Received 31 March 1995; revised 23 June 1995; accepted 6 July 1995

Abstract

The interactions of Bromophenol Blue (BPB) with bovine serum albumin and γ-globulin in acidic solutions were investigated by a spectrophotometric method. It was considered that the electrostatic force is the main binding force, and that the color change during the combination is due to the transformation of dye species of free acidic form into bound basic form as well as to the bathochromic and hyperchromic effects of conjugation. The formation of an isosbestic point in the absorption spectra was explained based on a new consideration about the solution equilibria. Two conditional constants, apparent binding constant and maximum binding number, were defined to express the binding ability of a dye to a certain protein under a given set of conditions, and two linear regression equations were derived to determine these two parameters and the molar absorptivity of bound dye. The Scatchard model is not appropriate in the treatment of data obtained here. The factors which influence the sensitivity of a dye binding protein assay were discussed, and the Sandell index was used to express the sensitivity of protein detection. It was found that sodium chloride concentration and acidity of the solutions have significant effect on the sensitivity of BPB protein assay.

Keywords: Bromophenol Blue; Bovine serum albumin; γ-Globulin; Acidic solutions

1. Introduction

Dye binding protein assays are commonly used in biochemical and clinical laboratories, but they are not well understood at the molecular level. A further theoretical study on this kind of reaction should be benficial not only with regard to the

quantitation of proteins but also to a deep understanding of the interaction between proteins and small ions or molecules.

Scatchard et al. [1] treated the reaction of small ions with albumin as a true combination of the ligand with specific sites on the macromolecule. Since then, this model has been widely used to describe this kind of reaction. However, Pesavento and Profumo [2] reported that the Scatchard model was not appropriate for the

* Corresponding author.

treatment of data obtained in the study of the combination of T-azo-R with bovine serum albumin (BSA) in acidic solutions. They considered that there were no evident specific combination sites on the BSA molecule, and proposed a two-phase distribution model to interpret their experimental findings. Congdon et al. [3] recently employed a modified Scathard equation and Hill equation to study the high-affinity dye binding sites of the interaction between Coomassie Brilliant Blue and proteins at high protein/dye concentration ratios, but they failed in their attempt to use these equations to estimate the total number of dye binding sites under normal conditions. Therefore, the question of whether the Scatchard model is suitable for the description of dye binding reactions still remains unanswered.

In this paper, a new attempt is made to interpret the interaction of Bromophenol Blue (BPB) with proteins [4,5]. BPB has been used as a staining reagent in the determination of urinary proteins [6,7], yet no theoretical study on its staining reaction has been found in the literature. It will be shown that the BPB–protein binding reaction can be successfully treated by using a new method proposed in this paper, and that the Scatchard plot obtained here is completely different from that expected.

2 Experimental

2.1. Reagents

BSA 99%, was obtained from Sigma and used without further purification. All calculations reported by BSA are in terms of a molecular weight of 65 000. The aqueous BSA solution $(2.0 \times 10^{-5} \, \text{mol} \, l^{-1})$ was prepared by dissolving 0.262 g BSA reagent in 200 ml deionized water. γ-Globulin Human (γ-G) was obtained from Serva (Germany). Calculations reported for γ-G are in terms of a molecular weight of 160 000. The aqueous γ-G solution $(6.25 \times 10^{-6} \, \text{mol} \, l^{-1})$ was prepared by solving 0.100 g γ-G reagent in 100 ml deionized water. BPB was purchased from BDH and purified by recrystallization from boiling glacial acetic acid [8]. The BPB stock solution

$(1.5 \times 10^{-3} \, \text{mol} \, l^{-1})$ was prepared by dissolving 0.100 g purified dye in 20 ml 95% ethanol, and then diluting it to 100 ml with water. The operating solution of BPB was prepared by diluting the stock solution with water. Britton–Robinson buffer was prepared by adding a given amount of $0.2 \, \text{mol} \, l^{-1}$ NaOH to 100 ml of mixed-acid solution containing phosphoric acid, acetic acid, and boric acid each with a concentration of $0.04 \, \text{mol} \, l^{-1}$. All other reagents were of analytical or guaranteed reagent grade.

2.2. Apparatus

A Shimadzu Model UV-265 double-beam spectrophotometer was used for recording absorption spectra, and a Shimadzu UV-120-02 spectrophotometer for the measurement of absorbance at a given wavelength. A Model 821 pH/mV meter (Zhongshan University, China) was used for the pH measurements.

2.3. Method

Aliquots of 5% NaCl solution, pH buffer or HCl solution, and BPB operating solution were transferred into a series of 25 ml volumetric flasks, and then protein solution was added to each flask in different amounts. The mixtures were diluted to the mark with water and mixed thoroughly. After 20 min [4–7], spectra or absorbances of these solutions were measured with reference to water.

3. Results and discussion

3.1. Absorption spectra and binding mechanism

Fig. 1 shows the absorption spectrum of BPB. It was obtained by keeping the BPB concentration constant and changing the pH of the solutions. In Fig. 1, two absorption peaks appear at 435 nm and 591 nm. A well-defined isosbestic point is observed at 494 nm. This spectral feature corresponds to the proton dissociation of BPB:
and its dissociation constant is $pK_a = 3.85$.

For simplicity, the above equation can be written as

$$HL^- \rightleftharpoons L^{2-} + H^+ \qquad (1)$$

Fig. 2 shows the absorption spectra of BPB–BSA mixtures. They were obtained by keeping the BPB concentration and pH constant and increasing the BSA concentration. With the increase in BSA concentration, the absorption peak at 591 nm increases strikingly and shifts to 604 nm, while the absorption peak at 435 nm decreases and shifts to 440 nm. An isosbestic point is formed at 502 nm. Fig. 2 indicates that there are interactions between BPB and BSA.

In view of the molecular structure of BPB and BSA, it is not possible to reach a conclusion that

BPB combines preferentially with a particular group on BSA to form a complex. Compton and Jones [9] suggested that the binding of Coomassie Brilliant Blue G-250 on protein is a result of Van der Waals forces and hydrophobic interactions. This mechanism is not convincing in this study, because the hydrophobic groups on the BPB molecule were not predominant compared with the hydrophilic groups, although the Van der

Fig. 1. BPB absorption spectra at various pH values. BPB concentration constant at 3.01×10^{-5} mol l^{-1}. In order of increasing peak absorbances at 591 nm. pH values are 2.67, 2.98, 3.12, 3.28, 3.56 and 3.72.

Fig. 2. Absorption spectra of BPB–BSA mixtures. BPB concentration constant at 1.2×10^{-5} mol l^{-1}, pH 3.28, 0.5% NaCl. In order of increasing peak absorbances at 600 nm, BSA concentrations are 0.0, 4.0×10^{-7}, 8.0×10^{-7}, 1.2×10^{-6}, 1.6×10^{-6}, 2.4×10^{-6}, 3.2×10^{-6}, 4.0×10^{-6}, 5.2×10^{-6}, 6.4×10^{-6}, 8.0×10^{-6}, 1.2×10^{-5} and 1.36×10^{-5} mol l^{-1}.

Waals forces and hydrophobic interactions may play a part in the binding process. A reasonable explanation of these molecular events is that BPB interacts with BSA by non-specific, electrostatic forces [2,4,5,10]. Under the conditions of Fig. 2, the pH (3.28) is lower than the isoelectric point of BSA ($pI = 4.8$). Lysine, arginine and other amino acid residues on the BSA molecular chain are in the protonated form and therefore the whole BSA molecules are positively charged. However, the BPB species, HL^- and L^{2-}, have negative charge. Therefore, BSA and BPB species should be bound together by electrostatic forces:

$$L^{2-} + P^+ \rightleftharpoons L' \qquad (2)$$

$$HL^- + P^+ \rightleftharpoons HL' \qquad (3)$$

where P^+ represents the non-specific binding sites on protein, and the primed symbols, L' and HL', refer to bound L^{2-} and HL^- respectively. Since L^{2-} has more negative charges than HL^-, it takes priority in binding to protein. As the free L^{2-} species is used up in the binding process, equilibrium (1) shifts to the right to restore the concentration of L^{2-}, thereby resulting in an increase of absorbance in the vicinity of 600 nm. However, as BSA is in the positively charged state, the bound HL^- should more easily lose H^+ than free HL^-:

$$HL' \rightleftharpoons L' + H^+ \qquad (4)$$

This reaction also results in an increase of absorbance in the vicinity of 600 nm.

Considering all the four possible reactions in the binding process, the overall solution equilibria may be expressed as

$$HL^- \rightleftharpoons L^{2-} + H^+$$
$$P^+ \,\big\updownarrow \quad P^+ \,\big\updownarrow \qquad\qquad (5)$$
$$HL' \rightleftharpoons L' + H^+$$
There are two paths to carry the binding process through according to this equilibria model: either the free HL^- first dissociates its H^+ and then binds to BSA; or else it first binds to BSA and then dissociates H^+. Both paths have the same final state and therefore the same free energy change, so both paths have no difference in terms

of thermodynamics. Adding Eq. (1) to Eq. (2) or adding Eq. (3) to Eq. (4) gives the same total reaction equation

$$HL^- + P^+ \rightleftharpoons L' + H^+ \qquad (6)$$
An increase in BSA concentration will shift equilibrium (6) from the left to the right, causing spectral changes as can be seen in Fig. 2.

The red shift and hyperchromic effect observed in Fig. 2 can be explained by the conjugation theory [3]. Binding of dye to lysine and arginine side-chains may allow donation of electrons by an auxochromic amino or guanidino group to the π electron system, thereby increasing the degree of conjugation and lowering the energy of a π^* state of the dye. Such electron donation provides an explanation for the hyperchromicity, while the lower-energy excited state explains the bathochromicity.

3.2. Explanation of the formation of the isosbestic point

The formation of an isosbestic point in Fig. 1 is due to the transformation of two BPB color species from one into another [11]. In the conditions of Fig. 2, however, there are four color species in solution according to the equilibrium model (5). The existing theory [11] cannot give an explanation in this case. In the following discussion, an attempt will be made to give an interpretation for the formation of the isosbestic point in Fig. 2. This discussion will also lead to a new method for the treatment of dye binding reactions.

Define $\{L\}$ as the total concentration of free BPB, $\{L'\}$ as the total concentration of bound BPB, and c_L as the analytical concentration of BPB, that is (omitting electrical charges):

$$\{L\} = [HL] + [L] \qquad (7)$$

$$\{L'\} = [HL'] + [L'] \qquad (8)$$

$$c_L = \{L\} + \{L'\} \qquad (9)$$

The absorbance of the dye–protein mixtures is (with a 1 cm cell)

$$A = \varepsilon_{HL}[HL] + \varepsilon_L[L] + \varepsilon_{HL'}[HL'] + \varepsilon_{L'}[L'] \qquad (10)$$

where ε_{HL}, ε_L, $\varepsilon_{HL'}$ and $\varepsilon_{L'}$ are molar absorptivities of HL, L, HL', and L' respectively. Define distribution coefficients as

$$\delta_{HL} = [HL]/\{L\} \tag{11}$$

$$\delta_L = [L]/\{L\} \tag{12}$$

$$\delta_{HL'} = [HL']/\{L'\} \tag{13}$$

$$\delta_{L'} = [L']/\{L'\} \tag{14}$$

Substitution of Eq. (7) into Eq. (11) gives:

$$\delta_{HL} = [HL]/([HL] + [L])$$
$$= [HL]/([HL] + k_a[HL]/[H]) = [H]/([H] + k_a) \tag{15}$$

Similar substitution leads to

$$\delta_L = k_a/([H] + k_a) \tag{16}$$

$$\delta_{HL'} = [H]/([H] + k_a') \tag{17}$$

$$\delta_{L'} = k_a'/([H] + k_a') \tag{18}$$

where k_a and k_a' are the dissocation constants of HL and HL':

$$k_a = [H][L]/[HL] \tag{19}$$

$$k_a' = [H][L']/[HL'] \tag{20}$$

k_a' is an unknown constant. Note that distribution coefficients are merely the functions of pH and are independent of BSA concentration.

Substituting Eqs. (11–14) into Eq. (10) yields

$$A = (\varepsilon_{HL}\delta_{HL} + \varepsilon_L\delta_L)\{L\} + (\varepsilon_{HL'}\delta_{HL'} + \varepsilon_{L'}\delta_{L'})\{L'\} \tag{21}$$

Let

$$\varepsilon = \varepsilon_{HL}\delta_{HL} + \varepsilon_L\delta_L \tag{22}$$

$$\varepsilon' = \varepsilon_{HL'}\delta_{HL'} + \varepsilon_{L'}\delta_{L'} \tag{23}$$

where ε and ε' are the mean molar absorptivities of free and bound dye $(mol^{-1} l\,cm^{-1})$ respectively. They are constants when pH and measuring wavelength are given. So Eq. (21) may be simplified as

$$A = \varepsilon\{L\} + \varepsilon'\{L'\} = \varepsilon c_L + (\varepsilon' - \varepsilon)\{L'\} \tag{24}$$

If $\varepsilon' = \varepsilon$ at a certain wavelength (502 nm in Fig. 2), Eq. (24) becomes $A = \varepsilon c_L$, which is a constant,

unchanging with increase of BSA concentration, and so the isosbestic point appears.

3.3. A new method for the treatment of the dye binding reaction

Apparent binding constant

According to Eq. (6), the equilibrium constant of the total binding reaction should be

$$K = [L'][H]/[HL][P] \tag{25}$$

where [P] represents the concentration of unoccupied binding sites on protein

$$[P] = Nc_P - \{L'\} = (N - \bar{n})c_P \tag{26}$$

where c_P is the anlaytical concentration of protein, N the total number of binding sites per protein molecule (it is an unknown constant, since there are 60 lysines, 26 arginines, and other aromatic amino acids on BSA molecule, the total number of binding sites on BSA should be more than 86) [12], $\bar{n}$ the average binding number of die molecules per protein molecule (see Eq. (36)). If $\bar{n}$ can be omitted when compared with N (see Table 1), then Eq. (26) may be written approximately as

$$[P] = Nc_P \tag{27}$$

This approximation leads to an easy mathematical treatment, and it holds under normal conditions.

From Eqs. (11–14), we have $[HL] = \delta_{HL}\{L\}$, and $[L'] = \delta_{L'}\{L'\}$. Substituting these two equations and Eq. (27) into Eq. (25) gives

$$K = \delta_{L'}\{L'\}[H]/\delta_{HL}\{L\}Nc_P \tag{28}$$

If [H] (or pH) has been given (as in Fig. 2), then $\delta_{L'}$, δ_{HL}, and N have fixed values. Thus, we can define a new constant:

$$K_c = NK\delta_{HL}/\delta_{L'}[H] = \{L'\}/\{L\}c_P \tag{29}$$

K_c is a conditional constant. It is a measure of the dye binding ability of a protein under certain conditions. Similar to the apparent stability constant used in the treatment of complexation equilibria, we call K_c the apparent binding constant.

Theoretically, K_c is a constant when experimental conditions are given; it has been proved by experiment that K_c is indeed a constant under certain conditions (see Table 1).

Table 1
Data used for linear regressions. $c_P \sim \Delta A$ data were obtained from Fig. 2. $c_L = 1.2 \times 10^{-5}\,\text{mol}\,l^{-1}$, pH = 3.28, 0.5% NaCl, $\Delta A_{max} = 0.804$ at 605 nm

c_P (mol l^{-1})	ΔA	$\Delta A/c_P$	$\bar{n}$	$\bar{n}c_P$	$\bar{n}/\{L\}$	$\log K_c$
0.4×10^{-6}	0.144	3.60×10^5	5.38	2.15×10^{-6}	5.46×10^5	5.737
0.8×10^{-6}	0.254	3.18×10^5	4.75	3.80×10^{-6}	5.79×10^5	5.763
1.2×10^{-6}	0.322	2.68×10^5	4.01	4.81×10^{-6}	5.58×10^5	5.747
1.6×10^{-6}	0.378	2.36×10^5	3.53	5.65×10^{-6}	5.56×10^5	5.745
2.4×10^{-6}	0.456	1.90×10^5	2.84	6.82×10^{-6}	5.48×10^5	5.739
3.2×10^{-6}	0.520	1.63×10^5	2.43	7.77×10^{-6}	5.74×10^5	5.759
4.0×10^{-6}	0.556	1.39×10^5	2.08	8.31×10^{-6}	5.64×10^5	5.751
5.2×10^{-6}	0.598	1.15×10^5	1.72	8.94×10^{-6}	5.62×10^5	5.750
6.4×10^{-6}	0.628	9.81×10^4	1.47	9.39×10^{-6}	5.63×10^5	5.751
8.0×10^{-6}	0.654	8.18×10^4	1.22	9.78×10^{-6}	5.50×10^5	5.740

Determination of apparent binding constant

A method for the determination of the apparent binding constant K_c may be developed from Eq. (24). Rearranging Eq. (24) yields

$$\{L'\} = (A - \varepsilon c_L)/(\varepsilon' - \varepsilon) \qquad (30)$$

where A is the absorbance of dye–protein mixtures, and εc_L the absorbance of a zero-protein solution. Both A and εc_L can be measured. Let

$$\Delta A = A - \varepsilon c_L \qquad (31)$$

$$\Delta \varepsilon = \varepsilon' - \varepsilon \qquad (32)$$

then Eq. (30) may be simplified as

$$\{L'\} = \Delta A/\Delta \varepsilon \qquad (33)$$

If ε' and ε are determined previously from the absorbance of solutions with an excess of BSA and without BSA, then $\Delta \varepsilon$ is a known quantity. Therefore $\{L'\}$ can be calculated according to Eq. (33). Furthermore, since $\{L\} = c_L - \{L'\}$, K_c may be calculated directly by using Eq. (29).

The above method for the determination of K_c is simple in principle but inconvenient in use, because the values of ε' and ε have to be determined in advance. For this reason the following linear regression method was developed.

Substituting Eq. (33) and Eq. (9) into Eq. (29) gives

$$K_c = (\Delta A/\Delta \varepsilon)/[(c_L - \Delta A/\Delta \varepsilon)c_P]$$

Rearranging this equation yields

$$\Delta A = \Delta \varepsilon c_L - Kc^{-1}\Delta A/c_P \qquad (34)$$

where K_c is a constant, and $\Delta \varepsilon c_L$ has a fixed value. In fact, $\Delta \varepsilon c_L$ is the maximum value of ΔA, which can be measured directly at high protein/dye concentration ratios. Therefore, we write

$$\Delta A_{max} = \Delta \varepsilon c_L \qquad (35)$$

There is a linear relationship between ΔA and $\Delta A/c_P$ according to Eq. (34). From the slope $(-Kc^{-1})$ and intercept $(\Delta \varepsilon c_L)$ of the regression line, Kc and $\Delta \varepsilon$ (and then ε') can be calculated.

Binding number and maximum binding number

Define the (average) binding number of dye molecules per protein molecule as

$$\bar{n} = \{L'\}/c_P \qquad (36)$$

Substituting Eq. (33) into Eq. (36) yields

$$\bar{n} = \Delta A/\Delta \varepsilon c_P \qquad (37)$$

Since $\Delta \varepsilon$ has been determined, $\bar{n}$ can be calculated by using Eq. (37).

Multiplying Eq. (34) by $K_c/\Delta \varepsilon$, we get

$$K_c\Delta A/\Delta \varepsilon = K_c c_L - \Delta A/\Delta \varepsilon c_P$$

Substituting Eq. (37) into this equation and rearranging gives

$$\bar{n} = K_c c_L - K_c \bar{n}c_P \qquad (38)$$

Since K_c is a constant and c_L is a fixed value, a plot of $\bar{n}$ vs. $\bar{n}c_P$ should give a straight line with slope $-K_c$ and intercept $K_c c_L$.

Table 2
Effect of NaCl concentration on binding of BPB on BSA. pH = 3.1, $c_L = 1.2 \times 10^{-5}$ mol l^{-1}, at 605 nm

NaCl (%)	log K_c	n	ε ($\times 10^3$)	ε' ($\times 10^4$)	S	R
0	6.18	18.0	4.45	7.01	0.054	−0.997
0.04	6.10	14.8	5.13	6.90	0.069	−0.997
0.10	6.01	12.1	5.63	6.69	0.088	−0.996
0.20	5.94	10.3	6.13	6.45	0.11	−0.997
0.50	5.80	7.5	7.22	6.44	0.15	−0.993
1.00	5.67	5.5	7.82	6.33	0.21	−0.996
2.00	5.49	3.7	8.74	6.57	0.31	−0.996

Note that the physical meaning of the intercept $K_c c_L$ on the $\bar{n}$ axis is the maximum value of $\bar{n}$ under the experimental conditions. Therefore we call this extrapolated value the maximum binding number n:

$$n = K_c c_L \qquad (39)$$

The maximum binding number n is also a conditional constant. As will be seen later on, it is a useful parameter for expressing the dye binding ability of a protein under certain conditions.

Table 1 gives a group of data taken from Fig. 2. Using these data, a $\Delta A \sim \Delta A / c_p$ regression equation and a $\bar{n} \sim \bar{n} c_P$ regression equation were obtained:

$$\Delta A = 0.804 - 1.79 \times 10^{-6} \Delta A / c_P \quad R = -0.998$$

$$n = 6.63 - 5.57 \times 10^5 \bar{n} c_P \qquad R = -0.998$$

From the slopes and intercepts of these two equations, $\log K_c = 5.75$, $\Delta A_{max} = 0.804$, and $n = 6.63$ are obtained.

It is shown in this example that the theory discussed above is coincident with the experimental findings.

A question which must be asked is that with more than 86 binding sites on the BSA molecule, why do so few of these sites bind to dye? This question may be addressed from the position that the dye binding is indeed a process of competition between the dye species and anions for the same binding sites on protein [1]. For controlling the acidity and the ion strength, buffer and salt must be added to the solution. The concentrations of the anions are usually 1000 ~ 10 000-fold higher than that of the dye species, so the binding sites

are actually surrounded by anions which prevent the die species from binding to protein. The higher the concentration of the anions, the fewer the binding numbers (see Table 2).

3.4. Test of Scatchard model

In the Scathard model, the binding equation is given by [3]

$$\bar{n} / \{L\} = kN - k\bar{n} \qquad (40)$$

where k is the intrinsic binding constant.

Using the data listed in Table 1, a plot of $\bar{n} / \{L\}$ vs. $\bar{n}$ was drawn, and it was found that the plot does not conform to Eq. (40), because the $\bar{n} / \{L\}$ values are essentially constant. Actually, the term $\bar{n} / \{L\}$ in Eq. (40) is just the apparent binding constant K_c defined in this paper. Therefore the Scatchard model is unsuitable for this study.

3.5. Sensitivity of a dye binding protein assay

Define the molar absorptivity of a dye–protein complex as

$$\varepsilon_p = n\varepsilon' \qquad (41)$$

According to Beer's law, the absorbance of a solution of dye–protein complex may be expressed as (with a 1 cm cell)

$$A = \varepsilon_p c_p \qquad (42)$$

The absorbance of a solution containing protein and an excess of dye is

$$A = \varepsilon_p c_p + \varepsilon(c_L - n c_p) \qquad (43)$$

In the practice of a proetin assay, the absorbance of a dye–protein mixture is measured against the blank solution of dye, so the net absorbance is

$$\Delta A = [\varepsilon_P c_P + \varepsilon(c_L - nc_P)] - \varepsilon c_L \tag{44}$$

Using Eq. (41), this equation may be simplified as

$$\Delta A = n(\varepsilon' - \varepsilon)c_P \tag{45}$$

Eq. (45) indicates the factors which influence the sensitivity of a dye binding protein assay. For a given amount of protein, the net absorbance depends on three factors: the maximum binding number n; the mean molar absorptivity of bound die ε'; and the mean molar absorptivity of free dye ε.

It should be noted that Eq. (45) has been obtained before [12] from a simpler consideration not involving the binding of protonated forms of the dye to protein. It is interesting that essentially the same result is found by this more complex treatment.

The Sandell index (S, $\mu g\, cm^{-2}$) [13], which represents the number of micrograms of the determinand per millilitre of a solution having an absorbance of 0.001 for the path length 1 cm, is a suitable parameter for expressing the sensitivities of a protein assay under different conditions and for comparing the variability of color development among proteins with different molecular weights. The relationship between the Sandell index and the above three parameters is

$$S = F/n(\varepsilon' - \varepsilon) \tag{46}$$

where F is the molecular weight of the protein assayed.

3.6. Influence of experimental conditions on dye binding reaction

It is shown in Table 2 that an increase in salt concentration causes a significant decrease in $\log K_c$ and n values, thus decreasing the sensitivity of the BPB protein assay. This effect may be explained as a competition between anions and dye species for the same binding sites on BSA [1]. Even when no salt was added to the solutions, the concentrations of anions coming from the addi-

Table 3
Effect of pH on binding of BPB on BSA. $c_L = 1.2 \times 10^{-5}\, mol\, l^{-1}$, 0.5% NaCl, at 605 nm

pH	$\log K_c$	n	$\varepsilon\,(\times 10^3)$	$\varepsilon'(\times 10^4)$	S	R
2.12	5.74	6.5	0.76	1.99	0.52	−0.995
2.49	5.79	7.3	2.02	3.60	0.26	−0.999
2.80	5.83	8.0	4.20	4.88	0.18	−0.995
3.10	5.80	7.5	7.23	6.44	0.15	−0.993
3.28	5.75	6.7	10.6	7.75	0.15	−0.997
3.42	5.72	6.2	14.9	8.20	0.16	−0.998

tion of buffer are still much higher than that of the dye species. This is probably the reason why the maximum binding numbers determined in this paper are no more than 18.

The influence of acidity on BPB binding reaction is shown in Table 3. From Table 3 we know that in the tested pH range the change of pH has no great influence on $\log K_c$ and n values, but has significant influence on ε and ε' values. The Sandell index S has the best value at pH 3.2.

The influence of BPB concentration on the binding reaction is shown in Table 4. From this test we know that an increase in BPB concentration causes a decrease in $\log K_c$ but an increase in n values, while ε and ε' remain practically constant. However, the dye concentration cannot be too high because of the restriction of spectral measurement.

3.7. Combination between BPB and γ-G

The combination of BPB with γ-G was investigated by using the above method. Fig. 3 shows the absorption spectra of BPB–γ-G mixtures. Using the spectral data measured at 610 nm, a

Table 4
Effect of BPB concentration on binding of BPB on BSA. 0.5% NaCl, pH = 3.1 at 605 nm

$c_L\,(mol\, l^{-1})$	$\log K_c$	n	$\varepsilon\,(\times 10^3)$	$\varepsilon'(\times 10^4)$	S	R
0.6×10^{-5}	6.01	6.1	7.39	6.45	0.19	−0.997
0.9×10^{-5}	5.90	7.1	7.40	6.38	0.16	−0.991
1.2×10^{-5}	5.80	7.5	7.23	6.44	0.15	−0.993
1.5×10^{-5}	5.76	8.4	7.16	6.24	0.14	−0.994
1.8×10^{-5}	5.68	8.6	7.08	6.26	0.14	−0.995

Fig. 3. Absorption spectra of BPB–BSA mixtures. BPB concentration constant at 1.2×10^{-5} mol l^{-1}, pH 3.28, 0.5% NaCl. In order of increasing peak absorbances at 600 nm, BSA concentrations are 0.0, 4.0×10^{-7}, 8.0×10^{-7}, 1.2×10^{-6}, 1.6×10^{-6}, 2.4×10^{-6}, 3.2×10^{-6}, 4.0×10^{-6}, 5.2×10^{-6}, 6.4×10^{-6}, 8.0×10^{-6}, 1.2×10^{-5} and 1.36×10^{-5} mol l^{-1}.

$\Delta A \sim \Delta A / c_P$ linear regression equation was obtained:

$$\Delta A = 0.384 - 1.50 \times 10^{-6} \Delta A / c_P \qquad R = -0.993$$

From the slope and intercept of this equation, $\log K_c = 5.83$, $\Delta A_{max} = 0.384$, and $n = K_c c_L = 11.8$ were obtained.

4. Conclusions

The combination of BPB species with proteins in acidic solutions is due mainly to the non-specific electrostatic forces. This kind of combination allows a transformation of BPB species from free acidic form into bound basic form and allows a donation of electrons by the protein to the π electron system of BPB, thereby causing bathochromicity and hyperchromicity. These spectral effects establish the foundation of the BPB protein assay.

The Scatchard model is not appropriate for this study. Instead a new linear regression method based on a new consideration about the solution equilibria is able to give a reasonable description

of the dye–protein combination under different conditions. Both the apparent binding constant and the maximum binding number proposed in this paper depend on experimental conditions. Therefore they are different from the Scatchard intrinsic binding constant and the number of binding sites.

It seems that this method is useful and convenient for the investigation of dye-binding protein assays, because the parameters defined in this paper describe the conditions of the dye–protein binding reaction, and these parameters can be determined easily.

To use the method, the experiment should be carried out under proper conditions. That is to say, the dye/protein concentration ratios should not be too high or too low so that the free dye species and the unoccupied protein binding sites are substantially coexistent under experimental conditions.

The intercept ($\Delta \varepsilon c_L$) of the $\Delta A \sim \Delta A / c_P$ regression equation and the intercept ($K_c c_L$) of the $\bar{n} \sim \bar{n} c_P$ regression equation have definite physical meaning—$\Delta \varepsilon c_L$ is the maximum net absorbance ΔA_{max} and $K_c c_L$ is the maximum binding number n. These two parameters had to be determined under extreme dye/protein concentration ratios (with an excess of protein or an excess of dye) using the previous method. Now, they can be determined by using the linear regression (extrapolation) method under proper concentration ratios.

Experimental conditions such as acidity, ion strength, and concentration of dye have different effects on the maximum binding number and the molar absorptivities of free and bound dye, thereby influencing the sensitivity of a protein assay.

Potentiometric study of the protonation and distribution equilibria of 2-chlorophenol in NaCl medium at 25°C. Construction of a thermodynamic model

Ainoa Rios, Gorka Arana*, Nestor Etxebarria, Luis A. Fernández

Kimika Analitikoaren Saila, Euskal Herriko Unibertsitatea (UPV/EHU), P.K. 644, E-48080 Bilbao, Basque Country, Spain

Abstract

The potentiometric determination of the protonation constant of 2-chlorophenol in NaCl media at different ionic strengths and its distribution coefficient between these media and two organic solvents at 25°C are presented. An automated potentiometric system was used, and the determination of the constants was carried out using both graphical and numerical methods. A thermodynamic model using the modified Bromley methodology has been constructed for the prediction of protonation constants and distribution coefficients in NaCl media. The relevance of this study to the development of supported liquid membrane recovery systems is discussed.

Keywords: Protonation equilibria; Distribution equilibria; Potentiometry; Thermodynamic model; 2-Chlorophenol

1. Introduction

2-Chlorophenol is a priority pollutant phenol and, like many other phenols, may be found in the wastewaters of some manufacturing industries, such as coke production, paper and pulp processing, oil refining, coal gas liquefaction, etc. Some of the consequences of the uncontrolled disposal of this kind of compound are toxicity to water-life, increase in chemical and biological oxygen demand, and bad taste and smell in water [1–4].

As the toxicity of chlorophenols is high they are used as disinfectants; however, some of them are suspected of being carcinogenic, and a concentration of phenols of higher than $2\,mg\,dm^{-3}$ is dangerous to water-life. For the reasons, chlorophenols containing wastewaters have to be controlled [4]. By improving analytical methods, these pollutants have been detected and reported in industrial and city wastes.

There are several methods for treating phenolic wastes and their choice depends on the concentration levels of the phenols. For high concentrations, recovery and reuse or disposal by incineration is possible. Intermediate concentrations can be treated biologically or by adsorption onto active surfaces. In more diluted wastes chemical oxidation can be used. Apart from these methods,

recovery using membrane processes is possible [5]. One of these membrane processes, the use of supported liquid membranes, has proved to be a valid option [6]. Such processes require knowledge of the chemical model, and some thermodynamic studies have been carried out in order to simulate and model the separation and recovery of these compounds [7].

Since membrane processes are based on the extraction of chlorophenol into an organic phase and the driving force of the transport is the concentration gradient, it is necessary to know the acid–base and distribution equilibria of the species involved in order to design selective liquid membrane separation processes and to interpret the permeation results obtained. One of the main requirements for an organic solvent to be part of a liquid membrane is that it is immiscible with water. It also needs to have a high boiling point in order to avoid evaporation of the membrane. Kerosene or aliphatic solvents are normally used for these purposes. However, it might also be interesting to try aromatic solvents in order to enhance the separation, since the solutes are aromatic in nature and thus should have higher distribution coefficients. As well as the liquid membrane itself, the influence of the aqueous media in the permeation process should be taken into account. In a previous work [8], the distribution coefficients of several phenols between 1.0 mol dm^{-3} NaCl and different organic solvents were determined. NaCl has been reported as a common medium in the wastewater of epoxy resin manufacturing; therefore, in this work the acid–base and distribution equilibria were determined in this medium at different ionic strengths (0.5, 2.0 and 3.0 mol dm^{-3}) in order to build a thermodynamic model, taking 2-chlorophenol as an example to demonstrate the usefulness of the methodology used. One-phase potentiometric titrations were used for the determination of the acid–base equilibria. This is one of the commonest techniques, together with spectrophotometry, although some other methods, such as liquid chromatography, are used for the study of the acid–base equilibria of chlorophenols [9]. Two-phase potentiometric titrations were used for the distribution equilibria, as described in Refs. [10]–[12].

2. Experimental

2.1. Chemicals and solutions

2-Chlorophenol (Aldrich, >99%), sodium chloride (Merck, p.a.), sodium hydroxide (Merck p.a.) and hydrochloric acid (Fluka, p.a.) were used without further purification.

The organic solvents n-decane (Fluka, 98%) and 95 A 16/18 — an industrial aromatic mixture manufactured and kindly supplied by CEPSA, in Bilbao, Spain — were washed several times with 0.1 mol dm^{-3} NaOH and 0.1 mol dm^{-3} HCl in order to eliminate the acid and basic impurities, and were finally saturated in the corresponding ionic medium.

All solutions were prepared using MilliQ water. The NaOH solutions were prepared in N_2 atmosphere and standardized against potassium phthalate with phenolphthalein as indicator. These solutions were used as titrants. The HCl solutions were standardized against Tris(hydroxymethyl)-aminomethane with bromocresol green as indicator. Different solutions of the phenols were prepared with the following general composition:

$$B \text{ mol dm}^{-3} \text{ 2-chlorophenol} + 0.01 \text{ mol dm}^{-3}$$

$$\text{HCl} + (I - 0.01 - B) \text{ mol dm}^{-3} \text{ NaCl}$$
where B is 0.01 or 0.03 and I is the concentration of the ionic medium. I was checked by weighing the solid residue after evaporation of a known volume of the solution.

2.2. Procedure

Potentiometric one-phase or two-phase titrations of 2-chlorophenol were carried out using an automated system developed in this laboratory [13] and a thermostatic bath at $25.0 \pm 0.1°C$ by measuring the emf of the cell:
$$\text{Ag/AgCl(s)} \left| \begin{array}{c} I \text{ mol dm}^{-3} \text{ NaCl} \\ \text{sat. in AgCl} \end{array} \right| \left| \begin{array}{c} \text{NaCl} \\ I \text{ mol dm}^{-3} \end{array} \right|$$

$$\left| \begin{array}{c} \text{Test} \\ \text{solution} \end{array} \right| \begin{array}{c} \text{Glass} \\ \text{electrode} \end{array}$$

Table 1
Values of j_{ac}, j_{bas} and K_w for the different ionic strengths and electrode systems used in this work

I/NaCl (mol dm^{-3})	j_{ac} (mV mol^{-1} dm^3)	j_{bas} (mV mol^{-1} dm^3)	log K_w
0.5	-90 ± 1	250 ± 4	-13.69 ± 0.01
2	-28.5 ± 0.3	110 ± 2	-13.72 ± 0.01
3	0	42 ± 1	-13.93 ± 0.02

where I is the concentration of the ionic medium (0.5, 2.0 and 3.0 mol dm^{-3}) and the test solutions were

B mol dm^{-3} 2-chlorophenol/h mol dm^{-3} H$^+$/

$(I - h - B)$ mol dm^{-3} Na$^+$/$(I - B)$ mol dm^{-3} Cl$^-$

where B is 0.01 or 0.03.

For the two-phase titrations, 0.070 dm^3 of the test solution was equilibrated with 0.025 dm^3 of one of the organic solvents, which was in contact with the aqueous phase. However, there was no contact with the electrodes in order to obtain more stable readings of emf from the electrodes.

The values of h were varied by stepwise addition of the titrant using a Metrohm 665 automatic burette connected to the computer via a RS-232C interface. The emf of the cell was measured using a glass electrode (Metrohm 6.0101.100) and an Ag/AgCl (s) double junction reference electrode (Metrohm 6.0726.100). The signals from the electrodes, preamplified by an operational amplifier in order to adequate the electric signal, were measured by a Hewlett-Packard HP-E1326B voltmeter incorporated into the VXI data acquisition system connected to the computer. When the standard deviation of the emf over a preset period of time (about 3 min) was less than 0.04 mV, or a certain number of measurements were taken (more than 20), an instruction for new addition was given by the computer to the burette. Each titration took between 12 and 72 h to be completed, depending on the number of chemical phases and the solvent used, and all of them were repeated at least three times.

Throughout the titrations N$_2$, presaturated in the corresponding ionic medium, was bubbled through the solution in order to avoid the pres-

ence of CO$_2$. The solution was continuously stirred making use of a magnetic stirrer immersed in an oil bath at a constant temperature of 25°C.

2.3. Determination of h

The free hydrogen ion concentration (h) was determined by measuring the emf of the cell, which at 25°C can be expressed as follows:

$$E(\text{mV}) = E° + 59.16 \log h + E_j(h) \tag{1}$$

where $E_j(h)$, the liquid junction potential, can be expressed as

$$E_j(h) = j_{ac} h + j_{bas} K_w \cdot h^{-1} \tag{2}$$

Therefore, in order to be able to determine the value of h in the phenolic solutions, the values of the acid liquid junction potential coefficient (j_{ac}), the basic liquid junction potential coefficient (j_{bas}) and the autoprotolysis constant of water in this medium (K_w) must be previously known, whereas the standard potential of the glass electrode, $E°$, is determined for each titration since it may vary from day to day [14].

The values of j_{bas}, j_{ac} and K_w can be considered constant, since the ionic strengths of the solutions were kept constant throughout the titrations and were determined by means of $E°$ titrations as explained elsewhere [15]. The values of these constants for the different ionic strengths are shown in Table 1.

Once the values of these constants are known and $E°$ is calculated for each titration using Gran's method [16], h can be calculated for each experimental point. Since the equation to calculate the value of h cannot be analytically solved, an iterative procedure such as the Newton–Raphson method is used.

3. Results and discussion

3.1. Acid–base equilibria

The chemical systems studied in the one-phase titrations can be described by the following equilibrium:

$$H^+ + B^- \rightleftharpoons HB \tag{3}$$

where HB is 2-chlorophenol with the stochiometric constant

$$\beta = \frac{[HB]}{[H^+][B^-]} \tag{4}$$

For each titration, the total concentrations of 2-chlorophenol (B_{tot}) and hydrogen ions (H_{tot}) were known, and the free hydrogen ion concentration can be calculated from Eq. (1). H_{tot} is calculated using the following expression:

$$H_{tot} = \frac{C_0 \cdot V_0 + C_a \cdot V_0 - C_b \cdot V}{V_0 + V} \tag{5}$$

where C_0 is the initial HCl concentration, C_a is the initial 2-chlorophenol concentration and C_b is the titrant concentration. V_0 is the initial volume and V is the titrant volume.

The average number of protons bound to the phenol is evaluated as follows:

$$Z = \frac{[HB]}{B_{tot}} = \frac{H_{tot} - h + K_w \cdot h^{-1}}{B_{tot}} = \frac{h\beta}{1 + h\beta} \tag{6}$$

The results obtained were treated both graphically and numerically. A normalized variable method was used to carry out the graphical treatment. The following normalized variable is defined:

$$u = h\beta \tag{7}$$

Therefore, Eq. (6) can be transformed into

$$Z = \frac{h\beta}{1 + h\beta} = \frac{u}{1 + u} \tag{8}$$

Comparing the experimental formation curves Z vs. $-\log h$ (Fig. 1) with the theoretical curves Z vs. $-\log u$, the value of $\log \beta$ can be calculated from the point along the pH-axis at which both curves overlap. This method allows estimation of the errors in the fit by shifting the theoretical

curve to the left and to the right while the curves still overlap, as well as the systematic errors that may arise. Moreover, it was proved that there is no aggregation of 2-chlorophenol since the Z curves corresponding to the two different concentrations of phenol overlap.

Numerical treatment, in order to refine the results from the graphical method, was carried out using the NYTIT version of the LETAGROP program [17] and the BSTAC program [18]. For all N_p experimental points the sum of square errors U, defined as

$$U = \sum_{N_p} (X_{calc} - X_{exp})^2 \tag{9}$$

was minimized, where $X = H_{tot}$ in NYTIT and $X = E$ in BSTAC. Using NYTIT, H_{exp} and H_{calc} are the experimental and calculated total concentrations of protons for each experimental point based on a set of formation constants and E°, j_{ac}, j_{bas} and K_w values. This program allows the detection and correction of any possible systematic error arising in the titrations, such as the concentration of 2-chlorophenol, H_{tot}, etc. Using BSTAC, E_{calc} and E_{exp} are calculated and experimental potentials of the cell. Systematic errors can be detected and corrected using this program, but the basic liquid junction potential cannot be considered. It is also possible to treat all the titrations corresponding to the same ionic strength together. The results of the graphical and numerical calculations are the same, and the values of the formation constants for the different ionic strengths with the statistical parameters given by NYTIT are

^{b} R (Hamilton's factor) $= (U/\Sigma H_{tot}^2)^{1/2}$.

summarized in Table 2 together with the data found in the literature.

There is not much possibility of comparing the results obtained in this work with bibliographic data, since the values found in the literature are determined in different ionic media.

3.2. Distribution equilibria

In the case, together with the acid–base equilibria showed in Eq. (3), it is necessary to consider the distribution equilibria, which can be described as follows:

$$HB \rightleftharpoons \overline{HB} \tag{10}$$

where HB is the 2-chlorophenol and $\overline{HB}$ is the phenol in the organic phase. This equilibrium has the corresponding equilibrium constant:

$$K_d = \frac{[\overline{HB}]}{[HB]} \tag{11}$$

The distribution of the phenol into the organic phase affects the acid–base equilibrium as a side-reaction.

As in the one-phase titration, for each titration point B_{tot}, H_{tot} and h can be calculated.

The average number of protons bound to the phenol, taking into account the distribution equilibrium, is evaluated as follows:

$$Z = \frac{[HB] + [\overline{HB}]V_r}{B_{tot}} = \frac{H_{tot} - h + K_w h^{-1}}{B_{tot}}$$

$$= \frac{h\beta(1 + K_d \cdot V_r)}{1 + h\beta(1 + K_d \cdot V_r)} \tag{12}$$

where V_r is the organic phase to aqueous phase volume ratio (V_{org}/V_{aq}). The results obtained were treated both graphically and numerically. A normalized variable method with one parameter was used to carry out the graphical treatment. As well as the normalized u variable defined in Eq. (7), the following parameter is expressed:

$$p = K_d \tag{13}$$

Therefore, Eq. (12) can be transformed into

$$Z = \frac{u(1 + pV_r)}{1 + u(1 + pV_r)} \tag{14}$$

Comparing the experimental formation curves Z vs. $-\log h$ with the theortical curves Z vs. $-\log u$, since β is already known, an approximate value of K_d can be calculated as that which makes both curves overlap (Figs. 2 and 3). Again, it was proved that, in the range of concentrations studied, there is no aggregation equilibrium in the organic phase, since the Z curves corresponding to the two different concentrations of phenol
Fig. 2. Graphical representations of Z vs. $-\log h$ of 2-chlorophenol with the theoretical curves Z vs. $-\log u$ in the position showing the best fit in the two-phase titrations containing n-decane at different ionic strength: $\square$, 0.5 mol dm^{-3}; $\blacklozenge$, 2.0 mol dm^{-3}; $\bigcirc$, 3.0 mol dm^{-3}.

Fig. 3. Graphical representations of Z vs. $-\log h$ of 2-chlorophenol with the theoretical curves Z vs. $-\log u$ in the position showing the best fit in the two-phase titrations containing 95 A 16/18 at different ionic strength: $\square$, 0.5 mol dm^{-3}; $\blacklozenge$, 2.0 mol dm^{-3}; $\bigcirc$, 3.0 mol dm^{-3}.

overlap. Once these values were obtained they were refined using numerical methods.

The numerical calculations were carried out using the MODEL FUNCTION version of the LETAGROP program [22]. This program allows all the titrations corresponding to the same solvent to be treated together. The calculations were carried out minimizing the sum of square errors:

$$U_Z = \sum_i (Z_{i,\text{calc}} - Z_{i,\text{exp}})^2 \tag{15}$$

were Z_{calc} is defined as follows:

$$Z_{\text{calc}} = \frac{h\beta(1 + K_d \cdot V_r)}{1 + h\beta(1 + K_d \cdot V_r)} \tag{16}$$

and $Z_{i,\text{exp}}$ is calculated as in Eq. (12). The final values of the distribution coefficients corresponding to both solvents and the different ionic strengths are compiled in Table 3.

No data have been found in the literature of the distribution equilibria for the solvents used and 2-chlorophenol. It is noteworthy that many of the distribution data are determined in batch experiments on measuring the concentration of the distributed substances in both phases after equilibrium has been reached. However, there are other methods in the literature such as the technique of countercurrent distribution [23] or gas chromatography [24], mainly chromatographic methods based on the relation of the chromatographic capacity factor and the distribution coefficient [25], with the advantage that a very small amount of the substance is needed. The two-phase titration technique is not new, but is not very

common either; it allows the detection and correction of systematic errors both in the graphical and numerical treatment of the data. This is possible because the distribution coefficient is determined from a fairly large number of measurements (i.e. emf readings) transformed into the Z function, rather than from a single measurement of concentration, in which a minor error can give rise to large errors in the distribution coefficients.

3.3. Thermodynamic model

The behaviour of the chemical system studied, the acid-base and distribution equilibria of 2-chlorophenol in NaCl media at different ionic strengths, can be explained by a thermodynamic model. In order to construct this model, when the stoichiometric formation constants and distribution coefficients at different ionic strengths are known and making use of a model of the calculation of the activity coefficients, the thermodynamic constant of the system at infinite dilution can be calculated. The calculation is not direct, and numerical methods must be used. Unknown parameters, which depend on the model, are calculated in order to adjust the experimental values to the theoretical function.

A modification of Bromley's methodology [26] for the calculation of activity coefficients, which can be applied to molar as well as to molal concentrations, has been successfully used with both inorganic and organic solutes in aqueous systems [27–30] for the calculation of thermodynamic formation constants at infinite dilution $(°\beta)$ and of the interaction parameters between the species taking part in the equilibria and the ions of the ionic media.

Considering the activities, Eq. (4) can be rewritten as

$$°\beta = \frac{\{HB\}}{\{B^-\}\{H^+\}} = \beta \frac{\gamma_{HB}}{\gamma_{B^-}\gamma_{H^+}} \tag{17}$$

and taking logarithms

$$\log \beta = \log °\beta - \log \gamma_{HB} + \log \gamma_{B^-} + \log \gamma_{H^+} \tag{18}$$

According to the modified Bromley methodology, the individual activity coefficient of a charged species can be expressed as

Table 3
Values of the distribution coefficients corresponding to both organic solvents at different ionic strengths

Solvent		I/NaCl(mol dm^{-3})			
		0.5	2.0	3.0	1.0 [8]
n-Decane	K_d	7.5 ± 0.01	12.29 ± 0.01	19.4 ± 0.3	8.97 ± 0.08
	σ [a]	0.0008	0.01	0.016	
	R [b]	1.18×10^{-2}	1.61×10^{-2}	1.66×10^{-2}	
95 A 16/18	K_d	21.6 ± 0.1	39.6 ± 0.2	70 ± 1	19.6 ± 0.2
	σ [a]	0.01	0.01	0.02	
	R [b]	1.57×10^{-2}	1.44×10^{-2}	3.07×10^{-2}	

[a] $\sigma = (U_z/(N_p - N_k))^{1/2}$; N_p = number of experimental; N_k = number of parameters.
[b] R (Hamilton's factor) = $(U/\Sigma Z^2_{exp})^{1/2}$.

$$\log \gamma_M = -\frac{A Z^2_M \sqrt{I}}{1 + \sqrt{I}} + \sum_X \dot{B}_{M.X}(|Z_M| + |Z_X|)^2 \frac{c_X}{4}$$

$$(19)$$

where $A = 0.5109 \text{ dm}^{2/3} \text{ mol}^{-1/2}$, I is the ionic strength on the molar scale, Z_M is the ionic charge of M, Z_X is the charge of the ionic species with opposite sign to M, and c_X is its molar concentration. The parameter $\dot{B}_{M.X}$ can be expressed as

$$\dot{B}_{M.X} = \frac{(0.06 + 0.6_{M.X})|Z_M Z_X|}{\left(1 + \frac{1.5}{|Z_M Z_X|} I\right)^2} + B_{M.X}$$

$$(20)$$

where $B_{M.X}$ is the interaction parameter of the ion pair M and X on the molar scale. In this case, using Eqs. (19) and (20), the activity coefficient of B^-(γ_{B-}) is a function of the concentration of Na$^+$ in the ionic media, and the contribution of H$^+$ can be neglected as its concentration is much lower. The ionic medium, NaCl, is a 1:1 salt; thus, the concentration of Na$^+$ is the same as the ionic strength, and γ_{B-} can be expressed as a function of I and the interaction parameter B_{B^-,Na^+}. Similarly, the activity coefficient of H$^+$ is a function of the ionic strength and the interaction parameter B_{H^+,Cl^-}, which has been previously determined using values from the literature of activity coefficients of solutions containing hydrochloric acid, its value being 0.1648 [31]. The activity coefficient of the neutral species HB in the ionic medium NaCl is expressed by means of the salt coefficient proposed by Long and McDevit [32] where, in this case, C_{NaCl} equals the ionic strength:

$$\log \gamma_{HB} = S_{HB.NaCl} C_{NaCl}$$

$$(21)$$

Considering activities, Eq. (11) can be rewritten as

$$°K_d = \frac{\{\overline{HB}\}}{\{HB\}} = K_d \frac{1}{\gamma_{HB}}$$

$$(22)$$

where the activity coefficient of the neutral species in the organic phase is considered constant since only the ionic strength in the aqueous solution changes and therefore it is taken as part of the stoichiometric distribution coefficient. Taking logarithms gives

$$\log K_d = \log °K_d + \log \gamma_{HB}$$

$$(23)$$

where there are no interaction parameters the salt coefficient $s_{HB.NaCl}$ being the only parameter.

In order to relate the distribution to the acid–base data we can consider the acid–base and distribution equilibrium together, obtaining the following equilibrium:

$$H^+ + B^- \rightleftharpoons \overline{HB}$$

$$(24)$$

with the corresponding formation constant

$$°K = °\beta °K_d = \frac{\{\overline{HB}\}}{\{B^-\}\{H^+\}} = \frac{K}{\gamma_{B-} \gamma_{H+}}$$

$$= \frac{\beta K_d}{\gamma_{B-} \gamma_{H+}}$$

$$(25)$$

Taking logarithms in Eq. (25) gives

$$\log K_d = \log °K_d + \log °\beta - \log \beta + \log \gamma_{B-}$$
$$+ \log \gamma_{H+}$$

$$(26)$$

Substituting Eqs. (19), (20) and (21) into Eqs. (18) and (26) leads to

$$\log \beta = \log {}^{\circ}\beta - S_{\mathrm{HB,NaCl}}I - 2\frac{0.5109\sqrt{I}}{1+\sqrt{I}}$$

$$+ \left[\frac{(0.06 + 0.6B_{\mathrm{B^-,Na^+}})}{(1+1.5I)^2} + B_{\mathrm{B^-,Na^+}}\right]I$$

$$+ \left[\frac{(0.06 + 0.6B_{\mathrm{H^+,Cl^-}})}{(1+1.5I)^2} + B_{\mathrm{H^+,Cl^-}}\right]I \quad (27)$$

$$\log K_{\mathrm{d}} = \log {}^{\circ}K_{\mathrm{d}} + \log {}^{\circ}\beta - \log \beta - 2\frac{0.5109\sqrt{I}}{1+\sqrt{I}}$$

$$+ \left[\frac{(0.06 + 0.6B_{\mathrm{B^-,Na^+}})}{(1+1.5I)^2} + B_{\mathrm{B^-,Na^+}}\right]I$$

$$+ \left[\frac{(0.06 + 0.6B_{\mathrm{H^+,Cl^-}})}{(1+1.5I)^2} + B_{\mathrm{H^+,Cl^-}}\right]I \quad (28)$$

The correlation of the experimental β and K_{d} values with ionic strength was made with both Eqs. (27) and (28), making use of the MODEL FUNCTION version of the LETAGROP program. The results of the formation and distribution thermodynamic constants at infinite dilution and the interaction parameters obtained are collected in Table 4. Figs. 4 and 5 show the fit between the experimental data and the theoretical curves (Eqs. 27 and 28) of the acid–base equilibria and distribution equilibria, respectively. The slope of the plots in Fig. 5 is the salt coefficient of 2-chlorophenol. The fact that the representation of $\log K_{\mathrm{d}}$ vs. ionic strength follows a linear trend with the same slope for both organic solvents as predicted in Eq. (23) confirms the previously made assumption that the activity coefficients of the neutral species in the organic phase are constant. Therefore, making use of the salt co-

Fig. 4. Variation of $\log \beta$ with ionic strength together with the theoretical function (Eq. 27).

efficients found in the literature [32], values of K_{d} at a given ionic strength can be predicted once the value of K_{d} is known at another ionic strength of the same salt for any organic solvent. The salt coefficients can be determined either by determining distribution coefficients using any of the techniques available at different ionic strengths of the corresponding ionic medium or by measuring activity coefficients of the substance under study as a function of ionic strength in the corresponding ionic media, making use of Eq. (21). It should be taken into account that these salt coefficients depend on the ionic medium to be used, i.e. the salt coefficient is different for KCl and NaCl media, but is independent of the organic solvent, as long as the activity coefficient of the substance in the organic phase is kept constant, which is feasible for low concentrations.

In order to be able to predict the stoichiometric formation constants of 2-chlorophenol or any other substance it is necessary to know the values
Table 4
Thermodynamic constants in infinite dilution and parameters calculated in the construction of the thermodynamic model

$\log {}^{\circ}\beta$	8.49 ± 0.05
${}^{\circ}K_{\mathrm{d}}$ (n-decane)	5.5 ± 0.1

of the corresponding B parameters, which depend on the ionic medium and the substance itself. A further discussion on the values of calculated B parameters for many ion pairs is under preparation in a different work. Thus, it is possible to predict the values of the stochiometric formation constants of many chemical equilibria for any ionic strength within an appropriate range (it should be an interpolation and not an extrapolation) in many ionic media, once the corresponding thermodynamic formation constant at infinite dilution is known.

The value of the thermodynamic formation constant of 2-chlorophenol obtained is similar to that found in the literature, although it is not very clear how this was determined. The value obtained for the salt coefficient of 2-chlorophenol is close to that given by Long and McDevit [32] for phenol in the same ionic medium.

Using the values collected in Table 4 and the value of B_{H^+,Cl^-} it is possible to calculate the stoichiometric formation constants and distribution coefficients for any value of ionic strength of NaCl in the range 0–3 mol dm^{-3}. Fig. 6, the distribution diagram of the system 2-chlorophenol/H_2O/n-decane for two different ionic strengths, shows the different behaviour of the system as a function of ionic strength.

As was pointed out above, the aim of this work is the construction of a thermodynamic model for application to a supported liquid membrane system for the separation of phenols as well as seeking practical aspects of the membrane technique, we are interested in its basic chemistry. The correct interpretation of the permeation results

requires a good knowledge of the chemical system, i.e. acid–base equilibria and distribution equilibria, in such a way that it is possible to predict the optimum experimental conditions, pH, organic solvent to be used or ionic strength, for the best separation of the corresponding phenols. It is also possible to use the model in the interpretation or prediction of the permeation results obtained with wastewaters of varying concentration of NaCl, since a significant proportion of the parameters needed are from the model. However, apart from the interest in the elimination or separation of the priority pollutant 2-chlorophenol, the model constructed shows the usefulness of the procedure employed and can be applied to any other chemical system with different applications, e.g. sample preparation using solvent extraction, etc.

PA·FPNS: its synthesis and use in spectrophotometric determination of magnesium

Hui-Min Ma *, Yue-Xian Huang, Shu-Chuan Liang

Institute of Chemistry, Chinese Academy of Sciences, Beijing 100080, China

Received 19 April 1995; revised 19 July 1995; accepted 21 July 1995

Abstract

A new polymeric chromogenic reagent PA·FPNS has been synthesized by condensing polyallylamine (PA) with 3-(4-formylphenylazo)-4,5-dihydroxynaphthalene-2,7-disulfonic acid (FPNS) and its properties studied. In alkaline media, PA·FPNS reacts with magnesium to form a water-soluble blue complex, whose absorption maximum is at 604 nm. The molar absorptivity (ε) of the complex is $5.2 \times 10^4 \, l \, mol^{-1} \, cm^{-1}$, which is four times that of the FPNS–Mg complex, and Beer's law is obeyed over the range $0–0.35 \, \mu g \, ml^{-1}$ magnesium. Compared to the corresponding low-molecular-weight FPNS and other chromogenic reagents, PA·FPNS offers considerably improved sensitivity and selectivity for magnesium, which may be attributed to incorporating FPNS into a water-soluble polymer and the effect of the polymeric chain on the reaction microenvironment. Also, a simple and sensitive spectrophotometric method for the determination of magnesium has been developed and applied to water and human fluid samples with satisfactory results.

Keywords: PA·FPNS; Magnesium; Spectrophotometry

1. Introduction

Water-soluble polymers such as poly(vinyl alcohol) have been widely used in photometric analysis to improve the sensitivity, stability and solubility of reaction systems, which may be described as enhancing effects. It is interesting to see whether by incorporating a chromogenic group into a water-soluble polymer, the resulting polymeric reagents will have simultaneously chromogenic and enhancing functions. Such an idea

has been realized for the first time in our laboratory. For example, we had synthesized two polymeric chromogenic reagents, PV·FPNS and PV·FPAQ, by condensing poly(vinyl alcohol) (PV) with 3-(4-formylphenylazo)-4,5-dihydroxynaphthalene-2,7-disulfonic acid (FPNS) and 7-(4-formylphenylazo)-8-quinolinol (FPAQ) respectively. The two reagents did have the predicted desirable properties such as greatly improved sensitivities and stabilities of color reactions with some metal ions [1,2]. However, they are somewhat unselective. According to the rule of soft and hard acids and bases, the condensation prod-

* Corresponding author.

ucts contain a large number of hard base ligands such as hydroxy, and hence their reactivities are strengthened for other hard acid metal ions.

Obviously, in order to improve the reagent selectivities it is necessary to link the low-molecular-weight reagents to some other water-soluble polymers. Although there are a lot of photometric reagents for magnesium, few of them are superior to chromotrope 2R in terms of both sensitivity and selectivity [3–7]. Therefore, in this paper FPNS with an active formyl group and the structure feature of chromotrope 2R is chosen as a constituent to be incorporated. The water-soluble polymer employed is polyallylamine rather than poly (vinyl alcohol), because the former has active amino groups which condense easily with aldehydes, and the nitrogen donors intrinsically show more preference than oxygen for Mg^{2+} over Ca^{2+} [8]. This is conducive to improvements in reagent selectivity. Thus in this work the new polymeric chromogenic reagent PA·FPNS has been synthesized by incorporating FPNS into polyallylamine with different weight ratios of the two reactants. Furthermore, its analytical properties and applictions have been studied. The results show that PA·FPNS has a large advantage over PV·FPNS and other chromogenic reagents for magnesium determination, indicating that incorporation of the chromogenic part into water-soluble polymers can be used as an important measure for improving analytical functions of photometric reagents.

2. Experimental

2.1. Apparatus and reagents

Spectral and absorbance measurements were made with a Hitachi-340 ultraviolet–visible spectrophotometer and a Model 721 spectrophotometer (Shanghai, China). The pH values were obtained with a Model 25 pH meter (Shanghai, China). Infrared spectra were taken with a Perkin-Elmer 683 spectrometer. Microanalysis was performed on a Carlo Erba 1102 elemental analyzer.

Poly(allylamine hydrochloride) with average M_n 8500–11 000 was purchased from Aldrich,

and chromotropic acid(disodium salt) and p-aminobenzaldehyde were obtained from Beijing Chemical Factory, China. Magnesium stock solution (1.0 mg ml^{-1}), 0.1% (w/v) of FPNS and PA·FPNS (9.8% amino groups substituted) solutions, and 0.1 mol l^{-1} of Na_2HPO_4–NaOH buffer solution (pH 11.50) were used. Deionized-distilled water was employed throughout. All other chemicals used were of analytical grade.

2.2. Synthesis of PA·FPNS

Poly(allylamine hydrochloride) (2.0 g) was dissolved in 100 ml of pH 11 aqueous buffer (Na_2CO_3–$NaHCO_3$). To this was slowly added a solution of 2 g FPNS (prepared following our previous method [1c]) in 100 ml of water with stirring at room temperature. After 1 h the reaction solution was neutralized to pH 8–9 with dilute HCl. The resulting precipitate was filtered off, washed thoroughly with water, and dried in vacuo. The crude product was purified by dissolving in aqueous NaOH and reprecipitating with dilute HCl to give 2.0 g of PA·FPNS as a dark red solid. The product is soluble in alkaline solution (purplish red color) and slightly in water, but not in ethanol, acetone or dioxane. The alkaline solution of PA·FPNS is stable for 20 days at room temperature. After that its concentration decreases slowly. IR (KBr pellets): 3600–3300 cm^{-1} (brs, OH, NH); 1640 cm^{-1} (C=N); 1600, 1570, 1495 cm^{-1} (C=C, N=N); 1240–1150 cm^{-1} (brs, C–O, S=O); 1040 cm^{-1} (S=O). A 6.32% sulfur content was determined by barium salt titration. Absorption spectra of PA·FPNS were recorded against the corresponding reagent blank.

2.3. Procedure for magnesium determination

2.5 ml of pH 11.50 aqueous buffer (Na_2HPO_4–NaOH) and 2.0 ml of 0.1% PA·FPNS were added to a sample solution containing not more than 3.5 μg of magnesium and the final volume adjusted to 10 ml with water. The absorbances were measured at 604 nm in 1 cm cells against the reagent blank.

3. Results and discussion

3.1. Synthesis of PA·FPNS and its infrared and UV–visible spectra

A 1% solution of poly(allylamine hydrochloride) has a pH of 4 and an isoelectric point at ≈pH 9, at which polyallylamine has low solubility and precipitates easily. Accordingly, the condensation products of polyallylamine with aldehydes are conveniently purified by reprecipitation. Moreover, in alkaline media aromatic aldehydes react readily with aliphatic amines to give Schiff's bases [9]. Thus, neither the preparation nor the purification of PA·FPNS are difficult. In addition, by using different weight ratios of the two reactants, PA·FPNS with different degrees of substitution of amino groups could be prepared. For example, by using the three different weight ratios (2, 1 and 0.5) of PA to FPNS, PA·FPNS with three different sulfur contents (4.93%, 6.32% and 8.39%) could be obtained, and their degrees of substitution by amino groups were 6.6%, 9.8% and 17.3% respectively.

IR spectral analysis showed that, after reacting with PA, the carbonyl absorption peak (1685 cm^{-1}) of FPNS disappeared and a new one for the C=N double bond was observed at 1640 cm^{-1}, indicating that the condensation reaction between FPNS and PA did take place.

UV–visible spectra of PA·FPNS and its magnesium complex are shown in Fig. 1. Compared with FPNS [2c], PA·FPNS has a similar absorption spectrum except for the absorption maximum at 530 nm with a 5 nm red shift, which may be attributed to the increased conjugation of the whole molecule in the presence of a C=N double bond. The magnesium complex absorbs maximally at 604 nm.

The PA·FPNS structure is proposed as follows:

Fig. 1. Absorption spectra of PA·FPNS and its magnesium complex at pH 11.5. Experimental conditions: (A) 0.0015% of PA·FPNS solution against water blank; (B) the solution containing 0.15 μg ml^{-1} of Mg^{2+} and 0.02% of PA·FPNS against the corresponding reagent blank.

Fig. 2. Effect of pH on the determination of magnesium (0.2 μh ml^{-1}).

It should be pointed out that the distribution of the chromogenic group in the polymer is uncertain.

3.2. Effect of amino group substitution

PA·FPNS with the three different degrees of substitution prepared above has little effect on the sensitivity of determining magnesium. Higher substitutions do not enhance the sensitivity except by giving stronger background absorbance. In this work, PA·FPNS with a moderate substitution (9.8%) was chosen to study the spectrophotometric determination of magnesium.

PA·FPNS

3.3. Conditions for spectrophotometric determination

Effects of pH and buffer systems

PA·FPNS is apt to precipitate in media with $7 < pH < 11.0$ and hardly reacts with magnesium at $pH < 7$. However, at higher pH ($\geqslant 11.0$) it gives a very sensitive color reaction with magnesium. The optimum pH range for the color reaction is 11.0–11.7, and at pH values higher than 11.7 the absorbance of the complex decreases (Fig. 2). Therefore, a pH of 11.5 ± 0.2 was used and maintained with aqueous Na_2HPO_4–NaOH buffer in this study, the optimum amount of which was 2.5 ml. No difference was observed with other buffers such as $Na_2B_4O_7$–NaOH.

Effect of PA·FPNS concentration

For the determination of 0.2 µg ml^{-1} Mg^{2+}, the absorbance reached a maximum value in the volume range 1.5–2.5 ml of 0.1% PA·FPNS solution, and 2.0 ml of PA·FPNS was used.

Characteristics of the color reaction

The blue PA·FPNS–Mg complex is immediately formed and the absorbance remains constant for at least 12 h. Variation of the temperature within the range 15–35°C does not affect the absorbance of the complex. Beer's law is obeyed over the range 0–0.35 µg ml^{-1} of magnesium and the linear regression equation is $A_{(absorbance)} = 2.122 \cdot C$ (µg Mg^{2+} ml^{-1}) $- 0.007$, $n = 6$, $r = 0.9960$. The molar absorptivity (ε) of the complex has been found to be 5.2×10^4 l mol^{-1} cm^{-1}, and according to IUPAC's recommendation [10] the detection limit is 14 ng ml^{-1}, based on 15 blank measurements ($k = 3$).

Effects of ethanol and surfactants

Ethanol and nonionic surfactants such as Triton X-100 and poly(vinyl alcohol)-1750 do not interfere with the determination of magnesium. Anionic surfactant (sodium dodecyl sulfate) leads to a negative error (-13%), whereas cationic surfactants, such as cetyltrimethylammonium bromide, associate with the reagent anion to form a precipitate and thus influence magnesium determination.

Effects of foreign ions

The potential interferences of more than 30 ions were examined for the determination of 2 µg of magnesium in the presence of each foreign ion. The tolerable amount was that of a species which gives a relative error of less than $\pm 5\%$ in the analytical signal(absorbance) of magnesium, i.e. for 2 µg of magnesium in 10 ml of solution, the tolerable amounts of the foreign ions are: at least 50 µg of A(III) and La(III); 5 µg of Ag(I), Au(III), Cr(VI)*, Ga(III), Mo(VI), Sc(III), Sn(IV), Sr(II) and Ti(IV); 2.5 µg of As(V); 10 µg of Ba(II)*, Cd(II), Co(II), Cu(II), Ge(IV), Hg(II), In(III), Pb(II), W(VI) and Zn(II); 0.5 µg of Be(II)*; 20 µg of Ca(II)*, Mn(II) and V(V); 30 µg of Fe(III); 400 µg of K(I); 2 µg of Ni(II)*, Pd(II) and Pt(IV); 1 µg of Rh(III); 500 µg of Cl$^-$, NO$_3^-$ and SiO$_3^{2-}$; 200 µg of SO$_4^{2-}$ (where an asterisk indicates that an ion with the given amount causes a maximum error of $\pm 5\%$). The tolerable amounts of Be(II) and Ni(II) are small, but concentrations of these two ions are naturally much lower than that of magnesium.

3.4. Comparison with FPNS

Under its optimum condition (pH 11.0), FPNS reacts with magnesium to form a complex with a maximum absorption at 600 nm and a molar absorptivity of 1.3×10^4 l mol^{-1} cm^{-1}, whereas the molar absorptivity of PA·FPNS–Mg complex is 5.2×10^4 l mol^{-1} cm^{-1}, which is four times that of the FPNS–Mg complex.

3.5. Comparison with other methods

There are few spectrophotometric methods for determining magnesium which possess simultaneously high sensitivity and selectivity. The methods with good selectivity are usually less sensitive [11,12]. Although increased sensitivities are achieved by using extraction or the formation of a multicomponent complex, the procedures become tedious and some suffer from nonselectivity [13,14]. Fortunately, the new polymeric reagent PA·FPNS could be directly used to determine magnesium in many samples without separation and masking treatment.

Table 1
Analytical results of magnesium in samples and recovery tests

Sample [a]		Volume used (µl)	Mg added (µg)	Mg found [b] (µg)	Mg concn. in sample (µg ml^{-1})	Recovery (%)	Mg concn. in sample detd. by AAS (µg ml^{-1})
Serum	1	120	0	3.02 ± 0.23(5)	25.2 ± 1.9	–	24.3
		60	1.0	2.55 ± 0.23(3)	–	104	
	2	150	0	3.15 ± 0.24(5)	21.0 ± 1.6	–	20.8 (certified value)
Urine	1	40	0	3.37 ± 0.28(3)	84.3 ± 7.0	–	90.0
		20	1.5	3.08 ± 0.26(3)	–	93	
	2	30	0	1.90 ± 0.21(3)	63.3 ± 7.0	–	60.3
	3	20	0	2.68 ± 0.23(3)	134.0 ± 11.5	–	132.5
Tap water	1	60	0	2.16 ± 0.18(5)	36.0 ± 3.0	–	35.0
		30	1.0	2.03 ± 0.21(3)	–	95	–
	2	60	0	2.25 ± 0.22(3)	37.5 ± 3.7	–	37.3
	3	60	0	1.00 ± 0.23(3)	16.7 ± 3.8	–	15.0

[a] Serum 1: serum mixtures of normal humans were provided by Zhongguancun Hospital, Beijing; serum 2: a human serum reference material (GBW 09135) was obtained from the National Research Center for Certified Reference Materials (Beijing, China). Fresh urine and tap water were acidified with a few drops of dilute HCl. Appropriate volumes of these samples were taken and analyses were then conducted following the procedure given in the text.
[b] Mean $\pm t S_{y_0}(m)$ [21] at the 95% confidence level, $S_{y_0} = S_{y \cdot x} \cdot 1/b \cdot \{1/m + 1/n + 1/b^2 \cdot (y_0 - \bar{y})^2/\Sigma(x_i - \bar{x})^2\}^{1/2}$, m = the number of determinations.

3.6. Analytical applications

Atomic absorption spectrometry is considered to be the best method for the assay of magnesium in water and human fluids such as serum and urine, but spectrophotometric methods are more often used because of their simplicity and low cost [15–18]. Different chromogenic reagents such as Methylthymol Blue, formazan dye, magon and especially Calmagite have been proposed for determining Mg^{2+} in biological fluids [16,19]. In practical applications, Calmagite needs a nonionic surfactant and masking agents (e.g. NaCN and EGTA) to improve its selectivity for Mg^{2+}. Most sensitive spectrophotometric methods for determining Mg^{2+} in water also require previous treatments such as separation or masking [15,18,20]. Compared with those methods described above, however, the present proposed method is simple, needs no masking and can be satisfactorily applied to the direct determination of magnesium in water and human fluids (Table 1). The results, given in Table 1, were evaluated by the paired t-test [21] and showed that there was no significant difference between the proposed method and AAS at the 95% confidence level.

4. Conclusions

The present results further demonstrate that incorporation of a chromogenic group into water-soluble polymers can be used as an effective way for improving the analytical properties of photometric reagents. By replacing the hydroxy group in the polymer used with an amino group, the resulting condensed product PA·FPNS provides better analytical properties than PV·FPNS in terms of both sensitivity and selectivity. PA·FPNS is one of the best chromogenic reagents for determining magnesium. When applied to the analysis of human fluids, it requires only small sample volumes and needs no previous treatment. Of course, the presented method may also be adapted for improvements in other analytical reagents such as fluorimetric reagents. We are currently focusing on such an attempt.

Determination of glycerol in alcoholic beverages using packed bed reactors with immobilized glycerol dehydrogenase and an amperometric FIA system

M.I. Prodromidis, C.D. Stalikas, S.M. Tzouwara-Karayanni, M.I. Karayannis*

University of Ioannina, Laboratory of Analytical Chemistry, Ioannina, Greece

Abstract

A flow injection analysis system incorporating amperometric detection and enzyme reactor for glycerol determination in alcoholic beverages is described. The reactor is based on the glycerol dehydrogenase system, and the enzyme was immobilized through chemical modification on several supporting materials such as aminopropyl and isothiocyanate controlled pore glass, aminopolystyrene resin and m-aminobenzyloxymethyl cellulose. NADH, the product of the enzymatic reaction, was monitored amperometrically with a three-electrode wall-jet type flow through cell, at $+0.5$ V vs. Ag/AgCl. The method was evaluated in the presence or absence of potassium and the following linear dynamic ranges were found: $2 \times 10^{-5} - 2 \times 10^{-4}$ mol l^{-1} and $4 \times 10^{-5} - 4 \times 10^{-4}$ mol l^{-1}, respectively. The interference effects of various compounds were also studied. The relative standard deviation was found to be better than 1.0% ($n = 6$). The reactors are stable for over a period of 3 months and after about 2500 injections. Under optimum working conditions the sampling frequency was 30 samples h^{-1}. The successive application of the method was confirmed by comparison with a reference method. The mean relative error is 2.2% and the recovery 95–102%.

Keywords: Amperometric FIA; Glycerol determination; Isothiocyanate CPG; Immobilized enzyme

1. Introduction

Glycerol in grape juice has been shown to be an indicator of defects in harvested grapes [1]. It is also a secondary fermentation product in wine contributing to the sensory properties, while it is added to the beer and other alcoholic beverages in order to improve their taste. Therefore, a rapid, sensitive, reliable and at the same time economical

*Corresponding author.

method is desired for the determination of this analyte. The official methods for determining glycerol are that recommended by the AOAC and also liquid chromatography [2,3]. Both methods are either very time-consuming and tedious or expensive and not suited to routine analysis. However, several enzymatic methods have been developed for the analysis of glycerol, combining the selectivity of the enzymes involved with different detection systems [4–11]. In these cases the shortcomings of the methods arise from the use of

more than one enzymatic pathway, the tedious pretreatment of the sample, the need for preparation of many reagents and the use of complicated instrumentation. Here we present a simple, precise and reproducible procedure which links a reactor bearing immobilized glycerol dehydrogenase (GDH) and the amperometric detection of the produced NADH, using a graphite electrode mounted on a wall-jet type flow through cell. A fully automated flow injection analysis (FIA) manifold is used for performing the determinations. The GDH is immobilized on several inorganic and organic polymeric supporting materials for the construction of packed bed reactors (PBRs). The resulting enzymatic reactors are evaluated and the superior one is used for the determination of glycerol. Moreover, the proposed method does not use additional reagents, such as mediators or other co-immobilized enzymes, except the NAD^+ required for the operation of the immobilized enzyme. Many attempts have led in the past to similar enzymatic schemes, but to our opinion without the analytical advantages of the present work [4,9].

The glycerol concentration is proportional to the yield of NADH, the product of the enzymatic reaction:

$$Glycerol + NAD^+ \xrightarrow{GDH} dihydroxyacetone$$

$$+ NADH + H^+ \qquad (1)$$
2. Experimental

2.1. Apparatus

An automated dual-channel, in-house built FIA manifold was used for the determinations. The FIA system consists of a four-way pneumatically actuated injection valve (Rheodyne, Type 50 Teflon, Cotati, CA, USA) and an in-house electronic actuator, assembled from a transformer (DC, 5–12 V, 2 A, 5 W) and a 12 V coil. The coil is actuated by resident software developed in our laboratory which controls the passage of compressed air through the valve as well as a four-channel peristaltic pump (Gilson Minipuls 3, Villiers-le-Bel, France). The three-electrode elec-

trochemical detector, model 656 (Metrohm, Herisau, Switzerland) comprises a wall-jet type thermostatted cell (volume < 1 μl), a graphite working electrode (RW001, 3.0 mm i.d., Ringsdorff-Werke GmbH), a built-in gold auxiliary electrode and a Ag/AgCl reference electrode. The potentiostat is the Autolab Electrochemical Analyser (Eco Chemie, Utrecht, The Netherlands).

2.2. Reagents

A glycerol dehydrogenase, (glycerol:NAD^+ 2-oxidoreductase; EC 1.1.1.6, cellulomonas species, 49 U mg^{-1} solid) was purchased from Sigma, Cat. No. G-3512 (St. Louis, MO, USA). The aminopropyl and isothiocyanate controlled pore glass (CPG, 500 A, 200–400 mesh) as well as the aminopolystyrene resin (APSR) and m-aminobenzyloxymethyl cellulose (m-ABMC) were also purchased from Sigma. Boehringer (Mannheim, Germany) was the supplier of the enzymatic Test Kit which was used as a reference method. All the other chemicals were of analytical-reagent grade and were obtained from Sigma. Tris–HCl buffer 0.05 mol l^{-1}, pH 9.0 was prepared by dissolving 0.76 g Tris–HCl and 5.47 g Trizma base in 1 l distilled water.

2.3. Preparation of the immobilized enzyme reactors

Before immobilizing the enzyme, the supporting materials are chemically modified. The isothiocyanate CPG was purchased preactivated with thiophosgene [12]. The PBRs were prepared by packing the derivatives (80 mg) in glass tubes (2 mm i.d × 30 mm length). A 0.05 mol l^{-1} solution based on a phosphate buffering system of suitable pH (Table 1), containing 2.5% v/v glutaraldehyde, was pumped through the columns of aminopropyl-CPG and APSR at a flow rate 0.2 ml min^{-1} for 2 h at room temperature in order to preactivate the support, followed by washing of the columns with doubly-distilled water for 2 h. The m-ABMC was activated by diazotation with $NaNO_2$ as described elsewhere [13]. GDH (343 U) was loaded onto the supporting materials by cir-

culating the enzyme in phosphate buffer solution of appropriate pH for 36 h at a flow rate of 0.2 ml min^{-1}, and 4°C. The solution with the enzyme was directed along the reactor by reversing the flow for time intervals (15 min) specified by means of a computer program, in order to achieve better efficiency of immobilization. The support was then washed with water (5 min), NaCl 0.5 mol l^{-1} (60 min), water (60 min) and finally with the phosphate buffer solution 0.05 mol l^{-1} (30 min). An increase in circulation time up to 48 h did not significantly improve the efficiency of immobilization. The reactors were stored at 4°C filled with the buffer of immobilization. In all cases the concentration of the enzyme solution was 7 mg GDH/3.5 ml of 0.05 mol l^{-1} phosphate. The immobilization on APSR and m-ABMC was carried out at pH 7.0 and 7.8, respectively [14,15]. Higher concentrations of GDH did not improve the response.

2.4. Procedure

The flow diagram of the FIA system is shown in Fig. 1. The streams of the carrier (Tris–HCl 0.05 mol l^{-1} pH 9.0, containing 1.45×10^{-2} mol l^{-1} K^+) and the NAD^+ solution (1×10^{-2} mol l^{-1}) in the working buffer solution were continu-

ously pumped at flow rates of 0.21 ml min^{-1} and 0.17 ml min^{-1}, respectively. Standards or real samples were introduced automatically as shots of 170 μl via the loop injection valve. The peak height of the current response was taken as a measure of the glycerol concentration.

According to previous investigations, the graphite electrodes proved to be very efficient with respect to stability, reproducibility and sensitivity for the determination of NADH [16]. They were maintained and regenerated as follows: graphite rods were first polished using wet emery paper (Nr.240), washed thoroughly with deionized water and finally dried at 60°C for 30 min prior to heating in a muffle furnace at 700°C for 90 s, in order to remove tiny particles from their surface [17]. After cleaning, the electordes were pretreated by cycling between + 1.0 and − 1.0 V at a scan rate of 100 mV s^{-1} for about 20–30 scans in 10% H_2SO_4.

3. Results and discussion

The amount of immobilized enzyme was determined as proteinic molecules by measuring the absorbance of the GDH solutions at 280 nm before and after the immobilisation [18]. The use of APSR and m-ABMC did not give considerable yields of immobilization. The immobilization of GDH on CPG was performed with efficiencies between 67 and 85% (Table 1). The results prove that these materials are very good functionalized supports for the immobilization of GDH, and, to the best of our knowledge, this is the first time they have been used as such. The response of the system was high enough to avoid the use of

diaphorase which has been previously used as a link in reaction schemes given by Eq. (1) [4].

Parameters such as immobilization and working pH, concentrations of NAD^+ and flow rates of the reagents were optimized. The different parameter variations were implemented with a glycerol standard solution of 1×10^{-4} mol 1^{-1}.

The optimum pH for the activation of GDH has been previously reported to be 9.0 and 8–10 [19,20], while pH 11 leads to inactivation of the enzyme. The effect of pH on the system was also investigated. Several buffering systems of different concentration and pH were used. Fig. 2 illustrates that Tris–HCl buffer 0.05 mol 1^{-1}, pH 9.0, is the most suitable for the operation of the system. The buffer based on the glycine system yielded slightly higher responses but in a narrower range of pH, which restricted the operational conditions of the system.

Several flow rates in the range 0.10–0.60 ml min^{-1} were used in the experiments. An overall flow rate of 0.38 ml min^{-1} gave fairly high peak intensities and satisfactory sampling throughput (30 samples h^{-1}). A 9:7 flow ratio (buffer carrier to NAD^+ solution) offered low dilution of the sample and therefore satisfactory peak current. A sample volume of 170 μl was selected for performing the experiments which compensates for
Fig. 3. Effect of sample size on the response of the system. Buffer concentration 0.05 mol ml^{-1}; glycerol concentration 1×10^{-4} mol 1^{-1}.

no peak broadening and fairly high sensitivity (Fig. 3). No influence on the system was observed by positioning a plain reactor beyond the meeting point of the sample with NAD^+ for better mixing.

Since the equilibrium of the employed reaction favours glycerol breakdown only in the case of NAD^+ being in large excess [21], a final concentration of 4.5×10^{-3} mol 1^{-1} was chosen for the experiments, providing high sensitivity.

Systems using the electrochemical oxidation of NADH at electrode surfaces need special emphasis on the use of mediators, which allow operation at lower potentials. The system described here is without mediators since no interference of ascorbic acid or other electrochemically active compounds is encountered in the tested real samples. In addition, most of the mediators are strongly pH dependent [16]. The majority of commonly used mediators such as Meldola Blue, Nile Blue, p-benzoquinone, ferrocenes and Methylene Blue are inactive in alkaline media (> 8) [22]. Ferricyanide and DCIP tested at pH 9.0 showed good electrochemical behaviour, but their analytical performance was limited in the absence of the enzyme diaphorase.

According to the literature [23], it is possible to regenerate NAD^+ from NADH at naked electrodes under ideal conditions (0.1 M NADH, pH

Fig. 2. Effect of pH on the response of the system. □, Tris–HCl; ■, glycine. Buffer concentration 0.05 mol 1^{-1}; glycerol concentration 1×10^{-4} mol 1^{-1}.

7) although a large overvoltage is needed, i.e. + 1.1 V vs. SCE, and prolonged usage results in fouling of the electrode surface. However, the direct anodic oxidation of NADH has been reported by Laval et al. using a Blaedel and Wang type pretreatment of the electrode [24], by Eggers et al. using diluted NADH [25], and by Blaedel and Engstrom at + 0.875 V vs. SCE using an NAD$^+$ concentration of 1–5 mM [26]. As noticed, the NAD$^+$ was shown not to cause fouling of the electrode [26]. In the present work, a lower potential of + 0.5 V vs. Ag/AgCl was applied in order to improve the stability of the baseline while minimizing the graphite surface fouling. Replicate measurements of a glycerol standard solution during our experiments showed no fouling effect at the electrode surface.

The behaviour of commonly considered interferents, normally present in real samples, was also investigated. All the tested compounds (metals, amino acids and organic acids) were present at concentrations of 1×10^{-3} mol l^{-1} in mixtures containing 1×10^{-4} mol l^{-1} of glycerol. As expected, the results displayed in Table 2 show that only potassium and ascorbic acid give positive interferences. In this case, potassium functions as an activator of the enzyme [19] leading to an increase in the system sensitivity. For routine experiments, the potassium is led to the FIA

Table 2
Interference effect of various compounds on the assay of glycerol in a standard solution of 1×10^{-4} mol l^{-1}. The concentration of interfering compound in all cases was 1×10^{-3} mol l^{-1}

| Interfering compound	Relative activity (%)
None	100

system along with the carrier at a concentration of 8×10^{-3} mol l^{-1} as indicated in Fig. 4. Owing to the high concentrations of glycerol in real samples large dilutions were performed, thus minimizing the interferences present.

Under the optimum working conditions, good linearity was achieved in the follow concentration ranges of glycerol: 4×10^{-5}–4×10^{-4} mol l^{-1} without potassium and 2×10^{-5}–2×10^{-4} mol l^{-1} in the presence of potassium. The correlation coefficients were 0.997 and 0.998, respectively. The relative standard deviation for both reactors was 0.8% for a 1×10^{-4} mol l^{-1} standard glycerol solution (six replicate measurements). The detection limit (for signal-to-noise ratio = 3) in the presence of potassium was 5×10^{-6} mol l^{-1}.

The reactors displayed very good operational and storage stability if kept in the buffer of immobilization at 4°C when not in use. Under the conditions described above, after more than 2500 injections over a period of 3 months, the reactor retained 85% of its initial activity.

Although several methods have been suggested for the determination of glycerol in food samples, the proposed method surpasses those previously given in the literature in terms of simplicity and low cost.

The method was applied to the determination of glycerol in several types of wines, beers and champagne. Dilutions of 1:100 to 1:500 are neces-

Study of chemical modifiers for direct determination of silver in sea water by ETA-AAS with deuterium background correction

P. Bermejo-Barrera*, J. Moreda-Piñeiro, A. Moreda-Piñeiro, A. Bermejo-Barrera

Department of Analytical Chemistry, Nutrition and Bromatology, Faculty of Chemistry, University of Santiago de Compostela 15706, Santiago de Compostela, Spain

Abstract

Methods for the direct determination of silver in sea water samples by ETA-AAS using different chemical modifiers were studied. The effect of salinity was studied using synthetic sea water of high (72.8‰) and low (34.2‰) salinity, and the results were compared with aqueous standard solutions. The charring temperatures achieved were 800 and 900°C for magnesium nitrate and ammonium dihydrogen phosphate respectively, being 1100 °C for palladium nitrate and their mixtures. The best sensitivity obtained in the peak-height measurement mode was achieved by using reduced palladium (limit of detection (LOD) between 0.5 and 1.1 μg l^{-1} for an injection volume of 20 μl) with analytical recoveries close to 100% for synthetic and real sea water samples. The use of ammonium dihydrogen phosphate (LOD of 1.3 μg l^{-1} for an injection volume of 20 μl) produced good recoveries for low salinity; at high salinity an increase of around 25% was obtained, the method being unsuitable for sea water analysis. Finally, an interference study of the major components of sea water was carried out and applied to the analysis of surface sea water from the Galicia coast.

Keywords: ETA-AAS; Silver determination; Sea water; Chemical modifiers

1. Introduction

Silver has been recognized as a toxic element owing mainly to its abundance in marine environments [1]. Therefore, it is necessary to know the concentrations of silver in sea water. Despite the fact that silver determination is one of the most sensitive determinations by ETA-AAS, there are only a few reports on its implementation in sea water using a graphite furnace [2-6]. A reason for this could be the strong interference of chloride [7] and the high silver volatility. In fact, losses of silver were reported [8] at temperatures higher than 400°C, and also incomplete volatilization of the inorganic matrix of the sea water samples at these relatively low charring temperatures.

The above problems could be reduced considerably with the use of chemical modifiers, ensuring silver stabilization at higher charring temperatures, and hence allowing better elimination of the sea water matrix resulting in a decrease in the

matrix interference effects. For this reason, Rettberg and Holcombe [2] used tantalum as a second atomization surface. To avoid the matrix effect, the separation of silver from sea water using extractive procedures or by coprecipitation methods was also carried out; these procedures are summarized in Table 1. However, the use of analyte separation methods presents some disadvantages because of the laborious procedures required, and the possible loss of analyte and sample contamination during these procedures. Thus, a direct method with chemical modifiers appears more suitable.

Among the different chemical modifiers previously proposed for silver determination, ammonium dihydrogen phosphate [6], ascorbic acid [13,14], nitric acid [15] and EDTA, alone or combined with ammonium dihydrogen phosphate [16], were used for silver determination in oyster, sea water, mineral water and geological samples. Recently, Bhattacharyya [17] studied the effect of platinum, iridium, palladium, cadmium, magnesium, vanadium and titanium modifiers, and proposed the use of palladium acetate as a chemical modifier for silver determination in coal fly ash.

Some authors have successfully used palladium reduced by different reducing agents such as ascorbic acid and hydroxylamine hydrochloride, with 5% hydrogen as purge gas [18]. The addition of a reducing agent ensures that palladium is reduced to the metal early in the temperature program, improving the sensitivity for metals such

thallium and lead [18], and mercury [19] in sea water samples.

Thus, in the present work, a comparative study of palladium nitrate, alone or combined with magnesium nitrate and reducing reagents, and ammonium dihydrogen phosphate will be carried out for the direct determination of silver in real and synthetic sea water samples of low and high salinity, using a deuterium background correction system.

2. Experimental

2.1. Apparatus

Silver absorbance was measured with a Perkin-Elmer 1100 B atomic absorption spectrotometer equipped with a deuterium lamp for background correction, a HGA-700 graphite furnace atomizer and an AS-70 autosampler. The operating conditions are shown in Table 2.

2.2. Reagents

All solutions were prepared from analytical-reagent grade chemicals using ultrapure water, resistivity 18 MΩ cm^{-1}, which was obtained from a Milli-Q water purification system (Millipore).

The solutions used were: silver nitrate stock standard solution, 1.000 g l^{-1} (BDH chemicals, Poole, UK); palladium stock standard solution,

3.000 g l⁻¹ (99.999%, Aldrich, Milwaukee, WI, USA), prepared according to Welz et al. [20]; magnesium nitrate stock standard solution, 2.000 g l⁻¹, prepared from magnesium nitrate (Merck, Darmstadt, Germany); ammonium dihydrogen phosphate, 2.000 g l⁻¹, prepared from ammonium dihydrogen phosphate (BDH Chemical Ltd.); hydroxylamine hydrochloride (HONH₃Cl), 1.000 g l⁻¹, prepared from hydroxylamine hydrochloride (Merck); L(+)-ascorbic acid, 1.000 g l⁻¹, prepared from L(+)-ascorbic acid (Merck); citric acid, 1.000 g l⁻¹, prepared from citric acid (Merck).

Two synthetic sea water (SSW) samples [21] were prepared from the following components. SSWI: 30 g l⁻¹ of sodium chloride (Merck), and 10 g l⁻¹ each of magnesium chloride, potassium chloride, calcium chloride and strontium chloride (Merck), giving a salinity of 72.8 ‰. SSWII: 32 g l⁻¹ of sodium chloride, 14 g l⁻¹ of magnesium sulfate heptahydrate (Merck) and 0.15 g l⁻¹ of sodium hydrogencarbonate (Merck), giving a salinity of 34.2‰.

Ammonium nitrate, 1.000 g l⁻¹, was prepared from ammonium nitrate (Merck), and argon N-50 purity (99.999%) was obtained from SEO, Madrid, Spain.

2.3. Procedure for sample collection

Sea water samples, with a salinity between 28 and 30‰, were collected from coastal surface water of Galicia (north–west, Spain) in 100 ml glass bottles and immediately acidified with 200 μl of concentrated nitric acid [22]; this gave pH < 1.6, avoiding silver adsorption onto the glass bottle walls.

2.4. Procedure for measurements

Each real or synthetic sea water sample (200 μl), along with the appropriate volumes of the different chemical modifiers to obtain a concentration that will be referred to in the next section, was transferred into the autosampler cup. The volume was then made up to 1 ml and the solution stirred before measurements. Volumes of 20 μl were injected into the atomizer. A sequential dry–ash–atomize–clean electrothermal program (Table 2) was run and the integrated absorbances recorded.

3. Results and discussion

3.1. Charring and atomization temperatures

A study on silver stabilization in sea water samples, i.e. synthetic sea water spiked with 10 μg l⁻¹ of Ag⁺ and an aqueous standard solution of 10 μg l⁻¹ of Ag⁺ using (a) nitric acid (3.5%, v/v), (b) palladium nitrate (20 μg l⁻¹), (c) magnesium nitrate (20 μg l⁻¹), (d) palladium (20 μg l⁻¹)–magnesium nitrate (20 μg l⁻¹), (e) palladium (20 μg l⁻¹)–ascorbic acid (200 μg l⁻¹), (f) palladium (20 μ l⁻¹)–hydroxylamine hydrochloride (200 μg l⁻¹), (g) palladium (20 μ l⁻¹)–citric acid (200 μg l⁻¹) and (h) ammonium dihydrogen phosphate (20 μg l⁻¹), was performed. The optimum charring temperatures obtained are shown in Table 3. As can be observed, when aqueous standard solutions were used, optimum charring temperatures of 1000 and 1100°C were reached when using palladium nitrate, palladium–magnesium nitrate and reduced palladium; in contrast, for nitric acid, magnesium nitrate and ammonium dihydrogen phosphate, loss of silver was observed at charring temperatures of 600, 800 and 900°C respectively.

Table 2
Graphite furnace temperature program and spectrometer operating conditions [a]

Step	Temperature	Ramp	Hold	Argon flow
Drying	150	15	20	300
Charring	700–1500	15	30	300
Atomization	1800–2500	0	3	0 (read)
Cleaning	2500	1	3	300

[a] Ag hollow cathode lamp; wavelength = 328.1 nm; lamp current = 4 mA; spectral bandwidth = 0.7 nm; integration time = 3 s; peak-area and peak-height measurements; pyrolytically coated graphite tubes and pyrolytic platform; deuterium background correction; injection volume = 20 μl.

	Char. temp.	Atom. temp.	Char. temp.	Atom. temp.	Char. temp.	Atom. temp.	Char. temp.	Atom. temp.
Pd (20 mg l^{-1})	1100	2200	1100	2200	1200	2200	1100	2000
Pd (20 mg l^{-1})–Mg(NO$_3$)$_2$ (20 mg l^{-1})	1000	2100	1100	2100	1100	2100	1100	2100
Pd (20 mg l^{-1})-L(+)-ascorbic acid (200 mg l^{-1})	1100	2100	1100	2100	1100	2200	1100	2000
Pd (20 mg l^{-1})–HONH$_3$Cl (200 mg l^{-1})	1100	2000	1100	2100	1100	2100	1000	2000
Pd (20 mg l^{-1})–citric acid (200 mg l^{-1})	1000	2200	1100	2100	1000	2200	1000	2000
Mg(NO$_3$)$_2$ (20 mg l^{-1})	800	2200	800	2200	800	2300	900	2100
(NH$_4$)H$_2$PO$_4$ (20 mg l^{-1})	900	2200	900	2200	900	2200	1000	1900
HNO$_3$ (3.5%, v/v)	600	2100	–	–	–	–	–	–

When real and synthetic sea water samples of low salinity (SSWII) were used, similar results to those found when using aqueous standard solutions were obtained for all the chemical modifiers tested (except when nitric acid was used). For synthetic sea water samples of high salinity (SSWI), an increase in charring temperature of about 100°C was observered when palladium nitrate, magnesium nitrate and ammonium dihydrogen phosphate were used as chemical modifiers. This could be due to some beneficial effect of the high content of sodium chloride matrix on silver stabilization.

For all the chemical modifiers tested, real and synthetic sea water samples gave a scatter of silver absorbance signals for charring temperatures lower than 700°C; this is due to the incomplete salt volatilization at these temperatures. The use of HNO$_3$ as a chemical modifier is thus inadequate, owing to the low charring temperatures obtained.

The atomization temperature was also studied for these chemical modifiers, using the corresponding optimum charring temperatures obtained previously. The atomization temperature was varied between 1800 and 2500°C. Similar optimum atomization temperatures, around 2200°C, were achieved (Table 3) for all chemical modifiers and samples. However, the peak profile related to the use of palladium reduced by ascorbic acid was better (higher peak height) when the atomization temperature was increased to over 2200°C. For palladium alone or combined with magnesium nitrate, hydroxylamine hydrochloride and citric acid, the improvement to the peak profile was small. For ammonium dihydrogen phosphate and magnesium nitrate, the increase in atomization temperature did not modify the peak profiles. This can be also seen in Fig. 1, for different silver absorbance–time profiles obtained using palladium nitrate, palladium–magnesium nitrate, palladium reduced by ascorbic acid, magnesium nitrate and ammonium dihydrogen phosphate. In addition, early appearance times were obtained when atomization temperatures were increased for all the chemical modifiers tested. For lower atomization temperatures, the peaks present tailed off, owing to poorer precision in the measurements, and the peak heights were correspondingly lower.

It may be concluded that the use of nitric acid as a chemical modifier does not allow the direct determination of silver in sea water samples, and that magnesium nitrate and ammonium dihydrogen phosphate produce poorer silver stabilization compared with palladium nitrate and their mixtures.

3.2. Background signal

The background signal values obtained previously for the optimum charring temperatures and

for each chemical modifier, when a real sea water sample was used, were low (around 0.010 absorbance units (a.u.)), except in the cases of magnesium nitrate and ammonium dihydrogen phosphate. For these chemical modifiers, the

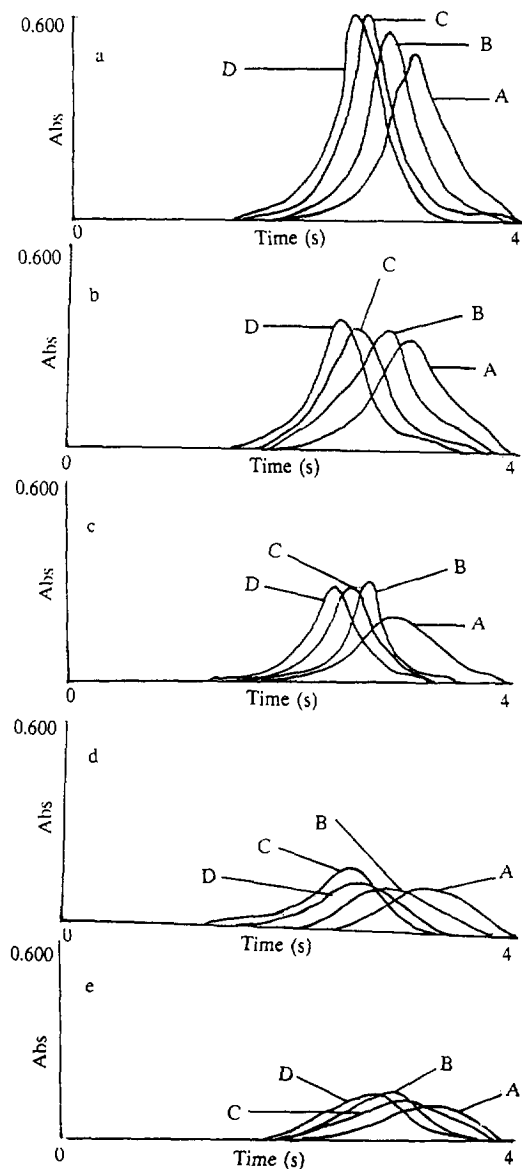

Fig. 1. Peak profiles obtained for a real sea water sample when (a) palladium–ascorbic acid, (b) palladium nitrate, (c) palladium–magnesium nitrate, (d) magnesium nitrate, and (e) ammonium dihydrogen phosphate were used as chemical modifier for different atomization temperatures: (A) 2100°C, (B) 2200°C, (C)2300 °C and (D) 2400°C.
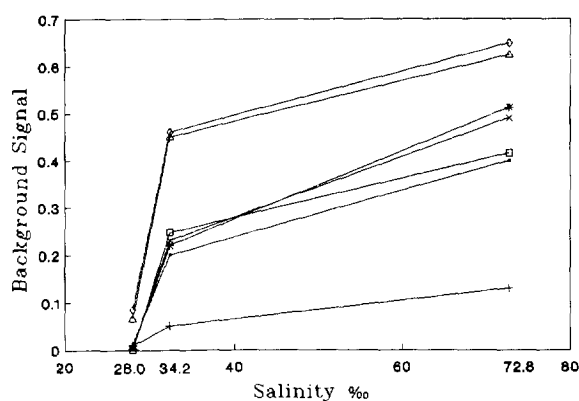

Fig. 2. Background values related to different salinities for several chemical modifiers: palladium nitrate (■), palladium–magnesium nitrate (|), palladium–ascorbic acid (□), palladium–hydroxylamine (*), palladium–citric acid (×), magnesium nitrate (△) and ammonium dihydrogen phosphate (◇).

background signal values were 0.090 and 0.070 a.u. respectively, due to the lower admissible charring temperatures (800 and 900°C), which do not allow efficient removal of the sea water matrix.

When synthethic sea water of low and high salinity was used, the background signal values increased strongly (Fig. 2) for all chemical modifiers, except the mixture palladium–magnesium nitrate. The use of palladium nitrate and reduced palladium offered background signal values of around 0.200 and 0.400 a.u. for low and high salinities respectively, while the highest background signal values obtained were for ammonium dihydrogen phosphate, i.e. 0.450 and 0.600 a.u. for low and high salinities respectively.

The addition of ammonium nitrate to real and synthetic sea water samples was carried out to increase the removal of sodium chloride from samples when magnesium nitrate and ammonium dihydrogen phosphate were used. From the results obtained, it can be said that the addition of ammonium nitrate does not offer sufficient volatilization of sodium chloride, which necessitates a charring temperature higher than 900°C [23].

Finally, when palladium nitrate plus magnesium nitrate was used the background signal values obtained were considerablely low, around 0.050 and 0.130 a.u. for low and high salinity
Fig. 3. Peak profiles obtained for a sea water sample spiked with Ag^+ (10 μg l^{-1}) corresponding to the use of (A) palladium nitrate (20 mg l^{-1}), (B) palladium (20 mg l^{-1})-magnesium nitrate (20 mg l^{-1}), (C) palladium (20 mg l^{-1})-ascorbic acid (200 mg l^{-1}), (D) magnesium nitrate (20 mg l^{-1}) and (E) ammonium dihydrogen phosphate (20 mg l^{-1}).

respectively. Thus, the addition of $Mg(NO_3)_2$ has some beneficial effects, problably due to matrix oxidation, which increase the advantages of the use of palladium [24].

3.3. Peak profiles

The peak profiles obtained for a sea water sample spiked with 10 μg l^{-1} of Ag^+ and for each chemical modifier, at a concentration referred to previously, are shown in Fig. 3. As can be seen, the best peak profile (highest peak height and smallest tails) corresponds to the use of palladium reduced by ascorbic acid. The other reducing reagents (hydroxylamine hydrochloride and citric acid) did not improve the peak profile when added to palladium nitrate. Finally, the worst

peak profiles correspond to the use of magnesium nitrate and ammonium dihydrogen phosphate.

3.4. Calibration and standard addition graphs

A study of the calibration and addition graphs with the chemical modifiers tested for silver determination was performed. The charring temperature was an optimum one related to a real sea water sample and the atomization temperature employed was 2300 °C, as the best peak profiles were obtained for some of the chemical modifiers at this atomization temperature. The calibration and addition slopes obtained using peak-area and peak-height measurements are shown in Table 4. As can be seen, these slopes, related to all kinds of samples for each chemical modifier (except when ammonium dihydrogen phosphate was used), are very similar, no statistical differences being found when the F-test [25] was applied for a confidence level of 99.5%. Thus, it can be assumed that the matrix effect for high salinity is small. Consequently, the calibration method using aqueous standard solution may be used independently of the salinity of the sea water sample. When $(NH_4)H_2PO_4$ was used, an increase of about 100% in the slope value was obtained for synthetic sea water of high salinity (SSWI), the calibration method employing aqueous standard solutions being unsuitable in this case. For this situation a standard addition method will be carried out.

The increase in the slope values obtained when peak-height measurements were used (Table 4)

[a] These detection limits were obtained using 400 µl of sea water sample (filled to 1 ml) and by hot injection of 40 µl aliquot into the atomizer.

was strong when palladium reduced by ascorbic acid and citric acid was utilized. This is due to the good peak profile (high peak height) of the silver signal for these chemical modifiers. When palladium nitrate was used alone, a smooth increase in the slope values was obtained using the peak-height measurement mode, while for palladium–magnesium nitrate, magnesium nitrate, palladium–hydroxylamine hydrochloride and ammonium dihydrogen phosphate some improvement of the slope values was achieved.

3.5. Precision

The within-batch precision of the methods, obtained for 11 replicates of a sea water sample solution spiked with 0, 5 and 10 µg l^{-1} of Ag$^+$, was studied for all the chemical modifiers tested. The mean RSD (%) values are shown in Table 5. The precision obtained using peak-area and peak-height measurement modes is acceptable, RSD < 3.2%, corresponding to the best within-batch precision when the peak-height mode was used.

3.6. Sensitivity

A study of the sensitivity achieved for each chemical modifier was performed. The sensitivity was examined using the following parameters: limit of detection (LOD), limit of quantification (LOQ) and characteristic mass (m_0) [26]. Table 5

shows the values of these parameters obtained with each chemical modifier, and related to the use of both measurement modes (peak height and peak area). The slopes in each case were the calibration graphs using SSWII, and the standard deviation (SD) was related to 11 replicates of the blank of the calibration using SSWII.

As can be seen (Table 5), the use of the peak-height measurement mode for palladium nitrate, palladium–ascorbic acid and palladium–citric acid offers better LODs than the use of the peak-area measurement mode. When the other chemical modifiers were used, similar LODs were obtained in both measurement modes. In addition, for both measurement modes, the use of palladium reduced by ascorbic acid offers the best sensitivity, giving LODs of 0.7 and 0.5 µg l^{-1} for the peak-area and peak-height modes respectively.

These detection limits can be improved by introducing a large volume of sea water into the autosampler cup and by increasing the volume introduced into the graphite tube. Thus, when 400 µl of sea water sample was used to prepare the final solution and 40 µl aliquot was introduced into the atomizer by the hot injection technique (at 120°C), the detection limits could be reduced as shown in Table 5. Thus, when palladium–ascorbic acid was used the LOD obtained was reduced to 0.2–0.1 µg l^{-1} for each measurement mode. When magnesium nitrate and ammonium dihydrogen phosphate were used, the increase in

Table 6
Analytical recovery corresponding to each chemical modifier

Chemical modifier	Sea water		SSWII (34.2‰)		SSWI (72.8‰)	
	Area	Peak	Area	Peak	Area	Peak
Pd (20 mg l^{-1})	91.3	96.7	93.0	109.0	103.7	98.6
Pd (20 mg l^{-1})–Mg(NO$_3$)$_2$ (20 mg l^{-1})	93.3	103.0	97.8	102.0	104.2	107.4
Pd (20 mg l^{-1})-L(+)-ascorbic acid (200 mg l^{-1})	96.0	98.6	97.0	101.3	95.8	105.6
Pd (20 mg l^{-1})–HONH$_3$Cl (200 mg l^{-1})	105.7	97.5	102.1	102.5	105.3	103.3
Pd (20 mg l^{-1})–citric acid (200 mg l^{-1})	102.7	102.5	94.8	104.7	102.3	98.7
Mg(NO$_3$)$_2$ (20 mg l^{-1})	104.5	104.0	103.0	97.4	102.1	100.7
(NH$_4$)H$_2$PO$_4$ (20 mg l^{-1})	105.0	97.6	103.5	105.8	157.5	130.7

salt content obtained for a large injection volume produced a scatter in the silver absorbance signal due to inefficient volatilization of the sea water matrix and more pronounced matrix effects.

3.7. Accuracy

Owing to the fact that a reference material of sea water with certified silver concentration is not available, the accuracy was studied by analysis of a reference material (plant materials of aquatic origin) BCR-61, with an indicative silver concentration of 2.0 mg kg^{-1}. The results expressed for a confidence level of 95% as mean $\pm$ confidence limit were 2.5 $\pm$ 0.4, 2.3 $\pm$ 0.4, 2.6 $\pm$ 0.3, 2.4 $\pm$ 0.3, 2.4 $\pm$ 0.4, 2.5 $\pm$ 0.4 and 2.6 $\pm$ 0.4 mg kg^{-1} for palladium, palladium–magnesium nitrate, palladium–ascorbic acid, palladium–hydroxylamine hydrochloride, palladium–citric acid, magnesium nitrate and ammonium dihydrogen phosphate, respectively. In addition, the accuracy was studied

through the analytical recovery. As can be seen (Table 6), the use of palladium nitrate, magnesium nitrate, palladium–magnesium nitrate and reduced palladium ensures excellent recoveries, close to 100% for all silver concentrations and all salinities when both measurement modes were used. However, when ammonium dihydrogen phosphate was employed, only acceptable recoveries were obtained for low salinity; at high salinity (with respect to Milli-Q water), the analytical recovery increased to 150%, owing to the significant interference of salts from the sea water which will be discussed in the next section.

3.8. Interference study of the major components of sea water

The influence of the increasing concentration of sodium chloride and potassium sulfate (the major components of sea water) on the integrated absorbance signal of a sea water sample spiked

Table 7
Percentage of silver absorbance variation produced with the addition of NaCl and K$_2$SO$_4$ on a sea water sample spiked with Ag$^+$ (10 µg l^{-1})

Interferent	Conc. added (g l^{-1})	Pd	Mg(NO$_3$)$_2$	Pd–Mg(NO$_3$)$_2$	Pd–ascorbic acid	Pd–HONH$_3$Cl	Pd–critic acid	(NH$_4$)H$_2$PO$_4$

	1	−10.7	−41.9	−55.3	−16.2	−30.6	−31.6	−35.4
	2	−20.6	−55.5	−68.5	−23.6	−48.1	−53.0	−55.9

with Ag^+ (10 μg l^{-1}) for each chemical modifier tested is shown in Table 7. We assume that these species begin to interfere at a concentration corresponding to a 10% increase or decrease in the signal in their absence.

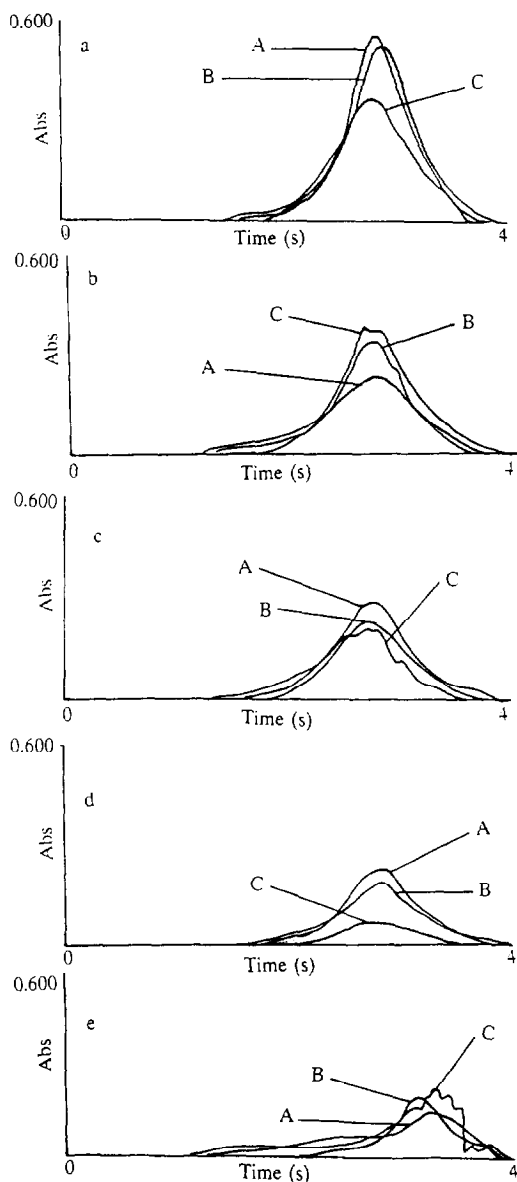

Fig. 4. Effect of increasing concentration of NaCl, (A) 0 g l^{-1}, (B) 5 g l^{-1} and (C) 10 g l^{-1}, on the peak profile of a real sea water sample spiked with 10 μg l^{-1} of silver when (a) palladium–ascorbic acid, (b) palladium–magnesium nitrate, (c) palladium nitrate, (d) magnesium nitrate and (e) ammonium dihydrogen phosphate were used as chemical modifiers.

At concentrations of sodium chloride of up to 5 g l^{-1} there was no effect on the silver signal for the different chemical modifiers used, except in the case of palladium reduced by ascorbic acid for which a sodium chloride concentration of 10 g l^{-1} did not exhibit significant interference.

The increase in sodium chloride concentration (Fig. 4) produces the worst peak profile (small peak height) for all the chemical modifiers, except for the mixture palladium–magnesium nitrate for which an increase in the peak height was obtained. Finally, as can be seen in Fig. 4, a scatter of the silver peak was obtained for high sodium chloride concentration when ammonium dihydrogen phosphate was used as chemical modifier.

The addition of potassium sulfate did not produce any interference at concentrations higher than 0.5 g l^{-1} for all the chemical modifiers tested. However, the addition of this species produced a distorted peak profile, as was also observed on addition of sodium chloride.

4. Application

The method using the mixture palladium–ascorbic acid as chemical modifier was applied to the determination of silver in sea water samples from the Galicia coast (north–west Spain) using the peak-height mode and a calibration method with standard aqueous solution. Two sub-samples for each sea water sample were then analyzed. A volume of sea water of 200 μl was transferred into the autosampler cup with the appropiate volume of palladium and ascorbic acid to obtain the concentration referred to previously; it was then diluted to 1 ml. A 20 μl aliquot was injected into the atomizer. Owing to the low silver concentration of the sample 6, a 40 μl aliquot was introduced into the atomizer by hot injection at 120°C. The silver concentrations obtained are given in Table 8, together with the RSDs, and are seen to vary between 0.4 and 11.7 μg l^{-1}.

5. Conclusions

Palladium reduced by ascorbic acid was found to be the most adequate chemical modifier, with

Table 8
Silver levels in sea water samples [a]

Sample	Silver concentration ($\mu g\, l^{-1}$)	RSD (%)
1	7.8	2.1
2	2.9	2.5
3	5.3	1.8
4	11.7	3.4
5	5.9	1.4
6	0.4	3.1
7	3.3	2.6

[a] $n = 4$.

the lowest LOD (0.5 μg l^{-1}) obtained using the peak-height mode, for the direct determination of silver in sea water samples of low and high salinity. The other reducing reagents did not provide a more consistent performance. Thus, the behavior of the palladium modifier depends on the reduction method used. The analytical recoveries were close to 100% for all salinities and chemical modifiers, except for $(NH_4)H_2PO_4$ at high salinity. Thus, a single calibration curve using aqueous standard solution may be used for the analysis of sea water samples. When $(NH_4)H_2PO_4$ is employed for sea water of high salinity, the standard addition method must be used, owing to the matrix effect observed with this chemical modifier. Finally, the peak-height measurement mode was found to be more adequate when palladium, both alone and combined with reducing agents, was used, because better detection limits and within-batch precision are observed.

Trace level voltammetric determination of manganese, iron and chromium in real samples in the presence of each other

Clinio Locatelli

Department of Chemistry "G. Ciamician", University of Bologna, Via F. Selmi 2, I-40126 Bologna, Italy

Abstract

The determination of manganese in the presence of iron and chromium by differential pulse voltammetry and fundamental harmonic alternating current voltammetry was compared, including the case of very high element concentration ratios. The voltammetric measurements were carried out using a stationary mercury electrode in ammonia–ammonium chloride buffer (pH 9.6). The analytical procedure was verified by the analysis of the standard reference materials Portland Cement BCS 372, Spectrographic Zinc Spelter NBS-SRM 631, Stainless Steel (AISI 321) NBS-SRM 121d and Highly Alloyed Steel Eurostandard 281-1. Precision and accuracy, expressed as relative standard deviation and relative error respectively, were of the order of 3–5%, while the detection limit for each element was around 1×10^{-9} M. The standard addition technique improved the resolution of the voltammetric methods, within a maximum experimental error of 5%, even in the case of very high concentration ratios, that is outside the non-interference concentration ratios $69:1 > c_{Fe}:c_{Mn} > 1:74$; $35:1 > c_{Fe}:c_{Cr} > 1:30$ and $63:1 > c_{Fe}:c_{Mn} > 1:65$; $32:1 > c_{Fe}:c_{Cr} > 1:31$ for the differential pulse and alternating current techniques respectively, extrapolating the linear section of the i_p vs. concentration analytical calibration function for the element present at the lowest concentration. In contrast, the element with the greatest concentration was determined by the relevant calibration curve.

Keywords: Voltammetry; Manganese; Iron; Chromium; Reference materials

1. Introduction

The simultaneous determination of several elements at trace and ultratrace level concentrations in real matrices is one of the main aims of an analytical procedure, which however must always have both good selectivity and very high sensitivity. In the metal determination, several techniques are employed such as neutron activation analysis, atomic absorption spectrometry, atomic emission spectrometry with inductively-coupled plasma excitation and X-ray fluorescence. Usually such techniques need enrichment steps and, furthermore, as regards selectivity and sensitivity, often favour only one of these two aspects. For the above reasons, the voltammetric techniques appear to be very suitable, versatile and rapid for multicomponent determinations, having good selectivity and sensitivity without requiring metal enrichments before the analytical measurements

[1,2]. In previous works [3,4] sensitive and selective voltammetric methods were employed for the simultaneous determination of various elements in real matrices. The present work, regarding the determination of manganese in the presence of chromium and iron—these three elements are often present together in various real matrices—is the continuation of that endeavour.

Manganese is an essential micronutrient: in fact it is very important in various biochemical cycles regarding man, animals and plants. In addition, it is present in a great deal of inorganic matrices, in which chromium and iron are also almost always present. Adsorptive stripping voltammetry was proposed for the determination of manganese in the presence of several interferents [5] and in real samples [6]. Also, differential pulse anodic stripping voltammetry was employed successfully for determining manganese in natural water [7-9] and in sea water [10,11]. Finally, manganese was also determined in real matrices by a potentiometric stripping technique [12], taking into account either interference problems [13] or batch and flow procedures [14-16].

In the literature a lot of papers, using PIPES together with a chelating agent as supporting electrolyte, appeared to determine the various metal species by adsorptive voltammetry. Often such a technique suffers the effects of interferent ions, either as peak overlaps or as voltammetric signal depression, with consequent sensitivity reduction of the analytical method. In the specific case of manganese, employing PIPES and Eriochrome Black T as chelating agent, the presence of iron, chromium, nickel, copper, titanium, etc. produces considerable signal depression up to 35%, depending on their concentration. With regard to this, the results obtained by Wang and Mahmoud [5] have also been generally confirmed in our laboratory. For this reason a new selective and sensitive method has been set up to determine manganese, iron and chromium in real samples in the presence of each other, employing differential pulse voltammetry (DPV) and fundamental harmonic alternating current voltammetry (ACV); such analytical procedures require ammonia–ammonium chloride buffer (pH 9.6) as supporting electrolyte.

2. Experimental

2.1. Apparatus

Voltammetric measurements were carried out with an AMEL Mod. 433 instrument employing, as working electrode, a hanging mercury drop electrode (HMDE) consisting of a glass capillary having an internal diameter of 0.1 mm and a cone-shaped tip. An Ag/AgCl, KCl sat. electrode and a platinum wire were used as the reference and auxiliary electrodes respectively. The voltammetric cell was thermostatted at $25.0 \pm 5°C$. The solution was deaerated with pure nitrogen for 15 min prior to measurements, while a nitrogen blanket was maintained above the solution during the analysis. Standard additions were made with Gilson micropipettes with diposable plastic tips. The solutions were deaerated for 2 min after each standard addition.

2.2. Reagents and reference solutions

All solutions were prepared with deionized water (Millipore, Milli-Q). Suprapure grade acids, ammonia and sodium hydroxide were used. Ammonia–ammonium chloride buffer solution (pH 9.6) was prepared by mixing an appropriate amount of hydrochloric acid and ammonia solutions. Aqueous stock solutions of manganese, iron and chromium were prepared by dilution of the respective standard 1000 mg l^{-1} BDH solutions. The Teflon voltammetric cell was rinsed every day with suprapure concentrated nitric acid in order to prevent any contamination.

The following standard reference materials were chosen for the analyses: Portland Cement BCS 372, Spectrographic Zinc Spelter NBS-SRM 631, Stainless Steel (AISI 321) NBS-SRM 121d and Highly Alloyed Steel Eurostandard 281-1.

3. Results and discussion

3.1. Aqueous reference solutions

Prior to the analysis of standard reference materials, a preliminary study was carried out

employing aqueous reference solutions. The experimental conditions are reported in Table 1. The solution pH affects the peak height of each element; the pH vs. i_p behaviours of Mn, Cr and Fe (Fig. 1), employing the differential pulse technique, show that the best pH value compromise for all three elements is 9.6. When considering ACV the best analysis pH is also 9.6 (the pH vs. i_p behaviour is practically the same). The standard addition method was used for the measurements of the analytical calibration functions for both DPV and ACV (Tables 2 and 3). The correlation coefficient was found to be satisfactory in all cases, while the precision of the techniques, expressed in terms of the residual standard deviation, was excellent ($s_r < 5\%$). Tables 2 and 3 also report the detection limits for each element.

The simultaneous determination of manganese, iron and chromium was studied in a large range of concentration ratios of the components. More precisely, employing the experimental conditions of Table 1, the element concentration ratios, within which each single element could be determined without mutual interference, were investigated. To a fixed, but very small, concentration of
Fig. 1. Behaviours (i_p vs. pH) of Mn (curve 1), Fe (curve 2) and Cr (curve 3) with ammonia–ammonium chloride buffer (pH 9.6) as supporting electrolyte; $c = 2.5 \times 10^{-7}$ M for all the elements. Voltammetric technique: DPV. Experimental conditions: see Table 1.

Experimental conditions for the determination of Mn, Fe and Cr by DPV and ACV. Supporting electrolyte: 1.0 M ammonia–ammonium chloride buffer (pH 9.6)

Experimental condition [a]	Method	Mn, Fe, Cr
E_i	–	−1.300
ΔE	ACV	10
	DPV	50
ϕ	ACV	270 + 88 (Mn)
		270 + 83 (Fe)
		270 + 84 (Cr)
f	ACV	100
dE/dt	–	10
τ	DPV	0.065
v	DPV	0.250

[a] E_i = initial potential (V/SCE); ΔE = amplitude of alternating current voltage (ACV) and pulse (DPV) superposed (mV); ϕ = demodulation phase angle (degrees); f = frequency (Hz); dE/dt = potential scan rate (mV s^{-1}); τ = pulse duration (s); v = pulse repetition (s).
Experimental peak potentials E_p (V/SCE): −1.665 ± 0.005 (Mn); −1.495 ± 0.005 (Fe); −1.420 ± 0.005 (Cr).

the element of interest, standard additions of the interfering element were added in such a way as to change their concentration ratios. Then the peak current values of the former element were compared to those determined by using the analytical calibration function of the individual element (cf. Tables 2 and 3) and the relative errors were calculated. Such errors are plotted in Figs. 2 and 3. It is apparent that the determination of the metals is possible, within a maximum error of 5%, in the concentration ranges $69:1 > c_{Fe}:c_{Mn} > 1:74$, $35:1 > c_{Fe}:c_{Cr} > 1:30$ and $63:1 > c_{Fe}:c_{Mn} > 1:65$, $32:1 > c_{Fe}:c_{Cr} > 1:31$ employing DPV and ACV techniques respectively. Such concentration ratios have also been confirmed by mono- and bivariate [3,4,17,19–21] analyses. In all cases, within the considered concentration ratios interval, the slopes of the statistical functions were practically equal to the analytical calibration function of the single element, and, moreover, the slope of the interfering element (bivariate analysis) was negligible, thus indicating non-interference between neighbouring species (Tables 2 and 3). The same Tables 2 and 3 also emphasize that there were no significant differences in the employment of the

two voltammetric techniques: DPV is slightly more sensitive than ACV.

The most interesting aspect of the work concerns the determination of the metal with the lowest concentration and an unfavourable concentration ratio as to the interferent species, that is, outside the concentration ratios interval where the regression function obtained from bivariate analysis of the data was valid. In this situation, bringing the concentration ratio within the interval valid for bivariate analysis by appropriately adding the standard solution of the metal with the lowest concentration was enough to determine the metal itself. In fact, the i_p vs. concentration plots showed non-linear behaviour. A linear section was obtained when the concentration ratios attained values within the validity of the bivariate analysis. An extrapolation of this linear section permitted the evaluation of the metal content in the mixture with acceptable accuracy (behaviour as in Fig. 5 in the following section). The limit within which linearity prevails was statistically evaluated according to the method of Liteanu et al. [22] using the t-test criteria.

3.2. Practical application

Once established for aqueous reference solutions, the method was transferred to real matrices in order to confirm the applicability of the analytical procedure.

Sample preparation and analytical results

Portland Cement BCS 372 was prepared according to Riley [23]. Approximately 0.1 g cement, weighed accurately in a platinum crucible, was dissolved in 1 ml of 60% (m/m) perchloric acid, 3 ml of 40% (m/m) hydrofluoric acid was added, and the mixture was evaporated almost to dryness. After cooling, the soluble salts were dissolved in 250 ml of 1.0 M ammonia–ammonium chloride buffer solution (pH 9.6).

Spectrographic Zinc Spelter NBS-SRM 631, Stainless Steel (AISI 321) NBS-SRM 121d and Highly Alloyed Steel Eurostandard 281-1 were prepared as described by Thomerson and Price [24]. According to the metal content of the standard reference material employed, approximately

[a] Number of samples: 5.
[b] e: relative error; RSD: relative standard deviation.

0.1–0.3 g, weighed accurately in a platinum crucible, was dissolved in 1 ml of 37% (m/m) hydrochloric acid, and 1 ml of 69% (m/m) nitric acid was added. After the initial reaction had subsided, 2 ml of 60% (m/m) perchloric acid was added and the solution evaporated until the sample was fully oxidized and fumes of perchloric acid appeared. After cooling, the soluble salts were dissolved in 250 ml of 1.0 M ammonia–ammonium chloride buffer solution (pH 9.6). The solutions were analyzed under experimental conditions listed in Table 1.

Table 4 shows the slopes of the analytical calibration functions calculated in the real samples for each element, together with those determined in the aqueous reference solutions (cf. Tables 2 and 3). Their comparison emphasizes that, in all cases, no matrix interferences were present, there being no significant differences at 5% error level.

The simultaneous determination of Fe, Mn and Cr was not difficult in the cases of the Portland Cement BCS 372—in such a matrix Cr is not present—and the Stainless Steel (AISI 321) NBS-SRM 121d, since the concentration ratios in the sample solution did not exceed the values of reciprocal interference at the 5% error level reported above. Then, each element was determined by the respective calibration curves (cf. Tables 2 and 3). The analytical results are listed in Table 5.

Spectrographic Zinc Spelter NBS-SRM 631, however, contains an excess of Fe, which interferes with the chromium peak ($c_{Fe}:c_{Cr} = 46.6$). The subsequent chromium standard additions enabled the analytical calibration function to show linear behaviour as soon as the concentration ratio $c_{Fe}:c_{Cr}$ equal to 35 and 32 for DPV and ACV respectively was attained. An extrapolation of this linear portion allowed the determination of

Fig. 5. Analytical calibration function of Mn in Highly Alloyed Steel Eurostandard 281-1. Voltammetric technique: differential pulse voltammetry. Experimental conditions: see Table 1.

chromium, while iron and manganese were determined using the respective analytical calibration functions (Tables 2 and 3).

The manganese determination was also difficult for the Highly Alloyed Steel Eurostandard 281-1 ($c_{Fe}:c_{Mn} = 88.1$ vs. a maximum concentration ratio equal to 69), but, employing the same method described above, it is possible to evaluate the metal content and Figs. 4 and 5 show, as examples, the relevant differential pulse voltammogram and the manganese analytical calibration function. In this case, manganese (Fig. 4, peak 3), being outside the non-interference concentration ratio interval, has been determined by extrapolating the linear section of the i_p vs. concentration fitting (Fig. 5). Chromium and iron (Fig. 4, peaks 1 and 2), however, were determined by the respective analytical calibration curves (cf. Tables 2 and 3), since the concentration ratio is inside the non-interference interval ($c_{Fe}:c_{Cr} = 3.9$). The experimental data fall in the confidence interval of the certified values for each element of the standard reference materials (cf. Table 5). The precision of the analyses, expressed as relative standard deviation, and accuracy, expressed as relative error, were less than 5% in all cases, confirming the validity of the proposed method.

It can be concluded that an appropriate employment of voltammetric techniques, supporting electrolytes and the standard addition method can be a selective and sensitive procedure, suitable for a multicomponent determination in real samples.

Sodium di-*n*-propyldithiophosphinate and activated carbon used for the concentrating of bismuth and its determination by atomic emission spectroscopy with inductively-coupled plasma

Hr.G. Malakova *, Z.M. Mateva

Centre of Analytical Chemistry, University of Plovdiv, 24, Tsar Assen Street, 4000 Plovdiv, Bulgaria

Abstract

Sodium di-*n*-propyldithiophosphinate has been proposed as a reagent to improve the sorption properties of activated carbon. The conditions for sorption concentration and separation of bismuth from aqueous solutions were studied. Possibilities for desorption and subsequent determination of bismuth by atomic emission spectroscopy with inductively-coupled plasma were shown.

1. Introduction

Activated carbon is widely used as a sorbent for concentrating micro-impurities. Its sorbtion properties can be improved by adding complexing compounds. Very few complexing agents to be used together with activated carbon are given in the literature. The reagents proposed are dithizone and sodium diethyldithiocarbamate but they have some disadvantages such as low stability of the reagent solutions and the fact that they reduce the degree of extraction of some elements [1]. Pre-concentration of bismuth, lead and cadmium for their determination in sea water was carried out by sorption of the respective diethyl- and

di-*n*-propyldithiophosphate complexes [2,3] on activated carbon. Ammonium diethyldithiophosphate and activated carbon were used in the analysis of pure aluminium and gallium [4]. Dithiophosphinic acids are compounds having the same functional group as dithiophosphoric acids and form complexes with a great number of elements (at various pHs and under different conditions) [5]. The alkali salts of dithiophosphinic acid are stable in acid medium and in storage. In the literature the most frequently proposed methods for determination of elements after being concentrated are atomic absorption spectroscopy and spectrophotometry.

In order to expand the range of organic compounds suitable for sorption concentrating, the conditions and possibilities of sorption concen-

trating and separating of small amounts of bismuth from solutions by means of sodium di-*n*-propyldithiophosphinate and activated carbon and its subsequent atomic emission spectroscopy—inductively-coupled plasma (AES–ICP) determination were studied.

2. Experimental

A solution of 5×10^{-2} M Bi was prepared by dissolving $Bi(NO_3)^{3\cdot}5 H_2O$ (Fluka) in 1 M HNO_3. The exact concentration was determined by complexometry using EDTA [6]. Sodium di-*n*-propyldithiophosphinate was synthesized by a known procedure [7], and the purity was controlled by thin layer chromatography [8]. Aqueous solutions with a concentration of 5×10^{-2} M were used The activated charcoal, pure granular form (Riedel-de-Haenag, Seelze Hannover) was treated before use as follows: activated charcoal granules were ground to powder in a china mortar, treated with HCl (1:1), filtered through a fritted glass filter and rinsed with doubly-distilled water until the pH was 7. It was dried in a drying furnace at 60°C [2].

The required pH of the solution was achieved using the following buffer systems [9]: universal buffer mixture (0.04 M solutions of acetic, boric and phosphoric acids, and a 0.04 M solution of sodium hydroxide); the system of aminoacetic acid–0.1 M HCl; acetate buffer; borate buffer. All the reagents used were of analytical grade.

Spectral grade dichlorethane (Merck) was used for extraction.

The abosrption of the extracts was read on a Specord UV VIS (K. Zeiss) spectrophotometer; pH of the solutions was measured with a pH meter (Radelkis 208).

The analysis of the solution obtained after the respective treatment of the activated carbon was done on a AES-ICP instrument (Spectro flame, Spectro Analytical Instruments), with quartz plasma-torch and a Cross-Flow pulverizer. Air light optics and a monochromatic system were used. The bismuth analytical signal was measured at $\lambda = 223.049$ nm. The optimal instrumental parameters were $E = 1$ kW; Neb = 2.4 bars;

Aux = 0.8 1 min^{-1}; Cool = 17 1 min^{-1}; peristaltic pump with a sample consumption of 1 ml min^{-1}.

The content of bismuth in the aqueous phase was determined by EAAS with Zeeman correction, with a Perkin-Elmer 5100-Zeeman spectrophotometer with AS-40. The determination was carried out directly: 20 ml of the solution was dosed with AS-40 in a graphite furnace equipped with a pyrolith platform of Lvov. Parameters of the analysis: a nullode Bi = 8 mA; wavelength = 223.0 nm; slit = 0.2; integration time = 3 s; non-selective absorption corrector = Zeeman.

The procedure for adsorption concentration of bismuth on activated carbon with the aid of sodium di-*n*-propyldithiophosphinate was as follows. A portion of the standard solution of bismuth (20–150 µg) was placed in a beaker of 300 ml. It was diluted up to 100 ml with buffer solution or water (pH 1–7). A reagent solution in a quantity relevant to the proportion Bi:L = 1:10 and 0.05g of activated carbon were consecutively added. The mixture was left to stand for 30 min, being stirred at regular intervals, and then filtered. The desorption of bismuth di-*n*-propyldithiophosphinate was carried out by treating the activated carbon with nitric acid (1:3) [2] and the analysis of the solution was done on a AES–ICP instrument. The content of bismuth in the filtrate was determined by EAAS or by extraction with 10 ml dichloroethane.

3. Results and discussion

As pointed out in the literature, the most appropriate element in studying adsorptioin processes is the one that shows amphoteric properties [10]. A selection of elements with these properties, allowing one to study the adsorption over a wide range of acidity led us to the study of bismuth. When a solution of bismuth and an aqueous solution of di-*n*-propyldithiophosphinate are mixed, a yellow precipitate soluble in organic solvents is obtained. In the electronic spectrum of a dichloroethane solution of the complex there are two clearly pronounced maxima, at 340 and 420 nm (Fig. 1). Kabanova et al. [11] studied the interaction between bismuth and sodium di-
Fig. 1. Absorbance spectrum of bismuth di-n-propyldithiophosphinate in dichloroethane.

ethyldithiophosphinate and found the conditions for extraction-spectrophotometric determination of this element. Sodium di-n-propyldithiophosphinate can be expected to have similar behaviour, because the length of its alkyl radical carbon chain is not much different from that of diethyldithiophosphinate. The optimal acidity for complexation to take place was experimentally determined to be pH 1–6. The buffer composition exerts a certain effect. The universal buffer was found to be appropriate. A ten-fold excess of reagent and 1 min extraction at a ratio of water phase to organic phase of 1:10 and 1:20 are needed. The bismuth determination limit established in this way was 1–20 μg ml^{-1}. The study of the possibility of extracting bismuth with sodium di-n-propyldithiophosphinate allows the control of its content in the aqueous phase after the adsorption. The distribution coefficient and extraction degree in

dichloroethane have been calculated (log $D = 2.3$; $R = 99.50$).

Depending on the acidity of the medium the ions of the elements were adsorbed on activated carbon to a different degree. In strongly acid medium the adsorption was negligible. For this reason, the adsorption of the element without addition of the reagent was studied before the adsorption of the complex of bismuth with sodium di-n-propyldithiophosphinate on activated carbon. The results showed that the process is strongly dependent on the composition of the aqueous phase. In the pH range 1–9, achieved with the buffers mentioned above, the degree of adsorption did not exceed 75%. When the acidity of the medium was adjusted with solutions of hydrochloric acid and ammonium hydroxide, the degree of adsorption was 80–90%. Besides the acidity of the medium the effect of the amount of bismuth and sodium di-n-propyldithiophosphinate as complexing agent were also studied (Table 1). The results obtained agree with those in the literature for Cu, Fe and Ni [12]. For quantitative evaluation of adsorption we have determined q [2] by the formula:

$$q = \frac{(C_0 - C_p) \cdot V}{m}$$

where C_0 is the total concentration of Bi in the water phase, C_p is the equilibrium concentration of Bi in the water phase after adsorption, V is the volume of the water phase and m is the mass of the activated carbon.

The above-mentioned procedure was also used in the study of the adsorption of bismuth on

Table 1
Adsorption of bismuth on activated carbon (pH = 1; $V = 300$ ml; $m = 0.05$ g, complexing agent = sodium di-n-propyldithiophosphinate)

Bi content in the solution analyzed (μg)	Content on activated carbon without complexing agent		Content on the activated carbon with complexing agent	
	Bi (μg)	$10^3 q$ (mmol g^{-1})	Bi (μg)	$10^3 q$ (mmol g^{-1})
100	80	7.8	100	9.6
200	120	11.4	200	19.2
300	134	12.6	300	28.8
400	150	14.4	400	38.4

activated carbon in the presence of the proposed organic reagent. In the literature there are two methods proposed. One of them requires the complex compound to be prepared first and then adsorbed on activated carbon. In the second, the activated carbon is modified with a complexing reagent before contact with the ions of the metal. We used the former method which ensures a greater excess of the reagent and a quantitative completion of the complexation process.

The adsorption of bismuth on activated carbon in the presence of sodium di-n-propyldithiophosphinate was studied at pH 1–9. Though the complexation with alkali dithiophosphinate takes place at pHs up to 7, the adsorption process was studied in the alkali region in order to find whether adsorption of bismuth hydroxide was possible. The results suggest that the quantitative extraction is achieved at a pH of the aqueous phase up to 7, accompanied by a significant effect of the buffer composition. Preference should be given to buffer systems free from organic compounds. The quantitative extraction of bismuth ions from the aqueous phase is possible at the milligram level too. An amount of 0.05 g of activated carbon was found to be sufficient for extraction of microgram levels of bismuth from an aqueous phase of up to 500 ml under the above-mentioned experimental conditions. The adsorption time, with occasional stirring, was 15–30 min. The ionic strength of the aqueous phase had an effect on the degree of extraction of the bismuth complex. The increase in the ionic strength leads to a decrease in the degree of extraction regardless

chloride, ammonium chloride, sodium sulphate and sodium nitrate.

Various methods for metal chelate desorption from activated carbon have been pointed out in the literature. Some of them do not involve destruction of the comlex adsorbed. Attempts to extract bismuth di-n-propyldithiophosphinate by treating activated carbon with an organic solvent which dissolves the complex well, such as CCl_4, $C_2H_4Cl_2$, and $CHCl_3$, did not give a good result. This shows that bismuth dithiophosphinate is adsorbed and not mechanically held on the activated carbon. Another method for metal chelate desorp-

tion from activated carbon involves a competitive complexation by adding a reagent to the activated carbon collector which forms more stable complexes than the respective chelates. The new complexes obtained are not adsorbed on activated carbon [13]. Such reagents are the metal complexonates with EDTA and DTPA. Usng a procedure proposed by the authors, the possibility of desorption of bismuth di-n-propyldithiophosphinate with a solution of EDTA was studied. The amount of bismuth after the desorption was determined by AES-ICP (Table 2). An appropriate method for desorption by treating the activated carbon with nitric acid was proposed [2,14–16]. Experiments for desorption of bismuth dithiophosphinate were carried out by this procedure (Table 3) [1]. The most appropriate reagent for this purpose was nitric acid at a concentration of 1:3.

The concentration of bismuth ions by the procedure proposed is also possible with an aqueous phase volume of 500ml.

The alkaline and alkali earth elements as well as the aluminium, zinc and tin compounds do not have an interfering effect. Cu, Ag and Hg do have an inter-

Liquid–liquid distribution of ion associates of hexachloroplatinate(IV) with quaternary ammonium counter ions

Koichi Yamamoto *, Shinichi Katoh

Department of Materials Science, Yonago National College of Technology 4448, Hikona-cho, Yonago-shi, Tottori 683, Japan

Abstract

The distribution behavior of ion associates of $PtCl_6^{2-}$ with quaternary ammonium cations (Q^+) between aqueous phase and two organic phases (chloroform and carbon tetrachloride) was examined, and the extraction constants ($\log K_{ex}$) were determined. A linear relationship was found between $\log K_{ex}$ and the total number of carbon atoms in Q^+; from the slope of the line, the contribution of a methylene group to $\log K_{ex}$ was calculated to be 0.6. The extractability with alkyltrimethylammonium cations was larger than that with symmetrical tetraalkylammonium cations. From the extraction constants obtained, an extraction method based on the ion association of $PtCl_6^{2-}$ with Q^+ can be used for the separation and determination of platinum at the 10^{-6} M level.

Keywords: Liquid–liquid distribution; Hexachloroplatinate(IV); Quaternary ammonium ion

1. Introduction

An extraction of platinum from an aqueous halide medium into an organic solvent has been frequently used for both the separation and spectrophotometric determination of platinum. Spectrophotometric methods for the determination of platinum by an extraction into nitrobenzene as an ion associate formed between a 1,10-phenanthroline–iron(II) chelate cation and a hexachloroplatinate(IV) anion [1], and by a dissolution of an ion associate of a platinum(IV)–chloro complex with

* Corresponding author.

Crystal Violet precipitated by flotation with benzene in ethanol [2] have been reported. Mirza [3] studied an extraction of platinum metals with tri-iso-octylamine from hydrochloric and hydrobromic acids, and methods were devised for a separation of gold from platinum and its determination and also for the simultaneous determination of palladium and platinum. Hara et al. [4] investigated a solvent extraction of gold and platinum by zephiramine (tetradecyldimethylbenzylammonium)–iodoaurate(III) or iodoplatinate(IV)–chloroform systems, which were used for a pretreatment in the simultaneous atomic absorption spectrometric determination of gold and plat-

inum. Several aspects of the extraction of a platinum(IV)-chloro complex by salts of trioctylamine and organic acids [5], alcohols [6] and tributylphosphate [7] from hydrochloric-sulphuric acid solutions, NTAB-182 from hydrochloric acid solution [8], a mixture of amines and organophosphoric acids [9], and high molecular weight amines [10] have also been reported.

In the present work, the authors studied the extraction of ion associates of hexachloroplatinate(IV) anion with various quaternary ammonium cations (Q^+) and proposed an extraction method for the separation and determination of platinum by using Q^+ as counter ions of hexachloroplatinate(IV).

2. Experimental

2.1. Apparatus

A Japan Spectroscopic (Uvidec-430) spectrophotometer was used for recording spectra and absorbance measurements in quartz cells of 10 mm light pathlength. An Iwaki (Model V-SX type KM) shaker was used for horizontal shaking of the 25 ml stoppered test-tubes for extraction. An Iwaki (Model V-DN type KM) shaker was used for vertical shaking of the 50 ml separatory funnel for extraction.

2.2. Reagents

A standard platinum(IV) solution (1.03×10^{-4} M) was prepared by diluting 4 ml of a 1000 ppm standard platinum(IV) solution (5.13×10^{-3} M hydrogen hexachloroplatinate(IV) in 1 N hydrochloric acid solution, Wako Pure Chem.) to 200 ml with 1 N hydrochloric acid solution.

Quaternary ammonium ion (Q^+) solutions were prepared from the salts listed in Table 1, which were dried under reduced pressure. Accurately weighed amounts of the dried salts were dissolved in distilled water to give stock standard solutions, which were diluted before use.

Commercially available chloroform was used without further purification, and was saturated with distilled water before use.

All of the reagents were of analytical-reagent grade and were used without further purification.

2.3. Standard procedure for stoichiometry measurement

Two milliliters of a 1.03×10^{-4} M platinum (IV) solution were transferred to a 25 ml stoppered test-tube; then 1 ml of a 3 N hydrochloric acid solution and an appropriate amount of aqueous quaternary ammonium salt solution were added. The solution was diluted to 5 ml with distilled water. This brought the ionic strength to 1.0. The aqueous solution was mechanically shaken with 5 ml of an extracting solvent for 40 min at 25°C. After phase separation, the absorbance of the aqueous phase was measured at 262 nm against distilled water as a reference; the concentration of platinum in the aqueous phase was then calculated from the molar absorptivity of the hexachloroplatinate(IV).

2.4. Recommended procedure for spectrophotometric determination of platinum

A 44 ml portion of a sample solution containing platinum up to 4.66×10^{-6} M and 1 N hydrochloric acid was transferred to a separating funnel (about 65 ml). To this 4 ml of a 1.5 N hydrochloric acid solution and 2 ml of 6×10^{-3} M tetraamylammonium chloride (TAA) solution were added. To this mixture, 5 ml of chloroform was added; the funnel was then shaken for 40 min. After phase separation, the absorbance of the organic phase was measured at 269 nm against chloroform.

3. Results and discussion

3.1. Absorption spectra

The absorption spectra of the hexachloroplatinate(IV) ion in aqueous solution are shown in Fig. 1. The maximum absorbance of the hexa-

chloroplatinate(IV) ion was at 262 nm, where the absorbance of the reagent blank was negligibly small. A calibration graph obtained for platinum was linear over the $0-4.1 \times 10^{-5}$ M range. The molar absorptivity for platinum was about 2.4×10^4 l mol^{-1} cm^{-1} at 262 nm.

3.2. Effect of conditions

5.13×10^{-3} M hydrogen hexachloroplatinate-(IV) stock solution (in 1 N hydrochloric acid solution) was diluted 50 times with distilled water, 0.5 M sulphuric acid and 1 N hydrochloric acid to prepare a 1.03×10^{-4} M standard platinum(IV) solution. In both distilled water and 0.5 M sulphuric acid, the absorbance at 262 nm in the aqueous solution gradually decreased as the time after preparation passed. In 1 N hydrochloric acid, the absorbance remaind constant. Therefore, 1 M chloride was used for the formation of the hexachloroplatinate(IV) ion.

3.3. Determination of extraction constants and some considerations of extractability of ion associates

In the aqueous phase, platinum(IV) reacts with chloride to form $PtCl_6^{2-}$. This complex anion distributes between the aqueous and organic phases:

$$PtCl_6^{2-} + 2Q^+ \rightleftharpoons ((Q^+)_2 \cdot PtCl_6^{2-})_{org} \qquad (1)$$
Fig. 1. Absorption spectra of the platinum(IV) chloro complex in water. Platinum(IV): (1) 4.1×10^{-5} M, (2) 0 M; chloride ion, 1 M; reference, distilled water.

and

$$K_{ex} = [(Q^+)_2 \cdot PtCl_6^{2-}]_{org}/[Q^+]^2[PtCl_6^{2-}] \qquad (2)$$

where K_{ex} is the extraction constant; the subscript "org" refers to the organic phase and the absence of a subscript indicates the aqueous phase. The distribution ratio of platinum between the aqueous and organic phases (D_{Pt}) is given by

$$D_{Pt} = \frac{[(Q^+)_2 \cdot PtCl_6^{2-}]_{org}}{[PtCl_6^{2-}]} \qquad (3)$$

Hence, the following equation can be derived from Eqs. (2) and (3):

$$D_{Pt} = K_{ex} \cdot [Q^+]^2 \qquad (4)$$

where

$$\log D_{Pt} = \log K_{ex} + 2 \log[Q^+] \qquad (5)$$

The side-reaction coefficient for the quaternary ammonium ion ($\alpha(Q^+(Cl^-))$) is given by

$$\alpha(Q^+(Cl^-)) = \frac{[Q^+]'}{[Q^+]} = \frac{[Q^+] + [Q^+ \cdot Cl^-]_{org}}{Q^+]}$$

$$= 1 + K_{ex}(Q^+ \cdot Cl^-) \cdot [Cl^-] \qquad (6)$$

where $[Q^+]'$ is the total concentration of the quaternary ammonium ion that is not bound in ion associates with hexachloroplatinate(IV), and $K_{ex}(Q^+ \cdot Cl^-)$ is the extraction constant of a quaternary ammonium ion with a chloride ion. $[Q^+]$ can be calculated by

$$[Q^+] = [Q^+]'/\alpha(Q^+(Cl^-)) \qquad (7)$$

In the extraction for hexachloroplatinate(IV), the distribution ratios of platinum at different concentrations of the quaternary ammonium ions were determined. The values of $\log D_{Pt}$ were plotted against $\log[Q^+]$. The results obtained for chloroform and carbon tetrachloride are shown in Figs. 2 and 3 respectively. The plots for all quaternary ammonium cations were linear with slopes equal to two, calculated by the least-squares method. This means that the extraction equilibrium shown in Eq. (1) holds and that the extracted species was $(Q^+)_2 \cdot PtCl_6^{2-}$. The extraction constants calculated from Eq. (5) are summarized in Table 2; the standard deviation is very small.
Fig. 2. Plots of $\log D_{Pt}$ vs. $\log[Q^+]$. Q^+: 1 (○) Zeph, 2 (△) STMA, 3 (□) CTMA, 4 (△) TDTMA, 5 (□) DDTMA, 6 (○) DTMA, 7 (□) OTMA, 8 (○) TAA, 9 (△) TBA; extracting solvent: chloroform.

3.4. Relationship between the extraction constants and the number of carbon atoms in the quaternary ammonium ion

The values of the extraction constants ($\log K_{ex}$) were plotted against the number of carbon atoms in the quaternary ammonium ion (N_c). The results obtained for chloroform and carbon tetrachloride extraction systems are shown in Figs. 4 and 5 respectively. For the same carbon number, the extractability ($\log K_{ex}$) with long-

Fig. 5. Relation between log K_{ex} and number of carbon atoms in quaternary ammonium ion. Alkyltrimethylammonium cations: (a) STMA, (b) CTMA, (c) TDTMA, (d) DDTMA, (e) DTMA; extracting solvent: carbon tetrachloride.

Fig. 4. Relation between log K_{ex} and number of carbon atoms in the quaternary ammonium ion. Alkyltrimethylammonium cations (●): (a) STMA, (b) CTMA, (c) TDTMA, (d) DDTMA, (e) DTMA, (f) OTMA; tetraalkylammonium cations (○): (g) TAA, (h) TBA; extracting solvent: chloroform.

chain alkyltrimethylammonium cations (group I) is larger than that with symmetrical tetraalkylammonium cations (group II) for the chloroform extraction system, and the difference in log K_{ex} values between these groups is about 3.9 for an identical carbon number. This indicates that the electrostatic attraction of the cations in group I for the anionic complex is larger than that of the cations in group II. In the log K_{ex}-N_c plot for the carbon tetrachloride extraction system, the points for the quaternary ammonium ions having more than 17 carbon atoms (group I-II) deviate from the straight line for those up to 17 (group I-I), which may be because the increment in spread of the hydrophobic alkyl chain of the cations in group I-II is smaller than that of the cations in group I-I. The slopes of all the lines in Figs. 4 and 5 were identical, and by dividing the slope by two, the contribution of a methylene group to the extraction constants (log K_{ex}) was found to be about 0.6 on average, in good agreement with the value previously reported [12-16].
Fig. 6. Absorption spectra of the ion associate of hexachloro-platinate(IV) with TAA in chloroform. Volumes of the aqueous and organic phases were 50 ml and 5 ml respectively; initial concentrations in aqueous phase of platinum(IV): (1) 4.1×10^{-6} M, (2) 0 M, TAA 2.4×10^{-4} M, chloride ion 1 M; reference. chloroform.

3.5. Separation and determination of platinum based on the formation of an ion associate of hexachloroplatinate(IV) with quaternary ammonium cations

For example, we consider the chloroform extraction of the ion associate of $PtCl_6^{2-}$ with TAA, in which the initial concentrations of platinum, TAA and chloride ion are 4.1×10^{-5} M, 2.4×10^{-3} M and 1 M respectively, and the volumes of the aqueous and organic phases are equal. For more than 90% of the platinum to be extracted into the organic phase, the logarithm of the extraction constant must be greater than 11.3, which can be calculated by using Eqs. (2), (6) and

(7). This extraction constant agrees closely with that given in Table 2. Experimentally platinum could be extracted almost quantitatively into chloroform under the experimental conditions described above. Fig. 6 shows the absorption spectra of the ion associate $[(TAA^+)_2 \cdot PtCl_6^{2-}]$ and of the reagent blank in chloroform obtained by the recommended procedure. This proposed method can be applied to the determination of trace amounts of platinum up to 4.1×10^{-6} M by measuring the absorbance at 269 nm. This extraction procedure can be used for the separation and determination of platinum.

Abstract

The complex formation between Mn(II) cations and N_3^- anions was studied in aqueous medium at 25°C and ionic strength 2.0 M ($NaClO_4$). Data of average ligand number, $\bar{n}$ (Bjerrum's function), were obtained from pH measurements on the $Mn(II)/N_3^-/HN_3$ system followed by integration to obtain Leden's function, $F_0(L)$. Graphical treatment of data and a matrix solution of simultaneous equations have given the following overall formation constants of mononuclear stepwise complexes: $\beta_1 = 4.15 \pm 0.02\ M^{-1}$, $\beta_2 = 6.61 \pm 0.04\ M^{-2}$, $\beta_3 = 3.33 \pm 0.02\ M^{-3}$, $\beta_4 = 0.63 \pm 0.01\ M^{-4}$. A linear plot of $\log K_n$ vs. $(n-1)$ shows no change in the configuration during complex formation. Slow spontaneous oxidation of solutions to Mn(III) occurs when the N_3^- concentration is greater than 1.0 M.

Keywords: Complex formation; Manganese; Azide

1. Introduction

Studies of azide complex formation with several metal ions, such as Co(II) [1], Co(III) [2], Cu(II) [3], Ni(II) [4], Fe(III) [5] and U(VI) [6], have been done by our research group in recent years, with special interest in determining the stability constants and analytical applications.

Some of our studies were concentrated on the autoxidation of Co(II) azide complexes induced by S(IV) in order to develop one alternative method for analytical determination of S(IV) of

environmental interest [7–13].

The complexes of Co(II) formed in aqueous solutions of N_3^-/HN_3 buffer were slowly oxidized to a mixture of complexes of Co(III) by dissolved oxygen, with a marked colour change from blue to brown–yellowish. It has been found by Senise [13] that S(IV), as SO_2, HSO_3^- or SO_3^{2-}, accelerates these oxidation processes significantly instead of hindering them, leading to a spot-test.

The synergistic effect of Mn(II) on sulfite autoxidation of metal ions was investigated for the $Co(II)/N_3^-$ and aquated Fe(II) systems [2]. The results indicate that Mn(II) has a significant catalytic effect, but that the synergistic effect actually

---

occurs in the presence of Co(III) and Fe(III) respectively. These metal ions, in the oxidation state (III), can rapidly oxidize sulfite to $SO_3^{\bullet-}$ radical, which in turn initiates a series of free radical propagation reactions in which sulfite is oxidized by the dissolved oxygen to mainly sulfate.

A thorough study of the mechanism of the autoxidation of Mn(II) and Co(II) azide complexes and Fe(II) in aqueous solutions was done by some of the authors [9–12].

The determination of the stability constants of Mn(II)/N_3^- complexes brings additional information about the distribution complex species, according to the azide concentration, and more contributions to the elucidation of the above synergistic effect of Mn(II).

2. Experimental

2.1. Reagents and standard solutions

All reagents were of AR or CP specification (Merck or Fluka Chemie A.G.).

Sodium azide solution was prepared directly from the salt. Standardization was carried out by adding a known volume of standard sulfuric acid, boiling to remove volatile hydrazoic acid (HN_3) and then back titrating with standard sodium hydroxide solution.

Sodium perchlorate solution, used for making up the ionic strength of working solutions, was standardized by taking a small volume of solution and then drying in an oven at 120 °C until constant weight.

Standard perchloric acid solution was used in the working solutions to displace HN_3 from the azide ions.

Manganese(II) perchlorate solution was prepared from the direct reaction of excess carbonate with 6 M perchloric acid for 2 days, with stirring at room temperature. After filtering, free perchloric acid was used to adjust the pH to 5.5, in order to avoid hydrolysis. Standardization was carried out by complexometric titration with EDTA [14].

2.2. Working solutions

Several series of working solutions were prepared by adding different volumes of 1.002 M $Mn(ClO_4)_2$ solution to 10.06 cm³ of several N_3^-/ HN_3 buffer solutions with $NaClO_4$ (ionic strength, I, 2.0 M). Five additions of Mn(II) solution changed its concentration in the final solution from 0.02 M to 0.1 M. The azide concentration in the working solution was in the range 0.025–1.8 M.

In order to keep such working solutions free from oxygen, with no volatile hydrazoic acid being lost, all standard solutions were previously bubbled with purified nitrogen before mixing.

2.3. Potentiometric measurements and data treatment

A Metrohm 654 pHMeter adapted to a glass electrode (Metrohm AG Herisau) combined with an Ag/AgCl reference electrode filled with 3 M NaCl was used in the pH measurements at $(25.0 \pm 0.1)°C$. To standardize the glass electrode, a 0.05 M potassium phthalate buffer solution (conditional pH = 3.795) was used, at the same ionic strength of the working solution (2.00 M $NaClO_4$), in order to measure hydrogen ion concentration instead of activity. This buffer had previously been calibrated from free strong acid (0.01 M) at the same ionic strength (held at 2.0 M with $NaClO_4$).

The change of pH measured from initial pH_1 to final pH_2 by adding manganese(II) to N_3^-/HN_3 buffer was followed potentiometrically with the calibrated glass electrode (see experimental data in Table 1).

QUICK BASIC programs were used to make the calculations on an IBM PC-AT desk computer.

3. Results and discussion

The Henderson–Hasselbalch equation for buffer systems and mass balances was applied to the present system, where N_3^- acts as both ligand for the metal cation and as a component of the buffer solution [15].

An initial conditional equilibrium was reached. for which measurement of PH_1 provided the equilibrium concentrations of $[N_3^-]_1$ and its acid $[HN_3]_1$. Subsequent addition of a volume of a metal cation solution resulted in a new conditional equilibrium for pH_2 and $[N_3^-]_2$ and $[HN_3]_2$ [1]. A conditional pK value of the N_3^-/HN_3 system, at ionic strength 2.00 M ($NaClO_4$) and

$25.0 \pm 0.1°C$, was determined for each pH experiment. The use of the pK value from each experiment proved to be a reliable procedure because it corrects any drift in junction potentials, small losses of volatile hydrazoic acid and eventual slope deviation of the glass electrode. The average pK of the hydrazoic acid at this strength was 4.530.

The average number of ligands, $\bar{n}$ (Bjerrun's function) [15], was obtained as described elsewhere [1,15].

Since the same curve of $\bar{n}$ vs. $[N_3^-]_2$ (Fig. 1) was obtained for four different manganese(II) concentrations, no significant polynuclear complexation was evident in the metal cation concentration range employed.

Table 1 shows the experimental data of pH and the calculated values of $\bar{n}$, free ligand concentrations and metal ion analytical concentration for each equilibrium condition. An appropriate computer program was used to obtain data of the Leden function, $F_0(L)$ [15], by integration of the curve of $\bar{n}$ vs. log $[N_3^-]_2$ from several consecutive small increments of ligand concentration [1].

The treatment of $F_0(L)$ data, to find the stability constants, was done by two different methods. The first was the familiar graphical procedure, extrapolating the subsidiary $F_n(L)$ function to zero ligand concentration [1,15]. The graphical treatment has clearly shown the existence of four stepwise complexes. Computer methods of calculation, based on properly weighted simultaneous equations, were also used for the final results [16].

Both solutions gave very similar values. However, the best set of constants came from matrix calculations [16], by solving the following system of weighted simultaneous equations:
Fig. 1. Formation curves for (■) the Mn(II)/N_3^- system at several metal concentrations (see Table 1) and (▲) the Co(II)/N_3^- [1] system.
Fig. 2. Distribution diagram of the species in the Mn(II)/N_3^- system calculated from the equilibrium constants.

$$6.838 \times 10^3 = (8.078 \times 10^2 \times \beta_1) + (3.667$$
$$\times 10^2 \times \beta_2) + (2.681 \times 10^2$$
$$\times \beta_3) + (2.707 \times 10^2 \times \beta_4)$$
$$4.404 \times 10^3 = (3.667 \times 10^2 \times \beta_1) + (2.681$$
$$\times 10^2 \times \beta_2) + (2.707 \times 10^2$$
$$\times \beta_3) + (3.348 \times 10^2 \times \beta_4)$$
$$4.307 \times 10^3 = (2.681 \times 10^2 \times \beta_1) + (2.707$$
$$\times \beta_2) + (3.348 \times 10^2 \times \beta_3)$$
$$+ (4.58 \times 10^2 \times \beta_4)$$
$$5.320 \times 10^3 = (2.707 \times 10^2 \times \beta_1) + (3.348$$
$$\times 10^2 \times \beta_2) + (4.658 \times 10^2$$
$$\times \beta_3) + (6.942 \times 10^2 \times \beta_4)$$

The solution for a 95% confidence level in the values is $\beta_1 = 4.15 \pm 0.02$ M^{-1}, $\beta_2 = 6.61 \pm 0.04$ M^{-2}, $\beta_3 = 3.33 \pm 0.02$ M^{-3}, $\beta_4 = 0.63 \pm 0.01$ M^{-4}. The distribution diagram is represented in Fig. 2.

The β_1 value is in good agreement with the literature data (Table 2). The complexes are weak and follow the Irving–Williams rule:

$$Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$$
The coordination of one or two ligands is quite easy as can be inferred from the values of the constants. This behaviour suggests that a larger entropic factor favours the initial steps. In fact the formation of the less hydrated neutral species from highly hydrated ions does affect the reaction. On this basis, the formation of the third species

a Present work.

b Results are also given for the polynuclear complexes.

should be unfavoured, consistent with the low β_3 value.

The linear relationship of $\log K_n$ vs. $(n - 1)$, Fig. 3, means that the magnitude of the free energy involved in complex formation linearly decreases for each ligand introduced. On this basis, no configuration change has been found to occur, as could happen with other systems
Fig. 3. Log K_n as a function of $(n - 1)$ for $Mn(II)/N_3^-$ complexes: $K_1 = 4.2$ M^{-1}; $K_2 = 1.6$ M^{-1}; $K_3 = 0.5$ M^{-1}; $K_4 = 0.18$ M^{-1}.

such as $Co(II)/SCN^-$, where a change from octahedral to tetrahedral geometry is observed [17].

All the experiments were carried out in the absence of oxygen. At ligand concentrations higher than 1.0 M conditions exist for a slow spontaneous autoxidation of manganese(II) to manganese(III) complexes, with remarkable spectral changes. The manganese(III) complexes have a maximum absorbance peak at 428 nm [9,10].

As was pointed out previously a synergistic effect of the manganese ions [7,8,12] on the induced autoxidation of metal ions by S(IV) occurrs and, it is important to compare the formation curves of complexes of Co(II) [1] and Mn(II) azide complexes. It was found that the 0.5 M azide concentration is the best experimental condition for analytical purposes for determination of S(IV), based on the cobalt(II)-induced autoxidation. At this azide concentration the average number of ligands is 2 and 1.3 for Co(II) and Mn(II) complexes respectively (Fig. 1).

Differential pulse anodic stripping voltammetric determination of ziram (a dithiocarbamate fungicide)

L. Mathew, M.L.P. Reddy, T.P. Rao *, C.S.P. Iyer, A.D. Damodaran

Regional Research Laboratory (CSIR), Trivandrum 695 019, India

Received 30 May 1995; revised 20 July 1995; accepted 7 August 1995

Abstract

A d.c. polarographic technique has been used previously for the determination of the pesticide, ziram, in aqueous samples. this paper reports differential pulse anodic stripping voltammetric determination of ziram zinc in rice samples using a static mercury drop electrode. The procedure developed distinguishes inorganic zinc and ziram zinc in sodium acetate–sodium chloride media. The procedure developed is suitable for the determination of concentrations as low as 10 ppb of ziram with a precision of 2.1% for five successive determinations of 150 ppb of ziram.

Keywords: Ziram; Zinc: Anodic stripping voltammetry

1. Introduction

Ziram, or cuman L, is the common name for zinc dimethyl-dithiocarbamate and is used as an agricultural fungicide because of its low phytotoxicity, and as a vulcanization accelerator and antioxidant in the rubber industry. Ziram is relatively non-toxic to plants and is particularly useful in controlling diseases of vegetable crops such as anthracnose of tomatoes and cucurbits and early blight of tomatoes and potatoes. Ziram causes irritation to the mucous membrane in the dust or powder form [1].

Common methods of determination of ziram are spectrophotometry [2–7], head space CG [8]

and HPLC [9]. Electrochemical techniques have not been widely used. One method [10] reported for zineb (a related dithiocarbamate fungicide) is based on the d.c. polarographic studies at −0.18 V vs. SCE. Our studies on differential pulse anodic stripping voltammetry (DPASV) determination of ziram revealed that inorganic zinc and ziram zinc could be differentiated as they give well-resolved peaks at −1.18 and −1.08 V vs. the Ag/AgCl electrode in sodium acetate–NaCl media. Based on this, a simple and sensitive DPASV procedure is described for the determination of ziram. The method is free from interference due to other dithiocarbamate pesticides and can be used for the determination of concentrations as low as 10 ppb of ziram in rice samples.

2. Experimental

2.1. Apparatus

Stripping voltammograms were recorded with a Princeton Applied Research Model 174 with Model 303 static mercury drop electrode (SMDE). Deaeration was done with purified nitrogen. The reference electrode was Ag/AgCl with an auxillary Pt electrode. The recordings were made on an Omniscribe XY/T recorder.

2.2. Reagents

Ziram stock solution (Hindustan Ciba-Geigy Ltd.; 10^{-3} M) was prepared by dissolving 0.0762 g ziram in hot 0.01 N HCl and making up with water to 250 ml. Sodium acetate (1.0 M) and sodium chloride (1.0 M) were prepared in distilled water.

2.3. Procedure

Transfer a suitable aliquot of sample solution containing 0.1–6 µg ziram (up to 8 ml) into a 10 ml calibrated flask. Add 1 ml of sodium acetate and 1 ml of sodium chloride, dilute to volume with water, transfer the solution into the electrochemical cell and place the SMDE in it. After deaeration, deposit for 4 min at −1.4 V vs. Ag/AgCl with stirring, switch off the stirrer, allow 30 s for the turbulence to cease and anodically scan the potential from −1.4 to −0.8 V with a scan rate of 2 mV s^{-1} and a pulse amplitude of 25 mV. Construct a calibration graph for various concentrations of ziram by plotting peak current vs. concentration of ziram.

2.4. Analysis of rice samples

Rice samples (100 g) were sprayed with known amounts of zinc and ziram and left for 2–4 h. The extracts were prepared by extraction of a crushed sample with 100 ml of acetone. The extract was evaporated to dryness. The residue was dissolved in 5 ml of 0.01 M HCl and transferred to a 50 ml volumetric flask.

3. Results and discussion

Preliminary studies were carried out to determine ziram by following the DPASV stripping peak of zinc. These studies revealed that ziram zinc gives a stripping peak at −1.08 V after deposition at −1.4 V for 4 min (curve B, Fig. 1). In contrast, for inorganic zinc the stripping peak occurs at −1.18 V under identical conditions (curve A, Fig. 1). This indicates that DPASV studies can distinguish ziram zinc and inorganic zinc in sodium acetate–NaCl medium. This shift in the E_p value of zinc in ziram is possibly due to the formation of a complex. Detailed optimization studies for the determination of ziram were conducted and the results obtained are described below.

3.1. Effect of supporting electrolyte

The determination of 5×10^{-7} M ziram using the SMDe with deposition for 4 min at −1.4 V was studied in different supporting electrolytes. The results are shown in Table 1, from which it is clear that the acetate–chloride medium gives the maximum stripping current signal compared to acetate or chloroacetate or NaCl. Furthermore, the stripping peaks of ziram zinc and inorganic zinc are resolved in NaCl or acetate–chloride but
Fig. 1. Differential pulse anodic stripping voltammograms recorded for 5×10^{-7} M inorganic zinc (curve A) and ziram zinc (curve B) after deposition at −1.4 V vs. Ag/AgCl for 4 min (0.1 M sodium acetate + 0.1 M sodium chloride, scan rate 2 mV s^{-1}).

Table 1
Stripping current obtained for ziram in various supporting electrolytes

(Ziram concn. = 5 × 10^{-7} M, t_d = 4 min, E_d = −1.4 V vs. Ag/AgCl, scan rate = 2 mV s^{-1}, pulse amplitude = 25 mV)

Supporting electrolyte	I_p (μA)
HCl (0.1 M)	4.2
Chloracetic acid (0.1 M)	34.0
Ammonium acetate (0.1 M)	37.8
Sodium chloride (0.1 M)	39.6
Sodium acetate (0.1 M)	41.6
Sodium acetate (0.1 M) + NaCl (0.1 M)	55.0

not in acetate solutions. An acetate–sodium chloride medium (pH 5) was chosen for further studies.

3.2. Variation of deposition potential

In order to ascertain the optimum deposition potential (E_d) the cathodic limit of the deposition potential was varied in the range −1.0 to −1.5 V vs. Ag/AgCl in steps of 0.1 V with deposition for 4 min at each deposition potential, followed by a DPASV scan rate of 2 mV s^{-1} and a modulation amplitude of 24 mV. The magnitude of the stripping signal attains a maximum at a deposition potential of −1.3 V vs. Ag/AgCl and remains unaltered on further increase. −1.4 V was chosen as the deposition potential in subsequent studies.

3.3. Variation of deposition time

The effect of deposition time (30–480 s) on the magnitude of the stripping signal was studied. The stripping signal varied linearly with the deposition time and a deposition time of 240 s was chosen to offer reasonable sensitivity and a reasonable number of samples that can be determined in a given time.

3.4. Variation of scan rate

The effect of scan rate in the range 0.1–100 mV s^{-1} was studied during DPASV determination of ziram. At 2 mV s^{-1} the sensitivity and resolution of the ziram zinc and inorganic zinc were found to be optimum. The stripping signal

was found to be the same for successive determinations.

3.5. Variation of modulation amplitude

The modulation amplitude was varied from 5 to 50 mV during DPASV determination of ziram. At 25 mV the resolution of ziram zinc and inorganic zinc was optimum and reasonably sensitive.

3.6. Effect of other interferents

The influence of other coexisting interferents on DPASV determination of ziram was investigated. Ten-fold amounts of Thiram, Mn^{2+}, Fe^{3+}, Pb^{2+}, Cd^{2+}, Ni^{2+} and sodium diethyldithiocarbamate did not interfere in the DPASV determination of ziram.

3.7. Sensitivity and precision

The DPASV signal was found to be linear in the range 10–600 ppb of ziram at a deposition potential of −1.4 V vs. Ag/AgCl for 4 min with a scan rate of 2 mV s^{-1}. The coefficient of variation of 150 ppb of ziram was 2.1% for five successive determinations.

3.8. Application of the method to rice samples

Suitable aliquots were analysed according to the procedure described in the Experimental. The results obtained are shown in Table 2. The recoveries on addition of known amounts of ziram and inorganic zinc to the rice samples are also given in Table 2. Rice samples were spiked with known amounts of ziram and inorganic zinc prior to

Table 2
Analysis of rice samples (100 g)

Amount of ziram added (ng)	Amount of zinc added (ng)	Amount of ziram found (ng)	Amount of zinc found (ng)
100	50	98.0	49.5
200	20	199.0	19.5
400	40	395.0	38.0

extraction with acetone. A blank was also run to check whether there were any interferences present at the same current signal. The recoveries were found to be in the range 95–99%. From these results, it is evident that the developed DPASV procedure can be reliably used for the determination of zinc in rice samples.

4. Conclusion

In general, the analysis of ziram by spectrophotometry is based on the determination of zinc. These methods therefore cannot distinguish from the zinc naturally present in rice or soil samples. Conventional spectrophotometric methods are not adequately sensitive. Head space GC and HPLC methods are used only for the determination of ziram. In contrast, by using the present method, it is possible to determine inorganic and ziram zinc simultaneously in rice samples. The present procedure is free from the interference of other dithiocarbamate fungicides.

Determination of traces of chromium in cocaine and heroin by flameless atomic absorption spectrometry

Pilar Bermejo-Barrera*, Antonio Moreda-Piñeiro, Jorge Moreda-Piñeiro, Adela Bermejo-Barrera

Department of Analytical Chemistry, Nutrition and Bromatology, Faculty of Chemistry, University of Santiago de Compostela, 15706-Santiago de Compostela (A Coruña), Spain

Abstract

A method for the determination of total chromium in cocaine and heroin by flameless atomic absorption spectrometry is presented. Cocaine samples were dissolved in 2 ml of HNO_3 35.0% (v/v) and diluted to 10 ml with ultrapure water; heroin samples were dissolved in ultrapure water, adding 0.4 ml of HNO_3 35.0% (v/v) to dissolve inert species, and also diluted to 10 ml. $Mg(NO_3)_2$ and HNO_3, as chemical modifiers, were compared in terms of sensitivity, precision and accuracy, a lower detection limit being obtained for the use of $Mg(NO_3)_2$, 5.77 μg kg^{-1} (7.23 μg kg^{-1} for HNO_3). Within-batch precision was found to be 6.19% and 1.48% for drug solution spiked with 0 and 10 μg l^{-1} of Cr^{3+}, respectively, when using $Mg(NO_3)_2$, and 7.45 and 1.19% for the same respective concentration levels when using HNO_3. Similar results on analytical recovery were obtained for both $Mg(NO_3)_2$ and HNO_3. $Mg(NO_3)_2$ was selected as the more adequate of the two chemical modifiers. A study of the introduction of a cooling-down step of 50°C was carried out and compared in terms of sensitivity to the programme without a cooling-down step, but no advantage was observed. Studies on the variation in precision and analytical recovery with the amount of sample, and interferent effects of different species on chromium determination were developed. Finally, chromium concentrations obtained in cocaine samples varied between 0.02 and 0.14 mg kg^{-1}, the levels in the heroin samples being in the 0.05-0.59 mg kg^{-1} range.

Keywords: Chromium; Cocaine; Heroin; Chemical modifiers; Magnesium nitrate modifier; Flameless absorption spectrometry

1. Introduction

The remarkable increase in the improper use of cocaine and heroin, two of the more dangerous

narcotics, has led to the imposition by the International Community of a control on the trade and utilization of these drugs. Therefore, it is very important to determine whether a confiscated drug comes from a certain geographical area. In this way, it is possible to discover its trading routes. Such studies are usually based on organic

---

*Corresponding author.

compounds present in drugs, and thus extensive information is available on the organic constituents in cocaine and heroin. However, knowledge about the inorganic constituents of these substances is very poor. In this sense, only few data have been found in the literature on metallic species [1], chromium being one of the metals whose presence has been reported. According to the chromium concentration found [1], it can be concluded that it is a trace constituent in cocaine, being present in levels between 0.2 and 1.6 mg kg^{-1}. The concentration interval reported for heroin [1] is 0.2–140 mg kg^{-1}. The chromium concentration in a great number of samples cannot be determined easily by inductively coupled plasma-atomic emission spectrometry, which is the technique employed by Violante et al. [1] in their studies, because it is lower than the detection limit of the technique.

Flameless atomic absorption spectrometry (FAAS) has been recognized as one of the best techniques for determining metal content, chromium being one of the metallic species requiring very sensitive detection [2].

As there is no literature on the determination of chromium in samples such as cocaine and heroin, in order to select the most adequate chemical modifier, a bibliographic search was carried out on the determination of chromium in biological and environmental materials and waters [3–28]. It should be mentioned that as a consequence of the refractory behaviour of chromium [2,29], it has been proposed not to add a chemical modifier [3–5]. However, it is evident that the low charring temperatures obtained in the absence of a matrix modifier do not offer satisfactory matrix volatilization when the samples contain complex matrices; thus, the addition of a chemical modifier appears to be necessary. The use of nitric acid [6–8] as a chemical modifier was therefore proposed, charring occurring at 1300°C. The addition of Na$_2$WO$_4$, in solution [7–9] or the use of W-coated graphite tubes [10,11], has also been reported; the former was of more advantage, owing to the large difference in charring temperatures reported, i.e. 1600°C for addition in solution and 900°C for the use of coated graphite tubes. The use of graphite tubes coated with Zr [9], Ta

[11,12] and La [13,14] has also been reported. Vanadium and molybdenum [15] have been proposed for chromium determination, achieving a charring temperature of 1400°C. Finally, NH$_3$ [16] and ascorbic acid [17] have also been used as chemical modifiers for chromium.

Magnesium nitrate alone [7,9,18–24], or in conjuction with palladium [25] or calcium [26,27], appears to be the most adequate chemical modifier for chromium, owing to the higher charring temperatures reported. In this sense, palladium has also been proposed as an adequate chemical modifier [14,28]. In addition, these species present the advantage, in comparison with the other chemical modifiers cited, that their content is not frequently determined by FAAS; hence, their use in large amounts, mg l^{-1}, as chemical modifiers does not lead to contamination of the graphite furnace.

In this paper, the use of nitric acid and magnesium nitrate as chemical modifiers for chromium determination is compared, investigating also palladium and the mixture palladium–magnesium nitrate proposed by Welz et al. [30]. Finally, a method for chromium determination in cocaine and heroin was developed and applied to different samples.

2. Experimental

2.1. Apparatus

AAS measurements were performed with a Perkin-Elmer model 1100B atomic absorption spectrometer equipped with an HGA 700 graphite furnace, an AS-70 autosampler and a deuterium arc background corrector. A Cr hollow cathode lamp (Perkin-Elmer) operated at 25 mA, which provided a 357.9 nm resonance line, was used. The spectral bandwidth was 0.7 nm. Pyrolytically graphite-coated graphite tubes and L'vov graphite platforms were used throughout.

2.2. Reagents

All the solutions were prepared from analytical-reagent grade chemicals using ultrapure water,

resistivity 18 MΩ cm^{-1}, which was obtained by means of a Milli-Q (Millipore, USA) water purification system.

Nitric acid stock standard solution, 35.0% (v/v), was prepared from nitric acid Aristar, 69.0–70.5% (v/v) (BDH Chemicals, Poole, UK) with a maximum chromium content of 0.05 mg l^{-1}.

Chromium nitrate stock standard solution, 1.000 g l^{-1}, was obtained from Merck (Darmstadt, Germany).

Magnesium nitrate stock standard solution, 2.000 g l^{-1}, was prepared by dissolving 2 g of magnesium nitrate (Analar, BDH Chemicals) in 1 l of ultrapure water.

Palladium stock standard solution, 3.000 g l^{-1}, was prepared according to Welz et al. [31] by dissolving 300 mg of palladium (99.999%, Aldrich, Milwaukee, WI, USA) in 1 ml of concentrated nitric acid and diluting to 100 ml with ultrapure water. If the dissolution was incomplete, 10 μl of hydrochloric acid (Aristar, 35.0% (v/v), BDH Chemicals, with a maximum chromium content of 0.005 mg l^{-1}) was added to the cold nitric acid and heated to gentle boiling in order to volatilize the excess chloride.

2.3. Procedure

Cocaine samples, 0.5 g, were dissolved in 2 ml of nitric acid 35.0% (v/v), diluting to 10 ml with ultrapure water. For heroin samples, 0.25 g of sample was dissolved in ultrapure water, and 0.4 ml of nitric acid 35.0% (v/v) was added to dissolve any remaining undissolved inert substances. The solutions were then diluted to 10 ml with ultrapure water. All samples were kept in polyethylene vials at 4°C.

0.5 or 0.25 ml of cocaine and heroin solution, respectively, was transferred to an autosampler cup, adding an adequate volume of magnesium nitrate to obtain a concentration of 15 mg l^{-1} after dilution to 1 ml. Calibration was performed over the 0–10 μg l^{-1} range, injecting 20 μl into the atomizer, and running the sequential dry–charring–atomization–cleaning programme of the graphite furnace shown in Table 1.

3. Results and discussion

3.1. Comparative study of palladium, magnesium nitrate, palladium–magnesium nitrate and nitric acid as chemical modifiers

A comparative study on the use of palladium, magnesium nitrate, palladium–magnesium nitrate and nitric acid as chemical modifiers for the determination of chromium in cocaine and heroin was developed. Charring curves corresponding to each chemical modifier were obtained for a cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+}, for a heroin sample solution and for an aqueous standard solution of 15 μg l^{-1} of Cr^{3+}, Figs. 1(a), 1(b) and 1(c), respectively. The atomization temperature used was 2500 °C (Table 1) and the concentration of the chemical modifier in these experiments was 10 mg l^{-1} of palladium and magnesium nitrate, and 3.5% (v/v) of nitric acid, i.e. the concentration of nitric acid obtained after dissolution and dilution of the cocaine in the autosampler cups, according to Section 2.3. As can be seen in Figs. 1(a)–1(c), the optimum charring temperatures ranged between 1500 and 1700°C for the different chemical modifiers and solutions. A lower charring temperature, 1500°C, was found for heroin solutions than for cocaine and aqueous standard solutions, 1600 °C, when using palladium–magnesium nitrate. Therefore,

Table 1
Graphite furnace temperature programmes and spectrometer operating conditions[a]. Values in brackets correspond to the use of nitric acid as a chemical modifier

Stage	Temperature (°C)	Ramp (s)	Hold (s)	Ar flow (ml min^{-1})
Drying	150	15	15	300
Charring	1600	10	15 (20)	300
Atomization	2500	0	4	0 read
Cleaning	2600	2	3	300

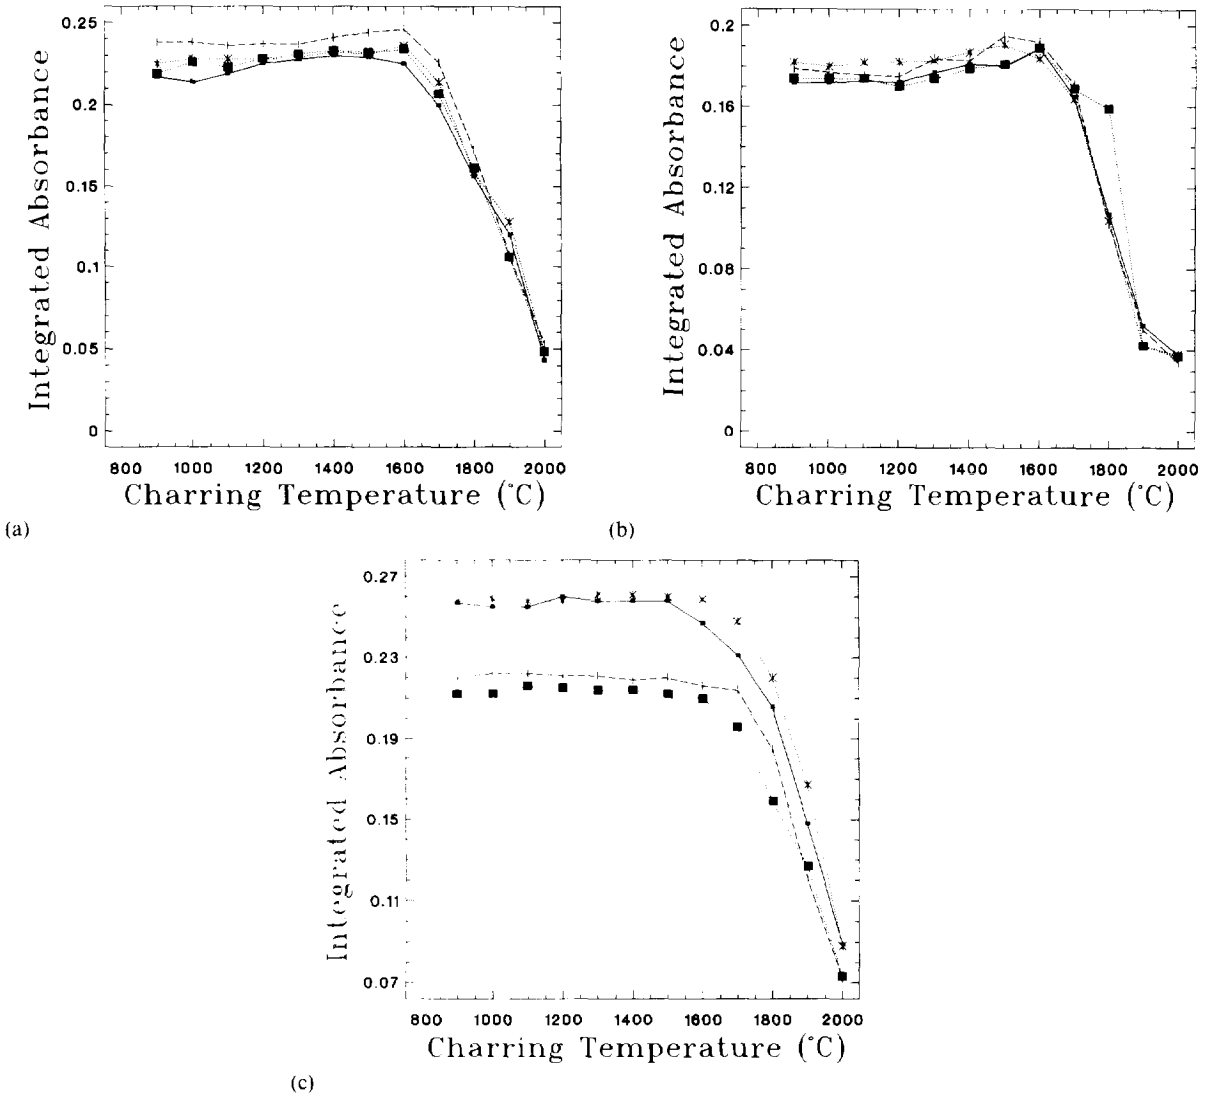
[a]Cr hollow cathode lamp operating at 25 mA; wavelength 357.9 nm; spectral bandwidth 0.7 nm; integration time 4s; peak-area measurements; injection volume 20 μl; pyrolytic graphite tubes and L'vov platforms.


Fig. 1. Charring curves corresponding to (a) cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+}, (b) heroin sample solution and (c) aqueous standard solution of 15 μg l^{-1} of Cr^{3+}, obtained for 10 mg l^{-1} of palladium (■), 10 mg l^{-1} of palladium and magnesium nitrate (*), 10 mg l^{-1} of magnesium nitrate (|) and 3.5% (v/v) of nitric acid (■).

for the use of this chemical modifier, an optimum charring temperature of 1500°C was selected. Similarly, the charring temperature observed for the aqueous standard of Cr^{3+}, 1500 °C, was selected as optimum for palladium. Finally, an optimum charring temperature of 1600°C was chosen when using magnesium nitrate and nitric acid.

Because chromium levels are lower for cocaine than for heroin samples, and hence a greater amount of cocaine is required to prepare the solutions, the following studies were performed on cocaine solutions, considering the results obtained for cocaine solutions are applicable to heroin sample solutions owing to their greater dilution.

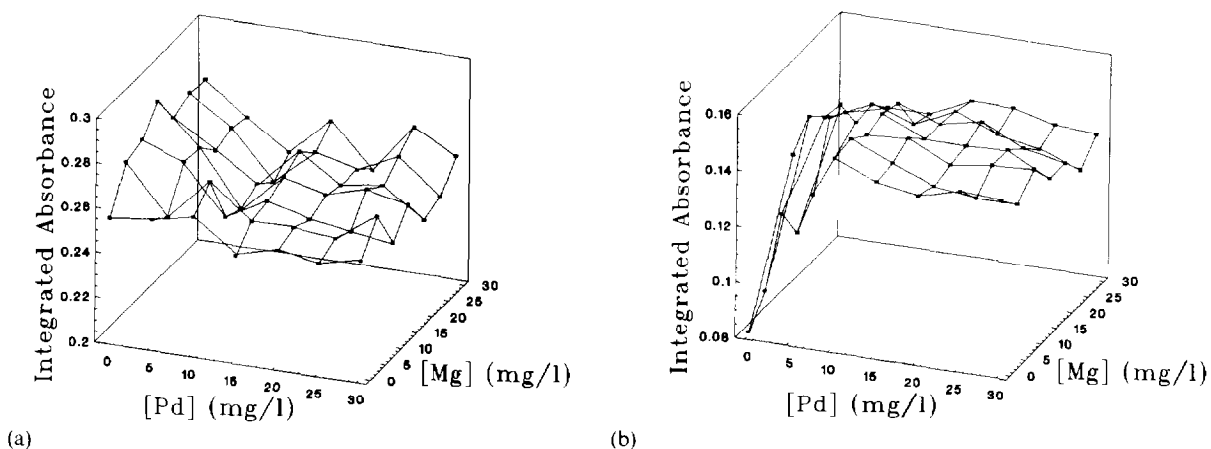
(a)   (b)


Fig. 2. Dependence of the chromium absorbance signal on the combined effects of various amounts of palladium and magnesium nitrate added to (a) cocaine sample solution spiked with 10 $\mu g\ l^{-1}$ of Cr^{3+} and (b) aqueous standard solution of 15 $\mu g\ l^{-1}$ of Cr^{3+}.

