where $[X_i]$ represents the free concentration of the ith reagent. When the equilibrium constants, β, are "known", we have a system of nr non-linear simultaneous equations in nr unknown free concentrations. When these equations have been solved, the concentrations of all the species present in the equilibria will be "known". The solution of these equations is therefore required whenever we require the concentrations of the species, in HYPERQUAD, Hyphen, HydrapH and HydraSP. The calculation proceeds in two stages. First estimates must be made of all the free concentrations. Then these estimates are refined by Newton–Raphson iteration. Finally, the refinement must be terminated with a suitable criterion.

At the first point in a titration curve, or with batch data, we obtain first estimates by use of a modified Newton–Raphson technique with damping as suggested in the program ES4EC [53]. The modification is drastic: we set all off-diagonal elements of the Jacobian to zero, and improve each free concentration in turn. Subsequent points in a titration curve can utilise the last values calculated for the initial estimate. In the HYPERQUAD calculation some improvement in the initial estimate can be made on the second and subsequent iteration cycles. To illustrate this, consider the free hydrogen ion concentration at the jth point in a titration curve at the kth iteration cycle, $^k[H]_j$. A better estimate than $^k[H]_{j-1}$ (the concentration at the previous point in the titration curve) of this quantity is given by postulating that the slope relating to the free concentration is the same in the two iteration cycles, i.e. $^k[H]_j -$

$^k[\mathrm{H}]_{j-1} = {}^{k-1}[\mathrm{H}]_j - {}^{k-1}[\mathrm{H}]_{j-1}$. The time saved by improving the initial estimates of free concentrations is worthwhile as this calculation is the most time-consuming part of a HYPERQUAD calculation.

When it is known that the data points are equally spaced, as in Hyphen, the calculation can be speeded up by a simple extrapolation technique [54]. We have found that quadratic extrapolation works very well: $[\mathrm{X}]_i = [\mathrm{X}]_{i-3} - 3[\mathrm{X}]_{i-2} + 3[\mathrm{X}]_{i-1}$.

A serious problem can arise during a refinement if one or more of the equilibrium constants becomes negative. We allow this to happen as experience has shown that the "offending" constant may return to being positive later in the refinement. However, when an equilibrium constant is

tions are calculated to a relative precision of better than 1 part in 10^{15}.

2.12. Calculation of weights

In the "automatic" weighting scheme, the calculation of weights requires estimates of the errors on e.m.f., volume and absorbance. The last-named are derived from the empirical error function determined by the program HABER. Then, still assuming one electrode and nl wavelengths and assuming that the potentiometric and absorbnce data derive from a titration curve the variance–covariance matrix, M, for a single point is given by the "rigorous" method of least squares to be [4].

	E	A_1	A_2	$\cdots$	A_{nl}
E	$s_E^2 + \left(\dfrac{\partial E}{\partial v}\right)^2 s_v^2$	$\left(\dfrac{\partial E}{\partial v}\right)\left(\dfrac{\partial A_1}{\partial v}\right)s_v^2$	$\left(\dfrac{\partial E}{\partial v}\right)\left(\dfrac{\partial A_2}{\partial v}\right)s_v^2$	$\cdots$	$\left(\dfrac{\partial E}{\partial v}\right)\left(\dfrac{\partial A_{nl}}{\partial v}\right)s_v^2$
A_1		$s_{A_1}^2 + \left(\dfrac{\partial A_1}{\partial v}\right)^2 s_v^2$	$\left(\dfrac{\partial A_1}{\partial v}\right)\left(\dfrac{\partial A_2}{\partial v}\right)s_v^2$	$\cdots$	$\left(\dfrac{\partial A_1}{\partial v}\right)\left(\dfrac{\partial A_{nl}}{\partial v}\right)s_v^2$
A_2			$sA_2^2 + \left(\dfrac{\partial A_2}{\partial v}\right)^2 s_v^2$	$\cdots$	$\left(\dfrac{\partial A_2}{\partial v}\right)\left(\dfrac{\partial A_{nl}}{\partial v}\right)s_v^2$
$\vdots$	symmetrical			$\vdots$	$\vdots$
A_{nl}					$s_{A_{nl}}^2 + \left(\dfrac{\partial A_{nl}}{\partial v}\right)^2 s_v^2$

negative, there is no guarantee that all the free concentrations can be positive. (The condition is guaranteed by the existence of a unique free energy minimum at equilibrium when all the equilibrium constants are positive.) Now, we impose a non-negativity constraint on the free concentrations, as do most others, if for no other reason that we wish to take logarithms of free concentrations. Therefore, it can happen that the free concentration calculation may fail to converge. When this happens, we return to the main minimization routine and reduce the length of the shift vector for the equilibrium constants.

We attempt to satisfy the conditions of mass balance as nearly as is possible within machine accuracy. As double precision arithmetic is used throughout this means that the free concentra-

The parital derivatives $\partial E/\partial v$ and $\partial A/\partial v$ required for the above formula are estimated from the observed data by means of piece-wise fitting of a seven-point cubic polynomial (simpler estimates are used for the first and last three points). We note that in SIRKO [14] the derivatives are obtained from the calculated values by analytical differentiation, but the authors remark that the weight should then be recalculated at every refinement cycle. The weight matrix, W, would be the inverse of M, but it is not actually calculated. Instead we perform a Choleski factorisation, $M = m^T m$ and invert the lower-triangular factor, m, to obtain the weight matrix factor, w, such that $W = w^T w$. The lower triangle of this factored matrix is stored in a single-precision one-dimensional array in order to conserve computer mem-

ory. Other weighting schemes are available. Diagonal weights may be used if the automatic scheme requires too much memory. Diagonal weights would be invoked automatically with batch as opposed to titration data.

For spectrophotometric data the alternative function

$$U = \sum_k \left(\frac{\Delta A_k}{A_k^{obs}}\right)^2; \quad \Delta A_k = A_k^{calc} - A_k^{obs}$$

may be minimized by means of the use of another weighting scheme. To see how this comes about, we derive the ith unit-weighted least-squares normal equation in the usual manner [4] as

$$\sum_k \sum_j J_{ki} J_{kj} \Delta p_j = \sum_k J_{ki} \frac{\Delta A_k}{A_k^{obs}}$$

The elements of the Jacobian, J, are given by

$$J_{ki} = \frac{1}{A_k^{obs}} \frac{\partial A_k^{calc}}{\partial p_i}$$

where p_i is a refinable parameter. When this expression is substituted into the normal equation we obtain

$$\sum_k \sum_j \frac{\partial A_k^{calc}}{\partial p_i} \frac{\partial A_k^{calc}}{\partial p_j} \left(\frac{1}{A_k^{obs}}\right)^2 \Delta p_j$$

$$= \sum_k \frac{\partial A_k^{calc}}{\partial p_i} \left(\frac{1}{A_k^{obs}}\right)^2 \Delta A_k$$

Thus, setting the weights as $W_k = (1/A_k^{obs})^2$ and minimizing the sum of squared residuals is equivalent to minimizing the sum of squared relative residuals with unit weights. However, when this weighting scheme is used it is not possible to give an expectation value for U.

2.13. The program Handout

The HYPERQUAD program produces a standard file, OUTPUT.RES, which contains all the useful information that was generated during the equilibrium constant refinement(s). The program HANDOUT has four main functions. Two of these relate to viewing the results on screen or dumping selected items to a printer. The third allows the model file to be updated with the refined values for the equilibrium constants.

Lastly, there is a facility for drawing species distribution diagrams. These diagrams, which perforce relate to the experimental conditions, can be annotated by an interactive process involving the mouse, and the final diagram sent to a file. In that case, Hewlett-Packard (HP) Graphics Language is used so that the file may be dumped to an HP-compatible plotter or laser printer or imported into Word or WordPerfect as a picture.

2.14. Programming details

All programs were written in FORTRAN and compiled with MS FORTRAN 5.0 or 5.1 for an AT-style PC. They also appear to function correctly in a DOS window under Windows 95. They assume the presence of a Microsoft-compatible mouse, VGA graphics and a maths coprocessor. For HYPERQUAD there are no formal restrictions on the data. All arrays are dimensioned at run-time. This is achieved by first making a dummy pass through the data files to count all the quantities needed for the allocatable arrays. The arrays are then allocated and the data are read in. A similar system is used in HEDIT and most of the other programs. Thus, the only restriction on the data is imposed by the amount of memory available. It is our intention in the near future to recompile the programs with a 32-bit compiler; that will effectively remove all restrictions on data. Some restrictions may still remain that are imposed by what can be placed on the screen at the same time, but important screens, such as the one that shows the equilibrium constants, are already paged.

HYPERQUAD has been on beta release (mostly in Italy) for more than a year. All programs are fully documented. It has to be stated that we have encountered occasional difficulties with installation that we suspect are due to the use of non-standard mouse and keyboard routines (non-standard only in the sense that the routines are not in the compiler library).

3. Discussion

HYPERQUAD is different from all programs

that have been written before, in this field, in that it is not a single program but a suite of inter-related programs. This has been made possible by the developement of an associated data structure so that the HYPERQUAD programs access a common set of data files. By dividing the data conceptually into data relating to a model and data relating to experimental measurements of different kinds, it becomes possible to perform operations that were not possible before. For example, the model file can be used alone in the program Hyphen to simulate titration curves, that is, to find good experimental conditions, and then together with experimental data in the HYPERQUAD calculation. It is also possible that a model file which was designed for use with the program HypNMR [36] can be used in the simulation program Hyphen.

Within the suite there are many novelties. An important one is the idea of deriving an empirical function to relate the error on a spectrophotometric absorbance measurement to the absorbance value (program Haber). This function permits the construction of an approximate variance–covariance matrix for absorbances without the need to estimate the error on each absorbance measurement. That matrix is essential when it comes to determining the weights to be given to experimental observations in the least-squares calculation, particularly so when the observations may be of different kinds such as potentiometric and spectrophotometric.

Other new features are the creation of plot files in Hewlett-Packard Graphics Language for export to a plotter or laser printer, the use B-spline functions to locate end-points in potentiometric data, an offset procedure for coping with baseline errors in spectra and trial and error procedures for manual fitting of both potentiometric and absorbance data.

In summary, HYPERQUAD provides facilities, in one coherent package, for doing almost all processing of solution equilibrium data that has been done in the past, using standard data files and standard procedures for recalling data from files, for editing data and for saving data to files. The greatest novelty of the system is its comprehensive nature, with each program taking as input a standard model file and/or an experimental data file. The main difference between SUPERQUAD and HYPERQUAD is that the new program can handle spectrophotometric data in addition to potentiometric data.

4. Future developments

We do not believe that it is sensible for us to develop a program, such as SIRKO [14] or MIC-MAC [31], which claims to be able to handle any kind of data. Our experience has been that each kind of experimental data imposes certain requirements that are not present with the other. Thus, we are not attempting to integrate HypNMR [36] with HYPERQUAD because the NMR data usually consist of just single data points whereas HYPERQUAD is oriented towards data from titration curves. Likewise, we have a program PHAB already in an advanced stage of development as a separate entity. PHAB will deal with absorbance data at measured pH values so, unlike HYPERQUAD, the total hydrogen ion concentration is not known and the mass balance in protons is irrelevant. This imposes the need to calculate the free concentrations in a different way. The HYPERQUAD programs are highly modular so it is relatively easy to construct a new program for each substantially different kind of data. In addition, the user interface is standardized because it is based on a set of some 70 routines that constitute a HYPERQUAD subroutine library.

On the programming side, we must consider developing a Windows version of the software. The main advantages will be twofold. On the one hand we will be able to eliminate all restrictions on experimental data. At present the restrictions arise from the fact that we are limited to 640 k bytes of memory for program and data; that restriction disappears under Windows or with the use of a 32-bit compiler. The program which suffers most from this restriction is HydraSP, which can take a maximum of 57 344 data points (up to 28 spectra, each spectrum containing 2048 points). Second, there are restrictions imposed by what can be seen on the screen at any one time.

These restrictions can be removed by using automatically scrolling windows.

Simultaneous flow injection determination of iron(III) and vanadium(V) and of iron(III) and chromium(VI) based on redox reactions[1]

N. Teshima, K. Ayukawa, T. Kawashima*

Laboratory of Analytical Chemistry, Department of Chemistry, University of Tsukuba, Tsukuba 305, Japan

Abstract

A flow injection analysis (FIA) method is presented for the simultaneous determinations of iron(III)–vanadium(V) and of iron(III)–chromium(VI) using a single spectrophotometric detector. In the presence of 1,10-phenanthroline (phen), iron(III) is easily reduced by vanadium(IV) to iron(II), followed by the formation of a red iron(II)–phen complex ($\lambda_{max} = 510$ nm), which shows a positive FIA peak at 510 nm corresponding to the concentration of iron(III). On the other hand, in the presence of diphosphate the reductions of vanadium(V) and/or chromium(VI) with iron(II) occur easily because the presence of diphosphate causes an increase in the reducing power of iron(II). In this case iron(II) is consumed during the reaction and a negative FIA peak at 510 nm corresponding to the concentration of vanadium(V) and/or chromium(VI) is obtained. The proposed method makes it possible to obtain both positive (for iron(III)) and negative (for vanadium(V) or chromium(VI)) FIA peaks with a single injection.

1. Introduction

Redox potentials of metal ions vary upon the addition of a suitable ligand [1]. This phenomenon has the potential capacity for the development of new redox systems which are applicable to potentiometric titration [2–9]. By

[1] Presented at the 1995 International Chemical Congress of Pacific Basin Societies (PACIFICHEM '95) in the Symposium on Kinetic and Mechanistic Aspects of Analytical Chemistry, Honolulu, Hawaii, USA, December 17–22, 1995.

using the ligand effect, we have developed methods for the potentiometric titration of chromium(VI) and copper(II) with iron(II) in the presence of diphosphate and/or neocuproin [10], and for vanadium(V) with iron(II) in the presence of ligands such as citrate, diphosphate and EDTA [11]. We also showed that a redox reaction of iron(III) with vanadium(IV) proceeds completely in the presence of 1,10-phenanthroline (phen) [12]. By using these redox systems, new types of spectrophotometric flow injection analysis (FIA) methods have been developed for the determination of chromium(VI) [13] and the simultaneous

determination of vanadium(IV) and vanadium(V) [14]. The aim of the present study was to develop simultaneous photometric FIA determinations of iron(III)–vanadium(V) and of iron(III)–chromium(VI) based on new redox systems in which phen and diphosphate participate. The present method is simple: it is possible to observe both positive (for iron(III)) and negative (for vanadium(V) or chromium(VI)) FIA peaks with a single injection of the sample solution with a single detector.

2. Experimental

2.1. Reagents

All reagents were of analytical-reagent grade and were used without further purification. The water used to prepare the solutions was purified with a Milli-Q PLUS water system (Millipore).

A stock solution of iron(III) (0.1 M) was prepared by dissolving 4.82 g of iron(III) ammonium sulfate dodecahydrate in 100 ml of 0.5 M sulfuric acid and was standardized with EDTA. Stock solutions of vanadium(V) and iron(II) were prepared as described previously [11]. A stock solution of vanadium(IV) (5×10^{-2} M) was prepared by dissolving vanadium oxide sulfate (vanadyl sulfate) n-hydrate in 100 ml of 5×10^{-2} M sulfuric acid. The concentration of vanadium(IV) solution was determined by a standard potassium permanganate titration. A stock solution of chromium(VI) was prepared by dissolving appropriate amounts of potassium dichromate (a primary standard) in 5×10^{-2} M sulfuric acid. Working solutions of metal ions were prepared by suitable dilution with 5×10^{-3} M sulfuric acid. Ligand solutions (0.1 M) of phen and diphosphate were prepared as described previously [14].

2.2. Apparatus

A schematic flow diagram for the simultaneous determinations of iron(III) and vanadium(V) and of iron(III) and chromium(VI) is shown in Fig. 1. Two double-plunger micro pumps (Sanuki Kogyo, DMX-2000) and two six-way injection valves (Sanuki Kogyo, SVM-6M2) were used to assemble

the system. The flow lines were made from Teflon tubing (0.5 mm i.d.). The absorbance change was measured at 510 nm with a spectrophotometer (Soma Kogaku, S-3250) equipped with a 10-mm micro flow cell (8 μl) and recorded on a recorder (Chino, EB 22005). The pH of the waste solution was continuously monitored with a Corning Model 12 pH/mV meter.

2.3. Procedure

In the flow system (Fig. 1), a carrier solution of 5×10^{-3} M sulfuric acid (C), 0.1 M acetate buffer solution in reservoir R_1, a mixed solution of vanadium(IV) (5×10^{-5} M) and iron(II) (5×10^{-5} M) in reservoir R_2 and 1×10^{-3} M phen solution in reservoir R_3 were pumped at a flow rate of 1.0 ml min^{-1}. A 400 μl volume of sample solution (iron(III)–vanadium(V) or iron(III)–chromium(VI)) and 100 μl of a mixture of diphosphate and acetate buffer solution were loaded into SL and RL, respectively. The sample solution and the diphosphate solution were injected into the carrier of sulfuric acid and acetate buffer streams simultaneously: the former and the latter were passed through a 0.1 m long coil (C_1) and a 1.5 m long delay coil (C_2), respectively. By monitoring the absorbance of the iron(II)–phen complex at 510 nm, both a positive peak for iron(III) and a negative peak for vanadium(V) or chromium(VI) were obtained with a single injection of the sample solution. All measurements were carried out at room temperature.

3. Results and discussion

The conditional standard potential of the Fe(III)–Fe(II) system increases in the presence of phen because of the formation of the iron(II)–phen complex, i.e. log β_3 of the iron(II)–phen complex is higher than that of the iron(II)–phen complex [15]. Hence a redox reaction of iron(III) with vanadium(IV):

$$Fe^{3+} + VO^{2+} + H_2O \overset{K_{Fe-V}}{\rightleftharpoons} Fe^{2+}$$

$$+ VO_2^+ + 2H^- \tag{1}$$
occurred completely in the presence of phen, producing the iron(II)–phen complex ($\lambda_{max} = 510$ nm), although the redox reaction would not take place without phen [12]. Iron(III) can thus be determined by measuring the absorbance of the iron(II)–phen complex which shows a positive FIA signal at 510 nm.

On the other hand, the presence of diphosphate causes a decrease in the potential of the Fe(III)–Fe(II) system. In other words, the reducing power of iron(II) increases owing to the presence of diphosphate. Thus, the reduction of vanadium(V) with iron(II):

$$Fe^{2+} + VO_2^+ + 2H^+ \overset{K_{V-Fe}}{\rightleftharpoons} Fe^{3+} + VO^{2+}$$

$$+ H_2O \tag{2}$$
takes place easily [11]. The reduction of chromium(VI) to chromium(III) with iron(II):

$$6Fe^{2+} + Cr_2O_7^{2-} + 14H^+ \overset{K_{Cr-Fe}}{\rightleftharpoons} 6Fe^{3+} + 2Cr^{3+}$$

$$+ 7H_2O \tag{3}$$
also occurred completely in the presence of diphosphate [10]. In these reduction reactions, the absorbance at 510 nm of the iron(II)–phen complex produced in the reaction coil RC_2 (Fig. 1) decreases with increase in the concentration of vanadium(V) and/or chromium(VI) because of the consumption of iron(II) with vanadium(V) and/or chromium(VI). Hence the determination of vanadium(V) and/or chromium(VI) is possible from the decrease in the absorbance of the complex at 510 nm.

In the FIA system shown in Fig. 1, the baseline absorbance is kept constant (about 0.14) as a

Fig. 2. Successive merging profile of the sample solution with reagent solutions.

result of the formation of the iron(II)–phen complex in RC_2 (2 m long). Fig. 2 shows a successive merging profile of the sample solution with reagent solutions. The phen stream merges into the front of a mixed sample zone and the reduction of iron(III) with vanadium(IV) proceeds in RC_2; a positive FIA peak for iron(III) appears. The diphosphate zone which passed through the delay coil (1.5 m long) merges into the rear of the sample zone, and the reduction of vanadium(V) and/or chromium(VI) with iron(II) proceeds in RC_1; the appearance of a negative FIA peak for vanadium(V) and/or chromium(VI) follows after the positive peak. By monitoring the absorbance of the iron(II)–phen complex at 510 nm, both positive (for iron(III)) and negative (for vanadium(V) or chromium(VI)) FIA peaks are thus obtained with a single injection of the sample solution.

3.1. Effect of variables

The optimum conditions for the simultaneous determination of iron(III) and vanadium(V) were studied by injecting an aliquot (400 μl) of a mixed sample solution of iron(III) and vanadium(V) (both the iron(III) and vanadium(V) concentrations were 2×10^{-5} M) into the FIA system shown in Fig. 1. Similarly, to establish the optimum conditions for the simultaneous determination of iron(III) and chromium(VI), an aliquot (400 μl) of a mixed sample solution of iron(III) and chromium(VI) (both the iron(III) and vanadium(V) concentrations were 2×10^{-5} M) was injected into the system. The concentrations of iron(II) (5×10^{-5} M) and vanadium(IV) (5×10^{-5} M) in R_2 were selected for the procedure based on the previous results [14].

The effect of pH on the peak height was examined over the range 3.4–5.5 and the results are shown in Fig. 3. In the simultaneous determination of iron(III)–vanadium(V) (Fig. 3(a)), the positive peak height for iron(III) was maximum and constant in the pH range 4.8–5.5, whereas the negative peak for vanadium(V) gradually decreased with increase in the pH of the solution up to 4.8, being kept constant in the pH range 4.8–5.5. A pH of around 5 was selected for the procedure because the heights of the positive and negative peaks were almost same at this pH. In the case of iron(III)–chromium(VI) (Fig. 3(b)), the positive peak height was maximum and constant in the pH range 4.2–5.5, while the magnitude of the negative peak for chromium(VI) was about three times larger than that of the positive peak for iron(III) at pH around 5. The result is attributable to the number of electrons that took part in the oxidation of iron(II) with chromium(VI). A pH of around 5 was also selected for the procedure.

The effect of the phen concentration was examined over the range 1×10^{-4}–1×10^{-2} M at a constant concentration of diphosphate (2×10^{-3} M). As shown in Fig. 4(a), both the positive and negative peaks for iron(III) and vanadium(V) rapidly increased with increasing phen concentration, and were almost constant at phen concentrations higher than 3×10^{-4} M. Similarly, in the case of iron(III)–chromium(VI) (Fig. 4(b)), both the peaks for iron(III) and chromium(VI) were

Fig. 4. Effect of phen concentration on the FIA peak heights for (a) iron(III) and vanadium(V) and (b) iron(III) and chromium(VI). The broken line denotes the baseline. Other conditions as in the text.

almost constant at phen concentrations higher than 3×10^{-4} M. The concentration of phen was selected as 1×10^{-3} M.

The effect of the diphosphate concentration loaded into RL was examined over the range 1×10^{-4}–1×10^{-2} M at a constant concentration of phen (1×10^{-3} M). In the case of iron(III)–vanadium(V), the positive peak height for iron(III) was maximum and constant over the concentration range examined, whereas the negative peak for vanadium(V) rapidly increased with increase in the diphosphate concentration, as shown in Fig. 5(a). In the case of iron(III)–chromium(VI) (Fig. 5(b)), the peak height for iron(III) was also independent of the diphosphate concentration, whereas the negative peak for

Fig. 3. Effect of pH on the FIA peak heights for (a) iron(III) and vanadium(V) and (b) iron(III) and chromium(VI). The broken line denotes the baseline. Other conditions as in the text.

Fig. 5. Effect of diphosphate concentration on the FIA peak heights for (a) iron(III) and vanadium(V) and (b) iron(III) and chromium(VI). The broken line denotes the baseline. Other conditions as in the text.

chromium(VI) rapidly increased with increase in the diphosphate concentration because the oxidation of iron(II) with chromium(VI) should be favored in the presence of diphosphate. A 2×10^{-3} M diphosphate concentration was selected.

The effect of RC_1 length was examined by varying the coil length. Almost constant peak heights for iron(III) and vanadium(V) were obtained over RC_1 lengths of 0.1–5 m. The negative peak for chromium(VI) increased with increase in the coil length of RC_1 up to 1 m because the oxidation of iron(II) with chromium(VI) should be favored with an increase in the coil length of RC_1. A 0.2 m length of RC_1 was used, taking into account the sample throughput.

The effect of RC_2 length was examined over the range 0.5–5 m. The positive peak for iron(III) gradually increased with increase in the RC_2 length up to 2 m, and remained constant at RC_2 lengths of 2–5 m, while the negative peak for vanadium(V) gradually decreased with increase in the RC_2 length. In the case of iron(III)–chromium(VI), both the positive and negative peaks for iron(III) and chromium(VI) exhibited curves similar to those for iron(III)–vanadium(V). A 2 m length of RC_2 was selected for the procedure because at least a 2 m length was needed to obtain a stable baseline.

3.2. Calibration graphs and simultaneous analysis of synthetic mixtures

Calibration graphs for iron(III), vanadium(V) and chromium(VI) were individually prepared; each sample solution was injected together with diphosphate solution into the flow system. The calibration graphs for iron(III) and vanadium(V) were linear over the range 1×10^{-6}–2×10^{-5} M, whereas the graph for chromium(VI) was slightly curved over the range 1×10^{-6}–2×10^{-5} M. The reproducibility of the method was satisfactory with relative standard deviations of 0.54, 0.82 and 0.47% for 10 determinations of 2×10^{-5} M iron(III), vanadium(V) and chromium(VI), respectively. The proposed method permits the analysis of 30 samples h^{-1} (60 peaks h^{-1}).

