximum at 487 nm (at pH 5.25). It and its nickel(II) complex have low solubility in water but the reaction in the presence of Triton X-100 overcomes this inconvenience.

The order of addition of reagents was studied and the results demonstrated that it did not affect complex formation.

3.2. Effect of pH

The effect of pH on the nickel(II)-Br-PADAP system was studied and the results demonstrated that the derivative signal is maximum and constant in the pH range 5.0-6.0, as can be seen in Fig. 1. The effect of the buffer concentration on the nickel(II)-Br-PADAP complex was studied and the results demonstrated that it does not affect the derivative signal when the buffer is in the concentration range 0.10-0.40 M in acetate.

3.3. Effect of Triton X-100 surfactant on the nickel(II)-Br-PADAP system

Br-PADAP and its nickel(II) complex have low solubility in water, this is overcome by using Triton X-100 as surfactant [11]. The solubilization of 250 μg of reagent is obtained with 24 mg of Triton X-100 per 25 ml. Thus, 32 mg was selected as optimal. The study of the effect of the amount of Triton X-100 on the nickel(II)-Br-PADAP complex revealed that it does not affect the absorbance signal of the system when Triton X-100 is in the concentration range 1.0-1.6 mg ml^{-1}.

3.4. Conditions for measurement of first-derivative value

The effects of the scan speed and of the slit width (Δl) on the measurement of the first-derivative signal were examined. The results showed

that the scan speed had no effect. Hence a scan speed of 400 nm min^{-1} was chosen. It was also found that there was no significant difference in sensitivity at various Δl values, but an increase in slit width decreased the noise, hence a slit of 4 nm was selected for the measurements. The methods used for the quantitative evaluation of derivative signals were the peak-zero method and zero-crossing method [8,12,13].

3.5. Effect of interfering ions

Solutions containing 1.00 μg of nickel(II) and various proportions of several cations and anions were prepared and an ordinary procedure [4] was followed. The tolerance level for an ion was taken as the amount which caused a change of $\pm$ 2% in

the absorbance. The results are listed in the Table 1 and demonstrate that the main interferents are cobalt(II), iron(II) and copper(II). The copper(II) interference can be easily eliminated with thiosulfate [4] and iron(III) with EGTA [3]. The iron(II) interference is substantial and cannot be eliminated with EGTA as masking agent or by first-derivative technique. The interference of the iron(III) cation is lower in the presence of chloride ion. The effect of ionic strength on the system is negligible for 0.1 M concentrations of sodium chloride and potassium nitrate.

3.6. Nickel determination in presence of cobalt by derivative spectroscopy

Cobalt is one of the main interferents in nickel determination. It reacts with Br-PADAP in the pH range adopted, forming a complex with absorption maxima at 589 and 570 nm and molar absorptivities of 8.30×10^4 and 7.87×10^4 l mol^{-1} cm^{-1}, respectively. Nickel determination in the presence of cobalt by the ordinary method shows results with positive errors, increasing with increase in the amount of cobalt. However, the derivative technique allows this determination when the zero-crossing method is used. Table 2

presents the results obtained during the determination of nickel in the presence of different amounts of cobalt.

The experiments described below also showed that nickel determination by the derivative procedure using the zero-crossing method is independent of the presence of cobalt at different concentrations.

Four calibration curves were prepared for standards having nickel concentrations in the range 10–200 ng ml^{-1} in the presence of 0, 1.0, 3.0 and 5.0 μg per 25 ml of cobalt. The first-derivative spectra were recorded and the heights were measured using the zero-peak and zero-crossing methods. The slope, intercept and correlation coefficient obtained are summarized in Table 3. The results demonstrated that nickel determination by the peak-zero method has a negative error, decreasing proportionally with increase in the amount of cobalt present. However, this can be avoided by using the zero-crossing method; the equations obtained revealed that nickel determination is independent of the presence of cobalt.

Fig. 2 shows the absorption spectrum of the nickel complex, the corresponding spectrum of the cobalt complex and total spectrum of a mixture of both complexes. All measurements were
Fig. 2. Absorption spectra of (A) nickel complex, (B) cobalt complex and (C) mixture of nickel and cobalt complexes. Reference, reagent blank. [Ni(II)] = 0.04 μg ml^{-1}; [Co(II)] = 0.20 μg ml^{-1}. A = Absorbance.

recorded against a reagent blank. In it can be seen that nickel cannot be determinated with Br-PADAP in the presence of cobalt by ordinary spectrophotometry. Fig. 3 shows the first-derivative absorption spectra of the complexes of nickel and cobalt with Br-PADAP and a mixture of both complexes. It shows that the nickel determination must be performed using the zero-crossing method by measuring the derivative signal at 563 nm.

It can also be seen that cobalt can be determined in the presence of nickel by measuring the derivative signal at 616 nm, hence allowing the simultaneous determination of nickel and cobalt.

3.7. Nickel determination in presence of cobalt by dual-wavelength spectroscopy

The interference of cobalt in the determination of nickel using Br-PADAP can also be eliminated

Table 3

Molar absorptivity		1.10×10^5 l mol^{-1} cm^{-1}	

by using dual-wavelength spectroscopy [12,13]. This can be performed by measuring the absorbances at 562 nm (absorption maximum for the nickel complex) and 596 nm, where the cobalt(II)–Br-PADAP complex has the same absorption as at 562 nm. Thus, the calibration curve for nickel determination is established by the relationship between the nickel concentration and the difference in the absorbances measure at 562 and 596 nm:

$$A_{562\ nm} - A_{596\ nm} = KC_{Ni}\ (\mu g/ml)$$

where A is the absorbance, K is the slope of the curve or calibration sensitivity and C is the nickel concentration.

Table 4 demonstrates the application of the technique to the determination of nickel in the presence of different amounts of cobalt.

3.8. Analytical characteristics

In the conventional spectrophotometric procedure, Beer's law was obeyed in the nickel concentration range 0–0.50 μg ml^{-1} and the graph passed through the origin with a molar absorptivity of 1.10×10^5 l mol^{-1} cm^{-1} at 562 nm. The calibration graph for the derivative method was linear from 0 to 250 ng ml^{-1} of nickel.

The slope of the analytical curve in the dual-wavelengh technique is normally lower than that obtained with conventional spectrophotometry; however, in the present case the slopes were virtually identical because the molar absorptivity of the nickel(II)–Br-PADAP complex is very low (5.42×10^2 l mol^{-1} cm^{-1}) at 596 nm.

The derivative technique has a higher sensitivity that the ordinary method, as can be seen from the calibration sensitivity, analytical sensitivity and

Table 6
Nickel determination in steels by different procedures

Standard	Ni certified (%)	Ni found[a]		
		First-derivative spectrophotometry	Dual-wavelength spectrophotometry	Ordinary spectrophotometry

the inverse. The analytical sensitivity [14], calibration sensitivity [14], the limit of detection [15] and other analytical characteristics of the methods are summarized in Table 5.

3.9. Application

The derivative procedure and dual-wavelength spectroscopy were applied to the determination of nickel in steel standards. The results are presented in Table 6 and demonstrate that there is no significant difference between the certified value and the value found with the proposed procedures at the 95% confidence level. The compositions of standards analysed are given in Table 7.

Samples were prepared using hydrochloric acid, nitric acid and hydrofluoric acid. The iron(III) cation was extracted as the chloride complex using ethyl acetate as extraction solvent.

The great sensitivity of the derivative technique allowed the determination of nickel in sea water.

4. Conclusion

Br-PADAP is one of the most sensitive reagents for nickel determination by spectrophotometric

methods. The derivative technique allowed the selectivity during nickel determination using Br-PADAP to be increased. The results of analyses in comparison with certified values for two steel standards indicated that the proposed procedures have very good accuracy and precision.

Abstract

Theoretical and experimental investigation have been made on a method called the second reciprocal derivative constant-current stripping analysis (SRD-CCSA). The SRD-CCSA is based on the measurement of the d^2t/dE^2 signal given by the curve of (d^2t/dE^2) versus the electrode potential (E). The d^2t/dE^2-E curve gives a maximum value (d^2t/dE^2)$_{max}$ and a maximum value (d^2t/dE^2)$_{min}$, which show as two peaks on the curve. Either of the heights of the peaks and the sum of absolute values of the two peaks are proportional to the bulk concentration of the analyte in solution, and they are much larger than (dt/dE)$_p$ in the first reciprocal derivative constant-current stripping analysis (FRD-CCSA). The ratio of peak–peak height in the SRD-CCSA to peak height in the FRD-CCSA is about 43n (where n represents the number of electrons transferred during the electrode process for the analyte). Potential difference (W_{pp}) between the two peaks is 48.2 mV n^{-1} at 25°C in the SRD-CCSA, which is noticeably smaller than the half-height width $W_{p/2}$, 65.5 mv n^{-1}, in the FRD-CCSA. The theory was verified with a home-made multireciprocal derivative measuring instrument. The experimental results were in good agreement with the theoretical ones.

1. Introduction

Studies on the theory and applications for chronopotentiometric stripping analysis (CPSA) or constant-current stripping analysis (CCSA) were very active [1–9]. The first reciprocal derivative constant-current stripping analysis (FRD-CCSA), once called reciprocal derivative constant-current stripping analysis (RD-CCSA)

[1] enhanced the sensitivity of CPSA or CCSA by about 13 n times and the resolution of the method was improved to 65.5 mV n^{-1}, represented by the half-height peak-width $W_{p/2}$. The theory of the FRD-CCSA was applied to chronopotential analysis (CPA) [3] and to adsorptive constant-current stripping analysis (ACCSA) [4] which is the same as adsorptive voltammetric stripping analysis (AVSA) during the preconcentration step, resulting in reciprocal chronopotentiometry analysis (FRD-CPA) and reciprocal derivative adsorptive

Fig. 3. SRD-CCSA stripping curve: solid line, experimental curve; black dots, theoretical values calculated using Eq. (10). 4.0×10^{-7} mol 1^{-1} Cd^{2+}, $t_d = 60$ s, $i_s = 5$ μA.

constant-current stripping analysis (SRD-ACCSA). This make noticeable improvements in sensitivity and resolution for both of the methods.

In this paper we present a new thoery called the second reciprocal derivative constant-current stripping analysis (SRD-CCSA), i.e. deducing the $d^2t/dE^2–E$ curve and measuring $(d^2t/dE^2)_{pp}$ as the analyte signal instead of $(dt/dE)_p$ in FRD-CCSA. The $(d^2t/dE^2)_{pp}–E$ curve gives one maximum value $(d^2t/dE^2)_{max}$ and one minimum value $(d^2t/dE^2)_{min}$ (see Fig. 1b), which show as two peaks on the $d^2t/dE^2–E$ curve. Potential differ-

ence between the two peaks is noticeably smaller than the half-height peak-width $W_{p/2}$, 65.5 mv n^{-1}, at 25°C in FRD-CCSA. The sum of the absolute values of the two peak heights, or either of the two peak heights is proportional to the bulk concentration of the analyte in solution, and is much larger than $(dt/dE)_p$ in the FRD -CCSA. The theory was experimentally verified with a home-made multi-reciprocal derivative measuring instrument. The experimental results were in good agreement with the theoretical ones. This new approach to CCSA can enhance the sensitivity of the method by about 43 n times and its resolution is improved by about 25%, compared to those in FRD-CCSA.

2. Theory

2.1. Stripping curve of the SRD-CCSA

Equations describing the $E–t$ curve in the CCSA (or CPSA) and describing the $dt/dE–E$ curve in FRD-CCSA at the thin mercury-film electrode (TMFE) are as follows:

$$E = E' + RT \ln(t^{1/2}/\tau - t)/nF \text{ [10]} \tag{1}$$

$$dt/dE = nf[(2\tau + e^{-x})/(4\tau \, e^x + 1)1/2 - e^{-x}] \, [1]$$

$$\tag{2}$$

respectively, in which $f = F/RT$, and $x = 2nf(E - E')$ with

$$E' = E^o + RT \ln[2l/(\pi D_o)^{1/2}]/nF \tag{3}$$

where l is the thickness of the mercury film; τ is the transition time; D_o is the diffusion coefficient of the metal ion (M^{n+}) in solution; t is the stripping time for M^{n+}; and the other symbols have their normal electrochemical meanings. Differentiating Eq. (2) versus E and rearranging yields an equation describing the SRD-CCSA stripping curve, i.e. the d^2t/dE^2-E curve as follows:

$$d^2t/dE^2 = 2(nf)^2[e^{-x} - e^{-x}/(4\tau \, e^x + 1)^{1/2}$$
$$- 2\tau(2 \, e^x + 1)/(4\tau \, e^x + 1)^{3/2}] \tag{4}$$

Resolving Eq. (4) by numerical analysis and combining with Eq. (1), obtains a maximum value denoted by $(d^2t/dE^2)_{max}$

(a) INDIUM CONCENTRATION, $\times 10^{-8}$mol/l

(b) LEAD CONCENTRATION, $\times 10^{-7}$mol/l

(c) THALLIUM CONCENTRATION, $\times 10^{-8}$ mol/l
(d) CADIUM CONCENTRATION, $\times 10^{-8}$mol/l

Fig. 4. The dependence of $(d^2t/dE^2)_{pp}$ on C^0: curve a, $(d^2t/dE^2)_{pp}$ versus $[In^{3+}]$ curve b, $(d^2t/dE^2)_{pp}$ versus $[Pb^{2+}]$; curve c, $(d^2t/dE^2)_{pp}$ versus $[Tl^+]$; curve d, $(d^2t/dE^2)_{pp}$ versus $[Cd^{2+}]$. For other conditions see Fig. 3.
$$(d^2t/dE^2)_{max} = 0.2276(nf)^2\tau \tag{5}$$

at potential

$$E_{max} = E' - 0.805RT/nF - (RT \ln \tau)/2nF \tag{6}$$

and a minimum value denoted by $(d^2t/dE^2)_{min}$

$$(d^2t/dE^2)_{min} = -0.1520(nf)^2\tau \tag{7}$$

at potential

$$E_{min} = E' + 1.051RT/nF - (RT \ln \tau)/2nF \tag{8}$$

Eqs. (5) and (7) show that the d^2t/dE^2-E curve has two peaks, one of which is positive and the other negative. Either of the peak heights, are proportional to the transition time τ and to the bulk concentration of the analyte (C^0), considering that τ is proportional to C^0. By making the two extreme values absolute and then putting them together one obtains the height of the two peaks, denoted by $(d^2t/dE^2)_{pp}$: $(d^2t/dE^2)_{pp} = |(d^2t/dE^2)_{max}| + |(d^2t/dE^2)_{min}| = 0.3796(nf)^2\tau$

$$= 575.2n^2\tau \text{ (at 25°C)} \tag{9}$$

Substituting Eq. (9) into (4) yields

$$d^2t/dE^2 = 2(nf)2[e^{-x} - e^{-x}/(4k \, e^x + 1)^{1/2}$$
$$- 2\tau(2 \, e^x + 1)/(4k \, e^x + 1)^{2/3}] \tag{10}$$

in which $k = 1.9 \times 10^{-8}n^{-2}T^2(d^2t/dE^2)_{pp}$. Eq. (10), describing quantitively the relationship between the signal and the potential, is then called the stripping curve of SRD-CCSA.

2.2. Principle of the second reciprocal derivatization measurement

In principle,

$$d^2t/dE^2 = d(dt/dE)/dt \cdot dt/dE \tag{11}$$

If assuming $y = dt/dE$, then

$$d^2t/dE^2 = dy/dt \cdot y \tag{12}$$

Based on Eqs. (11) and (12), the principle of the second reciprocal derivatization measurement is as follows. Signal dt/dE from the derivative inverter described earlier [1] is first differentiated, yielding the signal $d(dt/dE)/dt$, then the signal $d(dt/dE)/dt$ is multiplied by the signal dt/dE, resulting in the signal d^2t/dE^2. It is very impor-

Fig. 5. The dependence of $(d^2t/dE^2)_{pp}$ on t_d and $\omega^{1/2}$: curve a, $(d^2t/dE^2)_{pp}$ versus t_d, 1.0×10^{-7} mol l^{-1} Cd^{2+}, $i_s = 5$ μA, $\omega = 2000$ rev min^{-1}; curve b, $(d^2t/dE^2)_{pp}$ versus $\omega^{1/2}$, 1.0×10^{-7} mol l^{-1} Cd^{2+}, $t_d = 55$ s, $i_s = 8$ μA.

tant to eliminate noises from 50 Hz city power and the electrolysis cell, for SRD-CCSA is very sensitive to both analytical signals and noises. Signals from the electrolysis cell are, therefore, first filtered by a high-frequency filter and a bandstop filter for 50 Hz city power, and then picked up by a computer. Other blank noises are eliminated by computer software. Sampling frequency of the computer should be carefully selected. A sawtooth-like curve might result if the sampling frequency is too high because if the sampling frequency is too high, the sign collected will be too small when compared with noises of about 6 mV irregularly from the instrument. On the other hand, an odd curve would emerge if the sampling frequency is too low for alot of signals will not be collected. Suitable sampling frequency for our instrument is in the range from 500 to 10 000 Hz. The operating principle of the instrument set-up for the SRD-CCSA is shown in Fig. 2.

2.3. Peak–peak width, resolution and specific potential

Combining Eq. (6) with eq. (8), the potential difference (W_{pp}) between the maximum and the minimum and the minimum vales of the stripping curve of SRD-CCSA is then obtained as follows:

$$W_{pp} = 1.876RT/nF = 48.2 \text{ mV n}^{-1} \quad (\text{at } 25°C) \tag{13}$$

Eq. (13) shows that the resolution of SRD-CCSA is much higher than that of linear sweep voltamme-

try, 173 mV n^{-1} [11], differential pulse polarography, 90.4 mV n^{-1} [12], semidifferential voltammetry, 54.4 mV n^{-1} [13], and the FRD-CCSA, 65.5 mV n^{-1} [1]. The resolution of SRD-CCSA and SRD-CCSA can be compared in Fig. 1.

Substituting Eq. (9) into (6) and (8), and rearranging the equations yields:

$$E^{M_{max}} = E_{max} + (RT \ln(d^2t/dE^2)_{pp})/2nF$$

$$= E' - (RT/nF)(1.309 - \ln(nF/RT)) \tag{14}$$

$$E^{M_{min}} = E_{min} + (RT \ln(d^2t/dE^2)_{pp})/2nF$$

$$= E' + (RT/nF)(0.567 + \ln(nF/RT)) \tag{15}$$

respectively. Apparently, E^M_{max} and E^M_{min} are functions of the standard potential (E^0) of the M^{n+}/M couple, the mercury film thickness (l), and the diffusion coefficient of the ion M^{n+} in solution, but independent of the signal $(d^2t/dE^2)_{pp}$, i.e. concentration (C^0) of the determined ion M^{n+} and other experimental conditions. E^M_{max} and E^M_{min}, therefore, can be used as parameters for qualitative identification. Eqs. (14) and (15) can be used to test if the measured signal $(d^2t/dE^2)_{pp}$ contains any noise or other signals from interfering ions, because $E_{max} + (RT\ln(d^2t/dE^2)_{pp})/2nF$ and $E_{min} + (RT\ln(d^2t/dE^2)_{pp})/2nF$ should be constants according to Eqs. (14) and (15).

2.4. Peak–peak height and factors affecting the peak–peak height

It is known that τ is proportional to the concentration (C_M) of metal M in a film of thickness l, i.e.

$$\tau = lC_M/\lambda \quad [10] \tag{16}$$

with

$$C_M = 0.62\omega^{1/2}D_0^{2/3}\mu^{-1/6}l^{-1}t_dC^0 \quad [1] \tag{17}$$

where $\lambda = i_s/nFA$, i_s is the stripping current (μA); A is the electrode area (cm^2); ω is the angular rotational velocity (s) during preconcentration; μ is the viscosity of the solution (cm^2 s^{-1}); t_d is the deposition time (s); and C^0 is the bulk concentration of the determined metal ion M^{n+} in solution. Dimensions of D_0 and l are cm^2 s^{-1} and cm, respectively.

Substituting Eq. (17) into (16), and then into (9) yields

$$(\mathrm{d}^2 t/\mathrm{d}E^2)_{pp}$$

$$= 3.058 \times 10^{15} n^3 T^{-2} A \omega^{1/2} D_0^{2/3} \mu^{-1/6} i_s^{-1} t_d C^0$$

$$= 3.44 \times 10^{10} n^3 A \omega^{1/2} D_0^{2/3} \mu^{-1/6} i_s^{-1} t_d C^0 \text{ (at 25°C)}$$

$$(18)$$

From Eq. (18), it can be seen that the peak–peak height of SRD-CCSA is proportional to the bulk concentration of the analyte in solution which is the basis for the quantitative application of SRD-CCSA. The peak–peak height is also proportional to the electrode area (A), deposition time (t_d), the square root of the angular rotational velocity of the working electrode during deposition, and it is a inverse function of the stripping current.

3. Experimental method

3.1. Apparatus

A laboratory-built multi-reciprocal derivative PSA/CCSA instrument equipped with a Compaq 386 computer and LQ 1600 typer were used. A thin mercury-film electrode deposited on a rotational glassy carbon electrode was used as the working electrode. Reference and counter electrodes were Ag/AgCl saturated with KCl and platinum respectively. A model DL-501 thermostat system was used to control the temperature of the solution.

3.2. Reagents

All the chemicals were analytical or guaranteed grade. Solutions were prepared with water triple-distilled in quartz. Cadmium and lead standard solutions were prepared from the nitrates and those of indium and thallium from the pure metals.

The supporting electrolyte, sodium nitrate (2.5 mol 1^{-1}) was pruified by catholic mercury-pool electrolysis for over 24 h and diluted to 0.25 mol 1^{-1} in use. Nitric acid was used to adjust the solution pH to about 4. The nitrogen used for deaeration was purified by passage through vanadium (ii) chloride solution.

3.3. Procedure

The disc rotational carbon electrode was first polished with alumina powder, then cleaned consecutively with nitric acid solution (1 + 1) and ammonia solution (1 + 1), 95% ethanol, and finally rinsed with triple-distilled water before use if the electrode had been used for about ten days, otherwise, the electrode only needed polishing with filter paper. The thin mercury-film electrode was prepared by depositing mercury from 2.0 × 10^{-4} mol 1^{-1} mercuric nitrate solution at $E_d = -1.0$ V. The predeposition of the analyte in the sample solution was done with a rotational velocity of $\omega = 2000$ rev min^{-1} or 209 s^{-1} and stripping was done in quiescent solution. Before deposition the solution was deaerated by the passage of nirtrogen for 15 min. After that a stream of nitrogen was passed over the surface of the solution to prevent oxygen from redissolving in the solution during the deposition and the stripping. All experiments were done at 25.0 ± 0.2°C.

4. Results and discussion

4.1. Validation of the SRD-CCSA stripping curve equation

A simulation method was used to validate the SRD-CCSA stripping curve equation, i.e. Eq. (10). $E_{\max}$ and $(\mathrm{d}^2 t/\mathrm{d}E^2)_{pp}$ values obtained from experimental stripping curves were first substituted into Eq. (14) to calculate the corresponding theoretical values of E'. Then the E' and $(\mathrm{d}^2 t/\mathrm{d}E^2)_{pp}$ values were substituted into Eq. (10) to calculate the $\mathrm{d}^2 t/\mathrm{d}E^2$ values at some potentials for the theoretical values. These were compared with the experimental curve. One of the results is depicted in Fig. 3. It can be seen from Fig. 3 that the theoretical values are in good agreement with the experimental curve in most regions, but slightly different at the beginning and the end, of the curve. This proved Eq. (10) to be correct, taking into consideration the capacitance effect

Table 1
Comparison between SRD-CCSA, FRD-CCSA and CPA signals

Element	τ (s)	y'_p (s V^{-1})	y''_{pp} (s² V^{-2})	y''_{pp}/τ (s V^{-1})			y''_{pp}/y'_p (s V^{-1})

y''_{pp}, y'_p, Exptl, Thetl and RD represent $(d^2t/dE^2)_{pp}$, $(dt/dE)_p$, experimental, theoretical and relative derivation, respectively. $t_d = 100$ s, $i_s = 5$ μA, $\omega = 2000$ rev min^{-1} $[Cd^{2+}] = [Pb^{2+}] = [In^{3+}] = [Tl^+] = 7.2 \times 10^{-7}$ mol l^{-1}. The attenuations of SRD-CCSA for Cd, Pb, In and Tl are 1908, 190.8, 394.8 and 47.7, respectively, when the signals were measured with the instrument.

when the electrode potential changes quickly and negligibleness in theory at the extreme situations.

4.2. Factors affecting the peak–peak height $(d^2t/dE^2)_{pp}$

According to Eq. (18), there is a linear relation among $(d^2t/dE^2)_{pp}$ and the bulk concentration C^0 of the ion determined, the predeposition time t_d, the square root of electrode rotational speed, ω, during predeposition and the inverse value of the stripping current i_s. The dependence of the stripping peak–peak height $(d^2t/dE^2)_{pp}$ of the SRD-CCSA for Cd^{2+}, Pb^{2+}, In^{3+} and Tl^+ on $\omega^{1/2}$, i_s^{-1}, t_d and C^0 was studied independently one by one, while keeping the others constant. The plots of $(d^2t/dE^2)_{pp}$ versus C^0 for Cd, In, Tl and Pb are shown in Fig. 4, and versus t_d and $\omega^{1/2}$ shown in Fig. 5. The linear relations shown in Fig. 4 and Fig. 5 are in good agreement with the prediction

Fig. 6. The dependence of E_{max} and E_{min} on $(d^2t/dE^2)_{pp}$: curve a, E_{max} versus $(d^2t/dE^2)_{pp}$; curve b, E_{min} versus $(d^2t/dE^2)_{pp}$.

of Eq. (18). A non-linear relationship between $(d^2t/dE^2)_{pp}$ and i_s^{-1}, however, was observed in our experiment, although $(d^2t/dE^2)_{pp}$ increased with i_s^{-1}. This experimental phenomenon was discussed in an early paper [1].

4.3. Comparison of SRD-CCSA, FRD-CCSA and normal CPSA signals

To make a reliable comparison of SRD-CCSA with normal CPSA signals, the CPSA should be large enough to be measured precisely. The SRD-CCSA signal, however, will be over thousand volts, which is much too large for a normal integrated circuit. Even though those of the CPSA last only a second. Signals carried and exported by the laboratory-built instrument were, therefore, attenuated with five levels: 13.4, 47.7, 94.7, 190.8 and 399.7 times. The experimental results for Cd, Pb, In and Tl are listed in Table 1 and compared with the theoretical ones.

It can be seen from Table 1 that y''_{pp}/τ values for Cd^{2+}, Pb^{2+} and Tl^+ are close to those predicted from Eq. (9), but much smaller for In^{3+}, which may be caused by the lower reversibility of the In^{3+}/In couple.

The relation between FRD-CCSA and CPSA is as follows:

$$(dt/dE)_p = 0.343nf\tau = 13.35n \tau \text{ (at 25°C)} \quad (19)$$

Combining Eq. (9) with Eq. (19) yields:

$$(d^2t/dE^2)_{pp}/(dt/dE)_p = 43.3n \text{ (at 25°C)} \quad (20)$$

Table 2

RD (%)	0.1		0.2		0.2		0.1	

$(d^2t/dE^2)_{pp}/(dt/dE)_p$ values for Cd^{2+}, Pb^{2-}, In^{3+} and Tl^+ in Table 1 show that the experimental results are in good agreement with the theoretical ones, indicating that the sensitivity of the SRD-CCSA is enhanced by about 43.3n times, compared with that of the FRD-CCSA. It is also observed from Table 1 that the difference between the experimental values and the theoretical ones in $(d^2t/dE^2)_{pp}/(dt/dE)_p$ rises with an increase in electron number transmitted in the electrode process. The deviations may also come from the instrument.

4.4. Verification of the E_{max}, E_{min}, E_{max}^M and E_{min}^M equations

Plots of E_{max} against $\log(d^2t/dE^2)_{pp}$, and of E_{min} against $\log(d^2t/dE^2)_{pp}$ should give straight lines with a slope of $2.3RT/2nF$ according to Eqs. (6) and (8). From Fig. 6 we can see that the linear relations are very well demonstrated. The slopes

Table 3

Peak–peak width, W_{pp}, values (mV) for Cd^{2+}, Pb^{2+}, In^{3+} and Tl^+ calculated using Eq. (13)

	Cd^{2+}	Pb^{2+}	In^{3+}	Tl^+
Experimental values	25.3	18.4	47.9	25.9
Theoretical values	24.1	16.1	48.2	24.1
Relative error (%)	5.0	14.3	−0.6	7.6

of the lines for cadmium nitrate solution, however, are 17.8 mV for the E_{max}–$\log(d^2t/dE^2)_{pp}$ curve and 18.0 mV for the E_{min}–$\log(d^2t/dE^2)_{pp}$ curve, respectively, which are larger than the theoretical value of 14.8 mV. This may be due to the lower reversibility of the electrode process in the CCSA.