3.2. Optimization of the amount of chemical modifier

In order to investigate the use of magnesium nitrate, palladium–magnesium nitrate and palladium as chemical modifiers, and to determine their optimum amounts, a study involving different combinations of palladium and magnesium was performed. The charring temperature used was the optimum found for palladium–magnesium nitrate, 1500 °C, and the atomization temperature was 2500 °C. These experiments were carried out on cocaine sample solutions spiked with 10 $\mu g\ l^{-1}$ of Cr^{3+}, Fig. 2(a), and Cr^{3+} aqueous standard solutions of 15 $\mu g\ l^{-1}$, Fig. 2(b). The addition of palladium does not have any influence, as shown in Fig. 2(a). However, chromium absorbance values increase slightly, in the absence of palladium, until a concentration of 15 mg l^{-1} of magnesium nitrate is reached. These facts can also be observed in Figs. 3 and 4, where different peak schemes, corresponding to 0 mg l^{-1} of palladium and various amounts of magnesium, and 15 mg l^{-1} of magnesium and different amounts of palladium, respectively, are represented. In Fig. 2(b), which shows the results obtained for aqueous standards of Cr^{3+}, it can be seen that the addition of palladium increases the chromium absorbance signal. However, it should

be mentioned that the higher chromium absorbance signals correspond to combinations between $Mg(NO_3)_2$ and Pd, where the amount of magnesium nitrate is greater than that of Pd. Therefore, the highest chromium absorbance is obtained for concentrations of 10 and 15 mg l^{-1} for palladium and magnesium nitrate, respectively. Because the addition of palladium to cocaine sample solutions does not offer a significant increase in chromium absorbance, we select magnesium alone, at a concentration of 15 mg l^{-1}, as adequate for stabilizing chromium.

The amount of nitric acid was optimized in the same way, increasing the concentration up to 10% (v/v) for aqueous standard solutions of 15 $\mu g\ l^{-1}$
Fig. 3. Effect of 0 mg l^{-1} of palladium and different amounts of magnesium nitrate on the peak scheme corresponding to a cocaine sample solution spiked with 10 $\mu g\ l^{-1}$ of Cr^{3+}: (A) 0 mg l^{-1} (0.254 A.s.); (B) 5 mg l^{-1} (0.272 A.s.); (C) 15 mg l^{-1} (0.285 A.s.); (D) 25 mg l^{-1} (0.272 A.s.).
Fig. 4. Effect of 15 mg l^{-1} of magnesium nitrate and different amounts of palladium on the peak scheme corresponding to a cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+}: (A) 0 mg l^{-1} (0.285 A.s.); (B) 5 mg l^{-1} (0.267 A.s.); (C) 10 mg l^{-1} (0.243 A.s.); (D) 20 mg l^{-1} (0.246 A.s.).

of Cr^{3+} and a cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+}. Chromium absorbance was not statistically varied in the range studied and no variation in the peak scheme was found with larger amounts of nitric acid for both cocaine and aqueous solutions. Therefore, because an increase in the concentration of nitric acid results in faster damage of graphite tubes, we selected an optimum concentration of nitric acid of 3.5% (v/v), i.e. the concentration obtained after dissolution and dilution of cocaine samples in the autosampler cups (Section 2.3).

3.3. Optimization of the graphite furnace temperature programmes

Although chromium absorbance is stronger when magnesium nitrate is used instead of nitric acid, a temperature programme for nitric acid has also been developed and compared in terms of sensitivity, precision and accuracy to that for magnesium nitrate. The use of nitric acid as a chemical modifier is simpler than the use of magnesium nitrate because the optimum concentration of nitric acid, 3.5% (v/v), is that obtained after dissolution and dilution of cocaine in the autosampler cups; thus, it is only necessary to dilute the cocaine samples, without the addition of other species.

As mentioned previously, in the cases of nitric acid and magnesium nitrate a charring temperature of 1600°C was found to be optimal. Optimum values of the ramp and hold times for the charring step, corresponding to the use of magnesium nitrate and nitric acid, are shown in Table 1.

In order optimize the atomization temperatures for each chemical modifier, a range of temperatures between 1800 and 2600°C was studied for a cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+} and an aqueous solution of 15 μg l^{-1} of Cr^{3+}; these were the optimum temperatures for each chemical modifier and solution shown in Table 2.

Optimum drying conditions, temperatures and times, for each chemical modifier, were determinated by observing the sample in the graphite tube. In order to provide smooth evaporation of the solvent with no sputtering of the sample, an optimum temperature of 150°C with ramp and hold times of 15 s was achieved for both chemical modifiers.

3.4. Linear range, and calibration and standard addition graphs

The linear range was established for the use of magnesium nitrate and nitric acid, being 0.15-15 and 0.18-15 μg l^{-1} of Cr^{3+}, respectively. In order to determine the matrix effects for both methods, the standard addition method was applied over the same range of concentrations. The equations obtained for the use of magnesium nitrate were

calibration graph:

$$Q_A = 0.008 + 0.017[Cr^{3+}] \quad r = 0.999$$

standard addition graph:

$$Q_A = 0.049 + 0.020[Cr^{3+}] \quad r = 0.999$$

Table 2
Optimum atomization temperatures corresponding to different chemical modifiers

Chemical modifier	Atomization temperature (°C)	
	Cocaine sample solution	Aqueous Cr standard
Palladium	2600	2600
Palladium-magnesium nitrate	2600	2600
Magnesium nitrate	2500	2600
Nitric acid	2500	2600

Table 3
Analytical recovery ($n = 11$) corresponding to the use of magnesium nitrate and nitric acid as chemical modifiers

Cr^{3+} concentration added (μg l^{-1})	$Mg(NO_3)_2$			HNO_3		
	Cr^{3+} concentration found (μg l^{-1})	Analytical recovery (%)	RSD (%)	Cr^{3+} concentration found (μg l^{-1})	Analytical recovery (%)	RSD (%)
5.0	4.87 ± 0.07	96.4 ± 1.4	2.3	5.23 ± 0.09	104.5 ± 2.0	2.8
7.5	7.32 ± 0.09	97.6 ± 1.2	1.8	7.53 ± 0.05	100.4 ± 0.7	1.0
10.0	10.3 ± 1.2	103.5 ± 1.2	1.7	9.88 ± 0.09	98.8 ± 0.9	1.4

and for the use of nitric acid were

calibration graph:

$$Q_A = 0.011 + 0.017[Cr^{3+}] \quad r = 0.997$$

standard addition graph:

$$Q_A = 0.041 + 0.014[Cr^{3+}] \quad r = 0.999$$

where Q_A is the integrated absorbance and $[Cr^{3+}]$ is in units of μg l^{-1}.

The F-test [32] was applied to comparison of the slopes in each graph and for each chemical modifier; in both cases, the slopes of the calibration and standard addition graphs were statistically the same, and thus there are no matrix effects in the determination of chromium when using magnesium nitrate or nitric acid. Aqueous calibration was found to be a real possibility for developing the analysis for the use of both chemical modifiers.

3.5. Sensitivity

The sensitivity of magnesium nitrate and nitric acid as chemical modifiers was studied for the two programmes (Table 1). The limit of detection (LOD), limit of quantification (LOQ) and characteristic mass (m_0) [33] were the parameters used in the study.

The blanks were solutions of 3.5% (v/v) nitric acid when using nitric acid as a chemical modifier, and 3.5% (v/v) of nitric acid and 15 mg l^{-1} of magnesium nitrate when using magnesium nitrate as a modifier. The values obtained, for 11 replicate injections, were 0.008 ± 0.001 and 0.006 ± 0.001 A.s. for magnesium nitrate and nitric acid, respectively.

The LODs, corresponding to 0.5 g of drug sample, were 5.77 and 7.23 μg^{-1} for the use of magnesium nitrate and nitric acid, respectively, the LOQs being 19.24 μg kg^{-1} for magnesium nitrate and 24.20 μg kg^{-1} for nitric acid. The values of m_0 obtained were 5.2 ± 0.34 and 4.6 ± 0.67 pg for magnesium nitrate and nitric acid, respectively. As can be seen, the sensitivity is better for magnesium nitrate as a chemical modifier.

3.6. Precision and accuracy

Precision was studied for the use of both chemical modifiers, magnesium nitrate and nitric acid. The within-batch precisions obtained for 11 replicate injections of cocaine sample solutions spiked with 0, 5, 7.5 and 10 μg l^{-1} of Cr^{3+}, expressed as RSDs, were 7.45, 2.21 0.86 and 1.19%, respectively, for nitric acid, and 6.19, 1.78, 1.52 and 1.48%, respectively, for magnesium nitrate. As can be seen, similar precision is achieved by both chemical modifiers.

The accuracy of the methods was studied by analytical recovery. This parameter was obtained for cocaine solutions spiked with 5, 7.5 and 10 μg l^{-1} of Cr^{3+}, which were injected into the atomizer 11 times. The results are shown in Table 3. As can be seen, analytical recoveries close to 100% were achieved for all concentration levels for both chemical modifiers.

Good precision and analytical recovery were discovered for both the chemical modifiers investigated, and a similar linear range was achieved. Therefore, owing to the lower LOD obtained with the use of magnesium nitrate, we consider magnesium nitrate to be a more suitable chemical

modifier than nitric acid. In the following studies, magnesium nitrate, at the optimum concentration of 15 mg l^{-1}, will be used.

3.7. Study of the introduction of a cooling-down step

The introduction of a cooling-down step, which has been reported for the determination of lead and aluminiun [34], has also been implemented in the determination of chromium in foodstuffs [24]. Therefore, in this section a graphite furnace temperature programme incorporating a cooling-down step, just before atomization, with ramp and hold times of 10 s for each and cooling temperatures between 50 and 350°C, was studied. The within-run precision, for seven replicate injections of a cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+}, was studied for each cooling temperature, obtaining good precision (< 10%) for measurements in the peak-area and peak-height modes. However, the RSD (%) values for higher cooling temperatures were larger than those for lower cooling temperatures and those similar to the values obtained without the introduction of a cooling-down step (Table 1). An increase in chromium absorbance, measured in the peak-area mode, compared to that obtained using the former programme, was obtained for all cooling temperatures.

A cooling temperature of 50°C was selected as the most adequate cooling temperature owing to good within-run precision and the peak scheme attained. However, the sensitivity achieved was poorer than that obtained using the former programme (Table 1), the LOD being three times higher (19.24 μg kg^{-1}) than the standard programme (5.77 μg kg^{-1}).

3.8. Interferences

A study on the effects of species that could interfere with the chromium absorbance signal was carried out. We assume a species to be an interferent when, at a specified concentration, it produces a variation in the chromium absorbance signal of ± 10% of the signal measured in the absence of the species. Therefore, several different

cations, Al^{3+}, Ba^{2+}, Ca^{2+}, Cd^{2+}, Co^{2+}, Cu^{2+}, Fe^{3+}, K^+, Li^+, Mn^{2+}, Na^+, NH_4^+, Ni^{2+}, Pb^{2+} and Zn^{2+}, and anions, Cl^-, PO_4^{3-}, SO_4^{2-}, SiO_3^{2-} and citrate, were studied. Different amounts of each species were added to a cocaine sample solution spiked with 10 μg l^{-1} of Cr^{3+}; the results obtained are shown in Table 4, which gives the lowest concentration corresponding to 0.5 g of the drug sample, the percentage chromium absorbance variation and the levels for some species reported in the literature [1]. As can be seen, species that can be considered as major constituents, such as Ca^{2+}, Mg^{2+} and Zn^{2+}, do not exhibit interfering behaviour. Similarly, for anions such as Cl^-, PO_4^{3-} and SO_4^{2-}, that could also be considered as major constituents, the addition of 100 mg l^{-1} (4000 mg kg^{-1} corresponding to sample) does not statistically vary the ab-

Table 4
Effects of different elements on the chromium absorbance signal of a cocaine sample solution spiced with 10 μg l^{-1} of Cr^{3+}

Interferent	Lowest concentration with respect to sample (mg kg^{-1})	Concentration interval (mg kg^{-1})	% Chromium absorbance variation

^{a} Data not available.

sorbance signal. Interfering behaviour is only obtained at concentrations of Fe^{3+} and Al^{3+} greater than 2000 mg kg^{-1}. Although this fact has been observed by several authors [7,8,35,36], no explanation has been reported. Finally, for the other species whose concentration levels are available, there are no observed interfering effects at the highest concentration tested, which is greater than that reported in these kinds of samples.

3.9. Study of precision and analytical recovery with the amount of sample

A study on the precision and analytical recovery for different amounts of drug samples was developed in order to reduce the LOD and LOQ, and to verify if the amount of drug sample chosen, 0.5 g, is a representative mass to carry out the analysis. Therefore, 0.25, 0.5, 1.0 and 2.0 g cocaine samples were prepared as indicated in Section 2.3, obtaining sample concentrations of 2.5, 5.0, 10.0 and 20.0% (m/v), respectively, after dilution to 10 ml. The volume of nitric acid used to dissolve the samples was 2 ml (Section 2.3); however, for an amount of sample of 2 g, it was necessary to increase the volume of nitric acid to 2.5 ml to totally dissolve the sample.

The effect of the different sample concentration precisions was studied through the within-run precision, for 11 replicate injections of the solutions prepared from each amount of sample. To obtain similar chromium absorbance values, different volumes of an aqueous standard solution of Cr^{3+} were added to the solutions of lower sample concentrations. The RSD values obtained were 2.03, 0.72, 1.38 and 1.36% for 2.5, 5.0, 10.0 and 20.0% (m/v), respectively. As can be seen, the increase in the amount of sample does not impair the precision.

To study the effect of the amount of sample on the analytical recovery, each cocaine sample solution, corresponding to each amount of sample, spiked with 5 and 10 μg l^{-1} of Cr^{3+}, was injected 11 times into the graphite furnace, and the analytical recoveries were determined. The results are shown in Table 5, where it can be seen that for all sample concentrations and for the two concentra-

Table 5
Analytical recovery ($n = 11$) corresponding to different sample concentrations

Sample concentration (% (w/v))	Analytical recovery (%)	
	$+5\ \mu g\ l^{-1}\ Cr^{3+}$	$+10\ \mu g\ l^{-1}\ Cr^{3+}$
2.5	102.4 ± 1.0	99.6 ± 0.9
5.0	97.4 ± 1.4	103.5 ± 1.2
10.0	96.6 ± 2.6	101.6 ± 1.6
20.0	92.8 ± 3.6	102.0 ± 1.9

tion levels tested, analytical recoveries closed to 100% were achieved.

Therefore, the amount of sample can be increased to 2 g of drug sample without a loss of analytical performance, attaining a LOD of 1.44 μg kg^{-1}.

However, 0.5 g of drug sample can be considered as an adequate and representative mass for developing the analysis due to precision, and analytical recovery is not statistically varied in the 0.25–2.00 g range, obtaining an adequate LOD for the determination of chromium in a great number of samples.

3.10. Application

The method, using magnesium nitrate as a chemical modifier, was applied to the determination of chromium content in cocaine and heroin samples from various geographical areas. One subsample was taken from each sample and prepared as in Section 2.3, and two subsamples from each were subjected to FAAS twice. The results obtained are shown in Table 6, together with the SDs for four analyses of each drug sample. The obtained concentrations of chromium are low, those in heroin (0.05–0.59 mg kg^{-1}) being slightly bigger than those in cocaine (0.02–0.14 mg kg^{-1}). This can be attributed to the lower purity of the heroin samples compared to the cocaine samples. It can be said that the chromium levels found for cocaine and for some heroin samples are lower than 0.2 mg kg^{-1}, which is the lowest concentration of chromium reported by Violante et al. [1].

Table 6
Chromium levels found in several heroin and cocaine samples

Sample		Chromium level (mg kg^{-1})	SD^a (mg kg^{-1})
Heroin	1	0.33	0.05
	2	0.15	0.10
	3	0.05	0.04
	4	0.32	0.12

	4	0.06	0.04
	5	0.07	0.04
	6	0.08	0.04
	7	0.06	0.04
	8	0.13	0.06
	9	0.06	0.05
	10	0.06	0.05
	11	0.06	0.03
	12	0.02	0.03

$^a n = 4$.

4. Conclusions

The results of this work confirm the advantageous application of magnesium nitrate as a chemical modifier for the determination of chromium. With the use of this chemical modifier, matrix effects are satisfactorily removed and aqueous calibration is a real possibility. In addition, magnesium nitrate offers the lowest LOD and LOQ, thus giving acceptable precision and accuracy. Finally, it should be mentioned that the introduction of a cooling-down step before atomization, recommended by several authors for chromium determination [24], does not offer any advantage in terms of sensitivity.

Received 1 March 1995; revised 14 August 1995; accepted 17 August 1995

Abstract

The stability constants of the fluoride complexes of cerium(IV) in 1 M $(HClO_4, NaClO_4)$ medium have been measured potentiometrically using a fluoride ion-selective electrode. Quantitative oxidation of cerium to its tetravalent state and its stabilisation in the perchlorate medium were accomplished by oxidation with AgO followed by quick addition of a known amount of fluoride ion. This procedure ensures stability of the oxidation state and prevents hydrolysis and polymerisation of Ce(IV). Logarithms of the average values of β_1, β_2, β_3 and β_4 were estimated to be 7.57 ± 0.04, 14.50 ± 0.03, 20.13 ± 0.37 and 24.14 ± 0.10 respectively.

Keywords: Cerium(IV); Stability constants; Fluoride complexes; Ion selective potentiometry

1. Introduction

The oxidation state of cerium(IV) is not stable in aqueous perchloric acid medium (standard electrode potential of the Ce(IV)/Ce(III) couple is 1.61 V). Ce(IV) is slowly reduced to Ce(III) as water is decomposed to liberate oxygen. In addition, Ce(IV) is very susceptible to hydrolysis and polymerisation like other tetravalent cations and a high acidity must be maintained in the medium. Stability constant data for Ce(IV) complexes are

* Corresponding author. Fax: 91-22-5560750; E-mail: fuelchem@magnum.barct1.emet.in.

very scarce mainly due to these difficulties. We are interested in the stability constant values of Ce(IV) fluoride complexes in perchlorate medium, which have not been reported in the literature so far, for correlating the stability constants of the tetravalent actinides [1] with the values of other cations in general [2] and tetravalent cations in particular.

In a preliminary study we established that AgO (standard electrode potential of the Ag(II)/Ag(I) couple is 1.98 V) could be used for quantitative oxidation of Ce(III) to Ce(IV) in 3–4 M perchloric acid medium and that the reduction of Ce(IV) could be arrested by immediate addition of some

known quantity of fluoride ion. The addition of fluoride before dilution prevented the hydrolysis and polymerisation of Ce(IV). Ion selective potentiometry using a lanthanum fluoride membrane electrode has been recommended as the best method for the study of fluoride complexes [3]. In the presence of cations forming strong complexes with fluoride, the lanthum fluoride electrode responds to free fluoride ion concentration three decades below 10^{-6} M, the accepted detection limit in non-complexing solutions. This has been validated experimentally and theoretically by several workers [4,5]. Various difficulties associated with the study of fluoride complexing in a highly acidic medium and the procedure developed by us to overcome these difficulties have been discussed in our earlier papers on the fluoride complexes of actinides [1,6]. In the present work the same experimental procedure has been followed while ensuring the stabilisation of the tetravalent state in the perchloric acid medium.

2. Experimental

2.1. Reagents

Cerium perchlorate stock solution

G.R. grade ammonium cerric nitrate, $(NH_4)_2$-$Ce(NO_3)_6$, from LOBA Chemie was dissolved in 1:1 $HClO_4$, evaporated to near dryness and fumed repeatedly with $HClO_4$. Finally a stock solution was made in 4 M $HClO_4$. During this process some of the Ce(IV) was reduced to Ce(III). Ce(IV) was determined by potentiometry after adding an excess of ferrous sulphate and then back titrating excess ferrous ions with standard potassium dichromate solution. Total Ce was determined by potentiometry after oxidation of Ce(III) to Ce(IV) with AgO in sulphuric acid medium. An aliquot of the stock solution containing 3-4 mg of Ce was taken in dilute sulphuric acid medium. Excess silver(II) oxide powder (about double the amount theoretically required) was added with constant stirring. After about 3 min, when the redox potential reached a stable maximum the excess AgO was destroyed with sluphamic acid. Ferrous sulphate solution was

then added and excess ferrous ions were back titrated with standard dichromate solution. It was observed that about 50% of the cerium in the stock solution was in the trivalent state. An aliquot of the stock solution was analysed for nitrogen at the trace level and showed complete absence of nitrogen. The hydrogen ion concentration of the stock solution was determined by titration with standard NaOH in a citrate medium using a glass pH electrode for end-point detection.

AgO

Silver(II) oxide was prepared in our laboratory following the procedure of Milner et al. [7]. The dry silver oxide powder was analysed for Ag(II) content by adding a known weight of the powder in standard ferrous sulphate solution and back titrating excess ferrous ions potentiometrically with standard potassium dichromate solution. 57% of silver was found to be in the bivalent state.

Standard $NaClO_4$ and NaF solutions were prepared as given in our earlier communication [1].

2.2. Apparatus and equipment

A combination fluoride electrode from Orion Research Inc. (Model-9609) coupled to a digital ion analyser (EA 940) was used for the determination of equilibrium free fluoride concentration. A polyethylene weight burette was used for precise addition of the titrant by weight which was converted to volume using the density of the solution. The temperature of the titration vessel was maintained at $23 \pm 1°C$ using a thermostat. A Teflon-coated bar magnet was used for stirring. A digital potentiometer with a freshly cleaned platinum electrode and a saturated calomel electrode was used for measurement of the redox potential in redox titrations. All labware used was made of polypropylene. Water used was double quartz distilled.

2.3. Procedure

Before each experiment for the determination of the stability constant, the fluoride electrode was freshly calibrated using standard fluoride solution

to obtain the standard electrode potential (E_F^0) and the electrode slope (S). The relation between $[H^+]$ and liquid junction potential (E_j) was evaluated using the procedure described in our earlier work [1,6]. For the determination of the stability constant an aliquot of cerium stock solution containing about 10 mg Ce was taken in a thermostated polypropylene beaker. About 30–40 mg AgO powder (at least twice the amount theoretically needed for complete oxidation) was added and immediately a known weight of NaF solution was added with constant stirring. Dilute perchloric acid solution was then added to the solution to bring the acidity below 1 M while maintaining the ionic strength at 1 M. Small increments of fluoride solution were added and the potentials (stable to within ± 0.2 mV) were noted. About 35–40 readings were taken in each experiment. The experiment was repeated with different quantities of total cerium. The electrode was washed thoroughly immediately after each experiment and kept in a very dilute fluoride solution for conditioning.

3. Results and discussion

3.1. total conversion to Ce(IV) and its stabilisation

At the outset it was necessary to ascertain that Ce(III) was completely oxidised to Ce(IV) by AgO. It was observed that in perchloric acid medium Ag(II) decomposed rapidly and almost completely within 10 min. Ce(IV), obtained by the oxidation of Ce(III) by AgO in perchloric acid medium, also underwent reduction to Ce(III) slowly. The recovery of Ce(IV) on potentiometric analysis decreased with waiting time. However, when an amount of fluoride was added immediately after addition of AgO, the oxidation state of Ce(IV) remained stable. Fluoride prevented the reduction as it brought down the reduction potential by preferably complexing with Ce(IV). This was confirmed by analysis of Ce(IV) in the presence of small amounts of fluoride (with varying waiting time) which showed 100% recovery. The amount of fluoride

thus added initially was taken into account of the total fluoride added during titration. Ag^+ introduced in the solution and the H^+ consumed by the oxide were taken into account in adjusting the total ionic strength of the medium of 1 M. Total H^+ concentration of the medium, H_T, was corrected for the H^+ consumed by the dissolution of the silver oxide.

3.2. Prevention of hydrolysis and polymerisation of Ce(IV)

As Ce(IV) is extremely susceptible to hydrolysis and polymerisation the stock solution had to be made in very highly acidic medium and used within a few days. It must not be stored for a long time. Even in 4 M $HClO_4$ medium problems were encountered when the solution was aged for a few weeks. It was very important to treat the aliquot of metal ion stock solution in 4 M $HClO_4$ medium with AgO and NaF solutions before diluting to below 1 M with respect to $HClO_4$. The role of F^- in preventing hydrolysis and polymerisation is well known [8]. In an experiment the redox potential of the Ce(IV)/Ce(III) couple in the presence of fluoride (the same amount as added initially before dilution in our titration) was noted while adding micro drops of NaOH solution with vigorous stirring. As Ce(IV) is more susceptible to hydrolysis a drop in potential is expected when hydrolysis begins. The potential remained constant (at 1.265 V vs. standard calomel electrode) up to the addition of a certain amount of NaOH. The addition was stopped at the point where the potential started falling (1.254 V) with the appearance of a faint turbidity in the medium. The H^+ concentration of the medium determined at this point by titration with standard NaOH in citrate buffer was 0.6 M. The initial acidity of the medium in our experiments was maintained higher than 0.7 M with respect to $HClO_4$. In the absence of fluoride a much higher acidity (much exceeding the desired ionic strength of the medium) might be required, which was found to be detrimental to the life and performance of the fluoride-sensing electrode.

3.3. Calculation of concentration stability constants

The measured fluoride electrode potential, E_F (corresponding to each addition of fluoride to the metal ion solution), was used for the determination firstly of approximate and then of more corrected values of free fluoride ion, free hydrogen ion and the liquid junction potential using the iterative procedure described in the earlier work [1]. The total hydrogen ion concentration, H_T, and the free fluoride ion concentration, $[F^-]$, at each point were used for the evaluation of the fluoride attached to H^+ as HF and HF_2^- using their stability constant values [1]. The average number of F^- ions attached to the metal ion ($\bar{n}$) was then calculated. Stability constants were obtained by non-linear least-squares fitting to Bjerrum's equation for mononuclear complexes (program BETA). The MINIQUAD program [9] using least-squares fitting to mass balance equations was also used to obtain another set of results on the same experiments. A typical set (set I) of

primary and processed data is presented in Table 1. The concentrations of HF and free F^- in the equilibrium mixture increased with the increasing amount of added fluoride leading to a progressive decrease in the tendency of Ce(IV) to undergo hydrolysis and polymerisation. As evident from Table 1, towards the end of the titration the free H^+ ion concentration dropped appreciably. However, by then, large concentrations of HF and free F^- had accumulated, the value of $\bar{n}$ was above two and almost all the Ce(IV) ions were attached to one or more fluoride ions. These factors combined to prevent hydrolysis at the lower acidity encountered towards the end of titration. Average log values of the overall stability constants obtained for the three sets by the two methods of calculation are presented in Table 2. A speciation plot is shown in Fig. 1. The best fit was obtained when four constants (β_1–β_4) were included. Inclusion of higher constants decreased the goodness of fit and increased the standard deviation. The possibility of some fluoride ion being attached to silver ion and its effect on the final results were

examined by including silver fluoride complex in fluoride mass balance equation in the MINIQUAD program. Though the concentration of Ag^+ was high the amount of fluoride attached to it was very negligible. The value of $\log \beta_1$ for AgF is
Fig. 1. Speciation plot of cerium(IV)–fluoride system.

reported [3] to be -0.32. The values for Ce(IV)–fluoride complexes remained unchanged after the correction. Only one work [10] in 3.8 M ionic strength medium containing 3 M H_2SO_4, in which Ce(IV) is stable, is reported in the literature. However, sulphate also forms a strong complex with Ce(IV). No measurement in the perchloric acid medium was reported in the literature, mainly because of the instability of the oxidation state. This has been taken care of by the particular procedure followed in the present work. Close agreement of the β values in different sets of experiments with varying metal ion concentration indicated that only mononuclear complexes were formed in this experimental condition.

An attempt was made to examine whether this value of the stability constant of the Ce(IV)–F complex agrees with the general trend of the fluoride complexes of other cations as correlated with their fundamental properties such as charge and radius [11] and, in a more generalised way, their electronic structure as well (Brown–Sylva–Ellis or BSE equation) [12]. Values of stability constants [3] of monofluoro mononuclear complexes of various metal ions were collected. Generally values obtained in perchlorate medium of 1 M and, in a few cases, 0.5 M ionic strength and at temperature $298 \pm 5°C$ were taken and converted to so-called thermodynamic values at zero ionic strength using the Debye–Hückel equation modified by Davies [13] as given below:

$$\log \beta_1^\circ = \log \beta_1 - A\,\Delta Z_i^2 [\mu^{1/2}/(1 + \mu^{1/2}) - 0.3\mu]$$

where
Fig. 2. Position of Ce(IV) in the linear correlation of thermodynamic stability constants of the monofluoro complexes of metal ions with the BSE parameter [12] involving charge, radius and electronic structure.

$$\Delta Z_i^2 = \sum Z_{i\,(\text{products})}^2 - \sum Z_{i\,(\text{reactants})}^2$$

The value of "A" was taken as 0.5115. The values of ionic radii were obtained from the compilation of Shannon [14]. Among the various relations, the columbic attraction parameter, $[Z_M \cdot Z_L/(r_M + r_L)]$, and the BSE parameter, $g_1(Z_M/r_M^2 + g_2)$, gave good linear relations with β_1° (regression coefficients 0.9686 and 0.9928 respectively). The slope and intercept of the former were 7.965 and −6.11 respectively. A plot of the latter is presented in Fig. 2. The measured value of Ce(IV)

fits in very well in both the plots. However, unlike Zr^{4+}, the values of Hf^{4+} could not be compared as the values reported in the literature are obtained only in very high acidity and ionic strength media.

Studies on the formation of Cu(II) and Ni(II) complexes of 1,2-dihydroxy-9,10-anthraquinone and lack of stimulated superoxide formation by the complexes

Saurabh Das, A. Saha, P.C. Mandal *

Nuclear Chemistry Division, Saha Institute of Nuclear Physics, 1/AF, Bidhannagar, Calcutta-700 064, India

Abstract

Formation of Cu(II) and Ni(II) complexes of 1,2,-dihydroxy-9,10-anthraquinone (DHA) has been studied by the spectrophotometric method. Both the metals form stable complexes of the type $[M(LH)_3]^-$ where LHH_1 represents DHA. The effective stability constant of the Cu(II) complex is 5.135×10^{29} while that of the Ni(II) complex is 3.446×10^{25}. These complexes, unlike free DHA, do not catalyze the flow of electrons from NADH to molecular O_2 through NADH dehydrogenase.

Keywords: 1,2-Dihydroxy-9,10-anthraquinone(DHA); Cu(II)–DHA; Ni(II)–DHA; Stability constant; Cardiotoxicity

1. Introduction

Anthracyclines constitute an important class of chemical compounds. The presence of a quinone chromophore which acts as a mediator in electron transport processes in many living systems has prompted an extensive study of these compounds. Techniques such as spectrophotometry, fluorescence studies and circular dichroism have been applied as probes [1–5] to understand the nature and chemical characteristics of such molecules. These compounds gained more importance with the discovery that they could be used as drugs in the treatment of cancer. Among the chemotherapeutic drugs in use today, quinone anti-tumor agents such as daunorubicin and adriamycin are important [6–13]. However, the principal drawback from which these drugs suffer is that they are cardiotoxic [14–19] and should not be applied to patients for a prolonged period of time. These compounds are reduced to semiquinone [20–23] by enzymatic systems and then reoxidised by molecular oxygen to give superoxide radicals and other reactive oxygen species [24–26]. In fact these radicals are responsible for the anti-tumor activity and cytotoxic properties of these compounds. Earlier studies [27,28] have shown that formation of metal complexes with these drugs greatly influences the toxicity imparted by them. In fact, complexation of adriamycin and carminomycin by Fe(III) gives complexes which are less

---

* Corresponding author. Fax: (91)033-374-637.

cardiotoxic [29–31] than the parent drug but quite
effective as an anti-tumor agent against P 388
leukemia.

A number of metal complexes [27,32–34] of the
anthracyclines have been tried for the treatment
of cancer and their use has aroused growing inter-
est in the study of the role of metal ions in these
compounds. It is now well established from vari-
ous studies conducted on model nucleic acid bases
[35–39] and hypoxic tumor cells [40,41] that tran-
sition metal ions are quite effective as radiosensi-
tizers. These metal ions are also good binding
agents for cellular target DNA [42–44]. Hence
complexation of these drug molecules with suit-
able transition metals [45,46] to give a soluble
complex would result in a compound which
would be less cardiotoxic [27,28] but could be
better targetted to cellular DNA. However, there
is also a possibility that due to complexation with
metal ions the drugs may lose a certain amount of
their chemotherapeutic significance.

Previous studies have shown that metal ions
such as Fe^{3+} form complexes with quinizarin
derivatives [47,48] while the formation of long-
chain polymers was observed for Cu^{2+} and vari-
ous dihydroxyquinoid ligands [49] in the solid
state. A very recent study [2] has indicated that
Al^{3+} ions show a profound tendency to bind
molecules such as quinizarin and quinizarin-2-sul-
phonic acid which are essentially the core
molecules of the anthracycline antibiotics. The
stability of these compounds has been reported to
be comparable to those of the Al^{3+}-adriamycin
complexes. Studies on the complexation of 1,2-di-
hydroxy-9,10-anthraquinone with metal ions have
not been reported. In this investigation we have
studied the complexation of this molecule with the
transition metal ions Cu(II) and Ni(II) and have
determined their stability constants.

Furthermore, we have prepared the Cu(II)
and Ni(II) complexes of 1,2-dihydroxy-9,10-an-
thraquinone (DHA) and characterized them by
spectroscopic techniques. Also, their ability to be
reduced by enzymatic processes was assessed by
following their catalytic role in the flow of elec-
trons from nicotinamide adenine dinucleotide
(NADH) to molecular oxygen, forming superox-
ide radical through the enzyme NADH dehydro-
genase [29].

2. Materials and methods

2.1. Materials

DHA (BDH) was purified by recrystallization
from pure ethanol and was used in the present
investigation. Concentrations of solutions used
were of the order of 10^{-5} M. Substances contain-
ing the quinone moiety being sensitive to light, all
solutions used were prepared just before the ex-
periments or if required were stored in a dark
place. Standard Cu(II) and Ni(II) solutions were
prepared using analytical reagent grade $CuSO_4 \cdot
5H_2O$ and $NiSO_4 \cdot 7H_2O$ respectively. Sodium ni-
trate of analytical grade was used to maintain the
proper ionic strengths in the medium. Cy-
tochrome c (extrapure) was purchased from the
Sisco Research Laboratories, India. β-Nicotin-
amide adenine dinucleotide, reduced form (β-
NADH), and NADH dehydrogenase were pur-
chased from Sigma. The enzyme activity was
assayed [50] by following the increase in ab-
sorbance at 550 nm of cytochrome c in the pres-
ence of NADH dehydrogenase at pH 7.4.
Superoxide dismutase (SOD) was obtained as a
gift from the Department of Biochemistry, Uni-
versity of Calcutta. The specific activity of the
enzyme was 6500 units mg^{-1} of protein. Hepes
buffer [51] (4-(-hydroxyethyl)-1-piperizine ethane-
sulphonic acid; 0.05 M) was used for maintaining
the pH of the solutions. All solutions were pre-
pared in triply-distilled water.

Absorption spectra were taken on a UV-2101
Shimadzu spectrophotometer.

3. Elemental analysis of the complexes

Analyses of carbon and hydrogen were carried
out at the Central Drug Research Institute, Luc-
know, India. Estimations of copper and nickel in
the DHA complexes were carried out by the
methods described in the literature [52].

3.1. NADH dehydrogenase assay

The enzymatic assay was done at 25°C by a
method described earlier [50] where cytochrome c

was used as the electron acceptor. DHA and complexes of DHA with Cu(II) and Ni(II) were assayed for their NADH–cytochrome c reductase activity by following the reduction of cytochrome c at 550 nm. The reaction mixture contained 0.05 M Hepes buffer (pH 7.4), 80.5 μM cytochrome c, 157.5 μM NADH, 3 U l^{-1} NADH dehydrogenase and the substance of interest. The concentrations of the compounds which included DHA, Cu(II)–DHA and Ni(II)–DHA were varied from 0 to 15.75 μM. The activity of the enzyme NADH dehydrogenase is expressed in units where one unit of activity reduces 1.0 μ mole of oxidized cytochrome c per minute at pH 7.4 at 25°C. The formation of superoxide radical anion catalyzed by the DHA and its complexes was measured from the cytochrome c reduction [29,53,54] inhibited by SOD in the presence of NADH and NADH dehydrogenase. The enzymatic assay was carried out using kinetics software (Shimadzu Corporation).

4. Results and discussion

4.1. Acid dissociation of DHA

DHA can exist in three distinctly different forms depending on the pH of the solution. These forms can be represented as LHH_1, LH_1^- and L^{2-}. In LHH_1, H corresponds to the hydrogen present on the $-OH$ group at the C_2 carbon atom while H_1 represents the hydrogen on the $-OH$ group at the C_1 atom of the carbon of DHA.

$$LHH_1 \rightleftharpoons H^+ + LH_1^- \qquad K_1 = \frac{[H^+][H_1L^-]}{[H_1HL]} \qquad (1)$$

$$LH_1^- \rightleftharpoons H_1^+ + L^{2-} \qquad K_2 = \frac{[H_1^+][L^{2-}]}{[H_1L^-]} \qquad (2)$$
Fig. 1 shows the absorption spectra of an aqueous solution of DHA at different pH values. At pH 5.1, the absorption spectrum shows two peaks at 307 nm and 433 nm respectively (Fig. 1). On further decreasing the pH by 2.0 to 3.1 there was no significant change in the absorption spectrum indicating that the protonation of DHA to the form
Fig. 1. Absorption spectra of DHA in aqueous solution at different pH values: (a) 5.16; (b) 6.35; (c) 7.10; (d) 9.0; (e) 11.07. [DHA] = 12 μM, [NaNO$_3$] = 0.04 M, T = 25°C.

LH_3^+ [55] takes place at much higher acid concentration. When the pH of the solution is increased beyond 5.1, there is a little increase in the absorbance of the UV peak at 307 nm, but the absorbance of the 433 nm peak decreased. However, with further increase of pH to 6.4, the peak at 433 nm disappeared and a new peak at ≈ 500 nm appeared. With further increase in pH the peak is further red-shifted to 520 nm with gradual increase in the absorbance at this wavelength. This red shift of the peak and gradual increase of the absorbance, therefore, indicate that the ligand DHA has undergone some prominent changes in its structure. The changes can be attributed to the dissociation of a proton from a phenolic-OH group on the ligand. With further increase of the pH beyond 11.07, it was observed that the peak is shifted further to 550 nm. This shift with wavelength is due to the dissociation of a second phenolic-OH proton from a ligand. The dissociation of the first proton from a phenolic-OH group present on the ligand corresponds to the phenolic-OH at the C_2 position. The second dissociation then corresponds to the proton on the phenolic-OH at C_1. To determine the proton dissociation constants, the absorbance of the compound at 520 nm was followed in the pH range 4–12. The observed absorbance, A_{obs}, at 520 nm would be given by

$$A_{obs} = A_1/(1 + 10^{pH - pK_1} + 10^{pH - pK_2})$$

$$+ A_2/(1 + 10^{pK_1 - pH} + 10^{pH - pK_2})$$

$$+ A_3/(1 + 10^{pK_1 - pH} + 10^{pK_2 - pH}) \qquad (3)$$

where A_1, A_2, and A_3 refer to the absorbances attributed to the forms LHH_1, LH_1^- and L^{2-} respectively and pK_1, pK_2 are the pK values corresponding to dissociation of LHH_1 given by relations (1) and (2) respectively. By fitting the experimental data according to Eq. (3), as shown in Fig. 2, we obtained the pK_1 and pK_2 values at 5.98 ± 0.05 and 9.88 ± 0.05 respectively.

The dissociations of the two protons from DHA can be explained if one carefully examines the structure of the molecule. DHA exists in two canonical forms I and II [56]:
The phenolic-OH at C_1 in structure I is associated by strong hydrogen bonding with the neighboring carbonyl at C_9. In the other canonical form II the hydrogen bonding exists but in this structure the
Fig. 2. Spectrophotometric titration of DHA, shown by the variation of absorbance at 520 nm; [DHA] = 12 μM, [NaNO₃] = 0.04 M, $T = 25$ °C. The solid line represents the fitted data according to Eq. (3).

carbonyl is in C_1, thus rendering an electron withdrawing effect on the phenolic-OH at C_2. As a consequence of this the phenolic-OH at C_2 becomes more acidic than one would normally expect ($pK = 5.98$) and dissociates first. Owing to the presence of the intramolecular hydrogen bonding, the phenolic-OH at C_1 dissociates later and this therefore corresponds to the pK of 9.88. Similar values for the pK (10.0) of phenolic-OH at C_{11} of the anthraquinone moiety have been reported for such molecules as doxorubicin and daunorubicin [33].

It was further seen that upon complexation of the ligand with metal ions through the carbonyl group at C_9 and the phenolate anion at C_1 the I structure for the ligand molecule predominates. As a result it was found as expected that in the complexed state the dissociation of the phenolic-OH at C_2 is decreased and it now has a $pK \approx 8.2$ (discussed later). The dissociation of the ligand in the presence of metal ions therefore occurs as shown by the following equation:

$$LHH_1 = H_I^+ + LH^- \qquad (4)$$

where H_I^+ corresponds to the dissociation of a proton from $-OH$ at C_1. This deprotonation step of $-OH$ at C_1 has been characterized by pK_2 for the free ligand.

4.2. Formation of the Cu(II) and Ni(II) complexes of DHA

When $CuSO_4$ was added to a solution of DHA at neutral pH an absorbance peak at 520 nm was observed. In order to determine the stoichiometry of the complex formed between DHA and Cu^{2+} a fixed concentration of the metal ion was taken and the concentration of the ligand (DHA) in solution was varied. The pH was maintained at 7.0 using Hepes buffer. It was found that with a gradual increase in the concentration of the ligand (DHA) with respect to a fixed concentration of the metal ion absorbance of the solution measured at 520 nm gradually increased. When the molar concentration ratio of the metal ion to ligand reached 1:3, the absorbance at this wavelength reached a maximum value and it remained unchanged even after subsequent increase in the
Fig. 3. Schematic diagram of the Na [M(DHA)₃] complex.

ligand (DHA) concentration for a fixed concentration of the metal ion. Thus one can suggest that Cu^{2+} forms a 1:3 complex with DHA in solution which may be represented by the schematic diagram (Fig. 3). However, it was also seen that when the concentration of Cu^{2+} in solution was increased with respect to DHA a purple to violet coloured polymeric insoluble substance resulted. The polymeric material precipitated out of the solution as soon as it was formed.

For accurate characterization of the complex, spectrophotometric titration of the Cu(II)–DHA system at 1:3 molar ratio was performed at an ionic strength of 0.05 M. The pH of the DHA solution was first lowered to 2.9 and Cu(II) solution was added to it. Then the solution was slowly titrated with 0.1 M NaOH solution. Fig. 4 shows the absorption spectra at various pH values. At
Fig. 4. Absorption spectra of DHA in the presence of Cu^{2+} at different pH values: (a) 2.90; (b) 4.16; (c) 4.70; (d) 5.50; (e) 7.20. [DHA] = 19.84 μM, [CuSO₄] = 6.613 μM, T = 25°C.
Fig. 5. Spectrometric titration of DHA in the presence of Cu^{2+} as shown by the variation of absorbance, at 520 nm; [DHA] = 19.84 μM, [CuSO₄] = 6.613 μM, [NaNO₃] = 0.04 M, T = 25°C. The solid line represents the fitted data according to Eq. (10).

pH 2.9, the solution shows an absorption peak at 423 nm which, however, increases in intensity with increasing pH until it reaches a pH ≈ 5.50. At this pH, the intensity of this peak decreased with the formation of a new absorption peak at 520 nm. This change in peak indicates deprotonation of one of the OH groups of the DHA molecule. For a further increase in pH, the intensity at 520 nm increases. The change in absorbance at 520 nm with an increase in pH was followed as shown in Fig. 5. It was observed that in the pH range 5–6 one of the protons from the OH groups has been released. The formation constants for the complex, β^* and β, can be described as follows:

$$Cu^{2+} + 3HH_1L \rightleftharpoons \{Cu(LH)_3\}^- + 3H_1^+ \qquad (5)$$

$$\beta^* = \frac{[\{Cu(LH)_3\}^-][H_1^+]^3}{[Cu^{2+}][HH_1L]^3} \qquad (6)$$

$$Cu^{2+} + 3LH^- \rightleftharpoons \{Cu(LH)_3\}^- \qquad (7)$$
$$\beta = \frac{[\{Cu(LH)_3\}^-]}{[Cu^{2+}][LH^-]^3} \qquad (8)$$

From Eqs. (4) and (8) one gets

$$\beta = \frac{\beta^*}{K_2^3} \qquad (9)$$

where K_2 is the equilibrium constant for the dissociation of the proton of DHA as shown in Eq. (4).

The release of the proton from the phenolic-OH at C_2 corresponding to K_1 occurs later during the course of complexation. The formation constant β^* of the Cu(II) complex was determined from the above spectrophotometric titration. The absorbance A_{obs} at 520 nm could then be described as

$$A_{obs} = A_1/(1 + 10^{pH - pK}) + A_2/(1 + 10^{pK - pH}) \quad (10)$$

where A_1 and A_2 are the absorbances corresponding to the forms LHH_1 and LH^- respectively. Fitting the experimental data as shown in Fig. 5, one gets a pK value of 4.98 ± 0.05. The value of the formation constant β for $[Cu(II)(LH)_3]^-$ can then be determined from relation (9) and was found to be 5.135×10^{29}. This stability constant value obtained by us is almost the same $(10^{31}-10^{34})$ as that for the Fe(III) [27,29,32] complexes of anthracyclines having identical stoichiometry. However, the reported stability constant value of the 1:2 Cu(II)–doxorubicin [45,46] complex is 2×10^{17}. Pd(II) [34] ions also bind to anthracyclines with stability constants of the order of 10^{22}.

When formation of the Ni(II) complex with DHA was followed, it was observed that, similar to the behavior of the Cu(II) species, Ni(II) also forms a 1:3 complex of DHA represented by $[Ni(II)(LH)_3]^-$ (Fig. 3). The value of pK for the Ni(II) complex of DHA was obtained as 6.47 ± 0.05. the formation constant of this complex was then evaluated and found to be 3.446×10^{25}.

4.3. Preparation of the Cu(II) and Ni(II) complexes with DHA

The Cu(II) complex of DHA was prepared by mixing $CuSO_4$ and DHA in the molar ratio 1:3 in an aqueous medium at $\approx 30°C$ at neutral pH. The solution was then heated to about 60°C with constant stirring and allowed to react. It was then reduced to a smaller volume and allowed to stand for some time until a purple-coloured solid gradually separated out. The solid complex thus obtained was then filtered and recrystallized from an ethanol–water mixture.

Formation of the complex was ascertained by studying its UV absorption and IR spectra. The IR spectrum of pure DHA indicates a band at $3350\ cm^{-1}$ which is usually attributed to the presence of a strong intramolecular hydrogen bonding that occurs between a carbonyl group and an –OH group [57]. There are also sharp bands at $1190\ cm^{-1}$ and $1280\ cm^{-1}$ which are attributed to the O–H deformation and C–O stretching combinations due to the presence of the phenolic-OH functional group. The bands obtained at $1450\ cm^{-1}$ and $1580\ cm^{-1}$ may be assigned to the interactions of the keto group with the neighbouring –OH on the C_1 atom. The peak at $1665\ cm^{-1}$ is characteristic of the carbonyl group (C=O) stretching in quinones (with both carbonyl groups in the same ring) [57]. In the Cu(II)–DHA complex the band in the $3350\ cm^{-1}$ region flattened due to the absence of interaction of the phenolic –OH at C_1 with the carbonyl group, indicating the introduction of the metal ion. At the same time the appearance of a peak at about $1530\ cm^{-1}$ indicates the formation of a metal chelate with participation of one of the carbonyl groups. Thus the IR spectrum of the complex indicates that metal–DHA complex is formed with the Cu^{2+} coordinated by the carbonyl group and the phenolate anion at the C_1 carbon atom. The appearance of a new band at $830\ cm^{-1}$ in the IR spectrum of the complex which was not present in the IR spectrum of DHA suggests the formation of an octahedral Cu(II)–DHA complex.

The Ni(II)–DHA complex was also prepared by a very similar method as has been described for Cu(II). The solid was isolated from an aqueous solution and recrystallized from ethanol–water mixtures. In a similar solution the formation of a Ni(II)–DHA complex was ascertained by comparing its IR spectrum with that of the free ligand.

The molecular formulae of the complexes prepared were determined from their elemental analyses and it was found that both Cu(II) and Ni(II) formed complexes which can be represented as $[Cu(LH)_3]^-$ and $[Ni(LH)_3]^-$ respectively.

4.4. Effect of the compounds on the superoxide formation by NADH dehydrogenase

It has been pointed out that the cardiotoxicity [14–19] induced by the anthraquinone anticancer drugs is related to the formation of reduced oxygen radicals such as superoxide radical anion [20–24] and other oxygen radical species by enzymatic reduction processes. We have tested the ability of these complexes to be reduced by NADH through NADH dehydrogenase. For this purpose the formation of superoxide anion radical in the presence of the compounds was followed by measuring the cytochrome c reduction inhibited by SOD. The results are shown in Fig. 6. It is evident from this figure that with an increase in the concentration of DHA, the yield of O_2^- increased, indicating that DHA catalyzes the flow of electrons from NADH to molecular oxygen through NADH dehydrogenase. However, when the ligand is complexed with Cu(II) and with Ni(II), the formation of O_2^- is greatly reduced. In fact the Cu(II) complex is more effective in comparison to the Ni(II) complex in reducing the formation of O_2^-. Thus the reduction in car-
Fig. 6. Effect of DHA and complexes of DHA on superoxide formation by NADH dehydrogenase. Superoxide formation was determined spectrophotometrically by the rate of superoxide dismutase–inhibitable cytochrome c reduction. Reaction mixture composition was 0.05 M Hepes buffer (pH 7.4), 80.5 µM cytochrome c, 157.5 µM NADH, 3 U l^{-1} NADH dehydrogenase, 0 or 39.2 µg ml^{-1} SOD and the indicated amount of compound. ($\triangle$, DHA; $\square$, Ni(II)–DHA; $\bigcirc$, Cu(II)–DHA.)

diotoxicity would be greater with the Cu(II) complex than with the Ni(II) complex.

As already mentioned the formation of superoxide (O_2^-) in such enzymatic reactions occurs when the semiquinones are oxidized by molecular oxygen (O_2). As a result of complexation the carbonyl at C_9 of DHA is engaged in coordinating the metal ions Cu(II) and Ni(II) in their respective complexes. Consequently one of the quinone carbonyls in DHA is unable to form semiquinone any more. This therefore decreases the chances of formation of superoxide (O_2^-) to a considerable extent in the case of the complexes. However, semiquinones may form through the reduction of C_{10} carbonyl. Due to the presence of a metal ion in the complex an electron will be transferred from the semiquinone centre to the metal ion in the complex which will therefore decrease the ability of the semiquinone to interact with molecular oxygen (O_2). Thus there is observed an overall decrease in the superoxide (O_2^-) formation in the case of the complexes in comparison to free DHA. That the Cu(II) complex is more effective in reducing the formation of O_2^- over the Ni(II) complex can be attributed to the higher redox potential of Cu(II) over that of Ni(II). It can be concluded from the above observations that the complexes would be less cardiotoxic than the parent drug and could be safely used for cancer therapy.

The use of chlorophenol red for the selective determination of chlorine dioxide in drinking water

Deborah L. Sweetin, Elizabeth Sullivan, Gilbert Gordon*

Hughes Laboratories, Miami University, Oxford, OH 45056, USA

Abstract

In recent years, the use of chlorine dioxide as an alternative disinfectant for drinking water has become increasingly attractive. As a result, an accurate method for the determination of mg l^{-1} concentrations of chlorine dioxide is needed. Improvements to chlorophenol red (CPR) spectrophotometry result in a selective method for ClO_2 with few interferences. CPR selectively reacts with $0.1–1.9$ mg l^{-1} ClO_2 at pH 7, yielding a linear response (0.9994) with a limit of detection of 0.12 mg l^{-1} ClO_2. Several species, ClO_2^-, ClO_3^-, NH_2Cl, and free available chlorine (FAC), were studied as potential interferents using this method. There was found to be less than 2% interference due to 1.38 mg l^{-1} ClO_2^-, 9.87 mg l^{-1} ClO_3^-, and 5.31 mg l^{-1} NH_2Cl. The interference from up to 1.19 mg l^{-1} FAC was $\leqslant 3.7\%$ and could be further reduced by the addition of oxalic acid, sodium cyclamate or thioacetamide.

*Keywords:*Chlorine dioxide; Chlorophenol red; Drinking water

1. Introduction

The primary goal of water disinfection is to remove or inactivate pathogens that exist in our water supply. At present, chlorine is the most widely used chemical for disinfection of water and wastewater in the United States. However, it was reported in 1974 that chlorination of drinking water [1] often results in the formation of trihalomethanes (THMs). THMs [2] are known carcinogens, and in order to comply with the maximum contaminant level for total THM content, many water utilities are switching to alternative oxidants [3] for water disinfection.

In recent years, the use of chlorine dioxide as an alternative disinfectant for drinking water has become increasingly attractive. In addition to removing some of the THM precursors [4,5] from drinking water, the use of chlorine dioxide does not result in the formation of THMs. Because there are some health effects [6] associated with chlorine dioxide and its inorganic byproducts, chlorite and chlorate ions, accurate methods for the determination of these species are required.

There are very few specific and accurate colorimetric methods [7] available for the determination of chlorine dioxide. In 1978, Wheeler et al. [8] developed titrimetric and spectrophotometric procedures for the determination of chlorine dioxide, based on the oxidation of chlorophenol red (CPR). Both procedures were carried out at pH 7.0, and the titrimetric procedure required a com-

*Corresponding author. Fax: (513) 529-5715.

plex standardization procedure for CPR. The authors reported no interferences due to OCl^-, ClO_2^-, ClO_3^-, Fe^{3+}, MnO_4^- or CrO_4^{2-} in the ClO_2 determination. This method is suggested for a 0.05–2.5 mg l^{-1} ClO_2 concentration range.

Harp et al. [9] developed improvements to the CPR spectrophotometric method. A pH 5.2 citrate buffer and a pH 10 2-amino-2-methyl-1-propanol buffer were used in this procedure, which was developed for three concentration ranges of chlorine dioxide: 0–1.0 mg l^{-1}, 0–0.2 mg l^{-1}, and 0–0.1 mg l^{-1}.

In 1985, Fletcher and Hemmings [10] reported additional improvements to the CPR spectrophotometric method, carried out using a pH 7.0 phosphate buffer. The authors reported no interferences from ClO_2^-, ClO_3^-, NH_2Cl, $NHCl_2$ or NO_2^-. However, FAC was found to react with CPR at FAC concentrations as low as 0.5 mg l^{-1}. The FAC interference was removed by the addition of sodium cyclamate and thioacetamide to the sample. This method is recommended by the authors for ClO_2 concentrations of up to 0.4 mg l^{-1}.

As a follow up to the previously reported results, we carried out preliminary experiments in order to improve the CPR method. Initially, the standardization procedure for the CPR titrimetric method was studied, requiring acidification of CPR with concentrated sulfuric acid prior to titration of the solution with 0.01 N potassium dichromate. Because this reaction is slow [8], the titration was carried out at 100°C. The stoichiometry of the $K_2Cr_2O_7$–CPR reaction was found to be 2:1. Because the standardization procedure is complex, the spectrophotometric method was studied. The molar absorptivity of CPR is 1.51×10^4 M^{-1} cm^{-1} at 574 nm. In this work, experiments were carried out in order to improve the analytical characteristics of the CPR spectrophotometric method and to determine the extent of interferences from selected species.

2. Experimental

All of the solutions were prepared using deionized triply-distilled water. Three different CPR

reagents were studied: MC/B indicator grade (3.40×10^{-4} M), Aldrich indicator grade (3.54×10^{-4} M), and Aldrich water soluble, 70% dye content (2.51×10^{-4} M–2.67×10^{-4} M). Sodium chlorite from Eastman Kodak was triply recrystallized [11,12] and the purity was greater than 99%. FAC (35.78 mg l^{-1} Cl_2) and NH_2Cl (48.02 mg l^{-1} Cl_2) were prepared [8] and delivered directly into the sample cell via 50.00 ml burets. The N,N-diethyl-p-phenylenediamine (DPD) titrimetric method [13] was used in order to determine the concentrations of the FAC and NH_2Cl solutions.

Chlorine dioxide was prepared [14] with a laboratory scale generator. Owing to its volatility, chlorine dioxide was added directly to the pH 7.3 buffer in the sample cell using a Metrohm Herisau E535 Autoburet and placing the tip of the titrator below the surface of the solution in the cell. The resulting stock solution was kept in a brown bottle in ice in order to minimize any loss of chlorine dioxide over time. Its concentration was calculated from its absorbance using a molar absorptivity [15] of 1250 M^{-1} cm^{-1} at 360 nm.

The CPR species at different pH values are shown in Fig. 1. Because the spectrophotometric method is based on the absorbance of the red species at 574 nm, it was necessary to keep the reaction conditions at pH 7 or higher to ensure the presence of only one CPR species in the solution. Therefore, in this work a 1 M, pH 7.3 phosphate buffer was used in order to maintain a stable pH between 7.0 and 7.5. The buffer concentration at the time of the CPR–ClO_2 reaction was 0.06–0.22 M. This was shown to be high enough to minimize any effects of variations due to water hardness and the like.
Fig. 1. CPR species [8] at different pH values.

Table 1
Comparison of absorbance values at pH 7.3–7.5 for different CPR reagents without chlorine dioxide in solution

CPR reagent	CPR concentration (M)	Absorbance ($\lambda = 574$ nm)
Indicator, MC/B	1.26×10^{-5}	0.0509
Indicator, Aldrich	1.31×10^{-5}	0.2370
Water Soluble, Aldrich	9.30×10^{-6}	1.557

An HP8450A UV/visible spectrophotometer was used to measure the absorbances of the solutions. A 3.00 cm fused-silica cell of 9.048 ± 0.007 ml volume was used. All solutions were delivered directly into the sample cell. The absorbances for the solutions in the CPR method were measured at the maximum wavelength of 574 nm.

3. Results and discussion

3.1. CPR reagent quality

In order to determine if the quality and/or source of the CPR reagent are factors in this method, the absorbances of the diluted CPR solutions (pH 7.3–7.5) were measured; the results are shown in Table 1. Although the concentration of the water soluble reagent solution was less than those of the indicator grade reagent solutions, the former has a higher absorbance value.

The higher absorbance value for the water soluble reagent solution may be attributed to the greater solubility of CPR in the solution or to a higher purity of CPR in the reagent. Since the water soluble CPR reagent has the highest absorbance value without chlorine dioxide in the solution and the CPR method is based on the decrease in absorbance of the CPR indicator solution when CPR reacts with chlorine dioxide, the water soluble CPR reagent was used in the optimization and interference studies of the CPR method.

3.2. Optimized CPR method

1 mol of CPR reacted with 2 mol of ClO_2 in basic solution to form a colorless product. In the absence

of sufficient CPR, the absorbance of the CPR–ClO_2 solution increased over time. In other words, less of an overall absorbance change occurred than expected from competitive side-reactions. Therefore, the concentration of CPR must be kept in excess. This effect is reflected in the %SD column of the results shown in Table 2.

When the concentration of CPR was greater than that of chlorine dioxide (0.23 mg l^{-1}), the absorbance change over time was only 0.4%. However, when the ClO_2 concentration (0.92 mg l^{-1}) was greater than that of CPR, the absorbance change was 12.1%. Therefore, it is necessary to have an excess of CPR in solution in order to minimize the errors associated with the determination of the ClO_2 residual by this method.

For the determination of ClO_2, a CPR concentration of 1.18×10^{-5} M was used. The pH 7.3 buffer concentration was 0.22 M in order to maintain a constant pH for all of the solutions studied, and the CPR absorbances were measured.

Typical absorbance values for the CPR–chlorine dioxide reaction with a 0.13–1.94 mg l^{-1} ClO_2 concentration range are depicted in Fig. 2. A plot of absorbance change versus chlorine dioxide concentration (mg l^{-1}) yields a linear response ($R = 0.9994$) with a slope of 0.7899 and a y-intercept of -3.119×10^{-2}. This results in an LOD [13] of 0.12 mg l^{-1} ClO_2.

Interferences

Experiments were carried out in order to determine if chlorite ions, chlorate ions, monochloramine, and FAC react directly with CPR, and if these species interfere with the determination of the chlorine dioxide concentration.

Table 2
Comparison of absorbance changes over 11 min for 11 samples with decreasing concentration ratios of CPR to ClO_2 at pH 7.3–7.5

ClO_2 (M)	CPR (M)	Average absorbance	%SD[a]
3.425×10^{-6}	4.15×10^{-6}	1.940 ± 0.008	0.4
1.023×10^{-5}	4.15×10^{-6}	0.635 ± 0.017	2.7

[a]Standard deviation.
Fig. 2. Plot of CPR–ClO_2 absorbance data.

Fig. 3. Absorbance spectra of ClO_2, ClO_2^-, and ClO_2–ClO_2^- solutions without CPR.

Because the chlorite ion is a byproduct of ClO_2 decomposition, it will almost certainly be present in ClO_2 samples. The direct reaction of chlorite ions with CPR was studied by mixing a 41.4 mg l^{-1} chlorite ion solution with CPR. The absorbance change was 0.011, which is only a 0.5% difference from the blank absorbance value (CPR only).

The interference of chlorite ions in a solution of ClO_2 was also studied. Table 3 shows the results obtained for various concentrations of chlorite ions with 1.03 mg l^{-1} chlorine dioxide in solution. When the chlorite ion concentration is equivalent to or less than the chlorine dioxide concentration, the percentage difference is $\leqslant 2.0\%$ which is an acceptable level of error. However, as the chlorite ion concentration is increased, the percentage difference also increases.

Because the absorbance increases with increasing chlorite ion concentration and, as a result, the

change in absorbance is negative, it appears that the concentration of chlorine dioxide is less than that originally added to the CPR solution. However, when both chlorite ions (41.44 mg l^{-1}) and chlorine dioxide (1.03 mg l^{-1}) are present in solution without CPR, there is no decrease in the ClO_2 absorbance at 360 nm. This is shown in the absorbance spectra in Fig. 3. Therefore, the ClO_2 concentration in the CPR solution is unchanged.

The results obtained in Table 3 and shown in Fig. 3 can be attributed to the formation [16] of a $ClO_2 \cdot ClO_2^-$ complex. When the chlorite ion concentration is greater than that of ClO_2, a significant amount of $ClO_2 \cdot ClO_2^-$ complex is formed. The formation of this stable complex under pH 7 conditions was observed by Gordon and Emmenegger in 1966 [16], and is reported in considerably more detail by Crawford [17]. When the $ClO_2 \cdot ClO_2^-$ complex is in solution, the stoichiometry of the ClO_2–CPR reaction appears to change.

Based on the results obtained in this work, it can be concluded that chlorite ions do not interfere in the CPR method as long as the chlorite ion concentration is equivalent to or less than the chlorine dioxide concentration. However, at high concentrations, chlorite ions are potential interferents.

The direct reaction of chlorate ions with CPR was studied by mixing a 9.87 mg l^{-1} chlorate ion

Table 3
Chlorite ion interference in the CPR method

ClO_2 (mg l^{-1})	ClO_2^- (mg l^{-1})	Average absorbance	Change in absorbance	% difference

0.99	0.40	1.658 ± 0.007	0.056	3.3
0.99	1.19	1.650 ± 0.030	0.064	3.7
0.99	4.75	1.578 ± 0.063	0.136	7.9
0.99	9.89	1.561 ± 0.052	0.153	8.9

solution with CPR. The absorbance change was −0.014 which is only a 0.7% difference from the blank absorbance value (CPR only). At chlorate ion concentrations of up to 49.33 mg l^{-1} with 1.03 mg l^{-1} ClO_2, the percentage difference is 1.4–2.4%. Therefore, it can be concluded that chlorate ions do not significantly interfere in the CPR method.

Monochloramine was also studied as a potential interferent in the CPR method. A 5.31 mg l^{-1} Cl$_2$ solution of monochloramine was mixed with CPR in order to study the direct reaction of NH_2Cl with CPR. The absorbance change was −0.005 which is only a 0.2% difference from the blank absorbance value (CPR only).

The interference of monochloramine in a solution of chlorine dioxide was studied for monochloramine solutions of 5.31 mg l^{-1} Cl$_2$ and 10.61 mg l^{-1} Cl$_2$ concentrations with 0.99 mg l^{-1} ClO_2 in solution. At monochloramine concentrations of up to 10.61 mg l^{-1} Cl$_2$, the percentage difference is 0.3–0.5%. Therefore, it can be concluded that monochloramine does not interfere in the determination of chlorine dioxide by the CPR method.

Fletcher and Hemmings [10] reported that FAC was an interferent in the CPR method. As a result, experiments were carried out in order to determine the extent of FAC interference. The direct reaction of FAC with CPR was investigated for concentrations of FAC ranging from 0.40 to 19.77 mg l^{-1} Cl$_2$, and the results are shown in Table 4.

As the concentration of FAC is increased the change in absorbance also increases, reflecting the direct reaction of FAC with CPR. At low FAC concentrations (0.40–1.19 mg l^{-1} Cl$_2$), the percentage difference is 0.5–2.4%, there being a minimal degree of reaction between FAC and CPR. However, as the FAC concentration is increased, the reaction between FAC and CPR becomes significant.

The interference of FAC in a solution of chlorine dioxide was also studied. Table 4 shows the results obtained for various concentrations of FAC with 0.99 mg l^{-1} ClO_2 in solution, all of which exhibit interference in chlorine dioxide determination. The extent of this interference increases with increasing FAC concentration. However, at FAC concentrations of 0.40 mg l^{-1} Cl$_2$ and 1.19 mg l^{-1} Cl$_2$, the percentage differences are only 3.3% and 3.7%, respectively. These errors may be acceptable in situations in which only an estimation of the chlorine dioxide residual concentration is needed, rather than an exact determination.

In order to eliminate FAC interference in this method, oxalic acid was studied as a masking agent for FAC. The concentration of oxalic acid was 3.5×10^{-3} M in the sample, and it was allowed to react with the FAC–ClO_2 solution for 10 min prior to the addition of the pH 7 buffer and CPR reagent. When 1.19 mg l^{-1} Cl$_2$ and 4.75 mg l^{-1} Cl$_2$ from the FAC solution was added to a 0.99 mg l^{-1} ClO_2 solution along with oxalic acid,

the error in the CPR method was less than 1.3–1.5%.

4. Conclusions

Improvements to the CPR method for the accurate and specific determination of chlorine dioxide are presented. The use of water soluble CPR indicator solution with a stock concentration of 2.1×10^{-4} M is recommended. In addition, the pH of the reaction should be maintained between 7.0 and 7.5 using a high-capacity buffer.

All reagents should be added directly to a 3.00 cm cell and a blank absorbance of a diluted, buffered CPR solution measured. The procedure developed for this method is as follows:

(1) add 1.0 ml of a pH 7.3 buffer (1 M) to a 3.00 cm cell;

(2) add sample or water;

(3) add 0.5 ml of a 2.1×10^{-4} M CPR solution;

(4) dilute to the cell volume and measure the absorbance at 574 nm.

The CPR method for the selective and accurate determination of chlorine dioxide is linear in the 0.13–1.94 mg 1^{-1} ClO_2 concentration range with an LOD of 0.12 mg 1^{-1}. The interferences from $\leqslant 10$ mg 1^{-1} chlorate ions and $\leqslant 5$ mg 1^{-1} monochloramine are minimal. In addition, when the concentration of chlorite ions is less than or equivalent to that of chlorine dioxide, the interference is less than 2.0%. When the FAC concentration is $\leqslant 1.2$ mg 1^{-1} Cl_2, the interference is only 3.7%. In order to further reduce the FAC interference, oxalic acid, sodium cyclamate or thioacetamide can be used as an effective chemical mask. The CPR method for the determination of chlorine dioxide warrants further study, and automation of this method is recommended.

Abstract

Regenerated silk fibroin prepared from waste silk was employed as immobilization matrix for peroxidase and the structures of the blend membranes of regenerated silk fibroin and peroxidase were first investigated with IR and scanning electron microscopy. There was intermolecular interaction between peroxidase and regenerated silk fibroin in the immiscible state. Cyclic voltammetry and constant applied potential measurement showed that Methylene Green efficiently mediated electron transfer from oxidized horseradish peroxidase in regenerated silk fibroin membrane to a glassy carbon electrode. A sensor coupling immobilized peroxidase with Methylene Green responded rapidly to low H_2O_2 concentration and achieved 95% of the steady-state current in less than 25 s with a detection limit of 1.0×10^{-7} M H_2O_2. The sensor was stable in continuous operation, indicating that peroxidase was entrapped in regenerated silk fibroin membrane and did not freely diffuse away from the sensor surface into solutions.

1. Introduction

Horseradish peroxidase (HRP) can catalyze four kinds of reactions: peroxidation, oxidation, dismutation and hydroxylation [1]. Peroxidation is the predominant reaction in the presence of a hydrogen donor such as phenols, aromatic amines and certain other heterocyclic compounds. The enzymatic reaction of horseradish peroxidase involves compound I (HRP-I) containing Fe(IV) and a porphyrin-radical cation, and compound II (HRP-II) with one Fe(IV) in the following sequential reaction [2–6].

$$HRP + H_2O_2 \longrightarrow HRP\text{-}I + H_2O \qquad (1)$$

$$HRP\text{-}I + AH \longrightarrow HRP\text{-}II + A \qquad (2)$$

$$HRP\text{-}II + AH \longrightarrow HRP + A^{\bullet} \qquad (3)$$
where AH represents the hydrogen donor and $A^{\bullet}$ the free radical formed during the reaction. The radicals are bound to the enzyme throughout the enzymatic process and dimerize before they are

* Corresponding author.

reduced at a certain potential. The mediatorless activation of electroreduction of H_2O_2 in the presence of horseradish peroxidase at carbon black [6], spectrographic graphite [7], non-platinized activated carbon electrodes [8] and pyrolytic graphite [9] has been reported. Entrapment of horseradish peroxidase in carbon paste [10] or in polypyrrole [9] has been investigated. However, they are insensitive to submicromolar H_2O_2. Amperometric coupling of peroxidase with mediators is a highly sensitive detection method for H_2O_2, in which peroxidases provide electrochemical H_2O_2 sensors with a detection limit as low as 10^{-8}–10^{-7} M by employing a dissolved electron mediator [11] such as (2-aminoethyl)ferrocene [12], $[Ru(NH_3)_5py]^{2+}$ [12], o-phenylenediamine [13], ferrocene [14], or tetrathiafulvalene [15].

Although silk fibroin obtained directly from silk larvae has been applied to immobilization of peroxidase [16], it is only available several times a year. In this paper, we employed regenerated silk fibroin prepared from waste silk to entrap peroxidase and first investigated the structures of the blend membrane of regenerated silk fibroin and peroxidase. We have shown for the first time the feasibility of Methylene Green mediating electron transfer between horseradish peroxidase in regenerated silk fibroin membrane and a glassy carbon electrode. Sensor stability and the dependence of the steady-state current on pH, temperature of the supporting electrolyte and applied potential were investigated.

2. Experimental

2.1. Materials

Peroxidase from horseradish (POD) (EC 1.11.1.7, type VI) was obtained from Sigma and Methylene Green (MG) was purchased from Aldrich. Hydrogen peroxide (30% w/v solution) was purchased from Shanghai Chemical Reagent Company. The concentration of more dilute peroxide solutions prepared from this material was determined by titration with cerium(IV) to a ferroin endpoint [17]. All other chemicals were analytical grade. All the solutions were prepared with doubly distilled water.

Silk fibroin solution

The waste silk of a silk mill was degummed with 0.5% $NaHCO_3$ solution at 100°C for 30 min and then washed with distilled water. The degummed silk was dissolved in 9.3 M LiBr aqueous solution. After dialysis against distilled water for 3 days, the solution was purified by filtering and the regenerated silk fibroin solution was collected.

Membranes were cast by using the regenerated silk fibroin solution or the mixture solution of the given weight of the silk fibroin and horseradish peroxidase on glass plates at room temperature in air.

2.2. Apparatus

Cyclic voltammetry and amperometric measurements were carried out with FDH 3204 and FDH 3206 cyclic voltammetry apparatus (Scientific Equipment Company of Fudan University, China) in line with a type 3086 x–y recorder (Tokyo, Japan). All experiments were carried out in a thermostatted, stirred electrochemical 5 ml cell at $20.0 \pm 0.5°C$, which is equipped with a H_2O_2 sensor as working electrode, a saturated calomel reference electrode and a platinum wire auxiliary electrode. All experimental solutions were thoroughly deoxygenated by bubbling nitrogen through the solution for at least 10 min. In the constant potential experiments, successive additions of stock H_2O_2 solution in the buffer were made and the current–time data were recorded after a constant residual current had been established. Changes in the measured reduction current were recorded as a function of time, following the addition of H_2O_2. The sensor response was measured as the differences between total and residual current.

IR spectra were recorded using an FT-IR 5DX spectrometer (Nicolet) at room temperature. The spectra of the membranes in the dry state were obtained by the reflection method and those of the peroxidase KBr disc were run by the transmission method.

Scanning electron micrographs were recorded on a Hitachi S-520 instrument operating at 20.0 kV.

2.3. Construction of H_2O_2 sensor

Glassy carbon electrodes (4 mm in diameter) were polished to a mirror-like finish with 0.3, 0.1 and 0.05 μm Al_2O_3 paste, rinsed thoroughly in deionized water between each polishing step sonicated in 1:1 nitric acid, acetone and doubly distilled water successively and dried in air before use. 20 mg peroxidase in 0.25 ml regenerated silk fibroin was completely mixed. Aliquots (8 μl) of the mixture were deposited on a glassy carbon electrode and allowed to dry in ambient conditions for 20 h. A 5 μl aliquot of 75% ethanol was syringed onto the sensor and allowed to dry in air for about 5 min. The sensor was kept in air at 4°C in a refrigerator between the measurements.

2.4. Calculation of Michaelis–Menten constant

The apparent Michaelis–Menten constant K_M^{app} can be obtained from the electrochemical Eadie–Hofstee form of the Michaelis–Menten equation [18]

$$j_{ss} = j_{max} - K_M^{app}(j_{ss}/C)$$

where j_{ss} is the steady-state catalytic current, j_{max} refers to the maximum current measured under saturating substrate conditions, C is the H_2O_2 concentration and K_M^{app} represents the apparent Michaelis–Menten constant of the system as a whole, not that of peroxidase itself, and provides a measure of the H_2O_2 concentration range over which the response of the sensor is approximately linear.

3. Results and discussion

3.1. IR spectra of membranes

Without ethanol treatment, the regenerated silk fibroin in the membrane exists in silk structure 1, because its absorption bands are $1706\ cm^{-1}$ (amide I), $1571\ cm^{-1}$ (amide II) and $1293\ cm^{-1}$ (amide III). With ethanol treatment, the regenerated silk fibroin in the membrane ex-

ists in a mixed structure of silk I and silk II because the absorption bands are split into two groups. One is the same as that characteristic of silk structure 1 and the other is $1687\ cm^{-1}$ (amide I), $1559\ cm^{-1}$ (amide II), $1275\ cm^{-1}$ (amide III), characteristic of silk structure II. This indicates that part of silk structure I is transferred into silk structure II after ethanol treatment. Before ethanol treatment the regenerated silk fibroin in the blend membrane containing peroxidase shows a red shift of absorption bands to 1660^{-1} (amide I), $1537\ cm^{-1}$ (amide II), $1240\ cm^{-1}$ (amide III), attributable to a characteristic of silk structure 1. After ethanol treatment, the regenerated silk fibroin in the blend membrane containing peroxidase also possesses two kinds of structure: silk structure 1, as it has absorption bands at $1668\ cm^{-1}$ (amide I), $1550\ cm^{-1}$ (amide II) and $1240\ cm^{-1}$ (amide III) and silk structure II as it has absorption bands at $1625\ cm^{-1}$ (amide I), $1531\ cm^{-1}$ (amide II) and $1265\ cm^{-1}$ (amide III). In both cases of the blend membrane, the corresponding absorption bands of regenerated silk fibroin are of smaller wavenumbers than those in pure regenerated silk fibroin membrane. This is attributed to intermolecular interaction between peroxidase and regenerated silk fibroin. Immobilization of peroxidase in regenerated silk fibroin is based on its conformation transformation from silk structure I to silk structure II resulting from ethanol treatment.

3.2. SEM of the blend membrane

SEM (Fig. 1) indicates that the blend membrane containing 10% peroxidase has a sea island-like structure which is attributed to the microphase segregation between both macromolecules in the blend membrane. The bright islands are peroxidase domains distributed randomly (Fig. 1(a)). Fig. 1(b) shows that the enzyme in the blend membrane has relatively free microenvironments because there are many empty spaces in the enzyme domains and that the enzyme can change its conformation to the favourable state in which its activity is maintained.

3.3. Cyclic voltammetry

Fig. 2 depicts typical cyclic voltammograms of Methylene Green in 0.1 M phosphate buffer (pH 7.0) containing 0.25 mM Methylene Green. In the absence of H_2O_2, the enzyme contributes no response and only Methylene Green generated voltammograms complying with a reversible electron redox agent because a linear plot of peak current vs. square root of scan rate $(i_p/V^{1/2})$ at constant concentration of Methylene Green was observed for the oxidation and reduction of Methylene Green in aqueous solution under diffusion control.

(a)
(b)

Fig. 1. Scanning electron micrograph of the regenerated silk fibroin membrane surface containing 10% peroxidase.
Fig. 2. Cyclic voltammograms of the H_2O_2 sensor at various scan rates (from inner curve to outer one): 15, 25, 45, 65, 85, 105, 125, 145, 165 mV s^{-1} in 0.1 M phosphate buffer containing 0.3 mM Methylene Green.

3.4. Electrocatalytic reduction of H_2O_2 at the sensor

No electrocatalytic reduction current is found at a glassy carbon electrode when H_2O_2 is added to the phosphate buffer containing 0.25 mM Methylene Green. Fig. 3 shows characteristic cyclic voltammetric results for the H_2O_2 sensor. In the absence of H_2O_2, the peroxidase yields no response and only typical oxidation and reduction peaks for Methylene Green in solution are ob-

served in Fig. 3 (curve a). Adding H_2O_2 to the cell produces a dramatic change in the cyclic voltammogram with an increase in cathodic current and a concomitant decrease in anodic current (Fig. 3 (curve b)). At slow scan speeds (<1 mV^{-1}) the anodic peak disappears completely and the cathodic peak appears as a plateau. Comparison of the voltammograms with and without H_2O_2 demonstrates that Methylene Green can effectively shuttle electrons between peroxidase in regenerated silk fibroin membrane and a glassy carbon electrode. The peroxidase (POD) reduces hydrogen peroxide to water:

$$H_2O_2 + POD(red) \longrightarrow H_2O + POD(ox)$$
Fig. 3. Cyclic voltammograms of the H_2O_2 sensor at a scan rate of 15 mV s^{-1} in 0.1 M phosphate buffer (pH 7.0) containing 0.3 mM Methylene Green in absence of H_2O_2 (curve a) and presence of 0.5 mM H_2O_2 (curve b).
Fig. 4. Amperometric response of the H_2O_2 sensor to successive increase of H_2O_2 of 80 μM in solution containing 0.3 mM Methylene Green at an applied potential of -0.20 V.

and then oxidized peroxidase converts the Methylene Green (MGH) to MG$^+$:

$$POD(ox) + MGH \longrightarrow POD(red) + MG^+ + H^+$$
Finally MG$^+$ is reduced at the sensor, resulting in cathodic current:

$$MG^+ + H^+ + 2e \longrightarrow MGH$$
3.5. Steady-state amperometric response of the sensor to H_2O_2

Fig. 4 displays calibration data for H_2O_2 at the sensor. A well-defined and fast amperometric response is observed at -0.20 V with successive injections of H_2O_2 and the time required to reach 95% of maximum response is less than 25 s. Fig. 5 shows the calibration plot of the sensor response. The linear response is observed up to 4.0 mM. An extremely low detection limit of 1.0×10^{-7} M H_2O_2, at a signal-to-noise ratio of 3, can be estimated.
Fig. 5. Calibration plot for the H_2O_2 sensor. Steady-state current was measured in 0.1 M phosphate buffer (pH 7.0) containing 0.3 mM Methylene Green at 20°C.
3.6. Effect of applied potential on sensitivity of the sensor

The steady-state response to 0.5 mM H_2O_2 was measured at several applied potential values in the buffer containing 0.25 mM MG (Fig. 6). The cathodic current increased with decreasing positive applied potential and reached limiting values at approximately -0.35 V vs. SCE, which indicates that the sensitivity and Michaelis–Mentens con-
Fig. 6. Effect of applied potential on the response of sensor to H_2O_2.
Fig. 7. The influence of the amount of Methylene Green on sensitivity of the sensor in the presence of 0.5 mM H_2O_2.

stant are dependent on the working potential. Michaelis–Mentens constants at -0.15, -0.20, -0.25 and -0.30 V are 4.6, 6.1, 7.2 and 8.4 mM H_2O_2 respectively. The increased sensitivity with applied potential can be assigned to an increased driving force for the fast reduction of POD (ox).

3.7. Influence of concentration of Methylene Green on sensitivity of the sensor

The effect of amount of mediator on the response of the sensor to H_2O_2 is shown in Fig. 7.

The reduction current increases substantially with increased amount of Methylene Green in solution from 0.1 to 0.3 mM. Further increasing the mediator concentration results in a decrease in the sensor response. Moreover, the higher concentration of Methylene Green causes an increase in background current.

3.8. Effect of pH and temperature on the H_2O_2 sensor

The pH dependence of the sensor was as shown in Fig. 8, exhibiting an optimum between pH 6.0 and 6.5, which indicates that the pH profile is controlled by the enzymatic activity.

The effect of temperature on the sensor has been examined between 15 and 60°C. The immobilized enzyme loses about 50% of its activity at

50°C after 3 h operation. The experiment shows that the current response increases with increasing temperature between 15 and 55°C, and that further increase in temperature gives rise to a decrease of the response current because of the partial denaturation of the enzyme.

3.9. Studies of interference

Several substances have been examined as possible interferents for the hydrogen peroxide sensor. Analyses of phosphate buffers containing 0.5 mM H_2O_2, to which the possible interferents are added, were executed. L-Tyrosine (0.2 mM), L-lactate (0.5 mM), glucose (5.0 mM), uric acid (0.2 mM), galactose (5.0 mM), L-leucine (0.2 mM), L-cysine (0.2 mM), L-tryptophan (0.2 mM), L-cysteine (0.2 mM), L-aspartic acid (0.2 mM), L-histidine (0.2 mM), and L-glutamic acid (0.2 mM) do not cause any observable interference to the determination of H_2O_2. However, L-proline (0.5 mM) and ascorbic acid (0.5 mM) decrease response currents by 0.8% and 27.5% of the initial values respectively. The decrease in response current results from consumption of H_2O_2 involved in oxidation of ascorbic acid because the sensor displays no response to adding ascorbic acid (5 mM) to phosphate buffer without H_2O_2.

Fig. 9. Stability of the H_2O_2 sensor under dry storage at 4°C.

3.10. Stability of the sensor

The reproducibility of the current response of the sensor is tested at an H_2O_2 concentration of 0.5 mM and the relative deviation is 1.5% ($n = 9$). The sensor possesses good storage characteristics. The H_2O_2 sensor was stored in air at 4°C when not in use. The response of the sensor decreased about 13% after storing for 2 months (Fig. 9).

4. Conclusion

Entrapment of peroxidase in regenerated silk fibroin offers a useful retention of enzyme and there is intermolecular interaction between regenerated silk fibroin and peroxidase. The enzyme in the membrane surface maintains a relatively free microenvironment. The advantages of the H_2O_2 sensor employing Methylene Green as electron transfer mediator between peroxidase in regenerated silk fibroin membrane and a glassy carbon electrode include high stability and sensitivity of the electrochemical signal. The simple method of sensor construction should be applicable to other enzyme–substrate systems for a variety of practical situations. In addition, we have found that organic mediators such as Meldola Blue, phenazine methosulphate, cresyl fast biolet, Catechol Violet, Methylene Violet, Brilliant Cresyl Blue, Toluidine Blue and Methylene Blue effectively mediate electron transfer between peroxidase and

Fig. 8. Effect of pH on H_2O_2 sensor. Steady-state current measured in the presence of 0.5 mM H_2O_2 in phosphate buffer (pH 7.0) containing 0.3 mM Methylene Green at 20°C.

a glassy carbon electrode. These results will be reported in the future.

Chemiluminescence flow sensor for the determination of ascorbic acid with immobilized reagents

Zhujun Zhang *, Wei Qin

Department of Chemistry, Shaanxi Normal University, Xian 710062, China

Received 26 May 1995; accepted 4 August 1995

Abstract

A novel flow sensor based on chemiluminescence (CL) for the determination of ascorbic acid has been proposed. The analytical reagents, luminol and ferricyanide, were both immobilized on an anion-exchange resin column. The CL signal produced by the reaction between luminol and ferricyanide, which were eluted from the column through sodium phosphate injection, was decreased in the presence of ascorbic acid. The CL emission intensity was linear with ascorbic acid concentration in the range $0.01-0.8$ $\mu g\ ml^{-1}$; the detection limit was 5.5×10^{-3} $\mu g\ ml^{-1}$. The whole process, including sampling and washing, could be completed in 1 min with a relative standard deviation of less than 5%. The sensor could be reused more than 100 times and has been applied successfully to the analysis of ascorbic acid in pills and vegetables.

Keywords: Chemiluminescence; Flow sensor; Ascorbic acid; Immobilized reagents

1. Introduction

Ascorbic acid (vitamin C), found in citrus fruits and vegetable products, is mainly a cure for scurvy, drug poisoning, liver disease, allergic reaction and atherosclerosis. In addition, it is helpful for building up one's resistance to disease. Various methods have been proposed for determination of ascorbic acid, such as titrimetry [1], spectrophotometry [2,3], fluorimetry [4], chromatography [5] and electrochemical detection [6,7] by a manual technique or by flow injection analysis. Each has its advantages and disadvantages [8].

In recent years, biosensors with high selectivity based on an electrode coated with ascorbate oxidase or plant tissue for ascorbic acid determination have appeared especially attractive [9–12]. In these sensors, the consumption of dissolved oxygen takes place in an enzymatic reaction and is detected by an oxygen electrode. However, these sensors still suffer from stability problems.

Chemiluminescence (CL) has been successfully applied to deterine ascorbic acid with excellent sensitivity over a wide linear dynamic range and with the use of simple instrumentation [13–15]. Recently, various CL biosensors have been investigated [16–19]. Most of them are based on immobilized enzymes with dissolved CL reagents

* Corresponding author.

which react with hydrogen peroxide released from the enzymatic reactions to produce a CL light signal. In this paper, a novel CL flow biosensor for ascorbic acid determination is presented. It is based on the inhibition of vitamin C in the CL reaction between luminol and ferricyanide and the CL light decrement is related to the amount of ascorbic acid. The two CL reagents, luminol and ferricyanide, used in this sensor, are both immobilized on Amberlyst A-27 anion-exchange resin. Through injection of a volume of sodium phosphate, the reagents on the anion-exchange resin column are eluted from the resins and in the presence of ascorbic acid the CL reaction is inhibited, by which ascorbic acid can be sensed. Compared with electrodes and other methods, the sensor offers potential advantages of simplicity, rapidity and high sensitivity for ascorbic acid determination.

2. Experimental

2.1. Reagents and ion-exchange resin

All the reagents were of analytical grade; doubly-distilled water was used for the preparation of solutions of all dilutions. A stock solution of ascorbic acid $(1 \times 10^{-2} \text{ g ml}^{-1}$ in water) was stored in the refrigerator. Working standards were prepared daily from the stock solution by appropriate dilution. A 0.25 M luminol solution was prepared by dissolving 44.3 g of luminol in 1 l of 0.5 M NaOH solution. Other solutions were $\text{Na}_3\text{PO}_4 (2 \times 10^{-4}$ M), $\text{K}_3\text{Fe(CN)}_6 (0.2$ g ml^{-1}) and NaOH (0.6 M). Amberlyst A-27 anion-exchange resin (20 + to 50 − mesh) purchased from Rohm and Haas Co. was used for reagent immobilization.

2.2. Preparation of immobilized reagents

Amberlyst A-27 (0.5 g) was stirred with 25 ml of 0.25 M luminol or 0.2 g ml^{-1} potassium ferricyanide for 12 h, then the resin was filtered, washed with doubly-distilled water and dry-stored. The most convenient method to determine the amounts of luminol and ferricyanide immobi-

lized is to measure the losses of these reagents from the immobilization solutions. This was done by UV–Vis absorbance. The concentration was monitored at 360 nm for luminol and at 420 nm for ferricyanide. The amounts of luminol and ferricyanide immobilized were 1.64 mmol g^{-1} and 1.18 mmol g^{-1} resin respectively.

2.3. Apparatus

The flow injection system used in this work is shown in Fig. 1. A peristaltic pump was used to deiver all flow streams at a flow rate of 2 ml min^{-1} on each flow line. PTFE tubing (0.8 mm i.d.) was used between all components in the flow system. The anion-exchange resins containing immobilized luminol (0.06 g) and ferricyanide (0.12 g) were mixed together and packed into a glass column with an internal diameter of 4 mm and total volume of about 0.6 ml, and plugged with glass wool at both ends to prevent the resins from leaking. Sodium phosphate solution (200 µl) was injected by an injection valve. Before reaching a flow cell (200 µl), the streams of luminol, ferricyanide, sodium hydroxide and analyte were combined in mixing tubing (80 mm in length). The light signal produced in the flow cell was detected with an R456 photomultiplier tube (PMT) and recorded with an XWT-204 recorder (Shanghai Dahua Instrument and Meter Plant).

Absorbance monitoring was done using a UV-spectrophotometer Model-752 (Shanghai Third Analytical Instrument Plant).

Table 1
Character of eluants for ascorbic acid determination [a]

Type of CL intensity	Relative CL intensity						
	NaCl	NaAc	NaOH	$NaNO_3$	Na_2SO_4	Na_2CO_3	Na_3PO_4
I	23	16	14	37	55	49	100
II	11	10	10	14	20	18	24
III	12	6	4	23	35	31	76

[a] The concentration of each eluant was 2×10^{-4} M. The relative CL intensity corresponds to the normalized maximum light intensity. (I): CL intensity in the absence of ascoribc acid; (II): CL intensity in the presence of 0.1 μg ml^{-1} ascorbic acid; (III): decreased CL intensity.

2.4. Procedures

Flow lines (a), (b), (c) and (d) were inserted into NaOH solution, eluant solution of sodium phosphate, water carrier and sample solution respectively. The pump was started to wash the whole flow system until a stable baseline was recorded. Then 200 μl of eluant containing 2×10^{-4} M or 8×10^{-4} M sodium phosphate was injected into the carrier stream and luminol and ferricyanide were released quantitatively. The concentration of ascorbic acid was quantified by the CL intensity.

3. Results and discussion

3.1. Influence of eluant

Different amounts of luminol and ferricyanide could be released by anions with different eluting abilities being injected through the resin columns, which had an effect on the CL intensity. The results are shown in Table 1. The eluant sodium phosphate with the highest relative CL intensity (type II) and decreased CL intensity (type III) was chosen for subsequent work.

3.2. Effect of ratio between resins with immobilized luminol and ferricyanide

To examine the influence of the mixing ratio, resins (0.18 g) with different mixing ratios were packed into the glass column. By injection of sodium phosphate at a fixed concentration of 2×10^{-4} M, different amounts of luminol and

ferricyanide were eluted from the resins and caused a CL intensity, which is shown in Table 2. The mixing ratio 1:2 between the amount of luminol resin and that of ferricyanide resin was selected in the present work not only for the relatively high CL intensity but also for the most effective inhibiting effect of ascorbic acid.

3.3. Effect of eluant concentration

The release of luminol and ferricyanide was determined by the concentration of sodium phosphate. Various concentrations of sodium phosphate were injected through the anion-exchange resin column. The immobilized luminol and ferricyanide released were measured by UV–Vis absorbance and by the CL reaction with 2.5×10^{-4}

Table 2
Effect of mixing mass ratio between resins with immobilized luminol and ferricyanide [a]

Mass ratio (luminol:ferricyanide)	Relative CL intensities		Decreased CL intensity
	Blank [b]	Signal [c]	
1:4	84	40	44
1:2	100	24	74
1:1	60	20	40
2:1	18	6	12
4:1	9	3	6

[a] The concentration of each eluant was 2×10^{-4} M. The relative CL intensity corresponds to the normalized maximum light intensity.
[b] CL intensity in the absence of ascorbic acid.
[c] CL intensity in the presence of 0.1 μg ml^{-1} ascorbic acid.
Fig. 2. Effects of eluant concentration on (▲) amount of luminol released ($n = -8$) amount of ferricyanide released ($n = -10$) and (♦) CL intensity in the presence of 0.1 μg ml^{-1} ascorbic acid.

M luminol (pH 12) respectively. The results are shown in Fig. 2. It can be seen that the amounts of luminol and ferricyanide released both increased linearly with the concentration of sodium phasphate injected. Naturally, it can be predicted that increasing the eluant concentration gives an increased CL intensity. This situation is also illustrated in Fig. 2. Considering lifetime and linear range of the sensor (discussed in detail below), 2×10^{-4} M or 8×10^{-4} M sodium phosphate was used for the linear range 0.01–0.1 μg ml^{-1} ascorbic acid respectively.

3.4. Effect of sodium hydroxide concentration

Luminol reacts with ferricyanide to produce CL light in basic solution. Therefore, sodium hydroxide was added in flow line (a) to improve the sensitivity of the sensor. Since the sodium hydroxide concentration versus CL intensity plot shows a maximum for sodium hydroxide levels around 0.6 M, this concentration was used in subsequent experiments (Fig. 3).

3.5. Performance of the sensor for ascorbic acid measurements

Since ascorbic acid is detected as an inhibitor, it is obvious that small amounts of ascorbic acid can be sensed linearly by the CL reaction with small amounts of luminol and ferricyanide, and vice versa. Therefore, the linear range of the sensor is determined by the amounts of luminol and ferricyanide released, and is in turn determined by the eluant concentration. To gain a relatively long lifetime of over 100 times, 2×10^{-4} and 8×10^{-4} M sodium phosphate was chosen for ascorbic acid determination over the range 0.01–0.1 μg ml^{-1} with a correlation coefficient of 0.9991 and over the range 0.1–0.8 μg ml^{-1} with a correlation coefficient of 0.9986 respectively (Fig. 4). At a concentration of >0.8 μg ml^{-1}, the linearity disappears because of smaller amounts of luminol and ferricyanide being released as a result of the eluant concentration used. Increasing the sodium phosphate concentration can widen the linear range of the sensor, but unfortunately may shorten the sensor's lifetime. At a flow rate of 2.0 ml min^{-1}, the determination of ascorbic acid could be performed in 1 min including sampling and washing, giving a throughput of about 60
Fig. 3. Effect of NaOH concentration on CL intensity in the presence of 0.1 μg ml^{-1} ascorbic acid with 2×10^{-4} M Na$_3$PO$_4$ as eluant.
Fig. 4. Relative CL intensity vs. ascorbic acid concentration (type II): ($\blacklozenge$) $n = -2$, ($\blacksquare$) $n = -1$.

times h. The detection limit of the sensor was $5.5 \times 10^{-3}\ \mu g\ ml^{-1}$ (3σ), and the relative standard deviation was less than 5% for $5 \times 10^{-2}\ \mu g\ ml$ ($n = 7$).

3.6. Interferences

Interferences of foreign substances were tested by analysing a standard solution of ascorbic acid ($0.3\ \mu g\ ml^{-1}$). The tolerable concentrations of some interfering inorganic ions and organic compounds are listed in Table 3.

Table 3
Tolerable concentration ratios with respect to ascorbic acid for some interfering species ($< 5\%$ error)

Substance	Tolerable concentration ratio
K^+, Na^+, Cl^-, Br^-, F^-, SO_4^{2-}, HCO_3^-, HPO_4^{2-}, NO_3^-, amylum, acetic acid, tartaric acid, citric acid	> 1000

A polypyrrole-based amperometric ammonia sensor

Ilkka Lähdesmäki, Andrzej Lewenstam, Ari Ivaska*

Laboratory of Analytical Chemistry, Åbo Akademi University, FIN-20500 Turku-Åbo, Finland

Abstract

An ammonia sensor is described in this work. The sensing membrane is a thin layer of oxidized polypyrrole (PPy) on a platinum substrate. This sensor is used as the working electrode in a conventional three-electrode system for amperometric measurement of ammonia in aqueous solutions in the potential range of $+0.2$ to $+0.4$ V (vs. Ag/AgCl). Contact with ammonia causes a current to flow through the electrode. This current is proportional to the concentration of free ammonia in the solution and ammonium ions do not contribute to the measured signal. The signal is due to reduction of PPy by ammonia with subsequent oxidation of PPy by the external voltage source. The sensor is able to detect ammonia reproducibly at the μM level. The main interference is the doping effect of small anions such as Cl^- and NO_3^-, also giving a response on PPy at the mM level. This anionic response can, to a certain degree, be reduced by covering the polymer surface with dodecyl sulfate. The sensor gradually loses its activity when exposed to ammonia concentrations greater than 1 mM. The sensor has been tested by the flow injection analysis technique.

Keywords: Ammonia sensor; Polypyrrole; Conductive polymer; Amperometry; Flow injection analysis

1. Introduction

Gaseous ammonia is known to reduce the oxidized form of the conducting polymer polypyrrole (PPy) [1]. Josowicz and Janata [2] utilized this property to prepare a sensor for gaseous ammonia where oxidized PPy formed the active membrane. They used the conductivity of PPy as a measure of the concentration of ammonia in gaseous samples.

Trojanowicz et al. [3] described an amperomet-

ric ammonia sensor for the determination of dissolved ammonia in aqueous samples, where PPy deposited on platinum is the working electrode in a three-electrode system. They also presented the optimized conditions for preparation of the sensor and for measurement of ammonia. The influence of some common interfering species in clinical samples on the response of the sensor was also studied. The sensor was found to be deactivated in the process of detecting ammonia. In this work, we have further studied and tried to eliminate the interfering effect of common inorganic anions and cations. Sensor preparation and ammonia measurements were carried out under optimized conditions, as given in Ref. [3].

---

2. Experimental

2.1. Chemicals

Pyrrole (Aldrich, 99%) was purified by distillation and stored in a refrigerator under a N_2 or Ar atmosphere. Sodium dodecyl sulfate (NaDS) (Fluka, p.a.), 25% aqueous ammonia solution (Riedel-de Haën, p.a.), and NaCl, NaOH, sodium borate ($Na_2B_4O_7 \cdot 10H_2O$) and NH_4Cl (Merck, p.a.) were all used as received. Distilled deionized water was used to prepare the solutions.

2.2. Instrumentation

Electrochemical polymerization of pyrrole was carried out using a PAR model 273 potentiostat–galvanostat in a single compartment three-electrode electrochemical cell. The working electrode was a Pt electrode (area 0.16 mm^2) and the reference electrode was a Ag/AgCl/3 M KCl electrode. The counter electrode was a graphite electrode.

Amperometric measurements were performed using a BAS model CV-37 potentiostat connected to a three-electrode cell, where both the reference and the counter electrodes were the same as above, but the working electrode was a Pt electrode modified by a PPy film on top of it. The three-electrode cell was used as a detector in a Tecator FIAstar 5010 flow injection analyzer. An ABB Goerz model SE 120 strip chart recorder was used to record the signal given by the detector. Cyclic voltammetric measurements were carried out with either of the potentiostats using a scan rate of 20 mV s^{-1}. Energy dispersive analysis of X-rays (EDAX) was performed with a Leica Cambridge S 360 scanning electron microscope.

2.3. Sensor preparation

Before polymerization of the PPy layer, the Pt electrode was polished with 0.3 μm alumina and rinsed with water and methanol. Polymerization was carried out in a stagnant aqueous solution containing 0.1 M NaCl and 0.1 M pyrrole monomer. The polymerization was performed at a constant potential of +0.80 V for 3 min. The electrolyte solution was deareated by purging with

N_2 for 15 min prior to addition of the monomer, and an inert environment was maintained in the cell during the polymerization by a N_2 atmosphere.

2.4. Amperometric measurements in the flow injection analysis (FIA) system

The PPy ammonia sensor was used as an amperometric detector in an electrochemical wall-jet cell in the flow injection analysis (FIA) system shown in Fig. 1. A sample volume of 100 μl was injected into a water carrier stream, which was then mixed with a stream of borate buffer (pH 9.2) to convert a substantial amount of NH_4^+ in the sample into NH_3 and to keep the $[NH_3]/[NH_4^+]$ ratio constant. The flow rates of the carrier and the buffer were both 1.15 ml min^{-1}. The current was normally measured at +0.30 V, but +0.35 V was also used in some experiments.

2.5. EDAX measurements

PPy samples for EDAX measurements were prepared by polymerizing pyrrole for 10 min on indium–tin oxide (ITO) glass. The procedure of polymerization was as described above. The ITO glass pieces had been cleaned with ethanol and water prior to use. After preparation, the PPy samples were treated as shown in Table 1. The supporting electrolyte in all experiments where the PPy sensor was used at +0.3 V in a NH_3 solution was 0.05 M Na_2SO_4 (i.e. treatment of samples #2 and #4). Likewise, in all these experiments, 5 M H_2SO_4 was used to acidify the solution before switching off the potential in order to avoid reduction of PPy by NH_3 during removal of the electrode from the cell. All samples were then rinsed with water and dried in a flow of N_2 before the EDAX measurements.

2.6. IR measurements

PPy samples for IR measurements were prepared on pieces of ITO glass in the same way as described above for the EDAX measurements. A total of three samples were prepared: one of them was treated by applying +0.30 V to the PPy–
Fig. 1. The FIA system used in the ammonia measurements. C, carrier (deionized water); B, buffer (0.05 M borate, pH 9.2); S, sample injection point; D, wall-jet amperometric detector; P, pump; W, waste. The flow rates of the carrier and the buffer stream were both 1.15 ml min^{-1}. The volume of the injected sample was 100 μl.

ITO electrode in an aqueous 0.15 M solution of NH$_3$ for 15 min, another was soaked in the same solution of NH$_3$ for the same time but at open circuit potential and the third sample was left untreated. A cyclic voltammetric measurement in 0.1 M NaCl was performed to confirm that the first sample, i.e. that treated in ammonia at + 0.30 V, was completely deactivated. After rinsing the samples with water and drying them in N$_2$, the PPy films were peeled off the ITO glass and their transmission spectra were taken using a Bruker IFS66 FT-IR spectrometer.

Table 1
Treatment of PPy by ammonia in different solutions. The EDAX spectra are shown in Fig. 6. The background electrolyte used in experiments #2–4 was 0.05 M Na$_2$SO$_4$

Sample #	Treatment
1	Soaked in water for 15 min
2	Kept at +0.3 V in 0.15 M NH$_3$ for 10 min
3	Soaked in 0.15 M NH$_3$ for 15 min (at open circuit potential)
4	Kept at +0.3 V in 0.003 M NH$_3$ for 1 min
5	Kept at +0.3 V in 0.15 M H$_2$SO$_4$ for 0.5 min

3. Results and discussion

3.1. Sensor operation

The response of the Pt/PPy sensor to ammonia in aqueous solutions was tested by injecting 100 μl of different concentrations of NH$_4$Cl into the FIA system. The recorder trace is shown in Fig. 2. The calibration line within the studied concentration range 10–120 μM was linear with $r = 0.995$, and RSD = 2.2% and 1.1% at the lower and upper limit, respectively. These RSD values were determined by ten injections of the 10 μM and 120 μM NH$_4$Cl solutions. As can be seen in Fig. 2, the limit of detection is well below 5 μM NH$_3$ ($\approx$ 10 μM NH$_4$Cl at pH 9.2). The short-time stability of the sensor was tested by injecting 60 times 100 μl of 100 μM NH$_4$Cl. The signal was found to be stable with RSD = 0.7%.

In order to study the intefering effect due to small ions on the ammonia response at the PPy electrode, NaCl was selected as the model compound. Since NaCl levels in clinical samples normally fall within 0.08–0.18 M, concentrations of 0.05 M and 0.2 M were chosen in the interference studies. The current responses of injections of 100 μl of the solutions are shown in Fig. 3A. As can
Fig. 2. Injections of ammonia at different concentrations: (1) 10 μM, (2) 20 μM, (3) 50 μM, (4) 70 μM, (5) 100 μM and (6) 120 μM NH$_4$Cl.

be seen, NaCl at these concentrations really does interfere since, for example, 0.05 M NaCl gives an approximately equally strong response as 50 μM NH$_4$Cl. The interfering signal is due to the involvement of small anions such as chloride in the doping process of PPy:

$$PPy^0 + Cl^- \rightleftharpoons PPy^+Cl^- + e^-$$
The participation of small anions in the doping process has been used to construct conducting polymer-based amperometric anion sensors [4-7].

In order to diminish the effect of chloride ions on the signal at the PPy electrode, the concentration of NaCl in the buffer stream was set at 0.4 M. This procedure did not give any great improvement to the interfering effect of chloride. The buffer stream was then adjusted to 60 μM with respect to the anionic surfactant sodium dodecyl sulfate, NaDS. This compound is adsorbed at the electrode and forms an anionic layer on the surface. A similar experiment to that shown in Fig. 3A was performed but, as explained above, now with DS$^-$ in the buffer stream. The

results are shown in Fig. 3B and, as can be seen, the interference from Cl$^-$ is considerably decreased. The ratio of signals (120 μM NH$_4$Cl):(0.2 M NaCl) is 1:2.2 before and 1:0.56 after the addition of 60 μM NaDS. The decreased interference of Cl$^-$ is probably due to the fact that the DS$^-$ surfactant anions form a negatively charged layer on the *surface* of the PPy film. Owing to their bulky size, the DS$^-$ ions are not capable of penetrating the polymer film and doping it [8]. The DS$^-$ layer repels anions and thus creates a strong diffusional barrier to the flux of Cl$^-$ to the PPy film. This hypothesis is confirmed by the cyclic voltammograms shown in Fig. 4. The cyclic voltammogram of PPy in 0.2 M NaCl + 0.05 M borax (pH 9.2) shows that there are two different redox processes taking place in the PPy film: one at -0.05 V and another at -0.4 V. Li and Qian [9] observed similar behavior in PPy(NO$_3^-$) and attributed the two processes to anion and cation insertion. More specifically, the more anodic process corresponds to anion insertion and the more cathodic process to cation insertion. After addition of 0.05 M NaDS to the electrolyte solution, the redox peak pair at -0.05 V disappeared, which means that anion insertion was no longer taking place. The cation insertion, in contrast, could still be observed. This confirms our assumption that DS$^-$ forms a permselective layer on the electrode that prevents Cl$^-$ entering the PPy film by charge exclusion.

As can be seen in Figs. 3A and 3B, there are negative peaks (those pointing downwards) preceding the Cl$^-$ signal. These may originate from small changes in the potential of the working electrode that are not immediately compensated by the potentiostat. The current observed obviously has contributions both from Faradaic and charging currents.

The interfering signal from injections of NaCl could further be diminished by increasing the concentrations of NaDS and NaCl in the borax buffer stream to 0.05 M and 0.4 M, respectively (see Fig. 3C). The negative peaks, however, are an interfering phenomenon in the determination of ammonia, and although addition of NaDS and NaCl to the buffer stream clearly reduced these peaks, NaCl levels of 0.1-0.2 M still interfered to
Fig. 3. Interference caused by NaCl: (A) under normal measuring conditions; (B) after the concentration of NaDS in the buffer stream had been set at 60 μM; (C) after the buffer stream had been adjusted to 0.05 M with respect to NaDS and 0.4 M with respect to NaCl. The injected solutions were: (1) 50 μM NH$_4$Cl, (2) 120 μM NH$_4$Cl, (3) 0.05 M NaCl, (4) 0.2 M NaCl.

some extent in the determination of ammonia at low, i.e. μM, ammonia concentrations.

3.2. Response mechanism

The exact mechanism behind the ability of a PPy electrode to detect ammonia is not clear. The response is obviously based on the capability of ammonia to reduce PPy. Gustafsson et al. [10] reported that when PPy was exposed to gaseous ammonia at low concentrations and for short times, the conductivity of the PPy film was decreased but was reversibly recovered after flushing with Ar. However, when the PPy film was exposed to 1 atm gaseous ammonia for a long period (14 days) an irreversible increase in the resistivity of the polymer film was observed. Gustafsson et al. also explained that the reversible

change in conductivity is due to a compensation effect where ammonia acts as an electron donating species. In addition, the authors discuss the possibility of proton transfer between the polymer and ammonia as the compensation reaction. The irreversible change of conductivity was explained as a nucleophilic attack by ammonia or hydroxide on the polymer, which leads to loss of conjugation in the polymer structure and thus to increased resistivity.

Trojanowicz et al. observed a continuous decrease in the amperometric response of PPy for repetitive injections of ammonia. The rate of the signal decrease was found to be proportional to both the potential of the measurement and the concentration of ammonia in the solution. This was confirmed by our experiments in which repeated injection of a solution where [NH$_3$] > 1
Fig. 4. Cyclic voltammograms at a Pt–PPy electrode (area 0.16 mm²) in two different media. Medium "1" is 0.05 M borax + 0.2 M NaCl (pH 9.2). Medium "2" is 0.05 M borax + 0.2 M NaCl + 0.05 M NaDS (pH 9.2). The sweep rate is 50 mV s⁻¹.

mM resulted in sensor deactivation as shown in Fig. 5. The signal was partly restored when only the carrier solution was pumped past the electrode for 10 min. This is also demonstrated in Fig. 5. These results suggest that sensor deactivation is not an entirely irreversible process.

The IR spectra of three identically prepared but differently treated PPy samples were measured. One of the PPy samples was not treated with ammonia, one was treated for 15 min at open circuit potential and the other for 15 min at +0.3 V. No big differences could be found between the spectra. The only variation was a shift in the baseline, such that the untreated sample showed the lowest transmission and that treated in 0.15 M NH₃ at +0.30 V showed the highest transmission. Gustafsson et al., on the contrary, found big changes in the IR spectrum of their PPy samples when treated with gaseous ammonia. These changes were explained by chemical variations in the structure of PPy. The most important result in our measurements is that the chemical structure of PPy remained virtually the same after exposure to ammonia in aqueous solution. Deactivation of the sensor was therefore to be the result of another type of attack by ammonia on PPy. Since the degree of IR transmission of a conducting

polymer decreases with its conductivity, the observed shift in baseline reflects the change in the degree of doping. The untreated sample had the lowest transmission and therefore the highest degree of doping. The sample treated with ammonia at +0.3 V was most reduced. Our IR measurements indicate that ammonia is capable of reducing doped PPy.

The EDAX measurements were used to study the content of counterions in PPy after different kinds of treatment with ammonia. The procedures are shown in Table 1 and the results in Fig. 6. These results can be interpreted by looking at the peaks for Cl and S. It can clearly be seen that the content of Cl⁻ in the PPy film was unaffected when the film was not treated with ammonia (samples # 1 and # 5). It should be pointed out that a quantitative analysis of the curves in Fig. 6 is not possible owing to the fact that, although all they were prepared in exactly the same way, there are always some morphological differences between the individual films. Therefore, the doping and undoping processes of the different films are not exactly comparable. Some clear trends, however, can be observed. Sample # 2 was treated with 0.15 M ammonia for 10 min at +0.3 V in 0.05 M Na₂SO₄ supporting electrolyte. As can be

seen in Fig. 6, the Cl peak decreased and a clear
S peak appeared, indicating a decrease in Cl
content and increase in S content in the PPy film.
The film doped with Cl^- was reduced when ex-
posed to ammonia, i.e. undoped, and Cl^- ions
were expelled from the film. Because the film was
continuously held at $+0.3$ V it would have been
reoxidized immediately, i.e. doped with anions of
the electrolyte, SO_4^{2-}. Therefore, the peak for S
appears in the EDAX spectrum of sample #2.

In experiment #3, the PPy film doped with
Cl^- ions was soaked in 0.15 M ammonia with
0.05 M Na_2SO_4 at open circuit potential. The film
was reduced by ammonia but was not reoxidized.
Therefore, the Cl peak decreasesd but no S peak
could observed. In experiment #4, the film was
soaked in a solution of 0.003 M ammonia and 0.05
M Na_2SO_4 for 1 min, and a potential of $+0.3$ V
was applied. The Cl peak decreased and a clear
peak for S appeared, indicating undoping of Cl^-
and redoping with SO_4^{2-}. Experiment #4 was
Fig. 5. Signal degradation caused by measuring relatively high
ammonia concentrations. A standard solution of 0.01 M
NH_4Cl was injected into the FI analyzer as follows: ten
injections, 10 min break, five injections. The volume of the
injected sample was 100 μl.

similar to #2, but the ammonia concentration
was lower and the soaking time shorter. By study-
ing the curve for #4, it can be seen that the Cl
peak decreased to the same level as in experiment
#2, but the S peak did not increase as much as in
#2. This is obviously due to the physical differ-
ences between films #2 and #4. In experiment
#5, the PPy film was soaked in 0.15 M H_2SO_4 for
30 s. No change compared to curve #1 can be
observed. This indicates that the PPy film doped
with Cl^- remained doped at this potential and
that Cl^- could not be exchanged for SO_4^{2-} with-
out first undoping the PPy film. The results in Fig.
6 indicate that the reaction behind the amperomet-
ric PPy-based ammonia sensor is — at least for
the most part — the ordinary, reversible redox
reaction of PPy rather than an irreversible reaction
between ammonia and PPy.

The redox characteristics of ammonia were ex-
amined further by cyclic voltammetry at a bare Pt
electrode. Fig. 7 shows the cyclic voltammogram
of a solution of 0.15 M NH_3 in 0.2 M NaCl at pH
11.2. There is also a reference voltammogram
taken in a solution whose ionic strength and pH
were identical to the ammonia solution, but that
did not contain any ammonia. It can be seen that
an increase in oxidation current is observed in the
ammonia solution even at the bare electrode.
Since Pt is a chemically inert material, there is no
possibility of an oxidation reaction between am-
monia and the electrode material, and the current
has to originate from an oxidation process of
ammonia alone. This experiment clearly proves
that an irreversible reaction between PPy and
ammonia is not necessarily needed for oxidation
of ammonia and reduction of PPy. Of course, it
does not prove that such an irreversible reaction
does *not* take place, but it makes reversible un-
doping–doping more plausible as the reaction for
the signal observed with the PPy electrode.

When the PPy electrode comes into contact
with an aqueous solution of ammonia, the ammo-
nia — according to the undoping–doping model
— reduces PPy. If a potentiostat is used to keep
the potential of the PPy electrode at a constant
positive potential, the PPy film is immediately
reoxidized, doped, to its original redox state. In
experiments #2 and #4, it can be seen that Cl^-
Fig. 6. EDAX spectra of PPy samples treated in different ways. The treatment procedures are given in Table 1.
was exchanged with SO_4^{2-}. The electrochemical reoxidation step produced an oxidation current that was the signal of the sensor. A representation of the model for the results in Figs. 2–4 is given in Scheme 1.

The oxidation product of ammonia is denoted by OxP. Fig. 8 shows a cyclic voltammogram where the catalytic oxidation of ammonia at a PPy electrode is clearly seen: the presence of only 5 mM ammonia resulted in an increase of 3.2 μA mm^{-2} in the oxidation current on the PPy-coated electrode. The same concentration of ammonia, however, increased the oxidation current by only 0.071 μA mm^{-2} when measured at a bare Pt electrode. We have not been able to identify the oxidation product. It may also be somehow at-

tached to the polymer as described by Gustafsson et al. in their mechanisms. It should be pointed out that the reaction mechanism as presented above refers to the reversible reduction of PPy describing the response of the sensor at the μM concentration level. The mechanism for the irreversible reduction, however, is not yet clear and is therefore not discussed further in this paper. A proposal for the irreversible reaction mechanism is presented elsewhere [11].

4. Conclusions

The PPy-based ammonia sensor is shown to work satisfactorily. However, it has two major

$$NH_3 \rightleftharpoons OxP + e^-$$	oxidation of NH_3

$$PPy^+(Cl^-) + e^- \rightleftharpoons PPy^0 + Cl^-$$	reversible reduction of PPy

$$PPy^+(Cl^-) + NH_3 \rightleftharpoons PPy^0 + OxP + Cl^-$$	overall chemical reduction of PPy by NH_3

$$PP_y^0 + Cl^- \rightleftharpoons PPy^+(Cl^-) + e^-$$	electrochemical reoxidation of PPy

$$NH_3 \rightleftharpoons OxP + e^-$$	overall reaction of ammonia detection

Scheme 1.

problems. Firstly, high concentrations of small inorganic anions such as Cl$^-$ cause considerable interference by giving rise to false signals. Secondly, the sensor is deactivated when measure-

ments at high ammonia concentrations are performed. The first problem can be diminished to a certain extent by adding the anionic surfactant dodecyl sulfate to the buffer stream. This

procedure, however, results in a new interference caused by cations, which can be reduced to a certain extent by addition of sodium chloride to the buffer stream. These measures do not remove the problem completely, but they do make it much less severe.

The second problem is the deactivation of the sensor, when measuring relatively high concentrations of ammonia. EDAX and IR studies of ammonia-deactivated PPy samples supported the theory that PPy remains virtually chemically intact in the ammonia measurements. Exposing the sensor to ammonia concentrations greater than 1 mM resulted in a decrease of the sensor signal that was partly reversible and partly permanent. The deactivation may thus be thought of as being due partly to the oxidation product(s) of ammonia sticking to the electrode surface, and partly to irreversible electrochemical degradation of PPy.

Abstract

A porous polytetrafluoroethylene (PTFE) junction reference electrode with an air-tight inner solution chamber containing saturated potassium chloride (KCl) was developed for flow analysis. This reference electrode is not influenced by a change in the sample pressure, and is not necessary to supply the KCl inner solution. The pore size of the porous PTFE junction is about 150 μm, although the conventional porous ceramic junction is 0.1 ~ 0.3 μm. The large pore size of the porous PTFE junction promotes the continuous exudation of KCl from the liquid junction and the higher surface tension of PTFE is effective to prevent the overflow of KCl. The porous PTFE was made by putting 74% of PTFE powder and 26% of KCl powder in a mold, pressing with a pressure of 200 kgf cm^{-2}, and sintering at 365°C. The quantity of KCl exuded from the disposable reference electrode is closely related to the life of the electrode. The relationship between the diffusion rate of the PTFE reference electrode and its characteristics was investigated. The quantity of KCl exuded from this reference electrode was initially of the order of 10^{-5} mol h^{-1} and decreased to the order of 10^{-6} mol h^{-1} after a year. This is approximately one-tenth of that exuded in a conventional reference electrode with a ceramic junction. The junction potential of the developed reference electrode was stable in the pH range 2 ~ 12 with a total ionic strength of more than 10^{-3} mol l^{-1}. This reference electrode containing 8 ml of the KCl inner solution was able to be used continuously for one or two years.

Keywords: Stable reference electrode; PTFE; Liquid junction

1. Introduction

One of the most important performances in the use of the reference electrode is continuous outflow of the potassium chloride (KCl) inner

* Corresponding author. Fax: (81)422-52-2042.

solution from the liquid junction [1]. In the conventional reference electrode, 0.1 ~ several ml day^{-1} of the KCl internal solution exudes constantly through the liquid junction of the reference electrode. If the outflow of the KCl internal solution from the inside of the reference electrode to the outside (into the sample solution) was stopped, the KCl concentration at the surface of

S. Ito et al./Talanta 43 (1996) 135–142

the liquid junction would become low, the reference electrode would lose its normal function and liquid junction potential errors would occur. As a result, the liquid junction potential would become unstable or fluctuating. Generally, to get a stable junction potential, a technique of pressing the KCl inner solution against the sample pressure has been used when the sample has some pressure or else the KCl inner solution for KCl consumption has been supplied using a head tank of the KCl solution. This is a very annoying matter in the treatment of the reference electrode. It is an obstacle to the miniaturization of a reference electrode in the case of flow analysis in which the sample pressure is particularly changeable. If we simply make a smaller-sized electrode by making the KCl chamber airtight, the continuous outflow of the KCl solution from the liquid junction become impossible and its performance is lost.

Up to now, many attempts to improve the reference electrode have been done for flow analysis. As an example, a solid-state reference electrode of the coated-wire type based on the silver/silver chloride (Ag/AgCl) electrode was reported. It is easy to miniaturize and is not influenced by the sample pressure, furthermore it is free from the direction in case of installation [2–6]. An example of an ion-selective field effect transistor with a inert polymer membrane has also been reported [7]. However, in our experiences, the solid-state reference electrodes do not give satisfactory stability and reproducibility of the reference electrode potential. As a reference which belongs between the conventional reference electrode and the solid-state reference electrode, we have developed an air-tight structured reference electrode with a KCl inner solution. As mentioned above, in an air-tight structured reference electrode with a ceramic junction, continuous outflow of the KCl inner solution could not be expected. At first, we tried to use a ceramic junction (5 mm in diameter and 5 mm in length) with an air-tight structure. However, the outflow of the KCl inner solution from the reference electrode was too high. We decided that a plastic with higher surface tension than an alumina or a silica ceramic was a good material to use. We adopted polytetrafluoroethylene (PTFE) because of the

easy plastic molding operation and its anti-corrosion ability in the various sample solutions. To make small holes to exude the KCl inner solution through PTFE, a mixture of PTFE powder and KCl powder was molded, and when it was washed by water after a cutting process, it became porous PTFE. The KCl powder was selected to give porosity to the PTFE junction because it was easy to arrange the uniformed particles, stable above 365°C and soluble in water. This reference electrode with the porous PTFE junction has an air-tight KCl inner solution chamber, and the KCl inner solution should be packed so as not to allow any air in this chamber. In this reference electrode, there is not outflow of the KCl inner solution but diffusion of K^+ and Cl^- ions from the reference electrode to the sample solution. By the diffusion of K^+ and Cl^- ions, the liquid junction potential is kept stable. We studied the processes for producing the porous PTFE liquid junction and its performances. A long-term stable and maintenance-free reference electrode with porous PTFE liquid junction was developed and applied to flow analysis with the ion electrode.

2. Experimental

2.1. Apparatus and reagents

A DKK Model IOL-50 ion-meter, a DKK Model EL7020 chloride ion electrode, and a DKK Model EL4083 reference electrode were used for outflow or diffusion rate measurements of Cl^- ion from the reference electrode.

PTFE powder for molding Model M12 (grain size = 20 μm) and Model M33 (grain size = 750 μm) were purchased from Daikin Industries (Osaka, Japan). All chemicals used were of analytical reagent grade. Potassium chloride, hydrochloric acid, acetic acid, trimethanolamine and sodium hydroxide were obtained from Wako Chemicals (Osaka, Japan). The KCl was sieved using a sieve of 40 ~ 80 mesh to get uniform particles. Pure water obtained by a MILLI-Q SP Reagent Water System was used in this work. A model F11 porous ceramic was purchased from Kyocera (Kyoto, Japan), and was used as the

ceramic junction by molding and cutting to 2 mm in diameter and 10 mm in length. The material, mean porosity and pore rate of this ceramic junction are 99.9% of alumina (Al_2O_3), 0.3 mm and 47% respectively, according to the maker.

2.2. Manufacture of porous PTFE junction

The KCl powder of uniform size was obtained as follows. The KCl was dried for about 1 h in an oven at 120°C, ground to find powder by a mortar, and was sieved in two ranks: 100 ~ 60 mesh (147 ~ 246 μm grain size); and 80 ~ 48 mesh (175 ~ 295 μm grain size). If the grain size is less than 147 μm, the outflow of KCl solution through the PTFE junction was not observed. Furthermore, if it is more than 295 μm, the outflow of KCl solution is too much to use at the liquid junction. The standard deviation of the outflow rate of this PTFE junction for the grain size or the content of KCl is not small, i.e. about 30%. The KCl grain size of 147 ~ 246 μm with smaller standard deviation was adopted practically.

As the grain size of PTFE powder did not influence the outflow rate of this PTFE junction, PTFE of finer size was used for Model M12.

The developed reference electrode consisted of the PTFE body and the PTFE junction which were pressed and sintered together. PTFE powder only was used in the part of the body, the mixture of PTFE powder and KCl powder was used in the part of the junction. The PTFE–KCl mixture was made, that is, the PTFE powder was mixed with KCl powder for 10 min at 1520 rev min^{-1}. Firstly, 80 g of the PTFE–KCl mixture was stuffed in the bottom part of the stainless-steel cylinder mold (25 mm in diameter and 250 mm in length). Next, 200 g of the PTFE powder was stuffed in the upper part of it. The PTFE powder and mixture were pressed for 5 min at 200 kgf cm^{-2}. In this way a stick 25 mm in diameter and 70 mm in length was obtained. One part of this stick consists of the PTFE, another part consists of the mixture. This stick was sintered for 2.5 h at 365°C, and was cut by a lathe in the shape of the reference electrode body. The part of the liquid junction (porous PTFE) consists of the sides of 12 mm diameter and 10 mm in length, and the

bottom. Its surface area is about 5 cm^2. The relationship between the wall thickness and the outflow of KCl through the PTFE junction was observed to be inversely proportional. When the wall thickness was less than 1.5 mm, the outflow of KCl was too much to use for a long period. When it was more than 2.5 mm, the outflow of KCl was too low for the junction potential to become unstable. The wall thickness of the sides and the bottom was made to be 2 mm. At the end of the process, the reference electrode body was left in water overnight at room temperature for making porous PTFE by solving and removing the KCl powder.

2.3. Structure of reference electrode

The structure of the reference electrode is shown in Fig. 1. The reference electrode and the liquid junction are in a body, and there is a screw for installation of a flow cell. The inner electrode used is the silver/silver chloride electrode. As an inner solution, the saturated KCl solution and the KCl sludge are enclosed in it. The super-saturated KCl enclosed in the electrode body would decrease by diffusion to the sample solution in practical use as the source of KCl.

2.4. Measurement of diffusion rate of KCl

The diffusion rate of KCl in the PTFE reference electrode to the sample solution was measured as follows. A junction part of each reference electrode was soaked in 40 ml of water at room temperature. After 24 h exactly, the 40 ml of water-diffused KCl was made up to 50 ml exactly, and the molar concentration of Cl^- ion was measured by a chloride ion electrode. The diffusion rate was calculated as the number of moles of KCl diffused in a unit time (1 h). This measurement was made using ten developed reference electrodes and the percent standard deviation was calculated. It was measured once a month, and was continued for 12 months. The first measurement was made a week after manufacture. During the test terms, the junction part of the reference electrode was soaked in water, which was renewed once a week to keep its electrtonic conductivity low.
Fig. 1. The structure of the PTFE reference electrode.

Fig. 3. The ionic strength effect of the PTFE reference electrode.

The change in the KCl diffusion rate is shown in Fig. 2. The open circles show the KCl diffusion rate of the PTFE junction. The filled circles show the KCl diffusion rate of the ceramic junction. The reference electrode with ceramic junction prepared for the test was manufactured by holding the porous ceramic (2 mm in diameter and 10 mm

Fig. 2. The change in the KCl diffusion rate of the PTFE reference electrode.

in length) with rubber packing at one end of the glass tube (12 mm in diameter). The head pressure of the KCl inner solution was kept at 0.1 kgf cm^{-2} (about 1 m in a column of water) by supplying another KCl inner solution occasionally. In the case of the PTFE junction, the KCl diffusion rate was 2.5×10^{-5} mol h^{-1} initially and it became 3.0×10^{-6} mol h^{-1} after a year. However, in the case of the ceramic junction, it was 1.25×10^{-4} mol h^{-1} throughout the year. The relative standard deviation of the KCl diffusion rate was $\pm 60\%$ after a week, $\pm 45\%$ after a month, and $\pm 20\%$ after a year in the PTFE junction. It was $\pm 10\%$ after a week, $\pm 20\%$ after a month and $\pm 20\%$ after a year in the ceramic junction.

2.5. Measurement of ionic strength effect

Generally in the reference electrode, the liquid junction potential is growing when the outflow of the diffusion of KCl is scant, because it is being blocked by particles of dirt or soil in the sample solution [8]. The PTFE liquid junction is influenced by the ionic strength of the sample solution when the diffusion of KCl is in short supply too.

Fig. 3 shows the ionic strength effect of this PTFE reference electrode. The ionic strength was adjusted by KCl. The liquid junction potential was measured against the standard Model 4083 reference electrode with a glass sleeve junction. The measurement was performed on each of ten pieces a month, six months and a year after manufacture. There was a slight tendency for the junction potential to become large with the lapse of time after manufacture. The magnitude of the junction potentials mostly corresponded to a little diffusion of KCl. It was 3.3 ± 2 mV at 10^{-4} mol l^{-1} and 1.1 ± 0.5 mV at 10^{-3} mol l^{-1} of the ionic strength. When the ionic strength was above 10^{-2} mol l^{-1}, the junction potential was nearly zero.

2.6. Measurement of pH effect

The PTFE liquid junction is also influenced by the hydrogen ion activity (H$^+$ or pH). In Fig. 4, pH 0–3 was adjusted by addition of hydrochloric acid, pH 4–7 with acetic acid and sodium hydroxide, pH 8–12 with triethanolamine and hydrochloric acid, and pH 13–14 with sodium hydroxide, using a pH meter. The ionic strength of each solution was adjusted in 0.01 mol l^{-1} steps by KCl. The liquid junction potential was measured against the standard Model 4083 reference electrode with a glass sleeve junction. The measurement was performed on ten pieces a month, six months and a year after manufacture. The magnitudes of the junction potentials correspond to the diffusion of KCl mostly. They were 10.5 ± 4.9 mV, 4.2 ± 1.8 mV, 1.1 ± 0.4 mV, -0.5 ± 0.2 mV, -1.4 ± 0.4 mV and -4.1 ± 1.4 mV at pH 0, 2, 12, 13, and 14 respectively. In the pH range 3–11, they were almost zero.

2.7. Relationship between KCl diffusion rate and temperature

The diffusion rate of KCl seems to increase with a rise in temperature. Fig. 5 shows the relationship between the diffusion rate and the temperature. The measurements were made at 5, 10, 20, 30, 40 and 50°C with the same reference electrode after six months. A junction part of each

reference electrode was soaked in 40 ml of water at each temperature. After 24 h exactly, the sample of 40 ml including diffused KCl was made up to 50 ml exactly, and Cl$^-$ ion molar concentration was measured by the chloride ion electrode. The diffusion rate was calculated as the number of moles of KCl diffused in a unit time (1 h). Although it was 4×10^{-6} mol h^{-1} at 5 or 10 °C, it increased to 8×10^{-6} mol h^{-1} at 40°C. When the temperature exceeds 40°C, the diffusion rate increased to 1.5×10^{-5} mol h^{-1} at 50°C.

2.8. Aplication to flow analysis

In order to apply this PTFE reference electrode to flow analysis with the ion electrode, the flow cell and the system were devised. Fig. 6 shows a flow cell and a flow system. The flow cell was made from a transparent polyacrylate resin. The ion electrode and the reference electrode were mounted on the cell by a screw, and were shielded by a rubber O-ring. A fluoride ion electrode was used, and a fluoride ion electrode membrane (lanthanum fluoride, LaF$_3$, single crystal) which is not as easily influenced by the sample pressure change as a solid state membrane, and has very good characteristics among many sorts of ion electrode membrane such as stability, high sensitivity, good reproducibility and response. The fluoride ion electrode was manufactured by pasting an epoxy resin tube with a LaF$_3$ single crystal membrane (8 mm in diameter and 2 mm in length), by putting 1 mol l^{-1} sodium chloride and 0.01 mol l^{-1} sodium fluoride as an inner solution in it, and by leading out the silver/silver chloride inner electrode. The sample was admitted to the cell with the peristaltic pump or could be sucked in by the peristaltic pump behind the flow cell. Inner diameters of the sampling tube and the passage in the flow cell are 1 mm. The sample flows through a very small region of the ion electrode membrane. The size of this region is 5 mm in diameter and 0.2 mm in depth, i.e. the volume is about 0.04 ml, and the cross-section of the sample passage in the neighborhood of the ion electrode membrane is about 0.01 cm^2. When the sample flow rate is 5 ml min^{-1}, the line flow rate of the ion electrode membrane surface becomes
Fig. 4. The pH effect of the PTFE reference electrode.

8.3 cm s^{-1}. However, in the neighborhood of the liquid junction of the reference electrode, the passage diameter is 14 mm as against the liquid junction diameter of 12 mm. The line flow rate of the liquid junction surface becomes about 0.05 cm s^{-1}. It is about two orders of magnitude smaller than that of the ion electrode.

To study the performance of the flow system

Fig. 5. The relationship between the diffusion rate and the temperature.

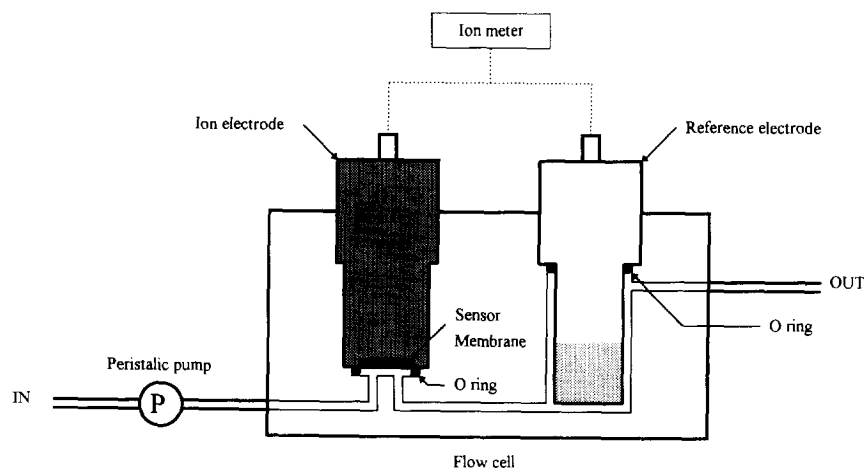
with the PTFE reference electrode in Fig. 6, the batch cell measurement was used as a reference standard method. The fluoride ion electrode and the Model 4083 (with glass sleeve junction) reference electrode are placed in a 200 ml beaker. The sample of 100 ml in a beaker was stirred by a 30 mm length of magnet on a magnetic stirrer at 400 rev min^{-1}. The line flow rate of the fluoride ion membrane surface becomes about 63 cm s^{-1} if its membrane is located very close to the magnet edges and the viscosity of a sample is neglected. As the sample solution, F$^-$ standard solution— NaF of 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5} and 10^{-6} mol l^{-1}—were prepared based on KCl solutions of 10^{-2}, 10^{-3} and 10^{-4} mol l^{-1}, respectively. However in the batch cell, F$^-$ standard solutions only based on 10^{-2} mol l^{-1} KCl were used as the concentration of the sample solution increases owing to exudation of KCl from the liquid junction. Table 1 shows the reproducibility of this reference electrode in the F$^-$ measurement of different concentrations. The measurement was performed as follows. Before use, electrodes and cell were sufficiently conditioned with the blank solution (based on the same concentrated KCl solution with each standard solution, did not contain the F$^-$ ion). With four kinds of F$^-$ standard solution and the blank solution, measurements were repeated several times, from 10^{-6} mol l^{-1} F$^-$ solution to 10^{-5} mol l^{-1} F$^-$ solution, from 10^{-5} to 10^{-4} mol l^{-1}, from 10^{-4} to 10^{-3} mol l^{-3} to 10^{-2} mol l^{-1}, from 10^{-2} to 10^{-3} mol l^{-1}, from 10^{-3} to 10^{-4} mol l^{-1}, from 10^{-4} to 10^{-5} mol l^{-1}, from 10^{-5} to 10^{-6} mol l^{-1}, from blank solution to 10^{-6} mol l^{-1}, from blank solution to 10^{-3} mol l^{-1} and from blank solution to 10^{-2} mol l^{-1}. All data were obtained when the measuring value was constant within 0.1 mV for 30 s as a final value. Reproducibility shows double the standard deviation of the final values. It is important that the sample solution is stirred powerfully in the low level measurement by the fluoride ion electrode. In Table 1, the reproducibility of the 10^{-6} mol l^{-1} F$^-$ standard solution may be caused not by the reference electrode but by the F$^-$ ion electrode. However, it can be said that a flow cell measurement with the PTFE reference electrode is equal to a batch measure-


Fig. 6. The structure of the flow cell system for ion analysis.

ment when the ionic strength of the sample solution is over 10^{-3} mol 1^{-1}.

3. Results and discussion

3.1. Performance of PTFE reference electrode

The results of the fluoride ion measurement are shown in Table 1. In the case of measurements with the conventional reference electrode (with glass sleeve junction), the reproducibility of the potential could be said to be within ±1 mV. A potential error of 1 mV causes ≈4% concentration error in fluoride ion (mono-ion) measurements, and a ≈8% concentration error in divalent-ion measurements. These are regarded as adequate for the ion electrode measurements. In the measurements with the PTFE reference electrode, when the total ionic strength of the sample solution is more than 10^{-3} mol 1^{-1}, the performance can be said to be nearly equal to that with the conventional reference electrode.

3.2. Restriction of application and errors

In the practical use of the solid-state reference electrode or the disposable reference electrode, occurrence of the unnecessary liquid junction potential should be paid attention to when considering the pH or the total ionic strength of the

sample solution. In the case of using this PTFE reference electrode in pH measurement with a glass pH electrode, errors of about +0.1 pH in the sample with liquid resistance of about 20 mS m^{-1}, +0.3 pH in the sample of 0 pH, +0.1 pH with 1 pH and −0.1 pH with 14 pH had to be expected respectively, at 25°C, as shown in Figs. 3 and 4.

3.3. Amount of inner KCl in reference electrode and electrode life

The content of the inner solution in a manufactured reference electrode such as that shown in Fig. 1 is about 10 ml. Though the amount of KCl contained in a saturated KCl solution is 3.1 g, 10 g of KCl can be contained in it when KCl sludge is considered. This amount of KCl (10 g) is equivalent to 0.134 moles. If the average diffusion rate from the PTFE junction is 5×10^{-6} mol h^{-1}, the electrode could be durable for 3.1 years of use with 10 g KCl. If it is 10^{-5} mol h^{-1}, its life could be about 1.5 years under continuous measurement conditions.

3.4. Mechanism of porous PTFE liquid junction

In the reference electrode, errors in the liquid junction potential seem to occur by decrease in KCl concentration on the liquid junction surface [9]. Essentially, the surface of the liquid junction

Table 1
Reproducibility of fluoride ion measurement

Concentration of standard solution	Batch cell measurement (with Model 4083) 10^{-2} mol l⁻¹ of KCl		Flow cell measurement (with PTFE reference electrode)					
			10^{-4} mol l⁻¹ of KCl		10^{-3} mol l⁻¹ of KCl		10^{-2} mol l⁻¹ of KCl	
	Potential (mV)	Reproducibility (mV)	Potential (mV)	Reproducibility (mV)	Potential (mV)	Reproducibility (mV)	Potential (mV)	Reproducibility (mV)
10^{-2} mol l⁻¹ of F⁻	−20.3	±0.3	−20.1	±1.3	−20.5	±0.5	−21.7	±0.3
10^{-3} mol l⁻¹ of F⁻	38.8	±0.3	38.0	±1.7	38.6	±0.6	37.4	±0.3
10^{-4} mol l⁻¹ of F⁻	97.6	±0.5	95.5	±1.6	97.3	±0.8	96.2	±0.4
10^{-5} mol l⁻¹ of F⁻	156.1	±0.7	152.5	±2.7	155.9	±1.1	154.8	±0.6
10^{-6} mol l⁻¹ of F⁻	212.2	±2.1	208.3	±4.2	213.6	±2.1	212.3	±1.1

should be filled with concentrated KCl. The conventional type of reference electrode has a KCl supply system (head tank or compressed air); the fresh KCl inner solution exuded through the liquid junction keeps the concentration of KCl high on the liquid junction surface. However, in the solid-state type of reference electrode or the reference electrode with an air-tight structured inner solution chamber, such as this PTFE reference electrode, decrease of KCl concentration on the liquid junction surface cannot be prevented. As this decrease of KCl concentration is caused by the dilution of the inner solution (concentrated KCl) with the sample solution, ease of replacement or supply of KCL becomes important in the junction material and the inner solution. An aqueous inner solution is easily replaceable compared with the solid-state electrolyte, the gel or high viscosity solution. Furthermore, as the porous PTFE junction has a larger pore size compared to the porous ceramic junction, quicker replacement or supply of KCl can be expected.

We noticed that a stable liquid junction potential of this reference electrode with the PTFE junction does not lead to outflow of KCl solution but to diffuse K⁺ and Cl⁻ ions. Though the porous PTFE junction has larger pore size and wider junction surface than the ceramic junction, diffusion of K⁺ ion and Cl⁻ ion from the inside to the outside of the reference electrode is much less than for a ceramic junction. In addition, as it has higher surface tension then ceramics, miscibility between the inner solution and the sample solution became smaller. As a result, it can be said that this PTFE reference electrode is compact, disposable, long-lived, and has good performance compared to the conventional reference electrode.

Abstract

The potentiometric and impedance characteristics of polymeric membranes, based on aliphatic polyurethane (Tecoflex) as a matrix, are described and interpreted by theory and experiments for H^+ and alkali metal ion-sensitive sensors. Both dummy plasticized membranes and proton carrier-loaded membranes can show pH response. The pH response of dummy membranes is due to protonated natural negative sites in the polyurethane matrix. The electrodes with added proton carrier show improved rejection of Li^+, Na^+, and K^+ responses and give useful analytical responses. Optimal performance requires control of negative site concentration by addition of lipophilic salt (e.g. tetraphenylborate derivatives). Impedance analyses show surface-rate semicircles and, depending on the bathing electrolyte solution, appearance of a diffusional Warburg impedance. In addition to these time-dependence surface region effects, changes in the bulk membrane resistance with soaking time can be well correlated with equilibrium water content of plasticized membranes.

1. Introduction

In recent years, there has been an increasing interest in the design and fabrication by solid-state technology of electrochemical sensors that respond to blood gases and ions as well as various organic substrates such as lactate and glucose in blood [1-7]. In these sensors, the poly-meric membranes are cast on solid surfaces with no internal electrolyte solution [8] or with very small volumes of isotonic buffer solution [1,2,9] incorporated into a thin hydrogel layer. The substrate (platform) of these devices is either silicon, alumina or polyimide (Kapton), which often includes integrated electronics. The hydrogel layer (e.g. poly (2-hydroxyethyl methacrylate); poly-HEMA) is loaded with a buffered aqueous solution containing a required

*Corresponding author.

salt that ensures a thermodynamically defined interface.

While several polymeric matrices have been used in macro ion-selective electrodes (conventional type with a large volume of inner solution), poly (vinyl chloride) (PVC) remains one of the best membrane matrices. A few other materials, such as silicone rubber [10], ethylene vinyl acetate [11], and polyimide [12], were proposed as membrane matrices in polymeric ion-selective electrodes. However, reduction of macro- to micro-electrodes has uncovered new problems with these materials. One of the main causes of failure in the miniature probes has been the poor adhesion of these membranes to the substrate surface, leading to electrolyte shunts around the membrane making the sensor inoperative. The lifetime of the sensor can be enhanced significantly with improved membrane adhesion. Thus, the problem of adhesion of different polymeric ion-selective membranes to the substrates (platforms) determines which of many suggested materials is optimal.

Additional polymer materials have been suggested by Meyerhoff and his co-workers [13–16] and by others [17–20]. Some of these materials have improved adhesion to various substrates but may show inferior electrochemical performances when compared to PVC. Carboxylated PVC (PVC-COOH) and aminated PVC (PVC-NH$_2$) have found many applications in biosensor fabrication and in planar ion-selective sensors produced by microelectronic technologies [1–3,7,20,21,23]. In two recent papers Meyerhoff and co-workers [15,16] showed that both biocompatibility and adhesion may be improved by using a mixture of polyurethane (PU) and hydroxylated PVC (PVC-OH) or PU-terpoly(vinyl chloride/vinyl acetate/vinyl alcohol). However, they showed that the response slope and selectivity of potassium selective membranes prepared with pure polyurethane matrix were inferior to those of the standard PVC matrix membranes [15]. In contrast to this observation, we found that aliphatic polyurethane (Tecoflex) have very good analytical performances in Ca^{2+} and K$^+$ selective sensors with normal and reduced amounts of plasticizer [24,25]. Additionally, the membranes with reduced plasticizer content had better adhe-

sive properties, less anion interference, extended lifetime and better biocompatibility [24].

Recently, our work has focused on using unmodified aliphatic PU as a polymeric matrix for pH sensors with possible biomedical applications. We were surprised to find that dummy membranes (matrix + plasticizer) showed pH responses as PVC-COOH or PVC-NH$_2$ do. In this paper, we demonstrate the ion-exchange properties of PU membranes and interpret the ion exchange for H$^+$- and M$^+$-sensitive membrane sensors theoretically and experimentally. The nature of anionic sites in the plasticized PU membranes remains unknown, but they are believed to be residual ionic components from the manufacturing process. Additionally, PU may be protonated by acidic electrolytes, and this phenomenon is responsible for leveling the pH response and introducing anion responses of these plasticized membranes. By incorporating a proton carrier in the PU plasticized membrane, the pH response range is significantly improved. Addition of both controlled sites (tetraphenylborate) and proton carriers produces a superior pH sensor. Impedance analysis was used to understand the behavior of the membranes in various bathing electrolyte solutions, over 2 days of electrolyte contact.

2. Experimental

2.1. Reagents and solutions

For all experiments, deionized water (Barnstead NAN-O-Pure II) and chemicals of p.a. grade were used. Most of the products were supplied by Fluka (Ronkonkoma, NY): H$^+$ carrier ETH 5294 (Chromoionophore I, Ch1, #27086); 2-nitrophenyl octyl ether (o-NPOE, #27086); bis (2-ethyl-hexyl) sebacate (DOS, #84818); potassium tetrakis (4-chlorophenyl) borate (KTpClPB), #60591). The material used for the membrane matrix was aliphatic polyurethane (Tecoflex 85A) supplied by Thermedics Inc. (Woburn, MA). During this work, the following buffer solutions were used for the determination of pH sensitivity and potentiometric selectivities of the electrodes based on PU matrix: (1) citrate–borate buffer with

60 mM Li⁺ ion background; (2) a Tris buffer with 140 mM Na⁺ ion background; and (3) a Tris buffer with 200 mM K⁺ ion background [18]. The pH values of the solutions were adjusted using a hydrogen-selective glass electrode (Orion, Model 91-57). Solutions of alkali metal chlorides (10^{-1}–10^{-5} M) were prepared by serial dilutions from the respective 10^{-1} M stock solution and were used for both potentiometric calibrations and selectivity coefficient determinations.

2.2. Membrane and electrodes

The solvent polymeric membranes were cast as described elsewhere [26] Dummy membranes contained only aliphatic PU, and the plasticizer in a weight ratio of 1:2. Additionally, membranes containing about 3% proton carrier (ETH 5294), and 2% proton carrier plus 1% potassium tetrakis p-chlorophenyl borate respectively, were prepared and investigated. All studied membranes were incorporated into Phillips IS-560 liquid membrane electrode bodies (Moller- Glassblaserei, Zürich, Switzerland) and evaluated for their electroanalytical properties. The inner filling solution varied, depending on the performed experiment. For pH sensors, containing 'normal' membranes (e.g. carrier and added sites), a Tris buffer of pH 7.0 was used throughout.

2.3. EMF measurements

Measurements of emf were performed at room temperature in an air-conditioned laboratory at $25.0 \pm 0.5°C$ with an Orion pH/mV meter (Model 701A) connected to an Orion Model 605 electrode switch box. As a reference electrode, an Orion Model 90-02 Ag/AgCl double junction was used throughout (1.0 M lithium acetate solution in the outer compartment). The measured emf values were corrected for changes in the liquid junction potential according to the Henderson equation [27].

2.4. Selectivity coefficients

The selectivity coefficients, $K_{H,M}$, for dummy membranes were determined by the separate so-

lution method at the 10^{-3} M concentration level [28]. The mean activity coefficients were calculated with the extended Debye-Huckel equation [27] and the measured emf values were corrected for changes in the liquid junction potential according to the Henderson equation [27]. The selectivity coefficients, $K_{H,M}$, for "normal" membranes containing proton carrier and TPB⁻ derivative were evaluated by using the calibration curves obtained with the three buffer solutions listed above.

2.5. Impedance spectra of dummy and "normal" membranes

The bulk and surface resistances (R_{bulk} and R_{surf} respectively) were determined from the impedance plots for each membrane using a Solartron 1250 frequency response analyzer (FRA), a Solartron 1186 electrochemical interface, and a Hewlett-Packard 85B computer. The amplitude of the applied sinusoidal voltage was in all cases 0.25 V. Membranes with 0.5 cm² active surface areas were tested in Philips electrode bodies with an Ag/AgCl double junction reference electrode as an external reference element.

2.6. Equilibrium water content

The equilibrium water content (EWC) of aliphatic PU membranes based on both o-NPOE and DOS as plasticizers was evaluated using the gravimetric method. Dry membranes weighing about 125 mg (w_1) were immersed in the appropriate soaking medium for 5 days, and the swollen membranes were blot-dried with a paper towel and immediately weighed (w_2). Then, the swollen membranes were dried at room temperature to a constant weight (w_3). The EWC values were calculated using the following equation:

$$EWC(\%) = [(w_2 - w_3)/w_2] \times 100$$

The loss of plasticizer from the membrane into the water phase was evaluated from the difference between w_1 and w_3.

3. Results and Discussion

3.1. Properties of PVC Membranes for comparison with PU membranes

Poly (vinyl chloride) (HMW-PVC) has been considered as an inert matrix for the plasticizer to yield a structureless organic membrane that dissolves the neutral carrier [29]. Later, this matrix was found to possess a more heterogeneous structure [30] and to contain various anionic sites. The exact nature and origin of anionic sites in PVC has not been well established in spite of the interesting study and postulates of van den Berg et al. [31]. In order to identify the ionic components in PVC polymer, these authors used impedance measurements, X-ray fluorescence, secondary ion mass spectrometry and X-ray photoelectron spectroscopy. They postulate that sulfate or sulfonate groups act as the anionic sites. Frequency response analysis measurements indicated that these sites may be present in the form of emulsifier residues and are not bound to the polymer matrix [31]. From conductivity measurements [30,31] it was shown that ionic sites gradually leach out from the plasticized membrane. This finding does not prevent carboxylate from remaining immobilized in the membrane, covalently attached to the PVC backbone structure. These anionic sites create permselectivity for cations in ionophore-free membranes and are crucial for the performance of ion sensors [32,33]. Neutral carrier-based ion sensors can be optimized by the addition of lipophilic salt additives such as tetraphenylborate- and tetraalkylammonium derivatives for cation- and anion-selective sensors respectively.

3.2. Dummy PU-based membranes: potentiometric cationic response due to residual sites

Aliphatic PU used in our studies is a commercial product manufactured by Thermedics Inc. (type 80A). It is specially formulated for medical applications and it is synthesised from methylene bis (cyclohexyl) diisocyanate (HMDI), poly (tetramethylene ether glycol) (PTMEG), and 1,4-bu-

tane diol chain extender [34]. Generally, from the manufacturing process of polyurethanes, it is possible to have in the finished product traces of isocyanates, metalloorganic compounds used as catalysts, as well as various surfactants [35].

Dummy membranes (aliphatic PU and plasticizer only; weight ratio of 1:2) show cationic potentiometric responses when placed in solutions of different alkaline or alkaline-earth salts of varying activities. This response is also observed with non-modified PVC [36]. In the case of modified PVC (aminated or carboxylated) the potentiometric response to H^+ and to H^+ or M^+ respectively, is clearly understandable and it was theoretically and experimentally described [13,22,37].

Surprisingly, PU shows a much better selectivity than PVC-COOH for H^+ over Na^+, K^+, Li^+, NH_4^+ and Ca^{2+} [22]. For an electrode containing a dummy membrane of PU-NPOE, the following selectivity coefficients ($-\log K_{H,M}$) were calculated: 2.08, 1.95, 2.19, 2.04 and 2.47 respectively. This much better potentiometric response to protons (pH linear range between 3 and 5; slope of 43.3 mV pH^{-1}) is probably due to the presence of natural protonated sites in PU. The process of protonation by solvent acid to form a conjugated acid of urethane is a predominant factor in the dissociation [38]. Under extreme conditions (concentrated acid, high temperature and pressure), the dissociation proceeds by eliminating isocyanate from the positively charged conjugated acid of urethane, which donates a proton to the solvent molecule (a termolecular mechanism):

(I)

$$\rightleftharpoons S^+H_2 + R_1\text{-}N\text{=}C\text{=}O + R_2\text{-}OH + S^-$$
State I

In state I, simultaneously, one solvent S acts as a base to accept a proton and the other acts as an acid to donate a proton. By the shift of an

electron pair, state **I** may dissociate to a very
small extent, but enough to create negative sites
for protonation by ion exchange in the system.
The latter could be responsible for H^+ potentio-
metric response. At pH < 3 the anion effect inter-
ference (Donnan failure) was observed as the case
of aminated PVC or proton carrier-based mem-
branes [37]. This process is protonation of nitro-
gen or oxygen atoms to create NH^+X^- from the
extracted HX.

3.3. Water uptake by dummy aliphatic PU membranes

We found that the aliphatic PU takes up water
as other polymers do [21,39–43]. The water up-
take depends on the polarity of the plasticized
membrane as well as on the aqueous solvent
(solution) used to hydrate the membrane. Higher
EWC values were observed in pure water, when a
polar solvent, such as o-NPOE, was used as the
solvent plasticizer ($\varepsilon\varepsilon_0 = 23.9$). With DOS
($\varepsilon\varepsilon_0 = 3.9$) the water uptake was less from pure
water than from 10^{-3} M NaCl solution (Table 1).
Interesting is the fact that a non-polar solvent
such as DOS showed poor "compatibility" with
the aliphatic PU. Freshly prepared membranes
were "oily" and this plasticizer was exuded when
the membrane was placed in contact with aqueous
solutions. The exuded plasticizer surface layer was
greater for DOS than for o-NPOE plasticizer
(Table 1). Confirmation came from dummy mem-
branes with DOS that showed a very high surface
layer resistance as evaluated by impedance analy-
sis (see below). These membranes also showed
unstable potentiometric readings. This effect was
also found in membranes containing a proton
carrier, namely the phenoxazine derivative ETH
5294. The high surface membrane resistance
could be and was, reduced significantly by
adding the lipophilic salt additive potassium te-
trakis (4-chlorophenyl) borate in our optimal
compositions.

3.4. Impedance analysis of PU dummy membranes

Impedance analysis with dummy membranes

showed that o-NPOE-based membranes revealed
a second, so-called "kinetic", semicircle at
medium frequencies lying between the geometric
bulk semicircle at highest frequencies and the
Warburg impedance at lowest frequencies. As was
shown by Buck [44], the second semicircle occurs
for two well-known reasons: (i) slow, potential-
dependent transfer rates for ions that cross the
interface; and (ii) slow, potential-dependent trans-
fer of ions through a high-resistance (relative to
bulk) surface film. Both processes cause a second
semicircle that disappears when surface rates be-
come fast compared to bulk bathing electrolyte
transport rates. Both processes are equivalent to a
surface resistance (R_{surf}) in parallel with a low-fre-
quency capacitance, approximating the double-
layer value at each membrane/electrolyte interface
[32].

Because of the very high surface resistance of
PU-DOS membranes, reflected in the unstable
potential measurements as well, we investigated
only the polar membranes with o-NPOE as plas-
ticizer (polymer:plasticizer ratio of 1:2 by
weight). Interesting is the fact that in many situ-
ations (different symmetric concentrations of
bathing electrolyte) the second semicircle dimin-
ished or disappeared, but in all cases the 45°
line, indicating a Warburg impedance (current is
controlled by diffusion of the counterions from
bathing electrolyte), was observed (see Fig. 1
(a–c)). Because counterions must be combined
with sites, this feature indicates that mobile sites
are present in dummy membranes, possibly from
intrinsic charged impurities, and that concen-
tration changes of sites, and corresponding
diffusion, may occur. Alternative explanations
seem less likely: (1) a porous surface layer
through which solution species diffusion occurs;
(2) an organic layer or site-free layer extracts
whole salts that then diffuse to the bulk mem-
brane.

The size of the bulk resistance depends on the
concentration of the bathing electrolyte. During
48 h soaking (symmetric electrolyte concentration,
i.e. 0.1 M or 0.01 M NaCl) the bulk resistance
decreased gradually with elapsed time, as shown
in Fig. 2. In an acidic medium (0.1 M NaCl of
pH 2.0), the bulk resistance of the dummy mem-

brane was about 25% less than in the neutral pH range. This may be explained by HX extraction and by protonation of the PU in the membrane, creation of positive sites and anions X^- that lower the membrane resistance.

In an asymmetric bathing solution (internal, 10^{-3} M; external, H_2O), the impedance plane plots consistently showed two semicircles (bulk and surface resistances) with the first one approximately constant (3.2 MΩ) and the second (surface resistance) progressively increasing up to 25 MΩ during a 48 h soaking period (Fig. 3). This can be explained by the leaching of sites from the surface region.

3.5. Membranes containing a proton carrier

Addition of ETH5294 chromoionophore I (a proton carrier) to fresh, unsoaked membranes, decreased initial bulk resistance to about a half, and this value remained approximately constant during the 48 h soaking period. The second semicircle showed a high resistance for the first 3 h and then it decreased dramatically. After 24 h of membrane soaking the surface resistance disappeared and was replaced with a Warburg impedance (Fig. 4). We can surmise that the presence of ionophore and counterions (bound together as $ChlH^+$) retains the original mobile sites. The ionophore–counterion sites are much more hydrophobic species and so are favored in the membrane. Extraction of sites into bathing

H^+ Site$^-$ does extract from dummy membranes is realistic.

The electrode containing the proton carrier ETH5294 (Ch1) in its PU-based membrane showed a linear pH response in the range 4–10, but the emf readings were not stable enough for practical use, and the electrode drifted badly in the alkaline pH region. Subsequent addition of potassium tetrakis (*p*-chlorophenyl) borate had three important advantages, namely, increasing the stability of potential measurements, reducing the membrane resistance and reducing the anion interference effect. As shown in Fig. 5, the electrode with "normal" membrane composition, i.e. polymer–plasticizer–ion carrier–lipophilic salt,

displayed a linear pH response in the range pH 4–11, with near-Nernstian sensitivity. The impedance plots of "normal" membranes with *o*-NPOE as a plasticizer showed one very small semicircle (bulk resistance of about 140 kΩ) and relative large surface resistance (about 5 MΩ) after 2–3 h of soaking in symmetric bathing electrolyte (0.1 M NaCl). Leaching of the plasticizer from the membrane surface region again produced site-free surface resistive films which have, as a consequence, the appearance of the second "kinetic" semicircle. As in the case of dummy PU membranes, the size of the second, surface-rate

Drive (mV h⁻¹)	0.05	0.12

[a] Data based on four electrodes of each type.

semicircle depends on the polarity of the plasticizer as well as on the concentration of the bathing electrolyte. The same behavior was observed with "normal" DOS-based membranes. In this later case, the bulk resistance was much higher (about 7 MΩ); the surface resistance varied continuously and reached a value of 12.9 MΩ after 24 h soaking time.

Table 2 lists additional data showing the good analytical performance of pH sensors based on aliphatic PU as a polymeric matrix. Both potential reproducibility and drift were smaller for o-NPOE-based relative to DOS-based membrane electrodes. These membranes will be investigated in planar microsensors for biomedical applications and the results reported later.

4. Conclusions

This work shows that aliphatic PU contains mobile and fixed residual sites which are responsible for the H⁺ and M⁺ potentiometric response of plasticized membranes in the solvent polymeric membrane type of sensor. The dummy membranes (PU-plasticizer) show much better responses to H⁺ than towards alkali and alkaline-earth cations. The relatively wide range, but sub-Nernstian, pH response of dummy mem-

branes is attributed to the ion exchange of protons into the PU. In the acidic medium, however, acid extraction (with anions) produces sub-Nernstian responses as predicted by theory. The electrodes with proton carrier-containing membranes and added mobile sites show good pH response, potential reproducibility and small potential drift. Both dummy membranes and "normal" membranes (containing proton carrier and added sites) show, by low frequency impedance measurements, surface-rate (so called "kinetic") semicircles and can also show a Warburg impedance which occurs when the current is controlled by diffusion of different ionic species into the membrane phase. Detailed interpretation postulates different extents of mobile site extraction depending on the hydrophobicity of the counterion-carrier complex compared to uncomplexed counterions, as well as differing dielectric constants of plasticizers.

Accumulation and voltammetric determination of complexed metal ions at zeolite-modified sensor electrodes

Chen Bing, Lars Kryger*

School of Science, National Institute of Education, Nanyang Technological University, 469 Bukit Timah Road, Singapore 1025, Singapore

Abstract

Chemically modified electrodes based on zeolite-containing graphite pastes were constructed and evaluated as sensor electrodes for the voltammetric determination of traces of metallic species in solution. Zeolite molecular sieves with pore sizes of 3, 4, 5, and 10 Å were all suitable for chemical deposition and subsequent voltammetric quantitation of traces of Cu(II), Cd(II), and Zn(II). The highest sensitivity was obtained using the zeolite with the 10 Å pore size. The detection limit obtained for Cu(II) was 0.3 μM following a 2 min chemical deposition. The detection limits for Cd(II) and Zn(II) following a 4 min chemical deposition were 87 nM and 145 nM, respectively. The effects on the zinc signal of coexisting metallic species in the ammonia deposition medium were studied. While the addition of Hg(II) gave rise to increasing zinc signals, the addition of Ag(I), Cu(II), Cd(II), Ni(II), and Co(II) resulted in decreasing zinc signal amplitudes. Most notably, the magnitude of the interference from these latter metal ions correlated well with the coordination numbers of their ammonia complexes. Thus the electrode acted as a device which was sensitive to the size and shape of the interfering metal complex.

Keywords: Chemically modified electrodes; Voltammetric determination; Zeolite

1. Introduction

Chemically modified electrodes (CMEs) [1] with chemically selective groups attached to their surfaces are potentially useful as sensor electrodes in electroanalysis, in particular in conjunction with electrochemical stripping procedures where they offer the possibility for introducing an additional dimension of selectivity in the preconcentration

step [2–11]. In such procedures, the analyte is first accumulated on the electrode via a non-electrochemical interaction with the modifier, e.g. a covalent linkage [2], complexation [3–7], or ion exchange [8–11], and is subsequently quantitated by a voltammetric approach. Cage structures, such as zeolites, which may act as ion exhangers, and which may exhibit selectivity according to molecular size and shape, offer interesting possibilities as electrode modifiers [12,13]. However, while several reports on mechanistic studies of zeolite-modified electrodes have been published [14–18], only a few workers have investigated the

analytical possibilities of such electrodes. Hernandez et al. [10] have constructed an Hg(II)-sensitive electrode based on a natural zeolite obtained from volcanic rock. Furthermore, Wang and Martinez [11] have described the accumulation and voltammetric determination of Ag(I) at a carbon-paste electrode modified with the zeolite Linde 4A, with an effective pore diameter of 4 Å. In the present investigation, the possibilities afforded by zeolite CMEs with smaller and larger pore diameters were studied. The electrodes were constructed using graphite paste modified with four different zeolites having pore diameters of 3, 4, 5, and 10 Å. Cu(II), Cd(II), and Zn(II) were chosen as target analytes. The study included a series of experiments in which suitable experimental conditions for the determination of the metal ions were established, including the composition of the electrode matrix, and of the solutions for chemical deposition, voltage scanning and regeneration of the electrode surface. Furthermore, the sensitivity and detection limits for the target analytes were evaluated. Finally, since the accumulation of metallic species in the zeolite cage structure might potentially reflect the size and shape of these species, experiments were carried out to study whether such effects could be observed.

2. Experimental

2.1. Apparatus

Voltammetric measurements were carried out using a computerized potentiostat/galvanostat (model 273A, EG&G, Princeton Applied Research with model 270/250 Research Electrochemistry software 4.0). The three-electrode assembly included a 50 ml glass cell, a saturated calomel electrode, a platinum wire counter electrode, and a rotating disk electrode assembly (model 616, EG&G, Princeton Applied Research).

2.2. Equipment, chemicals, and reagents

Ultrafiltered deionized water (model D 4755, Barnstead, USA) was used for all solutions of complexing agents and electrolytes. Dilute solutions (100 mg l^{-1} or lower) of metal ions were prepared daily by dilution from 1000 mg l^{-1} stock solutions. Before use, flasks and containers were soaked in 6 M HNO_3 for at least 24 h, then rinsed with deionized water. Molecular sieves, types 3A, 4A, 5A, and 13X (Union Carbide, BDH) were used as received. Extra-pure graphite fine powder (Merck), silicone oil DC 350 (Merck), DC 710 (Fluka) and nujol oil (Specac, UK) were used as bonding agents for the graphite pastes.

2.3. Preparation of electrodes

Mixtures (1:1 and 1:2 (w/w)) of the zeolite modifier and graphite were prepared in a mortar by grinding and mixing 2.5 g portions of zeolite molecular sieve pellets with 2.5 g and 5 g of graphite powder, respectively. Graphite pastes, 1:1 and 1:2, were prepared from these powders by further mixing with silicone or nujol oils; 3 ml and 4 ml of the oil were added to the 1:1 and 1:2 mixtures, respectively. Plain (unmodified) carbon paste was prepared in the same fashion from 5 g of plain graphite powder and 3 ml of silicone oil. Electrode bodies were made by removing the tips from disposable 1 ml polyethylene syringes using a razor blade, thus producing tubes (0.5 cm i.d.). The CMEs were prepared by filling the tubes with modified or plain graphite paste and polishing the surfaces on paper until a shiny surface appeared. The CMEs were attached to the disk arbor via rubber tubing filled with graphite paste using a copper wire inserted in both pastes to establish electrical contact between the CME and the rotating electrode assembly.

2.4. Analytical procedure

The analytical procedure included chemical deposition of the analyte in question (by exposure of the electrode surface to a solution of the analyte), transfer of the electrode to the electrochemical cell, and voltammetric quantitation of the deposit. Furthermore, in order to regenerate the electrode surface, the CME was finally exposed to a purging solution under open-loop conditions. Prior to the voltammetric measurements, the electrolytic medium was deaerated for at least 5 min using

nitrogen gas which had first been passed through a vanadous chloride scrubber solution then through 50 ml of the electrolyte solution. During the voltammetric measurements, a flow of nitrogen was passed over the electrolytic medium. Several variations of this procedure were evaluated, using different materials and media for the above-mentioned steps. These included the construction of CMEs using representative combinations of graphite powder, and the different zeolite molecular sieves and bonding agents. Furthermore, the effects on sensitivity of a CME conditioning programme were studied. This programme included a 30 s exposure of the CME to 0.1 M HNO_3 under convective conditions then exposure to blank ammonia medium (pH 9) followed by a CME polarization programme which included at least five cyclic scans of the CME potential beginning and ending at $+0.6$ V and shifting at a vertex potential of -1.2 V.

The experimental conditions for chemical deposition and voltammetric quantitation were optimized for Cu(II), Cd(II), and Zn(II) separately using chemical deposition from and square wave voltammetric scanning in several combinations of media. Voltammetric scanning was carried out first in 0.1 M HNO_3 mixed with increasing amounts of concentrated ammonium hydroxide then in Na_2HPO_4–NaH_2PO_4 buffers. Chemical depositions were carried out from dilute solutions of the three metal ions in the above-mentioned media. Regeneration of the CME after chemical deposition and voltage scanning was also attempted by exposing the CME surface to different media including H_2O, 0.05 M Na_2CO_3, HOAc–NaOAc (pH 4.2), and 0.1 M HNO_3.

In addition, the effects of variations in the square-wave voltage excitation frequency, and hence the scan rate, were studied, using constant values for the scan increment (2 mV) and for the amplitude of the superimposed square wave (50 mV). Moreover, the suitability of procedures which included a constant potential reduction step, carried out in unspiked electrolytic medium, between the chemical deposition and the voltage scanning quantitation was investigated.

Finally, the effects of Ag(I), Cu(II), Cd(II), Hg(II), Ni(II), and Co(II), on the CME accumula-

tion of Zn(II) from ammonia medium were studied.

3. Results and discussion

3.1. Sensitivity to Cu(II)

The experiments showed that all types of CME could be used for the chemical accumulation and voltammetric quantitation of Cu(II). However, since the highest sensitivity was obtained using silicone oil DC710 and the 1:1 mixture of graphite powder and zeolite 13X, this type of CME was chosen for the remaining part of the study. Experiments also revealed that the highest sensitivity was obtained if the CME was conditioned using the above-mentioned acid/ammonia/polarization programme. Thus the exchange of H^+ ions (in ZO^-H^+) or NH_4^+ ions (in $ZO^-NH_4^+$) with Cu^{2+} ions was more efficient than the exchange of Na^+ ions (in ZO^-Na^+) with Cu^{2+} ions. Fig. 1 shows the cyclic square-wave voltammogram obtained using the conditioned CME following exposure to ammonia buffer spiked with Cu^{2+}. Analogous experiments with unmodified electrodes and with unspiked media resulted in featureless voltammograms. The most efficient accumulation of Cu^{2+} (judged by the magnitudes of the currents resulting from both the reduction and oxidation of the copper deposit) was achieved for $4 < pH < 8$ with a maximum at pH 6. As a consequence of these observations, the remaining part of the study was carried out with chemical deposition from Na_2HPO_4–NaH_2PO_4 buffer (pH 6). While the reduction of the copper deposit invariably gave rise to single peaks, the oxidations were typically more complex, with double peaks, presumably because of stepwise oxidation (oxidation states 1 and 2) of the metallic copper generated by the reduction. Consequently, the reduction signal was chosen for quantitation. Since the maximum reduction current was obtained when ammonia buffer (pH 9) was used as a medium for voltage scanning, this medium was chosen for the remaining part of the study. The experiments also revealed that the analyte deposit formed by chemical deposition could be partially
Fig. 1. Cyclic square-wave voltammogram obtained after 1 min open-loop exposure of the CME to ammonia buffer (pH 9) spiked with 0.002 M Cu(II), (solid curve, cathodic scan; broken curve, anodic scan). (Medium for voltammetry, ammonia buffer (pH 9); square-wave frequency, 60 Hz; pulse amplitude, 50 mV; scan increment, 2 mV.)

dissolved by long-term exposure of the CME to H_2O, to 0.05 M Na_2CO_3, or to HOAc–NaOAc (pH 4.2). However, since a 40 s exposure to 0.1 M HNO_3 removed all evidence of previous chemical deposition/voltage scanning cycles, this purging solution was used for further experiments, such that a single CME surface could be used for several deposition/scanning cycles. Experiments in which the square-wave frequency was gradually increased (10, 20, 30, 60, and 100 Hz) showed that the width of the reduction signal increased with frequency, leading to poorer resolution. The reduction peak current, on the other hand, initially increased and reached a maximum at 30 Hz. Going to higher frequencies, and hence to higher scan rates, resulted in a gradual decrease of the current, presumably due to non-exhaustive reduction of the deposit. In view of these observations, a frequency of 30 Hz was chosen for the remaining part of the study. Table 1 summarizes the experimental conditions for the determination of Cu(II) thus established. Using these conditions, the copper reduction peak current increased with deposition time and, as shown in Fig. 2, with

concentration of Cu(II). Moreover, when the voltammogram obtained after CME regeneration (broken curve in Fig. 2) was used as a reference baseline, the baseline-corrected signal amplitudes obtained in the standard addition experiment correlated well with the added concentrations of Cu(II) (correlation coefficient, 0.9992). The limit of detection for a 2 min chemical deposition was estimated from eight consecutive analyses of a solution which contained 30 μM Cu(II). The mean value and 95% confidence limits for the analytical signal obtained under these conditions were 28.05 μA $\pm$ 0.30 μA; thus the detection limit was estimated as $30 \times 0.30/28.05$ μM, which equals 0.3 μM.

3.2. Sensitivity to Cd(II)

Table 1 gives the experimental conditions for the determination of Cd(II), as established by optimizing the cadmium signal by variations of the media used for chemical deposition and voltage scanning. In contrast to the observations for Cu(II), no well-developed reduction peak for

Table 1
Experimental conditions for the determination of Cu(II), Cd(II), and Zn(II) using the modified electrode[a]

Experimental conditions	Cu^{2+}	Cd^{2+}	Zn^{2+}
Deposition medium	Phosphate buffer, pH 6	Ammonia buffer, pH 9	Ammonia buffer, pH 9
Voltage scanning medium	Ammonia buffer, pH 9	Phosphate buffer, pH 6	Phosphate buffer, pH 6
CME regeneration medium, time	0.1 M HNO_3, 40 s	0.1 M HNO_3, 40 s	0.1 M HNO_3, 40 s
Analytical electrode process	Reduction	Oxidation[b]	Oxidation[c]
Square-wave frequency (Hz)	30	60	60

[a] Graphite paste composition: 2.5 g graphite powder, 2.5 g zeolite 13X, 3 ml silicone oil DC 710.
[b] After reduction of the deposit for 120 s at -1200 mV.
[c] After reduction of the deposit for 150 s at -1300 mV.

the cadmium deposit was observed, regardless of the combination of media chosen. Consequently, the procedure for Cd(II) was modified to include an additional step in which the cadmium deposit was reduced to oxidation state 0 immediately after transfer of the CME from the cadmium-containing sample to a fresh solution of electrolyte. Quantitation of the analyte was subsequently carried out by oxidation of the deposit. Using these conditions, the cadmium oxidation peak current increased with deposition time, and, as shown in Fig. 3, with concentration of

Cd(II). Moreover, the signal amplitudes obtained in the standard addition experiment correlated well with the added concentrations of Cd(II) (correlation coefficient, 0.9998). The limit of detection for a 4 min chemical deposition was estimated from 10 consecutive analyses of a solution which contained 600 μg 1^{-1} Cd(II). The mean value and 95% confidence limits for the analytical signal obtained under these conditions were 1.84 μA $\pm$ 0.03 μA; thus the detection limit was estimated as 600 × 0.03/1.84 μg 1^{-1}, equal to 87 nM.
Fig. 2. Standard addition experiment for Cu(II). (Chemical deposition time, 5 min.) Curve a, 0.30 mg 1^{-1} Cu(II); curve b, 0.50 mg 1^{-1} Cu(II); curve c, 0.70 mg 1^{-1}; curve d, 1.00 mg 1^{-1} Cu(II). Broken curve, baseline.
Fig. 3. Standard addition experiment for Cd(II). Concentrations: curve a, 0.2 mg l^{-1}; curve b, 0.4 mg l^{-1}; curve c, 0.6 mg l^{-1}; curve d, 0.8 mg l^{-1}; curve e, 1.2 mg l^{-1}; curve f, 1.6 mg l^{-1}; curve g, 2.0 mg l^{-1}. (Chemical deposition time, 5 min; electrolytic reduction, 150 s.)

3.3. Sensitivity to Zn(II)

Suitable experimental conditions for the determination of Zn(II) are given in Table 1. As for Cd(II), regardless of the combination of media, no well-developed reduction signal was observed for the zinc deposit. Therefore the voltammetric quantitation of Zn(II) was preceded by a reduction step, and the oxidation signal was used as the analytical response. Using these conditions, the zinc oxidation peak current increased with deposition time and with concentration of Zn(II). Furthermore, the signal amplitudes obtained in a standard addition experiment (0.00, 0.20, 0.50, 0.80, and 1.20 mg l^{-1} Zn(II), chemical deposition for 5 min, electrolytic reduction for 5 min) correlated well with the added concentrations of Zn(II) (correlation coefficient, 0.9997). The limit of detection for a 4 min chemical deposition was estimated from 10 consecutive analyses of a solution which contained 200 μg l^{-1} Zn(II). The mean value and 95% confidence limits for the analytical signal obtained under these conditions were 2.10 μA $\pm$ 0.10 μA; thus the detection limit was estimated as 200 × 0.10/2.10 μg l^{-1}, equal to 145 nM.

3.4. Competing species in the zeolite accumulation of Zn(II)

The zinc signal obtained following a 4 min chemical deposition from 1 mg l^{-1} Zn(II) in ammonia medium was significantly affected by additions of milligram per litre concentrations of Ag(I), Cu(II), Cd(II), Hg(II), Ni(II), and Co(II) to the deposition solution. The additions of Hg(II) gave rise to steadily increasing zinc signal amplitudes, an effect which could be attributed to the reduction of Hg(II) and hence the formation of metallic mercury, such that the zinc oxidation took place by the oxidation of zinc amalgam. On additions of Ag(I), Cu(II), and Cd(II), the zinc signal initially increased (compare Fig. 4 for Ag(I)). This observation was explained by the possibility of the linear Ag(NH$_3$)$_2^+$, planar Cu(NH$_3$)$_4^{2+}$, and tetrahedral Cd(NH$_3$)$_4^{2+}$ ions entering the 10 Å zeolite pores simultaneously with the tetrahedrally coordinated Zn(NH$_3$)$_4^{2+}$ ion such that elemental silver, copper, and cadmium, formed during the reduction step, exerted a catalytic effect on the reduction of the zinc complex. However, the overall trend was a decrease in the
Fig. 4. Effects of Ag(l) additions on the zinc signal obtained following a 4 min chemical deposition from 1 mg l^{-1} Zn(II).

zinc signal. Since the concentrations in the deposition medium of the analyte Zn(II) and the interfering species Ag(I), Cu(II), and Cd(II) were all of the same order of magnitude, and, since the electrode was transferred to a clean electrolyte medium and reduction of the deposits was carried out before voltammetric quantitation, Zn(II) as well as the interfering species (e.g. Cd(II)) existed in oxidation state 0, before the anodic potential scan was started. Consequently, the decreasing zinc signals could not be explained by a simple

redox exchange (e.g. between Cd(II) and Zn(0)), which would be possible only if voltage scanning was carried out in the the bulk of the deposition medium. The decrease in the zinc signal and the increasing silver signal observed upon the addition of Ag(I) were therefore attributed to an increasing competition from $Ag(NH_3)_2^+$ ions for available sites in the zeolite. Qualitatively, the effects on the zinc signal of the addition of Cu(II) and Cd(II) were analogous to those observed for Ag(I). However, quantitatively, the decreases were more pronounced. This latter observation could be explained by the increased size of the competing ions $Cu(NH_3)_4^{2+}$ (planar coordination), and $Cd(NH_3)_4^{2+}$ (tetrahedral coordination). The $Ni(NH_3)_6^{2+}$ and the $Co(NH_3)_6^{2+}$ complexes were not reducible at the potentials covered in this experiment; thus no oxidation signals for nickel and cobalt were observed. However, the effects of both Ni(II) and Co(II) were significant. Most notably, as shown in Fig. 5, the addition of 1 mg l^{-1} Co(II) completely eliminated the zinc signal. This dramatic effect was attributed to the ability of the octahedrally coordinated ions to enter the zeolite pores and thereby, because of their size, efficiently prevent simultaneous accumulation of $Zn(NH_3)_4^{2+}$. Figs. 6 and 7 shows the changes in

Fig. 5. Effects of Co(II) additions on the zinc signal obtained following a 4 min chemical deposition from 1 mg l^{-1} Zn(II).
Fig. 6. Effects on the zinc signal (following a 4 min chemical deposition from 1 mg l^{-1} Zn(II)) of additions of Ag(I), Cu(II) and Cd(II).
Fig. 7. Effects on the zinc signal (following a 4 min chemical deposition from 1 mg l^{-1} Zn(II)) of additions of Hg(II), Ni(II) and Co(II).

the zinc signal amplitude (obtained following a 4 min chemical deposition from 1 mg l^{-1} Zn(II)) as a result of the addition of the above-mentioned species. If expressed as the average percentage decrease of the zinc reduction current per μM added of the interfering species, the effects of the interferences were as follows: Ag(I), 0.65; Cu(II), 0.93; Cd(II), 2.35; Ni(II), 2.39; Co(II), 3.20.

Thus, if the metallic species were placed in order according to their suppression of the zinc signal, the following order was obtained: Co > Ni > Cd > Cu > Ag.

This order was identical to the trend of the metal ions when listed according to decreasing coordination number with ammonia. Thus the results underline the ability of the zeolite modifier to discriminate according to size. Conversely, if the zinc concentration in the ammonia medium and the deposition time were kept constant, and if the attenuation of the zinc response was taken as the analytical signal, the CME acted as a device

which was sensitive to the size and geometry of the interfering species.

Abstract

A simple and rapid preconcentration technique, based on collecting trace nitrite on a membrane filter and dissolving the membrane filter in an organic solvent, has been applied to its spectrophotometric determination in water. At pH 2.0, nitrous acid diazotizes with p-aminoacetophenone, which is then coupled with N-(1-naphthyl)-ethylenediamine, at the same pH. The azo dye formed is collected on a 0.45 μm nitrocellulose filter at pH 4.7 as its ion associate with dodecyl sulfate. The ion associate and filter are dissolved in a small volume of 2-methoxyethanol (methylcellosolve), and acidized with 0.05 ml of 2 M hydrochloric acid and the absorbance of the resulting solution is measured at 555 nm against a reagent blank. Detection limits better than 0.1 μg/dm^{-3} as NO_2^- can be achieved. The ions normally present in water do not interfere when sodium metaphosphate is added as a masking agent. The proposed method has been applied to the analysis of water samples from several sources, the recoveries of the nitrite added to the samples are quantitative, and results found are satisfactory.

Keywords: Nitrite; Photometric determination; Preconcentration; Soluble filter

1. Introduction

It has become very important to determine trace amounts of nitrite in environmental protection, some chemical processes, the food industry and hygiene applications. Many reagents for the spectrophotometric determination of nitrite at very low concentrations have been reviewed and

_____
* Corresponding author. Fax: (86)10-841-6837.

usually employed with one of the modifications of the Griess–Ilosvay reactions [1]. The procedure using the Griess–Ilosvay reaction seems to be a satisfactory one, but in order to enhance sensitivity extraction has been proposed. It was reported [2] that nitrous acid diazotizes p-aminoaceto-phenone, which is then coupled with m-phenyl-enediamine; the 2,4-diamino-4'-acetyl-azobenzene formed is extracted into toulene at pH 9, and the absorbance measured at 450 nm. The molar absorptivity is about 2.3×10^4 l mol^{-1}. An improve-

ment to this extraction system was later suggested by Zhou and Xie [3]. It was reported that nitrite diazotizes with p-aminoacetophenone at pH 2.0, and is then coupled with N-(1-naphthyl)-ethyldiamine; the azo dye formed is further associated with β-naphthyl sulfonic acid in acid medium and extracted into n-butanol in the presence of aluminium nitrate and salted-out at the same pH; the absorbance of the extract is measured at 555 nm and the molar absorptivity is about 4.8×10^4 l mol^{-1} cm^{-1}.

Though solvent extraction of the nitrite has achieved considerable success in increasing the sensitivity and improving the detection limit to better than 10 μg dm^{-3}, the enrichment factor is usually limited by the mutual solubility of organic solvent and water. It is also especially tedious to twice introduce pollution of the solvent.

Recently, solvent-soluble membrane filters (MFs) have been reported for the rapid and simple preconcentration of trace components in water [4–6]. This new pre-concentration technique, which is based on collecting the analyte on a membrane filter and dissolving the membrane in an organic solvent, resembles solvent extraction but has many advantages over solvent extraction. Maximum possible concentration factors are not limited by the mutual solubility of water and organic solvent. Concentration factors greater than 100 can easiy be obtained.

In previous studies, this preconcentration technique has been used by one of the authors in place of solvent extraction for the determination of nitrite in water [7]. A ten-fold preconcentration (with 50 ml sample volume) can be done in a short time (with high sample throughout >50 ml min^{-1}) with a detection limit of 0.5 μg dm^{-3} as NO$_2^-$. Nitrite ion is converted to 4-sulfobenzenediazonium ion and then coupled with 1-aminonaphthalene to form an azo dye, which is collected on a nitrocellulose membrane filter as its ion-associate with benzyldimethyltetradecylammonium ion at about pH 4.7. The resulting compound is dissolved in methyl-cellosolve.

In the present investigation, the authors developed a more sensitive and selective preconcentration-spectrophotometric method for trace nitrite

ion in water samples by applying the principle mentioned above. The main improvements on this method have been suggested.

The conditions for the formation of a coloured ion associate are similar to those reported in earlier work on extraction of nitrite [3]. The volumes of reagent added are varied in proportion to the sample volume. The most attractive features of the new pre-concentrated methods are diazotizing with p-aminoacetophenone which has a hydrophobic substitutive group, associating with an anion surfactant having a long-chain alkyl such as sodium dodecyl sulfate and collecting the ion associate in a acid medium. Therefore the sensitivity and selectivity of the present method are enhanced. The detection limit is 0.1 μg dm^{-3}NO$_2^-$ on a 3σ basis under 100-fold preconcentration (with 500 ml sample volume), and Beer's law is obeyed in the range 0.1–1.0 μg NO$_2^-$ in 5 ml of solvent with excellent reproducibility. In this paper optimum conditions of the experiment and analytical results are reported.

2. Experimental

2.1. Reagents

Standard nitrite solution

Dissolve 0.492 g anhydrous sodium nitrite (dried in desiccator for 4 h) in 100 ml water (1.00 mg nitrogen or 3.28 mg nitrite per ml). Prepare a working solution by suitable dilution and store in a brown bottle in a refrigerator. Standardize iodometrically before using.

p-Aminoacetophenone hydrochloride solution

Prepare a 0.5% (w/v) solution in 1 + 9 hydrochloric acid, and store in a brown bottle: N-(1-naphthyl)-ethylenediamine dihydrochloride solution.

Dissolve 0.5 g N-(1-naphthyl)-ethylenediamine dihydrochloride in 100 ml of 1 + 99 hydrochloric acid.

Sodium dodecyl sulfate solution

Prepare a 1.00×10^{-3} M aqueous solution. Dissolve 0.288 g sodium dodecyl sulfate in 1 l water.
Fig. 1. Azo dye formation from nitrite, *p*-amino acetophenone and *N*-(1-naphthyl)-ethylenediamine.

β-Naphthyl sulfonic acid 0.5% (w/v)

Dissolve 0.5 g *β*-naphthyl sulfonic acid in 100 ml water. Adjust to pH 6.0 with sodium hydroxide solution.

Sodium metaphosphate solution: 5.0% (w/v).

Unless stated otherwise, all reagents used are of analytical pure grade, and all solutions are diluted with nitrite-free water, which is obtained by distilling alkaline permanganate–distilled water using an all-glass distillation apparatus.

2.2. Apparatus

A UV–visible spectrophotometer UV-265 Model (Shimadzu, Japan), visible spectrophotometer 723 Model (Shanghai Third Analytical Instruments Factory, China), a pH Meter pHs-2 Model (Shanghai Second Analytical Instruments Factory, China) were used.

Membrane filters and holder: Most of the data presented in this paper were obtained with a nitrocellulose membrane (25 mm in diameter, 0.45 μm pore size, Adjective Factory of Chemical Engineering College of Beijing, Beijing 100029). A Toyo KG-25 filter holder (effective filtration area 1.3 cm²) was used.

2.3. Procedure

Add about 50 ml of sample solution containing 0.1–1.0 μg nitrite-N to a 150 ml beaker. Add 1.0 ml of *p*-aminoacetophenone hydrochloride

solution and adjust to pH 2.0 with either sodium acetate solution or hydrochloric acid. After 15 min standing at room temperature, add 1.0 ml of *N*-(1-naphthyl)-ethylenediamine dihydrochloride solution and swirl. Add 2.0 ml of sodium dodecyl sulfate solution and mix thoroughly again. Filter off the ion associate on the membrane filter, and wash the membrane with about 10 ml of water. Dissolve the filter in 5 ml of 2-methoxyethanol and acidize with 0.05 ml 2 M hydrochloric acid. Absorbance due to the associate in the solvent is measured in a 10 mm cell at 555 nm against a reagent blank.

3. Results and discussion

3.1. Reactions for colour development

In an acidic solution, nitrite reacts with a primary aromatic amine to produce diazonium salt, which in turn couples with an aromatic amine or phenol to form a coloured azo dye. In the orignal Griess reaction, sulfanilic acid was used and diazotized, but the azo compound formed cannot be collected quantitatively by the membrane filter becauase of the hydrophilic nature of the sulfonic group. By using *p*-aminoacetophenone in place of sulfanilic acid [2], the hydrophobic ability of the azo compund is enhanced, favouring collection on a membrane filter. The reactions for colour development are as shown in Fig. 1.