The simultaneous determinations of iron(III)–vanadium(V) and of iron(III)–chromium(VI)

were carried out on synthetic mixtures by using each calibration graph and the results are summarized in Table 1. Typical flow signals when equimolar mixed sample solutions of both ions were injected into the FIA system are shown in Fig. 6. The recovery and reproducibility of the method were satisfactory.

4. Conclusions

A simple and rapid flow injection procedure is proposed for the simultaneous determinations of iron(III) and vanadium(V) and of iron(III) and chromium(VI) by using the effect of ligands on the redox potential of the Fe(III)–Fe(II) system with a single spectrophotometric detector. The method can be successfully applied to the determination of iron(III)–vanadium(V) and iron(III)–chromium(VI) in synthetic mixtures.

Chemiluminometric method for the determination of glycerol in wine by flow-injection analysis with co-immobilized glycerol dehydrogenase/NADH oxidase

Nobutoshi Kiba*, Naoki Azuma, Motohisa Furusawa

Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan

Abstract

A flow-injection method for the determination of glycerol in wine is described. Glycerol dehydrogenase and NADH oxidase were co-immobilized on poly (vinyl alcohol) beads and incorporated in a flow-injection system. The hydrogen peroxide produced was detected chemiluminometrically via a luminol–hexacyanoferrate (III) reaction. Wine was diluted 1000-fold with water and sample solution (50 μl) was injected into the carrier stream. The calibration graph was linear in the range 3×10^{-7}–3×10^{-4} M; the detection limit was 7×10^{-8} M and the sample throughout was 30 h^{-1} without carryover.

Keywords: Chemiluminescence; Enzyme reactor; Flow injection; Glycerol; Wine

1. Introduction

Glycerol, which is a by-product of alcohol fermentation, affects the sensory characteristics of wine, especially richness of taste.

Enzymatic flow-injection (FI) methods for specific determination of glycerol in wine have been developed using immobilized glycerol dehydrogenase (EC 1.1.1.6, GDH) [1,2]. In this system a basic buffer (pH 10.0) and a high concentration of NAD^+ (10 mM) were used to shift the reaction equilibrium towards dihydroxyacetone production, since the reaction is reversible and the equilibrium consant [3] of the reaction [Glycerol

$+ NAD^+ \rightleftharpoons$ dihydroxyacetone $+ NADH + H^+$] is 5×10^{-12}. Co-immobilized GDH/NADH oxidase reactor, which was prepared by covalently bonding to CNBr-activated Sepharose 4B, was used in a FI system for the determination of glycerol in wine with a Clark-type oxygen electrode [4]. In this system, a lower pH (9.2) and a lower concentration of NAD^+ (5 mM) were used because NADH oxidase (NAOD), which catalyzes the reaction in which NADH is oxidized by molecular oxygen to form hydrogen peroxide [$NADH + O_2 + H^+ \rightleftharpoons NAD^+ + H_2O_2$], serves as a trapping enzyme. In spite of much experimental effort, the method is not very sensitive; the lower limit of detection was 100 μM.

A chemiluminometric FI method has been proposed in which GDH and NAOD are separately

immobilized on controlled pore glass (CPG) and used in series under conditions of pH 9.0 and 5 mM NAD^+; the method is moderately sensitive, with a detection limit of 25 μM [5]. However, the method is unsuitable for use in routine analysis because CPG, used as a support for the enzymes, is unstable in alkaline solution [6]. An FI system [7] with co-immobilized glycerol kinase and glycerol-3'-phosphate oxidase and the chemiluminometric detection of H_2O_2 with luminol has been reported which provides a lower sensitivity than the amperometric FI methods with an immobilized GDH reactor [1,2]; the lower limit of detection was 138 μM.

FI methods with an immobilized enzyme reactor are subject to interference from polyphenols and dyes in wines because the compounds are adsorbed by the reactor and the accumulation of the compounds causes the inactivation of the enzyme [8,9]. Sensitive detections system permit the use of the method without the need for tedious sample pretreatment, except for dilution. This paper describes a chemiluminometric FI system for the sensitive determination of glycerol in wine with a co-immobilized GDH/NAOD reactor. A simple chemiluminometric FI system for the determination of glycerol can be achieved by coupling a co-immobilized GDH/NAOD reactor with a luminol chemiluminescence assay for the detection for H_2O_2, since the chemiluminometric reaction was carried out in media buffered at pH 10–11 [10,11]. In the present system, the enzymatic reactions and the chemiluminometic reaction were performed in the same buffered solution (0.1 M carbonate buffer pH 10.0). GDH and NAOD were co-immobilized on poly (vinyl alocohol) beads. GDH from Cellulomonas sp. [5] was used in this work and is much more stable than enzymes from Entrobacter aerogenes [1,2,4]. This method was applied to the determination of glycerol in wines without any pretreatment procedure, except for dilution.

2. Experimental

2.1. Reagents

GDH (from Cellulomonas sp., 56 U mg^{-1}) and

NAOD (EC number not assigned, from Bacillus stearothermophilus, 55 U mg^{-1}) [12] were obtained from Toyobo (Osaka, Japan) and Asahi Kasei (Tokyo, Japan) respectively. The activity for each enzyme was measured spectrophotometrically at 340 mm with glycerol or NADH as substrate at pH 10.0 at 38°C.

NAD^+ (free acid, 95%) and NADH (disodium salt, 99.5%) were purchases from Kohjin (Tokyo, Japan) and Boehringer Mannheim respectively. Glycerol was purchased from Sigma (St. Louis, MO). Poly (vinyl alcohol) beads (GS-520, 13 μm) were obtained from Showa Denko (Tokyo, Japan). All other chemicals, which were from Wako Pure Chemical (Tokyo, Japan), were of analytical-reagent grade.

A stock solution (1 mM) of glycerol was prepared by dissolving in water. Standards were prepared by diluting the stock solution with 5 mM ethanol solution. A potassium hexacyanoferrate (III) stock solution (200 mM) was prepared and diluted tenfold with water before use. Luminol solution (1.2 mM luminol in carbonate buffer (pH 10.0 comprising 0.3 M potassium carbonate/0.3 M potassium hydrogen carbonate) was prepared and allowed to stand for 2 days at room temperature to attain stability before use [11,13]. NAD^+ solution (1.5 mM NAD^+ in 0.01 M phosphate buffer (pH 7.0) was prepared daily.

2.2. Enzyme immobilization

The beads (2.0 g) were suspended in 30 ml of 30% chloromethyloxirane in 3 M NaOH. The suspension was incubated at 50°C for 1.5 h with shaking. The beads were allowed to react with concentrated aqueous ammonia (30 ml) at 40°C for 3 h. The attached amine amounted to 3.0 meq g^{-1} of dry beads. The aminated beads were packed into a stainless-steel column (4 cm × 4 mm i.d.) by the slurry-packing method. Glutaraldehyde (2% w/v) in 0.05 M phosphate buffer pH 7.0 was pumped through the column for 40 min at 0.2 ml min^{-1} and then the column was washed with deaerated water for 15 min at 0.6 ml min^{-1}. Enzyme solution (5 mg GDH (280 U) and 5 mg NAOD (275 U) in 10 ml of 0.1 M phosphate buffer pH 7.0) was circulated through the column

at 0.2 ml min⁻¹ for 6 h at 10°C. The time course
of the immobilization process for NAOD was
monitored by a spectrophotometer (Jasco Uvidec-
100-VI) with a flowthrough cell at 380 nm. The
immobilization yield was evaluated by the de-
crease in absorbance. NAOD was immobilized
with a 88% yield. The reactor was washed with
the NAD solution and stored in a refrigerator
when not in use.

For the purpose of comparison, an immobilized
GDH reactor was prepared in the same manner
by using an enzyme solution without NAOD.

2.3. Flow system and procedure

Fig. 1 shows a block diagram of the FI system
used in this work. The system consisted of four
piston pumps (Hitachi L-6000), an injector valve
(Sanuki SVI-6M2) equipped with a 50 μl loop, a
reactor, a water bath, a luminometer (Soma S-
3400) with a flowthrough cell (100 μl) connected
to a signal cleaner (SIC SC77) and a recorder
(TOA FBR-251A).

Wine was diluted 1000-fold with water and an

aliquot (50 μl) was injected into a carrier stream.
The results obtained by the present method were
compared with those obtained by use of an F-kit
(Boehringer Mannheim) with soluble enzymes,
glycerokinase (GK), pyruvate kinase (PK) and
lactate dehydrogenase (LDH), and co-factors,
ATP and NADH.

3. Results and discussion

3.1. Reactor performance

To establish the optimum conditions for the
co-immobilized GDH/NAOD reactor, the system
shown in Fig. 2 using a luminometer was used
and measurements were made to study the influ-
ence of pH, temperature and the NAD⁺ concen-
tration.

The effect of pH on the peak height was studied
in the range 9.0–11.0 using 0.2 M K₂CO₃/

KHCO$_3$ carbonate bufferes by injecting 100 μM glycerol (50 μl). The optimum pH for the enzymatic reactions was about 10.0. The peak height was not affected when the concentration of carbonate buffer (pH 10.0) was varied in the range 0.2–0.3 M; 0.3 M carbonate buffer was used in this system (Fig. 1). The effect of temperature on the peak height was examined in the range 30–45°C. The maximum peak height was obtained at 35°C. The reactor was kept at 30°C to prolong its lifetime. The effect of NAD$^+$ conentration on peak height was investigated in the range 0.1–5 mM by injecting 100 μM glycerol (Fig. 3). The maximum peak height was obtained between 1 and 3 mM NAD$^+$; the NAD$^+$ concentration in the reactor is between 0.5 mM and 1.5 mM. For GDH reaction at lower NAD$^+$ concentrations the equilibrium of the reaction is shifted to the left, but for NAOD reaction higher NAD$^+$ concentrations are undesirable for the production of H$_2$O$_2$. A 1.5 mM NAD$^+$ solution was used in this system; as shown in Fig. 1, as the solution was diluted three-fold with the luminol solution and

carrier stream, the concentration in the reactor is 0.5 mM. The result was compared with that of an immobilized GDH reactor. The dependence on NAD$^+$ concentration in an immobilized GDH reactor was studied in the range 0.1–5 mM using the system shown in Fig. 2 with a spectorfluorimeter (Jasco FP-210, with flowthrough cell (15 μl), $\lambda_{ex} = 340$ nm, $\lambda_{em} = 465$ nm) instead of the luminometer, by rotating the rotor of the three-way valve. The variation of peak height with the NAD$^+$ concentration is depected in Fig. 3; for NAD$^+$ below 4 mM, there was dependence of the concentration on the peak height. The results show that NAOD functions as a trapping enzyme in the co-immobilized GDH/NAOD reactor.

The influence of luminol concentration on the peak height was studied from 0.3 mM to 6 mM, using the system shown in Fig. 1. The peak height increased with an increase in the concentration. However, the inactivation of the reactor commenced at concentrations > 1.5 mM. As a compromise between sensitivity (peak height) and stability, a luminol solution of 1.2 mM was used; the luminol concentration in the reactor is 0.4 mM.

Under the conditions shown in Fig. 1, standard glycerol solution (100 μM) was injected into the system and the peak height was compared with the peak height for hydrogen peroxide. The conversion efficiency was 68%. The relative activities for glycerol (50 μM), 1, 2-propanediol (50 μM), 1, 2-butanediol (50 μM), 1, 2-ethanediol (50 μM) and ethanol (1 mM and 5 mM) were 100, 28, 20, 3, 4 and 5 respectively.

The operational stability of the reactor was evaluated over a period of 4 weeks. The reactor was used for 3 h per day (90 injections of 100 μM glycerol solution containing 3 mM ethanol) and then washed with the NAD$^+$ solution and stored in a refrigerator when not in use. The activity decreased slowly to 83% of the initial value after 4 weeks (2500 injections).

The influence of sulfite on the peak height for glycerol (50 μM) was measured in the range 5–50 μM. The presence of equimolar amounts of sodium sulfite depressed the peak height to 85% and the peak height was not influenced by the presence of < 15 μM sulfite; since normally the

Fig. 3. Effect of NAD$^+$ concentration on the peak height: (○) = chemiluminescence detection, the peak height for 1 mM NAD$^+$ solution was taken as 100; (●) = fluoresence detection, the peak height for 5 mM NAD$^+$ solution was taken as 100. The results were obtained by using the system shown in Fig. 2.

concentration of glycerol in wine is not less than 10 times that of total sulfite [14], this method is not subject to interferenes from sulfites in wine. Under the same conditions, the peak height did not change with the presence of carbonates such as tartrate, citrate, lactate, succinate and acetate up to 1 mM.

The peak height was measured by changing the flow rates of the NAD^+ solution, the luminol solution and the carrier stream under the conditions shown in Fig. 1, keeping the flow rate ratio of the solutions at 1.0. The peak height decreased linearly on altering the total flow rate from 0.3 to 0.9 ml min^{-1}. Glycerol reacted in 92 and 44% yields at flow rates of 0.3 and 0.9 ml min^{-1}, respectively, and the half-peak width for the former was about twice that of the latter. A total flow rate of 0.6 ml min^{-1} (0.2 ml min^{-1} each) was selected, as a compromise between sensitivity (peak height) and sample throughout; at this flow rate the sample throughput was 30 h^{-1}.

3.2. Calibration

The plot of peak height against glycerol concentration was linear from 0.3–300 μM. Each standard solution contained 5 mM ethanol because in this reactor 1–5 mM ethanol concentrations were oxidized at a 5% relative activity of glycerol and normally wine contains 1.5–3 M (7–14%) ethanol; in this method wine was diluted 1000-fold with water. The least-squares calibration equation for glycerol was $Y = 0.9524X + 7.076$, where Y is log(peak height (cm)) and X is log(glycerol concentration (M)), with a linear correlation coefficient of $r = 0.9998$ (15 data points). The relative standard deviation (RSD) for seven replicate injections of 50 μM glycerol was 0.51%. The RSD ($n = 7$) for 50 μM glycerol in the system shown in Fig. 2 was 1.3% because of incomplete mixing of the luminol solution with the reactor eluent. The lower limit of detection (signal-to-noise ratio = 3) was 7×10^{-8} M.

3.3. Application

This system was used to determine the amount of glycerol in wine.

3.3.1. Precision and reproducibility

Red wine was repeatedly analyzed over a period of 3 weeks. The reactor was used for analyses of 90 samples per day and standards were measured at 30-sample intervals, in order to check the variation of the conversion efficiency. Since the conversion efficiency decreased linearly to 81% of the initial value after 3 weeks (1990 injections) because of the accumulation of polyphenols and dyes, the reactor was renewed every 10 days. This method gave precise and reproducible results; for red wine containing 73.4 mM glycerol (6.75 g 1^{-1}), the intra-day RSD was 0.67% and the outer-day RSD was 0.98%.

3.4. Comparison

The results ($n = 25$:13 red wines, 57.6–91.8 mM; 12 white wines, 45.8–57.3 mM) were compared with those obtained by use of an F-kit with soluble GK, PK and LDH. The calculated linear regression equation was $Y = 0.9997X + 1.126$ with a correlation coefficient of $r = 0.9988$ respectively. The present method gave slightly bigger values, because GDH oxidizes the diols present in wine.

4. Conclusion

The FI system with a co-immobilized GDH/ NAOD reactor and chemiluminescence detection is useful for the sensitive measurement of glycerol in wine without the need for any pretreatment procedure, except for dilution. Compared with the chemiluminometric FI method utilizing immobilized GDH and NAOD reactors [5] in series, the NAD^+ concentration is about three times lower and the sensitivity is 250 times higher. The co-immobilized GDH/NAOD reactor is stable enough to permit the measurment of more than 900 samples.

Adsorption–desorption and leaching of phenylurea herbicides on soils

Christine M. Fouqué-Brouard, Josette M. Fournier*

Centre Régional d'Etude des Produits Agropharmaceutiques (CREPA), 8 rue Becquerel, 49070 Beaucouzé, France

Abstract

Adsorption–desorption equilibria of phenylurea herbicides (chlortoluron, isoproturon, metobromuron, chloroxuron, difenoxuron) were determined in two different soils. Organic carbon content of the soils ranged from 1.1–5.6% and the clay fraction from 25–30%. Spiked aqueous suspensions of soils were centrifuged and urea derivative concentrations in the aqueous phase were determined using a HPLC–UV system. Adsorption isotherms conformed to the Freundlich equation. Freundlich K_f values indicated that organic carbon was the main factor affecting urea sorption in the studied soils. The R_f values calculated from the soil column displacement closely correlated with the adsorption K_f values. Results indicated that chloroxuron and difenoxuron were sorbed to a larger extent than the other three ureas on the two soils; as expected their mobilities through soil columns were very limited. The similarity between the molecular structures of chloroxuron and difenoxuron enables us to assume the phenoxy group to be the main structural feature in the adsorption phenomenon. The relationships between sorption, leaching and some characteristics of urea molecules such as water solubility and octanol–water partition coefficient were also examined.

Keywords: HPLC; Leaching; Phenylurea herbicides; Soil; Sorption

1. Introduction

Extensive information is required concerning the persistence and leaching of organic herbicide compounds which come into contact with soil. This is important for agronomic and environmental reasons. Persistence and leaching determine the possible contamination of groundwater. The behavior of pesticide residues in soils mainly depends on the amount of water moving through

the soil and to the extent to which pesticides are retained in soils, which in turn depends on the sorption properties of the soil. Soils are multicomponent mixtures [1,2]. Sorption of pesticides in soil systems has been extensively studied, but desorption is not yet fully understood [3–5]. Organic pesticides adsorb on both organic and inorganic surfaces depending on the chemical properties of the adsorbents and adsorbates involved [6]. Adsorption results in the binding of molecules in thin layers on the surface of solids and the binding forces vary from weak (van der Waals interac-

tions) to very strong (specific adsorption of ions). Several investigators have shown that herbicidal efficiency and performance are related to the organic carbon content of soils [7,8]. Correlations between adsorption and soil organic carbon content are common [3,9]. Soil organic carbon is considered to be the most important adsorbing material for un-ionized pesticides.

The purpose of this analytical study was to obtain information on which structural groups of phenylurea are concerned in adsorption–desorption phenomena of two soils with different organic matter contents. After reaction of the soil with a solution of urea derivative of known composition at fixed temperature and pressure for a prescribed period of time, chemical analysis of the soil solution was performed to determine its urea composition using a HPLC-UV system. Ureas may be persistent herbicides and are frequently used in crop production.

Batch tests and soil column displacement studies were performed. The chosen ureas were isoproturon (N'-(4-isopropylphenyl)-N,N-dimethylurea), chlortoluron (N'-(3-chloro-4-methylphenyl)-N,N-dimethylurea), metobromuron (N'-(4-bromophenyl)-N-methoxy-N-methylurea), chloroxuron (N'-[4-(4-chlorophenoxy)phenyl]-N,N-dimethylurea), and difenoxuron (N'-[4-(4-methoxyphenoxy)phenyl]-N,N-dimethylurea). The adsorption–desorption processes determine the bioavailability and potential leaching of the ureas. A common parameter for modelling the transport of organic pesticides in soil is the adsorption coefficient K_{oc}, which is a measure of the partition of the chemical between the soil organic matter and the water phase. Adsorption of non-polar pesticides is mainly attributed to hydrophobic bonding. The octanol–water partition coefficient K_{ow} is widely used to predict the

behavior of organic pesticides in the environment [10–12].

2. Experimental

2.1. Herbicides and soils

Two soils (from Grignon (Yvelines, France) and Becon (Maine et Loire, France)) were chosen to provide different organic matter contents. Classical physical and chemical characteristics of these soils are given in Table 1 (data from Laboratory of Soils Analysis, Ancenis, Loire-Atlantique, France). The soils were air-dried and sieved through a 2 mm screen. They contained 3% and 10% w/w moisture respectively.

The herbicides were metobromuron, isoproturon, chlortoluron, chloroxuron and difenoxuron (Fig. 1). All herbicides had 97–100% purity (Dr. Ehrenstorfer, GmbH). Their water solubilities were 1300, 350, 330, 13 and 70 μmol l^{-} respectively [13,14]. The octanol–water partition coefficients (log K_{ow}) for metobromuron, isoproturon, chlortoluron and chloroxuron were 2.41, 2.25, 2.29 and 3.20 respectively [13]. In the case of difenoxuron, the octanol–water partition coeffi-

Difenoxuron	14.95	246.8

cient is calculated from the retention time obtained with reversed-phase HPLC [15].

2.2. Materials and methods

2.2.1. Materials

Methanol was HPLC-grade obtained from S.D.S. (Peypin, France). Water for HPLC was purified with a Seral System (Grosseron, St. Herblain, France).

2.2.2. Liquid Chromatograph System

HPLC analysis was performed with a Waters 600 liquid chromatograph equipped with a photodiode array detector (Waters 991) and an integrating system (NEC Powermate SX Plus and Waters 5200 Printer Plotter). The analysis were performed on a 25 cm × 4.6 mm i.d. Lichrospher RP-18 column and on a 1.4 cm × 4.6 mm i.d. Lichrosorb RP-18 pre-column. The injected volume was 25 μl (syringe, Model U6K, Hamilton), the flow rate was 1 ml min^{-1} and the eluent was a mixture of deionized water and methanol (40:60 v/v) (isocratic mode). The wavelength of maximum absorption for the five ureas ranged from 241–245 nm and retention times were between 12 and 15 min with the exception of that of chloroxuron which was 30 min (Table 2).

2.2.3. Preparation of standards

Standard stock solutions (2 × 10^{-3} M) were

prepared from the crystalline solids using methanol. Working standards were obtained by suitable dilutions of the stock solutions with methanol.

2.2.4. Linearity study

Standard concentrations ranging from 4 × 10^{-7} –2 × 10^{-4} M with internal standard (diuron at 10^{-4} M) were used to determine peak area response vs. concentration of urea derivative. The limit of detection was 2 × 10^{-7} M.

2.2.5. Reproducibility study

Two standard solutions were analyzed several times on the same day and on different days to determine the intra- and inter-day HPLC variations. The intra-assay % RSD based on 10 determinations done on the same day was 0.6%. The inter-assay % RSD based on 10 determinations done on five different days was 1%.

2.3. Sorption rate experiments

Batch sorption tests were performed in 50 ml flasks at 21 ± 1°C. 10 g of air-dried soil was equilibrated with 20 ml of a urea solution (40 μM urea in demineralized water pH 6.1) and methanol mixture (40:1 v/v). The samples were shaken with a mechanical shaker (Gyrotory Water Bath Shaker Model G76, New Brunswick Scientific Co., USA) at 20–22°C.

The rate of each phenylurea adsorption versus time was measured and used for evaluating the equilibration period for later K_f determinations. At different times (5, 20, 50 min, etc.), the suspension was centrifuged at 5000g for 15 min (Grignon soil) or 30 min (Becon soil). The difference in the centrifuging time is due to the different organic matter contents of the soil. The concentrations of nonsorbed solutes in a 450 μl aliquot of clear supernatant, with 50 μl of internal standard added, were determined by an HPLC procedure. Soil-sorbed amounts of urea derivatives were calculated as the difference between the initial urea concentration and the equilibrium concentration previously determined.

Table 3
Freundlich parameters of ureas in the soils (K_f and n are calculated with the Freundlich equation; C, μM; x/m, μmol g^{-1}; $K_f = 100$ K_f)

Parameter	Mean ± d[a] Metobromuron	Isoproturon	Chlortoluron	Chloroxuron	Difenoxuron
Grignon soil

n	0.64 ± 0.03	0.66 ± 0.02	0.73 ± 0.03	0.90 ± 0.01	1.08 ± 0.03
r	0.99	0.99	0.98	0.99	0.97

[a] Absolute deviation.

For K_f determinations, the soil sample was stirred with 20 ml of a herbicide solution with different urea derivative concentrations (C_0, the initial concentration of urea, ranged from 4–200 μM). After the equilibration period (24 h), the suspension was centrifuged as described above. An aliquot of the liquid phase was analysed using the HPLC procedure. Urea derivative solutions without soil were prepared in the same way: no adsorption was observed on the walls of the flasks. Blank samples (soil with pure water) without urea derivative were also prepared in the same way: no peaks with the same retention times as urea derivatives were observed.

Adsorption isotherms parameters were calculated according to the Freundlich equation:

$$x/m = K_f \cdot C^n$$

where x/m is the rate of herbicide sorbed (per urea mass/soil mass), C is the herbicide concentration at equilibrium and K_f and n are empirical adsorption parameters calculated from experimental data using least-squares fitting. Each experiment was replicated twice with each soil and the reported results are the means of the two assays (Table 3).

Desorption studies were conducted on three herbicide solutions (20, 60 and 100 μM). After adsorption, according to the above experiment, and centrifugation, supernatant was replaced with a similar volume of demineralized water without

herbicide. Centrifuge tubes were shaken for 24 h at 21 × 1°C.