The element specific potentials for metal M, E_{max}^M and E_{min}^M, defined in Eqs. (14) and (15), respectively, are predicted to be constant, and are independent of the stripping signal, concentration of the determined ion and some experimental

Fig. 7. Stripping curves of cadmium, indium, thallium and lead mixture: $[Cd^{2+}] = [Pb^{2+}] = 8 \times 10^{-8}$ mol l^{-1} $[Tl^+] = 1.2 \times 10^{-7}$ mol l^{-1}, $[In^{3+}] = 5.0 \times 10^{-8}$ mol l^{-1}, $t_d = 50$ s, $i_s = \mu A$, $\omega = 2000$ rev min^{-1}, $(d^2t/dE^2)_{pp}/13.4$.
Fig. 8. Stripping curve for 1.0×10^{-10} mol l^{-1} Cadmium: curve a, SRD-CCSA curve for 0.25 mol l^{-1} NaNO$_3$ solution; curve b, FRD-CCSA curve for 0.25 mol l^{-1} NaNO$_3$ and 1.0×10^{-10} mol l^{-1} cadmium solution; curve c, SRD-CCSA curve for the same solution as in curve b.

variables such as t_d, ω and i_s. Results listed in Table 2 show that either E_{max} or E_{min} remains almost constant with a relative deviation of $\leqslant$ 0.2%, which indicates the accuracy of Eqs. (14) and (15).

4.5. Peak–peak width and resolution

Experimental peak–peak width (W_{pp}) values for Cd^{2+}, Pb^{2+}, In^{3+} and Tl$^-$ and their theoretical ones are listed in Table 3. In Table 3 we can see that the experimental values are close to the theoretical ones for the ions listed, although difference is observed in In. Taking into account the complexity of the electrode process and the errors from the responding and measuring signals in the instrument, Eq. (13) can be regarded to be correct.

Stripping curves given by both SRD-CCSA and FRD-CCSA for a mixture containing 10^{-8} mol l^{-1} levels of Cd^{2+}, Pb^{2+}, In^{3+} and Tl$^-$ are shown in Fig. 7. The peaks for these ions are more clearly separated from each other in SRD-CCSA than in FRD-CCSA, indicating very good resolution for SRD-CCSA.

4.6. Detection limit

Under the following experimental conditions: deaeration with high purified nitrogen for 30 min, predeposition with an electrode rotations velocity

of 2800 rev min^{-1} for 100 s at -1.0 V, a stripping current, i_s, 1 μA, the SRD-CCSA and FRD-CCSA signals for 1.0×10^{10} mol l^{-1} Cd^{2+} are shown in Fig. 8. Curve a is the stripping curve of SRD-CCSA obtained from a blank solution; a signal at a potential of -0.32 V was yielded by contaminating lead in the solution. Curve b, obtained by FRD-CCSA from the solution, shows no peak. Curve c obtained by SRD-CCSA from the same solution, however, shows a signal, 1.7 s^2 V^{-2} at a poential of -0.61 V for Cd^{2+} and another signal, 2.2 s^2 V^{-2}, at a potential of -0.32 V for contaminating Pb^{2+}. This detection limit shows that the sensitivity of the SRD-CCSA is very high.

5. Conclusions

From the description above it can be concluded that both the theory and the experimental results for SRD-CCSA show high sensitivity and excellent resolution. The theories describing the shape, and the change of the d^{2}t/dE^2–E curve are in agreement with the experimental results, proving that the theories presented in this paper are correct for SRD-CCSA, based on the d^{2}t/dE^2–E curve. It is believed that SRD-CCSA is one of the best methods, in terms of sensitivity and resolution for the determination of trace metal ions. The theory presented in this paper, by the way, could be applied to PSA, ACCSA, CPA etc. Applications of the theory are under way and the results will be given in later reports.

Effect of variables influencing $S_{1/2}$ in sequential injection analysis. Extrapolability of $S_{1/2}$ based results between SIA designs

A. Cladera*, E. Gómez, J.M. Estela, V. Cerdà

Departamento de Química, Universitat de les Illes Balears, E-07071 Palma de Mallorca, Spain

Abstract

The influence of variables including ionic strength, propulsion rate and instrumental design parameters on dispersion in a sequential injection analysis system was studied via $S_{1/2}$ and several other parameters related to the dispersion profile. The influence of such parameters on a real system was evaluated in the reaction of Fe(II) with o-phenanthroline by optimizing various instrumental designs using the simplex method and comparing the results.

Keywords: Sequential injection analysis (SIA); $S_{1/2}$

1. Introduction

Flow-through techniques in general and sequential injection analysis (SIA) in particular rely on the mutual dispersion of reactant segments being carried along a tube. Controlling dispersion in a given system is therefore very important with a view to its characterization and optimization. Ruzicka and Hansen [1] developed a dispersion coefficient for describing the dilution of a reagent plug on insertion into a flowing carrier stream:

$$D = \frac{C_0}{C} \tag{1}$$

* Corresponding author.

where C_0 is the initial concentration of reagent and C that after dispersion. While D is defined at any point of a system, use of D_{max} (the dispersion coefficient obtained when the maximum product concentration reaches the detector) is preferred.

As a rule, the type of dispersion a given system exhibits should be matched to the type of measurements it is intended to provide. Thus, direct meausurements (e.g. pH, conductivity, potentimetry) are best made at $D \simeq 1$ (minimum dispersion), whereas measurements of a chemical reaction can be carried out at intermediate D values (2–10); higher dispersion coefficients are usually reserved for cases involving high dilution.

Based on theoretical considerations for SIA, Gübeli et al. [2] proposed the parameter $S_{1/2}$, which denotes the injected volume that results in

$D_{max} = 2$, as the most convenient measure of dispersion in an SIA system irrespective of its symmetry and flow type. They also investigated the feasibility of using $S_{1/2}$ to extrapolate the results of a system to another of a different design.

It should be noted that the above considerations are based solely on physical dispersion in the system and take no account of the potential effects of chemical reactions and their kinetics. Also, the information provided by D and $S_{1/2}$ is always referred to a given point of the system rather than its dispersion profile, which can be of great significance regarding interpenetration of sample and reagent segments.

A literature scan revealed the absence of experimental work aimed at determining whether dispersion descriptors for a system can be used to extrapolate results to other systems. This paper reports a study of the effect of instrumental, physical and chemical variables on $S_{1/2}$ and the geometry of the dispersion profiles for sequential injection systems, which was undertaken to find out whether $S_{1/2}$ based results can be extrapolated to other systems.

2. Experimental

2.1. Reagents

The solutions used included methylene blue in 0.2 M $NaNO_3$, malachite green in 0.01 M acetic/acetate buffer at pH 4.5, and bromothymol blue in 0.01 M borax buffer at pH 9.2, all at variable concentrations. A 1.16×10^{-3} M o-phenanthroline solution in 1 M acetic/acetate buffer at pH 4.5, and another containing 2.1×10^{-5} M Fe(II) in 0.5% (w/v) hydroxylamine were also used.

2.2. Apparatus

The automatic SIA system used was designed by the authors and consisted of a PC compatible computer that actuated a Crison microBur 2030 titration autoburette, an electromechanically controlled 6-channel valve and a Hewlett-Packard HP 8452A diode array spectrophotometer. The instrumental design and control software used were

described in detail in a previous paper [3]. As can be seen in Fig. 1, the SIA manifold used was quite simple; the dimensions of the hold-up (A) and reaction (B) loops were altered as required to obtain various SIA systems exhibiting differential dispersion patterns. All connections were made from PTFE tubing with the dimensions stated in each case.

2.3. Procedure

2.3.1. Determination of $S_{1/2}$

$S_{1/2}$ for each system was determined from triplicate injections of increasing volumes of dye solution. The peak heights obtained were plotted against the injected volume and $S_{1/2}$ was calculated by interpolating the volume corresponding to one-half the absorbance of the undiluted dye.

2.3.2. Fe(II)/o-phenanthroline experiments

The design of the SIA systems studied was optimized using the reaction of Fe(II) with o-phenanthroline. In principle, the reaction involved four reactants, which were delivered via two channels by appropriate prior mixing of the compatible reactants. The experiments were carried out by aspirating preset volumes of o-phenanthroline and Fe(II) solutions, in this sequence, and subsequently propelling them to the detector via the reaction loop.

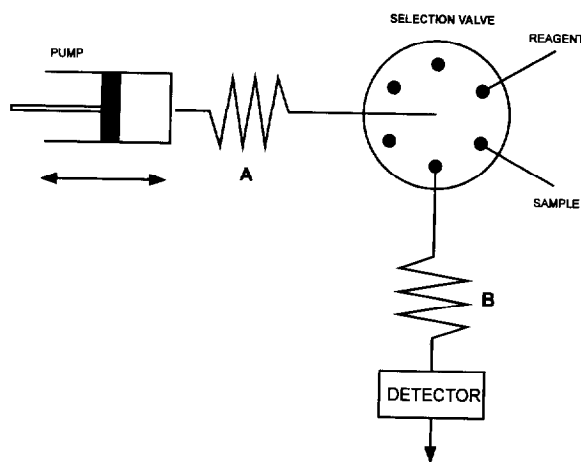

Fig. 1. Basic SIA manifold used in the experiments. A, hold-up loop; B, reaction loop.

Fig. 2. Variation of $S_{1/2}$ with the type of dye and its concentration: ×, malachite green; ◆, methylene blue with 0.2 M $NaNO_3$; +, bromothymol blue; ●, methylene blue without $NaNO_3$. Hold-up loop i.d. = 1.5 mm; reaction loop i.d. = 0.5 mm; reaction loop length = 1 m; q = 3.6 mL min^{-1}.

3. Results and discussion

3.1. Influence of experimental parameters on $S_{1/2}$

3.1.1. Influence of the injected reactant

In preliminary experiments, we observed that the $S_{1/2}$ values calculated by injecting methylene blue in the system was dependent on the dye concentration. In order to investigate this phenomenon and the influence of the nature of the species used to calulate $S_{1/2}$, this value was determined for various concentrations of three different dyes, namely, bromothymol blue (BTB), malachite green (MG) and methylene blue (MB). BTB and MG, two acid–base indicators, were made in a buffered medium (0.1 M HAcO/NaAcO for MG and 0.01 M borax for BTB). As can be seen from the results (Fig. 2), both BTB and MG behaved very similarly: the dye concentration had virtually no effect on $S_{1/2}$. On the other hand, the MB concentration was found to strongly influence $S_{1/2}$, particularly at low levels (<10 mg L^{-1}). The experiments with MB were repeated by preparing solutions in a medium of controlled ionic strength (0.2 M $NaNO_3$), where the dye behaved identically with the other two (see Fig. 2). Experiments performed at a variable

ionic strength revealed the anomalous behaviour of MB to disappear at $NaNO_3$ concentrations above 0.04 M. This phenomenon is rather difficult to interpret, yet we believe it may have originated from adsorption of the dye onto the walls of the Teflon tubes, which may be hindered by the presence of an electrolyte or a higher dye concentration.

The most important consequence of the above-described results is that the correct determination of $S_{1/2}$ entails using controlled conditions as regards the dye, its concentration, the ionic strength, etc. in order to avoid a potential effect of the dye concentration on $S_{1/2}$ values.

Based on the results, we chose to use 23 mg L^{-1} BTB in subsequent experiments.

3.1.2. Influence of propulsion rate and flow reversals

In order to compare our experimental design with the previously reported flow injection analysis (FIA) and SIA systems, we have investigated the influence of the flow rate and the flow reversals on $S_{1/2}$. The influence of the flow rate during the time that the reactants are propelled to the detector on $S_{1/2}$ was studied by using a hold-up loop of 1.5 mm i.d. and a reaction loop of 1 m length × 0.5 mm i.d. The propulsion rate was varied between 3.5 and 19.0 mL min^{-1}. Unfortunately, the propulsion system available at the time these experiments were carried out did not allow the aspiration rate to be programmed, so the potential influence of this factor could not be investigated.

The experiments revealed that decreasing flow rates resulted in increasing $S_{1/2}$ values, the effect being more marked at low rates. It should be noted, however, that the $S_{1/2}$ values obtained at high flow rates hindered correct identification of the peak maximum since the peaks were too narrow at the maximum acquisition rate available (2.5 data/s). The results are consistent with those obtained with FIA systems [4] and can be explained on the grounds of the same theoretical considerations.

A unique feature of SIA systems is that mutual dispersion of the reactants is favoured by flow reversals in the system. In order to assess the

significance of the effect, a series of experiments was carried out in which the aspirated dye was followed by 100 μL of carrier and several 50 μL aspiration/propulsion cycles. The results showed the dispersion to increase markedly in the first few cycles and then more gradually in subsequent cycles, which is consistent with the previous observations of Gübeli et al. [2].

3.1.3. Dimensions of the reaction loop

The results obtained in the experiments aimed at determining the influence of the dimensions of the reaction loop on dispersion showed both the reactor length and its inner diameter have a strong effect: the greater the diameter and length were, the higher was $S_{1/2}$ as a result of the increased residence time and longer path travelled by the dye inside the system. These results are consistent with those for FIA systems.

It should be noted that two pieces of tubing of identical nominal inner diameter (0.5 mm) supplied by different manufacturer provided different results. The differential behaviour of the tubes cannot be exclusively ascribed to divergences between the nominal and actual diameters—in fact, the differences, as determined by measuring the capacity of both loops, were negligible. A more plausible explanation is that, because the tubes were from two different sources, they differed in their inner microstructure and therefore affected dispersion within differently. We also observed an anomalous behaviour from newly purchased tubing: the size and shape of the peaks obtained in the first few injections vary markedly until the tubing is "aged". This ageing process can be accelerated by passing dilute nitric acid for a few minutes. This effect, which is absent in FIA, must be considered in SIA, where the carrier flow is not maintained at a constant rate for a long time.

3.1.4. Influence of the diameter of the hold-up loop and the travelled path

In the experiments performed so far, a dye was aspirated and immediately propelled to the detector; consequently, the path it travelled inside the loop was the minimum required for aspiration. On the other hand, a chemical reaction entails aspirating at least two reactants (sample and reagent). As

a result, every aspirated substance except the last must travel a longer path along the hold-up loop, which will inevitably increase their dispersion.

In order to assess this effect, a series of experiments was carried out where a preset volume of dye solution was aspirated first, followed by a fixed volume of carrier (water). The $S_{1/2}$ values as a function of the aspriated carrier volume (0, 100, 200, 300 and 400 μL) at various diameters of the hold-up loop (0.56, 0.8, 1.0, 1.5 mm) was obtained. As expected, the path travelled inside the hold-up loop greatly affected the dye dispersion as a result of the longer distance travelled; however, the dispersion was scarcely affected by the inner diameter of the hold-up loop because the latter did not alter the residence time, which was only dependent on the aspirated volume. In fact, $S_{1/2}$ was found to depend virtually linearly on the aspirated carrier volume in every instance (R^2 ranged from 0.9781 to 0.9986).

It sould be noted that the path travelled by a substance cannot be altered at will as it is dictated by the chemical reaction involved and the aspirated reactant volumes in each case. Therefore, the dimensions of the reaction loop are much more influential than those of the hold-up loop—the latter need only be large enough to hold the aspirated reactants and prevent them from reaching the propulsion system (syringe) and contaminating the carrier.

3.2 Dispersion profile shape

The $S_{1/2}$ value for an SIA system is a measure of dispersion but provides no spatial information on diffusion profiles. To find out whether the shape of such profiles is indicative of the extent of mutual reactant dispersion in SIA systems, the way it is influenced by the most significant experimental variables was studied. For this purpose, a series of experimental assemblies was tested by injecting a dye volume equal to $S_{1/2}$ and comparing the shape of the peaks thus obtained, which were virtually the same height. In the assemblies tested we varied the reactor i.d. (0.5, 0.56, 0.8, 0.86, 1.0 and 1.5 mm), the reactor length (0, 1, 2 and 3 m) and the path travelled inside the hold-up loop (0, 100, 200, 300 and 400 μL).
Fig. 3. Variation of peak width with $S_{1/2}$. Dye, BTB (23 mg L^{-1}); hold-up loop i.d. = 1.0 mm; $q = 3.6$ mL min^{-1}.

To summarize the results, two parameters related to peak shape were used, namely, the width at half-height (w) and a "symmetry factor" given by $f_s = w_1/w_2$ (the meanings of w, w_1 and w_2 are shown in Fig. 3). Figs. 3 and 4 show the variation of w and f_s, respectively, with $S_{1/2}$.

As can be seen from Fig. 3, whichever experimental variable is altered, peak width was linearly related to $S_{1/2}$ (the straight line thus obtained fitted the equation $w = 1.98 \cdot 10^{-3} + 5.1 \cdot 10^{-4}$

Fig. 4. Variation of peak symmetry with $S_{1/2}$. Dye, BTB (23 mg L^{-1}); hold-up loop i.d. = 1.0 mm; $q = 3.6$ mL min^{-1}.

$S_{1/2}$; $R^2 = 0.9858$), consistent with the expectations—in fact, the experimental design used ensured the same dispersion in every instance and hence a peak width proportional to the injected volume ($S_{1/2}$).

The situation of Fig. 4 is rather different. The symmetry of the dispersion profiles depends on both $S_{1/2}$ and the instrumental parameter fitted to obtain it. As can be seen in the figure, increasing $S_{1/2}$ by augmenting the reactor length or the path travelled along the delay coil also increased peak symmetry, probably as a result of the increased residence time, which is consistent with the theoretical predictions of Vanderslice et al. for FIA systems [5]. However, changes in symmetry with the reactor inner diameter followed the opposite trend, which in principle may have been the result of altering the tubing diameter resulting in an altered velocity profile within and hence in different dispersion mechanisms in each experiment.

As a rule, two systems having an identical $S_{1/2}$ value obtained from different combinations of instumental parameters may lead to dispersion profiles of the same width but different symmetry.

3.3. Optimization of systems involving a chemical reaction

In order to evaluate the effect of the parameters studied on a system involving a straightforward chemical reaction, four SIA systems for the determination of Fe(II) by its reaction with o-phenanthroline were assembled. They differed in the dimensions (length and inner diameter) of the reaction loop, which, as shown above, were the more influential of the parameters studied. The systems were designed in such a way that two had a very similar $S_{1/2}$ value—though obtained from different combinations of instrumental parameters—whereas the other two had a $S_{1/2}$ value below and above, respectively, the previous one.

The four systems were optimized using the simplex method with the aspirated sample and reagent volumes as optimization parameters (their concentrations and all other parameters were kept constant throughout). The simplex variant used was that of unidirectional advancement with contraction and interpolation [6], and the termination

Table 1
Characteristics of the systems optimized and optima obtained

System	Parameter			Optimum found			
	Reactor i.d. (mm)	Reactor length (m)	$S_{1/2}$ (μL)	$V_{reagent}$ (μL)	V_{sample} (μL)	F	No. iter.
A	0.86	0.59	264	295 ($1.12\ S_{1/2}$)	854 ($3.23\ S_{1/2}$)	152.3	21
B	0.56	2	250	255 ($1.02\ S_{1/2}$)	600 ($2.4\ S_{1/2}$)	164.3	16
C	0.5	1	110	256 ($2.3\ S_{1/2}$)	302 ($2.7\ S_{1/2}$)	172.2	20
D	0.86	1	487	291 ($0.60\ S_{1/2}$)	1078 ($2.21\ S_{1/2}$)	141.3	13

Reagent: 1.16×10^{-3} M o-phenanthroline in 1 M acetic/acetate buffer, pH 4.5.
Sample: 2.1×10^{-5} M Fe(II) in 0.5% (w/v) hydroxylamine.
$q = 3.6$ mL min^{-1}; hold-up loop i.d. $= 1.0$ mm.

criterion used was a difference less than 1% between the simplex vertices. The optimized object function was

$$F = \frac{h}{\exp\left(\dfrac{V_t}{V_{max}}\right)} \tag{2}$$

where h is peak height, V_t the total aspirated volume (sample and reagent) and V_{max} the maximum aspirable volume (4 mL in our case). This function was chosen in order to maximize simultaneously the analytical signal and the sample throughput (by minimizing the aspirated volume).

In principle, if the four systems had been equivalent, they should have exhibited similar optimal design parameters. Consequently, the differences between the optimum parameter values are measures of the degree of similarity between them.

Table 1 shows the experimental conditions used in each system and the position of its optima. Fig. 5 shows the dispersion profiles for the sample and reagent at each optimum, together with the analytical peak obtained in each case. The profiles were obtained by injecting two appropriate volumes of dye (23 mg L^{-1} BTB) and may not coincide fully with the actual profiles for the sample and reagent but are the best approximations one can obtain.

As can be seen, none of the four optima coincided. However, the two systems with the same

$S_{1/2}$ value were much more similar to each other than the rest regarding the position of their optima and the shape of their dispersion profiles.

4. Conclusions

From the results obtained in the study of the influence of experimental parameters, we can conclude that the FIA and SIA systems present similar behaviours as a consequence of their equivalent hydrodynamic foundation. However, SIA systems have a unique feature, the flow reversal, which modifies the interdispersion of the injected plugs.

The results obtained in this work allow one to draw several interesting conclusions about the design and optimization of SIA systems.

Thus, in studying the performance of a given system, one should bear in mind that dispersion profiles obtained by using a dye will possibly be somewhat different from the real profiles for the analytical reaction, even if the effect of the reaction and its kinetics are ignored. Consequently, such profiles can only be used as guidance.

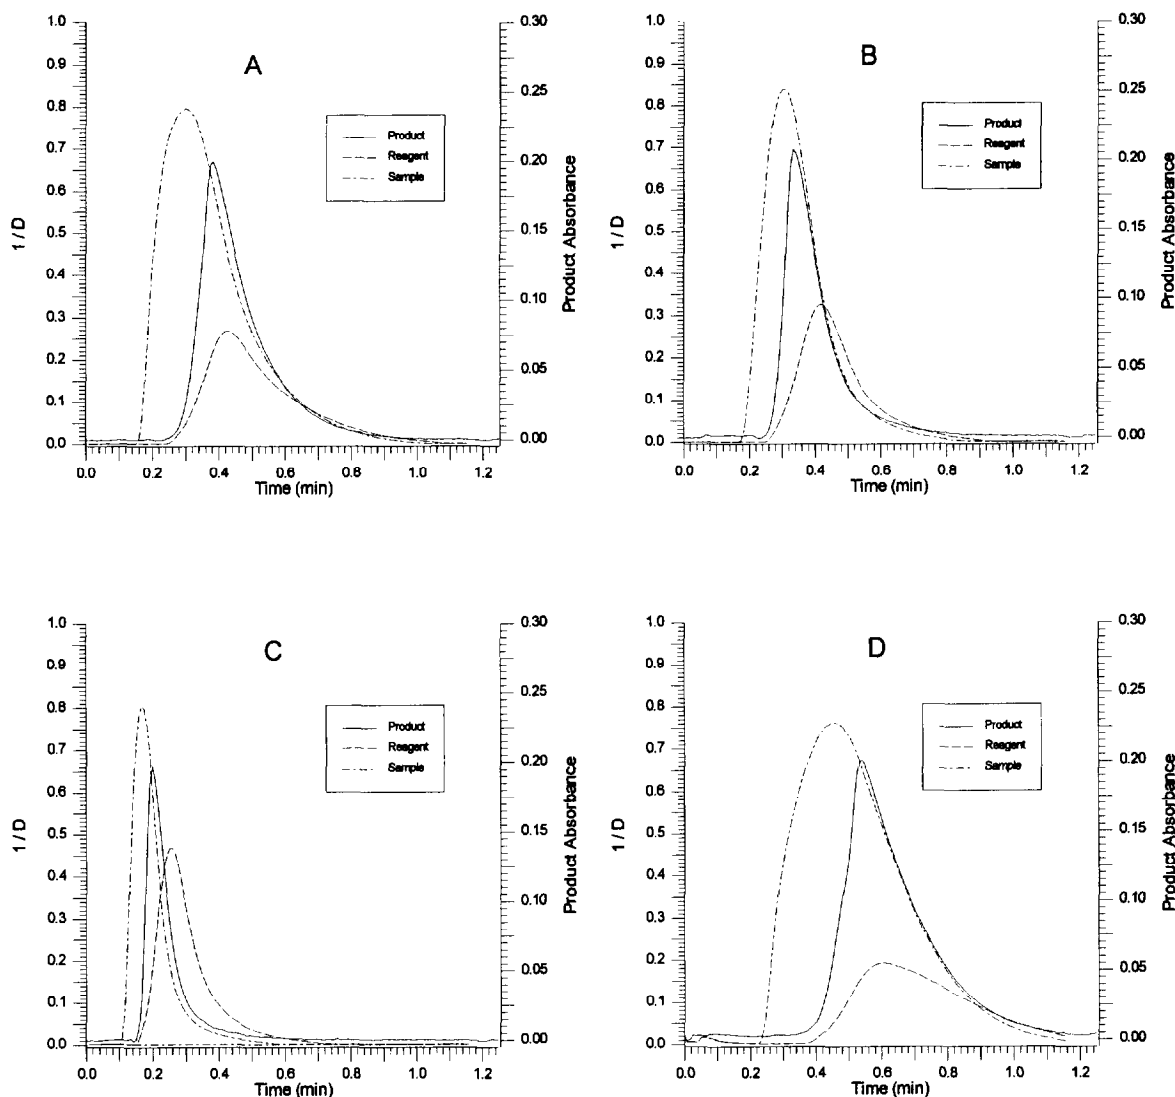
Appropriate choice of various parameters allows one to obtain $S_{1/2}$ values over a relatively wide range for any SIA system. The choice must be consistent with the purpose of the work concerned. It should be noted, however, that similar


Fig. 5. Dispersion profiles and response obtained at the optima for the four systems studied. For conditions, see Table 1.

$S_{1/2}$ values obtained from different combinations of parameters can cause different dispersion profiles and therefore to a different extent of sample–reagent interdispersion. This can be almost critical depending on the particular chemical system involved.

The most influential parameters on SIA system design are the length and inner diameter of the reaction loop.

$S_{1/2}$ values seemingly do not allow for direct extrapolation of the results to different systems. While $S_{1/2}$ is a measure of dispersion in a given system, it provides no information on geometric factors (particularly symmetry). Therefore, while $S_{1/2}$ can be used as a guidance to choose a starting point, it seems each particular system must inevitably be optimized specifically.

Abstract

The present work describes a selective, rapid and economical method for the determination of cobalt using the 2-(2-benzothiazolylazo)-p-cresol (BTAC) as a spectrophotometric reagent associated with a solid extraction on polyurethane foam. The BTAC reacts with Co(II) in the presence of Triton-X100 surfactant forming a green complex with maximum absorption at 615 nm. The reaction is used for cobalt determination within a pH range of 6.50–7.50, with an apparent molar absorptivity of 1.62×10^4 L mol^{-1} cm^{-1}. Beer's Law is obeyed for a concentration of at least 1.60 μg ml^{-1}. A selective procedure is proposed for cobalt determination in the presence of Fe(II), Hg(II), Zn(II) and Cu(II) up to milligram levels using masking agents. Polyurethane foam is used for the preconcentration and separation of cobalt from thiocyanate media and this procedure is applied to its determination in nickel salts and steel alloys.

Keywords: Cobalt determination; Spectrophotometric reagent

1. Introduction

Some highly sensitive reagents for the spectrophotometric determination of cobalt have been proposed, and their sensitivity, expressed in molar absorptivity, is as high as 6.0×10^3 M^{-1} cm^{-1} (4-bromodibenzoylmethane) [1], 1.00×10^4 M^{-1} cm^{-1} (3-hydroxy-propyl-1-phenylthiazine) [2], 9.80×10^4 M^{-1} cm^{-1} (5-Br-PADAP) [3], 11.60×10^4 M^{-1} cm^{-1} (5-Br-PADAB and TAMSMB) [4], and 1.20×10^3 M^{-1} cm^{-1} (2-nitroso-1-naphthol) [5]. Also, these reagents usually have low selectivity and interference occurs; especially when nickel, copper, mercury, molybdenum and iron are present in large quantities; therefore separation procedures are often required.