3.2. Absorption spectra

Absorption maximum of the azo compound formed by diazotization of nitrous acid with p-aminoacetophenone and its coupling with N-(1-naphthyl)-ethylenediamine in aqueous solution is 543 nm; that of the ion associate in organic solvent is at 480 nm and that of the species in organic solvent after acidation is at 555 nm. All absorbance measurements of the extract are made at the latter wavelength. Absorption spectra are shown in Fig. 2.

3.3. Selection of counter ion

In previous work [7] nitrite is converted to 4-sulfobenzendiazonium ion, which is then coupled with 1-aminonaphthalene to form an azo dye as in the conventional method, and the azo dye formed is collected on a nitrocellulose filter as its ion associate with a larger cation, benzyl-dimethyltetradecyl ammonum ion, at about pH 4.7 (acetate buffer). Collection is poor at pH lower than 4, where most of the azo dye is in the pink, zwitterionic form and the selectivity of the reaction is not good. In the present investigation the azo dye obtained by diazo coupling with p-aminoacetophenone and N-(1-naphthyl)-ethylenediamine is protonated in the acidic media as the

Fig. 2. Absorption spectra of the azo dye. Nitrite in aqueous solution: 1.0 μg per 50 ml. (A) No concentration, pH 2.0. (B) Membrane concentration, not acidified. (C) Membrane concentration, acidified.

cation form. By using a large anion, the dye cation can be collected on the membrane filter as an ion association complex. Hexoic acid, benzene sulfonic acid, naphthyl sulfonic acid and sodium dodecyl sulfate were investigated as sources of large anions. It was found experimentally that sodium dodecyl sulfate is preferable for obtaining efficient collection.

3.4. Effect of pH

A study of the effect of pH on the relevant diazo coupling reaction and collecting on the membrane filter disclosed that diazotization of p-aminoacetophenone should be carried out in acidic solution and a constant and maximum absorbance is obtained at pH 0–3; in the coupling of the diazonium cation with N-(1-naphthyl)-ethylenediamine, the coloured compound has a constant absorbance in the pH range 1.0–3.0; the ion associate of azo dye with dodecyl sulfate can be collected on the membrane filter at a pH between 1.0 an 5.0 without adjusting that of the solution. In practice, when 1.0 ml of p-aminoacetophenone hydrochloride solution is added to a sample, the pH becomes about 2.0, it remains almost the same even when N-(1-naphthyl)-ethylenediamine is added and after adding sodium dodecyl sulfate the pH of the aqueous solution is about 4–5 (4.7 in practice). In order to minimize the effect of foreign ions in diazo coupling a pH of 2.0 is preferred.

3.5. Effect of temperature

Diazotization and coupling are usually carried out at 0–5°C. However, reactions in this case proceed quantitatively at 10–30°C. Therefore the reactions may be carried out at room temperature.

3.6. Effect of standing time

A complete diazotization requires at least 5 min, and the coupling reaction requires 15 min or more. The azo compound formed in the aqueous phase is stable for at least 2 h, and in the organic phase for 24 h.

Table 1
Effect of other factors on formation and collection of azo dye (for 50 ml water sample)

Variable	Tested	Optimum	Preferred
Amount of p-aminoacetophenone (ml)	0.1–2.0	0.8–2.0	1.0
Amount of N-(1-naphthyl)-ethylenediamine (ml)	0.1–2.0	0.2–2.0	1.0
Amount of sodium dodecyl sulfate (ml)	0.5–3.0	1.5–2.5	2.0
Amount of solvent (ml)	5	5	5
Volume of washing water (ml)	10 × (1–5)	10 × (1–3)	10 × 3
Standing time after diazo coupling (min)	5	10–30	15
Stirring time after addition of surfactant (min)	1.0–4.0	2.0–4.0	3.0

3.7. Membrane filter for collection

Several filters of different types and with different pore sizes were examined for their usefulness for collecting the azo ion associate with nitrite. Nitrocellulose membrane filters are suitable because they readily dissolve in 2-methoxyethanol. Although any nitrocellulose membrane filter with pore sizes between 0.2 and 0.6 μm can be used, 0.45 μm filters are recommended because of their more stable absorbance of colour compound and acceptable filtration rate of about 50 ml min^{-1}.

The analyte on a membrane filter should be washed three times with water to decrease the reagent blank.

3.8. Solvent

Water-miscible organic solvents were tested as solvents for the wet membranes. Dimethyl sulfoxide (DMSO), N-N-dimethylformamide (DMF), acetone and 2-methoxyethanol readily dissolve the nitrocellulose and acetylcellulose membranes, but acetone is not recommended because of its high volatility. The colour intensity weakens obviously and decreases rapidly with time in DMSO and DMF. Absorbance of the colour compound is almost constant in 2-methoxyethanol for 24 h and is recommended as a proper solvent in the determination of nitrite. Other water-miscible solvents, such as ethanol, methanol and acetonitrile, will not dissolve the membrane under normal conditions.

3.9. Effects of other factors

Other factors, such as the amounts of reagents, time etc., recommended for the formation of azo dye and its collection on a membrane filter are shown in Table 1.

The volume of aqueous phase can be increased to 1000 ml and good concentration is still obtained on condition that the amount of reagents should be increased in proportion to the 50 ml water sample. For example, for treating a 250 ml sample of water the amount of reagents should be increased five fold. For convenience 500 ml sample of water is often used.

3.10. Sensitivity, precision and linear relation

Table 2 shows that microgram quantities of nitrite-nitrogen in 50 ml of sample can be determined with satisfactory precision. The lower limit of determination (taken as three times the standard deviation of the blank) is about 0.002 μg of nitrite-nitrogen per 100 ml of sample

3.11. Precision

Absorbances of 11 runs for 0.6 μg NO$_2^-$-N(50 ml) are 0.423, 0.424, 0.403, 0.417, 0.416, 0.406, 0.416, 0.406, 0.417. $X = 0.415$; $S = 9.0 \times 10^{-3}$; C.V. = 2.17%.

3.12. Linear relation

The regression equation in the range 0.1–1.0 μg NO$_2^-$-N is $y = -0.023 + 0.76X$ with a relative coefficient of 0.9997.

Table 2
Reproducibility at different nitrite levels[a]

Nitrite taken (µg) NO$_2^-$-N	Concn. of nitrite (µg dm^{-3})		Absorbance at 555nm		
	as N	as NO$_2^-$	$\bar{X}$	s	RSD (%)
0.2	4.0	13.1	0.121	0.005	3.8
0.4	8.0	26.3	0.254	0.006	2.4
0.6	12	39.4	0.403	0.007	1.7

Wellwater	0	0.434	39.5	–	–

3.13. Effect of diverse components

The effect of diverse components on the formation of azo dye and collecting of the ion associate by membrane filter was examined. In this study, the tolerance limit was set as the amount which caused an error of ±5% in the recovery of 1 µg of nitrite in a 50 ml sample. At the nitrite level no interference was found with the following ions (where present the amount in milligrams and the form in which they were added are given in parantheses): Na$^+$ (200, NaCl); K$^+$ (200, KCl); NH$_4^-$ (200, NH$_4^+$Cl); Ca^{2+} (5, CaCl$_2$); Mg^{2+} (5, MgCl$_2$); Sr^{2+} (2, SrCl$_2$); Mn^{2+} (2, MnSO$_4$); Cd^{2+} (2, CdCl$_2$); Cu^{2+} (1, CuSO$_4$); Pb^{2+} (1, Pb(NO$_3$)$_2$); Zn^{2+} (1, ZnSO$_4$); Hg^{2+} (0.5 Hg (NO$_3$)$_2$); Co^{2+} (0.1 CoCl$_2$); Mo(VI) (0.1, Na$_2$MoO$_4$); Al^{3+} (2000, Al(NO$_3$)$_3$); Ga^{3+} (1, Ga(NO$_3$)); Cr^{3+} (1, CrCl$_3$); As(III) (0.1, Na$_3$AsO$_3$); Sb(V) (1, Sb(NO$_3$)$_5$); Cl$^-$ (500, HCl); F$^-$ (40, NaF); CH$_3$COO$^-$ (30, CH$_3$COONa); BO$_2^-$ (14, Na$_2$B$_4$O$_7$); Br$^-$ (8, NaBr); I$^-$ (1, KI); PO$_4^{3-}$ (200, (NaPO$_3$)$_6$); citrate (30, citric acid); tartrate (30, tartric acid). Interference by large amounts of 5 mg or more of Fe^{3+} can be masked by addition of sodium metaphosphate.

3.14. Application of natural water samples

The proposed method was applied for the analysis of river water and groundwater samples filtered through a 0.45 µm membrane filter. Table 3 shows the analytical results of original samples and samples to which known quantities of nitrite has been added. Recovery of the added nitrite was nearly quantitative as shown in this Table.

Equilibrium studies of the diorganotin(IV) complexes with some amino acids and related compounds

Mohamed M. Shoukry

Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

Abstract

The interaction of dimethyltin(IV) and diethyltin(IV) cations with water and some amino acids and related compounds was investigated at 25°C and ionic strength 0.1 M $NaNO_3$ using a potentiometric technique. The results showed the formation of 1:1 and 1:2 (organotin:ligand) complexes and the corresponding stability constants were determined. The participation of different ligand functional groups in binding to organotin is discussed. The effect of the pK_a value of the respective ligand on the stability constant of its complex species was elucidated. The concentration distribution of the complexes in solution was evaluated.

1. Introduction

A variety of organotin complexes structurally related to *cis*-platin and its derivatives [1,2] have been investigated for antitumour properties [3-6]. Recent studies [7-9] of compounds of the type $R_2SnX_2 \cdot L$, where L is generally a bidentate ligand, have suggested a relationship between their antitumour activity and stability. In the case of nitrogen-bearing ligands [10], incresing stability is thought to reduce activity by hindering the dissociation of the ligand that is necessary for binding between tin and DNA. In view of this, encouraging results on the antitumour activity of diorganotin(IV) complexes with bipyridyl [7] and 2,2′-bi-imidazole [11] have led us to investigate the solution equilibria of organotin complexes. As part of our project dealing with the study of metal complexes of expected antitumour activity [12-14] and as a continuation of our previous studies on triorganotin(IV) complexes [15-17], the present investigation aims to characterize the complex formation equilibria of diorganotin(IV) with amino acids and related compounds.

2. Experimental

2.1. Materials and reagents

Dimethyltin(IV) and diethyltin(IV) chlorides were received from Alfa Inorganics Chem. Co.

The ligands used were glycine, alanine, phenylalanine, valine, leucine, serine, proline, hydroxyproline, methionine, histidine·HCl, histamine·2HCl, ornithine·HCl, lysine·HCl, bipyridyl and phenanthroline·HCl. These materials were supplied by Fluka Chem. Co. Carbonate-free sodium hydroxide stock solutions were prepared by diluting the contents of BDH concentrated volumetric solution vials. These solutions were systematically checked by titration against potassium hydrogen phthalate. All solutions were prepared in deionized water.

2.2. Procedure and measuring techniques

Potentiometric titrations were carried out using a Metrohm 686 titroprocessor equipped with a 665 Dosimat (Switzerland). The buffer solutions (pH 6.86 and 4.01) based on the NBS scale [18], now U.S. National Institute of Standards and technology (NIST), were used for calibration. The following mixtures (A)–(C) were prepared and titrated potentiometrically with sandardized NaOH solution:

(A) 0.02 mol dm^{-3} ligand (10 cm^3) + 0.13 mol dm^{-3} NaNO$_3$ (30 cm^3).

(B) 0.02 mol dm^{-3} organotin(IV) (10 cm^3) + 0.13 mol dm^{-3} NaNO$_3$ (30 cm^3).

(C) 0.02 mol dm^{-3} organotin(IV) (10 cm^3) + 0.02 mol dm^{-3} ligand (20 cm^3) + 0.40 mol dm^{-3} NaNO$_3$ (10 cm^3).

The titrations were performed in a special vessel described previously [19] at 25°C in a purified N$_2$ atmosphere. The ionic strength remained almost constant during titration, $\mu = 0.1$ M. The acid dissocation constants of the ligands were determined by titrating mixture (A), where the ligand is in the protonated form. The stability constants of the hydroxo complexes [R$_2$Sn(OH)$_n$] were determined by titrating mixture (B). The stability constants of the organotin(IV) complexes were determined by titrating mixture (C).

The species formed in the systems studied were characterized by the general equilibrium process (1), while the formation constants for these generalized species are given by Eq. (2):

$$p(M) + q(L) + r(H) \rightleftharpoons (M)_p(L)_q(H)_r \qquad (1)$$
$$\beta_{pqr} = \frac{[(M)_p(L)_q(H)_r]}{[M]^p[L]^q[H]^r} \qquad (2)$$

where M, L and H stand for organotin(IV), ligand and proton respectively. The calculations were performed using the computer program MINIQUAD-75 [20] loaded on an IBM-4336 computer. The stoichiometries and stability constants

of the complexes formed were determined by trying various composition models for the system studied. The model selected was that which gave the best statistical fit and which was chemically consistent with the titration data without giving any systematic drifts in the magnitudes of various residuals, as described elsewhere [20]. The fitted model was tested by comparing the experimental titration data points and the theoretical curve calculated from the values of acid dissociation constants of the ligand and formation constants

of the corresponding complexes. Tables 1 and 2 list the stability constants together with their standard deviations and the sum of the square of residuals as output by the program MINIQUAD-75.

3. Results and discussion

The acid dissociation constants of the ligands were determined under the same experimental conditions of ionic strength and temperature
Fig. 1. Concentration distribution diagram for the dimethyltin(IV)–OH system.

which are used for the study of organotin(IV) complex equilibria. The results obtained are in good agreement with literature values [21].

The acid–base chemistry of diorganotin(IV) has been characterized by fitting the potentiometric data (mixture B) to various acid–base models.
Fig. 2. Potentiometric titration curves in diethyltin(IV)–glycine system: (1) Glycine; (2) 1:2 DET–glycine.

The fitted model, according to the aforementioned method of calculation, was found to be consistent with the mono- and dihydroxo-organotin(IV) $[R_2Sn(OH)_n$, where $n = 1$ and 2]. The concentration distribution of the hydroxy-species is shown in Fig. 1.

The potentiometric titration curve of a solution mixture of dimethyltin(IV) and glycine (mixture C), taken as a representative, is given in Fig. 2. The curve starts at pH 3.2 and passes two inflections at $a = 1$ and $a = 2$ (a is the number of moles of base added per mole of organotin(IV)), corresponding to the formation 1:1 and 1:2 complex species respectively.

Diorganotin(IV) compounds form complexes with various structural geometries. It was concluded that the trigonal bipyramidal tin environment [22] characterizes the diaorganotin(IV)–mercaptocarboxylato complexes. It was demonstrated that 2-(arylazo)pyridine [23] and β-diketones [24] form octahedral complexes with diorganotin(IV). Seven-coordinate pentagonal bipyramidal tin stereochemistry [25] was observed in the 1:1 adduct of diphenyltin(IV) with triphenylphosphine. Accordingly, it is assumed that tin has an octahedral configuration with an equatorial alkyl group. The amino acid coordinates via the amino nitrogen and carboxylate oxygen atoms in the axial position. It should be mentioned that the carboxylate group may bind as bidentate [22,26]. However, if the amino acid interacts with diorganotin(IV) by the two carboxylic oxygen atoms, leaving the amino group non-coordinating, the amino group will be protonated. However, the fitted model, in this investi-
Fig. 3. Relation between pK_a value of the ligand and $\log \beta$ value of the complex.

gation, is found to consist of the deprotonated complex only. This reveals that the amino group is not free and is involved in the complex formation with $R_2Sn(IV)$.

Further studies are needed to support the structural elucidation of the coordination geometry of the organotin(IV) complexes, e.g. the crystal structure of the solid complexes. However, such studies are not yet available and will be considered in the future.

The amino acids methionine and serine have extra binding centres on the thioether and β-alcoholato groups. The thioether group in methionine [27] and β-alcoholato group in serine [28] were reported to participate in transition metal ion complex formation. The stability constants of organotin(IV) complexes of serine and methionine are in fair agreement with those of other amino acids studied, if the difference in the acid dissociation constants of the amino acids is considered. This indicates that serine and methionine chelate diorganotin(IV) as substituted glycinates.

Histidine is a tridentate ligand that has amino, imidazole and carboxylate groups as metal ion

binding sites. With metal ions having a square-planar coordination sphere, for steric reasons, only two of the three binding sites [29,30] i.e. either histamine-like or glycine-like complexes have to be formed. With regard to the protonated complex of histidine the question arises as to where the proton is located? This problem has been discussed by considering the acid dissociation constant of this species, given by Eq. (3) [15]:

$$pK^H = \log K^M_{MLH} - \log K^M_{ML} \qquad (3)$$

The values of pK^H are 4.95 and 5.20 for dimethyl- and diethyltin(IV) complexes respectively. These values compare favourably with the acid dissociation constants of the imidazole residue of histidine ($pK^H = 6.28$) if the increase in its acidity as a result of organotin(IV) complex formation is considered. Furthermore, it should be recognized that the stability constants of the deprotonated complexes of histidine are in fair agreement with the stability constants obtained for the other amino acid complexes. This provides further support for the view that histidine coordinates to organotin(IV) in an amino acid-like form. Lysine and ornithine may coordinate as bidentate ligands either by (N, N) or (N, O) donor sets. The stability constants of their complexes are higher than those of α-amino acids by about four logarithmic units. This may indicate that lysine and ornithine chelate by the (N, N) donor set.

It is reported that for metal complexes with a series of structurally-related ligands, a linear relationship holds between the stability constant of the complex and the acid dissociation constant of the ligand [31]. The importance of these plots is that they afford a means of estimating the stabilities of complexes that have not yet been studied. Fig. 3 demonstrates a relationship between $\log \beta_1$ and $\log \beta_2$ for the diethyltin(IV) complexes of α-amino acids. Lysine and ornithine complexes do not fall on these straight lines, providing further evidence for their different mode of coordination.

It is found (Tables 1 and 2) that the dimethyltin(IV) complexes are more stable than the corresponding diethyltin(IV) complexes. This is explained in terms of steric crowding between the ethyl group and the incoming ligand.

The concentration distribution diagrams in terms of formation precentage as a function of pH were obtained for complexes formed in solutions, using the program SPECIES [32]. The maximum percentages of formation of the various complexes given in Tables 1 and 2 are obtained under the prevailing experimental conditions. In all the species distributions the concentration of the complexes increases with increasing pH, thus making $R_2Sn(IV)$ biologically available in the physiological pH range.

Abstract

Derivative spectrophotometry was applied to solid-phase spectrophotometry in order to enhance its sensitivity and remove the large background noise caused by the absorption of the resin layer itself, and avoid the necessity of preparing a blank. The determination of micro-amounts of molybdenum (at the ng ml^{-1} level) with pyrocatechol violet to form a 1:1 blue complex in acid medium, which is fixed on a dextran-type anion-exchange resin (Sephadex QAE-A-25), is described as an example of the application of this technique. The absorbance of the resin, packed in a 1 mm spectrophotometric cell, was measured directly. The characteristic peak amplitude of the signal at 716 nm in the first-derivative spectra is useful for quantitative determination of molybdenum (2–8 ng ml^{-1}; RSD = 4, 30%) in natural and industrial water samples, plant tissues and soil extracts.

Keywords: Solid-phase spectrophotometry; Derivative spectrophotometry; Pyrocatechol violet; Molybdenum determination; Natural water; Industrial water; Plant tissues; Soil extracts

1. Introduction

Molybdenum is an essential element in plants, having important biochemical functions in nitrate reduction, biosynthesis of nucleic acids and biochemical processes related to the fixation of molecular nitrogen by micro-organisms and bacteria. As either a deficiency or an excess of molybdenum can cause damage to plants, its routine control is highly recommended for healthy plant growth.

Molybdenum is also present in soils and waters [1,2], but generally at lower levels than in plants. Therefore, very sensitive and accurate methods for its determination are required, which are crucial to the understanding of the status and fate of Mo in the environment, and for the detection of

* *Corresponding author.

Mo pollution in order to take timely control measures.

The spectrophotometric methods most commonly used for the determination of Mo require a previous step of pre-concentration. Generally, ion exchangers and other solid supports are used for pre-concentration, but the analyte has to be eluted if a spectrophotometric method is going to be employed and consequently an undesirable dilution is carried out. When spectrophotometry is used in combination with a solid phase, the analytical signal being provided by direct measurements of the absorbance of the species of interest sorbed on the solid support (solid-phase spectrophotometry, SPS), a large increase in sensitivity is achieved [3-8]. This operating technique proposed by Yoshimura et al. [9] was later applied using spectrofluorimetry [10-13]. The large background produced because of strong absorption of the solid phase could be avoided by using derivative solid-phase spectrophotometry (DSPS). This technique has been applied to the determination of both inorganic and organic compounds, but there are only a few cases cited in the literature [14-17].

In this paper, we propose a method for the determination of Mo at trace level by DSPS using pyrocatechol violet (PV) as a chromogenic reagent. The derivative signal of the blank is zero at the measurement wavelength; hence, the necessity of preparing a blank is avoided, reducing both the amount of work and the time required for carrying out the analysis.

2. Experimental

2.1. Reagents

All chemicals used were of analytical grade and the water was doubly distilled.

Molybdenum(VI) standard solution 1.000 ± 0.002 g l^{-1} was prepared from a Titrisol Merck solution of $(NH_4)_6Mo_7O_{24} \cdot 6H_2O$ in 0.7% aqueous NH_3. Solutions of lower concentration were prepared by dilution with doubly distilled water.

The ion exchanger was a Sephadex QAE A-25 (Aldrich). Anion-exchange resin was used in the chloride form and without pre-treatment.

Buffer solutions of pH 2.9 were prepared by dissolving 20.0190 g of KHphthalate in 1000 ml of doubly distilled water containing 257 ml of 0.2 M HCl solution.

PV solutions of various concentrations were prepared by dissolving analytical grade PV (Aldrich) in water.

2.2. Apparatus

A single beam GBC 911 microcomputer-controlled UV/vis spectrophotometer, from GBC Scientific Equipment Ply Ltd. which can store as many as 32 spectral scans and 15 operating programs, with 1 mm glass cells was employed for all spectral measurements. The GBC 911A UV/vis spectrophotometer was connected to a BRAVO AST/30 286 microcomputer by means of a serial port. The GBC SCAN MASTER V 1.62 and Data Leader Software (Beckman) were used for data acquisition and treatment. The spectra were recorded at a scan rate of 250 nm min^{-1}. A COMX PL80 plotter was used for graphical representations. The pH measurements were made using a Crison Model 2002 pH-meter fitted with a glass-saturated calomel electrode assembly and a temperature probe. An Agitaser 2000 rotating bottle agitator was also used.

2.3. Absorbance and first-derivative signal measurements

The absorbance (really attenuation) of the complex species sorbed on the resin (when the normal zero-order absorption spectra of the complex were used) was measured in a 1 mm cell at 663 nm (corresponding to the absorption maximum of the coloured species) and 800 nm (the wavelength at which the sample species no longer absorbs). The net absorbance for the complex was calculated as in a previous report [3].

The first-derivative spectra were recorded; in this case only a single wavelength was required for carrying out the measurements. The negative peak height at 716 nm is related to the concentration of Mo(VI).

2.4. Procedures

(I) A 100 ml water sample containing between 10 and 80 ng ml^{-1} of Mo(VI) was transferred into a 1 l polyethylene bottle, and 5 ml of 7.76×10^{-5} M PV, 15 ml of pH 2.9 KHphthalate/HCl buffer solution ($C_T = 0.2$ M) and 30 mg of Sephadex QAE A-25 resin were added. The mixture was stirred for 30 min, the resin beads collected by filtration and the resin slurry transferred to the spectrophotometric cell with the aid of a pipette. For absorbance measurements, a blank was required and values were obtained as indicated above. The signals of the first derivative were measured as described above.

The calibration graph was constructed in the same way using molybdenum solutions of known concentration.

(II) A 500 ml sample solution containing 5–18 ng ml^{-1} of Mo(VI) was transferred into a 1 l polyethylene bottle, and 5 ml of 2.06×10^{-4} M PV solution, 75 ml of pH 2.9 KHphthalate/HCl buffer solution and 30 mg of Sephadex QAE A-25 resin were added. The agitation time was 1 h, operating as indicated in the above procedure.

(III) To a 1000 ml sample solution containing 2–8 ng ml^{-1} of Mo(VI) (placed in a 2 l polyethylene bottle) was added 10 ml of 1.29×10^{-4} M PV solution, 150 ml of pH 2.9 KHphthalate/HCl buffer solution and 30 mg of ion exchanger. The mixture was agitated for 2 h, in the same way as in the above procedures.

2.5. Treatment of samples

Waters

Natural and industrial waters were filtered through a filter with a pore size of 0.45 μm (Millipore), and the analyses were performed immediately. The usual general precautions were taken to avoid contamination.

Vegetal tissue

Potato leaves were picked during the flowering period. The sample comprised the third or fourth leaves from the apex [18]. It was immediately dried in a forced draft oven for 24 h at 65°C to prevent decomposition or weight loss. After the

sample had been divided into pieces and ground with a small mill, a suitable portion was weighed (9 g dry material) into a quartz crucible; mineralization was carried out by heating slowly to 450°C over 2 h and holding at this temperature for other 2 h. The ashes were wetted down carefully with a fine stream of doubly distilled water, followed by the addition of 1 ml of concentrated HCl and heating until the first vapours were formed. The solution was filtered through Whatman no. 42 paper over a 25 ml standard flask. The filter paper was stored in a quartz crucible and heated in a furnace for 30 min at 550°C. The ashes were then treated with 5 ml of HF in a teflon crucible, taken to dryness, and finally 1 ml of concentrated HCl and warm water were added. The solution was filtered through Albet no. 242 paper in the same 25 ml standard flask and made up to volume with distilled water.

Soil extracts

A sample of soil was taken from 0–20 cm depth in the University Campus of Jaén. 50 g of sieved and air-dried material were weighed and placed in a 200 ml polyethylene bottle, adding 100 ml of water. After 12 h agitation, the solution was filtered through Albet no. 242 paper.

3. Results and discussion

3.1. Spectral characteristics

(a) Zero-order spectra

PV reacts with Mo(VI) in solution to give a chelate that is fixed on Sephadex anion-exchange resin, showing an absorption maximum at 663 nm and a green or blue colour (depending on the amount of reagent sorbed on the resin). PV is also fixed on Sephadex QAE A-25, showing a sharp absorption peak (basic medium) at about 630 nm (540 nm in solution); this peak disappears when the pH decreases to about 3. The spectra of the complex in solution and the solid phase are shown in Fig. 1. A strong increase in sensitivity in the solid phase compared to in solution can be seen.

(b) Derivative spectra

Derivative spectra of different orders were obtained from stored zero-order spectra using numerical differentiation with the program GBC SCAN MASTER V 1.62, being selected as more appropriate for the determination of first-order spectra. A scan speed of 250 nm min^{-1} was selected after verifying that this parameter did not influence the intensity or shape of the derivative spectra. A smoothing function was used in order to reduce the noise levels in the derivative spectra. This function was based on the Savitzky–Golay method [19]. The first-derivative spectra were smoothed using 25 experimental points.

The influence of the $\Delta\lambda$ value on the derivative spectra was tested between 0.5 and 11.5 nm. 5.7 nm was considered as suitable for the first-derivative spectrum.

Using the zero-crossing technique, we can avoid the necessity of preparing a blank by measuring the signal at $^1D_{716.0}$ ($^1D_{716.0} = 0$ for blank).
Fig. 1. Net absorption spectra of the Mo(VI)–PV complex: (A) on the resin (resin as reference), [Mo(VI)] = 1.04 × 10^{-6} M, [PV] = 6.47 × 10^{-6} M, pH 2.9, 100 ml sample, 30 mg resin, 1 mm glass cell; (B) in aqueous solution, [Mo(VI)] = 6.25 × 10^{-5} M, [PV] = 6.00 × 10^{-4} M, pH 2.9, 10 mm glass cell.

3.2. Optimization of variables

The optimum pH for the formation and fixation of the species was found within the range 2.5–3.0. The values of the first-derivative signal of the blank can be considered as zero at pH 3; at pH values above 3.0 this signal increases significantly. A 0.03 M concentration of pH 2.9 KHphthalate/HCl buffer was selected to obtain an adequate buffering capacity. The working wavelength selected was 716 nm corresponding to a maximum value of the first-derivative signal.

The effect of PV concentration was studied for 100 ml, 500 ml and 1000 ml samples, and the optimal values found were 3.88 × 10^{-6} M, 2.06 × 10^{-6} M and 1.29 × 10^{-6} M for a PV to molybdenum ratio of about 12, 16 and 16 respectively.

The optimum stirring times were 30, 60 and 120 min for 100, 500 and 1000 ml respectively. 30 mg of resin, the amount required to fill the cell and ease handling, was used in all measurements. The fixed complex was stable for at least 16 h after equilibration.

3.3. Nature and distribution of the fixed complex

The stoichiometry of the complex formed and sorbed on the resin at pH 2.9 was studied by the methods of Asmus and Job. In both instances, the ligand to metal ratio found was 1:1. This result agrees with that found in the literature [20].

The global complexation–fixation process can be represented by the following scheme:

$$MoO_2^{2+} + H_3L^- \rightleftharpoons MoO_2HL^- + 2H^+$$

(complexation process)

$$MoO_2HL^- + Cl_m^m \cdot R^{m+} \rightleftharpoons$$

$$MoO_2HL^- Cl_{m-1}^{(m-1)} \cdot R^{m+} + Cl^-$$

(fixation process)

$$MoO_2^{2+} + H_3L^- + Cl_m^m \cdot R^{m+} \rightleftharpoons$$

$$MoO_2HL^- Cl_{m-1}^{1)} \cdot R^{m+} + Cl^- + 2H^+$$

(global process)
Table 1
Analytical parameters

Parameter	Volume of sample system		
	100 ml	500 ml	1000 ml
Intercept	-2.11×10^{-3}	-4.986×10^{-3}	-5.031×10^{-3}
Slope	3.064×10^{-4}	1.602×10^{-3}	2.605×10^{-3}
Linear dynamic range (ng ml^{-1})	10–80	5–18	2–8
Correlation coefficient	0.9999	0.9971	0.9979
Detection limit (ng ml^{-1}) [26]	0.114	0.032	0.024
Quantification limit (ng ml^{-1}) [27]	0.377	0.107	0.080
RSD (%)	3.52	3.14	4.30

The distribution ratio of the complex was determined and an average value of $D = (4.9 \pm 0.2) \times 10^5$ ml g^{-1} was obtained from four replicate experiments.

4. Analytical parameters

The linear dynamic ranges of the calibration graphs of the first-derivative signal and the reproducibility (RSD%), for each proposed method, are shown in Table 1. It is noticeable that the system does not rigorously follow Beer's law, as a threshold concentration seems to exist below which there is no signal. We can verify that this also happens in the solution method. Other analytical parameters are shown in Table 1. It can be observed that the values of the limit of detection (LOD) and limit of quantification (LOQ) are lower than those reported by Vilchez et al. [13] for the determination of Mo by solid-phase spectrofluorimetry, and similar to those found by us for other elements by SPS [3,6,7]. Nevertheless, the LOD and LOQ values shown in this table are really apparent due to the mentioned threshold concentration. Consequently, in practice, these values should be increased in the corresponding threshold concentration, i.e. 6.89, 3.11 and 1.93 ng ml^{-1} for 100, 500 and 1000 ml respectively.

The sensitivity, expressed as apparent molar absorptivity, of the proposed methods was compared with that of spectrophotometric procedures (including extractive procedures and formation of ternary complexes with surfactants) described in the literature [21–24]. Whereas the sensitivity of

these methods is between 1.60×10^4 and 1.3×10^5 l mol^{-1} cm^{-1}, the procedures proposed in this paper offer a sensitivity 10^3–10^4 higher than these and also higher than another method of determination of Mo by SPS [25].

This effect is expected to be more intense when the distribution ratio has a high value. In our case, D is especially high (4.89×10^5 ml g^{-1}). Hence, the increase in sample volume will produce an increase in sensitivity if the amount of resin stays constant. Thus, one of the main advantages of SPS methods is the potential increase in sensitivity with an increase in the sample volume taken for analysis. This effect can be calculated by measuring the first-derivative signal of resin equilibrated with different volumes of solutions containing the same concentration of Mo(VI) and proportional amounts of the other reagents. Fig. 2 shows that the signal increases with sample volume up to a value of 1500 ml and becomes
Fig. 2. Influence of the sample volume on colour development. [Mo(VI)] = 1.04×10^{-7} M, [PV] = 3.88×10^{-6} M, pH 3, 30 mg resin.

Table 2
Effect of foreign ions on the determination of 50 ng ml^{-1} of molybdenum

Foreign ion	Tolerance level (ng ml^{-1})
SO_4^{2-}	2000
NO_3^-	1500
Ca^{2+}, PO_4^{3-}	1000
F^-	900
Al^{3+}, EDTA, Zn^{2+}, Mn^{2+}	500
Cu^{2+}	300
Mg^{2+}	250
Cl^-	100
W^{6+}	25
Fe^{3+}	5

independent of the volume at higher values, as usually found in SPS.

The increase in sensitivity with increase in volume of the sample can be calculated from the slope of the calibration graphs. The calculated values of the sensitivity ratio (S) for the samples analysed in this paper are $S_{1000-100} = 8.5$, $S_{1000-500} = 1.62$ and $S_{500-100} = 5.23$, where the subscripts represent the sample volume (ml).

4.1. Effect of foreign ions

A detailed study of interference effects on the determination of molybdenum at the 50 ng ml^{-1} level was carried out following the general procedure for a 100 ml sample system. A maximum level of potentially interfering ions of 2000 ng ml^{-1} was tested. Ions were considered as non-interfering when they produced an error of less than 5% in the determination of analyte. The tolerance limits for the ions studied are summarized in Table 2. The most severe interference was caused by iron and tungsten. The latter causes a positive error because tungsten forms a complex with PV that absorbs at the wavelength used in the procedures. With respect to Fe(III), the interference could be suppressed by using 1,10-phenanthroline after reduction to Fe(II) with hydrogen in acidic medium. The cationic complex Fe(II)–phenanthroline re-

mained in solution and was not absorbed onto the anionic resin.

4.2 Analytical applications

The proposed method was applied to the determination of molybdenum in natural and industrial waters, vegetal tissues and a soil extract.

As representative samples of natural waters, we selected tap water from the Jaén city supply (higher ionic content) and natural water from Ortigosa del Monte (Segovia) (lower ionic content). The molybdenum content in all waters was lower than the detection limit of the most sensitive proposed method in this paper (1000 ml).

A recovery study was therefore carried out. The mean percentage recovery obtained for Ortigosa del Monte water was 97.8 for a 500 ml sample volume, and for tap water was 98.3, 98.3 and 97.1 for 100, 500 and 1000 ml sample volumes respectively.

The results obtained for an industrial water from a manufacturer of steel (Insisur S.A.), potato leaves and soil extracts are summarized in Table 3. A matrix effect was found in Insisur S.A. water and soil extracts which was evaluated by the ratio of slopes between the standard and standard-addition calibration graphs, found to be 0.91 and 0.69 respectively.

The average value of the molybdenum content in potato leaves and soil extracts referred to the original sample was 0.47 mg kg^{-1} (0.51 mg kg^{-1} by EAAS) and 235 μg kg^{-1} (230 μg kg^{-1} by EAAS).

The average value of the molybdenum content in industrial water (Insisur S.A.) agrees with that found by EAAS (31 ng ml^{-1}).

Flow-injection fluorimetric determination of nabam and metham

Tomás Pérez-Ruiz*, Carmen Martínez-Lozano, Virginia Tomás, Rocio Casajús

Department of Analytical Chemistry, Faculty of Chemistry, University of Murcia, 30071 Murcia, Spain

Abstract

A simple and sensitive flow-injection fluorimetric method was developed to determine nabam or metham in water and cereal samples. The procedure is based on the oxidation of these pesticides by thallium(III) with the concomitant formation of fluorescent thallium(I). Lineal calibration graphs were obtained between 0.25 and 2.56 μml^{-1} for nabam, and between 0.26 and 2.65 μg ml^{-1} for metham. The sampling rate was 80 samples h^{-1}. The method was satisfactorily applied to the direct analysis of water, wheat, barley and oat samples spiked with nabam or metham.

Keywords: Nabam; Metham; Flow injection; Fluorimetry

1. Introduction

Metham (sodium N-methyldithiocarbamate) and nabam (disodium ethylenebis[dithiocarbamate]) are two well-known dithiocarbamate fungicides widely used against a variety of plant pathogenic fungi. They are highly mobile in soil and can leach into groundwater. Although dithiocarbamate pesticides are used primarily on field crops and cereals, appreciable amounts of lettuce and other vegetables and fruits are also treated. The maximum residue limits for dithiocarbamates (expressed as carbon disulphide) which are being considered by the European Union are 2–7 mg kg^{-1}.

Dithiocarbamates are generally determined on the basis of their decomposition by hot mineral acid to amines and carbon disulphide. This is then absorbed in methanolic potassium hydroxide solution and the potassium methyl xantate thus formed is titrated iodometrically [1]. Alternatively, carbon disulphide is absorbed in an ethanol solution containing copper(II) and an alkylamine to form copper dialkyldithiocarbamate chelates, which can be determined photometrically [2,3]. Gas chromatography, including head-space analysis [4,5] and liquid chromatographic methods [6,7], has also been used to determine dithiocarbamate residues.

Analytical methods which use processes other than acid decomposition include iodometry in anhydrous solvents [8,9], indirect titration with EDTA [9,10], polarography [11] and determination of the metallic component of herbicides using different approaches [12,13].

Flow-injection analysis has proved to be a very useful and versatile automated technique for the determination of a large number of inorganic and

---

*Corresponding author.

organic analytes [14,15]. However, no flow-injection method has been found to deal with the determination of the dithiocarbamates.

In this paper the development of a fluorimetric flow-injection method for the determination of metham and nabam is described. The determination is based on the oxidation of these pesticides by thallium(III) and the parameter measured is the fluorescence of thallium(I) formed during the reaction. This violet fluorescence has been attributed to the existence of the anionic $TlCl_4^{3-}$ complex [16,17] and hence the reaction is carried out in the presence of hydrochloric acid.

The proposed method is simple and sensitive, and enables these two pesticides to be determined in waters and cereals.

2. Experimental

2.1. Apparatus

A SLM-Aminco (Urbane, Illinois, USA) Series 2 spectrofluorimeter was used for recording spectra; excitation and emission spectra were corrected. A Perkin-Elmer (Norwalk, CA, USA) Model 3000 spectrofluorimeter equipped with a Hellma (Müllheim, Baden, Germany) 176.052 QS flow cell (inner volume 25 μl) and connected to a Linseis (Selb, Germany) 6512 recorder was used as the detector in the flow-injection system.

A Gilson (Villiers Le Bell, France) Minipuls HP4 peristaltic pump and an Omnifit (Cambridge, UK) injection valve were also used.

2.2. Reagents

All chemicals used were of analytical-reagent grade; doubly distilled water was used for the preparation of solutions and all dilutions.

Metham and nabam were obtained from Riedel-de Haën (Seelze, Germany) and used as received. Stock solutions (200 mg 1^{-1}) of these pesticides were prepared by dissolving 20.0 mg of each compound in doubly distilled water and diluting to 100 ml in a calibrated flask. Working solutions of lower concentration were freshly prepared by appropriate dilution with water.

Thallium(III) stock solution $(1.0 \times 10^{-3}$ M) was prepared by dissolving the required amount of $TlCl_3$ (Fluka, Buchs, Switzerland) in 0.5 M hydrochloric acid. Solutions of lower concentration were prepared from the stock solution by appropriate dilution with 0.5 M hydrochloric acid.

2.3. Manifold design

The configuration of the flow-injection (FI) manifold used is shown in Fig. 1 with the optimum conditions as stated. With the exception of the pump tubing (Tygon), PTFE tubing (0.5 mm i.d.) was used throughout the manifold. The fluorescence intensity of thallium(I) formed in the reaction between thallium(III) and the pesticides was measured at 419 nm with excitation at 227 nm. The spectrofluorimeter was set with 10 nm excitation and emission slits.

2.4. Basic procedure

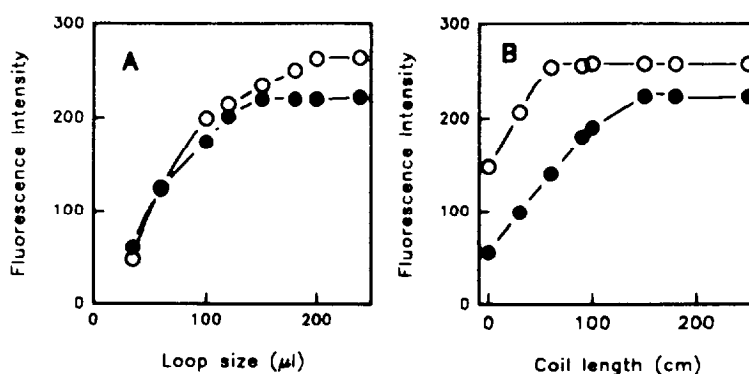
The samples containing between 0.25 and 2.56 μg ml^{-1} of nabam or between 0.26 and 2.65 of metham were aspirated into the sample loop (200 μl) of the injection valve by means of the peristaltic pump, and injected into the pre-mixed hydrochloric acid and the thallium streams of the FI manifold (see Fig. 1). The concentration of these pesticides was evaluated from the peak height with a calibration graph prepared using freshly prepared nabam or metham standard solutions.
Fig. 1. Manifold for the determination of nabam and metham: PP, peristaltic pump (with flow rates given in ml min^{-1}); M, mixing coil (20 cm); R, reaction coil (100 cm for nabam and 150 cm for metham); D, detector; W, waste.


Fig. 2. Effect of the loop size (A) and the reaction coil (B) on peak height for nabam ( ) and metham (●).

2.5. Determination of nabam or metham in water

The samples were diluted as appropriate with doubly distilled water and analysed following the basic procedure.

2.6. Determination of nabam or metham in grains

About 10 g of accurately weighed wheat, barley or oat was sprayed with 5 ml of an aqueous solution containing between 5 and 100 μg ml^{-1} of nabam or metham. The samples were then allowed to dry in the sun for 1 h and thereafter in the shade for 24 h to remove extraneous moisture. For each determination a blank assay was carried out by spraying the same amount of grain with 5 ml of water. The samples were weighed again in order to determine the amount of pesticide retained. The previously ground samples were treated with 50 ml of 0.1 M sodium hydroxide, sonified for 10 min and centrifugated at 2000 rpm for 5 min. Aliquots of the resulting solutions were filtered and processed following the basic procedure.

3. Results and discussion

We have found that nabam and metham are oxidized by thallium(III) to form fluorescent thallium(I). These reactions seemed more quantitative when performed in acid media. The nature of the acid proved important because the fluorescence intensity of thallium(I) increases with increasing

chloride and ion hydrogen concentrations [16–19]. A maximum, stable fluorescence intensity was obtained when the concentration of hydrochloric acid was 0.6 M for nabam and 0.3 M for metham.

Alternatively, both nabam and metham can be oxidized in a flow system by injection into a thallium(III) solution flowing on-line. A two-line FI manifold with fluorimetric detection is suitable for the determination of both pesticides. The manifold represented in Fig. 1 was used to investigate the effect of chemical and FI variables on the peak height.

3.1. Optimization of manifold parameters

The variables studied were volumed of injected sample, flow rate and length of the reaction coil. The reagent concentrations used in the experiments were as follows: thallium(III) line, 2.0 × 10^{-4} M; hydrochloric acid line, 0.3 M. The mixing ratio between both streams was always 1:1.

The sample volume was varied between 35 and 240 μl (Fig. 2A). A sample volume of 200 μl was pre-selected for both pesticides in order to obtain maximum peak heights.

The peak height obviously depends on the residence time of the sample zone in the system, i.e. on the total flow rate and the tube length. The effect of the flow rate was checked over the range 0.4–2.4 ml min^{-1}. The lower flow rates gave higher fluorescence intensities although, up to 0.5 ml min^{-1}, the peak-height reproducibility was poor and the peaks were so broad that the sample
Fig. 3. Influence of Tl(III) on peak height for nabam (○) and metham (●).

3.2. Optimization of reagent concentration

The effect of varying the concentrations of thallium(III) and hydrochloric acid was tested in the optimized flow system.

The peak heights for both pesticides increased with increasing thallium(III) concentration up to 9.0×10^{-5} M, above which they remained virtually constant (Fig. 3). The concentration selected was 1.0×10^{-4} M.

The concentration of hydrochloric acid used as a carrier was selected to obtain the required optimum level when the sample zone merged with the thallium(III) stream, which was 0.5 M in HCl. The carrier selected for nabam and metham was 0.7 and 0.1 M hydrochloric acid, respectively.

3.3. Calibration graph

A series of standard solutions of nabam and metham were injected into the manifold under the optimized conditions to test the linearity of the calibration graphs. The figures of merit corresponding at these two analytes are summarized in Table 1, from which the excellent sensitivity of the proposed method is evident. The sample throughput was about 80 samples h^{-1}.

3.4. Interferences

An interference study to determine nabam or metham in real samples was performed. Samples containing a fixed concentration of each pesticide and various concentrations of foreign substances were injected into the FI system. Tolerance was defined as the amount of foreign substance induc-

throughput was very low. A flow rate of 0.6 ml min^{-1} was pre-selected as a compromise between reproducibility, sensitivity and sample throughput.

The length of the reaction coil was examined over the range 0–240 cm. Fig. 2B shows that a coil of 100 cm for nabam and of 150 cm for metham permitted the maximum peak height to be obtained.

An iterative procedure was followed, in that after the first round of experiments the best conditions were taken as the starting point for a further optimization cycle. This resulted in only a very small improvement; thus, the new values can be considered as very close to the optimum: sample volume injected, 220 μl; flow rate, 0.6 ml min^{-1}; coil length, 110 cm for nabam and 170 cm for metham.

Table 1
Features of the calibration graphs for the determination of nabam and metham

	Nabam	Metham
Determination range	1.0×10^{-6}–1.0×10^{-5} M	1.0×10^{-6}–1.0×10^{-5} M
Slope (L_F M^{-1})	37.8×10^6	18.5×10^6
Intercept (L_F)	6.7	3.4
Correlation coefficient[a]	0.999	0.998
RSD (%)[b]	1.4; 0.8	1.2; 0.5

[a]The correlation coefficient was calculated using 11 different concentrations of each analyte.
[b]Relative standard deviation (n = 10). Concentration levels: 3×10^{-6} M; 7×10^{-6} M.

Table 2
Tolerance to different substances in the determination of nabam and metham

Substance added	Tolerance molar ratio Interferent: pesticide	
	Nabam	Metham
Urea. sulphate. chloride, acetate, perchlorate, sodium(I), potassium (I). ammonium	1000	1000
Phosphate, tartrate	1000	800
Calcium(II), magnesium(II), zinc(II)	800	500
Citric acid, glucose, alanine	800	100
Glycine, aluminium(III), cadmium(II), manganese(II)	50	20
Oxalate, nitrate	10	10
Thiamine, cysteine, ascorbic acid, uric acid	5	1
Lead(II), iron(III)	1	0.5
Copper(II), bismuth(III), mercury(II)	0.1	0.1

Pesticide concentration: 2.5×10^{-6} M.

ing errors lower than 3% in the determination of the analyte. Table 2 shows the results obtained.

The interference of metallic ions can be eliminated by passing the solution through strongly a acidic cation-exchange (sodium form) column. The interference of ascorbic acid can be minimized by heating the solution to 60°C in the presence of 0.1 M sodium hydroxide.

Nabam or metham, if present in other common dithiocarbamate pesticides such as thiram, disulphuram, zineb, maneb and ziram, can easily be separated by extraction with chloroform: nabam or metham will remain in the aqueous phase which can then be analysed following the basic procedure.

3.5. Analysis of real samples

To investigate the applicability of the proposed FI method to real samples, nabam and metham were determined in water and cereal grain. The results in Tables 3 and 4 show that the method is applicable to water and grains sprayed with solutions of these pesticides. Taking into account that the recoveries obtained are close to 100%, it may be assumed that no interfering substances were encountered.

The determination of residues of nabam in wheat grains under field conditions is summarized in Table 5. The results show that nabam residues as measured by the proposed FI procedure were in excellent agreement with those obtained by the manual carbon disulphide spectrophotometric method.

Quantitation of the global secondary structure of globular proteins by FTIR spectroscopy: comparison with X-ray crystallographic structure[1]

Thomas F. Kumosinski*, Joseph J. Unruh

U.S. Department of Agriculture, ARS, Eastern Region Research Center, 600 East Mermaid Lane, Philadelphia, PA 19118, USA

Abstract

Fourier transform infrared spectroscopy (FTIR) is potentially a powerful tool for determining the global secondary structure of proteins in solution, providing the spectra are analyzed using a statistically and theoretically justified methodology. We have performed FTIR experiments on 14 globular proteins and two synthetic polypeptides whose X-ray crystal structures are known to exhibit varying types and amounts of secondary structures. Calculation of the component structural elements of the vibrational bands was accomplished using nonlinear regression analysis, by fitting both the amide I and amide II bands of the Fourier self-deconvoluted spectra, the second-derivative spectra, and the original spectra.

The methodology was theoretically justified by comparing (via nonlinear regression analysis) the global secondary structure determined after deconvolving into component bands the vibrational amide I envelopes with the calculated structure determined by first principles from Ramachandran analysis of the X-ray crystallographic structure of 14 proteins from the Brookhaven protein data bank. Justification of the nonlinear regression analysis model with respect to experimental and instrumental considerations was achieved by the decomposition of all the bands of benzene and an aqueous solution of ammonium acetate into component bands while floating the Gaussian/Lorentzian character of the line shapes. The results for benzene yield all pure Lorentzian line shapes with no Gaussian character while the ammonium acetate spectra yielded all Gaussian line shapes with no Lorentzian character. In addition, all-protein spectra yielded pure Gaussian line shapes with no Lorentzian character. Finally, the model was statistically justified by recognizing random deviation patterns in the regression analysis from all fits and by the extra sum of squares F-test which uses the degrees of freedom and the root mean square values as a tool to determine the optimum number of component bands required for the nonlinear regression analysis.

Results from this study demonstrate that the globular secondary structure calculated from the amide I envelope for these 14 proteins from FTIR is in excellent agreement with the values calculated from the X-ray crystallographic data using three-dimensional Ramachandran analysis, providing that the proper contribution from GLN and ASN side chains to the 1667 and 1650 cm^{-1} component bands has been taken into account. The standard deviation of the

---

regression analysis for the per cent helix, extended, turn and irregular conformations was found to be 3.49%, 2.07%, 3.59% and 3.20%, respectively.

1. Introduction

Previous studies comparing the global secondary (2°) structure of globular proteins calculated from their X-ray crystal structure with those determined from Fourier self-deconvolution (FSD) FTIR spectroscopy were performed in D_2O. However, D_2O may cause increased hydrophobic interactions which could lead to spurious 2° structural changes in some proteins [1]. Using D_2O also results in the elimination of the amide II peptide band, which may be helpful for validation of the amide I assignments. With the use of an extremely short path length (6–12 μm) and accurate water vapor subtraction [2], the determination of protein secondary structure in H_2O, using both the amide I and amide II regions, is now possible. However, controversy exists among researchers concerning the deconvolution of the FTIR amide I and II envelopes into their component bands. Not only the number of bands, but also the character of the bands (whether they are of pure Gaussian, pure Lorentzian, or a combination of Gaussian and Lorentzian character) is suspect. In addition, when using FSD to ascertain the number of bands, the magnitude of the half-width at half-height of the band and the value of the resolution enhancement factor (REF) are also open to discussion. Additionally, when experiments are performed in H_2O, the amide II band, while present, is not always deconvolved. Analysts also routinely apply conservatively low values for the REF with large half-width at half-height values of 13–18 cm^{-1}, in order to not overdeconvolute the spectrum, and in the next step (nonlinear regression analysis), only the smallest number of component bands are used for the nonlinear regression analysis.

The rational for these procedures is to avoid the possibility of distorting the experimental spectrum. However, no studies analyzing the same spectrum using nonlinear regression analysis with varying FSD parameters have as yet been performed; thus the optimum parameter limits to use without causing distortion are unknown. Using higher REFs and narrower half-widths during FSD increase the number of component bands. We will attempt to show that properly choosing to use this increased number of bands (with equal half-widths at half-height) in the nonlinear regression fit of the experimental spectrum results in much lower root mean square (RMS) values (i.e. the square root of the average of the squares of the differences between the experimental spectra and the nonlinear regression fitted spectra).

While nonlinear regression analysis using an increased number of component bands is more difficult and more time consuming (and cannot be easily performed on older microcomputers), the correct number of peaks must be obtained to insure the correct band assignments to the secondary structure of the protein. If one band is used when two are predicted from theory, then a larger amount of disordered, helical or extended structure could be calculated because of incorrect assignments. With the methodology employed herein, the researcher can use the maximum number of component bands to fit the theoretical curve to the experimental data. This in fact yields the lowest RMS value, and the amide II envelope is fit simultaneously with the amide I envelope. It is critical to allow a zero slope baseline to vary to a calculated value. It is noted that during the calculations, the use of too many bands may result in the heights of the excess bands approaching a zero or negative value. The number of bands were controlled by use of the F-test as well as the agreement of calculated frequencies with previously reported experimental and theoretical assignments. Thus, the statement that excessive numbers of bands always yield better fits to the data is not valid. This statement only applies to the use of polynomial curve fitting algorithms and not to nonlinear regression analyses.

In this work we measure FTIR spectra in H_2O of 14 globular proteins and two polypeptides — with varying types and amounts of 2° structures — whose X-ray crystal structures are known. A more complete theoretically, experimentally, and statistically based analysis of the spectral data in H_2O using FSD, second-derivative spectra, and band curve-fitting techniques is presented. The analysis allows the individual 2° structural components to be distinguished and then compared with results in D_2O [3,4] and with the global 2° structural parameters calculated from the protein X-ray crystallographic data. Previous frequency assignments of structural components are also assessed and contrasted with the new information in H_2O.

2. Methods

2.1. Infrared measurement

The individual proteins were prepared as 4 solutions (by weight) in a 20 mM imidazole buffer, pH 6.7. All protein solutions and buffers were filtered using a HVIP 0.45 μm Millipore low-protein retention filter prior to the FTIR experiments. The protein concentrations after filtration were calculated from their respective absorptivities at 280 nm. All samples were introduced into a demountable cell with CaF_2 windows and a 12 μm Teflon spacer. Spectra were obtained using a Nicolet 740 FTIR spectrometer equipped with the Nicolet 660 data system. Data collection was carried out following a 30 min nitrogen purge of the sample chamber. Eight data sets of 512 drift and intensity correlated interferograms were collected, coadded (net for each spectrum was 4096 double-sided interferograms with 16 384 data points), phase-corrected, apodized (Happ-Genzel function), and fast-Fourier transformed. The eight data sets were routinely checked for drift using calculated second derivatives before summing. Nominal instrument resolution was 2 cm^{-1} with one data point every 1 cm^{-1}. Water vapor absorption was routinely subtracted from all spectra using the second-derivative method [2].

To reduce the water vapor in the sample chamber, the FTIR spectrometer is purged with nitro-

gen which has been passed through a Balston model 75-52 FTIR purge gas generator, drying the nitrogen to a dew point of $-100°F$. In addition, three additional nitrogen purging lines were added to the sample compartment of the FTIR spectrometer, the net effect being a purge rate of 60 l min^{-1}. The total amount of water vapor observed by the IR detector in the course of a typical protein solution scan is illustrated in Fig. 1A, where the water vapor spectrum is represented by crosses. For comparison purposes, the FTIR amide I and II envelopes of the FSD spectra of trypsin, the component bands obtained from the nonlinear regression fit of the amide I and II envelopes, and the resulting sum of the component bands are also illustrated (as single lines). (The use of nonlinear regression analysis for decomposition of the amide I and II envelopes into component bands will be discussed in another section of this manuscript.) As can be seen in Fig. 1A, the water vapor spectrum is significantly smaller than the actual protein amide I and II envelopes as well as the component bands derived from nonlinear regression analysis. The heights are 50–100 times smaller and the half-widths at half-height are also significantly smaller in magnitude. Thus, even if no vapor subtraction is performed on the protein FTIR spectrum, the water vapor spectrum cannot be a source of the component bands attributed to the protein. Hence, the proposition that the component bands derived from nonlinear regression analysis are useful in defining unique populations of protein vibrating molecular groups is valid.

It is important to emphasize that to obtain acceptable FTIR spectra of proteins in water, a good signal-to-noise ratio (SN) is mandatory. SN is dictated by the sensitivity, resolution and stability of the FTIR spectrometer and its computer. For our system, only a resolution of 2 cm^{-1} is possible due to the long scanning times required for a 1 cm^{-1} resolution spectrum, i.e. four times as long or approximately a 2 h scan. However for researchers having a quicker, more sensitive and stable instrument (such as a Nicolet 800 series spectrophotometer), a resolution of 1 cm^{-1} should be possible to attain, although for comparison purposes, an FTIR spectrum of one protein (with corresponding buffer, background and vapor spec-

(A)   WAVENUMBER, cm⁻¹

(B)   WAVENUMBER, cm⁻¹

(C)   WAVENUMBER, cm⁻¹
tra) was accumulated at a resolution of 1 cm^{-1}. Decomposition of this spectrum into component bands by nonlinear regression analyses yielded fractional areas for both the amide I and II envelopes in agreement to within 1% with fractional areas from the spectrum of the same protein solution collected at a resolution of 2 cm^{-1}. Also, using the 2 cm^{-1} resolution parameters, a protein solution was diluted to a concentration of 3% with buffer, and its FTIR spectrum was accumulated. Comparison of the areas of the component bands from nonlinear regression analysis agreed to within 1% with those determined using a 4% solution. These two tests add confidence to the methodology used in this study.

To ascertain whether the FTIR instrumental parameters yield line shapes that are Lorentzian, Gaussian or composites of both line shapes, FTIR spectra were obtained for benzene using KBr windows and an aqueous solution of ammoniuim acetate using CaF_2 windows. Our regression analysis program contains line shape parameters for the amount of Gaussian character (i.e. pure Gaussian, 1; pure Lorentzian, 0), the line shape is varied along with the frequency position, height, and half-width at half-height variables. The results conclusively show that all component bands

Fig. 1. (A) FSD FTIR spectra of the amide I and II envelopes of trypsin in H_2O, represented by the solid line; component bands from nonlinear regression analysis, and the composite sum of the bands are also represented as solid lines (note: the composite sum and the FSD overlap). The crosses denote the atmospheric water vapor FTIR spectrum experienced during a typical protein accumulation if no second-derivative water vapor subtraction is performed. The crosses also represent all instrumental and phase errors (see Section 2 of text). (B) FTIR spectrum showing the amide I and amide II envelopes of lysozyme in aqueous solution. The outer envelope double line represents the original spectrum. The single line on the outer envelope and the individual component bands underneath are the results of nonlinear regression analysis, as described in the text. The inset shows a plot of connected residuals or deviations between calculated and experimental absorbances vs. frequency. (C) Fourier self-deconvolution of the FTIR spectrum of lysozyme in Fig. 1. The single line on the outer envelope and the individual component bands underneath were found by nonlinear regression analysis as described in the text. The double line represents connected experimental data. The inset shows the unsmoothed second derivative of the original spectrum.

of benzene have pure Lorentzian line shapes —
the theoretical line shape for most pure condensed
phase samples and gases [5]. While the aqueous
ammonium acetate solution spectra yield pure
Gaussian line shapes — theoretically predicted by
Beer's law for the absorbance of a solid dissolved
in a liquid [5]. In addition, all residual plots had a
pseudorandom character, with a magnitude equiv-
alent to an instrument residual plot.

2.2. Data analysis

Protein spectra (amide I and II regions) were
obtained by subtracting the buffer spectra from
the respective protein solution spectra in the
$2000-1350$ cm^{-1} region. Subtractions were per-
formed interactively using the subtraction func-
tion in the Sx software of the Nicolet 660 data
system. The scaling factor (FCR) was individual-
ized during each subtraction by adjusting the
FCR parameter value until the region from 2000
to 1800 cm^{-1} was as flat as possible. The sub-
tracted region from 1800 to 1350 cm^{-1} was then
saved as the protein spectrum. This method for
subtraction does not take into account the spec-
tral modifications due to water–protein interac-
tions. Previous NMR studies by Kakalis and
Kumosinski [6] have shown that the water–
protein interaction is small on a molar basis (wa-
ter to protein), and therefore should not interfere
with this type of subtraction. The protein spectra
thus obtained were then used to calculate the
second-derivative spectra by a simple analytical
procedure that employs every data point [3]. Sec-
ond-derivative spectra served as sensitive indica-
tors for the identification of individual peak
positions, and the initial number of bands to be
used in subsequent nonlinear regression analysis.
The unresolved spectra were subjected to FSD
using an algorithm developed from that described
by Kauppinen et al. [7].

FSD was undertaken with a number of resolu-
tion enhancement factors. Qualitatively, under-
FSD was judged by the absence of peak positions
indicated in the spectra and over-FSD by the
appearance of side lobes in the flat portions of the
spectra [4]. Over-FSD also resulted in excessively
low baselines computed by the regression routine.

The methodology used will be illustrated for
lysozyme.

All spectra were deconvolved (decomposed into
their component structural elements) using a
Gauss–Newton nonlinear iterative curve-fitting
program ABACUS developed at this laboratory [8],
which can assume Gaussian, Lorentzian shapes or
a combination of both for the band envelope
shape of the resolved component bands. The de-
convolving curve-fitting program was applied only
to the amide I and II envelopes, which consisted
of at least 200 experimental points. In practice,
the four parameters of each component band
(Lorentzian character, height, peak frequency,
and half-width at half-height) were allowed to
float during the iterations, as was the baseline.
Integrated areas were calculated for those peaks
that correspond to conformational elements, e.g.
helices, sheets, turns, and loops [9]. This proce-
dure yielded the relative areas of the component
bands, which serve to estimate the fraction of the
various 2° structural elements in the protein
molecule.

3. Results

3.1. Sample calculation: analysis of lysozyme

A typical FTIR spectrum of hen's egg white
lysozyme showing the amide I and amide II re-
gions is shown as the outer envelope in Fig. 1B.
This spectrum can be considered to be the sum of
a variety of individual bands arising from the
specific structural components of the protein, such
as α-helix, β-sheets and turns. Identification of all
the components of the spectrum by fitting it di-
rectly with an undefined number of peaks by
nonlinear regression would be a daunting task. To
alleviate this dilemma, we first examine the second
derivative of the spectrum (inset, Fig. 1C) to find
the number of component bands and the approxi-
mate positions of those bands, and to compare
these assignments with those of Byler and Susi [3].

The next step in the analysis is to enhance the
resolution of the original spectrum via an FSD
algorithm. Care must be taken to choose the
proper half-width and REF values used in the

algorithm so that the FTIR spectrum is not over or under FSD.

Initially, all amide I component band assignments of Byler and Susi [3] are used to fit the FSD spectra, along with comparable theoretical amide II bands and side-chain assignments from Krimm and Bandekar [10]. Initial half-width at half-height values are assigned as 2 or 2.5 cm^{-1}, while the initial heights are assigned values higher than the FSD experimental data. The number of bands fit to the amide I and amide II envelopes is also controlled via the statistical F-test, which will be discussed later.

For faster convergence of the nonlinear regression analysis, the investigator may initially float only the heights, the half-widths at half-height, or the peak positions and the Gaussian/Lorentzian parameter in an alternating fashion during the process of the fitting program. Later, three of the parameters can be floated in an alternating fashion. And finally, all four parameters are floated simultaneously until the nonlinear regression analysis converges. The criteria for progress in the nonlinear regression analysis is a continually decreasing RMS value. If divergence takes place, the iteration factor that determines the step increase in the parameter values for the next iteration should be lowered. It is mandatory that the baseline value be allowed to vary during all of the above iterations. The imposition of a fixed baseline value adds error to the results, slows the convergence process, and in some cases causes calculations which ultimately diverge.

In addition, to alleviate the local minima problem, the whole process should be repeated starting with heights of the components that are lower in value than the FSD experimental data. The results of these two calculatons should be in agreement. Failure of these two calculations from different starting points to agree for all component bands indicates local minima resulting from use of a lower number of component bands. It is noted that all calculations using nonlinear regression analysis should be performed in this manner.

Fig. 1C shows the fit of 29 component Gaussian bands for the Fourier self-deconvoluted amide I and II FTIR envelope of lysozyme using deconvolution values of 13 cm^{-1} and 2 REF. The

RMS value for this fit is 0.000125 which is well within the criteria for acceptability as stated above. This lack of Lorentzian character is in agreement with the conclusions of Byler and Susi [3] that only Gaussian component band shapes occur in FSD spectra.

The use of a high REF value results in over-FSD of the FTIR spectra, usually an unacceptable RMS value, and a baseline value far below that expected from the experimental data. Repeating the above nonlinear regression process at a variety of FSD parameters for all the proteins in our database yielded the optimum FSD parameter values of 2.3 for the REF and 9 cm^{-1} for the half-width at half-height (see Fig. 4A).

After fitting the FSD spectrum of lysozyme, the next step was to use these results to fit the original spectrum shown in Fig. 1B. Here, the frequency positions from the FSD FTIR envelope of Fig. 1C were initially not allowed to iterate. Only the heights, half-widths at half-height, and the fraction of Lorentzian/Gaussian character of the band shape were allowed to alternately vary. For lysozyme as for all proteins in our database, the fraction of Lorentzian character vanished. Even when the peak positions were allowed to vary, only Gaussian band shapes were found to be present. A final convergent deconvolved original spectrum of lysozyme is presented in Fig. 1B. A plot of the difference between the experimental and the fit absorbences vs. frequency is presented in the inset of Fig. 1B. This deviation plot is seen to be pseudorandom in shape, which further adds validity to the analysis. Furthermore, the fractional areas of the component bands of the amide I envelope in Fig. 1B were in excellent agreement with those determined from the FSD spectra in Fig. 1C. These findings (random deviation plot and agreement of the original and FSD FTIR spectral fits) for lysozyme were used as criteria of acceptability for all the proteins analyzed in the presented database.

Since the lack of Lorentzian character in the original FTIR spectrum has not been reported, we initiated further studies on other systems to aid in the validation of this conclusion. Recently, we inherited the previously reported [3] FTIR spectra of proteins in D$_2$O. Fig. 2A shows the FSD

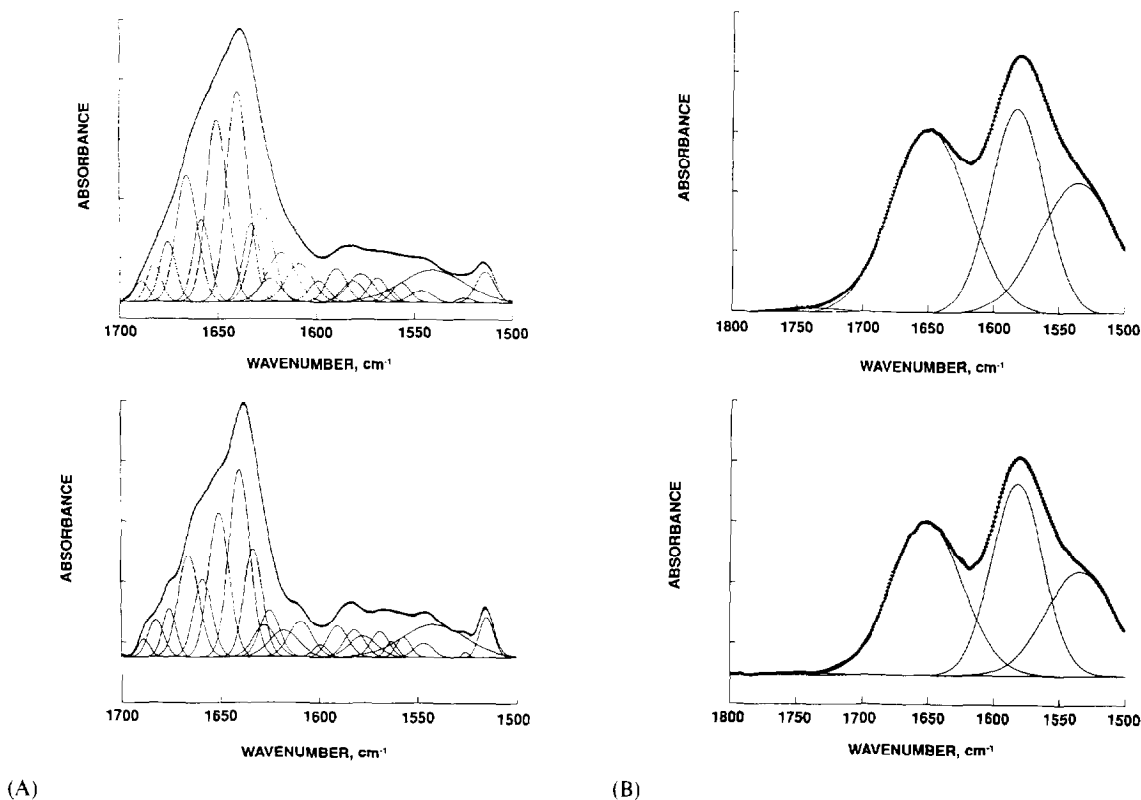
(A)   (B)


Fig. 2. (A) FTIR spectrum showing the amide I and II envelopes of ribonuclease in D_2O from the previously published work of Byler and Susi [3]. The outer envelope double line represents connected experimental data. The solid line on the outer envelope is the sum of component bands (solid line) calculated from nonlinear regression described in the text. The upper spectrum is the original FTIR spectrum; the lower spectrum is the Fourier self-deconvoluted spectrum. (B) FTIR spectra showing the amide I and II envelopes of polyaspartic acid under environmental conditions where the polymer adopts a disordered conformation. Same representation as in (A). The upper spectrum is the original FTIR spectrum; the lower spectrum is the Fourier self-deconvoluted spectrum.

(lower) and original (upper) FTIR spectra of ribonuclease A in D_2O [3]. In both cases a small amide II envelope due to incomplete exchange of the D_2O still exists. Using the above methodology for fitting both the amide I and II envelopes for both the FSD and the original spectra using Gaussian component bands was extremely successful, as seen in Fig. 2A. Ten amide I component bands for the FSD and original spectra with both fractional areas yielding equivalent global secondary structure result. No Lorentzian character bands were found by the nonlinear regression fitting analysis of either the FSD or the original spectra. Other FTIR spectra in D_2O, i.e. lysozyme, cytochrome C, conconavalin A, etc., yielded the same results.

Finally, FTIR studies of polyaspartic acid and polylysine at pH 7 in 0.08 M KCl and H_2O were initiated to further test the above results. At pH 7 in 0.08 M KCl, both polymers exist in a nonperiodic or random conformation. The above methodology presented for lysozyme was carried out on each of the spectra for each of the two polymers. For the FSD spectra, a half-width at half-height of 9 cm^{-1} and an REF of 2.3 was used. The nonlinear regression analysis was started with 29 component bands, and the Lorentzian/Gaussian character of the bands was permitted to vary. For polyaspartic acid, only three major bands at 1648 cm^{-1}, 1581 cm^{-1} and 1534 cm^{-1} with fractional area of 40%, 32% and 28%, respectively, were present. The nonlinear

regression program caused the excess bands to converge to the lower boundary of zero for the height, then these bands were removed from the calculation. The program's result also had all the bands with pure Gaussian character. The results of these calculations for the FSD and original FTIR spectra of polyaspartic acid are presented in Fig. 2B (lower spectra are FSD; the upper are original). Excellent fits for both spectra can be observed, and the fractional areas are equivalent for both spectra. Results for polylysine yielded only two major bands at 1646 cm^{-1} and 1536 cm^{-1} with fractional areas of 70% and 30%, respectively. A small band at 1745 cm^{-1} with a less than 0.4% fraction of the total area was also present for both of these polypeptide samples. The total study was also repeated at a lower salt concentration, which yielded the same results. It is apparent from these studies that the amide I assignment of 1646–1648 cm^{-1} for a random coil or irregular conformation is appropriate [3]. Also, the 1581 cm^{-1} band is most likely due to unprotonated side chain carboxyl groups.

Thus, the validity of the methodology for deconvolving FTIR spectra into component bands using nonlinear regression analysis is consistent for proteins in H_2O, proteins in D_2O, and polypeptides in H_2O. Even the number of component bands decreased markedly from 29 bands observed for lysozyme to 2 or 3 for the two polypeptides in irregular conformations. Also, no Lorentzian character is observable in any of the FTIR spectra.

Further validation of the calculated components of the amide I and II bands can be obtained by mathematical comparison of the second-derivative FTIR spectrum obtained from the original spectrum with the calculated second derivative obtained from the model fit. The result of such a fit to a second-derivative spectrum of lysozyme is shown in Fig. 3, where the irregular line represents the second-derivative spectrum of the fitted model and the smooth line that of the experimental data. The inset of this figure shows a pseudorandom plot of the connected residuals which further establishes the reliability of this methodology for quantitatively resolving FTIR spectra of proteins into component bands.

3.2. Number of parameters for the nonlinear regression analysis

To evaluate the effects of fitting a protein with too few component bands, let us examine the spectrum of lysozyme. Fig. 4A shows the fit of the Fourier self-deconvoluted amide I and II envelopes of lysozyme with 28 component Gaussian bands. The fit is excellent with no discernible difference between the resulting theoretical and experimental curves. However, when the band at 1659 cm^{-1} is removed and only 27 peaks ($N-1$) are utilized, nonlinear regression analysis yields a poor fit, with some component bands becoming much broader than others (see Fig. 4B). Also, it can be seen that the fit in the amide II envelope is affected even though no band was removed from that range of frequencies. In addition, as seen in Table 1, the RMS for 27 peaks is six times larger than for 28 peaks, i.e. 0.00157 versus 0.000251, respectively. If additional bands are removed
Fig. 3. Second-derivative FTIR spectrum of the amide I and II bands of lysozyme in aqueous solution. The single smooth line represents connected experimental data. The irregular line is the second derivative of the composite sum of the individual component bands from the nonlinear regression analysis as described in the text. The inset shows a plot of connected second-derivative residuals between calculated (composite sum of nonlinear regression analysis) and experimental second derivatives vs. frequency.

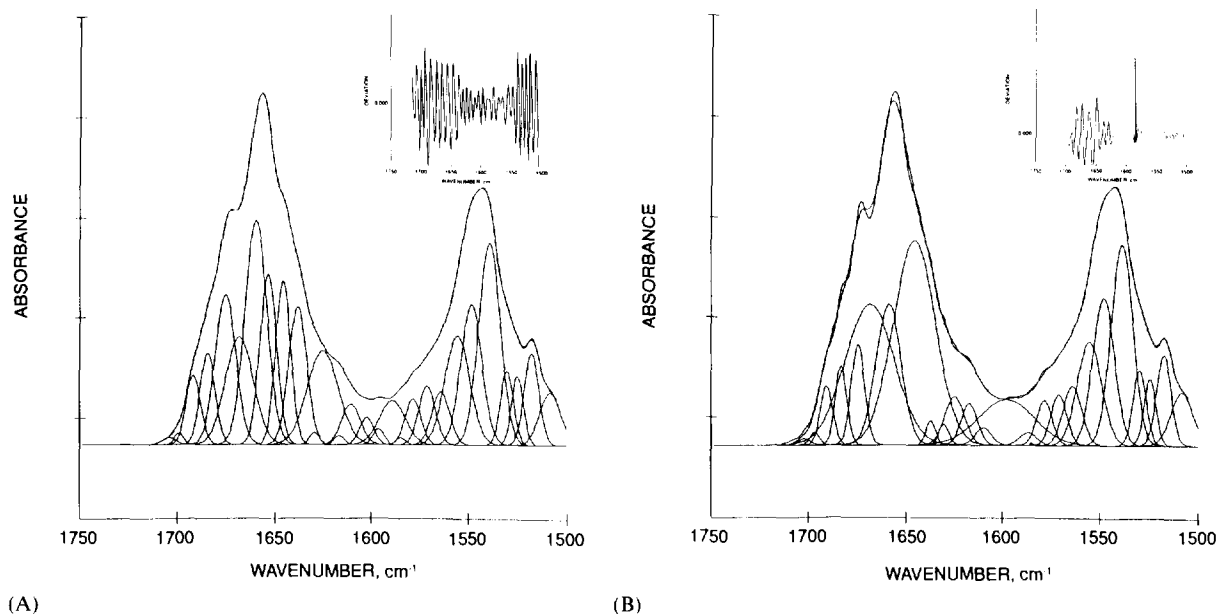
(A)   (B)


Fig. 4. Best fit for Fourier self-deconvoluted lysozyme FTIR spectrum using nonlinear regression analysis, a half-width at half-height (W) of $9\,cm^{-1}$, and a resolution enhancement factor, (REF) of 2.5. The light line represents connected experimental points; the dark line represents the theoretical sum of component bands shown by the light lines. (A) For 28 peaks; (B) for 27 peaks. Inserts in each show plots of connected residuals between spectra and composite nonlinear fit.

($N-2$ and $N-3$), the RMS continues to increase but at a smaller rate (see Table 1).

The above comparison is also observed for all the proteins reported here but is only illustrated in Table 1 for the fits of trypsin, elastase, and myoglobin. In all cases the fits after removing peaks ($N-1$, $N-2$, $N-3$) in the area of $1659\,cm^{-1}$ are extremely poor. Removing the peaks results in some extremely broad peaks in the amide I region, which in turn influences the fit of the amide II region. It should be noted that FSD causes the component bands to have almost equal half-widths at half-heights, and in the work of Byler and Susi [3], the appearance of overly broad component bands in the nonlinear regression analysis results were considered unacceptable. The RMS values of the unacceptably poor fits are on the order of three to six times higher than the best fits (see Table 1). Despite the improved fits (better RMS values), the number of peaks which exist under the amide I or II envelope should be based upon more theoretically and statistically sound concepts to prove the above hypothesis.

Rusling et al. [11] have successfully used the sum of squares principle and the extra sum of squares F-test to determine the confidence level of whether an electrochemically active compound binds to a detergent micelle according to a monophasic or biphasic mechanism. In our study, Eq. (1) (Eq. (14) of Rusling et al. (11)) relates the RMS and the degrees of freedom (which is defined as the number of data points (n) minus

$$F_{(p_2-p_1,n-p_2)} = \frac{(S_1-S_2)/(p_2-p_1)}{S_2/(n-p_2)} \tag{1}$$

the number of parameters (bands, p) in the nonlinear regression analysis) to an F-ratio, which in turn can be used in conjunction with standard F-test tables to obtain the confidence level with which the model with the smaller number of degrees of freedom fits the data better.

In the third column of Table 1, the probabilities (p) are calculated for N number of bands from the RMS values in the N and $N-1$ columns. In all cases, it is noted that the probability of N bands yields a confidence level of over 99%. Therefore using N bands is well-determined on a

Table 1
Influence of number of Gaussian peaks on RMS values

Protein	N	RMS_N p [a] (%)	RMS_{N-1}	RMS_{N-2}	RMS_{N-3}
Lysozyme	28	0.000251, >99	0.00157	0.00176	0.00187

Elastase	24	0.000624, >99	0.00174	0.00191	0.00197
Myoglobin	17	0.000306, >99	0.00154	0.00161	0.00166
Papain	26	0.000759, >99	0.00201	0.00213	0.00236

[a] Probability confidence level with which RMS_N can be considered significantly smaller than RMS_{N-1} after correction for degrees of freedom in each nonlinear regression fit analysis.

statistical basis. This calculation has been used for the remaining proteins in our database (see Table 2 for the list of proteins) which gives a statistical confidence for the number of component bands found for each protein. Such statistical tests should be utilized by all investigators when performing nonlinear regression analysis. The use of this statistical method clearly adds confidence to the choice in the number of component bands.

The above discussion deals with the error in choosing too few bands in the nonlinear regression analysis to fit the amide I and II envelopes. The opposite consideration would be choosing too many bands. One could argue that choosing an infinite number of infinitely narrow bands would lead to an exact fit. For an integral in calculus, this would be true, but in FTIR there are certain theoretical and realistic constraints available which control the maximum number of bands chosen. Theoretically, the number and position of bands should correlate with the calculated theoretical values of Krimm and Bandekar [10]. Realistically, the number of bands and their positions should approximate the number of bands observed in the second-derivative and FSD spectra. The approximate number of bands indicated by the second-derivative and FSD spectra will vary with the parameters chosen to carry out those analyses (e.g. the degree of smoothing chosen for the second-derivative spectra, or the REF and half-width at half-height chosen for the FSD spectra), so these values should not limit the number of bands in the nonlinear regression analysis, but should represent a good number to begin the regression analysis. The above theoretical and

realistic constraints should be considered when adding bands to the regression analysis.

An additional theoretical and realistic concern is that there can be no negative bands in fits for vibrational spectra. A feature of the ABACUS software we use for our nonlinear regression analysis is our ability to set a lower boundary for the heights of the bands at zero. So when we add too many bands, we have found the unnecessary bands $(N+1, N+2, \ldots)$ approach zero height. When this occurs, they are removed from the analysis and no additional bands are added.

3.3. Secondary structure assignment and theoretical justification

Controversy also exists in the literature concerning the assignment of the frequency of peaks to unique protein secondary structure. Studies attempting to resolve this issue have ranged from the theoretical to the experimental, as well as combinations of both.

Because of discrepancies with peak assignments, we have tentatively assigned our secondary structural elements to agree with the assignments of the following investigators: Byler and Farrell [4], Dong et al. [2], Dousseau et al. [12], Dousseau and Pezolet [9], Krimm and Bandekar [10], Kumosinski and Farrell [13], noting of course, that these assignments can change in the future. We shall assign the α-helix structure to 1650–1660 cm⁻¹, the irregular or disordered structure to 1642–1648 cm⁻¹, the strand or extended structure to 1624–1638 cm⁻¹, and the turn conformations to all frequencies above 1670 cm⁻¹ up to 1695 cm⁻¹. No attempt will be made to distinguish the

Table 2
Percent influence of side chain - glutamine and asparagine

type of turns assigned to frequency ranges in this study.

To add a theoretical basis for the nonlinear regression model and the tentative frequency assignments that were chosen, we turn our attention to the theoretical work of Torii and Tasumi [14–16]. In a series of papers they have developed a model for the calculation of amide 1 envelopes from the X-ray crystallographic data of proteins. Their model consists of assigning one oscillator with a transition dipole to each peptide group. Coupling between these oscillators is then introduced through a transition dipole coupling mechanism. While this method allows for faster computational times, contributions from disulfide bonds and side chain–side chain and side chain–backbone are nonexistent. In one paper by Torii and Tasumi [14], the theoretical FTIR amide I spectrum of lysozyme was calculated using the X-ray crystallographic data. In their calculation, they utilized a Gaussian envelope with a half-width at helf-height of 3.0 cm^{-1} for each peptide oscillator. Their calculations were used to qualitatively compare theoretical spectra of several proteins with their experimental counterparts in D$_2$O, so the force constants used were optimized to agree with D$_2$O and not H$_2$O results. For all the above reasons we cannot exactly compare our experimental results for lysozyme with their theoretical spectrum. We can, however, deconvolve their spectrum for lysozyme into the component

Gaussian peaks using nonlinear regression analysis and compare the number of peaks and fractional areas with our experimental FTIR spectrum. Here, it must be stressed that the theoretical spectrum must contain at least but not less than the same number of bands in our experimentally analyzed spectrum.

Fig. 5 shows the deconvolved theoretical FTIR spectra from Torii and Tasumi [14] with the best fit of the sum of 14 Gaussian bands for the amide I region. Attempts to use less than 14 bands resulted in poor fits, while the addition of more
Fig. 5. Best fits by nonlinear regression analysis using the amide 1 band of lysozyme. (From theoretical calculations of Torii and Tasumi [14].)

peaks caused the height of the extra bands to approach a zero or negative value. Calculation of the percentage of extended, helix, turn and irregular structure from the fractional areas of Fig. 5, and using the above assignments, yields values of 25.2%, 26.0%, 36.3% and 12.5%, respectively. Inspection of Tables 3, 4 and 5 yields experimental values of 28.9%, 23.4%, 32.6% and 15.3% for the percentage of extended, helix, turn and irregular conformation of lysozyme, respectively. The agreement between the theoretical calculations and the experimental data is acceptable because of the assumptions in the calculation of Torii and Tasumi [14]. Other proteins which were common to both studies (myoglobin, concanavalin A, trypsin, and ribonuclease) also yielded comparable results well within a 5% deviation. It also should be noted that the model of Torii and Tasumi [14–16] does not take into account any water interactions or internal dynamic motion of the structure which would occur for a protein in solution.

4. Discussion

4.1. Contribution of asparagine (ASN) and glutamine (GLN) side chains

Recently, Venyaminov et al. [19] performed FTIR experiments on amino acids in water and deconvolved the spectra into component bands to ascertain the influence of side chains on the overall amide I envelope. They found that large bands due to the side chains of arginine (ARG), ASN and GLN exist within the amide I envelope. In subsequent articles [17,18], they attempted to eliminate side-chain contributions to the amide I and II envelopes by subtracting, on a molar basis, the amino acid side-chain absorptions from the amide I and II regions of the protein absorptions. They assumed that the absorptivity of the side chains of free amino acids and those in proteins were equivalent. This assumption may not be valid, when the dipolar coupling and energy changes are considered for the side chain which now is part of a compact globular protein structure. Finally, the DuPont curve analyzer used in

the latter study has a limited range of applicability to FTIR experimental data.

Basing our starting point on their results, we obtained spectra of ARG, polyARG, ASN, polyASN, GLN, and polyGLN in order to analyze the results for side-chain contributions. We fit the spectra using our nonlinear regression methodology. For the free amino acids we found some differences in the frequencies for the proposed contributions. These differences are probably due to the fact that Venyaminov et al. [19] subtracted the spectrum of alanine to arrive at the possible side-chain contributions of the amino acids. The frequency and the ratio of height to half-width at half-height need to be the same for spectral subtractions to be valid; this is not the case when subtracting alanine from ARG, ASN, or GLN spectra. Our methodology permits the identification of the side-chain contributions without the subtraction of the aniline spectrum. We found that the possible contribution for ASN and GLN is the same at 1668 cm^{-1} with a small band at 1650 cm^{-1}, while the possible contribution for ARG is at 1679 cm^{-1}. Further differences are noted for the polyamino acids. Here the influence of dipolar coupling is observed for the side-chain

contributions of ASN and GLN but not for ARG. The contributions of ASN and GLN side chains relative to the amide I carbonyl band remains relatively the same while the ARG side-chain contribution relative to the amide I carbonyl decreases dramatically. Despite these differences we attempted to correlate the appropriate side-chain contribution to band area with their percent content in the proteins in our data base. We only found significant contribution and correlation for ASN and GLN combined. While the contribution of ARG appears to be negligible, it should not be discounted until further analysis is carried out on other proteins which have a higher ARG content than our proteins; in the latter case the results might correlate well.

Table 2 lists the area percent for the 1651 cm^{-1} and 1667 cm^{-1} bands in the first and second columns, respectively, for the indicated proteins in our database. Column 3 lists the combined percentage content of GLN and ASN residues present in the respective proteins. As can be seen, even though the global secondary structures of these proteins change with increasing row num-

bers (i.e. ranging from almost pure helix to turn, and then to strand structures), the percentage areas of the 1651 and 1667 cm^{-1} bands are relatively invariant, with the exception of myoglobin, hemoglobin and cytochrome C. Higher percent values of the 1651 cm^{-1} band for these first three helical proteins occurs as a result of the overlap of the E band of the x-helix structure. If the 1651 cm^{-1} bands of the three helical proteins are not considered, then a reasonable correlation exists between the experimental bands and the percentage of ASN and GLN residues. The results of the linear regression analysis of the area percent of the 1651 and 1667 cm^{-1} bands versus the percent GLN and ASN, where the percent areas of the 1651 cm^{-1} for the first three predominately helical proteins (hemoglobin, myoglobin and cytochrome C) are eliminated from this analysis, yielded an intercept value of 2.83 (standard error, 2.06; $\sigma = 0.184$) and a slope of 0.948 (standard error 0.292; $\sigma = 0.00388$). Thus, it appears that the intercept value could statistically have a zero value, with the slope having a value near unity. While the analysis suggests a correlation, it should

be viewed as an assumption. Only when the analysis of at least 50 proteins yields similar results would this assumption be considered proven. In addition, new studies of deaminated proteins in H_2O could help resolve this issue.

For this report, we will assign these bands to GLN and ASN side-chain modes. Most likely the 1651 cm^{-1} band is assigned to a C–N deformation and the 1667 cm^{-1} band is assigned to C=O stretch. The true fraction of GLN and ASN should be subtracted from the fractional areas of these bands and any excess area arising should be assigned to the appropriate global secondary structure. If the percentage of area is less than the percentage of GLN and ASN residues present, then the experimental areas should be subtracted from the amide I envelope and all the remaining bands should be normalized.

4.2. Ramachandran analysis

Of paramount importance to predicting the global secondary structure of proteins (by correctly interpreting the assignments of the FTIR amide I bands) is the correct calculation of the

secondary structure from the results of X-ray crystallography. Not only is the amount of α-helix, turn and extended conformation important, but the length of the helix and extended conformation is important as well. In addition, whether or not internal backbone hydrogen bonding exists may also be relevant descriptors for correlation with the percent areas of the component bands of the amide I region. Until recently, researchers in this field used the values provided in the Brookhaven Protein Data Bank. However, no quantitative algorithm has been used for subdividing the periodic structure. The values depend on the definitions of conformation adopted by each crystallographer. The definitions can, also, change over a period of time. What is needed, is an algorithm consistent with FTIR results to be used on all X-ray crystallographic structures. To date, no consensus in the scientific community for the appropriate algorithm has been found.

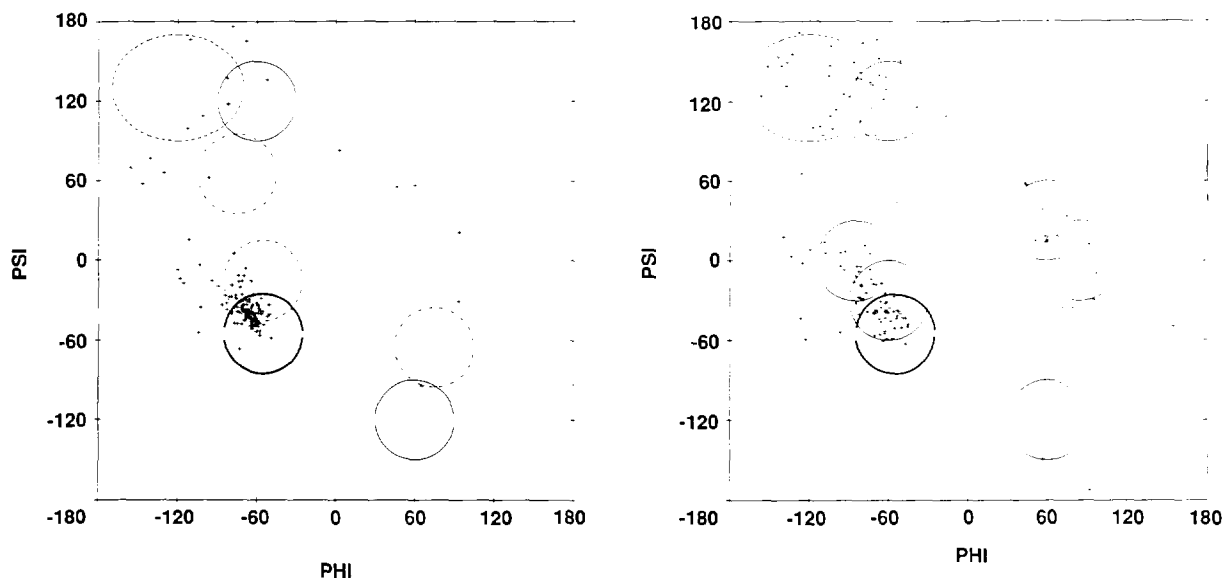
Kalnin et al. [18] have recently subdivided both the helices and sheets into hydrogen-bonded and non-hydrogen-bonded conformations, which along with the turn and all other conformations form a basis of six instead of four conformations.


Fig. 6. Ramachandran plot from X-ray crystallographic structure of (A) myoglobin, and (B) lysozyme.

Their calculations, however, are correlated with FTIR results using factor analysis instead of non-linear regression analysis. They normalize the structures in their analyses (i.e. the total conformation of an individual protein adds up to 100%) and show reasonable correlation with FTIR results. Other researchers using factor analysis (e.g. Pancoska et al. [20,21], Pancoska and Keiderling [22]) do not achieve the same good correlations — they use only four conformations and do not normalize structures to 100%.

An algorithm developed recently in Liebman's laboratory [23,24] shows good agreement with FTIR results when deconvolving the amide I into component bands. However, these experiments were performed only for serine proteases in D_2O and were correlated with helix and extended structures. While this method appears to be promising, it is still in its infancy and more correlations between experimental results and calculated fractions of conformations must be reported, and may ultimately be correlated with the Gaussian components described above. In this study, we use the traditional Ramachandran plot calculated from the X-ray crystallographic structure of proteins in conjunction with the secondary conformations reported in the protein data banks. We strongly stress at this time that the adoption of Ramachan-

dran analysis does not in any way imply that the transitional dipolar coupling mechanisms of Krimm and Bandekar [10] or Torii and Tasumi [14–16] do not apply here to the vibrational spectroscopy of proteins. We believe their mechanisms are valid.

Here, we use the Ramachandran plot as a method for corroborating the reported fractional values. If discrepancies exist, we use other molecular modeling techniques available in the Sybyl Molecular Modeling software (such as inspection by ribbon) in conjunction with the Ramachandran analysis. The latter analysis, of course, does not take into account the required minimum number of sequential residues to sustain a periodic conformation. In Figs. 6A and 6B the Ramachandran plots are given for myoglobin and lysozyme, respectively. Fig. 6A shows a template Ramachandran with theoretical curves for predominately helical proteins. The broken lines in the upper left are for a β sheet structure. The solid circle next to it is defined as the second position for a β turn type II. Directly under this circle is the theoretical envelope for a one-residue inverse "a" (γ) turn. Directly under the inverse "a" turn is the area which defines the 3/10 helix; the double line area represents the α-helix region. At the lower right hand region is an area representative

of a type II β turn, and above it is the area common for an "a" (γ) turn.

Fig. 6B uses a template plot which is more consistent with proteins containing a large amount of turn conformation. Here the broken lines and double lines represent the sheet and α-helix regions, respectively, as in Fig. 6A. Adjacent to the sheet region is the second position for the type II β turn and directly under that region is the envelope for the one-center inverse "a" turn. The third position for a type I and II β turn region is below the inverse "a" turn. Directly above the double-line acceptable region for an α-helix is the envelope for the second position of the type III β turn. In the lower right hand quadrant and proceeding upward are the acceptable regions for the conformations of the second position of a type II β turn, an "a" turn, the third position of type I and II β turn, and the second position of type III β turn, respectively. Also shown in Fig. 6B (as + symbols) are the calculated dihedral angles ϕ and ψ, from the Sybyl modeling program analysis of the X-ray crystallographic structure of lysozyme (6LYZ).

A three-dimensional Ramachandran plot, where the residue number is plotted on the third axis, can also be calculated using the Sybyl molecular modeling software. With this plot, adjacent residues within a periodic structure as well as those residues which are part of a turn conformation can easily be determined. With all the above analyses, the global secondary structure calculated from the crystallographic data for each of the proteins studied in the FTIR was calculated. The results along with the corresponding experimental values are presented in Tables 3, 4 and 5 for strand, helix, and turn with irregular, respectively. The results for each conformation will be discussed in the following sections of this report.

4.3. Extend (strand) content

Table 3 shows a comparison between the experimentally determined global 2° structure of the extended conformation (column 2, headed FTIR) along with values calculated by the composite Ramachandran analysis (column 3, headed R). The amount of extended conformation was deter-

mined from FTIR amide I results by summing the component bands from 1638 to 1623 cm^{-1}. Bands at frequencies lower than 1623 cm^{-1} and closer to 1615 cm^{-1} are presumed to be caused by unprotected side-chain carboxyl groups [10]. Note that we assumed the bands (1638–1623 cm^{-1}) quantitate not only the amount of sheet conformation but also extended or strand non-hydrogen-bonded structures, as did Prestrelski et al. [23–24]. For a proper comparison, we sum all the points in the upper left hand quadrant of the Ramachandran plot for ϕ values above 130°, as well as those within the sheet region. Connectivity for any extended structure was determined using a three-dimensional Ramachandran plot (not shown).

As shown in Table 3, comparison between the experimental (FTIR) and calculated (R) extended conformation is excellent. Only in carbonic anhydrase, a high helical protein, is the deviation greater than 4%. Quantitative correlation of the amount of extended structure determined via FTIR and Ramachandran analyses of the X-ray crystal structure for the 16 proteins in this database was accomplished using linear regression analysis and polynomial curve fitting analysis. Using the F-test, it was found for the helix, turn and irregular structure as well as the extended structure that linear regression analysis was the most statistically significant methodology. For the extended structure, linear regression analysis yielded an intercept of 0.65 ± 0.95 ($\sigma = 0.49$) and a slope of 1.03 ± 0.03 ($\sigma = 0.0001$). The standard deviation for the regression analysis was 2.07%. In addition, this good correlation for the extended structures is supported by the fact that all proteins except for carbonic anhydrase lie within the 0.95 confidence level in the linear regression analysis. For carbonic anhydrase, if the excess amount of bent extended structure (calculated from Ramachandran analysis in Table 4, last two columns) minus the amount from FTIR at 1667–1669 cm^{-1} (i.e. $7.1 - 1.7 = 5.4$) is added to the amount of extended structure from Ramachandran analysis in the last column of Table 3 (i.e. $36.0 + 5.4 = 41.4$), then good agreement is obtained with the experimental amount of extended structure via FTIR, 41.7. Thus, the need for better mathematical algorithms for the calculation of

global secondary substructure from the X-ray crystal structure is imperative for correlating with FTIR global secondary structure.

We compared our results for trypsin, α-chymotrypsin and elastase with those reported by Liebman's group — calculated and experimentally determined values in D_2O [23,24]. Values calculated using the Liebman algorithms were 42, 42 and 37. Their experimental results were 39, 45, and 46, while our experimental values were 41, 39 and 37, (all values respective to trypsin, α-chymotrypsin, and elastase). While both our experimental values for trypsin and α-chymotrypsin agree equally with the calculated values, our elastase value of 37 is more in agreement with the calculated value of 37 than the experimental value of 46% in D_2O [23,24]. This adds further support for our methodology and the supposition that the amount of GLN and ASN side-chain residues must be subtracted from the 1667 and 1651 cm^{-1} component amide I bands.

4.4. Helix content

Table 4 lists the calculated and experimental results for the α-helix (columns 1–3), 3/10 helix (columns 5, 6). Linear regression analysis of the amount of helical structure determined via FTIR versus the amount calculated from three-dimensional Ramachandran analysis of the X-ray structure for these 16 proteins yielded an intercept of 2.13 ± 1.81 ($\sigma = 0.26$) and a slope of 0.92 ± 0.06 ($\sigma = 0.0001$). The standard deviation of the regression analysis was 5.6%, which is significantly larger than the error calculated for the amount of extended structure, especially for the low content helical proteins. In fact, five proteins did not fall within the 95% confidence region. Close inspection of these differences may provide a rationale for the change. Not counting the high helical proteins (hemoglobin and myoglobin) we observe that the largest differences occur for ribonuclease, the serine protease system (i.e. pancreatic trypsin inhibitor (PTI), and trypsin), concanavalin A (CON A) and β-lactoglobulin. The last two proteins in this series contain significant amounts of β-barrel structures. Such structures appear as antiparallel β-sheets which are highly bent. The

Ramachandran plots of these proteins also yield points in the lower left quadrant which is normally considered a forbidden region. The Ramachandran plots for the serine proteases also contain some ϕ, ψ angles in this region. Hence, the discrepancy in the experimental and calculated helical content for concanavalin A, β-lactoglobulin and perhaps the serine proteases may be caused by β-barrels which could have bands at 1658 ± 2 cm^{-1}. More experimental and theoretical studies must be performed before this hypothesis can be concluded. But since ribonuclease contains no β-barrel, inspection of the work of Kalnin et al. [18] may provide an answer to the discrepancy. In their study, the α-helix was subdivided into an ordered and unordered class as was the sheet structure. They calculated values of 13% and 10% for their ordered and unordered α-helix and found experimental values of 11% and 8%, respectively. Upon inspection of the ribbon structure, a major distortion of the helical region of ribonuclease is found. In addition, a value of 10.3% has been obtained from the excess area of the 1667 cm^{-1} band which we have assigned as a 3/10 helix, in accordance with the results of Krimm and Bandekar [10]. If the α-helix and 3/10 helix values are summed they add up to more acceptable values. However, the Ramachandran plot for ribonuclease shows 11 residues within the type III or 3/10 helix region which calculates to a theoretical value of 8.8% for these possible conformations. It should also be stressed that Kalnin et al. [18] calculates an ordered α-helix conformation of 27% for lysozyme which agrees well with our experimental and theoretical values of 25.6% and 27.1%. Therefore, we believe that the discrepancy for the ribonuclease helical structure is the result of its structure, which our Ramachandran analysis could not adequately calculate.

The discrepancy between the amount of helix determined from Ramachandran analysis and FTIR experiments for trypsin can be easily explained by closer inspection of Table 4. Ramachandran analysis of trypsin yields 10.4% α-helix, and 8.3% 3/10 helix content where the experimentally determined values from FTIR are 17.4% and 0%, respectively. As can be seen in the Ramachandran plot for myoglobin (Fig. 6A),

there is a large overlap between the acceptable regions for the α and 3/10 helixes. This is due to the small differences between their respective ϕ and ψ values. For this reason it is not possible by this method to precisely determine the differences between these two structures. Moreover, a protein in solution does not adopt a static structure but an average dynamic structure. The dynamic structure, due to thermal fluctuations, causes internal motions within the solvated protein configuration. Under these circumstances, the ϕ, ψ angles for a 3/10 helix may easily change to those for an α-helix. Only intense molecular dynamics calculations of a protein in water can attempt to approximate the dynamic motions of a protein. However, for this study it will be assumed that the 3/10 helix calculated via Ramachandran analysis closely approximates an α-helix. Therefore, we now change the value of the α-helix calculated from Ramachandran analysis to 18.7% ($= 10.4\% + 8.3\%$) which more closely agrees with the experimental value of 17.4%.

It should be stated that the 1676 cm^{-1} band was also summed along with the excess area for the 1651 cm^{-1} band, and the 1658 cm^{-1} band for obtaining the total α-helix content of hemoglobin and myoglobin. The 1676 cm^{-1} band represented approximately 17% of the total helical structure. The areas of the 1658 cm^{-1} and 1651 cm^{-1} bands summed to 63%, and a value of 63% was also calculated as the amount of unordered helix content in myoglobin by Kalnin et al. [18]. Moreover, close inspection of the ribboned structures of hemoglobin and myoglobin reveal highly distorted helical segments which could not be observed using Ramachandran analysis. The 1676 cm^{-1} band, assigned by Krimm and Bandekar [10] as a turn may be reflective of a type III β-turn. Such a turn would have ϕ, φ values seriously overlapping the α-helical region of a Ramachandran plot (see Fig. 6B). Nevertheless, for high helical proteins (i.e. above 55%) it may be more prudent for investigators to utilize UV circular dichroism analysis, because as Torii and Tasumi [14–16] have recently reported, a serious overlap of E and A bands for α-helices with varying lengths occurs, thus resulting in theoretical amide I envelopes which contain bands well

below the 1650 cm^{-1} region. With lower helical proteins, FTIR correlates much better than circular dichroism since the turn conformation can be more easily determined.

Finally, the excess areas in the 1667 cm^{-1} band above the GLN and ASN side-chain contribution is shown in Table 4 as a 3/10 helix or bent strand, i.e. a possible "a" turn. These small values cannot be easily correlated with Ramachandran analysis and no firm assignments are made. Excellent correlation between three-dimensional Ramachandran analysis and FTIR determination of the α-helix at 1659 cm^{-1} and the 3/10 helix at 1667 cm^{-1} is obtained for papain (see Table 4). However, we do not observe any large amounts of 3/10 helix in lysozyme, especially in the 1638 cm^{-1} region where Prestrelski et al. [23,24] have concluded that such 3/10 helical bands exist. While we have not performed any experiments on α-lactalbumin, we still concur with the assignment of Krimm and Bandekar [10] that the 3/10 helix is in the range of 1665 cm^{-1} rather than in the low range of 1638–1640 cm^{-1} as reported by Prestrelski et al. [23,24]. Perhaps this discrepancy may be explained by the fact that their experiments were performed in D_2O rather than in H_2O.

With the above changes in the α-helix percentages, we can now recalculate the correlation (via linear regression analysis) between the experimentally determined FTIR values and the Ramachandran calculated amount of α-helix.

4.5. Turn and irregular content

Table 5 shows the turn and irregular content determined experimentally from analysis of the FTIR amide I band and calculated from the three-dimensional Ramachandran analysis of X-ray crystallographic structures of the 16 listed proteins. The turn content was determined from the sum of all amide I bands from 1670 to 1694 cm^{-1}. The irregular content was calculated from the normalized area of the 1646 $\pm$ 2 cm^{-1} band. The irregular theoretical structure was calculated as all other structure not defined by this analysis. Good agreement between the experimental and theoretical values is observed with the standard deviations from the regression analysis of 3.6%

and 3.2% calculated for the turn and irregular content, respectively. Linear regression analysis of the FTIR values vs. the Ramachandran values yielded an intercept of 0.97 ± 1.39 ($\sigma = 0.49$) and a slope of 1.00 ± 0.04 ($\sigma = 0.0001$) calculated for the turn conformation, and an intercept of -0.75 ± 1.02 ($\sigma = 0.98$) and a slope of 1.01 ± 0.03 ($\sigma = 0.0001$) calculated for the irregular or "all other" conformation. These values for the turn and irregular conformations are well within the standard deviations observed in the strand and α-helix content, i.e. 2.1% and 5.5%. However, it should be noted that in the case of cytochrome C and β-lactoglobulin, ϕ and ψ values exist in the upper right hand region of the Ramachandran plot. Although this region has been considered forbidden, closer inspection shows that these ϕ and ψ values are a result of twisted sheets. Hence, since no other proteins in this database exhibited ϕ and ψ values in this region, we have concluded that the 1676 cm^{-1} band may also be assigned to a twisted strand. However, more studies must be performed before a definite assignment can be made.

5. Conclusions

Calculation of the component 2° structural elements of the vibrational bands, i.e. approximately 25 Gaussian bands, was accomplished by fitting both the amide I and II bands using nonlinear regression analysis of the Fourier self-deconvoluted spectrum, the second-derivative spectrum, and the original spectrum. Fixed frequencies initially used in the original spectral analysis were obtained from both the FSD spectrum and the second-derivative analyses. The criterion for the acceptance of any analysis was that the fractional areas calculated from all three methods were in agreement (within experimental error calculated from the nonlinear regression analysis). Results clearly show that 2° structural conformations determined in water were in better agreement with global 2° structural analysis of X-ray structures than the previously reported values determined in D_2O. Also, with H_2O, the 2° structural elements can be calculated from the amide II envelope to

be used for validation of amide I assignments. In addition, the resolution of amide I spectra in water is greater than that in D_2O as observed in comparable second-derivative spectra and lower half-width values of 9 instead of 13–18 cm^{-1} for the H_2O and D_2O spectra, respectively. The deterioration of resolution of FTIR spectra in D_2O may result primarily from the incomplete exchange of protein protons to deuterons. These results lay the foundation for the study of conformational changes in proteins induced by ligands, consolutes or perhaps structural changes from site-directed mutagenesis [7], and in other system applications where for example D_2O may obscure water–protein interactions.

In this study, we have presented a method for analyzing the FTIR of proteins in water and determining their global secondary structure. Analysis of 16 proteins whose X-ray crystallographic structures are known showed agreement of secondary structure content to within 2–6% between the experimental FTIR and the X-ray coordinate calculations. The bands which are assigned to these structures are shown in Table 6 along with their tentative structural assignments. These assignments differ from previous assignments for only the GLN and ASN side-chain contributions and the 1675 cm^{-1} band which is now assigned to a turn rather than to an extended conformation. The high frequency β structure band at 1675 cm^{-1} reported by Byler and Susi [3] was not observed in this study. In our data base we have tentatively assigned this frequency as a turn conformation. This discrepancy may have arisen from the fact that Byler and Susi [3] did not consider turn conformations in their study, nor did they account for GLN or ASP side-chain contributions. In this study we tentatively assign the 1676 cm^{-1} band to the "a" turn conformation. While these results are quite promising, it must be stressed that only after a database of at least 50 proteins is obtained can any definite conclusions be reached. It is hoped that this study will inspire other investigators to adopt this methodology and add more information to increase this database above 16 proteins.

There are recent reports in the literature on the potential of FTIR to evaluate the global 2° struc-

ture of proteins which discuss the limitations of "band-narrowing" methodologies used to analyze FTIR spectra of proteins [25,26]. Our methodology addresses some of these limitations.

(1) We have eliminated atmospheric water completely with a thorough dry nitrogen purge and an accurate vapor spectra subtraction.

(2) We have considered the influence of side-chain absorptions, and recommend compensating for ASN and GLN side-chain absorptions as described above.

(3) We obtain a large number of interferograms to insure a high signal-to-noise ratio (S/N). A high S/N is necessary to ensure accurate vapor and buffer subtractions. A high S/N also reduces the influence of the instrumental noise.

(4) The ABACUS nonlinear regression program eliminates the operator influence on band shape — the relative Gaussian/Lorentzian contribution is determined by the fit.

(5) We statistically choose the number of bands used to fit the spectral data with the use of the extra-sum-of-squares F-test and the ABACUS program's ability to lower-bound all bands at zero height.

(6) Although we only use the amide I results for assignments, we fit both the amide I and II envelopes simultaneously. This improves the amide I fit compared to fitting the arbitrarily terminated amide I envelope alone.

(7) We use and analyze the original, the FSD, and the second-derivative spectra, accepting results only when all three regression fits statistically agree. This addresses the question of unique fits.

(8) We fit the spectra from two different starting values — small heights and large heights — requiring both analyses to come to the same answer. This eliminates the possibility of local minima being reached and ensures a unique fit.

(9) In general our methodology eliminates as much operator influence on the nonlinear regression fitting process as possible.

(10) Spectra are obtained in H_2O. This is the natural environment of proteins and the environment in which most X-ray crystal structures are analyzed. This eliminates any possible conformational distortions which may occur with the use of D_2O.

(11) We reanalyze each protein's X-ray crystal structure data using three-dimensional Ramachandran analysis. This ensures a consistent 2° structural X-ray analysis procedure from which to compare the protein structures obtained by FTIR.

(12) Finally, we recommend the use of amino acid secondary-sequenced-based prediction algorithms in conjunction with FTIR to analyze proteins with unknown structure.

Abstract

Silicon was quantitatively determined in respirable silica dusts and silica fume by FT-Raman spectroscopy using barium sulfate as an internal standard. Barium sulfate was selected as the standard as its Raman spectrum does not overlap with that of silicon and its scattering cross-section is significantly lower. This allowed silicon admixed with barium sulfate in ratios as low as 0.00003 to be detected. The laser beam was defocussed to cover the sample area. 128 scans at 4 cm^{-1} resolution with 600 mW of power at the sample achieved a detection limit of 0.1 μg of silicon in a 5 mg sample. Silicon to $BaSO_4$ ratios in the range 0.00003–0.06 showed a near linear response with any decade change being linear. The RSD for this analytical method was $\pm 2\%$. Silica fume and respirable silica dust showed silicon concentrations to be in the range 2.6–51.5 ppm and 0.05–0.7 mg m^{-3} respectively.

Keywords: Silicon; Silica dust; FT-Raman spectroscopy

1. Introduction

Silicon is manufactured by the reduction of high grade quartzite with charcoal and coal at temperatures of up to 1780°C using graphite electrodes in a submerged electric arc furnace. While there are a few less important reactions, the following represents the main reaction sequence [1]:

$$SiO_2(l) + C(s) \rightarrow SiO(g) + CO(g)$$

$$SiO(g) + 2C(s) \rightarrow SiC(s) + CO(g)$$

$$SiC(s) + SiO_2(l) \rightarrow Si(l) + SiO(g) + CO(g)$$
A by-product of the process is silica fume which is formed when unreacted silicon monoxide is oxidised in the upper reaches of the furnace:

$$2SiO(g) + O_2(g) \rightarrow 2SiO_2(s)$$
The silica fume is mainly comprised of amorphous silica but also contains approximately 4% free carbon, 2% silicon carbide, 4% crystalline silica and very low levels of silicon [2,3]. A knowledge of the silicon content of silica fume and respirable silica dusts is important for two reasons. There have been three reports of explosions when the levels of silicon in silica fume have exceeded 1%. The presence of silicon in silica fume leads to the formation of hydrogen gas

when the metal comes in contact with the alkaline environment. To prevent such occurrences, the maximum permissible quantity of silicon in silica fume has been set at 0.2% [4]. Occupational Health and Safety requirements demand that the air quality at the plant is regularly sampled near the tapping floor. While crystalline silica has a greater potential for causing silicosis [5–7], it has been shown that crystalline silicon can also induce silicosis [8]. The current exposure limit set for silicon in respirable silica dusts in Western Australia is 5 mg m^{-3} [9].

Current methods for determining low concentrations of silicon are complex and time-consuming [10,11]. Crystalline silicon has a tetrahedral diamond-like structure and its Raman-active symmetrical stretch occurs at 519 cm^{-1}. In the present paper the viability of this stretch was evaluated for quantitative solid state analysis. The major problems addressed, as with any solid state Raman method, were the selection of a suitable standard, homogeneous sample dispersion and full Raman illumination of the entire sample.

2. Experimental

2.1. Samples

The silica fume and respirable silica dust samples were provided by Simcoa Operations, Kemerton, W.A. The eight silica fume samples were taken at irregular intervals from the fume discharge line to the baghouse and the five respirable silica dust samples were collected at irregular in-

tervals by filtering 0.8 m^3 of air at the tapping floor.

2.2. Reagents

Barium sulfate, AR Grade, BDH, dried at 90°C for 24 h. Hydrofluoric acid, 48%, AR Grade, Merck. Silicon, 99.8%, Simcoa Operations, ground to <100 μm.

2.3. Internal standard

Barium sulfate was chosen as the internal standard as it possesses an intense sharp Raman peak at 986 cm^{-1}, sufficiently removed from the silicon peak at 519 cm^{-1}. The pressed powder standards were prepared by homogenising various ratios of the silicon and barium sulfate as shown in Table 1.

2.4. Preparation of samples for Raman analysis

The respirable silica dust and silica fume samples were analysed as pressed powders. The respirable silica dust samples were prepared by intimately hand-mixing, in an agate mortar and pestle, the required amount of barium sulfate to make the total weight of sample 30 mg. 5 mg of sample was then compressed, by hand, into a stainless-steel sample holder with a 1.7 mm diameter, 0.5 mm deep, conical sample cavity.

The silica fume samples were treated with hydrofluoric acid prior to Raman analysis to remove amorphous and crystalline silica. They were also heated to remove all the free carbon. Approxi-
Fig. 1. Duplicate Raman spectra of typical pressed powder standard.

mately 10 g of silica fume, in duplicate, was accurately weighed in a 500 ml Teflon beaker and treated with 40 ml of hydrofluoric acid. The solution was diluted to 400 ml and filtered through a Whatman 541 filter paper, dried at 110°C and weighed. The residue was then ashed in a porcelain crucible at 550°C for 2 h and reweighed when cool. The samples were determined in the same manner as the respirable samples.

2.5. Instruments

All spectra were obtained with a Bruker RFS100 FT-Raman Spectrometer using a 1064 nm excitation laser in the 180° back-scatter mode. 128 scans were taken at 4 cm^{-1} resolution using 600 mW of laser power at the sample. The software package was OPUS Version 1.5c Beta, enabling peak heights and areas to be determined with high accuracy. Standards were weighed using a Sartorius R200D semi-micro balance accurate to five decimal places.

3. Results and discussion

The Raman spectrum of pressed powder standard 4, in duplicate, is shown in Fig. 1. The sharp peaks of barium sulfate and silicon are seen at 986 cm^{-1} and 519 cm^{-1} respectively. The figure shows the high degree of precision that can be obtained by this method.

The calibration plot for the whole range of the intensity ratio versus the concentration ratio showed curvature, and thus calibration plots were established for low (0.0001–0.0008), middle (0.002–0.012) and high (0.01–0.06) range standards. The calibration plots for the low, middle and high standards all showed excellent linearity with correlation coefficients of 0.9987, 0.9999 and 0.9989 respectively. The equations for each line are:

$$I = 1.4542 + 806.875C \quad \text{(high)}$$

$$I = 0.1191 + 970.365C \quad \text{(middle)}$$

$$I = 0.01996 + 1137.550C \quad \text{(low)}$$

where I is the intensity of silicon(519 cm^{-1})/intensity of barium sulfate(986 cm^{-1}) and C is the weight of silicon/weight of barium sulfate. Acquiring 256 scans at 4 cm^{-1} resolution with 600 mW of defocussed laser power and a 5 mg sample mixed with 10 mg of barium sulfate gave a detection limit ratio of Si/BaSO$_4$ = 0.00002, which corresponds to 0.1 μg of silicon in the sample (i.e. 20 ppm). A greater number of scans could be used to improve this detection limit if required. A reduction of resolution to 8 cm^{-1} may then be useful to reduce acquisition times.

The results for the silicon content of the respirable dust samples are shown in Table 2. The

Table 3.
Silicon content of silica fume

Sample	Intensity ratio Si/BaSO$_4$	Conc. ratio Si/BaSO$_4$	Wt. Si (mg)	Si in dust (ppm)
1	0.7509	0.00071	0.05	2.6
2	1.9243	0.00191	0.21	5.3
3	4.5988	0.00465	0.49	4.0
4	9.8677	0.01003	1.06	51.5
5	2.4029	0.00234	0.33	5.9
6	2.3069	0.00230	0.54	21.7
7	0.8924	0.00086	0.13	5.5
8	3.4886	0.00351	0.30	4.5

silicon content of the respirable dusts was found to range from 0.04 to 0.55%, corrresponding to a silicon content in air of 0.05–0.7 mg m^{-3} respectively. A typical respirable dust weight of 10.6 mg gave a Si/BaSO$_4$ ratio of 0.000083 from a Raman intensity ratio of 0.114. The data obtained for the respirable dusts were well within the Occupational Health and Safety requirement of 5 mg m^{-3} [9].

The results for the silicon content of the silica fume samples are shown in Table 3. The silicon content was found to range from 2.6 to 51.5 ppm. A typical fume sample of about 100 mg gave a Si/BaSO$_4$ ratio of 0.0024 from a Raman intensity ratio of 2.403. The data for the fume samples indicated only trace levels of silicon in the fume and no cause for concern in relation to explosions in alkaline cement environments [4].

4. Conclusions

A quantitative method for the determination of low levels of silicon in respirable silica dust and silica fume has been developed. The method has good sensitivity, a good dynamic range and very good reproducibility. Concentrations of silicon in the respirable dusts and silica fume were found to range from 0.05–0.7 mg m^{-3} and 2.6–51.5 ppm

respectively. The detection limit for the analytical method was 0.1 μg of silicon in a 5 mg sample. The RSD for the analytical method was $\pm 2\%$. The values obtained for the respirable dusts were well within the Western Australian Occupational Health and Safety Standard for exposure to such dusts of 5 mg m^{-3}, while the values obtained for silica fume were also within the prescribed limit.

Determination of ATP using chelation-enhanced fluorescence

Gregory P. Foy, G.E. Pacey*

Department of Chemistry, Miami University, Oxford, OH 45056,USA

Received 23 June 1995; revised 1 September 1995; accepted 1 September 1995

Abstract

A method for the direct determination of ATP that exhibits reasonable sensitivity, and responds to very few interferants, has been developed. The chelation-enhanced fluorescence between N-(anthracen-9'-yl methyl)tris(3-aminopropyl)amine and adenosine 5'-triphosphate is utilized in this determination. The method was tested in batch and flow-injection analysis (FIA) modes. The typical detection limit for FIA determination of ATP is 1 μM, with a linear range of 0.5-100 ppm. A typical relative standard deviation at 20 ppm is 2.3%.

Keywords: ATP; Chelation-enhanced fluorescence; Flow-injection analysis

1. Introduction

Determination of the adenosine phosphate compounds (ATP, ADP, AMP) is performed in many biological systems. The current methods for this determination are the widely used firefly luciferase [1-6] chemiluminescent method and the spectrophotometric monitoring of the enzymatic conversion of ATP to ADP [1,7,8]. In general these methods suffer from numerous interferants as well as limited linear range. Typically, the detection limits are in the 10 μM region for the spectrophotometric methods [1], and at the 10^{-10} M level for direct detection with luciferase in a flow-injection system [3], with a level of 10^{-14} M having been reported [4]. These levels of detection are only achieved after separation from similar

compounds, or minimization of other interferants.

The ideal method for ATP determination would not destroy the ATP in the sample, providing the possibility of further analysis, and would provide a large range for determination as well as a low level of detection without stringent requirements for pH and temperature. The method would also be selective for ATP without prior separation. One approach would be to use an anthrylmethylpolyamine, N-(anthracen-9'-yl methyl)tris(3-aminopropyl)amine, and the chelation-enhanced fluorescence effect (CHEF) reported by Czarnik [9]. The CHEF effect measures the increase in fluorescence due to the formation of a chelate between the amine and the anion of interest. The magnitude of the formation constant for the chelation of the anion is proportional to the observed enhancement. This paper describes the investigation of the anthrylmethylpolyamine, N-(an-

thracen-9′-yl methyl)tris(3-aminopropyl) amine as an analytical reagent for ATP determinations.

2. Experimental

All starting materials were purchased from Aldrich. The amine, *N*-(anthracen-9′-yl methyl)tris(3-aminopropyl)amine was prepared by using tris(cyanoethyl)amine in the procedure of Van Winkle et al. [11]. The next step is hydrogenation over Raney Nickel following the procedure of Chin et al. [12]. In the synthesis of *N*-(anthracen-9′-yl methyl)tris(3-aminopropyl)amine the procedure of Hutson [10] was used, but with the following modifications. After the reaction was complete, the washing steps were performed, and the organic layer was dried over sodium carbonate. This was followed by solvent removal and drying on a rotovap. The elution through and alumina plug was not performed, because increased purity did not result from this step. The key to purity was the drying of the HCl salt under vacuum. The salt was dried in a drying pistol which was loaded with drying agent and held under vacuum for 24 h. If the sample was not completely dried, crystals would not form. Verification of the product was accomplished using 200 MHz NMR data which were compared to the reported proton and ^{13}C data of Czarnik [9]. The melting point of the crystals also matched Czarnik's reported data.

The general procedure for preparation of the amine for analysis was as follows. *N*-(anthracen-9′-yl methyl)tris(3-aminopropyl)amine (2.79 mg) was dissolved in 1 l of triply-distilled water to make 5 μM amine. 4-Morpholineethane-sulfonic acid (MES) (10.66 g) was dissolved in 1 l triply-distilled water to make 0.05 M buffer which was adjusted to pH 6.0 by addition of 50% NaOH. Standard concentrations of ATP were prepared by dissolving an appropriate amount of adenosine 5′-triphosphate, disodium salt hydrate, in triply-distilled water followed by appropriate dilution. The batch measurements were made by mixing 3 ml of amine, 5 ml of MES, and 4 ml of ATP. The relative fluorescence intensity (excitation 335 ± 3 nm, emission 417 ± 3 nm) was recorded. All batch

fluorescence measurements were performed on a LS-50 Perkin-Elmer luminescence spectrometer.

pH studies were performed using the above standard procedures, and by varying the pH of the MES buffer through addition of concentrated hydrochloric acid, or 50% NaOH. pH measurements were performed on a Fisher Scientific Accumet pH meter. A blank fluorescence measurement was performed for each pH by addition of 3 ml amine, 5 ml MES, and 3 ml of triply-distilled water.

The study of interferents was performed in several different ways. The initial screening of anions was done with many of the common anions at various concentrations to determine which compounds exhibited CHEF. The anions showing the largest enhancement (ADP and phosphate) were studied further by adding different concentrations of the possible interferant to a standard sample containing 10 ppm ATP, and recording the relative intensity of the signal.

Flow-injection analysis (FIA) was used to automate the determination of ATP using the manifold shown in Fig. 1. All FIA experiments were performed using a Tecator 5020 FIA analyzer with a Waters 470 flowthrough fluorescence detector with excitation at 335 ± 3 nm and emission at 417 ± 3 nm. The system is held at a constant pH by pumping a 0.5 M MES buffer (1.2 ml min^{-1}) which is mixed into a carrier stream of triply–distilled water (1.2 ml min^{-1}). The two streams are then mixed in a 60 cm × 0.5 mm i.d. mixing coil, and merged into a stream of 5 μM amine (1.2 ml min^{-1}). The final mixing is done in a 30 cm × 0.5 mm i.d. mixing coil. A 200 μL sample loop containing ATP is directly injected

Table 1

Responses of different anions relative to ATP. The relative responses have been normalizd to the response of a 10 ppm ATP sample

Anion	Relative response
ATP	17000
ADP	4035
Phosphate	12
Citrate	8
Potassium hydrogen phthalate	4
Morpholine ethane sulfonic acid	2
Sulfate	1.9
Chloride	0.3
Nitrate	< 0.1
Bromate	< 0.01

into the carrier stream. Interferant studies in the FIA system were performed by adding the possible interferant in varying concentrations directly to the ATP standard. Output from the fluorescence detector was recorded on a Linear® strip chart recorder. All reported data are based on peak height.

The pK_a values of the anthrylmethylpolyamine were determined by titrating a sample of the amine adjusted to pH 2.2 with standardized 0.005 M NaOH. Titrations were performed on a Radiometer Titrilab automated titrator.

3. Results and discussion

The work began with the characterization of N-(anthracen-9'-yl methyl)tris(3-aminopropyl)amine as an anion reagent. Initial studies based on the work described by Czarnik [9] suggested that phosphate ion produced the most intense response with the reagent. In Czarnik's work, no analytical data were presented; therefore, the capability of the reagent with phosphate was investigated. After optimization a linear range from 10–100 ppm was observed with a detection limit around 10 ppm. Given this level of detection it was clear that the compound was not particularly applicable to phosphate ion determinations. In fact given the overall response of the reagent to anions (Table 1) it was clear that the common anions did not produce significant CHEF. However, the data for

ATP and ADP show that the CHEF was significant and that a thorough investigation of the potential for ATP determination should be performed.

Current methods for ATP determination involve the use of firefly luciferase which is a very expensive reagent. In addition, the luciferase method suffers from a number of interferents. The method measures the amount of $MgATP^{2-}$, but responds to free ATP as a competitive inhibitor at 50% of the $MgATP^{2-}$ complex [8]. There is also an inhibitory effect of salts ($NaCl$, KCL, NH_4Cl, $LiCl$, $NaBr$, $MgCl_2$, and $NaHCO_3$) [13], which follows the Hofmeister series. The method also shows some inhibition by ADP which has been described in this manner: "... AMP and $MgATP^{2-}$ are bound 40 times more strongly than adenosine and MgADP is only fourfold as strongly bound as adenosine." [1]. The most logical interpretation of this statement is that adenosine does not respond to firefly luciferase, and ADP responds at a level which is approximately a 10% intereference in ATP determination at similar concentrations.

The initial CHEF studies with phosphate ion resulted in a determination of a set of optimized conditions. It was found that these conditions were also optimal for the investigation of CHEF with ATP. Amine concentrations at micromolar levels produced the lowest background fluorescence with the greatest possible enhancement. The background fluorescence signal was affected by pH (Fig. 2). The background signal is large at lower pHs, presumably due to the protonation of the amine. This point is critical because the most likely mechanism for CHEF is an electrostatic interaction between the protonated amine sites and the negative sites of the anion. Therefore, a compromise between a pH to ensure proper protonation of the amine and a pH to ensure deprotonation of the anion is necessary. The measured pK_a values of the amine are 5.95 (two terminal amines) and 9.4 (benzyl amine) with the terminal amines at the lower pK_a value. The initial studies with phosphate resulted in the optimum enhancement of the fluorescence at a pH of 6.05. The ATP study was therefore begun in the batch mode, holding the pH at 6.05 with MES as the

Fluorescence Response of Amine vs pH
Fig. 2. Change in relative intensity of fluorescence of the regeant amine with change in pH.

buffer and a 10 μM amine concentration. ATP was easily decected down to a 10 ppm level which was adequate for any interference or pH studies which were needed in the batch mode.

The method was converted for use in FIA. The adaptation to the flow-injection system was relatively straightforward. All flow streams were pumped at the same rate, with triply-distilled water as the carrier, MES buffer as reagent 1, and the amine as reagent 2 (see Fig. 1 for manifold details). The optimum conditions were the same as the batch method except for the amine concentration which was lowered to 5 μM in order to decrease the background signal of the amine. The decrease in background signal of the amine was necessary because of the increased sensitivity of the flowthrough detector. An enhancement in the signal was seen, thus allowing a lower level of detection. A typical calibration plot in the flow-injection system for ATP was $y = 0.8106(x)$ $(\pm 0.10) + 0.214$ (± 0.235) with a r^2 value of 0.9997. The calculated detection limit of 1 μM with a linear range of 0.5–100 ppm was observed.

At 10 μM, the percent recovery was 96.8%. A typical calibration curve is shown in Fig. 3.

The interferences in this method are minimal. The biggest possible interferents with this system can be identified from the enhancements seen in Table 1. The addition of phosphate to the 50 ppm ATP–amine system did not interfere until a concentration of 1000 ppm phosphate was added. At equivalent 50 ppm concentrations of ATP and ADP a 14% increase in the signal is observed.

The enhancement in the signal varied tremendously with a change in the pH, which should have an impact on the complexing properties of the host amine. Czarnik's [9] explanation of the CHEF effect describes an electrostatic interaction between the host amine and the anion which participates in the chelating. This interaction then results in an increase in the rigidity of the pendant arm of the amine which subsequently favors the fluorescence process. The enhancement of the signal is directly related to the concentration of the anion in solution. The signal should increase when the amine–anion interaction is favorable,

Low Level Det of ATP

R Squared=0.0999603

Lowest ppm Range

R Squared=0.998171
Fig. 3. Typical calibration curves for ATP CHEF.

but the anion should have no effect on the signal when it no longer possesses a negative charge, as is the case at low pH. This is not the observed trend at lower pH as can be seen from Fig. 4. ATP actually reproducibly quenches the signal at lower pH. Fig. 4 also indicates that ADP has

ATP and ADP Enhancements with Changing pH

with and without Buffer
Fig. 4. Change in CHEF of ATP and ADP with and without MES buffer with change in pH.
Fig. 5. Possible amine-ATP electrostatic interaction. These orientations result from the use of molecular mechanics simulation. The phosphate chain of ATP (below) aligns with the amine "arm" of the anthrylmethylpolyamine (above).
Fig. 6. The N-(anthracen-9'-yl methyl)tris(3-amino-propyl)amine molecule with movement of the pendant arm relative to anthracene over a 10 ps time scale. The movements are the result of a molecular mechanics simulation.

The explanation which Czarnik [9] has given in his description of CHEF is very straightforward, and it is the best description of the amine-anion interaction available. In order to strengthen this position, some molecular mechanics calculations (Hyperchem Version 3.0) were performed. Fig. 5 shows the results of the interaction between the host amine and ATP. The phosphate groups align themselves in the amine pocket for the best possible interaction between the protonated amines and the negative charges of the unprotonated phosphate groups. The longer chain of the ATP triphosphate group is able to interact more fully with the amine than the diphosphate group of ADP, and this reasoning rules out any interaction with AMP. There is the possibility of an increase in the electrostatic attraction as well as a decrease in the steric interaction of the bulky adenosine portion of the molecule. The initial calculations used when the host amine is allowed to move freely in space (Fig. 6) show that the amine arm of anthracene rotates from a position away from the pi face of anthracene to one close to the pi face in a matter of picoseconds. This free rotation of the arm promotes dissipation of energy which quenches the native fluorescence of the molecule. When ATP is chelated by the host amine, the free rotation of the arm is impeded by the steric bulk of ATP, and the fluorescence of the system is enhanced.

4. Conclusions

Determination of ATP at biological pH levels is a critical issue. The method described in this work is a simple, automated method for the detection of ATP with very little interference. The study of the CHEF effect with changing pH reveals a possible way to lower the small interference of ADP while improving the sensitivity. The detection limit of 1 μM and the linear range of an order of magnitude both compare favorably with current methods of ATP determination. The use of CHEF for ATP determination does not rely on enzymatic reactions, and can be used over a large range of pH including the biological pH region. All of the common interferants which

similar quenching properties at a much lower level. We have not been able to adequately explain this phenomenon, but can only present these data and assure their reproducibility.

have been tested show minimal interference. The method allows determination over a wide concentration range coupled with a low level of detection. Materials needed for synthesis of the anthrylmethylpolyamine are inexpensive, and synthesis of this compound is straightforward. The anthrylmethylpolyamine is readily soluble in water and stable for more than a week when stored below 5°C.

Homogeneous liquid–liquid extraction method for spectrofluorimetric determination of chlorophyll a

Takahito Sudo, Shukuro Igarashi*

Department of Materials Science, Faculty of Engineering, Ibaraki University, Nakanarusawa 4-12-1, Hitachi, Ibaraki 316, Japan

Abstract

A new homogeneous liquid–liquid extraction using a fluorocarbon ionic surfactant, Zonyl FSA (FSA), having a diethylthioether group as a spacer between the perfluoroalkyl group and carboxyl group has been developed. In this FSA method, the phase separation phenomena were observed at mild pH (below pH 6). Moreover, by using this extraction method as a preconcentration, a highly sensitive spectrofluorometric determination of chlorophyll a was established. The results for the standard chlorophyll a were as follows. The concentration factor (V_w/V_o) was 200 (water phase, V_w, 20 cm^3, water-immiscible phase, V_o, 100 μl), the distribution ratio, $\log D$, was 4.85, the extraction percentage, E, was 99.7%, and the procedure time was ≈ 30 min. The calibration curve was linear in the concentration range 2×10^{-11}–3×10^{-7} mol dm^{-3} and the detection limit $(S/N = 3)$ was 1×10^{-11} mol dm^{-3}. The relative standard deviation was 0.72% for 10^{-8} mol dm^{-3} (five determinations).

1. Introduction

Recently, we have found that the neutralization of perfluorooctanate ion (PFOA$^-$) in an aqueous water-miscible organic solvent solution induces a new type of phase separation which provides a small volume of an oily, transparent, water-immiscible liquid phase from a large volume of aqueous solution. By using this phenomenon, a new homogeneous liquid–liquid extraction based on pH-dependent phase separation was reported [1]. As a result, porphyrin chelates were rapidly

extracted into the water-immiscible precipitated phase, and were then easily concentrated by a factor of about 10^4. However, a strongly acidic condition (below pH 0.6) was necessary for this method, because the acid dissociation constant of the carboxyl group in PFOA$^-$ was low (i.e. the pK_a value of PFOA was 1.01 at 20°C and the ionic strength, $I = 0.1$) due to the electron withdrawing force of fluorine atoms in the perfluoroalkyl chain, which was a serious problem in the previous method. Therefore, we postulated the use of Zonyl FSA (FSA), which introduced a methylene chain (e.g. diethylthioether group) as a spacer between the perfluoroalkyl group and car-

* Corresponding author.

boxyl group in order to negate the effect of fluorine. As a result, phase separation at mild pH is possible. Compared with the PFOA method, important information from this FSA method is possibly applicable to homogeneous liquid–liquid extraction for many environmental samples or vital samples concerning denaturation under strongly acidic conditions. Details of homogeneous liquid–liquid extraction method based on the pH-dependent phase separation with FSA and the spectrofluorimetric determination for chlorophyll a (chl.a) in pond water will be discussed in this paper.

2. Experimental

2.1. Apparatus

The fluorescence measurement was made with a Hitachi Model F-4500 fluorescence spectrophotometer. The fluorescence spectrometer was equipped with a 150 W xenon lamp source. A Hitachi model 200-10 double beam spectrophotometer was used for the measurement of absorption spectra. A Toa HM-18B pH meter was used for the measurement of pH. A Karl–Fisher titrator (Mitsubishi Kasei Co., Type CA-06, Version 3.0) was used for the water content measurement in the precipitated phase. A Tomy LC-100 centrifugal machine was used for the phase separation. A Sibata CS-20 supersonic washer was used for the destruction of the phytoplankton cell.

2.2. Reagents

FSA was used as received from Du Pont and was a mixture that contained components with carbon numbers in the alkyl group from 6–10 (Fig. 1). In this study, FSA diluted to 25 wt.%

FSA

$$CF_3\text{-}(CF_2)_n\text{-}CH_2\text{-}CH_2\text{-}S\text{-}CH_2\text{-}CH_2\text{-}COOH \qquad n = 6 \sim 8$$
Fig. 1. Structure of FSA.

with water was used. Chl.a as a standard sample was then used as a biochemical reagent from spirulina which was obtained from Wako Pure Chemical Industry. The pH buffer aqueous solution was prepared at pH 4 by mixing 4 mol dm^{-3} acetic acid solution and 4 mol dm^{-3} sodium acetate solution. THF was obtained from the Kanto Chemicals Corporation. All other chemicals used were of analytical reagent grade.

2.3. Procedure

2.3.1. Homogeneous liquid–liquid extraction

A 12 cm^3 sample solution containing each type of solute, 6 cm^3 of water-miscible organic solvent such as THF or acetone, and 1 cm^3 of 25 wt.% FSA aqueous solution, was placed in a 50 cm^3 cylindrical glass vial fitted with a plastic cap. Acetic acid–sodium acetate mixture buffer solution (1 cm^3) was then added in order to adjust the pH value of the mixture to below pH 5. After centrifuging at 2500 rev min^{-1} for 15 min, the volume of the precipitated phase was determined using a 0.1 cm^3 micro-syringe. The concentrations of solutes in the precipitated phase were then determined spectrophotometrically or spectrofluorimetrically after dilution using 0.5 cm^3 of THF.

2.3.2. Determination of chlorophyll a

This procedure was similar to the previous procedure. Namely, 12 cm^3 of sample solution (e.g. pond water) containing chl.a, 6 cm^3 of THF and 1 cm^3 of 25 wt.% FSA aqueous solution was placed in a 50 cm^3 cylindrical glass vial fitted with a plastic cap. Next, the mixture was exposed to a 46 kHz supersonic vibration for 10 min using the supersonic washer. The phytoplankton cell was then destroyed, and chl.a was solubilized. Then, 1 cm^3 of pH buffer solution at pH < 5 was added. After centrifuging at 2500 rev min^{-1} for 15 min, the concentration of the extracted chl.a in the precipitated phase was spectrofluorimetrically determined by measuring the fluorescence intensity at λ(em) = 666 nm (λ(ex) = 430 mm) after dilution using 0.5 cm^3 of THF.
Fig. 2. Relationship between pH and the volume of sedimented phase: (curve A) FSA method; (curve B) PFOA method. $[FSA]_T = 1.25$ wt.%, $[THF]_T = 30$ vol.%, temperature = 20°C.

Fig. 3. Ternary phase diagram for water/THF/FSA solution. Point A: experimental condition. $[FSA]_T = 1.25$ wt.%, temperature = 20°C.

3. Results and discussion

3.1. Mechanism of pH-dependent phase separation

A fluorosurfactant such as PFOA or FSA dissolves in water at a higher pH value than its acid dissociation constant of the carboxylic acid group. If the pH of this aqueous solution is lower than its acid dissociation constant, the fluorosurfactant is precipitated as a needle-like crystalline solid due to the charge neutralization of the carboxyl ion. However, if small amounts of a water-miscible organic solvent such as THF or acetone coexisted in this system, the fluorosurfactant precipitated in the water-immiscible liquid phase. The solute was then extracted into the precipitated phase. The reaction formula in this phase separation phenomenon and the acid dissociation constant (K_a) are expressed as follows:

$$R_f-COO^- + H^+ \rightleftharpoons R_f-COOH \tag{1}$$

$$K_a = \frac{[R_f-COO^-][H^+]}{[R_f-COOH]} \tag{2}$$

where R_f in PFOA is C_7F_{15}. The R_f group in FSA is shown in Fig. 1.

The effect of pH during the phase separation is shown in Fig. 2. The acid dissociation constant (pK_a) of FSA was 6.5 in the 50 vol.% THF

solution. The precipitated phase was produced at below pH 6. Also, this phase separation phenomenon was reversible depending upon pH.

3.2. Effect of FSA concentration

A ternary diagram is shown in Fig. 3. It expresses the relationship between the volume content of the water/THF/FSA ternary component solution and the state of the phase separation. In this Figure, point A is the proposed experimental condition. The relationship between the concentration of FSA and the precipitated phase volume
Fig. 4. Relationship between the FSA content and the volume of sedimented phase. $[THF]_T = 30$ vol.%, temperature = 20°C.

is shown in Fig. 4. The volume of the precipitated phase increased in proportion with the amount of added FSA. However, if the concentration of FSA exceeded 2.5 wt.%, the experimental point deviated from a straight line that passes through the origin. In order to have a quantitative phase separation the amount of added FSA must be below 2.5 wt.%. The maximum concentration factor (the volume ratio between the water phase and the precipitated phase after the phase separation) was 1000. In practice, it was possible to concentrate the solute from 20 cm³ of aqueous solution to 20 μl of the water-immiscible liquid phase.

3.3. Effect of water-miscible organic solvent

The properties of the water-miscible organic solvent significantly influenced the phase separation behaviour. As previously mentioned, this phase separation occurred due to the existence of the fluorosurfactant and some types of water-miscible organic solvent. Water-miscible organic solvents such as THF, acetone, N,N-dimethylformamide, acetonitrile, 1,4-dioxane, dimethylsulfoxide and ethanol were then examined. Amongst these solvents, THF and acetone were best suited for this extraction method. In the case of acetone, however, the volume and viscosity of the precipitated phase were both greater than when using THF. Based on these findings, THF was selected for this extraction method. The effect of THF concentration on the phase separation is shown in Fig. 5 (curve A). When THF was added over the volume range 10–50 vol.%, the precipitated phase became oily and transparent. Also, when THF was added below 10 vol.%, FSA precipitated as a solid. Furthermore, when THF was added above 50 vol.%, the precipitated phase was not produced.

3.4. Composition ratio in the water-immiscible precipitated phase

The change in composition of the precipitated phase was examined using the following method. The water content was measured by coulometric titration with Karl-Fisher reagent. The FSA content was measured by weighing after the evapora-
Fig. 5. Relationship between the volume of THF added and the weight of components in the sedimented phase: (A) total weight; (B) FSA; (C) THF; (D) water. $[FSA]_T = 1.25$ wt.%, temperature $= 20°C$.

tion of water and THF using a vacuum dryer. Also, the content of THF was obtained by calculating the difference from the total weight. The results are shown in Fig. 5. The content of THF in the precipitated phase increased with increasing THF concentration. The water content of the precipitated phase in the FSA system was 5%, and this value was lower than that of the PFOA method (e.g. 23% when using acetone) [1]. As a result, the most suitable hydrophobic solute for the proposed method was postulated.

3.5. Extraction of some kinds of solute

The extraction of various porphyrin compounds was examined. The distribution ratio (D) and the volume ratio are given by

$$D = C_o/C_W, \qquad V = V_W/V_o \qquad (3)$$

where C_o and C_W are the concentrations of the precipitated phase and the water phase respectively and V_W and V_o are the volumes of the water phase and the precipitated phase respectively. The extraction percentage is given by Eqs. (3) and (4).

$$E = 100D/(D + V) \quad (\%) \qquad (4)$$

The extraction result is shown in Table 1. The extraction percentage of the hydrophilic compounds having a carboxyl or phenol group was

Table 1

[a] 5,10,15,20-Tetrakis(4-carboxylphenyl)porphine.
[b] 5,10,15,20-Tetrakis(4-hydroxylphenyl)porphine.
[c] 5,10,15,20-Tetraphenylporphine.

low. However, the extraction of chl.a (i.e. log D = 4.85, E = 99.7) was much better than for the other solutes.

3.6. Determination of chlorophyll a

The spectrofluorimetric determination of standard chl.a was then developed by combination with this extraction method. As a result, the calibration curve was linear in the concentration range 2×10^{-11}–3×10^{-7} mol dm^3, the detection limit (S/N = 3) was 1×10^{-11} mol dm^{-3}, and the coefficient of correlation for the calibration curve was 0.998. The relative standard deviation was 0.72% for 10^{-8} mol dm^{-3} (five determinations). For the determination of chl.a in an environmental water sample at concentrations of 10^{-11} mol dm^{-3}–10^{-8} mol dm^{-3}, the supersonic washer was used in order to disrupt the phytoplankton cell. As a result of the examination to determine the exposure time, 5 min was found to be insufficient. Also, the transformation of the cell occurred after 20 min. Hence, the exposure time was chosen to be 10 min in this study. The results, which were determined using this proposed method, correlated very well with those using a conventional extraction method [2,3] (Table 2). In the results, the RSD (4.99%) of the practical sample is much larger than that (0.72%) of the standard chl.a, because the

Table 2

Comparison with conventional method for pond water from Ibaraki University

Method	Chl.a (mol dm^{-3})	Relative standard deviation [a] (%)
This method	1.72×10^{-8}	4.99
Acetone extraction method	1.81×10^{-8}	4.87

[a] Five determinations.

former contains the determination procedure for destroying the cells, etc. This method remarkably reduced the processing time (i.e. the previous standard extraction method with acetone [2,3] was approximately 200 min, while that with the FSA method was approximately 30 min) because it did not require a filtration procedure. Therefore, this method is superior to the conventional method with respect to the treatment of many samples.

4. Conclusions

It is well known that chl.a is an important indicator for environmental evaluations. Chl.a is the magnesium complex of porphyrin, and the pheophitin is produced from chl.a by dissociating magnesium ion at approximately pH 3. Also, the phytole group is hydrolyzed under more acidic conditions (i.e. below pH 3). However, the FSA method was able to operate at near neutral pH suited for the extraction of chl.a. In addition, complicated procedures such as filtration or crushing were not needed in the proposed method. In conclusion, it is expected that this method will be extensively applied to various environmental waters in rivers, lakes, seas, etc. as a rapid, simple and highly sensitive determination of chl.a.

Abstract

A flow-injection manifold is proposed for determination of nitrite based on the reaction with 3,6-diamino acridine (proflavin sulfate) in hydrochloride acid medium. The assembly is adapted for nitrate determination by including a reductive column filled with copperized cadmium. The influence of foreign substances is also studied. The method gives a linear calibration graph over the range $0.06-4 \text{ mg l}^{-1}$ nitrite, with an RSD $<0.5\%$. The method was applied to nitrite and nitrate determinations in either waste water or coastal marine water samples.

1. Introduction

Nitrite and nitrate concentrations are routine parameters to be determined in different types of sample water (waste, underground, marine, etc.). Flow-injection analysis is a suitable methodology when a great number of samples are to be considered. A number of analytical papers have been published dealing with nitrite determination by a flow-injection assembly, mainly with the aid of spectrophotometric [1, 2] detection; electrochemical [3], fluorimetric [4] and chemiluminiscence [5] detectors have also been proposed.

Nitrate determinations have been based on direct spectrophotometric methods or on measurement after derivatization, usually as reduction to nitrite; these methods utilize a homogeneous reduction process or a heterogeneous reduction with amalgamated zinc [6], zinc [7], amalgamated cadmium [9], copperized cadmium [10] or copperized cadmium silver [11]. UV irradiation in a homogeneous system has also been proposed [12].

This paper deals with a simple flow-injection analysis (FIA) assembly for the spectrophotometric determination of nitrites and nitrates by reaction with a non-cancerous reagent, which is easily water-soluble, resulting in solutions which are stable for a long time; the reagent is the sulfate of

* Corresponding author.

3,4-diamino acridine (or proflavin sulfate). The acridine is a linear dibenzopyridine, with a molecular structure similar to anthracene and with pharmaceutical applications as a topical antiseptic. A relevant feature of this family of compounds is the chemical stability; they can be boiled without decomposition and no reaction occurs with NaOH fusion; they can be partially converted into the acridinic acid by permanganate. The proflavin is a white, hygroscopic compound, soluble in water (300 parts in cold water), slightly soluble in alcohol and insoluble in chloroform and ether [13]. In a previous paper we reported the reaction of nitrite with proflavin and some related compounds [14]. In the present paper we study the analytical characteristics of the reaction to be applied to nitrate and nitrite determination in a FIA assembly.

2. Experimental

2.1. Reagents and apparatus

Aqueous solutions of 3,6-diamino acridine sulfate (Sigma), sodium nitrite (Panreac), sodium nitrate (Panreac), metallic cadmium (Merck) and copper sulfate (Panreac) were used. All reagents used were of analytical-reagent grade unless stated otherwise. The buffer solution for the conversion of nitrates into nitrites was prepared by dissolving 13 g of NH_4Cl (Panreac) and 1.7 g of Na_2EDTA (Panreac) in pure distilled water, then the pH was adjusted to 8.5 by adding NH_3 solution dropwise, and finally the resulting mixture was diluted to 1 l with distilled water.

2.2. FIA manifold

Fig. 1 shows the continuous-flow manifold used. The sample injector was from Rheodyne, model 5041 and a Gilson Minipuls 2 pump was used. The determination of nitrite was carried out by means of a Lambda 3B spectrophotometer from Perkin-Elmer at 328 nm; the cell was provided with a quartz flow-cell of 18 μl and 1 cm pathlength (from Hellma). The PTFE tubing was of 0.5 mm i.d. A copperized-cadmium column

was used for the "in-situ" reduction of nitrates to nitrides to provide the determination of nitrates in water samples; the column (10 cm length and 0.5 cm i.d.) was filled with particles with a mean size of 4 mm.

3. Analytical characteristics of the system 3,6-diamino acridine–nitrite

The aqueous solutions of proflavin at pH 1 gave absorption spectra with maximum absorbances at wavelengths 236, 282, 362 and 452 nm; changes in absorption spectra were observed when the pH was increased, two absorption bands appearing in the regions 260–265 and 400–450. The acidic proflavin solutions remained stable against time or temperature changes (they were mostly protected from daylight).

A violet colour was developed by mixing solutions of nitrite and 3,6-diamino acridine in acidic media, mainly at pH < 3. The formed compound (stoichiometry 1:1) remains unchanged for more than 2 h at temperatures <40°C. Fig. 2 depicts the corresponding absorption spectra of the reagent in hydrochloride acid medium and the nitrite–proflavin compound in the same medium. The highest absorbances were observed in strong acid media. The absorption spectra of this compound (kinetic stability) remained unchanged for long periods of time.

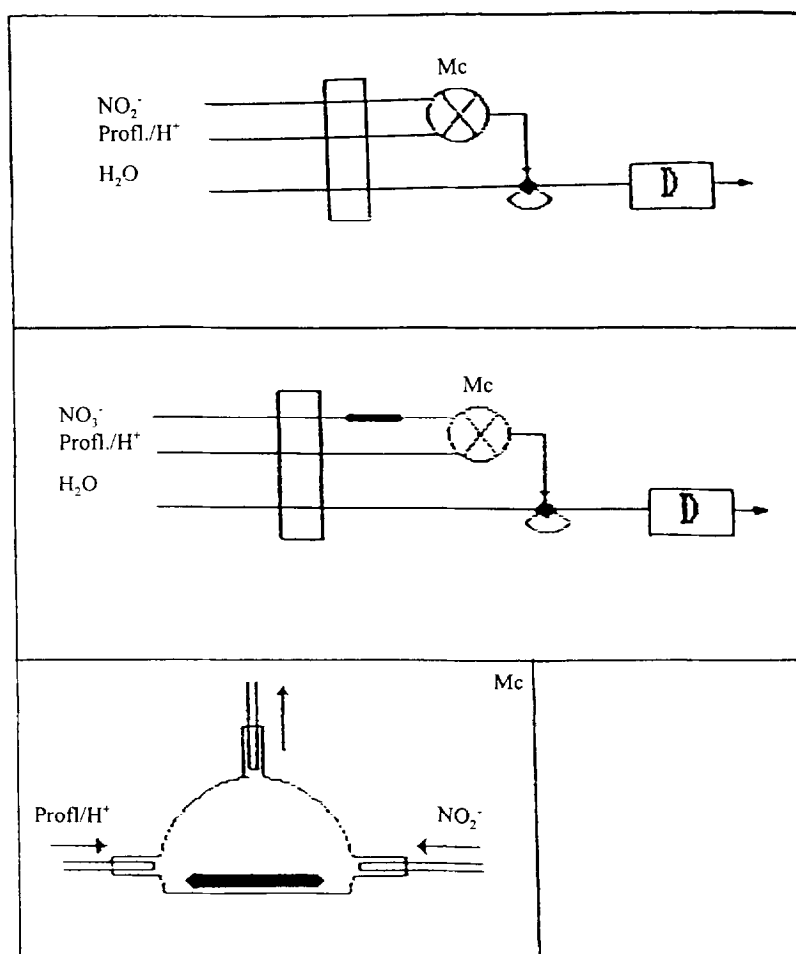
Different configurations of the FIA assembly were tested to select the most suitable. The selected manifold is depicted in Fig. 1. The selection procedure was carried out by performing series of experiments in which the reaction was studied under different chemical (pH) and manifold conditions. Different mixing chamber configurations were tested, the one giving the higher sample throughput (Fig. 1) was selected. The selected manifold allows a mixture of the nitrite (in pure distilled water) and the hydrochloride solution of proflavin to be formed by means of a mixing chamber. The resulting mixture is injected into a carrier stream of pure distilled water. The influence of the ratio flowrate of nitrite solution/ flowrate of the proflavin was studied and the


Fig. 1. Flow manifolds for determination of nitrite (upper panel) and nitrate (middle panel). The selected mixing chamber is also depicted (lower panel): height, 1 cm; diameter, 1.5 cm.

results are shown in Fig. 3; the ratio 1.45 was selected as the optimum that could be obtained.

Once the FIA assembly was selected, the chemical and FIA parameters influencing the degree of reaction and the sample dispersion were studied. The influence of acidity was important, according to the preliminary batch experiments where hydrochloric acid seemed to be the most suitable. Different concentrations of this acid were studied (2×10^{-4} mol 1^{-1} acridine, 2.0 mg 1^{-1} nitrite and distilled water as carrier) over the range 0.05–2.0 mol 1^{-1}. Best results (by considering both peak height and width of peak base) were observed with the solution containing 1 mol 1^{-1} HCl. The influence of other acids (acetic, perchloric and

phosphoric, all at 1 mol 1^{-1}) was also tested by means of the selected FIA manifold; the obtained transient signals, in absorbance units, were as follows: HCl, 0.502; $HClO_4$, 0.405; HAc, 0.018; H_3PO_4, 0.229. 1.0 mol 1^{-1} HCl was the medium selected for further work.

The influence of the proflavin content on the transient outputs was studied and the results are depicted in Fig. 4. The concentration 2×10^{-4} mol 1^{-1} (in 1 mol 1^{-1} hydrochloric acid) was selected for further work. A suitable carrier solution was selected from experiments with the following series: (a) 1 mol 1^{-1} HCl; (b) 2×10^{-4} mol 1^{-1} proflavin in 1.0 mol 1^{-1} HCl; (c) distilled water. Best outputs were observed with distilled water.
Fig. 2. Absorption spectra of the system nitrite–proflavin. (A) Reagent spectrum: 10^{-4} mol 1^{-1} proflavin solution in 0.1 mol 1^{-1} HCl. (B) Spectrum of the system nitrite–proflavin: nitrite (2.8 μg ml^{-1}) and proflavin (10^{-1} mol 1^{-1}) in 0.1 mol 1^{-1} HCl.

The influence of the temperature was tested up to 80°C, by introducing the sample loop into a water bath. The influence of temperature was

Fig. 3. Influence on the FIA output of the flow rate ratio nitrite solution/reagent stream.

shown to be irrelevant; peak height increased less than 2% (at 80°C) vs. the FIA peaks at room temperature. The formation of bubbles and lower reproducibility (as RSD, %) of the transient outputs lead us to select room temperature for further work.

The kinetic behavior of the system was studied by varing the contact time of the sample reagent in a stopped-flow mode and by changing the carrier flow rate and the distance from the injection valve to the flow cell. The reaction proved to be very quick (it was completed in the mixing chamber) and the carrier flow rate and the length of the injection valve flow cell only influenced the dispersion of the derivatized sample (increasing the base peak width), which lead us to select an injector to detector length as short as possible.

The influence of the sample volume was shown to be a relevant parameter. The increase of this parameter up to 457 μl resulted in increased peak heights; higher volumes resulted in higher absorbances (output height) with wider peak base (see Fig. 5). The set of influences studied, the
Fig. 4. Influence on the FIA output of the proflavin concentration: ($\triangle$) nitrite; ($\diamondsuit$) blank (H_2O); ($\star$) difference between nitrite and water outputs. 1 M HCl medium; carrier, water; carrier flow rate 1.79 ml min^{-1}; concentration of proflavin, 2×10^{-4} M.

tested range for each parameter and the values selected as the optimum that could be obtained are summarized in Table 1.

3.1. Application to the determination of nitrates

The proposed FIA manifold can be applied to determination of nitrate contents by adding a reductive column packed with cadmium-copperized particles and placed prior to the mixing chamber (Fig. 1). The chemical and FIA parameters influencing the conversion into nitrite (medium, flow rate, length and internal diameter of the column) were studied.

The conversion into nitrite was carried out in ammonia–ammonia chloride–Na_2EDTA medium

(pH 8.5) and different concentrations of the buffer were studied. The tested range was (millilitres of buffer solution/millilitres final volume) from 1/20 to 1/2. The influence of this parameter was shown to be irrelevant and the selected concentration was 1/4. The influence of the HCl content in the reagent solution was also tested over the range 0.1–2.0 mol l^{-1}, 1.0 being the most suitable.

The influence of the FIA parameters affecting the nitrate reduction (flow rate and reactor length) was studied by varying the reactor length (from 5 to 15 cm) at different flow rates (from stopped flow to 2.89 ml min^{-1}). The size (4 mm) of the solid particles packed into the reactor tubing was selected according to preliminary experiments. The obtained results showed a relevant
Fig. 5. Influence of the sample volume on the transient output. Conditions as in Fig. 4.

influence of the contact time between the sample and solid-phase reductor on the conversion degree and offered the possibility of working with different sensitivities (different linear calibration graphs and detection limits). The plot of absorbance vs. flow rate (in ml min^{-1}, 2 μg ml^{-1} nitrite) for a column 10 cm long, was as follows: 0.284, 2.89; 0.320, 2.16; 0.388, 1.43; 0.498, 0.70; 0.560, 0.21.

4. Analytical figures of merit

4.1. Determination of nitrites

The calibration graph was linear over the range 0.06–4 mg l^{-1} of nitrite with the equation $A = 0.277 + 0.184c$, with a correlation coefficient of 0.9995. The reproducibility and sample throughput were tested by injecting solutions containing

Table 1

Optimization of experimental parameters influencing the nitrite–proflavin FIA–spectrophotometric system

Parameter	Studied range	Selected value

Table 3
Analytical figures of merit from the determination of nitrate for two different sets of sample flow rates through the solid-phase reductive reactor

Flow rate 1.79 ml min^{-1}	Flow rate 0.19 ml min^{-1}
Equation ($r = 0.9995$)	Equation ($r = 0.9999$)
Abs. $= 0.003757$ (μg l^{-1}) $+ 0.1506$	Abs. $= 0.1165$ (μg l^{-1}) $+ 0.1481$
Range $0.1-25$ μg l^{-1}	Range $0.075-10$ μg l^{-1}
Detection limit 0.1 μg l^{-1}	Detection limit 0.075 μg l^{-1}
Sample throughput (h^{-1}) 68 (5 μg l^{-1})	Sample throughput (h^{-1}) 24 (5 μg l^{-1})
Reproducibility (RSD) 0.68	Reproducibility (RSD) 0.763

0.60 or 2.0 mg l^{-1} of nitrite and the calculated results were 0.5%–37 h^{-1} and 0.1%–26 h^{-1} respectively.

The influence of foreign compounds (inorganic ions) that are commonly found in water samples containing nitrites was investigated. To solutions containing 2.0 μg ml^{-1} of nitrite were added various concentrations of the possible interfering substances up to 1000 μg ml^{-1} or when the relative error (by comparison with pure nitrite solution, 2 μg ml^{-1}) was about 3%. The results in terms of concentration (μg l^{-1}) and relative error (5) are depicted in Table 2. Fe(III) was the most serious interferent; however, it is not interfering at concentrations lower than 1 mg l^{-1} which means that it is not an interferent for drinking water samples (Spanish legal regulations allow no more than 0.05 ppm of iron in tap water).

4.2. Determination of nitrates

Table 3 depicts the analytical figures of merit obtained with the two different flow rates through the column (column length, 10 cm; carrier flow rate, 1.79 ml min^{-1}), 2.89 and 0.21 ml min^{-1}, in order to test the analytical applications with high sample throughput and high sensitivity respectively.

The method was applied to the determination of nitrate or nitrite contents in water samples (industrial waste water and coastal marine samples) and the results compared with: (a) the standard colorimetric procedure of Griess (for the nitrite content); (b) the direct spectrophotometric procedure (for the nitrate content). Nitrite contents in a waste water sample: proposed FIA

method, 1.47 (sample 1) and 2.26 μg l^{-1} (sample 2); Griess, 1.50 and 2.30 μg l^{-1}; relative error, 2.0 and 1.7% respectively. Nitrate contents in a coastal water sample: proposed FIA method, 1.73 μg l^{-1}; UV measurement, 1.75 μg l^{-1}; relative error, 1.1%.

5. Conclusions

A simple and quick FIA spectrophotometric procedure is proposed for nitrite determination. The method is based on the reaction of nitrite ion with the non-cancerous reagent, 3,6-diamino acridine. The acridine aqueous solutions are stable for long time periods. The method shows competitive precision and selectivity and a wider linear range than many other FIA procedures. The method can also be applied to determination of the nitrate by adding a suitable reductive copperized-cadmium column to the proposed FIA manifold.

Ammonium tetraphenylborate–naphthalene adsorbent for the preconcentration and trace determination of iron in alloys and biological samples using 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol by third derivative spectrophotometry

Mohammad Ali Taher, Bal Krishan Puri*

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi 110 016, India

Abstract

A solid ion-pair material produced from ammonium tetraphenylborate on naphthalene (ATPB–naphthalene) provides a simple, rapid, economical and selective technique for preconcentrating iron from ≈ 500 ml of aqueous solution of standard alloys and biological samples. Iron reacts with 2-(5-bromo-2-pryidlazo)-5-diethylaminophenol (5-Br-PADAP) to form a water-soluble cationic complex. When the aqueous solution of this cationic species in the pH range 3.2–8.5 is passed over the adsorbent ATPB–naphthalene at a flow rate of 1 ml min^{-1}, it is quantitatively retained on naphthalene as an uncharged ion-associated complex. The solid mass from the column was dissolved out with 5 ml of dimethylformamide (DMF) and iron is determined by third derivative spectrophotometry by measuring the signal $d^3A/d\lambda^3$ between λ_2(773 nm) and λ_3(737 nm). The calibration curve is linear over the concentration range 0.10–25.0 μg of iron in 5 ml of DMF solution. Eight replicate determinations of 5 μg of iron gave a mean intensity (peak-to-peak signal between λ_2 and λ_3) of 1.534 with a relative standard deviation of 0.90%. The sensitivity of the method is 0.307 (d^3A/dnm^3)/μg found from the slope of the calibration curve. The interference of a large number of anions and cations has been studied and the optimized conditions developed were utilized for the trace determination of iron in various standard alloys and biological samples.

1. Introduction

Sodium tetraphenylborate (TPB) and its derivatives have been used in the estimation of alkali

*Corresponding author. Fax: (91)11-686-2037.

and univalent metal ions [1–3]. It has also been used as a counter-ion in the extraction and adsorption of some metal complexes into molten naphthalene [4–6] and microcrystalline naphthalene respectively [7–9]. A survey of the literature reveals that metal ions may be preconcentrated on various adsorbents such as thiol cotton [10], silanized glass beads [11], silica gel [12], Amberlite XAD-4 resin [13], cellulose [14], green tea leaves [15] and polythioether foams [16]. Some of these adsorbents may be fairly effective for preconcentration of metal ions, but their methods of preparation are lengthy and involve rigid control of conditions. The desorption of the metal is carried out by the slow process of elution (the metal complex is probably held by the interior surfaces of the adsorbent and thus the absorbed complex is not eluted easily), hence the procedure is time-consuming.

The reagent 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol(5-Br-PADAP) has been tried for the estimation of some metal ions by zero order spectrophotometry [17–20]. In the present work it has been tried for the trace determination of iron in various standard alloys and biological samples using third derivative spectrophotometry after preconcentration of the cationic complex on ammonium tetraphenylborate–naphthalene adsorbent from a large volume of the aqueous solution (≈ 500 ml preconcentration factor 100). The proposed reagent is fairly sensitive and more selective than most of the recently reported reagents in the literature for the estimation of iron [21–24]. The use of the preconcentration technique and third derivative spectrophotometry further enhance the sensitivity and selectivity of the method [25]. The interference of a number of metal ions and anions on the estimation of iron has been studied in detail and the developed method is found to be highly sensitive and selective and has been employed for the estimation of iron in complex materials. Iron may also be estimated by directly aspirating the DMF solution of the metal complex into the flame of the atomic absorption spectrometer after the preconcentration step, but the instrument is relatively expensive, day-to-day maintenance is high and it is not free from the matrix effect.

2. Experimental

2.1. Apparatus and reagents

A Shimadzu UV 160 spectrophotometer and Hitachi UV–vis model 330 spectrophotometer with 1.0 cm quartz cell were used. An Elico pH meter was employed for pH measurements. A funnel-tipped glass tube (60 mm × 6 mm) was used as a column for preconcentration. It was plugged with polypropylene fibres and then filled with the adsorbent to a height of 1.0–1.2 cm after pressing lightly with a flat glass rod. All glassware and the column were washed with a mixture of concentrated sulphuric and nitric acids (1 + 1) before use. All chemicals used were of analythical reagent grade. A 0.01% solution of 5-Br-PADAP was prepared in ethanol. Iron(III) chloride solution was prepared in distilled water in the presence of a few millilitres of hydrochloric acid and standardized by known methods. A more dilute solution of iron (5 ppm) can be prepared by diluting the standard solution. A buffer solution of pH ≈ 5 was prepared by mixing 50 ml of 0.5 M acetic acid and 100 ml of 0.5 M sodium acetate solutions.

2.2. Preparation of naphthalene–NH_4–TPB absorbent

A solution of naphthalene was prepared by dissolving 20 g of naphthalene in 40 ml of acetone on a hot-plate stirrer at 30–35°C. This solution was transferred into 1500 ml of distilled water containing 25 ml of 1 mol 1^{-1} ammonium acetate and 75 ml of 1 mol 1^{-1} ammonia solution (pH 9.5), in a fast stream continuous flow with continuous stirring at room temperature. Then, to this solution, 500 ml of an aqueous solution containing 1.7 g of TPB was added. The naphthalene coprecipitated with NH_4^+ and TBP^- was stirred for about 2 h and then allowed to stand for 2 h. The supernatant solution was decanted off and the remaining solid mass was washed twice with distilled water. The adsorbent in the form of a slurry was stored in a bottle for subsequent use.

2.3. General procedure

An aliquot of the solution containing 0.1–25 μg of iron was taken in a 25 ml beaker and 2.0 ml of 0.01% alcoholic solution of 5-Br-PADAP and 1.0 ml of acetate buffer of pH $\approx$ 5 were added to it and the final volume in the beaker was made up to approximately 15 ml with water if required. The column loaded with the adsorbent NH$_4$-TPB–naphthalene was conditioned to pH $\approx$ 5 by passing 2–5 ml of the acetate buffer solution at a flow rate of 1 ml min^{-1}. The iron sample solution prepared above was then passed at a flow rate of 1 ml min^{-1}. The packing in the column was washed with a few millilitres of distilled water and then aspirated strongly for 2–3 min, pushing down the solid mass in the column with a glass rod in order to eliminate the excess water attached to the adsorbent. The metal complex was dissolved out of the column along with napthalene with 5 ml of DMF. The third derivative absorption spectra in the range 650–850 mm were recorded against a blank solution prepared in the same way. The signal was measured between $\lambda_2 = 773$ nm and $\lambda_3 = 737$ nm. A calibration curve was prepared by taking various known amounts of iron under the conditions given above.

3. Results and discussion

3.1. Spectrophotometric measurements

The zero order and first, second and third order derivative spectra of the complex are shown in Figs. 1 and 2 respectively. As can be seen, the higher wavelength peaks of the third derivative spectra are more significant. The sensitivity of the third order derivative is much higher than for zero, first and second orders (zero order = A/μg = 0.10, first order = $(dA/dnm)/\mu$g = 0.08, second order = $(d^2A/dnm^2)/\mu$g = 0.19, and third order = $(d^3A/dnm^3)/\mu$g = 0.31). Third derivatization leads to sharper zero order bands and gives higher signals on the resulting spectra. The characteristics of derivative spectra, such as peak height and noise level, depend on the choice of parameters such as order of derivative, scan speed
Fig. 1. Zero order spectrum of the naphthalene–Fe(III)–(5-Br-PADAP)–TPB complex. Fe(III): 5 μg; buffer: 1.0 ml; pH: 5.0; 5-Br-PADAP: 2.0 ml(0.01%); flow rate: 1 ml min^{-1}; solvent: 5 ml DMF; reference: reagent blank.

and integration time during recording of the spectra. The optimum parameters were chosen from preliminary experiments. The best results were obtained from third derivative spectra due to high
Fig. 2. First, second and third derivative spectra of the naphthalene–Fe(III)–(5-Br-PADAP)–TPB complex. For conditions, see Fig. 1.

signals at $\lambda_1 = 806$ nm, $\lambda_2 = 773$ nm, $\lambda_3 = 737$ nm, with a length interval of 9 nm. Iron could be determined by measuring the signal between the baseline and the corresponding peaks. It could also be determined from the signal between λ_1 and λ_2 or λ_3 and λ_2. In the present work a peak-to-peak method between λ_3 and λ_2 was applied.

3.2. Retention characteristics of NH_4-TPB

The TPB^- forms a weakly bonded ion-pair with NH_4^+ in aqueous solution and coprecipitates with microcrystalline naphthalene as follows:
$$NH_4^+ + TPB^- \rightleftarrows (NH_4^+) + (TPB^-)(s)$$

From the experimental observation, the NH_4-TPB ion-pair produced from TPB^- and ammonium acetate in aqueous solution when supported on naphthalene was unstable and partly desorbed from the surface of the naphthalane in the column on passage of the buffer of pH 5. However, the NH_4-TPB ion-pair prepared in acetate buffer of pH 9.5 is highly stable and TPB^- is not desorbed even on washing with water or the buffer of pH ≈ 5. The adsorbent shows excellent absorption characteristics for various cationic metal complexes such as $Fe(1,1\text{-phen})_3^{2+}$. In this work, TPB^- has been selected as the counter-ion because of its purity and moderate price.

3.3. Reaction conditions

These were established with the use of 5 μg iron. The adsorption of iron on this adsorbent was found to be a maximum in the pH range 3.2–8.5 (Fig. 3). In subsequent studies, the pH was maintained at approximately 5.0. Addition of 0.5–15 ml of the buffer did not aflect the retention of iron and the use of 1.0 ml is recommended. Various amounts of 0.01% alcoholic solution of 5-Br-PADAP were tried. Iron was quantitatively absorbed on the absorbent over the range 1.0–4.0 ml of the reagent. Therefore, 2.0 ml of the reagent is recommended in the present study. The flow rate was varied from 0.5 to 8 ml min^{-1}. It was found that the flow rate did not affect adsorption within this range. A flow rate of 1 ml min^{-1} was recommended for all experiments. In the case of a
Fig. 3. Effect of pH. For conditions, see Fig. 2.

large volume of the aqueous phase, a flow rate of 5–8 ml min^{-1} may be used. The adsorption was constant and maximal when the volume of the aqueous phase did not exceed 500 ml, resulting in a preconcentration factor of ≈ 100. The retention started to decrease slowly as the volume of the aqueous phase was increased beyond 500 ml. The solid mass can be completely dissolved out of the column with less than 3 ml of the solvent (DMF); thus a preconcentration factor of ≈ 170 may be achieved. In subsequent study, 20 ml of the aqueous phase was used for convenience.

3.4. Choice of solvent

A number of solvents were tried to dissolve the metal complex along with naphthalene from the column. Since the solid mass is dissolved in a small volume (3–5 ml) of solvent from the column, it is essential to select a solvent in which the chelate is highly soluble and also sensitive for UV–vis spectrophotometric measurements. The solid material is insoluble in ordinary organic solvents such as toluene, 1,2-dichloroetane, n-hexane, nitrobenzene, isoamyl alcohol, n-amyl alcohol, ethyl acetate, methyl isobutyl ketone, chloroform and dioxane, but soluble in dimethyl sulfoxide, DMF, and propylene carbonate. DMF

was preferred because of its high solubility and stability. It was found that 2–3 ml of this solvent was sufficient to dissolve the entire mixture, thus further enhancing the sensitivity of the method. Since only a small volume (3–5 ml) of the solvent is required to dissolve the solid mass from the column, it was essential to study the effect of the surplus water attached to the absorbent. It was found that the surplus water caused the absorbance to decrease by 10–12% and led to an error in the determination. Thus it was necessary to eliminate the water attached to naphthalene in the column completely by aspirating it for 2–3 min.

3.5. Calibration, sensitivity, precision, stability and column capacity

On the basis of the optimum conditions developed above a calibration graph was constructed according to the standard procedure. It was linear over the concentration range 0.1–25 μg of iron in 5 ml of DMF solution (Fig. 4). Eight replicate determinations of 5.0 μg of iron gave a mean intensity in the third derivative spectrum, measured from the peak-to-peak signal between λ_2 and λ_3, of 1.534 with a relative standard deviation of 0.9%. The sensitivity was 0.307 $(d^3A/dnm^3)\mu$g from the slope of the calibration curve, the detection limit was 0.01 μg ml^{-1} (signal-to-noise ra-

tio $= 2$), the solution was stable for over 6 days and the capacity of the column was 1.1 mg Fe g^{-1} of adsorbent.

3.6. Interference of foreign ions

Various salts and metals ions were added individually to a solution containing 5 μg of iron and the general procedure was applied. The tolerance limit (error < 3%) is given in Table 1. Among the salts examined, most did not interfere at the gram per milligram level with the exception of EDTA. Among the metal ions studied, many did not interfere even at the milligram level. Thus the method is highly selective without the use of masking agents. The proposed procedure has therefore been applied to the determination of iron in alloys and biological samples without any prior separations.

3.7. Determination of iron in standard aluminium and zinc alloys

The proposed method has been applied to determination of iron in Nippon Keikinzoku Kogyo (NKK) CRM 916 NKK 3A30 aluminium alloys,

and National Institute of Standards Technology Standard Reference Materials NIST, SRM 929 Zinc Alloy. A 0.1 g sample of the standard alloy was completely dissolved in 4–5 ml of hydrochloric acid (1 + 1) by heating on a waterbath and then 1 ml of 30% hydrogen peroxide was added to the solution. The excess of peroxide was decomposed by heating the solution on a waterbath. The solution was cooled and filtered if needed and the filtrate was diluted to 100 ml with doubly-distilled water in a calibrated flask. An aliquot (1–2 ml) of this solution was taken and iron was determined by the general procedure (Table 2).

3.8. Determination of iron in chlorella, mussel and pond sediment

The proposed method has been applied to the determination of iron in National Institute for Environmental Studies (NIES) No. 3 Chlorella, NIES No. 6 Mussels and NIES No. 2 Pond Sediment. Chlorella or pond sediment (0.1 g) or mussel (0.5 g) were taken individually in a beaker and dissolved in concentrated nitric acid (≈ 5 ml) with heating. The solution was cooled, diluted and filtered. The filtrate was made up to 100 ml with water in a calibrated flask. An aliquot (1–2 ml) of the sample solution was taken individually and iron was determined by the general procedure. The results are given in Table 2 and are in good agreement with the certified values.

4. Conclusion

A solid ion-pair compound produced from NH_4^+ and TPB^- on naphthalene provides a simple and economical method for the preconcentration of iron from large volumes of alloys and biological samples using 5-Br-PADAP as the complexing agent. This reagent is fairly sensitive and selective for iron but with the preconcentration step and the use of derivative spectrophotometry its sensitivity and selectivity have been further improved and thus the developed method can be used safely for the estimation of iron in a number of complex materials such as environmental samples. Since the adsorbent provides TPB^- as the counter anion, the absorbent may therefore be used for the preconcentration of various types of cationic metal complexes. Although the metal may be estimated by AAS after the preconcentration step, AAS is however a relatively expensive instrument and day-to-day expenses and maintenance are high. Another, cheaper, technique is differential pulse polarography which could be tried for the estimation of iron after the precon-

centration step. As a whole the proposed method is highly sensitive, selective, simple and highly economical (it requires simple glassware, and a small volume of the organic solvent to dissolve the solid mass from the column) for the estimation of iron.

Catalytic-adsorptive stripping voltammetry of cobalt in the presence of 2,2'-bipyridine and nitrite

Zhiqiang Gao*, Kok Siong Siow

Department of Chemistry, National University of Singapore, Kent Ridge, Singapore 0511, Singapore

Received 7 June 1995; revised 20 September 1995; accepted 25 September 1995

Abstract

A highly sensitive and selective procedure is presented for the voltammetric determination of cobalt. The procedure involves an adsorptive accumulation of cobalt-2,2'-bipyridine complex on a hanging mercury drop electrode, followed by a stripping voltammetric measurement of the catalytic reduction current of nitrite at -1.25 V (vs. Ag/AgCl). The optimum conditions for the analysis of cobalt include 0.1 M ammonium buffer (pH 8.55–9.25), 2.0–5.0 μM 2,2'-bipyridine, 0.20 M sodium nitrite and an accumulation potential between -0.75 and -0.90 V (vs. Ag/AgCl). An accumulation time of 30 s results in a very low detection limit of 9.5 pM (0.56 p.p.t.) and a linear current–concentration relationship up to 2.0 nM. The relative standard deviation at 0.10 nM is 4.9%. Possible interferences from co-existing ions are also investigated.

Keywords: Cobalt; 2,2'-Bipyridine; Adsorptive voltammetry; Nitrite

1. Introduction

Interest in cobalt found in biological systems is due to the importance of this metal as an essential trace element; it is a component of vitamin B_{12} and participates in a number of enzymatic reactions [1–3]. Since the concentration of cobalt is extremely low in various natural samples (usually at sub-p.p.b. levels), a sufficiently sensitive and selective analytical procedure for the reliable de-

termination of cobalt in natural samples would be of great interest. Consequently, a large number of papers have been published on the determination of cobalt. The most commonly used methods for the determination of cobalt include spectrophotometry [4], atomic absorption spectrometry (AAS) [5], high performance liquid chromatography [6], neutron activation analysis [7], mass spectrometry [8] and fluorescence spectrometry [9]. Among these methods, only the highly costly neutron activation analysis and mass spectrometry have sufficient sensitivty for direct measurements of trace amounts of cobalt. AAS,

* Corresponding author. Fax: (65) 779-1691;
e-mail: CHMGAOZ@leonis.nus.sg.

which is frequently used for the determination of trace amounts of metals, is not highly reliable for analyzing cobalt at sub-p.p.b. levels, because such levels are comparable to the detection limit of the technique.

Electroanalytical methods for the determination of traces of cobalt, mainly involving the formation and adsorptive collection of cobalt complexes with various dioximes, such as dimethylglyoxime [10,11], nioxime [12,13], α-benzil dioxime [14], and α-furil dioxime [10], on a hanging mercury drop electrode (HMDE), have also been proposed. Further improvement in sensitivity has been reported by the application of the catalytic effect of cobalt–dioximes complexes on the reduction of nitrite [10–12,14]. Among those procedures, the most sensitive one for the determination of cobalt is based on the formation of cobalt-α-benzil dioxime complex coupling with the catalytic reduction of nitrite in ammonium medium. The detection limit of 41 pM was obtained following a short accumulation period (30 s). Furthermore the cobalt-α-benzil dioxime approach has been used to determine cobalt in zinc plant electrolyte [15] and in metallic zinc [16]. Some other complexing agents, including 1,10,-phenanthroline [17], 1-nitroso-1-naphthol [18], 4-[2-(5-bromopyridyl)azo]-1,3-dihydroxynaphthalene [19] and 2-quinolinethiol [20] have also been studied in attempts to develop highly sensitive methods for cobalt analysis. However, all those procedures are not so sensitive as the cobalt-α-benzil dioxime system.

The polarographic behaviour of cobalt-2,2'-bipyridine (Co(II)–BPY) complexes has previously been reported by Fungaro and Tokoro [21]. In acidified aqueous medium, the reduction product of Co(II)–BPY, Co(I)–BPY, catalyzes the reduction of hydrogen ions. Preliminary studies in our laboratory have shown that no obvious catalytic effect on the reduction of hydrogen ions is observed in alkaline solutions. Instead, remarkable improvement in sensitivity is observed using the catalytic effect of the Co(II)–BPY complex by adding sodium nitrite to the solution. In this paper the catalytic-adsorptive stripping voltammetry of the Co(II)–BPY complex at the HMDE was investigated. Compared to the adsorptive

stripping procedure, this method provides much better sensitivity and selectivity.

2. Experimental

2.1. Apparatus and reagents

A PAR Model 174A polarographic analyzer was employed in connection with a Model 303 SMDE (EG&G, PAR, USA) and a Graphtec X–Y recorder. A medium-sized HMDE electrode, with a surface area of 1.8 mm^2 was used. An Ag/AgCl (in saturated KCl) reference electrode was used in all experiments. All potentials reported in this paper are referred to the Ag/AgCl electrode. Solutions were deoxygenated with high-purity nitrogen for 4 min prior to each experiment and all experiments were performed under nitrogen atmosphere.

Water purified in a Milli-Q water purification system (Millipore) was used for all solutions and sample preparations. All chemicals were of certified analytical grade and above. Working solutions of cobalt (Co(II)) were prepared from a 1000 p.p.m. stock solution of Co(II) (atomic absorption standard, Aldrich). Stock solutions of 0.010 M BPY and 1.0 M nitrite were prepared by directly dissolving required amounts of BPY and sodium nitrite in water, respectively. Traces of cobalt in blank electrolyte were removed using Chelex-100 resin. Cobalt found in the purified electrolyte is generally less than 0.030 nM. Reagent containers and sample bottles were cleaned by soaking in 1:1 nitric acid for a few days. Then they were thoroughly rinsed with water and stored in 0.01 M nitric acid.

2.2. Procedure

The supporting electrolyte solution (10 ml 0.1 M ammonium buffer pH 9.2) containing 5.0 μM BPY and 0.20 M sodium nitrite was pipetted into the cell and purged with nitrogen for 4 min. The accumulation potential (-0.80 V) was applied to a fresh mercury drop while the solution was stirred (400 rev min^{-1}). Following the accumulation, a linear scan voltammogram was recorded

from -0.80 to -1.5 V, with a scan rate of 100 mV s^{-1}. After obtaining the background voltammogram, aliquots of the cobalt standard solutions were introduced into the cell while maintaining a nitrogen atmosphere over the solution. All data were obtained at room temperature in a clean environment.

3. Results and discussion

3.1. Voltammetric properties of Co(II)–BPY in nitrite medium

Fig. 1 shows cyclic voltammograms for BPY, NO_2^-, BPY–NO_2^-, and BPY–NO_2^-–Co(II) in 0.1 M pH 9.2 ammonium buffer solution. As can be seen in Fig. 1A, for the solution containing BPY alone, a couple of waves were observed at -1.4 V, which is due to the redox reaction of BPY at the HMDE. As shown in Fig. 1B, in the ammonium buffer containing nitrite alone, no obvious current peaks were observable between -0.50 and -1.5 V. Beyond -1.5 V a sharp increase in reduction current was observed, which is attributed to the reduction of nitrite. For the solution containing nitrite and BPY, two small cathodic peaks were observed (Fig. 1C). The one at less negative potential is due exclusively to

Fig. 1. Cyclic voltammograms for (A) 5.0 μM BPY, (B) 0.20 M nitrite, (C) A + B and (D) C + 2.0 nM cobalt in 0.1 M pH 9.2 ammonium buffer. Accumulation potential, -0.50 V, accumulation time, 0 s (dotted line) and 30 s (solid lines); potential scan rate, 100 mV s^{-1}.

traces of cobalt in the purified electrolyte. Voltammetric properties of Co(II)–BPY complex in slightly alkaline medium were investigated by several groups [22–24]. The Co(II)–BPY complex shows strongly adsorptive character at the mercury electrode. The reduction of the adsorbed Co(II)–BPY complex takes place around -1.53 V (vs. SCE) and the stripping peak current was used to determine trace amounts of cobalt with a detection limit of 5 nM after a few minutes of adsorptive accumulation [22,23]. On the other hand, as indicated in Fig. 1D, with the addition of a small amount of Co(II), a new cathodic peak located at -1.25 V was obtained when scanning the electrode potential in the negative direction, and the reverse scan gave another cathodic peak at -1.1 V, suggesting a catalytic process. In the absence of nitrite, no catalytic current was observed for the electrode process. As we know, nitrite may disproportionate to nitrate and nitrogen monoxide in aqueous medium [25]. When nitrate was substituted for nitrite, no obvious current peaks were observable between -0.50 and -1.5 V except the redox responses of BPY, indicating that nitrate is not involved in the catalytic reaction. The fact that a well-defined and intensive signal was obtained in cyclic voltammetry for 2.0 nM cobalt indicates the remarkable sensitivity associated with the catalytic process. The short accumulation period (stirred) resulted in a significant enhancement of the sensitivity, as compared with that of the non-accumulated response (broken line in Fig. 1D). The peak current decreased rapidly upon repetitive potential cycling and after a few cycles the peak currents approached that of the non-accumulated response, suggesting desorption of the complex from the HMDE surface.

The strongly adsorptive character of the Co(II)–BPY complex can thus be used as an effective means of an analyte accumulation step, prior to voltammetric measurement, making possible a highly sensitive voltammetric procedure for cobalt analysis. Fig. 2A displays linear scan voltammograms for 0.30 nM cobalt after different accumulation periods, ranging from 5 to 40 s. The longer the accumulation time, the more the Co(II)–BPY complex was accumulated and the
Fig. 2. (A) Catalytic-adsorptive stripping voltammograms for 0.30 nM cobalt following different accumulation periods: from bottom to top, 5–40 s in 5 s steps. (B) Stripping peak current versus accumulation time plots for (a) 0.050 nM, (b) 0.30 nM and (c) 1.0 nM cobalt. Accumulation at − 0.80 V; other conditions as in Fig. 1D.

higher was the current sensitivity, which again suggests the involvement of adsorption in the electrode process. As a consequence, the voltammetric measurement of cobalt at sub-nanomolar levels is feasible after a very short accumulation period. Fig. 2B shows plots of the stripping peak current against the accumulation time at different cobalt concentrations, namely, 0.050, 0.30 and 1.0 nM. In all cases, the stripping peak current increased linearly with increasing accumulation time from 0 to 60 s. For an accumulation time between 80 and 120 s, further gain in sensitivity is very small at 1.0 nM. In addition, non-linear behavior between the concentration and the stripping peak current was also observed after prolonged accumulation, which reflects the adsorption equilibrium at different concentrations.

3.2. Effects of various experimental parameters

Various experimental parameters affecting the stripping peak current of the Co(II)–BPY complex in linear scan voltammetry were explored and the results are presented in Fig. 3. Variation of pH produced a maximum in the stripping peak

current between 8.55 and 9.25. Substantial decreases in the stripping peak current were observed at both lower and higher pH values (Fig. 3A). Since BPY is an essential component for the formation of the adsorptive complex, it is expected that the stripping peak current is strongly dependent upon the BPY concentration. As shown in Fig. 3B, the stripping peak current increased sharply upon increasing the BPY concentration from 0.0 to 1.5 μM and then started to level off between 2.0 and 6.0 μM. Slight decrease in the stripping peak current was obtained for higher BPY concentrations, presumably due to the competitive adsorption of BPY. The nitrite concentration also had a strong effect on the stripping peak current. For example, the response for 1.0 nM cobalt increased linearly with increasing nitrite concentration (Fig. 3C). Due to the reduction of nitrite at potentials more negative than − 1.5 V, a rather broad reduction peak was observable at much higher nitrite concentration which was found to interfere with the determination of cobalt at low concentration levels. In addition, due to the cobalt impurity in purified electrolyte, especially in nitrite, increasing the ni-
Fig. 3. Dependence of the catalytic-adsorptive stripping current on (A) pH, (B) BPY concentration, (C) nitrite concentration and (D) accumulation potential. Accumulation time, 30 s; other conditions, as in Fig. 2B(b).

trite concentration resulted in a larger background current. Therefore 0.20 M nitrite was selected as the optimal concentration for a fairly good sensitivity.