Desorption was achieved by removing all the supernatant from the centrifuged samples and then replacing it with demineralized water. This equilibration process was repeated five times. Each time an aliquot of the supernatant was analysed by HPLC. The amount of herbicide that remained on the soil was calculated as the difference between the initial amount and the desorbed amount.

2.4. Soil column displacement studies

Movement of the urea derivatives through saturated soil columns was estimated using the displacement technique: chromatography columns (1.5 cm i.d. × 30 cm) were packed with 10 g of soil and saturated with demineralized water. The flow rate was constant (3 ml h^{-1}). Then, a urea derivative solution (4 × 10^{-6} M) was injected into the column. Elution was stopped when the effluent concentration approached, or became identical to, the input concentration. At this stage, demineralized water was injected into the column to observe the desorption of urea derivatives. Column effluents were collected with an automatic fraction collector (Gilson Fraction Collector FC 203B) every 30 min. The concentration of urea deriva tive in the effluent was determined by the HPLC procedure.

3. Results and discussion

3.1. Soil adsorption–desorption study

The equilibrium was attained practically within 8 h (Fig. 2). When equilibrium was reached more

chloroxuron than the other molecules was retained in the two soils. According to Gilchrist et al. [16], when a pesticide is mixed with soil it reacts with active sites that are available on the surfaces of the soil particles. Some are very reactive, so that they can hold pesticide molecules

strongly, while others are not reactive enough. The loosely bound pesticide molecules desorb.

With difenoxuron, chloroxuron and isoproturon, and Grignon soil, adsorption followed a rapid adsorption phase in which the amount of adsorbed urea increased rapidly. This first reaction phase is followed by some decrease before the attainment of a stationary state. Metobromuron and chlortoluron with Grignon soil, and all urea derivatives with Becon soil, did not show such a decrease. With atrazine the decreasing phase has been attributed to the diffusion of the molecules in the soil microporosities [16]. For the two soils significant amounts of chloroxuron and difenoxuron, compared to the other molecules, were retained in the soil. A greater amount of urea derivative was adsorbed by the Becon soil components than by the Grignon soil components.

Fig. 3 shows the adsorption isotherms of urea derivative in the Becon soil (Freundlich isotherms, $x/m = f(C)$). Adsorption isotherms in the Grignon soil are similar. The isotherms of metobromuron, isoproturon and chlortoluron are of the L-type according to the classification of Giles et al. [17] but the chloroxuron and difenoxuron isotherms are of the H-type. The H-type isotherms are usually interpreted as being due to a high relative affinity of the soil particles for the solutes, indicating a minor competition between solute and solvent molecules towards the adsorbing sites. The empirical Freundlich equation closely described the adsorption on the soil. The calculated parameters K_f and n, together with the coefficients r for the linear fit, are given in Table 3. Inspection of the data listed in this Table indicates that K_f follows the organic matter content in the soils. This trend agrees with the results of other studies which showed the part played by the organic matter in the adsorption processes [3,7,8,18]. With the exception of chloroxuron (Grignon) and difenoxuron (Becon), n values are less than unity, which is the result of decreasing adsorption as the adsorptive sites become occupied and this is in accordance with the results of Kozak and Weber [19] and Grover [20] for phenylurea herbicides.

For each urea, the x/m value was calculated with C equal to 20 μM from the Freundlich equations previously determined. The results were: 2.4×10^{-2} μmol g^{-1} for isoproturon, 3.5×10^{-2} μmol g^{-1} for metobromuron, 3.6×10^{-2} μmol g^{-1} for chlortoluron, 20.9×10^{-2} μmol g^{-1} for difenoxuron and 26.3×10^{-2} μmol g^{-1} for chlorxuron with the Grignon soil, and 7.3×10^{-2} μmol g^{-1} for isoproturon, 13.1×10^{-2} μmol g^{-1} for chlortoluron, 14.3×10^{-2} μmol g^{-1} for metobromuron, 69.5×10^{-2} μmol g^{-1} for difenoxuron and 114.8×10^{-2} μmol g^{-1} for chloroxuron with the Becon soil. These doses decrease in the order chloroxuron > difenoxuron > chlortoluron > me tobromuron > isoproturon for the Grignon soil and in the order chloroxuron > difenoxuron > metobromuron > chlortoluron > isoproturon for the Becon soil. The value of n for the adsorption of chloroxuron on the Grignon soil deviated from unity. This can be explained by the inversion of chloroxuron and difenoxuron according to the range of x/m values compared with the range of K_f values on the Grignon soil. The phenoxy group of chloroxuron and difenoxuron molecules is thought to be responsible for the increase in retention.

Fig. 3. Urea adsorption isotherms on the Becon soil.

Fig. 4. Desorption and adsorption isotherms of difenoxuron on Becon soil.

An example of urea derivative desorption curves (D) is presented (difenoxuron desorption) together with the adsorption curve (A) in Fig. 4, where C_0 is the initial concentration of urea derivative. The humic compounds which are present in the Becon soil increased the percentage of non-desorbable urea as shown in Table 4. Metobromuron, chlortoluron and isoproturon desorptions are higher than those of chloroxuron and difenoxuron. Desorption isotherms show hysteresis for the two phenylphenoxyureas, indicating specific interactions.

3.2. Leaching

Figs. 5 and 6 show the curves of urea derivative mobilities through soil columns. The eluent volume needed for a urea to obtain 50% of the inlet concentration in the effluent $(C/C_0 = 0.5)$ was used as a direct estimation of its retardation factor. No tracer experiments were made in this study to estimate the residence time and dispersion of a non-adsorbate solute. The retardation factors obtained for ureas in Becon soil columns were greater than in Grignon soil columns. The organic matter content, which is higher in the Becon soil, could be responsible for the low urea mobilities through the Becon soil column. Because of the strong retention of chloroxuron in the soils, we were not able to determine its retardation factor; the adsorption process was so long that the value $C/C_0 = 0.5$ could not be reached even after 300 ml (Grignon) and 1500 ml (Becon). The retardation factor of an urea derivative correlates directly with its K_f value. Therefore chlorox uron and, in minor proportion, difenoxuron, in

Table 4
Percentage of urea remained adsorbed after five desorptions (C_{init}, initial urea concentration in μM; Q_0, dose of urea adsorbed before desorption in μmol g^{-1})

10^{-4}	72	15.90	72	12.97	52	15.67	65	20.43	83	19.79

contact with a soil of high organic matter content might be less mobile in the soil profile than other urea derivatives. The close similarity in molecular structure and polarity of the two chemical compounds would suggest that other factors are involved in their different mobilities in soil. The most obvious cause could be their relative solubility in water. Chloroxuron is much less water soluble than difenoxuron. Since adsorption and leaching are often related to water solubility within a given herbicidal class, this may explain the reduced leachability of chloroxuron in comparison with other urea derivatives [21,22].

3.3. Relations with S_w and K_{ow}

Urea derivatives are adsorbed to a lesser extent in Grignon soil than in Becon soil. This difference may be attributed to the difference in soil characteristics since Becon soil has a higher organic matter content than Grignon soil. Because of the importance of the organic matter content in herbicide adsorption, especially with neutral molecules, the distribution coefficient K_f must be correlated with the organic matter content which is given by the relationship $K_{oc} = K_f/$%OC, where OC is the fraction of organic content in dry soil [3]. The solubilization in natural organic matter is due to a hydrophobic effect. Experimental and predicted thermodynamic data have shown that K_{oc} is closely correlated with

the octanol–water partition coefficient K_{ow} and the water solubility S_w [23] of the chemical product. Water solubility governs the retention of pesticides in soils. Chiou et al. [24] demonstrated that water solubility is the primary factor controlling the partition of nonionic organic solutes between soil organic matter and water.

Fig. 7 shows curves of log K_{ow} and log S_w versus log K_{oc}. Values of the sorption coefficient normalized by the organic carbon content of the soil (K_{oc}) are plotted on the horizontal scale, and solute water solubility (log S_w) and octanol–water partition coefficient (log K_{ow}) are plotted on separate vertical scales. As expected K_{oc} increases with the hydrophobic character of the molecules. As previously observed, binding is related not only to solubility parameters but also to the composition and molecular structure of both the soil and the associated molecules. The high binding of chloroxuron and difenoxuron could be attributed to the phenoxy group. The methoxy group of difenoxuron increases the electronic density on the aromatic ring. It may also be possible that the adsorption process involves charge transfers in the case of the difenoxuron molecule.

With the exception of chloroxuron, log K_{ow} correlates well with log K_{oc}. Therefore, the distribution of urea derivatives (except chloroxuron) can be viewed as partition (solubilization) between soil and water and distinguished from adsorption (surface condensation).
Fig. 5. Cumulative metobromuron (■); isoproturon (□); chlortoluron (◆); chloroxuron (▲); and difenoxuron (◇) leached in Grignon soil columns.

Fig. 6. Cumulative metobromuron (■); isoproturon (□); chlortoluron (◆); chloroxuron (▲); and difenoxuron (◇) leached in Becon soil columns.
Fig. 7. Variations of log (K_{ow}) ($\square$) and log (S_w) (μM) ($\blacksquare$) versus log (K_{oc}): (1) isoproturon; (2) chlortoluron; (3) metobromuron; (4) difenoxuron; (5) chloroxuron.

4. Conclusion

An understanding of the sorption mechanism is fundamental for predicting the fate and distribution of many organic contaminants. Analytical data indicate that sorption of these urea derivatives by soils in the presence of water exhibits the characteristics of a partition process. With respect to pesticide–soil interactions the environmentally important distribution of urea derivatives between soil and water has been estimated by measuring K_f and R_f values. It is confirmed that organic matter content is an important soil component [25]. Results presented here show a relatively high soil sorption (and low soil mobility) for chloroxuron and difenoxuron compared to isoproturon, metobromuron and chlortoluron. Therefore, it seems that the adsorption in soils is conditioned by the phenoxy group. The combination of the three factors (structural feature, hydrophobicity and organic matter content of soil) is responsible for the K_f and R_f values of chloroxuron being significantly higher than the others. However, the adsorption mechanism on soil is probably more

complex than that usually accepted for neutral molecules and hydrophobic partitioning is only one of the processes involved.

Fiber optic sensor for laser-induced room-temperature phosphorescence detection of polycyclic aromatic compounds

A.D. Campiglia,[1] T. Vo-Dinh*

Advanced Monitoring Development Group, Health Sciences Research Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6101, USA

Abstract

The development of a fiber optic sensor for the analysis of polycyclic aromatic compounds based on laser-induced room-temperature phosphorimetry is reported for the first time. A pulsed nitrogen laser was used to excite phosphorescence emission from compounds imbibed on filter-paper substrates. Thallium(I) acetate (0.1 M) was used to enhance phosphorescence emission from chrysene, 1,2-benzofluorene, 7,8-benzoquinoline, phenanthridine and 5,6-benzoquinoline. Lead(II) acetate (0.5 M) was employed for the determination of fluoranthene, which showed no phosphorescence signal on paper substrates pre-treated with thallium(I) acetate. Limits of detection at the ng/ml^{-1} level were estimated for all the compounds. An improvement in the limits of detection of the nitrogen heterocyclic compounds was obtained by using a low-background paper substrate. Satisfactory reproducibility of measurements was observed, varying from 6.1% (chrysene) to 11.9% (7,8-benzoquinoline). The linear behavior of the sensor response was also evaluated. Linear dynamic ranges extend over two and three orders of magnitude and show the potential of the device for the quantitative analysis of environmental pollutants.

Keywords: Fiber optic sensor; Laser-induced room-temperature phosphorescence detection; Polycyclic aromatic hydrocarbons

1. Introduction

The development of fiber optic sensors was initially conceived in the medical area [1]. Although a great deal of effort is still devoted to this field, more recent interests in optosensing technology have been directed toward environmental applications. The main reason for the fast development of environmental monitoring sensors is the continuous upgrading of legislation concerning ambient pollution. Such modifications include the addition of new pollutant targets, re-evaluation of limits of concentrations and an

increase in the frequency and number of measurements required [2]. Special emphasis in environmental analysis has been put on monitoring polycyclic aromatic hydrocarbons (PAHs) throughout the ecosystem [3]. Some PAHs are well known to exhibit carcinogenic and/or mutagenic effects in humans [4]. In aquatic systems, the major sources of PAHs release are oil spills and leakage from waste sites and coking plants [5]. Depending on the compound and the water supply, PAH concentrations usually range from pg ml^{-1} in pure ground water samples to μg ml^{-1} in heavily contaminated sewage. Among the analytical techniques adapted for on-site aquatic analyses for PAHs, laser-induced fluorimetry with optical fibers has shown to be a selective and sensitive approach [6–12].

In this paper, we report for the first time the evaluation of a laser-induced room-temperature phosphorimetric (LI-RTP) sensor for the determination of polynuclear aromatic compounds (PACs). In addition to PAHs, the application of the LI-RTP sensor was extended to nitrogen heterocyclic compounds (NHCs) of industrial, environmental and biological importance. To the best of our knowledge, this is the first time that an LI-RTP sensor has been reported. Very few studies involving phosphorimetry and optosensing have been reported previously [13–17]. The advantage of coupling fiber optics into laser sources to measure phosphorescence emission at 77 K was demonstrated by Hieftje and co-workers [13,14]. Fiber optics have also been employed to detect RTP emission with commercial spectrofluorimeters [15–17]. Selective chemical sensors have been developed for ultratrace aluminum determination [15], quantitation of tetracyclines in urine and pharmaceutical preparations [16] and glucose determination in serum and beverage samples [17].

In this study, advantage was taken of the high coupling efficiency of laser excitation sources into fiber optics to develop a universal RTP sensor adaptable to different analytical situations involving phosphorescent compounds. Filter-paper was used as a solid substrate to induce phosphorescence emission [18] from several model polycyclic aromatic compounds (PACs), which include three PAHs (chrysene, 1,2-benzofluorene and fluo-

ranthene) and three NHCs (7,8-benzoquinoline, phenanthridine and 5,6-benzoquinoline). External heavy-atom perturbation [18,19] was employed to enhance RTP emission from the studied compounds. Limits of detection (LODs) at the ng ml^{-1} were obtained, showing satisfactory sensitivity for environmental analysis. The linearity of response of the RTP sensor was also evaluated, showing linear dynamic ranges (LDR) extended over about three orders of magnitude. Finally, we demonstrated the usefulness of a paper background reduction treatment [20] in improving the LODs obtained with the LI-RTP sensor.

2. Experimental

2.1. Instrumental

Fig. 1 shows a block diagram of the instrumental system employed. Excitation at 337 nm was performed by using a pulsed nitrogen laser (Laser Science VSL-337) with a typical pulse energy of 120 mJ. The repetition rate was 20 Hz and the pulse width 3 ns. The laser beam was focused on to one end of a bifurcated optical fiber with an $f/4$ convex lens, and directed to the surface of the solid substrate probe. The bifurcated fiber (Fiber Guide Industries, silica–silica glass, 150 cm length) consisted of a 600 μm central optical fiber surrounded by 18 optical fibers of 200 μm diameter (emission). The phosphorescence signal from the sample was transferred into a 10 cm focal-length monochromator (ISA Model DH-10). The output from the photomultiplier (Hamamatsu R928) was amplified by a laboratory-constructed

amplifier and fed into a gated boxcar averager (Stanford Research Systems RS250). For all measurements, the delay and gate time were 1 and 4 ms, respectively. The time constant of the boxcar was 1 s. A stepper motor was used to control the scanning of the monochromator. An analog-to-digital converter card (MetraByte DASH-16) was used for instrumental control, timing and data collection. The software employed to control the instrumental system was develped in our laboratory.

The RTP sensor is shown in Fig. 2. Basically, the device consists of two cylindrical parts (a stainless-steel sheath and a Teflon stud) easily attached by concentric incised threads. The fiber optic bundle passed through the center of the sheath and reached the sample compartment of the RTP sensor located between the two cylindrical parts. A hole (0.3 cm diameter) at the distal end of the Teflon stud allowed the entry of solution into the sample cavity. By dipping the sensor into the liquid sample, the paper substrate in the

sample cavity was imbibed with the solution. The sample collected by the filter-paper was then excited by the laser radiation from the fiber optic. By means of a screw in the sheath, the distance between the fiber optic and the surface of the solid substrate was kept constant during all measurements.

A commercial spectrofluorimeter (Perkin-Elmer LS 50B) was used to record the excitation spectra of the studied compounds. In all cases, the delay and gate time were 1 and 4 ms, respectively. The excitation and emission slits were 10 nm.

The ultraviolet (UV) irradiation treatment for paper background reduction was carried out in a Rayonet photochemical reactor (Southern N.E. Ultraviolet Co., Middletown, CT, USA) using five lamps with maximum wavelengths (λ_{max}) of emission at 254 nm and seven with λ_{max} at 300 nm.

2.2. Reagents

Whatman No. 40 filter-paper and distilled, deionized water were used throughout. All chemicals were of analytical-reagent grade and used without further purification. Chrysene, 1,2-benzofluorene, phenanthridine, fluoranthene, 7,8-benzoquinoline and 5,6-benzoquinoline were purchased from Aldrich at the highest purity available. Thallium(I) acetate and lead(II) acetate were obtained from Sigma. Methanol was acquired from J.T. Baker.

Stock solutions of PACs (10^{-3} M) were prepared in methanol–water (80:20, v/v). Working solutions were obtained by appropriate dilution with methanol–water (80:20, v/v). Thallium(I) acetate (0.1 M) and lead(II) acetate (0.5 M), both prepared in methanol–water (50:50, v/v), were used as phosphorescence enhancers.

2.3. Procedure

The background emission of the solid substrate was reduced by a combination of solvent extraction and irradiation treatment [20]. Strips of chromatography paper were extracted with water in a Soxhlet apparatus for 8 h and exposed to UV irradiation in a photochemical reactor for the same period of time.

Filter-paper was cut into 0.4 cm diameter circles with a hole puncher. The circular substrates were immersed in the heavy-atom salt solution for approximately 1 min, dried under an infrared (IR) heat lamp for 3 min and then stored in a desiccator to be used as solid substrate probe.

The paper substrate was placed in the sample cavity of the RTP sensor. Sample collection was performed by immersing the sensor in a vial with the analyte solution. Although no effort was made to optimize the exact immersion time of the RTP sensor in the sample solution, we observed that a period of 30 s–1 min was enough to obtain the maximum RTP signal from the studied compounds. Prior to RTP measurements, a drying step was carried out, keeping the solid substrate in the sample compartment of the sensor. The hole at the distal end of the Teflon stud allowed direct irradiation of the reverse side of the solid substrate by an IR lamp. In most cases, the signal intensities and spectra collection were performed after 5 min of IR irradiation.

3. Results and discussion

3.1. Heavy-atom effect

The performance of the RTP sensor was evaluated by testing six well known phosphorescent compounds previously examined by SSRTP [18]. The phosphorescence characteristics of 7,8-benzoquinoline, 5,6-benzoquinoline, phenanthridine, 1,2-benzofluorene, chrysene and fluoranthene have been studied on a wide variety of solid substrates and phosphorescence enhancers [18,21–25]. The combination of paper substrate and thallium(I) ions as phosphorescence enhancers has been shown to be particularly efficient in improving the RTP signal of these compounds.

Our preliminary studies, therefore, were performed on paper substrates pre-treated with a 0.1 M thallium(I) acetate (TlOAc) solution. With the exception of fluoranthene, all the PACs showed strong phosphorescence signals. The emisson wavelengths obtained with the LI-RTP sensor are given in Table 1. The excitation maxima of the compounds were acquired with a commercial

spectrofluorimeter. The emission characteristics of the PACs obtained with the LI-RTP sensor were in agreement with those obtained with the spectrofluorimeter, which shows the feasibility of the device for their identification in unknown samples. From the values in Table 1, it can be seen that the maximum excitation wavelengths (λ_{exc}) of 7,8-benzoquinoline, 5,6-benzoquinoline and phenanthridine are close to the emission wavelength of the nitrogen laser (337 nm). This proximity probably allows a certain degree of overlap between their maximum excitation bands and the laser line, which is necessary for RTP emission. In addition, the excitation spectra of the studied NHCs presented featureless bands in the wavelength range 300–400 nm. Although those bands were less intense than the maximum excitation bands, they certainly contributed to the high degree of excitation obtained with the nitrogen laser. A similar effect was observed for chrysene and 1,2-benzofluorene. Their maximum excitation bands were located below 300 nm (see Table 1), with obvious difficulties for overlapping with the

laser line. However, these PAHs presented, at 337 nm, featureless absorption bands with approximately 20% of the maximum intensity observed at their λ_{exc}. Apparently, even when excited at a wavelength region of low absorption of energy, the high irradiance of the laser beam was sufficient to induce strong RTP emission from these compounds. On the other hand, fluorathene showed no RTP emission with the LI-RTP sensor. In the spectrofluorimeter, and still using 0.1 M TlOAc as phosphorescence enhancer, this compound showed a strong RTP signal with $\lambda_{exc}/\lambda_{em}$ at 284/555 nm. As a tentative means of shifting the λ_{exc} of fluoranthene towards 337 nm, and promote the necessary overlapping with the laser line to observe RTP emission with the fiber optic sensor, we employed a 0.5 M lead(II) acetate (Pb(OAc)$_2$) solution as a heavy-atom salt. This phosphorescence enhancer was chosen based on previous studies [24], which indicated strong phosphorescence emission from fluoranthene in the presence of lead(II) ions. As expected, the maximum excitation wavelength of the compound was observed at 365 nm, which is in agreement with the λ_{exc} previously reported [24]. As a consequence of the partial overlapping between its maximum excitation band and the laser line at 337 nm, we were able to detect fluoranthene's RTP emission with the LI-RTP sensor. Its maximum emission was observed at 545 nm.

3.2 Effect of drying time on the phosphorescence intensity and the precision of measurements obtained with the RTP sensor.

Previous studies [18,26–31] have shown that the presence of moisture and solvent molecules on the surface of the paper substrate might cause quenching of RTP signals. Either by competing with the analyte for bonding sites on the paper substrate, or by facilitating the transport of oxygen into the vicinity of the phosphor, the presence of water might also affect the reproducibility of measurements. To minimize its effect, a drying step prior to RTP detection is recommended. In addition, a flow of dry gas should be passed through the sample compartment of the instrument to avoid the presence of oxygen during
Fig. 3. Phosphorescence intensity as a function of drying time. Net RTP signals of (A) a 10^{-5} M solution of 7,8-benzoquinoline and (B) a 10^{-6} M solution of chrysene. In both cases, the analyte solutions were prepared in methanol–water (80:20 v/v) and 0.1 M TlOAc was used as a phosphorescence enhancer.

measurements. Interaction of triplet-state oxygen (the natural ground state of oxygen) with a molecule in the excited triplet state might cause radiationless deactivation of the excited molecule and production of excited singlet-state oxygen [18,22,32–34].

The drying conditions for the RTP detection of PACs have been studied previously [18,26–31]. When using filter-paper as a solid substrate, the usual procedure involves IR irradiation of the PAC solution spotted on the solid support. A similar procedure was therefore employed with the LI-RTP sensor. In our case, the IR radiation was directed towards the reverse side of the paper substrate probed by the fiber optic. Fig. 3 shows the net RTP intensities of 7,8-benzoquinoline and chrysene as a function of drying time. The drying temperature was adjusted to 60°C by varying the distance between the LI-RTP sensor and the IR lamp. The net signals plotted in the graphics were calculated from single measurements of three paper substrates impregnated with the blank and another three impregnated with the analyte solution. Chrysene emitted the maximum intensity after a drying time of 5 min. The RTP signal of 7,8-benzoquinoline reached its maxiumum value after 10 min of IR irradiation. The difference observed in the optimum drying times is not surprising, since it will depend on, among other parameters, the physico-chemical characteristics

of the phorphors [18,19]. In both cases, however, longer exposure to IR radiation caused intensity reductions. No changes in $\lambda_{exc}/\lambda_{em}$ were observed. Since our interest was focused on minimizing the drying time and therefore improving the sample throughout, we did not perform further studies to explain the observed reductions.

The reproducibility of measurements was evaluated after a drying time of 5 min. The relative standard deviations (RSDs) obtained with the RTP sensor are shown in Table 2. The RSD values were calculated with the equation RSD = $[(S_{A+B})^2 + S_B^2]^{1/2} \times 100/I_{A-B}$. Six measurements of analyte signals and respective blanks were used to evaluate the standard deviation of the analyte (S_{A+B}), the standard deviation of the blank (S_B) and the average of the analyte signal (I_{A-B}). All measurements were taken at the maximum emission wavelengths of the compounds. The best results were obtained for chrysene (6.1%). This is probably due to the drying time employed, which is within the optimum drying range of the compound (see Fig. 2). The phosphorescence intensity of 7,8-benzoquinoline after a drying time of 5 min, for example, was approximately 35% lower than its maximum intensity after 8 min of IR

Table 2
Precision of measurements obtained with the LI-RTP sensor[a]

[g] LOD = limit of detection; it was estimated as the concentration of analyte that yields a net RTP signal three times the standard deviation of the background.

irradiation. An improvement in the RSD value for this compound could have been obtained with a drying time of 8 min. A similar approach could have been used to improve the precision of measurements for all the PACs. In all cases, however, the RSD values obtained with the LI-RTP sensor were within the reproducibility range commonly observed with conventional instrumentation (5–15%) [18,19]. The effects of oxygen and humidity were probably minimized by the design of the LI-RTP sensor. The entry of oxygen in the sample cavity of the sensor is reduced to its diffusion through the filter-paper, since it can only occur by the hole at the distal end of the Teflon stud. In addition, the exposure of the dried substrate to atmospheric humidity is kept to a minimum. Considering the necessity for a short analysis time and simplicity of operation in field applications, and the satisfactory RSD values obtained, we performed all measurements in the absence of a flow of a dry gas and after a drying time of 5 min.