So far, cobalt has been separated from various interferents by solvent extraction from diethyldithiocarbamate using carbon tehrachloride at pH 10 [6] or from 4 M thiocyanate solution in

---

the presence of hydrochloric acid using methyl isobutyl ketone [7] with back extraction and spectrophotometric measurements. The anion exchange procedures for cobalt separation have been effectively used but metal elution frequently occurs at high (4–9 M) hydrochloric acid concentration [7]. Recently, a preconcentration method for cobalt determination has been proposed based on the adsorption of its ion associated complex with 2-nitroso-1-naphthol-3,6-disulphonate (nitroso R-salt) and tetradecyldimethylbenzylammonium iodide or chloride supported on naphthalene as a synthesized reagent [8,9]. The cobalt was measured by atomic absorption spectrometry or second derivative spectrophotometry, after solubilization of the loaded synthesized reagent in an appropriated volume of dimethilformamide.

Polyurethane foam (PUF) has been used as a solid organic sorbent for a wide variety of inorganic and organic compounds from different media [10–12]. The first detailed study on the separation and preconcentration of iron(III) and cobalt(II) in aqueous thiocyanate solutions was published by Braun and Farag in 1978 [11], and demonstrated that no more than five min was necessary to achieve quantitative (99%) extraction of cobalt from 0.2 M thiocyanate solutions in batch process. Hamon and Chow [13] published a systematic investigation of the extraction of cobalt from thiocyanate solution under a wide variety of conditions using cut cubes of PUF (1.3 cm edge), so that a volume of 150 mL of the cobalt–thiocyanate solution was equilibrated with 50 mg PUF by a batch squeezing extraction technique. This extraction was enhanced by high thiocyanate concentration and high ionic strength, between a pH range of 1.0–9.0, but it took a very long time to complete. PUF unloaded and loaded with 1-(2-pyridylazo)-2-naphthol has been shown to absorb quantitatively traces of cobalt, zinc and iron from acidic thiocyanate solutions and this formed the basis of subsequent cobalt determination by X-ray fluorescence [14,15] and neutron activation analysis [16] directly on the foam. The PUF thin layer spectrophotometry [17] was demonstrated as a technique; the colored complex was extracted and measured directly on the foam. Abbas et al. [18] presented a procedure for the microdetermination

of cobalt in water by direct PUF thin layer spectrophotometry based on the blue color of the cobalt–thiocyanate complex, which is quantitatively extracted from 1 M thiocyanate solutions, however the presence of Fe(III) and Mo(V) in large quantities cause interference.

The reagent 2-(2-benzothiazolylazo)-p-cresol (BTAC) was introduced by Gusev et al. [19] for the spectrophotometric determination of cadium, zinc and copper and layer by Fraga [20] as a spectrophotometric reagent for nickel determination in metal alloys.

This work describes the use of BTAC as a spectrophotometric reagent for cobalt, associated with solid extraction on PUF from thiocyanate medium to provide a selective, sensitive and rapid method for cobalt determination in the presence of large quantities of nickel, iron and molybdenum.

2. Experimental

2.1. Apparatus

Spectrophotometric measurements were made using a Micronal-B342II spectrophotometer with matched 1.00 cm quartz cells. A Porcyon-SA720 pH meter was used to measure the pH values of the solutions.

2.2. Reagents

All reagents were of analytical grade unless otherwise stated. BTAC (Pontifícia Universidade Católica-prepared [20]) solution (400 μg ml^{-1}) was prepared by dissolving the purified reagent in absolute ethanol (Merck). Standard cobalt(II) solution (1000 μg ml^{-1}) was prepared by dissolving cobalt(II) acetate in demineralized and double-distilled water, it was standardized by 4-(2-pyridylazo) resorcinol-EDTA complexometry. The buffer solution was prepared by mixing ammonium chloride solution with ammonium acetate solution in appropriate ratios and the pH was adjusted to 6.80.

Triton X-100 solution (5%) was prepared by dissolving 5.0 mL (Merck) in demineralized water and making to 100 mL. Potassium thiocyanate

solution (0.2 M) was prepared by dissolving the reagent (Carlo Erba) in demineralized water and adjusting to pH 3. The masking solution, containing thiocyanate, thiosulphate and tartarate (1%), was prepared by dissolving the sodium salts (P.A., Merck) in demineralized water.

A commercial, open cell, polyether-type PUF (Vulcan of Brazil—VCON 202, 42% resilience and 10–12 cells per linear cm) was pulverized and used as described previously [21].

2.3. General procedure

2.3.1. Spectrophotometric determination of cobalt (Procedure A)

A convenient aliquot of solution containing up to 16.00 μg of cobalt was transferred to a 10.00 mL standard flask; 1.00 mL of nitrate solution (1.0 M), 1.00 mL of masking solution, 1.00 mL of TRITON X-100 solution (5%), 1.00 mL of BTAC solution (200.00 μg mL^{-1}) and 2.00 mL of buffer solution (pH 6.80) were added. The standard flask was diluted to the mark with water and the absorbance at 615 nm measured against a blank prepared containing all the solutions except cobalt.

2.3.2. Separation of cobalt using PUF (Procedure B)

An aliquot of thiocyanate solution (0.2 M) at pH 3 [11,13], containing a convenient amount of cobalt was transferred to a stoppered flask; 100 mg of pulverized PUF was added and the volume was made up to 25.00 mL with the KSCN solution (0.2 M, pH 3). The system was then shaken mechanically (VKS-100 mechanical shaker, 100 counts per min) and the PUF was collected by vacuum filtration (filter paper $\phi = 2.0$ cm), washed with KSCN solution (0.2 M, pH 3), squeezed with a piston of Teflon and the cobalt was back extracted instantaneously with 10 mL of ethyl alcohol 80% solution [22]. The cobalt was measured as described in Procedure A, with a corresponding amount of alcohol added to the blank solution.

3. Results and discussion

3.1. Characteristics of the complex

The Co–BTAC complex has a low solubility in water, but when the reaction occurs in the presence of surfactant Triton X-100 it forms a green complex with maximum absorption at 615 nm in the pH range of 6.50 to 7.50. This complex is instantaneously formed, solubilized and it is stable for at least one hour. The stoichiometry was studied at pH 6.80 and a 1:3 (metal:ligand) molar ratio was achieved with the absorbance signal remaining unaltered up to 1:12, the molar absorptivity was $1.62 \pm 0.02 \pm 10^4$ L mol^{-1} cm^{-1}. The addition order of the reagents does not affect the complex formation.

3.2. Effect of pH

The effect of pH on the Co–BTAC system was studied and the results demonstrated that the absorbance signal is maximum and constant at the pH range 6.50–7.50 (Fig. 1). The general

Fig. 1. Effect of pH on the system Co–BTAC in 0.5 M ammonium chloride–ammonium acetate buffer. [Co] = 1.34 × 10^{-3} M; $\lambda = 615$ nm; [BTAC] = 1.48 × 10^{-2} M; 0.50% Triton-X100 and 0.1 M NaNO$_3$.
Fig. 2. Effect of surfactant Triton-X100 concentration on the system Co–BTAC in 0.5 M ammonium chloride–ammonium acetate buffer, pH 6.80. [Co] = 1.34 × 10⁻³ M; λ = 615 nm; [BTAC] = 1.48 × 10⁻² M; 0.1 M NaNO₃.

Procedure A was developed with an ammonium chloride–ammonium acetate solution adjusted to pH 6.80. The effect of the buffer concentration on the Co–BTAC system indicates that is does not affect the absorbance signal when the buffer analytical concentration varies up to 0.5 M.

3.3. Effect of Triton X-100 surfactant

The BTAC and its cobalt complex have a low solubility in water but they can be solubilized using Triton X-100. However, it was observed that the absorbance signal of the Co–BTAC system increases as the amount of surfactant is increased and a maximum signal is achieved between 0.4 and 1.0% (Fig. 2). Thus, 0.5% of Triton X-100 was selected as the optimal concentration in the general procedure.

3.4. Effect of interfering ions

The influences of some anions, cations and a number of complexing species that could be applied as selective masking agents were examined.

Solutions containing 10.00 µg of cobalt and various amounts of several cations and anions were prepared and measured under the optimum experimental conditions. The interference limit of an ion was arbitrarily established when a 2% change in the absorbance of the complex Co–BTAC was observed. Large amounts of thiocyanate (100 mg); chloride, fluoride, bromide, iodide, nitrate, acetate, thiosulphate and tartarate (10 mg); and sulphate and borate (5 mg) could be tolerated. Phosphate was tolerated at a low amount (0.01 mg) and EDTA interferes seriously. The metallic ions examined which did not interfere up to a 5 mg level are Cr(III), Mo(VI), Bi(III), Al(III), Fe(III) and Ga(III); and up to a 1 mg are Be(II), Mg(II), Mn(II), Sn(II) and Pb(II). However, up to 1 mg Fe(II), Hg(II), Zn(II), Cu(II) and Pd(II) could be masked with 1.00 mL of masking solution. Interference of Ni(II) was only eliminated by solid extraction on polyurethane foam (PUF).

3.5. Analytical characteristics of the method

The straight line calibration curve indicates that Beer's Law is obeyed up to a calculation of 1.60 µg mL⁻¹. The graph passes through the origin with the linear dynamic range between 0.08–1.06 µg mL⁻¹ and a coefficient of variation of 1.23%. The system Co–BTAC presents 273.5 mL µg⁻¹ as the analytical sensitivity [23], with 0.547 mL µg⁻¹ as the calibration sensitivity [23], 10 ng mL⁻¹ as the detection limit, and 80 ng mL⁻¹ as the limit of quantitation [24].

3.6. Solid extraction of cobalt using PUF as a separation procedure

Solid extraction of cobalt from 0.2 M thiocyanate solution at pH 3 was made in batch with 0.20 g of pulverized polyether-type PUF or in a column at a flow rate of 2.0 mL min⁻¹. Under this condition, the cobalt was completely extracted into the PUF while the nickel remained in solution. When the Fe(III) ion is reduced with ascorbic acid it is not extracted. Mo(V) is extracted only at low amounts and extraction is slow. To prevent Mo(V) interferences in the proposed procedure, 30% hydrogen peroxide (0.20

mL) was added before the addition of the Triton solution during Procedure A. Cobalt extraction is swift and 10 min was sufficient to extract up to 73.00 μg cobolt with 60 mg of PUF, or 1.20 mmoles cobalt per gram PUF. Ten min was used for all of the extractions. The cobalt was quantitatively recovered (Table 1) after back extraction with 80% ethyl alcohol solution by batch procedures. Experiments using the column system required a very long time for complete cobalt elution because the polyether-type PUF used swells greatly in this medium [22].

3.7. Application

Procedure A was successfully applied to cobalt determination in waste water and the results, compared with inductively coupled plasma atomic emission spectrometry (ICP-AES) (Table 2), indicate that the proposed procedures provide very good accuracy and precision. For cobalt determination in nickel salts and standard steel alloys matrices a separation step was needed, then a solid extraction with PUF was applied as described in Procedure B. The standard steel alloys samples preparation were made using hydrofluoric and hydrochloric acids with 1.00 mL of 30% hydrogen peroxide. In all of the cases the samples were heated, evaporated to dryness, solu-

bilized in 0.1 M hydrochloric acid solution and filtered, when necessary, before final dilution. Appropriate aliquots were taken and sufficient KSCN salt was added to make 0.2 M solutions; the pH was adjusted to 3 and ascorbic acid was used to reduce Fe(III). The results are presented in Table 3.

4. Conclusions

The solid extraction using PUF provides a simple, rapid, selective and economical method for preconcentration and separation of cobalt from samples containing large amounts of nickel, iron, and molybdenum into 0.2 M thiocyanate solution at pH 3. The back extraction with 80% ethyl alcohol solution was instantaneous and batch procedures may be recommended as more effective. This proposed cobalt separation procedure can be employed using another technique instead of spectrophotometry, and the PUF may be reused after washing with 80% ethyl alcohol solution and a large amount of distilled water [22]. The analytical appliation of the reagent BTAC is an original contribution for cobalt determination and the proposed method can be applied to the spectrophotometric determination of cobalt in matrices containing large amounts of nickel, iron and molybdenum.

An electrostatic micro-collection interface for aerosol collection. Automated ion chromatographic analysis of aerosols

Shaorong Liu, Purnendu K. Dasgupta*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, USA

Received 21 February 1996; revised 11 March 1996; accepted 11 March 1996

Abstract

A miniature aerosol collector based on electrostatic precipitation is described. The sampled aerosol is charged in the device by positive corona discharge and electrostatically collected. The device is operated as a collection interface for aerosol analysis, the collection surfaces can be washed in situ and the effluent subjected to chromatographic analysis on-line, all in a fully automated manner. At a sampling rate of 0.5 l min^{-1}, near unity collection efficiencies are obtained for aerosols of 1 μm and lower size, the size class of greatest environmental interest. Atmospheric aerosol constituents such as sulfate can be measured at the ng m^{-3} level. The disadvantage of the present system is that some artifact nitrate is generated (due to NO_x production in the corona) and reliable values of ambient nitrate aerosol cannot therefore be obtained.

Keywords: Aerosol collection; Automated ion chromatographic analysis; Electrostatic micro-collection interface

1. Introduction

Aerosols are ubiquitous in our environment. They affect visibility, climate, our health and quality of life. The exact role that atmospheric aerosols play depends on their chemical composition, size distribution, and concentration. A better understanding of the effects of aerosols requires a knowledge of all three of the above parameters. There are various techniques for aerosol collec-

tion and measurement; extant monographs describe these techniques [1,2]. For the measurement of aerosol particle size distribution and total mass concentration, many automated instruments are commercially available. However, at the present time, the measurement of the chemical composition of aerosols is usually carried out in discrete steps: first the sample is collected with filters, impactors or cyclones, and then analysis, usually preceded by a dissolution/extraction step, is carried out. Such multi-step methods are labor intensive and do not allow on-line analysis. A few automated schemes have been reported [3–10]. With the exception of the most recent papers

[3–5], these are largely aimed toward a specific species such as aerosol H_2SO_4 and rely on some unique physicochemical property of that species. In recent years, significant efforts have been devoted to the mass spectrometric analysis of individual aerosol particles [11]; however, the cost and bulk of such instrumentation precludes their widespread use in the near future.

Collection of particles by electrical means is well known [12]. The velocity of a charged particle in an electric field can be much higher than its gravitational or inertial velocity. This is exploited in the industrial use of electrostatic precipitators for the removal of aerosols. The two basic steps involved are (a) to charge the particles and (b) to subject them to an electric field such that their electrostatic field induced migration will cause them to deposit on a collection surface. One characteristic of electrostatic precipitators is their high collection efficiencies (99–100%) over a wide range of particle sizes (approximately 0.05–5 μm) [12].

In this report, we describe a miniaturized electrostatic collector, similar in geometry to a wire-in-tube electrostatic precipitator [12], coupled to an ion chromatograph (IC). This arrangement permits the automated analysis of soluble components of atmospheric aerosols, with the exception of nitrogen oxyanions (because some NO_x is produced in the system). The relationships between the collection efficiency and the experimental parameters have been evaluated and are discussed.

2. Experimental

A schematic diagram of the overall experimental arrangement is shown in Fig. 1. It consists of three major parts, an aerosol generation system, an aerosol collection interface and an IC analysis system.

2.1. Aerosol generation system

Monodisperse aerosols were generated by a model 3450 Vibrating orifice aerosol generator equipped with a 20 μm diameter orifice (TSI, St. Paul, Minnesota, USA) by nebulizing sodium sul-

fate solutions of various concentration, and were used to test the performance of the micro-collection interface. A model 3054 aerosol neutralizer (TSI) was installed in the drying chamber of the aerosol generator to neutralize the electrostatic charge that exists on aerosol particles generated by solution nebulization. The neutralizer contains a 10 mCi krypton-85 radioactive source and is capable of charge neutralizing an aerosol flow up to 150 l min^{-1}. It was used throughout the experiment. In order to generate uniformly sized aerosol particles, we selected a flow rate and vibration frequency of 0.139 m min^{-1} and 68 kHz, respectively; this satisfies the condition, $3.5D_j < L < 7D_j$ (where D_j is the diameter of the orifice and L is the length of the liquid jet between vibrations; for the presently used combination, $L = 5.4D_j$), for the generation of uniform liquid droplets [13]. The sodium sulfate solutions were prepared in distilled and deionized water (NANOpure, Barnstead); the level of nonvolatile impurities in the solvent was negligible. After evaporation of the solvent in the drying chamber, the spherical equivalent diameter of the dry particles is given by

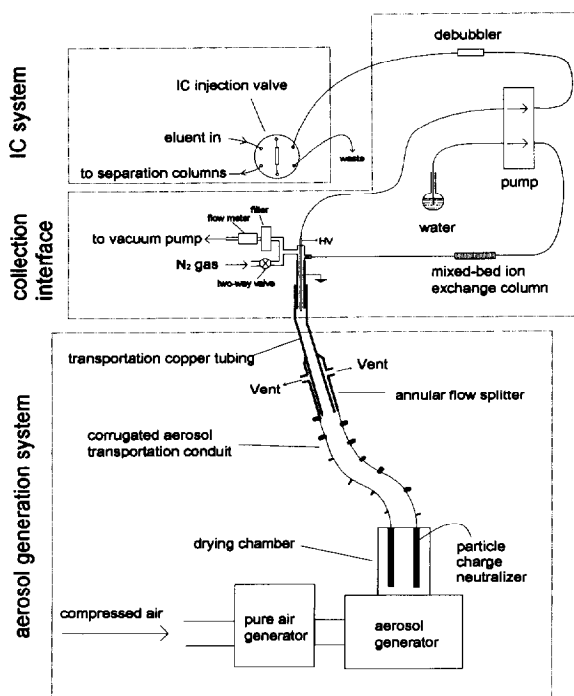

Fig. 1. Schematic diagram of the experimental arrangement.

$$d = d_i \cdot \sqrt[3]{\frac{C}{\rho}} \qquad (1)$$

where d_i is the diameter of the original droplet, C is the Na_2SO_4 concentration of the solution in g cm^{-3} and ρ is the density of solid Na_2SO_4.

A laser-based multichannel particle counter (model A2212-010115-1, Met-One, Grant's Pass, Oregon, USA) was used to measure the optical diameter of the particles. Although eq. (1) assumes spherical particles, aerosols of ionic salts produced by solution nebulization do not, of course, produce speherical particles. The diameters obtained from optical scattering experiments thus tend to be somewhat higher than the calculated spherical equivalent diameters. For a solution concentration of 15.6 μg cm^{-3} Na_2SO_4, a mass median diameter (MMD) of 1.26 ± 0.08 μm was obtained from the size distribution data generated by the laser particle counter. The aerosol formed by nebulizing sodium sulfate solution is probably in its most hydrated form: $Na_2SO_4 \cdot 10H_2O$ (molecular weight $= 322.19$ and $\rho = 1.464$). One thus calculates a particle diameter of 1.16 μm according to eq. (1), close to the results obtained with the optical instrument.

The dispersion and dilution air was provided by a model 737-14A pure air generator (AADCO, Clearwater, Florida, USA). These flow rates were set at 20 and 65 l min^{-1}, respectively. Under these conditions, the aerosol from the aerosol generator had a flow rate of about 85 l min^{-1}, which was much larger than the sampling flow rates (0.1–2 l min^{-1}) used in the present experiments. The aerosol flow was divided with a concentric annular flow splitter (Fig. 1). By adjusting the opening size of the split vents, the desired flow rate could be approximately obtained in the aerosol transportation tube (8 mm i.d. copper conduit). The collection device was directly inserted into the downstream end of the copper tube, the gap between the collection device body and the copper tube served as another vent.

2.2. Aerosol collection interface

The micro-collection interface in Fig. 1 is shown in greater detail in Fig. 2.

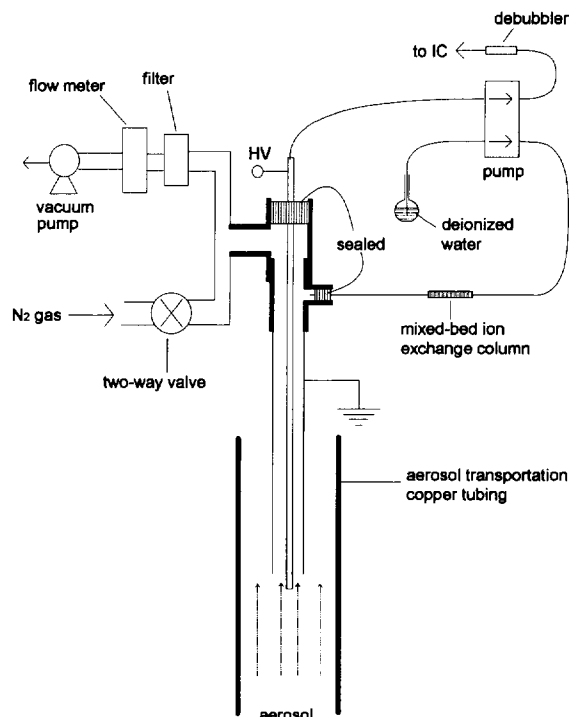

Fig. 2. Details of the collection interface.

The collection device consists of two concentric stainless steel tubes of about 30 mm × 2.7 mm i.d. × 3.4 mm o.d., and 80 mm × 0.2 mm i.d. × 0.4 mm o.d. These are referred to as the outer electrode and the center electrode, respectively. These tubes were fixed in position through two polypropylene tees (1/8" and 1/4", Ark-Plas Inc., Flippin, Arkansas, USA). The top end of the center electrode was extended through the tee and connected via a peristaltic pump to the preconcentration column of an IC system. The exposed part of this metal tube was connected to a high voltage power supply (Model PS350, Stanford Research Systems, Inc., Sunnyvale, California, USA). The outer electrode was electrically grounded. The bottom end of the center electrode protruded about 2 mm beyond the outer electrode end. This arrangement avoids arcing between the ends of the center and the outer electrodes. Such arcing must be avoided because it can occur before corona discharge begins. Arcing cause a current spike from which the high voltage power supply takes time to recover. Arcing could be eliminated

by making the center electrode protrude slightly below the outer electrode. The aerosol sample was aspirated into the collection chamber by a vacuum pump. The sampling flow rate was controlled by a mass flow controller (Model FC280, Tylan General, Torrance, California, USA) with an upstream filter to prevent aerosol intrusion. At any given sampling flow rate, an approximately isokinetic sampling condition [14] was obtained by adjusting the annular vent and thus the appropriate aerosol flow rate through the copper tube.

After the aerosol sample was collected for the desired period (typically 20 min), the collection surface was washed and the washings were preconcentrated on the IC system. Deionized water was delivered by a peristaltic pump. Before entering the annular aerosol collection area through the outer tube, the water was further deionized through a mixed-bed ion exchange resin (Dowex MR-3, Sigma) mini column. To ensure that all of the input liquid wash solution was aspirated back, the aspiration flow rate was set at nearly twice the input flow rate. Bubbles in the aspirated solution were removed before entering the IC preconcentration column by a debubbler. The debubbler was made by first cutting three rectangular openings (approximately 2 mm × 0.8 mm) on a segment of PTFE tube (approx. 30 mm × 1 mm i.d. × 1.4 mm o.d.) and then covering the openings by wrapping the tube with about 20 layers of stretched Teflon tape (plumber's tape). Without this debubbler, spikes and baseline shifts are observed in the chromatographic data output, complicating data interpretation. Typically, about 2 ml of deionized water was pumped through the system for complete washing. Before aerosol sampling was begun again, the system was cleaned and dried as follows. A two-way (on/off) valve was turned on and compressed nitrogen from a cylinder, regulated at 8 lb in^{-2}, was admitted into the annular space to blow away any lingering liquid and dry the whole system.

2.3. IC measurement system

The IC analysis system was based on a Dionex model DX-100 ion chromatograph equipped with a self-regenerating suppressor and a conductivity detector. The sampling loop of the IC injection valve was replaced with an AG 11 column (4 × 50 mm) for analyte preconcentration. An AS 11 column (4 × 250 mm) was used for separation. A 10 mM sodium hydroxide solution was used as the eluent at a rate of 1.0 ml min^{-1}.

2.4. Measurement of collection efficiency

The input aerosol concentration was measured by sampling the aerosol through a Millipore (type HA) membrane filter (0.45 μm pore size) at the same flow rate as that used by the collection interface, measuring the amount of sulfate in the aqueous extract of the filter by IC, and thus calculating the aerosol (sulfate) concentration. The ratio of the amount of sulfate collected by the collection device during the experiment to the amount of the sulfate aspirated through the collection device was considered the collection efficiency.

2.5. Experimental protocol

During the initilization step before each sampling/analysis cycle, the air and liquid pumps and the HV supply are switched off and compressed nitrogen is turned on for 60 s to clean and dry the system. The IC system is in the process of analyzing the sample from the previous cycle at this time. Sampling is conducted during the next step for a desired period (20 min is typical for ambient air experiments), with the sampling pump on and high voltage applied to the collector while the IC system continues its analysis of the sample from the previous cycle. In the final step, the collected sample is washed from the interface and loaded on to the IC preconcentration column. The sampling pump and the HV supply are turned off, the liquid pump is turned on and the IC injection valve is switched to the load mode. Washing/loading is conducted for 5 min to ensure that all the sample is loaded. The system then returns to the initialization step, with the IC valve simultaneously switching to the inject mode.

When a series of experimental runs were first commenced, the collection device was disconnected from the aerosol source tube to avoid any

residual water in the collection apparatus being blown into the aerosol source transportation conduit. The collection device was reconnected before step 2. There was no need to disconnect the collection device after the first measurement cycle.

Initially, the amounts of sulfate and nitrate were quantitated based on both peak area and peak height. Because there was no significant difference between these two approaches only peak heights were henceforth used.

3. Results and discussion

3.1. Dimension of the collection chamber

The dimension of the outer electrode for typical wire and tube geometry electrostatic precipitators is from approximately 15 cm i.d. × 2 m for small units, up to approximately 30 cm i.d. × 5 m for large units [15]. For the present experiments, this size was reduced to approximately 2.5 mm i.d. × 2.5 cm. With electrodes of this size, the collected aerosol could be washed off conveniently by pumping a modest amount of water through the annular space, because water covered the entire annular space as it flowed through this small gap. In principle, increasing the tube length will increase the particle collection efficiency. However, it is necessary that the center electrode be fixed concentrically in the system; this can be difficult when it is long, due to its flexibility. A stable corona discharge could not be generated if the center electrode was made significantly larger to improve rigidity. A center electrode that is too small is difficult to fix rigidly in position and exhibits high liquid flow resistance. This is problematic since it is the conduit through which the wash solution is aspirated.

3.2. Type of corona discharge

Generation of corona discharge inside the collection chamber results in charging of the particles and is important for high efficiency collection of the aerosol particles. Chemical composition of aerosols can vary as a function of size. If a collection device does not collect with a high,

preferably quantitative, efficiency, the analysis may be biased towards one end of the size spectrum.

Industrial electrostatic precipitators use negative corona discharge almost exclusively. This is reportedly because a negative corona is more stable when voltage on the center electrode was ramped; a spark discharge always preceded the establishment of a stable corona. The current spike associated with the discharge generally caused the high voltage power supply to shut itself off. This could be avoided by using the power supply in the constant current mode. A stable positive corona was obtained within a current range of about 6 to 70 μA. However, we could not obtain a stable negative corona. Even after the size of the collection electrode was increased to 4.4 mm i.d., only occasionally could we get a stable negative corona. Therefore, a positive corona was used throughout these experiments. A negative corona may nevertheless be feasible with the choice of alternative electrode materials.

We experimentally determined that a voltage of approximately 2.7 kV was the minimum required to generate a corona. Although this voltage varies with many experimental parameters, such as aerosol particle composition and concentration, gas phase composition, pressure, temperature, sampling flow rate, etc., no corona discharge was ever observed below 2.5 kV.