The influence of adsorption potential on the stripping peak current was examined over the range -0.1 V to -1.1 V. As illustrated in Fig. 3D, the stripping peak current increased gradually when the adsorption potential became increasingly negative. The highest stripping peak current was attained at -0.75 V and remained practically unchanged for accumulation potentials between -0.75 and -0.90 V. This pattern somehow reflects the charging state of the electrical double at the electrode–solution interface. For mercury electrodes, the potential of zero charge (PZC) is roughly around -0.4 V. On the positive side of the PZC, the electrode is positively charged. As we know, the Co(II)–BPY complex is cationic $(CO(BPY)_3^{2+})$; therefore the repulsive interaction between the Co(II)–BPY complex and the electrode surface prevents the Co(II)–BPY complex from accumulating onto the electrode surface at less negative accumulation potentials. As the accumulation potential becomes more negative, less net possitive charges are found at the electrode

surface and eventually the electrode is negatively charged once the accumulation potential is on the negative side of the PZC. Consequently, dramatic increase in the stripping peak current is observed. Due to the partial reduction of the accumulated complex, substantial decrease in the stripping peak current is expected when accumulation potentials are more negative than -1.0 V, indicating that only the Co(II)–BPY complex is accumulated at the HMDE surface, whereas the reduction product has no catalytic-adsorptive property.

Subsequent experiments were, therefore, performed using 0.1 M pH 9.2 ammonium buffer containing 5.0 μM BPY and 0.20 M sodium nitrite, and the accumulation time of 30 s at -0.80 V, taking into account the speed of the measurement and the performance.

3.3. Linearity, detection limit and reproducibility

Under these conditions, by taking advantage of the catalytic-adsorptive nature of the system, the sensitivity of the linear scan voltammetric method was improved significantly. The stripping peak current of the Co(II)–BPY complex was found to

be proportional directly to the cobalt concentration in the range of 0.050 to 2.0 nM (correlation coefficient 0.998) with a current sensitivity of 0.81 μA nM^{-1}, which is over ten thousand times higher than that of the simple diffusion-controlled current of cobalt ions. The detection limit, estimated from three times the standard deviation of repetitive measurements of 0.050 nM cobalt under optimal conditions, was found to be 9.5 pM (0.56 p.p.t.) using the adsorption time of 30 s, which is comparable with or better than various Co(II)–dioxime systems [10–14]. Further lowering of the detection limit through extending the accumulation time was limited by the cobalt impurity ($\leqslant 0.030$ nM) in the purified electrolyte. The reproducibility of the procedure was established by a prolonged series of 25 repetitive determinations of 0.10 nM cobalt with the 30 s accumulation period. Parts of these determinations are shown in Fig. 4. The mean stripping peak current was 107 nA, with a variation range from 102 to 114 nA and a relative standard deviation of 4.9%.

3.4. Interferences

In the voltammetric determination of cobalt in the catalytic-adsorptive systems, other trace ele-
Fig. 4. Catalytic-adsorptive stripping voltammograms for 0.10 nM cobalt. Conditions as in Fig. 3.

ments can interfere if they from a complex with BPY, adsorb on the HMDE, or produce a reduction current at potentials near that of the Co(II)–BPY complex. Because of the extremely high current sensitivity, it is expected that the influence of a large excess of another reducible species on the determination of cobalt with be minute, even with a similar peak potential to that of the Co(II)–BPY complex. The effect of co-existing ionic species and surface-active substances on the determination of cobalt was investigated. More than fifty ions were examined for their possible interferences in the determination of 1.0 nM cobalt. It was found that large amounts of alkali, alkaline earth metal and common anions have no effect on the determination of cobalt. Amounts of less than 5000-fold Al^{3+}, Sn^{2+}, Mn^{2+}, SbO^+, Ce^{3+}, Pb^{2+}, ZrO^{2+}, MoO_4^{2-}, VO^{2+}, WO_4^{2-}, Cd^{2-} and Hg^{2+}; 2000-fold In^{3+}, Bi^{3+}, Tl^+, Ti^{3+}, Ga^{3+}, Pd^{2+}, Cu^{2+} and Ag^+; and 1000-fold Fe^{2+} and Fe^{3+} had little effect on the determination of cobalt. Moreover, excellent selectivity was observed against zinc. It was found that the determination of cobalt is free from the interference of zinc up to 50 μM. The fact that zinc was not interfering is of particular significance considering its major interference in most of the Co(II)–dimethylglyoxime systems [26–32]. But it is inferior to the Co(II)–α-benzil dioxime procedure in terms of selectivity against zinc [14].

In ammonium buffer solution containing BPY and nitrite, however, nickel and chromium each produced a catalytic-adsorptive stripping current peak at -1.13 and -1.40 V, respectively. They were found to interfere with the measurement of cobalt at concentrations higher than 100 nM and 60 nM of nickel and chromium, respectively. Furthermore, owing to the adsorptive properties of the Co(II)–BPY complex, surface-active substances, such as natural organic surfactants, Triton X-100, sodium dodecyl sulfate and cetyl trimethyl ammonium bromide may interfere as a result of competitive adsorption at the electrode surface. For example, additions of 5.0 p.p.m. cetyl trimethyl ammonium bromide, Triton X-100 and sodium dodectyl sulfate resulted in 11–18% depressions of the stripping peak current. High concentration of complexing agents, such as EDTA

was also found to suppress the response. For example, only slight suppression (< 5%) was observed in the presence of 0.50 μM EDTA. However the signal was almost completely eliminated by the addition of 0.10 mM EDTA. Depending on the complexity of the sample, for direct determinations of cobalt, complexing agents and natural surface-active substances must be removed before the determination. Therefore necessary sample pretreatments, such as wet digestion and UV-irradiation, are strongly recommended.

4. Conclusions

In summary, the results obtained indicate that the procedure developed here offers a simple, fast, selective and sensitive method for the determination of trace amounts of cobalt by means of the coupling of catalytic and adsorptive effects in the system Co(II)–BPY–nitrite. Catalytic-adsorptive voltammetry of the Co(II)–BPY complex may serve as an inexpensive and convenient alternative for highly costly mass spectrometry and neutron activation analysis. The proposed method gives extreme sensitivity and a much lower detection limit compared to AAS. Good selectivity against nickel and zinc adds to the versatility of the procedure.

Extraction of azo dyes by polyurethane foam

R. Werbowesky, A. Chow*

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, R3T 2N3, Canada

Abstract

The extraction of 12 closely related mono-azo dyes by polyester- and polyether-type polyurethane foams was studied to gain more information regarding the mechanism of the extraction of organic compounds. The effects on extraction of solution pH, dye concentration and salt concentration were investigated. It was found that the extraction of the dyes involved a neutral zwitterionic species and is highly dependent on the parameters studied. The dependency of the extraction on these parameters can be explained in a manner consistent with solvent extraction; however, the dual-mode sorption mechanism seems a more likely model. This mechanism involves both absorption related to solvent extraction, and an added component for surface adsorption. While the dual-mode sorption model explains the observed extraction behaviour, the data suggest that surface adsorption plays a much larger role than previously considered.

Keywords: Azo dyes; Polyurethane foam; Extraction

1. Introduction

With a heightened sense of environmental responsibility comes a need for more economical methods of testing for, and removal of, organic pollutants. It is this area which has been a focus of research in organic applications of polyurethane foams. Because of its desirable characteristics, polyurethane foam has been evaluated for its use to remove preconcentrate, and separate a variety of organic substances including phenols [1,2], phthalates [3], PCBs [4], carboxylic acids [5], and insecticides [2,6–12]. The quasi-spherical and open cell structures offer much higher flow rates

___

and higher concentrating ability compared to other solid sorbents [1].

Polyurethane foams have been used for more than 20 years to extract and separate both organic and inorganic substances from liquid and gaseous media. The development of this field, since its beginning with Bowen's paper [13] in 1970, has been very well summarized by a number of reviewers [14–20]. However, aside from the work with insecticides, there has not been widespread acceptance and use of polyurethane foams for the extraction of organics from aqueous solutions, despite the number of advances made and the number of years for which this technology has been known. It is thought that the slow development of the area is at least partially due to the

lack of understanding regarding the mechanism of extraction.

Over the years a number of possible mechanisms have been proposed, namely surface adsorption, solvent extraction, ligand exchange, anion exchange and cation chelation. The cation chelation mechanism was first proposed by Hamon et al. [21] in 1981, for the extraction of metal ions. In this mechanism, cations are effectively solvated by the oxygen atoms of the poly(ethylene oxide) portion of the foam. These sections of polymer adopt a helical structure with inwardly-directed oxygen atoms and appear to have a cation selectivity similar to the crown ether, 18-crown-6. The polymer in polyester foam does not easily assume a helical structure which is thought to explain the lower observed extractions. For the extraction of organics, solvent extraction, also referred to as phase distribution, is the most commonly proposed mechanism. In this mechanism the foam acts simply as a solid phase organic layer, into which the analyte is diffused.

Much of the work done on the mechanism of extraction with organics has come in just a few papers. Schumack and Chow [22] were among the first to investigate this area. In their study they investigated the extraction of a variety of aromatic organic compounds and how the extractions were affected by extraction time, salt addition, solution pH, ethanol concentration and solution temperature. They concluded that the extraction of organic compounds occurs by an ether-like solvent extraction mechanism, and there was no evidence of a mechanism requiring an ionic species, as would be the case for ion exchange or cation chelation. In addition they found that hydrogen bonding was a significant factor in the extractions, and that compounds containing phenolic or carboxylic groups were better extracted with polyether-type polyurethane. The preference for polyether-type foam was attributed to its ability to form stronger hydrogen bonds than those formed with polyester-type foam.

Chow et al. [23] looked at the extraction of 59 organic dyes into polyurethane foams. Using a smaller subset of those dyes, they looked at the effects of salt addition, extraction from 50% methanol solutions, extractions using diethyl ether

and ethyl acetate, and ordered the dyes in terms of polarity using thin layer chromatography. While broad in scope, this study was fairly inconclusive and reported that the extraction of the organic dyes tested showed support for both solvent extraction and cation chelation mechanisms. It is currently thought that much of the confusion with their results is related to the researchers' use of the distribution ratio, D, for comparisons among the dyes. Such comparisons are only valid if the distribution ratio is a good approximation of the distribution coefficient, K_d. For organic acids and bases, this only occurs when the predominant species is in the neutral form [24,25]. Because the researchers did not optimize the extractions with regard to solution pH, the distribution ratio did not approximate the distribution coefficient. Results from the current study suggest that even when the predominant species is in its neutral form, additional factors must be considered before the distribution ratio is suitable for making direct comparisons.

Fong and Chow [26-28] published three papers studying the extraction of organic compounds into polyurethane foams. They first looked at the extraction of salicylic acid, 8-hydroxyquinoline, 1-amino-2-naphthol-4-sulphonic acid, and cinnamic acid. Based on salting-out effects and pH studies they concluded that the compounds were extracted as neutral molecules via a solvent extraction mechanism. Their work also confirmed the importance of hydrogen bonding as reported previously [22]. The second paper involved the extraction of alkali metal tetraphenylborates. Based on the extraction sequence of the alkali metals, they concluded that these extractions could be explained using the cation chelation mechanism. However in their following paper [28], which looked at the extraction of alkylammonium tetraphenylborates and dipicrylaminates, they could find no conclusive evidence to support the cation chelation mechanism. They concluded that the selectivity for the alkylammonium ions is affected by a combination of effects which are steric, inductive, and hydrophobic in nature.

While there seems to be a general consensus that the mechanism of extraction is a solvent extraction of a neutral species, cation chelation

remains a possibility. There are still many unanswered questions, especially regarding the role of functional groups attached to the analyte. Despite the shortcomings of the earlier dye study [23] it is thought that the wide variety of organic dyes available could be valuable probes into the sorption mechanism of organic species.

2. Experimental

2.1. Apparatus

Spectra and absorbance readings were taken using a Hewlett-Packard Model 8452A diode-array spectrophotometer. Solution pH was measured with an Orion Expandable Ion Analyser EA 940. A Burrell Wrist-Action shaker was used for sample agitation.

2.2. Reagents

All chemicals used were of reagent grade and water was obtained from a Barnsted Nanopure II™ purifiction sustem fed with water purified by reverse osmosis. The majority of the dyes used were obtained from the companies Sigma and Aldrich and were used without further purification. Polyether foam used was obtained by Union Carbide Corporation and the polyester foam was purchased as diSPo™ plugs from Baxter, Canlab, Canada.

2.3. Procedure

Both types of foam were cleaned before use. In order to remove inorganic contaminants, the foam was soaked and periodically squeezed in a 1 M hydrochloric acid bath for 6 h. The foam was then repeatedly soaked, squeezed and rinsed in water until the pH of the rinse water was unchanged after an hour of soaking. After removal of excess water, the foam was Soxhlet-extracted with acetone for 6 h to remove any soluble organic contaminants. The majority of the acetone was then squeezed out of the foam, which was then dried in a vacuum desiccator overnight. Finally the foam was ground into a coarse powder

by freezing the foam pieces in liquid nitrogen and grinding them in a metal container with a Waring blender. The ground foam was then stored in brown glass jars.

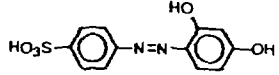
Stock dye solutions were prepared on the day of an experiment by accurately weighing a chosen amount of dye, dissolving it in water and quantitatively transferring it with water to a 500 mL or 1 L volumetric flask which was then filled to volume. Sample dye solutions of approximately 10^{-5} M were prepared by transferring a 60 mL aliquot of dye stock solution to a 100 mL volumetric flask. Parameters such as pH and salt concentration were then adjusted before dilution to volume.

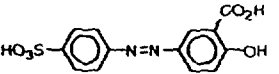
Each extraction was performed using approximately 0.1 g of foam accurately weighed into a 20 mL sample vial. A 15 mL aliquot of 10^{-5} M dye solution was added to the vial which was then sealed with plastic wrap and a screw cap. A comparison standard was prepared following the same method but omitting the foam. The vials were shaken for 24 h using an automatic shaker. After filtration through a #4 Whatman filter the pH and UV–visible spectrum (190–820 nm) of the aqueous layer were taken.

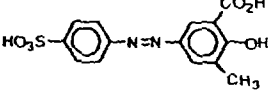
The degree of dye soprtion was reported as the distribution ratio, D:

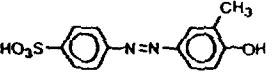
$$D = (VE)/W(100 - E) \tag{1}$$

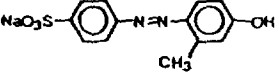
$$E = 100(C_0 - C_{eq})/C_0 \tag{2}$$

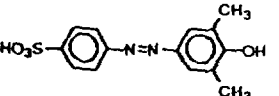
where E is the percentage extraction, C_0 is the initial molar concentration of solution (M), C_{eq} is the concentration of solution after sorption (M), V is the volume of solution (L) and W is the mass of foam (kg).












3. Results and discussion

3.1. Neutral species extraction

The effect of solution pH on extraction was studied in order to confirm that neutral species extraction was occurring. The results were analysed by plotting the distribution ratio of the extraction against the equilibrium pH of the solu-

tion, producing what will be called an *extraction profile*. Fig. 1 shows the extraction profile of 4-phenylazobenzenesulfonic acid (4-PABSA). An obvious trend can be seen in this and the profiles of the other 11 dyes, all of which are summarized in Table 1. The results of the extractions for all 12 dyes seem to follow a pK_a-type curve. There was little or no extraction from solutions more basic than pH 6. As the solutions became more acidic there was an increase in extraction, which was always followed by a decrease in extraction as the solutions became increasingly more acidic. This decrease in extraction generally begins to occur with solutions at about a pH of 2. Notable exceptions were those dyes containing an amino group, where the decrease in extraction occurred in solutions with a pH of 4 or less.

The results of this pH survey can be easily interpreted as showing only neutral species extraction. To aid in this interpretation, two of the dyes were chosen for further examination. Although the following arguments hold true for all of the dyes investigated, only these more extensively studied dyes will be discussed. For basic solutions of 4-PABSA, a large percentage of the species would be expected to be negatively charged be-
Fig. 1. Extraction profile of 4-PABSA. Conditions: $\approx 10^{-5}$ M dye solutions, 0.1 g foam, 15 mL solution, 24 h extraction time.

cause of the unprotonated sulfo groups (Fig. 2a). As the solutions become more acidic, the azo groups are expected to become protonated, and the molecules become zwitterions with an overall neutral charge (Fig. 2b). Such species therefore become extractable, as was observed. As solutions become very acidic (pH < 2) some of the sulfo groups also become protonated (Fig. 2c) producing an unextractable species (because of its overall positive charge); therefore a decrease in extraction is expected.

In order to further test the idea of neutral species extraction, the first pK_a value of 4-PABSA, that of the azo group, was experimentally determined and estimated to be 2.55. Using this pK_a value the percentage of monoprotonated species was plotted vs. the corresponding pH to produce the protonation profile shown in Fig. 3. When the sulfo group is unprotonated, upon protonation of the azo group the molecule becomes a neutral zwitterion. Because above a pH of 1 the vast majority of the sulfo groups are in an unprotonated state, a plot of the percentage of protonated azo groups is therefore also a plot of the neutral species available.

The relationship between the protonation profile and the extraction profile of 4-PABSA is emphasised by overlaying Figs. 1 and 3 as shown in Fig. 4. Although the extraction proceeds to some extent in solutions where there should only be a small percentage of neutral species, the sharp rise in extraction and the extraction maxima seem to correspond with the amount of neutral species available. These results suggest that the extraction mechanism can also explain the sharp decrease in the extraction in acidic solutions. This decrease is thought to occur because as the sulfo group becomes protonated, it gives an overall positive charge to the molecule. Unfortunately, because of the acidity of the solution and therefore the instrumental error associated with measuring such low values of pH, attempts to experimentally determine the pK_a value of the sulfo group were unsuccessful. Literature values for the acid constant in aqueous solutions of this or any similar dye were also unavailable.

The reliance of the mechanism on the presence of a neutral species can be more clearly illustrated

(a)

(b)

(c)
Fig. 2. Charge states of 4-PABSA.

by analysing the results of the extraction of Ethyl Orange. The first pK_a value of Ethyl Orange is for the amino group and as with 4-PABSA, the monoprotonation of the dye yields an overall neutral, extractable, zwitterion (Fig. 5b). As with 4-PABSA, upon being doubly protonated, this time with the protonation of the azo group, the molecule becomes positively charged (Fig. 5c) and unextractable. In this case the neutral species involves a protonated amino group and an unprotonated azo group. Therefore to graphically represent the percentage of neutral species
Fig. 3. Protonation profile of 4-PABSA showing the percentage of dye species with a protonated azo group.
Fig. 4. Overlay of Figs. 1 and 3 emphasizing the correlation between extraction of 4-PABSA and the percentage of neutral species available. Note: data points have been removed for clarity.

present, the percentages of both protonated amino groups and protonated azo groups need to be plotted. In Fig. 6 the two percentage curves are shown; the neutral species is represented by the protonated azo group curve on the acidic side of their intersection (pH < 4), and the protonated amino group curve on the basic side of their intersection (pH > 4)

The overlay of the extraction profile of Ethyl Orange and the protonation profile is shown in Fig. 7. Although the curves are shifted by 0.5 pH, the extraction using polyether-type polyurethane closely follows the percentage of Ethyl Orange that is predicted to be present as a neutral species.

(a)

(b)

(c)
Fig. 5. Charge states of Ethyl Orange.
Fig. 6. Protonation profile of Ethyl Orange. The percentage of neutral species is represented by the solid line, the percentage of protonated azo groups to the left of the intersection, and the broken line shows the percentage of protonated amino groups to the right of the intersection.

The increase and decrease of the Ethyl Orange extraction mimic those percentages, which leaves little doubt that the extraction is of a neutral species.

There is additional evidence that the majority
Fig. 7. Overlay of the extraction profiles of Ethyl Orange, polyester (broken line), and polyether (solid line) with Fig. 6 (dotted line). This emphasizes the correlation between the extraction of Ethyl Orange and the amount of neutral species present. Note: data points have been removed for clarity.

of the extraction is dependent on the charge of the dye species, and not on a foam-related phenomenon. This comes from the fact that the increase in extraction, from basic to acidic solutions, follows the pK_a curve of the dye being extracted. Specifically, this can be seen by comparing the extraction profiles of 4-PABSA and Ethyl Orange. If this were a foam-related phenomenon, the extraction increase would be expected to occur in solutions with similar pH regardless of the dye being extracted. Instead, the extraction appears to follow the pK_a curve of the dye being extracted.

It seems clear that the overriding mechanism involves the sorption of an overall neutral species. There is however some evidence of an additional extraction mechanism which has a less significant effect on the extraction. In Fig. 1, the slow increase in extraction of 4-PABSA as the solution is changed from pH 5 to 8, could be interpreted as showing two minor increases in extraction, between pH 7 and 8, and between pH 5 and 6. These small increases in extraction are not easily explained using a neutral species extraction. One possible explanation for this behaviour lies in the protonation of nitrogen- and oxygen-containing groups of the foam; as the foam group becomes protonated it might act as a ion exchange site. However, given the small amount of extraction attributable to this mechanism when compared to neutral species extraction, this hypothesis was not further explored.

3.2. Polyester vs. polyether

The composition and structure of a polyester-type polyurethane are quite different from those of the polyether-type, so it is not surprising that they have different extraction characteristics. Although the extraction profiles have the same general shape, extractions with polyester foam are usually different from those using polyether. The two main differences are in the maximum amount of dye extracted and the solution conditions necessary for extraction to occur.

The extraction profiles show that the increase in extraction from basic to acidic solutions, and the maximum extraction, occur in more acidic solutions with polyester than with polyether foam.

There seems to be a consistent need for solutions to be generally 1–3 pH units more acidic for a comparable extraction into polyester compared to polyether foam (see Table 1). This suggests that the above effect is not a dye-related phenomenon, but rather is probably due to the differences in the dielectric constants of the two foams [29]. This shift of two pH units does not apply for the decrease in extraction, which occurs in the same pH range for the two foams. Since the extraction with both foams decreases as the percentage of neutral species declines, this can be interpreted as further proof of a neutral species extraction by both types of foam.

Another difference, seen throughout the results, is that the extractions with polyether foam often have a higher maximum distribution ratio than with polyester. The extractions showing this behaviour involve dyes with either a hydroxyl or amino functional group. Trends similar to this have been reported by previous researchers [22,26]. Schumack and Chow [23] found that compounds containing phenolic or carboxylic groups were extracted more efficiently by polyether than polyester foam. Through a comparison of ortho-, meta- and para-nitrophenols they determined that the difference in extraction can be attributed to the presence of hydrogen bonding. Hydrogen bonds are likely to be much stronger with a polyether than with a polyester foam [30] and therefore compounds containing hydrogen bonding functional groups are likely to be better extracted by a polyether than a polyester foam.

From Table 1 it can be seen that differences between polyether and polyester extractions are greater with those dyes containing an amino group than with hydroxyl-containing dyes. Fong and Chow [26] reported similar results using 1-amino-2-naphthol-4-sulfonic acid. In their extraction, it is likely that the amino group was protonated; they suggested that an additional ion–dipole interaction might explain the greater differences in their distribution ratios. This interaction could also explain the extraction behaviour of the amino-containing dyes found in this study.

3.3. Comparison of maximum extractions

One of the aims of this study was to gain some insight into the role that functional groups play in the extraction process. This was to be done by comparing the maximum distribution ratios, D_{max}, of the similar dyes. It was thought that these comparisons would be valid since the maximum distribution ratio should be a good approximation of the distribution coefficient [24,25]. However, the strength of such comparisons is weakened, perhaps even invalidated, by the discovery of the dependence of the extraction on the equilibrium dye concentration, described next.

3.4. Equilibrium dye concentration

The discovery of an interesting trend was made while constructing the extraction profiles using data from several separate experiments. It appeared that the amount of extraction was somehow linked to the concentration of dye present during an extraction. In order to study this effect, an experiment was designed which varied the initial dye concentration from 5 mg L^{-1} to 500 mg L^{-1}.

The results of this experiment showed that the distribution ratio is very dependent on the equilibrium dye concentration. Fig. 8 shows the results using polyether foam; the results for the polyester-type (not shown) were similar. Initially, it was thought that this behaviour might be an indication that the foam was reaching capacity, i.e. it was becoming saturated with dye. To examine this, data were used to plot the actual amount of dye being sorbed per gram of foam. Fig. 9 shows that the polyether foam appears to approach its capacity, estimated to be approximately 12 mg of 4-PABSA per gram of foam. However, the experiments showing the greatest dependence on dye concentration occur under conditions well below this saturation level. In addition the polyester-type foam did not appear to become saturated. It was therefore concluded that the dependency of the sorption on equilibrium dye concentration was not related to the capacity of the foam.
Fig. 8. The effect of dye concentration on the extraction of 4-PABSA. Conditions: 0.1 g foam, 15 mL dye solution ($\approx 10^{-5}$ M, pH ≈ 2.5), 24 h extraction time.

To explain these results two models were evaluated; one involves the solvent extraction mechanism and how it is affected by the ionic strength of the solution, the other, called the dual-mode

Fig. 9. Amount of 4-PABSA extracted per gram of foam. Conditions: 0.1 g foam, 15 mL solution, 24 h extraction time.

sorption model [31], involves the solvent extraction mechanism and the adsorption mechanism.

3.4.1. Ionic strength

Examining the solvent extraction model shown below, we can better understand what might be occurring.

$$HA_{aq} \rightleftharpoons HA_{org}$$

$$K_d = \frac{a_{HA \cdot org}}{a_{HA \cdot aq}} = \frac{[HA_{org}]f_{HA \cdot org}}{[HA_{aq}]f_{HA \cdot aq}} = D\frac{f_{HA \cdot org}}{f_{HA \cdot aq}} \qquad (3)$$

where HA is a neutral dye species, K_d is the distribution coefficient, a_{HA} is the activity of the dye in the corresponding phase, and f_{HA} is the activity coefficient of the dye in the corresponding phase.

In this model there is an equilibrium between the neutral species in the aqueous phase and the neutral species in the organic phase, in this case the foam. This equilibrium can be expressed as a ratio of the activities of the dye in each phase, which in turn can be expressed as the distribution ratio multiplied by the ratio of the activity coefficients of the dyes in each phase. It is usual to assume for dilute solutions that the activity coefficients are both near unity and constant [32]. Therefore the distribution coefficient K_d is approximately equal to the distribution ratio and it is generally assumed that solvent extraction is concentration independent.

The problem then is to explain the extraction results using this solvent extraction model. One plausible explanation involves the assumption made regarding the activity coefficients. From Eq. (3) it can be seen that if either of the activity coefficients were not constant, the distribution ratio, D, would have to change since K_d, the distribution coefficient, is a thermodynamic constant. One thing that would change the aqueous activity coefficient of the dye is the ionic strength of the solution.

Although it has been shown that the extraction is largely of neutral species, the species involved are actually zwitterions. Therefore it might be possible that changing the concentration of the dye would also change the ionic strength of the solution, although no information regarding such
Fig. 10. Effect of potassium chloride concentration on the extraction of 4-PABSA with polyether foam. Conditions: 15 ml dye solution ($\approx 10^{-5}$ M, 0.001-4 M KCl), 0.1 g foam, 15 mL solution, 24 h extraction time. $\bigcirc$, Acidic conditions; $\bullet$ basic conditions.

effects was found in the literature. As the ionic strength of the solution increases, the activity coefficient of the dye in solution would decrease [32]. Again, looking at Eq. (3), it can be seen that this would cause the ratio of the activity coefficients to increase. Since K_d is a thermodynamic constant, the distribution ratio would have to decrease as the aqueous activity coefficient decreased. This is the exact behaviour observed in these experiments. While there is some doubt as to whether such small increases in dye concentration could affect its activity coefficient, additional strength is added to this argument by the salt concentration results shown in Fig. 10. This Figure shows that under acidic conditions, very small salt concentrations have a large effect on the extraction efficiency. The behaviour observed is similar to that with increasing dye concentration, and can be explained in the same way. As the salt concentration increases, the ionic strength of the solution will increase.

The behaviour observed in basic solutions is quite different from that found with acidic solutions. In this pH range there is originally no

extraction without salt present; upon the addition of salt there is an increase in extraction. These results are similar to the salting-out effect, where upon addition of a salt the extraction of a non-ionic solute increases. However, at the basic pH of the experiment, only charged species should exist. In this case it is possible that the potassium ion could associate with either the negatively charged sulfo group or with the pair of electrons on one or both of the nitrogens of the azo group. These possible associations would yield neutral species which could be extractable, as was observed.

Based on this model, as a solution approaches infinitely dilute conditions, the distibution ratio should become a closer approximation of the distribution coefficient and the maximum distribution ratio for an extraction should become more constant. However, even when the equilibrium dye concentration approaches the limits of detection, the distribution ratio showed no signs of levelling off, therefore no estimation of K_d can be made.

3.4.2. Dual-mode sorption

Dual-mode sorption is the second model used to try and explain the dependence of the extraction on the equilibrium dye concentration. In this model, the sorbed dye is classified into two groups: the absorbed dye (solvent extraction mechanism), and the adsorbed dye (surface adsorption described by the Langmuir equation). This model is mathematically represented as

$$C_{org} = C_{ab} + C_{ad} = K_d C_{aq} + \frac{SK_L C_{aq}}{1 + K_L C_{aq}} \qquad (4)$$

where C_{org} and C_{aq} are the equilibrium dye concentrations on the polyurethane foam and in solution, C_{ab} and C_{ad} are the equilibrium dye concentrations on the foam as an absorbed species and as an adsorbed species, S is the saturation value for the Langmuir adsorption, K_d is the distribution coefficient, and K_L is the Langmuir constant.

Eq. (4) can be solved for the distribution ratio, D as

$$D = K_d + \frac{SK_L}{1 + K_L C_{aq}} \qquad (5)$$

From Eq. (5) it is now obvious that the distribution ratio is not independent of the dye concentration. The equation can be fitted to the extraction data, shown in Fig. 11, giving the values $K_d = 30$ L kg^{-1}, $S = 0.012$ mol kg^{-1}, and $K_L = 300\,000$ L mol^{-1}. From Eq. (5) it can be seen that as the concentration of the dye increases, the contribution to D approaches the value of K_d. As the concentration approaches zero, D should approximate $K_d + SK_L$. No levelling off of D was observed as C_{aq} approached zero; however, as C_{aq} increased, a levelling off of D was observed. Therefore according to this model, the data obtained suggest that the absorption coefficient, K_d, is much smaller than previously thought.

Future studies will need to focus on soluble non-ionic dyes or other organic compounds to test these findings. This approach should eliminate any effect on the ionic strength of the solution but should not affect the amount of adsorption occurring.

4. Conclusions

The study of the extraction of 12 closely related mono-azo dyes shows that these compounds are extracted as neutral zwitterions and that their
Fig. 11. Graphical representation of the dependence of the distribution ratio on equilibrium dye concentration according to the dual-mode sorption model. Eq. (5) fitted to data from Fig. 8.

extraction may involve a number of mechanisms. When anionic species are present below a pH of 8, there is some evidence to support some form of ion-exchange mechanism. However, even when this mechanism is thought to be operating, its contribution to the overall extraction seems to be small. The extreme sensitivity of the extraction to dye concentrations which was found can be explained using either a solvent extraction model or a dual-mode sorption model.

The solvent extraction model requires that very small increases in the dye concentration will have large effects on the ionic strength of the solution. While doubtful, this idea is supported by the salt concentration experiments done under acidic conditions. However, the salt concentration results may also be explained by the cation being chelated or ion paired with the dye producing an unextractable dye species, mechanisms unrelated to ionic strength.

The dual-mode sorption model offers an excellent description of the observed behaviour and of the two models presented seems the most plausible. According to this model when analyte concentrations are low adsorption is responsible for the majority of the sorption, but when analyte concentrations are higher, absorption becomes the dominant mechanism because of its higher capacity. Although the model implies a much greater role of adsorption than previously considered, this seems logical given the large surface area of a foamed polymer.

The inability to confidently obtain the distribution coefficient for the extractions of the dyes has reduced our ability to make the comparisons between dyes that are necessary to study the effect of various functional groups. Despite this limitation the results show that there can be large differences in the extractions due to the presence and position of functional groups on the ring structure of the dyes. The cause of these differences and other extraction behaviour are not fully understood and need further study.

Previous researchers have relied heavily on the solvent extraction model to explain the extraction of organic compounds using polyurethane foam. The distribution ratio, while useful for describing the results of liquid–liquid extractions, has been

shown not to be adequate for comparisons between extractions using polyurethane foam, especially when dealing with low analyte concentrations. Once the dual-mode sorption mechanism is confirmed in future experiments, further studies will be able to easily estimate the extraction constants of both absorption and adsorption. Using those values researchers can then begin to make the proper comparisons necessary to study the mechanisms of extraction and the roles of the functional groups of the analytes.

Abstract

An approach for quantitative spectrophotometric analysis of binary mixtures based on first derivative spectra is developed. The proposed method is used for investigation of the complex formation of some aza-15-crown-5-containing ligands with Sr^{2+}, where the stability constant is low and the absorption spectrum of the complex cannot be obtained directly. The described general approach can be applied for quantitative analysis of any other two-component mixture where the absorption spectra of the components cannot be obtained experimentally.

Keywords: UV–Vis spectroscopy; Derivative spectroscopy; Complex formation; Aza-15-crown-5

1. Introduction

It is well known that the quantitative spectrophotometric analysis of complex mixtures where the spectra of the individual components is unknown is generally an impossible task [1], except in cases where some additional information allows the creation of a non-linear optimization model. Recently, some methods for analysis of binary systems based on such non-linear regression models [2], analysis of overlapped absorption bands [3,4] or by finding the individual absorption ranges of the components [5,6] have been developed, but it should be noted that these methods employ complicated mathematical algorithms and sometimes require massive computations.

* Corresponding author.

The application of these methods for investigation of complexation processes of the type

$$n\mathrm{L} + q\mathrm{M} = \mathrm{M}q\mathrm{L}n \equiv \mathrm{C}$$
is possible, but a simpler mathematical procedure could be used because in these cases the ligand (L) spectrum is known. At the same time the complexation process is very often characterized by a low stability constant, i.e. the equilibrium is not shifted totally to the complex (C) and so its spectrum cannot be obtained experimentally. Thus quantitative analysis is impossible, especially if the structure of the complex formed is unknown (i.e. n and q are unknown).

In order to overcome such problems the aim of this study is to modify the first derivative spectra method [7] and to use it for quantitative analysis of binary mixtures composed of individual pure

components with unknown spectra, and then to apply it to spectrophotometric investigation of complexation of aza-15-crown-5-containing chromoionophores with Sr^{2+}. During the last few years we have designed a series of such chromoionophores and studied their complexation with alkali and alkaline-earth ions [4,5,8–10].

2. Experimental

2.1. Synthetic procedure

The chromoionophores I–V (Scheme 1) are synthesized as previously described [8].
Scheme 1.

2.2. Analytical procedure

Absorption spectra were recorded on a Perkin-Elmer Lambda 17 UV–Vis spectrophotometer in dry acetonitrile (Uvasol). Acetonitrile used was dried as follows: after 4 h boiling over CaH_2 it was distilled and stored over a molecular sieve. $Sr(ClO_4)_2$ was obtained by treating SrO with concentrated $HClO_4$ (Merck).

The experimental spectra obtained were processed using a special program DERGSK for MATHCAD 3.0 (Windows version), based on the algorithm described above.

3. Theory

The quantitative analysis of a binary isomolar system is based on the additivity principle:

$$A(\lambda) = x_1 \cdot A_1(\lambda) + x_2 \cdot A_2(\lambda) \qquad (1)$$

where $A(\lambda)$ is the absorbance measured at the wavelength λ, x_1 and x_2 are the molar fractions of the components and $A_1(\lambda)$ and $A_2(\lambda)$ are the individual absorbances of the components at the wavelength λ. By differentiation Eq. (1) is transformed as follows:

$$\frac{dA(\lambda)}{d\lambda} = x_1 \cdot \frac{dA_1(\lambda)}{d\lambda} + x_2 \cdot \frac{dA_2(\lambda)}{d\lambda} \qquad (2)$$

Evidently when $A_1(\lambda)$ $(dA_1(\lambda)/d\lambda$ respectively) or $A_2(\lambda)$ $(dA_2(\lambda)/d\lambda$ respectively) are unknown the analysis of the system is generally impossible. However, if the absorption maxima λ_1 and λ_2 in both spectra are known then Eq. (2) is transformed into

$$\text{at } \lambda = \lambda_1 \Rightarrow \frac{dA_1(\lambda_1)}{d\lambda} = 0$$

$$\frac{dA(\lambda_1)}{d\lambda} = x_2 \cdot \frac{dA_2(\lambda_1)}{d\lambda}$$

$$\text{at } \lambda = \lambda_2 \Rightarrow \frac{dA_2(\lambda_2)}{d\lambda} = 0$$

$$\frac{dA(\lambda_2)}{d\lambda} = x_1 \cdot \frac{dA_1(\lambda_2)}{d\lambda} \tag{4}$$

Using the mass balance $(x_1 + x_2 = 1)$ and substituting for relations (3) and (4) in Eq. (2), a linear relationship for the first derivatives of a series of isomolar solutions at λ_1 and λ_2 is obtained:

$$\frac{dA'(\lambda_2)}{d\lambda} = \frac{dA_1(\lambda_2)}{d\lambda} - \frac{dA'(\lambda_1)}{d\lambda} \cdot \frac{(dA_1(\lambda_2)/d\lambda)}{(dA_2(\lambda_1)/d\lambda)} \tag{5}$$

From the intercept and slope of Eq. (5) the $dA_1(\lambda_2)/d\lambda$ and $dA_2(\lambda_1)/d\lambda$ values are estimated and using Eqs. (3) and (4) the molar fractions of both components can be calculated.

It is evident that the main problem for the successful application of this approach is the determination of λ_1 and λ_2, which could be made using:

— visual evaluation of the absorption spectra of the isomolar solution. This method, however, is very uncertain, especially in cases of strong overlapping of the bands of the individual components and when weak spectral changes are observed.

— estimation using the second derivative spectra. This estimation could be incorrect if the electronic bands have a vibrational structure [11,12].

4. Results and discussion

The complex formation between alkali and alkaline-earth metal ions and aza-15-crown-5-containing dyes can be described with the relation [13,14]:

$$L + M \rightleftharpoons C$$

If the ligand concentration is constant (i.e. the system is isomolar for the ligand) and the metal salt concentration (C_M^i) is different in each solution the following relations are valid:

Mass balance:

$$x_L^i + x_C^i = 1 \tag{6}$$

Stability constant:

$$\beta = \frac{x_C^i}{x_L^i \cdot C_M^i} \tag{7}$$

Additivity of the first derivatives:

$$\frac{dA'(\lambda_C)}{d\lambda} = \frac{dA_L(\lambda_C)}{d\lambda} - \frac{dA'(\lambda_L)}{d\lambda} \cdot \frac{dA_L(\lambda_C)/d\lambda}{dA_C(\lambda_L)/d\lambda} \tag{8}$$

where $i = 1-p$, p is the number of isomolar solutions, λ_L and λ_C are the absorption maxima of the ligand and the complex respectively, x_L and x_C are the molar fractions of the ligand and the complex respectively, and C_M is the concentration of the metal salt.

The experimental spectra obtained by adding different amounts of $Sr(ClO_4)_2$ to the solution of **I** are shown in Fig. 1a. It is evident that the complexation results in decrease of the ligand band intensity at approximately 540 nm and the appearance of a new band at approximately 450 nm due to the complex formed. On the whole, however, the spectral changes are rather weak. As long as the ligand spectrum is known the absorption maximum can be easily estimated (i.e. $\lambda_L = 537$ nm) and by means of the Golay–Savitzky method [15] the $dA_L(\lambda)/d\lambda$ value can be calculated. The value of λ_C cannot be determined
Fig. 1. [a] Using the method described in Ref. [5].
[b] Using classical multicomponent analysis, because the spectrum of the complex can be obtained experimentally.

from the spectra shown in Fig. 1a because the spectral changes in the range 400–500 nm are rather weak.

In Fig. 1b the first derivatives of the absorption spectra of Fig. 1a are shown. As is seen the spectral changes are rather weak. The situation for the second derivatives is the same and at about 450 nm no definite maximum characteristic for λ_C is observed. For this reason the following procedure was used to determine λ_C:

(1) The change in λ in the spectral range 400–500 nm with a small step, i.e. $\lambda^j = 400 + j \cdot \Delta\lambda$ ($\Delta\lambda = 1$ nm), was determined.

(2) For every j value the dependence $dA'(\lambda^j)/d\lambda = f[dA'(\lambda_L)/d\lambda]$ was obtained and the corresponding intercept (IY^j) was calculated according to Eq. (8).

(3) Calculation of the square (S) of the difference between the estimated IY^j value and the value calculated from the ligand spectrum $dA_L(\lambda^j)/d\lambda$:

$$S_j = \left(\frac{dA_L(\lambda^j)}{d\lambda} - IY^j\right)^2 \tag{9}$$

Evidently when $\lambda^j = \lambda_C$ then $IY^j = dA_L(\lambda^j)/d\lambda$ according to Eq. (8) and S_j tends to 0, i.e. $\lambda^j = \lambda_C$ S_j has a minimal value.

Using this procedure it was estimated that $\lambda_C = 452 \pm 1$ nm and in accordance with relations (8), (3) and (4) the molar fractions of the ligand in every solution were determined.

Using the dependence

$$\lg\frac{x_L^i}{1 - x_L^i} = \lg\beta + \lg C_M^i \tag{10}$$

which follows from Eqs. (6) and (7) the value of $\lg\beta = 1.32 \pm 0.17$ was obtained with a good regression coefficient (0.998). The same value was obtained by treatment of the spectral curves (Fig. 1a) with another approach as described in Ref. [5], thus confirming the reliability of the procedure described above (Table 1).

Using the data obtained for x_L in accordance with Eq. (1) the spectrum of the complex was calculated and is shown in Fig. 1a.

Similarly, using the same procedure, the stability constants for the Sr^{2+} complexes with the other ligands were estimated and the data obtained together with the spectral characteristics of the corresponding ligands and complexes are collected in Table 1. As seen in Table 1 standard deviations of $\lg\beta$ determined according to the present approach are bigger than those estimated according to Ref. [5] and this fact could be explained by the increase in the signal/noise ratio in the first derivative spectra. In spite of the relatively low accuracy of the present approach its application might be useful in cases where the classical spectrophotometric analysis could not be used.

5. Conclusion

An approach for quantitative spectrophotometric analysis of binary mixtures based on first derivative spectra has been developed. The proposed method is used for investigation of the complex formation of some aza-15-crown-5-containing ligands with Sr^{2+} where the stability constant is low and the absorption spectrum of the complex cannot be obtained directly. The results obtained are in good agreement with those obtained for complexation of these ligands with Ca^{2+} and Ba^{2+} described previously [9,10].

Enzyme sensors for determination of fish freshness

G. Volpe, M. Mascini

Dipartimento di Sanità Pubblica, Epidemiologia e Chimica Analitica Ambientale, Sezione di Chimica Analitica, Via G. Capponi 9, 50121 Firenze, Italy

Abstract

A simple and rapid procedure for the determination of fish freshness was developed and applied to the determination of the K_1 parameter (freshness indicator): $K_1 = ([HXR] + [HX])/([IMP] + [HXR] + [HX]) \times 100$, where [IMP], [HXR] and [HX] are inosine monophosphate, inosine and hypoxanthine concentrations, respectively. A platinum electrode is used to detect hydrogen peroxide produced by the enzymatic reaction catalysed by xanthine oxidase immobilised on the electrode surface. The determination of inosine and inosine monophosphate was performed by the addition of nucleoside phosphorylase, 5'-nucleotidase or alkaline phosphatase to the buffer solution. Parameters such as type of buffer, amount of enzymes and sample treatment were optimised. With this procedure a linear response was obtained in the concentration range $1 \times 10^{-6} - 2 \times 10^{-5} \, \text{mol} \, 1^{-1}$ for hypoxanthine, inosine and inosine monophosphate. The detection limit was $5 \times 10^{-7} \, \text{mol} \, 1^{-1}$.

1. Introduction

The establishment of a simple, rapid and accurate method for the determination of fish freshness is required in the food industry. Various indicators of spoilage such as volatile basic nitrogen [1], ammonia [2], amines [3], volatile acids [4], and pH [5] have been reported. However, fish freshness is difficult to measure satisfactorily from these indicators and, further, they require pretreatment and complicated procedures. In recent years, considerable attention has been focused on nucleotide degradation in fish muscle as a reliable indicator of the freshness of raw fish [6, 7]. Imme-

diately after the death of fish, ATP in fish muscles starts to degrade to uric acid through the following autolytic pathway:

$$ATP \rightarrow ADP \rightarrow AMP \rightarrow IMP$$
$$\rightarrow HXR \rightarrow HX \rightarrow X \rightarrow U$$

where ATP, ADP, AMP, IMP, HXR, HX, X and U represent adenosine triphosphate, adenosine diphosphate, adenosine monophosphate, inosine monophosphate, inosine, hypoxanthine, xanthine and uric acid respectively. To indicate fish freshness a K value, based on the degradation of these compounds in fish meat, is defined [8]:

$$K =$$

$$\frac{[HXR] + [HX]}{[ATP] + [ADP] + [AMP] + [IMP] + [HXR] \, [HX]}$$

$$\times \, 100$$

It has been shown that fishes with $K < 20$ are very fresh, fishes with $20 < K < 40$ must be cooked and those with $K > 40$ are not suitable for human consumption [9]. Since ATP, ADP and AMP disappear around 24 h after the death of the fish, the K value is defined as [10]

$$K_1 = \frac{[HXR] + [HX]}{[IMP] + [HXR] + [HX]} \times 100$$

It is then possible to estimate the fish freshness by measuring only three of the six parameters.

2. Proposed method for determination of fish freshness

The biochemical pathways of IMP degradation are:

$$IMP \overset{NT}{\to} HXR + P_i$$

$$HXR + P_i \overset{Np}{\to} HX + \text{ribose-1-phosphate}$$

$$HX + 2O_2 \overset{XO}{\to} UA + 2H_2O_2$$
where NT, NP, XO and P_i are 5′-nucleotidase, nucleoside phosphorylase, xanthine oxidase and phosphate respectively. IMP, HXR and HX can be determined by using oxygen or hydrogen peroxide electrodes coupled to the enzymes mentioned above.

The oxygen consumed or hydrogen peroxide formed on the electrode surface produce a current variation which is correlated to the concentration of these metabolites in solution. The determination of the K_1 value by oxygen-based probes has been reported in the literature. Analysis was carried out by immobilisation of the enzymes onto the electrode surfaces which were inserted in a flow cell [10], or by enzyme linkage on chitosan porous bead reactors [11]. The first method requires a software-controlled instrumentation, while the second is based on two reactors and two oxygen electrodes in a flow injection system. Moreover, for both the devices a calibration curve

for each metabolite is necessary.

In this study a fast and simple procedure based on a hydrogen peroxide probe was developed. Hypoxanthine was determined by immobilisation of xanthine oxidase on the electrode surface. Inosine monophosphate and inosine were measured by adding, in solution, 5′-nucleotidase and nucleoside phosphorylase using an end-point procedure. The method of determination is shown in Fig. 1: the first current variation upon the addition of fish extract was related to hypoxanthine, then nucleoside phosphorylase and 5′-nucleotidase were added and the relative current variations due to HXR and IMP were recorded. With this procedure the K_1 value can be measured as follows:

$$K_1 = \frac{\Delta_1 + \Delta_2}{\Delta_1 + \Delta_2 + \Delta_3}$$

Therefore, in principle, no calibration curve is required. Alternatively, the determination of IMP has also been performed by replacing 5′-nucleotidase (which is quite expensive) with much cheaper alkaline phosphatase (AP). Results are compared.

3. Experimental

3.1. Materials

5′-Nucleotidase (EC 3.1.3.5) from Crotalus
Fig. 1. Determination of the K_1 value using XO, NP and NT. A = sample addition, B = NP addition, C = NT addition; $\Delta_1, \Delta_2, \Delta_3$ = current variations due to HX, HXR and IMP respectively.

Adamanteus, alkaline phosphatase (EC 3.1.3.1) from bovine intestinal mucosa, nucleoside phosphorylase (EC 2.4.2.1) bacterial, xanthine oxidase (EC 1.1.3.22) from buttermilk, hypoxanthine, inosine, and inosine monophosphate were purchases from Sigma Chemical Co. (St. Louis, MO). The "Immunodyne Immunoaffinity" membrane (0.45 μm pore) was from Pall Biosupport Division (Glen Clove, NY). Cellulose acetate membrane (approximate molecular weight cut-off 100) was prepared in the authors, laboratory; the procedure is reported in the literature [12].

Polycarbonate membrane (0.03 μm pore size, 6 μm thick) was from Nucleopore Plesanton, CA).

3.2. Apparatus

The hydrogen peroxide-based platinum electrode (0.3 mm^2 nominal surface area) and the amperometric biosensor detector (ABD) were from Universal Sensors Inc., (Metairie, LA). The current output was recorded with an Amel model 868 recorder (Milan).

3.3. Electrode assembly

The biosensor probe consists of a platinum electrode polarised at +650 mV vs. a built-in silver/silver chloride reference electrode. This probe was assembled by placing the following membranes on an inverted electrode jacket in the given order: cellulose acetate (which protects the platinum electrode from electrochemical interferences), the enzyme membrane, and a polycarbonate membrane (which protects the enzyme from proteins or bacterial attack). The cellulose acetate membrane gives the advantage of selective measurement of H_2O_2. A solution of uric acid gives a current variation of only 3.5% of the current variation obtained by the same concentration of hydrogen peroxide. Xanthine oxidase produces from hypoxanthine two moles of hydrogen peroxide and one of uric acid. Therefore, with this membrane in place, we measure only hydrogen peroxide formation. The membranes were then secured with an O-ring. The electrode jacket was filled with a solution of 0.1 M potassium chloride,

the electrode was then inserted into the jacket and screwed down until the tip of the platinum was firmly in contact with the membranes.

3.4. Enzyme immobilisation

Xanthine oxidase was immobilized on the "Immunodyne Immunoaffinity" membrane. This membrane is intrinsically hydrophilic and contains functional groups which form covalent linkages with a variety of nucleophilic groups of enzymes/proteins. For a single membrane of 1 cm diameter, 0.1 U of dry enzyme was placed on the membrane, 10 μl of 0.05 M phosphate buffer pH 7.8 was added and the resulting mixture was homogeneously spread over the membrane with a glass stick. The membrane was air-dried for about 2 h, then washed in the same buffer and finally washed in the same buffer +KCl 1 M to remove the unbound enzyme. The enzymatic membrane was stored at 4°C in 0.05 M phosphate buffer pH 7.8 until used.

3.5. Preparation of fish extract

Two groups of authors [13, 14] proposed a treatment of fish sample according to the method of Ehira and co-workers [15, 16]: (1) deproteinization of fish fillet by precipitation with trichloroacetic acid; (2) centrifugation; (3) neutralization of supernatant with sodium hydroxide. A simpler method [17] was based on the homogenization of 5 g of fish meat with 15 ml of distilled water. The homogenate was then filtered through a membrane filter (0.2 μm pore size). The filtrate was made up to 20 ml with distilled water and used immediately as the sample.

After the preliminary experiments it was realised that the tedious procedure of deproteinization was not necessary for the measurement of current variation due to hypoxanthine. Therefore a simpler procedure was adopted for the rest of the work: a few microliters of liquid obtained by squeezing fish fillet was used directly. A small piece of fish fillet was packed into a hydrophobic nylon-net membrane and squeezed, preferably with a meat squeezer. No effort by the operator is required, even when the fish samples are fresh and high retention of water in tissues occurs.
Fig. 2. Calibration curve of hypoxanthine.

4. Results and discussion

4.1. Parameter optimisation

Different buffers were tested at room temperature, fixing the pH at 7.8, which represent a compromise for the three enzymes [17]. The buffers were Hepes, Mops, Tris and Imidazol. The latter gave a low and reproducible background current, and was therefore selected to calibrate the probe using standard solutions of hypoxanthine. As shown in Fig. 2 the linear range was from 1×10^{-6} to $2 \times 10^{-5} \, \text{mol} \, l^{-1}$ with a detection limit of $5 \times 10^{-7} \, \text{mol} \, l^{-1}$ of hypoxanthine. For the detection of inosine monophosphate and inosine it was necessary to optimize the amount of phosphate in the buffer; phosphate is a substrate of nucleoside phosphorylase and a product of 5'-nucleotidase. As is shown in Fig 3., for all three enzymes we obtained a response of 100% using a phosphate concentration of $20 \, \text{mmol} \, l^{-1}$. Total volume, buffer concentration and enzyme units of NT and NP added were optimized. When the volume of the buffer was decreased, keeping constant the enzyme amounts, the response time decreased. Using 0.4 U of NP and a concentration of $\text{HXR} = 2 \times 10^{-5} \, \text{mol} \, l^{-1}$ we obtained the following response times with different volumes of buffer: 20 ml, 10 min; 10 ml, 5 min; 3 ml, 3 min.

Keeping a constant volume of 3 ml and 0.4 units of NP the amount of NT was varied. At a concentration of $2 \times 10^{-5} \, \text{mol} \, l^{-1}$ IMP we obtained the following response times with different amounts of NT: 0.56 U, 6 min, 1.0 U, 4 min. One unit of NT gave an acceptable response time.

When 5'-nucleotidase was replaced with alkaline phosphatase we observed that the reaction time was too slow with a concentration of $20 \, \text{mmol} \, l^{-1}$ of phosphate, so we decided to eliminate phosphate during the reaction of alkaline phosphatase. Phosphate and then NP were added at the end of this reaction. It was observed that using standard solutions of IMP, 4 U of AP in 3 ml buffer converted $2 \times 10^{-5} \, \text{mol} \, l^{-1}$ of IMP to HXR completely in 1 min. With this procedure the determination of the K_1 value is obtained by analysing the fish sample twice (Fig. 4). The first measurement was performed in imidazol buffer $+20 \, \text{mmol} \, l^{-1}$ of phosphate with addition of a few microliters of fish extract and then NP (Fig. 4a). The current signals of HX and HXR are measured in this step. In the second measurement after addition of fish extract to the imidazol buffer, AP was added and after 1 min $\text{NP} + 20 \, \text{mmol} \, l^{-1}$ of phosphate were injected. In this step the current signals of HX and HXR + IMP were obtained (Fig. 4b). With this procedure the K_1 value can be defined as follows:

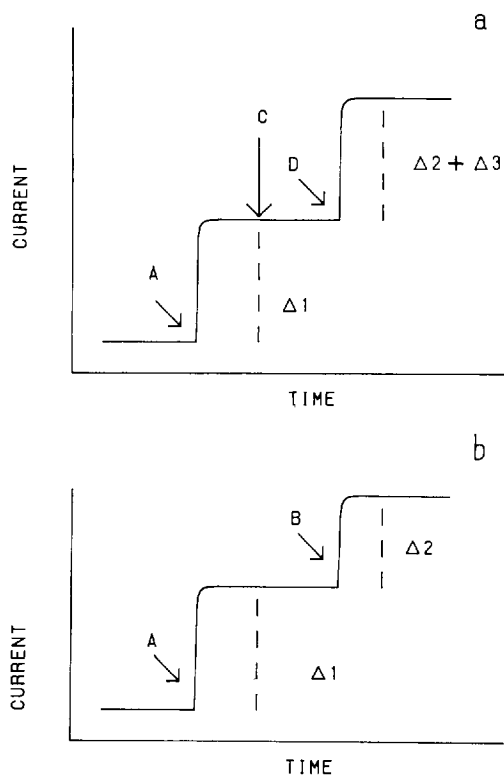
$$K_1 = \frac{\Delta_1 + \Delta_2}{\Delta_1 + \Delta_2 + \Delta_3}$$
Fig. 3. Optimization of phosphate concentration. [HX] = [HXR] = [IMP] = $2 \times 10^{-5} \, \text{mol} \, l^{-1}$.


Fig. 4. Determination of the K_1 value using XO, NP, AP. A = sample addition, B = NP addition, C = AP addition, D = NP and phosphate addition; $\Delta_1, \Delta_2, \Delta_3$ = current variations due to HX, HXR and HXR + IMP respectively.

4.2. Response of the biosensors to HX, HXR, IMP

In Fig. 5 three calibration curves are reported, with all parameters optimized, in the range $1 \times 10^{-6} - 2 \times 10^{-5}$ mol l^{-1}. As shown, these calibration curves established by using three different metabolites resulted in only one line, an indication of total conversion of inosine monophosphate and inosine to hypoxanthine.

5. Analysis of fish samples

For most measurements the procedure for determination of K_1 was realised with NT enzyme, which is more rapid. To 3 ml of imidazol buffer (0.05 M, pH 7.8) with phosphate (20 mM) 5 μl of fish extract was added and according to Fig. 1 a
Fig. 5. Calibration curves of HX, HXR and IMP with all parameters optimized.

current variation due to HX was recorded. Then NP (0.4 U) and finally NT (1 U) were added and the relative current variations due to HXR and IMP were recorded. The total analysis time is less than 10 min which is acceptable. Recovery studies were carried out by adding HX, HXR and IMP to the buffer after the fish extract addition. The results, reported in Table 1, show good recoveries of between 98% and 106%.

The determination of K_1 values in 12 fish samples is reported in Table 2. Two different species

Table 1
Recovery studies of HX, HXR and IMP added to three fish extracts

Sample	Added (10^{-6} mol l^{-1})	Expected (10^{-6} mol l^{-1})	Found (10^{-6} mol l^{-1})	Recovery
1	HX 5.0	6.8	7.2	106
	HXR 5.0	8.2	8.4	102
	IMP 5.0	19.4	19.4	100

of carp (common carp and mirror carp) were stored under different conditions and analysed. Five samples were analysed with both procedures using NT and AP. Both species showed an initial K_1 value of about 25–26%. During storage at 3°C the K_1 value increased to about 57% for common carp after 24 h, while it remained constant for mirror carp until 66 h. After 352 h of storage, if the fish fillet of common carp was kept at $-30°C$ the K_1 value reached 47%, while it is was stored at $-80°C$ the K_1 value remained constant.

6. Conclusions

A method for the determination of fish freshness was developed by measuring the K_1 parameter with a xanthine oxidase probe based on a hydrogen peroxide electrode. Measurement of HXR and IMP concentrations were carried out by NP, NT or AP addition in solution. The resultant procedure was fast and simple and moreover the biosensor technology allows the miniaturisation of the system for a field instrument.

Book reviews

The Directory of Controlled Release Technologies: Products and Organizations, by David Williams, Elsevier, Oxford, 1995, Diskette, £190. ISBN 1-85617-239-2.

This new diskette from Elsevier contains details of the major manufacturers, researchers and their products in the controlled release field across the world, in an easily accessible, flexible directory format. The diskette provides an overview of the technology, materials and future developments of controlled release products, as well as an alphabetical list of companies and products.

The overview technology section deals with the concepts, terminology and regulatory matters used in controlled release technologies together with diagrams and schemes to illustrate the types of mechanisms involved. The three main methods of containment are discussed, namely reservoir, matrix (oral and subdermal) and carrier. These mechanisms are well illustrated. As controlled release technology involves a combination of a drug with a type of device, the legal and regulatory position is also discussed. The text also elaborates on the methods of environmentally mediated release, such as osmotic pressure, vapour pressure, hydrodynamic pressure, pH activation and physically activated systems, namely infusion pumps, magnetic control and iontophoresis. Details are also provided of microcapsule, nanosphere and liposome technology. The section of the overview dealing with materials discusses polymers under the headings of types, biocompatability, biodegradation and permeability. The structures of both biodegradable and non-biodegradable polymers are illustrated. The overview section concludes with a discussion of future developments, and a list of references for further reading.

An A–Z list of companies comprises a further section, as well as being listed by geographical location and by application area. Selection of a letter will give companies beginning with that letter. Further selection of a particular company will provide various business details such as address, telephone and fax numbers, parent company and application areas. Personnel details and products are also provided.

The products section is also listed A–Z. This comprises a selected list of products manufactured by the companies. The uses, description and company are provided. The products are also listed according to application area, namely whether agricultural, cosmetic, household, pharmaceutical or veterinary.

There is also a search facility whereby a word or topic can be traced in the list of products and companies. This new diskette is certainly a useful means of gaining access to details of products and companies specialising in controlled release technology.

I reviewed the hardback version of this book 4 years ago (Talanta, 38 (1991) 1204–1205), and recommended it as a clear introduction to chemometrics, as well as being a very good self-teach manual for which it had the market largely to itself. The book has obviously stood the test of time well, since it now appears in paperback unchanged from the hardback version except that it is about £5.00 cheaper (which is not really a great price reduction).

It is a book concerned with experimental design moving at a leisurely pace, suitable for self-teaching, through a review of the necessary basic statistics, full factorial designs, fractional factorials, and response surfaces. Throughout there are summaries, aims and objectives clearly stated, all coupled with numerous self-assessment questions. Often large spaces (up to one page) are left blank for the students to write in their answers, but this is not always the case, and this is somewhat inconsistently used. However, it is an excellent book for the self-teaching environment, but would also provide a useful text to accompany a first course in experimental design. It is a pity that not more students learn about such design methods either as undergraduates or as postgraduates.

TrAC — Trends in Analytical Chemistry, Reference Edition, Vol. 13, edited by Y. Gohshi, J.F.K. Huber and A. Townshend, Elsevier, Amsterdam, 1994, 478 pp. +171 pp. (Supplement), US$400.00. ISBN 0-444-82110-4.

I have always had the sneaking suspicion that publishers never take any notice of my book reviews. Two years ago (Talanta, 41 (1994) 166) I wrote a review of the 1992 edition of TrAC in which my only concern was the steep price hike (14%) on the previous year. Imagine my surprise when this edition arrived on my desk costing $400 (a rise of only 3% over two years) and containing an extra 76 pages. So thanks are due to Elsevier. If this situation remained the norm I would not be faced with the miserable task of identifying titles we can no longer afford with our inflation linked budgets. Other publishers please note!

Most readers will not be aware of the philosophy behing the *Trends in* series. TrAC is a compilation of the archival material reprinted from the 10 issues of the journal published in 1994. Every year that I get the happy task of reviewing TrAC I point out that for little extra cost you can subscribe to the journal and obtain the reference edition *gratis*. This year's edition contains the usual mixutre of readable reviews of recent devel-

opments in instrumentation by established researchers (between 6 and 10 per issue). These include multidimensional GC, multidimensional protein NMR spectroscopy, atmospheric pressure ionisation mass spectrometry, Shpol'skii spectroscopy, scanning tunnelling microscopy, and capillary electrophoresis. There are a number of excellent articles specifically targeted at the analysis of environmental samples: pollution and pesticide analysis; stripping electroanalytical techniques; supercritical fluid extraction and enzyme immunoassay of soil pesticides; multivariate sensor arrays and analysis of complex environmental data using chemometric methods. Of general interest to analytical chemists are articles on Internet resources and quality assurance. Most issues contain a random mixture of the above, but in keeping with previous years, two issues are devoted to specific areas (June/July concentrating on Fourier transform mass spectrometry and October on water analysis).

The quality of TrAC is consistently high and is a superb resource for all teachers of University level analytical chemistry. The emphasis is always on relevance and accessibility. For the research worker, TrAC is a useful way of staying in touch with modern developments in areas outside one's own speciality. The only annoying feature of this edition is the supplement (171 pages) that contains the *'Directory of Hyphenated Techniques'*. I have reviewed this separately for Talanta and am still of the opinion that it serves no useful purpose.

Quantitative X-ray Spectrometry, Second Edition, edited by R. Jenkins, R.W. Gould and D. Gedcke, Dekker, New York, 1995, xi + 484 pp., US$150.00. ISBN 0-8247-9554-7.

The appearance of the second edition of Quantitative X-ray Spectrometry, as Volume 20 in the Practical Spectroscopy Series, is both timely and welcome. Timely, in that it is complementary to Volume 14 ("Handbook of X-ray Spectrometry"), and welcome because it is some 15 years since the

first edition was published. There are thirteen chapters, six appendices and an index, the main addition to the first edition being a chapter on special applications of the XRF method.

The scope of the book is quite considerable, ranging from description of the interaction of X-rays with matter, excitation sources, instrumentation, statistics, general computer applications, specimen preparation, and trace analysis to discussion of the main subject material — problems in quantitative analysis and methods and models for quantitative analysis. The authors quite rightly go into considerable detail in the latter two topics and here, as in all other chapters, very sensibly divide discussion between wavelength dispersive and energy dispersive methods. The book is very readable and interesting because every theoretical aspect is backed up with experimental results, usually displayed in graphical or tabular form. Another appealing aspect about the book is that it is written from a practical, no-nonsense standpoint, and contains a wealth of *practical* advice. For example, under Specimen Preparation the reader is not only provided with specific methods of specimen preparation, but is urged to use a common sense approach before even laying hands on a specimen (e.g. "...have analytical goals clearly in mind — precision, accuracy, concentration range, cost, speed...").

There are a few typographical errors, fortunately most are obvious, and one diagram is labelled incorrectly. A surprising feature in the chapter on radiation hazards in spectrometry is the authors' use of outdated terminology when referring to units of measurement for ionizing radiation, e.g. the *rad* and the *rem* as opposed to the ICRU- and ICRP-approved units, the *gray* and the *sievert*. Notwithstanding these remarks, Jenkins et al. have produced a work of considerable value to all current practitioners of XRF. In the preface to this edition, they state that they hope that it will enjoy the same success as the first, and take its place in the literature on X-ray materials analysis. I have no doubt that this will be the case.

Photochemical-fluorimetric method for the determination of total chlorophenoxyacid herbicides[1]

Sergei A. Eremin[2], Belkacem Laassis, Jean-Jacques Aaron*

1, Rue Guy de la Brosse, 75005 Paris, France*

Abstract

A room temperature photochemically-induced fluorescence (RTPF) method is proposed for the quantitative analysis of seven widely-used chlorophenoxyacid herbicides. The influence of organic solvent, pH (in aqueous solutions), methanol percentage, and UV irradiation time on the excitation and emission wavelengths and fluorescence intensity was investigated. It was found that the largest fluorescence signals were obtained in a mixture of methanol and pH 5 buffer (50/50, v/v), while organic solvents and water produced generally lower signals. The tri- and bichlorinated phenoxyacid herbicides were photolysed significantly more slowly than the monochlorinated derivatives, and the derivatives of 2-propionic acid were photodegraded more quickly than the corresponding derivatives of acetic and butyric acid. Selected UV irradiation times were found to be 15 min for all herbicides under study. Linear calibration graphs were established over about one to two orders of magnitude in the interval 0.1–10 μg ml^{-1}. The RTPF limits of detection were between 36 ng ml^{-1} and 179 ng ml^{-1}, according to the compound. Analytical application of RTPF to river water samples containing chlorophenoxyacid herbicides is discussed.

Keywords: Photochemically-induced fluorescence; Chlorophenoxyacid herbicides

1. Introduction

Monitoring of environmental samples for pesticide residues has become very important. The detection of their presence in surface water is a convenient indicator of contamination. Chlorophenoxyacid herbicides are of particular concern because of their potential toxicity towards animals and humans [1]. Some of them, such as 2,4-dichlorophenoxyacetic acid (2,4-D) and 2-(2-methyl-4-chlorophenoxy) propionic acid (MCPP or mecoprop), are still widely-used herbicides for broadleaf weed conrol, while another, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), has been restricted since 1969.

Established screening procedures for detection of these herbicides include gas chromatography [2], used after extraction of samples, or liquid chromatography with on-line selective preconcentration [3]. However, immunoassay methods provide simpler, cheaper, and more robust methods for the direct analysis of a large number of samples. Several radioimmunoassays [4,5] and enzyme-linked immunosorbent assays (ELISA) for specific determination of 2,4-D [6] and most phenoxyacid herbicides have been described [7,8]. Recently, more rapid, but less sensitive, polarization fluoroimmunoassays have been proposed for specific measurement of 2,4-D and 2,4,5-T [9].

The continued application of herbicides and growing concern about the potential contamination of ground water require regulations, such as the European Community drinking water ordinance, which set a very low upper limit for pesticide concentrations of 0.1 ng ml^{-1} for a single substance, and 0.5 ng ml^{-1} for total pesticides [10]. The higher, and more reasonable, detection limits in drinking water proposed as health advisory levels for individual pesticides have been established by the Office of Water of the US Environmental Protection Agency. For example, for 2,4-D, this limit is 70 ng ml^{-1}. However, real water samples can occasionally contain up to a hundred times higher concentrations. Moreover, high 2,4-D concentrations of about 2.5 μg ml^{-1} could be measured in the urine of workers involved in spraying this herbicide, 3 days after exposure [11].

Many pesticides are persistent and should be continuously monitored. Traditional analytical methods used in pesticide analysis are expensive because they require costly laboratory equipment, and they are generally time-consuming. The initial screening of pesticides should be technically simple, inexpensive, and useful for routine analysis of a large number of samples. Recently, we developed a simple method of detection of some aromatic pesticides based on a photodegradation reaction, which may be applicable to the very simple and quick preliminary monitoring of water samples [12]. The main advantages of the method, named room temperature photochemically-induced fluorescence (RTPF), are its simplicity, ra-

pidity, and the low cost of the required equipment [13].

The aim of this paper was to investigate the photochemically-induced fluorescence properties of a series of chlorophenoxyacid herbicides (Fig. 1) in different solvents, and to develop a rapid RTPF screening method for the determination of the chlorophenoxyacid herbicide total concentration in a bulk solution.

2. Experimental

2.1. Reagents

Chlorophenoxyacid herbicides were obtained from Sigma or Merck (analytical grade). The solvents (spectroscopic grade) were purchased from Merck. The buffer solutions were obtained from Janssen Chimica. Deionized water was utilized for preparing binary mixtures.

2.2. Apparatus

Fluorescence measurements were performed on a Kontron SFM-25 spectrofluorimeter, using a Kontron SFM-25 data control and acquisition program. The high voltage level on the instrument lamp was 600 V, and the gain factor varied from 1 to 10. A 200 W HBO Osram high-pressure mercury lamp with an Oriel model 8500 power supply was utilized for the photodegradation reaction. The photochemical set-up included a light box, consisting of a fan, a mercury lamp and a convenient quartz lens. A standard Hellma 1 cm^2 quartz reaction cuvette (sample cell) was placed on an optical bench at 45 cm from the mercury lamp [13].

2.3. Procedure

Standard stock solutions of chlorophenoxyacid herbicides (0.1–0.5 mg ml^{-1}) were prepared from the corresponding compounds by dissolving them in ethanol, and were stored at room temperature. Serial dilutions were freshly done for the working solutions. The photolysis reaction was performed by irradiating with UV light a 3 ml volume of
Fig. 1. Names and chemical structures of the chlorophenoxyacid herbicides under study.

dilute herbicide solution which was magnetically stirred at room temperature. For the analytical applications, a 50/50 v/v mixture of methanol and a pH 5 buffer and a 15 min irradiation time were chosen. The curves of the fluorescence intensity (I_F) vs. the various parameters (time, methanol percentage, pH) were plotted at constant excitation (276 nm) and emission (292 nm) wavelengths of the pesticide photoproducts.

3. Results and discussion

3.1. Photochemically-induced fluorescence properties

The chlorophenoxyacid herbicides have no native fluorescence, but they can be photolysed into strongly fluorescent photoproducts. The fluorescence intensity of photodegraded herbicide increased with negligible change in the shape of the emission spectra during UV irradiation (Fig. 2). For all chlorophenoxyacid herbicides, the excitation spectra of photoproducts presented a broad maximum centered near 276 nm. The latter value

was selected as the analytical excitation wavelength. The emission spectra varied slightly with the compound, its concentration, and the type of solvent (Table 1). To develop a screening method, we chose an emission wavelength of 292 nm for all chlorophenoxyacid herbicides under study. The photoproducts have an unknown structure, but they probably consist of a mixture of photodegradation products, including derivatives produced by hydrolysis, dechlorination and polymerization reactions. As is well known, the chlorinated phenols are very quickly (20-160 s) photodegraded [14]. The main identified products are lower chlorinated phenols, polymeric and dihydroxylated products, and phenol, which present excitation and emission wavelengths at 270 and 290-300 nm respectively [14].

3.2. Effect of solvent

The effect of several solvents on the photochemically-induced fluorescence properties of 2, 4-D was investigated. As can be seen in Table 1, no significant shift of the emission wavelengths occurred upon changing solvent but the fluorescence
Fig. 2. Effect of the ultraviolet irradiation on the fluorescence emission spectra of 5.0 μg ml^{-1} 2,4-D in 2-propanol, at room temperature. Irradiation times were 0, 5, 10, and 15 min.

Fig. 3. Effect of the percentage of methanol on the fluorescence intensity of 2,4-D (5 μg ml^{-1}) in a methanol/water mixture after 15 min irradiation.

signal was increased considerably in alcohols compared to water. Similarly, a strong influence of solvents on the fluorescence intensity of photoproducts was found in the case of other pesticides [12,15]. For analytical purposes, methanol was

Table 1
Photochemically-induced fluorescence properties of 2,4-D (5 μg ml^{-1}) in various solvents

Solvent	λ_{em} (nm)[a]	I_F^{b}
Water	296	1.0
Methanol	290	3.9
2-Propanol	293	4.3
Ethanol	292	3.8
Dimethylsulfoxide	295	0.8
Dimethylformamide	291	1.4
Acetonitrile	297	0.8
Buffer (pH 4)	296	0.7
Buffer (pH 10)	294	0.5

[a] λ_{em} = maximum emission wavelength.
[b] I_F = relative fluorescence intensity, normalized relative to the fluorescence intensity in water. A 15 min irradiation time was used for all solvents.

selected as the solvent giving the largest fluorescence signal, and for economic reasons.

3.3. Effect of the percentage of methanol

In order to evaluate the influence of water in binary mixtures on the fluorescence intensity of the photoreaction, we tested the effect of the percentage of methanol on the photochemically-induced fluorescence intensity of 2,4-D. As can be observed in Fig. 3, the photochemically-induced fluorescence signal in a 50/50 v/v methanol–water mixture is higher than in pure methanol or water.

3.4. Effect of pH

The influence of pH on the photochemical reaction of 2,4-D was investigated. The fluorescence intensity of the photoproducts changed considerably with the pH of the reaction medium (Fig. 4). A pH value of 5, corresponding to the maximum photochemically-induced fluorescence signal, was considered as optimum for analytical applications. The unbuffered water samples present pH values varying between 4 and 7. For all further analytical experiments we chose a methanol/pH 5 buffer mixture (50/50 v/v) as the ideal solvent for photodegradation of chlorophenoxyacid herbicides.
Fig. 4. Effect of the buffer pH on the fluorescence intensity of 2,4-D (5 μg ml⁻¹) in a 50/50 v/v methanol/pH 5 buffer mixture after 15 min irradiation.

3.5. Effect of irradiation time

The I_F vs. irradiation time curves exhibited two types of shape. For 2,4-D and 2,4,5-T the curves were characterized by a continuous increase of the fluorescence signal, no well-defined maximum value being reached up to a 30 min irradiation time (Fig. 5). However, in the case of MCPP and MCPA, the fluorescence intensity increased, reached a maximum value, and then a small decrease in intensity occurred (Fig. 5). For all compounds studied, the kinetics of photodegradation are rather slow. A very small influence of the herbicide initial concentration on the kinetics of photodegradation was observed. Generally, for
Fig. 5. Effect of the ultraviolet irradiation time on the fluorescence intensity of 5 μg ml⁻¹ 2,4-D (●) and 3 μg ml⁻¹ MCPA (○) in a 50/50 v/v methanol/pH 5 buffer mixture.

low herbicide concentrations the fluorescence intensity maximum was reached more quickly. For this reason, we chose an optimal irradiation time of 15 min for the RTPF detection of all chlorophenoxyacid herbicides, in order to achieve shorter analysis times with a minimum decrease in sensitivity. The tri- and bichlorinated phenoxyacid herbicides (2,4,5-T and 2,4-D) were photodegraded significantly more slowly than the monochlorinated derivatives (MCPP and MCPA), a behaviour which was also found for chlorophenols [14]. The derivatives of 2-propionic acid (MCPP and 2,4-DP) were more quickly photodegraded than the corresponding derivatives of acetic acid (MCPA and 2,4-D) and butyric acid (MCPB and 2,4-DB).

3.6. Analytical figures of merit

Linear log–log plots of the photochemically-induced fluorescence intensity of chlorophenoxyacid herbicides vs. initial concentration were established in the range 0.1–10 μg ml⁻¹ with good correlation coefficients (Table 2). As indicated by the slope values of the calibration plots, the sensitivity of the method was higher for the monochlorinated acetic acid derivatives than for the di- and trichlorinated derivatives.

The limits of detection (LODs) varied between 36 and 179 ng ml⁻¹, according to the compound. The lowest LOD value (36 ng ml⁻¹) was obtained for mecoprop. These RTPF LOD values were close to those determined by the polarization fluoroimmunoassay method [9], for which a specific reagent is needed.

The precision of RTPF measurements was satisfactory. For example, the relative standard deviation (RSD) found for a 2,4-D concentration of 1 μg ml⁻¹ was 1.3% (n = 5).

3.7. Application to river water

Water samples were collected from the Marne river, near Paris, at 1 month intervals, and were filtered through a Whatman filter paper. A pH value of 7.8 was measured for these samples. 5 ml portions of filtered river water samples were spiked with 0, 30, 60, 90, 120, and 150 μl meco-

Table 2
Analytical figures of merit for the RTPF determination of chlorophenoxyacid herbicides[a]

Herbicide	Concentration range (μg ml^{-1})	Regression equation[b]		r[c]	LOD[d] (ng ml^{-1})
		A	B		
2,4-D	0.2–2.5	1.56	0.74	0.997	103
2,4-DP	0.1–5.0	1.83	0.74	0.991	55
2,4-DB	0.3–10.0	1.50	0.80	0.992	179
2,4,5-T	0.3–10.0	1.50	0.65	0.992	119
MCPA	0.3–5.0	1.85	0.84	0.998	74
MCPP	0.1–5.0	2.13	0.85	0.999	36
MCPB	0.1–5.0	1.87	0.79	0.996	59

[a] In a 50/50 v/v MeOH/pH 5 buffer mixture
[b] $\log I_f = A + B \log C$; I_f = relative fluorescence intensity; C = analyte concentration (μg ml^{-1})
[c] r = correlation coefficient.
[d] LOD = limit of detection, defined as the concentration of analyte giving a signal-to-noise ratio of 3.

prop stock solution (166 μg ml^{-1} in ethanol), and a 5 ml methanol volume was added to each spiked solution. The final mecoprop concentrations were 0, 0.5, 1.0, 1.5, 2.0, and 2.5 μg ml^{-1} respectively. These samples were treated ultrasonically to remove dissolved air, and their fluorescence signal was measured after a 5 min irradiation time.

In order to evaluate the analytical usefulness of the RTPF method, recovery experiments of mecoprop were performed on the spiked Marne river samples, using the direct measurement procedure. Analytical results are shown in Table 3. It can be seen that satisfactory recoveries of mecoprop were obtained, with values ranging from 92 to 116%. In most cases, no interference was found in real samples, although one of the Marne river water samples showed the presence of residual mecoprop, or some other interfering compound, at the 100 ng ml^{-1} level. Therefore, our results demonstrate that RTPF does not suffer significantly from interferences due to the river matrix used.

In some "real" cases, the presence of other pesticides or different types of organic matter in the samples may interfere in the RTPF determination of chlorophenoxyacid herbicides. However, we feel that it is possible to improve considerably the selectivity of our method by selecting different UV irradiation times for other pesticides, or by applying to RTPF specific techniques such as

derivative spectra or partial least-squares (PLS) multivariate calibration [16,17]. Also, on-line liquid chromatography is adaptable to RTPF detection [13], and can be used for separation of the various chlorophenoxyacid herbicides, if more selectivity is required.

Table 3
Recovery of mecoprop in spiked Marne river samples by RTPF[a]

Sample[b]	Mecoprop (μg ml^{-1})		Recovery (%)
	Added	Found	
1	–	0.00	–
	0.50	0.47	94
	1.00	1.03	103
	1.50	1.56	104
	2.00	1.94	97
	2.50	2.56	102
2	–	0.00	–
	0.50	0.58	116
	1.00	0.92	92
	1.50	1.42	95
	2.00	2.06	103
	2.50	2.51	101

[a] The direct measurement procedure was used.
[b] The Marne river samples were collected at 1 month intervals. See text for details of the treatment of samples.

4. Conclusion

We can conclude that RTPF is a simple, precise, and rather sensitive method for the determination of the chlorophenoxyacid herbicide total content of samples. Therefore, RTPF may be used for preliminary, rapid screening of waste water or environmental samples and for pesticide control.

Synthesis and analytical properties of a chelating resin functionalised with bis-(*N*,*N'*-salicylidene)1,3-propanediamine ligands

Kapil Dev, G.N. Rao*

Department of Chemistry, Indian Institute of Technology, Delhi, Hauz Khas, New Delhi-110 016, India

Abstract

A polystyrenedivinylbenzene-based macroreticular resin was functionalised with bis-(*N*,*N'*-salicylidene)1,3-propane-diamine ligands and its analytical properties have been investigated. The pH dependence of metal resin chelation has been determined for Cu(II), Ni(II), Co(II), Zn(II), Fe(II), Mn(II), Pb(II), Cd(II) and Cr(III). Trace amounts of these metal ions were quantitatively retained on the resin at neutral pH and easily recovered by elution with 1 N hydrochloric acid. The resin exhibits good chemical stability and fast equilibration with the metal ion making it useful for rapid concentration of trace amounts of metal ions on the resin columns.

Keywords: Chelating resin; Bis-(*N*,*N'*-salicylidene)1,3-propanediamine

1. Introduction

Chelating resins have found widespread applications in the enrichment of metals from a variety of matrices. A large number of chelating resins incorporating a variety of ligands (e.g. ethylenediamine tetraacetic acid [1,2], iminodiacetic acid [3,4]) have been prepared and their analytical properties investigated. Fritz and co-workers synthesised and applied resins containing sulphonic acid, amide and hexylthioglycolate groups [5–7]. Sughi et al. reported polystyrene resin containing phenylalanine groups [8]. In our earlier communi-

cations we have reported resins containing *N*,*N*-bis(2-hydroxyethyl)glycine and *N*-hydroxyethylethylene-diamine groups [9,10].

Polymeric Schiff's bases constitute an important class of chelating resins. A number of such resins have been propared and studied for their ion-selective properties. Bayer [11,12] was first to introduce such polymeric ligands and reported relative stabilities of complexes formed with different metal ions. Bottino et al. [13] reported preferential complexation of nickel(II) over other metal ions with a polymeric Schiff's base chelating resin. A renewed interest developed for such chelating polymers with N,O-donor atoms, as they have been found to possess very good selectivity for

* Corresponding author. Fax: (91) 11-686-2037.

transition metals and show negligible affinity for alkali and alkaline earth metals. Most of these chelating resins have been prepared by polycondensation reactions. Though they possess high selectivity and capacity, their mechanical and chemical stability is not good [14].

In the present investigation we have prepared a Schiff's base of salicylaldehyde and 1,3-propanediamine (Bis-(N,N'-salicylidene)1,3-propanediamine) and incorporated it on a macroreticular polystyrene divinyl benzene-based resin (XAD-4). Polystyrene divinyl benzene support is expected to give additional stability while retaining the analytical properties of the Schiff's base ligand. The resin has been characterised, and the sorption behaviour of different metal ions on the resin has been studied.

2. Experimental

2.1. Instrumentation

An ECIL India 4139 flame atomic absorption spectrometer was used for monitoring the concentration of the metals. An Elico (India) digital pH meter LI-120 was used for pH measurements. Infrared spectra were recorded on a Nicolet DX FTIR spectrophotometer with KBr pellets. A Perkin 240C elemental analyser was used for elemental analysis. A mechanical shaker (Scientific Instruments, India) with an incubator, which had a speed of 200 strokes min^{-1}, was used for batch equilibration.

2.2. Reagents

The stock metal ion solutions were prepared by dissolving the reagent grade nitrate and chloride salts of the metal in water or the matrix acid and they were standardised by appropriate methods. XAD-4 was obtained from Fluka. Salicylaldehyde and 1,3-propanediamine were obtained from E. Merck and were used after distillation. The following buffer solutions were used to control the pH of the metal ion solution: hydrochloric acid–glycine (pH 1–3); acetic acid–sodium acetate (pH 3–5); disodium hydrogen phosphate–potassium

dihydrogen phosphate (pH 5–8); and sodium borate–hydrechloric acid (pH 8–9).

2.3. Preparation of bis-(N,N'-salicylidene)1,3-propanediamine (Salpen) [15]

1,3-Propanediamine (1.7 ml) in 50 ml of freshly distilled ethanol was taken in a round-bottomed flask and salicylaldehyde (3.81 ml) in 30 ml of freshly distilled ethanol was added dropwise with vigorous stirring. The mixture was cooled in an ice bath and the product was filtered and recrystallised from chloroform. On analysis of Salpen, the following elemental compositions (%) were found: C, 72.22; H, 6.24; N, 9.79. The calculated values are C, 72.34; H, 6.38; N, 9.92.

2.4. Preparation of XAD₄–Salpen resin

XAD-4 was functionalised via esterification. XAD-4 beads (10g) were refluxed with acetic anhydride (20 ml) and anhydrous aluminium trichloride (1 g) in petroleum ether (60–80°C) at 70°C for 30 h. The product was filtered off and washed with 50 ml hexane. The intermediate product (II, Scheme 1) was then stirred in 500 ml water containing 8.5 g potassium permanganate and 10 g sodium hydroxide at 40°C for 1 h. The product was filtered off, washed with water and then treated with hydrochloric acid (1:1). It was then refluxed with 50 ml thionyl chloride at 60°C for 30 min. The intermediate resin(IV) was refluxed with Salpen (2.5 g) and sodium ethoxide (11.3 mM) in DMF at 90°C for 8 h. A light yellow resin
Scheme 1. Synthesis of the resin.

was obtained. A total of 20 g resin was perpared and 200–250 mesh fraction of the resin was used for metal sorption studies.

2.5. pH dependence of metal ion uptake

The optimum pH of metal ion uptake was determined by batch equilibration technique. Excess metal ion (50 ml, 50 μg ml^{-1}) was shaken with 100 mg of resin for two hours. The pH of the metal ion solution was adjusted prior to equilibration over a pH range of 2–9 with buffer solutions. For determining the effect of pH on the trace metal ion uptake, a buffered solution (50 ml) containing 5μg ml^{-1} of metal ion was equilibrated with 100 mg of resin. The concentration of the adsorbed metal ion was determined after eluting with 1 N hydrochloric acid by atomic absorption spectrometry (AAS). Sorption experiments were carried out in duplicate each time.

2.6. Resin capacity

The capacity of the resin was determined by shaking the excess metal ion (50 ml, 100 μg ml^{-1}) with 100 mg resin (50 mg for cadmium and lead) for 6 h at the optimum adsorption pH. The resin was filtered off, and the concentration of the remaining metal ion in the solution was determined by AAS. The capacity was also checked after soaking the resin in 1 N HCl/1 N alkali for one day.

2.7. Equilibration time

To determine the time of equilibrium for the metal under investigation, the metal ion solution (50 ml, 10 μg ml^{-1}), at a constant pH, was sampled in six bottles. The first bottle was removed from the shaker after 5 min and the remaining bottles at intervals of 15 min. The last bottle was removed after 2 h. The concentration of the metal ion was determined by AAS. The time of equilibration for all the metal ions was determined in a similar manner. The duplicate values agreed with a precision of ± 2%.

2.8. Effect of diverse ions

Standard solutions of 50 ml of Cu, Ni, Co, Zn and Pb (1–5 μg ml^{-1} each) containing sodium chloride, Mg and Ca ions as interferents were analysed.

2.9. Enrichment of metal ions

Both batch as well as column methods were used to concentrate the trace metal ions. For batch equilibration, the sample solution (250–500 ml) containing (0.1 μg ml^{-1}) metal ion was adjusted at optimum pH of adsorption with buffer solution and then shaken with 100 mg of resin for about 15 min. Sorbed metal ions were eluted with 1 N hydrochloric acid (10 ml) and the concentration of the metal ion in the eluent was determined with AAS.

For the column method, the dry resin (0.5 g) was packed into a glass column (0.5 × 6 cm) and conditioned with the buffer solution. The metal ion solution (0.05 to 0.1 μg ml^{-1}) was passed through the column at a flow rate of 2.0 ml min^{-1}. The adsorbed metal ion was desorbed from the resin with 1 N hydrochloric acid (5 ml).

3. Results and discussion

The resin was synthesised according to Scheme 1. Spherical macroreticular styrenedivinyl benzene beads were used as starting material.

The coordination of the Salpen ligand to the polymer by the displacement of the –Cl is indicated by the absence of the ν_{C-Cl} band at 670 cm^{-1} in the spectrum of the final resin V (Scheme 1, Fig. 1). Another feature in the spectrum of resin IV is the absorption band at 1740–1765 cm^{-1}, probably resulting from Fermi resonance between the carbonyl band and the overtone of a longer wavelength band near 875 cm^{-1} [16]. This band appears in the spectrum of intermediate resin IV and disappears in final resin V. The presence of the all major absorption bands corresponding to the Salpen ligand in the final resin V with reduced intensities, confirms the incorporation of the ligand.
Fig. 1. Infrared spectra of resins (KBr disks): (III) carboxylated resin; (IV) acid chloride resin; (V) Salpen resin.

Salpen acts as a tetradentate ligand, coordinating with the metal ion through hydroxyl group oxygens and tertiary nitrogens [17]. However in polymer-bound Salpen, one of the hydroxyl group oxygens is used for binding to the polymer, leaving one free hydroxyl group and two tertiary nitrogens as binding sites for the metal ions.

Nitrogen analysis of the resin gave 1.72% nitrogen. Assuming that all the nitrogen is part of the intact Salpen groups, the capacity for the metal ion should be 0.61 mmol g^{-1} of resin. The values actually obtained are reported in Table 1. The lower values could be due to the rigidity of the polymeric matrix and the inability of all the Salpen groups to participate in chelation, due to steric restriction.

The resin was found to be fairly stable on successive treatment with dilute acid and alkaline solutions. The stability was checked by the change

of the hydrogen metal exchange capacity and the nitrogen content.

In a preliminary experiment, the sorption behaviour of some metal ions on XAD$_4$–Salpen resin at different pH values has been examined by

Table 1
Metal uptake capacities

Metal	Optimum pH	Capacity (± SD) (mmol g^{-1} resin)
Cu(II)	8.52	0.46(0.01)
Ni(II)	8.10	0.42(0.01)
Co(II)	8.03	0.43(0.01)
Zn(II)	8.05	0.38(0.02)
Cd(II)	6.59	0.40(0.02)
Pb(II)	6.04	0.39(0.01)
Fe(II)	5.05	0.24(0.02)
Mn(II)	8.01	0.36(0.02)

SD, Standard deviation
Fig. 2. Effect of pH on metal sorption with Salpen resin.

the batch method and the results are shown in Fig. 2. In most of the cases the sorption increases with increasing pH, reaching a limiting value in each instance, followed by a decrease in sorption, beyond the limiting value. Sorption of copper and cadmium reaches the limiting value at around neutral pH while for manganese, zinc, cobalt and nickel the maximum sorption is beyond pH 7.5. The XAD_4–Salpen resin shows relatively low affinity towards iron(II) and it does not interact with Cr(III) at any pH.

The capacity of the resin is an important factor to determine and is the quantity of resin required to remove quantitatively a specific metal ion from the solution. The capacity of each metal ion is reported in Table 1.

The sorption behaviour of the trace amount of metal ion on the resin is shown in Fig. 3. The sorption is quantitative for the trace metal ions in the region of pH 6.5–9 for Cu(II); 7.5–9 for Ni(II); 7–8.5 for Co(II); 7–9 for Zn; 7–9 for Mn(II); 5.5–6.5 and 8–9 for Pb(II); and 6–9 for Cd(II). Sorption of Fe(II) is 92% in the pH range

5–6. The time of equilibration was determined for all the metal ions at the optimum pH of sorption and the results are plotted in Fig. 4.

The kinetics of the resin–metal interaction is sufficiently rapid for most of the metal ions. Sorption reaches a 80–90% extraction level within 5–7 min of the interaction of the metal ions with the resin. This allows the resin to be used in a packed column as it requires fast equilibration because of the short contact time between the resin and the solution.

Manifold amounts of NaCl, Ca and Mg do not effect the recovery of the metal ions from the solution. The results in Table 2 show the recovery rates in the presence of excess of these foreign ions. This makes the resin useful for trace concentration of metal ions from natural samples which contain large concentrations of alkali and alkaline earth metals

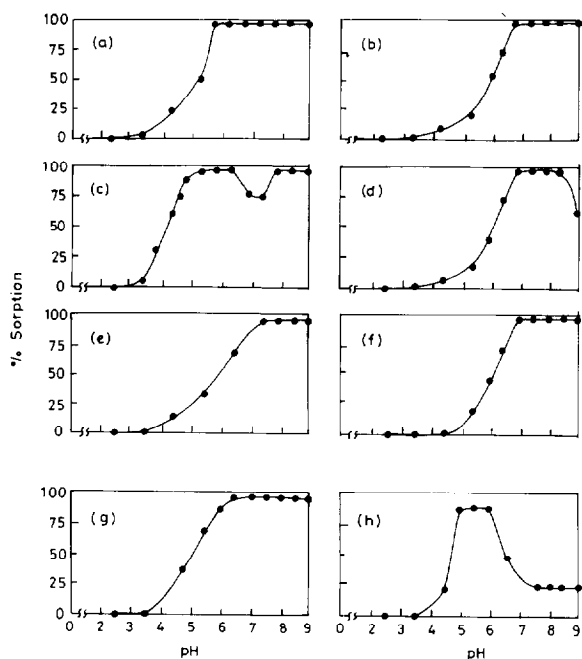
The resin shows good stability towards dilute acids and bases and its metal uptake capacity was not affected after regenerating it several times.


Fig. 3. pH dependence of the uptake of trace metals: (a) Cd(II); (b) Zn(II); (c) Pb(II); (d) Co(II); (e) Ni(II); (f) Mn(II); (g) Cu(II); (h) Fe(II).

Preconcentration of all metal ions on the resin-was carried out by batch and column methods, and the results are shown in Tables 3 and 4. Metal ions could be enriched up to 40–50 times with XAD_4-Salpen resin. The column method was
Fig. 4. Rate of uptake of metal ions.

found to be better for enrichment of the metal ions as the sorption is more complete and subsequent elution is easier. But the column method is more time consuming than the batch method for XAD_4-Salpen resin.

Table 2
Effect of diverse ions

Interfering ions[a]	Recovery (%)

Metal ion	Amount of metal ion ($\mu g~ml^{-1}$)	Sample volume (ml)	Metal found[a] ($\mu g~ml^{-1}$)
Cu(II)	0.05	250	2.45
Cu(II)	0.10	250	4.98
Ni(II)	0.05	250	2.48
Co(II)	0.05	250	2.42
Zn(II)	0.05	250	2.41
Pb(II)	0.05	250	2.51

[a] Values agree with a precision of $\pm 1\%$.

4. Conclusions

XAD$_4$-Salpen resin has been found useful for the concentration of trace metals from aqueous solutions. Fast equilibration of the metal on the resin makes it applicable for the conventional column method also. The capacity of the resin is also high enough for use in the simultaneous concentration and determination of several metals. Low affinity of the resin towards alkali and alkaline earth metals indicates its use for natural samples.

Abstract

A continuous monitoring system for vinyl chloride gas in air has been developed using an HCl monitoring tape and pyrolyzer consisting of a heater around a quartz tube. It is based on the color change of the tape by reaction with HCl gas produced by decomposition of vinyl chloride gas in the heated quartz tube. The conversion efficiency of vinyl chloride into HCl depends on the temperature of the pyrolyzer. The tape impregnated with a coloring solution that includes Metanil Yellow (pH indicator; pH 1.2–2.3, red–yellow), glycerin and methanol is a highly sensitive means of detecting HCl gas. When vinyl chloride gas was passed through the heated quartz tube (910°C) and the HCl gas produced was passed through the tape, the color of the tape changed from yellow to red. The degree of color change was proportional to the concentration of vinyl chloride gas with a constant sampling time and flow rate. The degree of color change could be recorded by measuring the intensity of reflecting light (555 nm). This method is scarcely affected by other gases with the exception of chlorinated hydrocarbons such as trichloroethylene and chloroform or strong acids such as HCl gas. Reproducibility tests showed that the relative standard deviation of the relative intensity ($n = 10$) was 4.5 for 5 ppm vinyl chloride. The detection limit was 0.4 ppm for vinyl chloride with a sampling time of 40 s and a flow rate of 300 ml min^{-1}.

Keywords: Vinyl chloride; HCl monitoring tape; Pyrolyzer

1. Introduction

Exposure to vinyl chloride gas in the workplace often occurs because of leakage or discharge during its storage, transportation or production. Vinyl Chloride (1000 ppm) is a colorless gas, with a distinctive chloroform-like smell and causes narcotic symptoms. Its threshold limit value (TLV) has been defined as 5 ppm by the American Conference of Governmental Industrial Hygienists [1].

The monitoring of vinyl chloride gas efficiently and reliably at levels below 5 ppm is needed. To achieve widespread routine use, the method

---
* Corresponding author.

should be simple, capable of unattended operation and inexpensive. However, while various methods have been developed [2–4] for the determination of vinyl chloride gas in air, few, if any, exhibit all these desirable characteristics. Although several methods have been used for the detection of vinyl chloride gas, including gas chromatography, absorptiometry and use of a gas detection tube, they are batchwise procedures and unsuitable for a continuous method. The chlorinated hydrocarbon can be determined by measuring HCl gas produced by its decomposition through a pyrolyzer [5,6]. We have already developed a continuous monitoring system for 1,1-dichloro-2,2,2-trifluoroethane in air by using a pyrolyzer consisting of a heater around a quartz tube and an electrochemical HCl sensor [7]. At first, we investigated this system for vinyl chloride gas, but it could not detect low concentrations (5 ppm). Furthermore, the lifetime of the electrochemical HCl sensor is short owing to the degradation of the catalyst and contamination of the electrolyte solution.

In this experiment, we tried to produce a new monitoring system using a pyrolyzer and the sensitive tape for HCl gas that had already been developed, instead of an electrochemical HCl gas sensor. Because the tape monitor [8–10] is highly sensitive and selective, easy to maintain and of low running cost it was thought to be suitable for our purpose. The sampling spot of the tape is renewed for every measurement. Thus the base level and sensitivity are constant for all measurements.

As no suitable reagents react with vinyl chloride gas to produce a color stain, we have developed a continuous monitoring system for vinyl chloride gas in air using a pyrolyzer consisting of a heater wound around a quartz tube and an HCl monitoring tape [9]. It is based on the color change of the tape by reaction with HCl gas produced by decomposition of vinyl chloride gas in passing through the heated quartz tube. We had investigated the tape using pH indicator (Metanil Yellow), with a color change from yellow to red for HCl, because of the high response. This method has the desirable attributes of high sensitivity, wide range of concentration, simplicity, portabil-

ity, and ease of adaptation to automatic, unattended operation. In this paper, we describe a study of the development of a continuous monitoring system for vinyl chloride gas in the range 0.4–10 ppm. The conversion efficiency of vinyl chloride gas to HCl gas at various heater temperatures, gas flow rates and sampling times and the reproducibility of response were investigated to evaluate the characteristics of the system for the determination of vinyl chloride gas.

2. Experimental

2.1. Gas samples

The standard vinyl chloride gas mixtures were prepared by controlling the flow rates of streams of primary standard 21 ppm vinyl chloride (N_2 balance; Nippon Sanso) and air from a cylinder (99.9%; Taiyo Sanso). Various standard chlorinated hydrocarbon gas mixtures were generated continuously by purging the diffusion tube containing various chlorinated hydocarbons (analytical reagent grade; Tokyo Kasei Kogyo) with a constant flow of purified air. The gas concentration was calculated from the flow rate and the mass loss of the chlorinated hydocarbons. The diffusion tube in a gas generating system (PD-1B; Gastec) was kept at $30 \pm 0.1°C$ in a thermostatically controlled water bath.

2.2. Pyrolyzer

The pyrolyzer consists of a quartz tube (4 mm i.d, 6 mm o.d. and 180 mm length), in which a cylindrical mass (4 mm diameter and 5 mm length) of gold wire (50 μm diameter and 10 m length) is packed at the center. Heater wire of 900 mm length ($\approx 13\Omega$) is wound around the quartz tube of 34 mm length. The distance between the windings is 0.5 mm.

When the applied voltage is 13.0 V the temperature in the quartz tube, which is measured by a Pt–Rh thermometer, is 910°C. The construction of the pyrolyzer is shown in Fig. 1.
Fig. 1. Cross-section of pyrolyzer.

2.3. Monitoring tape

The processing solution used had the same composition as that used previously [9]. The monitoring tape for HCl gas was prepared as follows: the porous cellulose tape (Whatman 1Chr papers, 20 mm wide, 0.18 mm thick, 25 m long) was immersed in the processing solution for 1 min, oven-dried at 40°C and stored in a desiccator.

2.4. Apparatus

Samples were introduced to the pyrolyzer and then to the monitoring tape for HCl gas with an air-pump as shown in Fig. 2. The tape monitor was connected to the pyrolyzer with Teflon tubing (4 mm i.d and 6 mm o.d.).

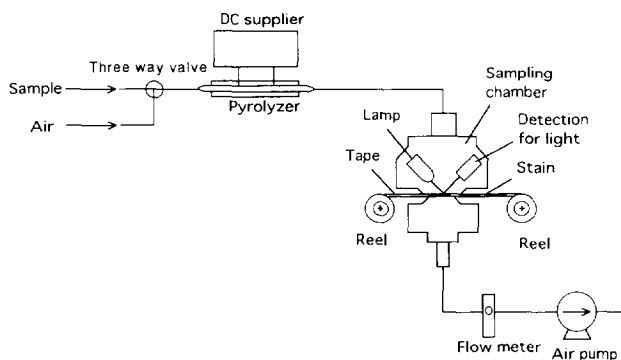
The end (approximately 2 cm in diameter) of the tube from the pump was attached tightly to the tape. The sample gas was sucked at a constant flow rate (300 ml min^{-1}) for a constant sampling time (40 s). The Metanil Yellow on the tape reacted with HCl produced by decomposition of vinyl chloride gas passing through the pyrolyzer to give a change in its homogeneous color. The


Fig. 2. Schematic diagram of monitoring system.

Table 1
Effect of weight of Au wire on response (Concentration of vinyl chloride. 5 ppm; sampling time, 40 s)

Weight (g)	Response
0.2	0.011
0.3	0.076
0.4	0.108
0.5	0.105

degree of color change was recorded by measuring the relative reflectance at 555 nm. The tape exposed was renewed by moving it 10 mm every 40 s. The response is defined by $A = -\log V_1/V_0$, where V_0 and V_1 are the outputs of a blank (atmospheric air) and the sample respectively. A period of 30 min was required to measure the responses after the tape was set in the apparatus. All measurements were carried out at 25 ± 2°C.

3. Results and discussion

3.1. Effect of mass of gold wire

To imporve the sensitivity for vinyl chloride gas, the effect of a cylindrical mass of gold wire packed at the center of the quartz tube was examined (Table 1). The response increased with increase in weight of the cylindrical mass ($\approx$ 4 mm diameter and 5 mm length) of gold wire and became nearly constant in the region 0.4–0.5 g. The optimum weight of the mass was found to be 0.4 g.

3.2. Effect of temperature of pyrolyzer on response

It was found that the system responded to vinyl chloride gas when the temperature of the pyrolyzer was greater than 600°C. Table 2 shows the effect of the temperature of the pyrolyzer on the response and conversion efficiency of vinyl chloride gas to HCl gas. The conversion efficiency is defined by (response of 5 ppm of vinyl chloride)/(response of 5 ppm HCl) × 100. As the temperature of the pyrolyzer increased, the concentration

Table 2
Effect of temperature of pyrolyzer on response and conversion efficiency (Concentration of vinyl chloride, 5 ppm; sampling time, 40 s)

Temperature (°C)	Response	Conversion efficiency (%)
670	0.051	3.7
720	0.073	5.2
770	0.086	6.1
820	0.099	6.8
870	0.106	7.2
910	0.113	7.7
970	0.116	7.9

of HCl (the detectable product) increased, but the response for vinyl chloride gas increased and became nearly constant above 910°C. Thus 910°C was chosen as the optimum temperature of the pyrolyzer.

3.3. Gas flow rate

Table 3 shows the effect of sample gas flow rate on the response. The response did not change very much in the region 200–400 ml min⁻¹. Thus 300 ml min⁻¹ was chosen as the optimum sample gas flow rate.

3.4. Calibration graph

Typical calibration graphs for vinyl chloride gas using the optimum experimental conditions are shown in Fig. 3. The detection limit (signal-to-noise ratio = 3) was 0.4 ppm for vinyl chloride gas with a sampling time of 40 s. Reproducibility tests ($n = 10$) showed that the relative standard deviation was 4.5% for 5 ppm vinyl chloride.

Table 3
Effect of sample gas flow rate on response (Concentration of vinyl chloride, 5 ppm; sampling time, 40 s)

Gas flow rate (ml min⁻¹)	Response
100	0.057
200	0.106
300	0.113
350	0.106
400	0.088
Fig. 3. Calibration graphs for vinyl chloride gas. Sampling time: (a) 60 s; (b) 40 s; (c) 20 s.

3.5. Selectivity

The responses of the monitoring system to various gases are given in Table 4. The responses for acetone, toluene, nitrogen dioxide, sulfur dioxide, carbon dioxide, hydrogen, acetic acid, hydrogen sulfide and hydrogen fluoride were less than 0.005. Hydrogen chloride and chlorinated hydrocarbons such as trichloroethylene and chloroform gave a high response. Consequently, this monitoring system for vinyl chloride gas in air is applicable to the working air in the manufacture of vinyl chloride polymer.

Table 4
Response for various gases

Gas examined	Concentration of gas (v/v)	Response
Acetone	5%	<0.005
Toluene	1%	<0.005
Nitrogen dioxide	105 ppm	<0.005
Sulfur dioxide	15.2	<0.005
Carbon dioxide	4.9%	<0.005
Hydrogen	5%	<0.005
Acetic acid	24 ppm	<0.005
Hydrogen sulfide	32 ppm	<0.005
Hydrogen fluoride	6.0 ppm	<0.005
Hydrogen chloride	1 ppm	0.081
Trichloroethylene	3 ppm	0.092
Chloroform	1 ppm	0.080
Vinyl chloride	5 ppm	0.113

Table 5
Long-term stability of the tape and pyrolyzer (Concentration of vinyl chloride, 5 ppm; sampling time, 40 s)

Day	Response
0	0.113
5	0.108
10	0.102
15	0.097

3.6. Long-term stability

The stability for long-term operation is a very important characteristic for monitoring systems. The responses for 5 ppm vinyl chloride were recorded every few days (Table 5). The result demonstrates that this monitoring system gives a reliable quantitative response to vinyl chloride even after two weeks under normal conditions. It is considered that the response factor decrease depends on the deterioration of the pH indicator and/or the change in concentration of reagents on the tape.

In conclusion, the continuous monitoring system using an HCl monitoring tape and a pyrolyzer consisting of a heater around a quartz tube is very suitable for the determination of vinyl chloride gas concentrations in the range 0.1–15 ppm. The method is simple, specific, capable of unattended operation and recommended for both laboratory and field operation.

Determination of ruthenium and osmium in each other's presence in chloride solutions by direct and third-order derivative spectrophotometry

Maria Balcerzak*, Elżbieta Święcicka

Department of Analytical Chemistry, Warsaw University of Technology, ul. Noakowskiego 3, 00-664 Warsaw, Poland

Abstract

Ruthenium and osmium (up to 20 μg Ru(Os) ml^{-1}) can be determined in chloride solutions directly after absorption of RuO_4 and OsO_4 in hydrochloric acid. In 9 M HCl, RuO_4 and OsO_4 are quantitatively converted into $RuCl_6^{2-}$ ($\lambda_{max} = 480.0$ nm, $\epsilon = 4.8 \times 10^3$ l mol^{-1} cm^{-1}) and $OsCl_6^{2-}$ ($\lambda_{max} = 334.8$ nm, $\epsilon = 8.4 \times 10^3$ l mol^{-1} cm^{-1}) respectively. Osmium does not interfere with the determination of ruthenium in the form of the $RuCl_6^{2-}$ complex by direct spectrophotometry. The absorbance of the obtained solution at $\lambda_{max} = 480.0$ nm corresponds only to the concentration of ruthenium. A derivative spectrophotometric method using numerical calculation of absorption spectra of the $RuCl_6^{2-}$ and $OsCl_6^{2-}$ complexes has been developed for the determination of osmium in a mixture with ruthenium. The interfering effect of ruthenium on the determination of osmium can be eliminated by measuring the value of a third-order derivative spectrum of the $OsCl_6^{2-}$ complex at 350.0 nm ("zero-crossing point" of ruthenium). Simple and rapid determination of ruthenium and osmium in a calibration standard solution of the noble metals (Ru, Rh, Pd, Os, Ir, Pt and Au) for plasma spectroscopy using the proposed methods has been achieved.

Keywords: Noble metal analysis; Ruthenium; Osmium; Derivative spectrophotometry

1. Introduction

Interest in the development of analytical techniques for determination of the noble metals is still growing as a result of rapid growth of their applications, e.g. in chemical engineering, microelectronics and medicine. Because of the great chemical similarity of the noble metals, small concentrations of the metals which are encountered in many types of samples and heterogeneity of the examined materials, chemical pretreatment of the samples and separation of the metals prior to their determination is necessary.

Selective isolation of ruthenium and osmium by distillation in the form of volatile RuO_4 and OsO_4

* Corresponding author.

is generally a preliminary step for analysis of multicomponent samples of the noble metals [1,2]. Ruthenium and osmium are converted into Ru(VIII) and Os(VIII) respectively in the presence of strong oxidizing agents (e.g. $HClO_4 + H_2SO_4$, $KMnO_4$) and escape from the samples as RuO_4 and OsO_4. Simultaneous determination of ruthenium and osmium directly in solutions obtained after absorption of both the tetroxides is still a challenge for analytical chemists. The very close chemical similarity of the complexes formed by ruthenium and osmium in various media [3,4] mostly necessitates separation of the elements from each other prior to their determination. Osmium can be selectively oxidized to OsO_4 and quantitatively separated from ruthenium in the presence of weak oxidation agents, e.g. dilute HNO_3 or H_2O_2 [1,2,4].

Simultaneous determination of ruthenium and osmium in chloride solutions obtained by absorption of RuO_4 and OsO_4 in hydrochloric acid is the aim of this work. Hydrochloric acid is the most frequently used absorption medium for volatile RuO_4 because the latter is easily reduced to lower oxidation states in this medium [4,5]. The $RuCl_6^{2-}$ complex ($\lambda_{max} = 485$ nm, $\epsilon = 4.8 \times 10^3$ l mol^{-1} cm^{-1}), the most stable reduction product of RuO_4 in 6–10 M HCl at room temperature, was obtained earlier [5]. Reduction of OsO_4 in hydrochloric acid requires more drastic conditions. For quantitative conversion of OsO_4 into the stable $OsCl_6^{2-}$ complex it was necessary to use 8–10 M HCl and 20 min heating at 100°C [6].

In this work detailed studies on simultaneous reduction of Ru(VIII) and Os(VIII) to Ru(IV) and Os(IV) in hydrochloric acid and their quantitative conversion into the $RuCl_6^{2-}$ and $OsCl_6^{2-}$ complexes have been carried out. The experiments have shown that osmium does not interfere with the determination of ruthenium in solutions obtained by absorption of RuO_4 and OsO_4 in hydrochloric acid using direct spectrophotometry, while ruthenium seriously interferes with the determination of osmium.

Attempts to eliminate the band-overlap interference of ruthenium on the determination of osmium using derivative spectrophotometry are described in the paper. Derivative spectrophoto-

metry [7–12] makes it possible to resolve the absorption band of a particular compound by analogue differentiation and mathematical processing of overlapping UV and visible absorption spectra. Very closely positioned absorption maxima that cannot be separated by conventional spectrophotometry appear as separated bands in the derivative spectra. These spectra can be recorded with the aid of new generation commercial spectrophotometers capable of operating in the derivative mode or by numerical calculation of zero-order absorption spectra. The absorbance value, the shape of the zero-order spectrum and the method of computing affect the quality of the obtained signals. Suitable selection of the wavelength range and the derivative order allow one to eliminate interfering signals. Second-order derivative spectrophotometry was used earlier [13] for determination of ruthenium (in the presence of osmium) and osmium (in the presence of ruthenium) after conversion of their chloride complexes into complexes with tin(II) chloride.

In this work rapid methods of simultaneous determination of ruthenium and osmium in chloride solutions, based on direct and third-order derivative spectrophotometry using numerical calculation of spectra of the $RuCl_6^{2-}$ and $OsCl_6^{2-}$ complexes, have been developed.

2. Experimental

2.1. Apparatus and reagents

The absorption spectra were recorded with a Hitachi U-3300 spectrophotometer (Japan) with 1 cm cells. Derivative spectra were obtained by numerical calculation with the aid of the GRAMS/386 program of Galactic Industries Corporation using the Savitzky–Golay algorithm.

Ruthenium standard solution (1 mg Ru ml^{-1}) was prepared according to an earlier procedure [5].

Osmium standard solution (1 mg Os ml^{-1}) was prepared by dissolving 0.2529 g of potassium hexachloroosmate (IV) (K_2OsCl_6) in 100 ml of 4 M HCl.

2.2. Procedures

2.2.1. Distillation of ruthenium and osmium

Place the test solution containing ruthenium and osmium in a distillation flask. Add 2 ml of concentrated $HClO_4$ and 6 ml of concentrated H_2SO_4. Attach the flask to a distillation apparatus equipped with two receivers in series. Place 10 ml and 5 ml of 9 M HCl in the first and second receivers respectively. Pass nitrogen continuously (2–3 bubbles per second) through the distillation apparatus and heat the solution in the flask until intense fumes of perchloric acid appear. Stop heating the solution and continue to pass nitrogen until the distillation apparatus has cooled to room temperature. Transfer the contents of the receivers into a 25 ml volumetric flask and dilute to the mark with 9 M HCl.

2.2.2. Determination of ruthenium

Measure the absorbance of the solution obtained at $\lambda_{max} = 480.0$ nm against the blank. Calculate the concentration of ruthenium using the appropriate regression equation.

2.2.3. Determination of osmium

Heat the obtained solution for 30 min at 90°C. Allow it to cool to room temperature. Record the absorption spectrum of the solution against the blank with the following instrumental parameters: wavelength 300–650 nm; slit 1 nm; scan speed 120

Fig. 2. Spectra of the $RuCl_6^{2-}$ complex (16 μg Ru ml^{-1}) in (a) 6 M HCl, (b) 8 M HCl, (c) 9 M HCl and (d) 10 M HCl (directly after absorption of RuO_4, curve 1; after 30 and 60 min, curves 2 and 3 respectively; after 24 h curve 4).

nm min^{-1}; sampling interval (interpoint distance) 0.2 nm. Calculate (with 55 points and 2nd degree polynomial) the third-derivative absorption spectrum of the solution. Measure the value of the third derivative of osmium at 350.0 nm. Calculate the osmium concentration using the appropriate regression equation.

Fig. 3. Effect of temperature on the reduction of OsO_4 (16 μg Os ml^{-1}) in 9 M HCl. Curves 1–8 correspond respectively to the temperatures 50, 60, 70, 80, 85, 90, 95°C and room temperature. Heating time (constant), 20 min.

3. Results and discussion

3.1. Studies on the reduction of RuO_4 and OsO_4 in hydrochloric acid.

Ruthenium and osmium are quantitatively oxidized to Ru(VIII) and Os(VIII) in a medium of
Fig. 4. Effect of the heating time on the reduction of OsO_4 (16 μg Os ml^{-1}) in 10 M HCl (5, 10, 15, 20 and 25 min at 90°C, curves 1–5 respectively; spectrum of OsO_4 solution in 10 M HCl at room temperature, curve 6).
Fig. 5. Effect of the heating time on the reduction of OsO_4 (16 μg Os ml^{-1}) in 9 M HCl (5, 10, 15, 20, 30, 45 and 60 min at 90°C, curves 1–7 respectively; spectrum of OsO_4 solution in 9 M HCl at room temperature, curve 8).

hot concentrated $HClO_4 + H_2SO_4$ (1 + 3) and selectively volatilized as RuO_4 and OsO_4 from the examined samples. The experiments carried out in this work have shown that both the tetroxides are quantitatively absorbed in hydrochloric acid medium with the formation of chloride complexes of the elements in lower oxidation states. The reduction rates of RuO_4 and OsO_4 and the type of complexes formed depend on the HCl concentration, temperature and reaction time.

It has been found that in 6–10 M HCl RuO_4 is easily reduced to Ru(IV) and the complex $RuCl_6^{2-}$ with λ_{max} at 480.0 nm is formed (Fig. 1; curves 1–4). Quantitative conversion of Ru(VIII) into this complex takes place at room temperature. Large amounts of decomposition products of $HClO_4$ and H_2SO_4 acids that pass during distillation into the absorbing solution may cause slight differences in the maximum absorbance of the solution obtained by distillation of ruthenium from a dilute $KMnO_4$ solution ($\lambda_{max} = 485.0$ nm) [5]. The maximum stability of the $RuCl_6^{2-}$ complex is observed in 8 M hydrochloric acid (Fig. 2b). The absorbance of the obtained complex at $\lambda_{max} = 480.0$ nm does not change significantly over a period of 24 h. Slow partial reduction of
Fig. 6. Effect of the heating time on the reduction of OsO_4 (16 μg Os ml^{-1}) in 8 M HCl (10, 20, 30, 60 and 120 min at 90°C, curve 1–5 respectively; spectrum of OsO_4 solution in 8 M HCl at room temperature, curve 6).

Ru(IV) to Ru(III) and the formation of the $RuCl_6^{3-}$ complex with maximum absorbance at 350 nm may take place with increasing HCl concentration. The maximum absorbance of the $RuCl_6^{2-}$ complex at 480 nm in 9 M and 10 M HCl decreases by about 9% and 11% respectively, within 24 h (Fig. 2c,d). The absorbance of the complex is practically constant 60 min after absorption of RuO_4 in both the examined media.

The experiments have shown that OsO_4 is very slowly reduced in hydrochloric acid medium at

room temperature. No chloride complexes containing osmium in lower oxidation states are formed directly after absorption of OsO_4 in 6–10 M hydrochloric acid (Fig. 1; curves 5–8). In 6 M and 8 M HCl solutions no reduction of OsO_4 was observed after 24 h at room temperature. Slow reduction of Os(VIII) to Os(VI) and the formation of the $OsO_2Cl_4^{2-}$ complex [4] with λ_{max} at 346.8 nm take place in 9 and 10 M HCl.

It has been found that the reduction of osmium(VIII) can be considerably accelerated by heating OsO_4 solutions in hydrochloric acid (Fig. 3). On heating OsO_4 solutions in 8–10 M hydrochloric acid Os(VIII) is rapidly reduced to Os(IV) and the stable $OsCl_6^{2-}$ complex ($\lambda_{max} = 334.8$ nm, $\epsilon = 8.4 \times 10^3$ l mol^{-1} cm^{-1}) is formed. Quantitative conversion of osmium into the $OsCl_6^{2-}$ complex takes place after 10 min, 15 min and 1 h heating of OsO_4 solutions in 10 M HCl (Fig. 4), 9 M HCl (Fig. 5) and 8 M HCl (Fig. 6) at 90°C respectively. In this work reduction of Os(VIII) to Os(IV) was carried out in 9 M hydrochloric acid upon heating for 30 min at (90 ± 1)°C.

3.2. Determination of ruthenium

Osmium does not interfere with direct spectrophotometric determination of ruthenium in all the examined media (Fig. 1; curves 5–8). OsO_4 in hydrochloric acid and the $OsCl_6^{2-}$ complex obtained after the reduction of Os(VIII) to Os(IV) have no effect on the absorbance of ruthenium at

Mean μg ml^{-1}	99.7			

[a] $n = 6$.

1. The relative standard deviation (RSD) does not exceed 6.0% and 6.4% respectively.

3.3. Determination of osmium

Ruthenium interferes with the spectrophotometric determination of osmium in hydrochloric acid media (Fig. 7a). The results of the determination of osmium are higher by about 50% when the concentrations of ruthenium and osmium in examined solutions are equal. It has been found that the interferences of ruthenium (up to 100 μg Ru ml^{-1} examined) can be completely eliminated when numerical calculation of absorption spectra

of the OsCl$_6^{2-}$ and RuCl$_6^{2-}$ complexes is carried out and derivative spectra are recorded. The derivative absorption band of ruthenium is partially reduced when considering the first-, second-, third- and fourth-order (Fig. 7b–e respectively) derivative spectra. The third- and fourth-order derivative spectra of ruthenium cross the zero line at 350.0 nm and 359.0 nm respectively (Fig. 7d,e) independently of the ruthenium concentration. The value of the corresponding derivative spectrum of osmium at these wavelengths depends only on the osmium concentration in the examined solution (Fig. 8b). The calibration curve for osmium determination by the third-order deriva-

tive values at 350.0 nm ("zero-crossing point" of ruthenium) is linear in the 0.02–20 μg Os ml^{-1} concentration range. The regression equation is $y = 2.22 \times 10^{-5}c - 1.6 \times 10^{-6}$ where y is the measured derivative value and c is the concentration of osmium (μg ml^{-1}); correlation coefficient $R^2 = 0.9992$. Sensitivity of the method ($u = s_{y/x}/m$) amounts to 0.015 μg Os ml^{-1}. The RSD does not exceed 2.2% in the absence of ruthenium in the final solution and 5.1% for a mixture of $OsCl_6^{2-}$ and $RuCl_6^{2-}$ complexes (Table 2).

4. Analytical application

The developed methods were applied to the determination of ruthenium and osmium in a calibration standard solution for plasma (ICP and MIP) spectroscopy (MBH Analytical LTD product), containing 100 μg ml^{-1} each of the noble metals Ru, Rh, Pd, Os, Ir, Pt and Au in 20% HCl. Ruthenium and osmium were selectively separated from the solution by distillation of RuO_4 and OsO_4 from $HClO_4 + H_2SO_4$ (1 + 3) medium. Both the tetroxides were absorbed in 9 M HCl and the ruthenium and osmium contents were determined according to the above procedure. The results are presented in Table 3. The RSDs for ruthenium and osmium were 1.8–3.8% and 2.2–4.3% respectively.

Behaviour of the dithiocarbamate complexes of arsenic, antimony, bismuth, mercury, lead, tin and selenium in methanol with a hydride generator

L. Vuchkova, S. Arpadjan*

Faculty of Chemistry, University of Sofia, 1126 Sofia, Bulgaria

Abstract

A study was carried out with a continuous hydride generator coupled to an atomic emission spectrometer with inductively-coupled plasma to determine whether hydrides of As, Bi, Pb, Sb, Sn and Se and mercury vapor could be generated in methanol solutions of their dithiocarbamate complexes. It was found that (with the exception of Pb) hydride generation with sufficient efficiency for simultaneous multi-element determination is achieved using 0.25% $NaBH_4$–0.6 mol l^{-1} HCl as reaction medium. The detection limit was found to be 0.2 ng ml^{-1} for As, 30 ng ml^{-1} for Bi, 0.03 ng ml^{-1} for Se, Sb and Sn.

Keywords: Inductively-coupled plasma atomic emission spectrometry; Continuous hydride generator; Dithiocarbamate complexes in methanol; Solid phase extraction

1. Introduction

The generation of volatile covalent hydrides and mercury vapor has become a widely-used technique in atomic spectrometry for analysis of As, Sb, Se, Sn, Ge, Te, Bi, Hg and Pb in various matrices. For the determination of extremely low element concentrations and for the elimination of matrix interferences a preliminary preconcentration is necessary. Liquid–liquid extraction preconcentration methods have been described in combination with subsequent hydride generation

(HG) directly in non-aqueous media without any mineralisation or re-extracting procedures [1–11]. However, the solvent extraction method offers limited enrichment factors and is unsuitable for automation of the analysis and for preservation and transportation of pretreated samples. This is the reason for the recent enhanced interest in preconcentration methods using column solid phase extraction. An effective preconcentration technique allowing higher concentration factors than with liquid extraction was developed using a water-insoluble ligand, such as ammonium hexahydroazepine-1-dithiocarboxylate (ammonium hexamethylenedithiocarbamate) (HMDC), physically immobilized on polyurethane foam, and dis-

---

* Corresponding author.

posable syringes as microcolumns [12]. In a pre-liminary study optimum conditions were estab-lished for quantitative solid phase extraction of As, Bi, Hg, Sb, Se, Sn and Pb. A complete elution was achieved by total dissolution of the sorbed analyte dithiocarbamate complexes in organic sol-vents [12,13]. The application of a water-miscible solvent such as methanol simplifies the analytical procedure due to the possibility of using the con-ventional hydride generator for aqueous solutions without any changes. However, no data are avail-able on whether elemental hydrides and mercury vapor could be generated from methanol solu-tions of chelate complexes of the analytes and then followed by inductively-coupled plasma atomic emission spectrometry (ICP-AES) mea-surements.

The aims of the present work are: (i) to investi-gate the hydride generation of As, Sb, Sn, Se, Bi and Pb when present as dithiocarbamate com-plexes in methanol solutions; (ii) to investigate the behaviour of Hg under the same conditions; and (iii) to optimize the working conditions for combi-nation of the HG in methanol solutions of the analyte dithiocarbamate complexes with an induc-tively-coupled plasma optimized for simultaneous determination of the above elements by atomic emission spectrometry.

2. Experimental

2.1. Reagents and apparatus

All reagents used were of analytical-reagent grade. Redistilled water was used throughout. Stock solutions of 0.25% and 0.5% $NaBH_4$ (Merck) in 0.4% NaOH were prepared daily and stored in a polyethylene bottle before use. The multielement standard solutions for all the studied elements were prepared from Titrisol (Merck, Germany). HMDC (Merck) was used as received. The solvent methanol (Merck) was additionally purified by distillation.

The ICP-AES measurements were performed with a simultaneous ICP spectrometer Spec-troflame combined with a continuous hydride generator 341-ARL. The ICP and HG operating conditions are given in Table 1.

The HMDC-immobilized polyurethane foam and the sorbent columns for solid phase extrac-tion were prepared as described earlier [12].

2.2. Preparation of test solutions

To 20.00 ml of a standard solution containing 50 ng ml^{-1} As(III), Sb(III), Bi(III), Se(IV); 60 ng ml^{-1} Sn(IV); 20 ng ml^{-1} Hg(II) and 100 ng ml^{-1} Pb 5 ml acetic buffer at pH 4.66 was added. This solution was pumped through a sorbent column filled with HMDC-immobilized polyurethane foam using the conditions reported previously [12]. Then the organic chelating ligand, HMDC, together with the analyte–dithiocarbamate com-plexes formed were completely dissolved in 9.0 ml methanol or in 9.0 ml aqueous methanol solution with 66% methanol (6.0 ml $CH_3OH + 3.0$ ml H_2O).

2.3. Recommended procedure

In 150 ml of a water sample 3 g KI is dissolved and heated gently at 60°C for 1 h to ensure that the analytes are present in their lower oxidation states. The pH is adjusted to 4.5 ± 0.5 with ac-

etate buffer or if necessary with some drops of dilute ammonia or HCl. The sample is pumped through the sorbent column at a flow rate of 2 ml min⁻¹. Then 5.0 ml CH₃OH is placed in a dry quartz beaker and passed six times through the sorbent with the aid of the syringe plunger. This methanol solution of the analyte–dithiocarbamate complexes is connected to the sample channel of the hydride generator. The calibration solutions were prepared from aqueous multielement standard solutions by appropriate dilution with a methanol solution of HMDC (10 g l⁻¹).

3. Results and discussion

The influence of methanol and of the chelate-forming ligand HMDC on the yield of hydride was investigated for the following reaction systems: A, 0.25% NaBH₄–0.6 M HCl; B, 0.25% NaBH₄–1.2 M HCl; C, 0.25% NaBH₄–0.6 M HNO₃; D, 0.25% NaBH₄–1.2 MHNO₃; E, 0.25% NaBH₄–2 M HNO₃; F, 0.5% NaBH₄–2 M HNO₃.

in methanol (I_o) was compared with that obtained for aqueous solutions (I_w) at the same experimental conditions. The results obtained for the relative intensity, I_r ($= I_o/I_w$), are shown in Figs. 1–6. The chelate-forming ligand HMDC affects the process of hydride generation. The HG reaction was realised with higher efficiency in methanol solutions without ligand than in those with ligand. The influence of HMDC depends on the stability of the dithiocarbamate complexes of the analytes in methanol and on the rate of hydride formation or reduction to the elemental state (Hg). In the

presence of methanol and HMDC Pb cannot form a volatile covalent hydride at all. The ligand HMDC strongly suppresses the formation of bismuthine in all the investigated reaction systems (Figs. 1–6) due to the high stability of the Bi–dithiocarbamate complex and the relatively slow rate of bismuthine formation. The determination of Bi in the presence of HMDC is possible only in 0.25% $NaBH_4$–0.6 M HCl with twice as poor sensitivity ($I_r = 0.5$).

Arsenic forms a volatile hydride independent of the presence of ligand and in the applied reaction

Fig. 6. As Fig. 1 but with 0.5% $NaBH_4$–2 M HNO_3 as reaction medium.

system in pure CH_3OH as well as in 66% CH_3OH (Fig. 1).

Selenium forms a volatile hydride in methanol solutions of HMDC with all the studied reduction systems. The efficiency of H_2Se formation is higher in HCl medium ($I_r \approx 1.9$–2.4, Figs. 1 and 2) than in HNO_3 medium ($I_r \approx 0.85$–1.15, Figs. 3, 4 and 6), except for the system 0.25% $NaBH_4$–2 M HNO_3 where $I_r = 4.3$ (Fig. 5).

In the case of antimony the efficiency of stibine formation is higher ($I_r \approx 2$) in hydrochloric acid-containing reaction systems (Figs. 1, 2) than in nitric acid medium ($I_r < 1$, Figs. 3, 4 and 6).

A strong depression of SnH_4 formation was observed in the presence of HMDC in the methanol solution for all reaction systems with HNO_3.

Mercury forms stable dithiocarbamate complexes. Nevertheless, the efficiency of mercury vapor formation is high in the reaction systems containing HCl ($I_r \approx 4.5$) and HNO_3 ($I_r \approx 1.13$). This is probably due to the high reduction rate of mercury to the elemental state.

The higher intensity signals for As, Hg, Sb, Se and Sn in methanol in the absence of the chelate-

Table 2
Detection limits (3 σ) for HG with ICP-AES for methanol solutions of dithiocarbamate complexes of the analytes

Reaction medium	Detection limit (ng ml^{-1})					
	As	Bi	Hg	Sb	Se	Sn
0.25% NaBH$_4$-0.6 M HCl	0.2	30	0.03	3	3.3	2.7
0.25% NaBH$_4$-1.2 M HCl	0.5	–	0.1	–	–	–
0.25% NaBH$_4$-0.6 M HNO$_3$	0.8	–	0.2	1.8	9	4
0.25% NaBH$_4$-1.2 M HNO$_3$	0.7	–	0.1	–	7	–
0.25% NaBH$_4$-2 M HNO$_3$	–	–	0.2	–	9	–
0.5% NaBH$_4$-2 M HNO$_3$	0.4	–	0.2	3	8.5	–

forming ligand HMDC (Figs. 1 and 2) than for their aqueous reference solutions could be explained by a lowering of the surface tension, promoting a higher rate of hydride or cold vapor liberation from the liquid phase. This is presumably the explanation for the higher efficiency in pure methanol than in 66% methanol. An exception is observed for bismuth and lead. The generation of bismuthine in HCl medium does not depend ($I_r \approx 1$) on the replacement of water by CH$_3$OH.

3.1. Choice of working conditions

A higher sensitivity and a more stable plasma were obtained for methanol solutions of HMDC in comparison to aqueous methanol solutions (66% CH$_3$OH).

Table 3
Comparison of the detection limits (3 σ) of HG–ICP in aqueous solutions and in methanol solutions of the analyte dithiocarbamate complexes after preconcentration by column solid phase extraction (recommended procedure)

Element	HG-ICP in aqueous solutions (ng ml^{-1})	Recommended procedure (ng ml^{-1})
As	0.2	0.008
Bi	0.35	1
Hg	0.02	0.001
Sb	0.5	0.1
Se	0.6	0.1
Sn	0.3	0.1

The optimum conditions for single element determination can be seen from the calculated limits of detection presented in Table 2. For simultaneous multi-element analysis, elution by total dissolution of the analyte–dithiocarbamate complexes in pure methanol and HG using the reaction system 0.25% NaBH$_4$-0.6 M HCl is recommended as the optimal compromise decision. In comparison with work with aqueous solutions under these experimental conditions the background signal for Bi does not change, but for As, Se, Sb and Sn it is enhanced 1.5-fold and for Hg it is enhanced 2.3-fold. The relative standard deviations of the measurements in methanol and aqueous media do not differ significantly, varying between 1 and 4%.

Table 3 presents the achievable best sensitivity for HG–ICP determination of the investigated elements in aqueous solutions using the optimal experimental conditions for aqueous media (0.5% NaBH$_4$-0.3 M HCl). It can be seen that whereas for As and Hg no substantial change in the sensitivity of their determinations was observed, for selenium the sensitivity in methanol solution of its dithiocarbamate complex is approximately five times worse than by HG from aqueous Se(IV) solutions. This lowering in sensitivity is about a factor of nine for Sn and almost two orders of magnitude for Bi. However, the combination of HG with preliminary 30 fold preconcentration of the traces by column solid phase extraction, as described in the recommended procedure, permits the determination of extremely low analyte concentrations with the exception of Bi (Table 3).

Table 4
Recovery (%) from spiked water samples (n-number of samples)

Sample	Recovery (%)					
	As	Bi	Hg	Se	Sb	Sn
Tap water (n = 4)	97 ± 5	95 ± 5	99 ± 2	97 ± 3	95 ± 4	96 ± 5
Mineral water (n = 3)	97 ± 3	96 ± 6	97 ± 3	96 ± 3	97 ± 3	97 ± 4
Ground water (n = 3)	96 ± 6	97 ± 5	98 ± 4	95 ± 4	96 ± 5	98 ± 2
Waste water (n = 4)	95 ± 4	95 ± 7	96 ± 5	93 ± 5	97 ± 4	95 ± 4
Sea water (n = 7)	96 ± 6	96 ± 6	97 ± 5	92 ± 6	94 ± 4	93 ± 5

3.2. Application of the method

The recommended procedure was applied to a number of water samples: sea water, waste water, tap water, mineral water and ground water. The recovery studies were performed by adding known amounts of the analytes to the samples prior to adjustment of the pH value to 4.5 ± 0.5. The results are shown in Table 4. The high recoveries obtained indicate that the foreign ions present in the samples do not interfere to any significant extent with the determination of As, Bi, Sb, Se and Sn after HG in methanol solutions of the analyte dithiocarbamate complexes. The highest concentrations of coexisting ions in the water samples analysed were 0.4 μg l^{-1} Cd, 2 μg l^{-1} Cr, 100 μg l^{-1} Cu, 300 μg l^{-1} Fe, 200 μg l^{-1} Mn, 1.2 μg l^{-1} Ni, 5 μg l^{-1} Pb and 150 μg l^{-1} Zn. The alkali and alkaline earth elements, aluminium and the anions are not sorbed and hence could not be present in the methanol solution.

The results for water samples with higher analyte content were compared with those of HG in aqueous solutions as shown for two cases in Table 5. The agreement is good and the difference between the standard deviations of both methods is not statistically significant. HG-ICP in aqueous solutions is undoubtedly a faster and simpler technique, but the proposed column solid phase extraction preconcentration in combination with subsequent HG in methanol solutions for simultaneous determination by ICP-AES allows higher sensitivity for As, Hg, Sb, Se and Sn, and permits better possibilities for the preservation and transportation of the water samples.

4. Conclusion

The conversion of the analytes from their dithiocarbamate complexes in methanol to covalent hydrides or cold vapor (Hg) through direct

Table 5
Results (μg l^{-1}) of the analysis of waste-water and sea-water samples (n = number of parallel determinations)

| Element	Waste water (n = 4)		Sea water (n = 5)	
	Recommended procedure	HG-ICP in aqueous solutions	Recommended procedure	HG-ICP in aqueous solutions
As	2.8 ± 0.3	2.8 ± 0.2	1.27 ± 0.08	1.32 ± 0.07
Bi	9.7 ± 0.8	9.3 ± 0.7	<1	<0.35
Hg	<0.001	<0.02	2.5 ± 0.3	2.3 ± 0.2

Abstract

We compared two extraction methods for use in GC-ECD determination of polychlorinated bi- and terphenyl contaminants (PCBs and PCTs respectively) in mussels (*Mytilus galloprovincialis*). Mussels spiked with standard PCB and PCT mixtures Aroclor 1260 and Aroclor 5460 were extracted with cold acetonitrile, or with 1:1 n-hexane/ dichloromethane in a Soxhlet extractor, which gave the better mean recoveries of $99.0 \pm 2.5\%$ and $59.5 \pm 8.3\%$ for PCBs and PCTs respectively.

Keywords: PCBs; PCTs; GC/ECD; Mussels

1. Introduction

Polychlorinated bi- and terphenyls (PCBs and PCTs respectively) constitute a family of environmentally persistent, synthetic chlorinated hydrocarbons which are highly lipophilic and are consequently water-insoluble [1] and tend to bioaccumulate in fatty tissues [2].

Both PCBs and PCTs have been used as insulating materials in electrical capacitors and transformers, and as components in hydraulic and lubricating fluids, plasticizers, paints adhesives and waxes. Use of both types of compound is now restricted [3]. However, although PCBs and particularly PCTs are subject to bio- and photodegradation [4], these compounds are highly stable in the environment and are now so widely distributed that detectable levels of PCBs [5–13] and PCTs [14–19] (although few studies are available) have been found in types of sample ranging from molluscs to mothers' milk.

Determination of PCBs and PCTs in environmental samples generally uses gas chromatography with electron-capture detection (GC-ECD), analysing organic solvent extracts of samples fol-

lowing pre-analysis clean-up on any one of a variety of solid phases [5–19]. In this work we compared two different extraction methods for determination of PCB and PCT mixtures (Aroclor 1260 and Aroclor 5460 respectively) in mussels (*Mytilus galloprovincialis*) from Galicia, N.W. Spain.

2. Experimental

2.1. Reagents

Pesticide-residue-analysis grade acetonitrile was purchased from Carlo Erba, pesticide-residue-analysis grade n-hexane and analysis-grade diethyl ether from Scharlau, pesticide-residue-analysis grade dichloromethane and residue-analysis grade anhydrous sodium sulphate from Merck and washed sea-sand from Panreac. Minicolumns (Sep-Pak® Florisil) were from Waters. Aroclor 1260 was from Monsanto Ibérica, S.A. and Aroclor 5460 from Chem Service; stock solutions containing 10 μg ml^{-1} and 7 μg ml^{-1} respectively were prepared in n-hexane. A working solution of 20 g l^{-1} sodium chloride was prepared with distilled water previously extracted with n-hexane.

2.2. Apparatus

Samples were homogenized with an Omni-mixer homogenizer 17106 and partially dried in a Heraeus T-340 laboratory oven. We used a Perkin-Elmer 8500 gas chromatograph, equipped with a 63 Ni ECD connected to a capillary column (Alltech RSL-200 0.25 mm × 25 mm; film thickness 0.2 μm) and samples were injected automatically (Perkin-Elmer AS-8300 autosampler).

2.3. Samples

Mussels were removed from their shells and homogenized. Aliquots (25 g) of mussel homogenate were then spiked with Aroclor 1260 (5–160 μg kg^{-1}) and 5460 (26–280 μg kg^{-1}) so as to roughly double the levels found in unspiked samples.

2.4. Extraction procedures

2.4.1. Extraction with acetonitrile [20]

Each spiked aliquot of mussel homogenate was extracted by stirring it for 30 min with 2 × 25 ml portions of acetonitrile. The liquid extracts were isolated by vacuum filtration through a Buchner funnel (AFORA Fef. 884/73, 20–40 μm), combined into a single sample and mixed with 150 ml of the NaCl solution. This mixture was sequentially extracted with 2 × 25 ml portions of n-hexane, and the combined hexane-soluble extracts were washed with 15 ml and 10 ml portions of distilled water (previously extracted with n-hexane) before drying them over anhydrous Na$_2$SO$_4$. Finally, the hexane solution was concentrated to 1 ml in a Kuderna–Danish type evaporator.

2.4.2. Soxhlet extraction [21]

Each spiked aliquot of mussel homogenate was mixed with 25 g of washed sea-sand and left at 40°C in a laboratory oven for 24 h. Next, the mixture was placed in a Soxhlet extractor and extracted with 200 ml of 1:1 n-hexane/ dichloromethane. After 6 h, the extractant was cooled, dried over anhydrous Na$_2$SO$_4$ and concentrated to 1 ml in a Kuderna–Danish type evaporator.

2.5. Clean-up

Suitable samples for GC-ECD analysis were obtained by passing the concentrate from each extraction method through Sep-Pak® Florisil minicolumns, eluting in each case with 5 ml of n-hexane, and then concentrating the eluates to 1 ml in a Kuderna–Danish type evaporator.

2.6. Gas chromatography

Gas chromatography was performed in the split/splitless injection mode (vent flow, 20 ml min^{-1}; splitless period, 1 min) on the apparatus described above. The injector and detector temperatures were 300°C. The oven temperature followed the following temperature programme: 1 min at 50°C, increasing at 20°C min^{-1} to 175°C, then at 3°C min^{-1} to 320°C. The carrier gas was
Fig. 1. Gas chromatogram showing optimal separation of standard mixtures of polychlorinated bi- and terphenyls (Aroclor 1260 and 5460 respectively).

nitrogen (N-50 grade) and the flow rate was 0.5 ml min^{-1}. Make-up gas was also nitrogen with a flow rate of 200 kPa.

2.7. Quantification

Quantification of the PCBs and PCTs was by the external standard method, using the following equation

$$C_m = \frac{C_s \times A_m}{A_s} \times 40$$

where C_m is the concentration (μg kg^{-1}) of the analyte (PCB or PCT) in the mussel sample; C_s is the concentration (μg ml^{-1}) of the Aroclor 1260 or Aroclor 5460 external standard, A_m is the total area of the peaks due to PCBs or PCTs in the sample, and A_s is the total area of the peaks due to the Aroclor 1260 or Aroclor 5460 external standard.

3. Results and discussion

Separation of the peaks due to the Aroclor

1260 and the Aroclor 5460 standards was optimized in a series of experiments in which mixtures of these standards were injected and the temperature programme was systematically varied. Fig. 1 shows the chromatogram obtained using the selected temperature programme.

Calibration curves were constructed by regressing the detector response at standard concentration for six mussel samples spiked with between 5 and 160 μg kg^{-1} of Aroclor 1260 (PCBs) or between 26 and 280 μg kg^{-1} of Aroclor 5460 (Table 1). Correlation coefficients (0.999$_8$ for PCBs, and 0.996 for PCTs) were high in both cases.

3.1. Efficiency of the extraction method

Twenty aliquots of homogenized mussel tissue were spiked with 160 μg kg^{-1} of Aroclor 1260 and 280 μg kg^{-1} of Aroclor 5460. Ten of these samples were then extracted using the acetonitrile method, and ten with 1:1 n-hexane/dichloromethane in a Soxhlet extractor; sample clean-up and GC-ECD analysis were the same for each series of samples. The realative efficiencies of the

Table 1
Correlation coefficient (r) and regression parameters for the calibration curves $y = bx + a$

Standard	Concentration range (μg kg^{-1}) in the six spiked samples	r	b	a
Aroclor 1260	5–160	0.999$_8$	5.29×10^5	1.65×10^4
Aroclor 5460	26–280	0.996	6.39×10^5	1.60×10^5

Table 2
PCB and PCT contents of mussels from the four major Galician estuarine bays (μg kg^{-1})

Source of mussels	No. of samples	Arithmetic PCB mean		Arithmetic PCT mean	
		Soxhlet	Acetonitrile	Soxhlet	Acetonitrile
Muros-Noya	11	183	165	0.60	nd[a]
Arosa	52	98	47	9.02	nd
Pontevedra	18	80	43	4.83	nd
Vigo	26	138	69	7.36	nd

[a] nd = not detected.

two extration methods were assessed by comparison of recoveries. The Soxhlet extraction method was the superior method, with recoveries of $99.0 \pm 2.5\%$ in the case of Aroclor 1260 (PCBs), and $59.5 \pm 28.3\%$ in the case of Aroclor 5460 (PCTs).

3.2. PCB and PCT content of Galician mussels

The results for the samples by estuarine bays are listed in Table 2. Using Soxhlet extraction high levels of PCBs are found, being, approximately, half those in the same samples extracted with acetonitrile (except in mussels from Muros-Noya). PCTs were not detected in samples extracted with acetonitrile and were detected in all the samples analyzed with hexane: dichloromethane although mean levels were low.

4. Conclusions

On the basis of these results, we suggest that levels of PCB and PCT contaminants in mussels should be determined using extraction with 1:1

n-hexane/dichloromethane in Soxhlet appartus, followed by sample clean-up on Sep-Pak Florisil minicolumns and GC-ECD using the external standard method.

Since recoveries were low for PCTs (59.5%) more extraction time may be required.

Determination of trace heavy metals in biological samples by inductively-coupled plasma atomic emission spectrometry after extraction with 1,5-bis-(di-2-pyridylmethylene)thiocarbonohydrazide

E. Vereda Alonso*, A. Garcia de Torres, J.M. Cano Pavon

Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, 29071 Málaga, Spain

Abstract

A sensitive inductively-coupled plasma atomic emission spectrometric sequential method for the determination of trace heavy metals (cadmium, cobalt, copper and nickel) in biological samples after extraction of the metals into isobutyl methyl ketone (IBMK) containing 1,5-bis-(di-2-pyridylmethylene)thiocarbonohydrazide (DPTH) is described. A systematic study was made to determine the optimum conditions for extraction of the metals into IBMK. The complexes formed are quite soluble in IBMK, so much so that this allows the use of aqueous-to-organic phase volume ratios of up to 40 and hence the determination of concentrations down to 40 times lower than those afforded by the direct non-extractive method. The method has been used for the determination of these elements in various biological materials with good results.

Keywords: Biological samples; Extraction; Inductively-coupled plasma spectrometry; 1,5-bis-(di-2-pyridyl-methylene)thiocarbonohydrazide

1. Introduction

Analysis of metals in biological samples is of appreciable interest due to the toxicity of some elements. Although various analytical techniques are available, electrothermal atomic absorption spectrometry (ETA-AAS) is adopted by most

trace metal analysts because of its speed, minimal sample preparation, automation possibilities and sensitivity for most of the commonly determined metals. However, there are several disadvantages associated with the use of AAS as the detection method. These result from the limited linear calibration range, the large matrix interferences, the very small amounts of sample that can be introduced into the graphite tube and the fact that it is a single-element technique.

---

* Corresponding author.

Inductively-coupled plasma atomic emission spectrometry (ICP-AES) has been widely recognized [1] as a suitable technique for the determination of trace elements, its particular advantages being multi-element capability, large dynamic range and effective background correction. However, several problems have been indicated by researchers, e.g. spectral interferences owing to matrix components, nebulizer blockage owing to the high solids content of the solution, and analyte emission enhancement. In addition, ICP-AES has a significant drawback because the detection limit is sometimes inadequate to comply with requirements for the determination of trace elements in biological samples.

Adequate detection power can be achieved using electrothermal vaporisation for sample introduction [2,3], but a number of interferences arise from the vaporisation and transport of the analyte to the plasma which have yet to be elucidated fully. The alternative to increasing the detection limit of the ICP-AES system is to pre-concentrate the elements of interest prior to their determination. Liquid–liquid extraction is one of the most frequently used sample pre-treatment techniques for the determination of trace metals by ICP-AES [4–9]. The extraction serves the dual purposes of concentrating the metals of interest and separating them from an interfering matrix. The extent of the concentration achieved depends on the ratio of the aqueous to organic phase volumes. However, isolation from the matrix significantly decreases the solids content of the solution, thus avoiding the nebulizer blockage.

Although there have been relatively few literature reports of solvent extraction combined with ICP spectrometry, solvent extraction procedures initially developed for atomic absorption spectrometry (AAS) can often be used in ICP-AES. The theoretical principles underlining these methods and compilations of numerous illustrative applications can be found [10–12]. In general, ammonium pyrrolidine-1-carbodithioates [13–17] and sodium diethyldithiocarbamate [18–22] are the most frequently used reagents, although other reagents such as 1-(2-pyridylazo)-2-naphthol (PAN) [23], dithizone [24] and 8-hydroxyquinoline [25], have been proposed. Normally, prior extrac-

tion increases the selectivity of the determination, but an adequate increase in sensitivity may not be obtained. In addition, only a few studies are available dealing with the suitability for preconcentration of digests of biological materials obtained with specific sample digestion procedures. However, since the major metallic elements that constitute the matrix of both animal material and seawater are of the same nature, procedures that are suitable for trace element preconcentration and matrix separation of seawater may also be applicable to solutions of mineralized biological fluids and tissues.

Watanabe et al. [26] described a preconcentration method for Cd, Cu, Fe, Mn, Ni, Pb and Zn from seawater prior to determination by ICP-AES. The method involved complexation of the metal ions with 8-hydroxyquinoline followed by (column) absorption of C_{18}-bonded silica gel. The authors reported excellent rejection of Cu, Fe, Mn and Ni, but, owing to high blanks, Cd, Pb and Zn could not be determined.

A method based on dithiocarbamate preconcentration for the simultaneous determination of Cd, Cu, Fe, Mo, Ni, V and Zn in seawater by ICP-AES was described by McLeod et al. [27]. The trace metals were extracted from the sample with a mixture of ammonium tetramethylene dithiocarbamate and diethylammonium diethyldithiocarbamate in chloroform and back-extracted into nitric acid. The concentrations of Cd, Cu, Ni and Zn, found at the ng ml^{-1} level, were consistent with the results of independent AAS analysis.

1,5-bis-(di-2-pyridylmethylene)thiocarbonohydrazide (DPTH) is a suitable complexing reagent for a number of metal ions. Most of the complexes it forms are coloured and can be extracted into a variety of organic solvents. Its synthesis and properties have been described in detail [28], as well as its use in the determination of nickel [29] and mercury [30]. In this work an ICP-AES method is described for the determination of trace amounts of three essential trace elements (Co, Cu, Ni) and one toxic heavy metal (Cd) in biological materials after extraction of these metals into isobutyl methyl ketone (IBMK) containing DPTH. The complexes formed are quite soluble

in IBMK, so much so that it allows the use of aqueous-to-organic phase ratios up to 40 and hence the determination of concentrations down to 40 times lower than afforded by the direct non-extractive method is possible. In addition, the extraction step enhances the selectivity. The method thus developed was applied to the determination of Cd, Co, Cu and Ni in various biological materials.

2. Experimental

2.1. Apparatus

The ICP-AES measurements were made on a Perkin-Elmer 40 sequential emission spectrometer controlled by an IBM XT-286 computer which was used to develop the method and for acquiring and storing the data. A standard torch and Meinhard concentric glass nebulizer (controlled by a peristaltic pump fitted with silicone pump tubes working at a flow rate of 1 ml min^{-1}) were used during the experiments. The r.f. generator of the nebulizer is internally mounted as a "free-running" oscillator-type with a nominal central frequency of 40 MHz and a nominal operating power level of 900 W. The measurements were made with the aid of a Crison Digit-501 pH meter furnished with a combined glass-calomel electrode. Separating funnels were shaken on a Gallenkamp flask agitator with variable rate and programmable time.

All glassware used was soaked in 10% nitric acid for 1 day and rinsed with water just before use.

2.2. Reagents

All chemicals were of at least analytical-reagent grade, and doubly-distilled deionised water was used throughout.

The ligand for the DPTH solution was synthesized as described elsewhere [29]. A stock solution in IBMK was prepared by dissolving 0.1 g of DPTH in 9 ml of N,N-dimethylformamide and diluting to 100 ml with IBMK. The solution was found to remain stable for at least 1 week in a refrigerator.

Stock solutions of cadmium (II), cobalt (II), copper (II) and nickel (II) were prepared from their commercial salts (nitrate or sulphate) and standardized titrimetrically or gravimetrically. Standards of working strength were made by appropriate dilution daily as required.

A glycine–HCl buffer of pH 3.6 was prepared by mixing 25 ml of 0.2 mol l^{-1} glycine and 2.5 ml of 0.2 mol l^{-1} HCl in a 100 ml volumetric flask and diluting to the mark with distilled water. A 1 mol l^{-1} solution of NaClO$_4$ was also used.

2.3. Procedures

2.3.1. Choice of optimum extraction conditions

The metal ions were extracted as follows: in 250 ml separatory funnels were placed 10 μg of each metal ion and variable volumes of HCl, NaOH and NaClO$_4$ solutions and the mixture was diluted to variable volumes of aqueous phase. Then 10 ml of DPTH solution in IBMK at different concentrations was added and the mixture was shaken vigorously on the mechanical agitator for different periods of time. Once both phases had been separated, the aqueous phase was collected and the equilibrium pH measured. The organic phase was introduced into the plasma by means of a peristaltic pump, the content of metals was determined using appropriate calibration graphs (the standards were prepared in water-saturated IBMK). Appropriate blanks were prepared and were run in the same manner.

2.3.2. Recommended procedure

Aliquots of samples or standard solutions containing the metal ions at pH 3.6 were placed in 250 ml separating funnels. Then, 10 ml of 0.1% DPTH in IBMK was added (the maximum volume ratio of the aqueous to organic phases was 20:1 for a single-stage extraction of 99–100%). The mixture was shaken vigorously on the mechanical agitator at 3000 rev min^{-1} for 5 min. The phases were allowed to separate, and the organic solvent layer (approximately 5 ml, when the volume ratio of the aqueous to organic phases was 20:1) was transferred into a polypropylene centrifuge tube (some samples needed centrifugation for up to 5–10 min to improve separation

between the layers). The organic phase was inserted into the plasma by means of a peristaltic pump and the metals were determined according to the instrumental conditions given in Table 1.

Two replicate measurements of the three individual sample preparations of the reference material were made and the metals were determined from the calibration graph, constructed with standard solutions treated in the same way, and for each sample examined the value of the blank was subtracted (blanks were always run in the same way); alternatively the standard addition method was also satisfactorily applied.

2.3.3. Sample preparation

The certified reference materials (CRMs) analysed were: Community Bureau of Reference (BCR), CRM 061 Platihypnidium Ripariodides (Aquatic Moss), 176 City Waste Incineration Ash, 186 Pig Kidney; National Research Council Canada (NRCC), CRMs TORT-1 Lobster Hepatopancreas, DOLT-1 Dogfish Liver; and National Institure of Standards and Technology (NIST), Standard Reference Material (SRMs) 2670 Human Urine Elevated Level. These samples were first dried in accordance with the norms of the respective analysis certificates. Three replicates of each dried sample were prepared according to the following procedure. In a reaction flask were placed 0.500 g of weighed sample and 10 ml of concentrated nitric acid, and the mixture was heated under reflux until the disappearance of nitrous fumes. Then, 2 ml of hydrogen peroxide was added and the mixture was evaporated to a small volume by heating on a hot plate to remove

Table 1
Operating conditions for ICP

R.f. generator frequency	40 MHz, incident power 1.1 kW
Photomultiplier voltage	600 V
Plasma gas flow rate	12 l min^{-1}
Auxiliary gas flow rate	0.5 l min^{-1}
Nebulizer gas flow rate	0.35 l min^{-1}
Plasma viewing height	15 mm above induction coil
Integration time	100 ms
Read delay	20 s
Peristaltic pump flow rate	1 ml min^{-1}

the nitric acid. Next, the mixture was neutralized with NaOH solution, and was transferred to a 500 ml standard flask. The pH was adjusted by means of glycine–HCl buffer solution (pH 3.6) and 12.5 ml of 1 mol ml^{-1} NaClO$_4$ solution was added; finally the contents were diluted with distilled water to the mark. The analysis of each sample was completed as described under "recommended procedure".

The SRM 2670 did not require mineralization and the sample was prepared from concentrates according to the directions supplied.

3. Results and discussion

3.1. Optimization of extraction conditions

Extraction of metal ions by an organic reagent is known to be dependent on several factors, such as type and amount of reagent, organic solvent, pH of solution, shaking time, etc. We have investigated the extraction process in order to obtain optimum conditions. IBMK has a significant solubility in water but was chosen as the organic solvent because of its high extraction efficiency for Cd(II), Co(II), Cu(II) and Ni(II)–DPTH complexes.

In a general previous study [31], the influence of the pH on the extraction of Cd(II), Cu(II), Co(II) and Ni(II) into IBMK containing DPTH was investigated. The results obtained showed that the optimum pH range for the quantitative extraction is different for each ion: Cadmium, 3.3–11.4; cobalt, 1.5–8.0; copper, 2.8–9.8 and nickel, 2.0–5.0. Therefore, pH 3.6, provided with glycine–HCl buffer, is adopted in all subsequent experiments. The volume of this buffer added had no effect.

The influence of the NaClO$_4$ concentration in the aqueous phase was examined. No appreciable variation in the percentage of extraction was observed, except for the Cu–DPTH complex; in this case and increase in the extraction was observed when the sodium perchlorate concentration was increased up to 0.025 M (Fig. 1). The optimal concentration of the anion was found to be 0.025 mol l^{-1} which was obtained by adding 5 ml of 1 mol l^{-1} NaClO$_4$ to 200 ml of aqueous phase.
Fig. 1. Influence of perchlorate concentration on the extraction. Concentration of each ion in the aqueous phase: 50 ng ml^{-1}. Concentration of DPTH in the organic phase: 2.3×10^{-3} M. Shaking time: 10 min. Aqueous to organic phase volume ratio: 20. □, Cd; △, Co; ⨉, Cu; ○, Ni.

The minimum shaking time was determined by varying the shaking time from 0 to 10 min (Fig. 2); 3 min was found to be sufficient, however, prolonged shaking had no adverse effect on the extraction of metal ions and 5 min was selected for subsequent experiments.

The reagent concentration in the organic phase was varied while keeping its final volume at 10 ml. The results obtained (Fig. 3) showed that the extracted fraction remains constant for DPTH concentrations equal to or greater than 1.37×10^{-3} mol l^{-1} (0.06%). A concentration of 2.3×10^{-3} mol l^{-1} (0.1%) was used in practice in order to prevent depletion by other extractable ions potentially occurring in the aqueous medium.

The extraction of metal ions was found to be quantitative up to an aqueous-to-organic phase volume ratio of 20, above which the organic phase volume was insufficient for the sequential determination of the four metal ions, because when the volume of the aqueous phase was increased, the volume of the organic phase after extraction decreased, for the reason that IBMK is not totally immiscible with water; however, the quantitative extraction of the metal ions could be verified from the analysis of the aqueous phase. When a phase ratio of 20 was used (200 ml of aqueous phase and 10 ml of organic phase), only approximately 5 ml of organic phase was ob-

tained after extraction hence the phase ratio is actually 40. This phase ratio allows the sensitivity of the direct non-extractive method to be increased by a factor of approximately 40.

3.2. Selection of measurement conditions

Several wavelengths were investigated for each metal. The following ICP lines were selected: 228.802 nm for cadmium, 237.862 nm for cobalt, 324.754 nm for copper and 352.454 nm for nickel. These wavelengths were selected using the minimum background equivalent concentration (BEC) as the optimization criterion. Other operating variables such as type of nebulizer, nebulizer flow rate, photomultiplier voltage and plasma observation height were established to achieve the best signal-to-noise (S/N) ratios. The operating conditions for the spectrometer are recorded in Table 1.

3.3. Calibration graph: precision and detection limit

The relationship between each metal concentration and emission intensity was studied in the range 0–1000 ng ml^{-1} of metal ion in the aqueous phase. A linear calibration graph was obtained for every metal ion in this range when an aqueous-to-organic phase volume ratio of 20
Fig. 2. Influence of shaking time on the extraction of 50 ng ml^{-1} of Cd, Co, Cu, and Ni in the presence of perchlorate (0.025 M). Concentration of DPTH: 2.3×10^{-3} M. Aqueous to organic phase volume ratio: 20. Symbols as in Fig. 1.

was used with a slope of 86.6 for Cd, 36.3 for Ni, 44.8 for Co and 418.9 for Cu. The blank levels for the analytes were: 1.9 ± 0.2 ng ml^{-1} for Cd, 10 ± 1.0 ng ml^{-1} for Ni (the presence of IBMK in the extractant produced a considerable background at the Ni lines), 1.7 ± 0.9 ng ml^{-1} for Co and 0.3 ± 0.1 ng ml^{-1} for Cu.

The limits of detection and determination of the method were established according to American Chemical Society Committee of Environmental Improvement definitions [32]. The values found for each metal when an aqueous-ot-organic phase volume ratio of 20 was used are listed in Table 2.

Under the optimum conditions, ten determinations of standard solutions containing 10 ng ml^{-1} of each metal ion in the aqueous phase gave a relative standard deviation of 3.6% for Cd, 4.0% for Co, 3.0% for Cu and 4.4% for Ni; and for 100 ng ml^{-1} (aqueous phase) gave 1.9%, 1.8%, 2.1% and 0.8% respectively.

3.4. Effect of foreign ions

The effect of various ions on the sequential determination of cadmium, cobalt, copper and nickel by the proposed method was examined under the optimum working conditions. For this study, different amounts of the ionic species tested were added to 25 ng ml^{-1} solutions of Cd, Co, Cu and Ni in the aqueous phase, the volume of

which was 200 ml, whereas the organic phase was 10 ml. The starting point was an interferent-to-metal ion ratio of 4000 m/m; if any interference occurred, the ratio was gradually lowered until the interference disappeared. The tolerance limits found (Table 3) show that these ions can be sequentially determined in the presence of a variety of foreign ions including most of those which commonly occur with them in natural and synthetic samples. The tolerance level for some metal ions can be increased by addition of a masking agent (see Table 3). However, some interferences were minimized by the addition of glycine as a masking agent. For this reason the glycine–HCl buffer was chosen for the determination of these metal ions.

3.5. Sample analysis

In order to test the accuracy and applicability of the proposed method to the analysis of real samples, six biological reference materials mineralized as described under "Sample preparation" were analysed. The standard additions method was used and the results were obtained by extrapolation (similar results were obtained from the calibration graphs). These results, as the average of three separate determinations, are shown in Table 4. As can be seen, the metal concentrations determined by the proposed method are in close agreement with the certified values.
Fig. 3. Effect of reagent concentration (organic phase) on the extraction of 10 μg of Cd, Co, Cu and Ni. Aqueous to organic phase volume ratio: 20. Shaking time: 5 min. Symbols as in Fig. 1.

4. Conclusions

Two of the most frequently stated advantages of ICP as a source for emission spectrometry are its multi-element capability and low detection limits. However, in certain instances, detection limits possible with the ICP are still inadequate, especially when the sample has a complex matrix. There are also many sample matrices that present difficulties in their own right. Problems may arise due to the high dissolved solid content of the sample solution, which can cause erratic nebulization and salt build-up on the torch aerosol injector tip. In these circumstances, solvent extraction can provide valuable analyte separation from an interfering matrix. This study has shown that the

ICP method described enables the determination of Co, Cd, Cu and Ni in biological materials. Detection limits for Cu, Cd, Co and Ni ranged from 0.25 to 3.7 ng ml^{-1}, which compares favourably with other ICP-AAS methods [33].

Table 2
Limits of detection and determination

Element	Limit of detection (ng ml^{-1}; aqueous phase)	Limit of determination (ng ml^{-1}; aqueous phase)
Cadmium	0.7	2.2
Cobalt	3.0	10.5
Copper	0.25	0.8
Nickel	3.7	10.8

Abstract

This work presents an overview of electrochemical techniques, namely potentiometry, amperometry, tensammetry, electrocapillary measurements and biosensors, recently applied for the determination of surfactants.

Keywords: Surfactant; Electrochemistry; Analysis

1. Introduction

Surface-active agents (surfactants) are produced worldwide in large amounts. The total world consumption was 4 500 000 tonnes in 1993 [1]. A surfactant is an amphiphilic molecule which contains in its structure a hydrophobic non-polar part and a polar part whose structures may differ according to the nature of the tensio-active molecule. Table 1 shows the global repartition between the four groups of surfactant [2].

Surfactants are widely used in household or industrial cleaners, cosmetics, research laboratories, etc. Even though at the present time most tensio-active products used are biodegradable, their accumulation, or the accumulation of their

biodegradation products in natural waters, induces water pollution which can, in extreme conditions, lead to the destruction of the surface water fauna and flora [3–8]. The literature devoted to the determination of surfactants is greatly expanding and a number of applications are oriented towards the analysis of environmental samples [9–11] and in the quality control of manufactured products [9,11].

The most widely used technique in surfactant analysis is the so-called two-phase titration. In this method, the surfactant is extracted in an organic hydrophobic solvent ($CHCl_3$) as a lipophilic ion-pair formed with the titrant. The latter is generally a surfactant of opposite charge. The titration is carried out in the presence of an ionic dye (or a mixture of ionic dyes) which colours the organic layer differently in the presence of an excess of anionic or cationic surfactants [9,12–16]. This procedure is currently used

---

as a standard method; however, it suffers from several drawbacks (Table 2).

Alternative analytical methods have been developed such as spectrophotometry [17-20], ion pairing [21] and thin-layer chromatography [22,23], gas chromatography after derivatisation or thermal decomposition [24,25], HPLC coupled with conductimetric detection or post-column extraction and UV detection [11,26-32] capillary electrophoresis with UV detection and electrochemistry [11,33]. This review is intended to provide an overview of recent electroanalytical methods devoted to surfactant analysis.

2. Potentiometry

Volumetric titration of a surfactant can be carried out in the presence of an ion-selective electrode (ISE) with potentiometric end-point detection. During the assay, the titrant and the surfactant to be analyzed form an ion-pair insoluble in water. Before the equivalent point, the analyte is in excess and, afterwards, the titrant is in excess. The electrode may be sensitive to the analyte or to the titrant. Basically, the electroactive part of an ISE membrane consists of an association of an ion-pair (C^+A^-): where A^- is an anionic surfactant (AS) and C^+ is a positively charged counter ion, e.g. a cationic surfactant (CS). This kind of ISE is suitable for the detection of A^- and C^+.

Three different types of ISEs have been developed: liquid impregnated inert membrane ISEs, conventional polymeric membrane ISEs (comprising an internal reference cell), and polymeric-coated wire ISEs.

2.1. Liquid impregnated membrane electrodes

The shape of this kind of electrode is approximately the same for all ISEs (Fig. 1a). A glass tube is stoppered at one end with a Teflon membrane or a hydrophobic glass frit impregnated by the sensing solution [9]. This solution is an ion-pair, e.g. hexadecyltrimethyl ammonium-dodecylsulphate [9], dissolved in a hydrophobic organic solvent often belonging to the nitroaromatic derivatives. The inner body of the electrode is filled with a

chloride solution of a diluted anionic surfactant and a Ag/AgCl reference electrode is dipped into this internal solution. The measurements are realized versus a second reference electrode (Ag/AgCl or SCE). Other liquid-membrane-based ISEs have been developed [9,34-37]. Ishibashi et al. [34] used a Crystal Violet salt (Fig.

2) in a nitrobenzene or 1,2-dichloromethane matrix as the active sensing part. This electrode is sensitive to aromatic sulfonates. The advantage of this membrane is the presence of hydrophobic groups in the Crystal Violet molecule which limit the dissolution of the sensing solution in aqueous samples. Sap et al. [37] used an Fe(II) bis [2,4,6-tri(2-pyridyl)]-1,3,5-triazine complex embedded in the sensor for the analysis of ASs such as dodecyl sulphate (DS^-). The authors reported a linear response range between 7×10^{-6} and 1.5×10^{-3} mol l^{-1} without any interference from inorganic salts. This ISE, however, is also sensitive to other organic ions. In such titrations, the end point is detected by a potential jump whose magnitude increases with the alkyl chain length of the surfactant (formation of a more hydrophobic ion-pair). A successful ISE for the titration of CS with sodium tetraphenylborate has also been developed [9]. The reaction mechanism will be discussed below.

Two major problems encountered with all liquid membrane electrodes are the drift of the potentiometric signal with time and a risk of membrane dissolution in the aqueous phase when the concentration of the surfactant approaches the critical micelle concentration (CMC). Actu-

ally, it is practically impossible to use liquid membranes in direct potentiometric measurements of surfactants. The electrodes are generally applied for end-point detection in volumetric titrations. A comparison of the results obtained with the electrode of Anghel et al. [35] and the two-phase titration procedure reveals great accuracy for both techniques. However, the analysis of commercial cosmetic products and washing powders gives better results with the potentiometric titration method [35].

2.2. Conventional polymeric membrane ISEs

Liquid membranes have been replaced by plasticised polymeric membranes. These electrodes are more robust and less sensitive to solubilization in aqueous media. The success of this kind of electrode is related to its simple membrane design (Fig. 1b) [38]. The first step of the fabrication consists of dissolving a polymer (generally PVC), a large amount of plasticiser, and the sensing component in an organic solvent (e.g. THF or cyclohexanone). The latter is allowed to evaporate, leaving a dry membrane. Then, the membrane is adjusted onto the body of the electrode. Using a plasticiser:PVC ratio of 70:30, this type of membrane can be regarded as a single phase homogeneous mixture [12]. The choice of the plasticiser is of considerable importance. The nature of this compound will influence the slope and the linear range of the ISE response. The amount of plasticiser determines the stability and the longevity of the electrode. Ortho-nitrophenyl octyl ether (NPOE) [2,12,36,39–53] and nitrophenyl phenyl ether (NPPC) [12,39,46,54–56] are currently the most commonly-used plasticisers. The polymeric substance must be insoluble in water and chemically compatible with the plasticiser and the sensing material. Moreover, the glassy transition temperature (T_g) of the membrane mixture must be below the working temperature. Note that the T_g of PVC is $+81°C$, but it falls to $-65°C$ when mixed with 70% of NPOE. However, due to the deleterious effect of the surfactants, direct measurements using polymeric membrane ISEs still suffer from instability of the electrode potential [9].

The first PVC-based ISEs used in surfactant titrations were nitrate and calcium ISEs, sensitive to AS and AS or CS respectively. However, it can be understood that these electrodes suffer from many interferences such as bivalent cations (Mg^{2+}, Sr^{2+}, ⋯) for the calcium ISE and anions (Cl^- or SCN^-) for the nitrate ISE. As explained above, the electrodes are sensitive to the variation of either the analyte or the titrant concentration. This explains why the nature of the titrant used can greatly influence the evolution of the titration. The titrant is usually sodium dodecylsulfate or tetraphenylborate for the determination of ASs. It is N-benzyl-N,N-dimethyl-N-[4-1,1,3,3-tetramethyl-butyl) - phenoxyethoxyethyl] - ammonium chloride (commercial name: Hyamine 1622), cetylpyridinium chloride or 1,3-dodecyl-2-methyl imidazolium [2,51,57] (commercial name: TEGOtrant A100; Metrohm) for the determination of CSs. The molecule of TEGOtrant A100 is more hydrophobic than Hyamine 1622 (Fig. 3) and its use gives higher potential jumps than with Hyamine. Moreover, the TEGOtrant permits the detection of alkyl sulphates with shorter chain lengths and less lipophilic molecules [57].

Today, it is possible to find some commercial ISEs specifically constructed for surfactant analysis, e.g. Orion model 93-42 [49,53], ASTEC model TSE 01/91 [48,51] and, more recently, the Metrohm "High Sense Tenside" ISE [2,41,42,51] whose sensing part is based on PVC + NPOE + an appropriate ionophore. The latter electrode is

Hyamine 1622
TEGOtrant A100

Fig. 3. Structure of Hyamine 1622 and TEGOtrant A100.

able to work for more than 7 months with a relative standard deviation (RSD) of between 0.2 and 1.3% for ASs [51]. The High Sense Electrode is stable over a wide pH range [1–12] and its use permits differentiation between some detergents in mixtures simply by changing the pH of the analyzed sample [57]. The successful analysis of a soap/alkyl sulfonate or amine/quaternary ammonium mixture has been reported [57]. Another important advantage of this electrode is its linear response over a large range of surfactant concentration. Recently, Szczepaniak and co-worker [48,50] proposed a mercurated organometallic polystyrene (R–Hg–Acetate) as the active sensing part in a PVC-ISE for AS determination. The plasticiser is a 1:1 mixture of NPOE and dodecyl phthalate. This electrode shows a Nernstian response (59 mV per decade of surfactant concentration) for many surfactants with response times of 10 s and 1 min for 1×10^{-3} and 1×10^{-6} mol l^{-1} of SDS respectively.

Buschmann and co-workers [2,41] have demonstrated that a PVC–NPOE–ionophore ISE is suitable for the determination of amphoteric (ZS) and cationic (CS) surfactants. Amphoteric surfactants are composed of a hydrophobic chain ending in two different polar groups, e.g. an amido or ammonium group at one site and a carboxylate or sulfonate group at the other. At pH < 1.5, the ZS reacts as a CS and can be titrated by a bulky counter ion such as tetraphenyl borate. Here, the ionophore is a TPB$^-$ – TPP$^+$ (tetraphenyl phosphate) or a TPB$^-$ –CP$^+$ (cetylpyridinium) ion-pair [41]. Using this procedure it is possible to detect a ZS in the presence of a CS by volumetric titration because the potential jumps are significantly distinct, the RSDs being 2 and 7.5% respectively.

Non-ionic surfactants (NS) have also been analyzed by potentiometric titration. Moody and co-workers [54,55] and Buschmann and co-workers [41,51] take advantage of the fact that the ethoxylated part of NSs can be complexed with a bivalent cation such as Ba^{2+}. The positive complex is titrated with TPB$^-$. Jones et al. [54] report a detection limit of 1×10^{-7} mol l^{-1} for Antarox 880. However, the analysis takes more than 1 h. Modified PVC electrodes with functional end

groups have also been tested [58,59] but, up to now, these probes do not seem to be as effective as the others.

All the described PVC membranes are homogeneous. The sensing material, e.g. an organic anion in the case of an electrode sensitive to CSs, is dissolved in this membrane. However, homogeneity is not an absolute criterion and an electrode sensitive to CSs can be constructed with a carrier insoluble in the membrane matrix. A synthetic clay, laponite, has been recently used as active material for such a membrane. The results obtained with this configuration are similar to those obtained with a "classical" membrane, e.g. a linear response of the potential is observed between 5×10^{-7} mol 1^{-1} and the CMC for dodecyltrimethylammonium with a response time of 1 s. An extended electrode life time of more than 1 month is reported [60].

2.3. Polymeric-coated wire electrodes

The titration of surfactants with an ISE having no inner solution (Fig. 1c), the so-called coated wire electrode (CWE), has been performed. In a CWE, a metallic or a carbon wire is coated with a plasticized polymer/ionophore solution. The electrode is ready after solvent evaporation. The nature of the metallic wire may interfere with the electrode response if the coating is non-uniform [61], and it also has to be chemically inert towards the membrane components [45]. Aluminium [12,43–45,47,56], graphite [62–64] and platinum [9] are commonly used as substrates. CWEs exhibit interesting properties, they can be machined in any shape, and they are characterized by a fast response time due to the reduced thickness of the membrane layer. They do exhibit, however, a shorter life time and a higher potential drift. For this reason, CWEs are better applied under hydrodynamic conditions, e.g. in flow-injection analysis, where the contact of the sample plug with the electrode surface is brief.

An interesting membrane has been constructed by Dowle and co-workers [63–65]. It is prepared by coating a graphite rod with a PVC solution containing tritonyl phosphate (TTP) plus an appropriate ionophore (0.1%). The latter is tetrade-

cylammonium dodecyl sulphate which is sensitive to ASs. The characteristics of this electrode are summarised in Table 3. This electrode operated well in ethanolic solutions (20% v/v) and can be used under flow conditions such as in HPLC. Later, this CWE was redesigned and integrated into a flow-through system [64]. The inner side of a graphite tube was coated with the active membrane. The disadvantages are a relatively poor life time and the need to calibrate the electrode several times per day.

The group of Vytras [43,44] has elaborated a CWE able to follow titration of CSs and ZSs by TPB$^-$. The addition of Ba^{2+} in the membrane permitted titration of NS. Results reported for the determination of the mean oxyethylene unit numbers per one TPB$^-$ ion are in the same range as those obtained by Gallegos [49] using an Orion electrode. The electrode appears to be stable for more than 7 months of intensive use [44].

A recent communication of Lowy et al. [62] shows the utilization of heteropolyanions (HPAs) for quaternary ammonium titrations. HPAs (α-P$_2$CoMoW$_{16}$O$_{61}$(H$_2$O)$^{8-}$) exhibit a high symmetry, high stability and are not influenced by the presence of inorganic salts, neutral and anionic organic molecules (alcohol, acrylonitrile, propanenitrile). The characteristics of HPAs in surfactant titration are reported in Table 4.

All of the above-mentioned electrodes are based on polymer membranes that dissolve when used in organic solvents. Actually, solid state and conventional polymeric electrodes which do not dissolve in mixed aqueous–organic titration systems are still needed.

3. Amperometry

The general measuring principle in amperometric analysis of surfactants is based on the monitoring of a faradaic current at an electrode, for a selected potential, due to the electrolysis of an electroactive species. Usually, the surfactant is not electroactive and it is necessary to use an indirect amperometric technique. In this case, the solution contains a certain amount of an electroactive species (a marker) which is oxidized or reduced amperometrically at the working electrode. The current due to the marker decreases in the presence of surfactant, which inhibits the electronic transfer at the electrode surface, and the concentration of surfactant can be related to the magnitude of the current decrease.

3.1. Indirect amperometric techniques

Polarographic maximum suppression by a surface-active substance can be used to determine, at a mercury electrode, the concentration of surfactants in solution. In polarographic measurements, faradaic current begins to flow as the electrode approaches the reduction or oxidation potential of the electroactive species involved. A classical polarogram has a sigmoidal shape and the electrochemical process is, at the wave plateau, usually controlled by adsorption, diffusion or kinetic parameters [66]. However, often, a greater current than the limiting current may appear; this is called a polarographic maximum. The amplitude of the maximum is affected by the presence of surfactants and it is possible to correlate the amount of a surfactant to the decrease of the maximum current, i.e. maxima of Hg(II) or oxygen [67–69]. The technique of polarographic maxima suppres-

Table 4

sion (TPMS) shows, however, limited selectivity. Actually, all impurities which are able to be adsorbed at a given potential on the electrode, such as those present in distilled water, in reagent-grade chemicals, in mercury, in containers, can be a source of interferences [66]. For this reason, the analysis of surfactants by the TPMS requires preferably one or more separation steps. Moreover, the experimentation is not always easy to perform. If the concentration of the surfactant is too high, the polarographic maximum is totally suppressed but the polarographic wave may be affected as well [66,70]. In fact, the total maximum suppression corresponds to a coverage of the electrode surface by 1/20 or 1/100 of the amount able to modify the faradaic process. This corresponds to 0.1% coverage of the surface [71]. The theory of TPMS can be found in the books by Bard [66] or Heyrovsky and Kuta [70]. The restricted useful concentration domain plus the lack of specificity are the main disadvantages of the TPMS and probably explain the limited interest devoted to this technique. However, the inhibition of a faradaic process can be advantageously exploited by other techniques.

The adsorption of a surfactant on the electrode surface can be monitored by its influence on the voltammetric response of an electroactive species at this electrode. For instance, the study of the reduction of a metal ion at a hanging mercury drop electrode (HMDE) through the adsorbed layer can lead to information on the surfactant concentration in solution [72]. In a similar approach, using a modified graphite working electrode, Skoog et al. [73] studied ASs, CSs and NSs by their influence on the amperometric and cyclic voltammetric responses of hexacyanoferrate. In a flow system, they noted that the presence of NSs has an irreversible blocking effect on the electrode response which required tedious surface reconditioning before further analysis.

The suppression by a surfactant of the adsorptive voltammetric response of the nickel–dimethylglyoxime complex at an HMDE, a glassy carbon mercury-film-coated electrode or a dropping mercury electrode was also reported [74,75]. Here, in contrast to the theory, the current decrease is approximately proportional to the sur-

factant concentration. However, the response is linear only within a narrow range of surfactant concentration: 0.5–3 mg l^{-1}, 0–65 mg l^{-1}, 0–300 μg l^{-1} for linear alkylbenzene sulfonate [74], hexadecyltrimethylammonium bromide [75] and cetyl pyridinium chloride [75] respectively. With the same method, it is possible to analyze both types of ionic surfactants. The reported limit of detection is 100 ppb for alkybenzene sulfonates. Tested in environmental and industrial conditions, this technique has the drawback of being influenced by some interfering materials which are also able to be adsorbed [74,75]. The study of the inhibition of *para*hydroquinone oxidation at a graphite electrode in the presence of a surfactant (phospholipid) was recently reported [76]. A decrease of the oxidation peak is observed by raising the surfactant concentration. Phospholipids in amniotic fluids were also determined by their inhibition of the oxygen reduction at the DME [77].

3.2. Modified gold electrode

In commercial formulations, surfactants are mixed in matrices which are becoming more and more complex. A first separation step is often required to eliminate interfering species (e.g. chromatography, BiAS precipitation, etc). For routine analysis, however, it is of interest to develop techniques which are able to work directly in such complex media. A self-assembled monolayer (SAM) modified gold electrode may be used for this purpose. Recently, Kawaguchi et al. [78] took advantage of the perturbation of a lipidic membrane structure fixed at a gold electrode to elaborate a new electrochemical assay for surfactants. The authors modified the surface of a clean gold electrode by chemisorbing a monolayer of alkane thiol [78]. The pretreatment of the surface is essential as it will define the characteristics of the SAM electrode [79–82]. The cleaning consists of polishing the gold surface with alumina or diamond paste and rinsing with a solvent (water, chloroform, ethanol, etc.) [77,79–83]. The structure of the alkane thiol SAM is quasi-crystalline [80,82], the alkyl chains are oriented primarily in an all-trans configuration and are nearly close packed (a $\sqrt{3}$x$\sqrt{3}$ $R30°$ adlattice forms on

Au) [79,84]. This monolayer represents a physical barrier between the electrode surface and an electroactive marker in solution (e.g. hexacyanoferrate) (Fig. 4a). The sensitivity of the SAM–Au electrode to the redox behaviour of Fe^{3+} [77], $Fe(CN)_6^{3-}$ [77,78,85], ferrocene dimethanol [85] and $Ru(NH_3)_6^{3+}$ [85] marker ions is very poor. However, the presence of a surfactant in solution will change the organisation of the SAM allowing one to observe the electroactivity of the marker (Fig. 4b). For instance, no reduction current of $Fe(CN)_6^{3-}$ ions is detected by cyclic voltammetry at an alkylthiol-modified SAM gold electrode (Fig. 5a, b) [86]. The introduction of a CS into the solution gives an increase of the reduction current (Fig. 5c). This current increase is related to the CS concentration and can be exploited by amperometry in flow-injection analysis (FIA) (Fig. 6) [86]. A linear response is obtained for cetyltrimethylammonium chloride solution (CS) between 5×10^{-6} and 1×10^{-3} mol l^{-1} with a response time of less than 2 s. The precise reaction mechanism of the observed phenomenon is not yet explained. It might be related to the formation of an ion-pair between the CS and the redox tracer which could diffuse through the monolayer and could be reduced at the gold electrode surface [77]. The electrode response is quite selective, i.e. by replacing CS by AS or NS only a weak baseline current decrease is observed. This can be the result of a steric effect and/or electrostatic repulsion [77].

The advantage of using a gold electrode modified with alkane thiol is related to the strong covalent bond between gold and the modifier sulphur head [87]. Methanol can be present in the solution since its presence is not affecting the SAM layer and it is possible to perform flow-injection or HPLC analysis [79]. The SAM electrode may be functionalized by judicious selection of the thioalkyl modifier allowing improved selectivity [85,88–90].

3.3. Carbon paste electrode

Recently, other sensor matrices have been investigated. Carbon paste electrodes (CPEs) have been considered since they are readily modified
Fig. 4. Schematic of the alkane thiol SAM gold electrode: (a) in the absence of surfactant; (b) in the presence of surfactant.

and display a very low residual current in a large potential range. Kim et al. [91] use ferrocene in the CPE as a redox tracer. They report a modification of the redox behaviour in the presence of different surfactants. In the presence of sodium dodecylsulphate, the oxidation peak current of ferrocene is enhanced by a factor of 3.5 [91]. A limitation of the technique is its duration since the electrode–solution contact time is 1 h. Change in the CPE surface area (erosion) is likely to occur in the process but clear explanation of the observed behaviour is not reported.

4. Tensammetry

The determination of electroinactive molecules which are surface active can be performed by another indirect technique, tensammetry. Tensammetry is the study of the differential capacity–potential curves and of parameters which are able to modify the double layer capacity, such as:

nature and concentration of an adsorbed species (here surfactant);

applied electrode potential (corresponding or not to the potential of maximum adsorption);

kinetic parameters (mass transport, adsorption rate, stirring, frequency of the superimposed alternative potential, ···).

The capacitative curves measured under conditions of adsorptive equilibrium present, in the ideal case, five different potential domains [92]. There is one central domain where the capacity passes through a minimum value which diminishes when the concentration of surfactant increases (domain III in Fig. 7). This corresponds to the maximum of adsorption for one concentration. There are two domains (I and IV) at extreme potentials where no more adsorption takes place. And, between these minimum and maximum potentials of adsorption, there are two domains (II and IV) which are characterized by an increase of the capacity with the increase of the surfactant

concentration. Cases II, III and IV are of analytical interest and the relation between the capacitative values and the surfactant concentration depends on the type of adsorption isotherm (Henry, Langmuir, ...) [92]. It follows that the relation between C_d and C is complex and depends on the frequency of the alternating current used.

In the ideal case [92] of a HMDE, i.e. where the adsorptive parameters (concentration C, charge q, interfacial tension γ and relative superficial excess Γ) can be determined with good accuracy, the differential capacity (C_d) can be expressed, at the state of adsorption equilibrium, as

$$C_d = \frac{dq}{dE} = \left(\frac{\partial q}{\partial E}\right)_\Gamma + \left(\frac{\partial q}{\partial \Gamma}\right)_E \frac{d\Gamma}{dE} \qquad (1)$$

and, in the case of the Henry isotherm, the relative superficial excess is proportional to the concentration

$$R \cdot T \cdot \Gamma = B(E) \cdot C \qquad (2)$$

where B is a function of the applied potential and C is the concentration of the surfactant [92,93]. By combining Eqs. (1) and (2), it appears that the differential capacity is thus related to the concentration of surfactant by a complex relation
Fig. 5. Cyclic voltammograms of 1×10^{-4} mol l^{-1} Fe(CN)$_6^{3-}$ in 0.1 mol l^{-1} KCl. 0.025 mol l^{-1} acetate buffer pH 4.74 and 20% acetone at a bare gold electrode (a), at the SAM-modified gold electrode (b) and at the SAM-modified gold electrode in the presence of a CS (c). Fig. 6. FIA of cetyltrimethylammonium chloride (CTA). Amperometric reduction at a SAM-modified gold electrode (at 0.0 V vs. Ag/AgCl reference electrode). 20 μl injection of CTA at concentrations of (a) 2.5×10^{-6}; (b) 2.5×10^{-5}; (c) 5×10^{-5}; (d) 1×10^{-4}; (e) 2.5×10^{-4}; (f) 5×10^{-4}; (g) 1×10^{-3} mol l^{-1}. Carrier as in Fig. 5 plus 1×10^{-5} mol l^{-1} hexacyanoferrate.

$$C_d = \text{cte} + \left(\frac{\partial q}{\partial \Gamma}\right)_E \cdot \frac{C}{R \cdot T} \cdot \left(\frac{dB(E)}{dE}\right)_\Gamma \qquad (3)$$

where cte is equal to $(\partial q/\partial E)_\Gamma$ and corresponds to the value of the capacity for a given coverage. As it appears in Eq. (3), C_d is directly proportional to the surfactant concentration C provided that
Fig. 7. Typical capacitance–potential curve for an aqueous solution of an analyte (——) and for an analyte in the presence of a surface-active substance (⋯).

the adsorption phenomenon follows the Henry isotherm. In other isotherms, e.g. Langmuir, Frumkin, ... the relationship is much more complex with no direct relation between C_d and C.

The presence of other compounds which are able to be adsorbed on the electrode surface reduces the selectivity and thus the applicability of tensammetry. Actually, one or more separation steps are necessary in complex sample analysis.