3.3. Analytical figures of merit (AFOM)

Table 3 shows the AFOM obtained with the LI-RTP sensor. Depending on the PAC, the linear dynamic ranges (LDR) of the calibration curves

extended over two to three orders of magnitude. In most cases, the slopes of the log–log plots and the correlation coefficients of the linear graphs were close to unity, showing the linearity of response of the sensing device. All the limits of detection (LODs) were estimated at the ng/ml^{-1} level, which is within the concentration range usually required for PAC determinations in contaminated samples [35,36]. By comparing the LODs reported in Table 3, it becomes clear that the values estimated for the NHCs are at least five times higher than those estimated for the PAHs. Although several experimental parameters can be optimized to improve the LODs in SSRTP analysis [37,38], we studied the effect of a paper treatment on background signal reduction [20,37–39]. Our choice was based on the position of the maximum emission peaks of the NHCs, which are in a wavelength region of higher background signal than the studied PAHs. The broad, featureless emission band of the paper substrate presents a plateau with maximum intensity between 470 and 500 nm. By applying a combination of water extraction and UV irradiation [20], we reduced the background emission of the paper substrate to approximately 85% of its original value. Table 4 shows the

Table 4

Effect of background reduction treatment of the analyte-to-background signal ratio and the LOD of some nitrogen heterocyclic compounds obtained with the LI-RTP sensor.

Compound[a]	S_A/S_B[b]		Treated paper: LOD[c] (ng ml^{-1})
	Untreated paper	Treated paper	
7,8-Benzoquinoline	4.4	15.3	53
Phenanthridine	2.0	17.4	38
5,6-Benzoquinoline	4.0	13.9	44

[a] Methanol–water (80–20 v/v) solutions were employed and 0.1 M TlOAc was used as a phosphorescence enhancer.
[b] Analyte-to-background signal ratio measured at the maximum emission wavelength of the analyte (see Table 3). Excitation wavelength = 337 nm.
[c] LODs obtained as those estimated in Table 3.

improvement obtained in the analyte-to-background signal ratios (S_A/S_B) for the NHCs. The LODs estimated on low-background filter-paper were from 3 to 7 times lower than those reported in Table 3. As expected, no modifications were observed to the $\lambda_{exc}/\lambda_{em}$ of the NHCs. The maximum peaks are in agreement with those reported in Table 1. Fig. 4 shows the RTP emission spectra of phenanthridine on a low-background paper substrate. Further
Fig. 4. Laser-induced RTP emission spectrum of a 10^{-5} M solution of phenanthridine (methanol–water (80:20 v/v)) obtained with the fiber optic sensor using a low-background paper substrate. TlOAc (0.1 M) was used to enhance phosphorescence emission. Laser excitation wavelength = 337 nm.

improvements in the LODs of the NHCs could have been obtained by drying each compound at its optimum drying time. In addition to low-background paper substrates, this possibility should be considered in the analysis of samples with PAC levels lower than ng ml^{-1}.

4. Conclusions

The LI-RTP sensor reported here has the potential to perform determinations of PACs in aquatic systems. The spectral characteristics obtained for six PACs and their AFOMs demonstrate the feasibility of the new sensor for qualitative and quantitative analyses of unknown samples.

The LI-RTP sensor presents several advantages over sensors based on laser-induced fluorimetry. Owing to the intrinsic characteristics of the phosphorescence phenomenon, a higher degree of selectivity should be expected from the LI-RTP device. The forbidden nature of the phosphorescence electronic transition [18,19] reduces the number of potential interferents in the analysis of complex mixtures. Furthermore, the long decay times of phosphorescence emissions (milliseconds to seconds) allow one to time discriminate against the interference from fluorescent concomitants, fluorescence background and other short-lived phenomena such as Raman effects and scattering. In the analysis of complex mixtures with several phosphorescent concomitants, the selectivity toward a target compound can be enhanced by selective external heavy-atom perturbation (SE-HAP) [24].

The proposed sensor also presents significant instrumental advantages. RTP emission usually occurs at longer wavelength regions than fluorescence, which allows the use of low-cost fiber optics for measurements beyond 450 nm. The measurements of triplet excited state lifetimes (microseconds to seconds) require less expensive instrumentation than fluorescence lifetimes, which are usually in the nanosecond range.

We believe that the RTP sensor is an attractive approach for field applications. The laser system is very simple to operate, relatively small and

requries minimum alignment. The design of the sensing device minimizes the contact of the analyte with quenching species such as oxygen and moisture, eliminating the need for the flow of dry gas usually employed with conventional instrumentation. By using appropriate heavy-atom salts, the λ_{exc} of compounds of interest can be shifted to overlap the excitation line of the nitrogen laser. As a consequence, a change in the excitation source might be avoided. Synchronous excitation techniques [40] can further improve the selectivity of RTP analysis. By spotting standard solutions on the paper substrates previously imbibed with the sample, on-site identification of compounds can be easily performed. Finally, by changing the paper substrate in the sample compartment, the LI-SSRTP sensor can be used for an infinite number of measurements. This represents a valuable feature for the analysis of a large number of environmental samples.

Flow injection analysis of L-lactic acid using an enzyme–polyion complex-coated electrode as the detector

Fumio Mizutani*, Soichi Yabuki, Yoshiki Hirata

National Institute of Bioscience and Human-Technology, 1–1 Higashi, Tsukuba, Ibaraki 305, Japan

Abstract

The concentration of L-lactic acid was determined by a combination of flow injection analysis with amperometric enzyme sensor detection. The enzyme sensor was prepared by immobilizing lactate oxidase in a layer of polyion complex consisting of poly-L-lysine and poly(4-styrenesulfonate). The sensor-based system can be used for the determination of L-lactate concentration up to 6 mM with a sampling rate of 120 h^{-1}, and is stable for 8 weeks after 1000 L-lactate injections. The permselectivity of the polyion complex matrix is effective for reducing the response from electrochemical interferents such as L-ascorbic acid, uric acid and acetaminophen.

Keywords: Amperometric enzyme sensor; Flow injection analysis; Lactic acid

1. Introduction

The accurate, rapid and automatic determination of L-lactic acid is necessary in clinical and industrial food laboratories. Flow injection analyis (FIA) using an amperometric enzyme electrode as the detector can accomplish this function [1]. Previously, we have prepared amperometric biosensors by immobilizing enzymes (e.g. lactate oxidase (LOD)) into membranes consisting of poly-L-lysine–poly(4-styrenesulfonate) complex [2,3]. First, an aqueous solution containing an enzyme and the polycation was placed on a glassy carbon electrode, then an aqueous solution of the polyanion was added and dried. The resulting L-lactate-sensing electrode showed high performance characteristics such as rapid response (100% response, less than 5 s), a wide linear range (0.1 μM–0.3 mM), high stability (usable for at least 8 weeks) and high selectivity for the analyte. The high selectivity originated in the permselectivity of the polyion complex membrane; the membrane was very effective in restricting the transport of typical electrochemical interferents such as L-ascorbic acid (MW 176), uric acid (MW 168) and acetaminophen (MW 151), whereas that of the analyte (MW 90) was not restricted in the layer [2]. Hence the interferencial response could

* Corresponding author

be suppressed compared with the response for L-lactic acid.

These characteristics are particularly promising for the use of the enzyme electrode in an FIA system to determine L-lactic acid in biological and food samples. In an FIA system, the dynamic range for determining the analyte can be varied by the choice of the measuring conditions such as sample volume. The injection of a small volume of sample causes the lowering of the sample concentration in the flowing stream compared with the original concentration owing to the dispersion of the sample zone [4] which is effective for shifting the determinable concentration range towards higher levels. When the determinable range for L-lactic acid becomes as high as several millimolar, the system can be used for the assay of non-diluted sera; the concentration of L-lactic acid in normal sera is around 2 mM. This paper describes the determination of L-lactic acid in sera and food samples by an FIA system using an LOD–polyion complex-coated electrode detector.

2. Experimental

2.1. Materials

LOD (EC number not assigned; from *Pediococcus* sp., MW 80 000 [5]; 40 U mg^{-1}), peroxidase (EC 1.11.1.7, from horseradish, Type VI, 330 U mg^{-1}), uricase (EC 1.7.3.3, from *Candida utilis*, Type IV, 10 U mg^{-1}), poly-L-lysine hydrobromide (MW 90 000), and lithium L-lactate were obtained from Sigma. Poly(sodium 4-styrenesulfonate) (MW 70 000) was purchased from Aldrich. Human sera was obtained from Sigma and ICN. Other reagents were of analytical-reagent grade (Nacalai Tesque). Deionized, doubly distilled water was used throughout.

F-kits (Boehringer Mannheim) were used for the spectrophotometric measurement of L-lactic acid and L-ascorbic acid. The kit for L-lactic acid uses the enzyme pair of lactate dehydrogenase (EC 1.1.1.27) and glutamate–pyruvate transaminase (EC 2.6.1.2). The concentration of uric acid in serum samples was measured by using uricase

with the peroxidase–phenol–4-aminoantipyrine chromogenic system [6].

2.2. Enzyme electrode

A glassy carbon electrode (Model 11-1000, Bioanalytical Systems), 0.14 cm^2 in area, was polished with a 0.05 μm alumina slurry, rinsed with water and dried. On the electrode surface, 10 μl of 0.04 M potassium phosphate buffer (pH 7) containing LOD (10 μM) and poly-L-lysine (10 mM in the momomer unit), and the same buffer solution (6 μl) containing poly(4-styrenesulfonate) (20 mM in the monomer unit) were placed successively. The electrode was then allowed to dry at room temperature for 24 h.

2.3. Instrumentation and measuring procedure

The FIA system employed (Bioanalytical Systems) consisted of a PM-60 double-plunger pump, an LC-4C potentiostat and an FT-1 thermostat equipped with a flow-through cell and an injection valve. A single-line manifold for the FIA was made from 0.25 mm PTFE tubing with a distance of 60 cm between the injection valve and the flow-through cell. Such a long tube is considered to be effective in lowering the sample concentration at the flow-though cell due to the dispersion of a sample zone [7]. The flow-through cell consisted of the enzyme electrode, an Ag/AgCl reference electrode, a stainless-steel auxiliary electrode and a PTFE gasket (thickness 25 μm). A 5 μl sample loop was used for injecting sample solutions, unless stated otherwise.

A potassium phosphate buffer (0.1 M, pH 7.7), which was saturated with air, was used as a carrier solution. The flow rate was usually 0.5 ml min^{-1}. The pH of the buffer is close to the optimum pH of LOD [2,8]. The potential of the enzyme electrode was set at 1 V vs. Ag/AgCl. This potential was sufficient for the oxidation of the hydrogen peroxide produced through the LOD reaction on a carbon electrode [9,10]. The temperature of the flow-through cell was kept at 30.0 ± 0.5°C. When not in use, the flow-through cell with the enzyme electrode was left at room temperature.

3. Results and discussion

3.1. Effect of sample volume and flow rate

The electrode current increased after the addition of L-lactic acid to reach a peak and then returned the baseline. The relationship between the peak current and the L-lactate concentration was examined by using 5, 10, 20, 50 and 100µl sample loops. The use of a sample loop with a small volume was found to be useful for the determination of higher concentrations of L-lactic acid. Fig. 1 shows typical results obtained by using the 5 and 50 µl sample loops. The use of the 50 µl sample loop gave a calibration curve whose linear region extended only up to 0.5 mM. On the other hand, when the 5 µl sample loop was employed, a linear relationship was obtained up to 2.5 mM and a significant increase in the current was still observed with L-lactate concentrations between 2.5 and 6 mM. The determinable concentration range, up to 6 mM, enables us to apply non-diluted serum as the sample. Hence the 5 µl sample loop was used for subsequent examinations.

Fig. 2 shows the effect of the flow rate on the peak current for 1 mM L-lactic acid and the time for reversion to the baseline. Both the current response and the baseline reversion time decreased with increasing flow rate, first rapidly and then more gradually. The decrease of the current

Fig. 2. Effect of flow rate on (○) the peak current for 1 mM L-lactic acid and (●) the baseline reversion time.

peak results from the increase in the dispersion of the sample in association with the increase in flow rate [4]. For subsequent measurements, the flow rate was set at 0.5 ml min⁻¹. In this condition, the travel time and the baseline reversion time were 10 and 30 s, respectively. These values agreed with those obtained from the semi-empirical model of Vanderslice et al. [7], where the detector response has been assumed to be very fast. The baseline reversion time provided a maximum sampling rate of ca. 120 h⁻¹.

Fig. 3. Current–time curves for the addition of (a) 1 mM L-lactic acid, (b) 0.2 mM hydrogen peroxide, (c) 1 mM L-ascorbic acid, (d) 0.2 mM uric acid, (e) 1 mM acetaminophen, (f) 1 mM NADH, (g) 2 mM L-lactic acid and (h) a mixture of 2 mM L-lactic acid, 0.05 mM L-ascorbic acid and 0.2 mM uric acid.

Table 1
Comparison of results obtained for L-lactic acid in sera by different methods

Sample no.[a]	Proposed method		F-kit method
	L-Lactate concentration (mM)	RSD (%)	L-Lactate concentration (mM)
1	2.80	1.5	2.75
2	1.75	1.1	1.71
3	2.07	1.3	2.01

[a] The concentrations L-ascorbic acid and uric acid were determined to be 0.03 and 0.14 mM for the serum 1, 0.04 and 0.12 mM for the serum 2 and 0.04 and 0.18 mM for the serum 3.

The detection limit at the standard sample volume and flow rate was 20 μM (signal-to-noise ratio = 5). The relative standard deviation for 100 successive measurement of 2 mM L-lactic acid was 1.4%.

3.2. Response for L-lactic acid and interferents

Curves a–f in Fig. 3 show the current responses after the injection of L-lactic acid, hydrogen peroxide, L-ascorbic acid, uric acid, acetaminophen and NADH (the concentration was 0.2 mM for hydrogen peroxide and uric acid and 1 mM for the other species), respectively. The peak current for hydrogen peroxide was several times larger than that for the same concentration of L-lactic acid. The L-lactic acid introduced in the flow-through cell would be partially consumed on the solution side in the LOD–polyion complex membrane. This brings about a decrease in the concentration gradient of the hydrogen peroxide produced through the LOD reaction near the glassy carbon electrode, which results in a smaller response to the injection of L-lactic acid than in the case of hydrogen peroxide.

The injection of L-ascorbic acid, uric acid and acetaminophen brought about discernible current responses, indicating that these species interfere in the measurement of L-lactic acid, whereas NADH, having a much higher molecular weight (665), did not give a discernible response. However, the current response for each interferent was much smaller than that for L-lactic acid (and for hydro-

gen peroxide): the ratios of the response for the interferent to that for the same concentration of L-lactic acid were 0.25, 0.35 and 0.55 for L-ascorbic acid, uric acid and acetaminophen, respectively. The small ratio between the interferent and the analyte responses (or that between each electroactive species with a molecular weight higher than 150 and hydrogen peroxide (MW 34) suggests that the polyion complex layer shows permselectivity based on the solute size. The permselectivity of the polyion complex-based membranes has been proved as follows [2,3]. The ratios of anodic current response on the membrane-covered electrode to that on a bare glassy carbon electrode were measured for a variety of electroactive species whose molecular weights ranged from 30 (hydrazine) to 665 (NADH). The ratio was >0.5 for the electoactive species having molecular weights <100 and decreased sharply with molecular weights >100 (to 0.23 for hydroquinone (MW 110) and 0.03 for L-ascorbic acid).

The concentrations of L-lactic acid, L-ascorbic acid, uric acid and acetaminophen in normal sera are around 2, 0.05, 0.2 and 0 mM, respectively. Hence the current change caused by the interferents is expected to be 4% for measureing L-lactate concentration in the sera. Curves g and h in Fig. 3 show the current response for 2 mM L-lactic acid and for the mixture of 2 mM L-lactic acid, 0.05 mM L-ascorbic acid and 0.2 mM uric acid, respectively. The injection of the mixture actually gave a 4% excess peak current compared with the pure L-lactate solution, as shown in Fig. 3. Hence, the present system is expected to be useful for the assay of L-lactic acid in normal sera with an error of within a few per cent.

3.3. Determination of L-lactic acid in sera and sour milks

Table 1 gives the results for the determination of L-lactic acid in three kinds of normal sera. Each serum was used without dilution and was injected 10 times. The concentration was determined from the average value of the peak current for the 10 measurements. The relative standard deviation for each set of 10 measurements was within those obtained by the F-kit method.

Table 2
Comparison of results obtained for L-lactic acid in sour milks by different methods

Sample no.[a]	L-Lactate concentration	
	Proposed method	F-kit method
1	63.8	61.4
2	74.6	73.0
3	53.3	53.6
4	87.9	86.1
5	72.4	74.4
6	55.0	54.6
7	61.0	60.4
8	89.2	88.9
9	71.7	73.2
10	75.9	27.8

[a] The concentration of L-lactic acid in each sample was less than 1 mM.

The FIA system was also used for the determination of L-lactic acid in sour milks. Ten kinds of sour milks were used (each sample was diluted 50-fold with 0.1 M phosphate buffer (pH 7.7)) and the results were compared with those obtained with the F-kit method. The agreement was excellent (Table 2); the regression equation between the results obtained with the FIA (x in

Fig. 4. Long-term stability of the enzyme electrode-based system. The electrode response for 1 mM L-lactic acid was measured 30 times a day. The average value for the 30 measurements is plotted against the number of days after the preparation of the enzyme electrode.

mM) and those with the F-kit method (y in mM) was $y = 0.975x + 1.078$ and the correlation coefficient was 0.991.

These results show that the present FIA system is useful for the simple and rapid determination of L-lactate concentration in non-diluted sera and (diluted) sour milks.

3.4. Stability of the sensor

The long-term stability of the enzyme electrode-based system was examined by determining 1 mM L-lactic acid 30 times a day on each day for 8 weeks. More than 1000 L-lactate injections were performed during this period. The system could be used even at the end of the eighth week. The average value for 20 measurements did not decrease for 3 weeks, as shown in Fig. 4. The current response gradually decrease after 3 weeks, but the current response on the 56th day was still more than 50% of the initial value. The relative standard deviation for the 30 measurements was within 1.5% on each day for the first 3 weeks, and increased slightly after 3 weeks to 2.5% on the 56th day. The present system thus showed a high stability.

High biocompatibility is another attractive feature of polyion complex membranes [11]. For example, the adhesion of platelets on a glass plate could be suppressed by coating the surface with a polyion complex [12]. The enzyme–polyion complex detector would therefore be useful for determining L-lactic acid in whole blood. Such an examination will be carried out in near future.

Abstract

A chelating ion-exchange resin (1-hydroxy-2-naphthaldoxime–formaldehyde polymer) containing nitrogen and oxygen donor atoms was prepared and characterized. The resin behaves as a selective chelating ion exchanger for some metal ions. The poly(vinyl chloride)-based membrane electrode of the resin shows a Nernstian response for Ni^{2+} over a wide concentration range (2.94×10^3–5.87×10^3 mg dm^{-3}) between pH 3.0 and 7.5. The electrode is found to possess adequate stability and specific selectivity with a response time of 10 s. The sensor can also be used in a partially non-aqueous medium having a 35% (v/v) non-aqueous content.

Keywords: Chelating ion-exchange resin; Membrane sensor; Nickel(II)

1. Introduction

Ion-exchange resins incorporating oxime and hydroxyoxime functional groups form an important class of polymeric ligands because of their strong chelating properties. The selectivity of a hydroxime resin prepared from substituted phenyl-acrylate polymer has been reported by Walsh et al. [1]. Resacetophenone oxime, after condensation with formaldehyde, forms a resin [2] which is highly selective to Cu(II) ions. A number of compounds having 2-hydroxyacryloximes [3] have been impregnated in polymeric matrices and these find extensive applications in the hydrometallurgy of Cu(II).

This class of compound, i.e. chelating ion-exchange resins, are found to possess specific selectivity for some metal ions and play an improtant role in separation processes. Recently we have reported the utility of salicylaldoxime–formaldehyde resin membranes for the estimation of zinc [4].

In this paper we report the electroanalytical applicability of a 1-hydroxy-2-naphthaldoxime–formaldehyde (HDF) resin membrane as a nickel ion sensor. The proposed sensor has very good selectivity for nickel over other cations.

Relatively few reports have appeared on the development of membrane sensors for nickel ions. Most of these involve an electroactive phase such as nickel–dimethylglyoxime complex [5,6], nickel phosphate [7] or nickel bis(2-ethylhexyl)phosphate [7,8]. Some liquid membrane electrodes in-

---

volving O,O'-diisobutyl dithiophosphatonickel(II) [9], nickel, 8-quinolinedithiocarboxylate [10], etc., in appropriate solvents, have also been tried for the estimation of nickel but most of these suffer from interference by metal ions which may be present as routine contaminants. The sensor reported in this paper can be prepared easily and exhibits much better selectivity for Ni^{2+} than that reported earlier.

Although the resin mentioned above shows a selective uptake of some metal ions in the sequence $Fe^{2+} > Pb^{2+} > Ni^{2+} > Zn^{2+} > Pd^{2+}$, the membrane selectivity does not necessarily follow the same pattern and is different to the pure material owing to the application of neutral binders, incorporated during fabrication. The presence of binding material affects the conductance of the membrane, which is an additional parameter of the sensor affecting the selectivity in comparison with the electroactive phase taken in the pure state.

2. Experimental

2.1. Reagents

All chemicals were of analytical-reagent grade. Solutions were prepared in doubly istilled water.

2.2. Synthesis and characterization of the resin

The procedure followed for the synthesis of the resin was similar to that followed for salicylaldoxime–formaldehyde and other compounds of the same series [11]. The procedure provides a product having optimum separation potential.

1-Hydroxy-2-naphthaldehyde (0.05 mol) was converted into the corresponding oxime using hydroxylammonium chloride and doubly distilled ethanol. 1-Hydroxy-2-naphthaldoxime was then mixed with formaldehyde in the molar ratio 1:4.2 and 3% (w/w) of 40% sodium hydroxide solution was added as a catalyst. The mixture was heated under reflux in an oil-bath at $115 \pm 1°C$ for 7 h. The resinous mass obtained was poured into a container and dried at $100 \pm 1°C$ for 10 h. The black granular resin obtained was powdered and sieved.

On the basis of elemental analysis (found, C 72.19, H 4.94, N 6.96; theoretical, C 72.00, H 5.00, N 7.00%) and infrared spectrometry the following structure of the repeating unit has been assigned to the product used as the electroactive phase:
The number-average molecular weight of the resin as determined by vapour-phase osmometry in tetrahydrofuran (THF) at 30°C was 2625. Differential scanning calorimetric (DSC) scans of the resin showed a melting temperature of 120°C and a decomposition temperature of 280°C. Thermogravimetric analysis showed no mass loss in the region of 100°C, thereby indicating no moisture absorption. Major mass loss (31.5%) took place in the range 300–400°C and the breakdown of the polymer was observed at 500–600°C. The char yield obtained at 600°C was 12%.

2.3. Preparation of membranes

A heterogeneous membrane of this compound was prepared using PVC as binder material and a 1:1 mixture of the two was dissolved in THF. The resulting solution was stirred well and poured into a casting glass ring on a glass plate and the THF was evaporated at room temperature. A membrane sheet about 0.05 mm thick and 6 mm in diameter was cut away from inner edge and glued to one end of a Pyrex glass tube with Araldite. The process was optimized, after detailed preliminary investigations, so that the membrane generates reproducible potentials and the fabrication of membranes was carefully controlled to have batch-to-batch reproducibility.

2.4. Potential measurement

The membrane was equilibrated in 1.00 mol dm^{-3} nickel ammonium sulphate solution for 4 days, the time after which it generates repro-

ducible, noiseless and stable potentials when interposed between the test solution and an internal reference solution of 0.100 mol dm^{-3} concentration. Potentials were measured, as reported earlier [12], at 25 ± 1°C by direct potentiometry with the help of ceramic junction calomel electrodes and a saturated ammonium nitrate bridge. The measurement of potentials was made from low to high concentrations to avoid memory effects. The ionic strength of various solutions was maintained using NH_4NO_3 (10^{-3} mol dm^{-3}) and pH adjustments were made with dilute acid or hexamine. The standard deviation of about 20 measurements was 0.2 mV.

2.5. Evaluation of selectivity coefficient

The potentiometric selectivity of the membrane was evaluated in terms of selectivity coefficients obtained by a mixed solution (fixed interference) method (as recommended by IUPAC).