3.3. Collection efficiency as a function of high voltage on the center electrode

The collection efficiencies for two different aerosol sizes are shown in Fig. 3(a) as a function of the volgtage applied to the center electrode. Based on the current voltage curve (Fig. 3(b)), the voltage range can be divided into two parts, voltages lower than 2.5 kV where no corona discharge occurred and higher than about 2.8 kV where a stable corona was present. As can be seen from Fig. 3(a), before the presence of any corona discharge, the collection efficiency was low. Even before discharge occurs, the collection efficiency increased linearly with increasing voltage. Aerosol collection occurs in this regime because even in the absence of charging by a corona, there is

equilibrium Boltzmann charge on the particles [16]. Similar to the situation with an electrical aerosal analyzer [17], more particles deposit on the collection electrode as a higher voltage is applied. After corona discharge initially starts at approximately 2.5 kV, the current was not stable between 2.5 and 2.8 kV and increased very quickly with the voltage in this range as shown in Fig. 3(b). Above 2.5 kV, the collection efficiency, like the corona current, increased exponentially with the applied voltage. A stable corona and a stable current–voltage behavior was observed at applied voltages greater than 2.8 kV. Fig. 4 shows the collection efficiency as a function of corona current. It increased essentially linearly with the corona current until a corona current of about 20 μA.

Similar to the process that occurs during an electrical thunderstorm [18], NO_x was generated as corona discharge occurred. Fig. 5 shows the amount of nitrate detected as a function of the voltage applied and the corona current. The level of artifact nitrate formed in this manner is clearly related to the corona discharge. A linear relationship exists between the corona current and nitrate

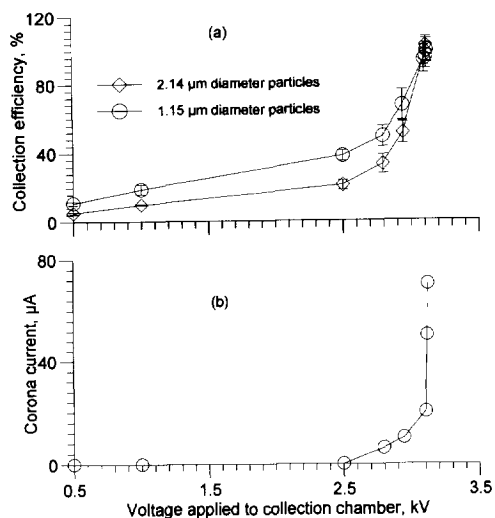

Fig. 4. Collection efficiency as a function of corona current.

amount collected (Fig. 5(b)). The nitrite levels found ranged from 5 to 10% of the nitrate concentrations. There is little doubt that the nitrate originates from the reaction of excited nitrogen and oxygen atoms in the corona followed by a reaction with water vapor. Substitution of cylinder nitrogen for air as the carrier gas virtually eliminated the occurrence of nitrate. Obviously, the present arrangement cannot be used to measure the levels of ambient aerosol nitrate.

Fig. 3. (a) Collection efficiency as a function of voltage on the center electrode: sampling flow rate: 500 ml min^{-1}; sampling time: 20 min, in this and all subsequent figures, as applicable. (b) Current–voltage curve of the collection device.

Fig. 5. (a) Nitrate detected as a function of voltage on the center electrode. (b) Nitrate detected as a function of corona current.
Fig. 6. Collection efficiency as a function of sampling flow rate. Corona current: 50 μA.

3.4. Collection efficiency as a function of sampling flow rate

Fig. 6 shows the collection efficiency as a function of sampling flow rate.

These experiments were conducted at sulfate levels (1.0–6.0 μg m^{-3}) that are typical of modest to high ambient sulfate concentrations. Almost quantitative collection was achieved at a flow rate of $\leqslant 0.5$ l min^{-1}. As the flow rate increased, the residence time of the particles inside the collection chamber decreased, and thence the collection efficiency decreased as well. An increase in the effective residence time in the collection area is expected to enhance the collection efficiency.

3.5. Collection of particulate sulfate as a function of sampling time

The collection of particulate sulfate increased linearly with the sampling time for both 2.14 μm and 1.15 μm diameter particles (Fig. 7). This is useful since measurement sensitivity can be improved by increasing the sampling time.

4. Conclusions

We have investigated a simple electrostatic aerosol collection device that is easily coupled to liquid phase analytical systems. Although the data here, particles of about 0.5 μm diameter have also been investigated, albeit in a less thorough manner. We could generate these smaller aerosols only in very low concetrations (about 100 ng m^{-3}); it therefore becomes tedious and time consuming to collect sufficient sample on the filter for IC analysis to determine the collection efficiency. The importance of filter blank corrections also becomes significant and becomes a significant source of error in computing collection efficiency. Preliminary data, however, indicated that collection efficiencies were $\geqslant 90\%$ at a flow rate of 0.5 min^{-1}. The error margin is such that this collection may have been quantitative. We believe therefore that this approach can be effectively used for the collection and analysis of ambient aerosols in the fine particle fraction ($\leqslant 2$ μm) which is generally the size class of importance both in regards to atmospheric visibility and human health effects. While

Fig. 7. Collection efficiency as a function of sampling time. Corona current: 50 μA; concentrations of the 1.15 μm and 2.14 μm diameter aerosols are 1.0 and 5.1 μg m^{-3}, respectively.

the generation of artifact nitrate is a disadvantage, the system can be readily used for the continuous collection and automated determination of slow or accidental release of hazardous substances that can be chromatographically determined. In the near future we expect to report on an electrical aerosol collection scheme from which nitrate production is eliminated.

Ionic medium effects on equilibrium constants
Part I. Proton, copper(II), cadmium(II), lead(II) and acetate activity coefficients in aqueous solution

Abstract

The molar single ion activity coefficients associated with hydrogen, copper(II), cadmium(II) and lead(II) ions were determined at 25°C and ionic strengths between 0.100 and 3.00 M (NaClO$_4$), whereas for acetate the ionic strengths were fixed between 0.300 and 2.00 M, held with the same inert electrolyte. The investigation was carried out potentiometrically by using proton-sensitive glass, copper, cadmium and lead ion-selective electrodes and a second-class Hg|Hg$_2$(CH$_3$COO)$_2$ electrode. It was found that the activity coefficients of these ions (y_i) can be assessed through the following empirical equations:

$$\log y_H = -0.542I^{0.5} + 0.451I; \log y_{Cu} = -1.249I^{0.5} + 0.912I; \log y_{Cd} = -0.829I^{0.5} + 0.448I^{1.5};$$

$$\log y_{Pb} = -0.404I^{0.5} + 0.117I^2; \text{ and } \log y_{Ac} = 0.0370I$$

Keywords: Ionic activity coefficients; Ionic medium effects

1. Introduction

Several complex systems of practical, biological, geological or general chemical interest comprise mixtures of electrolytes in aqueous solutions. One of the most important problems in the study of the equilibria involved in such systems is the knowledge of the individual activity coefficients of the species in the presence of a background electrolyte [1] and the derivation of equations relating the stability constants of these species and the ionic strength of the medium [2,3]. In such conditions, extra-thermodynamic considerations must be introduced to determine the individual activ-

* Corresponding author.

ity coefficient of an ionic or neutral substance, especially in the presence of an excess of inert electrolyte.

Following this reasoning, Uemasu and Umezawa [1] stressed that ion-selective electrodes (ISEs) provide activity values for individual ions rather than concentrations and, therefore, by using known concentrations, it is possible to evaluate ionic activity coefficients. They reported experimental and computational procedures to accomplish the aforementioned task for Cu(II) and Ca(II) ions at ionic strengths ranging from 0.010 to 3.00 M, held with different background electrolytes, in aqueous solution. Later, Capone et al. [4] determined the proton activity coefficients, also in aqueous solution, by using a proton-sensitive glass electrode, at 10, 25, 37 and 45 °C and $0.01 \leqslant I \leqslant 1.00$ M, in the presence of several background electrolytes.

Ochiai [5] also recognized that the activity and hence the activity coefficient of an individual ion can be measured, at least approximately, with an ion-selective electrode and suggested that traditional statements such as "activities or activity coefficients for individual ions cannot be measured because an individual ion cannot exist independently in a solution, and therefore the mean activity coefficient is the only meaningful parameter" may need revision, in spite of the fact that no solution containing only one kind of ion is possible.

In this paper, we propose a potentiometric method for evaluating the activity coefficients of hydrogen, copper(II), cadmium(II), lead(II) and acetate ions by using ion-selective electrodes in the presence of sodium perchlorate at 25 °C, adopting simple empirical equations relating these parameters with the ionic strength of the medium. In Part II, assuming that similar ions should display similar equilibrium parameters, simple equations are developed in order to calculate at least approximate values for equilibrium constants associated with some metal ion complexes, starting from the data obtained in this work.

2. List of main symbols

OAc   acetate ion

A_i	a function of λ_i and $[i]$ of the ions i involved in the system
d	a function of the λ_i values for the ions i involved in the system
E	electromotive force (emf) of the cell (mV)
$(E_i^{0'})_0$	limiting value of $(E_i^{0'})$ when $\log y_i = 0$ (mV)
E_j	liquid junction potential (mV)
h	molar hydrogen-ion concentration
i	a neutral substance or ion
I	ionic strength (M)
ISE	ion-selective electrode
p	for monovalent cations $p = 1$ and for bivalent cations $p = 2$
λ_i	actual equivalent conductance of i (ohm^{-1} cm^2 equiv^{-1})
λ_i^0	limiting equivalent conductance of i (ohm^{-1} cm^2 equiv^{-1})
M	molar or mol dm^{-3}
Me	metal ion
pa_{H}	$(-\log a_{\mathrm{H}^+})$
r	correlation coefficient of a linear regression
σ	standard error of estimate
T	temperature (°C)
[ ]	molar concentration

3. Experimental

3.1. Materials and solutions

All reagents were of analytical grade. Copper(II), cadmium(II) and lead(II) perchlorate were prepared from perchloric acid and the corresponding basic metallic carbonate. The products were recrystallized from ethanol and conveniently dried. Stock solutions were standardized complexometrically with EDTA. Stock solutions of sodium perchlorate were analysed by evaporating and drying to constant weight at 120 °C. Carbonate-free sodium hydroxide solutions were standardized potentiometrically with acid potassium phthalate and then stored in polyethylene bottles protected with soda-lime tubes. The perchloric acid solutions were standardized potentiometrically with standard sodium hydroxide solutions.

Chloride ions were not detected in these solutions. For the preparation of the solutions, distilled, deionized water and grade A glassware were used throughout.

3.2. Instruments

The emf values were read to the nearest 0.1 mV with a Metrohm 670 Titroprocessor. Metrohm ion-selective electrodes for hydrogen (EA 158), copper (6.0502.140), cadmium (6.0502.010) and lead (6.0502.170) ions and an Ag|AgCl double-junction reference electrode (6.0726.100) were used. A mercury(I) acetate electrode was prepared essentially as recomended by Larson and Mac-Dougall [6]. A thermostated titration cell (25.0 ± 0.1 °C) was employed. Volume measurements (± 0.001 ml) were made with Metrohm 665 automatic burettes. All experiments were performed in a thermostated room (25 ± 1 °C).

3.3. Potentiometric cells

The potentiometric cells used for the emf measurements in the study of the $i(ClO_4)_p$–$NaClO_4$ systems (where $i = H^+$, Cu^{2+}, Cd^{2+}, Pb^{2+}) were of the type

The x values were in the following ranges: $HClO_4$, $(1.00-6.00) \times 10^{-2}$ M; $Cu(ClO_4)_2$, $(0.200-6.00) \times 10^{-3}$ M, $pH = 3.005-3.204$; $Cd(ClO_4)_2$, $(0.200-6.00) \times 10^{-3}$ M, $pH = 3.505-3.693$; $Pb(ClO_4)_2$, $(0.200-6.00) \times 10^{-3}$ M, $pH = 2.608-2.966$; and NaOAc and HOAc, $(6.33-11.5) \times 10^{-2}$ M.

No flow of chloride ions from the reference electrode into the test solutions could be detected during the measurements. The glass electrode was stored in 0.1 M hydrochoric acid and washed thoroughly with water before use. The copper, cadmium and lead ISEs were polished with an abrasive strip for 1 min and then washed with water before use.
3.4. Convention

This work is based on several principles previously established by several workers [7-10]. The conventions adopted are as follows.
1. The emf of cells (a) and (b) may be defined by [8-10]

$$E = (E_i^{0'})_0 + S \log a_i + X_i[i] \tag{1}$$

where

(a)	$-$ Ag|AgCl	$[NaCl]_{(aq)} =$ $= 0.0100M$ $[NaClO_4]_{(aq)} =$ $= (I - 0.010)M$	$[NaClO_4]_{(aq)}$ $= IM$	$[i(ClO_4)_p]_{(aq)}$ $= xM$ $[NaClO_4]_{(aq)} =$ $= \left(I - \dfrac{(p + p^2)[i]}{2}\right)M$	ISE

The indicator electrode is the positive pole only in the case of glass and copper ISE. In the case of the $NaOAC$–$HOAc$–$NaClO_4$ system, the cell was of the type

(b)	$-$ Ag|AgCl	$[NaCl]_{(aq)} =$ $= 0.010M$ $[NaClO_4]_{(aq)} =$ $= (I - 0.010)M$	$[NaClO_4]_{(aq)}$ $= IM$	$[NaOAc]_{(aq)} = xM$ $= [HOAc]_{(aq)} = xM$ $[NaClO_4]_{(aq)} =$ $= (I - x)M$	Hg_2OAc_2|Hg|Pt$^+$

$E_i^{0'}$ = sum of all constant terms that contribute to the total measured emf (mV)

$a_i = y_i$ [i] = individual activity of an ion or a neutral substance i (mol dm^{-3})

[i] = molar concentration of an ion or a neutral substance i (mol dm^{-3})

y_i = molar activity coefficient of i

$(E_i^{0'})_0$ = limiting value of $E_i^{0'}$ when log $y_i = 0$ (mV)

S = experimental value obtained for the coefficient of the logarithmic term of the electrode potential (mV)

X_i = proportionality term between liquid junction potential (E_j) and [i] (mV mol^{-1} dm^3)

2. Within the considered concentration ranges, $HClO_4$, $NaClO_4$, $Cu(ClO_4)_2$, $Cd(ClO_4)_2$, $Pb(ClO_4)_2$ and NaOAc are strong electrolytes.

3. At constant T, maintaining constant and high enough I values, y_i will be constant [8].

4. The straight line obtained by plotting $E - S$ log [i] vs. [i] within a certain [i] range can be ex-trapolated for smaller [i] values (that is, $E_i^{0'}$ and X_i are valid, at least, for the entire 0–[i] range [8–10]).

5. For electrolyte (and non-electrolyte) mixtures, it is preferable to use empirical equations (with extra-thermodynamic but experimental and practical meaning) instead of theoretical equations [7].

3.5. Procedures

A 0.100 M $HClO_4$, $Me(ClO_4)_2$ or isomolar NaOAc–HOAc buffer solution, made up to the desired ionic strength value with $NaClO_4$, was added successively (in 0.3 ml increments) to a known volume of $NaClO_4$ solution of identical ionic strength in the potentiometric cell. After each addition, the emf of the cell was measured. In all cases equilibrium was easily reached (the criterion was to achieve constant emf values within ± 0.2 mV during 3 min, for $I \leqslant 1.0$ M and ± 0.1 mV during 1.5–2 min, when $I > 1.0$ M).

3.6. Calculation method

The emf of the cells (a) may be expressed by

Eq. (1). From this equation, we have

$$E = (E_i^{0'})_0 + S \log y_i + S \log [i] + X_i[i] \qquad (2)$$

If we consider (for each constant I value) that

$$E_i^{0'} = (E_i^{0'})_0 + S \log y_i = \text{constant} \qquad (3)$$

we obtain

$$E = E_i^{0'} + S \log [i] + X_i[i] \qquad (4)$$

From sufficient experimental $(E, [i])$ pairs of values, we can determine the $E_i^{0'}$, S and X_i parameters (corresponding to the fixed I value) using the multiple linear regression method. From the X_i value obtained we can find the $E_i^{0'}$ values corresponding to each experimental [i] value, calculated with Eq. (4), which will be used later.

The dependence of log y_i on ionic strength may be calculated by starting from the expression [7]

$$\phi_i = \log y_i = aI^{1/2} + bI + cI^{3/2} + \cdots \qquad (5)$$

where a, b, c, ... are empirical parameters.

From Eqs. (3) and (5), we obtain

$$E_i^{0'} = (E_i^{0'})_0 + S(aI^{1/2} + bI + cI^{3/2} + \cdots) \qquad (6)$$

By employing a suitable statistical program [11], and from sufficient $(E_i^{0'}, I)$ pairs, one can determine all parameters of Eq. (6) and, therefore, the mathematical relationship between y_i and I.

Similarly, for a cell of type (b), we have

$$E = (E_{OAc}^{0'})_0 - S \log a_{OAc} + X_{OAc} [OAc] \qquad (7)$$

$$E = (E_{OAc}^{0'})_0 - S \log y_{OAc} - S \log [OAc] + X_{OAc} [OAc] \qquad (8)$$

$$E_{OAc}^{0'} = (E_{OAc}^{0'})_0 - S \log y_{OAc} \qquad (9)$$

$$E = E_{OAc}^{0'} - S \log [OAc] + E_j \qquad (10)$$

$$E_{OAc}^{0'} = (E_{OAc}^{0'})_0 - S(aI^{1/2} + bI + cI^{3/2} + \ldots) \qquad (11)$$

The dependence between y_{OAc} and I may be obtained from Eq. (11).

Fig. 1. Y vs. h plot for the $HClO_4$–$NaClO_4$ system ($I = 0.100$ M). Only about one tenth of the experimental points, chosen at random, have been plotted.

4. Results and discussion

In the case of the hydrogen ion, Eq. (4) yields

$$Y = E - S \log h = E_H^{0'} + X_H h \qquad (12)$$

Y values can be obtained from the experimental E and S values. By plotting Y vs h, one obtains a set of points to which a straight line can be fitted (within a given h range), the intercept and slope of which are $E_H^{0'}$ and X_H, respectively. This linearity confirms that y_H remains constant at constant I.

At low h values, where $h \neq [HClO_4]$, the points move away from the straight line; at high h values

it is necessary to take care with the $h/[Na^+]$ ratio. According to Hartley et al. [12] substitution of ca. 5% of the inert electrolyte ions by other ions is possible without appreciable change in the activity coefficients of the latter. Beck and Nagypál [13] estimated this limit to be 20% if the total electrolyte concentration is kept at 3 M. On the other hand, we found a limit of 29%; this means that h cannot exceed 22.5% of the ionic strength of the medium. This fact can be easily observed at $I = 0.1$ M (Fig. 1). At higher I values, no deviation of the linear relationship is noted within the encompassed h range.

The data obtained for the X_H and S parameters are given in Table 1. The Henderson equation [17,18] for the $i(ClO_4)_p$–$NaClO_4$ systems may be simplified to

$$E_j = A_i \log\left(1 + \frac{[i]d}{I}\right) \qquad (13)$$

where A_i and d are functions of $[i]$ and/or λ_i involved in the system. For the ions studied in this work, and using λ_i^0 and data [18,19], we have the following $(A_i; d)$ values: H^+ ($-59.2; 2.55$), Cu^{2+} ($-14.9; -0.889$), Cd^{2+} ($15.7; -0.933$), Pb^{2+} ($9.92; -0.661$) and Ac^- ($59.2; -0.225$). On the other hand, from Eq. (13) and taking into account the X_H values determined for the $HClO_4$–$NaClO_4$ system from Eq. (4), we obtained

Table 1
y_H, pa_H, X_H and S data obtained for the $HClO_4$–$NaClO_4$ system ($h = 0.0100$ M, $T = 25.0 \pm 0.1$ °C)

[a] Calculated for the mean [i] value within the range employed (Eq. (13)).
[b] Calculated by linear regression from (E, log[i]) pairs. In all cases, r values higher than 0.999 were obtained.

$d = 2.28$ as a mean value. The difference between this value and that mentioned above (2.55) could be ascribed to the fact that for the application of the Henderson equation λ_i values should be used instead of λ_i^0 values. As far as the $Me(ClO_4)_2$–$NaClO_4$ and $NaOAc$–$HOAc$–$NaClO_4$ systems are concerned, the determination of liquid junction potentials from experimental data by using Eq. (4) was not possible because these values are of the order of magnitude of the experimental errors, as may be deduced from Table 2. Hence they were calculated through Eq. (13). These calculated values were used for $E_i^{0'}$ determination with Eq. (4), which provides also the X_i values ($X_i = E_j/[i]$).

In the computation of eq. (6) parameters, the following number of data were used: 112 ($E_H^{0'}$, I), 70 ($E_{Cu}^{0'}$, I), 88 ($E_{Cd}^{0'}$, I), 88 ($E_{Pb}^{0'}$, I) and 36 ($E_{OAc}^{0'}$, I). As a result, the following equations were obtained:

$$\phi_H = -0.542I^{1/2} + 0.451I \; (\sigma = 1.01) \tag{14}$$

$$\phi_{Cu} = -1.249I^{1/2} + 0.912I \; (\sigma = 0.63) \tag{15}$$

$$\phi_{Cd} = -0.829I^{1/2} + 0.448I^{3/2} \; (\sigma = 1.32) \tag{16}$$

$$\phi_{Pb} = -0.404I^{1/2} + 0.117I^2 \; (\sigma = 2.03) \tag{17}$$

$$\phi_{OAc} = -0.0370I \; (\sigma = 0.50) \tag{18}$$

The y_i values in Tables 1 and 2 were calculated with these equations. Among the various types of equations tested, none fit the experimental data as perfectly as these do. The coefficient of the first term of Eq. (14) is close to the theoretical A term of the Debye–Hückel equation, which is not the case for the Eqs. (15)–(18). The fitness of these equations to the ($E_i^{0'}$, I) points can be verified from plots shown in Fig. 2 and from statistical data given in connection with Eqs. (14)–(18).

Fig. 2. $E_i^{0'}$ vs. I for the ions studied. The values on the ordinate correspond to ($E_i^{0'}$)$_0$. The symbol's height on the curves represents maximum and minimum experimentally determined $E_i^{0'}$ values.

The proton activity coefficients estimated in this work differ from those reported by Capone et al. [4] at 25 °C, up to $I = 1.00$ M, which is the highest ionic strength stated in their work. However, it is worth noting that they used in the calculations an extended Debye–Hückel expression whose first term comprises the ion size parameter ($\mathring{a}$). It is known that this parameter changes with the composition of the medium and, therefore, it does not convey a sufficiently accurate representation of ion size effect, mainly in electrolyte mixtures [7,14]. The large discrepancy found between the theoretical and experimentally determined A and B parameters for an extended Debye–Hückel equation, i.e.

$$\log y_i = \frac{-AI^{0.5}}{1 + BI^{0.5}} + CI \tag{19}$$

by Uemasu and Umezawa [1], in so far as Cu(II) and Ca(II) ions are involved, makes the above statement clearly apparent. Curves with characteristic minima for the H^+, Cu^{2+}, Cd^{2+} and Pb^{2+} ions were obtained. A straight line, however, fits the ($E^{0'}_{OAc}$, I) points, at least for the I range considered for the $NaOAc$–$HOAc$–$NaClO_4$ system. In the third column of Table 1 we have pa_H values for a 0.0100 M $HClO_4$ solution calculated within the studied I range. Of course, these results could not be obtained with electrodes simply calibrated with buffer solutions [10]. As can be seen, the salt effect is in general significant, suggesting that structural changes of the solvent together with ionic and ion–solvent (hydration) interactions should be taken into account for a realistic description of the systems considered. It is known [20,21] that the Na^+ ion has a weak ordering effect on the water structure, whereas the ClO_4^- ion acts as a powerful structure breaker. This suggests that the ClO_4^- ion should have a dominant role among the structural effects acting on water. The significant changes of the activity coefficients of the H^-, Cu^{2+}, Cd^{2+} and Pb^{2+} ions as the ionic strength increases could be ascribed, at least in part, to the structure-breaking effect fostered by the ClO_4^- anion. This is not the case,

however, for the activity coefficient behaviour of the OAc^- ion; in fact, this ion, a strong structure builder, seems to compensate for the effect of the ClO_4^- ion.

Ionic medium effects on equilibrium constants
Part II[1]. Binary systems comprising some bivalent cations and monocarboxylates in aqueous solution

Abstract

Simple equations were derived relating stoichiometric protonation constants of several monocarboxylates and formation constants associated with 1:1 complexes involving some bivalent cations and selected monocarboxylates, in aqueous sodium perchlorate media, at 25°C, as a function of ionic strength (I), allowing the interconversion of parameters from one ionic strength to another, up to $I = 3.00$ M. In addition, thermodynamic formation constants as well as activity coefficients of the species involved in the equilibria were estimated. The results show that the proposed calculation procedure is very consistent with critically selected experimental data.

Keywords: Activity coefficients; Formation constants; Medium effects

1. Introduction

The scarcity of quantitative studies dealing with weak interactions among ions in aqueous solution and the difficulty in distinguishing these interactions from those arising through ionic medium effects may be the reason for the lack of an adequate treatment concerning the ionic strength dependence of activity coefficients and hence equilibrium constants, including protonation of ligands and the thermodynamic stability of metal

ion complexes. The associated equilibria are of fundamental importance in any area where a knowledge of the chemical form of an element is a prime requirement, such as in "real life" systems (for example, ground-, sea- and wastewaters, blood plasma, urine, gastro-intestinal juices, food extracts) and in research including radioactive waste disposal, assessment of metal-dependent side effects of pharmaceuticals, the bioavailability of metal ions from foods and the use of metal complexes to suppress the activity of microorganisms [1–3].

In view mostly of the aforementioned requirements some progress has been attained regarding

[1] For Part I, see Ref. [12].

the search for procedures allowing the interconversion of equilibrium parameters from one ionic strength to another as well as the estimation of thermodynamic equilibrium constants (i.e. at zero ionic strength). The main approaches employed to reach this purpose have been; (a) use of extended Debye–Hückel equations [4–6]; (b) use of of the specific interaction theory of Brønsted [7]; (c) estimation by chemical trends and free energy relationships, using the library of equilibrium data which already exists in compilations [8]; (d) assessing the robustness of data and models through sensitivity analyses of the type used in modelling radioactive waste disposal sites [3].

It is worth noting that thermodynamic constants are important for setting up correlations aiming at a better understanding of fundamental factors influencing the coordination chemistry of metals and ligands in aqueous solution [5,9–11].

In the current absence of a comprehensive theory that can answer the fundamental questions concerning the dependence of equilibrium constants on ionic strength, it is of considerable interest to find equations (even empirical ones) that would allow equilibrium constants, measured at a given ionic strength, to be recalculated for any other ionic strength.

In a previous work from this laboratory [12] empirical equations relating the molar activity

with the corresponding ones critically selected from the literature [13]. The approach is presently restricted to binary systems comprising some bivalent cations and monocarboxylates (aliphatic and aromatic), in aqueous medium.

2. Experimental

Unless stated otherwise, experimental conditions, apparatus and conventions were the same as previously described [12].