Bos et al. [94] used a gold electrode covered by a mercury film in a flow-injection system to analyze ionic and non-ionic surfactant solutions in the range 1×10^{-5}–1×10^{-4} mol l^{-1}. Generally, they applied a potential of -0.85 V (vs. Ag/AgCl) which corresponds to the analytically interesting domain.

One interesting application is the analysis of phospholipids [76] at the HMDE in acetonitrile–water–methanol media in the presence of LiClO$_4$ as support electrolyte. The C_d–E curves present a maximum at -1.65 V. This corresponds to the adsorption of the solvent at the HMDE. The diminution of the maximum of capacity at this potential with the increase of the concentration of phospholipids is the analytical information used to determine the quantity of phospholipids in solution. The variation of C_d with the concentration follows a sigmoidal curve. In FIA, a tensammetric peak is obtained which is the result of a "temporary" substitution of the solvent molecules by the phospholipids. The reported detection limit is 150–400 ng per 20 μl injection of phospholipid [76]. In their work, Schmidt and Emons [76] distinguish another domain of potential which can be used (corresponding to the central domain discussed before), but the range of concentration is less extended because of the formation of a limited superficial excess.

Szymanski and co-workers [95–99] have developed an indirect tensammetry method (ITM). Here, the analytical signal is the depreciation of the ethyl acetate peak current (at -1310 mV) by a competitive adsorption of NS at an HMDE. In this case, other molecules, i.e. AS, can be adsorbed but the authors took advantage of the fact that AS cannot be adsorbed at the HMDE if the potential is more negative than -1300 mV. They realised their tensammetric measurements from a starting

potential of -1400 mV and then scanned anodically [95]. A general discussion of mixed adsorption problems can be found in the paper by Jehring [93]. A single calibration curve, established with Triton X-100, can be used for the determination of many NSs [95,96]. The response of different NSs are roughly additive [100]. However, if the NS has less than five oxyethylene units, the method cannot be employed. Moreover, the response is highly affected by matrix effects. In a different strategy, Szymanski and co-workers [99,100] developed adsorptive stripping tensammetry (AST). They realised a preconcentration of the surfactant, at a required potential, before recording the tensammetric curves. In this technique, the observed tensammetric peak is a desorption peak. The results obtained are similar to those obtained using the standard bismuth-active substance (BiAS) method [101,102]. In a recent paper, Wyrwas et al. [98] combined the BiAS–ITM techniques for the selective determination of NSs having 3–30 oxyethylene subunits. An application of the ITM for the determination of NSs in surface water is given by the authors [103]. The latter also improved the BiAs precipitation and washing steps allowing better sensitivity (2–1000 μg of NS in the sample) and recovery [104].

Many other examples of tensammetric (and polarographic) analysis of surfactants have been described; a good review has been given by Bersier and Bersier in 1988 [105].

We may also point out that double-layer capacitance measurements have been realised using a SAM gold electrode [106,107]. Here the surfactant effect is due to a change of the magnitude of the electrode inlayer capacity.

5. Biosensor

During the last few years, many biosensors have been developed for monitoring the fluctuation of environmental parameters [10]. In this way, a novel bioreactor-type electrochemical sensor for the determination of linear alkylbenzene sulfonates (LASs) has been described [10]. The principle of this biosensor is based on the fact that, when the LASs are biodegraded by LAS degrad-

ing bacteria, their respiratory activity in solution increases with concomitant decrease in dissolved oxygen. The latter can be followed by an oxygen electrode positioned on-line in an appropriate flow set-up. Using this novel microbial sensor, a linear response up to 6 mg l^{-1} of LAS can be achieved in less than 15 min. Applications to surfactant analysis in river pollution are foreseen.

6. Electrocapillary measurements

The quantification of a surfactant can be realized by electrocapillary measurements [108]. In the presence of a surfactant, the interfacial tension (γ) of a mercury drop electrode changes and can be estimated by measuring the mercury drop time. Thus, the change of the drop time will give, at a potential corresponding to the maximum of adsorption, information about the amount of surfactant present in solution [108,109]. This kind of measurement is difficult to perform because many parameters have to be controlled, such as the state of the electrode capillary and the adsorption equilibrium. The latter can be achieved by convective adsorption accumulation. In the ideal case the equation relating γ to the drop time (t) can be expressed by the equation [109]

$$\gamma_{E,C} = K \cdot t \qquad (4)$$

Under standard conditions of capillary internal diameter, if the length of the capillary is lower than 100 cm, K is also a function of γ. The superficial excesses (Γ), which are representative of the quantity adsorbed, are functions of the concentration and applied potential, and are related to the interfacial tension by the equation

$$-\frac{1}{R \cdot T} \cdot \left(\frac{\partial(\Delta\gamma)}{\partial(\ln C)} \right)_E = \Gamma_{E,C} \qquad (5)$$

In this relation, concentration is equivalent to the activity. Electrocapillary mesurements, like all adsorptive techniques, are subject to interferences by other species able to be adsorbed on the mercury electrode. Due to these limitations and a tedious analysis time, the electrocapillary technique is applicable only with difficulty in routine analysis of surfactants. However, it is an interesting tool for fundamental studies.

Review

Combination of classical dry ashing with stripping voltammetry in trace element analysis of biological materials: review of literature published after 1978

Pavel Mader*, Jiřina Száková, Eva Čurdová[1]

Faculty of Agronomy, Czech University of Agriculture, 165 21 Prague 6-Suchdol, Czech Republic

Abstract

Critical statements have appeared recently in the literature concerning the need for classical dry ashing in trace element analysis of biological materials. In contrast, respected institutions (AOAC, Nordic Committee on Food Analysis, etc.) as well as numerous other laboratories have developed, verified, and/or successfully used classical dry ashing in practical analyses of a number of materials of biological origin. Hence, it is desirable to find out under which conditions the latter decomposition technique yields good and accurate results. Since electroanalytical techniques are among the most demanding with regard to the completeness of the biological matrix removal, we decided to critically review the literature published after 1978 in which classical dry ashing is combined with some version of electroanalytical measurement. It emerged from this review that in particular the charring step requires careful performing. When performed well, classical dry ashing leads to complete removal of the organic matrix and to accurate analytical results for a number of determined elements.

Keywords: Classical dry ashing; Stripping voltammetry; Trace element analysis; Biological materials; Literature review

"A number of sample preparation procedures used today have been in use for more than 100 years. For example, heating samples in open beakers over flames or burners, a technique that doubtless predates the era of the alchemists, is still widely used today, especially when the modern hot plate is added to the list of applicable heating sources. However, the experimental conditions that prevail in open-beaker digestions are, at best, empirical." [1].

"Decomposition of organic matter by dry ashing is often chosen for its seeming simplicity, especially by less experienced working places. From the general point of view, the dry ashing decomposition is very problematic especially in determinations of trace contents of heavy metals. ...Decomposition of organic matter by dry ashing

is in no case suitable for determination of mercury, selenium, arsenic, lead, cadmium, and zinc." [2].

"For the oxidation of organic materials with air or pure oxygen a variety of techniques has been established which produce very good results. Dry ashing however, though widely used in the past and still in use to a certain extent, should be completely abandoned from the protocols of trace analysis. The experimental parameters are poorly reproducible and make dry ashing very error prone." [3].

The essentiality of a number of trace elements for animal and/or plant organisms has been recognized long ago. Other (supposedly non-essential) trace elements such as Cd, Pb, or Hg, are also closely monitored in various environmental compartments including plants and animals in connection with growing awareness of their harmful effects as a consequence of environmental pollution. A number of sensitive analytical techniques has been developed and there exists powerful instrumentation capable of detecting trace or ultratrace amounts of these elements. The majority of these analytical methods belong to the group of so-called destructive methods, i.e. they require biological samples to be solubilized and at the same time mineralized as far as possible prior to the measuring step. There are at least three good reasons for solubilization and mineralization of biological tissues:

(1) In biological tissues, determined trace elements are present in several chemical forms; some of them do not give any signal during measurement, others give signals of different intensities. Mineralization transforms the analyte into a single chemical form with uniform response.

(2) Organic components of biological materials greatly interfere during measurement in many measuring techniques.

(3) Heterogeneity is a typical property of many biological materials. The possibility of using a larger amount of analyzed sample which, upon mineralization, turns into an homogeneous digest, helps to overcome this complicating factor.

In parallel with a great number of measuring techniques, there also exists a broad spectrum of decomposition methods in trace element analysis of biological materials. General evaluation of these methods as such is not possible. Other factors, namely the analyte(s), the matrix, and the technique

to be used for measurement must also be taken into consideration in such an evaluation. Thus for example, pressurized wet digestion with nitric acid at temperatures lower than 200°C in a number of instances was shown to be an inappropriate preparation step for anodic stripping voltammetry since it frequently leaves an interfering residue of incompletely degraded organic matrix in (and sometimes introduces very resistant nitro forms into) the digests [4–8], while for ICP-AES this is a very convenient method because chemical interferences practically do not exist here due to the very high temperature of the inductively-coupled plasma which removes all organics present in the digests very efficiently.

Classical dry ashing (i.e., dry ashing performed in air, in open vessels, and at atmospheric pressure) was, and to a lesser extent still is, one of the extensively used and popular means of organic matrix destruction in trace element analysis of biological materials. Recent criticism, however (see the opening quotes of this paper), pointed out several fundamental drawbacks of classical dry ashing and in a few instances it even requested the complete abandonment of this method of sample preparation [3]. However, a great number of authors have successfully used this method and repeatedly furnished accurate results, as demonstrated for example in interlaboratory testing of candidate certified reference materials. Hence, we decided to go through the literature and see in detail how successful laboratories proceed when applying classical dry ashing as their sample preparation step. In this literature survey, we have used the following two restrictions.

(1) In 1979, an excellent monograph by Bock [9] was published in which dry ashing, as well as a number of other decomposition techniques, was thoroughly and critically evaluated and discussed. Two years later, an important update review paper was published by Sansoni and Panday [10]. Hence, we restricted our literature survey only to papers published in 1979 and thereafter.

(2) From measuring techniques, we have selected electroanalytical methods. All versions of the technique require that the analyzed sample is solubilized prior to the measurement. As concerns the requirement for complete removal of the

organic matrix of biological samples (mineralization), individual versions differ to a large degree. In the case of liquid samples such as body liquids, just dilution of the sample and addition of suitable detergent without any mineralization is often sufficient. The best known example of such a procedure is stripping voltammetric determination of lead in whole blood according to Morell and Girvidhar [11]. The commercially available ASV instrument (Model 3010B by Environmental Science Associates, [12]) requires that the blood sample be diluted by a factor of 30 into an acidified medium containing Ca^{2+} and Cr^{3+} among other ingredients (Hg^{2+}, Bi^{3+}, EDTA, Triton X-100, cf. e.g. Refs. [13, 14]). According to Feldman et al. [15], this large dilution factor reduces accuracy and precision. Morell and Girvidhar [11] used only heparinized blood samples which were sonicated for 15 s and 100 μL was then transferred to 2.9 ml of the Metexchange reagent in a cell. Portable stripping analyzers are currently being developed in Wang's laboratory for clinical screening of blood lead levels in children; the procedure again uses simple sample pre-treatment without complete digestion [16]. According to Ostapczuk [17], for determination of lead and cadmium in blood by potentiometric stripping analysis it is even sufficient to dilute the blood sample with an appropriate supporting electrolyte (0.5 mol L^{-1} HCl), avoiding the use of any complexing agent, detergent, or other ingredients. Thus, this version of the electroanalytical measuring technique seems to be the least sensitive to the presence of small amounts or organic constituents during the steps of lead plating and dissolution.

For solid biological samples, digestion of the sample is very often necessary prior to electroanalytical determination [18]. However, here also in several instances mere solubilization of solid tissue with suitable detergent was demonstrated to be sufficient. An alcoholic solution of tetramethylammonium hydroxide is the detergent of choice for solubilization of solid animal and human tissues in atomic absorption and emission spectrometry (e.g. Refs. [19, 20]). In stripping voltammetry, a broader spectrum of detergents has been applied. Thus, benzyltrimethylammonium methoxide was used for Zn determination in SRMs bovine liver

and oyster tissue [21], and 2,5-dimercapto-1,3,4-thiadiazole was used as a ligand in adsorptive stripping voltammetry for Cd, Zn, Ni, As, Al and Se determination in SRMs oyster tissue and spinach [22, 23]. Wahdat et al. [24] used sodium dodecyl sulphate for Cd, Pb and Cu determination in muscle, fish and blood. In this case, prior to stripping the original sample solution was replaced by another electrolyte (diluted HCl). Without medium exchange, the voltammograms exhibited undesirable adsorption peaks caused by organic compounds present in the solution.

Various sample treatments and stripping modes for the determination of trace elements in blood, urine and solid biological samples have been summarized and discussed by Wang [25].

It can be concluded from the voluminous literature that, *in instances when the biological material is mineralized*, the remnants of the organic matrix and its degradation products *must be completely removed* from the digest prior to anodic stripping measurements. Hence, for the estimation of the mineralization efficiency of various *decomposition* techniques, anodic stripping voltammetry is very suitable.

Of the total of 35 papers which we found in the above survey, 20 ([26–45]) more or less differed from each other. Of the remaining 15 papers ([46–60]), one of the procedures published in the former group of papers was repeated. Ten parameters have been selected which give detailed insight into the proper procedure: M, analyzed material; A, sample weight; B, ashing aid (if applied before charring); C, temperature + time regime of charring; D, temperature + time regime of ashing; E, ashing aid (if applied after ashing); F, repeated ashing with ashing aid (if the latter was added after ashing); G, ash leaching; H, elements determined electrochemically; QA/QC, quality assurance/quality control system.

Table 1 gives details of classical dry ashing decomposition which were used in the more or less independent procedures published in Refs. [26–45]. In Table 2 frequencies and values of the chosen parameters from all 35 reviewed papers (i.e. from Refs. [26–45] given in Table 1 as well as from Refs. [46–60] in which some of the previous procedures were repeated) are summarized. The

Table 1
Details of classical dry ashing procedure used before determination of given elements in biological materials by electrochemical method. following conclusions can be drawn as to how classical dry ashing should be performed in order to yield good results.

(A) With one exception, the dry weight of the sample did not fall below 0.5 g, it mostly being between 1 and 5 g. The possibility to utilize relatively large amounts of biological material in classical dry ashing helps to overcome the heterogeneity of the analyzed material, and also results in increased concentrations of the analytes in the digest.

(B) An ashing aid was applied before charring in ≈50% of cases. When applied at this stage, it was almost exclusively in the form of a salt. H_2SO_4 used in five cases served not to increase the oxidation power but to bind analytes (especially Pb) into the less volatile chemical form. Magnesium nitrate, sometimes combined with nitric acid, was the reagent of choice.

(C) Charring is the most critical step of classical dry ashing. Slow continual or stepwise increase of temperature during charring is considered to be very important.

(D) Nobody ashes above 550°C, and even 550°C is something of an exception. The most frequently used ashing temperature is 450°C or 500°C. (In Ref. [34], where 580°C to 780°C ashing temperatures were used, only Co and Ni have been determined and the risk of losses due to volatilization at higher temperatures is not questioned.) Ashing time is rarely shorter than 8 h, the majority of laboratories ash overnight (16 h).

(E) In instances when an ashing aid was applied only after ashing, it was almost exclusively nitric acid. Since the ash of most biological materials contains several units to several tens of percent carbonates, nitrates are formed in situ after adding nitric acid to the ash. Additional ashing is then in fact melting with nitrates and should help to remove the most resistant degradation products of the organic matrix of biological samples.

(F) The temperature of additional ashing is again most often 450°C or 500°C, and the time of additional ashing is 30 min to 1 h.

(G) In about half of the cases, diluted hydrochloric acid and in the other half, diluted nitric acid are the favorite leaching media. Anodic stripping voltammetry (ASV) works well with both acids, HCl solutions yielding somewhat higher differential pulse (DP) peaks and higher reproducibility [31].

(H) The spectrum of determined elements reflects those elements which are more or less easily determined by electroanalytical techniques. Lead and cadmium by far exceed all the rest.

(QA/QC) Two-thirds of the reviewed papers [26–60] applied some form of quality assurance/quality control (reference material, round-robin test, recovery test, independent method). Seven of them (Refs. [40,50,51,53,54,58,59]) used two such forms simultaneously, while 12 papers (Refs. [26,30,36–39,41,42,44,48,57,60]) do not mention any such support of their analytical data.

Mn = 2 ×
Se = 1 ×

Below, we discuss in more detail several publications in which various modifications of classical dry ashing were methodologically tested, while the electroanalytical technique was selected to be a measuring step.

At the 95th Annual Meeting of the AOAC (October 19–22, 1981), a special symposium was held on "Analytical Methodology for Lead in Foods". Results of this symposium were presented in J. Assoc. Off. Anal. Chem., 65(4) (1982). Here, the results of a collaboration study of classical dry ashing and differential pulse anodic stripping voltammetry for lead and cadmium determination in foods were also presented by Capar et al. [27]. The procedure described schematically in Table 1 of Ref. [27] forms the basis of the AOAC method of classical dry ashing combined with voltammetry, which was published in 1984 in the 14th edition of *Official Methods of Analysis* [61] and reprinted virtually without change in 1990 and 1995 in the 15th and 16th editions [62]. It has been routinely used during the period (e.g. in Refs. [46,48,52,55,58]). In the AOAC procedure a controllable hotplate is used, but only for drying the samples after adding concentrated HNO_3 as an ashing aid. It was also found useful to carry out the ash leaching step (with diluted HNO_3) on the hotplate. The charring step is performed entirely in the muffle furnace. The procedure has been verified [27] for green beans, beef, fish, dried milk, apple juice, and cereals.

In 1984, Adeloju et al. [31] used very resistant liver tissue (Bovine Liver NBS 1577) and compared direct dry ashing without any ashing aid with two versions in which either nitric or sulfuric acid were used as an ashing aid; in both cases, they were applied before the charring step. (Magnesium nitrate was not tested "because purification of this reagent is often necessary for accurate determination of trace elements" [31].) Details of decomposition procedures are given in Table 1 of Ref. [31]. A controllable hotplate has been used for drying samples. Charring (or at least a substantial part of it, see below) and ashing were performed in a muffle furnace, and the ashing temperature was either 450°C or 500°C. Ashing was done overnight. As an ash leaching reagent either dilute nitric or dilute hydrochloric acid was used. Ash leaching was supported by heating on a water

bath. Reproducibility of the three dry ashing methods considered was excellent. Comparison with the certified values for Cd and Pb suggests that the method with sulfuric acid as ashing aid is superior. For ash leaching, the authors prefer dilute HCl over dilute nitric acid since it gives more reproducible results, and also somewhat higher sensitivity.

In 1989, Adeloju [63] considerably extended a previous investigation [31] from 1984 by also including magnesium nitrate as an ashing aid, and comparing all four procedures above with three versions of wet digestion. The spectrum of voltammetrically determined elements was considerably extended as well (besides Cd and Pb also As, Bi, Co, Cu, Ni, Se, V, and Zn). One plant and three animal standard reference materials from IAEA and NBS were used in this study. All four modifications of classical dry ashing were found to be suitable the only problem being an increased blank level when an ashing aid was applied. As a consequence, direct dry ashing without an ashing aid is preferred except for As and Se determination; here, $Mg(NO_3)_2$ as an ashing aid is necessary.

In 1987, Stryjewska et al. [64] published a statistical estimation of the influence of mineralization methods including classical dry ashing (0.5 g sample, 450°C for 2 h, H_2O_2 as ashing aid, additional ashing at 450°C for 1 h, HNO_3 for ash leaching), wet digestion, and pressurized wet digestion, on the results of heavy metals determination in cereals by the DPASV method. Dry ashing gave satisfactory results.

Since atomic absorption spectrometry (AAS) and inductively-coupled plasma atomic emission spectrometry (ICP-AES) are today by far the most frequently used measuring techniques in trace element analysis of biological materials, we also include brief discussion of several papers in which classical dry ashing in combination with AAS or ICP was used.

In 1984, Muys [65] described a procedure in which 1–5 g of sample was weighed into a quartz dish and 5 ml of magnesium nitrate solution added. After drying on a hotplate by gently raising the temperature, the samples were placed in the muffle furnace where stepwise charring was performed (2 h at 150°C, 2 h at 250°C, 3 h at

350°C). Ashing took place for 6 h at 450°C. If necessary, 1 ml of 65% nitric acid was then applied as another ashing aid, dried on a hotplate and reashed for 30 min at 350°C. For ash leaching, 1 ml of water and 5 ml of 65% nitric acid were added and the mixture was heated for a few minutes on a hotplate, and then rinsed with 25 ml of demineralized water into a 50 ml polyethylene bottle. Cd and Pb were then determined by ETA-AAS. The method was found to give accurate results for chicken meat, eggs, milk powder, fish products, bread, vegetables, and animal feedstuffs.

In 1986, Friel and Nguyen [66] described classical dry ashing of hair which gave good results for Cu, Mn, and Zn when flame (Cu,Zn) or flameless (Mn) AAS was used. Hair samples were ashed in a muffle furnace for 12 h at 450°C, after oven-drying at 250°C for 2 h. After they had cooled for 1 h, five drops of concentrated nitric acid were added and samples were returned to the muffle furnace, where they were heated at 250°C for an additional 8 h. Dilute HNO_3 was used for ash leaching.

In 1988, Miller-Ihli [67] compared four methods (wet ashing, dry ashing, microwave dissolution, direct solid analysis), all with the NBS SRM 1577 Bovine Liver. She used magnesium nitrate as an ashing aid in dry ashing and applied it before charring. The latter was performed in a muffle furnace under the following regime: 100°C, 1 h; 150°C, 1 h; 200°C, 1 h; 250°C, 1 h. Ashing temperature and time were 450°C and overnight respectively. For ash leaching, 5% HNO_3 was used. All sample preparation methods provided accurate analytical data for the four elements (Cu, Fe, Mn, Zn) determined.

For ICP-AES we will mention one paper which is according to our opinion of fundamental importance (considerable parts of it were reprinted in van Loon's monograph [68]). In 1983, de Boer and Maessen [69] compared classical dry ashing of the NBS SRM 1577 Bovine Liver (1 g sample in quartz beaker, cold muffle furnace, temperature increase 50°C h^{-1} until 520°C, then ashing for 14 h, ash dissolved in 30% HCl, dilution and filtration) with six other procedures: low temperature ashing in oxygen plasma; two direct approaches (extraction with dilute HNO_3; solubilization with tetramethylammonium hydrox-

ide); and three acid digestions (HNO_3 + $HClO_4$ in microwave oven; H_2O_2 + H_2SO_4; HNO_3 in Teflon-lined steel bomb). According to these authors, "muffle furnace ashing yielded accurate and precise results for Mn, Zn, Cd, and Pb. The principle source of error associated with this procedure is the loss of analytes by evaporation or by retention. Systematic error can be avoided or reduced by application of an experimentally well established temperature–time regime and by careful selection of the crucible material. The use of sulfuric acid for avoiding losses of the volatile elements Cd and Pb appeared to be superfluous. Small retention losses were observed for Cu and Fe.".

As follows from the above, the majority of laboratories which use classical dry ashing have applied an ashing aid (either before charing, or after ashing), and many of them also felt that the charring step should be performed with special care. The ashing aid serves more purposes than just to increase the oxidizing power which facilitates decomposition. It can transform the analyte into the less volatile form (e.g. Pb and sulfuric acid or sulfate), suppress the interaction between the analyte and reaction vessel walls (salts which form voluminous ash), or can also act mechanically (water drops which help to destroy the crust on the top of the ashed sample which hinders the approach of oxygen to the lower layers). Moderation of charring is realized by slow continuous or stepwise increase of temperature in the muffle furnace with extended prolongations at individual temperatures. All four above-quoted AAS papers [65–67,69] used only HNO_3 (mostly dilute) for ash leaching, obviously to avoid the well-known interferences by halides during the AAS measurement. In contrast, the ICP work [69] used HCl as an ash leaching medium (the chemical interferences practically do not exist during the ICP-AES measurement).

Our own practical experience with classical dry ashing began in 1983 with platinum dishes as reaction vessels, a sand bath for drying, and a muffle furnace for both charring and ashing. Since at that time we had at our disposal only electroanalytical instrumentation for measurement, we often ran into the problem of severe interferences

caused by the incompletely destroyed organic matrix of biological samples [70,71]. Replacement of Pt dishes with borosilicate glass Simax beakers and introduction of a stepwise increase of temperature in the muffle furnace during charring plus HNO_3 as an ashing aid (applied after ashing) in 1984 lead to considerable improvement in efficacy of decomposition in many cases (e.g. muscle and kidney [35]) but definitive solution of all the problems came only in 1985 when we decided to totally remove the charring step from the muffle furnace and transfer it instead to a hotplate located in a fume hood. A specially designed hotplate has been prepared and tested (for photographic documentation see Ref. [72]) and a standard operation procedure SOP-1 (cf. e.g. Ref. [73]) developed for soft animal tissues. The latter procedure was later gradually slightly modified in various steps to be optimized for decomposition of a number of other materials of biological origin (higher plants, yeast, green and blue–green algae, gelatine, meat-bone meals, various body liquids, sugar and sugar-containing foods, egg white and egg yolk, sewage sludge, etc.). The procedure has been tested by a number of quality control protocols. The facts that (i) all our laboratory means submitted so far in interlaboratory trials have been accepted [74]; (ii) analyses of many foreign (NBS/NIST, IAEA, BCR, etc.) biological RMs which were performed as a part of the quality assurance/quality control system of our Trace Element Laboratory repeatedly yielded results which agreed well with certified or recommended values for which the determined elements; as well as (iii) our continually good performance in external quality controls of our laboratory lead us to the conclusion that the introduction of the hotplate into the classical dry ashing procedure and adaptation of the details of the time–temperature program of charring to individual types of decomposed biological materials is a fundamental contribution which brings about dramatic improvement in its whole performance. In this connection it was of our great interest to learn at the end of 1992 about the standard operation procedure developed recently by the Nordic Committee for Food Analysis for determination of metals in foodstuffs by AAS [75]. Classical dry ashing is the only recommended procedure

for sample decomposition here, and it has two versions, depending on the availability of a programmable muffle furnace in the user's laboratory. If only an ordinary muffle furnace is available (which is still often the case), charring is performed on a hotplate, using a regime which is almost identical to that which we arrived at a few years earlier. With a programmable muffle furnace, both charring and ashing are done in the furnace, using a carefully selected time–temperature program. There are, however, cases when even laboratories which possess a programmable muffle furnace are strongly advised to pre-ash samples on a hotplate. Two mineral acids are used in the procedure: 6 mol l^{-1} hydrochloric acid as an ashing aid applied after ashing, and 0.1 mol l^{-1} nitric acid for leaching. The reliability of the method has been tested by collaborative study with 16 participating laboratories. It has been verified for the elements Cd, Cr, Cu, Fe, Ni, Pb, and Zn and recommended for their determination in all kinds of food products by AAS; it has also been used for the determination of Ca, Co, K, Mg, Mn, and Na.

All the above facts lead to the conclusion that classical dry ashing can perform well, if it is done well. Well-performed classical dry ashing requires in particular careful and moderate performance of the charring step. The words of deBoer and Maessen [69] deserve repetition at this time: "Systematic error [of classical dry ashing] can be avoided or reduced by application of an experimentally well established temperature–time regime...".

Pikhart [2] unfortunately disqualified himself from obtaining good results even before he begun his investigation. His extraordinarily high selected ashing temperature of 800°C and complete neglect of the need to moderate the charring step prevented him from being successful.

Even the experimentally well-established procedures of classical dry ashing largely lack an exact and objective interpretation in physico-chemical terms. Hence, Boardman [1] is right when he calls for greater elucidation of so far mostly empirically established procedures of classical dry ashing. We fully agree with this need and have performed a separate study [72] in which we studied how classical dry ashing actually proceeds in terms of dynam-

ics and chemistry of organic matrix degradation. Results revealed the strong exothermic character of decomposition during charring and great variability depending on the individual type of biological material. The former finding calls for sufficient moderation of the charring step in order to prevent local overheating of the sample and subsequent risk of loss of part of the analyte due to its mechanical removal from the sample in the form of solid particles of smoke. The latter finding explains why the time–temperature program for charring must be optimized for each type of biological material which is to be decomposed by dry ashing. Under the *controlled* conditions, classical dry ashing has the potential to yield accurate results.

As with every method, classical dry ashing, besides its advantages, also has limitations which have to be respected. Comparison of various decomposition techniques including classical dry ashing has been done many times (see e.g. Refs. [9,10,72,76–85]) and it is not the purpose of this paper to repeat what has been already said. What we cannot accept, however, is the attempt to create suspicion that classical dry ashing cannot give good analytical results under *any* circumstances. It is obvious from the above text that the statement [3] that classical dry ashing should be completely abandoned from the protocols of trace analysis is more of a wish than an actual need and it may well be that such statements should be removed from the scientific literature.

Flow-injection on-line column preconcentration for low powered microwave plasma torch atomic emission spectrometry

Dongmei Ye, Hanqi Zhang, Qinhan Jin*

Department of Chemistry, Jilin University, Changchun 130023, China

Abstract

This paper describes an improvement in detection capability of microwave plasma torch atomic emission spectrometry by using a flow-injection on-line column preconcentration system. The analytical performances of Cd, Cu, Mn and Zn were studied. The analytes were preconcentrated with a thiol resin. The preconcentration period, the pH of the sample solution and the HCl concentration in the eluant were examined in detail. Operating conditions were optimized as follows: sample uptake, 1.2 ml min^{-1}; preconcentration period, 1 min; pH of sample solution, 9; HCl concentration in the eluant, 1 mol l^{-1}. The experimental results show that flow-injection on-line column preconcentration can not only eliminate the effect of some concomitant elements, such as Li, Na and K, on the determination of analyte, but also enhance the sensitivity.

Keywords: Flow-injection; Preconcentration; Microwave plasma torch AES

1. Introduction

Microwave induced plasma (MIP) has been of interest as an excitation source for atomic emission spectrometry (AES) because it is a powerful emission source for a wide range of elements, and inexpensive and easy to operate. One of the major limitations of MIP for AES is its low tolerance to the introduction of aqueous sample. To perform aqueous sample analysis, the amount of water vapor entering the MIP must be restricted

through desolvation, or the power applied to the discharge must be increased. A low power applied to the microwave discharge does not provide sufficient energy to desolvate, atomize and excite the analyte for a large aqueous loading. However, a higher applied power can result in plasma device heating and microwave leakage. Therefore a water-cooled plasma device must be used [1]. Another approach to solving this problem is to improve the plasma device. Okamoto and co-workers [2,3] reported a circularly polarized wave mode cavity that facilitates the production of a high power (> 1 kW) annular atmospheric pressure plasma. The microwave plasma

* Corresponding author

torch (MPT) developed by Jin et al. [4] showed great promise for direct solution analysis. Since the plasma obtained with the MPT has a central channel and the analyte is forced to pass through the central channel, the analyte is efficiently vaporized, atomized, excited and ionized and causes minimal perturbation to the plasma. Matusiewicz [5] reported a new microwave cavity assembly: an integrated microwave plasma cavity/magnetron combination (MPCM). The introduction of wet aerosols can be accomplished by using direct nebulization with no desolvation system. Ng and Chen [6] used a dual, low-powered (<200 W total power) MIP system for direct liquid aerosol introduction. The MIPs are sustained in two Beenakker cavities arranged in tandem. The first plasma performs the major task of desolvation, volatilization, and atomization; the second plasma performs the major task of excitation.

Compared with an inductively-coupled plasma (ICP) source the MIP seems to be prone to interelement effects, especially when an easily ionized element (EIE) is also introduced. This is another major disadvantage of the MIP (the so-called matrix effect). The reason for the existence of the matrix effect is that the gas temperature of the MIP is lower than that for the ICP. There are two ways to overcome the matrix effect. One is to increase the microwave forward power. The other is to separate the matrix from the analyte prior to its introduction into the MPT.

It has long been recognized that off-line preconcentration and separation of trace constituents by using ion-exchange, adsorption or solvent extraction batch procedures are effective in improving the sensitivity and selectivity of atomic spectrometric methods [7]. Principal drawbacks of off-line separation procedures are that they are often time-consuming, frequently require a large sample volume, the sample may be contaminated, and the sample throughput is very low. With the implementation of on-line flow-injection techniques for separation and preconcentration, such drawbacks no longer exist, while the beneficial effects are further enhanced: sampling frequency can be increased by one or two orders of magnitude and consumption of sample and

reagent can be decreased by one or two orders of magnitude. On-line flow-injection techniques also have better precision and are easy to operate automatically [8].

The objectives for on-line pretreatment may be either to remove the interfering matrix or to enhance the sensitivity, or both. Of the different approaches, separations and preconcentrations based on column techniques seem to have undergone the most rapid development, probably owing to the simplicity of operation and the existence of a wealth of knowledge on related batch procedures. When a sample is introduced into an on-line column, the interest of the operator is focused on the complete collection of the analyte, while releasing the matrix to waste, and later on, the complete release of the analyte from the column into the detector. Although flow-injection (FI) on-line column preconcentration has been extensively applied to atomic spectrometry, such as atomic absorption spectrometry (AAS) and inductively-coupled plasma atomic emission spectrometry (ICP-AES)[9], very little has been done so far on coupling it with MIP systems[10]. Madrid et al. [10] determined Cu by applying FI on-line column preconcentration to MPT-AES with an ultrasonic nebulization system.

In this paper, the elements determined are preconcentrated using a thiol resin and introduced into the MPT with an FI-pneumatic nebulization system and the solvent is removed by a desolvation system. The results indicated that FI on-line column preconcentration can eliminate the EIE effects without causing losses in sensitivity or precision.

2. Experimental

2.1. Apparatus

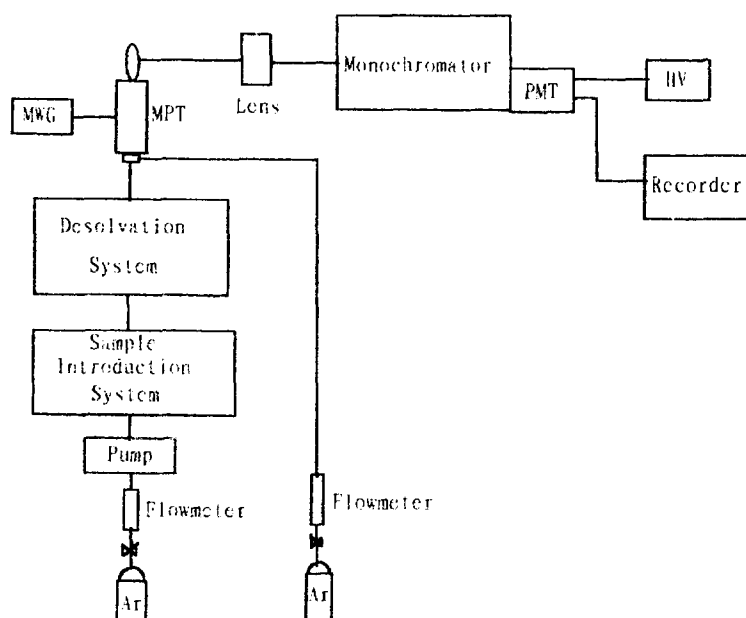
The FI-MPT-AES system was built in this laboratory. The block diagram of the system is shown in Fig. 1. The components of the system are listed in Table 1 and are described below in some detail. The operating conditions are listed in Table 2 unless otherwise stated.


Fig. 1. Block diagram of instrumentation: MWG, microwave generator; MPT, microwave plasma torch; PMT, photomultiplier tube; HV, high voltage.

2.1.1. FI on-line column preconcentration system.

The block diagram of the sample introduction system is shown in Fig. 2. The sorbent extraction

Table 1
Experimental instrumentation

Component	Model	Manufacturer
Torch	MPT	Laboratory built
Nebulizer	Concentric nebulizer	Laboratory built
Spray chamber	Diameter 25 mm, length 200 mm	Laboratory built
Microwave generator	DW-1, 0–100 W	Beijing Geological Instrument Factory
Monochromator	WDG30 $F = 30$ cm, grating 1200 grooves mm^{-1}	Beijing Optical Instrument Factory
Strip-chart recorder	XWT-164	Shanghai Dahua Instruments
Flow injection analyzer	LZ-1010	Shenyang Zhaofa Institute of Automatic Analysis
Lens	Diameter 30 mm, focal length 70 mm, quartz	Beijing Optical Instrument Factory

column (3 mm i.d., 3.5 cm long) was made in this laboratory. The packing filled two-thirds of the volume of the column and was held in place by two small plugs of plastic foam at either end.

Aqueous sample solutions were introduced into the plasma with a pneumatic concentric nebulizer with a desolvation system. In the load position of the actuated injection value, the carrier liquid (distilled water) flows from a peristaltic pump

Table 2
Operating conditions

Parameter	Value
Microwave frequency	2450 MHz
Forward power	60 W
Reflected power	2 W
Plasma viewing mode	Side-on
Plasma viewing position	0–15 mm above top of torch
Carrier gas flow rate	700 ml min^{-1}
Support gas flow rate	400 ml min^{-1}
Sample introduction rate	1.3 ml min^{-1}
Entrance slit height	2 mm
Entrance slit width	20 μm
Exit slit height	1 cm
Exit slit width	20 μm

directly through the pneumatic nebulizer into the plasma while the sample is simultaneously drawn into the sorbent extraction column. When the valve is rotated, the path of the carrier liquid is redirected to flow through the sorbent extraction column thereby carrying the sample plug into the MPT. The loading solution flow rate is 1.7 ml min^{-1} and the eluant flow rate is 1.3 ml min^{-1}.

2.1.2. Desolvation system

Although the MPT discharge will operate stably with a wet aerosol, a simple desolvation system consisting of a heated glass tube, a water-cooling condenser and a concentrated sulfuric acid desiccator is used. It was shown that the system effectively removed the water from the sample solution. Only 0.3% of water entered into the plasma [11].

2.1.3. Torch

The torch used in this study is similar to an ICP torch, consisting of three concentric metal tubes [4]. The plasma support gas is introduced through the intermediate tube and sample aerosol is introduced through the central tube by a carrier gas. The plasma forms between the intermediate tube and central tube near the top of the torch and extends into the surrounding air to form a flame-like discharge with a central channel. The microwave energy is coupled into the plasma via a 6 mm i.d. cylindrical antenna which surrounds the intermediate tube. The plasma can be ignited easily with a short burst from a Tesla coil or by a touch of a screwdriver on the top of the central tube.

2.2. Gas and reagents

Argon (99.99%) was used as carrier gas and support gas. All reagents used were of suprapure

grade or analytical grade. The stock solutions (1 mg ml^{-1}) of all elements were prepared according to standard procedures. To obtain desired concentration of different working solutions, volumetric dilutions of the stock solutions were made. Double-distilled water was used throughout the experiments. The resin used is a thiol resin (Type 190, produced by Nankai University, China) whose active group is -SH. It is similar to Duolite ES-465.

2.3. Intensity measurement

In this study, transient emission signal (peak-shaped plots of intensity vs. time) were recorded with a strip-chart recorder. The peak heights of the signals recorded were measured and taken as the relative intensities. Peak height was used to measure emission intensities and three replicate measurements (RSDs < 3%) were made each time unless otherwise stated. In Figs. 3-7, the intensity is plotted relative to the first signal and in Fig. 8 the intensity is plotted relative to that without an EIE at respective power levels.

Fig. 3. The effect of microwave forward power on emission intensity. Analytical line and analyte concentration in loaded sample: Cd 228.8 nm, 0.3 μg ml^{-1}; Cu, 324.7 nm, 0.3 μg ml^{-1}; Mn 257.6 nm 1.0 μg ml^{-1}; Zn, 213.9 nm, 0.3 μg ml^{-1}; HCl concentration of the eluent, 1 mol l^{-1}.

3. Results and discussion

3.1. Optimization of experimental parameters

To achieve the best analytical performance, the experimental parameters, such as microwave forward power, support and carrier gas flow rates, preconcentration time, preconcentration conditions, and HCl concentration in the eluant, were optimized by using a univariate optimization procedure for simplicity. Because the experimental parameters are known to be inter-dependent, the procedure may not yield the most optimal conditions.

3.1.1. Forward power

As shown in Fig. 3, at lower microwave power (< 60 W), the emission intensities of analytical lines increase as the microwave power increases, and at higher power (> 60 W) an increase in the applied power causes only a slight change in the emission intensities. It is also evident from Fig. 3 that the effects of microwave power on intensities of the ionic lines and atomic lines are very similar. These results are very similar to those obtained with an ultrasonic nebulizer [11] and very different from those obtained with a surfatron (a microwave device) under similar experimental conditions. When a surfatron is used and the experimental conditions are as follows: inner diameter of discharge tube 2-5 mm; carrier gas flow rate 200-800 ml min^{-1}; microwave power, 30-80 W; the emission intensity always increases with the microwave power and at higher power levels (> 60 W) the emission intensities of the "hard lines" (ionic lines and atomic lines with excitation potentials greater than 5 eV) increase more significantly than at lower power levels (< 60 W) [4]. The reason for this phenomenon is probably because for surfatron the plasma is sustained in a discharge tube, so that when the power increases the plasma becomes longer and the power density does not increase significantly. However, the plasma viewing mode is end-on, so the residence time of analytes in the plasma will by prolonged and the emission intensities of the analytical lines will increase. However, for the MPT the plasma is formed between the intermediate and central tubes near the top of
Fig. 4. The effect of microwave forward power on S/B. Analytical line and analyte concentration in the sample solution: Cu, 324.7 nm, 0.3 μg ml^{-1}; HCl concentration of the eluent, 1 mol l^{-1}.

the torch and extends into the surrounding air, so that the plasma expands with the applied power and the power density does not increase sharply.

The effect of microwave forward power on signal-to-background ratio (S/B) has also been studied. Since it was shown that the blank signal was identified with the background signal in this case, the blank signal was measured as background as described in the literature [12]. To measure the blank signal, the recorder is first adjusted to the zero position by blocking all radiation from entering the monochromator at the analytical wavelength. The blank signal is then measured by replacing the analytical sample with a blank that is identical to the analytical sample except that there is no analyte being studied at the same wavelength. The results are shown in Fig. 4. It is evident from Fig. 4 that the effect of microwave forward power on S/B is not significant. The reason is evident. As the power increases, the emission intensities of analytical lines and background emission increase simultaneously, so that S/B does not change with power. Because the concentration of the analyte is very low (0.3 μg ml^{-1}), the analyte signal is always smaller than that of the background.

3.1.2. Gas flow rate

Either carrier gas (central) or support gas (outer) has influence on the stability of the plasma and emission intensity of analytical lines. It is evident that the carrier gas flow rate has more significant influence on the analytical signals than the support gas flow rate [11]. As shown in Fig. 5, for the elements examined an increase in carrier gas flow rate initially causes significant increase in the emission intensities of analytical lines, and then levels off or decreases slightly. The results can be explained in the light of the effect of carrier gas flow rate on the nebulization efficiency, the temperature of the plasma and the residence time of the analyte in the MPT. The nebulization efficiency increases as the carrier gas flow rate increases, but the temperature of the plasma and the residence time of the analyte in the MPT decrease.

3.1.3. Preconcentration time

The effects of preconcentration time on emission signals are shown in Fig. 6. It is evident that an increase in preconcentration time causes an increase in the signal, but when the preconcentration time is greater than 5 min, the signal in-

Fig. 5. The effect of carrier gas flow rate on emission intensity. Analytical lline and analyte concentration in loaded sample: Cd, 228.8 nm, 0.3 μg ml^{-1}; Cu, 324.7 nm, 0.3 μg ml^{-1}; Mn, 257.6 nm, 1.0 μg ml^{-1}; Zn, 213.9 nm, 0.3 μg ml^{-1}; HCl concentration of the eluent, 1 mol l^{-1}.

Fig. 6. The effect of preconcentration time on emission intensity. Analytical line and analyte concentration in loaded sample: Cd, 228.8 nm, 0.3 μg ml^{-1}; Cu, 324.7 nm, 0.3 μg ml^{-1}; Mn, 257.6 nm, 1.0 μg ml^{-1}; Zn, 213.9 nm, 0.3 μg ml^{-1}; HCl concentration of the eluent, 1 mol l^{-1}.

creases slightly or does not increase at all. It is shown that under such circumstances the thiol resin is saturated and with the increase in preconcentration time the competition between analyte ion and other ions becomes more significant. In order to speed up the sample throughput, the preconcentration time used in this study is 1 min.

3.1.4. Preconcentation conditions

In order to preconcentrate the analyte completely, the effect of pH (1–14) of sample solution on preconcentration was studied. The results show that when the pH is about 9, the analyte is preconcentrated completely. The pH of the sample solution is, therefore, adjusted to about 9 with a buffer solution of NH_3–NH_4Cl. However, the concentration of NH_3–NH_4Cl was shown to have no significant effect on emission intensity. In this study the NH_3–NH_4Cl concentration used is 0.05 mol l^{-1}.

3.1.5. HCl concentration in eluant

The effect of the HCl concentration in the eluant (0–2 mol l^{-1}) was also studied. The results show that the effect of HCl concentration in

eluant on peak height is not significant. The only effect is on eluating time. The lower the HCl concentration, the longer the eluating time. In order to reduce the eluating time, an HCl concentration in eluant of 1 mol l^{-1} was selected in this work.

3.2. Detection limits and linear dynamic ranges

The detection limits (3σ) for selected elements obtained by this method under optimized conditions are listed in Table 3. The preconcentration time used here is also 1 min. For comparison, the results obtained by FI-MPT-AES without preconcentration are also included. It is clear from Table 3 that the detection limits obtained by this method are lower than those obtained by FI-MPT-AES under similar experimental conditions. The method appears particularly attractive in view of the enrichment factor and its simplicity of operation.

Enrichment factor (EF) is the criterion used most frequently for the evaluating preconcentration systems. However, the precise meaning of the term is often not defined. There are three different ways in the literature of defining EF. Some workers deduce enrichment factors by comparing the peak height before and after preconcentration [13,14], others do so by finding from a calibration graph of the unprocessed standard solution the concentration which gives the same peak height as the processed sample [15]. Yet another approach is to do the evaluation by comparing slopes of the linear portion of the calibration curves before and after the preconcentration [16]. The first approach is very straightforward, so we used it in this study. In order to obtain the peak height before preconcentration, a regular FI set-up was used, the volume of the sample loop being 150 μl. The EFs obtained are listed in Table 3.

For all elements studied, the linear dynamic ranges determined experimentally are over three orders of magnitude (see Table 3).

It is evident that the detection limits, linear dynamic ranges and EFs are relevant to the experimental conditions, especially the preconcentration time. The sample throughout is 20 per hour.

Table 3
The detection limits, dynamic linear ranges and enrichment factors

Element	line (nm)	Detection limit (ng ml^{-1})		Dynamic linear range (μg ml^{-1})	EF
		This method	FI-MPT-AES		
Cd	I 228.3	3.6	10	0.01–20	4.9
Cu	I 324.7	2.2	9.3	0.01–20	4.4
Mn	II 257.6	3.1	9.1	0.05–20	4.2
Zn	I 213.9	1.8	7.8	0.01–20	4.3

3.3. Precision

The RSDs for determination of selected elements are shown in Table 4. It is clear that the RSDs for selected elements are acceptable.

3.4. Effect of easily ionized elements (EIEs)

There are a large amount of EIEs, especially K and Na, in many natural samples. Study of the effect of EIEs on microwave plasma emission is of significance for developing MWP-AES and improving its application to real sample analysis. The effect of EIEs on emission intensities in MWP-AES has been studied by using TM_{010} (a specific operating mode of a microwave resonant cavity) [1,17–21], surfatron [22] plasma sustained devices and with various sample introduction systems, such as electrothermal vaporization [23–26], pneumatic nebulizer [27,28] and ultrasonic nebulizer [29,30]. The results indicated that the effect of EIEs is very closely related to the discharge system and sample introduction system. When

TM_{010} or surfatron is used, the plasma is sustained in a discharge tube, but for MPT the plasma is formed between the intermediate and central tubes near the top of the torch and extends into the surrounding air and hence the EIE effect may have different behavior. Madrid et al. [10] studied the effect of K and Na on emission of Cu, and a reduction in the K and Na effect by the use of the FI system was observed. In this study a similar reduction of the effect of EIEs on signals of Cu by using the FI pneumatic nebulization sample introduction system was also observed (Fig. 7). It should be noted that the on-line preconcentration is not applied in the EIE effect study. For the EIE effect study, the "column" in Fig. 2 was replaced by a 150 μl sample loop and the sample solution containing analyte and EIEs are introduced into the MPT by using the FI sample introduction system. It was observed that the existence of a large quantity of EIE caused a depression in analyte emission (EIE effect). However, this EIE effect can be reduced simply by an increase in the applied microwave power (Fig. 8).

Table 4
The RSDs for some elements

Element	Line (nm)	Added (μg ml^{-1})	Found (μg ml^{-1})	RSD (%)
Cd	I 228.8	0.30	0.29, 0.30, 0.29, 0.31, 0.30, 0,30, 0.30	0.69
Cu	I 324.7	0.30	0.29, 0.29, 0.30, 0.32, 0.30, 0.31, 0.30	1.1
Mn	II 257.6	1.00	1.0, 1.0, 1.0, 1.0, 0.98, 1.0, 1.0	0.76
Zn	I 213.9	0.30	0.30, 0.32, 0.30, 0.30, 0.30, 0.28, 0.30	1.2
Fig. 7. The effect of EIE using the FI sample introduction system. Analytical line and analyte concentration in the sample solution: Cu, 324.7 nm, 1 μg ml^{-1}; HCl concentration in the sample solution: 1 mol l^{-1}.
Fig. 8. The effect of microwave forward power on EIE interference. Analytical line and analyte concentration in the sample solution: Cu, 324.7 nm, 1 μg ml^{-1}; EIE concentration in the sample solution: Li, 1000 μg ml^{-1}; HCl concentration in the sample solution: 1 mol l^{-1}.

Table 5
The effects of EIE on relative emission intensities

EIE (μg ml^{-1})	Cd		Cu		Mn		Zn	
	a	b	a	b	a	b	a	b
Li (1000)	1.0	0.98	1.0	1.0	1.0	0.99	1.0	1.0
Na (1000)	1.0	0.98	1.0	1.0	1.0	0.99	1.0	1.0
K (1000)	1.0	0.99	1.0	1.0	1.0	0.99	1.0	1.0

[a] Without EIE.
[b] With EIE.

It is clear from Fig. 8 that as the power increases the effect of Li (1000 μg ml^{-1}) on Cu emission decreases. This is because the higher the applied power (energy), the more efficient the volatilization and atomization of the analytes and therefore the EIE effect is decreased. To eliminate the effect of EIE, an on-line column preconcentration technique as described above was adopted and it was shown (Table 5) that when the concomitant EIE concentration reaches 1000 μg ml^{-1}, the EIE still has no significant effect on the analyte emission intensity. The reason for this phenomenon is probably that the thiol resin preconcentrates the

analyte selectively. When a sample solution containing EIEs is pumped through the thiol resin, only the analyte can be preconcentrated and EIEs go to waste, not being introduced into the plasma, so there is no effect of EIEs on the emission intensity of the analyte.

4. Conclusion

The FI on-line column preconcentration technique has provided a first close connection between chemical modification of the sample and the final physical process of MPT-AES detection. It eliminates the matrix interference efficiently and enhances the sensitivity of MPT-AES for elements studied significantly. The FI on-line column preconcentration MPT-AES instrument is simple and fast in operation, and the running cost is low.

Studies on the extraction of Copper(II) with 4-alkyldithiocarboxylate derivatives of 1-phenyl-3,5-dioxopyrazolidine

Aurora Molinari, Raúl Ariz, Alfonso Oliva**

Institute of Chemistry, Catholic University of Valparaiso, Casilla 4059, Valparaiso, Chile

Received 5 May 1995; revised 15 September 1995; accepted 21 September 1995

Abstract

The extraction behaviour of copper(II) from acid solutions (pH 0–6) was studied with the new reagent 4-alkyldithiocarboxylate-3,5-dihydroxy-1-phenylpyrazol (HL; alkyl = n-butyl, n-dodecyl). The species extracted was found to be ML_2. The reagent was used to separate copper(II) from iron(III) in an acidic lixiviation solution of a mineral sample composed of enarguite (Cu_3AsS_4) and pyrite (FeS_2). Additionally, the extraction efficiency of this new reagent was compared with the commercially available LIX 984 N extractant of copper (II).

Keywords: Copper(II); Minerals; 1-Phenyl-3,5-dioxopyrazolidine

1. Introduction

It is known that 4-acyl-5-pyrazolones are good extractants for a wide variety of transition metals, actinides, lanthanides and other ions [1–5]. A few years ago we initiated a program concerning the synthesis and extractive properties of related compounds, where the acyl group is replaced by the alkyldithiocarboxylate. We have described the Cu(II) and Ni(II) complexes of 4-alkyldithiocarboxylate-5-pyrazolones [6] and shown that these ligands are good extractants for Cu(II) at pH 4–6 [7].

Looking for new extractants which can be efficiently used under more drastic acidic conditions with Cu(II), we have turned our attention to alkyldithiocarboxylate derivatives of five-membered heterocyclic diones. In this paper, we report the results of the extraction of Cu(II) in the presence of Fe(III) with ligands derived from 1-phenyl-3,5-dioxopyrazolidine which is also named 1-phenyl-3-hydroxy-5-pyrazolone in the literature [8,9]).

2. Experimental

2.1. Reagents

The ligands 4-butyldithiocarboxylate-3,5-dihy-

droxy-1-phenylpyrazol (HBDTP) and 4-dode-cyldithiocarboxylate-3,5-dihydroxy-1-phenylpyra-zol (HDDTP) were synthesized by the reaction of 1-phenyl-3,5-dioxopyrazolidine with sodium acetate, carbon disulfide and butyl or dodecyl bromide in dimethylformamide (DMF) as the solvent. Stock solutions containing 0.01 M copper (II) acetate and 0.1 M potassium nitrate at fixed pH 0–6 or 0.01 m iron(III) chloride and 0.1 M potassium nitrate at pH 0–2 were used in the extraction studies. Stock solutions of 0.01 M copper(II) acetate, 0.01 M iron(III) chloride and 0.1 M potassium nitrate at pH 0–2 were used for extractive separation studies at pH 0.

The initial metal content of the stock solutions was determined by complexometric titration with EDTA [10]. All the extraction experiments were performed by the batch method with a variable-speed vortex mixer (Orbital Shaker). A mineral mixture of enarguite (Cu_3AsS_4) and pyrite (CuS_2) containing 16.5% Cu and 23.7% Fe, analyzed according to standard ASTM methods and lixiviated with bromine electrogenerated in situ [11], was supplied by El Indio Mining Company (La Serena, Chile) to study the separation of Cu(II) in real mineral samples.

2.2. Extraction and analytical procedure

2.2.1. Extraction of Cu(II) from a 0.01 M copper(II) acetate solution as a function of pH

A portion of the stock solution 10.0 ml was acidified with HCl to a fixed pH and shaken for 10 min in a separatory funnel with an equal volume of a 0.02 m chloroform solution of the ligand. After the extraction, the pH of the aqueous phase was measured with a pH meter and its Cu(II) content was evaluated with 0.1 M EDTA and murexide as indicator. The amount of Cu(II) extracted into the organic phase was calculated from the difference between the metal concentration in the aqueous phase before and after extraction. The same procedure was used in the extraction studies of Fe(III) but with the use of 5-sulfosalicylic acid as indicator in the titration step.

2.2.2. Separation of Cu(II) from an aqueous solution 0.01 M in Cu(II) and Fe(III) at pH0

A portion of stock solution (10.0 ml) was acidified to pH 0 with HCl and shaken for 10 min with an equal volume of 0.03 M chloroform solution of HDDTP. The Fe(III) was precipitated from the aqueous phase with concentrated NH_3 and after filtration the Cu(II) content was evaluated as before.

2.2.3. Separation of Cu(II) from a lixiviation solution of enarguite and pyrite

A portion of the lixiviation solution (2.0 ml) was neutralized to pH 0 with concentrated NH_3 and extracted for 10 min with 3.0 ml of a 0.067M chloroform solution of HDDTP. After the separation of the organic phase, the extraction was repeated five more times, after which all the Cu(II) was transferred, free of Fe(III), to an organic phase. The Cu(II) content after each extraction was determined as follows: 1 ml of the aqueous phase was diluted to 100.0 ml and 10.0 ml of this solution was titrated with EDTA as before.

3. Results and discussion

According to the spectroscopic and analytical data, previously reported IR studies of tautomerism of five-membered heterocyclic ketones [12,13], and the reported ^1H or ^{13}C chemical shifts in related structures [14–17], the production of the reaction between 1-phenyl-3,5-diox-opyrazolidine, carbon disulfide and alkyl bromides is present in polar solvents as a dienolic form (Fig. 1). Chelation of copper(II) must occur through the thiono sulfur atom and 3-hydroxy or 5-hydroxy group.

The extraction of aqueous copper(II) solutions with chloroform solutions of both ligands was studied as a function of pH and the results are shown in Fig. 2. The following features of this study are of interest.

(1) A nearly constant 88–94% yield of extraction is observed in the pH range 0–6 and the best results are observed at pH 0 or 1. This can be seen as an important advantage, considering the strong acidity of the lixiviation solution from copper minerals.
Fig. 1. Dienolic form of 4-alkyldithiocarboxylate-1-phenyl
3,5-dioxopyrazolidine.

Compound	R
HBDTP	n-C$_4$H$_9$
HDDTP	n-C$_{12}$H$_{25}$

(2) There is not significant difference in the extractive properties of HBDTP and HDDTP in 0.02 M chloroform solutions. However, the better solubility of HDDTP in this solvent allows study of the extraction with a 0.067 M solution.

(3) In general, these ligands are better extractants than alkyldithiocarboxylate derivatives of 3-methyl-5-pyrazolones also studied in our laboratory. For example, 1-dodecyl-4-dodecyldithiocarboxylate-5-hydroxy-3-methylpyrazol extracts only 26% of copper(II) at pH 0 [7].

(4) The nature of the extracted species was

established by plotting log of distribution ratio (K_d) vs. log of ligand concentration at fixed pH (Fig. 3). This gave slopes close to two and similar values were observed for plots of log K_d vs. pH at constant ligand concentration. From these results it can be inferred that the main equilibrium in the extraction process is

$$Cu^{2+} + 2HL \rightarrow CuL_2 + 2H^+$$
The deduced stoichimoetry is in agreement with the elemental analyses of both copper(II) complexes.

In order to explore the use of HDDTP in the extraction of copper from minerals with a high content of iron in a strong acidic medium, the extraction of Fe(III) at pH 0 and 1 was also studied. Under these conditions Fe(III) is only 8–12% extracted and Cu(II) is 95% selectively extracted with a 0.03 M HDDTP chloroform solution from an aqueous 0.01 M solution of Cu(II) and Fe(III)

Using a lixiviation solution from a mineral mixture of enarguite and pyrite with 16.5% Cu and 23.7% Fe, Cu(II) was completely separated from Fe(III) at pH 0 with a chloroform solution of HDDTP. The results and conditions employed are summarized in Table 1.

If the extraction of the lixiviation solution is performed under the same conditions but replacing the chloroform solution of HDDTP by a 15% kerosene solution of LIX 984N, the amount of
Fig. 2. Plot of % extraction vs. pH. —■—, HBDTP, --*--, HDDTP.
Fig. 3. Plot of log K_d vs. log [ligand] (■, HBDTP: pH = 4.78; m = 2.04; +, HDDTP: pH = 4.32; m = 2.38).

Cu(II) extracted in each step is 8.0 mg and the process requires five steps.

Finally, and according to the results with analyzed mineral samples, this procedure can be succesfully applied to sulfide-type minerals with similar composition (bornite, cubanite, chalcopyrite, chalcosite and others) as well as to oxidized copper minerals (chrysocolla, brochantite, malachite and others).

In conclusion, under the experimental conditions of this study, these new compounds show extractive and selective properties closely related to industrial LIX resins which are used in solvent extractions of copper from lixiviated solutions with a high iron content. Ligands with this kind of β-hydroxydithioester structure could become an alternative to the β-hydroxyoxime arrangement of the commercial extractants mentioned. Studies on this matter are in progress.

Rapid, selective, direct and derivative spectrophotometric determination of titanium with 2,4-dihydroxybenzaldehyde isonicotinoyl hydrazone

O. Babaiah, C. Kesava Rao, T. Sreenivasulu Reddy*, V. Krishna Reddy

Department of Chemistry, Sri Krishnadevaraya University, Anantapur-515 003, A.P., India

Received 17 May 1995; revised 20 September 1995; accepted 25 September 1995

Abstract

A simple and sensitive spectrophotometric method is developed for the determination of titanium in aqueous medium. The metal ion forms a reddish brown coloured complex with 2,4-dihydroxybenzaldehyde isonicotinoyl hydrazone (2,4-DHBINH) in the pH range 1–7. The complex shows two absorption maxima, one at 430 nm and the other at 500 nm. The reagent shows appreciable absorbance of 430 nm and negligible absorbance at 500 nm at pH 1.5. Beer's law is obeyed in the range 0.09 to 2.15 μg ml^{-1} of titanium(IV). The molar absorptivity and the Sandell's sensitivity of the method are 1.35×10^4 l mol^{-1} cm^{-1} and 0.0049 μg cm^{-2}, respectively. A method for the determination of titanium by first-order derivative spectrophotometry is also proposed. The methods have been employed successfully for the determination of titanium in several alloy and steel samples.

Keywords: Spectrophotometry; Titanium; 2,4-Dihydroxybenzaldehyde isonicotinoyl hydrazone

1. Introduction

The potential of the analytical application of hydrazone derivatives for the spectrophotometric determination of metal ions has been reviewed by R.B. Singh et al. [1]. Very few hydrazones are reported for the spectrophotometric determination of titanium [2–5]. Among the sensitive methods reported, most of them involve extraction processes [6–12] and suffer from lack of selectivity. Classical methods using hydrogen peroxide [13] and chromotropic acid [14] suffer from the

disadvantages of interference and critical pH maintenance, respectively.

In the present paper a simple, rapid, selective, sensitive and direct spectrophotometric method is reported for the determination of micro amounts of titanium in aqueous medium by complexing with 2,4 dihydroxybenzaldehyde isonicotinoyl hydrazone (2,4-DHBINH).

Derivative spectrophotometry is a very useful approach for determining the concentration of single components in mixtures with overlapping spectra as it eliminates much of the interference. It has recently been used to eliminate interference during spectrophotometric analysis [15–25]. It has

---

* Corresponding author. Fax: (91) 08554-22150.

been widely used in pharmaceutical analysis, amino acid and protein analysis, clinical chemistry, environmental analysis etc., [26] but less often in inorganic analysis [27,28].

In this paper a first-order derivative spectrophotometric method is described for the determination of titanium(IV) in which the interference seen with the zero-order method is eliminated.

2. Experimental

A Shimadzu UV–visible spectrophotometer model UV-160A equipped with 1 cm quartz cells and a Phillips Digital pH meter model PP 9046 were used for absorbance and pH measurements, respectively. Suitable settings for first-order derivative are as follows: spectral band width 2 nm; wavelength readability, 0.1 nm increment; scan speed, fast (nearly 2400 nm min^{-1}); wavelength accuracy, ± 0.5 nm with automatic wavelength correction; recorder, computer controlled thermal graphic printer with cathode ray tube, and with nine degrees of freedom in the wavelength range 800–400 nm.

3. Reagents

3.1. 2,4-Dihydroxybenzaldehyde isonicotinoyl hydrazone

The reagent was prepared by condensing 2,4-dihydroxybenzaldehyde and isonicotinic acid hydrazide in methanol using a general procedure [29] (m.p. 290°C). The structure of the reagent is as follows:
A 0.01 M solution in dimethyl formamide is used in the studies.

3.2. Stock solution of Ti(IV)

This was prepared by dissolving the requisite quantity of $K_2TiO(C_2O_4)_2\cdot 2H_2O$ (AR, BDH) in doubly distilled water and made up to the mark in a 100 ml volumetric flask to give a 0.01 M solution. The resulting titanium solution was standardized gravimetrically [30]. Working solutions were prepared daily by diluting the stock solution to an appropriate volume. All other chemicals used were of analytical reagent grade.

3.3. Buffer solutions

For the preparation of buffer solutions, 1 M HCl and 1 M sodium acetate (pH 1 to 3), and 0.2 M acetic acid and 0.2 M sodium acetate (pH 3.2 to 7.0) were used.

4. Procedures

4.1. Direct spectrophotometry

In each of a set of different 10 ml standard flasks, 5 ml of buffer solution (pH 1.5) various volumes of 5×10^{-4} M titanium(IV) solution, 1 ml of n-butanol, 1 ml of dimethylformamide (DMF) and 1 ml of 2,4-DHBINH (1×10^{-2} M) in DMF were added and made up to the mark with distilled water. The absorbance was measured at 500 nm against the reagent blank. The calibration curve was prepared by plotting the absorbance against the amount of titanium.

4.2. First derivative spectrophotometry

For the above solutions, first-order derivative spectra were recorded with a scan speed of fast (nearly 2400 nm min^{-1}), slit width of 1 nm, with degrees of freedom 9, in the wavelength range from 800 to 400 nm. The derivative peak height was measured by peak-zero method at 580 nm. The peak height was plotted against the amount of titanium to obtain the calibration curve.

The calibration graphs follow the straight line equation $y = mx + b$ where x is the concentration of the solution, y is the measured absorbance or
Fig. 1. Absorption spectra of (a) Ti(IV)-2,4-DHBINH complex (2.5 × 10⁻⁵ M); (b) 2,4-DHBINH (1 × 10⁻³ M).

peak height, and m and b are constants. By substituting the corresponding experimental data into the above equation, calibration equations were calculated as $y = 0.292x + 0$ for the zero order data and $y = 0.076x + 0.001$ for the derivative data.

5. Results and discussion

5.1. Absorption spectra

The absorption spectra of the reagent and the complex were recorded in the wavelnegth range 400–800 nm at pH 1.5 against the buffer solution and reagent blank, respectively (Fig. 1). The complex shows two absorption maxima, one at 430 nm and the other at 500 nm. The reagent has appreciable absorbance at 430 nm and negligible absorbance at 500 nm. Hence analytical studies were made at 500 nm.

5.2. pH effect

It is observed that the reddish brown precipitate is instantaneously formed between Ti(IV) and 2,4-DHBINH in the pH range 1–7. The study of the effect of pH on the colour intensity of the reaction mixture showed that maximum colour is obtained in the pH range 1.2–3.5. The analytical studies were carried out at pH 1.5, as the interference due to foreign ions is at a minimum at this pH.

5.3. Effect of 2,4-DHBINH concentration

The studies revealed that a 30-fold molar excess of 2,4-DHBINH is essential for complete and constant colour development. Excess of the reagent has no effect on the absorbance of the complex.

5.4. Effect of solvent

It is observed that the reddish brown precipitate of Ti(IV)–2,4-DHBINH complex dissolves in 20% aqueous DMF. But there is a decrease in the colour intensity of the complex. The intensity of the colour is stabilized by adding 1 ml of n-butanol to the reaction mixture. Hence further studies are carried out in a 20% + 10% DMF–n-butanol mixture.

5.5. Colour and stability of the complex

The colour reaction between Ti(IV) and 2,4-DHBINH was instantaneous at room temperature. The absorbance of the complex was found to be constant for more than 24 h.

5.6. Order of addition of reactants

It is observed that the intensity of the coloured solution is independent of the order of addition of the reactants. However the reagent was added after the addition of n-butanol and DMF to avoid the precipitate formation.

5.7. Applicability of Beer's law

From the calibration plot, it is observed that in the present method Beer's law is obeyed in the concentration range 0.09–2.15 μg ml^{-1} of Ti(IV). The molar absorptivity of the complex at 500 nm and at pH 1.5 is calculated as $(1.35 \pm 0.05) \times 10^4$ l mol^{-1} cm^{-1}. The Sandell's sensitivity of the method in the determination of 1.2 μg of Ti(IV) is found to be 0.0049 μg cm^{-2}.

Other statistical data derived for the present method are as follows. The standard deviation of the method for ten determinations of 1.2 μg of Ti(IV) is 0.005. The zero-order calibration plot passes through the origin. The correlation coefficient (γ) of the calibration equation of the experimental data is 0.990.

5.8. Composition and stability of the complex

The composition of the complex was determined by the Job and mole ratio methods and found to be 1:2 (Ti(IV):2,4-DHBINH). The stability constant of the complex was determined by Job's method as 8.04×10^8.

5.9. Effect of foreign ions

The effect of various diverse ions on the determination of Ti(IV) was studied to find out the tolerance levels of these diverse ions in the present method. The tolerance limit of a foreign ion was taken as the amount that caused an error in the absorbance value by $\pm 2\%$. The data are presented in Table 1. Large numbers of commonly associated cations and anions do not interfere in the determination of titanium.

In the presence of ascorbic acid (6000 μg), Fe(III) (1764 μg), Cu(II) (30 μg) and V(V) (25 μg) are tolerable. Mo(VI) can be masked up to 10 μg by adding 440 μg of tartrate.

5.10. Determination of titanium(IV) by first derivative spectrophotometry

In the zero-order spectrophotometric determination of titanium with 2,4-DHBINH, the commonly associated metals interfere and have to be masked with masking agents. To avoid the use of masking agents, we have applied the first derivative technique. The technique enhances the detectability of minor spectral features as weak shoulders.

The first-order derivative spectrum of the Ti(IV)–2,4-DHBINH complex was recorded for the solutions of zero order as described before and is presented in Fig. 2. The peak-zero (h) method is followed for the preparation of the analytical calibration plot. The maximum peak is at 560 nm. However, it was observed that at 580 nm, many of the interfering ions do not interfere. The peak height at 580 nm is also proportional to the concentration of Ti(IV). Therefore 580 nm is chosen for analytical studies. Beer's law is obeyed between 0.048 and 2.39 μg ml^{-1} of titanium(IV).

Table 1
Tolerance limit of diverse ions in the determination (1.2 μg ml^{-1}) of titanium(IV)

Diverse ion	Tolerance limit (μg ml^{-1})	Diverse ion	Tolerance limit (μg ml^{-1})
Ascorbic acid	17600	Ba(II)	4110
Iodate	5730	Zn(II)	1950
Bromate	4317	Fe(III)	1764[a]
Thiourea	2283	Co(II)	1740
Nitrate	1860	Mn(II)	1650
Thiocyanide	1770	Ni(II)	1160
Iodide	1170	Mg(II)	720
Chloride	1065	Hg(II)	600
Citrate	472	Pb(II)	104
Tartrate	444	Pb(II)	414[b]
Oxalate	132	Cd(II)	336
Phosphate	48	Ce(IV)	210
Fluoride	10	Cr(III)	208
		Tc(IV)	127
		Cu(II)	95[b]
		Cu(II)	32[a]
		Al(III)	25
		Cu(II)	5[c]
		V(V)	25[a]
		V(V)	5[c]
		Zr(IV)	27[c]
		Mo(VI)	10[cd]

[a] Masked by 6000 μg ml^{-1} ascorbic acid.
[b] Masked by 2283 μg ml^{-1} thiourea.
[c] Masked by 132 μg ml^{-1} oxalate.
[d] Masked by 444 μg ml^{-1} tartrate.
Fig. 2. First-derivative spectra of Ti(IV): (a) Ti(IV) 0.48 μg ml^{-1}; (b) Ti(IV) 0.96 μg ml^{-1}; (c) Ti(IV) 1.44 μg ml^{-1}; (d) Ti(IV) 1.92 μg ml^{-1}.

Other statistical data derived for the present method are as follows. The standard deviation of the method for ten determination of 1.2 μg of titanium(IV) is 0.004. The intercept and the correlation coefficient (γ) of the calibration equation for the experimental data are +0.001 and 0.996, respectively.

5.10. Interference due to foreign ions

The interference of a 100-fold excess of Al(III) and a 20-fold excess of Cu(II), Mo(VI), Th(IV), V(V), U(VI) and Zr(IV) can be avoided by carrying out the determination of 1.2 μg Ti(IV) in the derivative mode.

6. Applications

6.1. Analysis of alloys and steel samples

Titanium present in various alloy and steel samples was determined by the zero-order and first-order derivative methods.

6.2. Preparation of sample solutions

Solutions of the nickel-based high temperature alloys, titanium alloy and low alloy steel were prepared by following the precedure reported by Busev et al. [31]. A weight of 0.1–0.5 g of sample was dissolved in 2 ml HCl + 10 ml HNO$_3$. The resulting solution was evaporated to a small volume. To this, 5 ml of 1:1 H$_2$O:H$_2$SO$_4$ mixture was added and evaporated to dryness. The residue was dissolved in 15 ml of distilled water and filtered through Whatman filter paper No. 41. The filtrate was collected in a 100 ml volumetric flask and made up to the mark with distilled water. The sample solutions were appropriately diluted to obta-in the titanium concentration in the required range.

The amount of titanium present in the sample solutions was calculated from the predetermined calibration plots. In zero order spectrophotometry, 1 ml of 1 M ascorbic acid was added to mask iron(III) and copper(II) and 0.5 ml of 0.03 M oxalate to mask molybdenum(VI). In the derivative technique, 1 ml of 1 M ascorbic acid was added to mask iron(III). The results obtained in these studies are presented in Table 2.

7. Comparison with other methods

The present method is compared with the standard hydrogen peroxide method, chromotropic acid method and other hydrazone methods and the results are presented in Table 3.

The hydrogen peroxide method is less sensitive than the present method and suffers from the interference of many cations. Although the sensitivity of the chromotropic acid method is slightly higher than that of the present method, it suffers from the disadvantage of critical pH and the separation of large amounts of Fe(III). Furthermore most of the other sensitive methods involve extraction. The present method has the advantage of high selectivity in the presence of ascorbic acid and is more sensitive than the other hydrazone methods.

The first-order derivative spectrophotometric method eliminates the interference of V(V), Cu(II), Zr(IV), Mo(VI), U(VI) and Th(IV), which causes problems in the zero order method. The only interfering cation, Fe(III), is easily masked, up to 1000-fold, with ascorbic acid. Thus the first-order derivative method is selective for the determination of Ti(IV) in the presence of ascorbic acid.

Sequential injection technique employed for stoichiometric studies, optimization and quantitative determination of some fluoroquinolone antibiotics complexed with iron(III) in sulfuric acid media

Fakhr Eldin O. Suliman, Salah M. Sultan*

Chemistry Department, King University of Petroleum and Minerals, KFUPM Box 2026, Dhahran 31261, Saudi Arabia

Abstract

A sequential injection spectrophotometric method for stoichiometric studies, optimization and quantitative determination of ciprofloxacin and norfloxacin was developed. The work is based on the complexation reaction of ciprofloxacin and norfloxacin with iron(III) in sulfuric acid media and a spectrophotometric measurement of absorbances of the corresponding complexes at 447 and 430 nm respectively. The stoichiometries and formation constants were determined. A 1:2 iron(III) to drug mole ratio was found to give the most predominant complexes for both drugs with 5.00×10^{-3} M H_2SO_4 and at 0.20 M ionic strength utilizing Job's method and the molar ratio method. A numerical method was utilized for the calculation of the formation constants, the logarithms of which were found to be 7.756 ± 0.121 and 7.839 ± 0.056, for ciprofloxacin and norfloxacin respectively. A factorial design together with the all-model-search method was utilized for the optimization of the concentration and aspiration volume of iron(III) as these were the variables which most affected peak absorbance. Working dynamic ranges of 50–500 ppm and 50–400 ppm were obtained for ciprofloxacin and norfloxacin respectively. The method was found to be suitable for the determination of these compounds in pharmaceutical preparations.

Keywords: Sequential injection spectrophotometry; Ciprofloxacin; Norfloxacin; Complexation

1. Introduction

Apart from the original papers describing the principles of sequential injection analysis (SIA) [1–5] few publications [6–11] have appeared in the literature so far. It is apparent that the SI technique is still in its infancy and that its full versatility and capacity have yet to be explored. The SI technique involves one pump, one valve, and a single channel, making it simpler than the conventional flow injection (FI) technique. Once constructed, the mechanical flow system of an SI

---

* Corresponding author. Fax: + 966 03-860-4277.

apparatus does not have to be reconfigured for different injection volumes, reaction times or mutual zone dispersion, because these parameters can be controlled directly by changing the volumes of flow reversals and the forward flow rate from the computer keyboard [12].

Cumbersome jobs which usually bother experimenters can be performed with some ease using SI. For instance, the determination of stoichiometries and formation constants of complexation reactions involves the preparation of a large series of solutions under carefully adjusted conditions and precise repetition of the procedure until acceptable results are obtained. When a valuable and expensive reagent is used, the above operations become difficult to repeat and usually the reporting of poor data is the ultimate result. Formation constants, or equilibrium constants for complexation reactions, are effective measures of the affinity of a ligand for a metal ion in solution and are used to provide valuable information essential to many other fields, e.g. medicine, electrochemistry, geochemistry, and pollution [13,14]. The advent of computers has enabled advanced mathematical treatment of huge equilibrium data to be carried out and has also encouraged amateurish chemists to determine the formation constants by making use of advanced computerized numerical methods rather than just studying the position of equilibria they encounter during the course of their investigation of a chemical reaction [13].

The aim of this paper is to demonstrate the versatility of the SI technique in conjunction with numerical methods for the determination of stoichiometries and stability constants for the complexation of two members of the flouroquinolone family of drugs, ciprofloxacin and norfloxacin. Two FI methods based on the complexation reaction of iron(III) with ciprofloxacin and norfloxacin have been reported by the present authors [15,16]. Therein, no detailed information was given on the stability and no stoichiometry studies were carried out on line by the FI micro-technique. The present work demonstrates the advantages of SI over FI, thus showing the inevitability of the utilization of SIA for such investigations. A method for the determination of ciprofloxacin and

norfloxacin, based on their complexation with iron(III) in sulfuric acid medium, is also proposed. A chemometric optimization approach is employed to select the best experimental conditions for the assay of these two drugs.

Fluoroquinolones, a group of synthetic antibacterial agents currently employed as broad spectrum antibiotics, are structurally related to nalidixic acid. It is believed that the mode of action of this family of drugs is through binding DNA-gyrase enzyme [17–19]. It is also reported that there is a direct correlation of fluoroquinolone bonding with inhibition of DNA-gyrase enzyme activity and induction of DNA breakage [19]. Because of this special mechanism of action, flouroquinolones are considered to be the most effective Gram-positive-Gram-negative pathogens to combat infections caused by microorganisms that are resistant to other microbials, such as tetracycline. Most of the methods available in the literature for the determination of ciprofloxacin and norfloxacin are suitable for the assay of these drugs in biological fluids [20–27]. It is interesting to note that no official methods have been reported so far by the British Pharmacopoeia (BP) or United States Pharmacopoeia (USP) for the assay of these two drugs in pharmaceutical products.

2. Experimental

2.1. Apparatus

The SI apparatus described recently [11] was used for SI measurements. The apparatus consists of a peristaltic pump (C4v, Alitea USA, Medina, WA), a Valco 10-port selector valve (Cheminert, Valco Instruments, Houston, TX), a holding coil, a reaction coil, and a Spectronic Mini-20 spectrophotometer (Milton Roy, Rochester, NY). All the tubing connecting the different units was made of Teflon (0.8 mm i.d.). The holding coil and the reaction coil were 1.5 m and 0.5 m long respectively. Pump tubings were Par-Med 1.02 mm i.d. (Upchurch) held on pump rollers by FI peristaltic pump tubing adapters (Upchurch). A personal computer (Austin Computer Systems, Austin,

TX) together with FIAlab software (Alitea USA, Medina, WA) was used to control the peristaltic pump, the valve and data acquisition. The communication between the computer and the other components of the apparatus was expanded by a general purpose I/O board (Model ADA-110, Real Time Devices (RTD), State College, PA).

A Perkin-Elmer lambda 5 UV–visible spectrophotometer equipped with 10.00 mm cells was used for preliminary investigations.

2.2. Reagents

2.2.1. Fluoroquinolones standard solutions

Stock standard solutions (2000 ppm) of the two fluoroquinolones were prepared by dissolving the appropriate amounts of the pure analytical reagent grade products in pure water for ciprofloxacin (supplied by Bayer representative, Batch No. (09867) for the east province of Saudi Arabia) and dilute sulfuric acid (5.0×10^{-3} M) for norfloxacin (Merck Sharp and Dohme, Haarlem, The Netherlands). Working solutions were prepared by appropriate dilutions.

2.2.2. Norfloxacin tablets

Five tablets of the proprietary drug Noroxin (Merck Sharp and Dohme, Haarlem, The Netherlands), claimed to contain 400 mg norfloxacin, were carefully weighed out. An amount of the powder equivalent to 400 mg was dissolved in about 300 ml dilute sulfuric acid (5.0×10^{-3} M) in a 500 ml volumetric flask. The mixture was warmed at 50°C in a water bath for 15 min, agitated by an electrical shaker for 15 min and filtered through an ordinary filter paper; it was then washed several times with warm dilute sulfuric acid and the filtrate plus the washings were made up to the mark with the dilute sulfuric acid solution after cooling to room temperature. Appropriate solutions were then obtained from this stock by dilution.

2.2.3. Ciprofloxacin tablets

Ten tablets of Ciprobay (Bayer), claimed to contain 250 mg ciprofloxacin, were weighed out and crushed. An exact amount of this powder equivalent to about 250 mg was dissolved in water

in a 250 ml volumetric flask. Working solutions were obtained by diluting appropriate portions of this stock.

2.2.4. Ciprofloxacin infusion

The solution of the proprietary drug Cibrobay (Bayer), claimed to contain 2000 ppm ciprofloxacin, was tested by appropriate dilution of the infusion in acidified water to make the required concentration of ciprofloxacin in a final solution of 5.00×10^{-3} M sulfuric acid and the ionic strenght was then adjusted to 0.20 M with ammonium sulfate solution.

2.2.5. Ammonium sulfate

A 0.20 M solution was prepared by dissolving about 13.4 g of AnalaR ammonium sulfate in water in a 500 ml flask.

2.2.6. Iron(III) solution

0.100 M iron(III) solution was prepared in 0.050 M sulfuric acid by dissolving exactly about 24.9 g of pre-dried ammonium ferric sulfate $NH_4Fe(SO_4)_2 \cdot 12H_2O$ in 0.050 M sulfuric acid in a 500 ml volumetric flask. This solution is only used after at least 24 h, to guarantee complete dissolution.

2.2.7. Sulfuric acid

1.0 M solution was prepared by diluting AnalaR concentrated acid.

2.3. Experimental design

The variables included in the optimization were aspiration volume and concentration of iron(III) which were found to greatly influence the peak absorbance. Preliminary investigations have revealed that other performance criteria, such as the precision, are of acceptable levels. Three levels of the aspiration volume were included, 29.5 μl, 88.5 μl and 147.5 μl, whereas five levels of iron (III) were selected in the range 2.0×10^{-3}–10.0×10^{-3} M. Iron(III) concentration was varied at each level of aspiration volume until no further improvement in the peak absorbance was observed, then five levels of iron(III) were selected to construct a factorial design. The factorial design

was then repeated by nesting the selected iron(III) solutions around the selector valve in a random manner in an attempt to minimize any possible bias. In all of these experiments 88 μl of 200 ppm solution of the appropriate drug was aspirated, and all experiments for each drug were run within 1 h.

2.4. Procedure

The SI manifold is shown in Fig. 1. The procedure starts by nesting the drug and iron(III) solutions around the selector valve. 80 μl of each solution was first aspirated into the lines from the ports by selecting one port at a time. The excess of the solutions introduced in the holding coil was then pumped through port 9 to waste. The steps of the procedure were then fed into the computer as follows. (1) The carrier solution (5.0×10^{-3} M sulfuric acid) is pumped through port 1, by setting
Fig. 1. Schematic diagram of the sequential analysis apparatus used: C, carrier solution; PP, peristaltic pump; HC, holding coil; SV, selector valve; 2, iron(III) solution; 3–8, drug solution; 9, auxiliary waste; RC, reaction coil; SP, spectrophotometer; W, waste; CM, computer.

the pump in the forward mode, for 25 s. (2) 147.5 μl of 1.0×10^{-3} M iron(III) solution is aspirated into the holding coil via port 2. (3) 88 μl of the appropriate drug solution is aspirated into the holding coil via ports 3–8. Both of the last two steps are achieved by setting the pump in the reverse mode. (4) Finally the carrier solution is propelled through port 1 to the reaction coil and then into the detector. The data were then acquired by the computer and transferred to a plotting software package for further manipulation. The volumes of the solutions were determined from the time of aspiration and the volumetric flow rate of the pump [11], which was 29.5 μl s^{-1} in this study.

Following Job's method of continuous variation, different aliquots of equimolar solutions of iron(III) and the drug were mixed to give solutions of identical total concentration (iron(III) + drug) but different mole fractions. Therefore, a total volume of aspiration of 162.0 μl was constantly maintained by adjusting the aspiration times. The volume of each reagent was varied between 14.8 μl (0.5 s) and 147.5 μl (5.5 s).

In the molar ratio method the total volume of the ligand was maintained constant by aspirating 147.5 μl into the holding coil by flow reversal, whereas the iron(III) solution was varied between 14.8 μl (0.5 s) and 192.0 μl (6.5 s). The ionic strength of all solutions was adjusted to 0.20 M with ammonium sulfate and the sulfuric acid concentration was 5.00×10^{-3} M.

3. Results and discussion

3.1. Determination of stoichiometry

In the sulfuric acid concentration range 5.0×10^{-3}–0.60 M, a deep yellow color is formed instantaneously when iron(III) solution is added to ciprofloxacin and norfloxacin solutions, indicative of complex formation. The spectra of the complex show absorption bands at 350 nm for ciprofloxacin and 370 nm for norfloxacin with shoulders extending into the visible region. The shoulder, which is responsible for the yellow color of the complex, shows a maximum absorbance at

447 nm for ciprofloxacin and 430 nm for norflox-acin. At these wavelengths the two drugs and iron(III) show negligible absorbance. It has also been observed that the intensity of the colored complex increases with a decrease in the concentration of sulfuric acid, which may be due to the dissociation of the complex at high acid concentration. The Job plot of continuous variation was used to determine the stoichiometry of the complexation of ciprofloxacin and norfloxacin with iron(III) in sulfuric acid media. Fig. 2(a) is a typical Job plot generated by using equimolar solutions of iron(III) and ciprofloxacin of 1.00×10^{-3} M, whereas Fig. 2(b) shows a Job plot for equimolar solutions of iron(III) and norfloxacin of 2.00×10^{-3} M. Both plots were produced using 5.00×10^{-3} M sulfuric acid and an ionic strength of 0.20 M. It is clear that the curves $A = f(X_{drug})$ exhibit a maximum for the mole fractions close to 0.66, indicating that the ratio of iron(III):drug in the complex is 1:2. Similar plots made at sulfuric acid concentrations greater than 0.025 M gave different results, and the 1:1 iron(III):fluoroquinolone complex was found to be the dominant species. These findings are in agreement with the results published by two independent groups, where a 1:1 complex was obtained by one group [15] when iron(III) was complexed with ciprofloxacin at acidities higher than 0.025 M, and a 1:2 complex was obtained for the complexation of norfloxacin by the other group [28] when 5.00×10^{-3} M sulfuric acid was used. It can also be observed that only 10 min at most is needed to generate the Job plot using SIA and less than 10 ml is enough to repeat the procedure as many times as necessary.

In the molar ratio method ideally two straight lines are obtained when the absorbance is plotted versus the iron(III) to drug ratio, and the point of intersection of these two lines corresponds to the stoichiometric ratio upon interpolation to the mole ratio axis. Fig. 3(a) shows a typical molar ratio plot for the complexation of iron(III) with ciprofloxacin, with peaks 1–11 being produced by varying the molar ratio of iron(III) to drug from 0.1 to 1.1 in steps of 0.1. In contrast Fig. 3(b) represents a molar ratio method for the complexation of norfloxacin with iron(III); here the molar

Fig. 3. SIAgram representing molar ratio plots: (a) [iron(III)] = [ciprofloxacin] = 1.00 × 10⁻³ M; (b) [iron(III)] = [norfloxacin] = 2.00 × 10⁻³ M; [H₂SO₄] = 5.00 × 10⁻³ M; ionic strength = 0.20 M; total volume of the drug was 147.5 µl; aspiration volumes of iron(III) solution were varied between 14.5 µl (peak 1) and 192 µl (peak 13).

acid concentration was 5.00×10^{-3} M. It is obvious from these plots that the point of intersection of the two lines is close to 0.5 when extrapolation is made to the molar ratio axis, indicating a 1:2 ratio for iron(III):drug.

It is likely that incomplete mixing of the reagents with the drug might take place due to dispersion and zone penetration; however, nesting the solutions around the valve, followed by getting rid of the excess, plus automated aspiration with exact computer control of timing would certainly minimize this problem. If mixing was still not complete it would lead to a constant error in both the drug and reagent concentrations that would pose no problem with the data obtained and in calculating the mole ratio. However, the correction factors which can be introduced from the zone penetration and dispersion were found to have a very minor effect on the data obtained.

It is well known that iron(III) has its greatest affinity for ligands that coordinate via oxygen [29]. It has also been reported [30,31] that fluoroquinolones are present in different forms in aqueous media, including neutral molecules and zwitterions, as well as monoprotonated and diprotonated species depending on the pH of the medium. For instance, at low acid concentrations the neutral species together with the monoprotonated species are the predominant forms, whereas at highly acidic concentrations the proportion of the diprotonated form increases greatly. Therefore it can be suggested that iron(III) complexes ciprofloxacin and norfloxacin by binding to the carboxylate group and to the adjacent keto group in the 3 and 4 positions respectively, thus forming a six-membered ring, as shown previously [12].

3.2. Formation constants

The formation constant and the composition of the complex of iron(III) with ciprofloxacin and norfloxacin were also investigated by numerical methods. The Jobcon program [32] was used to analyze the continuous variation data whereas the MRLET program was utilized to treat the molar ratio data [33]. Both programs were modified by the authors, were rewritten in C language and applied on a PC/AT computer. The calculations

are based on fitting a function $f(x, \beta)$ to a set of experimental data, using a least-squares method. Unknown parameters are estimated by minimizing U, the sum of squares of residuals defined by Eq. (1):

$$U = \sum_{i=1}^{n} (A_{\exp i} - A_{\text{calc} i})^2 \qquad (1)$$

where n represents the number of experimental points, $A_{\exp}$ the experimental absorbance, and $A_{\text{calc}} = f(x, \beta)$, the absorbance calculated by the program from the formation constants and stoichiometric ratios. Therefore, various equilibrium models could be fitted to the experimental data iteratively by varying the values of formation constants and the stoichiometric ratios.

In this study different total concentrations of iron(III) and drug were used to determine the equilibrium constants. The mean values of the logarithms of formation constants (log K_f) obtained for ciprofloxacin and norfloxacin in 5.00 × 10^{-3} M sulfuric acid and at 0.20 M ionic strength were 7.756 ± 0.121 and 7.839 ± 0.056 respectively. The value reported earlier for norfloxacin was 8.60 [28]. It is apparent from these results that the value of the formation constant for the 1:2 iron(III)–norfloxacin complex is close to the value reported earlier [28]. It was also observed that the stoichiometry and the value of the formation constant are independent of the total concentration of the metal ion and the ligand.

3.3. Optimization

The factorial design experimental data for ciprofloxacin and norfloxacin systems are given in Table 1. In order to determine the optimum experimental condition for the assay of these drugs, based on their complexation with iron(III) in sulfuric acid media, an ordinary least-squares method [33] was used together with an exhaustive search for the best regression model (all-model search) to find a model which correlates peak absorbance with the concentration and aspiration volume of iron(III). Before undertaking any statistical analysis the factors were scaled within the range ± 1 to simplify the interpretation of the regression coefficients when the relative impor-

[a] Coded levels

tance of factors is compared.

The all-model search was utilized to investigate all possible models with 1,2,..., k parameters. Quadratic, cubic and two-factor interactions were included to obtain the best model. The test statistic used here is an F ratio of the form [34]

$$F = \frac{(\text{SSE}_R - \text{SSE}_C)/r}{\text{SSE}_C/(N - P)}$$

where SSE_R and SSE_C are the residual sum of squares associated with the reduced model and the complete model, i.e. models with $i - 1$ and i parameters, respectively, r is the difference in the number of parameters in the reduced and complete models, P is the number of parameters in the complete model and N is the number of experiments. The best models, ones that are significant to the F test at the 97.5% level and characterized by the highest coefficient of multiple regression R^2, were found to be five parameter models for both ciprofloxacin and norfloxacin systems and are given as follows:

$$\text{PH} = 62.63 + 8.67I + 4.40V - 6.86I^2$$

$$- 4.00V^2 \quad (R^2 = 0.973) \qquad (3)$$
Fig. 4. Response surface plot as a function of iron(III) concentration and aspiration volume.

$$PH = 60.94 + 17.87I + 12.91V - 6.29I^2$$

$$- 5.30V^2 \quad (R^2 = 0.964) \tag{4}$$

for ciprofloxacin and norfloxacin systems respectively, where PH is the peak height (mm), I is the iron(III) concentration and V is the aspiration volume. When the five parameter (four independent variables and an intercept) model was compared with the four parameter model, using the F test described by Eq. (1), the F values obtained were 20.5 and 8.99, for ciprofloxacin and norfloxacin systems respectively, and were found to be highly significant at the 97.5% level ($F_{1,9} = 6.94$).

The predictive ability of the selected model was evaluated by the leave-one-out cross validation method [34]. The values obtained for the coefficient of multiple determination in prediction for ciprofloxacin and norfloxacin systems were

0.972 and 0.967 respectively suggesting that the models can be used for optimization purposes. Determination of the optimum experimental conditions for the assay of the two drugs was then executed using a modified simplex algorithm as a search method and the regression models obtained by this strategy were 147.5 μl for the aspiration volumes for both systems whereas 1.00×10^{-2} M and 8.0×10^{-3} M values were obtained for iron(III) concentrations for ciprofloxacin and norfloxacin systems respectively. Fig. 4 shows a surface plot as a function of iron(III) concentration and aspiration volume for the ciprofloxacin system. It is apparent from this figure that higher levels of both iron(III) concentration and aspiration volumes are favorable for the assay of this drug as the peak absorbance reaches a plateau region.
Fig. 5. Typical SI results of ciprofloxacin standard solutions of: (1) 50; (2) 100; (3) 200; (4) 300; (5) 400; (6) 500 ppm; (7) five runs of 215 ppm Ciprobay tablets; (8) 210 ppm Ciprobay infusion.

3.4. Analytical appraisal

Series of standard solutions were run for the two drugs as typically shown in Fig. 5 for ciprofloxacin. A weighted regression line [35] was plotted for absorbance vs. concentration by giving minimum weighting for the lower and upper concentrations and full weighting for the others. The linear range was found to be between 50 and 500 ppm for ciprofloxacin and between 50 and 400 ppm for norfloxacin with the following calibration equations:

$$A = 0.0280 + 4.592 \times 10^{-4}C \quad (R^2 = 0.995) \quad (5)$$

$$A = 0.0115 + 6.451 \times 10^{-4}C \quad (R^2 = 0.999) \quad (6)$$

where A is the peak absorbance and C is the concentration (ppm).

3.5. Application

The proposed method was applied to the assay of some proprietary drugs containing ciprofloxacin and norfloxacin and the results are shown in Table 2. Ciprobay tablets and ciprobay infusion (Bayer) with five runs are represented by the groups of peaks 7 and 8 respectively in Fig. 5. The method was statistically compared to the previous FIA methods [15,16] and the results obtained (Table 2) indicate that a similar degree of accuracy can be obtained with the SIA and FIA methods. In the FIA method both drugs were injected into a continuous stream of iron(III) solution to form a brown–red complex which is monitored at 447 nm and 430 nm for ciprofloxacin and norfloxacin respectively. It can also be suggested from these results that the proposed method is suitable for the determination of these two drugs in pharmaceutical products without any interferences from compounds usually added to such fomulations. The SIA method is superior to the FIA method with respect to considerably lower reagent consumption. Although FIA is characterized by a high sampling frequency SIA is easier to operate and optimize because only a single pump and a single valve are used. Also the ease of use of the automated SI system rendered the generation of plenty of data in a short period of time a simple task.

Table 2
Results obtained by the proposed SIA method an by FIA [15,16] for analysis of ciprofloxacin an norfloxacin in proprietary drugs.

Drug	Supplier	Active material	Mean recovery $\pm$ SD(%)[a]		t[b]

High performance liquid chromatographic method for the separation and quantification of some psychotherapeutic benzodiazepines optimized by the modified simplex procedure

Salah M. Sultan*, Aarif H. El-Mubarak

The Chemistry Department, King Fahd University, KFUPM Box 2026, Dhahran 31261, Saudi Arabia

Abstract

An accurate high performance liquid chromatography method for the separation and quantification of a solution mixture of nitrazepam, diazepam and medazepam and medazepam was developed. The modified simplex program has been utilized for the optimization of the chemical and chromatographic parameters using the chromatographic response function as the quality criterion and a photodiode array as a detector. The separation was achieved in 2 min using a 20 cm long, 4.6 mm diameter Lichrosorb C18 reverse phase column. A 5 μl solution mixture containing 10 ppm of each drug was injected into a mobile phase containing 89:11 v/v acetonitrile: acetate buffer and a flow rate of 3.44 ml min^{-1} was found to be optimal. The method was found to be suitable for the determination of these compounds in proprietary drugs without suffering interferences.

Keywords: High performance liquid chromatography; Diode array detector; Modified simplex optimization; Benzodiazepines

1. Introduction

High performance liquid chromatography (HPLC) in combination with a diode array detector (DAD) is now considered the most powerful multicomponent mixture separation technique. This paper demonstrates the novelty of this technique for the separation and quantification of an important family of drugs, the benzodiazepines.

Benzodiazepines, mainly nitrazepam (NZP), diazepam (DZP) and medazepam (MZP), are psychotherapeutic agents. They have hypnotic, tranquilizing, anti-depressive, sedative and anticonvulsant properties. Benzodiazepines are chemically characterized by the presence of a phenyl ring fused to a saturated seven-membered ring with nitrogen at the 1 and 4 positions. They undergo extensive metabolism, therefore it is essential that the assay method be sensitive, specific and capable of separating and determining parent

* Corresponding author. Fax: (966) 03-860-4277.

drugs and major metabolites. However, various methods for the separation of the benzodiazepines have been reported in the literature [1–12], most of which are HPLC methods. Different mobile phase combinations such as methanol–water and acetonitrile–water with and without phosphate or acetate buffer were used. In some cases triethylamine was added to the mobile phase to act as a modifier [11]. However, many workers have not used state-of-the-art technology for efficient, reliable optimization but have mainly relied on conventional one-factor-at-a-time methods. This paper utilizes the modified simplex program for successful optimization of instrumental as well as system parameters such as acetonitrile/acetate buffer comination ratio, flow rate of elution and sample volume, thus affecting the quality of the separation and the quantification of these compounds. It is important to note here that simplex optimization was first introduced with HPLC separation in 1973 by Morgan and Deming [14,15] and is now considered mandatory by virtue of its availability, simplicity and rapidity in obtaining proper optimal conditions in a pre-selected time.

2. Experimental

2.1. Apparatus

A Water system equipped with a Waters Model 600E multi-solvent delivery system, a Waters 991 series photodiode array detector, a Waters Intelligent Sample Processor (WISP) model 712, and an NEC Powermate 2 Data Station, equipped with Waters 5200 printer plotter, were used.

2.2. Stationary phase

A Lichrosorb RP-18 (C18), 10 μ, 20 cm × 4.6 mm i.d. stainless-steel column from Hewlett-Packard was used.

2.3. Mobile phase

Acetonitrile (Burdick & Jackson, HPLC grade) filtered through a 0.22 mm GV Millipore filter was used together with 0.1 M ammonium acetate

buffer (pH 6.0, adjusted with acetic acid) prepared with triply-distilled, organic-free water from a Milli-Q system (Millipore) and filtered through a 0.45 mm Millipore filter. The mobile phase was sparged with He gas at a rate of 20 ml min^{-1} prior to, and throughout, the analysis.

2.4. Standard stock solutions and drug tablets

Analytical grade samples of the drugs NZP (1,3-dihydro-7-nitro-5-phenyl-2H-1,4-benzodiazepine-2-one), DZP (7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzodiazepine-2-one) and MZP (7-chloro-2,3-dihydro-1-methyl-5-phenyl-1H-1,4-benzodiazepine) were supplied by Roche Co. (Switzerland). Standard stock solutions of NZP, DZP and MZP were prepared by dissolving exactly about 0.1 g in CH_3CN and making the volume up to 100 ml. To give a concentration of 1 mg ml^{-1}, working standards were prepared by appropriate dilutions.

Drug tablets were prepared by crushing to powder five tablets after accurate weighing. A weighed portion of powder, equivalent to 5 mg nitrazepam and 10 mg diazepam, was carefully transferred to a beaker. Then about 40 ml of mobile phase of acetonitrile: acetate buffer, 89:11, was added, sonicated while heating for 30 min and filtered through a 0.45 mm filter (Millipore). The filtrate was washed several times with warm mobile phase, and the volume was made up to 100 ml with the mobile phase to give a concentration of 50 ppm nitrazepam and 100 ppm diazepam. Further dilutions were made to yield claimed concentrations of 5 and 10 ppm respectively. A mixture of 10 ppm of each was used throughout the analysis.

2.5. System conditioning

All lines were degassed, the column was conditioned by passing the mobile phase for 30 min, the on-column pressure limit was set to 0–6000 psi, and the DAD was warmed up for 10–15 min prior to analysis to condition the optics, flow cell and diode array. The sampling time was adjusted to 55–63 × 8 ms to give maximum sensitivity, the wavelength range was 230–282 nm with a resolu-

Table 1
Simplex optimization of HPLC variables for method development for the mixture of benzodiazepines (10 ppm each). Steps of 4, 4, 0.6 and 98 were taken for CH_3CN, buffer, flow rate and drug concentration respectively.

tion of 1.4 nm, the analysis time range was a minimum of 0–3.5 min, with an interval of 1.96 s, accumulation and smoothing was for seven points, drift was 0.002 AU min^{-1}, the baseline was corrected from 0.03–3.5 min, and the Y-scale was 0.185 AU FS and then adjusted automatically by the system. These conditions enable peak detection of a minimum height of 1×10^{-4} AU and a minimum area of 1×10^{-5} AU min^{-1}.

2.6. Procedure

The mobile phase of acetonitrile: acetate buffer (89:11 v/v) was allowed to flow at a rate of 3.44 ml min^{-1} at room temperature for about 30 min to condition the column and the detector cell. A 5 μl solution mixture was injected into the column. The separated compounds were allowed

to pass the DAD through a 1 cm flow cell for a fixed time of 3 min. The absorbance was monitored in the range 230–282 nm but requested only at 254 nm on the screen, and finally recorded on the flow chart printer.

3. Results and discussion

3.1. Optimization

The modified simplex method [16–20] of the COPS (Chemometrical Optimization by Simplex) program (Elsevier, Amsterdam, was used for the optimization of the variables considered to be most affecting the separation of the mixture components. These are: the percentage of acetonitrile and the percentage of the acetate buffer combined
Fig. 1. Three-dimensional surface diagram showing the effect of the binary mobile phase (acetonitrile: acetate buffer) on the CRF.

and depending on each other, thus constituting a binary mobile phase as one variable. The other two variables are the flow rate of elution and the sample volume injected for a specific known concentration. The optimization procedure was carried out for a wide range (5–50 ppm) of concentration of each drug in the mixture and run at room temperature using a Lichrosorb C18 column of 4.6 mm diameter and 20 cm length, with absorption measured at 254 nm using the DAD.

The modified simplex program was started by introducing upper and lower boundary conditions for the above three factors, determined by conducting preliminary experiments as follows: 100–80% for CH_3CN; 0–20% for the buffer; 4.0–1.0 ml min^{-1} for the flow rate and 1–50 μl sample volumes of 10 ppm each results in 10–500 ng for the drug concentration. Experiments 1–4 in Table 1 show the values of the three parameters designated as the initial simplex conditions.

The chromatographic response function (CRF) earlier adopted by Wright et al. [21] of the follow-

ing form was chosen as the quality criterion:

$$CRF = \sum_{i=1}^{n-1} R_i + n - |T_A - T_L| \qquad (1)$$

where R_i is the resolution between adjacent peak pairs, n is the number of peaks detected, T_A is the target retention time in seconds for the last peak, and T_L is the retention time for the last peak. However, a computer program has been written in BASIC for the calculation of the CRF. It includes all necessary equations. The program ensures that any retention time for the last peak, that occurs within ± 1 min of the target time, T_A, is equally acceptable, since the last term in the CRF is only included if it exceeds 1 min. The target retention time used in the present work is 2 min.

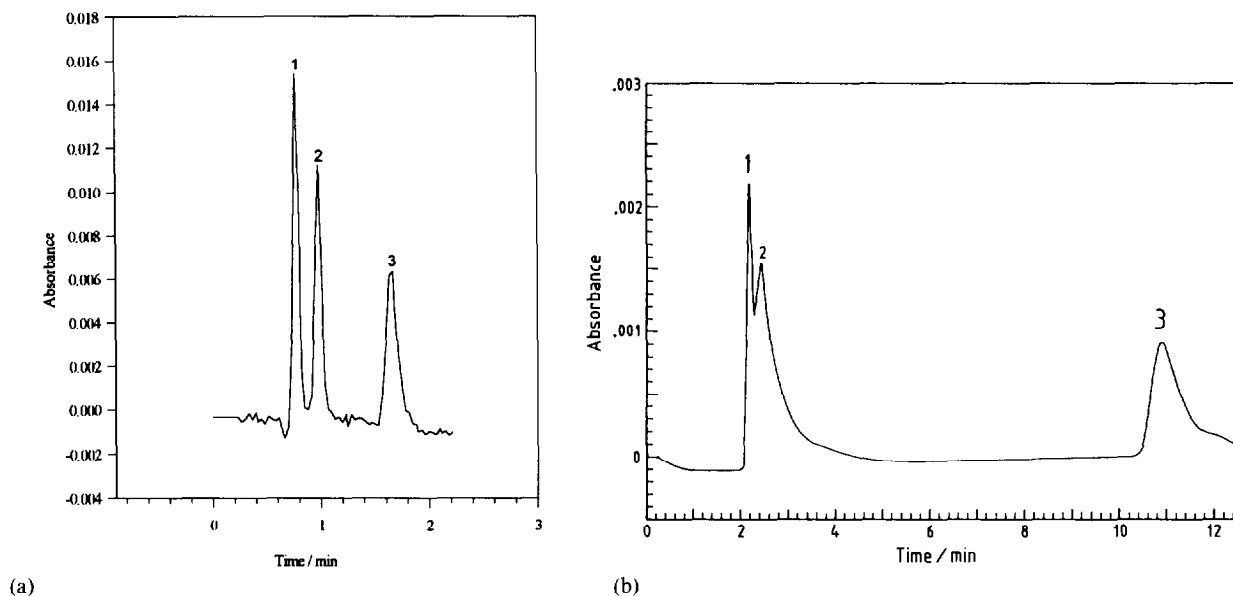
In the modified simplex program, the reduction step is simply one experiment and not $(n + 1)$, where n is the number of optimized parameters, as in the case of the normal simplex method. In the contraction step, the worst point is replaced by one in the middle of the worst and best points. In


Fig. 2. (a) An optimized chromatogram for experiment No. 21 during the simplex search for method development. (1) nitrazepam; (2) diazepam; (3) medazepam; column, Lichrosorb C18; mobile phase, acetonitrile: acetate buffer, 89:11; flow rate, 3.44 ml min^{-1}; detection, DAD at 254 nm; concentration, 10 ppm each. (b) An un-optimized chromatogram in the early investigation for method development. (1) nitrazepam; (2) diazepam; (3) medazepam; column, Lichrosorb C18; mobile phase, acetonitrile:acetate buffer, 50:50; flow rate, 2.50 ml min^{-1}; detection, DAD at 254 nm; concentration, 10 ppm each.

reduction, contraction, reflection and expansion steps, the modified simplex program uses the differences in the responses at the vertices to estimate the vertex with a better response. When the vertex with the worst response is reflected through the centroid of the simplex, three vertices are located on a straight line. After contraction or expansion the new vertex will also be on the same line. Measuring the response in the centroid results in three responses. An estimation of the position of the next vertex on the line, which probably gives a better response, is formed by fitting a second order model or a Gaussian model through these three responses. The position of the maximum of the fitted function provides the location of the next vertex. The results of the modified simplex progress are introduced in Table 1 and experiment number 21 indicates optimum conditions with the highest CRF value. The simplex was halted at experiment 25 as there was no further significant improvement towards the maximization of the CRF value. The data obtained indicate that the effect of variation of acetoni-

trile–buffer concentration ratio is more significant on the CRF value than the other two parameters are. This could be attributed to the acetonitrile being a highly dipolar aprotic solvent with a small autoprotolysis constant ($pK_{HS} = 33.6$) and a relatively high dielectric constant of $\epsilon = 36.0$ [22]. Fig. 1 shows the interactive effect of this binary mobile phase on the CRF on a three-dimensional surface, thus visualizing the movement of the simplex towards the optima in a hill-climbing way as the mobile phase combination changes, i.e. the CRF increases as actonitrile increases and the acetate buffer decreases.

It is worth mentioning here that.the mechanism of the retention of benzodiazepines in the reverse bulky hydrocarbonaceous moiety of Lichrosorb C18 stationary phase is stronger (London forces) than in the mobile phase [23]. The reverse holds true when considering parameters reflecting the ability of the solute to take part in different, stronger types of bonding such as charge transfer, hydrogen bonding, etc. With all the above considerations together with the help of the modified

Table 2
Analytical appraisal for standard solutions of nitrazepam and diazepam using the external addition method.

Compound	Calibration equation[a]	r^{2b}	Concentration (ppm)
Nitrazepam	$A = 6.3557 \times 10^{-5} + 1.0656 \times 10^{-4} C$	0.9993	0.2–200
Diazepam	$A = 1.0082 \times 10^{-5} + 1.0238 \times 10^{-4} C$	0.9991	0.2–200

[a] A = absorbance; C = compound concentration (ppm). [b] Correlation coefficient.

simplex optimization, it was feasible to separate the three components in the mixture in less than the 2 min predetermined initially. Fig. 2(a) shows the optimized chromatograms obtained around the optimum conditions; in comparison Fig. 2(b) shows a chromatogram under other conditions (same as optimum except an acetonitrile: acetate buffer ratio of 50:50 and a flow rate of 2.5 ml min^{-1} were used). Note that the run was carried out in 12 min and the separation was poor.

The optimum conditions are as follows: acetonitrile: acetate buffer, 89:11; flow rate, 3.44 ml min^{-1}; injected volume of 5 μl of each 10 ppm mixture; ambient temperature; a Lichrosorb C18 column of 4.6 mm diameter and 20 cm length; and UV DAD monitored at 254 nm. These conditions were used in the analytical appraisal as well as the application. Peaks were identified by the method of iterative elution of the drugs at the same optimum conditions. The order of elution was found to be nitrazepam, diazepam and medazepam.

4. Analytical appraisals

The external addition method was used to judge the analytical appraisal by using different series of standard solutions of the drugs. The results obtained are to be found in Table 2, and indicate excellent linearity and reasonable dynamic range.

For application and determination of the drugs in proprietary forms either the above external method or the internal addition method could be used as long as any of these compounds could be used as an internal standard.

The benzodiazepine drugs are controlled and the only two made available for our investigation

was Mogadon (Roche) containing 5 mg nitrazepam and Valume (Roche) containing 10 mg diazepam. A solution mixture was prepared as in the method above and used under the optimized conditions. No interference peak from excipients present with the tablets could be detected indicating successful application of the method to the dosage forms. The results of analysis of these proprietary drugs (see Table 3) were statistically compared with those obtained using the standard official method [24,25]. The parameters and conditions of both methods are summarized in Table 4. The Student t-test values obtained indicated no significant difference in the mean recovery results for diazepam between the official and developed methods.

The results obtained showed that our present method is precise, accurate and suitable for the determination of these compounds in drug formulations. It is faster (analysis time is 2 min) and more specific than the other existing methods.

5. Conclusion

The modified simplex program and the sophistication of the DAD system resulted in successful chromatographic and chemical optimization conditions thus giving an excellent separation in a reasonable requested time. This makes the current method the fastest of those adopted for these compounds. The modified simplex program could be used for the optimization of similar chromatographic separations.

Spectrophotometric determination of Isoproturon and Metoxuron using ethylacetoacetate and application to technical and formulation grade samples[1]

K. Ramakrishnam Raju, S.R.K.M. Akella, J.V.S. Murthy, U.T. Bhalerao*

Indian Institute of Chemical Technology, Hyderabad 500 007, India

Abstract

A simple and rapid spectrophotometric method for the determination of Isoproturon and Metoxuron is described based on alkaline hydrolysis of the compounds to their corresponding primary amines, followed by diazotization and coupling with ethylacetoacetate in alkaline medium. The chromogenic species obeys Beer's law up to 15 and 9 μg ml^{-1} for Isoproturon and Metoxuron respectively. The method is successfully applied for technical and formulation samples with RSD in the ranges 0.48–0.72, 0.86–1.32 and 0.66–0.74, 0.27–0.69 for technical and formulation grade samples of Isoproturon and Metoxuron respectively. The advantages over the earlier methods are discussed.

Keywords: Spectrophotometry; Isoproturon; Metoxuron

1. Introduction

Among the phenylurea herbicides, *N,N*-dimethyl-*N'*-[4-(1-methyl ethyl) phenyl] urea and *N'*-(3-chloro-4-methoxy phenyl)-*N,N*-dimethyl urea popularly known as Isoproturon (IPN) and Metoxuron (MTN) respectively, are widely used for the control of different weed species in cereals and carrots. The need for a simple method for their routine analysis and quality evaluation in technical and formulation grade samples is acknowledged. Titrimetric [1], GC [2] and UV spec-

trophotometric [3] methods are available for this purpose and are unsuitable for routine use for the reasons previously outlined [4,5]. The use of coupling reactions of diazo derivatives of primary amines with phenols, amines and carbanions is known for their analysis. Coupling reactions with carbanions have been by far the least explored, and in particular application to pesticides has not been reported. Ethylacetoacetate, with an active hydrogen atom, is a simple useful carbanion-yielding reagent that can be used for coupling with diazonium salts [6–8]. During further investigations on analytical methods, we developed yet another simple and rapid spectrophotometric method based on the coupling reaction of ethyl-

acetoacetate, a common chemical, in strong alkali medium with the diazonium salt obtained after hydrolysis and subsequent diazotization and the results are presented here.

2. Experimental

2.1. Apparatus

A Parkin-Elmer Model Lambda-2 UV–Visible spectrophotometer with 1 cm matched quatrz cells was used.

2.2. Reagents and materials

All the chemicals used were of AnalaR grade. The following solutions were prepared: 0.5 N and 0.8 N sulfuric acid (Loba Chemicals, Bombay) in water; 1.0% w/v sodium nitrite (Qualigens, Bombay) in water; 5.0% sulfamic acid (Loba Chemicals, Bombay) in water; 0.5 and 5.0% v/v ethylacetoacetate (Reidel, Germany) in methanol; 50.0% w/v sodium hydroxide (Qualigens, Bombay) in water; 0.5 N sodium hydroxide in methanol.

Standard IPN was supplied by M/s Bharat Pulverising Mills, Bombay and used as received. MTN was supplied by the Pesticides Division, IICT, Hyderabad and was used after recrystallization in hot water.

2.3. Preparation of standard herbicide solutions

Standard herbicide solutions were prepared by dissolving 80 mg herbicide in methanol and diluting to 50 ml in a standard flask from which 3.0 ml was taken and diluted further to 50 ml with methanol and then used as working solutions.

2.4. General procedure

A 1.0 ml portion of working sample solution was transferred into a 10 ml standard flask to which 1.0 ml 0.5 N methanolic sodium hydroxide was added and allowed to stand for 5 min to ensure complete hydrolysis. After evaporating the solvent, 1.25 ml 0.8 N and 0.75 ml 0.5 N sulfuric

acid were added for IPN and MTN respectively and the flasks were heated in a water bath for about 30 min (IPN) and 5 min (MTN). The flasks were then removed from the water bath and cooled to room temperature after which 1.0 ml and 0.75 ml of 1.0% sodium nitrite solution were added for IPN and MTN respectively and the flasks allowed to stand for 5 min. Then 0.5 ml (IPN) and 0.25 ml (MTN) 5.0% sulfamic acid solution were added, the flasks were stood for 5 min, 1.0 ml 0.5% ethyl acetoacetate solution and 2.0 ml 50.0% sodium hydroxide solution were added to each flask and distilled water was added to 10 ml. The absorbances of the solutions were measured at 398 nm (IPN) and 400 nm (MTN) against distilled water blank.

2.5. Technical grade samples

About 80 mg of technical grade sample was weighted accurately and dissolved in 50 ml methylene chloride. The solution was treated with 1 N hydrochloric acid and the organic layer was evaporated. The residue was dissolved in methanol and diluted to 50 ml in a standard flask. A 3.0 ml portion of solution was further diluted to 50 ml with methanol and then 1.0 ml was extracted and subjected to analysis using the general procedure.

2.6. Formulation samples

About 160 mg and 110 mg of formulations of IPN and MTN respectively were weighed accurately, 50 ml of methylene chloride was added and the samples were centrifuged. The organic layer was evaporated after treatment with 1 N hydrochloric acid. The residue was dissolved in methanol, diluted to 50 ml, and 3.0 ml portions of the solutions were diluted to 50 ml with methanol and 1.0 ml was used for subsequent analysis using the general procedure.

Synthetic formulations (80%) as wettable powders for MTN were prepared [9] and analysed owing to the non-availability of commercial formulations.

3. Results and discussion

3.1. Optimisation of reaction variables

Typical absorption spectra of IPN and MTN are shown in Fig. 1. The reaction variables have been optimised to obtain maximum colour development by varying one variable at a time while keeping the others constant. The optimum concentrations of the various reagents for IPN and MTN respectively are found to be 1.0 ml 0.5 N methanolic sodium hydroxide, 1.25 ml 0.8 N and 0.75 ml 0.5 N sulfuric acid, 30 min and 5 min heating time, 1.0 ml and 0.75 ml 1% sodium nitrite, 0.5 ml and 0.25 ml 5% sulphamic acid and 1.0 ml 0.5% ethylacetoacetate followed by 2.0 ml 50% sodium hydroxide.

Although methanolic sodium hydroxide brings about rapid hydrolysis [10,11] of the present herbicides, methanol affects the colour development
Fig. 1. Absorption spectra of IPN and MTN: (——) IPN; (-----) MTN. (1.0 ml 0.025% IPN/MTN + 1.0 ml 0.5 N methanolic NaOH + 1.0 ml 0.8 N H₂SO₄ + 1.0 ml 1.0% NaNO₂ + 0.5 ml 5.0% sulfamic acid + 1.0 ml 0.5% ethylacetoacetate + 2.0 ml 50% NaOH against distilled water blank.)

Table 1
Beer's law, precision and accuracy

Parameter	IPN	MTN
λ_{max} (nm)	398	400
Beer's law limit ($\mu g \ ml^{-1}$)	15	9
Molar absorptivity (E) (1 $mol^{-1} \ cm^{-1}$)	1.37×10^4	2.33×10^4
Slope	0.0608	0.0963
Intercept	0.0351	0.0192
Correlation coefficient	0.9995	0.9958
Regression equation	$y = 0.0608x + 0.0351$	$y = 0.0963x + 0.0192$

and therefore its evaporation is recommended for further procedure after hydrolysis.

Variations in absorption measurements are observed when made against reagent blank. Upon further investigation it is found that the reagent blank is not stable. It is found that the variation in the absorbance of the blank is due to insufficient quantity of sulfamic acid being used to destroy the excess nitrite [12]. However, with the use of further excess of sulfamic acid, although the blank absorption is found to be constant, the absorbance of the sample decreases (vide optimum conditions). However, the absorption measurements for samples are stable and reproducible when made against distilled water blank and hence the present work is carried out accordingly.

3.2. Beer's law, precision and accuracy

The absorption maxima (λ_{max}), the molar absorptivities, Beer's law limits and correlation coefficients are given in Table 1. Although the reaction is fast, 3 min standing time is necessary to obtain reproducible results and the colour is stable for 30 min in both cases.

3.3. Reaction mechanism

Compounds containing active methylene groups such as ethylacetoacetate can be used as reagents for the determination of primary amines as it is known that diazo derivatives undergo coupling reactions by means of electrophilic sub-

Scheme 1.
stitution with phenols, amines, and carbanions with active methylene groups [7]. Thus, the authors are also of the opinion that diazo derivatives of the amines formed after alkaline hydrolysis of IPN and MTN [10,11] are likely to couple with the carbanions of ethylacetoacetate, as reported earlier [8], yielding the yellow chromogenic species shown in Scheme 1.

3.4. Application

A series (7) of standard samples of IPN and MTN has been analysed and the average percent relative error is found to be 0.74 [1.04, 0.44] for IPN and 0.68 [0.99, 0.37] for MTN at the 95% confidence level. A number of technical and formulation grade samples of IPN and MTN are analysed using the present method and the data are shown in Table 2. The RSDs were in the ranges 0.48–0.72, 0.86–1.32 and 0.66–0.74, 0.27–0.69 for technical and formulation grade samples of IPN and MTN respectively. The recoveries with respect to a comparison method [1] are also given in Table 2 to indicate the applicability of the method.

3.5. Advantages

The present method does not involve time-consuming distillation, thermal and photo-decomposition as reported earlier [1–3]. Furthermore, the present method is superior to our earlier methods [4,5] in terms of the simplicity of the reagent and is much more sensitive than the latter method and comparable with the former. Therefore, the

present method is simple, sensitive, rapid and useful for routine analysis.

Abstract

A method is proposed for the simultaneous determination of iron(III) and molybdenum(VI) by first-derivative spectrophotometry based on the absorption spectra of their complexes with morin in the presence of a cationic surfactant. The zero-crossing measurement technique is found sutiable for the direct measurement of the first-derivative value at the specified wavelengths. Iron(III) $(0.9–1.5\ \mu g\ ml^{-1})$ and molybdenum(VI) $(0.3–4.2\ \mu g\ ml^{-1})$ in different ratios have been determined simultaneously. A critical evaluation of the proposed method is performed by statistical analysis of the experimental data. The method was applied to determine iron and molybdenum in different alloys.

Keywords: Iron; Molybdenum; Alloys; First-derivative spectrophotometry

1. Introduction

The development of spectrometric methods has allowed the resolution of the complex spectra of multicomponent mixtures [1–3]. The resolution of binary mixtures of compounds with overlapped spectra by derivative spectrophotometry is greatly simplified and their reliability is increased by the determination of the individual components without the need for chemical separation. Derivative

spectrophotometric procedures have been applied for simultaneous determination of aluminum and iron with 8-hydroxyqunioline [4], molybdenum and titanium with hydrogen peroxide [5], aluminum and beryllium with 5,8-dihydroxy-1,4-napthaquinone [6], iron and bismuth with EDTA [7], palladium and platinum with dithizone [8], palladium and ruthenium with 2-thiobarbituric acid [9], beryllium and magnesium with 1-hydroxy-2-carboxyanthraquinone [10], copper and magnesium with emodin [11], copper and iron with cyanide [12], nickel and manganese with 2-(2-

pyridylmethyleneamino)phenol [13], and gold and silver as rhodanine derivatives [14]. In contrast, morin has been used as a sensitive reagent for determination of iron [15,16] and molybdenum [17] in micellar media. It had been reported that molybdenum(VI) interferes strongly in the determination of iron(III), where their morin complexes show very close overlapping bands. The low seletivity of these methods makes them unsuitable for direct application without masking or a preliminary separation.

This paper reports a rapid and simple derivative spectrophotometric method for simultaneous determination of iron(III) and molybdenum(VI) in their mixtures. The method is based on the formation of colored complexes with morin in the presence of cetylpyridinum bromide. The first-derivative spectrum $(d_1A/d\lambda)$ is determined using the zero-crossing technique. The reported method was successfully applied to determine iron and molybdenum simultaneously in a range of diverse alloys.

2. Experimental

2.1. Apparatus

A Perkin-Elmer Lambda 3B spectrophotometer fitted with Perkin-Elmer Pecss software (controlled by a Mitsuba 368/33DX computer in conjunction with an HP Laser Jet 4L printer) and equipped with a 1 cm quartz cell was used for all measurements. The software was used to obtain the first-derivative spectra and to select the differential wavelength $(\Delta\lambda)$. The auto-option uses a width of $\Delta\lambda$ calculated by the method of Savitzky and Golay [18] at a scan speed of 120 nm min^{-1}. The pH measurements were made on an Orion Ionalyzer Model 920E fitted with a combined glass–calomel electrode.

2.2. Reagents

All materials used were of analytical grade and doubly-distilled water was used throughout. The certified cobalt/chromium, nickel/chromium, cobalt/chromium/nickel and ferromolybdenum al-

Switzerland) and by a standard chemical method [19].

A stock solution of iron(III) (1 mg ml^{-1}) was prepared by dissolving 0.7234 g Fe$_2$(NO$_3$)$\cdot$H$_2$O (Aldrich) in 100 ml 0.1 N HNO$_3$. The solution was standardized by direct EDTA titration [20].

A stock solution of molybdenum(VI) (1 mg ml^{-1}) was made by dissolving 0.2522 g of Na$_2$MoO$_4\cdot$2H$_2$O (Aldrich) in 250 ml of water and standardized by titration with EDTA [20].

Morin (2′,3,4′,5,7-pentahydroxyflavone) solution (5 × 10^{-3} M) was prepared by dissolving 0.3778 g of the reagent (Merck) in 250 ml of absolute ethanol.

Cetylpyridinium bromide (CPB) aqueous solution (10^{-2} M) was prepared by dissolving 1.006 g of CPB (Fluka) in 250 ml of water.

Potassium chloride–hydrochloric acid buffer solution of pH 2.5 was prepared by adjusting the pH of 0.2 M KCl solution with 1 N HCl. Iron-free hydrochloric acid (1:1) was prepared according to the procedure of Jackson and Phillips [21].

Potassium fluoride solution (0.2 M) was prepared by dissolving 2.9 g of KF in 250 ml water.

2.3. Procedures

2.3.1. Simultaneous determination of iron(III) and molybdenum(VI) as morin–CPB complexes with first-derivative spectrophotometry

Transfer aliquots of iron(III) (2–26 μg) and molybdenum(VI) (5–100 μg) to separate 25 ml volumetric flasks. Add 1 ml of morin solution and 5 ml of CPB and dilute to the mark with acid buffer solution. Record the D_1 spectra of the mixture against a reagent blank after 10 min of mixing. Measure the absolute $D_1(d_1A/d\lambda)$ values at 412 and 417 nm for determination of iron and molybdenum respectively.

2.3.2. Simultaneous determination of iron and molybdenum in diverse alloys

Weigh 0.4 g of the alloy sample into a 150 ml beaker. Treat with 40 ml concentrated HCl (1:1) and 10 ml of concentrated HNO$_3$. Heat on a steam bath to near dryness and then cool to room temperature. Dissolve the residue in 50 ml HCl and boil the mixture to dissolve the salt, followed by dilution to 100 ml with water. Transfer a suitable aliquot of sample to a 25 ml volumetric flask and add 2 ml of 0.2 M KF. The iron and

molybdenum contents are simultaneously determined as before starting from "Record the D_1 spectra . . . . ." in the previous section.

3. Results and discussion

Morin forms colored complexes with iron and molybdenum in aqueous media. A hyperchromic effect is usually observed in the presence of surfactants [15–17].

Fig. 1 shows the zero-order absorption spectra of morin–CPB complexes of iron(III) (curve 1) with a maximum at ≈ 417 nm and molybdenum(VI) (curve 2) with a maximum at ≈ 412 nm.

V^{5+}	3

[a] 2 ml of 0.2 M potassium fluoride.
[b] 1 ml of 0.5 M thiourea.

The total absorption spectrum of iron and molybdenum complexes is given in curve 3. However, the maximum absorption of morin reagent in acidic medium was 350 nm [15]. Consequently the absorption of iron(III) and molybdenum(VI) complexes and their mixture appeared as negative absorbance in the range 380–300 nm.

The complexation of iron and molybdenum with morin in the presence of CPB occurs over a wide pH range; the maximum absorption intensity is between 2 and 3 for iron and between 1.5 and 3 for the molybdenum complexes. The concentrations of morin (4×10^{-4} M) and CPB (2×10^{-3} M) in the final solution are selected to ensure that an excess of the reagent is present. Full color development is obtained 10 min after addition of acidic buffer to a mixture of iron(III)– and molybdenum(VI)–morin–CPB complexes. The absorbance remains constant for about 2 h.

Because of the large band overlap of the spectra of the two complexes, the determination of iron and molybdenum in their mixture by normal spectrophotometry is subject to considerable difficulties. For this reason, it was found to be more convenient and simple to resolve the problem of closely overlapped spectra by making use of the derivative spectra of the mixutre of both complexes.

A study of the first-, second-, third-, and fourth-derivative spectra of the mixture of iron and molybdenum complexes demonstrated that the first-derivative spectra gave results of highest accuracy and lowest detection limits. Fig. 2 shows the first-derivative spectra of the complexes shown

Table 3
Simultaneous determination of iron and molybdenum in diverse alloys using first-derivative spectrophotometry

[a] Average of five determinations.

in Fig. 1. It can be seen that the first-derivative spectra of the mixture of both complexes (Fig. 2, curve 2) are not sufficiently resolved to generate two distinct peaks. Therefore the zero-crossing measurement technique was utilized for resolving the mixture of the named complexes.

Fig. 3 (a)(b) shows series of first-derivative spectra of a mixture of iron(III)– and molybdenum(VI)–morin–CPB complexes. A series of first-derivative spectra of a mixture of 0.46 μg ml^{-1} iron(III) plus increasing amounts of molybdenum(VI) (0.63–3.36 μg ml^{-1}) are given in Fig. 3(a). Fig. 3(b) shows a series of first-derivative spectra of mixtures of 1.35 μg ml^{-1} molybdenum(VI) and increasing concentrations of iron(III) (0.1–1.0 μg ml^{-1}). The heights h_1 and h_2 in the first-derivative spectrum of the mixtures corresponding to values taken at wavelengths of 417 nm (zero-crossing wavelength of iron complex) and 412 nm (zero-crossing wavelength of molybdenum complex) are proportional to iron(III) and molybdenum(VI) concentrations respectively.

3.1. Calibration graphs and statistical treatment of results

The calibration graphs obtained by the recommended procedure are linear over the ranges 0.07–1.5 μg ml^{-1} of iron in the presence of 1.35 μg ml^{-1} molybdenum and 0.2–4.2 μg ml^{-1} of molybdenum in the presence of 0.46 μg ml^{-1} iron. The calibration graphs prepared by plotting the first-derivative values (h) vs. iron or molybdenum concentration all gave significant linearity with negligible intercepts, confirming the mutual independence of the derivative signals of the two complexes.

In Table 1 the statistical parameters for calibration graphs are given. The high values of correlation coefficients and intercepts on the y-axis (close to zero) indicate the good linearity of all calibration graphs and the conformity of Beer's law of first-derivative measurements. The precision of the method is determined for 10 samples, each containing 0.34 μg ml^{-1} iron(III) and 2 μg ml^{-1} molybdenum(VI). The values of $d_1\varepsilon$ for determi-

nation of iron and molybdenum at 412 and 417 nm are calculated from computing the corresponding values of d_1A and the results are given in Table 1. The $d_1\varepsilon$ value was equal to 8.64×10^{-2} and 1.61×10^{-2} μg ml^{-1} (the slopes of the regression lines in Table 1) for determination of iron and molybdenum respectively. The relative standard deviation is 1.5 and 1.7% for iron and molybdenum respectively. Moreover, the detection limits [22] are 0.04 and 0.2 μg ml^{-1} for iron and molybdenum respectively. The results in Fig. 3 and Table 2 suggest that a satisfactory resolution of two overlapping spectra is obtained by the first-derivative zero-crossing method.

3.2. Interference studies

The influence of the presence of diverse ions on the simultaneous determination of 0.46 μg ml^{-1} iron(III) and 1.35 μg ml^{-1} molybdenum(VI) was investigated by applying the recommended procedure to a solution containing a 2000-fold (mol/mol) ratio of interfering ion to iron; if interference occurred, this ratio was reduced until the interference ceased. Metal ions are added as the nitrate, chloride or sulfate, while the anions are added as ammonium, potassium or sodium salts. The criterion for interference was a deviation of more than ± 3% from the concentration of iron and molybdenum. The tolerance limits of some cations increased by addition of 2 ml of 0.2 M potassium fluoride. The results are given in Table 2.

The method has been applied to the simultaneous determination of iron and molybdenum in diverse alloys. The results obtained are presented in Table 3 and are in quite good agreement with those obtained by a standard chemical method [20] and by X-ray fluorescence.

Simultaneous determination of neodymium, erbium and holmium in rare earth mixtures with 2-phenyltrifluoroacetone and octylphenol poly(ethyleneglycol) ether by third-derivative spectrophotometry

Nai-Xing Wang*, Zhi-Kun Si, Jing-He Yang, Ai-Qin Du, Zhen-Dong Li

Department of Chemistry, Shandong University, 250100, Jinan, People's Republic of China

Received 13 April 1995; revised 5 October 1995; accepted 9 October 1995

Abstract

The complexes of the rare earth metals with 2-phenyltrifluoroacetone in the presence of TX-100 are reported. The characteristic absorbances of neodymium, holmium and erbium complexes can be increased by factors of 8.5, 31 and 15 respectively, compared to those of the cholrides. The third-derivative spectra have been used to eliminate the interference of cerium, and the sensitivities are increased again by factors of 7.4, 5.5 and 6.5. A method for the direct determination of neodymium, erbium and holmium in rare earth mixtures is proposed.

Keywords: Neodymium; Erbium; Holmium; Third-derivative spectrophotometry

1. Introduction

As colour-producing agents for the rare earth ions, there are a lot of highly sensitive reagents including arsenazo III [1] 1-(2-pyridylazo)-2-naphthol [2], chlorophosphonazo III [3] etc., but the determination of the individual rare earths in their mixture with these reagents is almost impossible because these reagents lack selectivity. There has

always been interest in the determination of individual rare earths, based on the absorption bands of their 4f electron transitions [4–12].

However, the determination of the rare earth elements with 2-phenyltrifluoroacetone has hardly been described. In this paper, we have discovered that 2-phenyltrifluoroacetone can form stable complexes with rare earth methal in the presence of TX-100. In the absorption spectra, the peaks of neodymium, holmium and erbium in the visible region are enhanced, the absorbances at λ_{max} being increased by factors of 8.5, 31 and 15 respec-

* Corresponding author.

tively, compared with those of the chlorides. However, direct determination by conventional spectrophotometry is still subject to interference from other rare earths. Accordingly, derivative spetra were studied, and the use of the third-derivative spectra was found to eliminate the interference and to enhance the sensitivity. On this basis, a method was developed for the determination of neodymium, erbium and holmium in rare earth mixtures. The analytical results obtained are quite satisfactory.

2. Experimental

2.1. Apparatus

A Shimadzu UV-3000 recording spectrophotometer with 4.0 cm cells was used.

2.2. Reagents

Standard solutions of rare earth metals were prepared from the pure oxides (Johnson Matthey) and mixed as required.

2-Phenyltrifluoroacetone (PTA) solution (0.05 M) was prepared by dissolving 1.080 g of PTA (Shanghai Chemical Reagent Plant) in ethanol and diluting to 100 ml with ethanol.

A solution of octylphenol poly(ethylengelycol) ether (TX-100; 2.0% v/v) was prepared by dissolving 5.00 ml of TX-100 (Rohm & Hass, Philadelphia, PA) in 250 ml of water.

Ammonium chloride solution (0.5 M) of pH 9.26 was used as a buffer.

All other reagents used were of analytical grade.

2.3. Procedure

Transfer a known volume of the lanthanide solution into a 10.0 ml volumetric flask, add 3.00 ml of PTA, 2.5 ml of TX-100 and 2.0 ml of buffer solution, dilute to volume with distilled water and mix. Record the absorption spectrum or its derivative spectrum against a reagent blank as reference.

3. Results and discussion

The absorption spectra of lanthanide ions and their complexes in the presence of TX-100 are shown in Fig. 1. It can be seen that curves 1 and 2 show some changes in the spectral features. The absorption band for the neodymium complex is shifted to longer wavelengths compared to the spectrum of the neodymium ion in the chloride, while those of erbium and holmium are shifted to shorter wavelengths. The sensitivity is enhanced considerably. A very sharp absorption band is found at 574 nm for neodymium, at 449 nm for holmium and at 521 nm for erbium, which allows their determination by means of their derivative spectra. Table 1 gives the spectral characteristics of the systems.

Fig. 2 shows that the normal spectrophotometric determination for neodymium, erbium and holmium is subject to interference by other rare earths. Cerium interferes to the greatest extent.
Fig. 1. Absorption spectra of ions and complexes. $[Nd] = 1.2 \times 10^{-4}$ M; $[Er] = [Ho] = 1.0 \times 10^4$ M; $[PTA] = 5.0 \times 10^{-3}$ M; $[TX-100] = 0.4\%$ v/v; pH 9.26; 4.0 cm cells. λ (nm)	575	572	584	450	449	523	521
ϵ (l mol^{-1} cm^{-1})	6.5	53	44.7	3.7	97	2.2	33
Spectral transition [2]	$^4I_{9/2} \rightarrow {}^2G_{7/2} + {}^4G_{5/2}$			$^5I_6 \rightarrow {}^5F_2 + {}^5F_1$		$^4I_{15/2} \rightarrow {}^2H_{11/2} + {}^4S_{3/2}$	

Therefore, in order to eliminate the interference and improve the sensitivity, the 1st–4th derivative spectra of the lanthanide complexes were investigated along with the variable measuring parameters of the instrument. It is found that the optimum instrumental conditions for neodymium, erbium and holmium proved to be the use of the third-derivative spectrum with $\Delta\lambda = 3.5$ nm, bandpass = 1.0 nm, scan rate = 50 nm min^{-1}.

Fig. 3 shows the third-derivative spectra of the representative lanthanide complexes, from which it is clear that the optimal analytical signals are at 572.2(+) and 569(−) nm for neodymium, at

513(+) and 516(−) nm for erbium and at 451.5(+) and 449(−) nm for holmium, where other lanthanides produce only constant absorption signals and cause no interference.

Fig. 4 shows the effect of pH on the absorption of the complexes. In the pH range 6.5–11.0, the highest absorption was obtained. Hence, a pH 9.26 buffer solution was chosen in subsequent experiments.

Fig. 5 shows the effect of the amount of reagent. In view of this, the amount of PTA used in the determinations was always at least 50 times that of the lanthanides present.
Fig. 2. Absorption spectra of complexes. $[Nd^{3+}] = 1.2 \times 10^{-4}$ M; $[Ln^{3+}] = 1.0 \times 10^{-4}$ M; other conditions as in Fig. 1, curve 2. (1) Nd; (2) Ho; (3) Er; (4) Ce(IV); (5) Pr; (6) Sm; (7) Y; (8) Eu; (9) PTA–TX-100 against water as a reference.
Fig. 3. Third derivative spectra of complexes. $\Delta\lambda = 3.5$ nm; bandpass = 1.0 nm; scan rate = 50 nm min^{-1}; other conditions as in Fig. 2, curves 1–8.
Fig. 4. Effect of pH on the third derivative absorption of the complexes. [Nd] = 6.1 × 10^{-5} M; [Er] = [Ho] = 5.0 × 10^{-5} M; instrumental parameters as in Fig. 3. Other conditions as in Fig. 1, curve 2. (1) Er peak-to-valley amplitude measurements are at 513(+) and 516(−) nm; (2) Nd peak-to valley amplitude measurements are at 572.2(+) and 569(−) nm; (3) Ho peak-to-valley amplitude measurements are at 451.5(+) and 449(−) nm.

As regards the effect of the amount of TX-100 on the absorption of the complexes, the experimental results showed that precipitation would occur at TX-100 < 0.1% v/v. Variation of the amount of TX-100 solution between 0.1 and 1.0%
Fig. 5. Effect of PTA on the third derivative absorption of the complexes. pH = 9.26; other conditions as in Fig. 4, except for the change in the PTA concentration.

[c] Result of neodymium.
[d] Result of erbium.
[e] Result of holmium.

v/v had no effect on the derivative absorption of the complexes.

The complexes formed quickly and were stable for more than 6 h.

The calibration graphs are linear up to ≈ 30 μg ml^{-1} for Nd$_2$O$_3$ and ≈ 35 μg ml^{-1} for Ho$_2$O$_3$ and Er$_2$O$_3$. The sensitivities for neodymium, holmium and erbium are 7.5, 5.5 and 6.5 times greater than those achieved with the ordinary method.

The precision of the studied methods was evaluated using ten samples, each containing 5.0 μg ml^{-1} of Nd, Er and Ho. The relative standard deviations are 1.2%, 1.6% and 1.9% for Nd, Er and Ho respectively. The detection limits (signal-to-noise ratio = 2) are 0.25 μg ml^{-1}, 0.70 μg ml^{-1} and 1.1 μg ml^{-1} for Nd, Ho and Er respectively.

In order to test the applicability of the method, two synthetic samples were prepared on the basis of the relative contents of rare earth oxides in Earth's crust [13]. The analytical results obtained are listed in Table 2.

Determination of serum selenium by hydride generation flame atomic absorption spectrometry

Da-Qing Hao*, Guo-Hong Xie, Yi-Min Zhang, Guo-Jun Tian

Institute of Occupational Diseases, Xinxiang, Henan 453003, People's Republic of China

Abstract

Serum is rapidly digested with a mixture of nitric and perchloric acids at a temperature of $180 \pm 10°C$, and hydrochloric acid is used to reduce selenium(VI) to selenium(IV). Selenium is determined by hydride generation flame atomic absorption spectrometry. The results show that this method has the advantages of being sensitive, accurate, rapid and simple. After the serum is digested and diluted, 4.0 ml is taken for the determination. The characteristic concentration, detection limit, variation coefficient, recovery rate and linear range are 2.93 μg l^{-1}, 1.55 μg l^{-1}, 1.6–5.0%, 97.3–99.2% and 0.0–320.0 μg l^{-1} respectively. Serum at 4°C and in frozen state can be preserved for at least 7 and 14 days, respectively.

Keywords: Serum; Selenium; Hydride generation flame atomic absorption spectrometry

1. Introduction

Selenium is an essential trace element [1]. With the development of science and technology, the selenium content in serum has become an important monitoring index in clinical medicine. Selenium is not only a nutritional anticancer element [2] but also a strong antioxidant. It can suppress the effect of chemical cancerogenic substances. Selenium plays a part in the study of tumours, cancer, cardiology, liver diseases [3] and endemic diseases [4], and has received great attention in the medical field.

* Corresponding author.

Many investigators have reported the determination of serum selenium using fluorimetry, polarography [5,6], neutron activation, graphite furnace atomic absorption spectrometry [7] and hydride generation atomic absorption spectrometry. Fluorimetry is a classical method with high sensitivity, but the preprocessing of samples is prolix and laborious. Polarography is a handy method but suffers from poor reproducibility. Neutron activation and graphite furnace atomic absorption spectrometry are seldom used in the determination of serum selenium due to the volatilization loss of selenium in the measurement process. Hydride generation atomic absorption spectrometry is a sensitive and accurate method;

the detection limit of the method is in the range 1–5 ng ml^{-1}, and it is often used in the determination of selenium [8–12]. In this paper, we use a mixture of nitric and perchloric acids to digest the samples, and then use $NaBH_4$ to reduce the tetravalent selenium to H_2Se in the acidic medium. The generated H_2Se was transported into a heated quartz tube by carrier gas for atomization, and the determination of selenium was performed by using atomic absorption spectrometry at a wavelength of 196.0 nm. To prevent the loss of selenium, special attention should be paid to the conditions of digestion and reduction. We used this method to quantitatively determine the selenium content of serum. The samples were collected from various cancerous and non-cancerous patients. Some attractive results were found and are reported in this paper.

2. Experimental

2.1. Sampling, shipment and storage

Wash skin with 3% nitric acid and then 75% ethanol. Take 2 ml venous blood into a stoppered plastic tube. Store for 1 h and then centrifuge the sample at 2000 rev min^{-1} for 10 min. Remove all the serum slowly and place it in a stoppered plastic tube to be stored at a temperature of 4°C or frozen. The serum has to be mixed homogeneously before analysis.

2.2. Procedure

2.2.1. Blood blank sample
Take serum from a calf or several normal people, and mix the serum for use.

2.2.2. Sample preparation
Place 0.5 ml serum in a small weighing bottle, add 1.0 ml mixed acid, mix homogeneously and cover with a glass coverslip. Heat on an electric hot plate at 180 ± 10°C until the digested solution becomes colourless and transparent with white fumes given off; cool to room temperature. Carefully wash the coverslip into a weigh-

ing bottle with 1.0 ml of deionized water. Add 0.6 ml of concentrated hydrochloric acid, mix homogeneously and heat for 20 min without covering. Cool. Transfer the remaining solution and wash the weighing bottle several times with heated deionized water into a 10 ml test tube, dilute to volume and mix homogeneously for determination. At the same time run a reagent blank with 0.5 ml water instead of serum.

2.2.3. Calibration
Take six small weighing bottles and fill them with 0.5 ml of standard selenium solutions of different concentrations and 0.5 ml of serum blank sample. Mix homogeneously and process as for the sample.

2.2.4. Measurement
Under the working conditions of the apparatus, place 4.0 ml of solution into an atomization reaction bottle, and cover the bottle. Add a fixed amount (2.0 ml) of sodium borohydride $NaBH_4$ alkaline solution. Determine the selenium concentration of the sample by reference to the absorbance values obtained concurrently for the calibration solutions. The absorbance value of the sample is corrected by subtracting that obtained for the blank solution.

2.3. Apparatus

The following apparatus was used. A Shimadzu model AA-670 atomic absorption spectrometer, equipped with a single-slot 10 cm air–acetylene burner. A selenium hollow cathode lamp (Hebei, People's Republic of China). A model VA-90 hydride generation system with quartz tube atomizer (Tong-Ji Medical University, Wuhan, People's Republic of China). ϕ 25 × 40 mm hard glass weighing bottle. The following spectrometer conditions were used: wavelength, 196.0 nm; slit width, 0.3 nm; lamp current, 8 mA; flow rate of acetylene, 1.9 l min^{-1}; flow rate of air, 8.0 l min^{-1}; burner height, 18 mm; flow rate of argon, 0.8 l min^{-1}; measurement mode, peak height.

2.4. Reagents

All glassware and plasticware were soaked overnight in 30% (v/v) nitric acid, thoroughly rinsed with water and dried. Deionized water is used throughout. The following reagents were used: hydrochloric acid, high purity grade; nitric acid, high purity grade; perchloric acid, high purity grade; mixed acid, nitric acid and perchloric acid (1 + 1); hydrochloric acid solution, 6% (v/v); nitric acid solution, 3% (v/v); ethanol solution, 75% (v/v).

2.4.1. Sodium borohydride solution

Dissolve 0.6 g sodium borohydride (high purity grade) and 0.5 g sodium hydroxide (analytical reagent) in water and dilute to 100 ml.

2.4.2. Standard solutions

Standard solution of 100 mg 1^{-1}. Working solutions of 40.0, 80.0, 160.0, 240.0 and 320.0 μg 1^{-1} prepared by dilution of the stock solution with 6% hydrochloric acid solution before use.

3. Results

3.1. Choice of conditions for reducing selenium(VI) to selenium(IV)

While serum is being digested, quite a lot of the selenium exists in the form of selenium(VI) as a result of heating and the action of oxidizing acid. In the determination with hydride generation atomic absorption spectrometry, it is very hard to reduce selenium(VI) to hydrogen selenide by sodium borohydride. Therefore, it is necessary to reduce selenium(VI) to selenium(IV) in heated hydrochloric acid medium before hydrogenates are generated and then carry out the determination [13]. Otherwise, the determination accuracy of serum selenium will be directly affected. We added a certain amount of selenium to the samples. It was digested in the same way the samples are treated. When the samples became colourless and transparent they were taken away for cooling. 0.2, 0.3, 0.4, 0.5, 0.6. 0.7 and 0.8 ml of concentrated hydrochloric acid was added to the sam-

ples. After digesting and diluting, under the working conditions of the apparatus the absorbance values of each sample were determined repeatedly six times. When the addition of hydrochloric acid was increased from 0.2 ml to 0.4 ml, the absorbance value of the sample was obviously increased. The maximum absorbance value was reached when addition of hydrochloric acid was increased to 0.6 ml. After that the absorbance was stable with further addition of hydrochloric acid (as seen in Fig. 1). It was found that choosing the addition of hydrochloric acid as 0.6 ml did not only reduce selenium(VI) to selenium(IV), but also satisfied the acid conditions demanded in the determining process.

3.2. Choice of amount of sodium borohydride solution

Sodium borohydride reduces selenium(IV) to hydrogen selenide in acid medium. The amount of sodium borohydride will affect the sensitivity of determination directly. We prepared a mixed serum sample with a high selenium concentration. The samples were treated with the aforementioned sample preparation method and different volumes of 0.6% sodium borohydride solution were added. It was found that, after four determinations, the relevant absorbance value reached a maximum when the amount of sodium borohydride was increased to 2.0 ml. With further increase the absorbance value increased slightly (as Fig. 2 shows), but as there is a booming sound as
Fig. 1. Relationship between amount of hydrochloric acid and absorbance value.
Fig. 2. Choice of amount of sodium borohydride.

a result of the high concentration of hydride in the reaction process, choosing 2.0 ml of sodium borohydride solution can satisfy the determination demand.

3.3. Choice of the flow of carrier gas

In this method, argon is used as the carrier gas to lead hydrogen selenide generated in the reaction bottle into the heated quartz tube atomizer. When the addition of hydrochloric acid is 0.6 ml, the samples are determined with the same concentration of selenium. The flow of argon was adjusted from 0.4 l min^{-1} to 1.2 l min^{-1}, when the flow rate of argon reached 0.8 l min^{-1}, the absorbance value reached a maximum. With four determinations, it was found that the result was stable and the RSD was 1.4%. Therefore, a flow of 0.8 l min^{-1} of argon was chosen.

3.4. Linear range, characteristic concentration and detection limit

Take standard selenium solutions of different concentration and 0.5 ml serum blank sample. Digest as for the samples and determine against a serum blank similarly prepared. Then carry out linear regression of the relevant concentration with the average absorbance value. When the determination range is 0.0-320.0 μg l^{-1}, the regression equation is $y = 0.0012x + 0.0056$, and the correlation coefficient is $r = 0.9994$. According to the requirement of atomic absorption spectrome-

Table 1
Precision of experiment ($n = 6$)

Addition of selenium into serum (μg l^{-1})	Absorbance value ($\bar{x} \pm s$)	RSD (%)
60.0	0.120 ± 0.006	5.0
100.0	0.170 ± 0.004	2.4
300.0	0.376 ± 0.006	1.6

try, it is found by experiment that this method's characteristic concentration is 2.93 μg l^{-1} and the detection limit is 1.55 μg l^{-1}.

3.5. Precision and method validation

3.5.1. Precision

Take serum of normal people, mix homogeneously and then into three groups. Add standard selenium solutions of different concentration; three samples with low, medium and high concentrations were prepared. Determine selenium six times. The results are shown in Table 1.

3.5.2. Method validation

Take serum of three different concentration—low, medium and high—and add different amounts of standard selenium solutions and then determine selenium six times. When the addition of selenium is 40.0-160.0 μg l^{-1}, the relevant recovery rates are 97.3-99.2%, as shown in Table 2.

3.5.3. Determination of standard matter

Cow serum standard matter (GBW 09131) from the Institute of Environmental Sanitation Moni-

Table 2
Method validation ($n = 6$)

Concentration of serum selenium (μg l^{-1})			Recovery rate (%)
Base value	Addition value	Determination value ($\bar{x} \pm s$)	
49.23	40.0	88.15 ± 2.01	97.3
81.15	80.0	160.5 ± 4.24	99.2
131.20	160.0	288.8 ± 6.66	98.5

Table 3
Preservation of samples ($n = 6$)

Preservation time (days)	4°C		Frozen	
	Determination value (μg l^{-1})	Recovery rate (%)	Determination value (μg l^{-1})	Recovery rate (%)
1	4.258	–	4.258	–
3	4.263	100.1	–	–
7	4.047	95.0	4.127	96.9
14	2.944	69.1	4.048	95.1

tor of Chinese Academy of Preventive Medicine was determined six times. The standard value was 38.9 ± 2.3 μg l^{-1}, the determination value was 37.57 ± 1.21 μg l^{-1}, and the relative deviation was -3.4%.

3.6. Interference experiment

In this method of determining serum selenium, only elements which are likely to form hydrogenates and some transition elements are likely to produce interference. In this experiment four metal ions of different concentrations are added to samples with a content of 113.2 μg l^{-1} selenium. Determinations show that 0.028 mg l^{-1} Ni^{2+}, 16.0 mg l^{-1} Fe^{3+}, 0.1 mg l^{-1} As^{3+} and 4.5 mg l^{-1} Cu^{2+} produce no interference.

3.7. Preservation of samples

Take serum from normal people and store it in two plastic bottles. Preserve at 4°C and in frozen state and determine selenium six times on the first day, the third day, the seventh day and the fourteenth day. The findings are shown in Table 3.

3.8. Applications

The method is used to determine serum selenium concentration in 101 normal people (age 19–63) and in 43 cancer patients of nine types, e.g. liver cancer, etc. The concentration of serum selenium in normal people is 81.6–140.4 μg l^{-1} (the average concentration is 97.4 μg l^{-1} and in

cancer patients it is 38.7–88.3 μg l^{-1}, average concentration (66.6 μg l^{-1}) which is remarkably lower than that of the normal people ($p < 0.001$). The serum selenium concentrations of both normal people and cancer patients correspond with those reported in the literature [14,15].

4. Discussion

A key problem in determining serum selenium is to control the digesting conditions of the samples to prevent selenium from being volatilized in the digesting process. We have compared several frequently used wet methods and decided to use the method of rapid digestion with nitric and perchloric acids. Attention should be paid to the digestion and in particular to the completion of the digestion of the samples. Preferably, digestion should be stopped when a white smoke separates from the transparent liquid. Never evaporate the samples to dryness.

As an acid medium for the sample solution, hydrochloric acid has characteristics of high sensitivity, a low blank value and good coincidence. The best hydrochloric acid concentration is decided according to the hydrogenate generation device used in the experiment.

According to the requirement of hydride generation atomic absorption spectrometry, the procedures of treating the samples and standards have to agree with each other so as to reduce errors.

After determining different types of serum samples, it is found that this method applies to sam-

ples whose basal body and selenium concentration vary greatly.

5. Conclusions

This paper has established a method for determining serum selenium by hydride generation flame atomic absorption spectrometry. When the concentration of selenium is in the range 60.0–300.0 μg l^{-1}, the RSDs are 1.6–5.0%, the recovery rates are 97.3–99.2%, the characteristic concentration is 2.93 μg l^{-1}, the detection limit is 1.55 μg l^{-1}, and the linear range of calibration is 0.0–320.0 μg l^{-1}. This method is sensitive, accurate, rapid and simple, and can satisfy the health monitoring requirements of normal persons and the clinical diagnosis of cancer patients.

Anion-exchange preparation of a ^{232}U radiotracer for α-particle liquid scintillation counting

Colin G. Ong*, James O. Leckie

Environmental Engineering and Science, Department of Civil Engineering, Stanford University, Stanford, CA 94305, USA

Received 7 August 1995; revised 19 September 1995; accepted 17 October 1995

Abstract

Daughter product ingrowths, which could act as analytical interferences, are removed from ^{232}U(VI) stock solutions prior to use as an α-particle emitting radiotracer in conjunction with detection by liquid scintillation counting. The preparative benchtop separation procedure employs elution with HCl through a BioRad AG1-X8 anion-exchange resin column, and fraction collection. The importance of the separation of the ^{232}U isotope from daughter products, characterized by high recovery, is illustrated by liquid scintillation energy spectra. Rapid ingrowth in the purified fraction also limits the period of time after purification in which the radiotracer is usable.

Keywords: Anion-exchange preparation; ^{232}U radiotracer; Liquid scintillation counting

1. Introduction

The environmental impact of uranyl ion UO_2^{2+}, one of several radionuclide species potentially released from a hypothetically breached radioactive waste repository [1], is being investigated with respect to ion sorption onto a variety of mineral surfaces representative of the surrounding geological material. Uranium radioisotopes in wastes likely to be stored in such a repository include ^{238}U and ^{234}U. An analytical methodology developed for experimental sorption studies involves the dosing of a mineral suspension with a radiolabelled uranyl solution principally comprising depleted naturally occurring uranium, and also containing a trace quantity of radioactive uranium which is detected with a liquid scintillation counter (LSC). ^{232}U, in the uranyl form, is employed as the radiotracer because it is artificial, and therefore absent from the depleted U solution. Daughter products in the ^{232}U stock standard solution which also emit α-particles (Fig. 1) typically have to be removed just prior to sorption experiments to eliminate interference with the ^{232}U α-particle scintillation energy spectrum during analytical detection.

It has long been known that anion-exchange resins can be used with HCl eluent to effect U(VI) solution cleanup by initial selective retention followed by elution [2-4]. Empirical partition coefficients on anion-exchangers indicate that U(VI) is strongly sorbed in 9-12 M HCl, and poorly retained in 0.1 M HCl [5,6]. Cation-exchange methods [7-9] and the use of other eluents for U separation [10-12] have also been published. A recently developed anion-exchange resin, U/ TEVA (EiChrom, Darien, IL), has been applied to cleanup of U-containing solutions [13,14], but did not improve U/Th separation over prior anion-exchange resins [15].

A brief description is presented here as an update of the basic anion-exchange preparative procedure for isolating the ^{232}U isotope in aqueous HCl media, and this illustrates the successful separation with α-particle scintillation energy spectra of the eluted fractions. Previous works differ in the radioisotope (i.e. ^{238}U and ^{233}U), and analytical instrumentation (e.g. neutron activation analysis, Geiger-Muller radiometric counter, laser kinetic phosphorimetry, mass spectrometry) used.

2. Experimental

A preparative ion-exchange column was set up by packing a 0.7 cm i.d. × 10 cm length borosilicate chromatography column (Kontes, Vineland, NJ) with a slurry made up of 100 mg 100-200 mesh AG1-X8 chloride-form anion exchange resin (Bio-Rad, Richmond, CA) and MilliQ-grade distilled-deionized water. A stopcock was attached to the column outlet for flow control. The resin was conditioned for storage until use by passing through 15 ml of 0.1 N HCl in 2 ml aliquots.

$$^{232}_{92}U \xrightarrow[68.9\,y]{\alpha} {}^{228}_{90}Th \xrightarrow[1.912\,y]{\alpha} {}^{224}_{88}Ra$$

$$\alpha \downarrow 3.66\,d$$

$$^{212}_{82}Pb \xleftarrow[0.15\,s]{\alpha} {}^{216}_{84}Po \xleftarrow[55.6\,s]{\alpha} {}^{220}_{86}Rn$$
Fig. 1. The α-particle radioactive decay series of ^{232}U.

In preparation for the ion-exchange procedure, the resin was conditioned by passing through 2 ml of concentrated HCl. Unless otherwise noted, all eluents in this procedure were added in 0.5 ml aliquots to minimise upwards diffusion of solutes. 25 μl of a nominal 100 μCi ^{232}U stock solution not in equilibrium with daughters (Isotope Products Laboratories, Burbank, CA) in 0.28 ml 2 N HCl was diluted with 10 ml of 2 N HCl, to produce a lower radioactivity reagent solution for handling in regular use for the preparative ion-exchange step. 0.5 ml of the diluted ^{232}U stock (≈ 0.45 μCi) was combined with 2 ml of concentrated HCl, then passed through the resin. The outflow was collected as fraction I. The resin column was then flushed with an additional 2 ml of 0.1 N HCl. The outflow was collected as fraction II. The pH was then raised by passing through 2 ml of concentrated HCl. The outflow was collected as fraction III. The stopcock was closed. The first 0.5 ml aliquot of another 2 ml portion of 0.1 N HCl was added, and the column was allowed to stand for 15 min. The stopcock was then reopened, and the remaining 0.1 N HCl portion was passed through. Outflow was collected as fraction IV. The resin was then washed by adding 5 ml of 0.1 N HCl. Before the last 0.5 ml aliquot was added, the stopcock was closed and the cap twisted on to prevent the resin drying out.

To determine that the separation was performed satisfactorily, 50 μl of each fraction was combined with 15 ml of Ultima Gold XR scintillation cocktail (Packard Instrument Company, Meriden, CT), and analyzed on a Packard TR2500/AB Liquid Scintillation Analyzer set to CPM mode. All analyses were performed with a count time of 60 min.

3. Results and discussion

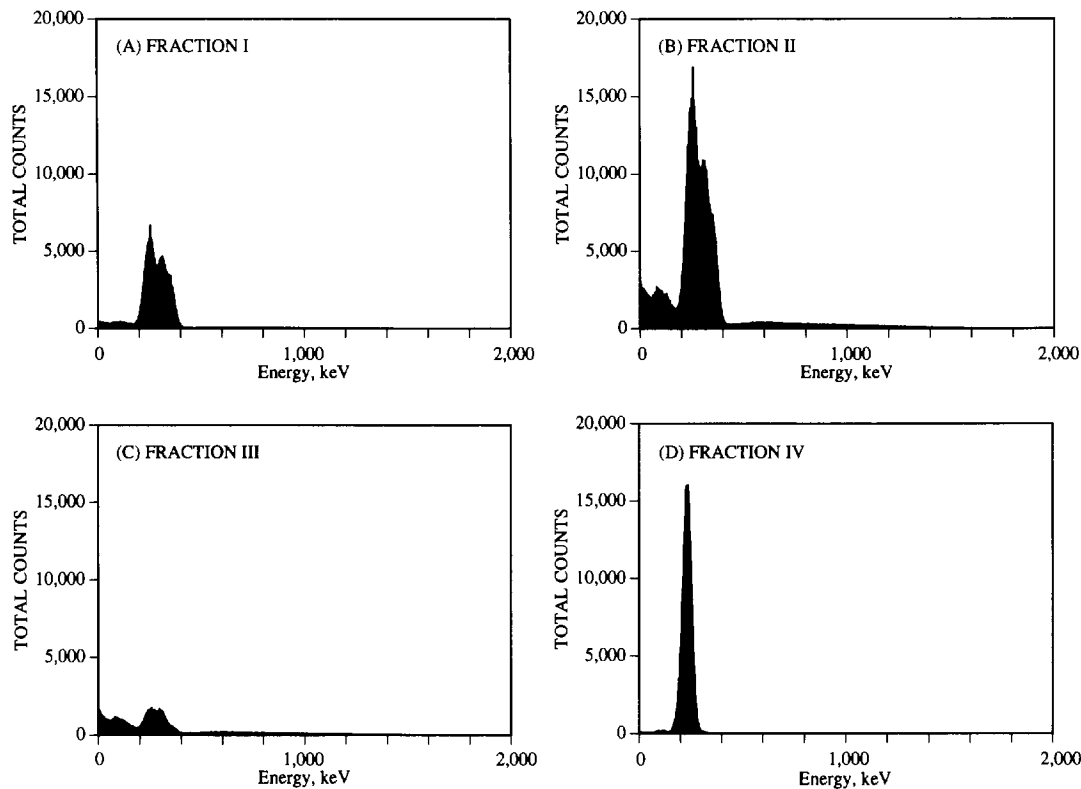
Scintillation spectra in the instrument's full scale detector range of 0-2000 keV of the collected fractions are shown in Fig. 2. It is important to note that experimentation with a variety of commercial cocktails showed that peak positions and height/width may differ. In practice, a more


Fig. 2. Liquid scintillation counting energy spectra of fractions from ^{232}U ion-exchange separation. Total counting time = 60 min.

narrow energy window is used for counting after establishing peak variations under a range of applicable experimental conditions [16], in order to ignore remaining low energy interferences, and relatively higher energy ingrowths that may occur before actual use of the purified radiotracer.

Fraction IV, characterized by a single peak over a narrow energy range in the energy distribution spectrum, indicates the successful separation of U(VI) from daughter products. The daughter products are also shown to have been mostly eluted in fractions I and II. The relatively low profile in the fraction III spectrum indicates that little U(VI) is eluted with the first 2 ml pass of 0.1 N HCl. A trace of β activity is observed in fraction IV, but it is much less than that found in other fractions.

The activity of daughter products is comparatively significant to the ^{232}U parent activity. ^{232}U decay accounts for about 2% disintegration of the parent atoms, and the supplier reported a small

(< 1%) error in the nominal starting activity. The extent of ^{228}Th ingrowth can be estimated from the equation [17]:

$$A_{\text{Th-228}} = A_{\text{U-232(0)}}(1 - e^{-\lambda_{\text{Th-228}}t}) \tag{1}$$

where

$$\lambda = \frac{0.693}{t_{1/2}} \tag{2}$$

and λ, $t_{1/2}$, A and $A_{(0)}$ respectively represent the decay constant, half-life, activity at time t, and activity at time $t = 0$. The anion-exchange separation was performed at approximately $t = 2.1$ years, which with Eq. (1) yields a $A_{\text{Th-228}}/A_{\text{U-232(0)}}$ value of about 53%. Additionally, since the decay series comprises daughter products with decreasingly smaller half-lives, and daughter products have had adequate time to be established in detectable quantities, each ^{232}U decay is essentially manifested as five α-particle emissions. Therefore, total α-particle activity due to daughter products
Fig. 3. Liquid scintillation counting energy spectra of ^{232}U radiotracer 2.1 months after purification.

is expected to be approximately 2.5 times greater than that of ^{232}U which is qualitatively illustrated by the data, and further iterates the importance of the preparative treatment.

To illustrate the significance of short-term ingrowth, 20 μl of fraction IV was analyzed about 2.1 months after purification. A shoulder to the ^{232}U peak is shown in Fig. 3. The ratio $A_{Th-228}/A_{U-232(0)}$ is calculated to be approximately 6%. In our isotope dilution procedure, we have typically discarded or repurified the radiotracer 1 month after purification when the calculated $A_{Th-228}/A_{U-232(0)}$ ratio is 3%.
Fig. 4. Count rate data from liquid scintillation analysis of ^{232}U anion-exchange preparation fractions.

In Fig. 4, the count rates are compared for the sequence of elutions including the initial separation (fractions I–IV), a pair of 2 ml washes with 0.1 N HCl (fractions V and VI), and the separation of fraction II using the same anion-exchange procedure (fractions VII–X). From analyzing post-separation wash fractions, it was found that up to 5% may elute with each wash. The minor quantity of ^{232}U retained on the resin might be attributed to mobile phase–stationary phase partitioning. Furthermore, the repeat of the ion-exchange separation procedure with fraction II showed that up to 13% of total ^{232}U activity (or 3% of the total activity) was subject to pass-through. All of the activity of fraction II is balanced by the activities observed in fractions VII–X, illustrating recoverability of the radioactive components.

4. Conclusions

^{232}U(VI) is purified on Bio-Rad AG1-X8 anion exchange resin using HCl as the eluent. The necessity for the preparative procedure in the use of ^{232}U(VI) as a radiotracer is illustrated by liquid scintillation detection of the anlayte of interest and daughter product ingrowth interferences overlapping in the α-particle energy region. ^{232}U(VI) not recovered was either passed through the column in earlier elutions or retained by the resin due to mobile phase–stationary phase partitioning.

Abstract

The computer program SPARC was used to calculate the pK_a values of some important pharmaceutical substances. The SPARC models proved to be suitable for estimating the pK_a values of beta-adrenergic blocking agents and benzodiazepine drugs. Ionization macroconstants, microconstants, zwitterionic equilibria, speciation curves as a function of the pH and the isoelectric points of a semi-essential amino acid, arginine, and an anti-inflammatory, niflumic acid, were calculated.

Keywords: SPARC computer program; pK_a; Pharmaceuticals

1. Introduction

Knowledge of the aqueous ionization of a substance is of great importance in drug design and environmental regulatory compliance in the pharmaceutical industry. For example, the pK_a value of a compound controls many aspects of drug metabolism, including the fate of the drug in the body and transport through membranes which are frequently permeable only to a particular species. In chemistry, pK_a values can be used to select conditions for synthesis by considering the effects of pH on reaction products and on the properties of postulated intermediates that may not be measurable. The pK_a values may also assist in the interpretation of pH titration curve measurements where multiple acidic and/or basic sites are present.

With sensitive electrodes, potentiometric measurements can be a rapid technique for the determination of pK_a, provided that the solubility of a substance is at least 10^{-5} M. If the substance is less soluble than this but possesses an analytically useful chromophore, then spectroscopic methods can be employed. When solubilities become extremely low, below 10^{-6}, experimental determination of many physical/chemical properties becomes difficult. In such cases, calculation

* Corresponding author. Fax: + 706-542-9454.

schemes may become the best alternative to characterize thermodynamic properties including ionization pK_a.

Recently, we have developed mathematical models for predicting chemical reactivity parameters and physical properties of a wide range of organic compounds using SPARC [1–5] (SPARC Performs Automated Reasoning in Chemistry). SPARC uses computational algorithms based on fundamental chemical structure theory to estimate ionization pK_a values of a wide range of molecules strictly from their molecular structure. SPARC predictive methods are based on a blending of the well-known, established methods of linear free energy reltionships [6] (LFER) and perturbed molecular orbital theory [7] (PMO). In general, SPARC utilizes LFER to compute thermodynamic or thermal properties and PMO theory to describe quantum effects such as delocalization energies or polarizabilities of π electrons. In reality, every chemical property involves both quantum and thermal contributions and necessarily requires the use of both of these methods for prediction.

2. Calculation of ionization pK_a

The details of the SPARC pK_a computational methods were presented in previous publications [1–5] and hence only a brief description will be given here. SPARC seeks to analyze chemical structure relative to a specific reactivity query in much the same manner as an expert chemist would. Molecular structures are factored into functional units called reaction center and perturber. The reaction center, C, is the smallest subunit that has the potential to ionize and lose a proton to the solvent. The perturber, P, is the molecular structure appended to the reaction center, C. The perturber structure is assumed to be unchanged in the reaction. The pK_a value of the reaction center is either known from direct measurement or is inferred indirectly from pK_a measurements. The pK_a of the reaction center is adjusted for the molecule in question using the mechanistic perturbation models described previ-

ous [1–4]. The pK_a value for a molecule of interest is expressed in terms of the contributions of both P and C.

$$pK_a = (pK_a)_C + \delta_P(pK_a)_C \qquad (1)$$

where $(pK_a)_C$ describes the ionization behaviour of the reaction center, and $\delta_P(pK_a)_C$ is the change in ionization behaviour brought about by the perturber structure. SPARC computes reactivity perturbations, $\delta_P(pK_a)_C$, which are then used to "correct" the ionization behaviour of the reaction center for the compound in question in terms of potential "mechanisms" for interaction of P and C as

$$\delta_P(pK_a)_C = \delta_{ele}(pK_a)_C + \delta_{res}(pK_a)_C + \delta_{solv}(pK_a)_C$$
$$+ \delta_{H-bond}(pK_a)_C \qquad (2)$$

where $\delta_{res}(pK_a)_C$, $\delta_{ele}(pK_a)_C$, $\delta_{sol}(pK_a)_C$ and $\delta_{H-bond}(pK_a)_C$ describe the differential resonance, electrostatic interaction, solvation and H-bonding of P with the protonated and unprotonated states of C respectively. Electrostatic interactions are derived from local dipoles or charges in P interacting with charges or dipoles in C. δ_{res} describes the change in the delocalization of π electrons of the two states due to P. H-bonding and solvation effects are derived from interactions of the structural elements of P that are contiguous to C with the two states through H-bonding or steric blockage of solvent access to C respectively.

Resonance effect models (including steric twisting and its impact on the π-resonance integrals) were developed and calibrated on light absorption spectra using PMO theory [4,7]. Electrostatic, solvation and H-bonding models were developed and calibrated using ionization pK_a values based on both LFER and PMO theory. These reactivity models have been used to estimate both ionization pK_a and electron affinity for a large number of molecular structures [2–5]. More recently, the SPARC pK_a calculator was rigorously tested on 4338 pK_a values for some 3685 compounds including multiple pK_a values up to the eight pK_a spanning a range of over 30 pK_a units [5]. The RMS deviation for this large set of values was found to be 0.37 pK_a units.

3. Results and discussion

Although β-adrenergic blockers were originally developed for the treatment of angina pectoris, they have numerous other clinical applications for the treatment of hypertension, arrhythmia, thyrotoxicosis, hypertrophic cardiomyopathy, migraine and glaucoma. According to Perrin et al. [8], beta-blockers are ionized and are not absorbed through the stomach. In the intestine, the pH is elevated and this will promote the absorption of these drugs. β-blockers are classified into two major groups according to their chemical structure: (i) amino alcohol derivatives such as amosulalol, bufuralolol, nifenalol and sotalol with the general structure

$$\underset{\substack{| \\ R_1CHCH_2NHCH}}{OH} \underset{\substack{\diagdown \\ R_3}}{\overset{\diagup R_2}{}}$$

I
(ii) phenylethers with amino-2-propanol such as propranolol, pindolol and practolol, with the general structure:

$$\underset{\substack{| \\ R_2OCH_2CHCH_2NHCR_1}}{OH} \underset{\substack{\diagdown \\ CH_3}}{\overset{\diagup CH_3}{}}$$

II
The pK_a value for the OH group in both structures is greater than 14 and is of less importance to this study. The acid–base characteristics of these chemical structures are mainly due to the ionization of the N atom in the N-terminal isopropyl group, which is necessary for the pharmacological action. The pK_a values for structures I and II (R = H) are 10.1 and 9.7 respectively. The $(pK_a)_C$ value of the N atom $(pK_a$ for ammonia including statistical correction of 0.6 (log 4) where there are four equivalent ionizable H sites and only one protonation site) is 9.2 and the perturbations in both structures are relatively small. Sigma induction from the two hydrophilic groups attached to the N atom tend to raise the pK_a while differential solvation effects tend to lower the pK_a. Direct electrostatic interaction of the dipole mo-

ment of the OH and ROR' groups will stabilize both the structures, making each one more acidic. For all the β-adrenergic blockers shown in Table 1 the pK_a values range from 8.9 to 10.1 depending on the strength of the dipole moment of the substituents in the structure R. The case for prizidilol is somewhat more complicated. There are five basic ionizable sites (three aliphatic N groups and two in-ring N groups) and one acidic–OH site. There are four major distinguishable microscopic species (concentration above 1%) between pH 2 and 12, as shown in Fig. 1. At pH values greater than 9.1 and less than 14 the prizidilol exists in solution as a neutral. At pH values below 9 the N atom begins to protonate. Below pH 4.6, both the in-ring N atoms start to convert from the basic to the acidic form.

The benzodiazepine drugs have hypnotic, tranquillizing, anticonvulsant and anxiolytic properties. The main chemical characteristic of bezodiazepines is the presence of a benzene ring fused with a seven-member ring with nitrogen atoms at the 1 and 4 positions. The acid–base properties of benzodiazepines are due to the nitrogen atom in position 4 (=N). The structural formula and calculated/observed pK_a values of some benzodiazepines are given in Table 2. These compounds have a low pK_a value and can be absorbed rapidly from the gastrointestinal tract to the blood where they become un-ionized. Such compounds are usually administered orally. However, if very rapid action is required they can be administered by intravenous injection.

4. Zwitterionic equilibria

There is not a huge body of literature on zwitterionic equilibria constants of drugs, although many molecules contain both acid and base functionality where both the base and the acid sites may be simultaneously ionized to form an internal salt. These substances are referred to as zwitterionic. At low and high pH, the cationic species and anionic species predominate respectively. The internal salt predominates as an intermediate over a wide range of pH. Actually, the zwitterion and the uncharged molecule are in equilibrium in

aqueous solution. In such cases, the ionization macroconstants which describe the overall acidity or basicity of these molecules cannot be assigned to individual species or fully describe such an

equilibrium. However, the microscopic constants are the equilibrium constants for equilibria involving individual species in solution. When two or more such species exist in solution, the micro-
Fig. 1. The fraction of the four major microscopic species of prizidilol between pH 2 and 12. The ionization of the OH group and any pK_a values < 2 were neglected (see text).

scopic constants may not be able to be determined distinctly. These constants provide informtion on the individual proton-binding sites and their interactions with other sites in the molecule. Thus, microconstants are the proper terms for exact characterization of both the speciation and basicity/acidity of multiple acidic/basic ligands. Estimation of these microconstants is useful in calculating the pH-dependent concentrations of the different microspecies, and in the calculation of zwitterionic equilibria.

Niflumic acid is a potent drug used in the treatment of inflammatory and rheumatic disor-

ders. The molecule contains three possible ionizable sites: two basic sites (in-ring N, NH_2) and the acidic CO_2H site. There are 12 possible microscopic species or states. Table 3 shows the observed vs. SPARC calculated microscopic and macroscopic constants for niflumic acid. The notation for the microconstants follows the scheme first proposed by Hill [9] and is shown in Fig. 2. The ionizing group of interest is indicated in the microscopic pK by the last number in the subscript. Any numbers preceding this in the subscript denote other groups in the molecule which already exist in the basic form when the ionization

[a] Observed values are from Ref. [15–17]

[b] Protonation of NH_2 not =N

under consideration is taking place. Thus pK_{23} denotes the pK value for the ionization of the in-ring N group when the NH_3^+ group has already been converted to the conjugate base, NH_2. Since the number 1 does not appear in the subscript 23, its absence denotes that group 1, the carboxyl, is still in the un-ionized form for the reaction in question. Only four of the eight possible microscopic species (indicated by an asterisk in Fig. 2) have appreciable concentration in the pH range between 0–10 as shown in Fig. 3. Hence, only four microscopic constants are needed to describe the equilibria as was suggested by Takacs-Novak et al. [10]. The zwitterionic equilibrium constant, k_{zw}, may be determined using the left or right path of the cycle of the major species in Fig. 2. Since both thermodynamic paths give the same zwitterion product, k_{zw} may be expressed as a function of the microscopic con-

stants within any loop as

$$K_{zw} = \frac{K_{23}}{K_{21}} = \frac{K_{123}}{K_{231}} \tag{3}$$

The integrity of the SPARC pK_a calculator can be checked by calculating k_{zw} using the two different loops. For niflumic acid, pK_{zw} is found to be 1.3 and 1.4 for the first and second paths respectively. k_{zw} values calculated from different thermodynamic paths ($pK_{zw} = 1.36$).

The fraction of each of the microscopic species formed by a molecule of interest with multiple ionizable sites can be expressed as function of pH in terms of the microconstants. If we start from the neutral species (uncharged species) rather than from the positively charged species, the fraction of any microscopic species for a molecule having N ionizable sites can be expressed in general as $D_{ij\cdots k}/D$ where D can be expressed as
Fig. 2. The eight microscopic states of niflumic acid and the 12 ionization constants which interrelate them. Asterisks identify the four major microscopic species.

$$D = \frac{1}{0!} + \frac{\sum_i k_i[H]^{L_i}}{1!} + \frac{\sum_i \sum_{j \neq i} k_i k_{ij}[H]^{L_{ij}}}{2!} + \ldots + $$

$$\times \frac{\sum_i \sum_{j \neq i} \cdots \sum_{k \neq i,j} k_i k_{ij} \ldots k_{ij \cdots k}[H]^{L_{ij \cdots k}}}{N!} \qquad (4)$$

where $L_{ij \cdots k}$ is the charge of the final state ($ij \cdots k$ state). The factorial is the number of different thermodynamic paths that lead to the $ij \cdots k$ state and $D_{ij \cdots k}$ is one of the terms in the denominator. For example, the fraction of neutral species would be $1/D$ and the fraction of a singly ionized species would be $k_i[H]^{L_i}/D$.

In addition, the isoelectric point can be estimated by plotting the fraction of neutral or zwit-

terionic species versus pH. The pH at the middle of the zwitterionic (or any other species where the total net charge of the molecule is zero) range is the isoelectric point. At the isoelectric point more than 90% of the niflumic acid exists in solution as a zwitterion. Because of this niflumic acid can be absorbed rapidly and distributed well in the body.

Arginine is a semi-essential amino acid which plays an important role in the binding of proteins, and as a metal-complexing agent. Due to its biological significance, the acid–base properties of arginine have been studied in detail [11]. It has five different ionizable sites: an acidic CO_2H site, a basic =N site and three NR_2 groups acting as a base (NR_2 as an acid was not ionized). Since each of the five groups may exist in either the acidic or basic state, there are 32 possible microscopic spe-

Fig. 3. Fraction of the four major microscopic species of niflumic acid as a function of pH: (1) the neutral species; (2) negatively charged species; (3) zwitterionic species; (4) positively charged species.

cies or states. The most positive of these 32 states is the cation, with net charge $z = +3$; the most negative is the anionic species, with $z = -1$. Each of the ionizable groups in arginine is characterized by 16 microconstants, since the tendency of each group to accept or donate a proton depends on the ionization state of the other four groups. Hence, there are 80 microscopic ionization constants connecting the 32 possible microscopic species.

SPARC calculates the 80 microconstants required to describe the fraction (population) of the varius microscopic species. Only four of the 32 possible microscopic species are calculated to have appreciable concentration (above 1%) in the pH range 0–15. The fraction of each of these microscopic species as a function of pH is shown in Fig. 4. At pH > 15 all five sites are completely ionized and the arginine is negatively charged. At pHs between 15 and 8.5 arginine exists in solution as a zwitterionic species where both the =N and CO_2H groups are simultaneously charged positively and negatively respectively. In addition, the titration curve (charge curve) in Fig. 5 can be determined by multiplying the fraction-species curve by the charge on the species and summing over all species.

The observed vs. SPARC-calculated ionization macroconstants of arginine are shown in Table

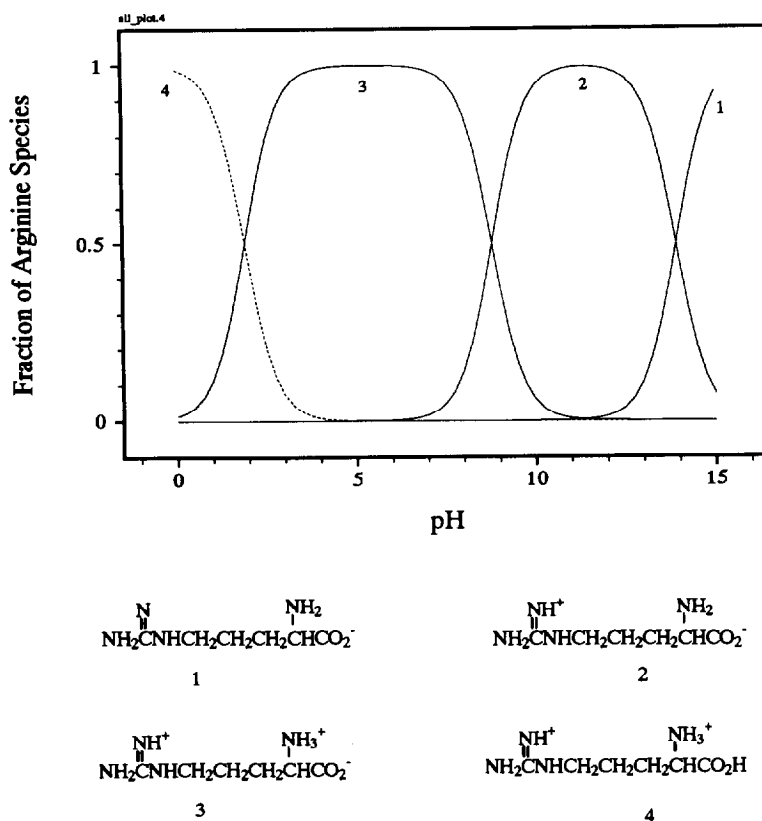
3. The estimated ambiguity of the observed values according to Noszal and Kassai-Tanczos [11] is 0.02–0.06 log K units except for the pK_1 value of arginine which was estimated to be 15 at $I = 2.0$ M, where the measurement error is 0.1–0.2 pK units. Although the measurement error may be as small as 0.2 pK_a units we believe that the ionic strength perturbation may make the actual error much larger and that it can be as high as 1.1 pK_a units for pK_1. It is expected that pK_1 would be higher than the pK_a value for guanidine (13.6 [12,13]), H_2NC (=NH) NH_2, by only a few tenths of a pK_a unit. The dipole field effect of the NH_2 group in the structure $(CH_2)_3C(NH_2)CO_2^-$ should stabilize arginine and make it more acidic than guanidine while the CO_2-charge field effect will raise the pK_1 value. For example, compare the pK_a values at 25°C for 3-hydroxybenzoic acid (10.2) and 3-hydroxyaniline (9.8), where the OH group is the ionizable site, to that of phenol (10.0). At a distance of separation r between the guanidine group and the CO_{2-}/NH_2 groups in the arginine, the effect of CO_{2-} will definitely oercome the effect of NH_2 because charge field effects depend on $1/r$ while the dipole field effect is $1/r^2$ (see Refs. [3, 4]). Because r is so large both effects are small and pK_1 is more basic than the pK_a value for guanidine by only a few tenths. In addition, pK_C^G, where the arginine is in the neu-


Fig. 4. Fractions of the four major microscopic species of arginine as a function of pH. The four major microscopic species are shown below the plots.

tral state (see Ref. [11]), is certainly expected to be lower than the pK_a value of guanidine because of the field effects of both dipole groups (CO_2H and NH_2) and not higher as reported by Noszal and Kassai-Tanczos [11]. Finally, the macroscopic pK_a ranges in all the other reported measurements [11], 11.5–12.6, 8.8–9.3 and 1.9–2.2 for pK_1, pK_2 and pK_3 respectively, are lower than their measured pK_a values. Even the upper limit of this range for pK_1 is still much lower than 15. Because of this, calculated values for pK^G_C, pK^G_{AC}, pK^G_A and pK^G of the =N group for the neutral, NH_3^+, NH_3^+/CO_2^- and CO_2^- species are expected to be higher than the actual values.

5. Summary

In this paper we applied the SPARC computational algorithms to estimate ionization pK_a values of several important pharmaceutical substances. The SPARC technique allows the calculation of all the microscopic ionization constants for complex molecules. The ability to calculate these microconstants allows this technique to calculate complex speciation as a function of pH. From this complex speciation several other important physical properties such as zwitterionic equilibrium constants and isoelectric points can be extracted.

Abstract

The polynuclear complexation of divalent 3d transition metal cations with N,N,N',N'-tetrakis(2-pyridylmethyl)-1,2-ethanediamine (tpen) in aqueous solution was investigated. It was found that copper(II) forms a dinuclear complex with tpen in an aqueous solution containing chloride. The composition of the complex was determined as $Cu_2Cl_2(tpen)^{2+}$. Furthermore, the stability constant of the complex was determined and its structure was postulated to be $(\mu\text{-Cl})_2$.

Keywords: Polynuclear complexation; Transition metal cations; Copper(II); Tpen

1. Introduction

The formation of stable charged complexes of metal cations with multidentate ligands in aqueous solution is very effective as a pretreatment method for separation and determination of the cations by capillary electrophoresis [1–8] or ion-interaction chromatography [9–16]. However, it is well known in the field of inorganic chemistry that the cations and ligands often form polynuclear complexes. These complexes can be regarded

as by-products and interfere with the determination of the cations using the formation reaction of mononuclear complexes. Therefore, to be able to use these mononuclear complexation reactions analytically it is very important to obtain information concerning the polynuclear complexations, such as stability constants.

N,N,N',N' - Tetrakis(2 - pyridylmethyl) - 1,2 - ethanediamine (tpen) [17] is an uncharged sexadentate ligand. This ligand forms very stable charged complexes with many divalent transition metal cations in aqueous solution [18], but it sometimes acts as a pentadentate ligand [18]. Although the

* Corresponding author. Fax: (81) 762-64-5742.

only analytical use of tpen reported previously [19,20] was as a masking agent of heavy metal cations for the measurement of Ca^{2+} in a cell, it can be expected that tpen is a useful ligand in analytical chemistry.
tpen

In this paper, the authors investigated the formation of polynuclear complexes of divalent 3d transition metal cations with tpen in aqueous solution. As a result, it was found that copper(II) forms a dinuclear complex with tpen, and the stability constant of the complex was determined.

2. Experimental

All reagents and solvents were of analytical-reagent grade and were used without further purification.

The synthesis of tpen was performed by modifying the method of Anderegg and Wenk [17] as follows. To a solution of 2-(chloromethyl)pyridine hydrochloride (3.3 g; 20 mmol) in water (8 cm³) previously neutralized with sodium hydroxide, 1,2-ethanediamine (0.34 cm³; 5 mmol) was added with stirring. The reaction mixture was heated (65°C) and more 4 M NaOH (5 cm³; 20 mmol) was added over a period of 1 h in small portions. The red solution was cooled and extracted with chloroform (5 × 10 cm³). The combined organic phases were dried over anhydrous sodium sulfate. After removal of the chloroform with a rotary evaporator, a red oily residue was obtained. By adding diethyl ether (10 cm³) to the residue, a brown precipitate was obtained. The precipitate was recrystallized twice from acetone (30 cm³).