2.6. Conductance measurement

The conductance of the membranes (in different cationic forms) was measured by the modified method adopted by Lakshminarayanaiah et al. [13], which makes use of a mercury pool on both sides of the membrane to minimize polarization at the membrane interface. The membrane was cemented between two Pt electrodes with epoxy resin and kept in contact with electrolyte solution of 0.1 mol dm^{-3} concentration. The solution was then replaced by mercury previously equilibrated with the electrolyte solution of the same concentration and the conductance was measured by connecting the platinum electrodes to a conductance bridge.

3. Results and discussion

The static response time of the proposed membrane electrode is about 10 s over the entire working concentration range and the potentials remain constant for more than 3 min, after which a very slow divergence is observed. Under laboratory conditions, if the membrane is properly

Fig. 1. Variation of membrane potential with (a) concentration/activity of nickel ions (taken as nickel ammonium sulphate) and (b) constant ionic strength.

stored in distilled water and if cross-contamination is avoided, it can be used for 2 months without observing any drift in potential. Thereafter it can be regenerated or else a new membrane can be fabricated and used.

The potential response of the membrane obtained with pure solutions is illustrated in Fig. 1(a). It is observed that the membrane electrode can measure Ni^{2+} ions in the range 2.35×10^3–5.87×10^3 mg dm^{-3} (4.00×10^{-5}–0.1 mol dm^{-3}) as per IUPAC recommendations and it also exhibits Nernstian behaviour (slope 28.50 mV per decade of concentration). Activity coefficients of solutions were obtained with the extended form of the Debye–Hückel equation and a potential vs. activity plot is also shown in Fig. 1(a). The working pH range of the sensor is 3.0–7.5 (Fig. 2). Fig. 1(b) depicts the potential vs. [Ni^{2+}] relationship obtained at constant ionic strength.

The performance of the proposed sensor system was also investigated in partially non-aqueous media using water–methanol and water–ethanol mixtures. The membrane works well in a partially non-aqueous medium up to a maximum of 35% (v/v) non-aqueous content (data not shown) without any change in the working concentration range or slope. However, at larger non-aqueous contents (> 35%) the slope and working concen-
Fig. 2. Variation of membrane potential with pH.

tration range decrease appreciably. It was also possible to use the membrane as an indicator electrode for the potentiometric titration of nickel ions. Fig. 3 depicts the titration of 10 cm^3 of 1.00×10^{-4} mol dm^{-3} Ni^{2+} ions with 1.00×10^{-3} mol dm^{-3} EDTA solution. The necessary adjustment of pH was made before adding the titrant. A sharp inflection point and perfect stoichiometry are noteworthy features of this titration.

The performance of an electrode is judged by the selectivity for the determinand ion in presence of foreign ions. The selectivity pattern of membranes fabricated with the help of an inert binder is usually different to that of pure membrane material. Table 1 presents the conductance data for the membrane embedded with different cations (it is not possible to obtain conductance data for pure polymeric resin). The magnitude of the conductance (Table 1) amply justifies its application as an ion-selective electrode especially for
Table 1
Specific conductance of PVC-based 1-hydroxy-2-naphthaldoxime–formaldehyde polymer membranes in different cationic forms

Cation	Specific conductance (10^2 milli mhos cm^{-1})	Cation	Specific conductance (10^2 milli mhos cm^{-1})
Li$^+$	2.8	Ni^{2+}	5.8
Na$^-$	2.5	Mn^{2+}	3.6
K$^+$	2.8	Zn^{2+}	5.4
Ca^{2+}	3.8	Cd^{2+}	3.6

Mg^{2+}	4.8	Fe^{3+}	4.2
Pb^{2+}	5.2		

the estimation of Ni^{2+}.

The selectivity coefficient values (Fig. 4) of a number of other ions in comparison with nickel were obtained at an interference level of 10^{-2} mol dm^{-3}. The membrane exhibits excellent selectivity for nickel ions and no interference is observed from normal interferents such as Zn^{2+}, Cd^{2+}, Co^{2+} and Pb^{2+}, even at this high concentration. Some monovalent cations register high selectivity coefficients and may cause some disturbance in the operation of this electrode at higher concentrations. To obtain a true assessment and tolerance limits of the sensor for the ions mentioned, above some mixed runs, i.e. monitoring of the

Fig. 3. Titration of 10 ml of 1.00×10^{-4} mol dm^{-3} Ni^{2+} ions with 1.00×10^{-3} mol dm^{-3} EDTA solution.

Fig. 4. Selectivity coefficients (log $K^{Pot}_{A,B}$) at 1.00×10^{-2} mol dm^{-3} concentration of interfering ions with respect to Ni^{2+} ions.
Fig. 5. Variation of membrane potential with concentration of interfering ions: (a) Na^+; (b) K^+.

sensor potential vs. concentration, were made with Ni^{2+} ions in contact with different concentrations of the interferents. The data (Fig. 5) reveal that Na^+ starts to interfere even at 10^{-4} mol dm^{-3} and the linearity range and the slope decrease, whereas with K^+ significant interference is only observed at 10^{-3} mol dm^{-3}. Other multivalent ions would normally not interfere unless present at very high concentrations, a situation which is hardly met.

The utility of the membrane electrode was also observed in solutions contaminated with proteinous matter and washings containing surfactants. Small amounts of these substances do not disturb the working of the membrane electrode. Potential vs. $[Ni^{2+}]$ plots obtained in the presence of 5.00×10^{-5} mol dm^{-3} of cationic (cetyltrimethylammonium bromide) and anionic (sodium dodecyl sulphate) surfactants (data not shown) correspond fairly well with the plot recorded with pure nickel ion solutions, but at higher concentrations, of which there is a slight possibility in actual practice, these can cause some disturbance of the working of electrode assembly.

4. Conclusion

Chelating ion-exchange resins provide a suitable matrix for the fabrication of membrane sensors. 1 - Hydroxy - 2 - naphthaldoxime – formaldehyde polymer membrane exhibits promising selectivity for Ni^{2+} ions and the proposed sensor can be used to estimate nickel over a wide concentration range.

Determination of doxorubicin hydrochloride by visible spectrophotometry

Chilukuri S.P. Sastry*, Jana S.V.M. Lingeswara Rao

Foods and Drugs Laboratories, Department of Organic Chemistry, Foods, Drugs and Water, Andhra University, Visakhapatnam-530 003, India

Abstract

Four simple and sensitive visible spectrophotometric methods (A–D) have been described for the assay of doxorubicin hydrochloride either in pure form or in pharmaceutical formulations. Method A was developed based on oxidation of the drug with Fe(III) to produce Fe(II), which subsequently reacts with 1,10-*ortho*-phenanthroline to form a red colored complex (λ_{max}: 510 nm) at pH 4.6. Method B involves the reduction of Folin–Ciocalteu (F–C) reagent by the drug and the reduced species formed possesses a characteristic intense blue color (λ_{max}: 770 nm). In methods C and D, oxidation of the drug with periodate at specified experimental conditions yields formaldehyde and dialdehyde, which in turn react either with 3-methyl-2-benzothiazolinone hydrazone hydrochloride to form an intensely brilliant blue cationic dye (λ_{max}: 620–670 nm, method C) or by condensation with phenylhydrazine hydrochloride (PHH) to form orange-red colored product (λ_{max}: 510 nm, method D) in the presence of potassium ferricyanide. All of the variables have been optimized and the reaction mechanisms presented. The concentration measurements are reproducible within a relative standard deviation of 1.0%.

Keywords: Doxorubicin hydrochloride determination; Visible spectrophotometry

1. Introduction

Doxorubicin hydrochloride (DXH) is an anti-cancer agent, widely used in acute lymphocytic leukemia and various carcinomas. It is chemically known as (8S-*cis*)-5, 12-naphthacenedione, 10-((3-amino-2,3,6-trideoxy-L-lyxo-hexopyranosyl) oxy)-7,8,9,10-tetrahydro-6,8,11-trihydroxy-8-(hy-

_____
* Corresponding author.

droxyl acetyl)-1-methoxy hydrochloride and is official in the United States Pharmacopoeia [1]. Only a few methods, such as fluorimetry [2,3], voltametry [4], differential polarography [5], liquid chromatography [6,7], thin layer chromatography [8,9] and high pressure liquid chromatography [10–15] have been reported for its determination in biological fluids and in dosage forms. However, there is no report on visible spectrophotometry except a qualitative test with aerosol samples containing DXH [16]. Even

though the drug is colored, its aqueous solution possesses an λ_{max} value at 500 nm with a low ϵ_{max} value of 2.60×10^3. It is not sensitive enough to carry out estimations in microamounts. Hence there is a need for the development of sensitive methods for its determination by exploiting suitable chromogenic reagents for color development. The properties of the analytically important functional groups of DXH have not been exploited so far in the design of sensitive, accurate and flexible visible spectrophotometric methods for the determination of DXH in pharmaceutical formulations. So the authors have made some attempts in this direction and succeeded in developing four visible spectrophotometric methods by exploiting different structural features of the drug molecule.

Ferric ammonium sulphate or ferric chloride plays a prominent role in the colorimetric determination of organic compounds. Acting as an oxidant, ferric salt converts into ferrous salt and it can be detected easily by the usual reagent for divalent iron, *ortho*-phenanthroline (PTL) [17], bipyridyl or triazine [18], etc. Phosphomolybdotungstic acid, the well-known Folin–Ciocalteu reagent [19] was preferred by number of researchers for the determination of drugs containing phenolic or amino groups [20]. α-Ketols or α-amino-ols are oxidized by periodic acid, liberating formaldehyde as one of the products [21,22]. Sawicki et al. [23] suggested 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) as a sensitive reagent for the determination of formaldehyde and other aldehydes. The Schryver reaction describes the estimation of formaldehyde with phenylhydrazine hydrochloride (PHH) in the presence of ferricyanide [24]. We have applied the above four reagents (Fe(III)/PTL, F–C, NaIO$_4$/MBTH and NaIO$_4$/PHH) for the determination of DXH in pure and pharmaceutical preparations.

2. Experimental

2.1. Instruments

A Systronics 106 digital spectrophotometer (Hyderabad) with 1 cm matched glass cells and an Elico LI-120 digital pH meter (Hyderabad) were used.

2.2. Reagents

All of the chemicals were of analytical reagent grade and all of the solutions were prepared with double-distilled water. Freshly prepared solutions were always used.

Fe(III) solution (2.0×10^{-2} M) was prepared by dissolving 0.96 g of ferric ammonium sulphate dodecahydrate (E. Merck) in 10 ml of concentrated HCl and made up to 100 ml with distilled water. F–C reagent (2.0 N), supplied by Loba Chemie Company was used directly for investigation.

Aqueous solutions of PTL (Burgoyene, 1.38×10^{-2} M), Na$_2$CO$_3$ (Sarabhai, 9.40×10^{-1} M), NaIO$_4$ (BDH, 9.35×10^{-3} M, for method C, and 4.0×10^{-2} M in 0.3 M HCl, for method D), MBTH (Fluka, 8.55×10^{-3} M), acetic acid (Qualigens, 3.5 M), PHH (Loba Chemie, 2.76×10^{-2} M) and potassium ferricyanide (Loba Chemie, 1.21×10^{-1} M) were prepared. A buffer solution was prepared by mixing equal volumes of 0.2 M acetic acid and 0.2 M sodium acetate and the pH of the solution was adjusted to 4.6.

2.3. Preparation of standard drug solution

A 1 mg ml^{-1} solution was prepared by dissolving 100 mg of pure DXH in 100 ml of distilled water and this stock solution was diluted stepwise with distilled water to obtain the working standard solutions of concentrations 20, 100 and 200 μg ml^{-1} for methods A and C, B, and D respectively.

2.4. Recommended procedures

2.4.1. Method A

Aliquots of 0.5–5.0 ml of the standard drug solution (20 μg ml^{-1}) were transferred into a series of 25 ml calibrated flasks and then solutions of 0.5 ml of Fe(III), 2.0 ml of PTL and 4.0 ml of pH 4.6 buffer were added to each flask successively. The flasks were heated on a boiling water bath for 30 min. The solutions were then cooled to the laboratory temperature and made up to the mark with distilled water. The absorbance values of the final colored solutions were measured at

510 nm within the stability period (1–60 min) against a reagent blank prepared in a similar manner but omitting the drug solution. The amount of drug was computed from a Beer–Lambert plot.

2.4.2. Method B

Aliquots (1.0–6.0 ml, 100 μg ml^{-1}) of the standard DXH solution were taken into a series of 25 ml calibrated tubes. Then 2.0 ml of F–C reagent and 9.0 ml of Na_2CO_3 solution were added successively and kept aside for 10 min at laboratory temperature. The solution was made up to the mark with distilled water and the absorbance of the solution was measured at 770 nm against a reagent blank prepared simultaneously within the stability period (5 min–5 h). The drug content was read from the calibration graph.

2.4.3. Method C

To a series of 25 ml standard flasks containing 0.5–4.0 ml of standard drug solution (20 μg ml^{-1}), 1.0 ml each of $NaIO_4$ (9.35 × 10^{-3} M) and acetic acid (3.5 M) were added. The total volume in each flask was brought to 10 ml with distilled water and kept in a boiling water bath for 15 min. After that 1.0 ml of MBTH solution was added and heated further for 1–2 min. It was later cooled and diluted to 25 ml with distilled water. The absorbance was measured at 620–670 nm against a reagent blank within the stability period (1–45 nm). The amount of DXH was computed from the Beer–Lambert plot.

2.4.4. Method D

Aliquots of the standard drug solution (0.5–2.5 ml, 200 μg ml^{-1}) were taken into a series of 25 ml calibrated flasks. Then 1.0 ml of $NaIO_4$ (4.0 × 10^{-2} M) was added and the solutions were allowed to stand for 30 min at room temperature. Later 1.5 ml of PHH solution and 1.0 ml of potassium ferricyanide solution were added successively and the solution was chilled in ice water for 5 min. Finally 5.0 ml of concentrated HCl was added and made up to the mark with methanol. The absorbance values were measured against a reagent blank at 510 nm within the stability period (1–15 min). The amount of DXH was computed from the calibration graph.

2.4.5. Analysis of pharmaceutical formulations for methods A and B

An accurately weighed amount of injection powder (vial) equivalent to 100 mg of DXH was dissolved in 100 ml of distilled water. This stock solution was further diluted to working standard solutions (20 μg ml^{-1}, for method A and 100 μg ml^{-1}, for method B) with the same solvent and was analyzed under the procedures described for pure samples.

2.4.6. Analysis of pharmaceutical formulations for methods C and D

An accurately weighed amount of injection powder equivalent to 100 mg of the drug was extracted with isopropyl alcohol (2 × 15 ml) and filtered. The combined filterate was evaporated to dryness and the residue was dissolved in 100 ml of distilled water to achieve a concentration of 1 mg ml^{-1}. This solution was further diluted stepwise with distilled water to working standard solutions (20 μg ml^{-1}, for method C and 200 μg ml^{-1}, for method D) and analysed under the procedures described for pure samples.

To compare the results obtained by the proposed procedures (A–D), an alternative or a reference procedure is necessary. A simple method has been developed as a reference method in our laboratory based on the earlier report [16] that the drug forms blue colored chromogen with NaOH.

2.4.7. Procedure for reference method

To each aliquot (0.5–4.0 ml, 50 μg ml^{-1}) of the aqueous solution of DXH (pure or formulation), 0.2 ml of 1.0 M NaOH was added and made up to 10 ml with methanol. The absorbance of the colored solution was measured at 560 nm during the stability period (1–15 min). The amount of the drug was computed from its Beer–Lambert plot.

3. Results and discussion

The optimum conditions for the development of the methods (A–D) were established by varying the parameters one at a time [25] and keeping others fixed, and observing the effect produced on the absorbance of the colored species.

In order to establish the experimental conditions in method A, DXH was allowed to react with Fe(III) in the presence of PTL. The effect of the reagent concentrations (Fe(III) and PTL), volume of buffer, temperature, time and order of addition of reagents were studied by means of control experiments. Optimization experiments reveals that the solutions of 0.5 ml of Fe(III) and 4.0 ml of buffer (pH 4.6) were necessary to attain the maximum color development. A volume of 2.0 ml of PTL solution and a heating time of 30 min on a boiling water bath were found to be optimal. The order of addition of the reagents has no effect on the absorbance of the colored species.

In order to establish the optimum volume of Na_2CO_3 solution in method B, the drug was allowed to react with F–C reagent in the presence of 10% Na_2CO_3 solution ranging from 1.0–14.0 ml. Constant absorbances were obtained with 8.0–10.0 ml; hence 9.0 ml was chosen. A volume of 2.0 ml of F–C reagent was found to be optimal. An increase in the volume of F–C reagent (> 2.0 ml) led to the precipitation. If the order of addition of the reagents (Na_2CO_3 and F–C), was reversed, the color was not noticed. Maximum color intensity was attained within 5 min after the addition of Na_2CO_3 solution and the colored product was stable for 5 h.

The influence of reagent concentrations ($NaIO_4$ and MBTH), temperature, volume of acid, heating time and order of addition of reagents with respect to maximum sensitivity, minimum blank, adherence to Beer's law and stability in method C were studied through control experiments. A volume range of 0.9–1.2 ml of $NaIO_4$ (9.35×10^{-3} M) was found to produce constant and reproducible absorbance values. So 1.0 ml of $NaIO_4$ was used in the procedure. A volume of 1.0 ml of acetic acid and 1.0 ml of MBTH were found to be necessary. A heating time of 15 min on a boiling water bath was required to produce maximum color development.

The influence of the concentration of $NaIO_4$ and the effect of oxidation time on color formation in method D has been optimized. The absorbances of the colored species remain constant within the volume range of 0.5–1.5 ml of $NaIO_4$ (4.0×10^{-2} M) and beyond the oxidation time of

30 min at room temperature. Hence 1.0 ml of $NaIO_4$ and an oxidation time of 30 min were selected for further work. A volume of 1.5 ml of PHH and 1.0 ml of potassium ferricyanide were found to be optimal. In the preparation of $NaIO_4$ solution, 0.3 M HCl was required. A minimum time of 5 min was found to be necessary for cooling in ice water prior to the addition of concentrated HCl. Maximum color intensity was attained within 2 min after the addition of methanol and the product was found to be stable up to 15 min after the attainment of maximum intensity.

The above optimum experimental conditions were incorporated in the recommended procedures for color development. Beer's law was found to be valid over the concentration ranges given in Table 1 at appropriate λ_{max} values (Fig. 1).

3.1. Reference method

The earlier report on the color test for DXH with NaOH in aerosol sample mentions the use of the solvent, dimethylsulphoxide (DMSO). However, in our systematic study of the effect of solvent (water, DMSO, dimethylformamide, methanol, acetic acid or 1,4-dioxane) in the DXH and NaOH reactions, methanol has been found to be superior when compared to other solvents with respect to maximum absorbance and stability. So in the reference method, the procedure mentioned above has been adopted. The sensitivity and precision data for this method is shown in Table 1.

3.2. Analytical data

The Beer's law limits, molar absorptivity, Sandell's sensitivity, detection limits [26], regression equation and correlation coefficients obtained by least squares treatment of these results are given in Table 1. The precision of each method was tested by analyzing six replicate samples containing 2.8, 16.0, 2.0 and 16.0 μg ml^{-1} of pure drug for methods A, B, C and D respectively. The percent standard deviation and the percent range of error at 95% confidence level of each method are given in Table 1.

Table 1

[a] $Y = a + bC$ where C is the concentration in μg ml^{-1} and Y is the absorbance units.
[b] Six replicate samples (concentrations of 2.8, 16, 2, 16 and 15 μg ml^{-1} of pure drug for methods A, B, C, D and reference respectively).

The interference studies in the determination of DXH in pharmaceutial formulation revealed that the normally existing excipients and additives like starch, lactose, talc, stearic acid, boric acid, gelatin, magnesium carbonate and sodium lauryl sulphate were found not to interfere even when present in excess (1–200 fold) in methods A and B. But in the case of methods C and D, substances possessing vicinal diols, α-amino-ol and α-ketol are expected to interfere since the above cited groups may undergo periodate oxidation leading to the formation of formaldehyde which proceeds the color reaction. In such cases, preliminary clean-up procedure with isopropyl alcohol is necessary to avoid interference due to the presence of starch and sugars like lactose prior to the estimation of DXH in formulations.

Commercial formulations (injections) containing DXH were successfully analyzed by the proposed methods. None of the excipients existing in DXH injections interfere in methods A and B even if water is directly used for solution preparation. However in methods C and D, the interfering excipients should be removed by selectively extracting DXH initially with isopropyl alcohol. The values obtained by the proposed and reference methods for injections were compared statistically by the t- and F-tests and found not to differ significantly. As an additional demonstration of accuracy, recovery experiments were performed by adding a fixed amount of the drug to the pre-analyzed formulations. These results are summarized in Table 2.

3.3. Chemistry of the colored species

In method A, the formation of the colored complex is due to the involvement of Fe(II) (formed through the oxidation of DXH with Fe(III)) and ortho-phenanthroline. The structure of this complex can be regarded as shown in Scheme 1, based on the previous reports [18,27].

The color formation by F–C reagent with DXH in method B may be explained in the following manner based on the analogy with the reports of the earlier workers [19,28]. The mixed acids in the F–C preparation involve the following chemical species: $3H_2O \cdot P_2O_5 \cdot 13WO_3 \cdot 5$

DXH-NaIO₄–PHH system (x──x) against reagent blank (x──x) versus distilled water: DXH 2.76 × 10⁻⁵ M; NaIO₄, 1.6 × 10⁻³ M; PHH, 1.65 × 10⁻² M; potassium ferricyanide, 4.84 × 10⁻³ M.

MoO₃·10H₂O and 3H₂O·P₂O₅·14WO₃·4MoO₃·10H₂O. DXH probably effects a reduction of 1, 2 or 3 oxygen atoms from tungstate and/or molybdate in F–C reagent (phosphomolybdotungstate),

thereby producing one or more of the possible reduced species which have a characteristic intense blue color.

As DXH contains α-ketol and α-amino-ol
Scheme 1.

groups, sodium metaperiodate offers a wider scope for analytical determination. The above groups are attacked in the manner shown in Scheme 2. The two methods avoid the distillation or diffusion step and permit the determination of the liberated formaldehyde directly in the reaction medium colorimetrically either by oxidative coupling reaction with MBTH (method C) or by the

DXH

Method C :

Method D:

FORMAZAN DYE
Where R' = H (formaldehyde)
Scheme 2.

Schryver's reaction with PHH and ferricyanide [24] (method D). Both of the reactions are not specific and are essentially aldehyde group methods. However formaldehyde reacts rapidly when compared to the involvement of the other oxidation products (dialdehyde).

In method C, MBTH on oxidation with excess periodate, loses two electrons and one proton forming an electrophilic intermediate which in turn reacts with the aldehyde forming a brilliant blue cationic dye as already illustrated by Sawicki et al. [23]. This reaction is presented in Scheme 2. Method D was based on the reaction of aldehydes with PHH in the presence of potassium ferricyanide giving formazan dye (Scheme 2).

4. Conclusion

Methods A–D are applicable to the intact molecule of DXH (obviating the need for any preliminary treatment) and have the advantage of wider range. The sensitivity order of the procedures is $A > C > D > B >$ reference method and the order of λ_{max} values of the colored species is $B > C >$ reference method $> A = D$. Although the λ_{max} values of two methods (A and D) are somewhat less than that of the reference method, the molar absorptivities of all of the four proposed methods are considerably higher than that of reference method. Moreover, no visible spectrophotometric method has been reported so far. Thus all the proposed methods are simple, sensitive and useful for the determination of DXH in pure samples and pharmaceutical formulations. They provide a wide choice, depending upon the needs of the specific situation.

Separation study of mercury through an emulsion liquid membrane

Quanmin Li*, Qi Liu, Xianjun Wei

Department of Chemistry, Henan Normal University, Xinxiang 453002, People's Republic of China

Abstract

A study of the transport of Hg(II) ions through a tri-n-octylamine (TOA) – sorbital monooleate (Span 80) – toluene liquid membrane has been performed with varying concentrations of HCl, KCl, TOA, Span 80 and NaOH in the feed, membrane and stripping solutions. Maximum transport was observed with 0.01 M KCl, 2.5×10^{-2} M HCl, 1.5×10^{-2} M TOA, 3% (w/v) Span 80 and 0.05 M NaOH. With this system, mercury could be completely separated from Cu, Zn, Fe, Co, Ni, Pb, Mn and Cd. The transport mechanism of this metal ion through the membrane is based on the association of metal anions ($HgCl_4^{2-}$) with protonated TOA molecules at the feed-side interface, diffusion through the membrane, decomposition of the complex at the strip-solution-side membrane interface under alkaline conditions, and backdiffusion of TOA molecules. Transport with the membrane is dependent on the concentration gradient but in the surrounding solutions it is inversely related to the concentration gradient.

Keywords: Emulsion liquid membrane; Mercury; Separation

1. Introduction

Tri-n-octylamine (TOA) has been studied as a supported liquid membrane mobile carrier to separate Pd and Mo [1,2] and as an emulsion liquid membrane (ELM) mobile carrier to separate Au [3], but it has not been applied for the separation of mercury from other metal ions, and also no transport studies have been made

---

* Corresponding author.

using an ELM. TOA is an important extractant and can be combined with $HgCl_4^{2-}$ ions after its protonation [4].