3. Calculation methods

3.1. Protonation constants

Protonation constants (K_H) of acetic acid at different ionic strengths (0.300–3.00 M range) were determined by applying a potentiometric method [14,15]. Acetic acid solutions (0.01052–0.01071 M) made up to the desired ionic strength by adding sodium perchlorate (initial volume 35.00 ml) were titrated with sodium hydroxide solutions (0.0950–0.1000 M) the ionic strength of which were adjusted to a fixed value with sodium perchlorate. The titration vessel was the compartment shown in the right-hand side of the cell:

$-Ag|AgCl$	$[NaCl]_{(aq)} =$ 0.0100 M $[NaClO_4]_{(aq)} =$ $(I - 0.100)M$	$NaClO_{4(aq)}$ $= I$ M	Test solution $[NaClO_4]_{(aq)} =$ I M	GE +

coefficients of H^+, Cu^{2+}, Cd^{2+}, Pb^{2+} and CH_3COO^- (in aqueous solutions, at 25°C) to ionic strength were established. In the present work very simple equations have been derived, making feasible the interconversion of protonation and stability constants, in so far as changes in ionic strength are concerned; also, thermodynamic constants and activity coefficients associated with 1:1 complex species are estimated, via extrapolation of linear relationships. The predictive power of the developed procedure has been evaluated by comparing the calculated constants

3.2. Other equilibrium parameters

For the equilibrium $H^+ + A^- \rightleftharpoons HA$ corresponding to a given monocarboxylic acid, in aqueous solution, the thermodynamic protonation constant is defined as

$$^T K_H = \frac{[HA]}{[H][A]} \frac{y_{HA}}{y_H \cdot y_A} \tag{1}$$

where charges are omitted for simplicity.
From Eq. (1)

$$\log {}^T K_H = \log K_H + \log y_{HA} - \log y_H - \log y_A \tag{2}$$

Table 1

Protonation constants of acetic acid in aqueous solution as a function of ionic strength, adjusted with $NaClO_4$; $T = 25.0 \pm 0.1°C$

I(M)	log K_H	
	This work	Literature [13]
0.100	–	4.56 ± 0.03
0.300	4.54 ± 0.04	–
0.500	4.55 ± 0.01	4.50 ± 0.02
1.00	4.60 ± 0.02	4.58 ± 0.03
2.00	4.79 ± 0.04	4.80 ± 0.01
2.50	4.94 ± 0.01	–
3.00	5.06 ± 0.03	5.015 ± 0.005

and

$$Y = \log K_H - \phi_H - \phi_A = \log {}^T K_H - \phi_{HA} \qquad (3)$$

Given sufficient K_H, ϕ_H, ϕ_A and I values, $\log {}^T K_H$ and ϕ_{HA} can be estimated via linear relationships. Similarly, for the equilibrium $Me^{2+} + A^- \rightleftharpoons MeA^+$ of a divalent metallic cation with a monocarboxylate, the thermodynamic formation constant may be defined as

$$^T\beta_1 = \frac{[MeA]}{[Me][A]} \frac{y_{MeA}}{y_{Me} \cdot y_A} \qquad (4)$$

and

$$Y = \log \beta_1 - \phi_{Me} - \phi_A = \log {}^T\beta_1 - \phi_{MeA} \qquad (5)$$

where β_1 is a stoichiometric formation constant of MeA species. Starting from sufficient (Y, I) pairs, we can calculate $\log {}^T\beta_1$ and ϕ_{MeA} values, also via linear relationships, as will be shown later in this work.

4. Results and discussion

The determined protonation constants for acetic acid, along with critically selected corresponding data from the literature [13] are given in Table 1. These data, coupled with previously estimated parameters [12], ϕ_H and ϕ_{Ac}, allowed the calculation of the associated $\log {}^T K_H$ and ϕ_{HAc} values, via Eq. (3); for this particular case $\phi_A = \phi_{Ac}$ and $\phi_{HA} = \phi_{HAc}$. It was found that a straight line can be nicely fitted to the (Y, $I^{0.5}$) points, giving $\log {}^T K_H$ and ϕ_{HAc} as intercept and slope respectively. The values found are displayed in Table 2. Eq. (3) was also tested for 11 other monocarboxylic acids (aliphatic and aromatic, with and without additional functional groups) by assuming $\phi_{Ac} = \phi_A$. The results are shown in Table 2. Our study has been restricted to only 12 monocarboxylates due to the paucity of critically

selected values from the literature [13]. Very good agreement is observed between literature and calculated $\log {}^{T}K_H$ values; this seems to be more than fortuitous, particularly when the chemical differences among the considered acids are taken into account. The results are somewhat surprising and very gratifying.

Regarding the $(\phi_{HA}/I^{0.5})$ data collected in Table 2, values within the range 0.112–0.155 were obtained for simple carboxylic acids, such as acetic, propionic, butyric, isobutyric, benzoic, furoic and phenylacetic. A higher set of data (i.e. between 0.190 and 0.291) is found for lactic, glycolic, pyruvic and mandelic acids; all these bear additional functional groups adjacent to the carboxyl. A high value (0.232) is provided by formic acid, which is apparently a simple monocarboxylate. However, its anomalous behaviour in aqueous solution is well known [16]. The behaviour of pyruvic acid will be discussed further in connection with its metal ion complexes.

In a similar fashion, Eq. (6) was used for the calculation of $\log {}^{T}\beta_1$ and ϕ_{MeA} associated with several Me(II)–monocarboxylate systems:

$$Y = \log \beta_1 - \phi_{Me} - \phi_{Ac} = \log {}^{T}\beta_1 - \phi_{MeA} \qquad (6)$$

By plotting Y vs. I, very good linear relationships are obtained for all systems considered in this work; some examples are given in Figs. 1–3. The calculated values for $\log {}^{T}\beta_1$ and (ϕ_{MeA}/I) are displayed in Table 3. Again, the set of formation constants used is limited by the paucity of reliable data for all bivalent cations other than Cu^{2+}, for which the gap is less pronounced. Within the restricted database available a very good agreement is generally found between the literature data and the corresponding values calculated via application of Eq. (6), in so far as $\log {}^{T}\beta_1$ values are concerned. As can be seen in Table 3 and Figs. 1–3, Eq. (6) was tested, for most of the considered systems, by putting the $\phi_{Me} = \phi_{Cu}$, ϕ_{Cd} or ϕ_{Pb}. The overall conclusion is that the effectiveness of the ion-selective electrodes in giving good estimates of y_{Me} follows the order Cu > Cd > Pb; it is noteworthy that this same order prevails with regard to the reliability of the aforementioned electrodes for analytical purposes [17].

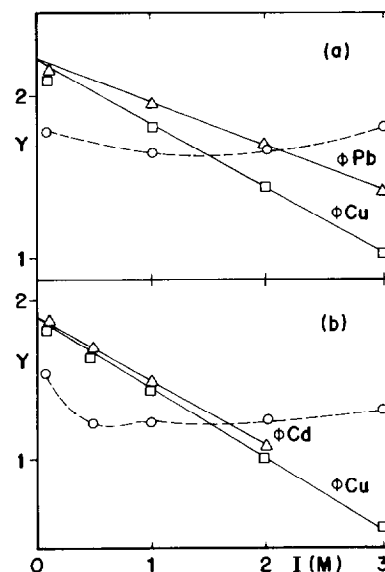

Fig. 1. Me^{2+}–acetate systems (a) Cu^{2+}; (b) Cd^{2+}. (○) $Y = \log \beta_1$; (□, △) $Y = \log \beta_1 - \phi_{Me} - \phi_{Ac}$. The ϕ_{Me} used for each correlation is indicated inside the Figure. The open circles are joined by a broken line just as a guide for the eye.

Most of the (ϕ_{MeA}/I) values found are within the range 0.3–0.4, the mean value being 0.38, except for the Hg^{2+}–monocarboxylate and Cu^{2+}–pyruvate complexes. The deviations for the Hg^{2+} complexes can be ascribed to an intrinsic behaviour of this cation as compared with the other ones considered in this work and/or to the greater uncertainty in the critically selected stoichiometric and thermodynamic stability constants for mercuric complexes, as shown in Table 3. It is known that the complexation of metal ions by pyruvate involves α-keto, diol (hydrated enol) and dimer species of this ligand [18–20]. The formation constants reported in the literature describe the net complexation; only a few papers give estimates for the individual complexation reactions, associated with each form of pyruvate in aqueous solution [19,20]. Furthermore, this feature seems to be characteristic for many α-keto-carboxylates [21–23]. Therefore, the uncertainty in the quoted formation constants for pyruvate complexes [13] is understandable and could explain, at least in part, why the ϕ_{MeA} for Cu^{2+}–pyruvate lie outside the observed range for most of the other systems encompassed in this work.

Assuming $\phi_{MeA} = 0.4\,I$ and taking into account that $\phi_{Ac} = 0.037\,I$ (see Ref. [12]), Eq. (6) can be rearranged as

$$\log \beta_1 \approx \log {}^T\beta_1 + \phi_{Me} - 0.36\,I \qquad (7)$$

Eq. (7) was tested in connection with systems for which β_1 is available at only one ionic strength in addition to an estimate for ${}^T\beta_1$. The results are shown in Table 4. In spite of the very few considered systems, it seems that Eq. (7) is able to predict stoichiometric constants from the corresponding thermodynamic ones and vice versa, at least for 1:1 Cu^{2+}–monocarboxylate complexes within about a tenth of a log unit. Such estimated values should have sufficient accuracy for most studies dealing with the modelling of environmental or physiological systems [8].

This work was based on the relatively small number of available critical protonation and stability constants for carboxylates and their Me^{2-} complexes [13]. The full test for the presently proposed calculation procedure requires the development of the largest possible database of reliable stability constants and associated protonation constants.

Fig. 2. Me^{2+}–acetate systems: (a) Pb^{2+}; (b) Zn^{2+}. (○) $Y = \log \beta_1$; (+, □, △) $Y = \log \beta_1 - \phi_{Me} - \phi_{Ac}$. The ϕ_{Me} used for each correlation is indicated inside the Figure. The open circles are joined by a broken line just as a guide for the eye.

Fig. 3. Me^{2+}–monocarboxylate systems: (a) Ni^{2+}–acetate; (b) Zn^{2+}–glycolate. (○) $Y = \log \beta_1$; (△) $Y = \log \beta_1 - \phi_{Cu} - \phi_{Ac}$. The open circles are joined by a broken line just as a guide for the eye.

An inherent advantage of the proposed methodology is that through linear relationships, reliable estimates of thermodynamic constants can be obtained, via extrapolation. There are a number of techniques for estimating thermodynamic stability constants [24–26]; these are more commonly obtained by extrapolating stoichiometric constants, determined at several ionic strengths, to infinite dilution. Plots of $\log \beta_1$ (or $\log K_H$) against I, I^2, $I^{1/2}$, $I^{1/3}$, $I^{2/3}$, etc. are sometimes extrapolated by eye or by using complex functions such as the right-hand side of Eq. (8):

$$\log {}^T\beta_1 = \log \beta_1 - \frac{AZ_+ \cdot Z_- I^{0.5}}{1 + aBI^{0.5}} - CI \qquad (8)$$

against I or $I^{0.5}$, where a, A, B and C are constants, some or all of which may be treated as adjustable parameters [24,25]. None of these extrapolations are very reliable, except in a few favourable cases (see, e.g., Ref. [24]). The functions involving $\log \beta_1$ (or $\log K_H$) and ionic strength are markedly curved for most systems (i.e., of the type shown in Figs. 1–3, particularly Fig. 3a), making extrapolations to $I = 0$ rather uncertain. In fact is has been shown that the

[c] Doubtful value, according to Ref. [13].

deviation for values of $^T\beta_1$ obtained by using different extrapolation procedures may amount to several hundred percent [25,26]. Thermodynamic stability constants for two systems, namely Cu^{2+}–methoxyacetate and Pb^{2+}–glycolate, for which the corresponding values have not yet been assigned [13], were calculated in this work and are given in Table 3.

Another gratifying feature of our procedure is the fact that its good predictive power is not limited only to systems for which ϕ_{Me} parameters are available; thus, good estimates of thermody-

namic stability constants were also obtained for Co^{2+}, Ni^{2+}, Zn^{2+} and Hg^{2+} complexes. However, ϕ_A is available exclusively for acetate; in spite of this, protonation and formation constants in line with critically selected ones could be achieved for 13 monocarboxylates, other than acetate (Tables 2 and 3). This lends some support to the assumption made in the first part of this series [12], namely that similar ions should display closely related equilibrium parameters.

In some of the Y vs. I correlations it has been noted that one point moves away from the linear

relationship built upon the remaining points, e.g. the Y value corresponding to the Zn^{2+}–glycolate system, at $I = 1.00$ M (Fig. 3b). This suggests that the associated β_1 value might be in error and that the system probably deserves reinvestigation. Studies on systems comprising other metal ions and ligands are currently in progress in this laboratory.

Abstract

The equilibrium water vapor pressures for the thermal dehydration of $Mg(HCO_2)_2 \cdot 2H_2O$, $Mn(HCO_2)_2 \cdot 2H_2O$ and $Co(HCO_2)_2 \cdot 2H_2O$ were measured by means of the transpiration method. These hydrates form isomorphous crystals with space group $P21/c$. In this structure, the water molecules lie in the planes parallel to the (100) planes. Thermodynamic data such as ΔG, ΔH and ΔS were derived from the values of the water vapor pressures. The relationship between these thermodynamic data and the crystal structures is discussed.

Keywords: Dehydration; Equilibrium water vapor pressure; Metal formate dihydrates; Transpiration method

1. Introduction

Crystalline hydrates cannot be distinguished from other solid reactants on chemical or structural criteria; however, the considerable interest which has been directed to the investigation of the dehydration of this group has made it convenient to discuss them as a single class. Generally, dehy-

drations are reversible reactions and the ease of water escape is influenced by the product phase, because such residual material tends to diminish the rate of diffusion of water from the reaction interface.

It is also known that the rate of thermal dehydration of hydrates is affected by the atmospheric water vapor pressure. Smith and Topley [1,2] found the phenomenon of an unusual variation in the dehydration rate with the atmospheric water vapor pressure. They reported that the rate constants for the dehydration of manganese oxalate dihydrate and copper sulfate pentahydrate vary unusually with the partial pressure of atmospheric water vapor. When the water vapor pres-

---

sure increases, the rate constant for the dehydration decreases sharply at first, passes through a minimum, increases more slowly and then decreases. This unusual phenomenon is known as the Smith–Topley effect. Garner and co-workers [3,4] carried out similar studies of copper sulfate pentahydrate and potassium ammonium chrome alum. A similar phenomenon has also been observed by Dollimore and co-workers [5,6] in the dehydration of calcium oxalate monohydrate and magnesium oxalate dihydrate. Recently, we have discovered similar phenomena in the dehydration of zinc, erbium and yttrium formate dihydrates [7–9].

Although the kinetics of the thermal dehydration of hydrates have been extensively studied by means of thermal analyses such as thermogravimetry (TG) and differential scanning calorimetry (DSC), the equilibrium water vapor pressures of the hydrates have been scarcely reported. It is very important to accumulate such fundamental thermodynamic quantities as the equilibrium water vapor pressure.

In this work, the equilibrium water vapor pressures for the dehydration of magnesium, manganese and cobalt formate dihydrates, which are known to form an isomorphous crystal structure with space group $P21/c$ [10,11], were measured by means of the transpiration method [12,13] using laboratory-made apparatus. The derived thermodynamic quantities such as the enthalpy changes, entropy changes and free energy changes for these thermal dehydrations were determined. It is of interest to discuss the relationship between the crystal structures and the thermodynamic quantities derived from the equilibrium water vapor pressures for the thermal dehydration of these hydrates.

2. Experimental

2.1. Reagents

Magnesium, manganese and cobalt formate dihydrates were purchased from Wako Pure Chemical Industries and recrystallized from a 10^{-4} M solution of formic acid. The crystals were air-

dried at room temperature. These samples were identified by means of TG and IR spectra. Each sample was pulverized in a mortar and pestle.

2.2. The transpiration apparatus

The equilibrium water vapor pressures for the dehydrations were measured using the laboratory-made apparatus shown in Fig. 1 [12,13]. Dry nitrogen at a known flow rate was passed through a loosely fitted plug of Pyrex glass wool into the saturation zone. This zone was about 80 mm in length in a 20 mm diameter Pyrex glass tube. The powdered sample (about 5 g) was piled in ridges to a depth of about 10 mm. A nitrogen stream saturated with the water vapor produced was discharged through another plug of Pyrex wool and a 20 mm length of 0.05 cm capillary. The exit gases were passed to absorbers made of magnesium perchlorate for analysis. The temperature of sample was determined with a chromel–alumel thermocouple fitted in the central thermocouple well shown in Fig. 1. The temperature of the furnace was controlled to ± 0.5 K with an EC-205 controller (Ohkura).

The equilibrium water vapor pressure, P_{H_2O}, was obtained in accordance with the equation

$$P_{H_2O} = \frac{n_{H_2O}}{n_{H_2O} + n_{N_2}} P(\text{a.p.})$$

where n_{H_2O} is the number of moles of water absorbed by the absorber in a given time interval, n_{N_2} is the number of moles of carrier nitrogen

Fig. 1. Transpiration apparatus. 1, Flow control bulb; 2, dry column; 3, electric furnace; 4, reaction vessel; 5, temperature controller; 6, absorption vessel; a, thermocouple; b, capillary zone; c, glass wool.

flowing in a given time interval and P(a.p.) is atmospheric pressure (1 atm).

2.3. Thermal analyses

The TG and differential thermal analysis (DTA) curves were simultaneously recorded on a Rigaku TAS 200-TG–DTA system [14,15]. About 10 mg of sample were weighed into a platinum crucible and measured using α-alumina as a reference material. The enthalpy change for the dehydration was determined from the DSC curve recorded on a Rigaku TAS 200-DSC instrument [14]. The instrument was calibrated with the enthalpy change of the phase transition of potassium nitrate (400.9 K, $\Delta H = 5.4$ kJ mol^{-1}) and the enthalpy changes of melting gallium, indium, tin, lead and zinc (Ga, 309.94 K, $\Delta H = 5.59$ kJ mol^{-1}; In, 430 K, $\Delta H = 3.3$ kJ mol^{-1}; Sn, 505 K, $\Delta H = 7.07$ kJ mol^{-1}; Pb, 600.6 K, $\Delta H = 4.77$ kJ mol^{-1}; and Zn, 692.7 K, $\Delta H = 6.57$ kJ mol^{-1}) [16].

2.4. X-ray powder diffraction and Fourier transform (FT) IR spectrophotometry

The X-ray powder diffraction patterns were obtained with Rigaku Geigerflex RAD-γA and RAD-R diffractometers equipped with a high-temperature sample holder [17]. Cu Kα radiation, a nickel filter and a graphite monochromator were used in all measurements. The diffraction data were taken in steps of width 0.02°.

IR absorption spectra was measured from 400 to 4500 cm^{-1} in KBr discs with a Horiba FT-IR spectrophotometer.

3. Results and discussion

TG–DTA of the hydrates (Fig. 2) showed that the dehydration took place as a one-stage reaction:

$$M(HCO_2)_2 \cdot 2H_2O(s) \rightarrow M(HCO_2)_2(s) + 2H_2O (g)$$

Fig. 3 shows the relationship between the flow rate of nitrogen carrier gas and the values of the equilibrium water vapor pressure, P_{H_2O}, for the
Fig. 2. TG (solid lines) and DTA (dotted lines) curves for the thermal dehydrations of magnesium, manganese and cobalt formate dihydrates.
Fig. 3. Relationship between the flow rate of carrier gas and P_{H_2O}.

dehydration of magnesium formate dihydrate at various temperatures. When the flow rate increases, P_{H_2O} first decreases, passes through a constant value and then decreases. A similar tendency was observed for the other hydrates, and is explained as follows. At a slow flow rate, the water molecules produced appear to self-diffuse to

Table 1

P_{H_2O} for the dehydration of magnesium, manganese and cobalt formate dihydrates

Sample	Temperature (K)	P_{H_2O} (Torr)
$Mg(HCO_2)_2 \cdot 2H_2O$	408	24.7 ± 1.08
	413	33.6 ± 0.768
	418	48.2 ± 0.349
	428	86.8 ± 3.00
	433	121 ± 3.86
$Mn(HCO_2)_2 \cdot 2H_2O$	368	62.1 ± 2.99
	373	99.0 ± 4.24
	383	164 ± 5.45
	388	211 ± 6.45
$Co(HCO_2)_2 \cdot 2H_2O$	403	33.7 ± 1.90
	413	60.8 ± 0.693
	418	82.3 ± 4.25
	423	106 ± 1.30

the absorption tube, so P_{H_2O} shows an apparently high value, and at a higher flow rate the carrier gas cannot be saturated with the dissociated water molecules. An average of approximately constant values obtained during the medium flow rate region was adopted as the equilibrium water vapor pressure, P_{H_2O}, for the given temperature.

The P_{H_2O} values were determined for various temperatures around the peak temperatures of the

DTA curves of these dihydrates (Fig. 2), and the values are shown with the standard deviations in Table 1. The enthalpy changes, $\Delta H°$ were calculated from the equation on the basis of the temperature dependence of P_{H_2O}:

$$2 \ln\left(\frac{P_{H_2O}}{Torr}\right) = \frac{-\Delta H°}{RT} + \frac{\Delta S°}{R}$$

The free energy changes could also be obtained from the equation

$$\Delta G = -2RT \ln\left(\frac{P_{H_2O}}{Torr}\right)$$

and the values at 373 K, $\Delta G(373$ K) are shown in Table 2 together with the temperatures, T_i, at which weight loss of the dehydration is initiated, and the enthalpy change, $\Delta H(DSC)$, measured directly by means of DSC.

The values of $\Delta H°$ are larger than those of $\Delta H(DSC)$. The enthalpy change for the dehydration consists of a number of components, due to the energy for the dissociation of the coordinated water molecules, lattice energy, hydrogen-bond energy, etc. Although further analysis of the enthalpy change cannot be given at present because the crystal structures of dehydrated salts have not yet been clarified, the difference between $\Delta H°$ and $\Delta H(DSC)$ may be discussed as follows.

Table 2

Thermodynamic data derived from P_{H_2O}

Sample	$\Delta H°$ (kJ mol^{-1})	$\Delta H(DSC)$ (kJ mol^{-1})	$\Delta G(373$ K) (kJ mol^{-1})	$\Delta S°$ (J mol^{-1})	T_i (K)[a]
$Mg(HCO_2)_2 \cdot 2H_2O$	186 ± 2.74	149 ± 1.79	-3.90	509	392
$Mn(HCO_2)_2 \cdot 2H_2O$	140 ± 12.4	112 ± 1.58	-27.9	451	367
$Co(HCO_2)_2 \cdot 2H_2O$	163 ± 2.72	115 ± 2.72	-9.70	463	390

[a] Initiation temperature of thermal dehydration.

Table 3

Crystal data for magnesium, manganese and cobalt formate dihydrates

| Sample	a(Å)	b(Å)	c(Å)	β(°)	r_{M2+}(Å)[a]	Interatomic distance (Å)	
						$M-H_2O(1)$	$M-H_2O(2)$
$Mg(HCO_2)_2 \cdot 2H_2O$	8.69	7.18	9.39	97.6	0.86	2.08	2.06
$Mn(HCO_2)_2 \cdot 2H_2O$	8.86	7.29	9.60	97.7	0.97	2.24	2.16
$Co(HCO_2)_2 \cdot 2H_2O$	8.63	7.06	9.21	96.0	0.79	2.07	2.06

[a] Ionic radius of metal ion.

Fig. 4. Projection of crystal structure of $M(HCO_2)_2 \cdot 2H_2O$ on the (010) plane.

Generally, the crystal structure of a hydrate must be broken by the dehydration and an amorphous dehydrated product may be formed immediately after the dehydration at the equilibrium state, and ΔH° seems to correspond to the reaction

$M(HCO_2)_2 \cdot 2H_2O(crystal)$

$\rightarrow M(HCO_2)_2(amorphous) + 2H_2O$ (g)
Crystalline anhydride products were obtained after the DSC measurement, so the value of $\Delta H(DSC)$ may correspond to the reaction

$M(HCO_2)_2 \cdot 2H_2O$ (crystal) $\rightarrow M(HCO_2)_2$ (crystal) + $2H_2O$ (g)
Therefore, the difference between ΔH° and $\Delta H(DSC)$ seems to be attributable to the enthalpy change for the exothermic crystallographic process:

$M(HCO_2)_2(amorphous) \rightarrow M(HCO_2)_2(crystal)$
It is known that the title compounds have a isomorphous crystal structure. The lattice parameters of these hydrates are shown in Table 3. The crystals are monoclinic, with space group $P21/c$. The unit cell contains two kinds of metallic ions, which are not equivalent. One of them is coordinated by six carboxyl oxygen atoms and the other is coordinated by two carboxyl oxygen atoms and four oxygen atoms of water molecules. Both are in an octahedral form, with the water molecules lying on the plane parallel to the (100)

planes (Fig. 4). The kinetics of the dehydrations of these salts was described by a two-dimensional phase boundary reaction model [7,18].

The T_i, ΔH° and $\Delta G(373$ K) values are correlated to the thermal stability of these hydrates, and the stability may be related to the strength of the $M-OH_2$ coordination bond. If the strength of the $M-OH_2$ bond is assumed to depend on the electrostatic force between the metallic ion and the lone pair electrons of oxygen of the water molecule, the bond strength is dependent on the length of the $M-OH_2$ bond. It is noteworthy that a mutual correlation appears to be found among T_i, ΔH° and $\Delta G(373$ K) and the bond length of the $M-OH_2$ bond.

Modified spectrophotometric method for the determination of selenium in environmental and mineral mixtures using 2,3-diaminonaphthalene

K.N. Ramachandran*, G.S. Kumar

Shriram Institute for Industrial Research, 14 15 Sadarmangala Industrial Area, Whitefield Road, Bangalore, 560-048, India

Abstract

Reaction of selenium with 2,3-diaminonaphthalene was reinvestigated with bromide ion as a catalyst. In acid medium, selenium reacts with the above reagent to form a complex extractable with cyclohexane and with an absorption maximum at 378.5 nm. The molar absorptivity of the complex is 17.5×10^3 l mol^{-1} cm^{-1}. Beer's law is obeyed in the range 0.5–12 mg l^{-1}. The method is reproducible and the standard and relative standard deviation for seven replicate analyses of 2 mg l^{-1} of selenium are 0.05 absorbance units and 2.5%, respectively. The limit of detection is 0.012 mg l^{-1}. The method was optimized for the determination of selenium in water, soil, cereal and mineral mixtures and cattle feed and was compared with the reported 2,3-diaminonaphthalene method.

Keywords: Selenium; Spectrophotometry; 2,3-Diaminonaphthalene

1. Introduction

Selenium is a widely distributed metalloid with ubiquitous properties. As its toxicological and physiological importance has become more evident, there been increasing interest in the determination of this element [1–3]. The most commonly used methods are atomic absorption spectrometry (Hydride generation and electrothermal atomization), molecular fluorescence spectrometry, gas chromatography and spectrophotometry. Spectrophotometric methods are popular because of their simplicity and are based on piazselenol

complex formation between the reagent and selenium. The common reagents are o-diamines, 3,3-diaminobenzidine [4], dithizone, o-phenylenediamine [5], 2,3-diaminonaphthalene [6], 8-hydroxyquinoline [7,8], 6-amino-1-naphthol-3 sulphonic acid (J-acid) [9,10] and 2,3-diamino-1,4-dibromonaphthalene [11]. These are sensitive to pH, temperature and other physico-chemical parameters. Some of the colour development reactions are very slow and are susceptible to interferences from a large number of ions. 2,3-diaminonaphthalene is a widely used reagent for standardization and pharmaceutical testing owing to its lack of toxicity and ready availability [12]. Several modifications of this method has been

---

* Corresponding author.

published in recent years [12–15]. These methods require extraction, pH optimization and a long time (110 min) for colour development and cannot be applied to cattle feed or mineral mixtures.

In this work, the 2,3-diaminonaphthalene method [6] was modified and applied to the determination of selenium in the above samples. The reagent was modified by adding hydroxylammonium hydrochloride and potassium bromide and the analytical parameters were evaluated. The method was applied to the determination of selenium in water, soil, cereal and cattle feed samples and was compared with the reported method.

2. Experimental

2.1. Apparatus

A Hitachi Model 3021 double-beam UV–visible spectrophotometer with 10 mm matched silica cells was used for all spectral measurements. pH measurements were made with a Philips pH meter.

2.2. Reagents

All reagents were of AnalaR grade. Selenium-free water was prepared by sub-boiling of deionized water.

2.2.1. Selenium solutions

A stock standard solution of selenium was prepared from metallic selenium as reported [15]. Working standard solutions were prepared by appropriate dilution of the stock standard solution.

2.2.2. 2,3-diaminonaphthalene

(A) A 3×10^{-3} mol l^{-1} solution of the reagent was prepared by dissolving 100 mg of the reagent in water along with 500 mg of hydroxylammonium chloride by slow heating. This was diluted to 100 ml and stored in an amber-coloured bottle at 4 °C. The reagent was prepared 1 h before use.

(B) A 50 ml volume of the above solution was taken in an amber-coloured volumetric flask and 25 mg of potassium bromide were added. The

solution was shaken well and filtered. This reagent was used for the present investigation.

2.3. Procedure

2.3.1. Preparation of calibration graph

To an aliquot of solution containing 5–60 μg (1–10 ml) of selenium in a 25 ml boiling tube, 2 ml of reagent B were added and the pH was adjusted to 2 by dropwise addition of 1 mol l^{-1} HCl. The solution was then kept in a boiling water-bath for 5 min. The solution was allowed to cool and the piazselenol complex was extracted into 10 ml (5 × 2 ml) of cyclohexane. The cyclohexane layer was dried over anhydrous sodium sulphate. The absorbance of the solution was measured at 378.5 nm against a reagent blank.