Table 1
Several equilibrium constants relevant to tpen [18] (20°C, $I = 0.1$ (KNO₃))

Acid dissociation constants	
$H_4tpen^{4+} \rightleftharpoons H_3tpen^{3+} + H^+$	$pK_{a_3} = 2.95$
$H_3tpen^{3+} \rightleftharpoons H_2tpen^{2+} + H^+$	$pK_{a_4} = 3.35$
$H_2tpen^{2+} \rightleftharpoons Htpen^+ + H^+$	$pK_{a_5} = 4.86$
$Htpen^+ \rightleftharpoons tpen + H^+$	$pK_{a_6} = 7.19$

Stability constants of mononuclear complexes	
$tpen + Mn^{2+} \rightleftharpoons Mn(tpen)^{2+}$	$\log \beta_1 = 10.27$
$tpen + Fe^{2+} \rightleftharpoons Fe(tpen)^{2+}$	$\log \beta_1 = 14.61$
$tpen + Co^{2+} \rightleftharpoons Co(tpen)^{2+}$	$\log \beta_1 = 16.59$
$tpen + Ni^{2+} \rightleftharpoons Ni(tpen)^{2+}$	$\log \beta_1 = 21.55$
$tpen + Cu^{2+} \rightleftharpoons Cu(tpen)^{2+}$	$\log \beta_1 = 20.54$
$tpen + Zn^{2+} \rightleftharpoons Zn(tpen)^{2+}$	$\log \beta_1 = 15.58$

Finally, a white precipitate of the desired chelating agent (tpen) was formed, filtered off, washed with cold acetone and diethyl ether, and dried under vacuum. Yield: 50%. ¹H NMR (CDCl₃); δ 2,76 (s, 4H, en), 3.78 (s, 8H, N–CH₂–R), 7.11 (m, 4H, py), 7.45 (d, 4H, py), 7.57 (m, 4H, py), 8.48 (d, 4H, py). Anal: calc. for C₂₆H₂₈N₆: C, 73.56; H, 6.65; N, 19.79; found: C, 73.41; H, 6.75; N, 19.87.

The synthesis of N,N,N',N'-tetrakis(2-pyrazolylmethyl)-1,2-ethanediamine (tpzen) and N,N,-N',N'-tetrakis(3,5-dimethyl-1-pyrazolylmethyl)-1,2-ethanediamine (tdmpzen) was performed by using the method of Driessen [21].

The absorption spectra of solutions at 20°C were recorded on a JASCO U-best 30 UV-visible spectrophotometer in the range 200–900 nm using 1 cm matched quartz cells. pH values were obtained using a Horiba F-12 pH meter with a Horiba 6366-10D combined glass electrode.

3. Results and discussion

3.1. Composition and stability of Cu^{2+}–tpen dinuclear complex

Table 1 shows the acid dissociation constants of tpen, which is a hexa-acidic base, and the stability constants of mononuclear divalent 3d metal complexes with tpen [17]. From these constants, the influence of protonation of tpen on the following study is obviously negligible.

First, Job's continous variation method [22,23] was applied to confirm the compositions of M^{2+}-tpen complexes (M = Mn, Fe, Co, Ni, Cu, Zn) in aqueous solutions containing 0.1 M NaCl, $NaNO_3$ or $NaClO_4$ to adjust the ionic strength $I = 0.1$. With the exception of the Cu^{2+}-tpen complex in 0.1 M NaCl, all of these compositions were confirmed as 1:1. However, as shown in Fig. 1, it was not confirmed that Cu^{2+} and tpen form only $Cu(tpen)^{2+}$ in the aqueous solution containing Cl^-. This result suggests the formation of a relatively unstable polynuclear Cu^{2+}-tpen complex containing Cl^-.

To study the composition of the polynuclear complex, the continuous variation plot for Cu^{2+}-$Cu(tpen)^{2+}$ was performed. In this experiment, the formation of $Cu(tpen)^{2+}$ was regarded as being complete. From the result shown in Fig. 2, it was proved that the polynuclear complex species having a ratio of Cu^{2+}:$Cu(tpen)^{2+}$ of 1:1, i.e. Cu^{2+}:tpen = 2:1, is formed in aqueous solution containing Cl^-. In other words, the polynuclear species is shown as $Cu_2Cl_n(tpen)^{(4-n)+}$.

To determine n, the following experiment was performed. In considering the equilibrium

$$Cu^{2+} + Cu(tpen)^{2+}$$

$$+ nCl^- \overset{K_{di}}{\rightleftharpoons} Cu_2Cl_n(tpen)^{(4-n)+} \qquad (1)$$
$$K_{di} = \frac{[Cu_2Cl_n(tpen)^{(4-n)+}]}{[Cu^{2+}][Cu(tpen)^{2+}][Cl^-]^n} \qquad (2)$$
Fig. 1. Continous variation plots for Cu^{2+}-tpen complex in 0.1 M NaCl aqueous solution ($I = 0.1$). $C(Cu^{2+}) + C(tpen) = 2 \times 10^{-3}$ M; pH 4.5; $\lambda = 685$ nm.
Fig. 2. Continous variation plots for Cu^{2+}-$Cu(tpen)^{2+}$ complex in aqueous solution ($I = 0.1$). $C(Cu^{2+}) + C(Cu(tpen)^{2+}) = 2 \times 10^{-3}$ M; pH 4.5; $\lambda = 685$ nm. (●) 0.1 M NaCl; (○) 0.1 M $NaNO_3$.

taking $C(Cu^{2+}) = C(Cu(tpen)^{2+}) = C_0$, there is the folllowing relationship concerning the concentration of each species in the equilibrium:

$$[Cu^{2+}] = [Cu(tpen)^{2+}]$$

$$= C_0 - [Cu_2Cl_n(tpen)^{(4-n)+}] \qquad (3)$$

Therefore the absorbance (A) of the solution is as follows:

$$A = \{\varepsilon_1[Cu_2Cl_n(tpen)^{(4-n)+}] + \varepsilon_2[Cu^{2+}]$$

$$+ \varepsilon_3[Cu(tpen)^{2+}]\}l$$

$$= \{(\varepsilon_2 + \varepsilon_3)C_0$$

$$+ (\varepsilon_1 - \varepsilon_2 - \varepsilon_3)[Cu_2Cl_n(tpen)^{(4-n)+}]\}l \qquad (4)$$

where l is the cell length and ε_1, ε_2 and ε_3 are molar decadic absorption coefficients for $Cu_2Cl_n(tpen)^{(4-n)+}$, Cu^{2+} and $Cu(tpen)^{2+}$ respectively. (The value of ε_1 can be obtained from Fig. 2.) By taking $A_1 = \varepsilon_1 C_0 l$ and $A_2 = (\varepsilon_2 + \varepsilon_3)C_0 l$

$$A_1 - A = (\varepsilon_1 - \varepsilon_2 - \varepsilon_3)\{C_0 - [Cu_2Cl_n(tpen)^{(4-n)+}]\}$$

$$\times l \qquad (5)$$

$$A - A_2 = (\varepsilon_1 - \varepsilon_2 - \varepsilon_3)[Cu_2Cl_n(tpen)^{(4-n)+}]l \qquad (6)$$

$$A_1 - A_2 = (\varepsilon_1 - \varepsilon_2 - \varepsilon_3)C_0 l \qquad (7)$$

$$K_{di} = \frac{(A - A_2)(A_1 - A_2)}{(A_1 - A)^2 C_0[Cl^-]^n} \qquad (8)$$

$$\log\left\{\frac{(A - A_2)(A_1 - A_2)}{(A_1 - A)^2}\right\}$$

$$= \log K_{di} + \log C_0 + n \, \log[Cl^-] \tag{9}$$

Therefore, by plotting $\log\{(A - A_2)(A_1 - A_2)/(A_1 - A)^2\}$ vs. $\log[Cl^-]$, the values of n and $\log K_{di}$ can be obtained.

Fig. 3 shows this plot for $C_0 = 1 \times 10^{-3}$ M, pH 4.5 and $I = 0.1$ (NaNO$_3$). From the slope of the line in the figure, n was determined as 2 and the dinuclear species was shown to be $Cu_2Cl_2(tpen)^{2+}$. Furthermore, the value of $\log K_{di}$ was determined to be 5.66 (20°C, $I = 0.1$) and the overall stability constant (β_{22}) for $Cu_2Cl_2(tpen)^{2+}$ was calculated as follows:

$$2Cu^{2+} + tpen + 2Cl^- \overset{\beta_{22}}{\rightleftharpoons} Cu_2Cl_2(tpen)^{2+} \tag{10}$$
$$\beta_{22} = \frac{[Cu_2Cl_2(tpen)^{2+}]}{[Cu^{2+}]^2[tpen][Cl^-]^2} = \beta_1 K_{di} \tag{11}$$

$$\log \beta_{22} = \log \beta_1 + \log K_{di} = 20.54 + 5.66$$

$$= 26.20 \,(20°C, \, I = 0.1) \tag{12}$$

As mentioned above, this dinuclear complexation reaction proceeds only under the conditions of excess Cu^{2+} and a large excess of Cl^-. Therefore, the reaction can be avoided by paying attention to the experimental conditions.

Fig. 4. Reported coordination structure of Cu(tpen)$^{2+}$ (a) [18] and proposed structure of Cu$_2$Cl$_2$(tpen)$^{2+}$ (b).

3.2. Estimation of the structure of $Cu_2Cl_2(tpen)^{2+}$

It was reported previously [18] that the coordination number of copper in Cu(tpen)$^{2+}$ is five and that the mononuclear complex has a square pyramidal structure having one uncoordinating pyridine N atom, as shown in Fig. 4(a). Possibly, the structure causes the deviation of $\log \beta_1$ for M(tpen)$^{2+}$ (shown in Table 1) from the Irving–Williams stability series.

Fig. 5 shows the absorbance spectrum of $Cu_2Cl_2(tpen)^{2+}$ calculated from the spectrum un-

Fig. 3. Relationship between the absorbance of Cu(tpen)$^{2+}$ – Cu^{2+} solution and the concentration of Cl$^-$ ($I = 0.1$(NaNO$_3$)). C(Cu^{2+}) + C(Cu(tpen)$^{2+}$) = 1 × 10^{-3} M; pH 4.5; $\lambda = 685$ nm. See text for details.
Fig. 5. Calculated absorbance spectrum of Cu$_2$Cl$_2$(tpen)$^{2+}$ (solid curve) and measured spectrum of Cu(tpen)$^{2+}$ (broken curve) in aqueous solution.

der several different conditions and the values of K_{di}. This spectrum is very similar to that of Cu(t-pen)$^{2+}$. From the result, it is considered that the coordination structures around the two Cu atoms are very similar to the structure in Cu(tpen)$^{2+}$, i.e. square pyramidal.

By regarding Cu$_2$Cl$_2$(tpen)$^{2+}$ as the (μ-Cl)$_2$ complex shown in Fig. 4(b), all of the above-mentioned criteria can be satisfied. In the proposed structure, it is considered that each Cu atom is surrounded by two pyridine N atoms, one amine N atom and two Cl atoms and these atoms adopt the square pyramidal structure.

Another supposed structure is that each Cu atom is surrounded in square planar fashion by two pyridine N atoms, one amine N atom and one Cl atom. However, the sturcture is obviously unsuitable from the viewpoint of the structural change around the Cu atom that occurs with the formation of the dinuclear complex.

tpzen

tdmpzen
For the strict study of the coordination structure, crystallographic characterization of the dinuclear complex is very effective. However, the isolation of the complex has not yet been accomplished. Accordingly, to prove the appropriateness of the (μ-Cl)$_2$ structure, continuous variation
Fig. 6. Continous variation plots for Cu^{2+}–tpzen and Cu^{2+}–tdmpzen complexes in 0.1 M NaCl aqueous solution ($I = 0.1$). (●) C(Cu^{2+}) + C(tpzen) = 2 × 10^{-3} M; pH 6.0; $\lambda = 635$ nm; (○) C(Cu^{2+}) + C(tdmpzen) = 1 × 10^{-4} M; pH 6.0; $\lambda = 655$ nm.

plots for Cu^{2+}–tpzen and Cu^{2+}–tdmpzen complexes in aqueous solution containing Cl$^-$ were performed. Fig. 6 shows the result. The plot for Cu^{2+}–tpzen suggested the formation of Cu$_2$Cl$_2$(tpzen)$^{2+}$. In contrast, that for Cu^{2+}–tdmpzen suggested the absence of Cu$_2$Cl$_2$(tdmpzen)$^{2+}$. It is supposed that the 3-methyl groups on the pyrazole rings in tdmpzen disturb the formaton of the μ-Cl bridge by steric hinderance. These results support the formation of Cu$_2$Cl$_2$(tpen)$^{2+}$ and Cu$_2$Cl$_2$(tpzen)$^{2+}$ complexes having two μ-Cl bridges. The Cu^{2+}–tpzen and Cu^{2+}–tdmpzen complexes are less stable than the Cu^{2+}–tpen complex, and a structural study concerning these complexes will be described in a forthcoming paper.

Abstract

A novel photothermal phase-shift spectroscopy configuration based on the retro-reflected beam interference has been developed and its operational principle is described. The weak absorption measurement ability of this technique is experimentally proven with a water/ethanol solution of standard Pyronine G dye and the limit of detection is found to be 1.8×10^{-6} absorbance. Potential applications of the technique are discussed.

1. Introduction

Photothermal spectroscopy is a sensitive spectroscopic technique for weak absorption measurement. Unlike conventional beam-transmittance spectrophotometry, photothermal methods directly measure the absorbed radiation of an excitation beam by monitoring temperature fluctuations produced within the medium. Absorbances as low as 10^{-7} are determined by thermal lensing (TLS) [1], photothermal deflection (PTDS) [2], and photothermal phase-shift spectroscopy (PTPS) [3] techniques. Photothermal phase-shift spectroscopy measures the phase change caused by absorption of the excitation beam by placing the sample under investigation in one arm of an interferometer. This technique was discovered by Stone [4] and by Davis and Petuchowski [5], who refer to it as phase fluctuation optical heterodyne (PFLOH) spectroscopy. Subsequently, many theories and applications of this technique have been investigated [3,6,7].

In this paper, we describe a novel photothermal phase-shift spectroscopy technique—retro-reflected beam photothermal interference spectroscopy. Fig. 1 shows the proposed photothermal interference spectroscopy technique schematically. Our proposed configuration differs from all other existing photothermal phase-shift or interferometric spectroscopy techniques in that we utilize the light of a focused probe laser beam reflected from the

front surface of a sample (or a cell containing the sample) as the reference beam, while the light passing through the sample and reflected from the rear surface of the sample (or the cell) is used as the signal beam. Due to the divergence of the focused probe laser beam, both reflected beams overlap in the far field and, as both originate from the same wave, they interfere, leading to a regularly spaced interference fringe pattern. The change in refractive index (RI) of the sample, resulting in a temperature rise within the sample caused by absorption of the energy of the excitation beam, induces phase shifts in the signal beam which, in turn, translate into lateral shifts of the interference fringes. Because the fringes are approximately equally spaced, shifts are conveniently detected with a position-sensitive detector. Upon calibration, the absorbance of the sample can be determined from the photothermal signal.

2. Experimental

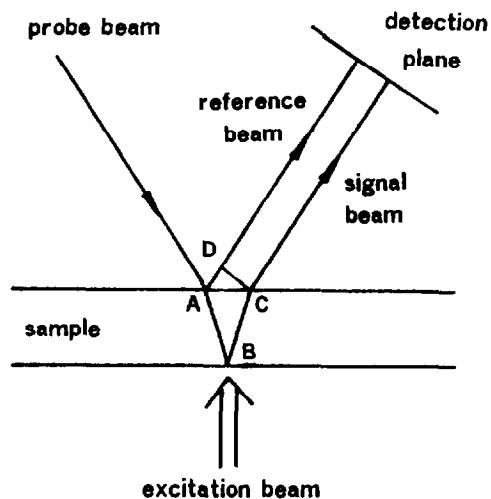
The experimental photothermal interference spectroscopy configuration is illustrated in Fig. 2. A Nd:YAG frequency-doubled pulsed laser (Quantel, France) operated at a wavelength of 532.1 nm is used as the excitation beam, illuminating the sample from the rear surface. The pulse duration is 8 ns and the repetition rate is 10 Hz.


Fig. 1. Schematic diagram of the proposed retro-reflected beam photothermal interference configuration.
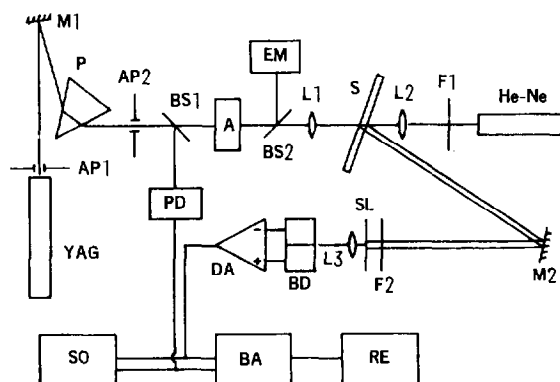

Fig. 2. Experimental arrangement of photothermal interference spectroscopy: YAG, Nd:YAG frequency-doubled pulsed laser; AP1, AP2, apertures; M1, M2, mirrors; P, prism; BS1, BS2, beamsplitters; PD, photodiode; A, attenuator; EM, energy meter; L1, L2, spherical lenses; S, sample; F1, F2, filters; He–Ne, He–Ne laser; SL, slit; L3, cylindrical lens; BD, bicell photodiode detector; DA, differentiating amplifier; SO, storage oscilloscope; BA, boxcar average; RE, recorder.

The output energy per pulse is adjustable from zero to a maximum of about 300 mJ. A 2 mW He–Ne laser operated at a wavelength of 632.8 nm is used as the probe beam. A bicell photodiode detector (Chongqing Institute of Photoelectronics, China) is used as a position-sensitive detector to measure the fringe shift in the interference field. The output of the detector is fed into the input end of a boxcar averager (EG&G Model 165/162, USA) after differentiation and amplification by a differential amplifier. The signal is monitored by a storage oscilloscope (Tektronix Model 446, USA) and the output of the boxcar averager is recorded by a recorder.

After propagating through an aperture of 5 mm diameter, a prism and another aperature of 6 mm diameter for improving beam quality and eliminating the light at a wavelength of 1.06 μm, and a variable attenuator for energy adjustment, the excitation beam is focused by a spherical lens (focal length 140 mm) onto the sample from the rear surface. A fraction of the laser energy is sampled by means of a beamsplitter and monitored by an energy meter. Another small part of the excitation beam is split and received by a photodiode to trigger the boxcar averager and the storage oscilloscope. Care is taken to adjust the energy of the excitation beam illuminating the

sample to prevent the occurrence of non-linear effects [2]. The probe beam is focused with a lens of 46 mm focal length onto the sample from the front surface. To maximize the interaction length of the excitation and probe beams and therefore the photothermal signal magnitude, the collinear photothermal configuration is used. The two beams are not paralled, but intersect with a small angle of about 4°; therefore the contribution of the cell wall absorption to the photothermal signal is eliminated. The relative position of the excitation and probe beams is adjusted by carefully moving the focusing lens L1 mounted on a micrometer-driven translation stage. The probe beam (and also the excitation beam) are incident on the sample surface with an incident angle of 15°; therefore the reflected probe beams do not pass through the focusing lens L2 again. A filter is used before the He–Ne laser to prevent the excitation beam from entering the resonator of the probe laser.

The reflected probe beams from the two surfaces of the sample interfere as they propagate away from the sample and an interference fringe pattern is formed at the far field. A slit with width approximately equal to the fringe spacing is used to select a suitable fringe for detection. The slit position is adjusted with a micrometer-driven translation stage to allow only one fringe to pass through the slit (in this case the two edges of the slit are located at the two minimum intensity points (destructive interference) of the selective fringe) and be detected by a bicell photodiode detector [8,9]. To gather more light at the detector, the fringe is compressed along the vertical direction by a cylindrical lens (focal length 40 mm). A 632.8 nm bandpass filter is placed at the front of the slit to eliminate the excitation laser light. The position-sensitive detector is mounted on a micrometer-driven two-dimensional translation stage for accurate alignment. The position of the bicell detector is adjusted vertically and laterally so that the center of gravity of the fringe is centered on the detector. A null complementary output current of the detector is produced, therefore the common-mode amplitude noise (such as intensity fluctuation of the probe beam) is eliminated and the measurement sensitivity is maxi-

mized. Because the present detection arrangement satisfies the optimum detection condition [8] (the detection point is located midway between constructive and destructive interference) the maximum linear measurement range is obtained.

The standard Pyronine G dye, purchased from Fluka (Buchs, Switzerland) is used in this experiment. Pyronine G dye is dissolved in 40/40 water/ethanol solution to required concentrations. The ethanol is added to enhance the photothermal signal [10]. Fig. 3 shows the absorbance spectrum of a 5.0×10^{-6} mol l^{-1} 40/60 water/ethanol solution of Pyronine G, measured with a UV–Vis spectrometer (Shimadzu UV-240, Japan). With a 10 mm pathlength cell, the absorbance of the Pyronine G solution at 532.1 nm is 0.132; therefore the molar absorbance of a 40/60 water/ethanol solution of Pyronine G is 2.64×10^4 cm^{-1} (mol $l^{-1})^{-1}$. The sample cell used in the experiment is a commercially available fused-silica tube (1.0 mm i.d., 1.7 mm o.d) used without additional optical processing for smoothing the tube walls (the surfaces). The sample is introduced into the tube by flowing with a constant-flow pump.

3. Results

Fig. 4 shows the interference fringe pattern of a 40/60 water/ethanol filled fused-silica tube, recorded using a photodiode and a pinhole of 0.2

Fig. 3. Absorbance spectrum of 5.0×10^{-6} mol l^{-1} 40/60 water/ethanol solution of Pyronine G.
Fig. 4. Interference fringe pattern of fused-silica tube (1.0 mm i.d., 1.7 mm o.d.) recorded at a plane 143 cm away from the sample.

mm diameter placed in front of the detector, at a plane 143 cm away from the fused silica tube. The recorded fringe pattern is a typical high-contrast interference pattern produced by the interference of two Gaussian laser beams having approximately identical intensities. This simple, regularly-spaced, high-contrast interference fringe pattern is ideal for measuring the phase shift caused by the refraction index change of the measured sample [8]. In this experiment, the fringe located near the central area of the interference fringe pattern, which has the maximum intensity and measurement sensitivity, is chosen for detection.

Fig. 5 shows the photothermal phase-shift signal transients of 1.0×10^{-8} mol l^{-1} Pyronine G 40/60 water/ethanol solution, recorded with different signal processing time constants of the boxcar averager. Taking the optical pathlength of the sample into account, the absorbance of the sample solution at this concentration is 2.64×10^{-5}. The curve in Fig. 5 (top) represents the photothermal phase-shift signal transient recorded when the time constant is set to be 1 s. The noise level of the photothermal signal transient is relatively high. To reduce the noise level, a longer signal processing time constant is chosen when recording the signal transient. Lengthening the time con-

stant increases the measurement data points and the signal-to-noise ratio is therefore improved. Fig. 5 (bottom) is the result obtained with a 10 s
Fig. 5. Photothermal signal transients of 1.0×10^{-8} mol l^{-1} Pyronine G 40/60 water/ethanol solution. The energy of the laser pulse is about 0.1 mJ. The signal processing time constant of the boxcar averager is (top) 1 s, (bottom) 10 s.
Fig. 6. Photothermal signal magnitude vs. concentration of Pyronine G solution. The energy of the laser pulse is about 0.1 mJ (●, experimental data).

time constant. Although the signal transient is distorted due to the long signal processing time constant, the noise level is considerably reduced and therefore the measurement sensitivity is improved. Increasing the signal processing time constant of the boxcar averager by a factor of N produces a factor of $\sqrt{N}$ improvement in the signal-to-noise ratio, resulting in a $\sqrt{N}$ improvement in measurement sensitivity. Because the blank absorbance caused by the water and ethanol is in the range $1 \times 10^{-7} - 1 \times 10^{-8}$ in this experiment [10], much lower than the absorbance detection limit determined by the photothermal signal measurement noise, the effect of the blank absorption is neglected when calculating the detection limit of absorbance. By using the IUPAC definition, the limit of detection (LOD) is determined to be 5.7×10^{-6} absorbance from Fig. 5 (top). With a factor of $\sqrt{10}$ improvement in Fig. 5 (bottom), the absorbance detection limit is 1.8×10^{-6}. A lower LOD can be obtained by setting a longer signal processing time constant of the boxcar averager, until the LOD determined by the blank absorbance is achieved.

Fig. 6 shows the photothermal signal magnitude as a function of sample concentration. For each measurement, the positions of the slit and bicell decector are carefully readjusted to maintain the optimum detection condition, so as to ensure identical detection response and sensitivity

at each measurement. At low sample concentration, the linear dependence of the phothermal signal on concentration is quite good. As the sample concentration increases, the phototermal results exhibit a marked non-linear response, which does not agree with the theoretical prediction of the conventional photothermal experiment. There are several reasons for the unexpected non-linear response. The most likely of these is the poor mechanical stability of the experimental system and environmental vibrations, which degenerate the performance of the photothermal system during the experimental procedure, especially when the measurements at different concentrations are made at widely separated times, resulting in a continuous decrease in the measurement sensitivity. Repeated experiments demonstrate the decline of the system performance with time. The photophysical and photochemical properties of the sample, such as photodecomposition, may be an important factor in the non-linearity. The photodecomposition phenomenon becomes very apparent when the sample concentration is increased to about 1.0×10^{-5} mol 1^{-1} and can be easily observed from the oscilloscope display by flowing the sample solution. The photothermal signal amplitude of the flowing sample is much higher than that of the static sample.

4. Discussion

Although the absorbance LOD obtained with the retro-reflected beam photothermal interference configuration is comparable with the values recently reported by Waldron and Dovichi [11] using the crossed-beam thermo-optical configuration and by Krattiger and co-workers [12,13] using a hologram-based thermo-optical configuration, accounting for the 1.0 mm i.d. of the fused-silica tube and the collinear photothermal configuration used in our experiment, the resulting probing volume is much larger than that using 50 μm and 20 μm i.d. capillaries and a crossed-beam configuration. It seems that our results are only moderately successful. However it should be pointed out that the experimental ap-

paratus reported on here is far from optimal. As the interference technique is extremely sensitive to environmental vibrations, the poor mechanical stability and poor vibration-isolation ability of the experimental system are the main factors limiting the measurement sensitivity in our experiment. The use of a short-duration pulse laser (the pulse duration is 8 ns in our experiment) as the excitation beam also severely limits further improvement in sensitivity of the photothermal measurement. Due to the high power of the pulse laser, the maximum pulse energy used in the experiment is relatively low ($\leqslant 0.1$ mJ), to avoid damage of the sample cell wall and occurrence of non-linear effects, and the waist radius of the excitation beam used is much larger than that used in photothermal experiments employing the continuous wave excitation laser. As the photothermal signal magnitude increases linearly with excitation beam energy or power, and decreases rapidly with the increase of the excitation beam radius, increasing the excitation beam energy or power and decreasing the excitation beam radius will effectively improve the sensitivity of the photothermal measurement. In this respect, use of a continuous wave laser of moderate power as the excitation beam in a photothermal experiment is more profitable in improving the measurement sensitivity and reducing the probing volume than the use of a pulse laser. Another source of noise which limits the sensitivity improvement is the electromagnetic radiation interference in the detector electronics, caused by the discharge of the pump lamp of the pulsed Nd:YAG laser. It is reasonable to believe that the sensitivity of the photothermal measurement reported here would be very much improved if all the limitation factors were eliminated and the experimental system optimized.

The most promising application of the proposed retro-reflected beam interference configuration should be as a universal RI decector in HPLC and capillary electrophoresis (CE) separation. This RI detector could also be readily used to perform sensitive absorption detection using a photothermal method with CE detection. Compared to the RI detection method based on transmitted beam interference developed by Bornhop and Dovichi [14], the retro-reflected beam inter-

ference method has the advantages that the interference fringe pattern is simple, well-spaced an of high contrast, while the optical arrangement is relatively simple. This high-contrast fringe pattern allowed us to conveniently select the fringe having the optium sensitivity for detection. Krattiger co-workers introduced the use of an index-matching fluid (RIMF) [8,15] and a holographic optical element (HOE) [16] to simplify the fringe pattern in order to improve the detection and improve the measurment sensitivity. In so doing the detection system was complicated. In the retro-reflected beam configuration, the sampling arm of the probe beam crosses the capillary through its center where the optical path is longer than that in the transmitted beam configuration, and if the probe beam is perpendicularly incident on the capillary wall (in this case a well-spaced, high-contrast circular fringe pattern is formed at the far field), the retro-reflected probe beam from the rear surface crosses the capillary twice in the same path, the optical path is doubled, and therefore the measurement sensitivity is further improved. The retro-reflected beam interference configuration has been successfully used as the on-column detector for CE separation of amino acids [17] with a 50 μm i.d. fused-silica capillary. The results are very encouraging. Employing both the transmitted and retro-reflected beam configurations in photothermal experiments, as the optical path in the retro-reflected beam configuration is longer than that in the transmitted beam configuration, we can safely predict that if all other experimental conditions are identical in the two photothermal experiments, the retro-reflected beam photothermal interference configuration has potentially higher measurement sensitivity than the transmitted beam photothermal interference configuration. As the capillaries usually employed in CE separations have enough good surfaces to form high-quality interference fringe patterns after the protective polymide coatings of the capillaries are removed, this retro-reflected beam interference method and its photothermal configurations are likely to find wide applications in CE detection. Further investigation on the performance optimization of the retro-reflected beam interference experimental system to improve the measurement

sensitivity and applications to CE detection are being undertaken in our laboratory.

5. Conclusions

We have demonstrated that a novel photothermal phase-shift spectroscopy configuration should be a sensitive detection technique for extremely weak absorption measurement. In common with other photothermal techniques, this photothermal technique based on retro-reflected beam interference is also useful for determination of optical and thermal properties of transparent materials. This sensitive detection technique is especially suitable for measurement on small volume samples. It may find extensive applications in trace analyses and HPLC and CE detections and thermo-optical characterization of optical materials. This configuration can be used for samples or sample cells having two approximately parallel, smooth surfaces of appropriate thickness, or a capillary with appropriate diameter.

Electroanalytical characteristics of enoxacin and their analytical application

Zheng-Qi Zhang*, Yan-Fei Li, Xiao-Mei He, Hong Zhang

Department of Chemistry and Chemical Engineering, Hunan University, Changsha, People's Republic of China

Abstract

In a 0.050 M HCl solution containing 0.12 M KCl, enoxacin yields a sensitive polarographic wave at -1.05 V, which can be used to determine trace amounts of the drug, the linear range being from 1.6×10^{-8} to 1.6×10^{-5} M with a detection limit of 6.25×10^{-9} M. The electrochemical characteristics of the drug were studied by normal polarography, cyclic voltammetry and potentiostatic coulometry. A single-sweep polarographic procedure for the determination of enoxacin has been worked out and applied to urine and serum samples.

1. Introduction

Polarography and voltammetry are widely applied to the determination of drugs. Several reviews have appeared covering the voltammetric determination of drugs [1–4]. In the first polarographic study of quinolone derivatives, the reduction and polarographic behaviour of nalidixic acid was investigated by d.c. polarography [5]. Van Oort et al. [6] used differential pulse polarography to determine nalidixic acid. Hoffman and Dybowski [7] reported a d.c. polarographic assay of pipemidic acid. Stripping voltammetric procedures were recommended for determination of ciprofloxacin [8], rufloxacin [9], ofloxacin [10,11] and norfloxacin

[12] drugs in tablets, urine and serum samples. Recently, we used a surfactant as a sensitizer to achieve higher sensitivity and better selectivity in a polarographic assay of ofloxacin [13].

Enoxacin (1-ethyl-6-fluoro-1,4-dihydro-4-oxo-7-(1-piperazinyl)-1,8-naphthyridine-3-carboxylic acid) is a new quinolone carboxylic acid derivative which shows a broad antimicrobial spectrum. Its primary effect is the inhibition of bacterial DNA-gyrase (topoisomerase II). After oral administration, the drug is rapidly absorbed and widely distributed to the body tissues and fluids. Various techniques, including HPLC, reversed-phase HPLC, ion chromatography, spectrophotometry and spectrofluorimetry, have been proposed for the determination of enoxacin. Squella et al. [14] used differential pulse polarography for the determination of enoxacin in tablet samples. However, other

* Corresponding author.

electroanalytical techniques for the determination of enoxacin have not been reported yet. The aim of this work was to develop a method for the determination of enoxacin by single-sweep oscillopolarography. The proposed method has been used for the determination of trace amounts of enoxacin in urine samples, no sample pretreatment being necessary. The detection limit is 6.25×10^{-9} M.

enoxacin
2. Experimental

2.1. Apparatus

The single-sweep polarograms were recorded on a JP-1A oscillopolarograph (Chengdu Instrumental Factory). The polarographic cell has the three-electrode system: a dropping mercury electrode (DME) as working electrode, a saturated calomel electrode (SCE) reference electrode and a platinum wire auxiliary electrode. A drop time of 7 s was selected using a knocker, with a rest time of 5 s and a scan time of 2 s, the scan rate being 250 mV s^{-1}. An XJP-821 neopolarograph (Jiangsu Electroanalytical Instrumental Factory) in connection with an LZ3-100 X-Y recorder (Dahua Instrumental Factory) and a JM-01 (manual micrometric screw delivery) hanging mercury drop electrode (HMDE) were used for cyclic voltammetry measurements. A static mercury drop electrode (SMDE), J-shaped capillary, was used for medium-exchange measurements. A PAR Model 273 potentiostat/galvanostat with a PAR Model 303 SMDE, controlled by PAR Model 270 software, was used for normal pulse polarography and other electrochemical measurements. For pulse polarography the instrumental parameters were as follows: accumulation time, 120 s; accumulation potential, -0.70 V; drop size, medium; pulse amplitude, 50 mV; pulse period, 2

s; equilibrium time, 15 s. Potentiostatic coulometry was carried out on an apparatus consisting of an M179 coulometer, an M273 potentiostat and an electrolytic cell with a mercury pool as cathode, a platinum electrode anode and an SCE reference electrode.

2.2. Reagents

2.2.1. Standard enoxacin solution

A stock solution (1.0×10^{-3} M) of enoxacin was prepared by dissolving 0.080 g of enoxacin (99.8%, from Hunan Institute for the Control of Pharmaceutical Products) in 25 ml of 0.10 M HCl solution, followed by dilution to 250 ml.

2.2.2. HCL solution, 0.50 M

42 ml of concentrated HCL was dissolved in 1000 ml of water, and titrated with Na$_2$CO$_3$ to prepare the standard solution.

2.2.3. Buffer solution

The test solutions under study were buffered using universal buffer for the pH range 2-11, containing 0.1 M citric acid, 0.1 M sodium phosphate and 0.1 M boric acid. The pH was adjusted with NaOH or HCl.

Other reagents were of suprapure or analytical-reagent grade. Water, redistilled in a fused-silica apparatus, was used throughout.

2.3. Procedures

2.3.1. Polarography of pure enoxacin solution

1.0 ml of 0.50 M HCl solution was mixed with 1.20 ml of 1.0 M KCl solution and various amounts of standard enoxacin solution. The mixture was diluted to 10 ml with water. The solution was transferred to the polarographic cell, and purged with oxygen-free nitrogen for 10 min. A flow of nitrogen was maintained over the cell throughout the analysis to prevent interference from oxygen. The derivative polarograms were recorded, starting the potential scan at -0.70 V. The peak potential is -1.05 V.

2.3.2. Serum and urine sampling

After 12 h of overnight fasting, rabbits received an oral dose of enoxacin (8.0 mg Kg^{-1}). After 2 h

the rabbits were killed and blood samples were taken. The samples were then centrifuged three times, and the blood serum was collected and kept at −10°C.

After the rabbits received the dose as described above, spontaneously voided urine was collected for 24 h. All samples were kept frozen at −10°C.

2.3.3. Analysis of urine samples

Urine was diluted 10 times with water. 0.50 ml of the solution was transferred to a 10 ml standard flask, and the procedure continued as described in the section on polarography of pure enoxacin solution above.

2.3.4. Analysis of serum samples

The enoxacin in serum samples was extracted by chloroform [15]. To 1.0 ml of serum were added 9.0 ml of chloroform and 2.0 ml of pH 7.50 phosphate buffer solution, and the solution was mixed thoroughly on a vortex mixer. The mixture was allowed to stand for 15 min and centrifuged at 4000g for 10 min. The aqueous phase was removed and the chloroform phase was filtered. The filtrate was evaporated to dryness at 50°C. The residue was dissolved with 1.00 ml of 0.50 M HCl solution. 1.20 ml of 1.00 M KCl solution was added to the solution and the procedure was continued as described in the section on polarography of pure enoxacin solution.

2.3.5. Recovery experiment

The amounts of enoxacin shown in Table 2 were added to a 50 ml beaker containing the No. 4 serum sample or the No. 4 urine sample and they were then treated as described above.

3. Results and discussion

3.1. Single-sweep polarography

In a pH 2–11 buffer solution, enoxacin yields a sensitive oscillopolarographic wave, the peak potential shifting in the negative direction with increasing pH value of the test solution. In a 0.050 M HCl solution containing 0.12 M KCl the peak potential of the drug is −1.05 V (Fig. 1(b)). In the

range 1.60×10^{-8}–1.60×10^{-5} M, the peak currents are linearly proportional to the concentration of the drug. The detection limit is 6.25×10^{-9} M, which was taken as the concentration that gave a signal equal to three times the standard deviation of the blank signal, calculated from the calibration slope. The reproducibility was evaluated by 15 repetitive experiments on a 5.0×10^{-7} M enoxacin solution. The relative standard deviation was 1.1%.

3.2. Effect of HCl concentraion

In a pH 2–11 buffer solution, the peak current of enoxacin increases with decreasing pH value of the test solutions. In a dilute acidic solution such as H_2SO_4, H_3PO_4, HNO_3 or HCl, enoxacin gives a good polarographic wave, and the best results were obtained in a HCl solution, so we used it as a background solution. The effect of HCl concentration on the peak current is shown in Fig. 2a. The optimal HCl concentration was from 0.040 to 0.060 M. Accordingly, a HCl concentration of 0.050 M was used throughout for maximum sensitivity.

3.3. Effect of KCl concentration

Support electroytes such as KCl, NaCl, KNO_3 and $NaNO_3$ were examined in 5.0×10^{-7} M

Fig. 1. Derivative single-sweep polarograms of enoxacin: (a) 0.050 M HCl, 0.12 M KCl; (b) 0.050 M HCl, 0.12 M KCl, 1.60×10^{-6} M enoxacin.
Z.-Q. Zhang et al. / Talanta 43 (1996) 635–641

Fig. 2. Effects on solutions of 1.0×10^{-6} M enoxacin: (a) effect of HCl concentration: 0.030 M KCl; (b) effect of KCl concentration: 0.050 M HCl.

enoxacin solution. The best results were obtained with KCl support electrolyte. The effect of its concentration on the peak current is shown in Fig. 2b. The peak current increases rapidly with increasing KCl concentration from 0.050 to 0.10 M and decreases greatly when the concentration of KCl exceeds 0.15 M. A concentration of 0.12 M for KCl was chosen for subsequent studies.

3.4. Adsorptive characteristic of enoxacin

The adsorption of enoxacin at the DME was demonstrated by constructing electrocapillary curves and by carring out medium-exchange experiments.

The electrocapillary curve of a solution containing enoxacin (Fig. 3(b,c) is lower than that of the background (Fig. 3(a)), indicating that enoxacin is adsorbed at the DME.

For medium-exchange studies, the SMDE with J-shaped capillary, used as a working electrode, was kept in contact with a solution containing enoxacin for 180 s with stirring. Following this, the electrode was cleaned in water for 15 s while stirring and transferred to another cell containing the background solution only. In the voltammogram obtained with the new cell there is a voltammetric peak at -1.05 V, and the peak

current is close to that obtained with the original cell.

The normal pulse polarogram of enoxacin $(3.0 \times 10^{-6}$ M) has a maximum, indicating that the adsorption process of enoxacin on the mercury electrode is reactant adsorption [16].

3.5. Dependence of peak current (i_p) on the potential scan rate (v)

Assume that $i_p = Av^x$; when the electrode process is diffusion-controlled, x should take a value of 0.5 [17], and for an adsorption-controlled process it should take a value of 1.0 [18]. As diffusing and adsorbed species were reduced simultaneously, the peak current had contributions from both diffusion and adsorption currents [19], so the value of x varied between 0.5 and 1.0. The dependence of peak current of enoxacin on the potential scan rate is affected by the concentration of the drug. The cycle voltammograms were recorded at constant rest times before the appearance of the peak and with different scan rates to estimate the value of x in the enoxacin concentration range from $1.0 \times 10^{-10}–1.0 \times 10^{-5}$ M. The peak cur-

Fig. 3. Electrocapillary curves of enoxacin: (a) 0.050 M HCl, 0.12 M KCl; (b) 0.050 M HCl, 0.12 M KCl, 5.0×10^{-7} M enoxacin; (c) 0.050 M HCl, 0.12 M KCl, 1.0×10^{-7} M enoxacin.

Table 1

Relationship between the value of x and the concentration of enoxacin[a]

Concentration of enoxacin ($\times 10^7$ M)	x
0.0010	0.97
0.0080	0.92
0.010	0.83
0.050	0.72
0.10	0.60
0.50	0.58
1.0	0.55
5.0	0.54
10.0	0.54
50.0	0.50
100	0.48

[a] 0.050 M HCl; mercury drop area of 0.0117 cm^2; rest time of 180 s; potential scan rate from 20 to 800 mV s^{-1}.

rent was measured and the regression of $\log i_p$ vs. $\log v$ gave the value of x listed in Table 1. Table 1 shows that the electrode process of enoxacin was essentially diffusion-controlled at a concentration of enoxacin greater than 5.0×10^{-6} M (diffusion region), whereas at the enoxacin concentrations below 8.0×10^{-10} M the electrode reaction was essentially adsorption-controlled (adsorption region) [20]. In the intermediate concentration range 1.0×10^{-9}–1.0×10^{-6} M the peak current includes both diffusion and adsorption components. These results were also supported by the a.c. impedance spectra of corresponding solutions.

3.6. Cyclic voltammetry

Fig. 4 shows the cyclic voltammograms for the enoxacin–KCl system. The drug gives a cathodic peak at about −1.05 V due to its reduction, and no peak was observed on the anodic branch, indicating the the reduction of enoxacin is irreversible. The width at the mid-peak of the drug was determined (curve a) and found to be 35 mV. The αn_α value was calculated and found to be 1.78 [21]. In Fig. 4 subsequent repetitive scans yielded significantly smaller (but stable) cathodic peaks corresponding to the reduction of dissolved species. This behaviour indicates that the adsorption of the drug on the mercury electrode is reactant adsorption [22], which agrees with normal pulse polarographic data.

3.7. Potentiostatic coulometry

Under optimum conditions the solution containing enoxacin was electrolyzed at −1.15 V until the electrolytic current was close to zero, and the expended charge Q_1 was measured. Similarly, the background solution was electrolyzed under the same conditions and charge Q_2 was obtained. The charge difference ΔQ ($Q_1 - Q_2$) is the charge expended by enoxacin:

$$\Delta Q = nFCV \qquad (1)$$

where C and V are the concentration and volume of the enoxacin solution respectively, and n and F have their usual meanings. From Eq. (1) the electron number of the electrochemical reaction can be found. For enoxacin $n = 1.96 \pm 0.05$.

The pH value strongly affects the position of the potential peak of the drug. The obtained dependence of E_p on the pH values of the test solution is the same as that described in the literature [14]. Over the HCl concentration range 0.50 to 0.010 M (pH 0.3–2.0), the coefficient of the regression equation of peak potential E_p vs. pH was 0.059, indicating that the molecules of the drug combined with one H^+ as soon as the drug obtained one electron. In acidic solution the drug is protonated. The possible electrode process could be assumed to be as follows:

Fig. 4. Cyclic voltammograms of enoxacin. 0.050 M HCl, 0.12 M KCl, 1.6×10^{-6} M enoxacin, scan rate 200 mV s^{-1}, accumulation time 120 s. (a) First scan; (b) second scan; (c) background solution.

(I)   + 2e + 2H⁺ ⇌   (II)

From the quantum-chemical point of view, the enoxacin was reduced, and the two electrons captured from the electrode belonged to the whole of the conjugated system and could move freely along the conjugated system [23] to form product (II).

3.8. Application

The main metabolite of the drug is 4-oxo enoxacin [24]. Its content in plasma is less than

15% of that of enoxacin so its interference was ignored.

We examined the interference of vitamins such as vitamin C, vitamin B_2 and vitamin B_{12}, which did not affect the determination of the drug.

3.8.1. Analysis of urine samples

Using the single-sweep polarographic procedure proposed in this paper to determine enoxacin in urine samples, no sample pretreatment was required, other than a dilution with the supporting electrolyte.

The standard enoxacin solutions used for the preparation of the calibration line were treated as described in the section on polarography of pure enoxacin. The regression equation of the calibration line has the form:

$$Y = 0.263X + 0.036 \qquad (2)$$

where Y is the peak current in μA and X is the enoxacin concentration in μg ml^{-1}. The correlation coefficient was 0.998. The results of the determination of enoxacin in the urine samples are summarized in Table 2.

3.8.2. Analysis of serum samples

The enoxacin in serum samples was extracted by chloroform because the proteins interfere in the determination of the drug in serum. The standard enoxacin solutions used for the preparation of the calibration line was treated as described in the section on analysis of serum samples. The slope of the calibration line is 0.110 μA ml μg^{-1}, and the intercept is 0.007 μA.

The results of the determination of enoxacin in serum samples are also summarized in Table 2.

Acid–base equilibria in γ-butyrolactone studied by use of pH-ISFETs

Kosuke Izutsu*, Masayuki Ohmaki

Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390, Japan

Abstract

pH-ISFETs were used in the study of acid–base equilibria in γ-butyrolactone (GBL). After the spectrophotometric determination of the pK_a value of 3,5-dichloropicric acid, the pK_a values and homo-conjugation constants of various acids (including the conjugate acids of bases) were determined potentiometrically using a Ta_2O_5-type pH-ISFET. The values of pK_a in GBL were in a linear relation with those in propylene carbonate (PC) and 1.0 units smaller on average. The difference in pK_a between GBL and PC was mainly attributable to the difference in proton solvation. The autoprotolysis constant of GBL, roughly estimated by a rapid titration with a Si_3N_4-ISFET, was about 30 on the pK_{SH} scale. A comparative study was made of the response speeds of the Ta_2O_5- and Si_3N_4-type pH-ISFETs and a conventional pH-glass electrode. The result was Si_3N_4-ISFET > Ta_2O_5-ISFET > glass electrode. Because GBL is not stable against acids and bases, the use of pH-ISFETs was much more convenient than the use of the conventional glass electrode.

1. Introduction

γ-Butyrolactone (GBL) is a dipolar aprotic solvent with a dielectric constant of 39, a donor number of 18 [1] and an acceptor number of 17.3 [2]. Because GBL is often used as a solvent for lithium batteries, aluminum electrolytic capacitors and electrical double-layer capacitors, the behavior of electrolyte solutions in GBL has been studied to a considerable extent [3]. Coetzee et al. [4] reported on the potentiometric characterization of

GBL using ion-selective electrodes. Though the acid–base behaviour in GBL is also important, detailed study of it does not seem to have appeared. In the present paper, we studied the acid–base equilibria in GBL. In the study, we used pH-ISFETs, which we recently found useful as pH-sensors in nonaqueous solutions [5]. The pH-ISFETs responded faster than a conventional glass electrode and their use in GBL was especially convenient because GBL tended to hydrolyze in the presence of acids and bases. The acid dissociation constants in GBL were compared with those in propylene carbonate (PC) [6,7].

2. Experimental

2.1. Apparatus

Ta_2O_5- and Si_3N_4-type pH-ISFETs, both obtained from Shindengen Industry Co. Ltd., were used. Because the contact between the ISFET tip and the leadwire was often attacked by the solvent, that part was protected by fixing with polyethylene. The reference electrode was Ag|5 mM AgClO₄ + 5 mM Et₄NClO₄‖10 mM Et₄NClO₄‖ and the gate voltage was measured with Shindengen ISFET mV/pH meter to 0.1 mV. The response of the ISFETs in GBL was compared with that of a conventional glass electrode (Horiba 1826A-06T9). The potential of the glass electrode was measured with a conventional pH/mV meter. The potential–time relations and titration curves were recorded with a Yokogawa two-pen recorder LR4110-3711 and a Metrohm 665 Dosimat autoburet. The titration data could be stored in a memory card inserted in the slot of the recorder and could be processed with a personal computer. A Shimadzu UV–visible recording spectrophotometer UV-260 was used in spectrophotometric measurements. All measurements were made at 25 ± 1°C.

2.2. Reagents

γ-Butyrolactone was a pure product (F-GBL, water content < 50 ppm) and was a gift of Mitsubishi Petrochemical Co. Ltd. It was used after further purification by adding p-toluenesulfonic acid to neutralize trace basic impurities and distilling under reduced pressure. The solution ≈ 0.1 M Bu₄NOH in MeOH–toluene (1:10 v/v) was prepared by the method of Selig [8] and used for titrating acids. Trifluoromethanesulfonic acid used for titrating bases was the reagent-grade Wako product. 3,5-Dichloropicric acid ($HPicCl_2$) and its tetraethylammonium salt were prepared by the method of Ref. [7]. Other acids and bases and their salts were also obtained as described in Ref. [7].

3. Results and discussion

3.1. Spectrophotometric determination of the pK_a value of 3,5-Dichloropicric acid

The absorption spectra of $Et_4NPicCl_2$ and undissociated $HPicCl_2$ were recorded and the molar absorption coefficient of the $PicCl_2^-$ ion at 430 nm was determined to be 4.31×10^3. The undissociated $HPicCl_2$ was obtained by adding trifluoromethanesulfonic acid to the $HPicCl_2$ solution. Then, measuring the absorbance of $HPicCl_2$ solutions between 10^{-4} M and 10^{-2} M at 430 nm, the dissociation constant K_a of $HPicCl_2$ was determined by the relation $K_a = \gamma^2[H^+][PicCl_2^-]/[HPicCl_2]$, where $[H^+] = [PicCl_2^-]$, and the ionic activity coefficient γ was obtained from the Debye–Hückel equation. As shown in Table 1, the pK_a value of $HPicCl_2$ was 5.86 ± 0.05 and there was no indication of a homo-conjugation reaction.

3.2. Potentiometric determination of pK_a values and homo-conjugation constants

The Nernstian response $(59.2 \pm 1.0 \text{ mV } pa_H^{-1})$ of the Ta_2O_5-type pH-ISFET was confirmed by titrating 20 ml of 5 mM $HPicCl_2$ in GBL with 0.1 M Bu_4NOH solution in MeOH–toluene (1:10 v/v). The ISFET showed an equilibrium potential 1 min after each addition of titrant. The effect of the MeOH–toluene on the proton activity (a_H) was neglected and the pH of the solution during titration was obtained by

$$a_H^2\gamma^2 C_s - a_H\gamma K_a[(C_s + C_a) + K^f(HA_2^-)(C_s - C_a)^2]$$

$$+ K_a^2 C_a = 0 \qquad (1)$$

where C_a and C_s are the concentrations of the acid and its salt and, for $HPicCl_2$, the homo-conjugation constant $K^f(HA_2^-)$ was equal to zero.

Using the Ta_2O_5-type pH-ISFET calibrated in the solution 1:1 mixture of $HPicCl_2$ and $Et_4NPicCl_2$, the solution of 5 mM picric acid (HPic) in GBL was titrated with the Bu_4NOH solution. The pK_a value of HPic was determined from the half-neutralization potential to be 8.35. Then the experimental results for the relation between $(pH - pK_a - \log \gamma)$ and (% titrated) were plotted and compared with the theoretical curves of the same relation for various $K^f(HA_2^-)$ values. Personal computer software Katto-Pro from the Ever Green Co. Ltd., Japan, was used in the data processing. With HPic, the best fit was obtained when no homo-conjugation reaction was assumed.

For other acids of the HA-type, the relations of $(pH - pK_a - \log \gamma)$ vs. (% titrated) were obtained by titrating the acids with the Bu_4NOH solution. For the acids of BH^+-type, the bases B were titrated with the trifluoromethanesulfonic acid solution in GBL. The pH-ISFET was calibrated before and after each titration with a buffer solution of 3 mM HPic–3 mM Et_4NPic. The pK_a values of the acids were obtained from the half-neutralization potentials while the homo-conjugation constants were obtained by fitting the theoretical titration curves to the experimental results. Eq. (1) was used for obtaining theoretical
Fig. 1. Relations of $(pH - pK_a - \log \gamma)$ vs. (% titrated) for the titration of 20 ml of 5 mM oxalic acid in GBL with 0.1 M Bu_4NOH in MeOH–toluene. Circles are experimental results and solid and dotted lines are theoretical relations for $K^f(HA_2^-) = 400$ and 0 respectively.

pH values during titration.

Some of the theoretical and experimental titration curves are shown in Figs. 1 and 2. The values of pK_a and $K^f(HA_2^-)$ are summarized in Table 2. For BH^+-type acids no appreciable homo-conjugation reaction occurred.

Fig. 2. Relations of $(pH - pK_a - \log \gamma)$ vs. (% titrated) for the titration of 20 ml of 5 mM 3,5-dinitrobenzoic acid in GBL with 0.1 M Bu_4NOH in MeOH–toluene. Circles are experimental results and solid and dotted lines are theoretical relations for $K^f(HA_2^-) = 3000$ and 0 respectively.

[b] Average of 2–5 measurements.

[c] ≈ 0 means $K^f(HA_2^-) < 50$. For conjugate acids of bases, $k^f(B_2H^+)$ values are shown.

3.3. Comparison of the pK_a values in GBL and PC

The relation between the pK_a values in GBL and PC [7] are plotted in Fig. 3. There is a linear relation with unit slope. The average difference between the pK_a values in the two solvents is 0.96.
Fig. 3. Relation between pK_a values in GBL and those in PC. Numbered circles refer to the acids listed in Table 2.

The solvent effect on pK_a can be represented by

$$pK_a(HA,S) - pK_a(HA,R)$$

$$= \log \gamma_t(H^+,R \to S) + \log \gamma_t(A^-,R \to S)$$

$$- \log \gamma_t(HA,R \to S) \qquad (2)$$

$$pK_a(BH^+,S) - pK_a(BH^+,R)$$

$$= \log \gamma_t(H^+,R \to S) + \log \gamma_t(B,R \to S)$$

$$- \log \gamma_t(BH^+,R \to S) \qquad (2')$$

where γ_t shows the transfer activity coefficient from solvent R to S. If $\log \gamma_t(A^-,R \to S) \doteqdot \log \gamma_t(HA,R \to S)$ or $\log \gamma_t(B,R \to S) \doteqdot \log \gamma_t(BH^+, R \to S)$, we can expect $pK_a(HA,S) - pK_a(HA,R) \doteqdot \log \gamma_t(H^+,R \to S)$ or $pK_a(BH^+,S) - pK_a(BH^+, R) \doteqdot \log \gamma_t(H^+,R \to S)$. In the previous paper [5], we confirmed that both pH-ISFETs and the glass electrode responded in near-Nernstian ways to $\log \gamma_t(H^+,R \to S)$. We determined $\log \gamma_t(H^+,GBL \to PC)$ using the ISFETs and the glass electrode, under the extrathermodynamic assumption of negligible liquid junction potential [9] which was considered to be reliable enough from our detailed study [10] on the liquid junction potential between different solvents. The values of $\log \gamma_t(H^+,GBL \to PC)$ obtained were between 1.0 and 1.5 and fairly near to the difference between pK_a values in PC and GBL. Thus the difference between pK_a values in PC and GBL can mainly be attributed to the difference in proton solvation. The donor numbers of PC and GBL are 15.1 and 18 respectively, and GBL is somewhat more basic than PC. However, the structures and properties of PC and GBL are somewhat similar to each other. Therefore, it seems reasonable that the relations $pK_a(HA,PC) - pK_a(HA,GBL) \doteqdot \log \gamma_t(H^+,GBL \to PC)$ and $pK_a(BH^+,PC) - pK_a(BH^+,GBL) \doteqdot \log \gamma_t(H^+,GBL \to PC)$ were obtained.

3.4. Comparison of the response of the pH-ISFETs and the glass electrode in GBL and rough estimation of the autoprotolysis constant of GBL

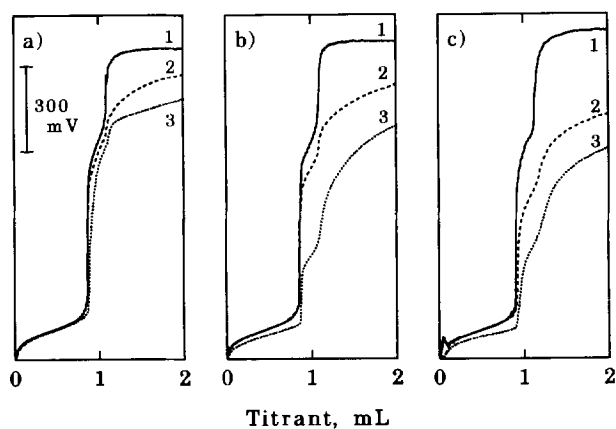
In the determination of pK_a values and homo-conjugation constants above, the Ta_2O_5-type pH-ISFET was mainly used. When the glass electrode


Fig. 4. Titration curves of 20 ml of 5 mM picric acid in GBL with 0.1 M Bu_4NOH in MeOH–toluene, obtained with three kinds of pH sensor and at three different speeds of titrant addition. Speed of titrant addition: (a) 0.075; (b) 0.5; and (c) 4.5 ml min^{-1}. pH sensor: (1) Si_3N_4-ISFET; (2) Ta_2O_5-ISFET; and (3) glass electrode.

was used, it took a few hours or more to get a whole titration curve and some distortion occurred in the curve mostly as the result of hydrolysis of GBL by acids and bases. Thus it was difficult to get reliable information with the glass electrode. The response of the Ta_2O_5-type ISFET was fast enough in so far as the titration curves were measured *manually*, waiting, after each addition of titrant, until the equilibrium potentials were reached.

In order to get titration curves more rapidly, the use of a pH sensor with higher response speed was essential. We ran a comparative study concerning the response speeds of the Si_3N_4- and Ta_2O_5-type pH-ISFETs and the glass electrode. Typical results are shown in Fig. 4. The titration curves of picric acid with Bu_4NOH were obtained at three different titration speeds using an autoburet. The recording of a titration curve took approximately 27 min for (a), 4 min for (b) and approximately 27 s for (c). It is apparent that the response speed is in the order Si_3N_4-ISFET > Ta_2O_5-ISFET > glass electrode. With the Si_3N_4-ISFET, the titration curve was almost satisfactory even in case (c) and the pH reached after the end point was the highest in this case. In cases (a) and

(b), the pH after the end point was lower than in case (c) because of the reaction of OH^- ions with GBL. In addition to the rapid response, the Si_3N_4-ISFET could respond in the Nernstian way to the pH in GBL.

The curve for the rapid titration of picric acid with Bu_4NOH obtained with Si_3N_4-ISFET (curve 1 of Fig. 4c) was used for the rough estimation of the autoprotolysis constant (K_{SH}) of GBL. It was between 29 and 30 on the pK_{SH} scale. The pK_{SH} of PC has been reported to be ≈ 29 [6,11]. This result also supports the fact that the acid–base property of GBL is close to that of PC.

4. Conclusions

In the present work, we used a Ta_2O_5-type pH-ISFET to determine the pK_a values and homo-conjugation constants of acids in GBL and a Si_3N_4-type pH-ISFET to estimate the pK_{SH} value of GBL. This seems to be the first use of pH-ISFETs for the practical study of acid–base equilibria in nonaqueous solvents. Due to their rapid response, the pH-ISFETs gave results which could not be obtained with a conventional glass electrode. pH-sensors with high response speeds are very important in nonaqueous solutions. They are applicable to unstable acid–base systems in nonaqueous solvents. They can also be used for pH measurements of flow systems as well as for high speed nonaqueous acid–base titrations. Systematic studies are now in progress in our laboratory to develop highly reliable pH-sensors for use in nonaqueous systems.

Dialkylphosphoric acids as carriers in separation of lanthanides and thorium on supported liquid membranes

A. Hrdlička*, I. Fialová, J. Doležalová

Department of Analytical Chemistry, Masaryk University, Kotlářská 2, 611 37 Brno, Czech Republic

Abstract

Permeation of seven lanthanides (Ln) and thorium through a supported liquid membrane containing di-(n-octyl)phosphoric (DOPA) or di-(n-pentyl)phosphoric (DPPA) acid as a carrier has been studied as a function of the chemical composition of the system. The results have been compared with a previous study in which di-(2-ethyl-hexyl)phosphoric acid was used.

Metal cations were transported from feed solutions of pH 1.1–4.8 (HNO_3) into strip solutions of 0.015–0.1 mol l^{-1} nitric acid. The ionic strength was kept constant at 0.1 mol l^{-1} (HNO_3, KNO_3). The initial lanthanide concentration and carrier concentration in the liquid membrane were varied from 0.5 to 500 μmol l^{-1} and from 0.01 to 0.5 mol l^{-1} respectively. To describe the mass transfer of metal cations, permeability coefficients have been determined by inductively-coupled plasma atomic emission spectroscopy or by on-line flow-injection analysis of metal concentrations in strip or feed solution.

Probably as the result of a higher solubility of the carrier in aqueous media, transport of Ln with DPPA was not observed. By using DOPA, La, Ce, Pr, and Nd permeated through the membrane while transport of heavier Ln was partly or totally suppressed. This enables these four Ln (separation factor $\alpha = 3.0$ for Nd and Sm) to be separated from the others. Furthermore, at a very low acidity gradient, only La (III) is transported over the membrane ($\alpha \geq 3.4$ for La, Ce and next Ln). The seven elements from La to Tb can be separated from Th(IV) because no evidence of its permeation through the membrane was found under the conditions of Ln transport. In contrast to previous studies on Ln transport with dialkylphosphoric acid carrier, the possibility of participation of species other than $Ln(AHA)_3$ in the transport has been discussed. The decrease of permeability observed at higher Ln concentrations and higher pH of the feed solution has been explained as the result of formation of species, e.g. polymeric ones, that are unable to permeate through the membrane.

Keywords: Lanthanides; Thorium; Membrane separation

1. Introduction

The commercial-scale separation and refining of rare earth elements (REE) have been mainly carried out by solvent extraction with di-alkylphosphoric acids (DAPAs), particularly with di-(2-ethylhexyl)phosphoric acid (DEHPA) [1,2]. Recently, new DAPA extractants, such as di-(4-ethylcyclohexyl)phosphoric acid [3] and isopropyl-3-pentadecylphenylphosphoric acid [4], have been investigated with the aim of improving extraction efficiency. Generally, better extraction properties were found with DAPAs with long and straight alkyl chains than with those with short and branched chains [5]. The extraction separation of adjacent lanthanides (Ln) follows the trend n-octyl < 2-ethyl-hexyl < 3-octyl, i.e. in the order of increasing steric hindrance by the alkyl group [6]. Another feature of lanthanide extraction with organophosphoric acids is an increase of extraction efficiency with atomic number owing to lanthanide contraction [3,6,7].

Among DAPA extractants for Ln, di(n-pentyl)phosphoric (DPPA) and di(n-octyl)phosphoric acid (DOPA) have been employed. In agreement with the conclusions reported above, considerably higher values of extraction constants of Ln with DOPA were found than those with DEHPA and the values of separation factors for adjacent Ln were lower when DOPA was used [5].

A new approach for selective extraction and enrichment is the supported liquid membrane (SLM) technique that is employed in both chemical technology and analytical chemistry [8,9]. The analytical application of this technique consists of sample preparation before analysis and field sampling. The basic principle is a continuous extraction from an aqueous phase (feed solution) into a liquid membrane, followed by a continuous stripping to aqueous acceptor phase (strip solution) on the other side of the membrane. The membrane is formed by an organic solvent of low polarity, immobilised in a thin porous hydrophobic support.

Application of DEHPA in the transport of REE through SLMs is currently under study [10–13]. In previous work [14–16], transport of Ln has been investigated as a function of hydrody-namic conditions, feed solution acidity and carrier concentration.

Here we present the results of our detailed study on the transport of Ln through SLMs containing DPPA or DOPA as a function of the chemical composition of the system, aimed at comparison of these carriers with DEHPA and the explanation of transport processes of Ln with dialkylphosphoric acid carriers. Furthermore, the transport of Th(IV) that coexists with Ln, e.g. in monazite and thorite, has been investigated. Separation of Th from REE is important in analysis and production of these elements which may be of particular interest in the future regarding the possible use of thorium in nuclear power plants.

2. Experimental

2.1. Reagents and solutions

Nitrates of La (Merck, Germany), Ce (Carlo Erba, Italy), Nd, Eu and Tb_4O_7 (Fluka, Switzerland) of analytical-grade purity as well as pure nitrates of Pr and Sm (Fluka) were dissolved in nitric acid. Stock solutions of 2.5 mmol l^{-1} Ln or $Th(NO_3)_4$ (analytical grade; Lachema, Czech Republic) in 0.1 or 0.15 mol l^{-1} HNO_3 respectively, were standardised by chelatometric titration.

DPPA and DOPA were synthesized and purified in the Department of Inorganic Chemistry of the University. Their purity was verified by ^{1}H-NMR and ^{31}P-NMR spectroscopy. Stock solutions of the dialkylphosphoric acids were prepared in kerosene (Lachema) which was previously purified by extraction with 0.5 mol l^{-1} sodium hydroxide, water, and 0.5 mol l^{-1} hydrochloric acid.

Feed solutions of pH 1.1–4.8 (pH adjusted with dilute nitric acid or ammonia) contained lanthanide or thorium at an initial concentration of 4.2 μg ml^{-1} with the exception of the study of the effect of metal concentration where the concentration of La, Pr, or Eu was varied in the range 0.5–500 μmol l^{-1}, i.e. between 0.07 and 76 μg ml^{-1}. As a strip solution, 0.015–0.1 mol l^{-1} nitric acid was used. The ionic strength of the feed and strip solutions was kept constant at 0.1 mol l^{-1} (HNO_3, KNO_3).

The reagent solution used in the flow-injection analysis (FIA) determination of Ln [17,18] contained 0.06 mmol l^{-1} Xylenol Orange (Lachema), 0.6 mmol l^{-1} cetylpyridinium bromide monohydrate (pure; Aldrich, USA) and 4% v/v ethanol (distilled; Lachema) in 0.2 mol l^{-1} acetate buffer pH 4.5.

Isothermally-distilled ammonia was used. All other reagents were of analytical grade purity and were purchased from Lachema.

2.2. Procedure and apparatus

Durapore GVHP 04700 (Millipore, USA), a laminar microporous poly(vinylidenedifluoride) film of 125 μm thickness and with an effective pore diameter of 0.22 μm, was used as a solid support for liquid membranes. The effective area of the liquid membrane, i.e. the product of the nominal porosity coefficient of the support (0.75) and its cross-sectional area in contact with solutions, was 8.51 cm^2.

SLMs were prepared, treated and reimpregnated by the method described earlier [14]. One membrane was reused up to 50 times without the observation of any inconsistency in the results. When not in use the purified membrane was stored in kerosene.

Transport experiments were performed in a two-compartment cell described elsewhere [19], in which the flat sheet membrane separated the feed from the strip solution (200 ml of each). Both solutions were stirred at 1300 rev min^{-1} [14].

Lanthanide concentrations in feed and/or strip solution were on-line monitored using a FIA spectrophotometric method [17] based on the reaction of Ln with Xylenol Orange and cetylpyridinium bromide at pH 4.5 which was adjusted by acetate buffer. By injecting samples of acidic strip solution, a negative signal was obtained due to insufficient capacity of the acetate buffer. The determination of lanthanide in the strip solution was established as the linear decrease of the absolute value of this negative signal with increasing metal concentration. The data used to determine the permeability coefficient values were collected at 3 min intervals 3–30 min from the beginning of the transport experiment. Feed solution acidity was monitored during the run.

A Model PCR 01 four-path peristaltic pump equipped with Tygon tubing (Labeco, Slovak Republic) was used to maintain the flows of the FIA reagent, carrier, and sampled solution each at 0.8 ml min^{-1}. As the carrier solution, 0.2 mol l^{-1} acetate buffer pH 4.5 was employed. The FIA manifold consisted of a Model 5020, six-port injection valve (Rheodyne, USA) with a sample loop of 72 ml volume, a Model VD 104 on-capillary photometric detector (Labeco), and a TZ4620 recorder (Laboratory Instruments Prague, Czech Republic). Transport lines, a 0.5 m mixing coil and a 1 m reaction coil were made with 0.8 mm i.d. Teflon tubing. Lanthanide concentration was monitored at 610 nm with 40 nm bandwidth.

To follow the effect of metal concentration on membrane transport of Ln and to study the transport of Th(IV), 1 ml aliquots were taken from the feed and strip solution at 5 min intervals during a 30 min membrane experiment and diluted 1:1 with nitric acid solution. A Model PU 7000 inductively-coupled plasma sequential atomic emission spectrometer with grid nebulizer and plasma generator working at a power input of 0.9 kW (Philips-Unicam, UK) was employed to determine the metal concentration. The samples in 0.1 mol l^{-1} HNO_3 were introduced at a flow rate of 1 ml min^{-1} by means of a peristaltic pump. The measurement of Th, La, Pr, and Eu was performed at wavelengths of 283.730, 333.749, 390.844 and 381.967 nm respectively. Nitric acid, 0.1 mol l^{-1}, was used as a reference solution.

A Model OP-208 pH-meter equipped with an OP-0808-P glass–Ag/AgCl combined electrode and phthalate and phosphate standard buffers (all Radelkis, Hungary) was used for acidity measurements.

3. Results and discussion

Mass transport of metal cations has been expressed in terms of permeability coefficients, P (cm min^{-1}). Their values were determined from sets of primary data in the form of a metal concentration vs. time dependence by using the linear relationship introduced by Danesi [20]:

$$\ln \frac{c_{f,0}}{c_f} = \frac{Q}{V_f} \cdot P_f t \tag{1}$$

where Q is the membrane effective area, V_f is the volume of feed solution, and $c_{f,0}$ and c_f are time-dependent bulk concentrations of the metal species in the feed solution at time zero and time t respectively. P_f represents the value of the permeability coefficient determined from the measurement of c_f.

In previous studies [14–16] on the permeation of lanthanide cations through SLMs containing di-(2-ethylhexyl)phosphoric acid, a decrease in permeability at pH > 2.5–3 and/or at higher DEHPA concentrations was noted. The presence of a waxy-gelled, metal-containing substance in the feed solution and at the feed–membrane interface has been interpreted in terms of chemical speciation and blockage of the membrane surface. The presence of the gel-like substance in the feed solution has also been observed by other authors [21,22]. To avoid discrepancies arising from formation of this substance, variations of metal concentration in the feed solution have been monitored as the difference between the initial concentration of the metal, $c_{f,0}$, and its concentration in the strip solution at time t, c_s. Therefore, the values of permeability coefficients P_s have been estimated by using the linear Eq. (2) [15]:

$$\ln \frac{c_{f,0}}{c_{f,0} - c_s} = \frac{Q}{V_f} \cdot P_s t \tag{2}$$

Thus, for the determination of P_s values, the separation function of the membrane has been considered for the strip–membrane interface.

3.1. DPPA

The application of DPPA as a carrier has been investigated under the conditions that have been found favourable for the membrane transport of lanthanides with DEHPA [14–16]. The DPPA and initial Nd(III) concentrations were kept at 50 mmol l^{-1} and 4.2 μg ml^{-1} respectively. The strip solution consisted of 0.1 mol l^{-1} HNO$_3$ and the feed solution acidity was varied in the range pH 2.8–5.5. In successive experiments, the carrier concentration was increased up to 250 mmol l^{-1} and the acidity gradient over the membrane,

which is a driving force in membrane transport with acidic carriers, was enhanced by using 0.5 mol l^{-1} HNO$_3$ as a strip solution (ionic strength in solutions kept at 0.5 mol l^{-1} (HNO$_3$, KNO$_3$). However, no evidence for the transport of Nd(III) cations into and/or through the liquid membrane was found during the 95 min experiments, probably due to the solubility of DPPA in the aqueous phase. In a SLM, the volume of the liquid membrane is negligible in comparison to those of the feed and strip solutions and thus higher solubility of the carrier in aqueous media has a detrimental effect on the transport process. Subsequent application of DOPA as a carrier possessing longer alkyl chains and hence having lower solubility in water media, resulted in a noticeable transport of Ln through the SLM under the experimental conditions mentioned above.

3.2. DOPA

3.2.1. Effect of acidity

In previous studies on lanthanide permeation through SLMs with DEHPA [10–16], which mostly used a dialkylphosphoric acid carrier, the effect of the strip solution acidity on transport has been investigated rarely or not at all. In Fig. 1,

Fig. 1. Effect of strip solution acidity on permeability coefficients. Feed solution: initial lanthanide concentration 4.2 μg ml^{-1}; pH: La, 3.10 $\pm$ 0.01; Ce, 3.08 $\pm$ 0.02; Pr, 3.04 $\pm$ 0.02; Nd, 2.90 $\pm$ 0.04; Sm, 2.87 $\pm$ 0.05; Eu, 3.12 $\pm$ 0.02; Tb, 3.10 $\pm$ 0.05. Ionic strength in feed and strip solutions: 0.1 mol l^{-1} (HNO$_3$, KNO$_3$). SLM: 50 mmol l^{-1} DOPA in kerosene.
Fig. 2. Effect of feed solution pH at higher acidity gradient. Strip solution acidity given by 0.1 mol 1^{-1} HNO_3. Other conditions as in Fig. 1.

the behaviour of Ln in transport with DOPA carrier is shown in terms of dependence on nitric acid concentration in the strip solution. The permeability coefficients decrease with increasing atomic number and those of light Ln from La to Nd are considerably higher than the values found for Sm, Eu, and Tb. The difference increases with acidity of the strip solution and at 0.1 mol 1^{-1} HNO_3 the membrane separation factor of the couple Nd–Sm, $\alpha = P_{s,Nd}/P_{s,Sm}$, equals 3.0, which can be used in separation of the groups of Ln. In contrast, permeability coefficients rapidly decrease in the case of nitric acid concentrations lower than about 70 mmol 1^{-1} (Tb) or 40 mmol 1^{-1} (Ce). However, La(III) permeability remains high even at 15 mmol 1^{-1} HNO_3. Thus, La(III) can be separated from adjacent cerium ($\alpha = P_{s,La}/P_{s,Ce} = 3.4$) or from the other Ln at low acidity of the strip solution.

The P_s vs. feed solution pH curves of light Ln presented in Fig. 2 (0.1 mol 1^{-1} HNO_3 as strip solution) exhibit maxima. With increasing atomic number, the maxima are lower and their position changes from pH 3.2 for La to pH 2.1 for Sm. The transport of Tb, a representative of the heavy Ln, practically does not proceed and the curve of Tb is flat. If the acidity gradient is decreased by lowering the concentration of nitric acid in the strip solution to 35 mmol 1^{-1} (Fig. 3), i.e. at lower force driving the transport, a plateau and

maximum appear on the curves of La, Ce, and Pr (maxima: pH 3.1 for La, 3.0 for Ce, 1.9 for Pr; plateau: pH 1.9–2.5 for La and Ce, 2.5–3.0 for Pr). The curves of Nd and Sm show maxima at pH 1.9 and 2.1 respectively. Only a slight deformation can be found on the Nd curve at pH ≈ 2.8 where the plateau should appear by analogy with praseodymium. The permeability of the next lanthanide, Sm, is already low and Tb is not transported over the membrane due to the low acidity gradient. The position of the maxima on the curves of La, Ce, and Sm and that of the plateau or deformation on the curves of Pr or Nd corresponds approximately to the maxima found at higher acidity gradient in Fig. 2.

The appearance of the plateau and maxima on pH curves measured at lower acidity gradient could be explained by the transport of two species with different permeability which are formed due to dependence on feed solution pH. This, of course, means that the commonly suggested [5,21,22] extraction equilibrium (A)

$$Ln^3 + 3\overline{(HA)_2} \leftrightarrow \overline{Ln(AHA)_3} + 3H^+ \qquad (A)$$

where overbars denote the species present in the organic phase of low polarity and HA represents DAPA extractant, is not the only one which could take place in the membrane transport processes. It is well known that LnA_3 species are formed in the solvent extraction with deficient amount of

Fig. 3. Effect of feed solution pH at lower acidity gradient. Strip solution acidity given by 0.035 mol 1^{-1} HNO_3. Other conditions as in Fig. 1.

DAPA [5] where the extraction equilibria could follow scheme (B):

$$2Ln^{3+} + 3\overline{(HA)_2} \leftrightarrow 2\overline{LnA_3} + 6H^+ \quad (B)$$

or scheme (C):

$$Ln^{3+} + 3\overline{HA} \leftrightarrow \overline{LnA_3} + 3H^+ \quad (C)$$

if the dimerization of DAPA does not proceed. Explanation of membrane transport of Ln by equilibrium (C) has been suggested in the literature [11]. However, the DOPA concentration in the liquid membrane in our study was about three orders of magnitude higher than the initial Ln concentration in the feed solution and, thus, the conditions were more favourable for equilibrium (A).

In contrast, the equilibria producing mixed-ligand complexes $Ln(AHA)_x(NO_3)_y(HA)_z$, where $x + y = 3$, could also proceed for the extraction from nitrate solutions. Taking into account the coordination number (six) of Ln(III) cation and the presence of dimeric $(HA)_2$ and anionic $(AHA)^-$ species, the complexes, e.g. $Ln(AHA)_2$-$(NO_3)(HA)_2$, could be formed in the membrane separation process and the equilibrium (D) could proceed with dependence on pH:

$$\overline{Ln(AHA)_2(NO_3)(HA)_2} \leftrightarrow \overline{Ln(AHA)_3} + H^+ + NO_3^-$$

$$(D)$$
The formation of similar mixed-ligand complexes in acetone solutions, referred to as Eu-$A(NO_3HA)_2$, and their decomposition to EuA_3 polymeric species appearing as a solid phase after dilution with water, have been described elsewhere [23].

3.2.2. Effect of carrier concentration

The effect of DOPA concentration in the liquid membrane on the permeation of Ln into strip solutions of 100 mmol l^{-1} (Fig. 4) and 35 mmol l^{-1} nitric acid (Fig. 5) was studied at pH 3.0 $\pm$ 0.1 of the feed solution, i.e. near the maxima (or plateau) observed in the pH curves in Figs. 2 and 3. All the plots of P_s vs. DOPA concentration have maxima at 50 mmol l^{-1} DOPA. In Fig. 5, i.e. at lower acidity gradient, lower P_s values are attained and the decrease of La and Ce perme-

Fig. 4. Effect of carrier concentration at higher acidity gradient. Feed solution pH: La, 3.07 ± 0.03; Ce, 3.03 ± 0.03; Nd, 2.95 ± 0.05; Sm, 2.93 ± 0.02; Tb, 3.13 ± 0.03. Strip solution acidity given by 0.1 mol l^{-1} HNO$_3$. Other conditions as in Fig. 1.

ability coefficients at $c(DOPA) > 50$ mmol l^{-1} is sharper.

3.2.3. Effect of lanthanide concentration

Studies on membrane transport involving the effect of metal concentration are few [12,24,25] although this variable can play an important role as shown in Fig. 6. The permeability coefficients of La and Pr determined from Eqs. (1) and (2) are

Fig. 5. Effect of carrier concentration at lower acidity gradient. Feed solution pH: La, 3.12 ± 0.01; Ce, 3.08 ± 0.01; Pr, 3.03 ± 0.03; Nd, 2.91 ± 0.03; Sm, 2.98 ± 0.03. Strip solution acidity given by 0.035 mol l^{-1} HNO$_3$. Other conditions as in Fig. 1.
Fig. 6. Effect of initial lanthanide concentration (mol l^{-1}) on permeability coefficients measured in feed and strip solutions. Feed solution pH: La, 2.83 ± 0.05; Pr, 2.80 ± 0.06; Eu, 2.84 ± 0.06. Other conditions as in Fig. 1.

practically independent of initial concentrations $c_{f,0} < 30$ μmol l^{-1}. For Eu, representing the group of heavier Ln, this limit is valid only for P_f values while those of P_s decrease even at $c_{f,0} > 5$ μmol l^{-1}. Furthermore, P_s values are lower than P_f values over the whole concentration range studied.

At $c_{f,0} > 30$ μmol l^{-1}, the ratio of c(DOPA)/$c_{f,0}$ is still high, ranging between 1.6×10^3 and 1×10^2. Thus Eq. (1) should be valid and the initial membrane flux, J_0, should vary with $c_{f,0}$ in compliance with the relation $J_0 = P \cdot c_{f,0}$ [20,25], where the permeability coefficient P is a proportionality constant. The curves of log J_0 vs. log $c_{f,0}$ in Fig. 7 (J_0 calculated by using the relation introduced above) show that this is valid only at lower concentrations and that the decrease of permeability in Fig. 6 is greater than could be explained by saturated flux through the membrane.

The observed decrease of permeability at higher lanthanide concentrations can be explained due to formation of species that are unable to permeate through the membrane. The heavier lanthanide species remain partially in the membrane or block the feed–membrane interface. As a result, P_s values lower than P_f are obtained.

In previous work on membrane transport of Eu(III) with DEHPA [21], formation of polymeric Eu–DEHPA species was presumed as an explana-

tion for both the origin of the gel-like coating found on the membrane surface and the drop in transmembrane conductivity. However, in contrast to studies [14–16,21,22] on Ln transport with DEHPA as a carrier, the presence of any gel-like material was not observed using DOPA.

3.2.4. Transport of thorium(IV)

Thorium(IV) can be extracted from its nitrate solutions in the form of mixed ligand complexes with DEHPA [2]:

$$Th^{4+} + NO_3^- + 3\overline{(HA)_2} \leftrightarrow \overline{Th(NO_3)(AHA)_3} + 3H^+$$

(E)
As assumed, Th(IV) extraction with DOPA would follow an identical scheme. The pH of feed solutions containing Th(IV) was varied between 1.1 and 3.0 to maintain sufficient acidity gradient over the membrane and to prevent Th(IV) hydrolysis [26,27], leading to the formation of Th(OH)$^{3+}$ and Th(OH)$_2^{2+}$ species at pH > about 3. The membrane containing 50 mmol l^{-1} DOPA and 0.1 mol l^{-1} nitric acid was used as a strip solution. The concentration of thorium in the feed solution remained at the initial level, $c_{f,0}$, and no evidence for transport of Th(IV) was found under conditions favourable for permeation of Ln. As a consequence, Th(IV) could be separated from the Ln studied under the given conditions.

Fig. 7. Initial flux through the membrane as a function of initial lanthanide concentration (mol l^{-1}). Conditions given in Fig. 6.

4. Conclusions

The dependences of P_s on carrier concentration and P_s on pH of the feed solution, which have been measured under identical experimental conditions using DEHPA [15,16] as carrier, are very similar to those with DOPA and their maxima are situated at identical or comparable values of carrier concentration and pH respectively. In the case of membrane transport with DEHPA, Ln are divided into two groups: light (inclusive of Tb), and heavy lanthanides which differ significantly in their permeability as can be demonstrated by the value of the membrane separation factor $\alpha = P_{s,Tb}/P_{s,Ho} = 1.4$ [16].

With DOPA carrier, the values of permeability coefficients of the Ln from La to Nd are comparable to those obtained with DEHPA. However, the permeation of heavier Ln is suppressed and a separation factor of 3.0 is achieved for the Nd, Sm couple. In contrast to DEHPA, the formation of any gel-like substance in solutions or on membrane interfaces has not been observed using DOPA.

This work shows that the transport efficiency of Ln with dialkylphosphoric acid carrier is not only a strong function of feed pH and carrier concentration, as observed in previous studies with DEHPA but that the strip solution acidity and initial lanthanide concentrations also play an important role. Furthermore, it was shown that $Ln(AHA)_3$ are not the only species which can take part in Ln transport through the membrane. However, the decrease of permeability at higher lanthanide concentrations and higher pH of the feed solution can probably be explained by formation of species which are unable to permeate through the membrane. The decrease of permeability observed at higher carrier concentrations, i.e. in the range $0.05-0.25$ mol 1^{-1} DOPA, could only be partially explained by the decrease of diffusion coefficients with increasing viscosity of the liquid membrane.

Abstract

We have developed a simple, rapid, inexpensive method for the determination of benzo[a]pyrene (BP, a known carcinogen) in smoking-flavour agents (water-soluble liquid smoke; WSLS). After purification of the WSLS by a single passage through a Sep Pak C18 Plus cartridge, BP in the hexane eluate was determined by second derivative constant-wavelength synchronous spectrofluorimetry. Method precision (RSD < 6%) and recovery ($\approx$ 92%) were satisfactory, and the detection and quantification limits (1.05 and 2.28 μg kg^{-1} respectively) indicated that the current maximum permissible concentration of BP in smoke flavourings (10 μg kg^{-1}) can be monitored by this method.

1. Introduction

Polycyclic aromatic hydrocarbons (PAHs) are formed when organic matter undergoes incomplete pyrolysis and then condensation. In recent years, their toxicology and analysis have been of interest because of the carcinogenicity of many of them, and the general ubiquity of PAHs in the environment due to the following factors: (a) aerial transport of PAHs from combustion sources and their subsequent deposition in bodies of water and in soil and into plants, from which they propagate along the food chain; (b) pyrolysis of food components (mainly carbohydrates, lipids and proteins) during food preparation involving high temperatures (500-700°C); (c) food processing, when food comes into contact with hydrocarbon-based materials such as agricultural and industrial lubricants or food packaging; (d) during the smoking of foods by natural or artificial methods (water-soluble liquid smoke; WSLS) [1-3].

Benzo[a]pyrene (BP) in particular is frequently sought as an indicator of the presence of other

* Corresponding author.

PAHs in such diverse matrices as water [4] and foodstuffs [5]. Human exposure to BP and PAHs in general can occur through ingestion of food, contaminated air and water [4]. Thus several legal measures aimed at limiting the levels of BP in foodstuffs have been adopted. In Council Directive 88/388/EEC [5], the EC (now the EU) set the maximum permissible level of BP in foods, derived from smoke flavouring, at 0.03 μg kg^{-1}. However, no limits are currently stated for other foods, although the EU intends to set a maximum level of 1 μg kg^{-1}, as well as introducing restrictions on cooking foods on an open flame [3]. In contrast, the FAO/WHO Joint Committee on Food Additives [6] has provisionally authorized the use of smoke flavourings when deemed necessary—which are typically used at a dose of between 1 and 2 g kg^{-1} of foodstuff—to levels of BP no higher than 10 μg kg^{-1}.

The analyses of smokes absorbed in liquids for commercial handling involve various analytical methods (GC, HPLC, etc.) [7–12]. In this work we develop a simple, rapid, inexpensive method for the determination of BP from "water-soluble liquid smoke" (WSLS). The method precision and recovery are satisfactory, and the quantification limit is considerably lower than the 10 μg kg^{-1} minimum suggested by the FAO/WHO Joint Committee.

2. Experimental

2.1. Reagents

WSLS was supplied free of change by a manufacturer of smoke flavourings; BP standard was purchased from Aldrich, residue-analysis-grade n-hexane was from Merck, and routine-grade acetonitrile for HPLC was from Scharlau. Stock solutions containing 100 μg l^{-1} and 100 mg l^{-1} of BP were prepared in n-hexane and acetonitrile/water (1:2), and were stable under refrigeration at 4°C; BP standards (0.5, 1, 2, 4, 8 and 16 μg l^{-1}) were prepared by appropriate dilutions of these stock solutions with n-hexane and with acetonitrile/water.

Table 1
Optimization of the polarity of the initial eluent used in the purification step ($n = 6$)

Solvent ratio		% R
Acetonitrile	Water	
1	1.0	59.6
1	1.2	78.1
1	1.4	94.2
1	1.6	98.0
1	1.8	99.6
1	2.0	100

2.2. Apparatus

All spectrofluorimetric measurements were performed with a Perkin-Elmer LS-50 luminescence spectrometer equipped with a xenon discharge lamp, Monk–Gillieson monochromators and 1 cm quartz cuvettes, and provided with Fluorescence DM software for acquisition and processing of spectral data. Moreover, the LS-50 was serially interfaced (RS232C) to a Handok HNS-286 PC linked to an HP Laserjet IIP printer for hard copies.

2.3. Procedure

2.3.1. Purification

A sample of the WSLS (2 g) was spiked with 15 or 30 ng of benzo[a]pyrene, mixed into 15 ml of a 1:2 mixture of acetonitrile/water in a beaker, and passed through a Sep Pak C18 Plus cartridge that had previously been activated by passage of 5 ml of acetonitrile followed by 10 ml of distilled wa-

Table 2
Precisions (% RSD) and recoveries (%R) obtained when 5 ml of n-hexane was used to elute the BP sorbed onto a Sep Pak Plus Cartridge during passage of 15 ml of a 1, 4 or 8 μg l^{-1} solution of BP in 1:2 CH$_3$CN/H$_2$O ($n = 6$)

BP in 15 ml of standard (ng)	BP determined in eluent (ng)	% RSD	%R
5	5.30	2.6	106

40	36.9	0.6	92

ter. The sides of the beaker were washed with a further 15 ml of 1:2 acetonitrile/water, which was then passed through the cartridge to complete the purification process. The aqueous acetonitrile eluate was discarded, and the BP retained on the cartridge was eluted into a volumetric flask with *n*-hexane (final volume 5 ml). A sample was transferred to a quartz cuvette for subsequent spectrofluorimetric determination of BP.

2.3.2. Spectrofluorimetry

Synchronous fluorescence spectra of the hexane solution obtained above were recorded between 200 and 500 nm at a scan speed of 240 nm min^{-1} and with excitation and emission slit-widths both

set to 5 nm. The excitation–emission wavelength difference was either 20 or 110 nm (see Results and discussion). Second derivative spectra were then generated by the data handling system of the spectrofluorimeter.

3. Results and discussion

Constant-wavelength synchronous spectrofluorimetry is a selective and sensitive analytical technique that is both rapid and easy to apply. As such, it has been widely used for the determination of BP in a variety of matrices [13–16], usually after an extraction/purification step that

Fig. 1 (a).

Fig. 1(a) Synchronous fluorescence spectra with $\Delta\lambda = 20$ nm of hexane solutions of an unspiked sample of WSLS (1); 3 μg l^{-1} BP standard (2) and WSLS spiked with 15 ng of benzo[a]pyrene (3). (b) Zoom-like expansion of the second derivative of the marked region in (a).

removes interferents present in the matrix. Such a step is necessary in the case of WSLS: it cannot be analysed directly due its inherent opacity, while its solutions in water or polar organic solvents show single broad peaks that mask the signal due to BP.

In the purification step elaborated in this work, the BP in the WSLS was separated from hydrophilic components and most of the interfering fluorescent compounds except other PAHs (these, however, do not interfere in the subsequent spectrofluorimetric determination [17]) by a single passage through a Sep Pak C18 Plus cartridge. The key to this step was careful balancing of the polarity of the initial eluent so that all the BP in the liquid smoke was retained on the cartridge. The optimum result was achieved using the 1:2 acetonitrile/water mixture described (Table 1). Subsequently, hexane was chosen to elute the BP because it was sufficiently apolar to allow com-

plete elution; it afforded a solution that was transparent in the wavelength region in which BP fluoresced; and it is the recommended solvent for determination of BP and PAHs in general by spectrofluorimetry [18]. A recovery of approximately 100% was attained by eluting the BP in 5 ml of hexane (Table 2).

For the spectrofluorimetric determination of the BP, the spectrometer settings were adjusted so that, as far as possible, the instrumental sensitivity and resolution were optimized. The wavelength interval $(\Delta\lambda)$ between the emission and excitation monochromators that afforded the best signal (i.e. that maximized signal intensity while minimizing interference) was evaluated from the results of 50 assays in which $\Delta\lambda$ was varied, in 5 nm increments, between 10 and 255 nm. A 20 or 110 nm interval gave the best results: the maximum peak intensity was obtained with a 110 nm interval (see Fig. 2); however, interference was less evident in the peak obtained with a 20 nm interval (Fig. 1(a)), and so this peak was used for quantification. The small amount of residual interference due to background absorption was effectively eliminated by taking the second derivatives of these spectra.

Having established $\Delta\lambda$, several combinations of slit widths were examined: the greatest sensitivity was obtained with widths of 2.5 (excitation) and 20 nm (emission); however, a cleaner spectrum resulted when both slits were set at 5 nm. The selected scan speed of 240 nm allowed rapid spectral acquisition without excessive noise.

3.1. Quantification and linearity of the instrumental response

Quantification of the BP was by measurement of the peak-to-trough height of the signal corresponding to the second derivative between 379 and 384 nm (Fig. 1(b)) of the direct spectrum obtained with $\Delta\lambda = 20$ nm (Fig. 1(a)). The presence of a signal at 296 nm in the direct spectrum obtained with $\Delta\lambda = 110$ nm served to confirm that the analyte being determined was indeed BP (Fig. 2).

The calibration line, constructed by regressing peak-to-trough height (I) of the second derivative
Fig. 2. Synchronous fluorescence spectra with $\Delta\lambda = 110$ nm of hexane solutions of an unspiked sample of WSLS (1); 3 μg l^{-1} BP standard (2) and WSLS spiked with 15 ng of benzo[a]pyrene (3).

signal due to BP on its concentration (c) for five of the standards (1–16 μg l^{-1}), gave the equation $c = 0.1146I + 0.0023$ with a correlation coefficient (r) of 0.9998.

The concentration (in μg kg^{-1}) of ben-

Table 3
Precisions (% RSD) and recoveries (%R) obtained for six replicate samples of WSLS spiked with 15 and 30 ng of BP

Amount added (ng)	Amount measured	% RSD	%R
15	13.7	5.2	91
30	28.0	5.9	93

zo[a]pyrene in the WSLS was obtained by multiplying its concentration (μg l^{-1}) in the hexane eluate by a factor of 2.5, which value was deduced from the purification process carried out [i.e. (15 ng/2 g)/(15 ng/5 ml)]. No BP was detected in unspiked WSLS (see Fig. 2).

3.2. Detection and quantification limits

Detection and quantification limits (calculated, following ACS guidelines [19], as the concentration corresponding to the signal (i.e. its peak-to-trough height) equal to the mean signal for 6

blanks plus respectively, three and ten standard deviations) were 0.42 and 0.91 μg l^{-1} respectively, for BP in the hexane eluate. These equate to a detection limit of 1.05 μg kg^{-1} and a quantitation limit of 2.28 μg kg^{-1} for BP in the WSLS. Clearly, the latter concentration limit is much lower than the 10 μg kg^{-1} maximum set by the FAO/WHO Joint Committee on Food Additives [6], which they considered to be the minimum concentration that could be quantified in smoke flavourings. In the light of these results, the maximum permissible concentration of BP in smoke flavourings should be reviewed, and accordingly reduced.

3.3. Precision and recovery

Method precision and recovery were determined by applying the full procedure to six replicate samples of WSLS (2 g) spiked with BP (15 or 30 ng). Table 3 lists the precisions (%RSD) and recoveries (%R) obtained.

4. Conclusions

The combination of a straightforward purification step and analysis by constant-wavelength synchronous spectrofluorimetry provides a simple, rapid, inexpensive method for the determination of benzo[a]pyrene in WSLS, a widely-used food additive. Method precision (%RSD < 6) and recovery ($\approx$ 92%) are satisfactory, and the quantitation limit (2.28 μg kg^{-1}) is considerably less than the maximum permissible concentration of BP in smoke flavourings (10 μg kg^{-1}), which, according to the FAO/WHO Joint Committee on Food Additives [6], corresponds to the minimum concentration of benzo[a]pyrene that can be quantified in such flavourings. In the light of these results, we recommend that the maximum permissible concentration of BP in smoke flavourings be reviewed, and accordingly reduced, in order to lessen human exposure to benzo[a]pyrene through ingestion of foodstuffs treated with smoke flavourings.

Kinetic analysis of arginase–urease coupled reaction with a surface acoustic wave enzyme sensor system

Dezhong Liu, Lihua Nie, Shouzhuo Yao*

Department of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, People's Republic of China

Abstract

An extended set of equations which describe coupled arginase–urease reactions is presented. The mathematical treatment leads to the development of new equations which relate the lag-time required for the concentration of urea to reach a defined fraction of its steady-state concentration to the kinetic parameters of the enzymes, when the steady-state concentration of urea is small compared to its Michaelis constant value. the coupled arginase–urease reaction was monitored with a surface acoustic wave (SAW) enzyme sensor system, to couple the biochemical selectivity of enzymes with the sensitivity of SAW sensors. The proposed theoretical expressions were verified experimentally. The kinetic parameters of urease and arginase (extracted directly from bovine liver) were examined under theoretical guidance. Dependence of the lag-time of the coupled enzyme reaction on the concentrations of urease and arginase is also described.

Keywords: Arginase–urease reactions; Kinetic analysis; Mathematical treatment; Surface acoustic wave enzyme sensor system

1. Introduction

As analytical reagents, enzymes offer the characteristic of high selectivity (and occasionally specificity). Enzymes have been widely used in analytical chemistry owing to their substrate specificity. Enzyme-based analytical procedures may be designed to determine the concentrations of substrates, coenzymes, activators and inhibitors.
All of these possible applications, together with enzymatic kinetic assay, are included in the term enzymatic analyses.

The equations relating the rate of an enzyme to the rate of appearance of a detectable product resulting from subsequent (auxiliary) enzyme reactions were first developed by McClure [1] for systems involving two auxiliary enzymes. These were later extended by others to include multienzyme systems and methods to minimize the cost of a two auxiliary enzyme system [2–4] were developed. So far there is no report on the deriva-

* Corresponding author.

tion of kinetic equations for an arginase–urease coupled reation. Kinetic procedures for the estimation of arginine or the activity of arginase have only been reported [5–7].

The purpose of this paper is to provide a theoretical derivation of the kinetic equations for an arginase–urease coupled reaction and to make an experimental evaluation. The kinetic parameters

$$
\underset{\substack{|\\ NH_2}}{\overset{\substack{H \qquad\qquad NH_2\\ |\qquad\qquad\ |}}{HOOC-C-(CH_2)_3-NH-C=NH}} + H_2O \xrightarrow{\text{Arginase}} \underset{\substack{|\\ NH_2}}{\overset{\substack{H\\ |}}{HOOC-C-(CH_2)_3-NH_2}} + O=C(NH_2)_2
\tag{2}
$$

of the arginase for arginine as substrate are also determined based on the proposed kinetic theory.

2. Theory

The derivations rely on the fulfillment of the following three assumptions: (1) the enzyme reaction obeys Michaelis–Menten kinetics; (2) the steady-state concentration of the substrate (urea) produced from the hydrolysis of arginine by arginase is much less than the apparent Michaelis constant for the subsequent urease; and (3) only the initial rate conditions are considered (the reverse reactions are negligible). Whereas none of the above conditions are necessary for the development of the kinetic theory for the coupled enzyme reactions, the last two conditions are easily achieved by selecting appropriate substrate concentrations.

In a previous paper [8], the correlation between the frequency shift of the SAW (surface acoustic wave) sensor system and the conductivity of the test solution was derived by using circuit network theory, and was also verified experimentally. There is a relationship between the frequency-shift (ΔF) of the SAW enzyme sensor system and the conductivity change of the test solution ($\Delta\kappa$) durint the enzymatic reactions:

$$
\Delta F = a\Delta\kappa + b
\tag{1}
$$

where a and b are constants resulting from the SAW oscillator, the detection cell, the solution conductivity range and other experimental condi-

tions. The sensor possesses a sensitive response to the change of ion species in the test solution. In addition, interferences caused by mass, viscoelastic properties can be avoided. Only the alteration of conductivity in the test solution can produce a frequency shift in the sensor system.

The enzymatic catalytic reaction proceeds via arginase as shown below:

Conductivity is not affected by the reaction. However, the reaction may be monitored with the SAW enzyme sensor system if it is coupled to a second reaction, in which the urea formed in the first reaction acts as a substrate for urease to hydrolyze:

$$
O=C(NH_2)_2 + 3H_2O \xrightarrow{\text{Urease}} HCO_3^- + 2NH_4^+ + OH^-
\tag{3}
$$
The second reaction involves the production of three kinds of charged species from a neutral compound (urea), resulting in an abrupt change in the concentration of ions, so the course of the reaction may be followed by measuring the frequency-shift response with time according to Eq. (1) by means of the SAW enzyme sensor system. The kinetic frequency-shift response of the SAW enzyme sensor system to the above coupled enzyme reaction was recorded and the reaction rate obtained. With careful selection of the reaction conditions, the rate of the second reaction will be an indicator of the rate of the first reaction.

The above-mentioned reactions can be considered as the general situation:

$$
A \xrightarrow[v_1]{E_1} B \xrightarrow[v_2]{E_2} C
\tag{4}
$$

The substrate A that has to be determined reacts under the catalysis of the enzyme E_1 to give B. The product is also hydrolyzed in the presence of enzyme E_2 and B can be easily detected. In the kinetic process of this system, the concentration of A is initially A_0, and drops to zero; the concentration of B is initially zero, rises until it achieves

a maximum and then drops to zero again. In the experiment, the response signal (frequency shift, ΔF), which is proportional to the concentration of B, is read at several intervals.

In general, the rate of [B] is given by

$$\frac{d[B]}{dt} = v_1 - v_2 \tag{5}$$

where v_1 is the rate of the first (primary) reaction and v_2 the rate of the second (indicator) reaction. As with the rate of any single-enzyme system, v_1 should reach a constant value almost instantaneously and remain at this value over the period of interest (the next few minutes). In contrast, v_2 will have an initial value of zero (since [B] is initially zero) and will rise as [B] rises, according to the Michaelis–Menten equation [9,10]:

$$v_2 = \frac{V_B[B]}{[B] + K_B} \tag{6}$$

where V_B is the maximum reaction rate for the enzyme E_2 and K_B is the Michaelis constant for the substrate B. Similarly, the following equation can also be obtained:

$$v_1 = \frac{V_A[A]}{[A] + K_A} \tag{7}$$

where V_A is the maximum reaction rate for the enzyme E_1 and K_A is the Michaelis constant for the substrate A.

The observed steady-state rate (v_{obs}) of the coupled enzyme reaction is simply the rate of enzyme E_2:

$$v_{obs} = V_B[B]_{ss}/(K_B + [B]_{ss}) \tag{8}$$

When the steady-state concentration $B([B]_{ss})$ is less than 0.01 K_B, Eq. (8) simplifies to the relationship:

$$v_{obs} = V_B[B]_{ss}/K_B \tag{9}$$

In order to calculate the elapsed time before the onset of the steady state, an expression for formation of B in terms of time (t) must be obtained. Combining Eqs. (5) and (6) gives the following expression:

$$\frac{d[B]}{dt} = v_1 - \frac{V_B[B]}{[B] + K_B} \tag{10}$$

The above equation is the difference between the rate of formation of $B(v_1)$ and the rate of its destruction. At steady state, when $d[B]/dt = 0$, Eqs. (10) and (8) predict:

$$v_1 = v_{obs} = d[C]/dt \tag{11}$$

Eq. (11) implies that, when the reaction reaches the steady state, the observed rate will be that of enzyme E_1. this is illustrated in Fig. 1. A plot of v_{obs} vs. v_1 gives a straight line with a slope of one until the rate of enzyme E_1 is equal to the rate of enzyme E_2; at this point and at all values of v_1 in excess of V_B, the observed rate equals V_B.

By assuming [B] = 0 at $t = 0$ and holding v_1 and V_B constant with respect to time, integration of Eq. (10) gives:

$$\int \frac{(K_B + [B])}{v_1 K_B + [B](v_1 - V_B)} d[B] = \int dt \tag{12}$$

From Eq. (12), the following equation for [B] at any time t is obtained:

$$(K_B v_1 - \phi[B]) \exp[\phi[B]/(K_B V_B)]$$
$$= K_B v_1 \exp[-t\phi^2/(K_B V_B)] \tag{13}$$

where $\phi = V_B - v_1$. When $v_1 \ll V_B$ and $[B] \ll K_B$, Eq. (13) gives:

$$[B] = K_B v_1/V_B(1 - \exp[-tV_B/K_B]) \tag{14}$$

By defining

$$\beta = [B]/[B]_{ss} \times 100\% \tag{15}$$

Fig. 1. Theoretical prediction from Eq. (11). Note that $v_1 = v_{obs}$ for all values of $v_1 < V_B$. The Figure presupposes measurements at infinite time.
Fig. 2. Theoretical relationship between $\log(v_1/V_B)$ and the time required for B to reach 99% of its steady-state value calculated from Eq. (17). Each curve represents a different value of V_B: (1) 16.0; (2) 8.00; (3) 4.00; (4) 2.00; (5) 1.00 kHz min^{-1}. K_B value (Michaelis constant for urease) was experimentally estimated as 1.65 mM.

where [B] is the concentration of the substrate B at any time t and $[B]_{ss}$ is the concentration of B in the steady state given by

$$[B]_{ss} = \frac{v_1 K_B}{(V_B - v_1)} = \frac{v_1 K_B}{\phi} \qquad (16)$$

We can combine Eqs. (13), (15) and (16) to obtain:

$$t_\beta = \frac{-K_B}{\phi^2}[\beta v_1 + V_B \ln(1 - \beta)] \qquad (17)$$

where t_β is the lag-time before B reaches a defined fraction of its steady-state concentration as given by Eq. (15). Provided that $v_1 \ll V_B$, Eq. (17) can be simplified as

$$t_\beta = -\frac{K_B}{V_B}\ln(1 - \beta) \qquad (18)$$

Fig. 2 shows the relationship between the lag-time (t_β, with $\beta = 99\%$) calculated from Eq. (17) and the ratio (v_1/V_B). Note that, as the ratio v_1/V_B increases above 0.1, the time required for B to achieve 99% of its steady-state concentration increases dramatically. If β is selected as 95%, the actual lag-times are shorter, but follow the same trends as seen for $\beta = 99\%$. Thus v_1/V_B should be

less than 0.1 if the steady-state rate is to be reached under conditions where the steady-state assumptions are still valid. This is particularly important when kinetic data for enzyme E_1 are examined at concentrations of substrate which are less than the value of the Michaelis constant. In addition, the t_β value reflects the time required for the substrate (B) concentration to achieve a defined fraction (β) of its steady-state concentration ($[B]_{ss}$). In order to determine the kinetic parameters of E_1 accurately, the amount of enzyme E_2 must be in as great an excess as possible so that the observed rate is directly proportional to the amount of substrate A or enzyme E_1 added. Therefore, the kinetic parameters of enzyme E_1 can be estimated by using a Lineweaver–Burke plot [10] which was derived from Eq. (7):

$$\frac{1}{v_1} = \frac{1}{V_A} + \frac{K_A}{V_A[A]} \qquad (19)$$

3. Experimental

3.1. Apparatus

The apparatus used in this work was in principle identical to that described previously [11], where 10 ml detection cell was used. The whole experimental set-up is illustrated in Fig. 3. In order to maintain constant temperature, the whole assembly was thermostated in a double-lay-

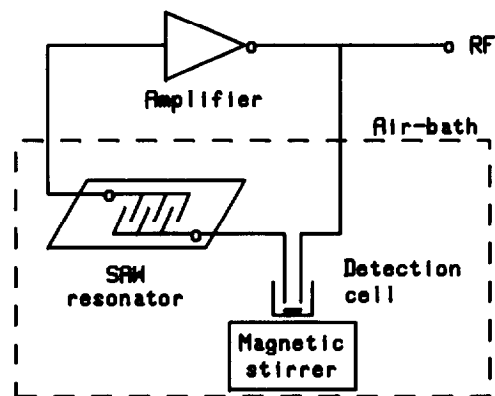

Fig. 3. Sketch of the whole experimental set-up.

ered air-bath thermostating equipment (laboratory made) which was monitored and controlled by a temperature controller (Modes WMZK-01, Shanghai Medical Instrument Corporation). This arrangement permitted the temperature of the system to be maintained within $\pm 0.2°C$.

3.2. Reagents

Urease (E.C. 3.5.1.5, from jack bean) was obtained from BDH Chemicals Ltd., Poole, UK. The enzyme activity, determined by the standard procedure [12], was found to be 1.7 E.U. mg^{-1}. Arginase (L-arginine urea hydrolase, E.C. 3.5.3.1, from bovine liver) was obtained from Shanghai Biochemical Institute of Chinese Scientific Academy. The enzyme activity, determined by the standard procedure [13], was found to be 25.0 E.U. mg^{-1}.

Arginase was also extracted from bovine livers (freshly obtained from a local slaughter house) using the following procedure. A fresh bovine liver (≈ 250 g) was sliced with a razor blade and kept frozen for several hours in a refrigerator. The frozen liver slices were disrupted carefully with a universal mincer. A portion (100 g) of the liver paste was mixed with 200 ml of 0.02% sodium azide–20% glycerol (all in w/v, pH was adjusted to 7.5 with a small volume of 0.1 M NaOH). The mixture was shaken on an oscillating machine for 30 min (275 times per minute) at room temperature and kept in a refrigerator for 6 hs. It was stirred periodically. Finally, the mixture was filtered with a vacuum pump and two phases were separated. The crude extract was directly used in the measurements below without further purification. The enzyme activity of arginase in the extract, estimated by the standard procedure [13], was found to be 3.0 E.U. ml^{-1}. When not in use, the arginase extract should be kept cold (4°C).

All other chemicals used were of analytical grade. Distilled–deionized water was used for preparing all solutions. 1.0 mM Tris-EDTA (pH 8.5) was used as working reagent. The stock arginine solution was 0.10 M in 1.0 mM Tris-EDTA working reagent. Urease was dissolved in 0.02% sodium azide–20% glycerol (pH 7.5) to yield a final concentration of 17 E.U. ml^{-1}.

3.3. Procedure

Working reagent, arginase solution and urease solution were prewarmed at 30°C just before use. In a typical experiment, 8.70 ml working reagent, 0.50 ml urease solution and 0.80 ml arginase extract were pipetted into the detection cell. The cell was placed in a thermostated air-bath chamber and incubated for 4 min. This allowed any side-reactions to reach completion since there is a small content of urea in the arginase extract. The platinum electrode was inserted into the cell. The reaction was started by the addition (with a microsyringe) of 50 μl of standard arginine solution into the cell (total volume of test solution was 10 ml). Frequency was recorded with time. The blank frequency-shift response was made in the same way but without adding arginine solution. The temperature of the test solution was kept at $30.0 \pm 0.2°C$ during measurements.

4. Results and discussion

4.1. Kinetic parameters of urease and arginase

To test the theoretical expressions proposed in the previous section, the coupled enzyme system involving both arginase and urease was examined. It is necessary to know the kinetic parameters of urease prior to the present study. Therefore, a kinetic assay was conducted to determine the value of K_B under the following conditions: 1.0 mM Tris-EDTA; pH 8.5; 30°C; 0.85 E.U. ml^{-1} urease; urea standards varying from 0.042 to 0.50 mM. The Lineweaver–Burke plot yields a K_m value for urease of 1.65 $mM(K_B)$, which is of the same order of magnitude as that reported for jack bean [14], and a corresponding maximum initial rate, V_B, of 6.25 kHz min^{-1}.

According to Eq. (17), a short lag-time is desirable when measuring the kinetic parameters of arginase. Hence an excess of urease was necessary in order to ensure prompt conversion of all the urea formed and that the observed rate is directly proportional to the concentration of arginine. Kinetic parameters of arginase were measured by using the SAW enzyme sensor system according

to Eq. (19). Under the selected conditions (1.0 mM Tris-EDTA; pH 8.5; 30°C; 0.24 E.U. ml⁻¹ arginase; 2.55 E.U. ml⁻¹ urease) arginine standards varied from 0.050 to 0.50 mM. Experimental results give $K_A = 12.0$ mM and $V_A = 4.78$ kHz min⁻¹. the K_m value of arginase is of the same order of magnitude as literature values of 10–20 mM (for rat liver arginase) [15,16].

4.2. Selection of reaction conditions

The reaction mixture must be buffered, and the buffer will contribute a background conductance. A low concentration of Tris-EDTA buffer (1.0 mM), with its low intrinsic conductivity, was selected as the reaction medium. One further factor which needs to be taken into account is the pH profiles of the various enzymes involved. Clearly, it is essential that all the component enzymes are active at the pH used for assay, and the narrow ranges of activity of some enzymes pose problems in this respect. However, in practice, arginase is active around pH 8–10 and urease around pH 7–8. Both enzymes are sufficiently active at about pH 8.5, but at no pH value are both enzymes active enough to be coupled together. Experimental results showed that the optimum pH was 8.5 and an especially sharp decrease of the reaction rate was observed above pH 9.0. Therefore, all supsequent investigations were performed at pH 8.5. The influence of temperature on the coupled reaction was similarly studied in the range 10–50°C. The reaction rate increases with increasing temperaure in the range 10–37°C, but decreases rapidly with increasing temperature above 40°C. 30°C was therefore selected for further experiments.

4.3. Response of the SAW enzyme sensor system

Typical responses of the SAW enzyme sensor system to different concentrations of arginine solution are depicted graphically in Fig. 4. It can be seen that frequency-shift response, or the reaction rate, increases with increase in arginine concentration. The slopes of the curves at any given time are related to the rates of the coupled enzyme reactions at that point in time. As described previously [11], there is a correlation between fre-

Fig. 4. Typical frequency-shift response curves for various concentrations of arginine: (1) 0.50; (2) 0.40; (3) 0.30; (4) 0.20; (5) 0.15; (6) 0.10; (7) 0.05; (8) 0.00 mM. The determination was carried out under the following conditions: 0.24 E.U. ml⁻¹ arginase extracted from bovine liver, 2.55 E.U. ml⁻¹ urease, 8.50 ml working reagent. Total volume of the detection solution was 10.0 ml and pH in the reaction medium was 8.5.

quency-shift (ΔF) and urea concentration ($\Delta F = 107.5$[Urea] + 3), or a relationship between the rate of urea hydrolysis (v_2) and urea concentration ($v_2 = 60.5$[Urea] + 13), where [Urea] is expressed in μg ml⁻¹, ΔF in Hz, and v_2 in Hz min⁻¹. The response curve of the SAW enzyme sensor system is analogous to that of a normal enzyme kinetic reaction [17]. Only about 10 s of lag-time was observed in this procedure since the concentration of urease was quite large (2.55 E.U. ml⁻¹ in 10 ml of test solution).

4.4. Dependence of lag-time of the coupled enzyme reaction on urease concentration

For the arginase–urease coupled reaction, the observed reaction rate changes over the time course of the experiment. The final steady-state rate is achieved after a definite lag-time. Hence it is important to calculate or measure the lag-time because the observed initial rate does not accurately reflect the rate of the arginase before a lag period has elapsed. Investigations show that the observed lag-time ($t_{99\%}$) depends on the kinetic constant of urease—maximum reaction rate of urease—which is directly proportional to its con-

centration. A short lag-time is desirable since the shorter the lag-time, the lower the steady-state concentration of urea in the coupled reaction and the less substrate is consumed before the steady state is observed. At the same time, it is worth noting that the shorter the lag-time, the more coupled enzyme is required (Table 1).

The arginase-urease coupled reaction has an appreciable lag-time (about 1 min) before the steady state is reached. The lag-time depends mainly on the concentration of urease. In addition, complete mixing of the sample and reagents cannot be achieved instantaneously and it may take seconds to reach the linear phase. Hence it should be possible to choose reaction conditions which ensure that the procedure gives a reasonable estimation of the initial rate.

Fig. 5 shows the frequency-shift response of the SAW enzyme sensor system to arginine with different concentrations of urease. It can be seen that the lag-time of the coupled enzyme reaction was reduced and the frequency-shift response increased with increasing urease concentration. The experimental and calculated results of lag-time are listed in Table 1. The values coincide with each other. As can be seen from Table 1, the lag-time

Fig. 5. Frequency-shift response of SAW enzyme sensor system for different amounts of urease: (1) 3.40; (2) 8.50; (3) 13.6; (4) 17.0; (5) 25.5 E.U. in 10 ml test solution. 0.15 E.U. ml^{-1} arginase and 0.50 mM arginine were selected in this procedure.

of the coupled enzyme reaction was reduced with increasing urease concentration. However, the reaction rate decreases when the concentration of urease added is greater the 1.70 E.U. ml^{-1}. This phenomenon shows that the excess urease has been added under these conditions.

4.5. Dependence of lag-time of the coupled enzyme reaction on arginase concentration

Fig. 6 shows the frequency-shift response of the SAW enzyme sensor system to arginine with arginase in different concentrations. It can be seen that the frequency-shift response, i.e. the reaction rate, increases with increase in arginase concentration. At the same time, the reaction rate is reduced provided that the concentration of arginase is greater than 0.24 E.U. ml^{-1}. This phenomenon shows that excess arginase has been added under these conditions. However, with the increase in arginase concentration, the lag-time of the coupled enzyme reaction changes only slightly as shown in Table 1. According to Eq. (18), the lag-time depends only on the values of K_B and V_B if $v_1 \ll V_B$. Hence the lag-time will not alter while the reaction conditions and the concentration of urease are kept constant. The experimental results are consistent with the theoretical prediction.

Table 1
Comparison between the experimental and theoretical lag-time results for the arginase-urease coupled reaction

Enzyme concentration (E.U. ml^{-1})		Lag-time, $t_{99\%}$ (s)	
Urease	Arginase	Experimental value[a]	Theoretical value[b]
0.34	0.15	105.2 ± 7.5	100.2
0.85	0.15	54.3 ± 5.0	58.5
1.36	0.15	42.9 ± 4.6	42.4
1.70	0.15	27.4 ± 2.9	30.0
2.55	0.15	11.5 ± 2.5	9.7
0.85	0.03	45.8 ± 4.5	43.4
0.85	0.09	47.4 ± 4.6	44.6
0.85	0.24	49.5 ± 4.4	47.1
0.85	0.30	40.5 ± 4.5	44.0

[a] The experimental results were obtained under the conditions: 1.0 mM Tris-EDTA; pH 8.5; 30°C; 0.50 mM arginine standard.
[b] Theoretical values were calculated according to Eq. (17) where $K_B = 1.65$ mM, $V_B = 6.25$ kHz min^{-1} and $\beta = 99\%$.
Fig. 6. Frequency-shift response of SAW enzyme sensor system for different amounts of arginase which was extracted from bovine liver: (1) 0.30; (2) 0.90; (3) 1.50; (4) 2.40 (5) 3.00 E.U in 10 ml test solution. 0.85 E.U. ml^{-1} and 0.50 mM arginine were selected in this procedure.

4.6. Reproducibility

The reproducibility of the lag-time was examined. For 0.85 E.U. ml^{-1} urease, 0.24 E.U. ml^{-1} arginase and 0.50 mM arginine, five measurements gave a relative standard deviation of 8.9%. As can be seen in Table 1, the absolute error of the lag-time becomes larger with the decrease of the lag-time (experimental values of lag-time given in this Table are obtained from three measurements).

In conclusion, the kinetic equations for the arginase–urease coupled reaction are derived. The theoretical results are verified experimentally. The kinetic parameters of the arginase (extracted directly form bovine liver) and the lag-time of the coupled enzyme reaction have been estimated satisfactorily under the theoretical guidelines.

A thin liquid film thickness shear mode bulk acoustic wave sensor for determination of *Proteus mirabilis*

Lili Bao, Le Deng, Lihua Nie, Shouzhuo Yao, Wanzhi Wei*

Department of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, People's Republic of China

Received 26 May 1995; accepted 2 October 1995

Abstract

A thickness shear mode bulk acoustic wave sensor coated with a thin liquid culture medium film was developed and applied to determine the concentration of *Proteus mirabilis* (*P. mirabilis*). Experiments demonstrated that there was a good linear relationship between the turning point time and the logarithm of the *P. mirabilis* concentration in the range 2.0×10^2–2.0×10^6 cells ml^{-1}. The detection was fast and accurate because of the sharp turning point of the response due to the thin culture film on the sensor surface. Other problems concerning the experiments are discussed in detail.

Keywords: Acoustic wave sensor; Thickness shear mode; Thin film; *Proteus mirabilis*

1. Introduction

The successful oscillation of the thickness shear mode (TSM) bulk acoustic wave sensor in the liquid phase in the 1980s initiated an entirely new field of research for the TSM sensor [1–3]. Since then, the TSM sensor, as a fast, convenient and sensitive analysis tool, has been used more extensively in various areas, e.g. for determining microcomponents in solution [4], for determining bio-macromolecules [5] and for monitoring blood clotting [6].

Recently, research concerning the use of the TSM sensor as a powerful tool for the determination of bacteria was reported [7,8]. These new methods, mainly based on mass or conductivity response, are faster and more sensitive compared with conventional methods such as the pour plate counts (PPC) technique, the most probable number technique, and the turbidity method, all of which are cumbersome and time-consuming. Therefore, these new methods are important in practice. However, when the techniques are used, the antibodies are usually difficult to acquire in the immune methods and in the conductivity response methods the accurate determination of frequency detection time (FDT) is not easy since the response curve change near the FDT is very slow,

* Corresponding author.

so the analysis precision strongly relies on the experience of the analysts. In addition, the amount of sample needed is considerable. Because of the above reasons, it is imperative to develop a better method.

P. mirabilis is Gram-negative, is a member of the genus *Proteus* within the family Enterobacteriaceae, occurs widely in humans, animals and in the environment, and can be readily recovered from sewage, soil, garden vegetables and many other materials. It is often found as a contaminant of shigellae, appears in the stools of patients recovering from bacillary dysentery, and occurs as a secondary invader in wounds and bedsores. Hence the determination of *P. mirabilis* is of practical importance in food hygiene, clinical medicine and environmental monitoring.

Usually, the TSM sensor, as a non-mass sensor, can response to viscosity and density changes of liquid. Kanzawa and Gordon's research [9] indicated that the following equation is effective under certain experimental conditions:

$$\Delta F = -F_s^{3/2}(\eta\rho_L/\pi\mu\rho_Q)^{1/2} \tag{1}$$

where ΔF is the resonant frequency change of the crystal, F_s is the resonant frequency, η is the viscosity of the liquid, ρ_L is the density of the liquid, μ is the shear modulus of quartz, and ρ_Q is the density of quartz. The detection of *P. mirabilis* with the TSM sensor presented in this paper was mainly based on the changes in viscosity and density. The response also included mass and surface stress effects. When the medium coagulated, the viscosity and density of the medium changed; meanwhile, complicated mass and surface stress changes took place. After some bacteria were added and grew in the liquid medium, the coagulation character of the medium was changed. The change was related to the initial bacteria concentration and so the gelation process was used to detect the bacteria concentration on the coagulation frequency curve, the time at which the frequency begins to increase was a sharp turning point. It was defined as turning point time (TT) and was found to be linearly related to the logarithm of the initial concentration of bacteria. The TT was very easy to determine because of the sharp turning point on the

response curve. Detection time and amount of sample needed were also reduced further. Only a micro-medium and less than 4 h detection time were needed.

2. Experimental

2.1. Stock medium

The composition of stock medium is as follows: beef extract, 1 g; yeast extract, 2 g; peptone, 5.0 g; NaCl, 5.0 g; doubly-distilled water, 1000 ml. The medium was dispensed into bottles and sterilized by autoclaving at 121°C for 15 min.

2.2. Stock culture

A 20 ml volume of medium was placed in a 50 ml sterilized conical vial and four loops of *P. mirabilis* on slant agar were inoculated with an inoculating loop. After incubation for 16 h at 37°C, the conical vial was removed from the incubator and stored in a refrigerator. The culture gave and approximate concentration of 3.1×10^7 cells ml^{-1}.

2.3. Coating solution of medium film

The composition of incubating medium is as follows: beef extract, 1.5 g; peptone, 2.5 g; gelatin, 0.4 g; doubly-distilled water, 1000 ml. The medium was sterilized before use. One aliquot of incubating medium and two aliquots of bacteria solution were mixed and, after incubation, the mixture was coated on the sensor surface and then the coagulation process was determined.

2.4. Incubation of P. mirabilis

The optimum temperature of a bacterium is approximately that of its natural habitat, i.e. about 37°C in the case of organisms that are parasitic in humans and warm-blooded animals [10], and the majority of commensal and pathogenic bacteria grow best in a neutral or very slightly alkaline reaction medium (pH 7.2–7.6) [10]. In order to ensure that the *P. mirabilis* grows

well and rapidly, and so as to obtain good reproducibility, the incubation was performed under the same conditions described in the literature [10].

2.5. Apparatus

The TSM sensor used was a 9 MHz AT-cut quartz crystal (diameter 12.5 mm) with silver electrodes (diameter 5.5 mm) on both sides. One side of the electrode was sealed and the other side was coated with liquid film. A thermostat was used to control the temperature at 37°C. A Model SC7200 Isutax universal frequency counter was employed to record frequency.

2.6. Frequency curve measurement

In a sterilized bottle, two aliquots of bacteria solution were added to one aliquot of medium and thoroughly mixed. Then, after incubation at 37°C for 4 h, the bottle was removed from the incubator and stored in a refrigerator. For the detection, 50 μl of mixture was coated on the sensor surface and the sensor was then placed in a thermostat and the frequency was recorded every 10 min or for a shorter time interval near the TT. At the end of the experiment it was observed that the film coagulated and a flat solid membrane formed.

2.7. Comparison of TT detection with standard PPC technique

P. mirabilis was inoculated in pure cultures of various concentrations and the TTs were determined with the TSM sensor. From Eq. (2), which will be discussed below, the numbers of cells were obtained. At the same time, the same amount of P. mirabilis was also measured by the standard PPC.

3. Results and discussion

3.1. Conditions of determination

The volume of coating solution was a key factor in the coating process of the film. Experimentally, 50 μl was suitable for practical deter-

minations. Firstly, 30–40 μl of solution was coated. It was found that the solution was not able to spread over the whole sensor surface. When 80 μl was coated, the solution was arched on the sensor surface (that is to say, the solution was able to spread over the sensor surface) and the film was apparently flat. Thus the reproducibility of the result was influenced in both cases. However, the use of 50 μl of solution made it easy for the solution to spread over the whole sensor surface and the film was not as arched. As a result, good reproducibility was obtained and a 50 μl volume was employed in the following experiments.

The composition of the medium film and the temperature and humidity of the coagulating process were related to the coagulation time.

When 50 μl of film, containing one aliquot of medium and three aliquots of water was coated on the sensor surface no obvious frequency change was observed after 6 h and it could be seen that the coated film did not coagulate. However, when a film with a mixture of one aliquot of medium and one aliquot of water was employed, although the coagulation time shortened, oscillation of the sensor was found to be difficult and so the TT could not be determined accurately. This was probably because the solid membrane formed at the end of the coagulation process was too thick. The film with the composition of one aliquot of medium and two aliquots of water provided quick coagulation and easy oscillation and was therefore used in the following experiments.

In order to study the effect of coagulating temperature, a mixture of one aliquot of medium and two aliquots of bacteria solution was coated on the sensor surface and the coagulation process was investigated at different temperatures. Results shown in Fig. 1 indicate that the increase in temperature reduces coagulation time. This may be because at higher temperature water in the medium is volatilized more rapidly. A coagulation temperature of 37°C was chosen because a higher temperature made the oscillation of the sensor unstable and at a lower temperature the coagulation time was too prolonged.

To test the effect of humidity on coagulation, a mixture of medium and water was used to observe
Fig. 1. Effect of coagulating temperature on detection. Coagulation of mixture of medium and water: (1) $T = 37°C$; (2) $T = 28°C$.

the coagulation process at different humidities. The TT was found to increase with the increase in humidity. The reason was that the decrease in humidity made the volatilization of water from the medium easier and more rapid. Thus the coagulation was performed at a relative humidity of about 50%.

3.2. Typical response curve

Typical response curves are shown in Fig. 2; it can be seen that the coagulation process of the medium was rather complicated. When no bacteria were added, the frequency decreased very slowly at first, then dropped quickly, and finally,

Fig. 2. Typical response curves. Initial concentration of P. mirabilis (cells ml^{-1}): (1) 2.0×10^6; (2) 2.0×10^4; (3) 0.

Fig. 3. TT calibration graph for the determination of P. mirabilis.

after an increase, reached a stable value. The time at which the frequency began to increase, i.e. the TT, was 132 min. After the growth of bacteria in the medium, the gelation curve shape was the same but the TT was delayed: the increase in the bacteria concentration results in an increase in the time delay. As the TT was sharp and the linear relationship between the TT and the logarithm of the bacteria concentration was good, the TT was employed in the practical determinations.

3.3. Determination of P. mirabilis

Various concentrations of P. mirabilis were inoculated in the medium and incubated at 37°C for 4 h, after which the mixture was stored in a refrigerator. When P. mirabilis was detected, it was coated on the TSM sensor and the frequency was recorded at different time intervals. Frequency curves were constructed and the TTs were measured, then a calibration graph of TT vs. logarithm of P. mirabilis concentration was constructed. The results (Fig. 3) showed that the TT was linearly related to the logarithm of the initial concentration (C) of the P. mirabilis, with C in the range of $2.0 \times 10^2 - 2.0 \times 10^6$ cells ml^{-1}. The regression equation is

$$\log C = 0.07 \,(\text{TT}) - 7.62 \qquad (2)$$

where C is the initial concentration of P. mirabilis in cell ml^{-1} and TT is the turning point time in

Table 1
Comparison of the bacteria concentration predicted by the TT tehcnique with that obtained from the PPC method

No.	Concentration predicted by TT method[a] (cells ml^{-1})	Logarithm of predicted value	Concentration obtained from PPC method (CFU[b] ml^{-1})	Logarithm of pour plate value
1	2.7×10^2	2.43	3.0×10^2	2.48
2	7.5×10^3	3.88	3.7×10^3	3.57
3	3.3×10^3	3.52	3.8×10^3	3.58
4	3.9×10^4	4.59	4.3×10^4	4.63
5	3.7×10^5	5.57	1.8×10^5	5.26
6	5.1×10^5	5.71	5.8×10^5	5.76
7	1.2×10^6	6.08	2.3×10^6	6.36

[a] Calculated by Eq. (2).
[b] CFU = colony forming units.

min; the correlation coefficient is 0.96 ($n = 5$). Hence, if the TT is determined the concentration of *P. mirabilis* can be calculated according to Eq. (2).

The standard error of the regressioin line is $S = 0.525$.

$$\log C = 0.07 \, (\text{TT}) - 6.57 \tag{3}$$

$$\log C = 0.07 \, (\text{TT}) - 8.67 \tag{4}$$

The area between the two lines plotted from Eqs. (3) and (4) is the 95% confidence range.

The concentration of the stock culture bacteria solution of *P. mirabilis* was obtained by the PPC technique. The solutions used in the determination were obtained by a series dilution of the stock culture solution. Therefore, the initial concentrations of the series bacteria solutions were calculated according to the dilution.

3.4. Comparison of the TT technique with the PPC method

The proposed method was compared with the conventional PPC method for determining *P. mirabilis*. The results are given in Table 1. It can be seen that all the PPC values fall inside the 95% confidence area of the TT predicted concentrations. Therefore it can be concluded that the TT method agrees well with the PPC technique.

3.5. Two further response parameters

After a thorough investigation of the response curve, two further response curve parameters were found to be related to the initial concentration of *P. mirabilis*. As shown in Fig. 2, after a horizontal portion of the curve, the frequency decreased very slowly at first, then dropped quickly, and finally, after an increase, reached a stable value. The time at which the frequency begins to decrease was defined as the decrease time (DT) and was found to be delayed when the concentration of *P. mirabilis* rose. There was a linear relationship between the DT and the logarithm of the *P. mirabilis* concentration (Fig. 4). The regression equation is as follows:

Fig. 4. DT calibration graph for the determination of *P. mirabilis*.

Fig. 5. Relationship between the increase in the slope of frequency and the logarithm of the P. mirabilis concentration.

$$\log C = 0.05\,(DT) - 3.19 \tag{5}$$

where C is the same as in Eq. (2) and DT is the time at which the frequency begins to decrease (min). The correlation coefficient is 0.97 ($n = 5$).

The slope of the increase of the frequency after the TT of the curve was also related to the initial P. mirabilis concentration. With the increase in the P. mirabilis concentration, the slope of the frequency increase was found to become more steep (Fig. 5).

The precision of the DT and TT methods when determining P. mirabilis was approximately the same and so both methods could be used for the quantitative detection of P. mirabilis. However, the DT was not so obvious on the frequency curve compared with the TT and thus was not so easy to determine. As for the slope of the increase in the frequency after the TT on the curve, the relationship between the slope and the logarithm of the P. mirabilis concentration was complicated. Therefore, the TT was preferred for quantitative detection in these experiments when considering its ease of determination and the simplicity of its relationship with the logarithm of the P. mirabilis concentration.

In conclusion, this method employed the evident coagulation process of the medium to detect microorganisms indirectly. The TT used for quantitative determination was easy to determine because of the sharp turning point of the response curve and was in good linear relationship with the logarithm of the bacteria concentration. This method is rapid and simple with high sensitivity, and only a micro-sample is needed. It can be used to determine the concentration of bacteria, to study the coagulation process of biomolecules and the influence of microorganisms on biomolecules. It can also be used in bacteria growth monitoring.

Abstract

A newly developed fiber-optic-based trichloroethylene (TCE) sensor previously described [F.P. Milanovich, S.B. Brown, B.W. Colston, Jr., P.F. Daley and K. Langry, Talanta, 41 (1994) 2189], was used to provide analyses of TCE in laboratory tests of retardation of TCE in ground water. The sensor enabled inexpensive real time analyses of TCE in retardation tests conducted in a sand-filled flow-through column. The simultaneous data analysis of TCE, ^{18}O and Cl^- breakthrough curves enabled the calculation of an estimated retardation coefficient which was found to be in good agreement with that predicted by the octanol/water partitioning K_d method. The fiber-optic sensor was demonstrated to be a fast and reliable method for conducting on-line laboratory analyses of TCE at the parts per billion level in a small volume of contaminated water, thus providing excellent temporal resolution of the data as well as minimizing volatile losses during sample collection and analysis.

1. Introduction

Throughout the world, major economic and public health decisions are being made in the investigation and attempted cleanup of aquifers contaminated by volatile organic compounds (VOCs), many of which are classified as probable human carcinogens, such as trichloroethylene (TCE).

In addition to the determination of the extent and degree of ground water contamination, the prediction of contaminant movement in aquifers is often required. The analysis of contaminant transport in ground water is very sensitive to the retardation factor, i.e. the relationship of the linear velocity of the ground water to the linear velocity of the contaminant. The retardation factor (R) for a ground water contaminant is calculated by [2]

$$R = V_w/V_c = 1 + (\rho_b/n)(K_d) \qquad (1)$$

where V_w is the velocity of the ground water, V_c is the velocity of the contaminant, ρ_b is the bulk density of the porous medium, n is the porosity of

*Corresponding author.

the porous medium, and K_d is the distribution coefficient.

Of the variables in Eq. (1) K_d is the most difficult to measure in permeable unconsolidated sediments. In addition, K_d is also sensitive to the amount of organic carbon present in the sediment. Schwarzenbach and Westall [3] have proposed 0.1% organic carbon as the lower limit for sorption of VOCs to be dominated by the organic carbon. Above this limit, a number of researchers have presented methods for estimating K_d values based upon the amount of organic carbon present in the sediments and the octanol/water partitioning coefficient of the VOC of concern. Several of these methods have been presented and compared by Domenico and Schwartz [4]. Using a series of laboratory batch K_d experiments, Piwoni and Banerjee [5] proposed a method for estimating K_d values of VOCs, in low organic carbon (< 0.1%) sediments, that they claim should be accurate within a factor of two or three:

$$\log K_d = 1.01 \log K_{ow} - 3.46 \qquad (2)$$

where K_{ow} is the octanol/water partition coefficient. Applying the values of K_{ow} for TCE taken from Schwarzenbach and Giger [6] to Eq. (2) provided an estimated K_d for TCE of 0.07 ml g^{-1}.

Laboratory batch K_d tests are commonly conducted by immersing a small amount of solid material in water containing the contaminant. The mixture is then agitated for a specified period of time, the solid removed, and the remaining water analyzed. The difference between the original concentration in the water and the concentration at the end of the test is assumed to be the amount retained by the solid. Because of the sample disturbance in the laboratory batch K_d experiments, the resulting K_d value does not account for the retardation mechanisms that are inherent in undisturbed sediments.

Among the mechanisms which contribute to apparent retardation are (not in order of priority): adsorption to the surfaces of inorganic materials; hydrodynamic dispersion; biotic and/or abiotic degradation; partitioning to organic carbon; diffusion into, and entrapment/retention in, constricted or dead-end pores; and diffusion into relatively immobile waters in lenses of finer-

grained materials. For some of these mechanisms we can assume instantaneous local equilibrium, some are destructive of the VOCs, and some are rate-limited. A retardation experiment using a column packed to approximate aquifer conditions can measure the sum of many of these retardation mechanisms, hereafter referred to as sorption. The experiments described here are the initial efforts in a longer term research project designed to evaluate the relative contributions of the various retardation mechanisms.

Fundamental to the investigation and remediation planning for VOCs is the ability to perform accurate and precise chemical analyses. To provide rapid and inexpensive TCE analyses a fiber-optic-based TCE sensor was designed and developed at Lawrence Livermore National Laboratory (LLNL) [1,7–9]. This paper reports on the laboratory utilization of this newly developed fiber-optic-based sensor to provide real time analyses of TCE in retardation tests conducted in a flow-through column. These column experiments were conducted at low flow rates designed to approximate ground water flow velocities. As a result, samples for TCE analysis had to be collected over a relatively long period of time, at atmospheric pressure, during which they were subject to volatile losses. The volatile losses could be minimized by the collection of the smallest possible sample over the shortest time period. In addition, greater temporal resolution of the data would be achieved by taking the smallest possible sample. The fiber-optic-based sensor allowed immediate analysis of a 7.5 ml sample with acceptable precision at concentration levels of 10 parts per billion or less.

2. Methods

2.1. Fiber-optic TCE analytical technique

The TCE analyses were conducted using a fiber-optic-based sensor where the concentration of TCE is determined by the rate of change of 560 nm light absorption, in basic pyridine reagent. This reagent develops a red color by reacting with TCE [1,7–9].

When the sensor is placed in a vapor stream containing the contaminant, or in the headspace of a water sample, as is the case in this experiment, the contaminant diffuses through a semipermeable membrane tubing, contacts the reagent, and produces the colored product. The onset of the color change is monitored remotely with optical fibers.

When the analysis begins, the computer attached to the control center of the system monitors the rate of change of light absorption, caused by the color production in the reagent. The rate of the color reaction is proportional to the concentration of the contaminant in the sample. The sensor itself is constructed from porous membrane tubing, which holds the reagent during the analysis [1]. The instrument is also equipped with syringe pumps for the reagent feed and reagent waste. When the analysis is complete, the computer controls the injection of new reagent into the sensor and the evacuation of the old, colored reagent. The sensor is then ready for the next analysis.

The daily calibration of the sensor, for this experiment, was accomplished by the analysis of standard solutions of TCE, prepared by dilution, at concentrations of 25 ppb, 100 ppb, 250 ppb, and 500 ppb. The light absorbance curves were plotted against the concentrations and the linear regression was calculated. The resulting linear relationships had correlation coefficients (r^2) that commonly varied between 0.97 and 0.99. All calibration and experimental analyses were conducted in vials containing 7.5 ml of sample with 7.5 ml of headspace. The estimated analytical error of this new methodology, in the 25–500 ppb range, is 10% [10]. Comparisons of TCE analytical results from a series of ground water samples using the fiber-optic-based sensor and purge and trap gas chromatography are included in Ref. [9].

2.2. The experimental column

A sand-filled column was designed to perform retardation tests on geological materials. Since the tests were to be evaluated based on the retardation of the contaminant through the column, the column was designed to approach complete and uniform contact of the contaminated water with the sediment and to minimize preferential flow through the sediments or along the boundaries of the column. In addition, the sediment was to be compacted to approximate field conditions. Another design constraint of the column was to minimize contaminant adsorption on the column construction materials.

To meet these design criteria, the column was constructed entirely of Teflon. The Teflon serves two important purposes: (1) many contaminants are minimally sorbed to Teflon [11]; and (2) under the compacting forces on the sediments, the sediment grains are forced into the softer Teflon, thereby minimizing the possibility of preferential flow along the walls of the column. The only exception to the Teflon materials is a 230 μm pore size nylon membrane placed at either end of the sediment ot help retain the sand (Fig. 1). A Teflon screen extends beyond the threads of the end-cap to allow the application of mechanical pressure to the sediments to assist in compaction. The nominal outside dimensions of the column are 6.75 cm in diameter and 15 cm in length and the nominal dimensions of the sediment chamber are 5 cm in diameter and 9.5 cm in length.

The distribution of the influent and effluent flows is through three ports equally spaced 120° apart at either end of the column (Fig. 1). Immediately inside the column is a void mixing space followed by a Teflon screen with 39 equally spaced 3 mm diameter holes.

The sediment used in the column was designed to approximate a low organic carbon (< 0.1%), fine-to medium-grained sand of known grain-size distribution. To achieve this, the sand was acid-washed and sieved into three fractions. The first fraction passed a 1000 μm sieve and was retained on a 500 μm sieve, the second was retained on a 250 μm sieve and the third on a 125μm sieve. The three fractions were then recombined in equal parts by weight and homogenized. The homogenization process consisted of combining the three fractions, splitting the result into another three fractions, and recombining. This process was repeated until there was no visible sorting of the different grain sizes.
Fig. 1. Diagram of the construction features of the influent end of the sand-filled column. The effluent end of the column (not shown) is similar to the influent end without the threaded end-cap.

After the sand was poured and compacted, the column was saturated by slowly applying water from the bottom up. Water was then drawn through the column using a vacuum system which also helped to remove any entrained air bubbles. To ensure that the column met its design requirements, flow tests were evaluated using magnetic resonance imaging (MRI) [12].

The bulk density and porosity of the sand were determined gravimetrically and the hydraulic conductivity was measured with a constant head flow test. The bulk density of the column was found to be 1.84 g cm^{-3} and the porosity 0.27. The hydraulic conductivity was 2.1 × 10^{-2} cm s^{-1}.

2.3. Retardation test procedures

The contaminant used in the experiments was TCE dissolved in water. Conservative tracers (Cl– and ^{18}O-depleted water) were also added to the solution. The velocities of the advective fronts for the TCE and the tracer were calculated from the breakthrough curves and retardation and distribution coefficients were determined from Eq. (1).

The experimental set-up is illustrated in Fig. 2. The influent water was made up in a 500 ml glass volumetric flask and was drawn into the syringe pump through a Y valve through PVC tubing. The Y valve was then turned such that the syringe

pump would pump the water to the column at 30 ml h^{-1}. Ahead of the column was a glass tee with a valve which allowed the collection and release of any air bubbles prior to the flow entering the column. This device was utilized only during the initial filling of the distribution system, since the syringe pump produced no bubbles. The column was held in a vertical position and the TCE-bearing water was introduced from the bottom up to avoid any buoyancy-induced fingering of the contaminant. The effluent from the column was then directed by a Y valve to one of two sample collection cells. When the cell had received 7.5 ml of effluent (after 15 min of operation) the flow was switched to the second cell and the fiber-optic TCE sensor was inserted into the first cell. Following the analyses for TCE, the effluent was poured from the cell into a sample collection vial for analysis of the conservative tracer. The procedure was then repeated for the second cell.

2.3.1. Experiment 1

In the first experiment a solution of 136 ppm NaCl and 500 ppb TCE was delivered to the column, which was saturated with deionized water. Each sample was analyzed for TCE using the fiber-optic-based sensor, as soon as it was collected, and was then stored for later chloride analysis by high performance liquid chromatogra-
Fig. 2. Schematic diagram of the sand-filled column experiment apparatus used to measure retardation and to estimte the K_d value of TCE in an acid-washed sand.

phy (HPLC) with a precision of 4%. The experiment was terminated after 500 min.

2.3.2. Experiment 2

The procedures for the second experiment were essentially the same as the first with the following exceptions. The influent water contained 500 ppb TCE, 128.5 ppm chloride and was made up with ^{18}O-depleted water (δ = 60%). When the concentration of TCE appeared to begin to level off, the influent water was replaced with distilled water with no detectable TCE, a chloride concentration of less than 10 ppm, and a $\delta^{18}O$ content of – 4‰. At this point, the column was inverted such that the influent entered the column at the top and moved to the bottom, to minimize buoyancy-induced fingering. The collected samples were analyzed for TCE and for chloride, as in experiment 1, and for [18]O by mass spectrometry with a precision of 0.2‰.
Fig. 3. TCE and chloride breakthrough curves from the first TCE sorption experiment. Application of Eq. (2) yields an R value of 1.34 and a K_d value of 0.05 ml g^{-1}.

During the course of this experiment the influent water was sampled and analyzed for TCE periodically. Some TCE was lost to volatilization during the experiment, and the value of the concentration of the influent was corrected accordingly.

3. Results and discussion

Most contaminant transport models assume that sorption is an equilibrium process. However, over the past decade, work on VOC plumes appears to indicate that sorption is a slow process, most notably in low organic carbon sediments, and that the kinetics and rates of VOC sorption/desorption remain poorly understood. At the Borden aquifer, monitoring of an injected VOC plume indicated that sorption was continuing to increase even 2 years after the experiment com-

menced [13]. In addition, in studies with field columns (columns pushed into sediment at the bottom of an augured hole and studied in place) at the same site, retardation coefficients varied inversely with the average pore water velocities indicating non-equilibrium transport conditions [14]. Knox et al. [15] discussed the differences in sorption rates between sediments which contain organic carbon (fast sorption) and those which do not (slow sorption). Since the sands in this column were acid-washed, resulting in low organic carbon content, we anticipated slow sorption.

In estimating the velocity differences of the water and of the contaminant, in this experiment we used the common convention [4] of selecting $C/C_0 = 0.5$ as the arrival of the advective front, where $C =$ the concentration of the solute at time t, and $C_0 =$ the concentration of the solute in the
Fig. 4. TCE, chloride, and ^{18}O breakthrough curves from the second TCE sorption experiment. Application of Eq. (2) yields an R value of 1.72 and a K_d value of 0.11 ml g^{-1}. At approximately $t = 668$ min, the influent water was replaced with distilled water.

influent. In both experiments (Figs. 3 and 4), it is apparent that sorption was continuing to occur, although at a decreasing rate, at the time that we terminated the injection of the TCE-containing influent. Although sorption is continuing to take place, at a rapidly decreasing rate, behind the advective front, this sorption does not have a significant effect on the velocity of the leading edge of the plume.

3.1. Experiment 1

Prior to the experiment, several hundred pore volumes of deionized water were slowly pumped through the column in an effort to ensure that no TCE was present at the start of the test. The breakthrough curves for this experiment are shown in Fig. 3. The initial analyses for TCE indicated that there was a small amount of TCE, approximately 20 ppb, present in the column at the beginning of the experiment. This TCE may

be residual TCE sorbed to the sand in the column from preliminary tests. About 120 min into the experiment, the TCE analyses indicated the beginning of a steady rise in concentrations until approximately 350 min. At that time, the rate of increase of the TCE concentrations began to decrease.

The analyses for chloride in the early portion of the experiment were erratic, possibly the result of analytical error or inadequate flushing of the column prior to the experiment. However, these results were followed by a smooth steady increase in concentration until the analyses leveled off near the C/C_0 ratio of 1.0.

The retardation and K_d value for the TCE in this low organic carbon sand was calculated using Eq. (1). The resulting retardation was 1.34 and K_d was 0.05 ml g^{-1}. This K_d value agrees closely with the value of 0.07 ml g^{-1} determined by the Piwoni and Banerjee method [5] with a log K_{ow} value for TCE of 2.29 [6].

3.2. Experiment 2

Prior to conducting the second experiment, the column was rapidly flushed with several hundred pore volumes of hot tap water followed by several hundred pore volumes of deionized water to ensure the removal of the residual contaminants seen in experiment 1. Following the flushing, the initial TCE analyses indicated no TCE and the chloride analyses were low and steady, supporting the hypothesis that the variations seen in the early parts of the first experiment were the result of inadequate flushing prior to beginning the test. As in the first experiment, the breakthrough curves were smooth and steady for all three tracers, and as the concentrations for each constituent approached a C/C_0 ratio of 1.0, they became more variable (Fig. 4).

At times 428 min, 593 min, and 668 min the feed water was analyzed for TCE. The sample at 668 min was taken as the feed water was switched to deionized water. These analyses indicated a steady loss of TCE throughout the experiment. To prepare the plot for TCE shown in Fig. 4, the volatile loss was assumed to be linear between analyses and the C_0 value was corrected for each syringe filling, since the volatile loss must have taken place in the feed water flask, and no appreciable further volatilization would have occurred after the water was drawn into the syringe. It is worthwhile noting that the volatilization that occurred in the first 300 min is relatively minor, i.e. less than 10%, and is within the range of analytical error. In future experiments with influent-containing volatile compounds, a collapsible bag as an influent supply reservoir, such as that used by Szecsody and Bales [16], or simultaneous injection of water and the VOC as described by Priddle and Jackson [17] would be preferable, to help reduce volatile loss.

The retardation and K_d value were calculated as in the first experiment. In this case, the retardation was 1.72 and the K_d value was 0.11 ml g^{-1}. This value is also similar to the value of 0.07 ml g^{-1} given by the Piwoni and Banerjee method [5].

The increased variability in concentrations near the top of the breakthrough curves for each of the constituents in the two experiments may be the result of the small scale heterogeneities in the sand seen in the MRI experiments [12].

Although sorption was continuing to take place, the feed water was switched to deionized water at 668 min to accommodate the time constraints of the experiment. The chloride breakthrough curve for the deionized water is a mirror image of the steep chloride and ^{18}O breakthrough curves for the contaminated feed water, while the TCE curve starts off steep and then begins to level off at a C/C_0 ratio of 0.3.

4. Conclusion

The fiber-optic-based TCE sensor developed at LLNL shows promise as an inexpensive rapid method for conducting TCE analyses in the field as well as in the laboratory. In this experiment, it enabled real time accurate analysis of TCE in tests conducted in a sand-filled flow-through column and was sufficiently sensitive to detect residual parts per billion TCE contamination in the column at the beginning of experiment 1.

The sensor is capable of accurate analysis of samples as small as 7.5 ml, which increased the temporal resolution of the data and minimized volatile losses. In addition, the real time analyses provided the opportunity to make adjustments in the experiment once it was underway.

This study used the sensor to examine the retardation of the leading edge of a relatively low concentration TCE plume in a low organic carbon fine- to medium-grained sand. The experiment is part of a longer term research project designed to study the relative contributions of the various mechanisms that result in apparent retardation of VOCs in ground water. On-line laboratory studies of contaminant retardation may be of major importance in planning and predicting the restoration of contaminated ground water. The use of the sensor in further experiments of this type may help to advance our understanding of TCE behaviour in ground water, and to inspire new cleanup technologies.

1. Introduction

Recently, there has been increasing interest in the application of piezoelectric sensors in solution chemistry [1–3]. In most of the applications, a piezoelectric sensor is used as a microbalance due to its high sensitivity to the mass change on the surface of the quartz crystal [4]. Besides the mass effect, applications based on the response modes in viscosity [5,6], conductivity [7,8] and permittivity [9] were reported.

To improve the stability and selectivity of the frequency response of piezoelectric sensors in the liquid phase, a type of series piezoelectric quartz crystal (SPQC) was reported recently [10–12]. It was shown that the SPQC possesses a selective frequency response to permittivity and conductivity with excellent frequency stability [13,14]. In this paper, the detection limit of the SPQC to conductivity is reported.

2. Experimental

2.1. Apparatus and reagents

The construction of the SPQC was described in detail previously [10,12]. The appartus used was the same as that in Ref. [10]. Analytical reagent grade chemicals and doubly-distilled water were used throughout.

2.2. Procedure for measurements

Before the experiment, 30 min was required to allow the oscillator to stabilize. Then a KCl solution of known conductivity was introduced into the detection cell. A stable oscillating frequency of the SPQC was recorded with a time window of 10 s. The average value of 30 oscillating frequencies in 5 min was recorded as the oscillating frequency; the standard deviation of the 30 oscillating frequencies was taken as the noise level.

3. Results and discussion

Generally, the detection ability of a chemical sensor is described by its detection limit, which is determined by the signal-to-noise ratio. For a change in conductivity $(\Delta\chi)$ due to the analyte concentration, the frequency shift signal in the SPQC, ΔF_{signal}, can be estimated as $\Delta F_{signal} = |S_\chi \cdot \Delta\chi|$, where S_χ is the sensitivity to conductivity (χ). By using the S_χ values measured experimentally, the ΔF_{signal} values with $\Delta\chi = 10^{-4}$ S m^{-1} are depicted in Fig. 1. It can be seen that the ΔF_{signal} values decrease with increasing cell constant and depend greatly on the background conductivity. In a solution of medium conductivity, there is a maximum of ΔF_{signal}.

If only ΔF_{signal} is considered, it seems that the detection ability of the SPQC can be improved by using a smaller cell constant. Detection ability in solutions of medium conductivity is better than that in low conductivity solutions. This statement is somewhat questionable, because the detection ability of a sensor depends not only on the signal but also on its noise level.

Fig. 2 shows the standard deviations of 30 oscillating frequencies recorded in KCl solutions, which are used as the noise level of the SPQC, ΔF_{noise}. Fig. 2 reveals that ΔF_{noise} is also related

Fig. 2. Dependence of ΔF_{noise} on background conductivity.

significantly to the background conductivity. In addition, ΔF_{noise} decreases with increasing cell constant. This result can be explained as follows.

In the SPQC, the noise level may be expressed as

$$\Delta F_{noise} = (\Delta F_{tem}^2 + \Delta F_{osc}^2 + \Delta F_{ins}^2)^{1/2}$$

where $\Delta F_{tem} = \partial F/\partial t \cdot \Delta t$ is the solution temperature noise, $\partial F/\partial t$ is the frequency–temperature coefficient of the SPQC [10], and Δt is the variation in solution temperature. $\Delta F_{osc} \approx 10^6 Q^{-2}$ is the noise level of the oscillator, where Q is the quality factor of the SPQC [14]. ΔF_{ins} is the noise level of the frequency counter, its typical value being less than 0.1 Hz.

Under general experimental conditions, the solution temperature can be controlled within $\pm 0.1°C$. According to the frequency–temperature coefficient of the SPQC discussed in detail previously [10], the ΔF_{noise} values arise mainly from ΔF_{tem}, except in the case of $\partial F/\partial t \approx 0$. Comparing the ΔF_{noise} value with the frequency–temperature coefficient, the variation in solution temperature is about $\pm 0.04°C$ during the measurement time under our experimental conditions.

In solutions of low conductivity, $\Delta F_{osc} \approx 0$, as the SPQC has a much greater Q value [14]. With increasing conductivity, the $\partial F/\partial t$ value decreases [10], and hence a decrease in ΔF_{noise} is obtained.

Fig. 1. Theoretical dependence of ΔF_{signal} on background conductivity; $\Delta\chi = 10^{-4}$ S m^{-1}.

Fig. 3. Dependence of signal-to-noise ratio ($\Delta_\chi = 10^{-4}$ S m^{-1}) and detection limit to conductivity on background conductivity.

The ΔF_{noise} value reaches its minimum in solution with $\chi \approx 4 \times 10^{-3}$ S m^{-1}, where $\partial F/\partial t \approx 0$, and the value of ΔF_{noise} is close to ΔF_{ins}.

In a solution of medium conductivity, ΔF_{noise} has a maximum that corresponds to the maximum frequency–temperature coefficient. In the solution with $\chi \approx 8 \times 10^{-2}$ S m^{-1}, there is a second minimum for ΔF_{noise}, where $\partial F/\partial t \approx 0$ again. As discussed previously [14], the Q values of the SPQC decrease significantly in medium conductivity solutions, and so ΔF_{noise} is determined mainly by ΔF_{osc} here.

With increasing background conductivity in highly conductive solutions, the $\partial F/\partial t$ value decreases, and hence a decrease in ΔF_{noise} is observed again as $\Delta F_{osc} \approx 0$.

Using the values of ΔF_{signal} and ΔF_{noise}, the signal-to-noise ratio (S/N) of the SPQC is illustrated in Fig. 3. As the S/N values depend only slightly on the cell constant, for clarity only the results in the SPQC with a cell constant of 1.04 cm are shown. With S/N = 2, the detection limit (DL) to conductivity is also shown in Fig. 3. It can be seen that the S/N and DL values are significantly dependent on the background conductivity.

In low conductivity solutions, the ΔF_{signal} values are nearly constant, while the ΔF_{noise} values de-

crease with increasing background conductivity. As a result, S/N increases and DL decreases with increasing background conductivity. The lowest DL value can be obtained in the solution with $\Delta F_{tem} \approx 0$. As the background conductivity continues to grow, ΔF_{signal} and ΔF_{noise} increase. Because the increase in ΔF_{noise} is more rapid than that in ΔF_{signal}, S/N decreases and DL increases with increasing background conductivity in medium conductivity solutions. The minimum S/N value corresponds to the point where $S_\chi \approx 0$.

With increasing background conductivity in high conductivity solutions, ΔF_{noise} and ΔF_{signal} decrease. The decrease in ΔF_{signal} is more obvious than that in ΔF_{noise}. Consequently, S/N decreases and DL increases as background conductivity increases.

4. Conlcusions

The noise level of the SPQC in electrolyte solutions arises mainly from the variation in solution temperature. The detection limit to conductivity is not influenced by the cell constant, but it depends significantly on the background conductivity. The detection limit in solutions of low background conductivity is much lower than that in medium conductivity solution, despite a higher sensitivity in the latter.

A nonlinear regression model applied to kinetic studies of ester hydrolysis with a surface acoustic wave sensor

Quingyun Cai, Ronhgui Wang, Liying Wu, Lihua Nie, Shouzhuo Yao*

Department of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, , People's Republic of China

Abstract

A non-linear regression model was derived for the simultaneous determination of the rate constant in alkaline hydrolysis of esters and the initial concentration of esters based on the linear relationship between the frequency response of the surface acoustic wave sensor system and the conductivity of the solution. The model was tested theoretically and experimentally with the methyl-, ethyl-, and n-propyl-acetate systems. The corresponding rate constants estimated at 25°C are 0.147, 0.103 and 0.0671 respectively.

Keywords: Nonlinear regression model; Kinetic studies; Ester hydrolysis; Surface acoustic wave sensor

1. Introduction

Surface acoustic wave (SAW) devices are very sensitive chemical sensors and considerable attention has been devoted to them [1–4]. SAW devices are most frequently used for the determination of low concentrations of species in the gas phase [5,6]. Although the application of SAW devices to liquid systems is of interest, many problems exist owing to the large energy loss in the propagation of the Rayleigh wave [7] when the SAW sensors are immersed in liquid.

By combining conductive electrodes with a SAW device, a new SAW sensor system for liquids was proposed by Yao et al. [8]. This SAW sensor system is very sensitive to the physical properties of the solution that will cause variations in the loop parameters in the oscillation circuit, such as conductivity and permittivity. Under certain experimental conditions, there exists a linear relation between the frequency response of the SAW device and the conductivity of the solution studied [8]. Compared to the normal conductivity method, the sensitivity is improved by employing a SAW device and the polarization potential that seriously affects normal conductivity measurements in a high background conductance solution does not exist owing to the high oscillation frequency of the SAW devices. As the SAW device is not in contact with the solution, the frequency stability of the sensor system is

* Corresponding author.

much better than that of normal SAW sensors operated directly in the analyte vapor or gas, where a large amount of energy dissipates from the SAW surfaces to polymer coatings. Some applications of the modified SAW sensor system have been reported [9,10].

The study of reaction mechanisms is important and usually involves a kinetic investigation of the factors that influence the rate of reaction. Such investigations have often been undertaken using a linear method of data analysis (e.g. a pseudo-first-order approach). Since only a small amount of information from the response curves is used, the precision relies strongly on the experience of the analyst and the experimental conditions. In contrast, regression analysis makes full use of information from the entire response curve, so that more parameters can be determined simultaneously and the precision is higher than using linearisation. For nonlinear least-square problems, the Levenberg–Marquardt–Fletcher (LMF) algorithm [11], a modification of the Levenberg–Marquardt (LM) method [12], is believed to be one of the most powerful methods. Owing to a powerful combination of the Steepest Descent algorithm and the Newton–Gauss algorithm and adjustment of the Marquardt parameter based on the ratio of the practical decrease of the residual sum of the squares, QS, to its decrease expected when QS is assumed to be a quadratic function, the LMF algorithm can rapidly converge to the minimum without good initial estimates of the parameters. Several applications of the LM algorithm have been reported [13,14] and a few reports have been published on the application of the LMF algorithm in chemistry.

The purpose of this work was to derive a nonlinear regression model for the simultaneous determination of the hydrolysis rate constant of ester in basic solution and its initial concentration, based on the linear relationship between the frequency shifts of the SAW sensor and the conductivity of the solution to be studied. The systems methyl-, ethyl- and n-propyl-acetate were investigated with the model. The rate constants, concentrations, and system parameters have been determined simultaneously.

2. Theory

The alkaline hydrolysis of esters is a second-order reaction [15] expressed as Eq. (1) and the rate equation is expressed as

$$CH_3COOR + OH^- \rightleftharpoons CH_3COO^- + ROH \quad (1)$$
$$dC_t/dt = k(C_0 - C_t)(C_{OH^-}) \quad (2)$$

where C_0 denotes the initial concentration of ester, C_t is the concentration of hydrolyzed ester at time t and k is the rate constant.

In alkaline solution the dissociation of acetic acid is almost complete, the presence of HAc can be neglected (this assumption is reasonable for an acid whose dissociation constant is greater than 10^{-9}), and the concentration of H^+ is far less than that of OH^-. Then:

$$C_{OH^-} = C_B - C_t \quad (3)$$

$$C_{Ac^-} = C_t \quad (4)$$

where C_B denotes the concentration of base (KOH) added. The integral of Eq. (2) is expressed as below. When $C_0 \neq C_B$:

$$C_t = C_B \cdot C_0 \cdot \{\exp[kt(C_B - C_0)] - 1\}/$$
$$\{C_B \exp[kt(C_B - C_0)] - C_0\} \quad (5)$$

When $C_0 = C_B$:

$$C_t = ktC_0^2/(1 + ktC_0) \quad (6)$$

With a set of initial estimates of k and C_0, C_t can be calculated. The frequency shift Δf and the residual sum of squares sum QS can then be calculated from Eqs. (7) and (8):

$$f = S'(r_{OH^-}C_{OH^-} + r_{Ac^-}C_{Ac^-} + r_{K^+}C_B) + f^{0\prime}$$
$$= -S'(r_{OH^-} - r_{Ac^-})C_t + S'(r_{OH^-} + r_{K^+})C_B + f^{0\prime} \quad (7)$$

$$\Delta f = f^0 - f = SC_t$$

$$QS = \sum_{points} (\Delta f^{calc} - \Delta f^{exp})^2 \quad (8)$$

where f^0 is the initial frequency (kHz) where $t = 0$, S is the sensitivity of the sensor system (kHz mol^{-1}), r is the molar conductivity of ions, and C is the concentration of corresponding ions (mol l^{-1}).

This is a nonlinear regression model. To obtain the model parameters S, C_0 and k, the partial derivatives of the parameters must be calculated:

$$\partial \Delta f / \partial k = S \partial C_t / \partial k \qquad (9)$$

$$\partial \Delta f / \partial C_0 = S \partial C_t / \partial C_0 \qquad (10)$$

$$\partial \Delta f / \partial S = C_t \qquad (11)$$

Once the partial derivatives $\partial \Delta f / \partial S$, $\partial \Delta f / \partial k$ and $\partial \Delta f / \partial C_0$ have been calculated, the Hessian matrix is directly built up and the standard LMF algorithm [11] is used to compute the parameters.

3. Experimental

3.1. Apparatus and reagents

The 62 MHz one-port resonator was used in the study with a y,z-cut $LiNbO_3$ crystal. The detection cell and the complete assembly were described previously [8]. The detection cell was suspended in a brass thermostatic bath at constant temperature. The frequency was measured using a SC7201 Universal Counter at a resolution of 1 Hz and data were collected at more than 12 points min^{-1}.

All chemicals used were of analytical-reagent grade. The concentration of KOH was prepared at about 5 mmol l^{-1} and calibrated with guaranteed-reagent-grade potassium biphthalate. Doubly-distilled water was used throughout.

3.2. Procedure

Under the protection of N_2, 10 ml of 0.005 mol l^{-1} KOH solution was transferred to a detection cell and stirred with a magnetic stirrer at a constant speed. The baseline noise was determined by using frequency data collected for 5 min before the experiment. Several microliters of ester were injected into the solution with a micro-syringe and the frequency shift vs. time was recorded. All experiments were repeated at least three times and for each curve at least 100 points were acquired.

3.3. Computation and analysis of data

A program written in FORTRAN 77 was compiled and run on an IBM PC/386 computer. The data were input from a data file by the DOS pipe command. All computations were in double precision. The run time for a set of data was less than 1 min. The program is available from the authors.

4. Validation of the non-linear regression model

The simultaneous determination of the concentration C_0 and the rate constant k relies on them being linearly correlated. The parameters C_0 and k occur in the form $C_0 k$ in Eq. (2). To test their correlation, the response of frequency shift with time is given in Fig. 1 for different k values, keeping $C_0 k$ constant. We can see that the effects of k and C_0 on the response are different. Therefore the simultaneous determination of k and C_0 can be achieved with the model.

To test the ability of the algorithm estimating parameters, synthetic frequency response curves vs. time were computed according to Eq. (7) for given parameters, and a random noise of 1% of the maximum frequency shift was added to the theoretical data. The parameters were then computed with the theoretical data with added noise. The regression results are listed in Table 1. The residual given by the program showed that all the

deviations were of random distribution, indicating a good fit of the theoretical model to the data. In all cases, the S parameters calculated were close to the expected values with small deviations. For k and C_0, if they are not too small, the technique can give accurate estimations. When they are too small, the response of the sensor is too low and no accurate k and C_0 values can be determined.

For non-linear regression, a good initial estimate of the parameter is generally important. The effect of the initial estimates of k and C_0 on the regression has been tested with the synthetic frequency response curve. The results are listed in Table 2. Owing to the use of analytical derivatives together with the LMF algorithm, there are no strict demands on the initial estimates, and they may be varied in a range of 100–0.1 times the true values for k and 50–0.05 times for C_0. The initial estimate of S has no limitation since it is linear.

If the dissociation constant K_a of the acid produced by hydrolysis of esters is small (e.g. $K_a < 10^{-9}$), the hydrolysis of RCOO$^-$ should be taken into account. Fig. 2 gives the response curves of

frequency shifts vs. time with different dissociation constants K_a. It shows that when $K_a > 10^{-9}$, there is little influence of K_a on the response, when K_a is in the range 10^{-9}–10^{-15}, the influence of K_a on the response is large, and when $K_a < 10^{-15}$ little response can be observed even with large rate constants and high initial concentrations of base. Since the dissociation of the acid is so small, no notable change of the conductivity can be observed. Therefore when $K_a > 10^{-9}$ the presence of RCOOH can be neglected (set $C_t = [RCOO^-]$); when $K_a = 10^{-9}$–10^{-15} neglect of RCOOH can influence the results seriously, and when $K_a < 10^{-15}$ no accurate results can be given by methods based on conductivity response.

5. Results and discussion

5.1. Relationship between frequency shifts and conductivity

In order to investigate the relationship between

the frequency shifts and conductivity, the re-
sponse of the SAW sensor system to conductivity
has been determined by titrating water with 0.1
mol l^{-1} KOH solution at 25°C. The result shows
that a linear relationship exists in a certain con-
ductance region where the corresponding KOH
concentration is up to 20 mmol l^{-1}. The linear
region can be changed by adjusting the loop
parameter in the oscillation circuit [8]. In this
work, the linear region was adjusted to that where
the corresponding KOH concentration was 1–6
mmol l^{-1} ($S_{Y/X} = 78$ Hz, $R = 0.999$, $n = 7$).

Fig. 4. The variation of apparent reaction rate ($d\Delta f/ dt$) with
time calculated from the experimental data in Fig. 3.

5.2. Estimation of the initial concentration of esters and the rate constant

The hydrolysis of methyl-, ethyl- and n-propyl-
acetate was done at four different concentrations
(0.05, 0.10, 0.50 and 1.0 mmol l^{-1}) of the ester.
The concentration of potassium hydroxide was
kept constant at 5.00 mmol l^{-1}. During the reac-
tion the variation of the ionic strength is slight
and the molar conductivity and sensitivity S can
be assumed to be constant. The experimental
temperature was kept constant at 25°C and 40°C
respectively. A part of the calculated and experi-
mental response curves is given in Fig. 3. The
apparent rate ($d\Delta f/ dt$ in Hz s^{-1}) at time t calcu-
lated from the experimental response curves in
Fig. 3 is given in Fig. 4. The estimated results of
the ethyl-acetate system are shown in Table 3.
The rate constants determined for methyl-, ethyl-
and n-propyl-acetate, together with the literature
values, are given in Table 4. The residual distribu-
tion for ethyl-acetate is shown in Fig. 5, indicating
that the residual distribution was random. Table 3
shows that the estimated concentrations agree
well with the actual values. The lowest concentra-
tion that can be determined simultaneously with k
is about 1×10^{-5} mol l^{-1}. The lower limit de-
creases with the increase of the rate constant k.
From Table 4 we can see that the rate constant k
estimated is higher than that published in the
literature [15,16], which results from the different
experimental conditions and the different rate

equation. From Fig. 4 we can clearly see that the reaction rate increases with the decrease in the number of $-CH_2-$ units.

5.3. A comparison of the SAW-sensing method with conductometry

The hydrolysis of ethyl-acetate was monitored with the SAW-sensing method and with conductometry for comparison. The response curves are given in Fig. 6. For the first 10 min the signal-to-noise ratio of the SAW-sensing method is 4000 with a noise level of 1 Hz and the signal-to-noise ratio of conductometry is 400 with a noise level of 0.1 μS cm^{-1} under our experimental conditions. The proposed method is more sensitive than conductometry. The lower limit of the concentration is 1×10^{-5} mol l^{-1} (SAW-sensing method). The similar form of the response curves demonstrates

the linear relationship between the frequency shift and the conductivity.

5.4. A comparison of the nonlinear regression analysis method with the normal linear method

With the proposed method, the concentration can be estimated with only one response curve. The concentration range that can be determined is only dependent on the linear region of frequency shifts vs. conductivity as well as the signal-to-noise ratio of the response curve. Owing to this the linear region can be changed by adjusting the loop parameters in the oscillation circuit; theoretically the concentration that can be determined has no limitation if the signal-to-noise ratio is large. For the normal linear method, however, a calibration curve of rate vs. concentration is usually needed so the concentration that can be deter-
Fig. 5. Residual plot from regression analysis of the experimental data at 25°C (●) and 40°C (▲) for the ethyl-acetate system $C(KOH) = 5$ mmol l^{-1}, $C_0 = 1.0$ mmol l^{-1}.

Fig. 6. Comparison of the SAW-sensing method with conductometry under the same experimental conditions for the ethyl-acetate system. $C(KOH) = 5$ mmol l^{-1}; $C_0 = 1.0$ mmol l^{-1}; $T = 25$°C.

mined is dependent on the linear region of the calibration curve. Therefore, a great deal of work needs to be done and the precision of the result strongly relies on the experience of the analyst.

5.5. Usefulness and applications

The technique introduced in this paper can be used as a simple and accurate method for determining hydrolysis rate constants of an ester and its initial concentration simultaneously. That the concentration and kinetic constant can be determined

simultaneously is a novel advantage, especially in biochemical systems where the accurate concentrations of reactants are usually unknown. With only a slight modification, the technique can be used to study the kinetic procedure in enzyme-catalysis reactions. Such works will be reported later.

Abstract

The complex formation between pyrophosphate ($P_2O_7^{4-}$) and protonated methylamine, ethylenediamine, diethylenetriamine, triethylenetetramine, tetraethylenepentamine and pentaethylenehexamine, has been studied potentiometrically, in aqueous solution, at 25°C. It was found that the species ALH_q (A = amine, $L = P_2O_7^{4-}$) are formed with $q = 1 \ldots n$ ($n = 3, 5, 6, 7, 7$ and 8 for the above amines respectively). Mono- and di-amines form species A_pLH_q too. The stability of these species is quite high [e.g. $H_4A^{4+} + HL^{3-} \rightleftarrows ALH_5^+$: $\log K = 8.1$ (A = pentaethylenehexamine)] and depends strictly on the charges involved in the formation reaction. Charges of reactants being equal, the stability trend is penten > tetren > trien > dien > en > meta and cationic mixed species are more stable than anionic ones. These results are discussed in relation to speciation problems in natural and biological fluids.

Keywords: Aliphatic amines; Pyrophosphate complexes; Formation constants; Potentiometry

1. Introduction

Pyrophospate (diphosphate, $P_2O_7^{4-}$) is involved in many natural reactions. Owing to its high charge, pyrophosphate is mainly present in biological and natural fluids as an ion pair or complex with different metal ions, which, in turn, may be of great importance in biochemical processes. As an example, the catalytic activity of PPase requires Mg^{2+} ions for the formation of the substrates $Mg(P_2O_7)^{2-}$ and $Mg_2(P_2O_7)^0$. Poly-

phosphates are also involved in eutrophization phenomena and it has been demonstrated that intracellular accumulation of phosphorus takes place in the form of polyphosphate granules, which have been recognised in algal cells. In all cases it is necessary to know as rigorously as possible the speciation of polyphosphates in order to study biochemical reaction mechanisms.

Metal pyrophosphate complexes have been studied extensively, in particular where alkali and alkaline earth cations are concerned. Recently it has been reported that pyrophosphate forms quite stable complexes with protonated polyamines [1],

and, in kinetic studies [2], it has been suggested that polyamines can substitute for Mg^{2+} as an activator in vitro. The complexation of $P_2O_7^{4-}$ with polyguanidine cations and some diamines has also been reported [3].

In order to make a contribution to work on the speciation of this ligand in natural and biological fluids, we thought it interesting to investigate its complexing ability towards polyamines. In this work we report a potentiometric study of the formation and stability of pyrophosphate complexes with methylamine (meta), ethylenediamine (en), diethylenetriamine (dien), triethylenetetramine (trien), tetraethylenepentamine (tetren) and pentaethylenehexamine (penten), in aqueous solution, at 25°C.

2. Experimental

2.1. Materials

Amines (methylamine, ethylenediamine, diethylenetriamine, triethylenetetramine, tetraethylenepentamine and pentaethylenehexamine, Fluka products) were purified by transformation into the corresponding hydrochlorides [4], and were used in this form. Tetrasodium diphosphate (Analar, BDH) was used without further purification. Solutions of NaOH and HCl were prepared by diluting concentrated Fluka ampoules and were standardised against potassium biphthalate and sodium carbonate respectively. Grade A glassware and doubly-distilled water were used for all solutions.

2.2. Appartus

Potentiometric measurements were carried out with two different sets of equipment: (a) an Amel 631 potentiometer coupled with Metrohm glass saturated calomel electrodes; the titrant was delivered by an Amel 231 dispenser; (b) an automatic system using a Metrohm E654 potentiometer coupled with a combination Ross-type electrode 8102 and connected to a Metrohm dosimat 665 dispenser; a computer program was used for the acquisition of the potentiometric data. The titration program for the equipment (b) allows the evaluation of equilibrium potential values and determines the amount of titrant based on the actual buffering properties of the titrated solution, so that there is a difference in pH values of 0.05–0.08 between two successive readings; the e.m.f. was considered to be stable when the variation was less than 0.1 mV within 5 min.

2.3. Procedure

25–50 ml of the solution containing $P_2O_7^{4-}$, HCl (in order to have the full protonated ligand) and the amine hydrochloride under study were titrated with standard NaOH up to 80–90% neutralisation. Other experimental details are reported in Table 1. Separate titrations of HCl at about the same ionic strength (adjusted with NaCl) as the sample under study were carried out for determining the standard electrode potential E^0. A stream of purified and presaturated N_2 was bubbled through all solutions in order to exclude the presence of CO_2 and O_2.

2.4. Calculations

The computer program ESAB2M [5] was used to calculate the purity of the reagents and to refine all the parameters related to the calibration of the electrode system. The computer programs BSTAC [6] and STACO [7] were used to calculate the formation constants from measurements carried out at variable ionic strengths. The ionic strength dependence of formation constants was taken into account by using the Debye–Hückel-type equation [6,8].

$$\log \beta = \log{}^T\!\beta - z^* \sqrt{I}/(2+3\sqrt{I}) + CI + DI^{3/2} \qquad (1)$$

$$C = c_0 p^* + c_1 z^*$$

$$D = d_1 z^*$$

$$p^* = \sum p_{\text{reactants}} - \sum p_{\text{products}};$$

$$z^* = \sum z^2_{\text{reactants}} - \sum z^2_{\text{products}}$$

where β = formation constants; ${}^T\!\beta$ = formation constant at zero ionic strength; p and z are the stoichiometric coefficients and the charges respectively. As previously reported [6,8], when weak interactions are taken into account [sodium complexes of $P_2O_7^{4-}$, anion (Cl^-) complexes of protonated amines, association of background salt], such as in this work, the empirical parameters of Eq. (1), i.e. values of C and D, can be considered independent of the type of reaction, and dependent on the charges only (for $I < 1$ mol dm^{-3}). For the calculations performed in this work we used the values $c_0 = 0.10$, $c_1 = 0.23$ and $d_1 = -0.1$ (these values are taken from Ref. [9], and are in good agreement with those reported in other works [6,8]). In some cases, when $I_{\text{max}} > 0.3$ mol dm^{-3}, the parameter C was refined together with the formation constants, and D was kept constant at $-0.1z^*$. The computer programs BSTAC and STACO can be used when dealing with measurements performed at variable ionic strength, by using Eq. (1) for the dependence of log β on I. Formation constants were expressed as follows (charges omitted):

$$\beta_{pq} = [ACl_p H_q]/([A][Cl]^p[H]^q) \qquad (2a)$$

$$\beta_{pq} = [Na_p LH_q]/([Na]^p[L][H]^q) \qquad (2b)$$

for the protonation constants and for the formation of amine–Cl^- or $P_2O_7^{4-}$–Na^+ complexes, and

$$\beta_{pq} = [A_p LH_q]/([A]^p[L][H]^q) \qquad (2c)$$

$$K_{[\text{reactants}]} = [\text{product}]/\Pi[\text{reactants}] \qquad (2d)$$

$$K_{ij} = [ALH_{i+j}]/([AH_i][LH_j]) \qquad (2e)$$

where A = amine and $L = P_2O_7^{4-}$. The overall formation constant β_{pq} is the constant obtained in the least-squares refinement, whilst $K_{[\text{reactants}]}$ are the equilibrium constants calculated according to the most probable formation reaction, in general $AH_i + LH_j \rightleftarrows ALH_{i+j}$ (K_{ij}). Concentrations and formation constants are given on the molar scale.

3. Results

3.1. Protonation constants of the ligands

Protonation of amines and pyrophosphate has already been studied, together with weak complexes with Cl^- and Na^+. Pyrophosphate forms [10], in addition to the five protonated species, weak complexes with Na^+ of the type $Na_p LH_q^{(p+q-4)}$ ($p, q = 1, 0$; 1, 1; 1, 2; 2, 0; 2, 1). Amines [1,11–14] form, in addition to the n protonated species (n = number of amino groups), weak complexes with Cl^- of the type $ACl_p H_q^{(q-p)}$ ($q = 1 \ldots n$, $1 \leqslant p \leqslant n - 2$). Protonation and weak complex formation constants are reported in Table 2. As can be seen, some formation constants of Na^+–$P_2O_7^{4-}$ and AH_i^+–Cl^- complexes are greater than one log unit and therefore NaCl interferences may mask other complex formation reactions, when $C_{\text{NaCl}} \gg C_{\text{reactants}}$.
3.2. Proton mixed-ligand systems

Experimental data of mixed systems (potentiometric titrations) cannot be explained by considering the protonation constants of the two ligands only. Therefore, the formation of mixed proton amine–pyrophosphate complexes must be taken into account. Least-squares calculations were con-

[a] Formation constants β_{pq} refer to the reactions [see Eqs. (2a), (2b)]:
$A^0 + pCl^- + qH^+ = ACl_pH_q^{(q-p)}$ (amines)
$L^{4-} + pNa^+ + qH^+ = Na_pLH_q^{(p+q-4)}$ (pyrophosphate)
[b] $I = 0.25$ mol dm^{-3}.

sistent with the formation of ALH_q species ($q = 1 \ldots n$; $n = 3, 5, 6, 7, 7$ and 8, for meta, en, dien, trien, tetren and penten respectively). In Table 3 we report the formation constants of mixed species as both overall and partial (according to the most probable formation reaction) constants. As one can see, the stability of these complexes is relevant and in some cases very high. Now, let us examine each system in detail.

3.2.1. $P_2O_7^{4-}$ –meta

In this system, six species are formed: ALH_q^{q-4} ($q = 1 \ldots 3$), $A_2LH_2^{2-}$, $A_2LH_3^-$ and $A_4LH_4^0$. Formation constants increase with increasing charge in both cation and anion. This rule is confirmed quantitatively for the formation of the species

ALH_2^{2-} and $A_2LH_2^{2-}$ (the same charges are involved in the formation reaction) for which very similar values of constants (log $K = 2.10$ and 2.06 respectively) are observed. In some cases, it is difficult to assign the correct partial formation reaction to each species. This is the case for the tetramine species $A_4LH_4^0$, for which only a semi-overall formation constant had been calculated. In Fig. 1a we report the distribution of the species vs. pH. At relatively high concentrations of reactants and with ratios $C_A/C_L \gg 1$ all the species are formed in significant amounts. If the above ratio is equal to one and with concentrations of the order of mmol dm^{-3}, only some species are significant [ALH_q ($q = 1, 2, 3$)] with formation percentages $< 15\%$. Therefore, at concentration levels

[a] Overall formation constants β_{pq} relate to the reaction [see Eq. (2c)]

$$pA + L + qH = A_pLH_q$$

[b] Partial formation constants [see Eqs. (2d), (2e)].

of natural and biological fluids these complexes are not very important.

3.2.2. $P_2O_7^{4-}$ -en

Seven species are formed in this system: ALH_q^{q-4} ($q = 1 \ldots 5$), $A_2LH_4^0$ and $A_2LH_5^+$. Also in this case one can observe a check (in the same system) for the strict dependence of the stability on the charges involved in the formation reaction. In fact the species ALH_4^0 and $A_2LH_4^0$ have partial formation constants which are quite close to each other. In Fig. 1b the distribution of the species vs. pH is reported. The speciation of this system, as a function of concentration and pH, is qualitatively very similar to that of meta. When the concentration of reactants is 1 mmol dm^{-3}, complex species A_pLH_q, with $q > 1$ disappear, but the formation percentages of the other species, in the range $2 \leqslant pH \leqslant 8$, are always > 35%. This means that this system can be consid-

ered fairly significant for natural and biological fluids.

3.2.3. $P_2O_7^{4-}$ -dien

Six species are formed in this system: ALH_q^{q-} $4(q = 1 \ldots 6)$. The ratio log K/z_t ($z_t = z_{cation} + |z_{anion}|$) is fairly constant ($0.9 \pm 0.2$), further confirming the strict dependence of formation constants on charges. However, the difference between positively and negatively charged species becomes relevant; in fact the formation constant for the species ALH_3^- is significantly lower than that of ALH_5^+ (even if charges involved in the reaction are the same absolute value). This indicates that the charge on the protonated amine is more important than the charge of the anion in determining the stability of mixed proton complexes. In Fig. 1c we report the distribution of the species vs. pH. Formation percentages are very high, and also, when the concentration of reactants is < 1 mmol dm^{-3}, significant presence of mixed complexes is observed.

3.2.4. $P_2O_7^{4-}$ -trien

Seven species are formed in this system: $ALH_q^{q-4}(q = 1 \ldots 7)$. Since all the species are formed in the range $3 \leqslant pH \leqslant 9$, in some cases it is difficult to detemine the correct formation reaction. For example, the formation of the species ALH_4^0 can be described by the reactions:

$H_3A^{3+} + HL^{3-} \rightleftarrows ALH_4^0$ (log $K = 6.6$)

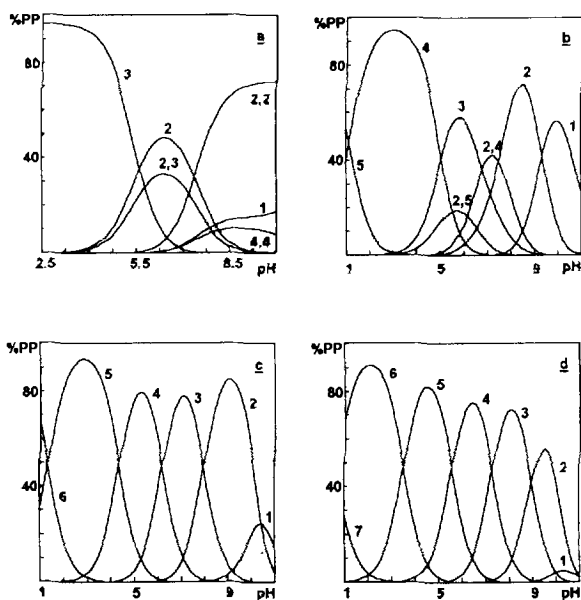
$H_2A^{2+} + H_2L^{2-} \rightleftarrows ALH_4^0$ (log $K = 6.1$)
In Table 3 we report the formation constant relative to the first reaction since in the real conditions of our experiments the third protonation constant of trien is significantly higher than the second one of pyrophosphate. However, at $I = 0$ mol dm^{-3}, log K_3^H (trien) $\cong$ log $K_2^H(P_2O_7^{4-})$, and under these conditions it is right to write the second reaction too. In Fig. 1d we report the distribution of the species vs. pH. When $C_L = C_A = 10$ mmol dm^{-3}, mixed species are predominant; at pH < 9 the sum of the percentages of ALH_q complexes is always > 90%. For $C_L = C_A = 1$ mmol dm^{-3}, the sum of the percentages in the above range is not lowered too much.


Fig. 1. Distribution of the species vs. pH in the systems H^+-$P_2O_7^{4-}$-meta (a), H^+-$P_2O_7^{4-}$-en (b), H^+-$P_2O_7^{4-}$-dien (c) and H^+-$P_2O_7^{4-}$-trien (d). Numbers which locate complexes (q) refer to the species ALH_q [or (pq) for A_pLH_q]. (a) $C_A = 0.25$, $C_L = 0.02$ mol dm^{-3}; (b) $C_A = 0.05$, $C_L = 0.01$ mol dm^{-3}; (c) $C_A = 0.025$, $C_L = 0.01$ mol dm^{-3}; (d) $C_A = 0.01$, $C_L = 0.01$ mol dm^{-3}; $T = 25°C$, $I = 0.15$ (NaCl) mol dm^{-3}.
Fig. 2. Distribution of the species vs. pH in the systems $H^+-P_2O_7^{4-}$-tetren (a, b) and $H^+-P_2O_7^{4-}$-penten (c, d). Numbers which locate complexes (q) refer to the species ALH_q. (a, c) $C_L = C_A = 0.01$ mol dm^{-3}; (b, d) $C_L = C_A = 0.001$ mol dm^{-3}; $T = 25°C$, $I = 0.15$ (NaCl) mol dm^{-3}.

3.2.5. $P_2O_7^{4-}$ –tetren and penten

In these systems seven [ALH_q ($q = 1...7$)] and eight [$ALH_q(q = 1...8)$] species are formed respectively. Apart from the values of formation constants, the same considerations as for trien apply to these systems. In Fig. 2a–2c the distribution diagrams of the species vs. pH are shown. In these systems, the formation of mixed species is almost quantitative for $C_L = C_A > 1$ mmol dm^{-3}. For the system penten–$P_2O_4^{4-}$, when the concentration is 1 μmol dm^{-3}, 40–45% of ligands are still present as mixed complexes in the pH range 3–6, and 20% at pH 7.

4. Discussion

4.1. General stability trends

Taking the formation constants of the different systems together, some general trends can be evidenced.

(a) The charges of the reactants being equal, formation constants for the amine–$P_2O_7^{4-}$ com-
plexes follow the trend: meta < en < dien < tetren < penten.

(b) The stability is in general directly proportional to the charges involved in the formation reaction.

(c) The sum of charges in the protonated amine and in pyrophosphate being equal the stability of mixed proton complexes follows the trends:

(i) cationic species > anionic species;

(ii) the stability of complexes is higher when the differences between charges in the amine and in pyrophosphate are smaller, i.e. log $K(\Delta|z_1|) >$ log $K(\Delta|z_2|)$, when $\Delta|z_2| > \Delta|z_1|$.