In this paper, an ELM with TOA as mobile carrier is studied for the transport of mercury. Various parameters influencing the transport of mercury across the membrane have been optimized to separate mercury from Cu(II), Zn(II), Fe(II), Co(II), Ni(II), Pb(II), Mn(II) and Cd(II). Under the chosen conditions, Hg_2^{2+} will precipitate Hg_2Cl_2 and will therefore not be transported.

2. Experimental

2.1. Reagents

A standard (1 mg ml^{-1} solution of mercury was prepared from $HgCl_2$ (analytical grade) and distilled, deionized water. TOA (analytical grade) was obtained from Fluka. Sorbital monooleate (Span 80; chemical grade) was obtained from Tianda Experimental Factory (Tianjin, People's Republic of China). A 0.1 M solution of TOA and a 3% (w/v) solution of Span 80 in toluene were used in this work.

2.2. Apparatus

The following instruments were used: a motor-driven emulsifier (range 0–6000 rev min^{-1}); motor-driven stirrers (range 0–600 rev min^{-1}); and a model 722 spectrophotometer (Shanghai Analytical Instrument Factory, People's Republic of China).

2.3. Procedures

2.3.1. Preparation of ELM

20 ml portions of solutions of TOA and Span 80 in tolune were emulsified at a stripping speed of 2000 rev min^{-1}. Stripping solution was added at a rate of 20 ml min^{-1} until the volume ratio of organic membrane solution to stripping solution was 1:1. The solution was then stirred continuously for 15 min to obtain a stable white ELM.

2.3.2. Transport of metal ions

To 10 ml beakers containing metal ion feed solution was added 20 ml of ELM and the contents stirred at 200 rev min^{-1} for a given transfer time; the phases were allowed to separate, clear feed solution was pippetted into a 25 ml volumetic flask and analysed for the amount of cation remaining.

2.3.3. Determination of mercury [5]

5 ml of 3×10^{-4} M 2-[(5-bromor-2-pyridyl)azo]-5-diethylaminophenol (5-Br-PADAP) alcohol solution was added to 5 ml of 0.1 M $Na_2B_4O_7 \cdot 10H_2O$ buffer solution in a 25 ml vol-

Feed phase: 100 μg ml^{-1} Hg(II) + 0.010 M KCl + HCl (M): (1) 2.5×10^{-2}; (2) 5.0×10^{-2}; (3)1.0×10^{-2}; (4) 5.0×10^{-3} ($HgCl_2^-$ precipitating HgO).

umetic flask containing mercury ions. After diluting to the mark the absorbance was read at 565 nm against the reagent blank.

In the separation experiment, the concentration of mercury as well as other cations was determined by inductively-coupled plasma atomic emission spectrometry (ICP-AES).

3. Results and discussion

3.1. The effect of hydrochloric acid concentration in the feed phase

The relationship between the concentration of

Fig. 2. Possible scheme for $HgCl_4^{2-}$ transport from HCl solution to NaOH solution through TOA Span 80–toluene liquid membrane.

Table 1
The effect of KCl concentration in the feed phase[a]

| Conc. KCl (M)	0	0.005	0.010	0.050	0.100
Percent extraction	93.0	96.3	98.5	97.8	97.3

[a] Membrane phase: 1.5×10^{-2} M TOA – 3% (w v) Span 80. Feed phase: 0.025 M HCl + 100 μg ml^{-1} Hg(II). Stripping phase: 0.05 M NaOH. Transfer time: 10 min.

hydrochloric acid in the feed solution and extraction of mercury is shown in Fig. 1. An acid concentration of 2.5×10^{-2} M was found to be the best for mercury transport. The H$^+$ concentration in the feed solution was measured and it was found that with transport of mercury into the stripping phase, the H$^+$ concentration in the stripping phase decreased. This proved that H$^+$ transport into the stripping phase also occurs. In the presence of HCl and KCl in the feed phase, the transport process of mercury through an ELM is illustrated by the following reactions:
TOA (shown as R_3N) in the membrane phase reacts with hydrochloric acid in the feed:

$$\underset{\text{(membrane)}}{R_3N} + \underset{\text{(feed)}}{H^+ + Cl^-} \rightleftharpoons \underset{\text{(membrane)}}{R_3NH^+Cl^-} \qquad (1)$$
In the feed, $HgCl_4^{2-}$ exchanges with Cl^- of R_3NH^-Cl in the membrane phase:

Fig. 3. The effect of TOA concentration in the membrane phase on the percent extraction of Hg(II). Feed phase: 100 μg ml^{-1} Hg(II) + 0.010 M KCl + 0.025 M HCl. Stripping phase: 0.05 M NaOH. Membrane phase: 3% (w v) Span 80 – TOA: (1) 1.5×10^{-2} – 2.0×10^{-2}; (2) 1.0×10^{-2}; (3) 7.5×10^{-3}; (4) 5×10^{-3}.

$$\underset{\text{(feed)}}{HgCl_4^{2-}} + 2R_3NH^+Cl^- \rightleftharpoons \underset{\text{(membrane)}}{(R_3NH)_2HgCl_4} + \underset{\text{(feed)}}{2Cl^-} \qquad (2)$$

NaOH in the stripping phases reacts with $(R_3NH)_2HgCl_4^{2-}$ to strip mercury into the stripping phase:

$$\underset{\text{(membrane)}}{(R_3NH)_2HgCl_4} + \underset{\text{(feed)}}{2Cl^-} \rightleftharpoons \underset{\text{(membrane)}}{R_3N} + \underset{\text{(stripping)}}{HgCl_4^{2-}} + 2H_2O \qquad (3)$$

The expected mechanism of mercury transport in the present case is shown in Fig. 2. The transport of H$^+$ along a concentration gradient supplied the energy for the transport of mercury against a concentration gradient. It was discovered that the decrease of H$^+$ in the feed phase was more than that of mercury. This was due to the formation of $R_3NH^+Cl^-$-type species and transport into the stripping phase. At an HCl concentration in the feed of $> 2.5 \times 10^{-2}$ M, more $R_3NH^+Cl^-$ ions were transported into the stripping phase, the liquid membrane emulsified sparingly and thus the transport of mercury decreased. When the concentration of HCl was $< 5.0 \times 10^{-3}$ M, transport of mercury abruptly decreased with time. This is because less H$^+$ is available to protonate R_3N, and precipitation of Hg^{2+} as HgO blocks the transport of mercury. From Fig. 1, it is also found that the transport of mercury can be completed in 5 min, this is because extraction and back-extraction occur simultaneously, and the degree of dispersion of the ELM in the feed solution is high [6].

3.2. The effect of KCl concentration in the feed phase
The influence of KCl concentration in the feed

Table 2
The effect of concentration of surfactant[a]

Conc. of Span 80 [%(w v)]	1	2	3	4	5
Percent extraction	93.1	95.0	98.5	97.0	96.0

[a] Membrane phase: 1.5×10^{-2} M TOA + Span 80. Feed phase: 0.025 M HCl + 100 μg ml^{-1} Hg(II) + 0.010 M KCl. Stripping phase: 0.05 M NaOH. Transfer time: 10 min.

solution upon the transport of mercury was also examined (see Table 1). Because KCl is a complexant for Hg^{2+} and a good salting-out agent [7], an increase in the KCl concentration increased the HgCl$_4^{2-}$ concentration and the stability of the membrane (preventing the membrane from emulsifying) and made separation easier. Therefore the extraction of mercury increased. We selected 0.01 M KCl in the experiment.

3.3. The effect of the concentration of TOA

The effect of the concentration of TOA (mobile carrier) in the organic phase on the extraction of mercury is shown in Fig. 3. The optimum concentration range of the carrier was 1.5×10^{-2}–2.0×10^{-2} M. In the experiment 1.5×10^{-2} M was selected for a rapid and complete transport of mercury.

3.4. The effect of the concentration of surfactant

Both the stability of the emulsion and the viscosity of the liquid membrane were altered by the proportion of surfactant in the organic phase. An increase in the concentration of Span 80 (surfactant) increased the stability of the emulsion; however, the extraction of mercury decreased. When the concentration of Span 80 was less than 2% (w/v), in the organic phase, the ELM was easy to break as the transfer time increased. A concentration of 3% (w/v) in the organic phase resulted in good extraction and stability (Table 2).

3.5. The effect of emulsion/feed volume ratio

Using 100 μg ml^{-1} mercury, 0.01 M KCl and 2.5×10^{-2} M HCl solution as the feed phase, 0.05 M NaOH solution as the stripping phase and 1.5×10^{-2} M TOA and 3% (w/v) Span 80 as the membrane phase, varying the emulsion/feed vol-

Fig. 4. The effect of KNO$_3$ concentration in the feed phase on the percent extraction of Hg(II). Membrane phase: 1.5×10^{-2} M TOA + 3% (w v) Span 80 + toluene. Stripping phase: 0.05 M NaOH. Feed phase: 2.5×10^{-2} M HCl + 100 μg ml^{-1} Hg(II) + KNO$_3$ (M): (1) 0.005; (2) 0.010; (3) 0.050; (4) 0.10; (5) 0.25.

Fig. 5. The effect of different salts in the feed solution on the percent extraction of Hg(II): (1) 0.01 M KCl; (2) 0.02 M K$_2$SO$_4$; (3) 0.01 M KNO$_3$; (4) 0.01 M KClO$_4$.

Table 3
Percent extraction of Hg(II) with different salts in the feed[a]

Salt (0.010 M)	KCl	KBr	KI	KSCN
Percent extraction	98	100	100	100

[a] Membrane phase: 1.5×10^{-2} M TOA + 3% (w/v) Span 80. Feed phase: 0.025 M HCl + 100 μg ml^{-1} Hg(II). Stripping phase: 0.05 M NaOH. Transfer time: 10 min.

ume ratio from 1.75:10 to 2.5:10 to measure the extraction, the experimental result showed that the concentration of mercury in the feed solution decreased to less than 2 μg ml^{-1} after 10 min of transport. Therefore the extraction efficiency was > 98%. In the experiment, a 2:10 emulsion/feed volume ratio was selected and a 10-fold higher concentration of mercury was obtained.

3.6. The effect of concentration of NaOH in the stripping phase

The NaOH in the stripping phase functioned as a back-extractant. When the composition of emulsion was fixed, an increase in the hydroxyl ions resulted in faster decomposition of the mercury complex and removal of protons from the amine molecules, thus resulting in higher transport. However, it has been observed that above a concentration of 0.1 M NaOH, the transport decreased. This may be because the HgCl$_4^{2-}$

Table 4
The percent extraction of other cations in the presence of various salts at a concentration of 0.01 M[a]

Feed phase	Percent extraction							
	Fe	Mn	Cu	Zn	Co	Ni	Pb	Cd

KSCN	0	0		70	50	4	0	5

[a] Membrane: 1.5×10^{-2} M TOA + 3% (w/v) Span 80. Feed phase: 0.025 M HCl. Stripping phase: 0.05 M NaOH. Initial amount of each ion: 100 μg ml^{-1}. Transfer time: 10 min.
[b] – means cation causes precipitation and no transport occurs.

precipitated HgO at higher NaOH concentrations and clogged the membrane. The maximum extraction was obtained in different feed solutions at 0.01–0.10 M NaOH. In the experiment, 0.05 M NaOH was selected.

3.7. The effect of other reagents in the feed phase

With a suitable acid concentration of the feed phase the concentration of KCl in the feed phase changed form 0.01 to 0.10 M and the extraction efficiency of mercury was always > 97%. If KCl was replaced by KNO$_3$, an increase in the concentration of KNO$_3$ obviously decreased the extraction of mercury (see Fig. 4), so the large NO$_3^-$ anion suppressed the transport of mercury. The regression equation of log E (logarithm of extraction of mercury) versus log C_{KNO_3} was log $E = 0.9139 - 0.4555$ log C_{KNO_3}; $r = -0.9983$.

KCl was replaced by KNO$_3$, K$_2$SO$_4$ and KClO$_4$ in turn and the results are shown in Fig. 5. ClO$_4^-$ is the biggest anion and so association with TOA resulted in a decrease in the transport of mercury. If 0.10 M KI, KBr and KSCN were added to the above systems respectively, the extraction efficiency of mercury reached 100% (Table 3). According to Ref. [8], Hg^{2+} can form a 1:4 complex with I$^-$, Br$^-$, SCN$^-$ and Cl$^-$; the logarithm of its accumulating stability constant (log β_4) is respectively 29.8, 21.0, 20.0 and 15.4. This shows that the more stable the anion complex, the less other anions interfere.

3.8. Separation of mercury from other metal ions

Under suitable conditions, transport of Cu, Zn, Fe, Co, Ni, Pb, Mn and Cd was studied in different feed solutions (shown in Table 4).

Results for the competitive transport of mercury and other common cations in mixed solution are shown in Table 5. (Note that the data of Table 5 come from ICP-AES measurements. All other data are from colorimetric measurements.) Selective transport of mercury was excellent in the KCl feed phase; under this condition the transport of Cu, Zn, Fe, Co, Ni, Pb, Mn and Cd was found to be negligible.

Table 5
Percent extraction of other cations from mixed solution[a]

Initial amount of each ion (μg ml^{-1})	Percent extraction								
	Hg	Mn	Cu	Zn	Co	Ni	Pb	Cd	Fe
50	99.3	0	0	0	0	1	0	1	1
100	98	2	0	2	0	1	2	2	1.5

[a] Membrane phase: 1.5×10^{-2} M TOA + 3% (w/v) Span 80. Feed phase: 0.025 M HCl + 0.01 M KCl. Stripping phase: 0.05 M NaOH. Transfer time: 10 min.

4. Conclusion

Extraction of mercury through a TOA-Span 80-toluene ELM was studied. The mechanism of transport of mercury was discussed and is presented in Fig. 2. The optimum conditions of transport have been found to be 0.01 M KCl and 2.5×10^{-2} HCl in the feed solution, 1.5×10^{-2} M TOA and 3% (w/v) Span 80 in the liquid membrane, and 0.05 M NaOH in the stripping solution. It is concluded that this method can be applied for the selective separation of mercury from a mixed solution of Cu, Zn, Fe, Co, Ni, Pb, Mn and Cd or as a preconcentrating step for measuring mercury. Small amounts of carriers are involved and the extraction efficiency is high.

Rapid procedure for the determination of gold at sub-ppm levels in geological samples by atomic absorption spectrometry

Arun Kumar Singh

Chemical Laboratory, Atomic Minerals Division. AMD Complex, Begumpet, Hyderabad-500 016, India

Abstract

A rapid and reliable procedure for the determination of gold in geological samples is reported that involves MnO_2 and HCl treatment of the samples followed by ethyl acetate extraction of gold and determination at the ppm and sub-ppm levels by flame atomic absorption spectrometry after evaporating off the organic solvent. The method was tested for the quantitative recovery of gold from the standard sample from the Kolar gold field and four other thoroughly analysed in-house standards from the Otha area, India. The procedure offers distinct improvements in speed of analysis and environmental safety. The higher RSD of the data is attributed ot the "nugget" effect.

Keywords: Atomic absorption spectrometry; Geological samples; Gold

1. Introduction

The continuing search of gold has led to improvements in analytical methodologies for its determination. Analytical procedures include the classical fire assay [1,2] and wet chemical treatment involving aqua regia, $HBr–Br_2$, $NaBr–H_2O_2$ and cyanide followed by separative preconcentration using anion exchange [3], solvent extraction [4,5], precipitation on tellurium and $Hg_2Cl_2–Hg$ or adsorption on activated charcoal [6] and polyurethane foam [7]. The gold content of samples has been determined using graphite furnace atomic absorption spectrometry (GFAAS) [8], flame atomic absorption spectrometry (FAAS) [9] and inductively coupled plasma

atomic emission spectrometry (ICP-AES).

Although GFAAS offers very high sensitivity, it suffers from poor precision. ICP-AES is less sensitive and not very selective. FAAS offers high selectivity and precision, although the determination limits are restricted to ppm and sub-ppm levels of gold in the solutions aspirated. Instrumental neutron activation analysis (INAA) also offers very high sensitivity. Using INAA, gold has been determined directly or after chemical pretreatment of the sample and its separation either by ion exchange or solvent extraction as the situation demands [10]. Although some bias has been reported between gold values determined by INAA and other techniques, this has been traced to variations in wet chemical methods of sample

treatment rather than to the efficiency of measurement by various instrumental techniques [11].

For a rapid appraisal of the gold potential of favourable areas, wet chemical procedures have found wider application. Work has been done on gold extraction by using $HCl-H_2O_2$ to leach the gold from manganese oxide ores [12] and subsequently using bleaching powder–HCl [13] and $KMnO_4$–HCl [14], which offers certain definite advantages. This prompted us to investigate other oxidizing solutions which could dissolve gold from geological samples quantitatively and rapidly.

Combinations of $NaClO_3$–HCl/$NaBiO_3$–HCl and MnO_2–HCl were investigated and this paper reports the results using MnO_2–HCl (1 M) for the wet chemical dissolution of gold (and palladium) from the sample matrix, followed by ethyl acetate extraction and final determination of gold using FAAS (242.8 nm) after evaporation of the organic solvent.

The procedure is simple, fast, quantitative. Since repeated evaporations of aqua regia solution to remove nitrates/nitrosyl compounds and bring it to only HCl medium are not required, the procedure is also environmentally safe.

2. Experimental

2.1. Instrumentation

All measurements were made using a Spectra AA-20 flame atomic absorption spectrometer, (Varian, Australia) with the operating parameters presented in Table 1.

Table 1
Flame AAS operating conditions

Wavelength	242.8 nm
Slit setting	1.0 nm
Lamp type	Au hollow cathode
Lamp current	4 mA
Background correction	Deuterium arc
Flame	Air acetylene
Flame condition	Lean

2.2. Chemicals

Reagents used included 1 M HCl (AnalaR), MnO_2 powder (AR grade) and ethyl acetate (AR grade).

A gold stock standard solution (100 μg ml^{-1}) was prepared by dissolving 1.0 g of $AuCl_3$ containing 25% Au (Johnson Matthey, London, UK) in 10% (v/v) HCl in a glass beaker on water-bath. The solution was cooled and transferred to a 250 ml volumetric flask and diluted to volume with 10% HCl. Working standard solutions were prepared by dilution of suitable aliquots with 10% HCl.

2.3. Procedure

A 10 g amount of gold-bearing sample (– 200 mesh) was taken and roasted at 650°C for 30 min in a porcelain dish and transferred into a 250 ml beaker, then 100 ml of 1 M HCl were added followed by 0.5 g of MnO_2. The solution was covered with a watch-glass and boiled for 1 h on a hot-plate. It was then cooled, filtered through a Whatman No.40 filter-paper (12.5 cm) and washed with 1 M HCl. The filtrate was concentrated to about 50 ml by boiling, cooled and extracted with 25 ml of ethyl acetate for 2 mn. The organic layer was collected in a separate extraction flask. The extraction was repeated three times with 25 ml of ethyl acetate each. The combined organic layer was scrubbed with about 20 ml of 1 M HCl to remove any extracted Fe and Mn. The organic extract was then cautiously evaporated in a beaker on a water-bath at 70°C. Aqua regia (2 ml) was added to the beaker and the mixture evaporated. The final solution was taken in 1 ml of aqua regia and made up to 10 ml with distilled water. At this stage 25% HCl can also be used, but the presence of HNO_3 keeps the gold in oxidized form. The gold absorbance was measured by FAAS (242.8 nm) using an air–acetylene flame with deuterium background correction. The gold content was determined by AAS after calibrating the instrument with suitable working standards.

[a] Sample 1 from Kolar gold field. Mineralogy: quartz and native gold [16]. Samples 2–4 from Otha. Mineralogy: quartz, sericite and chlorite [15].
[b] Mean of five results. The RSD varies between 2 and 9%.
[c] Mean of four results.

3. Results and discussion

The MnO_2–HCl system was tested on a standard gold sample from the Kolar gold field, Karnataka, India, and three in-house standard samples from Otha, Himachal Pradesh, India, where gold has been found associated with uranium [15], the gold level ranging from 0.31 to 23.7 ppm. The standard samples were analysed by INAA and aqua regia–GFAAS. Table 2 shows the agreement in the values (means of five values). The high RSD values are attributed to the "nugget" effect. The results show that the MnO_2–HCl system is able to solublize gold quantitatively. Trace amounts of Fe and Mn which are co-extracted by ethyl acetate are removed after scrubbing with 1 M HCl. The standard addition method was applied to chlorite, biotite and schist samples from the Singhbhum Thrust Belt (Bihar) and the recovery was found to be more than 95% (Table 3). The gold in the same solution was also determined by ICP-AES (242.795 nm), as indicated in Table 2 (mean of four values). The higher concentration of gold is in excellent agreement with the FAAS values, provided the gold solution is free from the presence of manganese in high amounts.

It is true that a method based on aqua regia dissolution or dissolution by a similar oxidizing acid mixtures could lead to low results, being dependent on the sample matrix and the mineralogical association of the gold present. If gold particles are enclosed in quartz then dissolution

by an acid mixture, to which quartz is inert, will largely be a function of the extent to which grinding has liberated or exposed the gold to make it accessible to acid attack and the gold recovery may approach 100%, but will always be less than 100%.

The gold values obtained with the present method, however, show that the gold recovery is nearly quantitative when sample ground to −200 mesh is taken for treatment with MnO_2–HCl, and the quartz mineralogy of gold occurrence shows complete amenability.

The procedure is broadly applicable to a wide variety of geological samples, viz. carbonaceous, refractory, quartz, sericite, etc. This method obviates HF treatment of samples, which is critical especially for gold locked in a quartz matrix. Further, the results obtained by this method are well within the acceptable RSD limits of 2–9% (Table 2).

The MnO_2–HCl treatment also offers another advantage in that it dissolves out quantitatively and simultaneously palladium if present in the sample. Results for this aspect will be published elsewhere.

Abstract

Four simple and sensitive methods for the assay of prazosin hydrochloride (PRH) are developed. These methods are based on the formation of coloured species by treating it either with excess N-bromosuccinimide (NBS) and determining the unconsumed NBS with p-N-methyl aminophenol sulphate (metol)-sulphanilamide (SA) reagent (method A. λ_{max} 520 nm); with 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) in the presence of ceric ammonium sulphate (CAS) (method B, λ_{max} 620 nm) or with acidic dyes such as orange-II (O-II) (method C, λ_{max} 490 nm) and alizarin violet 3B (AV-3B) (method D. λ_{max} 570 nm) under the specified experimental conditions. Regression analysis of Beer's law plot showed good correlation in the concentration range of 1.0–10.0, 2.5–25.0, 1.0–17.5 and 2.5–30.0 μg ml for methods A. B, C and D respectively.

Keywords: Prazosin hydrochloride; Spectrophotometry; Tablets

1. Introduction

Prazosin, 1-(4-amino-6,7-dimethoxy-2-quinazolinyl)-4-(2-furanylcarbonyl)piperazine, is a potent vasodilatory agent which has gained widespread acceptance in the management of hypertension [1] and also has been found to be value in the treatment of heart failure [2]. The drug and its formulations are official in the British Pharmacopoeia [3] and United States Pharmacopoeia [4]. Reported methods include titrimetric [5], UV spectrophotometric [6], fluorimetric [7], GLC [8], HPLC [9–11] and TLC [12]. As there is no visible-range spectrophotometric method for prazosin hydrochloride (PRH), sensitive and precise spec-

PRAZOSIN

Form 1

---
trophotometric methods would greatly aid in the determination of PRH in bulk samples and pharmaceutical formulations. This paper describes four visible-range spectrophotometric methods for PRH determination making use of its different structural features.

N-Bromosuccinimide (NBS) contains unstably bound bromine and is used for brominations and dehydrogenations of organic compounds. Sastry et al. [13] suggested a procedure for determining primary arylamines by treatment with p-N-methylaminophenol sulphate (metol) and NBS. Sawicki et al. [14] developed a procedure for determining aromatic amines and phenols by coupling with 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) in the presence of an oxidant to form an intensely coloured oxidative coupling product. The acid dyes Orange II (O-II) and Alizarin Violet 3B (AV-3B) have been used for the determination of many drugs which are basic in nature [15]. We have applied these sensitive procedures to the determination of PRH in bulk samples and pharmaceutical formulations.

In method A of the present study, PRH was treated with standard NBS in excess. The NBS consumed, corresponding to PRH, was obtained by determining the excess NBS spectrophotometrically with metol and sulphanilamide (SA) and subtracting it from the NBS initially taken (i.e. blank − unconsumed). Method B involves the spectrophotometric determination of PRH with MBTH in the presence of cerium(IV) ammonium sulphate (CAS). Methods C and D are based on the formation of chloroform-soluble ion-association complexes with O-II and AV-3B. respectively.

2. Experimental

2.1. Apparatus

A Systronics (Hyderabad. India) Model 106 spectrophotometer with 1 cm matched glass cells was used for all absorbance measurements. An Elico (Hyderabad, India) Model LI-120 digital pH meter was used for pH measurements.

2.2. Reagents

All reagents were of analytical grade and all solutions were prepared in triply distilled water. Freshly prepared solutions were always used.