2.3.2. Determination of selenium in water

To an aliquot of 100 ml of sample in a distillation flask, 1 g of potassium bromide and 10 ml of sulphuric acid were added and distilled as reported [6]. The distillate was collected in 5 ml of reagent B and analysed as above.

2.3.3. Selenium in soil samples

Depending on the available selenium concentration, 5 g of soil sample were place in a steam distillation flask with 200 ml of water and stirred thoroughly with a magnetic stirrer. A 5 ml volume of 10% sodium hydroxide solution was added and the mixture was concentrated to 50 ml by heating under vacuum. To this, 500 mg of potassium bromide were added after acidification with hydrochloric acid. The contents were distilled as reported [6] and the distillate was collected in 5 ml of reagent solution in a 100 ml impinger.

2.3.4. Determination of selenium in cereals and plant materials

A 5 g amount of cereal was placed in a 100 ml Kjeldahl flask and heated with selenium-free nitric acid for 20 min, 0.5 ml of perchloric acid was added and the mixture was heated gently with stirring in a fume-hood for 10 min. After cooling, 10 ml of water were added and the solution was heated for another 10 min. The contents were diluted to 50 ml after adding 10 ml of 0.1 mol l^{-1}

EDTA solution and analysed as recommended in Section 2.3.1.

2.3.5. Determination of selenium in mineral mixtures/cattle feed

For free selenium, 1 g of sample was taken in a flat-bottomed flask, 10 ml of water were added and the mixture was stirred at 50 °C for 10 min. The contents were filtered through a 0.45 μm filter under suction. The filtrate was acidified with HCl to pH 2 and analysed as above.

For total selenium to 1 g of the mineral mixture 10 ml nitric acid were added and digested for 10 min. To this 25 ml of water were added, filtered and the filtrate was analysed as recommended above.

3. Results and discussion

The absorption spectrum of the complex extracted with cyclohexane shows an absorbance maximum at 378.5 nm, whereas the reagent blank has negligible absorbance at this wavelength. The absorption was a linear function of concentration of selenium in the range 0.5–12 mg l^{-1}. The apparent molar absorptivity was 17.5×10^3 mol^{-1} cm^{-1}. The reproducibility of the method was assessed by calculation of the standard and relative standard deviations for a 2 mg l^{-1} solution of selenium, the values for seven replicate analyses being 0.05 absorbance units and 2.5%, respectively. The corresponding values for selenium using the reported method [6] were 0.092 absorbance units and 3.9%.

Under the optimum conditions, 6×10^{-3} mol l^{-1} of the reagent solution was sufficient for complete colour development. The effect of temperature on the colour development reaction was studied. The colour development requires 100–120 min at room temperature when the reagent mixture reported in the literature [6] is used. At higher temperature the reaction was not reproducible, probably owing to decomposition of the coloured complex. The optimum temperature range for complete colour development reaction was 80–100°C. The colour development reaction also depends on the pH of the solution. Maxi-

mum absorbance was obtained in the pH range 2 ± 0.3.

The effect of foreign ions on the determination of selenium was studied. The tolerance level for some of the investigation ions (in mg l^{-1}) are Ag$^+$, K$^+$, Ba^{2+} 5000; V^{5+}, Ca^{2+} 4800; Cu^{2+} 2500; Fe^{2+}, Fe^{3+}, 1200; Sb^{3+} 1000; Te^{4+} 800; Ce^{3+} 750; NO$_3^-$, NO$_2^-$, SO$_4^{2-}$ 1000; and Zn^{2+}, Bi^{3+}, Cd^{2+}, Sn^{2+} 250. Since most oxidants and reductants interfered, selenium was separated from the samples (soil, cereal and cattle feed) prior to its determination.

The presence of bromide ion enhances the colour development reaction and improves the precision of the method. The bromide ion helps the quantitative conversion of other forms of selenium to selenium(IV), which reacts with the dye in the bromide environment more rapidly and forms the complex. The role of bromide ion in the system is purely catalytic and even 5 ml of 2% bromide solution did not interfere in the reaction. Addition of bromide to the reagent makes it more stable at room temperature. It was found that in the presence of bromide ions at temperatures above 80°C the colour development reaction was fast and reproducible.

3.1. Application

The method was applied to the determination of selenium in several samples of water, cereals and mineral mixtures. The results (Table 1) were compared with those for the reported 2,3-diaminonaphthalene method [6]. The results obtained by the reported method [6] were high owing to interferences from other metal ions.

3.2. Comparison with another method

The proposed method has been compared with another reported method [6]. The current modification makes the reaction fast and enhances the reproducibility. Although the present method is less sensitive than J-acid methods, the modification is significant in view of its wide application. The proposed method will be useful for the accurate determination of selenium especially in complex mineral matrices.

Table 1
Application of the method[a]

Sample	Amount taken	Se added (mg l^{-1})	Se found (mg l^{-1})[b]		Recovery (%)	
			A	B	A	B
Water	5 ml	2	1.95	1.97	97.5	98.5
		4	3.81	3.95	95.3	98.7
		8	7.45	7.87	93.1	98.3

Catalytic effect of some inorganic ligands on a ligand substitution reaction involving mercury(II) and its application as a differential kinetic method of analysis[1]

Shinkichi Yamada*, Fumihiro Umika, Motoshi Nakamura, Shigeru Nakamura

Laboratory of Analytical Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432, Japan

Abstract

To design a sensitive and selective kinetic method for determining a catalyst, the kinetics of the ligand substitution reaction between the mercury(II)–4–(2-pyridylazo)resorcinol complex and 1,2-cyclohexanediamine-N,N,N',N'-tetraacetic acid together with the catalytic effect of some inorganic ligands on this reaction were studied. The rate constant for a catalyzed reaction path was found to be linearly correlated with the electron donor constant of the catalyst. From this correlation, the difference in reactivity between sulfite or thiosulfate and sulfate was established. Under the selected conditions, sulfite up to 1.5×10^{-6} M and thiosulfate up to 7×10^{-7} M could be determined with detection limits of 3×10^{-8} and 2×10^{-8} M in the presence of 10 000 and 25 000-fold molar amounts of sulfate, respectively. The tolerance level in the determination of 1×10^{-6} M of sulfite and 4×10^{-7} M of thiosulfate was studied for 15 inorganic anions and 44 metal ions.

Keywords: Differential kinetic analysis; Inorganic ligand catalysis; Ligand substitution reaction; Mercury(II)

1. Introduction

Ligand substitution reactions of a metal–chromogenic ligand complex (MR) with a polycarboxylic- or aminopolycarboxylic-type multidentate ligand (Y) can be written as

* Corresponding author.

[1] Presented at the 1995 International Chemical Congress of Pacific Basin Societies (PACIFICHEM '95) in the Symposium on Kinetic and Mechanistic Aspects of Analytical Chemistry, Honolulu, Hawaii, USA, December 17–22, 1995.

$$MR + Y \xrightarrow{k_f} MY + R \tag{1}$$

charges are omitted for simplicity, where k_f is the overall forward rate constant. This reaction system has been widely used in inorganic differential kinetic analysis [1–4]. It has been found that some reactions are catalytically accelerated by an additional ligand (A) and this catalytic effect provides a basis for the kinetic determination of the ligand carrying such a catalytic feature [5,6].

From mechanistic considerations concerning the formation constant of a mixed-ligand complex

[7,8], the catalytic effect of the additional ligand A on the substitution reaction (1) is found to be described by [9]

$$\log (k_f^A / k_f) = \alpha E(A) + \beta H(A) + \gamma E(A) \qquad (2)$$

where k_f^A is the overall rate constant for the catalyzed reaction path, E and H are the electron donor constant and basicity constant of catalyst A, respectively (their values are normalized to zero for A = H_2O and have been given for typical monodentate ligands [10] and some selected multidentate ligands [11] and α, β and γ are constants characteristic of the metal ion M; the values of α and β have been estimated from the stability of the metal complex [10] and that of γ from the reactivity of the metal ion and its complexes [9,12,13]).

For M = Hg^{2+}, which is a typical soft metal ion with negligibly small β and γ values compared with α, we have

$$\log (k_f^A / k_f) = \alpha E(A) = 5.8 E(A) \qquad (3)$$

With the value of $E(A)$, it has been demonstrated [9] that the catalytic effect of halide ions on the ligand substitution reaction of the mercury(II)-4-(2-pyridylazo)resorcinol (PAR; H_2R) complex with 1,2-cyclohexanediamine-N,N,N',N'-tetraacet-ic acid (CDTA; H_4Y) can be described by Eq. (3).

When the catalytic effect of an additional ligand other than halides on this ligand substitution reaction is assumed to be dscribed also by Eq. (3), some interesting differences in reactivity between related species are found. For example, the values of k_f^A for A = SO_3^{2-} and SO_4^{2-} are estimated to be $10^{14.0}$ and $10^{3.4}$ times larger than that of k_f, respectively. This marked acceleration effect of SO_3^{2-} and the large difference in reactivity between SO_3^{2-} and SO_4^{2-} provide an opportunity to design a sensitive and selective kinetic method for determining sulfite in the presence of sulfate with this reaction system.

In order to demonstrate this, we studied the kinetics of the substitution reaction between the Hg(II)-PAR complex and CDTA together with the catalytic effect of some inorganic ligands involving sulfate and sulfite.

2. Experimental

2.1. Reagents

All chemicals were of reagent grade. A solution of mercury(II) was prepared by dissolving the oxide in perchloric acid. The concentrations of mercury(II) and perchloric acid in the stock solution were 1.00×10^{-2} and 1 M, respectively. PAR and CDTA (Dojindo, Japan) were dissolved in 2.5 equivalents of sodium tetraborate and 2 equivalents of sodium hydroxide, respectively. The stock solutions used to study the effect of diverse ions were prepared by dissolving the corresponding sodium or potassium salt and the corresponding nitrate or perchlorate in distilled water for anions and metal ions, respectively. An equivalent amount of CDTA was added to the stock solution of sulfite in order to prevent possible air oxidation of sulfite catalyzed by trace amounts of heavy metal ions in the salt. This stock solution was freshly prepared just before use.

2.2. Measurements

Absorption spectra and absorbances were measured with a UV-3100 spectrophotometer (Shimadzu, Japan). Reactions were started by mixing the Hg(II)-PAR solution and CDTA solution with an MX-7 mixing device (Otsuka Electronics, Japan). The changes in absorbance at 500 nm were recorded as a function of reaction time. The temperature of the reaction solutions was maintained at $25.0 \pm 0.1°C$. The ionic strength (I) was maintained at 1 M with sodium perchlorate. The pH in the reaction solution was adjusted with borate buffer and was measured with a IM-20E digital ion meter (Toa Denpa, Japan) and a glass electrode.

3. Results and discussion

Among various chromogenic ligands [14,15] which form highly colored and water-soluble complexes with mercury(II) in weakly alkaline media, PAR was selected as R in Eq. (1). The mercury(II)-PAR complex was stable in the pres-

ence of a large excess (higher than 7×10^{-4} M) of PAR over the pH range 8.4–9.1. Employing CDTA, ethylenediamine-N,N,N',N'-tetraacetic acid (EDTA), glycol ether diamine-N,N,N',N'-tetraacetic acid (GEDTA) and diethylenetriamine-N,N,N',N'',N''-pentaacetic acid (DTPA) as Y in Eq. (1), the time necessary for complete substitution of the mercury(II)–PAR complex with ligand Y was studied at pH 9. This was found to be 15 min for 1×10^{-4} M CDTA, 30 s for 2×10^{-5} M EDTA and 1×10^{-4} M GEDTA and 20 s for 1×10^{-4} MDTPA. CDTA was therefore selected as the substitution ligand for the mercury(II)–PAR complex.

3.1. Substitution of mercury(II)–PAR complex with CDTA

Under the present experimental conditions in which $C_{Hg} = 1 \times 10^{-5}$ M, $C_{PAR} = (0.8-1) \times 10^{-3}$ M, $C_{CDTA} = (0.5-2) \times 10^{-4}$ M and pH = 8.4–9.1 (borate buffer), the reaction can be described as [5]

$$HgR_2{}^{2-} + HY^{3-} + H^+ \rightarrow HgY^{2-} + 2HR^-$$

$$(4)$$
and the rate equation as

$$-d[HgR_2{}^{2-}]/dt = k_{0(H,R,Y)}[HgR_2{}^{2-}]$$ (5)

The conditional rate constant $k_{0(H,R,Y)}$ involving concentrations of hydrogen ion, PAR and CDTA was determined from the spectrophotometric first-order plot. The values of $k_{0(H,R,Y)}$ obtained at various $[H^-]$, $[HR^-]$ and $[HY^{3-}]$ were analyzed in the same manner as in Ref. [5]. $k_{0(H,R,Y)}$ was thus found to be expressed by

$$k_{0(H,R,Y)} = (k_1 + k_2[H^+])[HY^{3-}]/[HR^-]$$ (6)

with $k_1 = 2.6 \times 10^{-2}$ s^{-1} and $k_2 = 1.9 \times 10^7$ M^{-1} s^{-1}. Taking the differences in the concentration ranges of the reactants and in the ionic strength into consideration, these rate constants are in fairly good agreement with the values reported previously (1.9×10^{-2} s^{-1} and 2.4×10^7 M^{-1} s^{-1}, respectively [5]).

3.2. Catalytic effect of inorganic ligands

At $C_{Hg} = 1 \times 10^{-5}$ M, $C_{PAR} = 8 \times 10^{-4}$ M, $C_{CDTA} = 1 \times 10^{-4}$ M and pH = 8.9, reaction (4) was followed in the presence of Cl^-, Br^-, I^-, SCN^-, NH_3, NO_3^-, SO_4^{2-}, SO_3^{2-} and $S_2O_3^{2-}$, representing A in Eq. (2). Among these inorganic ligands, up to 1×10^{-2} M NO_3^- and SO_4^{2-} had no effect on the rate of the substitution reaction. Above this concentration, the reaction was decelerated, probably owing to the salt effect. The reaction was accelerated by the other ligands. The conditional rate constant $k_{0(A,H,R,Y)}$ was determined from the first-order plot in the presence of A and was found to be linearly correlated with the concentration of A, as shown in Fig. 1. The value of the intercept of this plot, which corresponds to the rate constant for the reaction path independent of A, was the same as that found in the absence of A at the same pH. Hence the following relationship was observed:

$$-d[HgR_2{}^{2-}]/dt = k_{0(A,H,R,Y)}[HgR_2{}^{2-}]$$

$$= \{k_{0(H,R,Y)} + k_{0(H,R,Y)}{}^A[A]\}[HgR_2{}^{2-}]$$ (7)

where $k_{0(H,R,Y)}$ and $k_{0(H,R,Y)}^A$ correspond to k_f and k_f^A in Eq. (2) at given concentrations of hydrogen ion, PAR, and CDTA. The value of k_f^A was determined from the slope of the linear plot of $k_{0(A,H,R,Y)}$ against [A].

The plot of $\log k_f^A$ against E(A) gives a straight line with a slope of 2.9 and an intercept of -2.6 (Fig. 2). Although the logarithmic value of k_f^A for

Fig. 1. Effect of sulfite concentration on $k_{0(SO_3,H,R,Y)}$. $C_{Hg} = 1 \times 10^{-5}$ M, $C_{PAR} = 8 \times 10^{-4}$ M, $C_{CDTA} = 1 \times 10^{-4}$ M, pH = 8.86 ± 0.02.
Fig. 2. Plot of $\log k_f^A$ against $E(A)$.

$A = H_2O(-2.2)$ is in agreement with that of the intercept of the straight line in Fig. 2, within experimental error, the present slope is considerably smaller than that predicted by Eq. (3). Although the reason for this discrepancy is not clear at present, the sufficient difference in reactivity between $SO_3{}^{2-}$ or $S_2O_3{}^{2-}$ and $SO_4{}^{2-}$ enabled us to design a kinetic method for the determination of $SO_3{}^{2-}$ or $S_2O_3{}^{2-}$ in the presence of a large amount of $SO_4{}^{2-}$.

3.3. Catalytic determination of sulfite and thiosulfate

Under the selected conditions in which $C_{Hg} = 1 \times 10^{-5}$ M, $C_{PAR} = 8 \times 10^{-4}$ M, $C_{CDTA} = 5 \times 10^{-4}$ M and pH = 8.4, the difference in absorbance at 4 and 20 s after the start of the reaction was plotted against the concentration of A. This calibration curve was linear up to 1.5×10^{-6} M $SO_3{}^{2-}$ or 7×10^{-7} M $S_2O_3{}^{2-}$. The detection limits, defined as 3σ of the intercept of the respective calibration curves, were 3×10^{-8} M for $SO_3{}^{2-}$ and 2×10^{-8} M for $S_2O_3{}^{2-}$. As shown in Table 1, the presence of 10 000-fold and 25 000-fold molar amounts of $SO_4{}^{2-}$ can be tolerated in the determination of 1×10^{-6} M $SO_3{}^{2-}$ and 4×10^{-7} M $S_2O_3{}^{2-}$, respectively.

3.4. Effect of diverse ions

The tolerance level of typical inorganic anions in the determination of 1×10^{-6} M $SO_3{}^{2-}$ or

4×10^{-7} M $S_2O_3{}^{2-}$ was studied and the results are summarized, together with the $E(A)$ values, in Table 1. The tolerance level was defined as the amount of an ion causing an error of not more than 5%. As expected, an anion with a smaller $E(A)$ value can be tolerated to a higher level. The results also show that, for anions having $E(A)$ values smaller than 1.8, the presence of 100-fold or greater molar amounts can be tolerated, except for bromide.

The tolerance levels of diverse metal ions were also studied and the results are summarized in Tables 2 and 3. Metal ions that caused positive errors due to complexation with PAR include Al(III), As(III), Be(II), Bi(III), Cd(II), Ce(III), Ce(IV), Cr(III), Cr(VI), Cu(II), In(III), La(III), Lu(III), Mn(II), Mn(VII), Sc(III), Se(IV), Sm(III), Ti(IV), Tl(I), Tl(III) and Y(III). Au(III) and Pd(II) caused negative errors due to complexation with PAR. Co(II), Fe(III), Ga(III), Ni(II), Zn(II) and Zr(IV) caused no errors in spite of the complexation with PAR. Ba(II), Ca(II), Ge(VI), Mg(II), Pb(II), Pt(II), Se(VI) and Sr(II) caused negative errors in spite of no reaction with PAR. Metal ions that caused no errors due to an absence of reaction with PAR (and probably also with CDTA) include As(V), K(I), Li(I), Mo(VI)

methods based on different principles for determining sulfite [16–26] and thiosulfate [20,24,25,27–33] at micromolar levels have been proposed. Compared with these, the present method provides the highest tolerance level of sulfate and the lowest detection limit for both anions without resort to chromatographic separation or chemical treatment.

Solvent extraction kinetics of rare earth elements

Jinzhang Gao*, Bo Peng, Haiyan Fan, Jingwan Kang

Department of Chemistry, Northwest Normal University, Lanzhou 730070, People's Republic of China

Abstract

The kinetics of solid–liquid extraction of rare earth elements (RE) (La, Ce, Sm, Dy and Yb) were studied with 1-(2-pyridylazo)-2-naphthol (PAN) at 60°C using paraffin wax as a diluent. The rate of extraction is first order with respect to metal ion and hydrogen ion in the aqueous phase and second order with respect to the extractant in the organic phase. The rate-determining step is the formation of an $[RE(PAN)_2]^+$ complex between RE^{3+} and PAN in the aqueous phase. The rate constant for the extraction was found to be about 10^{11} l mol^{-1} s^{-1}. The temperature dependence of extraction rate was determined and the activation parameters were calculated.

1. Introduction

Solid–liquid extraction using a molten diluent at high temperature as a new branch of extraction chemistry has various advantages. In this technique, organic substances which are solid at room temperature, such as naphthalene, biphenyl and paraffin waxes, are employed as diluents. The water-insoluble complex is readily extracted into the molten diluent at high temperature to achieve distribution equilibrium. Phase separation can be obtained by cooling the extraction system to room temperature. This procedure can efficiently avoid emulsion, a third phase and vaporization of solvent. Furthermore, rapid phase separation and high concentrations are also benefits for extraction work. Normally, liquid–liquid extractions are carried out at low temperatures and few data involving temperatures above 50°C have been reported. Previous papers [1–6] have reported systematic investigations of the solid–liquid extraction behavior of lanthanides with some organic reagents in the temperature range 55–85°C. It was found there are some differences in extraction mechanisms and thermodynamics between solid–liquid extraction and liquid–liquid extraction. All the organic reagents employed, such as TOPO, DBM, PMBP and PAN are very effective and efficient for the extraction of lanthanides because of their large partition coefficients between the aqueous phase and organic phase.

Solid–liquid extraction of rare earth elements with PAN was studied in previous work [5]. Information obtained on thermodynamics helps in understanding the extraction mechanism. However, further understanding of the extraction behavior

and mechanism requires kinetic investigations of these high-temperature systems. This paper presents the results of a detailed study of the kinetics of the RE(III)–PAN–paraffin wax solid–liquid extraction system above 60°C (RE = rare earth element).

2. Experimental

2.1. Reagents

A 2×10^{-3} M 1-(2-pyridylazo)-2-naphthol (PAN) solution in acetone was prepared by dissolving the appropriate amount of PAN in acetone.

As buffer solutions, 0.1 M ammonium chloride and ammonia solutions were used.

Stock solutions of rare earth ions were prepared and the paraffin wax (m.p. 48–50°C) was purified according to Ref. [5]. Redistilled, deionized water was used throughout. All chemicals were of analytical-reagent grade.

2.2. Apparatus

A Model DF-101B magnetic stirrer (Zhejiang, China), a Model CS501 thermostat (Chongqing, China) with an accuracy ±0.1°C, a Model U-3400 spectrophotometer (Hitachi, Japan) and a Model PHS-10A digital acidity/ionometer (Xiaoshan, China) were used.

2.3. Procedure

A suitable amount of standard solution of RE(III) and buffer solution were placed in the extraction vessel with a water jacket (see the system in Ref. [5]). The volume of aqueous phase was kept to 10 ml with the ionic strength controlled at 0.1 with NaCl. A 1 g amount of paraffin wax was added to the vessel ($V_o:V_{aq} = 1.3:10$, where V_o is the volume of the organic phase and V_{aq} that of the aqueous phase). Water at the required temperature was introduced into the jacket with thermostatic control. After the wax had completely melted, 0.5 ml of 2×10^{-3} M PAN solution in acetone was added and magnetic
Fig. 1. Plot of $\ln([RE^{3+}]_{t=0}/[RE^{3+}]_{t=t})$ vs. time for Dy^{3+}–PAN–wax system. $[Dy^{3+}] = 2 \times 10^{-5}$ M, $[PAN]_o = 6.15 \times 10^{-4}$ M, $I = 0.1$ M (NaCl), $t = 60 \pm 0.1°C$, pH = (a) 8.60, (b) 7.93, (c) 7.83, (d) 7.65.

stirring was begun at a high speed, reaching a plateau region where a further increase in stirring speed had no effect on the rate of the extraction. The stirring was stopped after a period of time and the vessel was cooled to room temperature by circulation of cold water.

Fig. 2. Plot of $\ln([RE^{3+}]_{t=0}/[RE^{3+}]_{t=t})$ vs. time for Dy^{3+}–PAN–wax system. $[Dy^{3+}] = 2 \times 10^{-5}$ M, pH = 7.94, $I = 0.1$ M (NaCl), $t = 60 \pm 0.1°C$, $[PAN]_o = $ (a) 6.15×10^{-4} M, (b) 7.69×10^{-4} M, (c) 10.77×10^{-4} M, (d) 15.38×10^{-4} M.

After removal of the solid wax, the pH of the aqueous phase was measured and the amount of RE(III) determined as in Ref. [5]. The total recovery of RE(III) in both phases was calculated to be $100 \pm 2\%$.

3. Results and discussion

A preliminary series of experiments were performed to determine the effect on the rate of the extraction of varying the stirring speed. It was found that the rate of extraction increased rapidly at the high temperature of the experiments when the stirring speed was increased, up to a maximum value beyond which an increase in agitation had no significant effect on the rate of extraction. In all subsequent determinations, a stirring speed of 600 rpm within this "plateau region" was employed.

3.1. Reaction order with respect to the concentration of RE(III)

According to the general kinetic equation for the formation of metal chelates, the rate r of reaching extraction equilibrium is given by

$$r = -d[RE^{3+}]/dt = K[RE^{3+}]^a[HL]_o^b[H^+]^c \quad (1)$$

where K is the rate constant, RE^{3+} denotes rare earth ion Dy^{3+}, $[HL]_o$ denotes the PAN concentration the organic phase and a, b and c are the reaction orders of the reactants.

At constant pH and constant concentration of PAN in the organic phase, the above rate equation can be written as

$$r = -d[Dy^{3+}]/dt = k[Dy^{3+}]^a \quad (2)$$

where k is the observed rate constant. The reaction was assumed to be first order with respect to the concentration of Dy^{3+} ion in the aqueous phase, that is, $a = 1$, and we can integrate Eq. (2) and obtain

$$\ln([Dy^{3+}]_{t=0}/[Dy^{3+}]_{t=t}) = kt \quad (3)$$

where $[Dy^{3+}]_{t=0}$ and $[Dy^{3+}]_{t=t}$ are the concentrations of Dy^{3+} ion in the aqueous phase at time 0 and time t, respectively.

Fig. 3. Plot of $\log k$ vs. pH for Dy^{3+}–PAN–wax system. $[Dy^{3+}] = 2 \times 10^{-5}$ M, $[PAN]_o = 6.15 \times 10^{-4}$ M, $I = 0.1$ M (NaCl), $t = 60 \pm 0.1°C$, pH = (a) 8.60, (b) 7.93, (c) 7.83, (d) 7.65.

This assumption was validated when a plot of $\ln([Dy^{3+}]_{t=0}/[Dy^{3+}]_{t=t})$ vs. time was constructed and the points were found to lie on straight lines as shown in Figs. 1 and 2. Only the pH value is varied in Fig. 1 and only the concentration of PAN in the organic phase is varied in Fig. 2.

Fig. 4. Plot of $\log k$ vs. $\log[PAN]_o$ for Dy^{3+}–PAN–wax system. $[Dy^{3+}] = 2 \times 10^{-5}$ M, pH = 7.94, $I = 0.1$ M (NaCl), $t = 60 \pm 0.1°C$, $[PAN]_o = $ (a) 6.15×10^{-4} M, (b) 7.69×10^{-4} M, (c) 10.77×10^{-4} M, (d) 15.38×10^{-4} M.

Fig. 5. Plot of $\log K_1$ vs. $1/T$. $[PAN]_o = 6.15 \times 10^{-4}$ M, $I = 0.1$ M (NaCl), initial concentration of $RE^{3+} = 2 \times 10^{-5}$ M.

3.2. Reaction order with respect to hydrogen ion

Taking the above results with $a = 1$ into consideration, the following equation was obtained from Eqs. (1) and (2):

$$\log k = \log K + b \, \log[HL]_o c pH \tag{4}$$

In Fig. 3, the plot of $\log k$ vs. pH at a constant concentration of PAN in the organic phase is straight line with slope of 1, which indicates a first-order reaction with respect to the hydrogen ion.

3.3. Reaction order with respect to the concentration of PAN in the organic phase

In a similar fashion, a first-order reaction with respect to PAN was found according to the plot of $\log k$ vs. $[PAN]_o$ (Fig. 4).

3.4. Mechanisms of extraction reaction

Based on the data obtained above, the kinetic equation for the extraction can be rewritten as

$$r = -d[RE^{3+}]/dt = K[RE^{3+}][HL]_o^2[H^+] \tag{5}$$

Considering this rate equation and the major species in the extraction system, we suggest the

following steps in the extraction of RE(III) with PAN:

$$HL_o \rightleftharpoons HL_{aq}, \quad K_D = [HL]_o/[HL]_{aq} \tag{6}$$

$$H_2O \rightleftharpoons H^+ + OH^-, \quad K_{w,t} = [H^+][OH^-] \tag{7}$$

$$RE(OH)^{2+} \rightleftharpoons RE^{3+} + OH^-,$$

$$K_c = [OH^-][RE^{3+}]/[RE(OH)^{2+}] \tag{8}$$

$$RE^{3+} + 2HL_{aq} \xrightarrow{K_1} REL_2^+ + 2H^+ \tag{9}$$

$$REL_2^+ + Cl^- \rightleftharpoons REL_2Cl \tag{10}$$
where K_D is the partition coefficient of PAN between two phases [6], $K_{w,t}$ is the dissociation constant of water at different temperatures [7,8], $1/K_c$ is the first-order stability constant of rare earth element hydroxide [8] and K_1 represents the rate constant of the path expressed by Eq. (9).