In Fig. 3 we report log K vs. n (number of amino groups in the amine) for the reactions:

$$H_2A^{2+} + HP_2O_7^{3-} \rightleftarrows A(P_2O_7)H_3^-$$

$$H_3A^{3-} + H_2P_2O_7^{2-} \rightleftarrows A(P_2O_7)H_5^-$$

As can be seen, a significant linear trend is observed with positive slope [point (a)] for both types of complex, whilst the relative stability is in favour of cationic species [points (c), (i)].

Trends (a)–(c) can be expressed quantitatively by the simple relationship (all formation constants of different mixed systems are taken simultaneously into account):

$$\log K = 1.05z_{cation} + 0.67|z_{anion}| + 0.36n$$

$$- 0.28\Delta z - 0.90 \tag{3}$$

Where n = number of amino groups in the amine, with a mean deviation ε (log K) = 0.6.

Fig. 3. Dependence of log K on n (number of amino groups): (Δ) $H_2A^{2+} + HL^{3-} \rightleftarrows ALH_3^-$; (+) $H_3A^{3+} + H_2L^{2-} \rightleftarrows ALH_5^-$.

Steric factors influence the stability of ligand–ligand complexes, as observed in other investigations [1], but the electrostatic factor, namely the charges involved in the complexation reaction, plays a much more important role.

4.2. Ionic strength and medium dependence of formation constants

Formation constants of mixed systems were calculated under the assumption that all significant interactions among all the components have been taken into account, i.e. "true" formation constants were obtained. In particular, we took into account the formation of $Na^+–P_2O_7^{4-}$ and Cl^-–amine complexes, as reported in Table 2. Different assumptions are generally made in the literature: (a) Na^+ and Cl^- complexes are neglected altogether; (b) only Na^+ complexes are taken into account (c) the formation of Na^+ complexes is avoided by using tetrealkylammonium cations for the background salt and/or for the titrant strong base. The formation of Cl^- complexes has been neglected in most cases. Different assumptions (i.e. different complexation models) give rise to very different values of formation constants, in particular with Na^+ and Cl^- complexes with $K > 10$ mol^{-1} dm^3, as for many systems studied here. In order to show the magnitude of differences in log K_{ij} for the formation of mixed proton complexes due to the choice of different assumptions, we calculated formation constants at three different ionic strengths ($I =$ 0.1, 0.25 and 0.5 mol dm^{-3}) by (i) considering both Na^+ and Cl^- complexes; (ii) taking into account only Na^+ complexes; (iii) neglecting both Na^+ and Cl^- interactions. As can be seen (Table 4), in some cases the differences are very significant; for example log K_{62} (penten–$P_2O_7^{4-}$) is lowered by more than four units on going from (i) to (iii).

Empirical parameters of Eq. (1) were checked randomly for their dependence on ionic strength for different systems and complexes studied here. In particular, the value of c_1 was calculated for all systems and the obtained mean value was $c_1 =$ 0.225 ± 0.021 [the error in log K_{ij} introduced into the calculations, due to the use of Eq. (1), is $z^* \times 0.021 \times I$, i.e. in most cases < 0.05].

4.3. Comparison with similar systems

Very few amine–anion complexes have been studied quantitatively. Most studies in this field relate to the complexation of polyanions by cyclic protonated amines [15–20]. In this laboratory, different amine–anion systems have been investigated [1,21–26], and in all cases, a strict dependence between stability and charges has been found. As an example, we may compare the stability of tetren–$P_2O_7^{4-}$ complexes with the analogous complexes tetren–$Fe(CN)_6^{4-}$ [24] and tetren–btC^{4-} [4–25] (btc = butanetetracarboxylate): for log K_{20} we have 4.4 and 4.0 respectively (4.7 for $P_2O_7^{4-}$). The system en–$P_2O_7^{4-}$ has been studied by Dietrich et al. [3] at $I = 0.1$ mol dm^{-3} in Me$_4$NCl; they found log $K_{10} = 1.5$, log $K_{11} =$ 2.5 and log $K_{21} = 2.6$. These values are intermediate between our values (b) and (c) reported in Table 4. This is consistent with some observations already made, according to which Cl^- forms complexes with protonated amines [11–14] and Me$_4$N$^+$ forms very weak complexes with unprotonated amines [11,12], whilst N^{a+} forms fairly strong complexes with $P_2O_7^{4-}$ [10].

4.4. Statistical analysis and errors

The speciation model for each system was obtained by using some simple rules, including the statistical ones. Briefly, the procedure for selecting the best model includes these main points: (a) check for the absence of systematic errors (all the experimental conditions were randomised); (b) choose a suitable weighing scheme;(c) use the F test for the selection of the most suitable speciation model; (d) check for the absence of systematic trends in the residuals in order to avoid bias in the selecion of species. Nevertheless, it is important to bear in mind that the speciation models, together with formation constants obtained for each system, are strictly valid only within experimental conditions; in fact, it is not possible to exclude the formation of other species when the concentrations of reactants is higher than that used in the present work. Moreover, it is possible that some quaternary species such as AL(Cl)H$_q$ or AL(Na)H$_q$ are formed at higher Na^+ and Cl^- concentrations.

[a] I in mol dm^{-3}; i and j refer to the formation constant K_{ij} [see Experimental section, Eq.(2e)].
[b] Formation constants calculated by considering the formation of both Na^+ and Cl^- complexes.
[c] Formation constants calculated by neglecting Cl^- complexes.
[d] Formation constants calculated by neglecting both Na^+ and Cl^- complexes.
[e] $\log K_{ij} < 0$.

Errors associated with overall formation constants β_{pq} are reported in Table 3 as three times the standard deviation. In general these uncertainties can be considered satisfactory, but we must consider that by including small systematic errors, formation constants may be affected by substantially higher uncertainties. Values of log K_{ij} are reported to only one decimal place since they are affected by an error $0.1 \leqslant 3s \leqslant 0.4$.

4.5. Concluding remarks

The most important finding of this work relates to the quite high strength of pyrophosphate–amine complexes, in particular for polyamines with more than two amino groups. In some cases the formation constants of mixed proton–$P_2O_7^{4-}$–amine species are comparable with those of $P_2O_7^{4-}$–alkaline earth metal complexes [27], and in the case of penten higher log K_{ij} values are also observed.

The second remark to be made concerns the dependence of the medium of formation constants of complexes studied here. In fact, as reported in the text and in Table 4, different ionic strengths and different background conditions may cause a substantial lowering of formation constants. This is due to the high charges of pyrophosphate and protonated polyamines and to the strong interferences of Na^+ and Cl^-. Therefore, care must be taken when using these formation data in the speciation of different biological and natural fluids.

Finally it must be stressed that, in the light of present results, interaction of $P_2O_7^{4-}$ with polyamines may play an important role in natural systems, since it occurs also at very low concentrations. Semi-quantitative information for the stability of other complexes with biologically important amines can be obtained using Eq. (3).

Catalytic–adsorptive stripping voltammetric determination of molybdenum in plant foodstuffs

Zhiqiang Gao*, Kok Siong Siow

Department of Chemistry, National University of Singapore, Kent Ridge, Singapore 0511, Singapore

Abstract

In acetate buffer solution (pH 3.5) containing oxine and chlorate, ultratrace amounts of molybdenum can be determined after adsorptive accumulation of the Mo(VI)–oxine complex on a hanging mercury drop electrode, coupled with the catalytic effect on the reduction of chlorate. Under optimized conditions, the catalytic–adsorptive stripping voltammetric procedure gives excellent selectivity and an extremely low detection limit of 1.7 pM molybdenum (60 s accumulation). The stripping peak current increases linearly with molybdenum concentration between 10 pM and 5.0 nM. The procedure is applied to determine traces of molybdenum in plant foodstuffs.

Keywords: Adsorptive voltammetric determination; Molybdenum; Plant foodstuffs

1. Introduction

Molybdenum is a biologically essential trace element [1–3]. It always occurs in the hexavalent form (Mo(VI)) in aqueous solutions. Depending on the acidity of the solution, it may be cationic, anionic or polymeric [4]. Molybdenum plays an important role in a wide variety of plants and animals, particularly ruminants. Molybdenum deficiency eventually results in a diminished number of flowers on plants and severe interference in the development of pollen. In contrast a high concentration of molybdenum in soil causes abnormal growth of some plants [5,6]. Molybdenum also affects self-purification processes of natural

water. At about 5 ppm it inhibits biochemical self-purification processes. An even higher content of molybedenum in water prevents the growth of the appropriate microorganisms [7]. Since the concentrations of molybdenum in plants, water and soil are generally at parts per billion levels, sufficient sensitivity is therefore required for the determination of molybdenum.

Many electroanalytical procedures have been proposed for the determination of trace amounts of molybdenum [8–14]. On the basis of the adsorptive accumulation of a molybdenum complex, such as Mo(VI)–tropolone [8], Mo(VI)–oxine [9] or Mo(VI)–mandelic acid [10], on a hanging mercury drop electrode (HMDE), nanomolar amounts of molybdenum in various samples can be successfully determined. Further improvement in the sensitivity has been reported by the applica-

tion of catalytic effects of Mo(VI)–cupferron [11], Mo(VI)–mandelic acid [12] and Mo(VI)–3-methoxy-4-hydroxymandelic acid complexes [13] on the reduction of chlorate, and Mo(VI)–2-(2'-thiozolylazo)-p-cresol complex on the reduction of nitrate [14]. Picomolar detection limits have been achieved after a few minutes of adsorptive accumulation.

This paper describes an extremely sensitve and highly selective catalytic–adsorptive stripping voltammetric procedure for the determination of traces of molybdenum in plant foodstuffs. The procedure is based on the catalytic reduction of chlorate by the accumulated molybdenum complex with oxine. The voltammetric behavior of Mo(VI)–oxine complex in slightly acidic medium was first reported by van den Berg [9]. The reduction current of the adsorbed Mo(VI)–oxine complex was used for the direct determination of molybdenum in sea water with a detection limit of 0.10 nM (10 min accumulation). The catalytic–adsorptive procedure developed in this paper lowers the detectability further to the picomolar level with a relatively short adsorptive accumulation time.

2. Experimental

2.1. Apparatus and reagents

A PAR Model 174A polarographic analyzer equipped with a Model 303 static mercury drop electrode (EG&G, PAR, Princeton, NJ) and a Graphtec 2400 X–Y recorder were used for voltammetric study. A conventional three-electrode system, comprising an HMDE, a platinum wire counter electrode and an Ag/AgCl (in saturated KCl) reference electrode, was used in all experiments. All potentials reported in this paper were referred to the Ag/AgCl electrode. All experiments were performed under a nitrogen atmosphere in a clean environment.

Water purified in a Milli-Q water purification system (Millipore) was used for all solution and sample preparations. All chemicals were of certified analytical grade and above. A 1000 ppm stock Mo(VI) solution (atomic absorption stan-

dard, Aldrich) was diluted as required. Stock solutions of 1.0 mM oxine and 1.0 M chlorate were prepared by directly dissolving required amounts of oxine and sodium chlorate in water respectively.

2.2. Procedure

The supporting electrolyte solution (10 ml 0.050 M acetate buffer, pH 3.5), containing 0.20 M sodium chlorate and 50 μM oxine, was pipetted into a voltammetric cell and purged with nitrogen for at least 4 min. The accumulation potential was applied to a fresh mercury drop while the solution was stirred. After 60 s of accumulation, a period of quiescence of 10 s was allowed whereafter a linear scan voltammogram was recorded from -0.10 to -0.70 V, with a potential scan rate of 100 mV s^{-1}. After the background voltammogram had been obtained, aliquots of the Mo(VI) standard solution were introduced into the cell while maintaining a nitrogen atmosphere over the solution. All data were obtained at room temperature.

2.3. Reagent purification

All containers were thoroughly cleaned by soaking in 1:1 HNO$_3$ for several days. They were then rinsed and stored in 0.10 M HNO$_3$. All experiments were performed in a clean environment. Trace amounts of molybdenum in the electrolyte solution were removed by Chelex-100 ion-exchanger at pH 3.5. The ion-exchanger was purified according to the proposed procedure [10,12]. The contribution of molybdenum to the supporting electrolyte from the thus purified reagents was generally less than 5.0 pM.

2.4. Sample analysis

For the determination of molybdenum in plant foodstuffs, samples (0.50–1.0 g) were first ashed for 5–7 h at 500°C in a quartz crucible. After cooling, the ashes were carefully moistened with 2 ml of 1:1 nitric acid and the mixture was heated on a hotplate to near dryness. The residue was dissolved in 1.0 mM nitric acid. The solution was filtered and collected in a clean polyethylene bot-

tle. Aliquots of the solution were pipetted into the voltammetric cell and the concentrations of molybdenum were determined using the standard additions method.

3. Results and discussion

Fig. 1 shows cyclic voltammograms for different combinations of Mo(VI), oxine and chlorate in 0.050 M acetate buffer solution (pH 3.5). As illustrated in Fig. 1A, for a solution containing chlorate alone, no obvious current peaks were observed between 0.0 and − 1.0 V. However, in an acidic medium contining Mo(VI), chlorate gave a catalytic current peak at approximately

− 0.5 V (Fig. 1B). This catalytic current increased linearly with increasing molybdenum concentration in the range 0.10–1.0 μM [15]. When mixing Mo(VI) with oxine in the buffer solution, three adsorptive stripping current peaks were obtained (Fig. 1D). The first stripping current peak at approximately − 0.2 V corresponds to the reduction of Mo(VI) in the complex to Mo(V). The second current peak at approximately − 0.5 V should be the reduction of Mo(V) to Mo(IV). The last one represents the reduction of Mo(IV) to Mo(III). The peak current increased with increasing accumulation time prior to the potential scan, indicating that the Mo(VI)–oxine complex is readily adsorbed onto the HMDE. The stripping peak current was directly proportional to the

concentration of molybdenum up to 0.30 μM, with a detection limit of 4.0 nM, following 1 min of accumulation [9]. As indicated in Fig. 1C, upon adding chlorate to the Mo(VI)–oxine complex solution, a dramatic increase in peak current was observed. Furthermore, the catalytic current did not commence until the potential became considerably more negative than that of the first current peak of the Mo(VI)–oxine complex, suggesting that both Mo(VI) and Mo(V) have no catalytic activity towards the reduction of chlorate. As the electrode potential approached the peak potential of the second current peak, more and more Mo(IV) ions were generated at the HMDE surface upon the reduction of Mo(V), which catalyzes the reduction of chlorate in the solution.

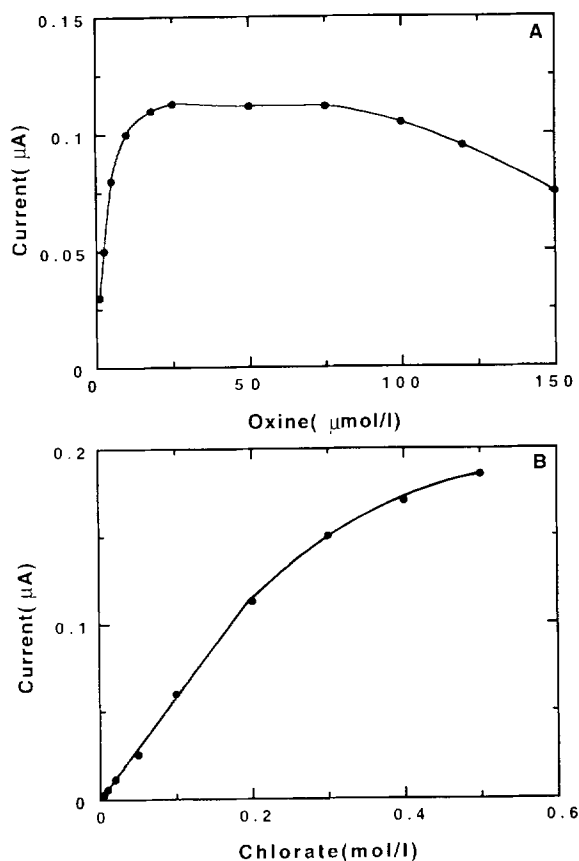

Fig. 3. Variations in the peak current for 0.20 nM Mo(VI) as functions of (A) oxine and (B) NaClO₃ concentration. Accumulation potential −0.10 V, other conditions as in Fig. 1C.

Fig. 2. Effect of pH on (A) peak potential and (B) peak current of Mo(VI)–oxine. Accumulation potential −0.10 V, other conditions as in Fig. 1C.

Referring to the well-known mechanism of the catalytic reduction of chlorate by molybdenum [15,16], a possible reaction mechanism is that uncomplexed Mo(IV), generated at the HMDE surface upon the reduction of the Mo(VI)–oxine complex, reduces chlorate, and in the mean time the regenerated Mo(V) is re-reduced at the electrode surface to Mo(IV), therefore contributing repeatedly to the reduction current. This is a typical EC process and the possible mechanism is as follows:

$$Mo(VI) + 2oxine \rightarrow Mo(VI)(oxine)_2 \qquad (1)$$

$$Mo(VI)(oxine)_2 \rightleftharpoons Mo(VI)(oxine)_{2ads} \qquad (2)$$

$$Mo(VI)(oxine)_{2ads} \rightarrow Mo(V) + 2oxine \qquad (3)$$

$$Mo(V) \rightarrow Mo(IV) \tag{4}$$

$$\boxed{6Mo(IV) + ClO_3^- + 6H_+}$$

$$\rightarrow 6Mo(V) + Cl^- + 3H_2O \tag{5}$$
The pH dependences of the catalytic peak po tential and peak current are shown in Fig. 2. As illustrated in Fig. 2A, the peak potential varied with the pH and was shifted in the negative direction by 112 mV pH^{-1}. A larger peak current was observed at higher pH. Good sensitivity was attained in the pH range 3.5–4.0. A substantial decrease in peak current was observed when the pH was lower than 3.0. The largest current was obtained at a pH of about 4.6 (Fig. 2B). However, a dramatic increase in the peak width was also observed at pH 4.6, which may cause inaccuracy in current measurements, especially at very low

Fig. 5. Catalytic–adsorptive stripping voltammograms for solutions of increasing Mo(VI) concentration: (1) 0.020; (2) 0.050; (3) 0.10; (4) 0.20; (5) 0.50 nM. Conditions as in Fig. 3.

concentrations, since the broadening of the current peak overlaps the reduction currents of oxine and traces of oxygen.

Since oxine is an essential component for the formation of the adsorptive complex, the oxine concentration would be expected to strongly affect the peak current. The peak current increased sharply upon increasing the oxine concentration between 1.0 μM and 20 μM, and then leveled off between 20 μM and 75 μM. Only a slight decrease in the peak current was observed for higher oxine concentrations (Fig. 3A). Chlorate concentration also had a profound effect on the peak current (Fig. 3B). For example, the peak current for 0.20 nM molybdenum increased linearly with increasing chlorate concentration up to 0.20 M, and then more slowly. A chlorate concentration higher than 0.40 M resulted in a larger background current, presumably due to the reduction of chlorate.

The influence of the variation of the accumulation potential on the peak current, examined over the range 0.0 to −0.40 V, is shown in Fig. 4A. The largest peak current was obtained for accumulation potentials between −0.050 and −0.15 V. The peak current decreased when accumulation potentials were more negative than −0.15 V and diminished substantially if an accumulation

Fig. 4. Dependence of peak curent for Mo(VI)–oxine on (A) accumulation potential and (B) accumulation time. (A) 0.20 and (B) 2.0 nM Mo(VI), other conditions as in Fig. 3.

Fig. 6. Catalytic–adsorptive stripping voltammograms for 0.085 nM Mo(VI) (solid lines) and 0.085 nM Mo(VI) + 0.50 μM Cu^{2+} (broken lines) in the presence of (A) mandelic acid, (B) oxine and (C) cupferron. Accumulation time 60 s, other conditions as in Ref. [12], Fig. 3 and Ref. [11] respectively.
potential was selected on the negative side of the first current peak, indicating that only the Mo(VI)–oxine complex is accumulated at the electrode surface, whereas the reduction product has no adsorptive property. The strong adsorptive character of the Mo(VI)–oxine complex can be used as an effective collection step, prior to voltammetric measurement, and provides an extremely sensitive procedure for molybdenum analysis. As shown in Fig. 4B, the longer the accumulation time, the more the Mo(VI)–oxine complex was accumulated and the higher was the current sensitivity. The peak current increased linearly with increasing accumulation time from 0 to 120 s. For accumulation times above 150 s, the gain in sensitivity was very small. Subsequent experiments were, therefore, performed using 0.050 M acetate buffer solution (pH 3.5) containing 50 μM oxine and 0.20 M sodium chlorate, and an accumulation time of 60 s at − 0.10 V, taking into account the speed of the measurement

and the performance.

Under these conditions, by taking advantage of the adsorptive–catalytic nature of the Mo(VI)–oxine complex, the sensitivity of the linear scan voltammetric method is improved significantly. The dependence of the catalytic–adsorptive stripping peak current on the concentration of molybdenum is shown in Fig. 5, which displays parts of the catalytic–adsorptive stripping voltammograms in calibration experiments. Well-defined peaks were obtained despite the very low molybdenum concentrations (subnanomolar levels). The catlaytic–adsorptive stripping peak current of the Mo(VI)–oxine complex was found to be directly proportional to the Mo(VI) concentration in the range 10 pM–5.0 nM (correlation coefficient 0.998), with a sensitivity of 0.56 μA nM^{-1}, which is more than 10 000 times higher than that for a simple diffusion-controlled current of molybdenum ions in an acidic medium. As shown in Fig. 6 (solid lines), the sensitivity obtained in this work

Table 1
Determination of molybdenum in plant foodstuffs (average of six determinations)

Sample	Mo content (ppb)	Mo added (ppb)	Mo after addition (ppb)	Recovery (%)
Cucumber	52	50	100	96
Cabbage	74	50	126	104
Tea[a]	210	200	398	94
Tomato	38	50	87	98
Wheat[a]	510	500	985	95
Potato	31	50	79	96

[a] Air-dried sample.

was higher than the most sensitive catalytic–adsorptive procedure, the Mo(VI)–cupferron system [11], and much higher than those of other catalytic–adsorptive stripping voltammetric procedures [12–14]. The detection limit, estimated from three times the standard deviation of repetitive measurements of 10 pM molybdenum under optimal conditions, was found to be 1.7 pM, which is about three orders of magnitude lower than that of the corresponding adsorptive stripping procedure [9] and is comparable with that of the most sensitive catalytic–adsorptive stripping voltammetric procedures [11–14]. The reproducibility of the procedure was established by two sets of 20 repetitive determinations of 20 pM and 2.0 nM molybdenum. The mean peak currents were 11.8 nA and 1.12 μA with relative standard deviations of 5.1% and 1.9% respectively.

In the voltammetric determination of molybdenum in the catalytic–adsorptive systems, interferences may be caused by the competitive adsorption of ions and their complexes on the electrode surface and competitive participation in the catalytic reaction. They may also be the result of the appearance of reduction peaks next to the Mo(VI)–oxine complex current peak. Owing to the extremely high sensitivity of the catalytic–adsorptive stripping current, it is expected that the influence of a large excess of another reducible species on the determination of molybdenum will be minor, even with a similar peak potential to the catalytic current peak potential. The effect of co-existing ions was tested at a concentration of 1.0 nM molybdenum. It was found that up to 1.0 mM of SO_4^{2-}, NO_3, F, BO_3^{3-}, CO_3^{2-}, Cl, NH_4^+, K^+, Sr^{2-}, Li^+, Be^{2+}, Ba^{2+}, Ca^{2+} and

Mg^{2-}; 0.10 mM of BrO_3^-, NO_2, SCN^-, Al^{3-} and Ga^{3-}; 10 μM of Cd^{2-}, Co^{2-}, Fe^{2+}, Fe^{3+}, Cr^{3+}, CrO_4^{2-}, $AuCl_4^-$, Pb^{2+}, Ag^+, Hg^{2+}, Zn^{2+}, Ni^{2+}, Mn^{2+} and Ce^{4+}; 5.0 μM of Cu^{2-}, Bi^{3-} and In^{3+}; and 2.0 μM VO^{2+} have little effect on the determination of molybdenum. However, SbO^- has a reduction current peak in the region of the stripping peak of molybdenum which interferes at concentrations of 1.0 μM. Additions of 3.0 μM I^- and 0.20 μM WO_4^{2-} lower the Mo(VI)–oxine peak by 12% and 15% respectively. In addition, due to the adsorptive nature of the Mo(VI)–oxine complex, surface-active substances, such as natural organic sufactants, Triton X-100, Tween-80, sodium dodecylsulfate (SDS) and cetyltrimethylammonium bromide (CTAB), may interfere as a result of competitive adsorption at the electrode surface. For example, additions of 0.50 μM CTAB and SDS resulted in 12 and 15% depressions of the peak current respectively. Depending on the complexity of the sample, for direct determination of molybdenum, necessary sample pretreatments, such as UV irradiation, ashing, acid digestion and microwave digestion, are recommended. Compared to other catalytic-adsorptive stripping voltammetric procedures, for example Mo(VI)–cupferron [11] and Mo(VI)–mandelic acid [12], better selectivity against copper was observed (Fig. 6, broken lines). In addition, better selectivity against tungsten was also observed.

The proposed method was sucessfully applied to detemine molybdenum in a number of plant foodstuffs. In order to eliminate the matrix effect, molybdenumm contents were determined using the standard additions method. The results are

listed in Table 1. The recoveries obtained by this method were good enough for practical use.

In conclusion, linear scan voltammetry offers a simple, fast and convenient method for the determination of ultratrace amounts of molybdenum by means of the coupling of adsorptive and catalytic effects of the molybdenum–oxine complex on the reduction of chlorate. The extremely high sensitivity and good selectivity, which are comparable with the most sensitive procedures, adds to the versatility of the proposed method.

Determination of trace amounts of iron by catalytic–adsorptive stripping voltammetry

Zhiqiang Gao*, Kok Siong Siow

Department of Chemistry, National University of Singapore, Kent Ridge, Singapore 0511, Singapore

Received 19 May 1995; revised 1 November 1995; accepted 2 November 1995

Abstract

A highly sensitive and selective voltammetric procedure is described for the determination of trace amounts of iron. The procedure is based on the adsorptive collection of an iron–thiocyanate–nitric oxide complex on a hanging mercury drop electrode. The adsorbed complex catalyzes the reduction of nitrite in solution, which gives a detection limit of 40 ppt iron (30 s accumulation). The stripping current increases linearly with iron concentration up to 80 ppb. The relative standard deviations are 4.2% and 1.6% at 0.5 ppb and 40 ppb respectively. Most of the common ions, except cobalt, do not interfere with the determination of iron. The procedure is applied to determine iron in biological samples, natural waters and analytical-grade chemicals.

Keywords: Iron; Adsorptive stripping voltammetry; Iron–thiocyanate–nitric oxide complex

1. Introduction

In recent years, substantial efforts have been devoted to the development of catalytic–adsorptive voltammetric procedures, which are based on the adsorptive accumulation of metal complex on a hanging mercury drop electrode (HMDE) followed by a homogeneous catalytic reaction [1–12]. This interest is due to the excellent sensitivity, selectivity, accuracy, precision and the low cost of instrumentation. The detection limit of catalytic–adsorptive voltammetry is usually lower than 0.1 ppb, making it one of the most sensitive analytical methods for ultratrace analysis.

A number of metals, including cobalt [1,2], chromium [3,4], molybdenum [5–8], titanium [8], platinum [9], tungsten [10,11], and vanadium [12] have been successfully analyzed using catalytic–adsorptive voltammetric procedures. The electrochemical behavior of iron makes its polarographic determination very difficult. Therefore, for the analysis of trace amounts of iron, most of the reported electroanalytical procedures are based on adsorptive stripping voltammetry. For example, in the presence of catechol [13], 1-nitro-2-naphthol [14], solochrome violet RS [15] or 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol [16], trace amounts of iron can be determined after adsorptive accumulation of the iron complexes with these ligands. Depending on the accumula-

* Corresponding author. Fax: + 65 779 1691.

tion time, iron at ppb levels in various samples has been determined following a few minutes of accumulation. However determination of iron by catalytic–adsorptive voltammetry has rarely been attempted. Golimowski [17] proposed a catalytic–adsorptive voltammetric procedure for measuring iron in the presence of triethanolamine and potassium bromate, but the detection limit (4 ppb) is relatively poor. A more sensitive catalytic–adsorptive voltammetric procedure was reported by Lu et al. [18]. A detection limit of 10 ppt was achieved after 10 min accumulation.

In this paper a novel method of catalytic–adsorptive stripping voltammetry of the iron–thiocyanate–nitric oxide complex at the HMDE is investigated and applied to the determination of trace amounts of iron in a number of samples. Compared to the adsorptive stripping voltammetric procedures, this method provides a very low detection limit (40 ppt) for a very short accumulation period and excellent selectivity against most co-existing ionic species.

2. Experimental

2.1. Apparatus and reagents

A PAR Model 174A polarographic analyzer was employed in connection with a Model 303 static mercury drop electrode (EG & G, PAR, Princeton, NJ) and a Graphtec X–Y recorder. A medium-sized HMDE electrode, with a surface area of 2.0 mm², was used. An Ag/AgCl (in saturated KCl) reference electrode was used in all experiments. All potentials reported in this paper are referred to the Ag/AgCl electrode. Solutions were deoxygenated with high purity nitrogen for 4 min prior to each experiment and all experiments were performed in a clean environment under a nitrogen atmosphere.

Water purified in a Milli-Q water purification system (Millipore) was used for all solutions and sample preparations. All chemicals were of certified analytical grade and above. A stock solution of 1000 ppm iron was prepared by directly dissolving the required amount of ammonium ferrous sulfate in acidified water. Traces of iron in

blank electrolyte were removed according to the procedure developed by Lazaro et al. [19]. Reagent containers and sample bottles were cleaned by soaking in 1:1 nitric acid for a few days. They were then thoroughly rinsed with water and stored in 0.01 M nitric acid.

2.2. Procedure

The supporting electrolyte solution (10 ml 0.1 M pH 4.0 acetate buffer), containing 0.1 M sodium nitrite and 0.05 M potassium thiocyanate, was transferred by pipette into a voltammetric cell and purged with nitrogen for 4 min. The adsorption potential (−0.15 V) was applied to a fresh mercury drop in quiescent solution. A linear scan voltammogram was recorded from −0.15 to −0.75 V following 30 s accumulation, with a potential scan rate of 100 mV s⁻¹. After the background voltammogram had been obtained, aliquots of the iron standard solution were introduced into the cell while maintaining a nitrogen atmosphere over the solution. All data were obtained at room temperature.

2.3. Sample analysis

Biological samples were first ashed for 5 h at 450°C in quartz crucibles. After cooling, the ashes were carefully moistened with 2 ml of 4.0 M ultrapure nitric acid and the mixtures were heated on a hotplate to near dryness. The residues were dissolved in purified acetate buffer. The resultant solutions were filtered and collected in clean polyethylene bottles. Water samples (15–25ml) were filtered through a 0.40 μm cellulose acetate membrane filter into a quartz crucible and the pH was adjusted to about 3.0 with acetate buffer. They were then UV-irradiated for 5–8 h. Analytical grade chemicals were directly dissolved in water and the pH of the sample solution was adjusted to 3.5–4.0 with acetate buffer solution. An aliquot of the sample solution was pipetted into the voltammetric cell and the concentration of iron was determined using the procedure described above.
Fig. 1. Cyclic voltammograms of iron in different solutions: (A) 0.05 M KSCN + 0.1 M NaNO$_2$ + 0.1 M pH 4.0 acetate buffer; (B) 0.05 M KSCN + 1.0 ppm Fe^{2+} + 0.1 M pH 4.0 acetate buffer; (C) as for (A) with the addition of 5.0 ppb Fe^{2+}. Accumulation potential 0 V; accumulation time 30 s; potential scan rate 100 mV s^{-1}.

3. Results and discussion

Fig. 1 shows cyclic voltammograms for NO$_2^-$ – SCN$^-$, Fe^{2+}–SCN$^-$ and NO$_2^-$–SCN$^-$–Fe^{2+} in 0.1 M pH 4.0 acetate buffer solution. As can be seen in Fig. 1A, for solutions containing nitrite and thiocyanate, a small current peak is observed,

Fig. 2. Dependence of peak current for 0.5 ppb iron on the accumulation time at – 0.15 V. Other conditions as in Fig. 1C.

which is due exclusively to traces of iron in purified electrolyte (see also Fig. 6, broken line). In the acetate buffer containing iron and thiocyanate, no obvious current peaks are observable between 0.0 and – 0.7 V (Fig. 1B). As we know, thiocyanate can only cause an oxidation current by forming Hg(SCN)$_2$ at the mercury electrode surface, which is oxidized at positive potentials. Previous study has shown that in an acidic medium containing thiocyanate, nitrite gives a catalytic reduction wave with a peak potential of about – 0.35 V [20]. The cayalytic current increases linearly with increasing nitrite concentration in the range from parts per million to 0.1%. However, this catalytic current disappears almost completely when increasing the pH of thiocyanate solution to about 3.8. In thiocyanate medium, ferrous iron exists mainly as thiocyanate complexes, Fe(SCN)$_n^{2-n}$. Depending on the concentration of thiocyanate, they may be cationic (FeSCN$^+$), neutral (Fe(SCN)$_2$) or anionic (Fe(SCN))$_n^{2-n}$, $n \geq 3$). However, none of these complexes are reducible in the studied potential range. However, with the addition of a small amount of iron to the solution containing NO$_2^-$
Fig. 3. Normal pulse polarogram for 30 ppb iron in 0.1 M pH 4.0 acetate buffer containing 0.05 M KSCN and 0.1 M NaNO₂. Potential scan rate 10 mV s⁻¹; drop time 1 s; pulse width 25 mV.

and SCN^-, one reduction peak appears at approximately -0.45 V during the negative-going scan. Scanning in the positive direction also produces a reduction peak, indicating a catalytic process. The fact that a well-defined and intense signal is obtained in cyclic voltammetry with iron concentration at ppb levels indicates the remarkable sensitivity associated with the catalytic process. Additional gains in sensitivity can be obtained with an adsorption period prior to the potential scan. As shown in Fig. 2, the peak current increases substantially when the accumulation period preceded the potential scan, suggesting the involvement of adsorption in the electrode process. Supportive evidence for the adsorptive character of the complex can also be found from normal pulse polarography (NPP). As demonstrated in Fig. 3, the appearance of the Barker–Bolzan peak in NPP indicates that the iron complex is strongly adsorbed on the mercury

electrode surface [21]. Furthermore, identical response was observed when adding Fe^{3+} to the solution instead of Fe^{2+}. Apparently, ferric iron in the iron–thiocyanate complex is reduced to ferrous iron at the initial potential, leading to the accumulation of the ferrous iron complex. Subsequent experiments were therefore conducted using ferrous iron solutions.

In addition, when nitrate was substituted for nitrite, no obvious current peaks were observable between 0.0 and -0.7 V, indicating that nitrate is not involved in the catalytic reaction. It is known that the reduction potential of nitrite is more negative than -1.0 V in acidic media. It is also known that in acidic media, nitrite disproportionates to nitrate and nitric oxide [22]. Nitrate cannot be reduced before the reduction of hydrogen ions. A plausible explanation for the reduction current is that nitric oxide is involved in the electrode process, most probably by forming a complex with $Fe(SCN)_n^{2-n}$, namely $[Fe(SCN)_nNO]^{2-n}$. It has been demonstrated that a ternary complex, $[FeSCNNO]^+$, is formed under the experimental conditions [23]. After potential-controlled electrolysis at -0.6 V, the resulting solution was tested qualitatively according to the proposed procedure [24]. A positive indication of the existence of hydroxyamine in the solution was observed.

On the basis of the above results and discussion, the catalytic reduction of nitrite in 0.1 M pH 4.0 acetate buffer solution containing iron and thiocyanate is typical electrochemical–chemical process and can be represented as follows:

$$Fe^{2+} + SCN^- + NO \rightarrow [FeSCNNO]^+_{ads} \qquad (1)$$

$$[FeSCNNO]^+_{ads} + e^- \rightarrow [FeSCNNO]_{ads} \qquad (2)$$

$$4[FeSCNNO]_{ads} + NO_2^- + 5H^+ \rightarrow 4[FeSCNNO]^-_{ads} + NH_2OH + H_2O \qquad (3)$$

Great sensitivity improvement is due to the co-existence of the adsorptive nature of the complex (Eq. (1)) and the electrochemical–chemical process of the catalytic reduction of nitrite (Eqs. (2) and (3)).
Fig. 4. Dependence of the peak current for 0.5 ppb iron on pH (A), $NaNO_2$ concentration (B), KSCN concentration (C) and accumulation potential (D). Conditions as in Fig. 2.

The dependence of the peak current on the pH of acetate buffer is shown in Fig. 4A: the stripping peak current is strongly dependent on the acidity of the solution. Decreasing the pH from 5.4 to 4.3 results in a sharp increase in peak current. Good sensitivity is attained in the pH range 4.0–4.3. Although the largest peak current is obtained at pH 3.5, this pH is not suitable for trace analysis of iron, due to interference from the co-existing catalytic reduction of nitrite by thiocyanate [20].

The concentration of nitrite has a profound effect on the catalytic–adsorptive stripping current. As can be seen in Fig. 4B, the stripping peak current for 0.5 ppb iron increases almost linearly with increasing nitrite concentration up to 0.05 M and then more slowly. Increases in response are obtained even at very low nitrite concentrations, namely less than 2.0 mM, but the optimal condition for good sensitivity was found to be in the range 0.1–0.2 M. Due to the reduction of nitrite at a potential of approximately −0.9 V [25], a broad reduction peak was observable at higher nitrite concentrations and was found to interfere with the determination of iron, especially at very low concentrations.

As expected, the stripping peak current exhibits a strong dependence on the concentration of thiocyanate (Fig. 4C). The peak current increases with increasing thiocyanate concentration up to 0.03 M and then starts to level off. In contrast, higher thiocyanate concentrations result in a considerable decrease in peak current, presumably because of competitive adsorption.

The dependence of the stripping peak current on the adsorption potential was examined over the range 0.05 to −0.3 V (Fig. 4D). The peak current increases as the adsorption potential becomes more negative up to −0.15 V, reaches a maximum between −0.15 and −0.2 V, and then decreases again until the potential of the onset of the reduction peak at −0.3 V is reached.

Optimal conditions for the determination of iron were therefore 0.1 M pH 4.0 acetate buffer as the supporting electrolyte, 0.1 M nitrite, 0.05 M thiocyanate and an accumulation period of 30 s at −0.15 V.

The dependence of the stripping peak current on the concentration of iron is shown in Fig. 5, which displays linear scan voltammograms for successive increases in the iron concentration in 1
Fig. 5. Catalytic–adsorptive stripping voltammograms (A) for solutions of increasing iron concentration: (a) 0; (b) 1; (c) 2; (d) 3; (e) 4; (f) 5; (g) 6; (h) 7 ppb and (B) the resulting calibration plot in the range 0.0–200 ppb. Conditions as in Fig. 2.

ppb steps. Well-defined peaks are obtained despite the very short accumulation time (30 s). The peak current is directly proportional to the iron concentration up to 80 ppb. The resulting calibration plot is also shown in Fig. 5. The slope of the initial linear portion is 76 nA ppb^{-1}, with a correlation coefficient of 0.998. The precision was estimated from two series of 20 repetitive mea-

surements of 0.5 and 40 ppb iron solution with the 30 s accumulation period. The mean stripping peak currents were 46.8 nA and 2970 nA and relative standard deviations were 4.2% and 1.6% respectively. For the 30 s accumulation, the detection limit, estimated from three times the standard deviation of repetitive measurements of 0.25 ppb iron under optimal conditions (Fig. 6, solid line), was found to be 40 ppt, which is limited by iron impurities in the purified electrolyte solution (Fig. 6, broken line).

In the catalytic–adsorptive stripping voltam-metric measurement of iron, interferences may be
Fig. 6. Catalytic–adsorptive stripping voltammograms for 0 (broken line) and 0.25 ppb iron (solid line) in 0.1 M pH 4.0 acetate buffer containing 0.05 M KSCN and 0.1 M NaNO$_2$. Conditions as in Fig. 2.

Table 1
Results of sample analysis (average of six determinations)

Sample	Iron found (ppm)	Reference value (ppm)	Recovery (%) (+0.5 ppm)
Apple	0.772	0.781	95.3
Potato	3.25	3.35	98.2
Tap water	0.135	0.131	102
River water	0.173	0.167	97.5
KNO$_3$	0.852	≤1.00	99.1

caused by the competitive adsorption of ions and their complexes on the electrode surface and competitive participation in the catalytic reaction. They may also be the result of the appearance of reduction peaks next to the stripping current peak. Due to the high sensitivity, it is expected that the influence of a large excess of another reducible species on the determination of iron will be minor, even with a similar peak potential to that of the stripping peak potential of iron. The effect of co-existing ionic species and surface-active substances on the determination of iron was investigated. More than 50 ions were examined for their possible interferences in the determination of 0.50 ppb iron. It was found that large amounts of alkali, alkaline earth metal, halide ions, NH_4^-, SiO_3^{2-}, $C_2O_4^{2-}$, BO_3^{3-}, SO_4^{2-}, ClO_3^-, NO_3^-, ClO_4^-, CO_3^{2-}, PO_4^{3-}, citrate and tartrate have no effect on the determination of iron. Amounts of less than 2000-fold (w/w) Al^{3+}, Sn^{2+}, Zn^{2+}, Mn^{2+}, Hg^{2+}, Ce^{3+} and WO_4^{2-}: 1000-fold Bi^{3-}, ZrO^{2+}, Tl^+, Ti^{3+}, VO^{2+}, MoO_4^{2-}, Ga^{3+}, Pd^{2-}, Cr^{3+}, CrO_4^{2-}, Ag^+ and Se^{4-}; and 200-fold Ni^{2+} have little effect on the determination of iron. However, Cd^{2-}, SbO^+, Cu^{2+}, In^{3+} and Pb^{2+} each have a reduction current peak in the vicinity of the stripping peak of iron which interfered at concentration of 0.50, 0.60, 0.13, 0.4 and 1.0 ppm of Cd^{2-}, SbO^- Cu^{2+}, In^{3+} and Pb^{2+} respectively. In thiocyanate medium containing nitrite, cobalt produces a catalytic–adsorptive current peak with a similar peak potential to that of iron [20], which severely interfered with the measurement of iron at concentrations higher than 5.0 ppb. Furthermore, owing to the adsorptive properties of the iron–thiocyanate–nitrite system, surface-active substances, such as natural organic surfactants, Triton X-100, Tween-80, sodium dodecylsulfate (SDS) and cetyltrimethylammonium bromide (CTAB) may interfere as a result of competitive adsorption at the electrode surface. For example, additions of 2.0 ppm CTAB, Triton X-100, Tween-80 and SDS resulted in 9, 13, 12 and 16% depressions of the stripping peak current respectively. Depending on the complexity of the sample, for direct determinations of iron, necessary sample pretreatments are strongly recommended.

The proposed method was successfully applied to determine iron in biological samples, natural waters and purified chemicals. The results are listed in Table 1. The results are in good agreement with the reference values for iron in the samples. The recoveries obtained by this method are also good enough for practical use.

In conclusion, the method developed in this paper provides a simple and fast procedure for the measurement of trace amounts of iron. The catalytic–adsorptive nature of the system results in a significant improvement in the detectability of iron, permitting convenient analysis of iron at sub-ppb levels. Good selectivity (which is better than that of adsorptive stripping voltammetric procedures) adds to the versatility of the proposed method.

Simultaneous determination of lithium, sodium and potassium in blood serum by flame photometric flow-injection analysis

George Narh Doku, Victor P.Y. Gadzekpo*

Department of Chemistry, University of Cape Coast, Cape Coast, Ghana

Received 13 February 1995; revised 30 October 1995; accepted 30 October 1995

Abstract

A simultaneous flow-injection analysis (FIA) manifold that could analyse three ions from a single injection was designed, constructed, calibrated and used successfully to analyse Li^+, Na^+ and K^+. This FIA method was 10 times faster than the batch technique. The sample volume required was a fraction of about 1/110 to 1/75 that of the batch technique. The outputs were quite reproducible and calibration curves were linear. Results obtained for artificial sera compared favourably with the actual known concentrations of ions and results obtained in the analysis of eight natural human blood sera compared well with those obtained by the traditional batch technique.

Keywords: Flow-injection analysis; Blood serum; Lithium; Sodium; Potassium

1. Introduction

Blood electrolytes are cations and anions present in sera which perform various functions [1] for human health. Regular monitoring of these ions is important because deficiency or excess of these ions can cause serious health defects. The routine determination of these ions is by separate batch techniques [2–4] where fresh blood serum is taken to determine each ion, i.e. one sample for every ion analysis. This is time-consuming, wasteful in terms of blood serum and labour-intensive. In this paper, the description of the design, construction and use of a flow-injection analysis

(FIA) manifold [5–7], involving sample zone splitting [8,9], which could analyse three blood ions simultaneously from just one sample injection, is given. The process involves the splitting of the injected sample zone into three different coils of different coil lengths, the three sample portions reach the detector at different times and are used to determine the ions in turn by moving the filter on the detector from one ion to another.

2. Experimental

2.1. Apparatus and manifold construction

The manifold designed to serve the purpose of one sample–three ion analysis is shown in Fig. 1.

---

* Corresponding author.

An air compressor system was used to force distilled water (carrier stream) out of an enclosed container to flow through the tubings. The tubings were made of PVC and had an internal diameter (i.d.) of 1.0 mm. An injection valve, equipped with a simple syringe, was used to introduce the sample, reproducibly, into the carrier stream. A splitting system split the sample zone at point S into three separate coils C_1, C_2 and C_3. Due to the different coil lengths, the sample portions reach the detector at different times and are used to determine the different ions in turn.

The splitting system, constructed on a perspex plate, is shown in Fig. 2. S, E, 1, 2 and 3 are smooth holes of 0.25 cm depth and 2.00 mm i.d. drilled on a perspex plate of 0.5 cm thickness. These holes sit on smaller holes of 0.25 cm depth and 1.0 mm i.d on the underside of the plate. On the underside of the plate, S is connected to the adjacent holes 1, 2 and 3 by smooth route paths of 1.0 mm i.d. The underside of the plate is sealed completely with PVC tape without blocking the holes and route paths. PVC tubings of 0.7 cm length and 1.0 mm i.d. were fixed into the larger holes on the upperside of the plate with a glue prepared by dissolving perspex powder in a 50:50 mixture of $CHCl_3$ and THF. The holes 1, 2 and 3 on one side are connected to 1, 2 and 3 respectively on the other side by PVC tube coils C_1, C_2 and C_3 respectively. Point E is a point of confluence which all sample portions pass before reaching the detector. Thus it was possible to determine one ion from one sample portion and then to turn the filter to another ion to be determined from the next sample portion. The detector used was the single window PFP 7 flame photometer manufactured by Jenway Ltd., UK. The Endim 621-02 recorder, produced by the "Neptum" Schlothin Company in Germany, was used in conjunction with the detector.

2.2. Reagents

Li^+, Na^+, and K^+ standard stock solutions, used to prepare calibration curves, were provided by Jenway Ltd. The concentrations of the standard stock solutions used were Li^+, 1.0 mmol l^{-1}; Na^+, 140.0 mmol l^{-1}, and K^+, 5.00 mmol

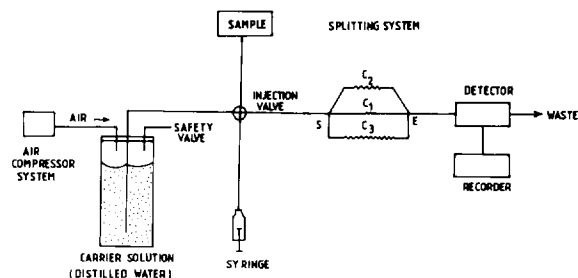

Fig. 1. Manifold design for one sample-three ion analysis.

l^{-1}. Doubly-distilled water was used as the blank/carrier solution. LiCl, NaCl, NaH_2PO_4, KCl and $MgSO_4 \cdot H_2O$ used for preparation of artificial blood sera were of reagent grade and were products of BDH (UK).

2.3. Calibration of analytical system (Optimum flow conditions)

The relative coil lengths C_1, C_2 and C_3 were optimised by successive injections of a 14.0 mmol l^{-1} Na^+ standard solution and adjustment of the lengths until the sample portions did not merge at the point of exit, E. The differences between the times when the sample portions reached the detector were sufficient to change the filter position from one ion to another and for a stable baseline to be obtained.

The respective dispersions D_1, D_2 and D_3 in the coils were determined by first aspirating directly a 14.0 mmol l^{-1} Na^+ standard solution and recording the detector output, then injecting this solution using doubly-distilled water as the carrier stream and recording the output from the coils,

Fig. 2. Diagram showing construction of splitting system.

and then calculating the dispersion, D, from the formula

$$D = \frac{\text{output of direct pumping}}{\text{output of coil after injection}} \quad (1)$$

Each coil had its own residence time [7] which was measured with a stop-clock, as the time from injection to output maximum.

Optimum sample volume range was obtained by injecting various sample volumes of a 14.0 mmol l^{-1} Na^+ standard solution, recording the output, determining the corresponding dispersions in coils and the various differences between the times when the sample portions reached the detector, choosing the optimum sample volume range as that which gave good dispersions in coils for reliable output and optimum time separations for changing filter positions, zeroing the instrument, and having good resolution of peaks.

The optimum flow rate [7] was also determined after varying only the flow rate on subsequent injections of the 14.0 mmol l^{-1} Na^+ standard solution until a good output, time separations for changing filter positions, zeroing of the instrument and good resolution of peaks were obtained. To measure the sampling rate [7], the time from injection to detection of the third ion was noted and the sampling rate was calculated as the number of ions analysed per hour. Different concentration levels of the standard stock solution were then prepared and aspirated directly to obtain batch calibration plots [10,11] and these were then injected to obtain FIA calibrations plots for Li^+, Na^+ and K^+.

2.4. Preparation of standard solutions

The required volumes of the standard stock solution were taken and diluted to different levels to obtain concentration ranges of 0.01–1.0 mmol l^{-1} for Li^+; 14.0–140.0 mmol l^{-1} for Na^+; and 0.5–5.00 mmol l^{-1} for K^+ which were used for calibration curves for Li^+, Na^+ and K^+ respectively.

2.5. Pretreatment of natural blood serum samples

Eight blood serum samples were obtained from

the Cape Coast central hospital. The serum samples were diluted ten-fold by adding 1 ml of 1.0 mmol l^{-1} Li^+ and 8 ml of doubly-distilled water to 1 ml of blood serum sample. The lithium was added to enhance the sensitivity of the flame photometer for Li^+ since the concentration of lithium in natural blood serum is very low (0.001 mmol l^{-1}).

2.6. Preparation of artificial serum

An artificial blood serum was prepared by taking 4.24×10^{-2} g of LiCl, 8.0716 g of NaCl, 0.1304 g of NaH_2PO_4, 0.381 g of KCl, 0.2792 g of $CaCl_2$ and 0.1408 g of $MgSO_4 \cdot H_2O$, dissolving in doubly-distilled water and diluting the mixture to the 1 l mark [12]. This gave concentrations of Li^+, 1.000 mmol l^{-1}; K^+, 5.113 mmol l^{-1}; and Na^+, 146.3 mmol l^{-1}. Similar preparations of other solution mixtures was done to obtain four other solutions with concentrations as follows:

Li^+ (mM)	K^+ (mM)	Na^- (mM)
0.500	3.00	138.0
0.700	3.50	140.0
0.800	4.00	142.0
0.900	4.50	144.0

These five solutions were used for the analysis.

2.7. Analysis of blood serum samples

2.7.1. Batch process

The various standard solutions were first aspirated directly into the flame photometer and the results were used to obtain batch calibration plots for Li^+, K^+ and Na^-. The volume aspirated in each case was 3.0×10^3 μl, giving a total of 9.0×10^3 μl for the three ions. The eight different natural sera were aspirated directly and the concentrations of the ions were determined.

2.7.2. FIA process

100 μl portions of the standard solutions were injected into the carrier stream and the readings obtained were used to plot calibration curves for Li^+, K^- and Na^+. After sample injection, the sample splits into the coils C_1, C_2 and C_3. The

Table 1
Actual concentration of Li^+ vs. FIA results for artificial serum

0.500	0.503	0.60
0.700	0.701	0.14
0.800	0.795	0.63
0.900	0.902	0.22
1.000	1.005	0.50

Table 3
Actual concentration of K^+ vs. FIA results for artificial serum

Actual conc. (mmol l^{-1})	FIA conc. (mmol l^{-1})	% Deviation
3.000	3.02	0.67
3.500	3.50	0.11
4.000	4.00	0.03
4.500	4.49	0.22
5.113	5.25	2.7

output reading for Li^+ was taken from the sample portion in C_1. When all the sample in C_1 had passed through, the filter knob was turned from Li^+ to Na^+ within 10 s and the instrument zeroed again to obtain a stable baseline as the carrier stream passed. The sample portion in C_2 reached the detector 5 s later and a reading was taken for Na^+. When the sample in C_2 had passed through, the filter knob was turned from Na^+ to K^+ within 10 s and the instrument zeroed again. The sample portion in C_3 reached the detector 10 s later and a reading was taken for K^+.

The artificial sera [2] containing the different concentrations of Li^+, K^+ and Na^+ were injected, after ten-fold dilution, to determine the ions with the FIA system in order to compare the FIA results with the actual known concentrations in the artificial sera. Percentage deviation and correlation curves [12] were used to compare the two sets of values.

The eight different natural sera were then injected and the ions determined by the simultaneous FIA method.

Table 2
Actual concentration of Na^+ vs. FIA results for artificial serum

Actual conc. (mmol l^{-1})	FIA conc. (mmol l^{-1})	% Deviation
138.0	136	1.1
140.0	141	0.57
142.0	142	0.14
144.0	145	1.0
146.1	146	0.34

3. Results and discussion

The i.d. of the tubings used was 1.0 mm. Optimised coil lengths were found to be $C_1 = 6.0$ cm, $C_2 = 100$ cm, $C_3 = 210$ cm, and the differences between the times when sample portions reached the detector were C_1 to $C_2 = 15$ s and C_2 to $C_3 = 20$ s. The dispersions in the coils were $D_1 = 3.46$ (limited dispersion), $D_2 = 13.2$ (about medium dispersion) and $D_3 = 25.7$ (large dispersion). After considering the relative sensitivities of the flame photometer for the ions Li^+, Na^+ and K^-, the allocations of the coils to the ions were C_1 for Li^-, C_2 for Na^+ and C_3 for K^+ so as to enhance the sensitivity of the flame photometer for all three ions. The residence times (T) for coils C_1, C_2 and C_3 were $T_{C1} = 8.0$ s, $T_{C2} = 31$ s and $T_{C3} = 100$ s.

For FIA, the optimum sample volume range was 80.0–120 μl whilst the batch method required 9.0×10^3 μl (9.0 cm^3) for three ions. Thus, the FIA sample volume was about 1/110 to 1/75 times smaller than that required for the batch technique. The optimum flow rate obtained and used in the process was 5.0 ml min^{-1}. The FIA sampling rate was 108 samples per hour whilst that of the batch technique was 10.5 samples per hour. Thus, the FIA method was 10.3 times faster than the batch technique. Data obtained for each ion in various standard solutions were quite reproducible and calibration plots were considerably linear, showing that the FIA design was reliable. FIA results compared with actual known concentrations of ions in artificial blood sera are shown in Tables 1–3. The correlation plots of actual concentrations versus FIA concentrations were

Table 4
Batch and FIA results for natural sera

Blood serum	Li$^+$ conc. (mmol l^{-1})			K$^+$ conc. (mmol l^{-1})			Na$^+$ conc (mmol l^{-1})		
	Batch	FIA	% Deviation	Batch	FIA	% Deviation	Batch	FIA	% Deviation
1	0.001	0.0011	10	3.80	4.00	5.3	144	142	0.90
2	0.002	0.002	0.00	3.70	3.40	8.1	135	134	0.96
3	0.001	0.001	0.00	3.75	3.40	9.3	110	107	2.7
4	0.000	0.000	0.00	3.90	3.80	2.6	120	118	2.1
5	0.002	0.002	0.00	3.50	3.00	14.0	130	30	0.08
6	0.002	0.0019	5.0	3.30	3.00	9.1	121	20	0.91
7	0.003	0.0029	3.3	4.80	4.72	8.0	130	134	2.8
8	0.000	0.000	0.00	4.00	4.0	0.00	122	122	0.41

straight lines passing through the origin with slopes of 0.99, 1.40 and 0.98. These results show the reliability and acceptability of the simultaneous FIA design.

The batch and FIA results of eight natural sera and the percentage deviations are shown in Table 4. The Li$^+$ concentrations for the eight natural sera were obtained after the added lithium was subtracted from the total lithium concentration.

4. Conclusions

FIA results for the artificial blood sera were quite similar to the actual known concentrations of ions. Also, FIA results for the natural blood sera were quite similar to those obtained with the batch technique.

The FIA method was 10 times faster than the batch method and required a sample volume that was 1/110 to 1/75 times smaller that that for the batch technique. Hence the FIA method saved time and sample.

Abstract

A simple, precise, rapid-colour-forming and stable spectrometric method has been developed for determining free chlorine in water. p-Amino-N,N-diethylaniline reacts with free chlorine almost instantaneously in the presence of alcohol to form a red oxidized product with absorption maximum at 513 nm. Beer's law is obeyed in the free chlorine concentration range of 0–2 μg ml^{-1}. The molar absorptivity is 1.79×10^4 l mol^{-1} cm^{-1}, limit of detection 0.0036 μg ml^{-1}, relative standard deviation 1.51%, and amount of free chlorine 7 μg. The colour reaction rate and absorbance are independent of temperature in the range 3–45°C and the stable absorptivity lasts for at least 1 h. The method is satisfactory for the determination of free chlorine in aqueous solution.

Keywords: Chlorine determination; p-Amino-N,N-diethylaniline; Colour reaction

1. Introduction

The methods of determining free chlorine were critically reviewed by Nicolson [1] early in 1965. Although a lot of methods, such as ion-selective electrode [2], pneumatic current [3], chromatography [4] and some new amperometry [5–7] and spectrophotometry [8–13] methods have been established, the most frequently used method is still N,N'-diethyl-p-phenylenediamine (DPD) spectrophotometry [14]. However, this method re-

quires modification as the colour fades with time, the absorbance is affected by temperature and some oxidizing agents interfere greatly with measurement [1]. In the present paper, a new method is reported for determining free chlorine based on its colour reaction with p-amino-N,N-diethylaniline sulfate (TSS) [15] in the presence of ethyl alcohol. Its principal advantages are the rapid colouring at room temperature, stable absorbance, the non-temperature dependence of the reaction rate and absorbance, wide linear range, simple and convenient procedure, and relatively high sensitivity and reproducibility.

2. Experimental

2.1. Apparatus

A spectrophotometer (Model 72G, Shanghai Analytical Instrument Factory) with a stoppered comparison cell of 1 cm optical path and a pH meter (Model 25, Shanghai Kanchuan Metals Factory) were used.

2.2. Reagents

The following reagents were used.
Alcohol (anhydrous).
EDTA solution (pH 4.5) 0.3 mol l^{-1}.

TSS alcohol solution. A mixture of 1.3 g TSS and 2.0 ml of 1:9 H_2SO_4 was dissolved in alcohol and diluted to 100 ml. The solution was stable for up to 9 months in a light-proof bottle in a refrigerator.

HAc-NaAc buffer solution of pH 4.7 (25°C). 20 g anhydrous sodium acetate was dissolved in a small amount of water, pH was adjusted to 4.7 with glacial acetic acid and the solution was diluted to 1000 ml with alcohol.

Chlorine solution. 8 g manganese dioxide and 8 g potassium permanganate were ground together in a mortar. 60 ml of 36% hydrochloric acid was slowly added to the mixture in a conical flask. The chlorine liberated was passed into 400 ml of 1 mol l^{-1} sodium hydroxide solution, whose pH had to be kept above 10 to prevent the formation of chlorate. The hypochlorite solution, whose concentration was determined by iodimetric titration to be in the range 0.19-0.25 mol l^{-1}, was placed in a light-proof bottle in a refrigerator. The stock standard solution should maintain its titre for 6 months in an amber-coloured polypropylene bottle. The 1.70 mg l^{-1} solution was obtained by subsequent dilution. Redistilled water was used. Other reagents were of analytical grade.

2.3. Procedure

Add 2.0 ml of the buffer solution, 1.0 ml of TSS solution and 3-4 drops (≈ 0.18 ml) of the EDTA solution to 12.5 ml comparison tubes. Shake the mixture, and then take a known volume of aqueous solution containing about 12 μg of free

chlorine in the tubes. After shaking the mixture, add 2.5 ml of the alcohol immediately and shake vigorously. Then dilute the solution to the mark with water and shake again. Measure the absorbance at 513 nm against the reagent blank prepared in the same manner.

3. Results and discussion

3.1. Absorption spectra

As shown in Fig. 1, under the experimental conditions the colour product exhibited maximum absorption at 513 nm. Pure TSS showed no peak in the wavelength range 400-600 nm.

3.1.1. Effect of acidity

The experimental results showed that pH 3.5-4.9 is suitable for colouring acidity (that is, the acidity having influence on the colour reaction) (see Fig. 2). As is well known, free chlorine in water exists primarily as Cl_2, HClO or ClO$^-$, depending on pH. Their distribution calculated

Fig. 1. Absorption spectrum of the colour reaction products (against reagent blank as reference).
Fig. 2. The absorbance and redox potentials of chlorine species as functions of pH. The potentials (SHE) were obtained by cyclic voltammetry at a Pt electrode [11].

from equilibrium constants [16] as a function of pH illustrates that free chlorine exists primarily in the form of HClO in the pH range 3.5–4.9. From Fig. 2 it can be seen that pH should be controlled in the range 4.5–4.9 in order to maintain the relative high potential relating to HClO, which influences the colour sensitivity, and to prevent interference from such non-free chlorine species as ClO_2^- and ClO_3^-. Hence, pH 4.7 was selected in the experiment.

3.1.2. Effect of reagent amounts

3.1.2.1. TSS Solution. The maximum, stable absorbance was attained as 0.5–2.0 ml TSS solution was added under the selected conditions. Therefore, 1.0 ml was selected.

3.1.2.2. HAc–NaAc buffer solution. The experiment showed that 1.0–8.0 ml buffer solution was suitable and 2.0 ml was recommended.

3.1.2.3. Alcohol. The colouring rate in the non-alcohol medium was slightly slower than in the alcohol medium and the absorbance was not stable. The colour compound is the more stable, the greater the alcohol content. The absorbance was stable for at least 1 h and increased by 10% in a

Fig. 3. Curves showing the dependence of the stability of the coloured product on alcohol content (volume ratio: (1) 0%; (2) 15%; (3) 30%; (4) ≥ 45%).

Table 1
The tolerance limits in the determination of 10 μg free chlorine with TSS in the presence of alcohol

Ion added	Amount tolerated (μg)
As(V), Pb(IV)	1600
Ni(II)	1200
Zn(II), Hg(II)	1000
Al(III), Mo(VI), W(VI)	800
Pb(II)	600
Fe(III), Cu(II), Sn(IV), Co(II)	400
ClO_3^-	75
NO_2^-	70
V(V)	40
ClO_2^-	38
Mn(VII)	2
Cr(VI)	0.4

solution of $\geq$ 45% alcohol (volume ratio). The results are shown in Fig. 3. Therefore a volume ratio of 45% was chosen.

3.1.2.4. EDTA. Some metal ions such as Fe^{3+} and Al^{3+}, which can oxidize TSS or produce hydroxide precipitation, will form complexes with EDTA. Maintaining 0.16% EDTA in the medium

was recommended. The absorbance will decrease as the concentration of EDTA increases.

3.2. Temperature

The experiment showed that the colouring rate and absorbance were virtually unaffected by temperature in the 3–45°C range.

3.3. Analytical characteristics

A calibration graph, shown in Fig. 4, was plotted. Beer's law is obeyed over the concentration range 0–2 μg free chlorine in 1 ml of the final solution. The molar absorptivity is 1.79×10^4 l mol^{-1} cm^{-1} and the limit of detection 0.0036 μg ml^{-1}.

3.4. Interferences

The influences of 39 diverse ions were examined. The ions were added individually to the tested solution. Ions such as Cl^-, Br^-, I^-, NO_3^-, SO_4^{2-}, Ac^-, $C_2O_4^{2-}$, HPO_4^{2-}, $H_2PO_4^-$, AsO_3^{3-}, H_2Y^{2-}, K^+, Na^+, NH_4^+, Ca^{2+}, Mg^{2+}, Ba^{2+},

Fig. 4. Calibration graph.

Table 2
Free chlorine in tapwater (μg ml^{-1})

Sample	Parallel measurements with (A)						Av. of (A)	RSD (%)	Av. of (B)[a]
1	0.93	0.95	0.93	0.92	0.96	0.95	0.94	1.65	0.93
2	0.83	0.84	0.84	0.83	0.85	0.85	0.84	2.26	0.84
3	0.99	0.96	1.00	0.99	0.98	0.97	0.98	1.51	0.97

[a] A reference method: O - toluidine method [17].

Bi^{3+}, Mn^{2+} and Fe^{2+} did not influence the determination of free chlorine. The tolerance limits (error $\leqslant$ 5%) of other ions are listed in Table 1. The interference of Cr(VI) and Mn(VII) was serious. However, it might be eliminated by the use of a hydrophobic, gas-ventilating membrane such as a microporous poly(tetrafluoroethylene) separator through which the free chlorine can pass into the solution of TSS, which will, as a colour reagent, react with it after the tested solution is acidified with hydrochloric acid because the free chlorine exists as Cl_2 in the medium.

3.5. Applications

The method (A) has been applied to tapwater samples. The results are shown in Table 2.

4. Conclusion

The colour reaction of free chlorine with TSS in the presence of ethyl alcohol provides a simple and rapid spectrophotometric approach for determining free chlorine. The method has a wide linear range, good reproducibility and excellent colour stability. The molar absorptivity is 1.79×10^4 1 mol^{-1} cm^{-1}, limit of detection 0.0036 μg ml^{-1}, relative standard deviation 1.51%, and amount of free chlorine 7 μg. The colouring is almost instantaneous and both its rate and absorbance are independent of temperature in the range 3–45°C.

Synthesis of 5-(5-nitro-2-pyridylazo)-2,4-diaminotoluene and its application to spectrophotometric determination of microamounts of palladium

Heqing Yang*, Guang Zhang, Linlin Zhang, Genqi Liu, Xinhuai Zhang

Experimental Centre, Shaanxi Normal University, Xi'an 710062, People's Republic of China

Abstract

A new pyridylazo reagent, 5-(5-nitro-2-pyridylazo)-2,4-diaminotoluene (5-NO_2-PADAT) has been synthesized, and found to be a good chromogenic reagent for palladium. In sulfuric acid, hydrochloric acid and perchloric acid palladium reacts with 5-NO_2-PADAT to form a 1:1 chelate, exhibiting an absorption maximum at 592 nm. The apparent molar absorptivity is 1.25×10^5 1^{-1} mol^{-1} cm^{-1}. Beer's law was obeyed in the range 0–0.9 μg ml^{-1} Pd. Relatively large amounts of co-existing elements, including all other noble metals, can be tolerated. The method is simple and rapid, with high sensitivity and good selectivity and was applied to the determination of palladium in some industrial samples with satisfactory results.

Keywords: 5-Nitro-PADAT; Palladium; Spectrophotometry

1. Introduction

A heterocyclic azo reagent is a good chromogenic reagent for spectrophotometric determination of palladium [1–6]. Its good selectivity is well known, but its sensitivity is not so good. Therefore, one would expect to obtain a new chromogenic reagent for palladium with high sensitivity and good selectivity by introduing a nitro group in the heterocyclic ring. In this paper, the preparation of 5-(5-nitro-2-pyridylazo)-2,4-di-aminotoluene (5-NO_2-PADAT), and the chromogenic reaction of this reagent with palladium in aqueous solution are reported. Its structure is

[a] TEADAT: 3-(5'-tetrazolylazo)-2, 6-diaminotoluene.

5-NO$_2$-PADAT reacted with palladium (II) in relatively strong acidic medium at room temperature to form a 1:1 chelate. The absorption maximum is at 592 nm and the molar absorptivity is 1.25×10^5 l mol^{-1} cm^{-1}. Compared with other typical reagents for the determination of palladium shown in Table 1, 5-NO$_2$-PADAT is the most sensitive. Relatively large amounts of other metal ions, including noble metal ions, do not react.

A simple, rapid spectrophotometric method for determination of palladium with high sensitivity and good selectivity is proposed, and was used to determine palladium in industrial samples with satisfactory results.

2. Experimental

2.1. Reagents

The following reagents were used.

Pd standard solution. 0.1000 g of pure palladium (99.99%) was dissolved in 50 ml of aqua regia. 1 ml of 20% sodium chloride was added, and the solution was heated until it was nearly dry. 2 ml of hydrochloric acid was added and the mixture was evaporated almost to dryness, repeating three times. The residues were dissolved in 1 M hydrochloric acid, transferred to a 100 ml volumetric flask and diluted to volume with 1 M hydrochloric acid. The concentration of this solution was 1.000

mg ml^{-1}, and it was diluted with water to contain 10.0 μg ml^{-1} Pd as required.

5-NO$_2$-PADAT solution, 1.0×10^{-3} M in ethyl alcohol.

Sulphuric acid (1:1).

0.25 M sodium acetate–0.25 M acetic acid buffer solution was used for pH adjustment.

All chemicals used were of analytical-reagent grade, and all solutions were prepared with redistilled water.

2.2. Apparatus

Absorbances and absorption spectra were recorded with a Model 722 (Shanghai Analytical Instrument Factory) and a Hitachi Model U-2000 spectrophotometer with 1 cm cells respectively. The pH measurements were made with a Model pHS-3E pH meter (Jiangsu Electroanalytical Instrument Factory). Elemental analyses were done with a PE Model PE-2400 analyzer. A Mattson Model PK-6000 infrared spectrophotometer and a Bruker Model AC-80 NMR spectrometer were used for recording IR and NMR spectra.

2.3. Synthesis of 5-NO$_2$-PADAT

Preparations of 5-nitro-2-amino-pyridine and its diazotate were described in Refs. [10,11].

Preparation of 5-NO$_2$-PADAT. Dissolve 5.7 g (0.03 mol) of diazotate of 5-NO$_2$-2-amino-pyridine

in 81 ml of aqueous ethanol solution (1:1), and cool the solution to 0°C. Dissolve 3.8 g of 2,4-diamino-toluene in 30 ml of ethanol, and add 7.8 ml of hydrochloric acid solution (1:3). Add this solution dropwise to the diazotized solution with vigorous stirring. Stir for 2–3 h, continue stirring for 2 h at room temperature, and then let the mixture stand overnight. Filter off the precipitate, wash with ethanol and recrystallize from ethanol. Purple lustrous flakes were obtained (m.p. 238.3°C), and the yield was about 40%. The structure has been verified by elemental analysis, IR and ^{1}H NMR. Elemental analysis: $C_{12}H_{12}O_2N_6$ requires 52.93% C, 4.44% H, 30.87% N; found 53.06% C, 4.37% H, 29.80% N. IR(KBr): νas(NH$_2$) 3503 cm^{-1}, νs(NH$_2$) 3400 cm^{-1}, νas(CH$_3$) 2918 cm^{-1}, νs(CH$_3$) 2860 cm^{-1}, νas(NO$_2$) δNH νC–C νN=N 1640, 1588, 1498, 1408 cm^{-1}, νs(NO$_2$) 1334 cm^{-1}, δC–N 1292 cm^{-1}. ^{1}H NMR (solvent: DMSO): δCH$_3$ 2.05 ppm, δNH$_2$ 3.53 ppm, δH$_3$ 5.92 ppm, δH$_6$ 7.30 ppm, δH$_3$, 7.73, 7.85 ppm, δH$_4$, 8.39, 8.42, 8.50, 8.53 ppm, δH$_6$, 9.20, 9.23 ppm.

was soluble in various organic solvents, e.g. ethanol dioxane, tributylphosphate, DMSO and DMF. The dissociation equilibrium of the reagent was studied by a spectrophotometric method as described in Ref. [12]. Four species of this reagent (H_3L^{3+}, H_2L^{2+}, HL^+ and L) were involved in the acid-dissociation behaviour. These four forms are related by the following equilibrium.

The absorbance curves of these four forms as a function of [H$^+$] (H$_0$ or pH) are plotted in Fig. 1.

The dissociation constants were determined by finding the centers of these curves for selected wavelengths. The mean values were pK_{a_1} = -5.35 ± 0.05, $pK_{a_2} = 0.05 \pm 0.05$, $pK_{a_3} = 6.10 \pm 0.05$. The pK_{a_1} value is assigned to the deprotonation of the nitrogen atom of the pyridyl ring; pK_{a_2} and pK_{a_3} correspond to the deprotonation of the 4 and 2-amine groups respectively.

3.2. Absorption spectra

The absorption spectra of 5-NO$_2$-PADAT and its palladium chelate were recorded and are

	$H_3L^{3+} \overset{pK_{a_1}}{\underset{H^+}{\rightleftharpoons}}$	$H_2L^{2+} \overset{pK_{a_2}}{\underset{H^+}{\rightleftharpoons}}$	$HL^+ \overset{pK_{a_3}}{\underset{H^+}{\rightleftharpoons}}$	L
λ_{max} (nm)	445	420	438	534
isosbestic point (nm)	(429)	(423)	(467)	
ε (l mol^{-1} cm^{-1})	5.36×10^4	5.48×10^4	5.54×10^4	3.41×10^4

2.4. General procedure

Transfer an aliquot of solution containing up to 9 μg of Pd (II) to a 10 ml volumetric flask. Add 1 ml of H$_2$SO$_4$ (1:1) solution and 0.5 ml of 1.0×10^{-3} M 5-NO$_2$-PADAT solution. Dilute to volume with water and mix well. After 10 min record the absorbance at 592 nm in a 1 cm cell against a reagent blank.

3. Results and discussion

3.1. Properties of the reagent

The reagent was sparingly soluble in water, but

shown in Fig 2. The absorption maximum of the reagent lies at 421 nm and the chelate has two absorption peaks, at 552 and 592 nm. The latter was chosen for measurements as its sensitivity is higher, and the absorbance of the reagent itself is smaller at 592 nm.

3.3. Effect of acid medium and its concentration

The colour reaction could be performed in sulphuric acid, hydrochloric acid or perchloric acid medium. The absorbance was at an equal maximum in 0.18–4.6 M H$_2$SO$_4$, 0.06–1.5 M HCl and 0.06–3.6 M HClO$_4$. Subsequent determinations were therefore carried out in 0.9 M sulphuric acid.
Fig. 1. Absorbance vs. pH curves for 5-NO₂-PADAT and its palladium complexes, 1 cm cell, 8.0×10^{-6} M reagent, at (1) 445 nm, (2) 420 nm, (3) 400 nm, (4) 438 nm, (5) 438 nm, (6) 534 nm. Complex [Pd (II)] = 3.48×10^{-6} M with a large excess of reagent, at (A) 664 nm, (B) 507 nm, (C) 592 nm.

3.4. Effect of the reagent concentration

The absorbances of a series of solutions containing 4.0 μg of palladium and various amounts of 1.0×10^{-3} M 5-NO₂-PADAT solution were measured. It was found that 0.1 ml of 1.0×10^{-3} M 5-NO₂-PADAT solution sufficed

to complex 4.0 μg of Pd; with higher reagent concentrations the absorbance was essentially constant. Therefore 0.5 ml of the reagent solution was used. The time for the absorbance to reach a stable value was only 5 min at room temperature and the absorbance was stable for at least 72 h.

Fig. 2. Absorption spectra of 5-NO₂-PADAT and its palladium chelate, 1 cm cell: (1) 5-NO₂-PADAT (1.0×10^{-5} M) vs. H₂O; (2) Pd(II) chelate (3.48×10^{-6} M) vs. reagent blank.

Table 2
Tolerance limits for the determination of palladium[a]

Ion added	Amount tolerated (mg)
NaCl	300
KNO$_3$, KBr, Li$_2$SO$_4$	100
Sn(IV), Cd(II), Zn(II)	20
Fe(III)	16
Al(III)	14
Mg(II), Ca(II)	10
Sb(V)	8
Cu(II)	7
Ni(II)	6
Mn(II)	3
Co(II), Bi(III), As(III)	2
Hg(II)	1
Cr(III)	0.3
V(V)	0.2
Ti(III), Ge(IV), Au(III), Rh(III), Ir(III), Ru(III), Pt(IV), Os(III)	0.1
Ag(I)	0.08
Pb(II)	0.06
Mo(VI)	0.04

[a] The solution contained 4.0 μg of Pd(II).

3.5. Composition of the chelate

The composition of the chelate was determined by the continuous variation and molar ratio methods. Both indicated that a 1:1 palladium reagent chelate was formed.

3.6. Calibration graph

The calibration graph obtained by the general procedure showed good linearity over the range 0–0.9 μg ml^{-1} palladium. The linear regression equation was $A = 1.158x + 0.011$ (x: μg ml^{-1}),

and the correlation coefficient was 0.9998. The apparent molar absorptivity was 1.25×10^5 l mol^{-1} cm^{-1}, and the Sandell sensitivity was 8.51×10^{-4} μg cm^{-2}.

3.7. Effect of diverse ions

Numerous cations and anions were examined by applying the method to a fixed amount of palladium in the presence of increasing amounts of the ion being studied. The tolerance limit was taken as the amount that caused an error of $\pm 5\%$ in the absorbance. For the determination of 4.0 μg of palladium by this method, the foreign ions can be tolerated at the levels given in Table 2. It was shown that cations and anions examined, including all other noble metal ions, do not interfere in the determination of palladium.

3.8. The probable mechanism of the reaction

Reactions of palladium with 5-NO$_2$-PADAT at different acidities were investigated by the spectrophotometric method, and the results are shown in Fig. 1. At pH 6–8 the major species of the reagent is L, it reacts with Pd(II) to form chelate A ($\lambda_{max} = 664$ nm); at pH 3.2–5.2 the major species of the reagent is HL$^+$, it reacts with Pd(II) to form chelate B ($\lambda_{max} = 507$ nm); at H$_0 = -2$–0 the major species of the reagent is H$_2$L^{2+}, it forms chelate C ($\lambda_{max} = 592$ nm) with Pd(II). At pH 0–2 the majority species of the reagent is HL$^+$, it reacts with Pd(II) to form chelate B, which could easily change into chelate C by protonation of the β-nitrogen of the azo groups.

Table 3
Results for the determination of palladium in the industrial sample

Sample	2,4-TADAT method		Proposed method	
	$\bar{X}$ (%)[a]	RSD (%)	$\bar{X}$ (%)[a]	RSD (%)
Molecular sieve[b]	0.204	0.7	0.206	0.4
Ni-alloy[c]	0.0925	1.0	0.0889	0.9

[a] Mean of nine determinations.
[b] Na$_2$O·Al$_2$O$_3$·2SiO$_2$ containing a trace of Pd.
[c] Major composition (%): Ni, 85; Cu, 10; Fe, 3; Co, 1.

Therefore, in the range $H_0 = -2$–pH 2, 5-NO$_2$-PADAT reacts with Pd(II) to form chelate C despite the two different major species of the reagent, this was used in the analysis. The structures of chelates A–C are
general procedure. The results obtained are consistent with those obtained by the 2,4-TADAT spectrophotometric method [3] (Table 3).

Chelate A

Chelate B

Chelate C

3.9. Applications

The proposed method has been applied to the determination of palladium in nickel alloys and molecular sieves. The procedure was as follows. Dissolve an accurately weighed sample in 20 ml of aqua regia and evaporate the solution to 10 ml. Add 0.5 ml of 20% sodium chloride, and evaporate the mixture until nearly dry. Add 2 ml of hydrochloric acid and heat the solution almost to dryness, repeating 2–3 times. Dissolve the residues in 1 M hydrochloric acid, and filter. Transfer the filtrate to a 100 ml volumetric flask, dilute to volume with 1 M hydrochloric acid and mix well. Take an appropriate aliquot of the sample solution and determine palladium by the

Ion-selective electrode for salicylate assay in blood serum

Takashi Katsu*, Yuki Mori

Faculty of Pharmaceutical Sciences, Okayama University, Tsushima, Okayama 700, Japan

Abstract

A salicylate-selective membrane electrode made with heptyl-4-trifluoroacetylbenzoate as a neutral carrier was successfully applied for the determination of salicylate in blood serum. This procedure is advantageous because the free concentration of the drug in serum can be determined without sample preparation. The free salicylate concentrations determined by the ion-selective electrode compared to those obtained by conventional colorimetry gave a linear correlation coefficient 0.997 in the salicylate concentration range 0.1–2.5 mM.

1. Introduction

Ion-selective electrodes have become important and useful in chemical and medical analyses [1–3]. We are interested in applying these electrodes to therapeutic drug monitoring in clinical analysis. Such monitoring is fundamental to pharmacotherapy, as it can be used to adjust the doses of drugs with similar therapeutic and toxic concentration ranges [4]. So far, a lithium ion-selective electrode has been successfully applied for monitoring blood concentration of lithium carbonate, which is administered to patients with manic disorders [5], and currently this electrode is widely used in clinical laboratories because of its easy handling. In addition to this electrode, we introduced new ion-selective electrodes to monitor the blood levels of the antiepileptic and antiarrhythmic drugs bro-

mide [6] and procainamide [7] respectively. As an extension of these studies, we applied a salicylate-selective electrode to drug monitoring in blood serum. Although various salicylate electrodes have been developed and applied to pharmaceutical and clinical analyses [2,8,9], the direct determination of salicylate in blood serum in situ has not yet succeeded owing to the low sensitivity of the electrodes under physiological conditions [9,10]. We were particularly interested in constructing a new salicylate-selective electrode using a carbonate ionophore [11]. This ionophore, of course, had originally been developed to make a carbonate ion-selective electrode [11], but was also found to be suitable for constructing a certain specific carboxylate electrode such as a benzoate electrode [12]. In the present study, we applied this ionophore for the construction of a salicylate electrode, which was especially effective for determining free salicylate concentration in blood serum.

2. Experimental

2.1. Reagents

The sources of the reagents were as follows: carbonate ionophore I (ETH 6010, heptyl-4-trifluoroacetylbenzoate), methyltridodecylammonium chloride (MTDACl) and o-nitrophenyl octyl ether (NPOE) from Fluka (Buchs, Switzerland); poly(vinyl chloride) (PVC; degree of polymerization 1020) from Nacalai Tesque (Kyoto, Japan); sodium salicylate from Kanto Kagaku (Tokyo, Japan); acetylsalicylic acid (aspirin) from Wako (Osaka, Japan). All other chemicals used were of analytical-reagent grade.

2.2. Electrode system

The salicylate-selective electrode was based on a PVC membrane [11,12] and its components were 1.7 mg of carbonate ionophore I, 1.2 mg of MTDACl (40 mol% relative to the ionophore), 30 mg of NPOE and 30 mg of PVC. The materials were dissolved in tetrahydrofuran and poured into a flat Petri dish (30 mm diameter) from which the solvent was allowed to evaporate at room temperature. The resulting membrane was cut out and stuck to a PVC tube (4 mm o.d., 3 mm i.d.) using tetrahydrofuran as the adhesive. The PVC tube was filled with an internal solution of 1 mM sodium salicylate and 10 mM NaCl, and the sensor membrane was conditioned overnight. The electrochemical cell arrangement was: Ag, AgCl | internal solution| sensor membrane | sample solution| 1 M lithium acetate (salt bridge) | 10 mM KCl | Ag, AgCl. The electromotive force (e.m.f.) between the silver/silver chloride electrodes was measured using a voltmeter of high input impedance made with a field-effect transistor operational amplifier (LF356; National Semiconductor, Sunnyvale, CA; input resistance $> 10^{12}\Omega$) and recorded. The selectivity coefficients of the electrode were evaluated by the fixed-interference method [13] using the respective sodium salts. The detection limit was defined as the intersection point of the extrapolated linear regions of the calibration graph [13].

A typical procedure for determining salicylate in serum was as follows. The electrodes were placed in 100 μl of serum under constant stirring with a stirring bar. This electrode system, including the reference electrode [14], is compact. Therefore, volumes as low as 100 μl can be assayed. Serum samples containing salicylate were prepared by adding sodium salicylate to human serum. All measurements were performed at a constant temperature of 25°C.

2.3. Colorimetry

Salicylate concentrations in sera were also determined by a colorimetric procedure based on the color formed when salicylate complexes with ferric ions [15]. The procedure is summarized as follows. The serum samples were ultrafiltrated through Centricon-30 (Amicon, Beverly, MA; molecular weight cut-off $> 30,000$) to remove salicylate bound to serum protein. The filtrate (100 μl) was pipetted into a test tube (10 ml) containing 1.2 ml of 24.8 mM ferric nitrate and 62 mM nitric acid, to produce a violet color. The absorbance at 540 nm was determined using a Shimadzu UV-2100 spectrophotometer.

3. Results and discussion

3.1. Response characteristics in blood serum

The clinical range of salicylate in serum required for anti-inflammatory therapy is 150–300 μg ml^{-1} (1.1–2.2 mM) [4,16]. Thus, we examined the response of the electrode to salicylate in serum to confirm whether the present method is applicable to this concentration range. A calibration graph was obtained by measuring a known amount of sodium salicylate added to a serum sample and plotting the concentration against the corresponding e.m.f. value. As is shown in Fig. 1 (curve a), the calibration graph of the electrode covered the clinical concentration range. However, the electrode exhibited a super-Nernstian response with a slope of -80 mV per concentration decade (in the range 1–10 mM). As will be discussed later, this abnormal electrode response

can be attributed to the binding of salicylate in proteins in the serum samples. The detection limit for salicylate in serum was 0.3 mM. The response time of the electrode (90% final signal) was below 10 s when the concentration of salicylate was changed from 0.5 to 2 mM. We also examined the response of the electrode without the ionophore and containing only the ion-exchanger MTDACl [17]. The detection limit for salicylate in serum became significantly higher (0.6 mM), showing that the salicylate electrode based on the lipophilic quaternary ammonium salt alone responded weakly to salicylate, as has been suggested previously [9,10]. Thus, the use of the carbonate ionophore was effective for determining salicylate concentration in serum.

We constructed a calibration graph after the serum sample was ultrafiltrated through Centri-con-30 (Fig. 1, curve b). The electrode exhibited a near-Nernstian response in the range 0.2–10 mM salicylate with a slope of −55 mV per concentration decade. The lower limit of detection for salicylate was remarkably improved to 0.04 mM. As salicylate binds serum protein such as albu-

min, [4,18], the free concentration of salicylate remarkably decreased in the presence of serum protein, and thus the calibration graph from the serum sample (curve a) shifted to a higher concentration of salicylate than that from the deproteinized sample (curve b). The deviation from the Nernstian response observed in blood serum can be explained by the concentration dependence of salicylate binding on serum [4]. That is to say, in the lower concentration range of salicylate most of the drug bound to serum proteins, while in the higher concentration region the portion of the drug bound to proteins decreased, thus generating a steep slope. The percentage of salicylate bound to protein can be easily estimated by comparing these two calibration graphs (curves a and b), as the concentration of free salicylate can be determined by the curve b calibration graph and the total salicylate (the sum of the concentrations of the free salicylate and that bound to protein) can be estimated from the curve a calibration graph. For example, when 1 and 5 mM salicylate were added to the serum, 79% and 54% of the salicylate bound to serum protein respectively.

3.2. Application to drug monitoring

For therapeutic drug monitoring, determining the free concentration of a drug is claimed to be physiologically more relevant than determining the total concentation of drug [4,9,16]. Thus, this method is very useful as the electrode is responsive only to free concentration. Although the free concentration of salicylate can be determined using the calibration graph shown in Fig. 1 (curve b), we were particularly interested in obtaining the calibration graph from a much simpler solution. We found that the calibration graph (Fig. 1, curve c), generated from physiological saline containing 0.15 M NaCl and 5 mM 4-(2-hydroxyethyl)-2-piperazineethanesulfonic acid–NaOH (pH 7.4) afforded similar results to the deproteinized serum sample (curve b) on a higher concentration range. Although the detection limit measured in the physiological saline (0.01 mM) was significantly lower than that in the deproteinized serum sample, the improved detection limit appeared to be mainly attributable to removing the interference

Fig. 1. Comparison of the response of the electrode to salicylate in (a) serum, (b) deproteinized serum, and (c) physiological saline containing 0.15 M NaCl and 5 mM 4-(2-hydroxyethyl)-2-piperazineethanesulfonic acid–NaOH (pH 7.4). The clinical concentration range required for anti-inflammatory therapy is also shown.

Table 1
Selectivity coefficients, $\log k_{i,j}^{Pot}$ [a]

Interfering ion (j)	Concentration (M)	$\log k_{i,j}^{Pot}$
Cl^-	0.5	−4.4
HCO_3^-	0.05	−2.4
CH_3COO^-	0.5	−3.9
Acetyl salicylate	0.0005	−0.6

[a] i = salicylate and j = interfering ion

of bicarbonate, as the serum samples contained a high concentration of bicarbonate (28 mM) [19] and the electrode responded to this significantly. However, the difference in the curves b and c of the calibration graphs was confined to the lower concentration range of salicylate. Thus the calibration graph shown in curve c can be used, except when the salicylate concentration range is extremely low. This agreement of the calibration graphs is useful as the free salicylate concentration can be estimated by comparing the e.m.f. readings measured in serum with the curve c calibraion graph. The total concentration of salicylate can also be evaluated using the curve a calibration graph. However, in this case, the calibration graph should be generated from an individual patient, since the protein content, such as that of albumin, significantly differs among individuals [4].

In Table 1, the selectivity coefficients of the electrode are summarized, together with the concentrations of interfering ions used. The electrode was sufficiently selective against the chloride ions present in serum at high concentration (103 mM) [19], whereas there was slight interference from bicarbonate ions due to the rather lower selectivity than that of chloride ions. This electrode did not respond strongly to acetyl salicylic acid (aspirin), which is the parent drug of salicylate medicines. Thus, the electrode avoided serious interference by this drug although aspirin is rapidly deacetylated in the body to produce pharmacologically active salicylate [4,18].

We compared the free concentrations of salicylate in serum samples, determined by potentiometry using the calibration graph (Fig. 1, curve c), with those determined by colorimetry [15]. As

Fig. 2. Correlation of the free salicylate concentrations in 20 serum samples determined by potentiometry using a salicylate-selective electrode and by colorimetry.

shown in Fig. 2, the correlation was good in the salicylate concentration range 0.1–2.5 mM. The colorimetric method requires deproteinization to estimate the free salicylate concentrations in serum samples, whereas the potentiometric method does not. Thus, the present method is much simpler, more rapid and economical. Free salicylate concentrations in whole blood can also be monitored, as the procedure is independent of sample color or turbidity. This new method will markedly reduce the workload involved in therapeutic drug monitoring for salicylate in the clinical setting.

Separation and preconcentration of ultratrace lead in biological organisms and its determination by graphite furnace atomic absorption spectrometry

Youwen Tang*, Bingren Chen, Shengjun Mo

Department of Chemistry, South China Normal University, Guangzhou 510631, People's Republic of China

Abstract

A biological organism (chitosan) was utilized to preconcentrate lead ions from tap water. This preconcentration was achieved by mixing 0.8 ml of chitosan slurry with 10–50 ml of lead-containing solution and subsequently separating by centrifugation. The chitosan paste was then dissolved in 1 ml of 0.2% nitric acid and analysed by graphite furnace atomic absorption spectrometry. The extraction efficiency can approach 100% in the pH range 4–10. The amount of chitosan used was not critical. The effect of some impurities was also investigated. If six samples were prepared simultaneously, the time needed to preconcentrate each sample was less than 3 min. Two different modes of standard addition (the standard lead solutions being added before and after preconcentration) were used for analysis of tap water samples, and the results obtained by the two modes were found to be quite consistent.

Keywords: Separation; Preconcentration; Lead; Biological organisms; Graphite furnace atomic absorption spectrometry

1. Introduction

Graphite furnace atomic absorption spectrometry (GFAAS) is one of the most common techniques used for ultratrace analysis because of its advantages such as high sensitivity, low detection limits and low sample volume requirement. However, use of atomic absorption spectrometry to directly determine some ultratrace components is often hindered by the following two factors: (1) the analyte concentrations are at or below the limits of detection; and (2) the matrix interferes with the determination. It is therefore essential to preconcentrate the samples prior to analysis.

Solvent extraction, ion exchange, coprecipitation and electrodeposition are useful techniques often used for preconcentration. However, these approaches may be time-consuming, have limited specificity for a particular class of ion and, in addition, their procedures may be complex. For this reason, attempts have been made to explore better techniques for preconcentration of specific ions.

* Corresponding author.

In general, the structures of biological organisms differ, and there are different functional groups on their surfaces. As a result, many biological organisms have the ability to adsorb (or absorb) selectively the analyte of interest without preconcentrating the matrix. Green et al. [1] reported that gold complexes can be quantitatively separated from solutions by a pure algae strain. Holcombe and co-workers have also demonstrated that unicellular green algae can be used successfully to quantitatively separate trace copper, nickel and cobalt from river and sea-water samples [2,3] and cadmium from river samples [4]. The advantages of using algae as a preconcentrator over other preconcentration techniques are convenience, minimum time requirement, a low blank and a high preconcentration factor.

In this research, we have investigated the possibility of using another bio-organism (chitosan) as a preconcentrator. Chitosan ((1,4)-2-amino-2-deoxy-β-D-glucosamine) is a amine polysaccharide, the deacetylated derivative of chitin. Chitin is a type of macromolecule and occurs widely in nature. Chitosan contains two kinds of functional groups, an amino group and a hydroxy group. It can be dissolved in acid solution and separated out in basic solution. Eiden and Tewell [5] have demonstrated the interaction of lead with chitosan. Their result suggested that the uptake of Pb^{2+} on chitosan is a Langmuir-type adsorption. But there is a paucity of data on how chitosan can quantitatively adsorb metal ions at very low concentrations, and how chitosan is used as a preconcentrator for ultratrace analysis. The objective of the present work was to study the ability of chitosan to preconcentrate lead ions at the parts per billion level from 10–50 ml water samples, as well as the conditions under which the preconcentration proceeds. The techniques have been used successfully to determine ultratrace lead in tap water.

2. Experimental

2.1. Materials

The preparation of chitosan has been described previously [6]. The chitosan used for this experi-

ment contained 83% water. Dry chitosan contained 9% amine groups.

2.2. Preparation of chitosan slurry

Before use, 0.5 g of chitosan was added to 10 ml of 0.3% nitric acid. After the polysaccharide was dissolved, seven drops of 1 mol L^{-1} sodium hydroxide were added to the polysaccharide solution. The chitosan sediments separated out, then the mixture was centrifuged and the supernatant was decanted and discarded. The chitosan biomass was subsequently washed with deionized water and centrifuged again. After discarding the washing solution, 10 ml of deionized water was added to the sediments. The mixture was then agitated and the chitosan slurry was ready for use.

2.3. Procedures

The sample was prepared by adding 0.8 ml (containing 6.8 mg dry polysaccharide) of chitosan slurry to 10 ml of a solution containing lead. The pH of each solution was adjusted by dropwise addition of nitric acid or sodium hydroxide solution. The mixture was agitated for 5 min, and then centrifuged. After the supernatant was decanted, 1 ml of 0.2% nitric acid was added to the chitosan paste, and the mixture was agitated to dissolve the biomass for determination later.

Due to the high volatility of lead, 0.5 μg of Pd was used as a matrix modifier, so as to be able to increase the thermal pre-treatment up to 900°C without loss of Pb. In this way, interfering biological matrix could be completely removed before atomisation.

Three replicates were carried out for each experiment. When a significant blank signal was detected, the blank value was subtracted from the corresponding sample signal. Typical blank values will be given later in the paper.

Table 1
Furnace operating conditions

Step no.	Temperature (°C)	Ramp time (s)	Hold time (s)	Argon flow (l min^{-1})	Read[a]
1	100	10	20	3	
2	900	10	30	3	
3	1600	0	5	0	*
4	2600	1	3	3	

[a] The absorbance to be recorded. The * indicates that the record begins in step number 3.

2.4. Apparatus

All experiments were conducted with a Perkin-Elmer 2380 atomic absorption spectrometer equipped with a HGA-400 graphite furnace atomiser. The operation conditions and temperature programmes are listed in Table 1. The Pb hollow-cathode lamp was operated at 4 mA. The spectral band pass and the wavelength of the monochromator were set to 0.7 nm and 283.3 nm respectively. The data were recorded with a Perkin-Elmer R100A recorder as peak heights.

3. Results and discussion

3.1. Effect of pH on Pb adsorption

To investigate the effect of pH on the adsorption of very low concentrations of lead, 10 ml of 10 ng ml^{-1} lead solution at various pH values was mixed with 0.8 ml of chitosan slurry. After 5 min of agitation, the mixture was centrifuged and the supernatant liquid decanted. The chitosan paste was then mixed with 1 ml of 0.2% nitric acid and 5 mg l^{-1} Pd solution to yield a Pb solution which was 10 times more concentrated than the initial solution (assuming 100% efficiency). Solutions thus obtained were subsequently analysed by GFAAS. Experiments showed that after the sample was preconcentrated by chitosan, the pH values of supernatant changed considerably. The pH value of acid samples was increased while that of basic samples was decreased. Table 2 indicates the effect of chitosan on the pH of samples.

Fig. 1 demonstrates the effect of pH on Pb adsorption by chitosan. It can be seen from this figure that the pH range for optimum Pb adsorp-

tion is wide. When the pH value of the samples was changed from 4.03 to 10.10, the recovery approached 100%. This result is better than that achieved with the use of algae to preconcentrate lead [7]. Mahan et al. [7] have reported that recoveries of 6 mg of Stichococcus bacillars, Chlorella Pyrenoidosa and Chlamydomonas reinhariti used to preconcentrate 0.5 μg lead in 25 ml samples were 80%, 40% and 75% respectively. It is obvious that the efficiency of Pb uptake by chitosan is much higher than that by algae.

3.2. Effect of chitosan mass on lead adsorption

In order to investigate the effect of chitosan mass on Pb adsorption, 0.2, 0.4, 0.6, 0.8, 1.0 and 1.2 ml chitosan slurry were added to 10 ml of sample solutions containing 0.1 μg Pb. After 5 min of agitation and centrifugation, all solutions were made up to 1 ml final volume with 0.2% HNO$_3$ and analyzed. Experiments indicated that when less chitosan was used, the efficiency of Pb adsorption was increased. However, when 0.6 ml of chitosan slurry was used, the recovery was almost 100%.

3.3. Effect of preconcentration factor on Pb adsorption

The aim of using chitosan to preconcentrate lead is to reduce the interference of the matrix in the original sample, and to increase the analyte concentration, so as to improve the analytical sensitivity and accuracy. As a result, the effect of sample volume on preconcentration should be determined, i.e. whether the ratio of initial to final sample volume can affect the extraction efficiency of chitosan for lead. Experiments were conducted

Table 2
Effect of Chitosan on the pH of samples

| pH of samples before preconcentration | 3.00 | 4.03 | 5.16 | 6.35 | 8.95 | 10.10 | 10.64 | 11.62 |
| pH of supernatant after centrifugation | 4.50 | 6.20 | 8.00 | 8.82 | 9.23 | 9.91 | 10.30 | 11.40 |

using 0.8 ml of chitosan slurry to preconcentrate 0.1 μg Pb^{2+} in different volumes. The final solution volume for analysis was 1 ml. The result of the experiment is shown in Table 3.

Table 3 shows that when 0.8 ml of chitosan is used, increasing the sample volume up to 25 ml has no effect on the recovery of lead, but increasing the initial volume to 50 ml makes lead recovery unfavorable.

3.4. Effect of impurities and matrix

Several ions which could affect Pb adsorption by chitosan (by competitive binding at the chitosan adsorption sites) were also considered. The effect of interfering ions on preconcentration was studied with 0.8 ml of chitosan slurry being added to 10 ml of sample containing interfering ions and 0.1 μg Pb^{2+}. The inorganic interfering ions were all added in the form of nitrates. 100 μg ml^{-1} Ca^{2+}, 100 μg ml^{-1} Mg^{2+}, 1 mg ml^{-1} Na^- and 1.0 μg ml^{-1} Fe^{3+} do not interfere with the preconcentration of lead, but 10 μg ml^{-1} Fe^{3+} is sufficient to reduce the recovery to 75%. Environ-

mental samples are often polluted by organisms and surfactants. For this reason, experiments to determine the effect of sodium citrate and surfactants on Pb adsorption were performed. 0.01% dodecyl sodium sulfate and sodium citrate decreased the recovery of Pb to 56% and 58% respectively. However, when 0.1% cetyltrimethyl ammonium bromide was added, the recovery was still 100%. Results indicate that the hydrophobic group does not affect the extraction efficiency of chitosan; however, anions of hydrophilic groups complexing Pb^{2+} decrease the extraction efficiency of chitosan for Pb.

3.5. Effects of the preconcentration and centrifugation times on extraction efficiency

A good approach for preconcentration should be simple and quick. To evaluate the dependence of extraction efficiency on the preconcentration and centrifugation times, 0.8 ml of chitosan slurry was aded to 10 ml of solution containing 0.1 μg Pb. After the sample was agitated for 1 min, the extraction efficiency of chitosan for lead was 77%, and after 2 min of agitation it was 83%. After the mixture was agitated for 3 min the recovery reached 100%.

The mixture could be separated completely after only 5 min centrifugation. The centrifugation available for this study allowed preparation of up to six samples simultaneously. Thus, if six samples

Fig. 1. The effect of pH on adsorption of lead by chitosan.

Table 3
Dependence of Pb adsorption of chitosan on sample volume

Initial sample volume (ml)	Final volume (ml)	Concentration factor	Recovery of Pb (%)
10	1	10	100 ± 2^a
25	1	25	100 ± 2^a
50	1	50	97 ± 3^a

[a]Standard deviation.

were prepared each time, the time spent to pre-concentrate one sample was less than 3 min. However, with most preconcentration techniques, the time required to preconcentrate one sample is 10–30 min. A minimum time requirement is one of the major advantages for using chitosan as a preconcentrator over other preconcentration techniques.

3.6. Preconcentration of ultratrace lead in tap water

To verify the capability of chitosan to precon-centrate lead in environmental samples, 0.8 ml of chitosan slurry was used to preconcentrate 10 ml of a tap water sample. The final volume of solution for analysis was 1.0 ml. A blank solution was analyzed with the same procedures. The blank value was subtracted from the corresponding tap water sample signal. The typical lead concentration of a blank solution was 1.5 ± 0.3 ng ml^{-1}. The blank lead value does not come from the chitosan; it most probably comes from impurities existing in the chemical reagents, e.g. sodium hydroxide and nitric acid. Because the matrix may also be concentrated and may interfere with the determination of Pb, two different standard addition approaches were used for analysis of the tap water samples. In the first approach, 0, 0.05, 0.10 and 0.15 μg of lead standard solution were added to 10 ml of four tap water samples. After the samples were preconcentrated by chitosan, 1 ml of

final solution was used for determination. The average value of three replicates determined for Pb in tap water was 7.6 ng ml^{-1}, and the standard deviation was 0.5 ng ml^{-1}. In the second approach, 0.8 ml of four chitosan slurrys was added to 10 ml of four tap water samples. After the samples were preconcentrated and the mixtures were centrifuged, 0, 0.05, 0.10 and 0.15 μg of lead standard solution were added to the four sediments. The final volumes of all solutions were made up of 1 ml in 0.2% HNO$_3$ and analyzed. The value determined for Pb with the second approach and its standard deviation were 7.5 ng ml^{-1} and 0.6 ng ml^{-1} respectively, which are in good agreement with that obtained by the first approach. These results suggest that chitosan can be effectively used to quantitatively preconcentrate ultratrace lead in environmental samples.

Simultaneous high performance liquid chromatographic determination of vanadium, nickel, iron and copper in crude petroleum oils using bis(acetylpivalylmethane)ethylenediimine as a complexing reagent

M.Y. Khuhawar*, S.N. Lanjwani

Institute of Chemistry, University of Sindh, Jamshoro, Sindh, Pakistan

Abstract

A method is described for the simultaneous high performance liquid chromatographic (HPLC) determination of copper, iron, nickel and vanadium, based on complexation of analytes by bis(acetylpivalylmethane)ethylenediimine (H_2APM_2en) followed by solvent extraction and HPLC separation on a reversed-phase. C-18. 5 μm column with UV detection at 260 nm. The method has been applied to the determination of metals in crude petroleum oils collected from the South Indus Basin oil fields. The results obtained are compared with those obtained by flame atomic absorption spectrometry.

Keywords: HPLC; Metal determination; Petroleum oils

1. Introduction

Heavy crude petroleum oils contain vanadium, nickel, iron and copper as organically bound metals, mostly as metalloporphyrins and metallo-non-porphyrins [1,2]. Their determination is of considerable importance, because the metal complexes may poison and foul catalysts or cause undesirable side reactions in refinery operations, such as fluid cracking and hydrodesulfurization

[3]. A number of analytical methods have been used for the determination of metal ions in crude petroleum oils, including atomic absorption spectrometry (AAS) [4], inductively-coupled plasma atomic emission spectroscopy (ICP-AES) [5], radioisotope X-ray fluorescence [6], neutron activation [7], gas chromatography (GC) [8] and liquid chromatography [9]. Zeng and Uden [10,11] have reported high temperature GC with microwave-induced plasma atomic emission spectroscopy for the determination of vanadyl, nickel and iron porphyrins in crude oils. In the present work bis(acetylpivalylmethane)ethylenediimine [N,N'-

ethylenebis(5,5-dimethyl-4-oxohexane-2-imine)] (H_2APM_2en) (Fig. 1) has been used to complex the metals of interest which are subsequently extracted, separated and determined by HPLC in crude petroleum oils.

Belcher et al. [12] have used H_2APM_2en for GC determination of copper and nickel in metal alloys and water samples. Dilli and Patsalides [8] have applied the reagent for the GC determination of vanadium in crude oils. Recently the reagent has also been used for the HPLC determination of copper and nickel in metal alloys and water samples [13].

2. Experimental

2.1. Solvent extraction

An aliquot of solution (1–5 ml) containing 0–100 μg of vanadium, nickel, iron and copper was transferred to a well-stoppered test tube and sulphur dioxide was passed for 30 s. Sodium acetate–acetic acid buffer (2 ml, 1 M) pH 6 was added and the contents were heated gently to near dryness. H_2APM_2en solution (1% w/v in methanol, 5 ml) was added and the contents were heated for 15–20 min. During heating the volume of the solution was reduced to about 1 ml. Water (2 ml) and chloroform (2 ml) were added and the contents were shaken well. The layers were allowed to separate and exactly 1 ml of the chloroform layer was transferred to a sample vial. The solvent was evaporated and the residue dissolved in methanol (0.5 ml). The methanolic solution (5 μl) was injected onto a Microsorb C-18, 5 μm column (150 × 4.6 mm i.d.) and complexes were eluted with methanol: acetonitrile: water (60:20:20 v/v/v) at a flow rate of 1 ml min^{-1}. Detection was achieved using a UV monitor fixed at 260 nm.

2.2. Analysis of metals in crude petroleum oils

The crude petroleum oil samples were collected from the Leghari, Halipota, Dabhi, Golarchi and Tando Alam oil fields located in the South Indus Basin near Hyderabad and Badin, Sindh, Pakistan. The samples were collected directly from the source, when oil was being pumped out of the wells. 20–100 g of sample was transferred to a beaker and sulphuric acid (95–98%; 400 ml) was added. The contents were heated on a hotplate until white fumes of sulphur trioxide were evolved. The mixture was allowed to partially cool, 400 ml of nitric acid (65%) was added slowly and the contents were heated gently. Perchloric acid (72%) (200 ml) was added dropwise to maintain vigorous oxidation with excessive evolution of brown fumes of nitrogen oxides. The clear solution was heated to near dryness. The residue was dissolved in water and the volume was adjusted to 25 ml. A 2–12 ml aliquot of the solution was taken, the pH was adjusted to 6 and the extraction procedure was followed as above. A blank was also prepared simultaneously.

The reagent H_2APM_2en was synthesized as previously reported [12].

2.3. Apparatus

A Hitachi 655A liquid chromatograph connected to a variable wavelength monitor, Rheodyne 7125 injector and Hitachi D2500 Chromato-integrator were used.

A Microsorb C-18, 5 μm (150 × 4.6 mm i.d.) column (Rainin Instruments, USA) was used.

A varian Spectra AA-20 atomic absorption spectrometer with an air–acetylene flame atomizer was used for the determination of copper, nickel and iron using the conditions recommended by the manufacturer.

R = CH₃

M = Cu(II), Fe(III), Ni(II), VO(IV)

Fig. 1. Structural diagram of metal chelates.

Fig. 2. Effect of pH on the extraction of (1) iron(II) (100 μg), (2) nickel(II) (200 μg), (3) copper(II) (200 μg) and (4) vanadium(IV) (200 μg) with H_2APM_2en in chloroform (5 ml).

3. Results and discussion

The derivatization of copper(II), nickel(II), oxovanadium(IV) and iron(II) in the aqueous phase with the reagent H_2APM_2en was investigated spectrophotometrically. The maximum absorbances were measured at 548 nm, ($\epsilon 428$), 570 nm ($\epsilon = 441$), 440 nm ($\epsilon = 1920$) and 456 nm, ($\epsilon = 377$) for copper(II), nickel(II), iron(II) and oxovanadium(IV) respectively. The optimal pH for the extraction of iron(II) was 6. The extraction of copper(II), nickel(II) and oxovanadium(IV) occured at pH 5–9 with a maximum at 7.5–8 (Fig. 2) [12]. However, at pH 7.5–8, a significant decrease in the extraction of iron(II) was observed. At pH 6 the derivatization and extraction of iron(II) and copper(II) was rapid, but they were slow for nickel(II) and heating times of 15–20 min were sufficient for quantitative transfer from aqueous to organic phase. Some difficulties were encountered in extraction of vanadyl from aqueous solution [8,9,14]. Thus, after reduction of vanadium(VI) to vanadium(IV) with sulphurous acid, the solution was heated to near dryness in the presence of acetate buffer at pH 6. The derivatization was carried out in methanol. Using these

conditions it was possible to extract copper(II), nickel(II), iron(II) and oxovanadium(II) as metal chelates simultaneously.

4. Conclusion

The complexes were easily separated using a reversed-phase HPLC column and isocratically eluting with a ternary mixture of methanol: acetonitrile: water (60:20:20 v/v/v) (Fig. 3). Linear calibrations were obtained by plotting average peak height ($n = 3$) against concentration with 0–100 μg sample in an aliquot of water. The coefficient of correlation (τ) was observed to be 0.994, 0.988, 0.994 and 0.995 for copper, nickel, iron and vanadium respectively. The detection limit was measured at least three times the background noise and was 1 μg per aliquot for each of the metal ions. Finally, the method was applied to the determination of metal ions in crude

Thermometric titrations of amines with nitrosyl perchlorate in acetonitrile solvent

Turgut Gündüz*, Esma Kiliç, Orhan Çakirer

Department of Chemistry, Faculty of Science, University of Ankara, Ankara, Turkey

Received 8 May 1995; revised 3 October 1995; revised 11 December 1995 accepted 11 December 1995

Abstract

Thirteen aliphatic and four aromatic amines, namely diethylamine, triethylamine, *n*-propylamine, di-*n*-propylamine, tri-*n*-butylamine, isopropylamine, di-isopropylamine, *n*-butylamine, di-*n*-butylamine, tri-*n*-butylamine, isobutylamine, *sec*-butylamine, *tert*-butylamine, aniline, N,N-dimethylaniline, 2-nitroaniline and 4-nitroaniline were titrated thermometrically with nitrosyl perchlorate in acetonitrile solvent. All the aliphatic amines gave very well-shaped thermometric titration curves. The calculated recovery values of the amines were very good. In comparison, the aromatic amines, aniline and N,N-dimethylaniline gave rather well-shaped titration curves, but the recovery values were fairly low. 2-Nitro- and 4-nitro anilines gave no thermometric response at all. The heats of reaction of the amines with nitrosyl perchlorate are rather high. However, the average heat of reaction of the aromatic amines is approximately two-thirds that of the average heat of the aliphatic amines. To support this method all the amines were also titrated potentiometrically and very similar results to those obtained with the thermometric method are seen. The nitrosyl ion is a Lewis acid, strong enough to titrate quantitatively aliphatic amines in acetonitrile solvent, but not strong enough to titrate aromatic amines at the required level in the same solvent.

Keywords: Aliphatic amines; Aromatic amines; Nitrosyl perchlorate; Thermometry

1. Introduction

A number of methods such as potentiometry, conductimetry, spectrophotometry and thermometry can be used for the titration of diverse chemical compounds in non-aqueous media. Among these however, thermometry, in some respects, has definite advantages over the other methods [1–6]. These advantages briefly are as follows: (i) low electrical conductivity of non-

aqueous media does not interfere; (ii) precipitation, which occurs during some titrations, does not affect this method; (iii) end points are generally very sharp; (iv) there is no electrode poisoning; and (v) the equipment can be set up in a medium equipped laboratory.

Furthermore, in contrast to other methods, thermometry can be applied to (i) redox titration; (ii) acid–base titration; (iii) complexometry and; (iv) volumetric precipitation. As is well known, these are the basic and major analytical reactions on which titrimetry is based [7–20].

* Corresponding author. Fax: + 90 312 2232395.

In the present work, due to the above mentioned advantages of thermometry, we have tried to titrate amines, in particular 13 aliphatic and four aromatic amines, namely diethylamine, triethylamine, n-propylamine, di-n-propylamine, tri-n-propylamine, isopropylamine, di-isopropylamine, n-butylamine, di-n-butylamine, tri-n-butylamine, isobutylamine, sec-butylamine, tert-butylamine, aniline, N,N-dimethylaniline, 2-nitroaniline and 4-nitroaniline. All the aliphatic amines gave very well-shaped titrations curves and from these, we have calculated the mean recovery values of the amines and have been found excellent results. Whereas the aromatic amines, aniline and N,N-dimethylaniline gave rather well-shaped titration curves, the mean recovery values calculated from these curves were fairly low. On the other hand, 2- and 4-nitroanilines did not give useful titration curve.

The heats of reaction of the aliphatic amines were calculated from the initial slopes (up to the 30% neutralization) of the titration curves of the amines. As is seen from Table 1 the reactions are rather exothermic. However, the heats of reaction of the aromatic amines are very low in comparison to the heats of reaction of the aliphatic amines.

There are many examples of the titration of amines with Brönsted acids [1–3,7,16–18], but unfortunately, titrations with Lewis acids are very limited due to the difficulties of finding appropriate Lewis acids and solvents [1,3,4,21–23].

2. Experimental

2.1. Apparatus

Thermometric titration is a titration performed in an adiabatic system, the temperature of which is plotted against the volume of titrant used. In order to meet the requirements of this definition, a small fume-cupboard was insulated carefully with polystyrene foam sheets. A small window was cut in the sheets to allow the operator to look at the titration assembly and use it properly. The assembly consisted of (i) a small Dewar flask with a capacity of 30 cm^3; (ii) a tin-tipped semi-mi-

croburette with a reservoir; (iii) a Beckmann and two accurate mercury thermometers; and (iv) a magnetic stirrer. The Dewar flask was placed in a 250 cm^3 beaker and the walls of the Dewar flask was insulated from the walls of the beaker with the foam polystyrene sheets. The bottom of the beaker was also insulated with the polystyrene sheets. The mouth of the Dewar flask was covered with a thick foam stopper with two holes, shaped from thick polystyrene. A Beckmann thermometer and a tin-tipped semi-microburette were pushed through the polystyrene into the Dewar flask. On top of the reservoir of the semi-microburette U-tubing filled with anhydrous calcium chloride was placed to prevent moisture entering. The Beckmann thermometer was immersed to a fixed depth of solution in each titration and temperature changes of 0.001°C were read. The volume of the titrant solution was read to 0.01 cm^3. Except for the graduated parts and the tap, the semi-microburette was also insulated with blown polystyrene to minimize heat exchanges during the titration. Two mercury thermometers were used to measure the ambient temperature of the assembly and to measure the temperature of the titrant in the reservoir. Both thermometers read the temperature to 0.01°C. The entire set-up has been schematically reported in our early work, which deals with the thermometric titration of urea with antimony pentachloride [24].

All the titrations were carried out at 20 ± 1°C in an insulated fume-cupboard. Under these conditions, the heat capacity of the reaction cell was determined by the method given in Refs. [1] and [18] and was found to be 30.1 J °C^{-1}.

The amine solution used for the determination of the percentage purity (recovery value) and the heat of reaction was kept in the insulated fume-cupboard for at least 2 h to allow it to reach thermal equilibrium with the titrant. However, for the determination of the percentage purity only, half an hour was sufficient, because in such cases thermal equilibrium was not necessary between titrand and titrant [2,8]. The volume of the amine solution taken into the Dewar flask was 15.0 cm^3 and this was magnetically stirred during the addition of titrant. The titrant was added in 0.25 cm^3 quanities. After each addition of titrant at least

one minute was allowed to elapse before measurements were made, to allow the solution to reach thermal equilibrium, and the temperature rise was read by the Beckmann thermometer. The temperature rise after each addition of the titrant was rather large to read with accuracy by the Beckmann thermometer. The overall time needed to complete a titration of an amine solution to obtain its percentage purity (recovery value) only is 45 min. Of this two-thirds of the time is spent waiting for thermal equilibrium and the remaining time is spent on the actual titration.

2.2. Chemicals

Nitrosyl perchlorate was prepared and purified as described in Ref. [25]. The main reaction taking place in the preparation of the compound are as follows:

$$NaNO_2 + HNO_3 \rightarrow NO + NO_2$$

$$NO + NO_2 + 2HClO_4 \rightarrow 2\ NOClO_4 + H_2O$$
The white crystals formed in the reaction medium were filtered, washed and dried for 24 h under high vacuum. The compound obtained in this way decomposed at 108°C, and as described in the reference method is pure enough. So, it was accepted as the primary standard and was used to prepare a 0.050 M solution.

Acetonitrile and triethylamine (both 99% purity) were purchased from Merck and used after purification [26]. n-Propylamine, tert-butylamine, n-butylamine and sec-butylamine (all 98% purity) and di-n-propylamine, isopropylamine, di-n-butylamine, tri-n-butylamine, diethylamine, di-isopropylamine, tri-n-propylamine and isobutylamine (all 99% purity) were puchased from BDH and used without further purification.

Aniline (pure) was purchased from Riedel de Haen and used after purification [26]. N,N-dimethylaniline (98% purity) was purchased from Merck and used without further purification. 2-Nitroaniline (99% purity) was purchased from Fluka and used without further purification. 4-Nitroaniline was purchased from Riedel de Haen and used after purification twice [26].

3. Results and discussion

Thirteen aliphatic and four aromatic amines were titrated thermometrically with nitrosyl perchlorate in acetonitrile solvent. As examples the titration curves of the four amines are given in Fig. 1. Each amine was titrated four times and the titration curves were drawn. From such titration curves the recovery values were calculated and from the recovery values a mean recovery value and relative standard deviation were found. These are given in Table 1. In the calculation of the recovery values, the amines present were accepted to be standards.

In order to choose an appropriate solvent for this work, we tested a number of dipolar aprotic solvents such as nitrobenzene, dimethylsulfoxide, acetone, acetonitrile and found acetonitrile most appropriate. The dipolar aprotic solvents were tested because of the polar characters of the titrant and titrands and, in addition to this, the titrant has a definite ionic character. Acetonitrile

Table 1

The mean recovery values and the heats of reaction of the aliphatic and aromatic amines (approx. 0.005 M) titrated thermometrically with nitrosyl perchlorate (0.005 M) in acetonitrile solvent at $20 \pm 1°C$

Amine	No. of tests	Mean recovery value (%)	Rel. std. dev. (%)	Mean $-\Delta H_R$ (kJ mol^{-1})	Std. dev. (kJ mol^{-1})
Diethylamine	4	98.37	0.72	87.8	7.3
Triethylamine	4	99.31	0.39	72.6	2.3
n-Propylamine	4	99.72	0.40	74.5	5.5
Di-n-propylamine	4	99.14	0.48	76.4	2.7
Di-isopropylamine	4	98.95	0.76	73.3	5.2
Isopropylamine	4	98.81	0.18	79.4	1.6
Tri-n-propylamine	4	98.89	0.56	76.3	3.8
n-Butylamine	4	100.76	0.55	79.5	3.0
Di-n-butylamine	4	98.00	0.57	87.3	1.7
Isobutylamine	4	98.00	0.58	78.1	4.6
Sec-butylamine	4	98.65	0.08	74.1	4.8
Tri-n-butylamine	4	99.19	0.92	70.0	7.7
Tert-butylamine	4	99.15	0.97	74.6	4.8
Anioline	4	97.68	0.32	53.8	6.8
N,N-Diethylaniline	4	95.38	0.93	57.1	6.5
2-Nitroaniline	4	–	–	–	..
4-Nitroaniline	4	–	..	..	–

readily dissolved all the reactants and products. No precipitate was observed during the titrations.

The concentration of the amines was prepared to be approximately 0.005 M and the concentration of the titrant was exactly 0.050 M. These were the best concentrations fixed by the experiments. The titrations were performed discontinuously and the amount of the titrant added at a time was 0.25 cm³. The amount of amine solution taken from the stock solution was 15.0 cm³.

In order to check the validity of this method, we have also titrated all the amines named above with a potentiometric method in the same solvent with nitrosyl perchlorate and have obtained very similar results to those obtained with thermometric method [27].

The heat of reaction of an amine was calculated from its corrected titration curves. To do this, four corrected titration curves were drawn for each amine and from the initial slopes of these curves four heats of reaction were calculated for each amine. The average of these was taken as the heat of reaction of that amine. The heats of the amines are also collected in Table 1 together with the standard deviations. As is easily discerned from Table 1, the average heat of reaction (55.4

kJ mol⁻¹) of the aromatic amines is approximately two-thirds that of the average heat of reaction heat (77.2 kJ mol⁻¹) of the aliphatic amines. The direct and corrected titration curves of isobutylamine are given in Fig. 2, as an example.

In the calculation of the heats of reaction H_R, we have used the following relation [1,7,18,28]:

$$\frac{\Delta T}{\Delta V} = \frac{\Delta H_R \cdot M}{c \cdot d \cdot V + C'}$$

where $\Delta T/\Delta V$ is the initial slope of the corrected titration curve; M is the molarity of the titrant; c is the specific heat of the solvent; d is the density of the solvent; V is the volume of the reaction mixture in the Dewar flask at the end-point; and, C' is the heat capacities of the Dewar flask, stirrer, etc.

$\Delta T/\Delta V$, as a rule, is calculated from the initial slope (up to the 30% neutralization) of the corrected titration curve. In this region, the reaction between titrant and titrand is considered to be complete (mass action law) and the other effects such as mixing heat, dilution heat, stirring heat, etc. are nearly negligible.

For example, by using the following data ΔH_R for isobutylamine is found to be 82.8 kJ mol^{-1}: $\Delta T/\Delta V = 0.07$; $V = 16.45$ cm^3; $C' = 30.1$ J °C^{-1}; $d = 0.782$ g cm^{-3}; $c = 2.26$ J g^{-1} °C^{-1}; and $M = 0.050$ mol dm^{-3}.

As is easily discerned from the Table 1, the mean recovery values of aliphatic amines are good, but the mean recovery values of the aromatic amines are not good. The higher mean recovery value of aniline than that of N,N-dimethylaniline indicates that some steric hindrance prevents the nitrosyl ion in the case of N,N-dimethylaniline from reaching (hyperconjugation). On the other hand 2-nitro and 4-nitro anilines did not give any significant titration curves due to the strong electron withdrawing character of the nitro group. Such electron withdrawing effect of the nitro group depletes the amine group electronically by means of the phenyl group.

The reaction between an amine and nitrosyl acid is in the 1/1 mole ratio.

$$R_3N + NO^+ \rightarrow R_3N-NO^+$$

Fig. 2. Direct (a) and corrected (b) thermometric titration curves of the isobutylamine (approx. 0.005 M) with nitrosyl perchlorate (0.050 M) in acetonitrile solvent at 20 ± 1°C.

(R stands for an alkyl, aryl or hydrogen group)

In order to support the reaction between an amine and nitrosyl ion, hydrochlorides of amines were also prepared and titrated with the nitrosyl ion under the same conditions as for the free amines, but no useful titration curves were observed. This clearly indicates that the reaction between an amine and nitrosyl ion is as shown above. A blank test for each amine was also performed under the same conditions and no significant mixing heat, dilution heat, stirring heat and heat exchange were observed taking into account Fig. 1 curve (5). The smooth increase of the titration curves from the beginning is also a good indication that the effects of these factors are not important in fixing end-points in such titrations. However, these effects have been taken into account in drawing corrected curves and in calculation of the heats of reaction of the compounds.

4. Conclusions

Common aliphatic amines can be titrated thermometrically with the nitrosyl ion in acetonitrile solvent, but aromatic amines under the same conditions cannot be titrated. The nitrosyl ion acts as a Lewis acid and is strong enough to titrate the aliphatic amines quantitatively, but it is not strong enough to titrate aromatic amines. The reaction between an aliphatic amine and nitrosyl ion is a typical Lewis acid–base reaction. The average heat of reaction in such cases is 77 kJ mol^{-1}.

Thermometric titrations can be accomplished by simple equipment in a medium equipped laboratory.

Abstract

A yeast alcohol dehydrogenase amperometric carbon paste-based biosensor, with Meldola Blue as a mediator and a dialysis membrane with a very small molecular weight cut-off for protection, is described. The influence of membrane pore size on the stability and overall kinetics of the biosensor is shown using cyclic voltammetry and stationary potential measurements. The operating potential is +50 mV vs. Ag/AgCl, KCl sat. reference electrode. Application of this device to the determination of ethanol in alcoholic beverages was achieved successfully. In these kinds of samples and at this working potential no interferences were found.

Keywords: Biosensor; Alcohol; Alcohol dehydrogenase; Meldola Blue

1. Introduction

The determination of all kinds of alcoholic compounds, particularly ethanol, in a variety of samples is important. The determination of ethanol is particularly relevant to the food industry, especially in alcoholic beverages such as beer, wines, and spirits.

Biosensors, devices involving immobilized biological material connected to an appropriate detector system, have been successfully used in several clinical, industrial, environmental, and food determinations Ref. [1–5].

In the case of ethanol, a number of enzyme-based electrochemical devices have been developed. There are two appropriate enzymes for this purpose: alcohol oxidase (AOD) Ref. [6–8] and alcohol dehydrogenase (ADH) Ref [9,10]. ADH has been used less frequently than AOD because this enzyme depends on NADH, the co-enzyme, for enzymatic activity, and consequently co-immobilization of both enzyme and co-enzyme is needed. In addition, this co-enzyme requires an overpotential of about 1 V for oxidation, and at this potential a number of other substances, present in food samples, are also oxidized and interfere in the measurement.

There is a way of improving the electron-transfer kinetics; this consists of the use of a substance with electrocatalytic properties (redox mediator) for oxidation of NADH. Biosensors based on ferrocene Ref. [11,12], quinones Ref. [13,14], viologen derivatives Ref [15], tetrathiofulvalene Ref. [16], phenoxazines Ref. [17], ruthenium Ref. [18], osmium polymers Ref. [19,20], several organic dyes Ref. [21–26], etc., have been reported. Water-insoluble mediators are preferred because of the facility of retaining in carbon paste. However, water-insoluble mediators are not always the best electrocatalysts. When water-soluble mediators are used they must be prevented from dissolving into the contact solution, and the electrode is frequently covered with different types of polymeric film. The preparation of these films takes time and the stability of the resulting biosensor is usually unacceptable.

The amperometric alcohol biosensor described in this paper consists of a modified carbon paste electrode (MCPE) into which the enzyme ADH, the co-enzyme NAD⁻, and a water-soluble mediator, Meldola Blue (MB) have been incorporated. To retain all of these substances in the paste for a reasonably long time, a dialysis membrane with a molecular weight cut-off (MWCO) of 500 Da has been used in this work.

MB has been chosen because of its convenient oxidation of NADH via a catalytic effect which permits the use of an applied potential of about 0.0 V. Using this potential most electrochemical interferences are eliminated. The replacement of the polymeric film by a dialysis membrane presents two advantages: (1) very simple and fast electrode fabrication; (2) high stability over time (stable response for about a month).

2. Experimental

2.1. Apparatus

Cyclic voltammetry and amperometric measurements were performed using a Polarecord E 506 Metrohm and a triangular wave generator VA-Scanner E 612 Metrohm connected to an X–Y recorder. All the experiments were carried out in a

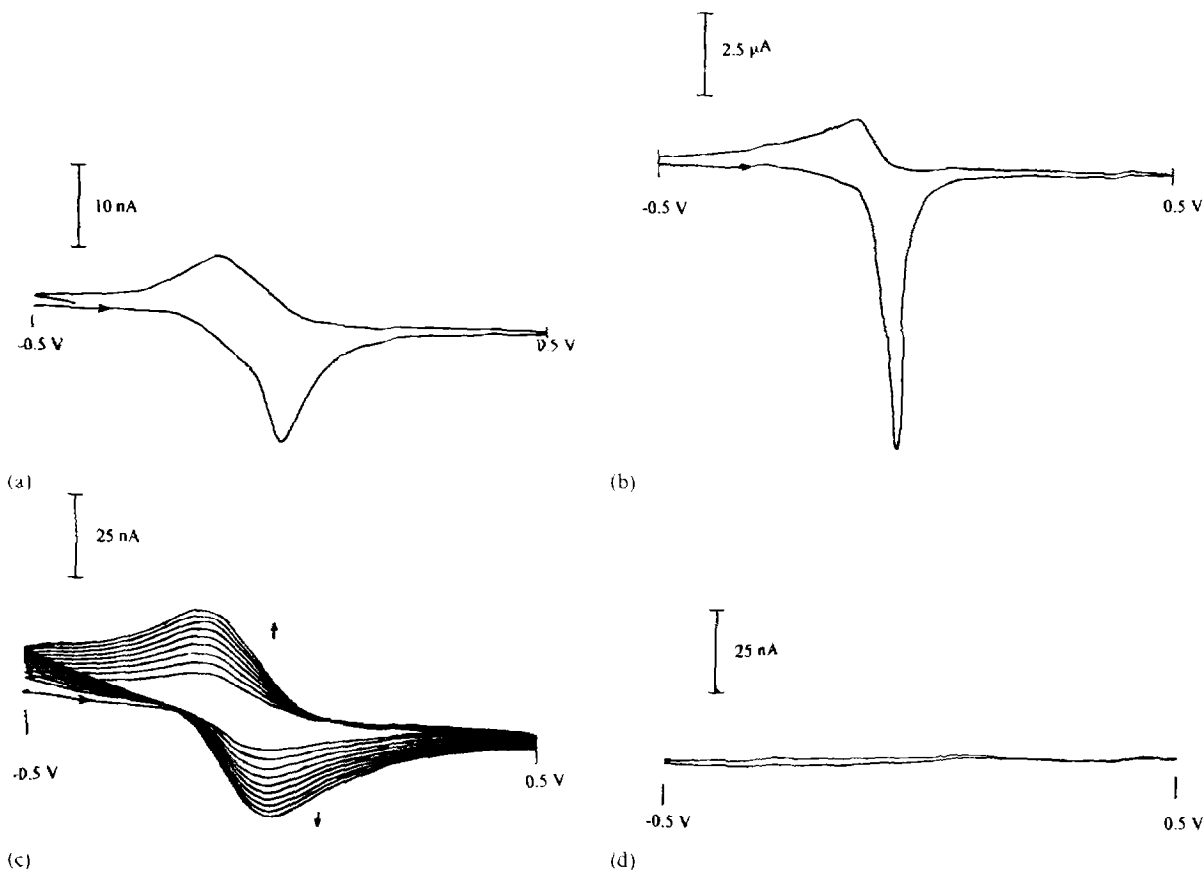
20 ml electrochemical cell using a platinum wire auxiliary electrode. a silver/silver chloride/saturated potassium chloride reference electrode, and the modified carbon paste working electrode.

2.2. Reagents

All solutions were prepared with distilled water. The enzyme ADH (EC 1.1.1.1) from baker's yeast, and β-nicotinamide adenine dinucleotide, in its oxidized form of NAD⁻ and reduced form NADH, were purchased from Sigma Chemical Co. MB was from Aldrich. The cellulose ester dialysis membranes, with MWCO 2000 and 500, were obtained from Spectra/Por. Graphite powder and paraffin oil were obtained from Fluka. All other reagents were of analytical-reagent grade. The buffer used was a 0.10 M phosphate buffer, pH 7.5.

2.3. Electrode preparation

The carbon paste was prepared by hand-mixing the graphite powder together with ADH (4%), NAD⁺ (8%) and/or MB (2%) in a mortar for about 15 min until a uniform paste was obtained. Then 30 μl paraffin oil was added for each 100 mg of paste, and mixed for another 15 min. The electrode was constructed using a 1.0 ml plastic syringe with a copper rod inside, with a diameter equal to the inner diameter of the syringe. The modified carbon paste was tightly packed into the syringe. The copper rod serves as electrical contact. The surface of the electrode was polished by rubbing gently on a sheet of white paper, to produce a flat, shiny surface. Finally, the electrode was covered with the dialysis membrane with the aid of an O-ring. Electrodes were stored at 4°C in phosphate buffer, pH 7.5, when not in use.



Scheme 1

Fig. 1. Cyclic voltammograms of 1.0×10^{-3} M MB in phosphate buffer solution: (a) unmodified carbon paste electrode; (b) glassy carbon electrode; (c) unmodified carbon paste electrode covered with a MWCO 2000 dialysis membrane; (d) unmodified carbon paste electrode covered with a MWCO 500 dialysis membrane.

3. Results and discussion

3.1. Cyclic voltammetry

Cyclic voltammetry was used to ascertain the electrochemical properties of the proposed sensor as well as the stability of the amperometric response to ethanol.

First of all, when continuous cyclic voltammograms of the MCPE modified with 3% MB were recorded, both anodic and cathodic currents decreased in each cycle. This confirmed the tendency of the MB to enter the solution because of its high solubility in water. After this, three different cyclic voltammograms for 1×10^{-3} M MB in buffer solutions were recorded and are shown in Fig. 1. Voltammogram (a) corresponds to an MB

solution using an unmodified CPE without membrane; MB reaches the electrode and shows quasi-reversible electrochemical behaviour with $\Delta E = 125$ mV. In addition, the shape of the anodic peak indicates that the reduced form is adsorbed on the electrode surface, probably due to the lower water solubility of this form. This peak changes its shape, showing the same aspect as the cathodic peak, when the concentration of MB is about 1×10^{-5} M. When a glassy carbon surface is used, a sharper peak is also present (Fig. 1(b)), confirming the different solubilities of the reduced and oxidized MB forms, and the electron transfer rate is significantly faster ($\Delta E = 78$ mV). When the CPE is covered with the MWCO 2000 dialysis membrane (Fig. 1(c)), MB also reaches the electrode surface and, from a reversibility point of

view, exhibits an electrochemical behaviour similar to its behaviour without the membrane ($\Delta E =$ 125 mV). However, the sharp anodic peak disappears and peak currents, both anodic and cathodic, increase with consecutive cyclic scans. In contrast, when the CPE was covered with the MWCO 500 dialysis membrane, no signal was observed (Fig. 1(d)). This means that the MB cannot reach the electrode surface, i.e. MB cannot pass through this membrane, confirming that this membrane can retain MB in the carbon paste electrode.

In the second set of experiments, MB was incorporated into the carbon paste (3% w/w) and the electrode was covered with the MWCO 2000 dialysis membrane. The MB exhibited a similar behaviour inside the paste to that in the solution, independent of the pore size of the membrane. The electron transfer rate seems slightly slower when MB is inside the paste; this must be due to the difficulty of diffusion in an oily medium. When MB is in solution, as well as when MB is inside the carbon paste, it always reaches the electrode surface by diffusion, as was shown by the straight line obtained when i_a was plotted vs. the square root of the potential scan rate.

The electrocatalytic oxidation of NADH in the presence of MB has been previously reported Ref. [20]. The cyclic voltammogram corresponds to that of the biosensor with a MWCO 500 membrane, in phosphate buffer, and shows a quasi-reversible behaviour similar to that shown by the MB in solution when a CPE was used. In the first scan $\Delta E = 195$ mV and $i_c/i_a = 3.36$, but in the last scan $\Delta E = 292.5$ mV and $i_c/i_a = 1.34$. Therefore the complete operation of the biosensor, including both enzymatic and electrochemical reactions, can be illustrated as shown below:

The electrochemical reaction $MBH \rightleftharpoons MB^+ + H^+ 2e^-$ that takes place at the electrode surface is reversible and closes the cycles of all these reac-

Fig. 2. Amperometric response for successive additions of 1.0 mM ethanol solution: (a) biosensor covered with a MWCO 500 dialysis membrane; (b) biosensor covered with a MWCO 2000 dialysis membrane.

tions. Therefore, the changes in anodic current produced by this biosensor are proportional to the alcohol concentration changes in the sample.

3.2. Stationary potential measurements

Fig. 2 shows the response of the biosensor at a constant potential of 0.05 V vs. Ag/AgCl KCl sat., immersed in a stirred phosphate buffer solution and when successive additions of ethanol were made. The biosensor response when covered with the MWCO 2000 membrane is slightly faster than when MWCO 500 membrane was used, probably due to the difficulty of MB crossing the membrane, but the increase in the current becomes lower and lower with successive additions, perhaps because of the loss of mediator facilitated by the stirring of the solution.

Fig. 3. Calibration graph for ethanol in a phosphate buffer solution, using the proposed biosensor: (a) covered with a MWCO 2000 dialysis membrane: (b) covered with a MWCO 500 dialysis membrane.
Calibration graphs were performed for each step of the biosensor preparation. In the first step only the enzyme was incorporated into the paste, and the co-enzyme and MB were in the solution to which the alcohol sample was added. In the second step, when enzyme and co-enzyme were added to the paste, the results were the same. However, the response of the biosensor was the highest, up to twice the response in all the other experiments described above, which proves that in order to obtain a rapid global reaction, physical contact between enzyme, co-enzyme and mediator is needed. The linear range was also the largest, 0.1–20 mM, showing a higher detection limit of 20 mM and a lower detection limit of 0.1 mM. In this case, as Fig. 3 shows, the smaller the pore size of the membrane, the larger the response. This could be due, as was indicated above, to the loss of the mediator.

3.3. Analysis of alcoholic beverages

The performance of the biosensor was tested by applying it to the determination of the ethanol concentration of different beverages: whisky, gin anis (aniseed liqueur) and wine have been analysed using the proposed biosensor.

The only sample treatment required was an appropriate dilution, (1:20000) for the wine and (1:50000) for the others, with phosphate buffer solution to fit the analyte concentration within the linear range of the calibration curve. The high dilution used presents an additional advantage because the greater the dilution, the lower the interferences that are detected.

The quantification method chosen was standard addition, because when the calibration curve method was employed the reproducibility of the results obtained on different days was lower. These samples were also analysed following the *Official Method of the European Community* (1985), consisting of a distillation. Table 1 summarizes the concentrations found and the recoveries obtained by the biosensor. As can be seen, the results show excellent agreement with the label of the beverage and with the results obtained by the *Official Method*.

4. Conclusions

The approach reported here consists of a physical immobilization of the enzyme, co-enzyme and mediator, without chemical reaction and without successive steps for each molecule. The dialysis membrane proposed is of such small pore size that all the molecules remain in the paste for an ex-

Table 1
Results for alcohol determinaiton in alcoholic beverages

Beverage	Label indicated alcohol content (%)	Experimentally obtained alcohol content (%) ($N = 5$)	RSD (%)	Recovery (%) ($N = 5$)
Whisky	40	38.0 ± 0.5	1.3	96.5 ± 1.4
Gin	40	34.6 ± 1.3	3.8	108.0 ± 13.5
Anis	36.5	37.9 ± 1.4	3.7	95.0 ± 17.0
Wine	12	12.7 ± 3.0	23.6	104.0 ± 3.5

tended period of time even when they are hydro-soluble. In addition, the preparation of the biosensor is very simple, and requires only a short time. The only requirement for reliable sensor response is the polishing of the surface before each determination. Therefore, the main advantages of this device are due to the presence of the dialysis membrane which permits easy preparation and provides a long period of stability of the biosensor. It also presents similar higher and lower limits of determination and linear range to those of previous alcohol biosensors. The analytical application of this biosensor in the ethanol determination of real samples has been demonstrated and offers an interesting alternative to other determinations of ethanol, with applications in clinical, biotechnological and agricultural analysis.

Abstract

A reagentless uric acid selective biosensor constructed by immobilising uricase and horseradish peroxidase (HRP) in carbon paste without the addition of an electron transfer mediator is described. The response of the electrode is based on the enzymatic reduction of hydrogen peroxide in the presence of uric acid. Uricase and HRP were dispersed in the carbon paste and the optimum paste mixture was determined. Poly(o-aminophenol) was electropolymerised at the working surface area of the electrode acting as a conducting polymer layer. Cyclic voltammetry was used to characterise the permselective characteristics of the polymer layer. At an applied potential of 50 mV vs. Ag/AgCl, a linear response was obtained up to 1×10^{-4} M, with a limit of detection of 3×10^{-6} M. The sensor had a response time of 37 s, a calibration precision of 2.2% ($n = 4$) and an estimated sample frequency of 20 h^{-1}. Responses to the analyte of interest were pH dependent. The sensor was incorporated into a flow injection system for the qualification of uric acid in human serum. Results compared favourably with a standard spectrophotometric method.

Keywords: Aminophenol(poly)-modified electrode; Enzyme electrode; Uric acid

1. Introduction

The detection, identification and quantification of uric acid (2,6,8-trihydroxypurine) in human physiological fluids is of great importance in the diagnosis and therapy of patients suffering from a range of disorders associated with altered purine metabolism, most notably gout and hyperuricaemia [1]. Other medical conditions, such as leukaemia and pneumonia, have been associated with enhanced urate levels. A number of detection methods based on the reduction properties [2] of the molecule have been employed. A more selective approach is the use of uric oxidase which specifically catalyses the oxidation of urate resulting in the production of allantoin (Eq. (1)).

$$\text{uric acid} + O_2 + 2H_2O \rightarrow \text{allantoin} + H_2O_2 + CO_2 \tag{1}$$
Allantoin, and its enzymatically reduced product, allantoic acid, account for 70–80% of the organic nitrogen in the xylem of nitrogen-fixing soybean plants and other species of tropical grain legumes [3]. Dilena et al. [4] utilised UV spectrophotometry to detect enzymatic degradation of uric acid by exploiting the chromophore existing at the C(4)=C(5) bond. Uric acid has been shown to rapidly adsorb onto carbon paste electrode surfaces [5–7]; this phenomenon has led to the development of a controlled adsorption process for its selective determination in flowing streams.

Various types of electrochemical enzyme sensors have been reported for urate determination [8–10]. The first amperometric method for its quantitative determination in biological fluids was reported by Nanjo and Guilbault based on the consumption of dissolved oxygen [11]. Janchen et al. carried out similar studies in the presence of oxygen [12]. Coulometry, using a porous carbon felt electrode, has also been applied to its determination in human urine. The compound of interest was electrolysed with nearly 100% current efficiency at the carbon surface. Hydrogen peroxide however, is not electroactive at this surface [13,14].

As previously stated, uricase specifically catalyses the oxidation of uric acid. The disappearance of oxygen, H_2O_2 or CO_2 production [15] may be exploited for urate sensing. In the first situation, dissolved O_2 may also be consumed by compounds such as ascorbic acid and thiol-containing substances [16]. Moreover, ascorbate and thiols may also react with peroxide produced by the uricase-catalysed reaction of uric acid. Electrochemical enzyme sensors have been developed based on the amperometric determination of enzymatically liberated H_2O_2 from the uricase reaction (Eq. (1)) [17–20]. These systems exploit the anodic electroactivity of peroxide. Unfortunately, its oxidation has been reported to require relatively high applied potentials (> 0.4 V) and is therefore susceptible to interferences from readily oxidizible molecules. The elimination of interfer-

ences was achieved by Kulys and colleagues when horseradish peroxidase (HRP) served as a catalyst for the reaction between H_2O_2 and hexacyanoferrate(II) followed by reduction of the resulting hexacyanoferrate(III) at 0 V vs. Ag/AgCl [21]. Tatsuma and Watanabe observed that with a uric acid oxidase/HRP bi-layer modified electrode, anodic current (at an applied potential of + 0.5 V) results primarily from urate oxidation and is only partially due to peroxide oxidation [19]. Operating at a lower potential of + 150 mV, coupled with a HRP mediator system, significantly reduces the magnitude of urate oxidation. Its detection in peroxidase-containing systems can be adversely affected, as oxidised urate can donate electrons to peroxidase, thus reducing its capacity to detect enzymatically generated H_2O_2 [22].

The feasibility of using HRP for the amperometric biosensing of organic peroxides is known [23]. In 1979, there was a report of an electron transfer between carbon black and the active sites of HRP without the addition of a mediator [24]. Peroxidases other than HRP such as cytochrom c peroxidase [25] and a fungal peroxidase from *Arthromyces ramosus* [26] have been applied in this fashion. Gorton has reviewed the increasing number of reports on mediatorless mode electrodes where charge transfer between the electrode and enzyme occurs only if the enzyme is in intimate contact with the conducting surface [27]. Peroxidase and glucose oxidase have been co-immobilized on graphite to provide a reagentless glucose sensor even though the nature of electron transfer was unclear [28]; Wollenberger et al. have suggested the possible role of surface functionalities in electron mediation [29].

In this paper, we describe the development of a novel reagentless bienzyme sensor for the indirect amperometric detection of uric acid via the bio-catalytic production of hydrogen peroxide. The co-immobilisation of uricase and HRP in carbon paste, coupled with the electropolymerisation of *o*-aminophenol at the surface of the electrode, has proven to be an interesting alternative to conventional methods for the preparation of biosensors. Such modified surfaces are of interest from an analytical viewpoint in that they may be used to enhance analyte permeability while reducing inter-

ference effects. The sensor was also examined for its applicability to urate quantification in human serum.

2. Experimental

2.1. Reagents

Horseradish peroxidase (HRP, E.C. 1.11.1.7, type VI A), uric acid, uricase (uric acid oxidase, E.C. 1.7.3.3) and cellulose membrane dialysis tubing (12 000 Da cutoff) were purchased from Sigma. Hydrogen peroxide was obtained from Aldrich. o-Aminophenol was purchased from Fluka Chemika.

Standard urate solutions were made up daily by dissolving uric acid in a stoichiometric excess of NaOH, made up in background electrolyte, 0.1 M phosphate buffer. Standards were then wrapped in aluminium foil to prevent thermal and photodegradation. Carbon paste was prepared by mixing 1.8 ml of paraffin oil (Uvasol, Merck) with 5 g of spectroscopic grade graphite powder (Ultra Carbon, Dicoex, Bilbao). All other reagents (sulphuric acid, sodium hydroxide) were of analytical grade. Serum samples obtained from Bio-Quim Laboratories (Oviedo), were diluted as deemed appropriate with background solution.

2.2. Apparatus

Cyclic voltammetry and amperometry were performed using a Metrohm E612 VA scanner in conjunction with an E641 VA detector, connected to a Linseis LY1600 x–y recorder plotter to record voltammograms. A Linseis L6012B revorder was used for recording amperometric measurements. Static measurements were carried out in a Metrohm glass cell, incorporating a conventional three-electrode system. The working electrode was a piston-type carbon paste electrode with a Teflon body and stainless steel contact. The active surface was a disk with a geometric area of 7.1 mm^2. Potentials were measured and referred to a silver/silver chloride/saturated potassium chloride reference electrode. A platinum wire served as an auxillary electrode. The test solution

(20 ml) was magnetically agitated (500 rev min^{-1}) when necessary. The rate of agitation was measured using an electronic speed meter (Heidolph 2001).

Flow injection amperometric measurements were carried out using a twelve cylinder Spetec Perimax 12 Peristaltic pump and a six-port rotary valve (Rheodyne 7125) as carrier propulsion and injection systems, respectively. Analysis was carried out in a home-made thin-layer flow cell (Kissinger design) [30], equipped with a working electrode of geometric proportions as described previously. A down stream compartment connected to the thin layer cell outlet contained the reference electrode incorporating a low resistance liquid junction and a stainless steel waste tube acting as a counter electrode.

The kinetic parameters k_m and V_{max} for the bienzyme electrodes were calculated using an Enzfitter programme.

2.3. Electrode preparation

Uricase, HRP and ferrocene (used in preliminary trials) were added to unmodified carbon paste and mixed thoroughly for 30 min. The resulting mixture was packed into the well of the working electrode to a depth of approximately 2 mm and the surface then smoothed on a sheet of white paper. Easily renewable surfaces are highly desirable as HRP undergoes inactivation upon exposure to increasing concentrations of peroxide [29].

Electropolymerisation of the monomer (o-aminophenol) at the working surface area of the electrode was carried out in 0.1 M acetic acid, pH 5.0, in the potential range 0–0.7 V for 10 min at a scan rate of 50 mV s^{-1}. The acetic acid medium was previously purged with helium to remove moleclar oxygen. The quality of the electropolymerised layer was verified by carrying out a cyclic scan in the aforementioned voltage range. The electrode was then rinsed for a short time in phosphate buffer. In both static and flow systems, the assembled cell was equilibrated with the supporting electrolyte (not purged with helium as molecular oxygen acts as a natural co-factor for uricase, thus depleting H_2O_2 production) while

applying a working potential. Signals were recorded after the transient signal decayed.

3. Results and discussion
3.1. Cyclic voltammetry

Cyclic voltammetry was performed on bare and polymer-modified electrodes to examine their permselective and electrocatalytic properties. Fig. 1(a) and 1(b) depict the electro-oxidation of uric acid to allantoin on bare and polymer-coated surfaces, respectively. Oxidation-type reactions of reduced biomolecules such as urate involve anodic processes, the magnitude of this current being proportional to increasing analyte concentration. This particular process occurs at both electrodes, at an almost identical potential (+ 0.4 V), the anodic current reduced approximately 50% at the poly(o-aminophenol)-modified electrode. This is expected as such membrane-covered electrodes generally yield signals of smaller magnitude due to the imposition of an additional diffusion barrier. The ratio between the current at the latter electrode and that of the bare electrode is a measure of coating permeability.

The permeability properties of poly(o-aminophenol) acting as a conducting polymer were compared to those of a cellulose dialysis membrane (12 000 Da cut-off) by amperometry. An optimised loading of enzyme was used (see later) in the carbon paste.

The polymer-modified electrode has a higher maximum enzymatic reaction rate, $V_{max} = 3.17 \times 10^{-1}$, compared to that of the cellulose membrane covered electrode, $V_{max} = 1.91 \times 10^{-1}$. The apparent Michaelis constant, K_m, of the latter electrode was 1.99×10^{-3}, which was slightly higher than that of the polymerised sensor ($K_m = 1.92 \times 10^{-3}$). The higher K_m value would suggest mass transfer limitations between the bienzyme layer and the analyte solution (Fig. 2).

Hydrolysis of membrane films has been reported to increase porosity [31]. A similar idea was investigated in the case of poly(o-aminophenol). On storage in 0.1 M phosphate buffer, pH 7.5, amperometric responses to standard additions

of uric acid increased by approximately 150% after 2 h. The enzymatic production of peroxide due to uricase catalysis may in some way alter the

selectivity properties of the polymer, causing an increase in film permeability with time. Such "increases" in signals remained for 24 h followed by a return to initial signal intensities; this phenomenon is probably due to a number of complex processes.

The effect of increasing the concentration of monomer during the electropolymerisation process was explored. An increasing concentration resulted in more intense signals to injections of uric acid standards, in stirred solutions. This phenomenon was also observed when the sensor was applied to a flowing stream set-up. Faster response times were recorded (24s for $t_{95\%}$ of signal) for a polymer layer built in a 5×10^{-4} M concentration of o-aminophenol as opposed to 39s for a 10-fold increase in monomer concentration (flow rate, 1 ml min^{-1}). Operation at a higher flow rate of 2 ml min^{-1} resulted in a reduction of 42% in estimated response times. These results indicate a rapid replenishment of the solution from the surface, i.e. lack of analyte trapping. Another explanation for this is that the faster the sample plug passes the electrode, the smaller the fraction of

consumed sample in the enzyme layer at the electrode surface (kinetic limitations) [28]. Fast sensor response times are an important prerequisite in flow injection applications, however a reduction in signal intensity usually results.

The polymer film was formed at the CPE surface by electrodeposition. This layer is required only for retaining the enzyme composition in the carbon paste [33]. Polymerisation of o-aminophenol continues until the surface is completely covered, which is signalled by the current decreasing to a minimum as the monomer cannot penetrate this film [34]. The dispersion of the flow at 0.85 and 2.48 ml min^{-1} was evaluated from measurements of 5×10^{-5} M uric acid. The dispersion factors, $D = (i_{\text{steady state}}/i_{\text{peak max}})$ [32] of the flow system was 1.0 for a flow rate of 0.85 ml min^{-1} and 1.15 for 2.48 ml min^{-1}.

3.2. Optimization of uric acid sensor design

A study was undertaken to examine the necessity for an electron transfer mediator [27]. Carbon paste electrodes containing 5% w/w ferrocene and 10% w/w enzyme (uricase + HRP), exhibited slow responses and small amperometric signals to uric acid additions. Removal of ferrocene from the electrode alleviated this problem. On addition of uric acid standards to the test solutions incorporating ferrocene-modified electrodes, peaks in current were followed by slow gradual decreases to the original baseline level due to the diffusion of ferricinium ions to the bulk solution. Coating the electrode surface with a cation-exchange membrane such as Nafion would prevent such a diffusional effect [35]. Non-ferrocene containing electrodes did not exhibit this behaviour.

An investigation was performed to find the optimum ratio of the amounts of HRP and uricase used in the reaction mixture for immobilisation. The amount of immobilised enzyme utilised in all preliminary investigations did not exceed 15% w/w. Greater percentages did not improve the response characteristics of the sensor. Different paste mixtures were prepared with one enzyme maintained at a fixed % (w/w) value while the proportion of the other was varied. Fig. 3 illustrates the responses to urate for various paste

compositions. A gradual increase with relative increases in % uricase was noted. Response times reduced with increasing proportions of uricase up to a certain point, after which they were stable. Electrodes modified with 3% (w/w) HRP gave rise to the greatest sensitivity; higher percentages gave no further improvement. The relationship that exists between the sensitivity of an electrode and the immobilised activity depends primarily on the affinity of the oxidase (uricase) for its specific substrate (uric acid) [36]. In bienzyme systems, it is appropriate that a higher auxillary enzyme activity be maintained compared with that of the detecting activity, in order to enzymatically oxidise as much intermediate metabolite in the microenvironment as possible into substances that can be detected by an electrochemical transducer. In addition, it appears unnecessary to load higher activity if no improvement in sensitivity is attained. Thus a paste mixture of 7% w/w uricase and 3% w/w HRP was subsequently used.

Our method for preparing the carbon paste/ paraffin oil mixture was similar to that of Cai et al. [7]. The procedure for incorporating HRP and

Fig. 3. Effect of enzyme loading on the sensitivity of the biosensor. (■) Uricase fixed at 7% w/w (●); HRP fixed at 3% w/w. Measurements were performed in 20 ml of 0.1 M phosphate buffer, pH 6.5 on addition of 3 × 10⁻⁴ M uric acid.

uricase into the carbon paste was based on that of Wollenberger et al. [29] and Domínguéz-Sanchez et al. [37]. It may be true that higher response currents are obtained in response to substrate additions when enzymes are added to graphite prior to adding paraffin oil [38]. As is well known, dry graphites have very high capacitive currents (one of the original reasons for producing paste electrodes was to lower the residual current). Mixing graphite with any solvent always decreases electron transfer rates as the hydrocarbon chain of the mulling agent lengthens [39]. It has been reported however that carbon paste electrodes incorporating paraffin oil as the mulling agent as opposed to such materials as silicone oil, bromonaphthalene and nujol (mineral oil), have the widest useful potential range [40].

3.3. Hydrodynamic studies

Even though amperometric signals are characteristic of membrane diffusion processes, it is important to ensure that current signals are due to enzymatically generated H₂O₂ and not due to direct electron transfer of uric acid at the working surface of the electrode. Hydrodynamic voltammograms (Fig. 4) were constructed for four electrode designs over the voltage range −0.1 to +0.35 V. Stepwise potential increases (50 mV) were applied and the resulting steady state currents were recorded and plotted versus applied potential (mV). At potentials more negative than −0.2 V, a rapid loss of activity was observed due to the irreversible reduction of HRP [41]. Reduction processes (cathodic current) were apparent for all electrode types, with the exception of the unmodified one (no enzyme present). Moreover, the respective electrodes containing uricase and peroxidase only, exhibited relatively weak cathodic currents in the presence of urate. However, reduction current was significantly enhanced with the bienzyme electrode. An operating potential of 50 mV was selected for further amperometric studies. Voltammograms for all electrode types show a sharp anodic rise in anodic current over the potential range 250-650 mV (full results not shown in Fig. 4). Direct oxidation of uric acid occurs at potentials above 0.25 V, peaking at
Fig. 4. Hydrodynamic voltammograms recorded in a stirred 0.1 M solution of phosphate buffer (pH 6.5 at 25°C) containing 4×10^{-4} M uric acid. All electrodes were poly(o-aminophenol)-modified. (■) 100% w/w carbon paste; (▲) 7% w/w uricase; (●) 3% w/w HRP; (▼) 7% w/w uricase and 3% w/w HRP.

approximately 0.5 V [19] (for a 100% w/w carbon paste electrode, no enzyme present). The magnitude of this oxidation current was greater when uricase was added to the paste (93% w/w and 7% w/w uricase). At this potential, a great deal of noise due to background currents and potential interference from other electroactive compounds was observed. It was previously attempted to elucidate this oxidation current by cyclic voltammetry; however, no cathodic return [42] was observed, similar to the findings of Jawad et al., therefore the oxidation process was considered irreversible. It appears that the urate oxidation wave masks the reduction (of uric acid) process observed. From the data obtained it was estimated that the reduction current at 50 mV was approximately 1% of the corresponding oxidation process at 650 mV.

As no mediator is incorporated into the carbon paste mixture, the existence of a naturally occurring mediator for the peroxidase reaction was investigated. An electrode modified with 3% w/w

HRP was used. Poly(o-aminophenol) and uric acid were considered as possible mediators to the reaction. Various configurations of the HRP electrode were designed for experiments: (A) CPE with poly(o-aminophenol) deposited at surface: (B) electrode similar to the latter except 5×10^{-3} M uric acid in solution (in voltammetric cell); (C) CPE with cellulose acetate membrane (12 000 Da cut-off) at working surface area with 5×10^{-3} M o-aminophenol in test solution.

The poly(o-aminophenol)-modified electrode (A) was compared to a cellulose membrane electrode employing (C) uric acid as a test mediator in solution. The latter electrode displayed a significantly higher affinity for H_2O_2 ($K_m = 2.83 \times 10^{-3}$ M) compared to that of the former ($K_m = 2.45 \times 10^{-5}$ M). The rate of reaction also increases in the presence of urate. In the case of monomer-modified electrodes, the affinity of peroxidase for hydrogen peroxide appears not to have been enhanced in the presence of uric acid. This would indicate that poly(o-aminophenol) does not act as mediator to the reaction, even though p- and o-aminophenol have been reported as being excellent electron donors to oxidised HRP. This was further illustrated when H_2O_2 was injected into a solution containing the monomer (cellulose membrane electrode, 12 000 Da). The resulting current was anodic in nature. A relatively small reduction current was produced from an electrode containing uricase and peroxidase (poly(o-aminophenol) at surface) on injecting urate relative to responses from the optimum design electrode. These data would seem to suggest that the electrocatalytic reduction of H_2O_2 by HRP immobilised on carbon paste takes place without electron-mediating substances suggesting that peroxidase is capable of performing electron transfer to the electrode.

The response of the biosensor is pH dependent (Fig. 5). The pH range studied was 5.0–9.0. Greater sensitivity was achieved at lower pH values; a best fit approximation suggests an optimum pH of 6.6. However, a "compromised" pH value of 7.5 was chosen in order to mimic the macroenvironment of physiological fluids and to promote the long term stability of the sensor. Noisy baselines were recorded when using background solutions in the pH range 5.0–7.0. As variation in the

ionic strength of the electrolyte solution is thought not to have an effect on sensitivity [20], it was not investigated. The pH of a working medium is a factor that affects the response of a biosensor when the enzymes' activity is controlled by ionising groups. It is important to determine the best pH range in order to make the electrode compatible with the matirx of interest. The reported optimum pH of uricase is in the range 8.5–9.2 [14,42,43]. However, the pH of most physiological fluids lies below this range. Keedy and Vagdama [20] reported a low pH dependence for a uricase electrode in solution. More significantly, pH response profiles were found to change when using different background solutions. Peroxidase has been utilised satisfactorily in the pH range 7.0–8.0 [44].

3.4. Calibration characteristics in static systems

Fig. 6 shows the typical amperometric responses recorded as a function of uric acid concentration. Responses were found to be linear up to 1×10^{-4} M urate with a detection limit of 3.14×10^{-6} M and a correlation coefficient of 0.9996. The reproducibility expressed in terms of

Fig. 6. Calibration plot for the amperometric determination of uric acid in a static system. Applied potential = + 0.05 V vs. Ag/AgCl. Carbon paste modified with 3% w/w HRP and 7% w/w uricase and coated with poly(*o*-aminophenol). Also shown are the typical responses in the 10^{-5}–10^{-4} M range.

relative standard deviation was 2.2% ($n = 4$) for a concentration of 2×10^{-5} M uric acid. The sensor had a response time ($t_{98\%}$) of 37s. The sensor response was found to be stable for 2 days while stored in background electrolyte at room temperature.

3.5. Interference studies

A prerequisite of quantifying an important analyte in physiological fluids is a high degree of selectivity. The sensor response should be specific for that analyte and not involve other electroactive substances in the sample. A range of naturally

Fig. 5. Effect of pH on the amperometric response of the poly(*o*-aminophenol)-modified carbon paste biosensor. Applied potential = + 0.05 V. Readings carried out in 0.1 M phosphate. (■) Experimental data; (---) Best fit curve.
occurring substances in blood were then examined for their potential interference effects. Results were compared with a standard urate response acting as a control (5×10^{-4} M). Alternate uric acid injections were made in a cell containing 0.1 M phosphate buffer and another cell containing a known concentration of the test compound made up in background solution. Ascorbic acid gave approximately 2 and 15% increases in signal for mean (2.8×10^{-4} M) and upper (3.41×10^{-4} M) levels found in blood respectively. The presence of bilirubin [45] was found to have a detrimental effect on urate signals. A concentration of 1.7×10^{-4} M resulted in decreases of 35% in signal intensity. As bilirubin is too big to pass through the polymer layer, it is possible that some form of interaction occurs with uric acid at the working surface area of the electrode, resulting in a diminished current. As the bilirubin level tested is high and anticipated physiological levels would be significantly lower, it was hoped that this fact coupled with dilution of serum samples would minimise this effect.

Fig. 8. Flow injection amperometric responses to uric acid standards. Conditions: carrier stream was 0.1 M phosphate buffer, pH 7.5; flow rate = 1 ml min^{-1}; sample loop volume was 500 μl; applied potential was +0.05 V vs. Ag/AgCl. (A) 2×10^{-5} M; (B) 4×10^{-5} M; (C) 6×10^{-5} M; (D) 8×10^{-5} M; (E) 1×10^{-4} M; (F) 2×10^{-4} M; (G) 4×10^{-4} M; (H) 6×10^{-4} M; (I) 8×10^{-4} M.

3.6. Application of sensor in a flow injection system

The bienzyme electrode was then investigated as the working electrode in a flow injection system. Preliminary results suggested that the detection of uric acid is feasible over a wide range of experimental conditions. The applied working potential was fixed at 50 mV vs. Ag/AgCl. The carrier stream was 0.1 M phosphate buffer, pH 7.5. Carrier solutions were not degassed by purging with helium prior to operation. Somewhat noisy baselines and high background cur-

rents were found with carrier streams in the pH range 5.0–7.0. As with analysis in quiescent solution, peak currents were marginally higher at pH values below 7; for a 2×10^{-4} M urate standard, an increase of 33% in signal was observed (using a carrier stream, pH 6.0) relative to injecting the same standard into a carrier stream of pH 7.5. Analysis in stirred solution showed a relative increase of 19.35%.

The effect of varying the flow rate of the carrier stream was then examined (Fig. 7). Three electrodes were examined in the flow system with a relative standard deviation of less than 6.0%. The highest sensitivity for 5×10^{-5} M injections of urate was obtained at a flow rate of 0.85 ml min^{-1} with appreciable decreases in signal intensity at higher flow rates. Moreover, operation at high flow rates resulted in distorted baselines. Decreasing the sample loop volume from 500 to 300 μl resulted in a decrease in sensitivity, a narrowing of the linear dynamic range and lower detection limits. Use of the smaller loop resulted in slight memory effects. Longer washing times at the expense of sample frequency could alleviate this problem; however, employing the larger sample loop eliminated this problem. The most suitable monomer concentration for poly(*o*-amino-phenol) coating of the electrode surface was found to be 5×10^{-3} M, even though a concentration ten times less than this improved response times and more rapid returns to baseline levels.

The calibration characteristics of the electrode in flowing streams were then examined. Fig. 8 shows typical signals for uric acid standards. The calibration plot provided a linear response up to 2×10^{-4} M with a slope, intercept and correlation coefficient of 2.13×10^4 nA mol^{-1} l, 0.71 nA and 0.9996 ($n = 6$), respectively. No linear ranges existed at higher concentrations. The L.O.D. was calculated at 6.8×10^{-6} M. Increasing the flow rate from 0.85 to 2.0 ml min^{-1} reduced the detection limit to 8.1×10^{-6} M and slightly reduced the dynamic range. A series of 6 repetitive injections of 1×10^{-4} M urate yielded a relative standard deviation of 2.0%. The maximum allowable sample frequency was estimated as being 20 h^{-1}. The electrode, incorporated into the flow system, was found to be more stable than in stirred solution. This phenomenon is probably due to the continuous flow of the carrier stream washing unreacted urate from the carbon paste of the working electrode.

The influence of allopurinol on uric acid amperometric signals was examined. The drug inhibits xanthine oxidase, in that its oxidised form (oxypurinol) binds tightly to the reduced form of the enzyme. The oxidase catalytically converts hypoxanthine to uric acid and hydrogen peroxide [46]. Allopurinol is used in the treatment of chronic gout and hyperuricaemia (symptoms associated with enhanced urate levels). A high concentration of the oxidase inhibitor (1×10^{-3} M) was added to the carrier stream. No adverse effects such as background current, baseline drift or signal noise were observed. Repeated injections of uric acid (1×10^{-4} M) were carried out in the presence and absence of the drug. A reduction in current signal of 10.5% was noted. Two possibilities may account for this: oxidation of allopurinol thus interfering with the oxidase catalytic mechanism and/or blockage or interaction at the working electrode surface. Again, it was hoped that dilution of samples could reduce such a problem.

3.7. Analysis of serum samples

Serum samples containing different concentrations of uric acid were then analysed using the optimum design sensor (Table 1). Samples were diluted 1:10 with carrier solution and the pH adjusted to 7.5 (when required). Diluted samples were then injected directly into the flow system and the concentration of uric acid present estimated from a calibration plot. Results were in reasonable agreement with those determined by UV spectrophotometry. Repeated exposure of the electrode to diluted serum had no adverse effect on amperometric signal size.

4. Conclusion

In this study, a novel reagentless sensor based on the co-immobilisation of HRP and uricase in a carbon paste for the detection of uric acid has been described. The electrode works at a very favourable potential and has a short response time. The composition of the carbon paste may go some way in explaining the nature of the response where heterogeneous electron transfer occurs between HRP and the electrode, however, the precise nature of this mechanism remains unclear [29].

Conducting polymer coatings can be electrodeposited at the working area of electrodes with great precision. We have noted that poly(o-aminophenol) is stable for a considerable length of time when stored in background electrolyte at room temperature. Physical characteristics such as film thickness can be easily controlled thus regulating the rate of analyte diffusion through the immobilised layer [47].

The advantage of this polymer is that it appears to have effectively protected the electrode from interferences and fouling. To our knowledge, analysis of unspiked human serum compared as well as, if not better, than other previously reported enzyme/electrode based methods for the detection of uric acid in a complex physiological matrix. Note here that in our interference studies the concentrations of potential interferents tested were much higher than

anticipated physiological levels. Moreover, serum samples were simply diluted with background electrolyte rather than extraction which is time consuming and restricts the sampling frequency.

Hydrogen chromate PVC matrix membrane sensor for potentiometric determination of chromium(III) and chromium(VI) ions

Saad S.M. Hassan[a,*], M.N. Abbas[b], G.A.E. Moustafa[b]

[a]Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt
[b]National Research Center, Dokki, Cairo, Egypt

Abstract

A novel potentiometric Cr^{6+} PVC matrix membrane sensor incorporating nickel tris(1,10-bathophenanthroline) hydrogen chromate as an electroactive material and 2-nitrophenyl phenyl ether as solvent mediator is described. In a phosphate buffer solution of pH 5, the sensor displays a rapid and linear response for Cr^{6-} over the concentration range 2×10^{-2}–8×10^{-6} M with an anionic slope of 55.5 ± 0.2 mV decade^{-1} and a detection limit of the order of 0.4 μg ml^{-1}. The sensor is used for sequential determination of Cr^{6+} and Cr^{3+} by direct monitoring of Cr^{6+} followed by oxidation of Cr^{3+} and measurement of the total chromium. The average recoveries of Cr^{3+} and Cr^{6+} at concentration levels of 0.5–50 μg ml^{-1} are $98.1 \pm 0.4\%$ and $99.1 \pm 0.4\%$ respectively. Redox and precipitation titrations involving Cr^{6+} as a titrant are monitored with the sensor. Cr^{3+} and/or Cr^{6+} in wastewaters of some industries (e.g., leather tanning, electroplating, aluminum painting) and the chromium contents of some alloys and refractory bricks are assessed. The results agree fairly well with data obtained using the standard diphenylcarbazide spectrophotometric method.

Keywords: Chromium(III); Chromium(VI); PVC matrix membrane sensor; Potentiometric determination

1. Introduction

Determination of chromium has received considerable attention because of the highly toxic nature of Cr^{6+} and the useful biological activity of Cr^{3+} [1]. Both forms of chromium enter the environment from various sources as the effluent

discharge of tanning industries, electroplating, oxidative dyeing, chemical industries, steel works and cooling water towers. Techniques and approaches in current use for the separate and sequential determination of both forms of chromium include spectrophotometry [2–4], spectrofluorimetry [5], atomic absorption spectrometry [6,7], differential pulse polarography [8], differential pulse voltammetry [9], ion chromatog-

* Corresponding author.

raphy [10], X-ray fluorescence [11] and gas chromatography [12,13]. Most of these methods involve several manipulation steps and require sophisticated instruments.

Direct potentiometric methods for determining chromium, however, are simpler, much faster and less expensive. Potentiometric sensors for Cr^{6-} based on the use of the chromate salts of quaternary phosphonium [14,15], quaternary ammonium [16–20], crystal violet [21] and barium [22,23] as electroactive materials dispersed in lipophilic solvents [18,21] and poly(vinyl chloride) [14–17,19] and silicon rubber [22] membranes have been suggested. A solid-state Cr^{3+} chalcogenide membrane sensor has also been described [24]. Many of these sensors, however, are not sensitive enough to permit measurement of chromium at concentration levels of $< 10^{-3}$ or 10^{-4} M [18,19,21,22], display poor selectivity in the presence of various common cations and anions (e.g. F^-, SO_4^{2-}, I^-, S^{2-}, Cu^{2+}, Ni^{2+}, Pb^{2+}, Fe^{2+}, Ba^{2+}, Ca^{2+}, Mg^{2+}) [16,22,23], exhibit non-Nernstian response [15,22] and have long response times.

The present work describes the preparation and potentiometric characterization of a novel Cr^{6+} PVC sensor based on the use of nickel tris-(bathophenanthroline) hydrogen chromate ion-pair complex as electroactive material and 2-nitrophenyl phenyl ether as a plasticizer. The sensitivity, stability and selectivity of the sensor are significantly better than many of those previously advocated. The sensor has been used satisfactorily for sequential determination of Cr^{3+}/Cr^{6+} in various industrial materials and for the monitoring of some redox and precipitation titrations involving Cr^{6+}.

2. Experimental

2.1. Apparatus

All potentiometric measurements were performed at $25 \pm 1°C$ using an Orion Model SA 720 digital pH/millivoltmeter with a nickel tris(1,10-bathophenanthroline) hydrogen chromate PVC matrix membrane sensor in conjunction with a double-junction Ag/AgCl reference electrode (Orion 90-02) containing 10% (w/v) potassium chloride in the outer compartment. A combination Ross glass pH electrode (Orion 81-02) was used for all pH measurements.

Spectrophotometric measurements were made at 540 nm with a Shimadzu UV-240 recording spectrophotometer using 10 mm matched fused silica cuvettes.

2.2. Reagents and materials

All chemicals were of analytical-reagent grade and deionized doubly-distilled water was used throughout. Bathophenanthroline monohydrate (phen) was obtained from Merck. Ni(II) sulphate, potassium dichromate, potassium chromate, diphenylcarbazide, tetrahydrofuran (THF) and poly(vinyl chloride) (PVC) powder were obtained from Aldrich. 2-Nitrophenyl phenyl ether (NPPE) was purchased from Kodak. A stock 10^{-1} M chromium(VI) standard solution was prepared by dissolving 1.94 g of K_2CrO_4 in 100 ml of deionized bidistilled water. Chromium(VI) solutions (10^{-2}–10^{-6} M) were prepared by serial dilutions. Phosphate buffer (7×10^{-2} M) pH5 was freshly prepared.

2.3. Nickel tris(1,10-bathophenanthroline) hydrogen chromate membrane sensor

A 10 ml aliquot of 10^{-2} M chromate solution was mixed with a 5 ml aliquot of 10^{-2} M Ni(II) tris(1,10-bathophenanthroline) solution. After stirring for 5 min, a yellow hydrogen chromate ion-pair complex was precipitated, filtred off on a Whatman filter paper No. 42, washed with cold water, dried at room temperature for 24 h and ground to a fine powder. A 10 mg portion of Ni(II) tris(1,10-bathophenanthroline) hydrogen chromate ion pair was thoroughly mixed in a glass Petri dish (5 cm diameter), with 0.35 ml NPPE, 0.19 g PVC and 5 ml THF. The petri dish was covered with a filter paper and left to stand overnight to allow slow evaporation of the solvent at room temperature. A PVC master membrane (≈ 0.1 mm thick) was obtained and used for the preparation of the sensor as previously described [25,26].

2.4. Determination of Cr^{6+} and Cr^{3+}

The hydrogen chromate PVC sensor was immersed in conjunction with a double junction Ag/AgCl reference electrode into a 9.0 ml phosphate buffer solution pH 5. After potential stabilization to ±0.2 mV, a 1.0 ml aliquot of 10^{-3}–10^{-5} M $K_2Cr_2O_7$ solution (≡ 52–0.52 μg ml^{-1} Cr^{6+}) was added. The potential reading was plotted as a function of the logarithm of Cr^{6+} concentration and the plot was used for subsequent measurement of unknown Cr^{6+} samples.

2.5. Determination of Cr^{3+}

A 10 ml aliquot of Cr^{3+} test solution containing 10–50 μg ml^{-1} Cr^{3+} was transferred to a 50 ml beaker, followed by addition of a 2–3 ml aliquot of 2×10^{-2} M $KMnO_4$ and 2 ml of 9 M H_2SO_4. The test solution was heated on a boiling water bath for 10 min. More $KMnO_4$ was added dropwise when the pink colour disappeared. A few drops of 2.5% w/v sodium azide were slowly added dropwise until complete decolourization. The solution was transferred to a 25 ml standard flask, diluted with deionized doubly-distilled water to the mark and shaken. A 1.0 ml aliquot of this test solution was transferred to a 50 ml beaker containing 9.0 ml stirred phosphate buffer (pH 5) and the chromium sensor. The chromium content was measured as described above.

Chromium(VI) and chromium(III) in synthetic mixtures and in industrial wastewaters were sequentially determined using the above procedures successively after appropriate sample dilutions.

2.6. Determination of chromium in alloys

A 0.5 g portion of chromium-containing steel (12–29% w/w Cr) was transferred to a 100 ml beaker and dissolved in 10 ml of 16 M HNO_3 and 15 ml of 70% $HClO_4$. The solution was evaporated until dense fumes of $HClO_4$ were produced and boiled gently for 5 min to oxidise the chromium. The beaker and contents were cooled rapidly and the solution was diluted by addition of 20 ml of deionized distilled water. The solution

was transferred quantitatively to a 500 ml volumetric flask and diluted to the mark with deionized distilled water. The chromium was potentiometrically determined as described above.

2.7. Determination of chromium in refractory bricks

A 0.2–0.3 g sample of the fine powder of the brick sample was transferred to a nickel crucible followed by addition of 0.3 g sodium peroxide and 5 g of potassium pyrosulphate. The mixture was fused at 800°C in a muffle furnace for 30 min. The residue was dissolved in ≈ 400 ml of 8 M hydrochloric acid solution and boiled to a final volume of 100 ml. The solution was transferred to a 500 ml volumetric flask and made up to the mark with doubly-distilled deionized water. The Cr^{6+} content was measured as previously described.

3. Results and discussion

3.1. Sensor characteristics

The potentiometric response characteristics of a Cr^{6+} sensor based on the use of nickel tris-(bathophenanthroline) hydrogen chromate ion-pair complex as a novel electroactive material and 2-nitrophenyl phenyl ether as a plasticizer in a PVC matrix were evaluated according to IUPAC recommendations [27] and the results are given in Table 1. In a phosphate buffer of pH 5, the sensor exhibits a linear and stable response for Cr^{6+} over the concentration range 2×10^{-2}–8×10^{-6} M with an anionic slope of 55.5 ± 0.2 mV decade^{-1} (Fig. 1), the lower limit of detection being 8×10^{-6} M(≡ 0.4 μg ml^{-1} Cr^{6+}). Although other buffer solutions of pH 5 (e.g. acetate) can be successfully used, a response graph with a lower limit of detection is obtained with the phosphate buffer solution. It should be mentioned that addition of aqueous Cr^{6+} test solution to 0.1 M phosphate buffer pH 5 does not cause a pH change of more than 0.15 pH units (≈ 9 mV) for final Cr^{6+} concentrations of 10^{-3}–10^{-6} M.

Table I

Response characteristics of a nickel tris(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor

Parameter	Cr^{6+} sensor[a]
Slope (mV decade^{-1})	-55.5 ± 0.3
Intercept (mV)	-91.1 ± 0.3
Correlation coefficient (r)	0.997
Lower detection limit (M)	8×10^{-6}
Lower limit of linear range (M)	2×10^{-5}
Response time for $[Cr^{6+}]$ change from 1×10^{-4} to 1×10^{-3} M (s)	20 ± 2
Working acidity range (pH)	4–6

[a] Average of five measurements.

The time required for the sensor to reach 95% of the steady potential response at pH 5, after successive immersion in a series of Cr^{6+} solutions, each having a 10-fold difference in concentration from the last, ranges from 20 s for $[Cr^{6-}] \geq 10^{-4}$ M to 30 s for lower concentrations. The standard deviation of the sensor potential readings over a period of 10 min is ± 0.2 mV. The sensor exhibits a day-to-day reproducibility of about ± 1 mV for the same solutions over a period of 6 weeks after preparation. The useful lifetime of the sensor is 6 weeks, during which the potential slope is reproducible to within ± 2 mV per concentration decade.

Chromium(VI) is present in aqueous solutions as chromate, dichromate, hydrogen chromate, chromic acid, hydrogen dichromate, trichromate and tetrachromate [28]. The last three ions have been detected only in strongly acidic solutions. Within the pH range 4–5.5, however, the monovalent hydrogen chromate anion is the predominant species. The pH of aqueous 10^{-2}–10^{-4} M Cr^{6+} solutions was changed by the addition of very small volumes of dilute NaOH or H_2SO_4 solutions and the potential of the solutions was monitored. The results reveal that the sensor response is relatively independent of the pH variation over the pH range 4–6. As the pH value increases up to 8, the starting potential of the chromium solutions is shifted towards more positive values. This corresponds to the decrease in the measurable concentration of $HCrO_4^-$. The calibration slope declines to < 30 mV decade^{-1} which is almost equivalent to the Nernstian slope for a doubly-charged anion. This behaviour can

Fig. 1. Potential response of nickel tris(bathophenanthroline) hydrogen chromate PVC matrix membrane to different concentrations of Cr^{6+} in 0.1 M phosphate buffer solutions of pH 5.

Table 2

Potentiometric selectivity coefficients of a nickel tris-(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor

Interferent (B)	$K^{pot}_{Cr,B}$	Interferent (B)	$K^{pot}_{Cr,B}$
Mn^{2+}	1.1×10^{-2}	F^-	1.1×10^{-3}
Mg^{2+}	1.0×10^{-2}	Cl^-	2.0×10^{-3}
Cu^{2+}	1.3×10^{-2}	Br^-	3.6×10^{-3}
Co^{2+}	1.2×10^{-2}	I^-	14.6
Ni^{2+}	1.1×10^{-2}	SO_3^{2-}	1.1×10^{-3}
Fe^{2+}	0.9×10^{-2}	SO_4^{2-}	1.76×10^{-3}
Pb^{2+}	1.2×10^{-2}	SCN^-	41.4
Zn^{2+}	1.4×10^{-2}	CN^-	1.4×10^{-3}
Cr^{3+}	7.0×10^{-2}	CH_3COO^-	2.4×10^{-3}
Al^{3+}	0.6×10^{-2}	NO_3^-	1.14
Hg^{2+}	26.5	ClO_4^-	87.2×10^2

be explained by the increased influence of OH^- and formation of the divalent $Cr_2O_7^{2-}$ anions. All subsequent measurements were performed in a phosphate buffer of pH 5.

The influence of some 22 different cations and anions on the hydrogen chromate sensor was investigated. The selectivity coefficients were determined by the separate solution method [27,29], at pH 5, using 10^{-3} M test solutions. Table 2 reveals no interferences by the cations—Mn^{2+}, Mg^{2+}, Cu^{2+}, Ni^{2+}, Fe^{2+}, Pb^{2+}, Zn^{2+}, Cr^{3+}, and Al^{3+}—and serious interference by Hg^{2+}. Addition of EDTA significantly reduces the effect of almost all cations. The sensor displays a good selectivity for $HCrO_4^-$ over many anions. However, anions which are more lipophilic than $HCrO_4^-$ interfere, as is expected for most ion-exchange-type membranes. The interference effect of the ions is in good agreement with the Hofmeister pattern [30] of selectivity sequence:

$$SCN^- > I^- > NO_3^- > HCrO_4^- > Br^- > CH_3COO^- > Cl^- > F^- \equiv SO_4^{2-}$$
Direct determination of $HCrO_4^- - Cr^{6+}$ in the presence of high concentrations (> 10-fold excess) of ClO_4^-, SCN^- and NO_3^- anions gives unacceptable results. A successful approach for determining $HCrO_4^- - Cr^{6+}$ in mixtures containing these interfering anions was achieved by treating

the sample test solutions with ascorbic acid to convert chromate $-Cr^{6+}$ into Cr^{3+} cation, followed by passing the solutions through an anion exchange column (Cl^- form) to retain all the interfering anions. Chromium(III) cations in the effluent were then oxidized to chromate–Cr^{6-} and monitored with the hydrogen chromate sensor. Typical determination of 1.0 mg of Cr^{6+} mixed with 1.0 mg each of ClO_4^-, SCN^-, and NO_3^- in a final volume of 100 ml following this procedure shows an average recovery of 98.1% Cr^{6+} and a mean standard deviation of 0.8% ($n = 5$).

3.2. Analytical applications

Analytical usefulness of the Cr^{6+} sensor was examined for direct determination of various concentrations of Cr^{6+} (0.5–50 μg ml^{-1}) using the standard addition (spiking) technique. Results of an average recovery of 99.5% and a mean standard deviation of 0.6% are obtained ($n = 10$). The sensor also proved useful for quantification of Cr^{6+} after prior oxidation with MnO_4^- followed by removal of the excess oxidant with sodium azide [31]. Table 3 presents results obtained for sequential determination of synthetic mixtures containing various proportions of Cr^{6+} and Cr^{3+}. Practically, Cr^{6+} is directly measured with

Table 3

Sequential potentiometric determination of Cr^{3+}/Cr^{6+} in some synthetic binary mixtures using a nickel tris-(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor

| Added (μg ml^{-1})		Recovery[a] (%)	
Cr^{3+}	Cr^{6+}	Cr^{3+}	Cr^{6+}
8.0	–	98.4 ± 0.5	–
8.0	2.0	98.7 ± 0.3	99.1 ± 0.2
8.0	4.0	97.9 ± 0.3	98.7 ± 0.4
8.0	6.0	98.1 ± 0.4	99.4 ± 0.4
8.0	8.0	97.8 ± 0.5	98.9 ± 0.3
6.0	8.0	98.2 ± 0.4	99.3 ± 0.4
4.0	8.0	97.6 ± 0.4	98.5 ± 0.5
2.0	8.0	97.8 ± 0.3	98.7 ± 0.5
–	8.0	–	99.8 ± 0.3

[a] Average of three measurements.

Fig. 2. Typical potentiometric titration curves for (A) 2.5, (B) 5.0, and (C) 7.5 ml of 0.1 N iron(II) with standard 0.1 N $K_2Cr_2O_7$ using a nickel tris(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor.

the sensor and, after oxidation of Cr^{3+}, the total chromium is sequentially determined and Cr^{3+} is obtained by difference. Average recoveries of 99.1% (standard deviation 0.4%) and 98.1% (standard deviation 0.4%) are obtained for Cr^{6+} and Cr^{3+} in their mixtures respectively.

The chromium sensor was utilized as an indicator electrode in conjunction with a Ag/AgCl reference electrode for titrimetric determination of high concentrations of Cr^{6+} ($> 10^{-3}$ M). The sensor was also used for following some redox and precipitation titrations. Fig. 2 shows typical potentiometric titration curves of Fe^{2+} with $Cr_2O_7^{2-}$. One (± 0.01) mole of $Cr_2O_7^{2-}$ is reproducibly consumed per 6 moles of Fe^{2+}. The shape of the titration curves is typical to those obtained in some other redox titrations using ion selective electrodes [32]. The inflection break at the equivalence point is -160 mV. Fig. 3 depicts a typical potentiometric precipitation titration curve of

Tl^+ with CrO_4^{2-}. A sharp inflection break of ≈ 60 mV is obtained at a 2:1 thallium:chromate stoichiometric reaction, the relative standard deviation being 0.3% ($n = 10$). Many other inorganic and organic species can be similarly determined by monitoring their reaction with Cr^{6+}.

The use of a Cr^{6+} sensor for the determination of chromium in some environmental samples was also examined. Hexavalent and trivalent chromium ions, in grab and composite wastewater samples collected from some industries (e.g. leather tanning, electroplating and aluminum painting), were determined. The chromium contents of some industrial materials (e.g. refractory bricks and alloys) were similarly assessed after appropriate dissolution of the test sample. The results (Tables 4 and 5) were compared with data obtained using the standard diphenylcarbazide spectrophotometric method [31]. A close agreement within 0.1–0.7% is obtained, indicating the

Fig. 3. Typical potentiometric titration curves for (A) 1.5, (B) 2.5, and (C) 3.5 ml of 0.1 N thallium(I) with standard 0.1 N K_2CrO_4 using a nickel tris(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor.

Table 4
Determination of chromium in some industrial wastewaters using spectrophotometry and potentiometry with a nickel tris-(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor

Wastewater source	Cr^{3+} found[a] (mg l^{-1})		Cr^{6+} found[a] (mg l^{-1})	
	Potentiometry	Spectrophotometry	Potentiometry	Spectrophotometry
Leather tanning	2.4 ± 0.1	2.2 ± 0.1		..

	8.7 ± 0.2	8.5 ± 0.2	15.2 ± 0.1	15.0 ± 0.2
	7.4 ± 0.2	7.3 ± 0.2	14.5 ± 0.2	15.0 ± 0.2

[a] Average of three measurements.

efficiency, accuracy and applicability of the proposed potentiometric sensor for determining Cr^{6+} and Cr^{3+} in various matrices and in coloured and turbid solutions. The proposed potentiometric sensor also has some significant advantages over many of those previously described [15,16,18,19,21–23], as it offers a lower limit of detection (8×10^{-6} M), covers a wider range of concentrations (2×10^{-2}–8×10^{-6} M), displays a faster response (20–30s) and exhibits reasonable selectivity in the presence of many common interfering ions.