Aqueous solutions of NBS (Loba Chemie. India: 2.53×10^{-3} M), metol (Wilson Labs., India; 8.71×10^{-3} M), SA (IDPL Labs., India; 1.16×10^{-2} M, initially dissolved in the minimum quantity of dilute HCl and acetic acid (Wilson Labs., India, 3.5×10^{-1} M) were prepared for method A. Aqueous solutions of MBTH (Loba Chemie; 8.56×10^{-3} M) and CAS (Wilson Labs.; 1.58×10^{-2} M) in 0.72 M H_2SO_4 were prepared for method B. Aqueous solutions of O-II (Merck, India; 1.41×10^{-3} M) and hydrochloric acid (Merck; 0.1 M) were prepared for method C. A pH 4.4 phthalate buffer and an aqueous solution of AV-3B (Chroma, Germany; 6.079×10^{-3} M) were prepared for method D.

2.3. Standard drug solutions

An accurately weighed quantity of pure PRH equivalent to 50 mg was dissolved in and made to 50 ml with glacial acetic acid. This stock standard solution was further diluted stepwise with distilled water to obtain working standard solutions with concentrations of 100 and 50 μg ml^{-1}.

2.4. Analysis of bulk samples

2.4.1. Method A

Into a series of 25 ml volumetric flasks containing aliquots (0.5–5.0 ml) of PRH solution (50 μg ml^{-1}), 2.5 ml of NBS and 5.0 ml of acetic acid solutions were added successively and the total volume in each flask was made up to 15 ml with distilled water and kept aside for 25 min at room temperature. Then 1.5 ml of metol and 1.5 ml of SA solutions were added at 1 min intervals and the volume was made up to the mark with distilled water. The absorbances were measured against distilled water at 520 nm during the stability period of 10–30 min. A blank experiment was also carried out, omitting the drug. The decrease in the absorbance corresponding to PRH was obtained by subtracting the absorbance of the

drug solution from that of the blank. The amount of the drug was calculated from the calibration graph.

2.4.2. Method B

Into a series of 10 ml of volumetric flasks containing aliquots (0.25–2.5 ml) of PRH solution (100 μg ml^{-1}), 3.0 ml of MBTH solution was added, made up to 6 ml with distilled water and kept aside for 2 min at room temperature. Then 3.0 ml of CAS solution were added to each flask, kept aside for 20 min and diluted to mark with distilled water. The absorbances were measured within 15 min at 620 nm against a reagent blank prepared in a similar manner but omitting the drug. The drug concentration was read from a calibration graph prepared under identical conditions.

2.4.3. Method C

Aliquots of 0.2–3.5 ml of the standard solution of PRH (50 μg ml^{-1}) were transferred into a series of 125 ml separating funnels, then 2.0 ml of 0.1 M HCl and 1.0 ml of O-II solution were added to each funnel and the total volume of the aqueous layer in each funnel was brought to 10 ml with distilled water. A 10 ml portion of chloroform was added to each and the contents were shaken for 2 min. The absorbance of the separated chloroform layer was measured after 5 min at 490 nm against a reagent blank prepared simultaneously but omitting drug. The amount of PRH present was calculated from the calibration graph.

2.4.4. Method D

Aliquots of 0.2–3.0 ml of the standard solution of PRH (100 μg ml^{-1}) were transferred into a series of 125 ml separating funnels, then 5.0 ml of buffer solution (pH 4.4) and 2.0 ml of AV-3B solution were added to each funnel. The total volume of the aqueous layer in each funnel was brought to 10 ml with distilled water. A 10 ml portion of chloroform was added to each funnel and the contents were shaken for 2 min. The absorbance of the separated chloroform layer was measured after 5 min at 570 nm against a reagent blank prepared simultaneously but omitting drug. The amount of PRH present was calculated from the calibration graph.
Fig. 1. Absorption spectra of PRH–NBS/metol–SA system (○) and NBS/metol–SA system (•). [PRH], 1.43 × 10^{-5} M; [NBS], 2.53 × 10^{-4} M; [metol], 5.22 × 10^{-4} M; [SA], 6.96 × 10^{-4} M; [CH$_3$COOH], 7.0 × 10^{-2} M.

2.5. Analysis of pharmaceutical formulations

Twenty tablets were accurately weighed and powdered and an amount of the tablet powder equivalent to 10 mg of PRH was treated with 8.0 ml of glacial acetic acid (warmed on a boiling water-bath for 5 min with occasional shaking). The solution was cooled to room temperature, filtered and made up to 10 ml with glacial acetic acid to give a solution of 1 mg ml^{-1}. This stock standard solution was further diluted stepwise with distilled water to obtain working standard solutions (for the above-mentioned methods) and were analysed by following the procedures in Section 2.4.

2.6. UV reference method

Twenty tablets were weighed and powdered. To a quantity of the powder containing the equivalent of 10 mg of PRH, 10 ml of glacial acetic acid were added and the mixture was warmed on a boiling water-bath. The solution obtained was cooled and filtered. To 1.0 ml of the filterate, sufficient distilled water was added to produce 200

ml. The absorbance of the solution was measured at λ_{max} of 248 nm. The content of the drug was calculated from the Beer–Lambert plot.

3. Results and discussion

The optimum conditions for the development of methods A–D were established by varying the parameters one at a time and keeping the others fixed and observing the effect produced on the absorbance of the coloured species.

3.1. Method A

The method involves two stages, namely oxidation with excess NBS and the determination of unreacted NBS using metol–SA reagent. Oxidation of PRH with 1.5–3.0 ml of NBS solution gave maximum and reproducible absorbance values. The effect of time and temperature of oxidation on the absorbance of the coloured species was studied by conducting the oxidation at different temperatures for different time intervals. Oxidation times ranging from 20–30 min at room temperature (28 ± 5 °C) gave constant and repro-

Fig. 3. Absorption spectra of PRH O-II system (○), its reagent blank (◆) and aqueous O-II dye in 0.1 M HCl (◇). [PRH], 2.38×10^{-5} M; [O-II], 1.41×10^{-4} M; [aqueous O-II], 1.38×10^{-5} M.

ducible absorbance values. Prolonging the oxidation time beyond 30 min and increasing the temperature gave erratic results. Maintaining the pH of the solution at 2.9 ± 0.2 was found to be the best for attaining the maximum sensitivity. This was achieved by the addition of 5.0 ml of 3.5×10^{-1} M acetic acid. Use of 1.0–2.0 ml of metol solution and 1.0–2.5 ml of SA solution afforded the maximum absorbance values. A waiting period of 1–3 min was necessary between the addition of metol and SA solutions for the generation of p-N-methylbenzoquinone monoimine (PMBQMI) by the action of NBS on metol. Prolonging the waiting period beyond 3 min resulted in low absorbance values, probably owing to the partial hydrolysis of the PMBQMI formed in situ to the quinone state. Among the water-miscible solvents examined, water was found to be the best for final dilution of the solution. Maximum colour intensity was attained within 10 min after the final dilution and remained stable for the next 20 min. The absorption spectrum of the coloured species is shown in Fig. 1.

Fig. 2. Absorption spectra of PRH MBTH system (○) and its reagent blank (◇). [PRH], 4.76×10^{-5} M; [MBTH], 2.56×10^{-3} M; [CAS], 4.74×10^{-3} M.

3.2. Method B

As the drug molecule possesses aromatic amino groups, the suitability of MBTH reagent for the determination was examined. The applicability of MBTH in conjunction with various oxidizing agents (potassium dichromate, sodium metaperiodate, chloramine-T, potassium hexacyanoferrate(III), iodine, iron(III) chloride and cerium(IV) ammonium sulphate (CAS)) for the determination of PRH was examined and CAS was found to be the best. The effects of reagent concentration (MBTH and CAS), temperature, H_2SO_4 strength in CAS solution, time and order of addition of reagents with respect to maximum sensitivity, minimum blank reading, adherence to Beer's law and stability of coloured species were studied through controlled experiments. For the colour development, 2.5–3.5 ml of MBTH solution, 2.5–3.5 ml of CAS solution and a temperature of $30 \pm 5°C$ were found to be optimum. An acid strength of 0.72 M H_2SO_4 was found to be optimum as a medium for the CAS solution. The order of addition drug, MBTH and CAS gives maximum sensitivity. Altering the order of addition (i.e. MBTH, CAS and drug or drug, CAS and MBTH) resulted in a loss of sensitivity. Maximum colour intensity was attained within 20 min after the addition of CAS solution. The coloured species was found to be stable for 20 min after the attainment of maximum colour intensity. The spectrum of the coloured species produced by the suggested procedure is shown to possess maximum absorbance at 620 nm (Fig. 2).

3.3. Method C

To establish the experimental conditions, the drug was allowed to react with O-II in dilute HCl ranging from 0.05 to 1.5 M and the complex was extracted into the chloroform layer. Constant absorbances were obtained with 0.08–0.12 M HCl, hence 0.1 M HCl was adopted. A 1.0 ml portion of O-II solution was found to be optimum. Shaking times of 1–4 min produced constant absorbance, hence a shaking time of 2 min was chosen.

3.4. Method D

In order to establish the optimum pH range, the drug was allowed to react with AV-3B in aqueous solution buffered to pH 4.0–5.0 and the complex formed was extracted into chloroform for measurement. Constant absorbances were obtained over the pH range 4.2–4.6 (phthalate buffer), hence a pH of 4.4 was adopted. A 2.0 ml portion of AV-3B solution was found to be optimum. Constant absorbance values were obtained for shaking periods between 1 and 4 min, hence a shaking time of 2 min was selected.

Chloroform was preferred among the water-immiscible solvents for the selective extraction of the drug-dye complexes in both methods C and D. A ratio of 1:1 aqueous to chloroform phases was required for efficient extraction of the coloured species. The absorption spectra of the coloured species are shown in Figs. 3 and 4.

The optical characteristics and data for methods A–D are presented in Table 1. The PRH values for tablet dosage forms with the proposed and reference methods are compared in Table 2 (the UV spectrophotometric method developed

for the assay of PRH was used as a reference method for ascertaining the accuracy of the proposed methods). The results of the recovery experiments by the proposed methods are also given in Table 2.

The commonly used excipients and additives in PRH tablets such as talc (up to a 250-fold m m excess, compared with PRH), starch (200-fold), boric acid (150-fold), stearic acid (60-fold), sodium lauryl sulphate (10-fold) and propyl paraben (5-fold) did not interfere in any of the

Scheme 1.

methods. The results in Tables 1 and 2 show that the proposed methods can be applied for the analysis of pharmaceutical preparations with considerable precision, accuracy and sensitivity.

3.5. Chemistry of the coloured species

3.5.1. Method A

This method is based on the oxidation of PRH by NBS to form oxidation products (probably a mixture but reproducible under proposed experimental conditions), excess NBS being determined with metol–SA reagent. The coloured complex may be regarded as a charge-transfer type, shown in Scheme 1, presumed to take place by electron transfer from the highest occupied molecular orbital (π^*) of SA to the lowest empty molecular orbitals (π) of the two adjacent PMBQMI (formed in situ from metol and NBS) molecules as in the metol, iodine and INH reaction [16].
3.5.2. Method B

Under the reaction conditons, MBTH, on oxidation with CAS, loses two electrons and one proton to form an electrophilic intermediate, which is the active coupling species. One mole of this species undergoes electrophilic substitution to form a coloured product as shown in Scheme 2.

[c] After adding three different amounts (0.5, 1.0 and 2.0 mg) of pure PRH to the pre-analysed pharmaceutical formulations.

Scheme 2.

3.5.3. Methods C and D

These two methods are based on the basic nature of the drug, which under specified experimental conditions forms ion-association complexes with certain acidic dyes (O-II and AV-3B) which are extractable into chloroform from the aqueous phase [17]. The stoichiometric ratio of PRH to O-II or AV-3B was determined with the slope ratio method and found to be 1:2.

3.5.4. Procedure for slope ratio method

Solutions of acid (for method C) or buffer (for method D) and dye (O-II for method C; AV-3B for method D) were taken in different 125 ml separating funnels and different concentrations of drug solutions were added such that on further addition of drug no dye to drug complex formation occurred. The complex was then extracted using chloroform. The maximum absorbance obtained in each case was termed A_{max} in that case. A linear graph was obtained when log q was

Scheme 3.

Scheme 4.
plotted against log r, where $q = A_{obs}/(A_{max} - A_{obs})$ and r is the concentration of the drug in mol l^{-1}. The slope dy/dx of the line gives the ratio of dye to drug in the complex.

The drug PRH (1 mol) and oppositely charged form of the dye (2 mol) behave as a single unit, being held together by electrostatic attraction. The structures are shown in Schemes 3 and 4.

4. Conclusions

The three proposed methods exploit different structural features (method A, unsaturation; method B, presence of amino groups in the quinazolinyl ring; methods C and D, basic property) of the PRH molecule. All the proposed methods have higher λ_{max} values and sensitivity. This is a decisive advantage since the interference from the associated ingredients will be less at higher wavelengths than at lower wavelengths. The sensitivity order of the procedures is A > C > D = B and the λ_{max} order of the coloured species is B > D > A > C. The proposed methods are simple, rapid and have reasonable precision and accuracy when compared with many of the reported methods. All the proposed methods are useful for the determination of PRH and provide a wide choice, depending on the needs of the specific situation.

Sorption recovery of metal ions using silica gel modified with salicylaldoxime

A.R. Sarkar, P.K. Datta, M. Sarkar*

Department of Chemistry, University of Kalyani, Kalyani 741235, India

Abstract

Trace metals in water were preconcentrated with silica gel modified with salicylaldoxime and determined by AAS. Optimum conditions for the maximum recovery of metal ions, viz. Cu(II), Ni(II), Co(II), Zn(II) and Fe(III), for both batch and column methods were developed. The efficiency of the adsorbent with respect to different experimental conditions was established.

Keywords: Atomic absorption spectrometry; Metal ions; Salicylaldoxime; Silica gel; Sorption recovery

1. Introduction

Toxic metals have become an ecotoxicological hazard of prime interest and increasing significance, owing to their tendency to accumulate in vital organs in man and animals. Continuous exposure to even low doses of toxic metals is of concern because they cause, according to their degree of accumulation, progressively increasing toxic actions over long periods of the life span of an individual [1].

In densely populated and industrialized regions, alarming amounts of toxic metals are emitted from anthropogenic sources into soils and the aquatic environment. Among the various environmental chemicals, toxic metals are almost the only pollutant class without biodegradability. Instead,

they pass into the enviornment in a biogeochemical cycle with relative accumulations and different residence times in various types of ecosystems and with transformations to sometimes more or less toxic chemical species. Accurate and reliable to sometimes more or less toxic chemical species. Accurate and reliable methods must therefore be developed for their determination. Because of their extremely low concentrations, a preliminary concentration step is usually necessary prior to the determination of the metals.

Solvent extraction, although one of the most popular techniques for the separation of metals, has limited application in concentrating trace amount of ions present in large sample volumes. Among the different types of adsorbents reported, active carbon [2], ion-exchange resins [3], chelating agents supported on various substrates [2–3] and waste materials such as fly ash [9], rice husk

ash [10] and waste Fe(III)/Cr(III) hydroxide [11] have beem applied for the removal or separation of metal ions. Kantipuly et al. [12] reviewed the application of chelating polymeric resins for the separation and concentration of trace metals from oceans, rivers and other natural systems. A review was presented by Terada [13] covering preconcentration by sorportion on activated carbon, porous polymers, C_{18}-bonded silica or glass beads, complex-forming adsorbents and natural polymers.

A survey of the literature on water analysis shows that silica gel can be used as a very successful adsorbing agent [14]. It does not swell or strain, has good mechanical strength and can undergo heat treatment. Moreover, chelating agents supported on silica gel as adsorbent are stable, easy to prepare and can be used selectively for the preconcentration of different metals. Preconcentration of metals with silica gel physically supporting sulphonated hydroxyazo dyes and sulphonaphthaleins [15] has been applied successfully to various samples of different origins. The use of chemically bonded silica gels [16–19] has also been reported. Recent progress in the preconcentration of metals using modified silica gel columns includes the use of surfactants as coating material on C_{18}-bonded silica [20], the formation of new stationary phases with a silica gel-bonded cationic polyelectrolyte with Ferron [21] as counter ion and ion-pair formation between a metal complex and a long-chain qaternary ammonium salt and subsequent sorption of this ion pair on the silica gel [22].

In the present investigation, Cu(II), Ni(II), Co(II), Zn(II) and Fe(III) in water were preconcentrated on silica gel loaded with salicylaldoxime and determined by AAS. Salicylaldoxime is widely applied in solvent extraction [23]. After being used successfully as a reagent for conductometric titration of some metal ions [24], it was chosen in the present study as a chelating agent for immobilization on silica gel. The substrate thus obtained can be used a number of times for the purpose of preconcentration of metals. Single-metal or multi-metal solutions can be preconcentrated from the same stock.

2. Experimental

All chemicals were of analytical-reagent grade. Silica gel H 4267 of particle size 60 μm, specific surface area 420 m^2 g^{-1} and pore size 120 Å was obtained from Sigma.

Stock solutions of Cu(II), Ni(II), Co(II), Zn(II) and Fe(III) (1mg ml^{-1}) were prepared by dissolving the respective metal salts in doubly distilled water. Multi-metal solutions (10–100 μg ml^{-1}) were prepared from the stock solutions. pH values were controlled using acetate buffer and phosphate buffer.

2.1. Apparatus

A Perkin-Elmer atomic absorption spectrometer was used for metal determinations and a Systronics pH meter was used to check the pH of the aqueous solutions. The column was a glass tube (160 × 6 mm i.d.) with a coarse sintered-glass disc and a tap at the bottom.

2.2. Synthesis of sorbent

First silica gel was refluxed with 6 M HCl for about 3 h to remove any contaminating metals such as iron. It was then washed with deionized water and dried under reduced pressure at 150°C. The dried silica gel was refluxed with salicylaldoxime in ethanol (10% w/w) at 70–80°C for 4 h. The solid thus obtained was filtered and dried under vacuum.

2.3. Procedure for adsorption experiment

The sorption of various metals was examined under both static and dynamic conditions. To determine the capacity and stability of the sorbent, the kinetics and pH of adsorption and the desorption behaviour, the static method was used. To determine the flow rate and sample volume in the column process, the dynamic method was used.

2.3.1. Static process

Volumes of 10 ml of each of the metal solutions (200 μg) and 10 ml of buffer solution were added

to 0.5 g of the adsorbent in a centrifuge tube and shaken in a mechanical shaker for 1 h at room temperature. The metal ion concentration in the supernatant was measured by AAS and the percentage retention of metal on the adsorbent was calculated.

2.3.2. Dynamic process

The chromatographic column was prepared by filling 10 g of the adsorbent, the bed length being about 10 cm.

A fixed volume of an aqueous solution of the metal ion was adjusted to a suitable pH and percolated through the column at a flow rate of 5 ml min $^{-1}$. After washing the column with about 20 ml of deionized water, an eluting solution of definite composition (4 M HNO_3) was passed through at a flow rate of 3 ml min $^{-1}$. The metal ion concentration in the eluate, after dilutions to the desired volume, was determined by AAS. Wet digestion of the samples with HNO_3 and H_2SO_4 was performed prior to estimating the concentration of metals by AAS following the methods of the APHA [25]. An air–acetylene flame was used with observation at 10 mm above the burner with the following wavelengths: Cu 324.8, Ni 232, Ca 240.7, Zn 213.9 and Fe 248.3 nm.

3. Results and discussion

3.1. Effect of pH

The adsorption behaviour of Cu(II), Ni(II), Co(II), Zn(II) and Fe(III) on the adsorbent at various pH values was investigated in the batch process. The results are shown in Fig. 1(A).

Cu(II) was adsobred quantitatively at pH 2.2 and for Ni(II), Co(II), Zn(II) and Fe(III) the maximum adsorption started at pH 3.5, 4.2, 5.5 and 7.3, respectively. A control measurement was done with untreated silica gel itself (Fig. 1(B)) and a remarkable difference in the retention of metal ions was observed between the adsorbent and the untreated silica gel. In all cases, except for Fe(III), quantitative retention occurred at much higher pH for the untreated silica gel compared with that for the adsorbent. Only for Fe(III) was the effect

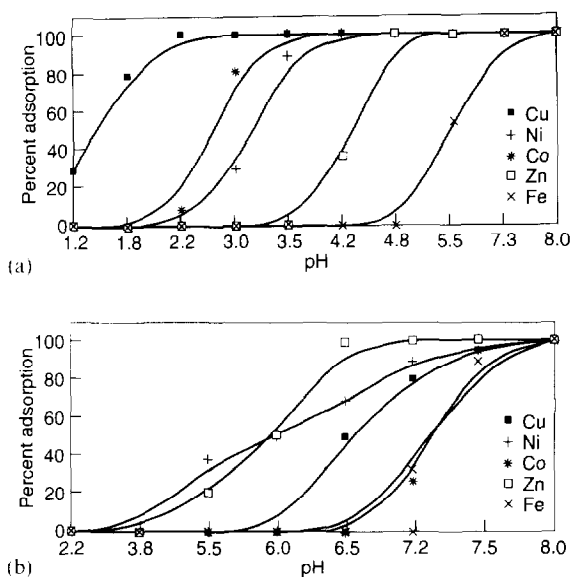

Fig. 1. Effect of pH on adsorption: (a) on salicylaldoxime-modified silica gel and (b) untreated silica gel.

of pH on both the untreated and treated silica gel similar.

From the results, the separation of Cu(II) from the rest of the metals is possible by varying only the pH of the solution. Similarly, Ni(II) and Co(II) can be separated from Zn(II) and Fe(III) and Zn(II) can be separated from Fe(III). However, Ni(II) and Co(II) cannot be separated from each other by this process and a modification is needed. The use of a surfactant or an organic modifier can be effective.

For a given ligand, the stability of complexes with dipositive metal ions follow the Irving–Williams order, which is considered to arise in part from a decrease in size across the series and in part from the ligand field effect. The observed

Fig. 2. Effect of time an adsorption.

Table 1
Sorption capacity of the adsorbent for different metal ions

Metal ion	Capacity (mmol g^{-1})
Cu(II)	0.08
Co(II)	0.06
Ni(II)	0.04
Zn(II)	0.04
Fe(III)	0.05

order of preferential adsorption of metal, i.e. Cu(II) > Ni(II) > Co(II) > Zn(II), is consistent with the Irving–Williams order of stability with the relative position of Fe(III) being ligand dependent, especially at the higher pH regions such as those examined here where hydrolysis may be substantiaal, and cannot be established with certainty.

3.2. Effect of shaking time

The effect of shaking time on the adsorption of the metals in the batch process is shown in Fig. 2. Compared with Cu(II), other metals needed a longer time to reach adsorptive equilibrium. The slower reaction kinetics seem to be due either to the slow rate of dissociation of their complexes if complexation is considered as the only mechanism during adsorption or due to their relatively small-size or ionic radii. The crystal field radii for these six-coordinate metals are reported to follow the order Co(II) > Fe(III) > Cu(II) > Ni(II) > Zn(II) [26], but the observed trend of adsorption, i.e. Cu(II) < Zn(II) < Co(II) < Ni(II) < Fe(III) [27], does not correspond to the relative sizes of the metal ions. It is in accordance with expectation that the characteristic lifetimes of water molecule exchange for these hexa-aquo ions. To retain all the metals, a shaking time of 2 h was allowed in the batch process.

3.3. Effect of flow rate

The effect of flow rate of the solutions through the column on the retention behaviour of the metals was studied over the range 1–10 ml min^{-1}. The adsorption of Cu(II) remains almost un-

changed regardless of any change in the flow rate. For Co(II), Ni(II), Zn(II) and Fe(II) no change in the percentage adsorption occurred up to flow rates of 7, 6.5, 8 and 9 ml min^{-1}, respectively. In subsequent experiments a flow rate of 5 ml min^{-1} was maintained for adsorption and 3 ml min^{-1} for elution.

3.4. Effect of volume of sample solution

By varying the volume of sample solution for a fixed amount of adsorbent and fixed amount of metal, no change in the percentage adsorption of metals was observed up to a volume of 1 l. As the present investigation was carried out with 25 ml of sample solution, a concentration factor of 40 was achieved and still higher concentration factors may be obtained by decreasing the elution volume.

3.5. Characteristics and effectiveness of the sorbent

To characterize the sorbent, the IR spectrum of the sorbent was measured first. The IR peaks obtained coincide with the peaks of the ligand (salicylaldoxime) itself, suggesting that the ligand was retained within the sorbent as such, without any structural change. In another experiment, ethanol was passed through the column packed with a weighed quantity of the sorbent to remove all the ligand from the sorbent. The absorption spectrum of the effluent was measured after suitable dilution. The effluent gave absorption peaks identical with those of an ethanolic solution of the ligand. Quantitative determination showed that the amount of ligand supported on the silica gel was 27 ± 2 mg g^{-1} of sorbent. The elemental analysis for C, H and N for the sorbent was again in conformity with the former data.

The adsorption capacity of the sorbent for each of the metals under study was measured by the batch method (Table 1). The adsorbent showed no change in its absorbability even when stored for 6 months. The process of adsorption and elution over the synthesized adsorbent was repeated several times and no decline in the percentage adsorption was found even after 10 such recy-

Table 2
Comparison of recoveries of metal ions

Metal	Initial concentration (ppb)	Recovery (%)		
		Solvent extraction [28]	Ion exchange [29]	Present method
Cu(II)	10	97	99	97
	20	98	100	99
Zn(II)	10	92	99	94
	20	93	99	96

clings. To judge the validity of the proposed method, a comparison of recoveries of the metal ions was made with other known methods and the results are given in Table 2. The results show that the present adsorbent can act as an effective adsorbent for preconcentration of the metals studied.