The first, second and third steps can be regarded as rapid equilibria, while the fourth is the rate-controlling step, with a first-order dependence with respect to RE^{3+} and second-order dependence with respect to PAN. The last step, however, is so fast that it can be neglected. In the given kinetic equation, a first-order dependence with respect to hydrogen ion is obtained, which means the RE^{3+} directly replaces the hydrogen ion in PAN before PAN dissociates. On the other hand, the presence of hydrated $RE(OH)^{2+}$ at the experimental acidity in the aqueous phase [9] and the dissociation of $RE(OH)^{2+}$ contribute to the first-order dependence with respect to hydrogen ion. Therefore, the above rate expression is equivalent to

$$-d[RE^{3+}]/dt = K_1[RE^{3+}][HL]_{aq}^2 \tag{11}$$

From Eqs. (6), (7), (8) and (11), we have

$$-d[RE^{3+}]/dt = K_1 K_c[RE^{3+}][H^+][HL]_o^2/K_{w,t}K_D^2 \tag{12}$$

This is the rate equation for the fourth step expressed by Eq. (9), which is rate controlling.

We can integrate Eq. (12) and obtain

$$\ln([RE^{3+}]_{t=0}/[RE^{3+}]_{t=t})$$

$$= (K_1 K_c[H^+][HL]_o^2/K_{w,t}K_D^2)t \tag{13}$$

	$\Delta_r^{\ddagger}G_m^{\ominus}$ (kJ mol^{-1})	6.454	6.905	10.33	12.16	14.39
	$\Delta_r^{\ddagger}S_m^{\ominus}$ (J K^{-1} mol^{-1})	438.43	477.44	495.20	533.21	583.57
343	K_1 ($\times 10^{11}$ M^{-1} s^{-1})	31.6	10.0	4.20	2.37	1.20
	$\Delta_r^{\ddagger}H_m^{\ominus}$ (kJ mol^{-1})	154.607	168.203	177.671	192.375	211.595
	$\Delta_r^{\ddagger}G_m^{\ominus}$ (kJ mol^{-1})	2.326	5.608	8.082	9.714	11.66
	$\Delta_r^{\ddagger}S_m^{\ominus}$ (J K^{-1} mol^{-1})	443.97	474.04	494.43	532.54	582.92
E_a (kJ mol^{-1})		157.459	171.055	180.523	195.227	214.447

The value of the rate constant K_1 in Eq. (12) at the experimental temperature can be calculated from the slope of the plot of $\ln([RE^{3-}]_{t=0}/[RE^{3+}]_{t=t})$ vs. time.

The temperature dependence of the rate constant K_1 of five rare earth ions (La, Ce, Sm, Dy and Yb) in the temperature range 55–70°C is shown in Fig. 5. The plots of $\log K_1$ vs. $1/T$ for the five ions are a series of straight lines. The activation energy E_a, activation enthalpy $\Delta_r^{\ddagger}H_m^{\ominus}$, activation free energy $\Delta_r^{\ddagger}G_m^{\ominus}$ and activation entropy $\Delta_r^{\ddagger}S_m^{\ominus}$ at different temperatures were calculated and the results are given in Table 1.

It can be seen from the data obtained that the activation enthalpy of the extraction increases from La to Yb. This is consistent with the degree of hydration of the rare earths from La to Yb due to the "lanthanide contraction". The hydrated $RE(OH)^{2+}$ prevents the formation of the extracted complex. Therefore, the rate constants decrease in the same order.

Re-examination of the structure of calcichrome (calcion) and its complexation with polyaromatic hydrocarbons in water

Bo-Long Poh*, Melati Khairuddean

School of Chemical Sciences, Universiti Sains Malaysia, 11800 Minden, Penang, Malaysia

Received 14 December 1995; revised 1 April 1996; accepted 5 April 1996

Abstract

A non-cyclic tetrameric structure has been suggested for calcichrome (calcion). This structure is consistent with its mass spectrum, proton NMR spectrum, elemental composition and complexing ability with polyaromatic hydrocarbons in water. The stability constants of the 1:1 complexes formed between calcichrome and seven polyaromatic hydrocarbons in water at room temperature have been measured.

Keywords: Calcichrome; Calcion; Complexation; Polyaromatic hydrocarbons

1. Introduction

Although calcichrome (also known as calcion) is used as a specific colorimetric reagent for the calcium ion, its structure is still controversial. Three structures have been suggested, the cyclic trimer 1 [1–3], the non-cyclic trimer 2 [4] and the dimer 3 [5,6]. Only structure 3 is consistent with the observed [5,7] elemental composition with a carbon to nitrogen ratio of 10:1 and the proton NMR spectrum indicating seven aromatic protons (one isolated and three pairs with the protons *meta* to each other) and three labile protons. However, structure 2 is the one that has found general acceptance in spite of a lack

of definitive analytical evidence (e.g. chemical suppliers assume this structure; see Scheme 1a).

Our interest in the structure of calcichrome arose when we observed that it formed strong complexes with polyaromatic hydrocarbons in water. The dimer 3, although consistent with the observed elemental composition and the proton NMR spectrum, could not account for this complexation ability because it has no hydrophobic cavity to enclose the polyaromatic hydrocarbons. We set out to establish the structure of calcichrome by examining its mass spectrum and re-examining its proton NMR spectrum. This paper suggests a non-cyclic tetrameric structure for calcichrome and reports the stability constants of the complexes formed between it and seven polyaromatic hydrocarbons in water.

Scheme 1a

2. Experimental

2.1. Chemicals

Calcichrome and the polyaromatic hydrocarbons were commercial samples and were used without further purification. Elemental analysis of C, H and N in calcichrome agreed with the molecular formula $C_{40}H_{20}N_4O_{28}S_8Na_6 \cdot 28H_2O$.

2.2. Instrumentation

An AC300 300 MHz superconducting NMR spectrometer and a Hitachi U-2000 UV–visible spectrophotometer were used.

2.3. Determination of stability constants

Stability constants K of the complexes formed

between calcichrome and the polyaromatic hydrocarbons were obtained according to two methods described previously, solid–liquid extraction [8] and a transport method [9]. In the former method, 15 mg of each of the solid polyaromatic hydrocarbons were extracted with 5.80×10^{-4} M of calcichrome (5.80×10^{-3} M in the case of naphthalene). In the latter, the concentration of the polyaromatic hydrocarbons in the hexane phase was varied from 1.0×10^{-3} to 5.0×10^{-3} M and the concentration of calcichrome used was 5.80×10^{-4} M. All experiments were performed at least in duplicate.

3. Results and discussion

3.1. Structure of calcichrome

Calcichrome is assigned the non-cyclic tetrameric structure 4 on the basis of its mass spectrum, proton NMR spectrum and elemental composition. The laser desorption mass spectrum (positive-ion mode) of the acidic form of calcichrome (Na^+ replaced by H^+ from Dowex 50W-X8 hydrogen-form ion-exchange resin) in a dihydroxybenzoic acid matrix shows a peak at m/z 1358 (Fig. 1) which could be assigned to the $[M + 5H_2O + H]$ ion (inclusion of water molecules in the molecular ion was observed previously [10]). The observed peak at m/z 1358 rules out the possibility of structures **1**, **2** and **3** whose acidic forms have much lower m/z values (991, 981 and 651, respectively).

Fig. 1. Laser desorption mass spectrum (positive-ion mode) of calcichrome (with Na^+ replaced by H^+) in dihydroxybenzoic acid as matrix.

4   **6 Na⁺**

Y = SO₃⁻

Structure **4** is consistent with the observed 10 peaks of equal integration in the proton NMR spectrum of calcichrome in DMSO-d_6 (Fig. 2). There are seven kinds of aromatic protons (one isolated at 8.20 ppm and six *meta* to each other at 7.23, 7.33, 7.49, 7.61, 7.89 and 7.94 ppm with typical *meta* coupling constants of 1.1-1.5 Hz) and three kinds of labile protons at 11.79, 11.99 and 17.13 ppm (they disappear in D_2O solvent). We assign the 11.79 and 11.99 ppm peaks to the two kinds of phenolic protons and the 17.13 ppm peak to the diaza protons (previous workers [5,6] attributed all the three peaks to phenolic protons). Our assignment of the 17.13 peak to the diaza protons is supported by its disappearance when the proton NMR spectrum of a sample of calcichrome neutralized with two equaivalents of sodium hydroxide was recorded (Fig. 3). The other two phenolic proton peaks are still present and they are shifted downfield to 13.41 and 14.65

ppm. This downfield shift is consistent with better hydrogen bonding between the phenolic hydrogens and the diaza nitrogens when the latter are not protonated (a partial structure for protonated diaza nitrogens is shown as **5** and those for non-protonated diaza nitrogens with hydrogen bonding involving the phnolic hydrogens are shown as **6** and **7**).

Fig. 2. 300 MHz proton NMR spectrum of calcichrome (0.1 g) in DMSO-d_6 (0.6 ml) at 25°C; solvent peak at 2.50 ppm (not shown) as internal reference. The inset is an expansion of the aromatic proton region.
Structure **4** is also consistent with the reported elemental composition with a carbon to nitrogen ratio of 10:1 [5,7] and the formation of two products from the selective cleavage of the azo
Fig. 3. 300 MHz proton NMR spectrum of calcichrome neutralized with two equivalents of NaOH (0.2 g) in DMSO-d_6 (0.6 ml) at 25°C; solvent peak at 2.50 ppm (not shown) as internal reference.

groups in calcichrome with tin(II) [6]. The two expected products from the azo cleavage reaction of structure **4** are **8** and **9** in a molar ratio of 2:1. The former, a smaller molecule, is expected to elute faster than the latter in column chromatography. It is expected to show four doublets with *meta* coupling constants in the proton NMR spectrum and the latter a singlet plus two doublets with *meta* coupling constants, in agreement with the reported results [6].

8   Y=SO₃Na

9   Y = SO₃Na
The formation of **4** could be explained in terms of a combination of two known mechanisms in diazonium ion reactions [11]. The first is the dimerization of two diazotized 1-amino-8-hydroxy-naphthalene-3,6-disulfonic acid (H-acid) with the loss of two nitrogen molecules. The second is the attack of two diazotized H-acid molecules on the two positions *ortho* to the two hydroxyl groups of the dimer.

Fig. 4. Relationship between absorbance at 251 nm of anthracene in the receiving hexane phase and time. The initial concentration of anthracene in the source hexane phase is 1.0×10^{-3} M. (A) 5.80×10^{-4} M calcichrome in the aqueous phase and (B) no calcicrhrome in the aqueous phase.

3.2. Complexation with polyaromatic hydrocarbons

That calcichrome is able to complex with polyaromatic hydrocarbons in water is shown by (1) its ability to increase the solubility of the polyaromatic hydrocarbons in water (for example, 5.8×10^{-4} M calcichrome increases the solubility of chrysene 250-fold) and (2) its ability to increase the transport rate of polyaromatic hydrocarbons from one hexane phase to another through an intermediate aqueous phase (an example is shown in Fig. 4 for the transport of anthracene). The non-cyclic tetrameric structure **4** is able to complex with polyaromatic hydrocarbons because in its folded conformation, as indicated by CPK molecular models, the four naphthalene units enclose a

hydrophobic cavity.

The stability constants K of the complexes formed were determined by two methods, solid–liquid extraction [8] and a transport method [9]. We have to make an assumption regarding the stoichiometry of the complexes since the usual mole ratio and Job plots to determine stoichiometry cannot be used in the solid–liquid extraction and transport methods. The solubility problem of the polyaromatic hydrocarbons in water also ruled out the use of electronic and NMR spectroscopic methods in our study. CPK molecular models indicate that the cavity size of the folded conformation of 4 is similar to that of cyclotetrachromotropylene, a cyclic tetramer formed from four naphthalene units [8,9]. Since the latter has been shown to form complexes of 1:1 stoichiometry [12–14], the same stoichiometry was assumed in this work. The K values (Table 1) are of the same order of magnitude as those of cyclotetrachromotropylene [8,9], indicating that calcichrome adopts a folded conformation in water and the size of its hydrophobic cavity is similar to that of cyclotetrachromotropylene. As with the latter host, log K increases linearly with increase in the number of aromatic rings in the guest molecule. For example, a plot of the log K values obtained from the transport method against the number of aromatic rings (N) in the guest molecules gives a straight line of slope 1.0 with a correlation coefficient of 0.978, close to the slope of 0.92 for cyclotetrachromotropylene as host [8].

Abstract

A luminol chemiluminescence (CL) method was developed for the determination of glutathione (GSH). GSH was indirectly determined by measuring the amount of hydrogen peroxide formed during the Cu(II)-catalysed oxidation of GSH with oxygen. The amount of hydrogen peroxide formed was continuously measured using the *Arthromyces ramosus* peroxidase-catalysed luminol CL reaction. The CL intensities at maximum light emission were linearly correlated with the concentration of GSH over the range 7.5×10^{-7}–3.0×10^{-5} M. The detection limit for GSH was about 10 times better than that of the spectrophotometric method using Ellman reagent.

Keywords: Chemiluminescence; Glutathione; Luminol; Peroxidase

1. Introduction

Glutathione (GSH) plays an important physiological role in the protection of cellular constituents against oxidative damage in living cells. Many spectrophotometric and fluorometric methods have been developed for the determination of GSH [1,2]. Recently, chemiluminescence (CL) methods have attracted attention owing to their sensitivity. The lucigenin (Luc) CL reaction has been employed for the determination of GSH [3], but the detection limit was higher than that of the spectrophotometric methods using Ellman reagent [1].

The peroxidase (POD)-catalysed luminol CL provides a sound basis for the assay of hydrogen peroxide (H_2O_2) and enzymatically generated H_2O_2 [4]. In the Cu(II)-catalysed oxidation of aminothiols (RSH) such as cysteine with oxygen, H_2O_2 has also been shown to be produced as an intermediate from oxygen [5]. We previously applied the POD-catalysed luminol CL to the detection of H_2O_2 formed during the course of the Cu(II)-catalysed oxidation of cysteamine ($H_2NCH_2CH_2SH$) [6]. H_2O_2 was detected by simultaneously performing the reactions

$$2RSH + O_2 \xrightarrow{Cu^{2+}} RSSR + H_2O_2 \tag{1}$$

$$luminol + H_2O_2 \xrightarrow{POD} aminophthalate + N_2$$
$$+ H_2O + h\nu \tag{2}$$

* Corresponding author.

When *Arthromyces ramosus* peroxidase (ARP) was used as a catalyst for the luminol CL, a light emission–time profile followed the production rate of H_2O_2 in the catalytic oxidation of cysteamine. The purpose of the present study was to develop a highly sensitive CL method for GSH via the use of ARP-catalysed luminol CL coupled with Cu(II)-catalysed oxidation of GSH with oxygen.

2. Experimental

2.1. Materials

ARP was kindly supplied from Suntory. Luminol, GSH, L-cysteine and L-(+)-ascorbic acid were obtained from Kanto Chemical and were guaranteed-grade reagents. EDTA, 1,10-phenanthroline (Phen) and 2,2-dithiobis(5-nitropyridine) (DTNP) were purchased from Dojindo Laboratory. Reduced nicotinamide adenine dinucleotide (NADH) was obtained from Sigma Chemical. Copper(II) nitrate, ammonium iron(II) sulfate, citric acid, boric acid and tertiary sodium phosphate were obtained from Wako Pure Chemical Industries and were of guaranteed grade. All chemicals were used without further purification.

ARP solution was prepared with Carmody's buffer (pH 9.0), containing 6.9×10^{-2} M boric acid, 1.7×10^{-2} M citric acid and 6.6×10^{-2} M tertiary sodium phosphate [7]. The concentration of ARP was determined spectrophotometrically with an ε_{403} value of 1.02×10^5 l mol^{-1} cm^{-1} [8]. A 1.0×10^{-2} M stock solution of luminol was prepared by dissoloving the compound in 0.1 M NaOH solution. A 1.0×10^{-2} M stock solution of Cu(II), prepared from Cu(II) nitrate in 0.1 M hydrochloric acid, was standardized with EDTA. Working standard solutions of ARP, luminol and Cu(II) were prepared by serial dilution of the stock solutions with water and Carmody's buffer solution. A standard solution of GSH was made daily. All solutions were prepared with deionized water from a Millipore Milli-Q water purification system.

All of the reagent concentrations shown in the figures are initial concentrations.

2.2. Apparatus

All CL measurements were made using a luminometer constructed in this laboratory. A glass cuvette (20 mm × 22 mm i.d.) was placed on a magnetic stirrer in a dark-box. The light output was detected with a Hamamatsu Photonics R453 photomultiplier (PMT). The resultant photocurrent was measured with a TOA Electronics PM-18 type current meter and displayed on a chart recorder. A Cu(II) solution and a GSH solution were injected through Teflon tubing into the cuvette by using an injector (Iatron Laboratories, Dualpette type). Absorption spectra were measured with a Hitachi U-2000 spectrometer equipped with 1 cm quartz cells.

2.3. Cu(II)-catalysed oxidation of GSH with oxygen

The catalytic oxidation was carried out at pH 9.0 using the following conditions. A 2.5 cm³ portion of buffer solution was added to a glass cuvette. A 0.25 cm³ portion of 1.2×10^{-4} M Cu(II) solution and a 0.25 cm³ portion of 1.2×10^{-2} M GSH solution were simultaneously injected into the cuvette, and the catalytic oxidation was initiated. The entire solution, thus prepared, is referred to as the final solution. Oxygen was bubbled continuously at 45 cm³ min^{-1} during the reaction.

2.4. Preparation of calibration curve

The recommended procedure for the determination of GSH consisted of pipetting a 1.0 cm³ portion of a solution containing 1.0×10^{-4} M luminol and 5.0×10^{-7} M ARP into a glass cuvette on a magnetic stirrer in the luminometer. The whole solution was saturated with oxygen. Next, a 1.0 cm³ portion of 1.0×10^{-5} M Cu(II) solution and a 1.0 cm³ portion of GSH solution were simultaneously injected into the cuvette and the CL reaction was monitored. The pH of the reaction mixture was 11.0. Oxygen was bubbled continuously at 45 cm³ min^{-1} during the reaction. All measurements were made at 25°C. The maximum light emission was corrected for the light

emission of a blank containing no GSH. These background-corrected CL values are referred to as CL intensity.

2.5. Analytical procedure for GSH and H_2O_2

The concentration of GSH consumed and H_2O_2 formed during the catalytic oxidation were determined under the following conditions. A 0.1 cm^3 portion of the reaction mixture was pipetted into the cell containing 0.1 cm^3 of 1.0×10^{-3} M EDTA solution. The catalytic reaction was terminated with EDTA. Then, GSH was determined with DTNP by measuring the absorbance at 386 nm [1] and H_2O_2 with Fe(II)–Phen complex at 510 nm [9].

3. Results and discussion

3.1. Catalytic oxidation of GSH

The Cu(II)-catalysed oxidation of GSH was carried out according to the procedure:

$$2GSH + O_2 \xrightarrow{Cu^{2+}} GSSG + H_2O_2 \qquad (3)$$

The time course for GSH consumption and H_2O_2 formation are shown in Fig. 1. The concentrations of GSH and H_2O_2 on the vertical axis are those in the final solution. The concentration of H_2O_2 formed increased with increase in the reaction

Fig. 1. Time course of GSH consumption and H_2O_2 formation during the catalytic oxidation. Curve 1, GSH consumption; curve 2, H_2O_2 formation. [GSH] = 1.2×10^{-2} M; [Cu(II)] = 1.2×10^{-4} M; pH = 9.0.

Fig. 2. CL response curve and time course of GSH consumption. Curve 1, time course of GSH consumption; curve 2, CL response curve. [GSH] = 5.0×10^{-4} M; [Cu(II)] = 1.0×10^{-5} M; [ARP] = 5.0×10^{-7} M; [luminol] = 1.0×10^{-4} M; pH = 9.0.

time. The amount of H_2O_2 formed was 1.5×10^{-4} M in the final solution. When GSH is converted quantitatively into H_2O_2, the reaction yield (mol%) should be 50% (reaction (3)), where the reaction yield is defined as the ratio of the amount of H_2O_2 formed to that of GSH used. However, the reaction yield of H_2O_2 was 30% after 25 min, as shown in Fig. 1. This is because part of the H_2O_2 formed was consumed as an oxidizing agent for the oxidation of GSH.

Next, we determined the amounts of GSH consumed during the reaction when coupled with the ARP-catalysed luminol CL reaction. The catalytic oxidation of GSH was performed at pH 9.0 according to the procedure in which 5.0×10^{-4} M GSH solution was used. The time course of GSH consumption is shown in Fig. 2 (curve 1). GSH was almost completely oxidized by 10 min after the start of the reaction.

PODs catalyse the oxidation of aminothiols such as cysteine through the POD cycle [10,11]. However, no reports have been found on ARP-catalysed oxidation of GSH. We then determined the concentration of GSH consumed during the catalytic oxidation by using ARP alone. The oxidation was carried out according to the same procedure as above, except that the buffer solution was employed in place of Cu(II) solution and luminol solution. After 10 min, nearly 2% of GSH was oxidized to GSSG. Therefore, GSH could be primarily oxidized by a Cu(II)-catalysed pathway (reaction (3)).

3.2. Light emission–time profile

We examined the CL measurement of H_2O_2 formed during the catalytic oxidation of GSH shown in Fig. 2 (curve 1). A typical CL response curve is shown in Fig. 2 (curve 2). The intensity of the light emission increased gradually with increase in the reaction time.

The time course of GSH consumption suggests that the maximum light emission may appear about 2 min after the start of the reaction. However, the maximum light emission appeared after 6 min, by which time GSH was almost completely oxidized. These results could be explained by the scheme proposed in Fig. 3. The numbers in parentheses show the effective oxidation level of iron in native ARP and ARP intermediates such as compounds I and II. Native ARP reacts with H_2O_2 produced by the catalytic oxidation of GSH and then catalyses the oxidation of luminol (LH$^-$) with the intermediates to form luminol radical (L$^-$) [12].

In the absence of GSH, the luminol radicals react with oxygen to yield endoperoxide (LO_2^{2-}). LO_2^{2-} then decomposes to yield an electronically

Fig. 4. Effect of pH on the CL intensity. [GSH] = 1.0×10^{-5} M; [Cu(II)] = 1.0×10^{-5} M; [ARP] = 1.0×10^{-7} M; [luminol] = 1.0×10^{-4} M.

exited 3-aminophthalate dianion (AP^{*2-}), which returns to the ground state by emitting light. On the other hand, GSH acts effectively as a quenching agent for luminol radicals [13], thereby preventing the oxidation of luminol radicals to aminophthalate and subsequent light emission.

The appearance of the CL from the start of the reaction suggests that the formation rate of luminol radicals in ARP-induced luminol oxidation may be higher than the disappearance rate of luminol radical with GSH, although the rate constant of luminol radicals with GSH is still not available. However, the quenching reaction of luminol radicals with GSH may proceed simultaneously as long as GSH is present. Therefore, the maximum light emission could appear after almost complete consumption of GSH.

3.3. Optimum conditions for the determination of GSH

In the ARP-catalysed luminol CL coupled with Cu(II)-catalysed oxidation of GSH, the CL intensity was dependent on the concentration of GSH, although part of the H_2O_2 formed as a result of reaction (1) was consumed for further oxidation of GSH. We then optimized the conditions for the determination of GSH. In subsequent studies, the optimum conditions were determined by measuring the CL intensities so as to be maximum under the optimum conditions.

The effect of pH in the final solution was examined in the range 8.5–11.0. Fig. 4 shows that

Fig. 3. Scheme of ARP-catalysed luminol CL coupled with Cu(II)-catalysed oxidation of GSH with oxygen.

the CL intensity increased with increase in pH. This can probably be attributed to an increase in the rate of formation of H_2O_2 accompanying an increase in pH, since $pK_{a,SH}$ of GSH is 8.8 [14]. Hence a pH of 11.0 was chosen for the recommended procedure by considering the buffer capacity of Carmody's buffer solution [7].

The dependence on the ARP concentration was investigated in the range 5.0×10^{-8}–2.0×10^{-6} M. The optimization curve for ARP concentration is shown in Fig. 5. The CL intensity increased to the maximum value at 5.0×10^{-7} M, after which it decreased with increase in ARP concentration. Hence the optimum ARP concentration was chosen as 5.0×10^{-7} M.

The influence of luminol concentration was tested in the range 5.0×10^{-6}–2.0×10^{-4} M. The CL intensity exhibited a broad maximum at 1.0×10^{-4} M. The optimum luminol concentration was thus determined to be 1.0×10^{-4} M.

3.4. Analytical results and parameters

The calibration curve was prepared under the optimum conditions. Typical CL response curves are shown in Fig. 6. A logarithmic calibration curve for GSH is presented in Fig. 7. The calibration curve was linear over the range from the detection limit of 7.5×10^{-7} M to 3.0×10^{-5} M initial concentration of GSH with a slope of 0.82. The relative standard deviation for five successive experiments was 1.6% at 3.0×10^{-6} M GSH. The detection limit for GSH was defined as the con-

Fig. 6. Typical CL response curves. [GSH]: 1, 1×10^{-6}; 2, 6×10^{-6}; 3, 1×10^{-5}; 4, 5×10^{-5} M. [Cu(II)] = 1.0×10^{-5} M; [ARP] = 5.0×10^{-7} M; [luminol] = 1.0×10^{-4} M; pH = 11.0.

centration of GSH yielding an analytical signal greater than three times the CL intensity of the blank, which contained no GSH. The detection limit of the present method for GSH is about 10 and 20 times better than those of the spectrophotometric method with the use of Ellman reagent [1] and the Luc-CL method [3], respectively.

Next, we examined the effects of biological reductants such as ascorbic acid, NADH and cysteine on the CL intensity according to the recommended procedure in which the reductants

Fig. 5. Effect of ARP concentration on the CL intensity. [GSH] = 1.0×10^{-5} M; [Cu(II)] = 1.0×10^{-5} M; [luminol] = 1.0×10^{-4}; pH = 11.0.

Fig. 7. Calibration curve for GSH. [Cu(II)] = 1.0×10^{-5} M; [ARP] = 5.0×10^{-7} M; [luminol] = 1.0×10^{-4}; pH = 11.0.

were added to a 3.0×10^{-6} M GSH solution. The tolerated concentration of each compound was taken as being the largest amount yielding an error of less than 5% in the CL intensity. The CL intensity decreased considerably in the presence of all of the reductants, even at a level equal to the concentration of GSH. This is because the reductants used act effectively as quenching agents for luminol radicals [13]. In the case of cysteine, the catalytic oxidation of GSH could also be influenced because Cu(II)-catalysed oxidation of cysteine could proceed simultaneously from the start of the reaction [15].

In conclusion, the ARP-catalysed luminol CL method provides excellent sensitivity for the determination of GSH. However, the method is not specific to sulfhydryl (–SH) compounds. Therefore, the proposed method could be applicable to the non-specific determination of aminothiols in analogy with the spectrophotometric method using Ellman reagent.

Abstract

A new suite of 10 programs concerned with equilibrium constants and solution equilibria is described. The suite includes data preparation programs, pretreatment programs, equilibrium constant refinement and post-run analysis. Data preparation is facilitated by a customized data editor. The pretreatment programs include manual trial and error data fitting, speciation diagrams, end-point determination, absorbance error determination, spectral baseline corrections, factor analysis and determination of molar absorbance spectra. Equilibrium constants can be determined from potentiometric data and/or spectrophotometric data. A new data structure is also described in which information on the model and on experimental measurements are kept in separate files.

Keywords: Equilibrium constant; Potentiometry; Solutions; Spectrophotometry

1. Introduction

The determination of equilibrium constants is an important process for many branches of chemistry [1]. Developments in the field of computation of equilibrium constants from experimental data were reviewed a few years ago [2,3]. Since that time, many more programs have been published, mainly so as to be able to use microcomputers for the computations. In this paper, we concentrate on the elaboration of potentiometric and spectrophotometric data;

* Corresponding author.

the most commonly used programs for solution equilibrium constant determination are given in Table 1.