Table 5
Determination of chromium in some refractory bricks and alloys using spectrophotometry and potentiometry with a nickel tris(bathophenanthroline) hydrogen chromate PVC matrix membrane sensor

Sample	Chromium found[a] (%w/w)	
	Potentiometry	Spectrophotometry
Refractory brick (1)	1.1 ± 0.1	1.1 ± 0.1
Refractory brick (2)	4.9 ± 0.2	4.8 ± 0.3
Refractory brick (3)	2.7 ± 0.1	2.6 ± 0.1
Chrome–steel alloy	28.0 ± 0.3	27.6 ± 0.2

Book reviews

Kirk-Othmer Encyclopedia of Chemical Technology, 4th edn., edited by J.I. Kroschwitz and M. Howe-Grant (Vol. 13, Helium Group to Hypnotics), Wiley, New York, 1995, xxviii + 1100 pp., £195.00. ISBN 0-471-52682-7.

Volume 13 of this encyclopedia continues and concludes with topics beginning with the letter 'H'. Twenty-nine entries are covered and in-depth treatments ranges from 155 pages devoted to Hormones to 10 pages devoted to Hydrogen-Ion Activity.

The first topic covers the Helium Group (helium, neon, argon, krypton, xenon and radon) and includes details of physical properties, quantum-mechanical effects, production, economic aspects and uses of the gases. A small separate entry covers compounds from this group—especially xenon compounds. The other element included in this volume is Hydrogen and although emphasis is placed on technological details I was surprised to see no mention of hydrogen bonding. Hydrogen Chloride, Hydrogen Peroxide and Hydrogen Energy are also dealt with as separate entries. The element holmium is included with the Lanthanides in another volume.

The section on Hormones is extensive and has sub-entries entitled: Survey, Anterior pituitary hormones, Anterior pituitary-like hormones, Posterior pituitary hormones, Human growth hormone, Brain oligopeptides, Sex hormones and Estrogens and antiestrogens. Two other bio-related topics in this volume include: Histamine and Histamine Antagonists plus Hypnotics, Sedatives, Anticonvulsants and Anxiolytics.

Obvious technological entries include: High Performance Fibers, High Pressure Technology, High Temperature Alloys, Hollow-Fiber Membranes, Holography, Hydraulic Fluids and Hydrothermal Processing. The latter section contains rare editorial omissions as there are no numbers associated with references to Tables and Figures.

Other entries include, Hemicellulose, Herbicides, Hydantoin, Hydrazine, Hydrides, Hydroboration, Hydrocarbons and some Hydroxy compounds.

As with all the other volumes in the fourth edition of this encyclopedia the range of topics covered and the depth of treatment given make this an essential work for inclusion in all good science libraries.

P.J. Cox

A Practical Approach to Chiral Separations by Liquid Chromatography, edited by G. Subramanmian, VCH, Weinheim, 1994, xvi + 405 pp., £72.00. ISBN 3-527-28288-2.

Methodologies for chiral separation continue to offer considerable challenges in the fields of chromatography and capillary electrophoresis. In the course of twelve chapters, this book with contributions from internationally recognised experts seeks to provide a broad framework spanning an introduction to the topic, through legislatory outlines and their implications to the "nuts and bolts" of the practical chromatographic application and its industrial uses. Separate chapters cover the use of the main recognised chemical classes of selective chiral stationary phases, without inclusion of an excessive amount of theory, yet providing sufficient theoretical background for a proper appreciation of the methodologies.

P.J. Cox

A Practical Approach to Chiral Separations by Liquid Chromatography, edited by G. Subramanmian, VCH, Weinheim, 1994, xvi + 405 pp., £72.00. ISBN 3-527-28288-2.

Methodologies for chiral separation continue to offer considerable challenges in the fields of chromatography and capillary electrophoresis. In the course of twelve chapters, this book with contributions from internationally recognised experts seeks to provide a broad framework spanning an introduction to the topic, through legislatory outlines and their implications to the "nuts and bolts" of the practical chromatographic application and its industrial uses. Separate chapters cover the use of the main recognised chemical classes of selective chiral stationary phases, without inclusion of an excessive amount of theory, yet providing sufficient theoretical background for a proper appreciation of the methodologies.

In some contrast the inclusion of a chapter on theoretical modelling techniques as an aid to understanding separation mechanisms, although an esoteric approach to many practical chromatographers, is a welcome deviation from the norm.

The book succeeds as a broadly aimed text which will provide a primer for the novice as well as a more in-depth discussion for the more experienced chromatographer seeking to extend his understanding of chiral methodologies. Regrettably the pace of rapid development in the field and the time taken in coming to publication is reflected in the useful, but dated references to each chapter (no references post 1991). In spite of this drawback, the book is to be recommended as an addition to the library of any aspiring analytical scientist.

D.G. Durham

Practical Guide to Infrared Microspectroscopy, edited by H.J. Humecki, Dekker, New York, 1995, x + 472 pp., US$150.00. ISBN 0-8247-9449-4

The strength of this book, as with others in the series, is its scope. There are chapters on forensic science (paint and fibres), pharmaceuticals, art, earth sciences and electronics; there are practical guides to sample handling and there are chapters on the application of theory to achieve optimisation. Each has been contributed by an experienced practitioner in the field and the extensive references at the end of each chapter would, alone, make it a useful source book.

However, it is badly and irritatingly flawed by the presence of typographical and grammatical errors. For example, spectra should be the plural of spectrum but it is not always so here. Also, there are three different definitions of the equation for the least resolvable separation (LRS) in three separate chapters and the book is also let down by an inadequate index.

Although the need to use other techniques is stressed throughout, the fact that infrared microspectroscopy is always operator intensive, and therefore relatively expensive, is not considered.

Nevertheless this book is a practical and stimulating guide to the technique. The fact that this is so, despite its flaws, is a measure of its usefulness to the practising infrared microscopist.

M. Underhill

Pharmacoepidemiology, by B.L. Strom, Wiley, Chichester, 1994. xviii + 741 pp., £75.00. ISBN 0-471-94058-5.

This substantial revision of the first edition (17 of the 41 chapters are totally new) reflects the rapid progress and growth in the field of pharmacoepidemiology. Although predominantly American, the book derives an international dimension from its 59 authors, with 38 from the United States, nine from Canada, five from the United Kingdom, three from Sweden, two from Australia and one each from the Netherlands and France.

The book is divided into five parts. In the introduction (Part I) the editor defines the subject and describes the historical background, purpose and potential. Epidemiologic study designs, including sample size considerations, are clearly and concisely presented. Reasons for performing pharmacoepidemiology studies and a consideration of risk tolerance complete a helpful introduction on the basic principles of the subject.

In providing various perspectives on pharmacoepidemiology, Part II indicates some of the organisations and professions for whom this book will be relevant. Views are expressed from a university department of epidemiology and preventive medicine, the pharmaceutical industry, a regulatory agency and the US courtroom.

The meat of the book lies within Parts III and IV which deal respectively with the systems available and with selected special applications and methodologic issues. The advantages and limitations of spontaneous reporting systems in the United States, Sweden, France and the UK are presented, as are those for intensive hospital-based cohort studies, such as the Boston Collaborative Drug Surveillance Program. These systems have influenced the US Joint Commission on Accreditation of Health Care Organisations to

Also, there are three different definitions of the equation for the least resolvable separation (LRS) in three separate chapters and the book is also let down by an inadequate index.

Although the need to use other techniques is stressed throughout, the fact that infrared microspectroscopy is always operator intensive, and therefore relatively expensive, is not considered.

Nevertheless this book is a practical and stimulating guide to the technique. The fact that this is so, despite its flaws, is a measure of its usefulness to the practising infrared microscopist.

Pharmacoepidemiology, by B.L. Strom, Wiley, Chichester, 1994. xviii + 741 pp., £75.00. ISBN 0-471-94058-5.

This substantial revision of the first edition (17 of the 41 chapters are totally new) reflects the rapid progress and growth in the field of pharmacoepidemiology. Although predominantly American, the book derives an international dimension from its 59 authors, with 38 from the United States, nine from Canada, five from the United Kingdom, three from Sweden, two from Australia and one each from the Netherlands and France.

The book is divided into five parts. In the introduction (Part I) the editor defines the subject and describes the historical background, purpose and potential. Epidemiologic study designs, including sample size considerations, are clearly and concisely presented. Reasons for performing pharmacoepidemiology studies and a consideration of risk tolerance complete a helpful introduction on the basic principles of the subject.

In providing various perspectives on pharmacoepidemiology, Part II indicates some of the organisations and professions for whom this book will be relevant. Views are expressed from a university department of epidemiology and preventive medicine, the pharmaceutical industry, a regulatory agency and the US courtroom.

The meat of the book lies within Parts III and IV which deal respectively with the systems available and with selected special applications and methodologic issues. The advantages and limitations of spontaneous reporting systems in the United States, Sweden, France and the UK are presented, as are those for intensive hospital-based cohort studies, such as the Boston Collaborative Drug Surveillance Program. These systems have influenced the US Joint Commission on Accreditation of Health Care Organisations to

require all hospitals to develop the capability to document and evaluate adverse drug reactions that occur in their patients.

Specific chapters are then devoted to particular systems utilising data from health maintenance organisations and other sources in North America (e.g., Puget Sound, Kaiser Permanente, Harvard, Medicaid and Saskatchewan). The record linkage approach to pharmacoepidemiology is illustrated by separate chapters on the Netherlands (where the experience of NARD and the WHO Drug Utilisation Research Group and the organisation of community pharmacies combine forces to provide unique pharmacoepidemiological opportunities) and the Tayside Medicines Monitoring Unit (MEMO) in Scotland. A number of American inpatient databases are examined, some of which are already capable of linkage to outpatient databases. Further chapters on the Clincial Pharmacy Surveillance Network (Buffalo), case-control surveillance and other approaches are rounded off with valuable advice on how to choose among the available alternatives.

Part IV will be of greatest interest to those readers with some background and experience in pharmacoepidemiology or those with specialised interests within the field. Less common applications of pharmacoepidemiology which are covered include premarketing studies and studies on beneficial drug effects. A review of the current status of descriptive epidemiologic approaches to the study of the processes of drug utilisation is usefully complemented by a chapter on evaluating and improving physicial prescribing. Important methodological issues, for example, determining causation from case reports, bias and confounding, validity of data and novel approaches to study design and statistical analysis are essential reading. Chapters on therapeutic drug monitoring, pharmacoeconomics, quality of life measurements, N-of-1 randomised clinical trials and meta-analysis examine the potential contribution and some of the current limitations of these methodologies in pharmacoepidemiological research.

Part V looks to the future, outlining the ever increasing importance attached to the subject from a number of perspectives, all of which point to the need for more trained personnel and more research. The appendices provide sample size tables and a glossary.

This comprehensive book succeeds admirably in its goal of serving both as an introduction to pharmacoepidemiology and as an excellent reference source for those with some background in the subject.

J.A. Cromarty

Quality Assurance in Analytical Chemistry, by W. Funk, V. Dammann and G. Donnevert, VCH, Weinheim, 1995, xxii + 239 pp., DM 125.00. ISBN 3-527-28668-3.

This volume should be a timely addition to the libraries of the many analytical laboratories in the UK currently progressing towards ISO 9000 and other accreditation standards. It should also be welcomed by analysts tasked with maintaining and improving established quality systems.

The book presents a four phase model of analytical quality assurance, but before doing so dedicates sixteen pages to symbols and definitions relating to the subject. With so many symbols, terms and acronyms relating to quality assurance appearing in modern scientific literature, it is refreshing to find a large number so clearly explained and accessible in one volume. The four phases are each very thoroughly dealt with by a separate chapter. Phase I is concerned with establishing a new analytical procedure and deals with, amongst many others, such matters as calibration, precision, accuracy and testing for linearity. This chapter contains some information (e.g., the conditions and limitations of the use of internal standards) which should be common knowledge to most analytical chemists. However, the mathematics involved are, at times, daunting and some understanding of statistics is essential. The first phase is concluded by an excellent summary of the information which should be included in the documentation of a fundamental analytical process. Phase II is concerned with preparative quality assurance, intended to be performed before the first routine use of a process, and to be primarily

of concern to personnel who will be carrying out the routine analyses. Here the more practical requirements of an analytical process are considered, starting with the determination of the quality required and ending with the preparation of quality control charts for the routine use to follow. Topics covered in this chapter include specificity, costs and external quality requirements (e.g., law, international agreements, etc.) but the greater part is devoted to the subject of control samples and the principles of quality control charting. Shewhart charts, R-charts and cusum charts are all dealt with in depth. Phases III and IV are concerned respectively with routine quality assurance and external analytical quality assurance and will be of particular interest to those establishing quality systems in accordance with an accreditation standard, whether with new or established methodology. Phase II deals with issues ranging from laboratory environment and management, outfitting equipment, materials and personnel, to the reporting of analytical results, problem solving and, in some depth, corrective measures and systematic trouble shooting. Phase IV deals with audits and interlaboratory tests and concludes with recommendations for the organisation of external quality assurance. A total of 154 references are given and appendices of sample calculations and statistical tablets are also included.

This work was first produced in Germany in 1992 and, according to the preface "···was quickly accepted by analysts as a textbook on analytical quality assurance and analytical quality control." The English edition is a revised and updated version of the original. There is little doubt that this very competent translation will be as well received in the UK as the original was in Germany.

S.R. Reddick

Neutron Spectroscopy, by Yu. A. Izyumov and N.A. Chernoplekov, Plenum, New York, 1994. xiv + 373 pp. US$89.50. ISBN 0-306-11033-4.

Covering the more theoretical and physical aspects of the subject, Neutron Spectroscopy is aimed primarily at the solid state physicist rather than the chemical community. This means the title should be read in its narrower sense, covering the very traditional areas of neutron scattering established in the infancy of the subject and pursued with vigour ever since. Concentrating as it does on magnetic and fundamental excitations, the chemical relevance of much of the material is limited.

That nonwithstanding, the text is a clear and comprehensive account of the fundamental aspects of neutron spectroscopy and while the applications covered are restricted to physical rather than chemical systems, the principles thus established are of more general applicability.

The book opens with a detailed account of basic neutron scattering theory applied in this area, augmented by valuable and comprehensively worked examples putting the theory into practice. The theory is accounted clearly and covers the main aspects of the microscopic mechanisms of the dynamics of materials and how neutrons can be used to elucidate these.

Subsequent chapters cover, again from a mostly theoretical standpoint, magnetic excitations and phase transitions, structural phase transitions, along with phonons and critical scattering. These are illustrated by brief reviews of some of the pertinent experimental data. Most of this again reflects the fact that these were the main subjects in the earliest days of neutron spectroscopy, with many of the classic early works referred to. A brief account of experimental techniques is given, and the work concludes with the most chemically relevant section, on metal hydrides.

In conclusion, a solid theoretical and physical text, with its strengths lying firmly in these areas. The weakness for this reader was the lack of experimental detail, especially the lack of account of the recent dramatic advances in neutron instrumentation and techniques. There are also better texts covering the wide use of neutrons in a range of chemically more relevant materials whatever the technical merits of this particular work.

Selectivity enhancements for the determination of thorium by flow-injection analysis through the formation of the Th-DTPA-HQS fluorescent ternary complex[1]

Liwen Ye, Charles A. Lucy*

Department of Chemistry, The University of Calgary, 2500 University Drive, N.W. Calgary, Alta., T2N 1N4, Canada

Abstract

Addition of diethylenetriaminepentaacetic acid (DTPA) to the fluorescent binary complex of thorium and 8-hydroxyquinoline-5-sulfonic acid (HQS) forms the Th-DTPA-HQS fluorescent ternary complex. The formation of this ternary complex enhances the selectivity for the determination of thorium. Excesses of DTPA and HQS are used as reagents in flow-injection analysis to detect thorium. The excess DTPA effectively masks potentially interfering ions by preventing the formation of fluorescent binary metal-HQS complexes. The presence of lanthanides and transition metals does not interfere with the thorium detection with this method (the ratio of molar intensity for metals to molar intensity for thorium is $< 0.3\%$ with the exception of lutetium, for which molar intensity ratio is 1.34%). The detection limit for thorium is 12 ng ml^{-1}.

Keywords: Selectivity enhancements; Thorium determination; Flow-injection analysis; Th-DTPA-HQS fluorescent ternary complex formation

1. Introduction

Determination of trace concentrations of thorium is important in nuclear technology and environmental chemistry. Several analytical techniques have been employed for the detection of thorium. Radiochemical neutron activation analysis [1-3], inductively coupled plasma [4], mass spectrometry [5], and inductively-coupled plasma mass spectrometry (ICP-MS) [6] are very sensitive methods for the determination of Th^{4+}. However, they require expensive and specialized instrumentation. Electroanalytical techniques [7-10] have been employed to determine thorium, but they lack satisfactory selectivity as the presence of lanthanides and transition metals interferes with the determination of thorium. UV-visible spectrophotometry has been widely used for the determination of thorium.

* Corresponding author. Fax: +403 289 9488; e-mail: lucy@acs.ucalgary.ca

The chromogenic ligands of Arsenazo III [11–17], Semimethylthymol Blue [18], *m*-carboxychlorophosphonazo [19], 1-(2-pyridylazo)-2-naphthol (PAN) [14], and DBF–Arsenazo [20] complex with Th^{4+} to form UV–visible absorbing complexes. The sensitivity of chromogenic ligands is typically 20–50 ng ml^{-1} [11–13] and with the exception of DBF–Arsenazo for which the claimed detection limit is 2 ng ml^{-1} [20], the sensitivity of the chromogenic ligand methods for Th^{4+} is not better than the other techniques mentioned. Furthermore, lanthanides and uranium also form complexes with these chromogenic ligands, and interfere with the detection of thorium. Therefore a chromatographic separation or sample pretreatment is generally required when thorium is determined in the presence of other metal ions [11,12,20].

Fluorescence can also be used to determine thorium. The reagent 8-hydroxyquinoline-5-sulfonic acid (HQS) forms a fluorescent binary complex with Th^{4+} [12]. "Binary" complex refers to the complexation of a metal by a single type of ligand. The complexation equilibrium can be expressed as

$$Th^{4+} + nHQS^{2-} \rightleftharpoons Th(HQS)_n^{(4-2n)} \qquad (1)$$
However, other metals, such as Mg^{2+}, Ca^{2+}, Cd^{2+}, Zn^{2+}, La^{3+} and Lu^{3+}, also form strongly fluorescent complexes with HQS [21]. Thus, like the UV–visible spectrophotometric methods discussed above, these metals interfere with the determination of thorium.

Addition of the strong chelating agent diethylenetriaminepentaacetic acid (DTPA) to the Th–HQS binary complex system can prevent the other metals from forming interfering fluorescent complexes. The manner in which DTPA does this is explained as follows. DTPA forms very strong binary complexes with metals.

$$M^{n-} + DTPA^{5-} \rightleftharpoons M(DTPA)^{(n-5)} \qquad (2)$$
Thus in a solution containing excess DTPA and HQS, metals will be present as DTPA complexes. Thorium is a multi-coordination site center metal ion. In certain media, the thorium is potentially of 10-coordination [22]. DTPA is an octadentate chelating ligand. After complexing with DTPA,

thorium still has two coordination sites available. These two "unsaturated" coordination sites further complex with the second ligand, HQS in this case.

$$Th(DTPA)^- + HQS^{2-} \rightleftharpoons [Th(DTPA)HQS]^{3-} \qquad (3)$$
This complex, which consists of one central ion and two types of chelating ligand is called a "ternary complex". The ternary complex of Th–DTPA–HQS can be classified as a "coordination-unsaturated" or "inner sphere" ternary complex. The formation of "coordination-unsaturated" [23] or "inner sphere" [24] ternary complexes provides great selectivity. The formation of the ternary complex depends on the coordination number of the metal, the dentation of the first type of ligand and the dentation of the second type of ligand. In fluorescence analysis, there is the additional criterion that the metal must form a fluorescent complex. In the case of the DTPA/HQS reagent, only thorium fulfills all of these criteria. DTPA effectively masks other metal ions, preventing the formation of fluorescent binary metal–HQS complexes.

Flow-injection analysis (FIA) is a simple and efficient instrumental technique. In FIA the analyte merges with one or more reagents to yield a product which is monitored by a detector. In this work, the fluorescent ternary complex of Th–HQS–DTPA is proposed to be an indicator for sensitive and selective determination of thorium. A simple FIA system using a DTPA and HQS mixture as reagent will be demonstrated. The optimum conditions for the system and the application to detection of thorium will be discussed.

2. Experimental

2.1. Apparatus

Fig. 1 shows a schematic of the FIA manifold used in this work. The FIA system consisted of a solvent delivery pump (Pump 1 in Fig. 1) (Model 625, Waters Associates, Milford, MA), a sampling valve (Model 9125, Rheodyne, Berkeley, CA) fit with a 50 μl loop and a fluorimetric detector (Model 470, Waters; $\lambda_{ex} = 360$ nm; $\lambda_{em} = 500$ nm).

The output signal from the fluorimetric detector was digitized at 2 Hz with a CHROM-1AT (Keithley MetraByte) data acquisition board enhanced for faster data acquisition, and analyzed using LabCalc (Galactic) on a 486-based microcomputer. The pump and injector were fit with PEEK tubing. A 15 cm column packed with 5 μm C_{18} particles was positioned between the pump and injector to provide sufficient back pressure for optimal pumping. The reagent was delivered by constant pressure pumping (Pump 2 in Fig. 1) through application of nitrogen pressure (40 psi) to a cylinder containing the reagent [25,26]. Low pressure tubing and fittings (Alltech Associate, Deerfield, IL) connected the reagent delivery system to the effluent stream. The carrier stream from the delivery pump (1.0 ml min^{-1}) merged with the reagent (0.3 ml min^{-1}) at the mixing tee (316 stainless steel, 90° ports), flowed through the reaction coil, 510 cm of tightly spiraled 0.50 mm i.d. knitted Teflon tubing (RXN 1000 Coil, Waters; 1000 μl volume), and then directly to the detector.

2.2. Reagents and standards

All reagent solutions were prepared by dissolving analytical or ACS grade reagents in distilled deionized water (Nanopure Water System, Barnsted). No special treatment was required throughout the solution preparation. The reagents HQS (Janssen Chimica) and DTPA (Janssen Chimica) were dissolved in deionized water to prepare the stock solutions. The 1 M stock buffer solution was prepared by dissolving 2-amino-2-methyl-1-propanol (AMP) (J.T. Baker Inc.) in deionized water and adjusting the pH to 11.0 by adding nitric acid.

Fig. 1. Schematic diagram for the FIA manifold used for Th^{4+} determination. See text for details.

The 1 mM stock Th^{4+} solution was prepared by diluting 1000 μg ml^{-1} thorium ICP standard solution in 5% HNO_3 (Johnson Matthey, Ward Hill, MA). (**Caution: thorium nitrate is corrosive, irritates skin and eyes, and is radioactive. Care required when handling.**) The other stock metal solutions were prepared using analytical grade salts. Lower concentrations were achieved by dilution in volumetric Nalgene-ware. All solutions were stored in Nalgene plastic bottles.

2.3. Procedures

In studies of sensitivity and interference, various concentrations of Th^{4+} and different metal ions were injected into the sampling valve and delivered by deionized water carrier stream (1 ml min^{-1}), merged with the reagent (1 mM HQS, 5 mM DTPA, and 100 mM AMP, pH = 11.02), allowed to react in the reaction coil and then passed through the detector. The fluorescent intensity was measured by the area of the peak.

For the rest of the experiments (e.g. pH effect and effect of HQS concentration, etc.), the specific solution, which contained certain concentrations of reagents and was adjusted to a certain pH value, was prepared in a volumetric flask. The solutions were then allowed to sit for a time period sufficient to ensure that the reaction goes to completion. This solution, which was the product of reagents, was injected into the sampling valve and carried to the detector by the deionized water stream. The effluent was detected by the fluorescent the detector and resultant peak areas were used for quantification.

3. Results and discussion

3.1. Optimizing conditions for fluorescent ternary complex of Th-DTPA-HQS

3.1.1. pH effect

Fig. 2 shows the effect of pH on both thorium (binary Th-HQS complex) and thorium-DTPA (ternary Th-HQS-DTPA complex) fluorescent response. The optimal pH for the Th-HQS complex is at pH 4 (Fig. 2 (curve a)) while the optimal
Fig. 2. pH effect for Th–HQS binary complex and Th–DTPA–HQS ternary complex. (a) Th–HQS binary complex. (b) Th–DTPA–HQS ternary complex. Experimental conditions: (a) 1×10^{-5} M Th^{4+}, 1×10^{-4} M HQS adjusted to various pH values; (b) 1×10^{-5} M Th^{4+}, 1×10^{-4} M HQS and DTPA at different pH values.

pH for the Th–DTPA–HQS ternary complex is around pH 11 (Fig. 2 (curve b)). Addition of DTPA shifts the optimal pH value to high pH by preventing formation of thorium hydroxides. The fluorescent intensity of the ternary complex is slightly higher (12%) than that of the binary complex when both optimal values are compared.

From Fig. 2, it could be concluded that the ternary complex of thorium does not significantly enhance the sensitivity for determination of Th^{4+}. However, when HQS is used as a reactant in a FIA system, some metal ions (e.g. Mg^{2+}, Ca^{2+}, Cd^{2+}, etc.) present as the matrix of the sample in the system form strongly fluorescent complexes with HQS [21]. These fluorescent complexes interfere with the determination of thorium. The addition of DTPA to the reagent results in the formation of DTPA complexes with these matrix metals, leaving the HQS isolated from these metals whereas Th–DTPA further complexes with HQS and forms the fluorescent ternary complex.

Based on the results shown in Fig. 2, the reagents are buffered to pH 11 in the rest of the experiments.

3.1.2. Concentration of DTPA

To study the effect of the concentration of DTPA on the fluorescent response, Th^{4+} and HQS concentrations were fixed at 1×10^{-5} M

and 1×10^{-4} M respectively, and the concentration of DTPA was varied from 5×10^{-6} M to 1×10^{-2} M. All the solutions were buffered at pH 11.0 using 10 mM AMP.

Fig. 3 shows that the fluorescent intensity remains constant after the concentration of DTPA reaches 1×10^{-5} M, which is the same concentration as that of Th^{4+}. DTPA is an octadentate ligand while Th^{4+} is a 10-coordination ion. The Th–DTPA complex should be present at 1:1 ratio. The results in Fig. 3 confirm that the ratio of Th^{4+}: DTPA is 1:1 in the Th–DTPA–HQS ternary complex. In Fig. 3, the intensity is almost constant (actually, it increases slightly) with increasing concentration of DTPA even up to a thousand-fold excess of DTPA. Thus addition of excess DTPA does not suppress the signal for the ternary complex. This is significant as the excess DTPA suppresses the background fluorescence from metal impurities in the reagent and samples. In a later section, we will discuss the role of excess DTPA in the selectivity of Th^{4+} determination.

3.1.3. Concentration of HQS

To determine the optimal concentration of HQS, Th^{4+} and DTPA concentrations were fixed at 1×10^{-5} M and 2×10^{-5} M respectively and the concentration of HQS was varied from 5×10^{-6} M to 5×10^{-4} M. All solutions were buffered at pH 11.0 with 10 mM AMP. The

Fig. 3. Concentration effect of DTPA. Experimental conditions: 1×10^{-5} M Th^{4+}, 1×10^{-4} M HQS, 10 mM AMP (pH 11.0) at DTPA concentrations from 5×10^{-6} M to 1×10^{-2} M.
Fig. 4. Concentration effect of HQS: (+) experimental data; (———) theoretical regression curve. Experimental conditions: 1×10^{-5} M Th^{4+}, 2×10^{-5} M DTPA, 10 mM AMP (pH 11.0) at different concentrations of HQS from 5×10^{-6} M to 5×10^{-4} M.

results are shown in Fig. 4. DTPA forms a much more stable complex with Th^{4+} than HQS does [27,28]. Thus DTPA will preferentially complex Th^{4+}, leaving only two coordination sites free for HQS complexation. In the presence of excess DTPA, the equilibrium governing the fluorescent intensity is expressed by Eq. (3). The stability constant for the formation of the ternary complex is

$$K_f = \frac{[Th(DTPA)(HQS)^{3-}]}{[Th(DTPA^-)]\alpha_{HQS^{2-}}[HQS]} \qquad (4)$$

The fluorescent intensity is proportional to the concentration of Th–DTPA–HQS complex. At pH 11, $\alpha_{HQS^{2-}}$ is 0.9974 based on literature stability constants [27]. A nonlinear fit (Slide Write plus, Advanced Graphics Software, Inc.) of the data in Fig. 4 yields a formation constant of $5.7 \pm 0.6 \times 10^3$ ($r^2 = 0.9995$). In Fig. 4, the solid line is a theoretical regression based on Eqs. (3) and (4). As the formation constant of the ternary complex is not large, the reagent HQS should be kept in large excess to insure optimal fluorescent intensity for the ternary complex.

To summarize the optimal conditions. the reagent should be adjusted to pH 11 and the concentrations of DTPA and HQS should be kept in large excess relative to the concentrations of the Th^{4+} sample. Thus, 1 mM of HQS and 5 mM of

DTPA in 100 mM AMP (pH 11.0) was employed as the reagent for the determination of thorium.

3.2. Application of thorium fluorescent ternary complex

3.2.1. Detection of Th^{4+}

The reagent mixture of DTPA and HQS merged with the distilled deionized water carrier stream into which Th^{4+} was injected. The complexation took place in the 1000 μl reaction coil and the ternary complex product flowed through the sample cell of the fluorescent detector. Concentrations of Th^{4+} ($0-1 \times 10^{-5}$ M) were injected into the sampling valve with a 50 μl sample loop. Distilled deionized water was tested as a blank sample. The response peak for blank sample had a peak area equivalent to the response peak area for 5×10^{-8} M Th^{4-} since the change in back pressure varied the flow rate of reagent at the moment of injection. Peak areas are used when the calibration curve is calculated. Linear response was observed for injection of 5×10^{-8} M (2.5 pmole)–1×10^{-5} M (500 pmole) Th^{4+} (slope: $1.911 \pm 0.065 \times 10^6$; intercept: 0.00483 ± 0.251; $r^2 = 0.9910$). The estimated detection limit is 12 ng ml^{-1}.

3.2.2. Interference of other metal ions

Some alkaline earth ions, transition metal ions and lanthanide ions can form fluorescent binary complexes with HQS [21]. Like the Lu–Hexadentate–HQS ligands for selective detection of Lu^{3+} [29], Th–DTPA–HQS has high selectivity for determination of Th^{4+}. The stronger chelating ligand DTPA competes with HQS and strips those metal ions from HQS to form more stable metal–DTPA complexes. These metal ions are fully complexed by the octadentate DTPA, and so no further complexation by HQS can occur. Thus DTPA masks the fluorescent response from these metal–HQS complexes.

To test the selectivity of the Th^{4-} reagent, 1×10^{-4} M concentrations of a number of metal ions were injected into the FIA manifold. The intensities were recorded and the interfering indexes were calculated based on the ratio of molar intensity of the metal vs. the molar intensity observed for Th^{4-}.

Table 1
Interfering indexes of metal ions with DTPA–HQS reagent[a]

Metal ion	Interfering index[b] (%)	Metal ion	Interfering index[b] (%)
Mg^{2+}	0.069	Zn^{2+}	0.0013
Ca^{2+}	0.016	Pb^{2+}	0.014

Ba^{2+}	0.045	La^{3+}	0.162
Mn^{2+}	0.034	Er^{3+}	0.0043
Co^{2+}	−0.00003	Gd^{3+}	0.086
Ni^{2+}	0.016	Lu^{3+}	1.34
Cu^{2+}	0.049	UO_2^{2+}	−0.23
Cd^{2+}	−0.0006	Th^{4+}	100

[a] Experimental conditions: 1×10^{-4} M of each metal was injected using a 50 μl sampling valve, reagent was 1 mM HQS, 5 mM DTPA, 100 mM AMP (pH 11.02).
[b] As defined by Eq. (5).

Interfering index

$$= \frac{\text{Molar intensity of metal ion}}{\text{Molar intensity of } Th^{4+}} \times 100(\%) \qquad (5)$$

Table 1 presents the metals tested along with the observed interfering indexes.

From the experimental results, the DTPA–HQS reagent system has high selectivity for Th^{4+}. Of the metals tested only Lu^{3+} (interfering index 1.34%) interferes significantly with Th^{4+} detection. All other metals display interfering indexes of < 0.3%. Therefore, the DTPA-HQS reagent is a potent FIA reagent system for the detection of Th^{4+} in complex matrices.

4. Conclusion

The DTPA–HQS reagent system can be used to sensitively and selectively determine Th^{4+} ion using FIA through the formation of the Th–DTPA–HQS ternary complex. The dynamic range for determination of Th^{4+} is from 5×10^{-8} M (2.5 pmole) to 1×10^{-5} M (500 pmole) Th^{4+}. The presence of transition metals and lanthanides does not interfere in the determination of Th^{4+}.

Abstract

Chromatomembrane cells proved to be applicable to flow-injection analysis whenever computer-operated manifolds for liquid–liquid or liquid–gas extraction procedures were required. Proceeding in accordance with the Methylene Blue method the determination of anionic surfactants was studied by applying the chromatomembrane cell for preconcentration and extraction of the ion-pair complex being formed. Spectrophotometric detection at 650 nm was made possible by using a flowthrough cell within a range of 0.02–5.0 mg dodecylsulfate per liter of water. The absorbance was found to respond proportionally to the product of preconcentration time and surfactant concentration, its slope factor being calculated with $\pm 3\%$ standard deviation. A mechanism for the preconcentration cycle inside the cell is suggested.

1. Introduction

The determination of anionic surfactants in wastewater by measurement of the Methylene Blue index (MBAS) according to ISO 7875-1 is a common practice. The method includes ion-pair extraction which unfortunately creates difficulties whenever automation is required [1–3]. The batch process [4] has the disadvantage of low distribu-

tion coefficients which restrict the detection limit to 0.05 mg l^{-1} under optimal conditions. Del Valle et al. [5] reported that the sensitivity can be improved to meet the requirements of environmental monitoring by using time-based continous sampling followed by flow-injection spectrophotometric determination.

Until now the performance of flow-injection (FI) liquid–liquid extraction systems has been limited by inadequate approaches to the problem of phase separation [6] at the end of the procedure. Eventually, Liu and Dasgupta [7] decided in favour of a technique which made phase separation unecessary. The amount of analyte extracted into the organic phase is calculated from its absorbance and the length of the organic segments passing a UV/Vis detector at the outflow of the extraction coil. The system is based on dual-wavelength spectrophotometric measurements and works with automated data processing.

An alternative approach to extraction procedures arises from the applicaton of chromatomembrane cells in FI systems. The novel extraction module consists of a rectangular block of biporous PTFE. Polar liquids fill the macropores whereas the micropores remain available only for non-polar liquids or gases. The capillary pres-

Fig. 1. Schematic flow diagram for the determination of dodecylsulfate. Broken line: automated extraction module (Fig. 2).

sure of polar liquids prevents their penetration into the macropores. We recently reported [8,9] on the special construction of a chromatomembrane cell which allows the two phases to flow independently through the unit and come into contact over an interfacial area of about 0.7 m^2 cm^{-3} biporous PTFE. Taking into account the very small volumes of the contacting phases it is easy to understand that the analyte transfer through the expanded boundary cannot be restricted kinetically. The pressures under which both phases are supplied into the cell have to comply with the physico-chemical requirements [9] and should be controlled to ensure stable operating conditions.

Fig. 3. Dependence of the absorbance of the ion-pair complex on the flow rate of the organic phase ($t_p = 60$ s; $c_w = 5$ μg ml^{-1}).

In the case of applying the "stop-flow-mode" the chromatomembrane cell is suitable for preconcentration procedures as well. An efficiently working manifold, however, will be designed by integrating this novel device into flow systems for automated analysis [10]. In general the choice of the method for detecting the analyte is an open one, even online delivery to an additional separation device such as GC or HPLC is possible.

In this paper a new automated FI system is introduced which demonstrates the advantages of the application of chromatomembrane cells to the critical step of ion-pair extraction intended for the Methylene Blue method. For meeting the requirements of environmental monitoring the sophistication of the procedure will increase as soon as the chromatomembrane cells are produced commercially (i.e. a second cell could be introduced further on for backwashing the chloroform phase from the matrix components).

2. Experimental

The ion-pair complex between dodecylsulfate and Methylene Blue (MB) was formed in acetate buffer at pH 4.7. The samples (S) containing different amounts of sodium dodecylsulfate dissolved in water had to be mixed for that purpose with equal portions of MB (R1: 1.25×10^{-4} mol l^{-1}; carefully purified before use, i.e. the aqueous MB solution was washed with CHCl$_3$ to remove components soluble in organic solvents) and sodium acetate buffer (R2: 0.1 mol l^{-1}). After merging the three conduits the ion pairs were formed. Throughout the period while the aqueous phase passed the reaction coil (Fig. 1) its outflow was delivered to a chromatomembrane cell (size $3.0 \times 0.5 \times 1.0$ cm^3; free volume of each phase about 0.2 ml; macropores 200 μm i.d.; micropores 0.3 μm i.d.) which was used for the preconcentration of the ion-pair complex and its subsequent extraction with chloroform.

An FI spectrophotometric system suitable for automated dodecylsulfate determination was realized by means of a combination of an FIAS 300 instrument and a UV/Vis spectrometer Lambda 2S (Perkin Elmer GmbH, Bodenseewerk, Germany). The FIAS 300 FI tool was equipped with an 8-channel, 16-port multifunctional valve [11] to perform computer-aided preconcentration procedures. The maximum absorbance of the ion-pair complex dissolved in chloroform is 650 nm.

The radial mixing of the three components R1, R2 and S (each flowing at 0.45 ml min^{-1}) was achieved with the use of a standard chemifold (Fig. 1: short coils of 30 cm length are provided for ion-pair formation). The aqueous phase containing the ion-pair complex passed the chromatomembrane cell with a flow rate of 1.35 ml min^{-1} (position 1 shown in Fig. 2). While the ion-pair is preconcentrating in the water/chloro-

Table 2
Absorbance dependence on the preconcentration time: $c_w = 5$ μg ml^{-1}; $R = 0.99917$

Absorbance	0.057	0.193	0.294	0.431	0.505	0.624	0.746	0.871	0.976
Time (s)	15	30	45	60	75	90	105	120	135

form phase boundary inside the cell the surplus of MB remains in the flowing aqueous phase. A definite period of time later (preconcentration time) the aqueous phase was stopped and the organic phase started to flow. The ion-pair complex now being extracted by chloroform passed a flow through cell ($d = 10$ mm; $v = 18$ μl) for detection by means of the spectrometer (position 2 shown in Fig. 2).

Given that both the preconcentration time (1 min) and the content of dodecylsulfate (5 μg ml^{-1}), need to be kept constant we optimized the measurement of absorbance by varying the flow rate of the organic phase. Fig. 3 shows the result. We decided that 0.60 ml min^{-1} was the optimum flow rate to be used in all further investigations. Taking into account a capacity of about 0.2 ml for chloroform inside the chromatomembrane cell it should be emphasized that the ion-pair complex is always finally dispersed in a volume of 3 ml organic phase.

Reasonable values of absorbance can be obtained by varying the preconcentration time. The more a sample had been diluted the longer the preconcentration time which had to be chosen. Table 1 shows that the detected absorbance is always at the same level as long as the product of concentration and volume having passed through the chromatomembrane cell remains constant. The corresponding mass of dodecylsulfate is 2.25 μg in all cases but it had to be diluted in different volumes of water which had to pass during the preconcentration time. Incidentally, this agrees with all observations we noticed from other applications of the chromatomembrane cell.

3. Results and discussion

In principle two different approaches exist, for working with the FI system just described. On the

one hand a standard solution containing 5 μg ml^{-1} dodecylsulfate was used to form the ion-pair complex which had to flow with the aqueous phase through the chromatomembrane cell for preconcentration inside. The quantity of the ion-pair complex later extracted by chloroform depends on the preconcentration time (t_p), i.e. the period for which the aqueous phase has flowed through the cell. The absorbance shows a linear response to the preconcentration time (Table 2).

On the other hand a normal calibration graph will be obtained in the case where the preconcentration time remains fixed and the concentration of dodecylsulfate varies (Table 3). Because of the fact that the detected quantity of dodecylsulfate (m) equals the product of its concentration in the aqueous phase (c_w) × flow rate of the aqueous phase (v_w) × preconcentration time (t_p) it is easier to standardize the x-axis in terms of m. If the original concentration is required it can be calculated from the formula

$$c_w = \frac{m}{v_w \cdot t_p}$$

It is worth mentioning that there is now the possibility of setting the parameters in the way required to obtain values of absorbance in the range of best confidence. Referring to the concentration of dodecylsulfate in the original sample the FIA system proved to be reliable in the range 0.02–5.0 mg l^{-1}. The slope factor of the calibration plot was calculated with a standard deviation of $\pm$ 3%. Corresponding to the preconcentration time the volume of the aqueous samples varied in the range 0.2–2.2 ml. Probably the limit of detection will decrease with prolonged preconcentration time. This is of interest for further investigation.

The results are altogether satisfying even though some notes seem to be necessary to explain the mechanism of the preconcentration cycle

Table 3
Calibration for dodecylsulfate: t_p = const.; R = 0.9983

inside the chromatomembrane cell. The procedures established up to now to determine anionic surfactants using the MB method suffer from the small-scale distribution coefficient of the ion-pair complex between water and chloroform. Often this is the reason for decreased confidence in results.

The chromatographic behaviour of the ion-pair complex inside the chromatomembrane cell was investigated under the condition of a stationary chloroform phase. A simple strategy was found: the micropores of the cell were filled with pure chloroform and then the inlet and outlet for the non-polar phase were shut. The ion-pair complex

Fig. 4. Preconcentration and extraction cycle inside the chromatomembrane cell.

in stoichiometric composition dissolved in water was pumped through the macropores of the cell. We measured the retention volume which was observed to be 350 times larger than the free volume of the cell in the case of a 1×10^{-5} mol l^{-1} aqueous solution. However, as this concentration increased the retention volume decreased correspondingly. In other words the concentration is inversely proportional to the retention volume observed.

This is comprehensible if it is assumed that the ion-pair complex is adsorbed at the interface boundary between the two liquids. The quantity of adsorbed complex can expand greatly because of the fact that the concentration area inside the cell extends over about 0.7 m^2 cm^{-3} biporous PTFE. The break point will not occur until the interface boundary has been saturated. Then the ion-pair complex will be able to leave the cell with the flowing aqueous phase.

Returning to the normal mode of operation with the chromatomembrane cell we understand that the extraction procedure requires a bigger volume of chloroform because it has to remove the entire quantity of ion-pair complex adsorbed at the phase boundary. As mentioned above the extraction volume of chloroform amounts to 3 ml in all cases.

Fig. 4 expresses our model of the preconcentration cycle in detail. The ion-pair complex completely adsorbs at the phase boundary as long as the aqueous phase flows through the cell. In the meantime the surplus of MB is flushed away with the water. The extraction procedure with chloroform must start before the phase boundary has been saturated. The volume of the organic phase required to desorb all ion pairs from the phase boundary depends on the extent of the contact area inside the chromatomembrane cell. As soon as the extraction procedure has finished the pre-
concentration cycle can start again. The mechanism suggested above is able to explain the strong retention volumes observed in spite of the knowledge that the distribution coefficient only amounts to five. In summary the chromatograpic process can be classified as liquid adsorption–liquid chromatography.

4. Conclusions

The application of chromatomembrane cells has been made possible by developing a computer-operated procedure to determine anionic surfactants corresponding to the MB method. Moreover, the distinguishing features of the process are good recovery and remarkable accuracy. Even though the current stage of development does not meet the recommendation of the European Committee for Standardization (ISO 7875-1) in all details further adjustments of the procedure reported here should be easily attainable. Wastewater samples normally contain Cl⁻ and NO_3^- which interfere by forming ion pairs with MB. To avoid excessive results for the MBAS in this case a backwashing step with aqueous buffer solution is provided. For this purpose a second chromatomembrane cell should be included in the FI analyzer. Otherwise a correction on the basis of adjusted calibration procedures has to be proved according to the paper of Burkhardt et al. [12].

Abstract

Speciation of elements in natural matrices, especially of trace metals, is one of the predominant development trends of modern inorganic analysis. The main part of the conventional speciation procedures is a suitable combination of separation and chemical conversion steps, for which the most appropriate methodology seems to be the use of flow-injection. A shorter time of performance of these operations in flow-injection manifolds is advantageous in terms of avoiding the shift of chemical equilibria during the speciation measurement. Numerous other advantages are also pointed out in this review based on 58 references. Among flow-injection analysis methods published so far for speciation the determination of different oxidation states predominates, while a much smaller number of papers have been published on the determination of the degree of complexation or the determination of organometallic compounds.

Keywords: Flow-injection analysis; Natural matrices; Speciation; Trace metals

1. Introduction

Most commonly in the chemical literature "speciation" is used to mean the analytical determination of the concentrations of various chemical species containing a given element in a particular material, although it is often also used to mean the existence of a given element in a particular matrix in various chemical forms. One can also find the term "speciation analysis", meaning the determination of the concentrations of the individual physicochemical forms of the element in a sample that together constitute its total concentration. The first meaning is used most frequently and this is the one adopted in this paper.

---

* Corresponding author. E-mail: mtrojano@post office. newisham.utas.edu.au

The importance of knowing that a given element occurs in different physicochemical forms in various natural matrices, not only for macrocomponents but also for trace elements, has been widely recognized in the last 20 years in environmental science, biology and medicine. This is evident from the hundreds of original research papers published in scientific journals and several books published in recent years [1–6]. Various chemical forms of binding of the element of interest exhibit different reactivity, toxicity and bioavailability. The most difficult problem encountered in speciation is to develop a procedure which does not disturb the chemical equilibria between forms of the element existing in a given matrix. It might then be concluded that the most satisfactory procedure should be based on the determination of the total amount of all elements in a given material followed by the computer-aided calculation of the concentrations of particular species based on ionic and redox equilibrium constants. It is obvious, however, that the success of such a procedure is limited by difficulties in taking into consideration all kinetic factors, adsorption proceses, polymerization reactions and heterogeneous processes. The number of available stability constants is also limited; hence in practice the procedures of analytical determination of particular species predominate with the use of different detection methods, separation operations and chemical conversion into detectable species.

Flow-injection analysis (FIA), intensively developed over the past 20 years, offers several valuable advantages for speciation of both macro- and microelements. Its main feature is a shorter analysis time than in conventional, manual procedures, because in many cases the condition of not disturbing the equilibria in analyzed samples is much better fulfilled. Also of very great importance is a reduced human participation in time-consuming operations such as sample conditioning, reagent manipulation and calibration of the measuring system. Very advantageous is the possibility of using on-line preconcentration techniques and non-chromatographic separations such as ion-exchange, dialysis, solvent or solid-phase extraction.

Early works on speciation using FIA were reviewed by Luque de Castro [7,8]; however, the last few years have brought significant progres in this field. Amongst the numerous ways to determine the distribution of elements in natural matrices the FIA speciation studies have focused on three areas: simultaneous determination of species in different oxidation states, determination of the complexation degree of metallic elements or determination of the content of a given complex compound. There were also some attempts to use FIA for the speciation of organometallic species, although FIA cannot by any means compete with chromatographic techniques.

2. General remarks on speciation using FIA

The literature concerning chemical speciation employing FIA methods provides a large variety of designs of the measuring systems utilizing various detectors as well as different examples of off-line and especially on-line sample manipulation. A relatively simple task is to design a set-up with several detectors, mostly two, where each of them can selectively produce the analytical signal corresponding to the concentration of a particular chemical form of a given element. They can be arranged in series, if in at least one of them a substantial dispersion of the sample segment does not occur, or in parallel with sample splitting between the two branches of the manifold. Simultaneous injection with two combined valves to various branches of the FIA manifold is also used.

Most often, however, single detector manifolds are employed, which usually require much greater creativity to design the whole measuring system successfully. The least complicated systems are developed when off-line sample pretreatment is involved. Such systems utilize the advantages of the flow-injection methodology to a limited extent. In most FIA systems designed for speciation, the determination of various species by the same detector is achieved through various methods of on-line sample manipulation. For each sample injection a single analytical signal is most often produced in the detector; however, the simple
Fig. 1. Manifold of the reversed FIA system used for speciation of chromium with pH measurements of aspirated sample [12]: q,q', peristaltic pumps; V_1, V_2, injection valves; L_1, L_2, reaction coils; M.E., pH glass microelectrode.

changing of reagent solutions in the manifold between successive injections or the simple and fast rearrangement of the manifold allows one to obtain a signal corresponding to different chemical forms of the element. Among methods of on-line chemical conversion the most frequently used are reduction and oxidation, selective sorption on appropriate sorbents or total retention followed by fractional elution as well as volatization. Kinetic discrimination is seldom utilized for this purpose, i.e. differences in the reaction rates among various sepecies. The change of reagents in the manifold for the determination of various forms is arranged by the use of selecting valves or by designing reversed FIA systems with injection of reagent into the stream of continuously aspirated sample.

Different pretreatment of various aliquots of the same sample is managed in the manifold with the splitting of the sample zone between different branches of the FIA manifold. This different pretreatment, followed by merging sample segments into a single stream approaching the detector, allows one to obtain, for instance, two independent analytical signals for one injected sample solution. Two signals for one injected sample can also be obtained for simultaneous injection with two combined valves into separate parts of the FIA manifold. The most common configuration, where two signals are obtained for different species, is a FIA set-up with selective on-line retention of one form or with retention of the total amount and then selective consecutive elution.

More detailed discussion of FIA manifolds used for speciation is given below together with presentation of their chemical applications. Although the presentation of FIA systems for speciation is the main aim of this review, we have decided to present all collected information not according to technical arrangements of FIA set-ups, but rather according to the nature of the chemical problems solved in this way. We hope that such a means of presentation may be more interesting for a larger circle of analysts than just those interested mainly in developing flow analytical methods.

3. Speciation of different oxidation states

The largest number of FIA systems have been developed for the speciation of different oxidation states of the target element. Two basically different concepts of measurement can be distinguished. In two consecutive measurements with some changes to the manifold, with different off-line sample modification or in a more complex manifold, firstly the total content of a given element is determined and then the content of particular species. In another type of FIA system the selective determination of each form of different oxidation state is carried out.

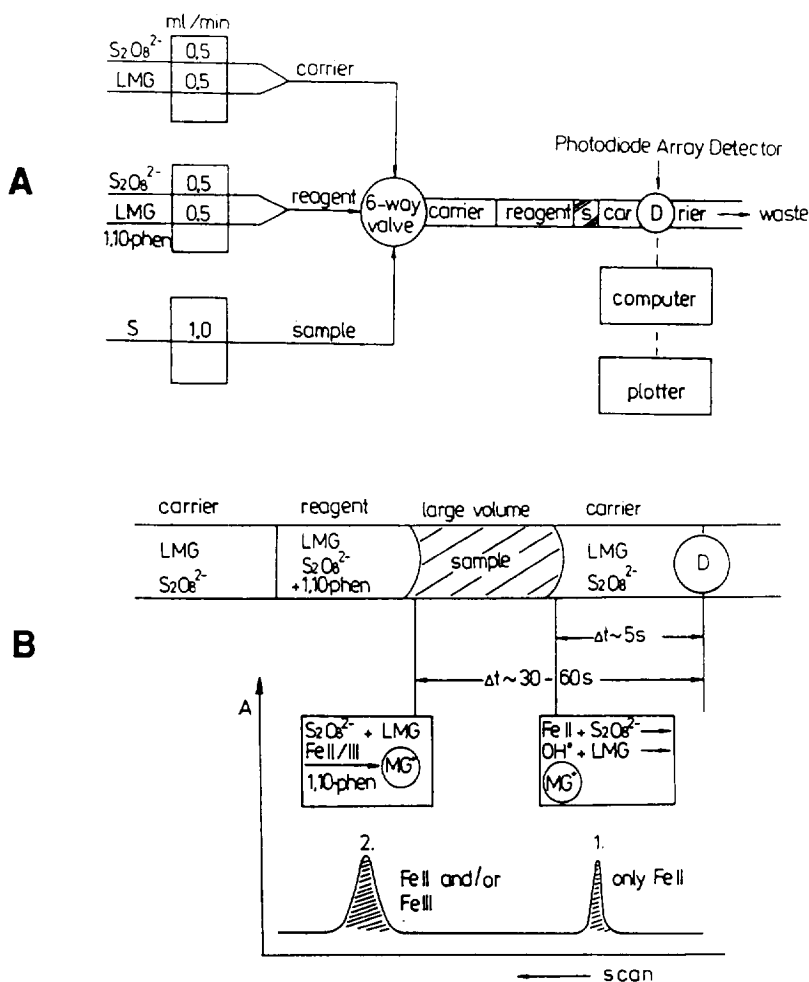
The first of these two options is usually simpler to be developed. Most often it has been used for the speciation of chromium, iron and arsenic,


Fig. 2. Manifold of the FIA system used (A) and schematic diagram of the sample/reagent sequencing (B) in speciation of iron utilizing kinetic discrimination of analytes in the reaction between Leucomalachite Green (LMG) and $S_2O_8^{2-}$ with 1,10-phenanthroline (1,10-phen) as activator [17].

although FIA systems for the speciation of other elements have also been reported.

In the speciation of chromium, besides determining the total content of Cr(III) and Cr(VI), Cr(VI) content is separately determined using spectrophotometric determination with diphenylcarbazide and AAS detection. In the least complicated manifold a series arrangement of the spectrophotometric and AAS detectors was applied [9]. Several systems were developed with a spectrophotometric detector only and on-line oxidation of Cr(III) to Cr(VI) in order to determine total chromium content [10–13]. In several sys-

tems reversed FIA measurements were employed with continuous sample aspiration and injection of reagents[11,12]. Especially worthy of mention is the system shown in Fig. 1, in which continuous monitoring of pH is performed [12]. The sample segment is split into two streams, where Cr(VI) and total chromium are measured, whereas knowledge of the pH value allows the calculation of the content of hydroxylated complexes of Cr(III) and protonated and polymerized forms of Cr(VI). Other configurations were developed with the use of double-beam detection with two spectrophotometric flow cells, which gave the most

reproducible results [13]. In determinations with AAS detection, the on-line sorption of the Cr(VI) complex with sodium diethyldithiocarbamate on C18 was adopted, whereas total chromium was determined after oxidation of Cr(III) with peroxydisulphate [14].

A FIA system with spectrophotometric and AAS detectors in series was also reported for the speciation of iron, where determination of Fe(II) was based on reaction with 1,10-phenanthroline [9]. This reaction was also utilized in three other FIA systems with spectrophotometric detection only [15–17]. In order to determine total iron, Fe(III) was on-line reduced on a column with Jones reductor [15]; alternatively a complex of Fe(III) with 1,10-phenanthroline was reduced photochemically [16]. A unique system for iron speciation was also developed with the use of kinetic discrimination (Fig. 2) [17]. It was based on different kinetic–catalytic behaviours of Fe(II) and Fe(III) in the redox reaction between Leuco-malachite Green and peroxodisulphate with and without the presence of 1,10-phenanthroline acting as activator.

Differences in on-line sample pretreatment were utilized in the design of FIA systems for the speciation of As(III) and As(V) with spectrophotometric [18] and AAS [19,20] detection. Sequential detection of $AsO_2^- - AsO_4^{3-}$ mixtures was based on the formation of heteropolyacids with MoO_4^{2-} [18]. When sample in the manifold merges with iodate solution, it oxidizes arsenite and the obtained signal corresponds to the sum of both arsenic anions. When sample is not oxidized it gives a signal corresponding to arsenate alone. Using hydride generation AAS for detection total arsenic was determined using arsine generation in 6 M HCl, whereas As(III) alone can be determined by generation of arsine in citrate buffer at pH 3 [19]. A more sophisticated AAS procedure was also used, which was based on the generation of arsine in a FIA system and its subsequent trapping in a graphite furnace coated with appropriate absorbers [20]. The arsine was transferred to the graphite furnace through an electronically-activated arm. As(III) was determined using addition of NaOH to a water carrier stream, while potassium iodide was used when total arsenic had to be determined.

Various chlorine-containing species can be determined in flow-injection systems with spectrophotometric detection. In the speciation of low concentrations of chlorite and chlorate ions chlorite was selectively determined by using its reaction with iodide at pH 2, which liberates iodine, while in 6 M HCl both species produce iodine, which is then measured spectrophotometrically [21]. Differentiation of residual free and combined chlorine was based on different reactions of the two species with 2,4-dinitrophenyldiazonium ion depending on the acidity in a reversed flow-injection system [22]. Iodide can be directly determined over a wide concentration range using potentiometry with an ion-selective membrane electrode, whereas iodine can be determined after on-line reduction to iodide with sodium metabisulphite [23].

Total phosphorus and orthophosphate were determined in wastewater in the FIA systm with two detectors [24]. Orthophosphate was determined as molybdovanadophosphoric acid using a spectrophotometric method and the solution from the flow cell of the spectrophotometer was directly introduced into an inductively-coupled plasma. In another reported system with spectrophotometric detection orthophosphate was determined as the sum of orthophosphate and pyrophosphate after on-line separation and preconcentration of both analytes on an inert support modified with a diorganotin extractant [25]. The sum of both anions was determined after preliminary hydrolysis of pyrophosphate to orthophosphate by use of inorganic pyrophosphatase dissolved in solution.

The speciation of inorganic selenium was carried out in FIA systems with cathodic stripping voltammetric detection with a mercury film on a glassy carbon electrode [26], with anodic stripping voltammetry at a gold electrode [27], and with hydride generation AAS detection [28], which allows Se(IV) detection. In all three cases the sum of Se(IV) and Se(VI) was determined after reduction of Se(VI) to Se(IV), carried off-line chemically [26,27] or on-line in a microwave unit [28]. In the system with anodic stripping voltammetry the on-line removal of the interfering cations on a Chelex-100 column was employed [27].

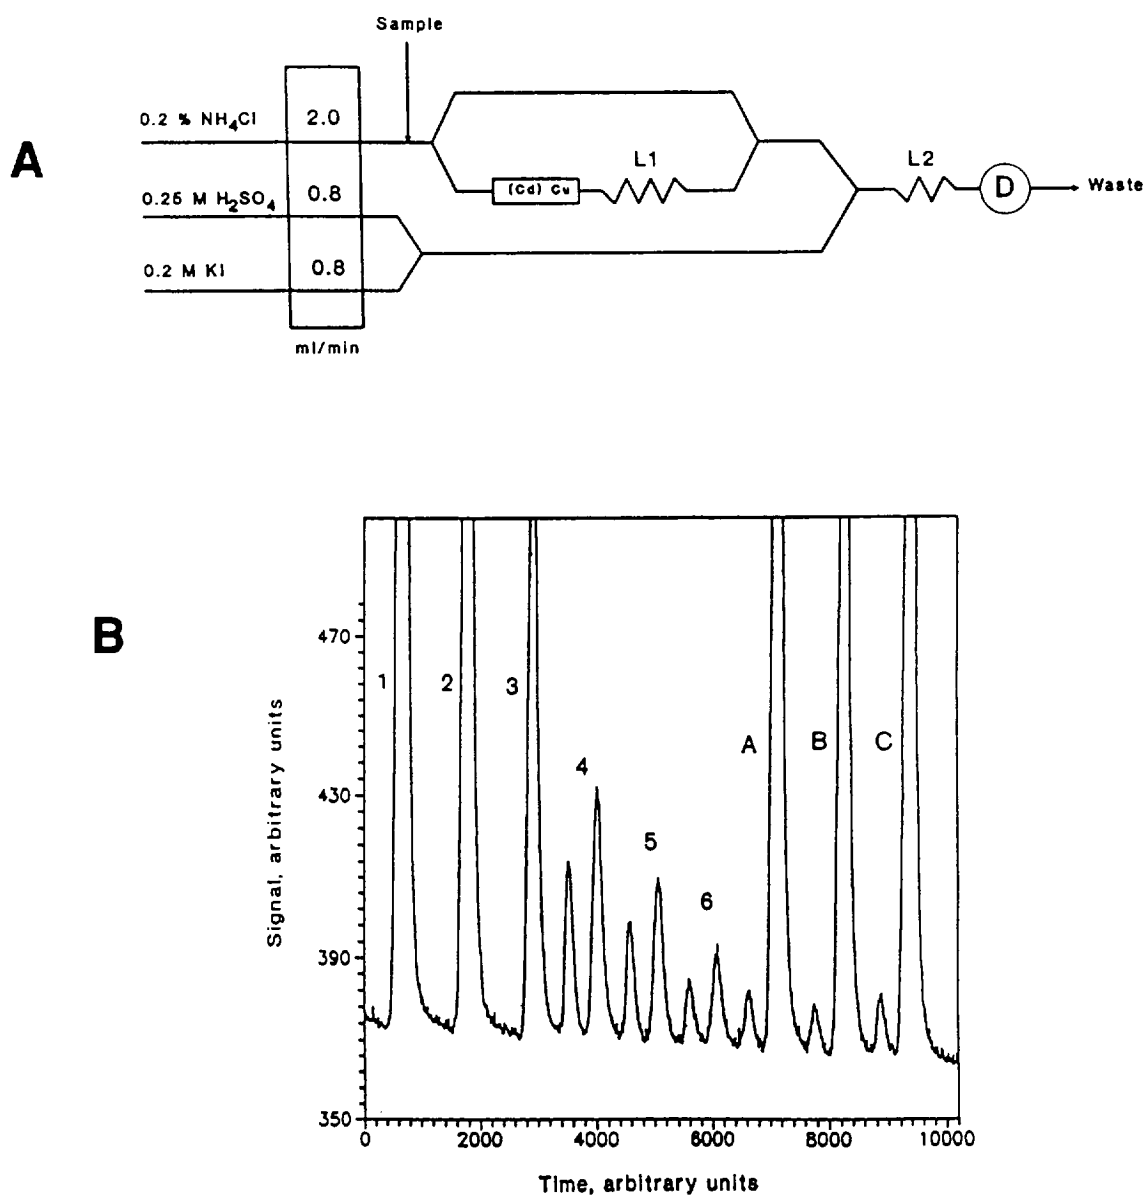
More complex and more difficult to design are FIA speciation systems with selective determina-


Fig. 3. Manifold of the FIA system used (A) and display of experimental data obtained (B) for simultaneous determination of nitrite and nitrate with indirect biamperometric detection [33]: L_1, L_2, reaction coils; (Cd)Cu, copperized cadmium microcolumn; 1–3, nitrate standard solutions; 4–6, nitrite standard solutions; A–C, natural water samples.

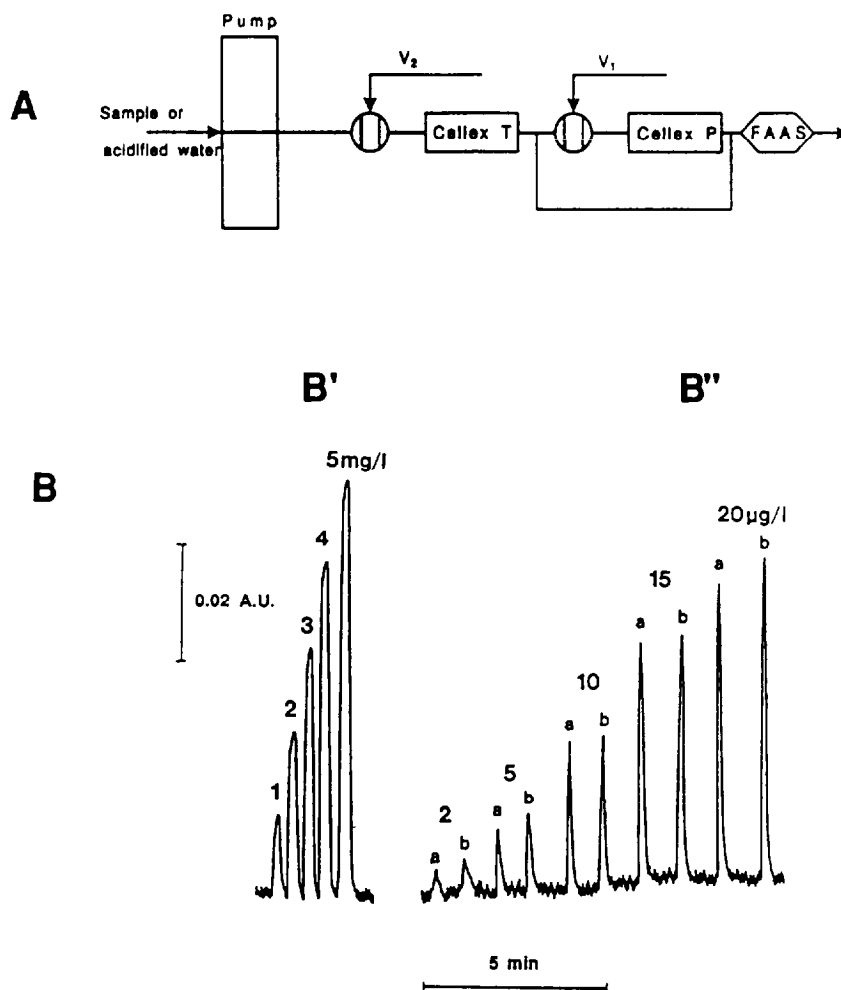
tion of each individual form of the element of interest. In this type of FIA system for speciation several papers reported manifolds for nitrate and nitrite, but also for chromium and iron speciation. Nitrogen in most samples does not occur as nitrate and nitrite only, hence the methods for their determination are included in this type of FIA system, although in most FIA speciation systems both these analytes are determined both together and separately. Simultaneous FIA determination of nitrate and nitrite was carried out with spectrophotometric [29–32], amperometric [33], AAS [34] and chemiluminescence [35] detection. In the measuring set-up with a dual absorbance monitor


Fig. 4. Manifold of the FIA system with AAS detection and on-line preconcentration on cellulose sorbents used for speciation of chromium (A) and comparison of recordings (B) obtained with (B′) conventional aspiration and (B″) with FI AAS system with preconcentration of (a) Cr(III) and (b) Cr(VI). In B″: aspirated sample volume, 100 ml; flow rate, 5.0 ml min⁻¹ [38].

connected to a dual-channel recorder both species were determined using common methods, where nitrite is diazotized and product is transformed into a coloured azo dye. The injected sample is split between two branches of the manifold and in one of them nitrate is on-line reduced to nitrite [29]. Two separate signals are measured for nitrate and the sum of nitrite and nitrate. The same method in FIA systems with single detector and two injection valves was used by other authors [30,31]. For the on-line reduction of nitrate to nitrite copperized metallic cadmium micro-columns are most often used [29–31,33]; however,

photo-induced reduction with UV radiation in the presence of complexones was also reported [32]. In the system with indirect biamperometric detection the analytical signal is observed when nitrite oxidizes iodide to iodine and the reversible couple is formed [33]. The injected sample is split in a FIA manifold into two segments (Fig. 3). One of them is transported through a reducing mini-column and a delay loop. For each injected sample two peaks are obtained, the first of which corresponds to nitrite and the second to the sum of nitrite and nitrate. Sequential determinations of nitrate and nitrite with AAS detection were based

on continuous liquid–liquid extraction [32]. Nitrate reacts with bis(2,9-dimethyl-1,10-phenanthrolinato) copper(I) to form an ion pair which is extracted into 4-methyl-2-pentanone in a flow-injection manifold. In one aliquot of sample nitrite is oxidized by Ce(IV), so that total nitrate is determined. In another, nitrite is converted to nitrogen with sulfamic acid, so that only original nitrate is determined. By measuring the AAS signal of copper in the organic phase, both species can be determined. Nitrite and nitrate were also determined in the reversed FIA system with chemiluminescence detection in the gas phase and transfer reduced NO to the gas phase through a PTFE membrane [35]. NO produced by injection of Ti(III) solution corresponds to the sum of nitrate and nitrite, whereas injection of iodide results in reduction of nitrite only. Detection is based on chemiluminescence from the reaction of NO with ozone. A reversed system with continuous sample aspiration and sequential injection of appropriate reagents was also used in the selective determination of nitrite with the formation of azo dye and ammonia using the Nessler method [36].

The speciation of chromium in FIA systems, where for each injected sample signals corresponding to Cr(III) and Cr(VI) were obtained, was reported with inductively-coupled plasma–atomic emission spectrometry, (ICP–AES) [37] and AAS [38] detection. In the first-mentioned system a microcolumn of activated alumina was used in the FIA manifold to separate and preconcentrate Cr(VI) from Cr(III). After detection of Cr(III), ammonia solution was injected to elute Cr(VI) from the column. In the system with AAS detection two columns with different functionalized cellulose sorbents were used for selective sorption of Cr(III) and Cr(VI) from continuously aspirated sample (Fig. 4) [38]. Sequential elution with appropriate solutions provides two peaks corresponding to Cr(III) and Cr(VI) contents in the sample.

Several different FIA methods were developed for iron speciation, where individual signals were obtained for Fe(II) and Fe(III). In the system with two spectrophotometric detectors and simultaneous sample introduction by two coupled injection valves, iron(II) was determined with

1,10-phenanthroline, whereas iron(III) was determined with thiocyanate [39]. In the system with AAS detection a packed bed reactor with Dowex 1 anion exchange resin was used to retain chloride complexes of Fe(III), whereas Fe(II) species passed through the reactor to the detector [40]. This was followed by the separate elution of Fe(III) to the detector by change of carrier solution. On-line solid-phase extraction was also employed in two other FIA systems for iron speciation with spectrophotometric [41] and AAS [42] detection. In the first system Fe(II) was preconcentrated on a C18 column with immobilized ferrozine and then eluted with methanol. Determination of Fe(III) required on-line reduction with ascorbic acid [41]. In the second one injected sample was mixed with ferrozine solution and while Fe(III) is directly carried to the flame AAS

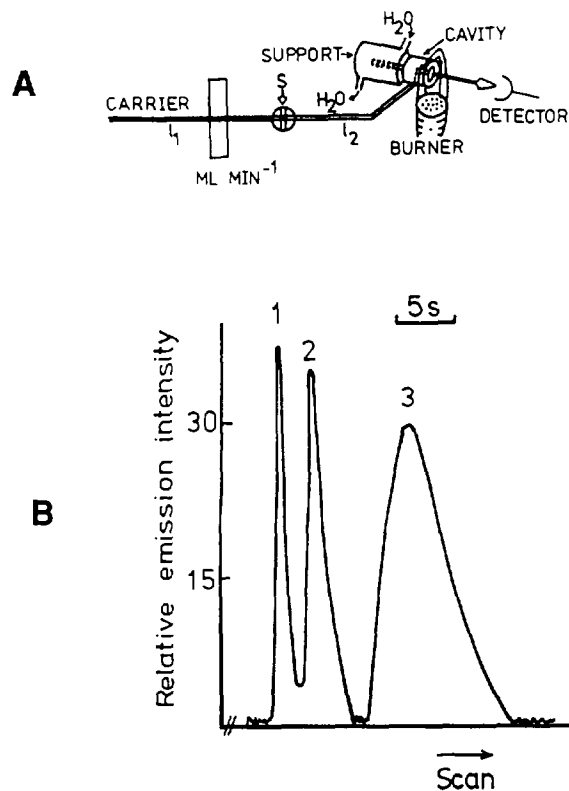

Fig. 5. Schematic diagram of the FIA system with molecular emission detection (A) used for speciation of sulphur anions and response from a mixture of sulphur anions (B): 1, sulphide; 2, sulphite; 3, sulphate [44].

detector, Fe(II)–ferrozine complex is temporarily retained on a C18 column and is then subsequently eluted with methanol.

Speciation of vanadium was carried out using flame AAS with an on-line procedure for the preconcentration of V(V) using silica-bonded ion-exchange resin [43]. While V(V) retention took place, the unretained V(IV) passed to an AAS detector, which was followed by elution of V(V) species with a plug of sodium hydroxide solution.

Simultaneous flow-injection determination of sulphite, sulphide and sulphate was reported in a system with a molecular emission cavity detector, which was based on the sequential appearance of S_2 emission peaks corresponding to these species (Fig. 5) [44]. In the system with an atomic absorption spectrometer operated in the emission mode a 3 μl sample was injected and detection limits for sulphur anions were in the range 0.06–0.15 ng for injected samples.

A list of the applications of flow-injection methodology to the speciation of different oxidation states of 10 elements is shown in Table 1. With a few exceptions optical methods of detection are mostly used, mainly molecular absorptive spectrophotometry in the visible range and AAS. The majority of practical applications concern natural waters, often spiked with analytes. Numerous developed methods exhibit a sufficiently low detection limit to find practical applications for natural samples. It seems that from the point of view of environmental analysis speciation procedures should also be developed for elements such as antimony, manganese, thallium and tellurium, as well as simpler methods for the speciation of oxidation states of sulphur. Especially desirable seems to be the development of simple speciation methods for medical applications [45].

4. Speciation of complexes

In most natural matrices elements occur only in a small fraction of cases as simple, hydrated cations and are mostly present in ion pairs or complex compounds with inorganic and organic ligands. In natural waters only a few percent of non-complexed cations of Al, Pb and Cr(III) can

be found, and above 80% only e.g. potassium or calcium [46].

Although it seems to be a simpler task than determination of different oxidation states, determination of the degree of complexation in FIA systems has been reported in a much smaller number of papers.

The possibility of speciation was investigated for a model mixture of Cu(II) with EDTA in a simple FIA system with AAS detection and a microcolumn containing chelating resin with salicylate-complexing groups [47]. Three different fractions of complexed species of Cd, Cu and Zn were determined in a FIA system with AAS detection and two microcolumns with Chelex-100 and strongly basic anion exchange resin (Fig. 6) [48]. Metal species such as hydrated free ions, labile metal complexes and possibly metals loosely associated with colloidal matter were retained on Chelex-100. The strongly basic anion exchanger retained negatively charged organic matter such as humic material. The third, unretained fraction includes metals strongly associated with very large colloidal matter that do not dissociate in any of the columns used.

Two different FIA methods with spectrophotometric [49] and fluorimetric [50] detection were developed for the speciation of aluminum complexes. In a set-up with spectrophotometric detection the determination was based on Pyrocatechol Violet chelation. The incorporation of on-line preconcentration on a cation-exchange column allows measurements of the concentrations of non-labile monomeric forms of Al, whereas total reactive aluminum and total monomeric Al were differentiated by off-line sample pretreatment [49]. The fluorimetric detection was based on the formation of an Al–salicylaldehyde picolinohydrazone fluorescent complex retained on C18 sorbent packed in the flow-cell located in a conventional spectrofluorimeter [50]. Three forms of Al (acid reactive, total monomeric Al, and non-labile monomeric Al) can be determined in a similar way, as was described for the system with spectrophotometric detection [49]. Two other forms, acid-soluble and labile monomeric Al, can be evaluated by difference by injecting three sample aliquots into the continuous system and the use of

an on-line ion-exchange microcolumn. The authors provide interesting results of the application of the developed methods to various natural waters, where practically no presence of non-labile monomeric aluminum was found.

5. Speciation of organometallic compounds

Organometallic compounds with covalent metal–carbon bonds have essentially different chemical properties than coordination complexes or hydrated metal cations. They are much more volatile and lipophilic and usually exhibit stronger toxicity, although the degree of toxicity is strictly related to the nature of the monitoring biosystem [51]. The known exceptions are organometallic compounds of arsenic, which are less toxic than inorganic arsenic compounds.

In all developed FIA systems for speciation of organometallic compounds atomic spectroscopy detectors were employed. Speciation of arsenic was carried out in a commercial set-up for hydride generation AAS [52]. By carrying out hydride generation in selected acidic media the

determination of As(III) alone, of the sum of mono- and dimethylated arsenic (with different sensitivities, which can be used for their differentiation), and of all these species together with As(V) is possible. The conditions of hydride generation are adjusted in the FIA system by changing the reagent solutions.

Sequential determination of inorganic mercury and methylmercury in a system with cold vapour–atomic fluorescence spectrometry detection on separation and preconcentration of methylmercury using a microcolumn of sulphydryl cotton of relatively high affinity for methylmercury has been described [53]. Inorganic mercury is not retained on the column and passed to the detector. The retained methylmercury is eluted with hydrochloric acid.

For FIA speciation of organolead compounds two approaches have been reported, so far, with flame AAS detection. In a simpler system oriented towards speciation in natural waters, both inorganic lead and alkyl-lead species were separated and preconcentrated on-line on cationic cellulose sorbent Cellex P with phosphonic acid functional groups [54]. Elution first with nitric acid and then

with ethanol allows one to obtain two signals corresponding to the sum of inorganic lead and di- and trialkyl-lead compounds and to tetraethyl-lead respectively. A more complex procedure was developed for FIA determination of total lead and speciation of tetraethyl- and tetramethyl-lead in gasoline [56]. In this case it was necessary to use on-line emulsification of the samples , which was achieved by injection of the sample into a stream of commercial emulsogen solution. For both speciation and determination of total lead, demetallation by means of iodine solution in petroleum spirit was also employed. As before and after

demetallation the two tetraalkyl-lead species exhibit different senstivities of AAS response, this difference was utilized for the speciation.

6. Conclusions

Among over 5000 papers published, so far, on various aspects of FIA [56], only about 50, to our knowledge, were devoted to speciation. Not many of them consider and indicate the advantages which FIA offers in comparison to manual procedures. Practical applications are focused mainly

on various natural waters, as speciation in other matrices is much more difficult, primarily in terms of preserving concentrations of all forms existing in a given material during sample pretreatment.

In our opinion the development of procedures for the determination of the total amount of an element of interest and of its speciation will be one of the development trends in FIA in the near future. It should also be mentioned that FIA can also be successfully applied to the facilitation of sample pretreatment prior to speciation analysis performed by much more powerful techniques such as capillary gas chromatography coupled with microwave-induced plasma emission spectrometry, which was used for speciation of organotin compounds [57] and mercury [58] in natural waters.

Head-space flow injection for the on-line determination of iodide in urine samples with chemiluminescence detection[1]

J.L. Burguera* , M.R. Brunetto, Y. Contreras*, M. Burguera, M. Gallignani, P. Carrero

IVAIQUIM (Venezuelan Andean Institute for Chemical Research), Faculty of Sciences, University of Los Andes, P.O. Box 542, Mérida, 5101-A, Venezuela

Abstract

A simple head-space (HS) flow injection (FI) system with chemiluminescence (CL) detection for the determination of iodide as iodine in urine is presented. The iodide is converted to iodine by potassium dichromate under stirring in the closed HS vial, and the iodine is released from urine by thermostatting and is carried in a nitrogen flow through an iodide trapping solution. The concomitant introduction of aliquots of iodine, luminol and cobalt(II) solutions by means of a time-based injector into an FI system allowed its mixing in a flow-through cell in front of the detector. The emission intensity at 425 nm was recorded as a function of time. The salting-out of the standard solutions affected the gas–liquid distribution coefficient of iodine in the HS vial. The typical analytical working graphs obtained under the optimized experimental conditions were rectilinear from 0 to 5 mg l^{-1} iodine, achieving a precision of 2.3 and a relative standard deviation of 1.8 for ten replicate analyses of 50 and 200 μg l^{-1} iodine. However, a second-order process becomes significant at higher iodine concentrations (from 10 to 40 mg l^{-1}). The detection limit of the method is 10 μg l^{-1} (80 ng) iodine when 8 ml samples are taken. Data for the iodide content of 10 urine samples were in good agreement with those obtained by a conventional catalytic method, and recoveries varied between 101 and 103% for urine samples spiked with different amounts of iodide. The analysis of one sample takes less than 20 min. In the present study the iodide levels found for 100 subjects were 86.8 ± 19.0 (61–125) μg l^{-1}, which is lower than the WHO's optimal level (150–300 μg per day).

Keywords: Chemiluminescence detection; Head-space flow injection; Iodide; Urine

1. Introduction

Iodine is an essential microconstituent in the human body, which contains an average of 14 mg of the element, concentrated mostly in the thyroid gland [1]. About 1 mg of iodine per week is needed by the body to ensure normal levels for the synthesis of the thyroid hormones thyroxin

---

and triiodothyronine [2]. An urinary iodine excretion below 40 g per day (80 μg I^- per day) is indicative of iodine deficiency in man, if renal clearance is normal [5], whereas a daily excretion of less than 60 μg I^- per day is indicative of the existence of endemic goiter in a community [6].

Of the many methods available for the determination of iodine, the most commonly used are colorimetry [7–10], neutron activation analysis (NAA) and those adapted from the serum-protein-bound iodine [11,12]. While colorimetric methods are time-consuming and require sample handling [13], NAA has an excellent intrinsic sensitivity for iodine; however, low levels of this element in biological materials cannot be easily measured by conventional reactor-flux instruments because of interferences from the high activities of thermal neutron activation products of Na, K, Mn, Br, and Cl which are generally present in large amounts [14]. The analytical sensitivity and sampling throughput has usually been improved either by the automation of catalytic [15], pneumatoamperometric [16] and colorimetric procedures [17] or by using stopped-flow and flow injection (FI) techniques [18–22]. On the other hand, iodine has also been determined by monitoring the chemiluminescence (CL) emissions from the iodine–luminol [23,24] and iodine–hydrogen peroxide–sodium hypochlorite systems [25]. However, the most important limitations are that several metal ions and other species may enhance the same reactions [26–29] so that separation or masking is required for real samples. This disadvantage can be eliminated by using head-space (HS) techniques [30,31]. These make use of the equilibrium between the volatile components of a liquid or solid sample and the surrounding gas phase in a sealed vessel, and aliquots of the gas being removed by an inert gas, usually for GC analysis. Thus the HS technique is a very convenient way to separate volatile analytes from the bulk of the matrix. This work presents an on-line HS-FI system for the sensitive and accurate determination of iodide in urine by a CL reaction. The iodine is generated in the HS device and carried in a nitrogen flow to a vial, where it is trapped in a KI solution, followed by the determination of iodine in the concentrate. The reproducible and sequential introduction of aliquots of

the iodine, cobalt(II) and luminol solutions into a FI system by means of time-based introduction device [32] allowed the generation of CL in front of the detector. The Co(II)-catalyzed reaction of iodine with luminol has been selected for its simplicity, sensitivity and speed [33–35].

2. Experimental

2.1. Apparatus

A schematic diagram of the HS-FI-spectrophotometric system is given in Fig. 1. The outlet of a

Fig.1. Schematic diagram of the HS-FI-spectrometric system used for the determination of iodide in urine. (A) Injecting mode of the FI system; (B) washing mode of the FI system. FTC, flow through cell.
Fig. 2. Flow-through cell used for CL measurements. Dimensions are in millimeters.

semiautomatic Perkin-Elmer HS sampler model HS-40 is connected through a capillary column (0.53 mm i.d.) with a vial which contains the iodine trapping solution of potassium iodide. Determinations were performed in a Varian 634 spectrophotometer operated in the visible mode with a glass home-made flow-through cell shown in Fig. 2. The system also included a seven-channel variable-speed Ismatec IPC persitaltic pump with Tygon pump tubes, a home-made time-based injector [32] controlled by a Gralab 900 timer which permitted the dispensing of electronically controlled pulses to the solenoid valve, and a Cole-Parmer 156 recorder operated with a chart speed of 2 cm min^{-1}. PTFE tubing of 0.8 mm i.d. was used throughout unless otherwise stated.

2.2. Reagents

Unless stated otherwise, all solutions were prepared from analytical-reagent-grade chemicals. Deionized, distilled water was used throughout. A stock iodide solution (250 mg l^{-1}) was prepared by dissolving 0.0300 g of potassium iodide in 100 ml of a salted solution containing 10 g l^{-1} and 5 g l^{-1} of NaCl and KCL, respectively. Working solutions of iodide were prepared by suitable dilution with the same salted solution. For iodine trapping purposes, a 0.2% (w/v) potassium iodide solution was prepared by dissolving 200 g of KI in 800 ml of water. A stock luminol solution

$(2 \times 10^{-3}$ mol l$^{-1})$ was prepared by dissolving 0.0123 g of luminol (B.D.H.) in 50 ml of 0.1 mol l^{-1} sodium carbonate buffer, pH 12.0. Stock cobalt(II) solution (0.1 mol l^{-1}) was prepared by dissolving 2.911 g of Co(NO$_3$)$_2 \cdot$6H$_2$O in 100 ml of water; working solutions were prepared daily by appropriate dilution with water. A stock potassium dichromate solution (0.01 mol l^{-1}) was prepared by dissolving 0.2942 g of K$_2$Cr$_2$O$_7$ in 1.0 mol l^{-1} of hydrochloric acid.

2.3. Procedure

The operating HS-FI-CL conditions were optimized and are given below. The optimization of these experimental conditions for the determination of iodide was carried out by means of the univariate method, with the aim of finding a suitable compromise between peak height, sample throughput, reproducibility and sample volume used per analysis. An 8 ml amount of potassium iodide solution (for calibration purposes) or a urine sample, and 1 ml of 0.01 mol l^{-1} potassium dichromate solution were placed in the HS sample vial. After an agitation time of 1.5 min, a selected thermostatting temperature of 140°C was applied for 15 min. During sample thermostatting, the HS system was in the "standby" position, and a carrier stream of nitrogen at a pressure of 24 psi flowed through the tube which connected the HS with the iodine trapping vial. At the end of the

thermostatting time, when the HS was in the "pressurization" position, the HS sampling needle descended, pierced the septum cap of the sample vial and entered the HS vial. The sample vial was pressurized with nitrogen at 45 psi during 0.2 min. At the end of the pressurization time, the flow of nitrogen was stopped, and the vapor from the HS vial passed for 2.5 min into a vial containing 3 ml of 0.1% (w/v) potassium iodide, where the trapping of iodine took place. Thereafter, the solenoid valve of the time based device was activated to open the valves V_4, V_5, V_6, V_7, V_8 and V_9 and to close the valves V_1, V_2, V_3, V_{10}, V_{11}, and V_{12} (Fig. 1A) for 3 s. In this way, the iodine, 1×10^{-5} mol 1^{-1} Co(II) and 1×10^{-3} mol 1^{-1} luminol solutions were pumped at pumping rates of 6.0 ml min^{-1}, 4.4 ml min^{-1} and 7.0 ml min^{-1}, which allowed the injection of 0.30 ml, 0.22 ml and 0.36 ml of each solution, respectively. The injected volumes of iodine and cobalt(II) solutions were premixed 10 cm before their entrance into the flow-through cell, and thereafter mixed in front of the detector with the injected volume of luminol solution, while the streams of water flowed within their respective closed-flow circuits. The emission intensity was recorded as a function of time over 10 s at 425 nm. The solenoid valve was then operated in the reverse mode for 30 s (washing position) to flush the reagents out from the flow-through cell with water (Fig. 1B). The alternation of both solenoid positions allowed the repetitive and reproducible introduction of sample–reagent mixture plugs into the carrier stream. A calibration curve was obtained by using the emission readings for each standard concentration. The iodide concentration of each sample was determined as iodine by reference to this analytical curve. The water streams were pumped continuously at 4.4 ml min^{-1} during the washing process to ensure a stable baseline.

3. Results and discussion

3.1. Preliminary observations

It was found that when luminol is oxidized by iodine in the presence of Co(II), the emission is of

such short duration that the mixing time becomes critical; consequently, seriously distorted emission with low sensitivity was obtained using a conventional 0.5 ml flow-through cell with a 10 ml optical path, which made meaningful studies impossible. Therefore, in this study the emission profile was obtained by employing a home-made flow-through cell (Fig. 2), which allowed the mixing of sample and reagents in front of the detector. Also, the stability of trace iodine in the trapping vial was of vital importance if the full analytical potential of this sensitive method for iodine is to be realized. Therefore, the glass vial was silanized and protected from light [36] during trapping, and the injections of aliquots of the iodine solution were made within 20 min of the sample absorption measurement.

### 3.2. HS experimental conditions

The choice of a septum for sealing the HS vial was important for obtaining reproducible analyses. Butyl rubber septa adsorb iodine, which made their use unsuccessful because of low reproducibility. On the other hand, PTFE coated with silicone rubber septa showed no affinity for iodine, which made their use preferable.

The sensitivity of the analysis improved as the volume of sample in the HS vial increased (Fig. 3a). A 5 ml sample volume provided adequate sensitivity. Although larger sample volumes than 5 ml did not make a great difference with regard to sensitivity, in order to achieve the minimum detection limit a volume of 8 ml was needed. As the volume of the liquid becomes particularly significant, it affects the ratio of liquid to gas in the HS vial [37]; therefore, less volatile iodine is likely to be found in the gas phase and low distribution coefficients (see below) [38] are obtained. These results are in close agreement with those previously reported by Ettre and Kolb [38], which concluded that in the case of samples with low distribution coefficients (less than 10), the sample volume has a significant influence on the "sensitivity" of the HS analysis.
An acidified potassium dichromate solution was used to oxidize iodide to iodine. This oxidant has some advantages over others, e.g. it is obtainable

in a state of high purity, being used as a primary standard, the solution does not change on standing, and it has an appropriate standard oxidation–reduction potential for the generation of iodine from iodide [39]. The effect of the oxidant concentration on the CL emission intensity was examined in the 300–900 mg l^{-1} range. Fig. 3b shows that better sensitivity was observed with a potassium dichromate concentration of 600 mg l^{-1}. There was little difference when the acidity of the oxidant solution was kept between 0.5 and 2.0 mol l^{-1} of hydrochloric acid.

Higher thermostatting temperatures of the sample increased the sensitivity of the analysis (Fig. 3c). This effect is likely to be due to an enhanced concentration of iodine in the gas phase owing to a higher partition coefficient of this volatile compound [37]. However, temperatures above 150°C were avoided due to the risk of degrading the sample, bursting the container or losing the analyte due to chemical interaction with the vial septum [40] and to a larger variation of the CL

signal. Besides, higher sample temperatures may lead to more water vapor purged on to the trapping adsorbent media with a reduction in the sensitivity and precision of measurements [41]. The CL signal increased with an increase of the thermostatting temperature up to 15 min; thereafter the emission intensity markedly decreased (Fig. 3d). Taking into account the sensitivity, sampling frequency and the error, the HS was thermostatted at a temperature of 150°C for 15 min.

The stirring of the sample with the potassium dichromate solution in the HS vial is necessary to prevent the entrapment of the volatile analyte within the matrix through homogenization during the extraction procedure. Fig. 3e shows that the iodine reached an equilibrium in 1.5 min.

3.3. Iodine trapping conditions

It is usual to dissolve iodine in a solution of potassium iodide for the preparation of standard iodine solutions [39]. Therefore, in this work an acidified potassium iodide solution was used as an efficient medium for trapping the iodine resulting from the vapor generated in the HS vial. It is generally assumed that in this process a complex compound, KI_3, is formed, but this is not very stable, for the solution behaves as thought it were a solution of iodine [39]. As long as the pH of the solution is below 8 it has little or no effect on the iodine–iodide system. Above this level, however, iodine reacts with hydroxyl ions to form hypoiodite which, being unstable, is converted to iodate [39]. Therefore, the acidity of the potassium iodide trapping solution must be maintained between certain limits. Hydrochloric acid concentrations higher than 1.0 mol l^{-1} maintained the iodide solution at the optimum pH range for the absorbance of iodine (Fig. 3f). Fig. 3g shows the effect of the iodide trapping solution concentration on the CL response. As the iodide concentration increased beyond 0.1% (w/v), a decrease in the CL peak height was observed due to the formation of the triiodide ion, I_3^- [23]. Although this ion increases the solubility of iodine and keeps the iodine from volatilizing, it does not react with luminol to generate CL.

The iodine trapping efficiency in the iodine trapping vial is compound-dependent and involves a knowledge of other factors also, including the vapor pressure of the compound, the HS sample vial pressure (carrier gas pressure) and the interaction between the analyte and the adsorbent solution. A sample pressurization of 45 psi during 0.2 min provided an adequate analyte vapor stream from the HS vial to the trapping adsorbent vial (Fig. 3h). The injection time was varied from 0.5 to 2 min (Fig. 3i). Sufficient sample quantity was delivered after 1.5 min with maximal absorbance efficiency in the KI solution.

3.4. CL experimental conditions

The CL peak height would be expected to vary according to certain parameters which affect the emission intensity, e.g. luminol, catalyst and oxidant concentration and pH of the luminol solution.

The effect of varying the luminol concentration is shown in Fig. 3j. The emission was most intense at a 1.6×10^{-3} mol l^{-1} luminol concentration in the solution injected in the FI system (Fig. 1). Characteristically there is a decrease in efficiency at higher luminol concentrations, which may be due to luminol (or its aminophthalate oxidation products) acting as an organic complex to reduce the "availability" of the metal ion for catalysis [35].

The effect of pH (10.5–13) on the intensity was investigated. CL was produced only in the alkaline environment. Higher intensity was observed at pH 12.0 (Fig. 3k). The buffer was prepared from sodium hydrogen carbonate, and a glass electrode was employed to measure the pH after the reaction has taken place, to ensure the buffer capacity was sufficient. The intensity maximum occurred at a relatively high pH value, as other investigators have reported a maximal quantum yield in the 10–11.5 interval [33,35,41]. This behaviour may be most likely attributed to the particular pattern of mixing in the flow cell [42] or to a particular catalyst [35]. The effect of the catalyst concentration on the CL intensity in the luminol oxidation by iodine was also investigated (Fig. 3l). The emission intensity was dependent on

Co(II) concentration. The final emission intensity chosen was 10^{-5} mol l^{-1} of Co(II).

3.5. FI experimental conditions

In the FI system used, a peristaltic pump was the driving force for the sample, luminol, catalyst and washing solutions. Therefore the volume of the sample and reagents to be injected depended on the pumping rate of each solution and on the time of solenoid activation during the injection (Fig. 1A). The flow rate of these solutions and therefore their mixed volumes in the flow-through cell were different. The pumping rate of each solution was varied between 2.0 and 8.0 ml min^{-1} and the time of the solenoid activation during the injection was varied between 1 and 14 s. In either case, the CL emission increased on increasing the injected volume, and thereafter a slight decrease was observed (Fig. 3m). Higher signals were observed with pumping rates of 6.0 ml min^{-1}, 4.4 ml min^{-1} and 7.0 ml min^{-1} of iodine, cobalt(II) and luminol solutions, which allowed the injection of 0.30 ml, 0.22 ml and 0.36 ml of each solution, respectively, for a solenoid activation time of 3 s.

3.6. Matrix matching of the standard solutions

It is known that matrix components in the liquid phase affects the HS behaviour of volatile substances [43]. To evaluate the effect of the sample matrix on HS analysis, a study was performed in which the recovery of the analyte from a pooled urine sample with "known" amounts of iodide and spiked with different amounts of this analyte was compared with those achieved from iodide solutions prepared in different matrixes and water. Because sodium, potassium and chloride are major components of urine [44], different samples were prepared with and without sodium chloride and potassium chloride addition. Table 1 shows that for samples prepared with 10 g l^{-1} NaCl and 5 g l^{-1} KCl the recovery was close to 100%. Also, the recovery of iodine added as iodide to urine was good and varied between 94 and 99%. It should be noted, however, that recovery problems were observed in two cases: the samples with high salt content (150 g l^{-1} NaCl and 70 g

Table 1
Recovery studies in different matrixes

Matrix	Iodide concentration (mg l^{-1})		Recovery (%)
	Spiked	Found	
Urine	1.5	1.56	99
	2.5	2.48	96
	4.0	3.90	94
Water	1.5	1.17	78
	2.5	1.93	77
	5.0	3.80	76
10 g NaCl + 5 g l^{-1} KCl	1.5	1.55	103
	2.5	2.55	102
	5.0	5.05	101
150 g l^{-1} NaCl + 70 g l^{-1} KCl	1.5	2.22	148
	2.5	3.73	149
	5.0	7.50	150

[a] 70 μg l^{-1} I^{-} endogenous content.

l^{-1} KCl) and solutions prepared in water. While in the high salt content sample the recovery was high (about 150%), in the solution prepared with water the recovery was generally poor, frequently less than 78%. This salting-out effect of high concentrations of NaCl and KCl may be due to the fact that inorganic salts are known to enhance the vaporization of volatile substances [43–47]. Whereas, the addition of physiological amounts of salt to the aqueous samples provided an adequate salting-out effect to produce good recovery values. In our case, the salting-out effect does not affect the results obtained for the determination of iodide in urine samples because the physiological levels of sodium, potassium and chloride in urine are about 3.85 g l^{-1} (from 0.9 to 5.0 g l^{-1}), 2.28 g l^{-1} (from 0.9 to 3.9 g l^{-1}) and 7.0 g l^{-1} (from 3.8 to 9.0 g l^{-1}), respectively [45,48,49].

Table 2 shows the regression equations of the CL signal as a function of iodine concentration obtained from standard iodide solutions prepared with and without salt addition and from iodide-spiked urine samples. These data were obtained by running calibration curves using the method of standard additions with overlapping ranges. Each calibration set included five data points and was run at least three times. It was found that regardless of the solution used for the iodide standard

preparation, the response was first order for the concentration range 0–5 g l^{-1} iodine, and second order for the range 10–40 g l^{-1} I$_2$. The occurrence of these first- and second-order processes are in agreement with results previously published by Seitz and Hercules [23,35]. Comparison of the slopes of the calibration graphs, obtained by preparing standard solutions in different media, further confirmed that there is a salting-out effect on sensitivity. When pure water and too high a concentration salting-out solutions were used, the response of the analyte was affected by the composition of the matrix. However, there was virtually no effect of the matrix on preparing standard solutions with a physiological salt content. As a consequence, the linear portion of the 0–5 g l^{-1} iodine curve served as a calibration graph for standard and working solutions prepared in solutions containing 10 g l^{-1} and 5 g l^{-1} NaCl and KCl, respectively.

As the concentration of the analyte in the gas phase is proportional to the concentration of the undissociated part of the analyte in solution, salting out by adding inorganic salts to an aqueous solution can produce an increase in sensitivity of over one-hundredfold in favorable cases. The liquid and gas phase concentrations are related to each other by the partition coefficient K (defined

Table 2
Regression equations of the CL signal obtained in different matrixes

Matrix	Regression line[a]	r	Iodine concentration range (mg l^{-1})
Water	$E_{CL} = -0.051 + 15.92\ X$	0.9990	0–5
	$E_{CL} = -10.843 + 3.745\ X$	0.9997	10–40

150 g l^{-1} NaCl + 70 g l^{-1} KCl	$E_{CL} = 0.038 + 7.940\ X$	0.9995	0–5
	$E_{CL} = -4.998 + 1.528\ X$	0.9990	10–40
Urine	$E_{CL} = 2.450 + 12.10\ X$	0.9986	0–5
	$E_{CL} = -8.500 + 3.069\ X$	0.9998	10–40

[a] E_{CL} and X indicate the CL emission intensity (peak height in millimeters) and analyte concentration in milligrams per litre, respectively. From 0 to 5 mg l^{-1} iodine (1mm represents 1 mV) and from 10 to 40 mg l^{-1} iodine (1 mm represents 10 mV), the recorder was operated at 1 mV and 10 mV full scale, respectively. The experimental conditions were as specified in Table 3.

as C_s/C_G where C_s and C_G are the equilibrium concentrations of the analyte in the sample and in the gas phase of the HS vial, respectively) [47,50,51]. The partition coefficient is matrix-de-pendent and is unknown for most analyses; it must therefore be accounted for by calibrating the sampling system. In our particular case, K for solutions prepared in water, 10 g l^{-1} NaCl + 5 g

	Time of injection	3 s
Spectrophotometry	Wavelength	425 nm
	Slit width	2.0 nm

1^{-1} KCl and 150 g 1^{-1} NaCl + 7 g 1^{-1} KCl solutions was 2.1, 2.6 and 4.1, respectively. Thus, the addition of salt to aqueous solutions containing iodide augmented K, so that sensitivity is reduced (Table 2). The magnitude of this effect depends on the amount of salt added and K of the compound [47]. According to our results, as $K < 10$, the ratio of the volumes of the two phases is particularly significant [47]. Therefore, this further confirms that an adequate addition of NaCl and KCl salts is important in order to minimize matrix effects.

3.7. Analytical figures of merit

On the basis of the above results, calibration graphs were prepared from 0 to 5 mg 1^{-1} for iodine determination using the HS-FI-spectrometric optimum conditions given in Table 3. The precision of this procedure was estimated by measuring the CL signal (peak height) from ten replicate analyses of 50 g 1^{-1} and 200 g 1^{-1} iodine solutions by the recommended procedure; the corresponding relative standard deviations were 2.3% and 1.8%, respectively. The detection limit for iodine, defined as three times the standard deviation of the peak height signals, was 10 g 1^{-1} I_2.

The accuracy of the proposed procedure was further tested by determining the iodide content in 12 urine samples of different "healthy" subjects by the iodine-catalyzed cerate–arsenite method with spectrometric detection [52] and the proposed procedure. Good agreement was obtained for all samples, which is an indication of satisfactory accuracy of the proposed method. By applying Student's t test and the F test [53] to the results (for a confidence limit of 95%), it was found that there were no statistically significant differences between the means of both populations.

From the experimental point of view, the HS sampling technique is very simple, and combined with the FI system provides precise and accurate results for the determination of iodide in urine. Also, the CL reaction used provided adequate sensitivity for the determination of low analyte contents in the samples under study and permitted sequential measurements with a low carry-over.

Abstract

CP-93,393 is a drug candidate at Pfizer. Flow-injection analysis–mass spectrometry (FIA–MS) was used to monitor reaction completion for CP-93,393 reaction mixtures. FIA–MS provides essentially instantaneous results, is relatively simple to operate, and is a universal system that can be used to monitor any reaction as long as the product has a molecular weight that differs from the molecular weights of the reactants. The mass spectrometer for these studies employed atmospheric pressure chemical ionization. Samples were introduced into the mass spectrometer with a flowing stream of solvent.

Keywords: CP-93,393; Flow-injection analysis; Mass spectrometry

1. Introduction

In-process control (IPC) assays are used in chemical and pharmaceutical production plants to assess the progress and completeness of chemical reactions. When a reaction has reached a predetermined level of completion, the reaction can be stopped and the product is either isolated or the next step of the reaction can be started. Reaction completion is usually determined by measuring the disappearance of a starting material.

An ideal IPC assay has the attributes summarized below. One of the most important features

of an IPC is that it provides meaningful data in a timely fashion to the process chemist controlling the reaction. For example, if a reaction is complete in 2 h, but the data from the IPC is unavailable for several hours, the product can be over-reacted, potentially producing unwanted side products. At the very least the time of the plant personnel is wasted, and the equipment in the production facility is unnecessarily occupied. Another highly desirable feature of an IPC is that the methodology is universal in nature and can provide quantitative data for all steps of a chemical synthesis. A methodology that could be used to monitor reaction completion of many different chemical syntheses (producing different final products) would be even more valuable. Other desirable attributes of IPC methodologies are that they are simple to operate and maintain, are

Fig. 1. Synthetic pathway of CP-93,393.

rugged, with a minimum amount of down-time, and are inexpensive in terms of both purchasing and maintainance.

Methodologies that have been traditionally developed to monitor reaction completion include high performance liquid chromatography (HPLC), gas chromatography (GC), and thin layer chromatography (TLC). Recently, near-infrared spectroscopy (NIR) has been applied to monitor reaction completion [1]. All of the above techniques, however, have drawbacks for use in monitoring reaction completion. HPLC, GC, and TLC require time for equilibration and running samples. Universal chromatographic systems can be developed for a complete synthesis but these usually involve gradient elution (HPLC) or temperature programming (GC) to elute and resolve all process intermediates. Thus for universal chromatographic systems, excessive times are often required to re-equilibrate the system between injections. HPLC is further limited to samples that have a chromophore, electrophore, or fluorophore. GC is limited to samples that are volatile and stable at elevated temperatures. TLC is inexpensive, but has limited peak capacity, resolution,

and sensitivity. In addition, the time required to equilibrate a TLC development chamber can be excessive and/or difficult to determine. Use of NIR for monitoring reaction completion has been limited because it measures bulk properties and is non-specific in nature. Additional problems are encountered with non-homogeneous (slurry-type) reaction mixtures.

Although mass spectrometry may be the ideal technique to monitor reaction completion, the prohibitive cost of a mass spectrometer in the past has discouraged its use for this purpose. Currently, several suppliers offer bench-top mass spectrometers that cost, on average, approximately $200 000. The resonable cost of these units, combined with the availablity of several soft ionization techniques, should significantly increase the use of mass spectrometry for reaction completion monitoring.

This paper describes the use of flow-injection analysis–mass spectrometry (FIA–MS) to determine reaction completion of CP-93,393 reaction mixtures. FIA–MS has previously been used for the determination of arsenic and chloroform [2]. The synthetic pathway used to produce CP-93,393 is shown in Fig. 1.

2. Experimental

Before FIA–MS was evaluated for CP-93,393 reaction mixtures, conventional methodologies were evaluated. For steps 1 and 2, an ion-pairing, reversed-phase LC system was developed. Conventional reversed-phase approaches failed to retain the very polar isocinchomeronic acid (compound 1). Disappearance of compounds 3-6 could not be monitored by LC because all of these compounds lack a chromophore, fluorophore or electrophore. Gas chromatographic conditions were successfully developed for compounds 3-5, but all GC experiments attempted for compound 6 were hampered by tailing and irreproducible peak areas. Compound 7, which contained a chromophore, could be monitored by conventional reversed-phase LC.

Samples were introduced into the mass spectrometer with a flowing stream of solvent, pumped through an atmospheric pressure chemical ionization (APCI) liquid chromatography-mass spectrometry (LC–MS) interface. A schematic diagram of the APCI interface is shown in Fig. 2. Flow-injection analyses often involve on-line mixing of reagent and sample solutions. For FIA–MS, the reagent is simply the carrier solvent; a separately pumped reagent solution is not needed. When the sample enters the APCI ion source it is nebulized with nitrogen. A corona discharge needle promotes ionization, and the reactions that occur in the ion source involve charge transfer among the ionized solvent molecules and the analytes. The ionized analytes enter the high-vacuum mass analyzer region through a small orifice. Skimmers and focusing lenses remove unionized species [3].

Fig. 2. Schematic diagram of the APCILC MS interface (courtesy of Fisons Instruments).

Fig. 3. APCI mass spectrum of CP-93,393.

Experiments have been done using either a Fisons Instruments Trio 2000 single quadrupole mass spectrometer or a Fisons Instruments Quattro triple quadrupole instrument. Both use identical APCI LC–MS interfaces. A Hewlett-Packard 1050 quaternary HPLC system was used to mix and deliver solvents. The autoinjector provided reproducible injections of samples into the flowing solvent stream. An in-line UV–vis detector recorded responses for UV-active components when appropriate. For these studies, the solvent used as a carrier and to dissolve samples was a 50/50 (v/v) mixture of acetonitrile and an aqueous 0.05 M ammonium acetate solution. The ammonium acetate promoted ionization of compound 1. The flow rate was 0.5 ml min^{-1} and the sample injection volume was 1 μl.

3. Results and discussion

The synthetic pathway used to produce CP-93,393 is shown in Fig. 1. Production steps 7 and 8 have been ommitted from the scheme, as they are non-synthetic, i.e. they comprise an optical resolution and a salt change.

The APCI mass spectrum of CP-93,393 is shown in Fig. 3. The abundant protonated molecular ion at m/z 330, combined with negligible fragmentation, is indicative of an ideal candidate for the application of FIA–MS to monitor reaction completion using APCI ionization. Although a small amount of fragmentation is acceptable, if the product has a fragment with the same m/z value as the protonated molecular ion of its precursor, successful application of this technique becomes more difficult. For the same reason, FIA–MS cannot be used to determine enantiomeric purity or the completeness of a reaction

wherein the reactant and product have the same relative molecular masses.

The mass spectra of compounds 1–7 are shown in Fig. 4. With the exception of compound 4, the mass spectrum of each intermediate shows an abundant protonated molecular ion with minimal fragmentation. With compound 4, however, a fragment of significant abundance at m/z 202 appears, and is consistent with the protonated molecular ion of compound 3, its synthetic pre-

cursor. Under these conditions, it would be difficult to deconvolute the percentage of the ion at m/z 202 that originated from residual (unreacted) compound 3. This could be accomplished through a standard addition approach, or by identifying conditions that would minimize fragmentation of compound 4. Careful selection of the mass spectrometer lens parameters and adjustment of the solvent flow rate into the LC–MS interface has minimized this interference for the

Fig. 5. Mass spectra of 1% (top) and 5% (bottom) spikes of compound 6 in compound 7.

present. Use of softer ionization approaches such as electrospray may eliminate this interference. Attempts using this latter possibility have not yet been explored.

To demonstrate the feasibility of this technique, synthetic reaction mixtures of step 6 were prepared. These samples contained the product (compound 7) and 1, 2 and 5% spikes of compound 6 (relative to compound 7). Traditional methodologies were previously unsatisfactory for monitoring this step. Fig. 5 illustrates the mass spectra of mixtures containing 1% and 5% spikes of compound 6 with respect to compound 7. The peak at m/z 171 corresponds to the residual starting material. These spectra represent a reaction mixture near completion; a reaction mixture at an earlier time frame would have a mass spectrum contain-

ing a larger peak at m/z 171 relative to m/z 249, the protonated molecular ion of compound 7, the product.

Quantitative data for 1%, 2% and 5% spikes of compound 6 are shown in Table 1. Target levels of residual starting material are typically 1–2%. If the level of starting material is below the target level, the reaction can be stopped. The data in Table 1 illustrate that 1% and 2% levels of compound 6 are readily distinguishable and that the precision of the method is adequate to serve as a limits test. Another point worth noting is that at the two higher concentrations, the response of compound 6 is slightly lower when present as a mixed standard with compound 7. This quenching may be attributed to a number of sources including the relative proton affinity of each species in the ion source. For quantitative purposes, quenching can be accommodated by matrix matching wherein the standard of the minor component is prepared in a solution containing the reaction product. The slightly higher response of compound 6 in the presence of compound 7 at the 1% level may be attributable to trace levels of compound 6 in the standard of compound 7 used to prepare the solution.

Responses of the mass spectrometer to six replicate injections of a 2% spike of compound 6 in the presence of compound 7 using specific ion monitoring at m/z 249 (product) and 171 (reactant) are illustrated in Fig. 6. The bottom trace in Fig. 6 was generated by digitally smoothing the m/z 171 selected ion trace using a moving average smoothing function — a feature of the mass spectrometer data system. The data listed in Table 1 were obtained after smoothing. The peaks at m/z 249 are off-scale and could not be used for quantita-

Table 1
Quantitative data of compound 6

Concentration (mg ml^{-1}) of compound 6	Relative concentration (%)	Peak area (% RSD^a) of compound 6	Peak area (% RSD^a) of compound 6^b
0.05	1	51 000 (14)	58 000 (15)

The bottom trace was generated by smoothing the m/z 171 (middle) trace. The numbers at the apex of each peak represent the time in minutes.

tive purposes. These are typical data and illustrate the reproducibility obtainable with this technique.

4. Conclusions

The feasibility of using FIA–MS for monitoring reaction completion has been demonstrated using the CP-93,393 synthetic pathway as a test case. Re-examination of the introduction reveals that FIA–MS does indeed have most of the desirable attributes of the methodology targeted for use in an IPC laboratory. One injection per minute is

clearly achievable (Fig. 6) and quantitative data can be provided in a matter of minutes. No time is needed for re-equilibration of the chromatographic system. Although the monitoring of residual levels of compound 3 with this technique may be difficult, all other synthetic steps in the CP-93,393 synthesis are amenable to FIA–MS analysis and this technique can be considered to be a universal system, albeit with a few exceptions. In addition, preliminary work on other drug candidates has indicated that FIA–MS will be widely applicable. Since most of the bench-top mass spectrometers use Windows-based PC controls,

with a minimum amount of training, IPC laboratories staffed with trained personnel should easily be able to adopt and use FIA–MS to monitor reaction completion.

In terms of ruggedness, a mass spectrometer will potentially have more problems than traditional methodologies used to monitor reaction completion. These instruments require periodic maintenance and must be operated by trained personnel. The vacuum pumps associated with mass spectrometers also require periodic maintenance. If there is a problem with these instruments, a mass spectrometer may require a longer down-time before it is operational again.

The cost of a bench-top mass spectrometer is roughly 3–4 times that of an LC system. If a single FIA–MS system can replace several LC and/or GC systems, this approach becomes competitive economically. In addition, the expense associated with developing chromatographic systems is saved.

Application of FIA–MS to the monitoring of reaction completion has several distinct advantages over traditional methodologies. It is anticipated that this technique will be adopted by IPC laboratories to complement existing equipment and that its use will increase as the cost of mass spectrometers decreases and the skill of IPC personnel increases.

Abstract

A simple flow-injection (FI) spectrofluorimetric method for the assay of total volatile aldehydes in auto exhaust gas and emission gas from thermal degradation was developed. Aldehydes, such as formaldehyde, acetaldehyde, propionaldehyde and n-butyraldehyde, reacted with cyclohexane-1,3-dione (CHD) to form more strongly fluorescent compounds. A two-channel flow system was assembled. Distilled water and 0.02% CHD were delivered at 0.75 ml min^{-1}. The optimum conditions were pH 5 (2.2 M CH_3COONH_4–CH_3COOH buffer solution), reaction temperature 70°C, reaction coil length 0.5 mm i.d. × 7 m, cooling coil length 2 m, sample size 60 μl, excitation and emission wavelengths, 376 nm and 452 nm. Aldehydes in sample gas (10 l) were collected by passing the gas at a flow rate of 0.5 l min^{-1} through two impingers connected in series. 10 ml of methanol was used as an absorbent and diluted sample solution was injected into the carrier stream. The calibration graph was linear in the range 100–1000 ppb. The detection limit was 30 ppb and a sampling frequency of 30 h^{-1} was attained. Relative standard deviation for 10 standard formaldehyde solutions (500 ppb) was 1.5%. This rapid and simple FI method was applied to the determination of the total amount of aldehydes, calculated as formaldehyde, in auto exhaust gas and emission gas from the thermal degradation of polymers.

The method is useful for monitoring aldehyde emissions and investigating the removal effect of aldehydes from various sources.

Keywords: Fluorimetric flow-injection analysis; Aldehydes; Auto exhaust gas; Emission gas; Cyclohexane-1,3-dione

1. Introduction

Aldehydes are present in the exhaust gases of-gasoline-powered vehicles and emission gases from thermal degradation of polymers and other organic compounds. Along with hydrocarbons, aldehydes are important air pollutants, in that they influence human health and plant growth [1].

Formaldehyde in particular is a well-known eye irritant and suspected carcinogen and inhibits active sites of protein. Acetaldehyde also shows a strong chemical activity. Methods for determining trace amounts of formaldehyde in atmospheric air and beverages have been reported [2–6]. Some of the methods mentioned in the literature have been developed as continuous flow-injection (FI) methods for rapid or selective determination of formaldehyde. High performance liquid chromatographic (HPLC) separation of aliphatic aldehydes such as formaldehyde, acetaldehyde, propionaldehyde and heptylaldehyde, has also been proposed [7] and the present authors have reported capillary gas chromatography (GC) with a flame thermionic detector for the selective determination of aldehydes in exhaust gas [8]. Although each aldehyde can be successfully analysed by FI, HPLC and GC, these methods have some drawbacks, i.e. a long reaction time, tedious sample pre-treatment and complicated derivatization.

Although Suzuki [7] has reported that aliphatic aldehydes react with cyclohexane-1,3-dione (CHD) to form fluorecent products, the reaction was time-consuming and tedious.

In this study, different analytical conditions with CHD were optimized for the rapid FI injection determination of volatile aldehydes in several kinds of gases, although individual aldehydes cannot be determined. Moreover, this system is simply and easily assembled.

2. Experimental

2.1. Apparatus

A combined sampling device (Model HS-6, Kimoto Electric, Osaka) was used for sampling gases including aldehydes. The volume of the impinger used was 30 ml and the flow rate was 0.5 l min⁻¹.

A Hitachi Model F-2000 spectrofluorimeter (Tokyo) was used for recording fluorescence spectra and measuring their intensity.

A Taiyo Mini 80 thermostat was used for controlling the derivatization temperature.

2.2. Reagents

2.2.1. CHD

20 g of ammonium acetate and 0.25 g of CHD (Tokyo Kasei Kogyo, Tokyo) were dissolved in 200 ml of distilled water containing 10 ml of acetic acid.

2.2.2. Formaldehyde standard solution

2.86 g of formaldehyde (35% Katayama Kagaku, Osaka) was dissolved in 100 ml of methanol to produce a 1% (w/v) methanolic solution. The stock solution was standardized by titrimetry [9].

2.2.3. Other aldehyde standard solutions

1 g of acetaldehyde (Merck, 99.5%), propionaldehyde or n-butyraldehyde was dissolved in 100 ml of methanol to prepare 1% solution. The stock solution was diluted to an appropriate concentration as required.

2.3. General procedure (batchwise method)

Mix 0.1–0.4 ml of 0.0001% of the standard aldehyde solution and 1 ml of 0.25% CHD in a 10 ml calibrated flask and dilute to the mark with distilled water. Allow to react for 30 min at 50°C in the thermostatted bath. After cooling, measure the relative fluorescence intensity at excitation and emission wavelengths of 375 nm and 452 nm respectively.
Fig. 1. Flow-injection manifold for aldehyde determination: CS, carrier solution (H₂O); R, 0.02% CHD solution; P, double-plunger micro-pump; S, sample injection (60 μl); RC, reaction coil (0.5 mm × 7 m); CC, cooling coil (0.5 mm i.d. × 2 m); TB, thermostatted bath; TB₁, 70°C; TB₂, 10°C; D, detector (fluorescence spectrophotometer); BPC, back pressure coil (0.25 mm i.d. × 2 m); flow rate 0.75 ml min⁻¹; excitation wavelength, 376 nm; emission wavelength, 452 nm.

2.4. FI procedure

The manifold of the FI system used is shown in Fig. 1. A double plunger micro-pump (Sanuki Kogyo Model DM2U-1026, Tokyo) is used to pump the solutions. Distilled water (carrier) and the reagent solution of 0.02% CHD in ammonium acetate–acetic acid buffer (pH 5) are delivered at a flow rate of 0.75 ml min⁻¹. The samples (60 μl), containing up to 1 ppm aldehyde, are injected into the carrier stream by means of a six-way injection valve to which a volume control loop is attached. The sample and reagent are mixed in a 7 m reaction coil placed in the thermostatted bath (70°C). After cooling the mixture (cooling coil, 2 m long), the relative fluorescence intensity of products is monitored by a spectrofluorimetric detector (Soma Optics Model S-3350, Tokyo) with a micro-flow cell (15 μl). A Sekonic SS-250F flat-bed recorder (Tokyo) is used. The PTFE tubing is 0.5 mm i.d. except for the back-pressure coil which is 0.25 mm i.d. (2 m long).

2.5. Collection of sample gases

The auto exhaust gas and emission gas from thermal degradation of polymer (polybutyl-methacrylate) were collected by drawing the gas through 10 ml of absorbent solution (methanol) in two impingers at a rate of 0.5 l min⁻¹ for 20 min. The solution in the first impinger was diluted 10–1000 fold with distilled water before injection.

3. Results and discussion

3.1. Fluorescence spectra

Aldehydes, such as formaldehyde, acetaldehyde, propionaldehyde and *n*-butyraldehyde, reacted with CHD to form the decahydroacridine-1,8-dione derivatives in the presence of ammonium acetate.

The reaction is as follows:

dione derivatives in the presence of ammonium acetate. The reaction is as follows
The derivatives gave strong fluorescence. The excitation wavelength was 376 nm and the emission wavelength was 452 nm.

3.2. Batchwise study

The reaction rate between each aldehyde and CHD was very slow and at room temperature the derivatives were not produced.

The effect of reaction temperature was investigated to accelerate the rate for 0.02 ppm of each aldehyde. As shown in Fig. 2, fluorescent derivatives did not form below 40°C. However, the relative fluorescence intensity was enhanced with increasing temperature. In the range 60–70°C, a considerable intensity enhancement was observed. Although higher temperature was favorable for sensitivity, the intensity of the background level
Fig. 2. Effect of reaction temperature in the batchwise method: aldehydes, 0.02 ppm; reagent, 0.025% CHD; buffer, 2.2 M CH₃COONH₄–CH₃COOH (pH 5); reaction time, 30 min; cooling temperature, 10°C; cooling time, 5 min; excitation wavelength, 376 nm; emission wavelength, 452 nm. (1) Formaldehyde; (2) acetaldehyde; (3) propionaldehyde; (4) *n*-butyraldehyde; (5) blank.

Fig. 3. Effect of pH in the batchwise method: aldehydes, 0.02 ppm; reagent, 0.025% CHD; reaction temperature, 50°C; reaction time, 30 min; cooling temperature, 10 °C; cooling time, 5 min; excitation wavelength, 376 nm; emission wavelength, 452 nm. (1) Formaldehyde; (2) acetaldehyde; (3) propionaldehyde; (4) n-butyraldehyde; (5) blank.

increased and also it was difficult to maintain a constant higher temperature. In the batchwise work, 50°C was chosen and the reaction time was fixed at 30 min. The effect of pH on the formation of derivatives was investigated in the range pH 3–6. The result is shown in Fig. 3. The derivatives were not formed below pH 4. At pH 5, the strongest fluorescence intensity was obtained, while at pH 6, the intensity decreased. It is assumed that an excess of electrons from the deprotonation of the ring nitrogen proton would inhibit fluorescence intensity. The effect of CHD concentration was investigated in the range 0.005–0.05%. Although the fluorescence intensity increased with increasing reagent concentration, the background level became excessively large. In this work, 0.025% CHD was used.

3.3. FI study

Although the conditions for the assay of volatile aldehydes by the batchwise method were determined, the method lacked reproducibility and rapidity and the background level was excessively large.

In unstable reaction systems such as this, the introduction of a FI method is favorable. Therefore, in order to determine total aldehydes more rapidly and simply than with the batchwise method, the FI system with spectrofluorimetric detection, as shown in Fig. 1, was investigated.

3.4. Effect of reagent concentration

The effect of the CHD concentration on fluorescence was studied for 1 ppm formaldehyde. A 2.2 M CH_3COONH_4–CH_3COOH solution buffered at pH 5 was used for preparing the reagent solution. The concentration of CHD was varied from 0.005 to 0.025%. The peak height increased with increasing reagent concentration. However, in this work, 0.02% CHD was used to obtain an appropriate peak signal and to maintain a lower background intensity.

3.5. Effect of temperature on the formation of fluorescence derivatives

Although 50°C was chosen in the batchwise method because of the ease of controlling temperature, the formation of derivatives was incomplete at 50–60°C in the FI system. Above 70°C, strong signals were obtained. For sensitive determination of aldehydes, 75°C was preferable. However 70°C was chosen to obtain constant peak heights. Because slight variations in temperature gave a larger error, reproducibility became poorer above 70°C.

3.6. Effect of flow rate and injection volume

The flow rate of the reagent solution was varied from 0.5 to 1 ml min^{-1} (Fig. 4). When the flow rate increased, the peak height decreased because the reaction rate was low and the formation of fluorescence derivatives at the faster flow rate was insufficient. A flow rate of 0.75 ml min^{-1} was used.

The injection volume was varied in the range 20–100 μl. A larger volume was suitable for greater sensitivity. However, a volume of 60 μl was used for rapid determination.

3.7. Effect of the reaction coil and cooling coil lengths

The effect of the length of the reaction coil was examined. The coil length was varied within the range 1–7 m. With lengths greater than 4 m, the peak height greatly increased. For good sensitivity without sacrificing sampling frequency, a 7 m reaction coil length was used. After reaction at 70°C, it was necessary to cool the mixture in the cooling bath to obtain reproducible signals. The effect of the length of the cooling coil was studied in the range 1–3 m. In general, an increase in coil length gives a lower peak height because of dispersion, but in this case the peak height increased slightly with increase in length. It is assumed that the reaction rate was low. Accordingly, a 2 m cooling coil was used.

3.8. Calibration graphs

Fig. 5 shows calibration graphs for aldehyde determinations in the range 100–400 ppb at 70°C, but the linearities were good up to 1000 ppb aldehydes when 60 μl portions of the standard solutions were injected. The slopes for both

Fig. 5. formaldehyde and acetaldehyde were large compared to those of propionladehyde and n-butyraldehyde. Since formaldehyde is a representative compound for the aldehydes and the sensitivity was best in its calibration graphs, the amount of aldehydes in the gases was calculated as formaldehyde in this study. Fig. 6 shows the flow signals for formaldehyde standard solution and diluted sample solutions in duplicate. The relative standard deviation was 1.5% for 10 runs with 500 ppb formaldehyde solution. The sample frequency was 30 samples h^{-1} in the proposed manifold. Although the FI method does not have a separating function for each aldehyde, it is acceptable for determining the total amount of these volatile aldehydes.

3.9. Determination of total aldehydes in auto exhaust gas and emission gas from thermal degradation

In previous reports [5–8], trace amounts of formaldehyde in atmospheric air and beverages and of aliphatic aldehydes such as formaldehyde,

Effect of flow rate in the FI method: formaldehyde, 1 ppm; sample size, 60 μl; reagent, 0.02% CHD; buffer, 2.2 M CH_3COONH_4–CH_3COOH (pH 5); reaction temperature, 70°C; raction coil, 0.5 mm i.d. $\times$ 7 m; cooling temperature, 10°C; cooling coil, 0.5 mm i.d. $\times$ 2 m; excitation wavelength, 376 nm; emission wavelength, 452 nm.
acetaldehyde and butyraldehyde have been determined sensitively and selectively. These methods are useful only for formaldehyde determination, however, and lack rapidity. In studies of atmospheric pollutants, however, it is very important to determine and monitor the total amount of volatile aldehydes, which are important environmental pollutants, as well as hydrocarbons, exhausted in air. The proposed FI method was applied to the determination of the total amount of volatile aldehydes in several kinds of gases exhausted under different combustion conditions. Up to 10 equivalents of ketones such as acetone and 2-butanone did not interfere with the determination of 1 ppm formaldehyde. The results obtained are shown in Table 1. The collection efficiency of the sample gas in the first impinger was 99.8%. In the case of the thermal degradation emission gas of polybutylmethacrylate (PBM), it

was found that the amount of aldehydes evolved peaked at 500°C. Also, it was possible to monitor the amount of aldehydes evolved at different engine speeds. Consequently, it is possible to apply the FI method for evaluating an engine function and for investigating thermal degradation conditions of polymers and other organic compounds.

4. Conclusion

Volatile aldehydes, such as formaldehyde and acetaldehyde, are exhausted from gasoline-powered vehicles and produced by thermal degradation of various polymers and thereby become important air pollutants. It is very important to monitor and decrease the amounts of these exhaust gases to preserve our atmospheric environment. Although this system does not have a separating function for the analysis of each aldehyde, the FI method proposed here can be applicable for the rapid and reproducible determination of total volatile aldehydes.

Determination of ultra-trace amounts of arsenic(III) by flow-injection hydride generation atomic absorption spectrometry with on-line preconcentration by coprecipitation with lanthanum hydroxide or hafnium hydroxide[1]

Steffen Nielsen, Jens J. Sloth, Elo H. Hansen*

Chemistry Department A, Technical University of Denmark, Building 207, DK-2800 Lyngby, Denmark

Abstract

A time-based flow-injection (FI) procedure for the determination of ultra-trace amounts of inorganic arsenic(III) is described, which combines hydride generation atomic absorption spectrometry (HG-AAS) with on-line preconcentration of the analyte by inorganic coprecipitation–dissolution in a filterless knotted Microline reactor. The sample and coprecipitating agent are mixed on-line and merged with an ammonium buffer solution, which promotes a controllable and quantitative collection of the generated hydroxide on the inner walls of the knotted reactor incorporated into the FI–HG-AAS system. Subsequently the precipitate is eluted with 1 mol l^{-1} hydrochloric acid, allowing ensuing determination of the analyte via hydride generation. The preconcentration of As(III) was tested by coprecipitation with two different inorganic coprecipitating agents namely La(III) and Hf(IV). It was shown that As(III) is more effectively collected by lanthanum hydroxide than by hafnium hydroxide, the sensitivity achieved by the former being ≈ 25% better. With optimal experimental conditions and with a sample consumption of 6.7 ml per assay, an enrichment factor of 32 was obtained at a sample frequency of 33 samples h^{-1}. The limit of detection (3σ) was 0.003 $\mu g\ l^{-1}$ and the precision (relative standard deviation) was 1.0% ($n = 11$) at the 0.1 $\mu g\ l^{-1}$ level.

In 1994, Tao and Hansen [1] for the first time introduced a procedure for on-line flow-injection (FI) preconcentration, in which ultra-trace amounts of the analyte (Se(IV)) were coprecipitated with an inorganic coprecipitant, i.e.

La(OH)₃. The preconcentration procedure combined on-line coprecipitation–dissolution in a knotted Microline reactor and hydride generation (HG) of the dissolved concentrate, the detection being achieved by AAS (quartz tube). The elegant aspect of this procedure is that the inorganic precipitate is easily dissolved in dilute acid (1 mol l⁻¹ HCl), which is also the required medium for the ensuing hydride generation reaction. With such an approach an ordinary FI–HG-AAS system without preconcentration is readily extendable to a time-based FI–HG-AAS system with on-line preconcentration. In their procedure, Tao and Hansen added the coprecipitating agent off-line by spiking each sample before the samples were introduced into the FI system. Recently, this procedure has been improved by facilitating on-line mixing of sample and coprecipitating agent [2]. As was shown, the results with on-line addition of the coprecipitant yielded similar results to those with off-line addition. However, the more automated FI system is obviously preferable as the sample manipulations are significantly reduced. As knowledge of how to optimally control and exploit the method of on-line preconcentration by coprecipitation–dissolution is still insufficient, the present methodological study is therefore devoted to obtaining a better understanding of the processes involved, thereby allowing identification of the significant operational parameters and devising means for their optimization. For the very same reasons, aqueous standards were applied throughout the experimental work.

The optimization procedure is illustrated for the determination of ultra-trace amounts of As(III) by coprecipitation with two different agents, namely La(III) and Hf(IV). According to the literature [3,4] these copre-cipitants are interesting as they have both been shown to coprecipitate As(III) quantitatively in batch methods. Further, the hydroxides of these coprecipitants, La(OH)₃ and Hf(OH)₄, are readily dissolved in dilute acid.

2. Experimental

2.1. Apparatus

A Perkin-Elmer Model 2100 atomic absorption spectrometer was used in combination with a Perkin-Elmer Model FIAS-400 flow-injection unit (equipped with two individually controlled peristaltic pumps and a five-port FI valve), with hydride generation accessories (the gas–liquid separator used in the chemifold was a Perkin-Elmer W-configuration unit). An arsenic hollow cathode lamp (S. & J. Juniper, Harlow, UK) was used at a wavelength of 193.7 nm with a spectral bandpass of 0.7 nm, and was operated at 9 mA. The temperature of the quartz atomizer cell was set at 900 °C. Special care was taken to make the conduit between the outlet of the gas–liquid separator and the quartz atomizer cell as short as possible (≈ 6 cm). The filterless knotted reactor precipitate collectors were made from 0.5 mm i.d., 1.8 mm o.d. Microline tubing (cross-linked ethyl vinyl acetate) by tying interlaced knots (the optimal length of the knotted reactor, L_{KR}, was 200 cm). The knots were made with approximately 5 mm diameter loops. All the other reaction coils, connections and conduits in the FI manifold (Fig. 2) consisted of 0.5 mm i.d. PTFE (polytetrafluoroethylene) tubing. The output signals were processed with a time constant of 0.5 s in the peak-height mode and recordings from the graphics screen were printed out by an Epson Model FX-850 printer. The actuation times of the injector valve and the two pumps were programmed with the use of the FI software of the Model 2100 atomic absorption spectrometer.

2.2. Reagents and standard solutions

All the reagents were of analytical-reagent grade, and distilled water was used throughout. Sodium tetrahydroborate solution (1.50% (m/v) in 0.05 mol l⁻¹ sodium hydroxide) was prepared fresh daily. Lanthanum nitrate solution (0.50% (m/v)) was made by dissolving 0.6662 g of lanthanum nitrate hexahydrate in 100 ml of distilled water. Hf(IV) solution (1.00%) was prepared by dissolution of 1.4869 g of HfOCl₂ in 100 ml of

distilled water. The buffer solution, made freshly every day, was in all instances 0.3 mol l^{-1} ammonium chloride adjusted to the appropriate pH by addition of 0.3 mol l^{-1} ammonia. Standard solutions of As(III) for calibration were prepared by three-stage aqueous dilutions of a 1000 mg l^{-1} stock solution, which was made by dissolving 1.724 g of NaAsO$_2$ in 25 ml of 20% (w/v) potassium hydroxide, followed by neutralization with 20% (v/v) sulphuric acid using phenolpthalein as indicator, finally making the sample solution up to 1000 ml with 1% (v/v) sulphuric acid.

All glassware was soaked for at least 24 h in 1 M nitric acid, and finally rinsed in distilled water before use.

2.3. Operational procedure

The time-based FI–HG-AAS system with on-line addition of the coprecipitant, La(III), is shown in Figs. 1 and 2, depicting the optimized experimental parameters. In the precipitation procedure (Fig. 1a), the sample (S), hydrochloric acid and sodium tetrahydroborate solutions were introduced by pump 1, and the buffer and coprecip-

itating agent (CA; either La(III) or Hf(IV)) were delivered via pump 2. During the precipitation sequence both pumps were activated for a period of 100 s. The sample and coprecipitant were premixed in the mixing coil (MC) of length (L_{MC}) of 6 cm, and subsequently merged with the buffer solution at the entrance to the knotted reactor (KR) which had a length (L_{KR}) of 200 cm. The precipitate, which was formed instantaneously after the merging point of the KR, was collected on the inner walls of the KR. The effluent emerging from the reactor was discarded. Simultaneously, the acid was pumped through the by-pass of the rotor of the valve and directed into the hydride generation system. During this stage, the baseline for the final readout was established.

At the end of the precipitation period pump 2 was stopped, and the valve was actuated automatically from the fill mode to the inject mode for a period of 10 s (dissolution–hydride-generation procedure; Fig. 2a), by which the acid was introduced directly into the KR where the precipitate adhering to the inner walls of the reactor was dissolved. This concentrated plug zone was directed from the KR to the hydride generating
Fig. 2. (a) Schematic diagram of the time-based FI–HG-AAS system as shown in the dissolution–hydride generation stage. (b) Identification of the operational parameters which influence the dissolution–hydride generation procedure. For explanation of symbols and abbreviations. see Fig. 1.

system, where the analyte was merged with a reducing solution of sodium tetrahydroborate. After passing through a reaction coil (RC) of length $L_{RC} = 60$ cm, the gas–liquid mixture was guided into the gas–liquid separator (SP) in which the arsine and the evolved hydrogen were separated from the liquid phase and swept into the atomizer cell by a steady argon carrier flow. The absorption signal was then recorded. The waste from the gas–liquid separator, which included unreacted sodium tetrahydroborate, acid and some argon, was removed by aspiration. The elution stage lasted for 10 s. During this interval the sample solution was interchanged so that the remainder of the previous sample in the sample pump tube could be effectively washed out and the next sample kept ready for precipitation.

3. Results and discussion

3.1. Basis of the optimization procedure

The interpretation of the peaks recorded by the AAS instrument formed the basis for an effective optimization of the FI preconcentration procedure, as the peaks reflect the effect and efficiency of the preconcentration technique incorporated into the FI system, that is, the coprecipitation–dissolution process, and, following elution, the chemical and/or physical modifications of the analyte in the concentrate into a detectable species via hydride generation and subsequent gas–liquid separation. However, in order to exploit a method completely and thereby reach the limit of detection of the detector concerned, the optimization procedure must be performed most systematically. Thus the optimization was controlled by estimating the gradient of every single peak, that is, the ratio between the area (I) and the absorbance (A) of the signals was evaluated. As the maximum effect of preconcentration was desired, resulting in maximum peak areas, the FI procedure was optimized so as to obtain the lowest I/A ratios. To achieve this end it was imperative that the final

optimization of the FI procedure was completely controllable and reproducible.

Since the coprecipitation and dissolution/hydride generation processes are completely separate and individual, they will also be treated as such in the following, where the optimization procedure will be described by firstly setting the present investigation into context with current knowledge, and secondly by identifying and detailing the individual parameters/factors important to the two individual processes and the overall operation. The optimization procedure is thus based on a factorial approach, where the response function was the minimization of the I/A ratio.

3.2. Introduction to the procedure of coprecipitation

First of all, as the time available for the coprecipitation process under dynamic conditions is limited, typically from a few seconds to a few tenths of a second, this process must happen extremely fast to allow a quantitative recovery of the analyte. Furthermore, this requires a close and compatible interaction between the precipitate collector and the precipitate generated, i.e. the character of the precipitate. From previous work [2] the authors achieved some very important experiences with on-line coprecipitation in KRs, the geometrical design of which leads to the generation of a strong secondary flow pattern, which promotes quantitative coprecipitation although the KR is filterless. Thus, the material of the KR is a very important factor. In order to achieve quantitative coprecipitation of the analyte, the KR has to be tightly knotted, the material of its construction must have a high affinity to the precipitate formed, and the inorganic precipitate must in turn be gelatinous to facilitate the entrapment of the analyte species. Unfortunately, the number of commerically accessible tubular polymer materials with a high hydrophilic character and suitable dimensions (preferably of an inner diameter (i.d.) of about 0.5–0.7 mm [5]) is rather restricted. However, in the experimental work with on-line coprecipitation of Se(IV), where the coprecipitant and sample were mixed on-line, the results strongly indicated that the collection of the

analyte in $La(OH)_3$ in a knotted Microline reactor $(i.d._{KR} = 0.50$ mm) was quantitative below a sample flow rate of $Q_S = 6.4$ ml min^{-1} [2], although the hydrophilic character of Microline (vinyl acetate) is not particularly high. Since no better material appears to be available, this material was also selected for use herein to make the KRs.

Another important factor, as identified previously [2], is the total flow rate through the KR. Hence, it is not sufficient to optimize the capacity of the KR. This is due to the fact that if the flow rate through the KR is too high the efficiency of adherence of the precipitate on the inner walls of the KR decreases condsiderably, and with that the enrichment factor (EF) and the concentration efficiency fator (CE) decrease too [2]. With this experience in mind a sample flow rate of $Q_S = 4.0$ ml min^{-1} seemed to be a rational choice. Further, it is essential that the developed FI procedure should possess practical applicability, and therefore the preconcentration period (T_c) was limited to $T_c = 100$ s, which in turn determined the obtainable value of EF. Thus, at $T_c = 100$ s and with a subsequent elution period (T_E) of 10 s, which is sufficient for cleaning the system between each analytical cycle, the sampling frequency (f) became 33 h^{-1}.

From a practical point of view the FI procedure should be able to handle samples in acidic media, since environmental samples are typically preserved by addition of acid to a pH level of ≈ 3. Therefore all aqueous standards were prepared at a pH of 3.

3.3. Optimization of the experimental parameters for the on-line preconcentration by coprecipitation of As(III) with La(III)

The experimental parameters which have an influence on the coprecipitation process are identified in the inset of Fig. 1, (part b, where brackets refer to the individual parameters), and comprising the concentration of the coprecipation agent La(III) (C_{CA}), the pumping rate of this constituent (Q_{CA}), the characteristics of the buffer (pH, C_0 and $Q)_{Buffer}$, and the lengths of the mixing coil (L_{MC}) and KR (L_{KR}). To achieve an effective preconcentration procedure and to exploit the

capacity of the KR, these parameters must be optimized very carefully, because the process of coprecipitation is very sensitive under the dynamic conditions prevailing, and because the residence time of the coprecipitation media in KR is only of the order of a few seconds. Consequently, every single liquid element must be accounted for during the process of coprecipitation.

As AS(III) is to be determined at ultra-trace levels through coprecipitation under weakly alkaline conditions by mixing the sample with large excesses of La(III) and ammonium buffer, it is preferential if the flow rates of these constituents (Q_{CA} and Q_B) can be kept as low as possible in order to avoid excessive dilution of the sample and to limit the flow rate through the KR. Experimentally it was found that conditions were optimal for Q_{CA} and $Q_B \approx 0.5$–0.6 ml min^{-1}.

Since the sample and the coprecipitant are mixed on-line prior to entering the KR, it might be expected that it is necessary to utilize a certain pathlength in order to effect this, but, as was also verified in previous work [2], the shortest possible length of MC (here corresponding to 6 cm) was, in fact, sufficient. This is not surprising considering that the ratio of the flow rates of the coprecipitant and the sample was 1/8.

Using $Q_{CA} = Q_B = 0.5$ ml min^{-1} and a sample flow rate Q_S of 4.0 ml min^{-1}, the residence time (T_{KR}) of the coprecipitating media in a KR of L_{KR} 200 cm and i.d.$_{KR}$ 0.5 mm will be ≈ 4.7 s. Considering this very short residence time, the effects of the pH value of the buffer (the concentration of which was fixed at $C_{OB} = 0.3$ M in order to maintain a high buffering capacity) and the La(III) concentration (C_{CA}) were closely investigated. The results are shown in Fig. 3.

As can be seen, optimal conditions for preconcentrating As(III) by collecting the analyte in the generated lanthanum hydroxide are found in a fairly narrow pH interval, i.e. $9.50 < pH_B < 9.70$, while the concentration of the coprecipitating agent should be in the range $90 < C_{CA} < 180$ ppm. This clearly demonstrates that the process or mechanism of coprecipitation is critical under the dynamic conditions, particularly the pH_B value, which for off-line applications has been found to be optimal over a much wider range, i.e. 9–11 [3].

As is apparent from Fig. 3, the efficiency of collection decreases at higher concentrations of La(III) and/or higher values of pH_B. A reasonable explanation might be that large particles are formed under these conditions, whereby the efficiency of adherence to the inner walls of KR is reduced as larger particles are dislodged and carried to waste (W2, Fig. 2) [1]. Thus, it is essential that the inorganic precipitate is generated in the form of small, curdy particles which willingly adhere to hydrophilic Microline tube. During the following investigations $pH_B = 9.60$ and $C_{CA} = 100$ ppm were used.

The optimization of the capacity of the KR is very important. Its i.d. must necessarily be small, i.e. i.d.$_{KR} \approx 0.50$–0.70 mm, in order to allow for the creation of a strong secondary flow pattern within it. Settling for an i.d. of 0.5 mm, the optimal capacity was therefore determined by optimizing the length of the reactor, L_{KR}.

For $L_{KR} < 175$ cm, the collecting capacity of KR was found to increase almost linearly, while at lengths exceeding 175 cm it remained practically constant (Fig. 4). These results contain some very interesting information about the coprecipitation process. Thus, by depicting the normalized absorbances (A/A_{AV}) for a given length of KR, where A_{AV} (here $A = 0.229$) is the average value of

Fig. 3. The influence of the La(III) concentration on the efficiency of the coprecipitation process at different pH values as measured by the recorded output signals. All measurements were made on As(III) standards at a concentration of 0.50 μg l^{-1} at a sample loading time (T_C) of 100 s and for $L_{KR} = 200$ cm. Operational conditions are otherwise as given in Figs. 1 and 2.
Fig. 4. Effect of the length of the KR on the recorded output signal as determined for a 0.20 μg l^{-1} As(III) standard. $T_C = 100$ s and $L_{KR} = 200$ cm. Operational conditions are otherwise as given in Figs. 1 and 2.

the absorbances obtained for $L_{KR} \geq 175$ cm, an indication for the concentration distribution of the analyte within the KR at the end of the coprecipitation period can be obtained, provided that it can be assumed that the composition of the precipitate is generated uniformly throughout any cross-section of the KR–an assumption which seems reasonable according to the flow pattern in the KR, and becuse the coprecipitation takes place on-line. Such a concentration distribution curve is shown in Fig. 5 for a reactor of length 200 cm (other experimental parameters are shown in the Figure legend). The highest A/A_{AV} value (concentration) was obtained at a length of ≈ 50 cm, and in fact 57% of all the precipitate is collected within this part of the reactor, while only a minor fraction is contained in that part of the reactor which exceeds 100 cm. This observation strongly indicates that the length of MC (6 cm) is sufficient for mixing sample and coprecipitant on-line, and that the coprecipitation process takes place very quickly. Furthermore, as the signals are constant for $L_{KR} \geq 175$ cm, the coprecipitation is obviously quantitative for a reactor of 200 cm. Consequently, the affinity between the Microline reactor and the precipitate La(OH)$_3$ is adequate. To keep the KR as short as possible,

and thereby avoid unneccesary back pressure during the period of coprecipitation and in the moment of dissolution, $L_{KR} = 200$ cm was selected. Back pressure in the FI system might possibly cause fluctuations resulting in non-reproducible results, but with the conditions used no such problems were encountered, which confirms that lanthanum hydroxide is readily dissolved in 1 M HCl.

The last parameter of the coprecipitation sequence to be optimized was the sample loading period (T_C). Obviously, for increasing values of T_C the amount of precipitate increased: thus it was found that the preconcentration effect increased almost linearly up to $T_C = 150$ s, which indicates that the collection is quantitative. However, long sample loading times will—for a fixed value of the sample flow rate, which, as stipulated earlier, for practical reasons was fixed at 4.0 ml min^{-1}—lead to lower sampling rates. A T_C value of 100 s was therefore adopted, although only two-thirds of the capacity of the reactor was thus exploited.

The time that the coprecipitating media takes to reach equilibrium, T_{Eq}, may be found by extrapolating the curve for absorbance (A) vs. T_C to $A = 0$ or by calculating the line of regression.
Fig. 5. Calculated concentration distribution of the analyte (As(III)) in a KR of 200 cm at the end of the coprecipitation period, using an As(III) concentration of 0.20 µg l⁻¹. Operational conditions are otherwise as given in Fig. 4.

Using the latter approach T_{Eq} was determined to be -2.4 s. Of course, a negative value of T_{Eq} is impossible, but this value again emphasises that the coprecipitation happens very quickly and virtually instantaneoulsy.

3.4. Optimization of the experimental parameters for the on-line dissolution of the precipitate in the KR and hydride generation of As(III)

To achieve a high sensitivity via the ensuing hydride generation procedure, the precipitate in the KR must be dissolved immediately to obtain a plug zone of concentrate. Thus the approach of dissolution–hydride generation will be virtually identical to the common FI–HG-AAS system without preconcentration. Therefore the flow rate, Q_{HCl}, and the concentration of the acid, C_{HCl}, are very important factors. Apart from the fact that the geometrical design of the KR promotes the conditions for achieving an effective preconcentration, it also, via the inherent secondary flow pattern, facilitates effective dissolution. Consequently, the degree of dispersion and the extent of inhomogeniety of the concentrate formed by the dissolution process are both limited, which in turn

promotes the conditions for achieving low I/A values via effective hydride generation and strict control of the FI processing of the concentrate from the KR to the quartz tube atomizer.

The parameters which are of importance for the dissolution–hydride generation procedure are identified in Fig. 2b. Optimization of this part of the assay sequence is well described elsewhere [5,6], and therefore only a few comments will be linked to the hydride generation part of the procedure.

As it was found previously [1] that 1 M HCl readily dissolved the La(III) precipitate quickly and effectively, even if elevated flow rates were used (around 8–9 ml min⁻¹), this medium was also used herein. Higher concentrations did not have any significant effect. However, the efficiency of the hydride generation is very much dependent on the concentration of the sodium tetrahydroborate. Thus it was found that the optimal concentration of this constituent was 1.50% (m/v). Pumped at a rate of 1.50 ml min⁻¹, this means that the concentration of sodium tetrahydroborate in the final reaction medium is 0.22% (m/v) while that of HCl is 0.085 M. These conditions caused a vigorous evolution of hydrogen in the RC. The evolved hydrogen therefore undoubtedly

contributes considerably to the stripping of the analyte from the RC to the gas–liquid separator (SP), which explains why a rather low optimal flow rate of argon, $Q_{Ar} = 29$ ml min^{-1}, sufficed. In spite of the relatively large pressure fluctuations generated by the discontinuous release of hydrogen, the gas segmentation actually does limit the dispersion of the concentrate in the RC, which, for the same reasons as for the KR, is knotted. The length of RC was optimized to $L_{RC} = 60$ cm (i.d.$_{RC} = 0.50$ mm), which indicates that the hydride generation happens immediately. By prolonging the reaction time, i.e. $L_{RC} > 60$ cm, the signals obtained were very reproducible, indicating that the analyte is transported smoothly from the RC to the quartz-tube atomizer via the gas–liquid separator. However, to achieve maximum signals, it is extremely important to control the flow rate of the liquid withdrawal from the gas–liquid separator, Q_{W1}. By varying this parameter, it was noticed that the signals dropped significantly, i.e. up to 10–15%, if $Q_{W1} > Q_{W1,opt.}$ (≈ 22 ml min^{-1} with the ultimately optimized flow rates). This shows that unless the waste flow of W1 (Q_{W1}) is very conscientiously adjusted, there is a possibility of considerable loss of analyte into the waste.

3.5. The influence of sample flow rate on the performance of the FI–HG–AAS system

As mentioned earlier, the collection efficiency gradually decreased at higher sample flow rates which was the reason why it was fixed at 4.0 ml min^{-1}. However, if the sample flow rate was varied at levels below 4.0 ml min^{-1} while keeping the total amount of analyte introduced constant, virtually identical calibration curves were obtained. Thus, when comparing two calibration runs where the aspirated sample volume (V_S) of As(III) in both cases was 6.7 ml, but where the sampling time (T_C) and the sample flow rate (Q_S) in the first instance were 100 s and 4.0 ml min^{-1} respectively and 200 s and 2.0 ml min^{-1} in the second one, the linear slopes of the two calibration graphs deviated by less than 10% from each other (the slope being highest for the lower flow rate). If the difference in the two calibration runs

is beyond the experimental error, it does, however, show that it is a reasonable assumption to consider the coprecipitation quantitative up to a sample flow rate of 4.0 ml min^{-1} and with T_C equal to 100 s. The characteristics of performance under these conditions are given in Table 1.

As mentioned above, the ratio between the area (I) and the absorbance (A) of the individually recorded peak signals was a guiding parameter in the optimization procedure. Since the area reflects the effect of the coprecipitation, it is not surprising that it remained practically constant for aspiration of identical amounts of As(III), but as the optimization progressed the absorbances increased, i.e. the I/A ratio decreased progressively. By calibration at $(T_C, Q_S) = (100$ s, 4.0 ml min$^{-1})$, the average value of the I/A ratio, $(I/A)_{AV}$, in the concentration range of As(III) 0.05–0.30 μg l^{-1}, approached a value of around 1.91, which seemed to be the optimal efficiency obtainable. By comparison, calibration at $(T_C, Q_S) = (200$ s, 2.0 ml min$^{-1})$ yielded an $(I/A)_{AV}$ value of 1.93. Thus, these results show that (1) La(OH)$_3$ effectively collects As(III) on the inner walls of a knotted Microline reactor under the dynamic conditions prevailing, and (2) the dissolution of La(OH)$_3$ is effective and so is the hydride generation reaction. Apparently the concentration distribution of the analyte in the KR (Fig. 5) promotes appropriate conditions for dissolution of the coprecipitate.

In the concentration range investigated (i.e. 0–0.20 ppb As(III)), the presence of As(V) did not influence the signal provided that the concentration was below 0.20 ppb. Whether higher concentrations of this species can be tolerated in the coprecipitation reaction with La(III) or Hf(IV) can only be estimated by optimising the dissolution–hydride generation conditions to eliminate, if possible, the differences in kinetic behaviours of As(III) and As(V).

3.6. Evaluation of the preconcentration effect

To estimate the effect of the preconcentration obtained the same FI–HG-AAS system was used to determine As(III) without preconcentration. The optimal parameters obtained by optimizing the elution/hydride generation procedure with

Table 1

Characteristics for the FI–HG-AAS system with on-line coprecipitation–dissolution

Parameter	Analyte		
	Se(IV)[a]	As(III)[a]	As(III)[b]

[a] Coprecipitation with La(OH)$_3$.
[b] Coprecipitation with Hf(OH)$_4$.
[c] Not determined.

La(III) were reused except that the argon flow rate had to be readjusted. A sample volume of 100 μl was employed, which in turn required an optimal argon flow rate of 43 ml min^{-1}. Consequently, the elution/hydride generation procedures with and without preconcentration were almost identical, which again indicates that the dissolution of La(OH)$_3$ is very effective. With a calibration series comprising As(III) standards in the range 2.0–10.0 μg l^{-1}, the (I/A)$_{AV}$ value was found to be approximately 2.28, that is somewhat higher than the value found for the optimized system with on-line preconcentration (1.91). The characteristics of performance are given in Table 2.

3.7. On-line preconcentration of As(III) by coprecipitation–dissolution with Hf(IV) as coprecipitant

As mentioned earlier, Hf(IV) has proved to be an effective coprecipitating agent for As(III) in batch procedures, and therefore it would be highly interesting to estimate its potential capacity on the FI–HG-AAS approach (also because this

element, in fact, is named after the capital of Denmark). To compare the efficiencies of La(III) and Hf(IV), the coprecipitation procedure with the use of Hf(IV) was optimized according to the same principles as described above for La(III). Thus, in the FI preconcentration procedure for collection of As(III) in Hf(OH)$_4$ the parameters of the elution/hydride generation procedure as employed for La(III) were reused. The results obtained are given in Table 1, to which the following comments should be added.

Table 2

Characteristics for the FI–HG-AAS system without preconcentration

Sample volume, V_s (μl)	100
Calibration range (μg l^{-1})	0.50–10.0
Regression equation in calibration range (7 standards, $n = 3$, C_{As} in μg l^{-1})	0.037 C+0.006 ($r = 0.999$)
Sampling frequency, f (samples h^{-1})	120
Relative standard deviation ($n = 11$; 5 μg l^{-1}) (%)	0.4
Limit of detection (3σ) (μg l^{-1})	0.081

By comparison with the results attained by using La(III), the investigation with Hf(IV) yielded a surprising outcome as optimal results could be achieved within wider ranges of the values of the critical parameters. Thus, similar responses were found for $9.10 \le pH_B \le 9.40$ and $180 \le C_{Hf(IV)} \le 300$ ppm. Therefore the coprecipitation of As(III) seemed, in fact, to be more robust using Hf(IV) rather than La(III) under the dynamic conditions in the FI system.

During the ensuing investigations pH_B was fixed at 9.10 and [Hf(IV)] at 220 ppm. Analogous to the results obtained by La(III) similar indications can be drawn. Thus the concentration distribution of the analyte achieved using Hf(IV) was almost identical to the distribution in Fig. 5. By varying T_C the results obtained indicate that the coprecipitation of As(III) is quantitative or almost quantitative until $T_C = 175$ s using the optimal length of the KR, $L_{KR} = 200$ cm, whereby only $\approx 60\%$ of the capacity of collection of the KR is exploited at $T_C = 100$ s. The results obtained by varying T_C are interesting. Thus while the collection efficiency of La(III) decreased slightly for $T_C \ge 50$ s, it remained constant in the range $75 \le T_C \le 175$ s for Hf(IV), which indicates that the coprecipitation is quantitative or almost quantitative during that part of the coprecipitating period.

Two calibrations were performed by coprecipitation with Hf(IV) using equal amounts of As(III), where the aspirated sample volume (V_S) was 6.7 ml and (T_C, Q_S) was (100 s, 4.0 ml min^{-1}) and (200 s, 2.0 ml min^{-1}). Contrary to the observation made for collection of As(III) in La(OH)$_3$, the highest sample flow rate for Hf(IV) exhibited the steepest slope of the calibration curve ($\approx 5\%$ higher than for the lower flow rate), although the integrated signals were of the same order of magnitude, i.e. the effect of preconcentration was identical. This indicates that the efficiency of dissolution is reduced by preconcentrating equal sample volumes at increasing T_C. By calibration at (T_C, Q_S) of (100 s, 4.0 ml min^{-1}) and (200 s, 2.0 ml min^{-1}) the $(I/A)_{AV}$ values were 2.11 and 2.29 respectively, in the concentration range of As(III) 0.05–0.40 μg l^{-1}. This effect will be explained in the following section. The characteristics of performance for Hf(IV) are given in Table 1 at calibration conditions of $(T_C, Q_S) = (100$ s, 4.0 ml min^{-1}).

3.8. Comparing the efficiency of La(OH)₃ and Hf(OH)₄ as collecting agents for coprecipitating As(III) in a knotted Microline reactor.

By comparing the results of the calibration curves that were achieved using La(III) and Hf(IV), the difference in the collection efficiencies of As(III) in the two hydroxides can be estimated because the conditions of the elution/hydride generation procedures were identical for the two calibrations. The comparison is described for the conditions $(T_C, Q_S) = (100$ s, 4.0 ml min^{-1}).

By collecting As(III) the effect and efficiency of preconcentration obtained are highest using La(OH)$_3$, as the integrated signals are higher and the I/A ratios are lower than by using Hf(OH)$_4$. The efficiency ratio of Hf(OH)$_4$ to La(OH)$_3$ was $= 77.4\%$, as calculated from the respective slopes. Consequently, As(III) is more effectively collected in La(OH)$_3$ than Hf(OH)$_4$ using a knotted Microline reactor.

As both La(III) and Hf(IV) coprecipitate As(III) instantaneously, the explanation for the less effective collection of As(III) by Hf(IV) could be ascribed to a less effective adherence of the coprecipitate and/or collection of the analyte in Hf(OH)$_4$. These possibilities were evaluated by a simple experiment, where As(III) was coprecipitated in the batch mode with the two agents. It was observed that the precipitates of both La(OH)$_3$ and Hf(OH)$_4$ were generated very fast but, while La(III) formed small, fine hydroxide particles, the precipitate of Hf(OH)$_4$ appeared very bulky. Such a precipitate might reduce the efficiency of adherence to the inner walls of the knotted reactor and/or promote the dislodgement of particles from it. Furthermore, the efficiency of adsorption of the analyte on the precipitate might be reduced as the very bulky precipitate of Hf(OH)$_4$ limits the surface area of the precipitate on which the analyte can be adsorbed.

Thus the formation of a bulky precipitate of Hf(OH)$_4$ explains why the efficiency of the FI procedure decreased when longer sampling periods (T_C) were employed. This caused the genera-
Fig. 6. The influence on the recorded output signal of a 0.20 μg l^{-1} aspirated As(III) sample at increasing concentrations of Cu(II) and Se(IV). Operational conditions are otherwise as given in Figs. 1 and 2.

tion of a disproportionately large amount of Hf(OH)$_4$, i.e. the ratio of analyte/precipitate decreased with increasing T_C although identical sample volumes were aspirated. This deteriorated the ensuing dissolution process which in turn led to broadening of the recorded peak signals. Hence, a suitable coprecitating agent should possess the ability to form small, gelatinous particles, which willingly adhere to the hydrophilic Microline tube and easily dissolve. From a thermodynamic point of view, the chance of obtaining many, smaller particles at the expense of fewer larger ones is much higher when the mixing occurs fast and abruptly, and this is quite feasible in a FI system. This is also probably the explanation why the optimal operational conditions under the dynamic conditions of FIA are different from those of batch assays, and also why it is by no means a trivial exercise to transform a batch assay into a FI procedure [1].

3.9. Investigations of interferences

If the FI–HG-AAS system with on-line preconcentration is to have any practical utility, e.g. for assays of natural water samples, it is essential that it can tolerate the presence of pertinent ions and at the concentration levels at which they may be found in such samples. In this work, which by no means was intended to be a thorough investigation of interferences, the work was therefore centered on two representative interferents, i.e. Cu(II) and Se(IV). The former is known to generally interfere in the hydride generation reaction [7], while the latter has been shown to be coprecipitated with La(OH)$_3$. To investigate the extent of these two interferences, 0.20 μg l^{-1} As(III) samples were spiked with increasing levels of these two constituents. The results are shown in Fig. 6.

It appears that concentrations of Cu(II) up to 1 ppm, i.e. at 5000 times excess, could be tolerated without any interference, yet at higher concentrations the recorded As(III) signal decreased. Thus, at a Cu(II) level of 10 ppm, the signal was reduced $\approx$ 30% compared to the signal without addition of Cu(II). In comparison, Tao and Hansen [1] found that by preconcentration of Se(IV), using a similar FI system but with off-line addition of the coprecipitating agent to the sample, the signal for a Se(IV) sample of 0.50 μg l^{-1} was reduced by 36% at a Cu(II) level of 0.50 ppm. Consequently, the determination of As(III) is much more tolerable of Cu(II). In determinations of 10 μg l^{-1} As(III) samples with the FI–HG-AAS system without preconcentration and by spiking samples off-line with Cu(II) at a level of

40 ppm it was found that the signals were only reduced by 19%. This strongly indicated that the decreasing signals for Cu(II) concentrations above 1 ppm are mainly due to the fact that the conditions of the coprecipitation process are impaired in the presence of Cu(II).

As for the investigation concerning Se(IV), it is seen from Fig. 6 that the interference of Se(IV) is much stronger than that exhibited by Cu(II). Already, at a Se(IV) concentration of 5 μg l^{-1} the signal for the 0.20 μg l^{-1} As(III) sample is reduced by 15%. For comparison, Tao and Hansen found that for the determination of Se(IV), at a level of 0.50 μg l^{-1}, the signal was reduced by less than 5% at an As(III) concentration of 50 μg l^{-1} [1]. Again, the interfering effect of Se(IV) in the determination of As(III) is probably due to the fact that the conditions of the coprecipitation process are impaired by the presence of Se(IV). Yet, the Cu(II) as well as the Se(IV) interference are non-signal yielding interferences, and therefore they can readily be compensated for by applying the standard-addition approach, which under any circumstances would be the option of choice when assaying natural samples.
Fig. 7. Typical peak readout for a 0.20 μg l^{-1} aspirated As(III) sample as obtained by the Fl–HG-ASS system depicted in Figs. 1 and 2. Note that the area under the peak up to the peak maximum (which is reached 1.4 s after initiation of the peak) corresponds to approximately 30% of the total area, while the remaining 70% is 'distributed' over the remaining 5–6 s.

3.10. The gas–liquid separator

As each of the experimental parameters was systematically optimized, whereby it was possible to identify any limiting factors of the FI procedure with the incorporated quartz-tube atomizer, it became of interest to investigate if the technical conditions could somehow be improved.

Attention was especially focused on the gas–liquid separator. As detailed in Section 2, the separator used herein was the one commercially available from Perkin-Elmer; the so-called W model, which has a 'dead volume' of 3 ml. Recently an alternative gas–liquid separator has been developed by Fang [6] and such a unit was placed at the disposal of the authors at his proposal. This separator, which has a dead volume of 4.5 ml, proved unfortunately to have an inferior performance, which clearly shows that in order to develop an improved gas–liquid separator—at least for measuring analyte concentrations below 1 μg l^{-1}—attention must be focused on minimizing its dead volume.

The following observations indicate that the sensitivity can indeed be improved by minimizing the dead volume of the Perkin-Elmer W model separator. The dissolution of the precipitate in the knotted reactor happened instantaneously, which was readily visible by the ensuing 1–2 s of vigorous gas liberation/foaming in the gas–liquid separator. With the dimensions selected, the hydride generation reaction itself was completed within ≈ 1 s, and from the readout on the monitor it was evident that the essential part of the signal (the peak height maximum) was available after ≈ 1.4 s, while the time required to record all of the signal peak was about 6.5 s (Fig. 7). These feats indicate that an essential part of the gas concentrate became delayed by approximately 2–3 s by the passage of the gas–liquid separator or, more specifically, that the argon stream and the hydrogen developed caused a pronounce dilution of the concentrate in this unit. To minimize this effect it would be very interesting to test a Perkin-Elmer W model with a dead volume of less than 3 ml.

4. Conclusion

With the results obtained in previous work [1,2], and the work reported in this paper, it is apparent that the FI approach for preconcentration of trace levels of elements by on-line coprecipitation–dissolution in inorganic media offers itself as an attractive and effective option.

The coprecipitation process is very sensitive under the dynamic conditions prevailing, especially regarding the optimal value of the pH of the buffer used and the concentration of the coprecipitating agent. This is amply demonstrated in the difference of the optimal values of these two parameters for the preconcentration of As(III) and Se(IV), although the very same coprecipitating agent, La(III), was used in the two cases (Table 1).

Although the coprecipitation process proceeds extremely fast using either La(III) or Hf(IV), it was found that La(OH)$_3$ collected As(III) more effectively than Hf(OH)$_4$ using a knotted Microline reactor. This is probably due to the fact that the precipitate of Hf(OH)$_4$ was generated as bulky particles, which impaired both the conditions for the on-line coprecipitation process and also the ensuing on-line dissolution of the precipitate. This, in turn, proved that an ideal precipitating agent should give rise to the formation of small, gelatinous particles, which promote conditions for willing adherence to the hydrophilic Microline tube and subsequently give rise to ready dissolution.

From the experience gained by on-line preconcentration of As(III) and Se(IV) via coprecipitation–dissolution in inorganic media it is expected that subjecting other hydride-forming elements to a similar procedure should not pose any serious problems. Further, as the FI procedure presented herein seems to have reached completion, it should in the future be of great interest to investigate the possiblities to include on-line speciation of As, Sb, Se and Te. Whether the on-line reduction should be incorporated in the period of preconcentration or in the period of elution remains to be answered. In this context it must be borne in mind that the threshold of tolerance of the coprecipitation process towards interfering species was low. Therefore the on-line reduction of the analyte might preferably be executed during the period of elution, which requires that the on-line preconcentration and the sensitivity of the analyte species measured are identical. Similar considerations must be made for achieving a selective determination of the analyte at the lowest oxidation state, as the same method of hydride generation is to be used.

Presently, work is in progress along these lines, with As, Se and Sb as analytical species.

Non-linearity with metal–metal indicator complex reactions in flow-injection analysis [1]

J.F. van Staden *, D. Malan

Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received 13 August 1995; revised 21 November 1995; accepted 21 November 1995

Abstract

The linearity of the standard calibration curve in a flow-injection system involving a calcium–cresolphthalein complexone reaction was improved by replacing the organic base, 2-amino-2-methylpropan-1-ol, with the weak inorganic acid–conjugate base, boric acid–borate system as buffer. This was done after a theoretical study done on the relationship between the amount of coloured complex, $Ca_2(CPC)^{2-}$, as major chromophore formed and the total amount of calcium added at different pH values, and employing the knowledge obtained via proton side-reactions. It was shown that a linear calibration curve between 150 and 1000 mg l^{-1} of standard Ca^{2+} solutions was obtained with a buffer solution containing 0.05 mol l^{-1} boric acid, 0.05 mol l^{-1} KCl and 35 g l^{-1} sodium acetate at a pH of 8.5.

Keywords: Calcium–cresolphthalein complexone reaction; Flow-injection; Non-linearity; Standard calibration curve

1. Introduction

Non-linear calibration curves are sometimes obtained in flow-injection systems. These curves are either non-linear over the whole concentration range or only linear over a limited concentration range and furthermore tend to flatten when an element is determined over a wide concentration range. This has an influence on the accuracy and precision of results obtained. Although this is not such a big problem with modern technology involving computers and chemometrics, many routine laboratories do not have these facilities or access to these facilities and therefore have problems in reporting the correct results. There are two main factors that may contribute to this phenomenon, i.e. the physical and chemical parameters involved in the optimisation of a flow-injection system. Physical parameters such as sample volume, line length, tube diameter, etc. are usually easily optimised in order to obtain linear calibration curves in the working concentration range of a specific element. With chemical parame-

[1] Presented at the Seventh International Conference on Flow Injection Analysis (ICFIA '95), held in Seattle, WA, USA, August 13–17, 1995.

ters, the reaction involved governs the optimisation process and therefore optimisation in this regard is not always such an easy process.

In flow-injection systems where spectrophotometry is used as the detection method, the intensity measured at a certain wavelength of the coloured complex formed is directly proportional to the amount of the metal ion present in a sample if only one complex is formed [1]. The reaction must however fulfill all the requirements needed for flow-injection spectrophotometry. Although the reaction may not reach completion in the flow-injection system, each standard and sample is treated in exactly the same way due to the hydrodynamic nature of the system. This normally results in a linear calibration curve.

Complexation reactions between metals and ligands often result in the formation of more than one product [2–8]. An in-depth discussion on this phenomenon formed the subject of many papers from a number of authors including a recent valuable detailed publication by Budesinsky [8] on the optimal acidity of complexes by solution of polynomials and by iteration. If a metal ion M with analytical concentration (total metal ion concentration) C_M reacts with a ligand L to form a number of complexes as illustrated above, the mass balance (material balance) [3,6,7] on the metal ion is given by

$$C_M = [M] + [ML] + [ML_2] + [ML_3] + \cdots + [ML_n]$$
$$= [M] + \beta_1[M][L] + \beta_2[M][L]^2 + \beta_3[M][L]^3$$
$$+ \cdots + \beta_n[M][L]^n$$

where n is the maximum coordination number of the complexes, [ ] are the concentrations of the different substances, K_1, K_2, $K_3 \cdots K_n$ are the formation constants for each step in the overall reaction process, and β_n is the overall formation constant with $\beta_1 = K_1$, $\beta_2 = K_1 K_2$, $\beta_3 = K_1 K_2 K_3$, etc.

The extent to which a complexation reaction proceeds to form any of these complexes is determined by the experimental conditions and the formation constants for each step in the overall reaction process. In order to quantify the concentration of each complex in solution, the degree of formation [6] (complex formation fractions), α, is given by the general equation

$$\alpha_n = \alpha_{ML_n} = \frac{[ML_n]}{C_M} = \frac{\beta_n[M][L]^n}{C_M} = \beta_n[L]^n \alpha_0$$

where $n = 0, 1, 2, 3, \ldots$ and

$$\alpha_0 = \alpha_M = \frac{[M]}{C_M} = (1 + \beta_1[L] + \beta_2[L]^2 + \beta_3[L]^3 + \cdots$$
$$+ \beta_n[L]^n)^{-1}$$

The α values represent the ratios of the concentrations of the individual metal-containing species to the analytical concentration of the metal C_M. It can however be seen from the expressions that the α values are functions of the equilibrium constants and the free (i.e. not bound to M) ligand concentration. Hence it is possible to plot a series of component distribution curves [6] ($n + 1$ of them) of α_n vs. [L]. The α_n function is used as an atlas of metal–ligand equilibria in aqueous solution to show at a glance the relative proportions of each of the species in solution [9]. In order to visualize how these quantities of different complexes vary with the addition of a ligand to a metal, it is useful to employ graphs, called logarithmic concentration diagrams, having log concentration along the vertical y axis vs. log [L] or pL along the horizontal x axis. It is further possible to construct a complexometric titration curve by transforming the results in a logarithmic concentration diagram into a titration curve, where a metal ion is titrated with a ligand. The pattern obtained with this titration curve resembles the calibration curve actually obtained when the intensity of a coloured complex product at a certain wavelength is measured in a flow-injection spectrophotometric system. It is clear from this information that due to the formation of a number of complexes the calibration curve is only linear over a limited concentration range and that a non-linear calibration curve is obtained when extended to a full concentration range.

It is possible to extend the linearity of the calibration curve to the full concentration range by manipulation of the reaction conditions through side-reactions [2,4,5,7] of the ligands or metal ions in the complexes. When another metal ion, N, or proton, H^+, is added to the complex, ML_n, there is a competition between the other metal, N, or proton H^+, for the ligand, L, and the ligand, L, is 'withdrawn' from the complex,

ML_n. The dissociation of ML_n is enhanced and the concentrations of these complexes are decreased by the amount bound in the side-reaction complexes. To evaluate the extent of the side-reaction quantitatively in order to control the side-reaction, a side-reaction coefficient (α) is introduced which for the addition of a proton is given by

$$\alpha_{L(H)} = \frac{[L']}{[L]}$$

$$= \frac{[L] + [HL] + [H_2L] + [H_3L] + \cdots + [H_mL]}{[L]}$$

$$= 1 + \beta_1^{H^+}[H^+] + \beta_2^{H^+}[H^+]^2 + \beta_3^{H^+}[H^+]^3$$

$$+ \ldots + \beta_m^{H^+}[H^+]^m$$

where $[L']$ is the conditional free ligand concentration.

This clearly shows that the side-reaction coefficient is only dependent on the concentration of the proton added and if this is carefully controlled then the dissociation of the original complex can be controlled.

The complexometric reaction between calcium as metal ion and cresolphthalein complexone (CPC) as metallochromic indicator was chosen as a scale model to illustrate this concept. In flow-injection analysis the standard curve is non-linear when calcium is determined over a wide concentration range measuring the calcium–CPC complex. At high calcium concentrations the calibration curve tended to flatten. The reasons for the non-linearity of the standard curve have been investigated and this paper gives an account of the results obtained. This paper also describes conditions used with side-reactions to extend the linearity of the calibration curve and the results obtained in this regard.

2. Experimental

2.1. Reagents and solutions

All reagents were prepared from analytical-reagent grade chemicals unless specified otherwise. Doubly-distilled, deionised water was used throughout. All solutions were degassed before

measurements with a vacuum pump system. The main solutions were prepared as follows.

2.2. Standard calcium solution

A calcium stock solution was prepared by dissolving 24.9800 g of analytical-reagent grade calcium carbonate carefully in approximately 0.5 mol l^{-1} hydrochloric acid which was added dropwise until all of the calcium had just dissolved. The solution was boiled for a few minutes in order to remove carbon dioxide. The calcium solution was then neutralised with approximately 0.1 mol l^{-1} sodium hydroxide solution, adjusting the pH to ≈ 9, whereafter it was diluted to 1 l with distilled water in order to obtain a stock solution containing 10 g l^{-1} of calcium. Standard working solutions containing 1, 4, 8, 15, 40, 100, 150, 250, 500, 750 and 1000 mg l^{-1} of calcium were prepared by suitable dilution of the stock solution.

2.3. CPC reagent

The solution was prepared by dissolving 50 mg of CPC, obtained from BDH, and 1.0 g of quinolin-8-ol in distilled water to which a few drops of concentrated hydrochloric acid were added. The pH of the solution was adjusted to ≈ 4 with sodium hydroxide, whereafter it was quantitatively diluted to 2 l with distilled water.

2.4. Base solution

Four buffer solutions were prepared by taking 50 ml of stock solution containing 0.1 mol l^{-1} boric acid and 0.1 mol l^{-1} KCl for each buffer solution and adding amounts of sodium acetate to

Table 1
Buffer solutions: experimental design

| Buffer	pH	[Sodium acetate] (g l^{-1})
A	8.5	35
B	8.5	10
C	9.5	35
D	9.5	10

Fig. 1. A schematic diagram of the flow system used. S, sample; M, mixing coil; D, detector; W, waste; M1 = 30 cm; M2 = 405 cm; tube i.d. = 0.76 mm.

each as indicated in Table 1. The pH of each buffer solution was adjusted with 0.1 mol l^{-1} NaOH to the pH values given in Table 1. The final buffer solutions were each quantitatively diluted to 100 ml with distilled water.

2.5. Instrumentation

A schematic diagram of the flow system used is outlined in Fig. 1. The manifold consisted of Tygon tubing (0.76 mm i.d.) cut to the required lengths and wound around glass tubes with an o.d. of 10 mm. The following equipment also formed part of the flow-injection analysis (FIA) system: a Gilson minipuls peristaltic pump (operating at 10 rev min^{-1}) was used to supply the different streams and a VICI Valco 10-port multifunctional valve was used for injection of 25 μl samples. A Unicam 8625 UV/Vis spectrophotometer equipped with a 10 mm Hellma-type flow-through cell (volume: 80 μl) was used as the detector. The whole FIA system was controlled from a computer with a FLowTEK program [10] and the signal output of the detector was fed to the same program for data processing.

3. Results and discussion

CPC is a metallochromic indicator that has been used successfully for a long period for the determination of metal ions such as calcium, strontium and barium. The indicator was originally introduced by Anderegg et al. [1,11] as a complexometric reagent for the determination of calcium in complexometric titrations with EDTA. Under these circumstances there is a reasonably well-defined colour change with a small change in metal ion concentration at the endpoint of the titration. The value of CPC as an indicator for the direct spectrophotometric determination of the alkaline earth metals was soon realised [12] and it was adapted for the colorimetric estimation of calcium in serum [13]. Many variants of the method have been used. Most continuous-flow analytical procedures involve the use of a procedure similar to that used by Kessler and Wolfman [14] for the determination of calcium with CPC and diethylamine—sodium acetate as a base component. The absorbance of the calcium–CPC complex is measured at 580 nm and pH 12.0. Working at this pH and wavelength gave less interference from magnesium. Gitelman [15] improved this method by introducing quinolin-8-ol to eliminate interference from magnesium and by measuring the absorbance of the complex at 570 nm. Some methods also incorporated cyanide as stabiliser and to complex other potentially interfering metals. Moorehead and Biggs [16] modified this method by replacing the toxic and volatile diethylamine (pK_a 11.0) with the more stable 2-amino-2-methylpropan-1-ol (AMP) (pK_a 9.6) as a base solution. The CPC reagent is almost colourless at pH 10, but highly coloured at pH 12; therefore, the blank was reduced and the sensitivity increased. Moorehead and Biggs reported that as the interference from magnesium was eliminated by using quinolin-8-ol, it was not necessary to work at higher pH. Basson and van Staden [17] found that AMP as a base gave a sufficiently stable solution for the FI determination of calcium in animal feeds, which obviates the use of toxic potassium cyanide as stabiliser. An organic base is used to provide the necessary alkaline conditions, inorganic alkalis tending to cause high blanks [18].

Although the sensitivity of the method was excellent, a major problem was the narrow linear range of the calibration curve. CPC does not only

function as a metallochromic indicator, but also at the same time acts as an acid–base indicator. A fully protonated CPC indicator in acidic conditions can be represented as $H_6(CPC)$. $H_6(CPC)$ is deprotonated under alkaline conditions to various ionic forms of CPC. The actual amount and x values of each ionic form at different pH values can be calculated from the pK_a values for the dissociation of CPC given by Anderegg et al. [2,11] and these are outlined in a x distribution diagram of x vs. pH in a simple graphical form in Fig. 2. The spectrophotometric method for the determination of free calcium is based on the reaction between the metallochromic CPC indicator and calcium using the correct pH conditions. However, with CPC indicator, the equilibrium situation is rather involved, and the choice of the best experimental conditions is not quite simple. CPC forms $Ca(CPC)^{4-}$, $CaH(CPC)^{3-}$ and $Ca_2(CPC)^{2-}$ complexes with Ca^{2+} (or Mg^{2+}). A weak absorbing complex $H_2(CPC)^{4-}$ is also formed [11]. The concentration of these species is a function of pH, metal ion concentration and ionic surroundings. The colour formation is enhanced by bivalent metals and an increase in pH. A graphical presentation [2] of the equilibrium, based on the values of the stability constants determined by Anderegg et al. [11], offers a guide to choosing the most favourable conditions. Corns and Ludman [19] postulated the type of equilibrium involved as

Fig. 2. An x distribution diagram of x vs. pH for the different ionic forms of CPC.

$$Ca^{2+} + H_2(CPC)^{4-} \rightleftharpoons CaH_2(CPC)^{2-}$$
with the ionisation of the complex so formed:

$$CaH_2(CPC)^{2-} \rightleftharpoons CaH(CPC)^{3-} + H^+$$
According to these authors further reaction could then occur between this complex and a second calcium ion

$$Ca^{2+} + CaH(CPC)^{3-} \rightleftharpoons Ca_2H(CPC)^-$$
with subsequent ionisation to

$$Ca_2H(CPC)^- \rightleftharpoons Ca_2(CPC)^{2-} + H^+$$
Anderegg et al. [11] postulated that the formation of the coloured complex only occurred on binding of the second calcium ion, in the same way that full colour development of phenolphthalein only occurs on ionisation of the second phenolic hydrogen atom, and formation of a quinoid structure. However, the $H(CPC)^{5-}$ ion is pale pink in colour [11], which implies that the $CaH(CPC)^{3-}$ ion may also be coloured, although the $Ca_2(CPC)^{2-}$ ion would be exected to be the major chromophore.

Corns and Ludman [19] studied the reasons for the non-linearity of the standard curve for the CPC reaction. They found that calcium forms both 1:1 and 2:1 complexes with CPC; at low calcium concentrations the 1:1 complex predominates and caused non-linearity. At high concentrations the CPC concentration becomes limiting, resulting in flattening of the calibration curve. Cowley et al. [20] improved the linearity of the calibration curve to a certain extent in the physiological range 20–200 mg l^{-1} with the addition of sodium acetate to the AMP buffer solution. The option was investigated for FIA with the addition of various amounts of sodium acetate (15–35 g l^{-1}) to various amounts of AMP (15–35 g l^{-1}) in different combinations using the FI system in Fig. 1, but with the pH of the CPC indicator solution at 1.5 as previously described. Calibration curves in the range 0–1000 mg l^{-1} of standard free calcium solutions were recorded and the final pH measured. The following conclusions were drawn from the results obtained. Addition of various amounts of sodium acetate to the buffer stream had only a minor effect on the calibration curve if
the addition was done to a buffer with a high concentration of AMP. However, with smaller amounts of AMP in the buffer the amount of sodium acetate added had an influence on the calibration curve. The disappointment was that all efforts tried did not give a linear calibration curve. It seemed that the acetate anion as ligand was a minor role player in the reaction and that it was not possible to use manipulation of reaction conditions through the side-reaction of acetate as ligand in order to get a linear calibration curve. It was, however, observed that the final pH of the different experiments above varied considerably for the different solutions, depending on reaction conditions. It followed from the results that pH played a bigger role in the linearisation of the calibration curve than the acetate anion.

A theoretical study was done on the relationship between the amount of coloured complex $Ca_2(CPC)^{2-}$, as major chromophore formed and the total amount of calcium added at different pH values. Calculations were done using a Lotus-123 spreadsheet. The overall constants, $\log \beta_{11} = 7.8$, $\log \beta_{21} = 12.8$, the conditional formation constants corresponding to the proton side-reaction, $\log K_{1H} = 11.6$, $\log K_{2H} = 7.6$, and the pK_a values of the CPC indicator ($pK_{a_1} = 2.2$, $pK_{a_2} = 2.9$, $pK_{a_3} = 7.0$, $pK_{a_4} = 7.8$, $pK_{a_5} = 11.4$ and $pK_{a_6} = 12.0$) given by Bishop [4] were used. The results for number of pH values are outlined in Fig. 3. It is clear from the results that the best chance for linearity was at a pH of 8–9. Although a beautiful titration curve was obtained at a pH of 10, linearity over a wide range was not possible. The results also showed that the possibility of linearity decreased drastically with an increase in pH above 11 and that the flattening of the calibration curve as experienced by various authors came into operation.

The method was then modified by replacing the organic base, AMP (pK_a 9.6) with the weak inorganic acid–conjugated base, boric acid–borate system as buffer. Boric acid with the lower pK_a value of 9.23 was chosen as it tended to keep the pH value of the buffer to 9 easier than AMP. This was nearer to the linear goal as illustrated in Fig. 3. Various concentrations and buffer systems of the boric acid–borate buffer without the addition

of sodium acetate were studied, but without success. Results were not repeatable which showed that the formation of the major chromophore was not consistent. This was confirmed by the instability of the final pH measured in the FI system. The preparation of the CPC reagent solution was changed to the preparation described in Section 2 where the pH of the final CPC reagent solution was changed from 1.5 to 4. This resulted in a more stable final pH measured in the FI system. The calibration curve was, however, still not linear.

A factorial experiment was used to investigate the influence of the amount of sodium acetate added and the pH of the buffer solutions at the same time. The following four buffer solutions were prepared by taking 50 ml of stock solution containing 0.1 mol l^{-1} boric acid and 0.1 mol l^{-1} KCl for each buffer solution and adding amounts of 0.1 mol l^{-1} NaOH and 250 g l^{-1} sodium acetate as indicated in Table 2. The final buffer solutions were each quantitatively diluted to 100 ml with distilled water.

The calibration curves obtained using these buffer solutions in the FI system are given in Fig. 4. It is clear from these results that both the proton and acetate ligand side-reations as well as interaction between the two had an influence on the linearity of the calibration curve. An amount of 35 g l^{-1} (14 ml of 250 g l^{-1} sodium acetate added) gave a sufficient side-reaction with the calcium to decompose the major chromophore to such an extent that the calibration curve A became linear. The proton side-reaction at pH 8.5 was sufficient to enhance this tendency. The final pH of the FI system was measured as 8.1. It is, however, also clear from the response that the sensitivity of the method decreased due to the decomposition of the major chromophore under the influence of proton and ligand side-reactions. The reaction capability of the $H_2(CPC)^{4-}$ species at pH 8.5 is also not fully utilised as seen from the α distribution diagram in Fig. 2. Enlargement of calibration curve A (in Fig. 4) showed that the calibration curve is actually linear between 150 mg l^{-1} and 1000 mg l^{-1} of standard Ca^{2+} solutions as illustrated in Fig. 5. It is possible to increase the sensitivity of the method by increas-

Preparation of buffer solutions

Buffer	pH	Volume NaOH (ml)	Volume sodium acetate (ml)
A	8.5	10.1	14
B	8.5	10.1	4
C	9.5	34.6	14
D	9.5	34.6	4

ing the concentration of CPC in the CPC reagent solution.

4. Conclusion

The linearity of the standard calibration curve in a FI system involving a calcium–CPC reaction was improved by replacing the organic base AMP with the weak inorganic acid–conjugate base, boric acid–borate system as buffer. This was done after a theoretical study done on the relationship between the amount of coloured complex, $Ca_2(CPC)^{2-}$, as major chromophore formed and the total amount of calcium added at different pH values and employing the knowledge obtained via proton side-reactions. It was shown that a linear calibration curve between 150 and 1000 mg l^{-1} of standard Ca^{2+} solutions was obtained with a buffer solution containing 0.05 mol l^{-1} boric acid, 0.05 mol l^{-1} KCl and 35 g l^{-1} sodium acetate at a pH of 8.5.

Enhanced surfactant determination by ion-pair formation using flow-injection analysis and dynamic surface tension detection[1]

Toby E. Young, Robert E. Synovec*

Department of Chemistry, Box 351700, University of Washington, Seattle, WA 98195, USA

Abstract

Chemical analysis of surface active species (surfactants) is of interest for many applications, such as in process monitoring, biomedical applications, environmental monitoring and surface science investigations. Recently, we reported a dynamic surface tension detector (DSTD) based upon optically probing the size of a repeating drop resulting from constant flow of an aqueous solvent out of the end of a capillary. Presence of a surfactant in a growing drop reduces the surface tension at the air–solvent interface, causing the drop to detach at a smaller volume, which is detected. The DSTD has a kinetic dependence, and with increasing flow rate the sensitivity decreases due to diffusional and adsorption effects. We report that for the sodium salt of dodecylsulfate (DS), the DSTD performs significantly better with a stainless steel (S.S.) capillary dropper than with a fused silica dropper because the S.S. dropper exhibits a smaller adsorption effect as a function of time. Flow-injection analysis with the DSTD of DS was found to enhance sensitivity 50-fold by in-situ reaction with the ion-pair reagent tetrabutylammonium hydroxide (TBA) in water, even though the TBA alone was not very surface active. The TBA–DS system serves as a model for a selective detection method in which surface activity is exploited and enhanced. The detection limit for DS, as TBA–DS, was 400 ppb. Additionally, weakly surface active species such as TBA could be analyzed "indirectly" by ion-pair formation with DS. The enhanced sensitivity is due to increased packing of the ion-pairs at the air–aqueous solvent interface. The flow rate dependence on the sensitivity of detecting the TBA–DS ion-pair was examined. Two limiting conditions were observed as a function of ion-pair concentration: sensitivity decreases linearly with inverse flow rate at high flow rates and approaches a steady state at slower flow rates.

1. Introduction

The rapid detection of surfactants in a liquid stream traditionally relied upon methods common to the detection of other classes of chemical compounds. Conductively [1], evaporative light scattering [2], and refractive index [3] (RI) detection have been used but do not provide the selectivity and chemical information often desired. UV/Vis [4] absorbance and fluorescence [5] detection are popular and can be extended to surfactants which do not possess a chromophore by derivatization.

For the detection of charged surfactants, a common approach to supplying a chromophore is through the addition of an ion-pairing agent which possesses a chromophore [6–9]. This approach has been used in chromatography [1,10–12] as well as in flow-injection analysis (FIA) [13,14]. While all of these approaches work, they fail to take advantage, as a detection mechanism, of the very physical property of surfactants which characterize them as a class of compounds, namely, an ability to alter the surface tension of a liquid. The dynamic surface tension detector (DSTD) however, does take advantage of this property and is able to selectively detect only those species in a matrix which alter the surface tension of a solvent–air interface in a dynamic, repeating fashion. The original report relating the experimental DSTD work to FIA and liquid chromatography demonstrated excellent sensitivity and selectively for surfactants, with a time dependence [15]. We then improved the limit of detection by incorporating a true-volume-based detection mechanism, as applicable in this work [16].

Surface tension measurements of liquids have long been of interest to researchers and numerous methods such as the Wilhelmy plate [17,18] and drop weight method [19–23] exist for their quantification. These methods, however, are employed under static conditions making their use in a real-time laboratory or process analyzer impractical. The DSTD differs in that it measures bulk surface tension in a dynamic mode. Based on the drop volume method which has been developed as a standard method in surface and interfacial studies [24–30], the DSTD works by forming a repeating drop at the tip of a capillary under a constant volumetric flow rate, and monitoring the change in drop volume when a surfactant is present. The presence of a surfactant in the drop will cause the surface tension to lower and consequently the drop will detach at a smaller final volume relative to the solvent drop volume.