All of these programs use a least-squares approach, the principles of which have been expounded in detail [4]. Many programs follow what we may call a standard approach. In this, the sum of squares is minimized by means of the Gauss–Newton–Marquardt algorithm. The derivatives required by this algorithm were originally obtained numerically, but following Nagypal et al. [5] some programs used derivatives calculated analytically. The free concentrations are calculated by solving the non-linear simultaneous equa-

tions of mass balance using the Newton–Raphson method. Potentiometric data points are weighted by formula that allows for greater pH errors in the region of an end-point than elsewhere. For absorbance data points a relative weighting scheme is used.

Some noteworthy exceptions are as follows. Minimization using pit-mapping (LETAGROP [6,7] and ABLET [8] families), Davidon–Fletcher–Powell method (STEW [9]), direct search (EY608 [10]), the method of steepest descent (CFTSP [11]) orthogonal decomposition (CLINP [12], ELORMA [13], SIRKO [14]). MINUITS [15] used regression equations of the Padé type. In DHMINOPT [16] there are three minimization routines and if one using derivatives fails the Nelder–Mead simplex method is called automatically. Solution of the mass-balance equation using a bisection algorithm (CFTSP [11]) or "another procedure which iterates by systematically modified increments" (MAXIPOT-F [17]) or a projection method due to Bugaevsky (SIRKO [14]). There have been attempts to make corrections for activity variation (SCOGS2a [18], SPECA [19]) and to use extended Debye–Hückel theory (DCLET [8] and BSTAC [20], an augmented version of SUPERQUAD [21]). Refinement of stoichiometric indices is included as an option in POLET [22] and SQUAD84 [23]. ECORM [24] was a computer implementation of the old (pre-computer) graphical methods, as are KATCOM [25] and Sidrak and Aboul-Seoud's program [26].

PKAS [27] is notably original in many respects. As it treats only protonation/deprotonation reactions (cf TITRA [28], TITAN [29]), it is possible to apply procedures that cannot be applied in the more general case. Thus, there are only two mass-balance equations in the two unknowns [L] and [H], say. [L] is eliminated to leave a polynomial in [H] which is solved by Newton–Raphson iteration. The minimization involves some kind of direct search method which, unfortunately, was not specified in detail. The program is highly interactive and requires much input of chemical knowledge. Having said that, the authors claim that the program never crashes. BEST [30] also employs a direct search method described as fol-

lows: "perturb a small fraction of the basis set [of refinable parameters] by an increment, see the effect on the sum of squares [of residuals in pH] and repeat in an appropriate direction to affect further improvement". This sounds like something akin to a simplex minimization.

Perhaps the most interesting developments have been the two attempts to write programs that can handle *any* equilibrium data. SIRKO [14] has a universal response function and a system whereby analytical derivatives are generated for the Jacobian. MICMAC [31] requires the programming of a module (MOSP) specific to a particular type of experimental data, but because of this numerical derivatives must be employed in the Jacobian.

Our own work has had two fundamental motivations: to provide a robust program for the computation of equilibrium constants and to tackle the problem of model selection. Although MINIQUAD [32,33] was robust, and is still being used, Motekaitis and Martell [30] have articulated the criticism, of which we were only too well aware, that the function minimized did not involve experimentally observed quantities directly. This was put right in SUPERQUAD [21], which therefore had the significant advantage of providing a statistically sounder basis for model selection.

The problem of model selection arises with systems in which it is impossible, a priori, to state what chemical species will be present in appreciable concentrations in the reaction mixtures. In those cases there is a need for some criteria both to determine whether or not the computed equilibrium model is satisfactory in a chemical sense and to see if the calculated data points agree with those observed, within experimental error. We have discussed these criteria previously [21]. What emerges from the analysis is that the expectation value for the sample variance will be unity if, and only if, a weight matrix is used that is the inverse of the variance–covariance matrix of the experimental data [4].

Now, in order to help with the model selection process, it seems a good idea to make use of more than one kind of measurement simultaneously on the same set of reaction solutions. We therefore have developed HYPERQUAD, which can determine equilibrium constants from both potentio-

metric and spectrophotometric (absorbance) data. However, working simultaneously on different kinds of data makes it imperative that a full, rigorous weighting scheme is used. Only when this is so will it be possible to apply simple statistical tests for the goodness of fit, with an expectation value of unity for the sample variance. In order to implement this procedure we have developed a new means of estimating the error in a measure of absorbance.

We have previously outlined the main features used in the HYPERQUAD program [34]. Since that publication, we have developed a suite of inter-related programs which are directed towards data preparation, preliminary model exploration, simulation and preparation of speciation dia-

grams. Together these programs provide almost all the facilities which have previously been used on an ad hoc basis in the process of mode selection. The one exception is that we have not explicitly included an electrode calibration program. We assume that electrodes will be calibrated by means of a strong acid–strong base titration, which HYPERQUAD can handle. MAGEC [35] is a program designed for electrode calibration.

Another set of programs in the HYPERQUAD suite, HypNMR, is described elsewhere [36]. The principal program in that set can be used to determine equilibrium constants from NMR chemical shift data. It is assumed that the species in equilibrium are in rapid exchange on the NMR time-scale so that each value of chemical shift is

the concentration-weighted average of the shifts of the individual species.

2. The HYPERQUAD suite of programs

2.1. The data structure

It became clear very early on that the treatment of different kinds of experimental data logically required a well defined data structure. Previously all programs had used a single file for all the data. With a suite of programs, however, the data files serve as input to different procedures and must therefore be standardised. Conceptually there are four kinds of data file as follows.

(i) A model file. This file contains only the data relevant to a chemical model, viz. the names of the reagents, the equilibrium constants defined by initial value and stoichiometric coefficients, keys to indicate refinable quantities and whether or not a species absorbs light. In addition, our model file may hold the wavelengths at which measurements were made and any known molar absorbances. The model files are given the extension PAR.

(ii) Potentiometric data file. We have Instrument Potentiometric Data (extension IPD) and Program Potentiometric Data (extension PPD) files. The former are ASCII data files such as may be produced by an automatic titrator whilst the latter are suitable for HYPERQUAD. There is a facility in the data editor (HEDIT) for converting IPD to PPD. The PPD file contains the conditions (total amounts, burette concentrations, etc.) of a titration curve as well as the titration data (volume added, e.m.f. of pX measurement).

(iii) Spectrophotometric data. Instrument Absorbance Data (extension IAD) files are ASCII data files typically produced by a spectrophotometer, that is, they contain an absorbance spectrum. Three forms are at present acceptable: initial wavelength and increment, followed by absorbance values, wavelength and absorbance value pairs or the standard JCAMP-DX format [37,38]. A Base Absorbance Data (.BAD) file contains the concentrations, etc., used when the spectrum was recorded and it holds a complete spectrum in HYPERQUAD format. A Program

Absorbance Data file (extention PAD), on the other hand will contain absorbance data at wavelengths selected in the HydraSP program, and may hold data in the form of a spectrophotometric titration curve of batch data.

(iv) Output files. These are files produced during the computations. For example, HYPERQUAD produces a standard output file OUTPUT.RES which may be used in post-run processing of the results of a computation by means of the program HANDOUT.

The fact that the model files do not hold experimental data is a great advantage. For example, it means that one model file may be used with different data sets without the duplication that would have arisen with, say, SUPERQUAD [21]. Furthermore, the model file serves as input to the speciation program HYPHEN where experimental data are irrelevant. Other ways in which the data structure is advantageous are in the determination of end-points (program HENNA) where the model is irrelevant and in factor analysis (program HydraSP), where again the model is irrelevant.

2.2. Linking potentiometric and spectrophotometric data

Each titration curve or experimental spectrum is assigned a unique label. Absorbance Data files carry a second label which may or may not be the same as the label of a potentiometric data file. If this second "corresponding to" label is the same as one in the potentiometric data file then the concentrations, etc., are taken from that file. In this way, it is possible to process either potentiometric or spectrophotometric data on its own, or to process them together.

HYPERQUAD is distributed with a large number of specimen data files. Also, there is a set of template files which can be used for entering new data.

2.3. The HYPERQUAD data editor

The HYPERQUAD data editor HEDIT is designed to make data entry as chemist-friendly as possible. In fact, when this facility is used as

standard, users will not need to know how the data are actually stored in the data files. The data present in a model file (PAR), a potentiometric and/or spectrophotometric data file (PPD, BAD or PAD) are offered for editing in an intelligible form, i.e. reagents are identified by the names specified in the model file, quantities and concentrations are clearly labelled as such, and so forth.

There are two limitations at present to the type of data that may be handled in HEDIT. No more than two electrodes are allowed. Few people have made measurements using two electrodes, and no-one (at least to our knowledge) has yet made measurements using more. The maximum number of reagents is determined by screen resolution and is 12 at present. Otherwise, if the amount of data is more than can appear at one time on the screen there are screen-paging options. One great advantage of using HEDIT is that the user does not require any instructions on how to imput data to HYPERQUAD, although specifications are included in the documentation should anyone prefer to use a text editor.

In addition to being able to process Program data files, the data editor can convert Instrument data files to Program form. Also, if a BAD file corresponds to a single species in solution, this can be input into the model file in the form of a set of molar absorbances. For example, the spectrum of a metal ion could be recorded and transferred into the model file as just described. This is possible because the BAD file holds the concentration of the species which give rise to the spectrum, thus permitting the calculation of molar absorbance from the measurements.

2.4. The programs JOIN and SUPPER

JOIN is a utility·program that links the data from more than one titration curve into one data file. We have kept this as a separate program, rather than include the option in HEDIT, for this reason. The experimental data for any one titration will be stored in a file which is the primary record of the experimental data. Files containing data from more than one titration curve are secondary sources of data. SUPPER will take SUPERQUAD [21] data and convert it into PPD form.

2.5. The program Haber

This program is concerned with the estimation and treatment of errors in absorbance measurements. It is well known that errors in absorbance measurements may depend on the absorbance value. For example, when using a photomultiplier the signal error is often assumed to be proportional to the signal value. However, it is also clear that the magnitude of errors will depend on instrument settings. Therefore, we have devised a scheme whereby the error can be expressed as a simple empirical function that can be incorporated in a model file.

First it is necessary to collect a number of spectra obtained under identical conditions. This means that not only must the instrument conditions be the same but also the spectrum must not vary with time. We prefer to use solid samples such as doped glass filters for this purpose. Suppose n spectra have been obtained; we suggest $n = 9$ as a minimum. Then the abosrbance value is given by the mean of the n measurements and an estimate of the error at that absorbance value is given by the standard deviation of the n measurements:

$$\bar{A} = \frac{\sum_{j=1,n} A_j}{n}$$

$$s_A = \sqrt{\frac{\sum_{j=1,n} (A_j - \bar{A})^2}{n-1}}$$

The values of s_A are plotted on the screen as a function of $\bar{A}$ and the whole set of data is approximated by a simple four-parameter function. The first parameter specifies the function type, either quadratic or exponential. For a quadratic function we have $E = a + bA + cA^2$ and for the exponential function $E = a + be^{cA}$. The values of the parameters a, b and c may be adjusted interactively. It is possible to set one or more of these parameters to zero if that is required.

It may be noted that there is no attempt made to allow for the correlation that undoubtedly exists between the errors at different wavelengths in the same spectrum. Some evidence for this

correlation will be seen in the plots of s_A against $\bar{A}$ in the form of two values of s_A for some values of $\bar{A}$: there is one value when the absorbance curve has a positive slope and another when it has a negative slope. In any case one would normally choose an error function that passes through the middle of the data. We have taken the view that since the weights are only approximate, it is not worth correcting for correlation of errors.

The four parameters of the chosen error function are then entered into a model file. It is possible to have a different error function at each wavelength (thus allowing for the use of different detectors at different wavelengths) or that the error function is the same at all wavelengths.

In a HYPERQUAD calculation, the error at each absorbance value is calculated automatically from the error function in the model file and this is used to construct an approximate variance–covariance matrix for the absorbance measurements, from which the weights are derived. (see below)

2.6. The program HydrapH

This program takes as input a model file and a program Potentiometric Data file and is to be used for preliminary examintion of potentiometric data. The program offers 10 facilities. Six of these relate to presentation of the experimental data on the screen, i.e. e.m.f. or pH on the y-axis, volume, pH or a user-defined coordinate on the x-axis. Then there are species distrubution plots both as formation percentages relative to the total concentration of one reagent and as logarithms of concentration.

At least two programs have been already published concerning the simulation of titration curves, ESTA [39] and SCALPO [40]. We have included the interactive simulation of the titration curve(s) in HydrapH. In this, data in the model file may be amended in any way desired and either the calculated/observed titration curves are displayed or the difference (observed pH − calculated pH). It does not matter if the experimental readings are in mV or pH units. In parallel with the changes in the simulated titration curve there will also be changes in the speciation diagrams. Thus, it is possible to make a thorough prelimi-

nary analysis and ascertain both that the model is reasonable and that all the species postulated to be present and are in appreciable concentrations.

2.7. The program Henna

This is another program for the preliminary analysis of potentiometric data, concerned with end-point determination. The traditional methods used for end-point determination have limitations. Gran's method [41] fails for overlapping end-points [42]. First-derivative methods fail if the data are relatively sparse. For these reasons, we have developed a new algorithm in which the titration curve is fitted, by the method of least squares, by B-spline functions. A derivative of the B-spline function is used to determine the position of the end-point (maximum slope in the first derivative, zero in the second derivative, etc.). A similar procedure has been used to fit spectra [43]. For the purposes of the present application, the user needs to make only two choices: first the derivative required, the degree of the spline function being automatically chosen so that the derivative is a quadratic spline function, and second the number of B-spline pieces. These choices are made interactively. Optimal knot positions are determined automatically by repeated use of procedure called NEWNOT [44] and the observed/calculated titration curves are displayed along with the residuals and the desired derivative. After the user has indicated the approximate position of the end-point to be determined, its optimum position is calculated.

The only problem with this method arises when the number of data points in an interval between knots becomes equal to the degree of the spline function. In that case the calculated titration curve passes exactly through the observed data points, usually with wild oscillations. Since this does not normally happen near an end-point, it is not a serious problem for end-point determination.

2.8. The program HydraSP

This is the main program to be used for preliminary analysis of spectrophotometric data. It takes as input a model file and up to 28 spectra in the

form of BAD files. It offers five main facilities, as follows.

(i) Scaling and correction of data. Spectra can be scaled to equal concentration and path length in order to reveal isosbestic points. Scaling to equal areas can be used for the same purpose and will reveal isosbestic point in some circumstances where the simple scaling does not do so [45]. There is an offset facility which can be used to remove some baseline errors from the spectra. It works as follows. Assuming that the absorbance at the nth wavelength, λ_n, can be written as

$$A_{\lambda_n} = l \sum_j \varepsilon_{\lambda_n,j} c_j + B$$

where B is a constant baseline error, it follows that if the absorbance at one wavelength, λ_b, is subtracted from data at all wavelengths the Beer–Lambert law will still be obeyed but a constant baseline error will have been eliminated:

$$A_{\lambda_n} - A_{\lambda_b} = l \sum_j (\varepsilon_{\lambda_n,j} - \varepsilon_{\lambda_b,j}) c_j$$

The penalty for using this facility is that the molar absorbances are composite but if λ_b is chosen in a region where there is little absorbance this will be of little significance. Therefore, we recommend that spectra be recorded if at all possible with data near the true baseline. To make our procedure more robust we use a smoothed value for the absorbance to be subtracted.

(ii) Selection of wavelengths for HYPER-QUAD calculation. This is an interactive procedure so that the user can choose those wavelengths most suitable for the calculation. Now, in principle, data at one wavelength are sufficient for the purpose of calculating equilibrium constants. One would seek that wavelength which exhibits the maximum change in absorbance with changes in the experimental conditions. Choosing some points on either side of this will help to reduce the effect of noise in the spectroscopic data. However, if different species absorb in different parts of a spectrum, it may be very useful to include data from the different zones. We recommend that relatively few wavelengths are used for a HYPERQUAD calculation;

there is a separate facility for the calculation of the molar absorbances at all wavelengths.

(iii) Trial and error fitting. This is similar to the facility in HydrapH. It works at a single wavelength, which is first chosen interactively. The procedure works as follows. The species concentrations are calculated from the model and the experimental conditions. These concentrations (c_j above) are then used to determine the molar absorbances at the chosen wavelength, from the Beer–Lambert law by weighted linear least squares. The weights are chosen as $1/(\text{absorbance})^2$ so as to minimize the sum of relative errors (another weighting scheme may be used in HYPERQUAD).

(iv) Calculation and display of the molar absorbances at all wavelengths. This calculation proceeds in the same manner as in (iii), but at all wavelengths. The calculated spectra may be stored in ASCII form for plotting by another program, such as EXCEL or ORIGIN. This calculation is a particularly useful check on the validity of a chemical model. Indeed, one would be loath to accept any model for which the calculated spectra of the absorbing species were unreasonable, as, for example, when they had many negative values.

(v) Factor analysis. Factor analysis was first introduced in this field by Kankare [10]. Since then, Zuberbühler and co-workers have developed the concept of Evolving Factor Analysis (EFA) [46,47], which they also describe as model-free analysis of spectrometric data. A similar approach, called "self-modelling curve resolution in studies of spectrometric titrations", has also been published [48]. There is no doubt that factor analysis has the potential to be very useful in studies of equilibria, but in practice it is not easy to apply.

The basis of the application of factor analysis is the Beer–Lambert law, implying that the total absorbance at any wavelength is a linear combination of the absorbances due to a few factors. When the number of (multi-wavelength) observations exceeds the number of factors, it is possible to smooth the data by back transformation using the correct number of abstract factors, as was done in CLINP [12]. However, it is not generally appreciated that this process is based on the

method of least squares. Indeed, the eigenvalues calculated in factor analysis are nothing other than the Langrangian multipliers of a constrained least-squares problem. Therefore, the application of factor analysis in equilibrium studies can be seen as another application of the method of least-squares.

We have used singular value decomposition of the matrix of absorbance values, A, to derive the eigenvalues and eigenvectors of $A^T A$. This procedure eliminates the accumulation of errors inherent in the matrix multiplication. A variety of statistics are provided for 1, 2, ..., eigenvalue models as suggested by Malinowski and Howery [49]. With the aid of these statistics, it should be possible to deduce the number of light-absorbing species present in the equilibria.

The difficulty with factor analysis is that the relationship between the eigenvalues and the experimental errors is an implicit one. It is therefore difficult to establish criteria to determine if a small eigenvalue is effectively non-zero. Conny and Meglen [50] have made an analysis of the effects of experimental noise on the calculated eigenvalues, but their conclusions are not very precise.

As far as Target Factor Analysis is concerned, we see no value in this technique, given that it is possible to perform a full equilibrium analysis. The idea is as follows. Suppose that there are n species to be considered. Then the first n eigenvectors are the abstract factors. To convert them into molar absorbances, a large rotation matrix must be found. The rotation matrix has too many variables to be determined correctly, but some progress can be made by, for example, imposing the condition that molar absorbance must be positive. This will establish ranges for the molar absorbances. The technique was first described in 1974 [51].

By contrast, EFA may be useful as long as one remembers that one is dealing with abstract fators. A careful reading of the original papers [46,47] will reveal that key words such as "species" and "concentration profiles" are written in quotation marks, as here.

2.9. The program Hyphen

This program is different from the other programs in the HYPERQUAD suite in that it does not require experimental data. It can be used to simulate titration curves or to give species distribution diagrams for a wide variety of conditions. Thus, it is a speciation program limited to homogeneous equilibria in solution. There is a large literature referring to speciation programs which we feel is inappropriate to be discussed here. Suffice it to say that the core of the program is the solution of the equations of mass balance by the Newton–Raphson method. This is a sub-problem as far as HYPERQUAD is concerned, so we use the same routines in Hyphen as are used in HYPERQUAD. The model used for these calculations is in a PAR file, but the conditions are stored separately in scratch files that serve merely to allow one to start again where one left off before.

In addition, Hyphen has the facility to calculate the species' concentrations at a single data point defined by knowing, for each reagent, either the total concentration or the free concentration (e.g. pH).

2.10. The program HYPERQUAD

As far as potentiometric data are concerned, the algorithm used in the HYPERQUAD is virtually the same as in SUPERQUAD [21]. Thus the new mathematical features are concerned with the treatment of spectrophotometric data or with the simultaneous treatment of both potentiometric and spectrophotometric data. There are significant differences between the present version of HYPERQUAD and that described in a preliminary account [34]. These arose out of the need to apply a rigorous weighting scheme to the data. The following outline is presented in terms of a relatively simple system of potentiometric measurements using an electrode responding to the hydrogen ion and absorbance measurement at nl wavelengths; there are three reagents, M, L and H, and nk equilibrium constants.

The objective function is given in matrix notation simply as $U = r^T W r$, where r is a vector of residuals, $r = (y^{observed} - y^{calculated})$, $y^{observed}$ repre-

sents a measurment in mV, pH or absorbance and W is a matrix of weights. The residuals are ordered with potentiometric first and absorbance second. To minimize the objective function, we use the Gauss–Newton–Marquardt method summarized by the system of normal equations

$$(J^TWJ + \lambda D)\Delta p = J^TWr$$

where J is the Jacobian matrix and Δp is a vector of shifts to be applied to the parameters. D is taken as equal to the diagonal elements of J^TWJ and λ is the Marquardt parameter which may, of course, be zero. The method requires that the parameters be given initial values; these may be obtained with the aid of HydrapH or HydraSP.

The elements of the Jacobian relative to any unknown parameter p are obtained from the defining equations, the modified Nernst law (ionic charges are omitted for simplicity of notation):

$$E = E^0 + f\frac{RT}{nF}\ln[H]$$

$$\frac{\partial E}{\partial p} = \frac{\partial E}{\partial [H]}\frac{\partial [H]}{\partial p}$$

and the Beer–Lambert law:

$$A_\lambda = l\sum_{j=1,na}\varepsilon_{\lambda j}c_j$$

$$\frac{\partial A_\lambda}{\partial x} = l\sum_j\varepsilon_{\lambda j}\frac{\partial c_j}{\partial x}$$

$$= [M] + \sum p_k c_k$$

is the equation for reagent M; similar equations may be written for L and H. Moreover, the total concentration T_M is obtained from the initial amount n_M, burette concentration a_M, initial volume v_0 and added volume v. Thus the three mass-balance equations are

$$\frac{n_M + va_M}{v_0 + v} = [M] + \sum_{k=1,kn}p_k c_k$$

$$\frac{n_L + va_L}{v_0 + v} = [L] + \sum_{k=1,nk}q_k c_k$$

$$\frac{n_H + va_H}{v_0 + v} = [H] + \sum_{k=1,nk}r_k c_k$$

These are solved by the Newton–Raphson method and the normal equations matrix is used to derive $\partial[H]/\partial\beta_k$ as described earlier [34]. Other Jacobian elements such as $\partial E/\partial E^0$, $\partial E/\partial n$ and $\partial E/\partial a$ are easy to derive. When quantities such as E^0 are refined they are termed dangerous parameters. Now, with these equations the Jacobian for one data point can be constructed, as in the following example applicable to a system with one electrode, na absorbing species, nl wavelengths, nk equilibrium constants and nd dangerous parameters, denoted by $\alpha_1, ..., \alpha_{nd}$. Note that we further assume here that there is a molar absorbance for each species at every wavelength.

$$
\begin{array}{cccccccc}
0 & \cdots & 0 & 0 & \cdots & 0 & \cdots & 0 \\
\dfrac{\partial A_1}{\partial\varepsilon_{1,1}} & \cdots & \dfrac{\partial A_1}{\partial\varepsilon_{1,na}} & 0 & \cdots & 0 & \cdots & 0 \\
0 & \cdots & 0 & \dfrac{\partial A_2}{\partial\varepsilon_{2,1}} & \cdots & \dfrac{\partial A_2}{\partial\varepsilon2_{,na}} & \cdots & 0 \\
\vdots & \cdots & \vdots & \vdots & \cdots & \vdots & \ddots & \vdots \\
0 & \cdots & 0 & 0 & \cdots & 0 & \cdots & \dfrac{\partial A_{nl}}{\partial\varepsilon_{nl,1}}
\end{array}
$$

In addition, the system is subject to the constraint that the equations of mass balance are satisfied.

$$T_M = [M] + \sum_{k=1,nk}p_k\beta_k[M]^{p_k}[L]^{q_k}[H]^{r_k}$$

$$
\begin{array}{cccccccc}
\cdots & 0 & \dfrac{\partial E}{\partial\beta_1} & \cdots & \dfrac{\partial E}{\partial\beta_{nk}} & \dfrac{\partial E}{\partial\alpha_1} & \cdots & \dfrac{\partial E}{\partial\alpha_{nd}} \\
\cdots & 0 & \dfrac{\partial A_1}{\partial\beta_1} & \cdots & \dfrac{\partial A_1}{\partial\beta_{nk}} & \dfrac{\partial A_1}{\partial\alpha_1} & \cdots & \dfrac{\partial A_1}{\partial\alpha_{nd}} \\
\cdots & 0 & \dfrac{\partial A_2}{\partial\beta_1} & \cdots & \dfrac{\partial A_2}{\partial\beta nk} & \dfrac{\partial A_2}{\partial\alpha_1} & \cdots & \dfrac{\partial A_2}{\partial\alpha_{nd}} \\
\cdots & 0 & \vdots & \cdots & \vdots & \dfrac{\partial A_1}{\partial\alpha_1} & \cdots & \vdots \\
\cdots & \dfrac{\partial A_{nl}}{\partial\varepsilon_{nl,na}} & \dfrac{\partial A_{nl}}{\partial\beta_1} & \cdots & \dfrac{\partial A_{nl}}{\partial\beta_{nk}} & \dfrac{\partial A_{nl}}{\partial\alpha_1} & \cdots & \dfrac{\partial A_{nl}}{\partial\alpha_{nd}}
\end{array}
$$

At this point the normal equations matrix J^TWJ and right-hand side J^TWr can be built up by accumulation. To do this we use the factored weight matrix, $W = w^Tw$. First the Jacobian and residual are left-multiplied by the factor and then the normal equations are accumulated as

$(wJ)^T(wJ)$ and $(wJ)^Twr$. This process destroys the block-diagonal structure[1] that was previously described for the normal equations matrix [34]. The normal equations that result have the dimensions of $na \times nl + nk + nd$. It is obvious that the number of wavelengths, nl, should not be large, otherwise the normal equations become large and hence slow and difficult to solve.

Solution of the normal equations provides shifts for all the parametes. However, the shifts on the molar absorbances are not used. Instead, the equilibrium constants and dangerous parameters are updated with the shifts and the molar absorbances are calculated using the updated values by linear least-squares applied to the Beer–Lambert law. In this procedure we follow what appears to be standard practice going back to LETAGROP–SPEFO [6]. However, some authors have applied a non-negativity constraint to the molar absorbances (SPECA [19], STAR [52]). We have not done this because we believe that a negative molar absorbance is a good indicator that something is wrong with the chemistry.

To understand how a negative molar absorbance, $\varepsilon_{\lambda j}$, can arise we must write out the Beer-Lambert law in full:

$$A_\lambda = l \sum_{j=1,na} \varepsilon_{\lambda j} \beta_j [M]^{p_j} [L]^{q_j} [H]^{r_j}$$

Since the molar absorbance is multiplied by the equilibrium constant, this expression shows that we can expect the molar absorbances to be highly correlated with the equilibrium constants so that a small error in the latter can easily lead to a negative value in the former. Thus, negative molar absorbances indicate that the calculated equilibrium constants are in error.

The high correlation between molar absorbances and equilibrium constants is masked, but not eliminated, by the two-stage refinement process. It is a central problem in the determination of equilibrium constants from spectrophotometric data that can only be resolved by good experimental design. The calculation of all molar

---

[1] The normal equation will have the block-diagonal structure if a diagonal weight matrix is used, but no special provision is made for this eventuality.

absorbances with the aid of HydraSP may reveal negative values at wavelengths not used in a HYPERQUAD calculation, so that it would be good practice to calculate all molar absorbances as a check on the results of a calculation based on selected wavelengths.

2.11. Calculation of the free concentrations

The equations of mass balance can be written in the most general form as $(i = 1, nr)$

$$T_i = [X_i] + \sum_{k=1,nk} q_{ik} \beta_k \prod_{j=1,nr} [X_j]^{q_{jk}}$$