4. Conclusion

Preconcentration of the metals studied is possible by the use of silica gel modified with salicylaldoxime. The sorbent is easy to prepare and is stable and provides reproducibility and fast adsorbability. Separation of metals from a mixture is even possible. A large volume of water sample can be treated with a relatively small column and preconcentrated metals can be eluted in a small volume of eluent, resulting in a high concentration factor.

Further research will concentrate on the effects of various cations and anions, complexing ligands, background electrolytes, ionic strength, surfactants and alkali and alkaline earth metal ions on the preconcentration of metals. It is intended to develop a mathematical model to describe the metal preconcentration for the batch and column methods.

Study of coordination equilibria in systems of coexisting mononuclear and polynuclear complexes by an isosbestic point–spectrophotometric method

Jie Zhou*, Hong-Zong Yin, Xiang-Jin Qu, Yan-Hua Shun

Department of Basic Sciences, Shandong Agricultural University, Taian, Shandong, People's Republic of China

Abstract

This paper reports a method for determining the stability constants of complexes in a system of coexisting mononuclear and polynuclear complexes based on analysis of dual isosbestic points. First it is necessary to determine the dissociation degrees of either of the two complexes concerned in two directions, and then their stability constants. With this method, the conditional constant can be evaluated by appropriate treatment and selection of the proper equations for solutions. For demonstration purposes the scandium/Xylenol Orange system was used to test the model and satisfactory results were obtained.

Keywords: Coordination equilibria; Isosbestic point; Mononuclear complexes; Polynuclear complexes; Stability constants

1. Introduction

Systems of coexisting mononuclear and polynuclear complexes are found repeatedly in coordination chemistry, where the compositions of the complexes are usually MR and M_2R or MR_2 and M_2R_2 [1–4]. Because their equilibrium relation is quite complicated, methods previously reported for the determination of stability constants of complexes cannot be used for this type of coordination equilibrium. One of use [5] has developed a

method for the determination of the constants in the system of coexisting MR and M_2R complexes, although it is not suitable for the MR_2 and M_2R_2 model. New approaches are still required for this model. Making use of the characteristics of the isosbestic points of the absorption spectra found as system compositions vary, from which the dissociation degrees of MR_2 or M_2R_2 complexes in two directions can be obtained, we have developed a method to determine the stability constants of complexes in this case. The method is simple and reliable. It has been applied to the scandium/Xylenol Orange system, and satisfactory results are obtained.

2. Theory

Suppose the reactions between metal ion M and ligand R are as follows (the charges are omitted for simplicity):

$$M + 2R \rightleftharpoons MR_2 \tag{1}$$

$$MR_2 + M \rightleftharpoons M_2R_2 \tag{2}$$
Their respective stability constants can be expressed as

$$K_1 = [MR_2]/[M][R]^2 \tag{3}$$

$$K_2 = [M_2R_2]/[MR_2][M] \tag{4}$$

From the mass balance equation, we obtain:

$$C_M = [M] + [MR_2] + 2[M_2R_2] \tag{5}$$

$$C_R = [R] + 2[MR_2] + 2[M_2R_2] \tag{6}$$

where C_M and C_R represent the total concentrations of the metal ion and ligand respectively. If there are three coloured species—R, MR_2 and M_2R_2—in the system. their absorption spectra are as shown in Fig. 1, which is usually obtained as

Fig. 1. Schematic diagram of the absorption spectra of R. MR_2. and M_2R_2.

C_M is gradually increased at fixed pH and C_R. If the two reactions take place strictly in this order, then MR_2 is first formed by reaction (1), and M_2R_2 is not formed by reaction (2) until R is fully consumed. In the first process, $[M_2R_2]$ is almost equal to zero. From Eq. (6), we obtain:

$$C_R = [R] + 2[MR_2] \tag{7}$$

The absorbance of the solution is expressed as

$$A = \varepsilon_R[R] + \varepsilon_{1.2}[MR_2] = (\varepsilon_{1.2} - 2\varepsilon_R)[MR_2] + \varepsilon_R C_R \tag{8}$$

In the second process, [R] is almost zero. According to Eq. (6), we obtain:

$$C_R = 2[MR_2] + 2[M_2R_2] \tag{9}$$

$$A = \varepsilon_{1.2}[MR_2] + \varepsilon_{2.2}[M_2R_2]$$
$$= (\varepsilon_{2.2} - \varepsilon_{1.2})[M_2R_2] + \varepsilon_{1.2}C_R/2 \tag{10}$$

From earlier discussions of the characteristics of isosbestic points [6,7]. we obtain $\varepsilon_{1.2} = 2\varepsilon_R$ at λ_p and $\varepsilon_{1.2} = \varepsilon_{2.2}$ at λ_q. According to Eq. (8) and (10) the absorbances of the solutions corresponding to the points p and q are expressed as

$$A_p = \varepsilon_R C_R \tag{11}$$

$$A_q = \varepsilon_{1.2} C_R/2 \tag{12}$$

In accordance with Eqs. (11) and (12), A_p and A_q are constant when C_R and the pH are fixed. Hence two isosbestic points p and q appear caused by the transformation of R into MR_2 and MR_2 into M_2R_2.

In practice, it is impossible for the two reactions to take place strictly in this order, as M_2R_2 can be formed before R is exhausted. Namely, reactions (1) and (2) overlap. In this case, the curves in the absorption spectra do not pass through the two isosbestic points but instead pass below them. Therefore, the absorbance of the solution is expressed as

$$A = \varepsilon_R[R] + \varepsilon_{1.2}[MR_2] + \varepsilon_{2.2}[M_2R_2]$$
$$= (\varepsilon_{1.2} - 2\varepsilon_R)[MR_2]$$
$$+ (\varepsilon_{2.2} - 2\varepsilon_R)[M_2R_2] + \varepsilon_R C_R$$
$$= (\varepsilon_R - 0.5\varepsilon_{1.2})[R]$$
$$+ (\varepsilon_{2.2} - \varepsilon_{1.2})[M_2R_2] + 0.5\varepsilon_{1.2}C_R \tag{13}$$

If the measuring wavelength selected is λ_p and $\varepsilon_{1,2} = 2\varepsilon_R$, then Eq. (13) can be written in the form

$$A_1 = (\varepsilon_{2,2} - 2\varepsilon_R)[M_2R_2] + \varepsilon_R C_R \qquad (14)$$

Substituting Eq. (11) into Eq. (14) yields:

$$[M_2R_2] = (A_p - A_1)C_R [2(A_p - A_0)] \qquad (15)$$

where A_0 is the saturation absorbance of M_2R_2 ($A_0 = 0.5\varepsilon_{2,2}C_R$) and is obtained by fixing C_R and increasing C_M to keep the absorbance of solutions constant. If λ_p is selected as the measuring wavelength, and $\varepsilon_{1,2} = \varepsilon_{2,2}$, Eq. (13) can be simplified to

$$A_2 = (\varepsilon_R - 0.5\varepsilon_{1,2})[R] + 0.5\varepsilon_{1,2}C_R \qquad (16)$$

Substituting Eq. (12) into Eq. (16) yields

$$[R] = (A_q - A_2)C_R (A_q - A_R) \qquad (17)$$

where A_R is the absorbance of pure reagent $R(A_R = \varepsilon_R C_R)$. If C_R is fixed and A_p, A_q, A_0 and A_R are held constant, then $[M_2R_2]$ and $[R]$ are only functions of A_1 and A_2 respectively according to Eqs. (15) and (16). In this case we can think of MR_2 being dissociated in two directions, the dissociation reactions being written as

$$M + 2R \underset{}{\overset{\alpha}{\rightleftharpoons}} MR_2$$
$$(X + \alpha - \beta)C_R 2 \quad \alpha C_R \quad (1 - \alpha - \beta)C_R 2$$
$$\overset{\beta}{\rightleftharpoons} M_2R_2 - M$$
$$\beta C_R 2 \quad (X + \alpha - \beta)C_R 2$$

where α and β represent the dissociation degrees of MR_2 in the left and right directions respectively at the equivalence point. $C_R/2$ represents the total concentration of MR_2, and the equilibrium concentrations of relevant species are as follows:

$$[MR_2] = (1 - \alpha - \beta)C_R 2 \qquad (18)$$

$$[M_2R_2] = \beta C_R 2 \qquad (19)$$

$$[R] = \alpha C_R \qquad (20)$$

$$[M] = (X + \alpha - \beta)C_R 2 \qquad (21)$$

In Eq. (21), $X = (2C_M - C_R) C_R$. Substituting Eqs. (18)–(21) into Eqs. (3) and (4), we obtain:

$$K_1 - (1 - \alpha - \beta) [(X + \alpha - \beta)(\alpha C_R)^2] \qquad (22)$$

$$K_2 = \beta [(x + \alpha - \beta)(1 - \alpha - \beta)C_R 2] \qquad (23)$$

Substituting Eqs. (19) and (20) into Eqs. (15) and (17) yields:

$$\alpha = (A_q - A_2)/(A_q - A_R) \qquad (24)$$

$$\beta = (A_p - A_1)/(A_p - A_0) \qquad (25)$$

According to the above discussion, A_p, A_q, A_R and A_0 are held constant at fixed C_R. A_1 and A_2 are measurable values and α and β can be evaluated from Eqs. (24) and (25) respectively. In addition, x is the given value in the experiment. Substituting these known values into Eqs. (22) and (23) gives K_1 and K_2.

3. Experimental

3.1. Apparatus

A Shimadzu UV-240 double-beam spectrophotometer and a pHs-2 acidimeter were used.

3.2. Reagents

A 1.98×10^{-4} M solution of Xylenol Orange (Xo) was prepared from commercial Xo which was purified by diethylamino ethyl–cellulose column chromatography [8] and its accurate concentration was determined by a spectrophotometric method [9]. A 1.00×10^{-2} M stock solution of scandium (III) was prepared from the pure oxide of scandium (Johnson Matthey). The working standard solutions were obtained by diluting the stock solution. HOAc/NaOAc buffer solution (pH 5.50) and 1 M potassium nitrate were prepared with analytical-reagent-grade chemicals.

3.3. Procedure

To each of a series of 25 ml calibrated flasks, add 2.5 ml of buffer solution, a known volume of Xo solution, a different volume of Sc solution and 2.5 ml of 1 M potassium nitrate. Dilute to the mark with distilled water and mix. Stand for 10 min and measure their absorption spectra or absorbance. Maintain the temperature of the solutions at $20 \pm 1°C$ throughout.

4. Results and discussion

Two different complexes were found in the determination of scandium using Xylenol Orange as colour reagent [4,10] when the pH or the mole ratio of the reactants was varied. Zou and Han [4] investigated their compositions in detail. They found $Sc(Xo)_2$ and $Sc_2(Xo)_2$ complexes at pH > 4.5 and thought that the formation of the two species depended on the mole ratio of the reactants. The results we obtained were the same as those in the literature [4]. However, their equilibrium relation has not been investigated in detail. Therefore, in this work the equilibria between 1:2 and 2:2 complexes and the reactants were studied.

4.1. Absorption spectra

When pH and C_{Xo} were fixed and C_{Sc} was gradually increased, a series of solutions resulted with absorption spectra as shown in Fig. 2, which shows that Sc(III) can form two complexes with Xo. Their maximum absorption wavelengths are 490 nm and 557 nm. In addition, two isosbestic points exist in Fig. 2. According to the literature [4], the compositions of the complexes with maxima at 490 nm and 557 nm are $Sc(Xo)_2$ (1:2) and $Sc_2(Xo)_2$ (2:2) respectively. In the presence of a large excess of Sc(III) with respect to the ligand, the 2:2 complexes predominate. With a large excess of the ligand, the 1:2 complexes predominate. The first isosbestic point p is at 456.5 nm and the second isosbestic point q is at 517.0 nm at pH 5.50.

4.2. Determination of stability constants

As discussed previously, in Fig. 2 all curves passing through point p correspond to reaction (1) and all curves passing through point q correspond to reaction (2). The curves passing through neither p nor q indicate that reactions (1) and (2) overlap. The experiments proved that the curves passed through neither p nor q in the C_{Sc}/C_{Xo} range 0.60–1.20. $Sc(Xo)_2$ complexes are thought to dissociate in two directions in this range. Their dissociation degrees α and β are obtained from

Fig. 2. Absorption spectra for the Sc–Xo system at different C_{Sc} values. $C_{Xo} = 2.00 \times 10^{-5}$ M, pH 5.50, 1 cm cells, distilled water as reference $C_{Sc}(\times 10^{-5}$ M): (1), 0.00; (2), 0.40; (3), 0.80; (4), 1.60; (5), 2.40; (6), 3.20; (7), 4.00.

curves passing through neither p nor q, such as curve 4 shown in Fig. 2. It should be explained that, according to the mechanism of complexation reactions and the above discussion, if the two species determined (R and M_2R_2) exist in the same solution, then the allowed C_M/C_R range is limited. The reason is simple, namely when $C_R > C_M/2$ the value of $[M_2R_2]$ tends towards zero and when $C_M > C_R$ the value of [R] tends towards zero. In addition, the C_M/C_R range relates to the absorption spectra of relevant species. Thus it is quite difficult to estimate it theoretically, and the range can only be found from the experiments approximately.

Table 1

Values of $\log K_1$, $\log K_2$ and associated parameters from the various solutions ($A_q = 0.518$, $A_p = 0.406$, $A_0 = 0.027$, $A_R = 0.074$)

x	A_1	A_2	$\chi(\%)$	$\beta(\%)$	$\log K_1$	$\log K_2$
0.60	0.390	0.430	19.82	4.22	10.81	3.87
0.70	0.385	0.437	18.24	5.54	10.84	3.94
0.80	0.381	0.448	15.77	6.60	10.94	3.98
0.90	0.375	0.456	13.96	8.18	11.02	4.04
1.00	0.369	0.461	12.84	9.76	11.06	4.09

A series of solutions were prepared at fixed C_{X_0} when C_{S_c} was gradually increased ($0.60 < C_{S_c}/C_{X_0} < 1.20$). We measured A_1 at 456.5 nm (λ_p) and A_2 at 517.0 nm (λ_q) with distilled water as reference. Substituting the values of A_1 and A_2 obtained into Eqs. (24) and (25), we could evaluate χ and β. K_1 and K_2 were then calculated from Eqs. (22) and (23) respectively. These results, and the values of the associated parameters, are listed in Table 1. The mean values of $\log K_1$ and $\log K_2$ are taken to be 10.93 and 3.98 respectively. The results given in Table 1 indicate that the method developed in this paper is comparatively reliable. However, the values of $\log K_1$ or $\log K_2$ determined increase somewhat with the ratio C_M/C_R. Such a regular increase cannot be ignored and demands further study.

Finally, it should be noted that, for a stepwise complexing system that consists of two complexes and a system of coexisting MR and M_2R complexes, two isosbestic points similar to those in this paper also appear in the absorption spectra as the system compositions vary. The stability constants of these complexes can be evaluated by a similar treatment and by selecting the appropriate equations for solutions. Thus this method is generally applicable and could be used for most systems of coexisting mononuclear and polynuclear complexes.

Abstract

A solid-state nitrate ion-selective electrode based on an Urushi matrix membrane was developed. Urushi, a natural oriental lacquer, has excellent mechanical strength and binding affinity for metal electrodes. Using the same technique for a dip-coating ion-selective electrode, an electrode was prepared by coating and hardening a sensing membrane on the metal base. The effects of the metal electrode on the electrode potential stability, the liquid-membrane components and the oven temperature for hardening of membrane were studied. The sensing membrane, consisting of 27.5 wt.% of o-nitrophenyl octyl ether, 27.5 wt.% of tri-n-octylmethylammonium nitrate and 45 wt.% of raw Urushi latex, was coated with a thickness of 0.5 mm on a silver disc which was plated with Ag/AgCl, then plated with copper and hardened in the oven at 80°C for 50 h. A semi-logarithmic calibration curve of potential versus nitrate ion concentration was obtained over the range 6–60 000 mg l^{-1} NO$_3^-$. The slope of the linear part of the curve was -56 mV per decade change in NO$_3^-$ concentration. Compared with a PVC matrix nitrate ion-selective electrode, the Urushi matrix nitrate ion-selective electrode was superior in terms of hardness and mechanical strength of the membrane, short response time and long life. The combination of an Urushi matrix nitrate ion-selective electrode with a porous PTFE junction reference electrode, air-tight structured KCl solution chamber and a temperature sensor was applied to field measurements of nitrate-nitrogen concentrations in upland soils. The values obtained for upland soils containing 30–50% of water were good agreement with those for soil solution.

Keywords: Ion-selective electrode; Nitrate; Soil; Urushi matrix membrane

1. Introduction

An ion-selective electrode is very useful as a detector in protable field analyses. The nitrate (NO$_3^-$) ion-selective electrode has been used to measure the environmental pollution of waste water, underground water, river water, etc. Nitrate ion measurement plays an important role in the

nutrition diagnosis of upland soils and plants. Nitrogen is one of the most important components together with phosphate and potassium in plants and crops. Althouth nitrogen fertilizer is applied to farm land as ammonium-nitrogen (NH_3-N), after nitrification it exists mainly as nitrate-nitrogen (NO_3-N) in soils. In recent years, as chemical fertilizers have become available at lower prices, serious problems have arisen with over-supply. In the measurement of vegetable crop soils, the solution obtained by centrifugation (i.e. soil solution) or by water extraction (i.e. 1:5 water extraction method) is analysed using an ion-selective electrode, ion chromatography or spectrophotometry [1-3]. However, farm land is extensive and variable and the nitrogen composition is uneven. Therefore, rapid and direct measurements in the field are requried instead of taking samples for laboratory measurement.

We examined the direct measurement of nitrate in upland soils in the field with a nitrate ion-selective electrode. We also studied a solid-state nitrate ion-selective electrode and developed a combination electrode for nitrate ion consisting of a solid NO_3 ion-selective electrode and a reference electrode. Phenanthrolinenickel(II) nitrate (Orion exchanger [4]), tridodecyl-hexadecylammonium nitrate (Corning exchanger [4]) and methyltricaprylylammonium nitrate [5,6] have been reported as nitrate liquid ion exchangers. Concerning liquid membrane electrodes, the coated wire electrode (CWE) and the PVC matrix electrode were introduced by Freiser [7], Moody and Thomas [8] and others. Zhang et al.'s method for vitamin B_1 with a PVC matrix membrane seems to be very useful and practical [9]. Compared with the lanthanum fluoride single-crystal membrane for a fluoride ion-selective electrode or the silver chloride/silver sulphide heterogeneous membrane for a chloride ion-selective electrode, the above liquid membrane electrode for a nitrate ion-selective electrode is inferior in mechanical strength and durability. Although this PVC matrix membrane is so soft that it can be readily used in water, it is unsuitable in contact with upland soils. To measure the membrane potential, one needs an inner so-

lution containing chloride (Cl^-) ion and nitrate (NO_3^-) ion, and an inner electrode such as a silver/silver chloride (Ag/AgCl) electrode. On the other hand, Hiiro and co-workers [10-18] reported an Urushi matrix membrane which had excellent durability and mechanical strength. We tried to adapt the Urushi matrix method to the nitrate ion membrane and improved the electro-chemical contact between the Urushi matrix membrane and the metal electrode. We studied hardening conditions so as not to damage the liquid membrane components by heating. We also studied metal electrodes and their surface treatment. We developed an Urushi matrix nitrate ion membrane that had hardness, mechanical strength, good electrode potential stability and good sensitivity.

We fabricated a combination of an Urushi matrix nitrate ion electrode with a reference electrode and a temperature sensor, and applied it to the direct measurement of upland soils with a portable potentiometer operated with dry batteries. As the reference electrode, a maintenance-free and a semi-solid porous PTFE junction reference electrode with an air-tight structured KCl solution chamber [19] was used. Upland soils usually contain 30-50 wt.% of water [20]. When a laboratory-use reference electrode with a ceramic junction is used directly in such upland soils, the potential of the reference electrode is unstable and inaccurate. The porous PTFE junction reference electrode, with a large junction area and large pore size, was found to give a stable liquid junction potential in contact with upland soils contained 30-50 wt.% of water. Furthermore, we developed an Urushi membrane tip which could be easily exchanged when the surface of the Urushi matrix membrane was damaged by small pieces of gravel in the soils.

2. Experimental

2.1. Apparatus and reagents

A DKK Model IOL-40 multi-channel ion meter was used for laboratory measurements, a DKK Model HPH-110 handy pH/mV meter for field

measurements and a DKK Model PK-5 electrical conductivity meter for measuring the impedance of the liquid membrane. A Sakuma Model 50B centrifuge was used to obtain the soil solution.

Several kinds of Urushi latex were obtained from Saito (Osaka, Japan). Tri-*n*-octylmethylammonium nitrate (TOMAN) and *o*-nitrophenyl octyl ether (*o*-NPOE) were obtained from Dojindo Laboratories (Kumamoto, Japan). Potassium nitrate, potassium chloride, potassium sulphate, potassium phosphate, hydrochloric acid, sulphuric acid, phosphoric acid, trimethanolamine, sodium hydroxide, boric acid and Devarda's alloy were obtained from Wako (Osaka, Japan). All chemicals were of analytical-reagent grade.

PTFE powder for moulding (M12, grain size ca. 20 μm) was purchased from Daikin Industries (Osaka, Japan). Pure water obtained with a Millipore Milli-Q SP system was used throughout.

2.2. Preparation of Urushi matrix membrane
The structure of the Urushi matrix membrane

Fig. 1. Comparison of NO_3^- ion-selective electrode structure with PVC matrix and Urushi matrix.

Fig. 2. Structure of combination nitrate ion electrode for direct analysis of upland soils.

tip is shown in Fig. 1. The three types of the metal disc, that is, the copper disc, the silver and that plated first with Ag/AgCl and then with copper, were examined. The electrode body tips were prepared by sticking a silver disc or a copper disc (6 mm in diameter, 1 mm in thickness) on one side of the epoxy resin body with an epoxy bond. The silver disc or the copper disc had a silver wire connected on the inside. The surface of the silver disc or the copper disc was flattened and polished with emery paper (No. 1200 grain size).

Some of the electrode body tips with silver disc were used as they were, others were plated as

Table 1
Membrane composition, contact metal. hardening conditions and characterists of Urushi matrix NO_3^- ion-selective electrode

No.	Composition			Contact metal	Hardening conditions			Characteristics		
	Urushi (%)	TOMAN (%)	o-NPOE (%)		Temperature (°C)	Time (h)	Slope (10 100 mg l^{-1} NO_3-N)	Impedance ($10^3\Omega$)	Stability (mV h^{-1})

PVC matrix	19 (PVC)	1	80		30	12	−56	200	<1

follows before use. The silver disc was plated with Ag/AgCl in 0.1 M potassium chloride solution (2.5 × 10^{-5} A current, 0.5 h). Further, it was plated with copper in 0.1 M copper sulphate solution (2.5 × 10^{-5} A current, 1 h). The Urushi matrix membrane was prepared by the following procedure. Suitable amounts of Urushi, TOMAN and o-NPOE were mixed on a glass plate and the mixture (about 10 mg) was coated on the surface of the metal side of the electrode tip, and allowed to harden in an oven at 80°C for 50 h or at 100°C for 18 h.

2.3. Preparation of PVC matrix membrane

A PVC matrix membrane was prepared by the following procedure. PVC (0.19 g), TOMAN (0.01 g) and o-NPOE (0.8 g) were dissolved in 10 ml of tetrahydrofuran (THF). A drop of the THF solution was dropped on a PTFE membrane filter disc (0.45 μm pore size) that was left on the membrane side of the PVC electrode body, and the THF was allowed to evaporate in an oven at 30°C for 10 min. After the THF evaporation step had been repeated 15–20 times, about a 0.5 mm thickness of PVC matrix membrane was formed and left for 24 h in the room air.

After filling an inner solution (1 × 10^{-2} mol l^{-1} KCl, 1 × 10^{-2} mol l^{-1} KNO$_3$) and inserting an inner electrode (Ag/AgCl electrode), a PVC matrix electrode tip such as that shown in Fig 1 was fabricated.

2.4. Electrode assembly

A combination electrode body fabricated for laboratory and field measurements is shown in Fig. 2. This consisted of a reference electrode, a temperature sensor to compensate for the temperature effect of the NO_3^- ion electrode and a receptacle to connect with the NO_3^- ion electrode tip. An NO_3 ion electrode is attached to this body by the attachment rubber of the NO_3^- ion electrode tip. The reference electrode has an Ag/AgCl inner electrode and a porous PTFE junction. The saturated KCl solution and the KCl sludge are enclosed in it. The porous PTFE junction was made as follows. PTFE powder and uniform particles of KCl powder were placed in a mould, compressed and sintered at 350°C for 5 h in an oven. The PTFE with KCl powder was cut into the shape of the electrode body and the liquid junction part of it was washed with water to make it porous by dissolution of KCl in the PTFE junction.

2.5. Potential measurements

Potential measurements with the Urushi matrix membrane NO_3^- ion electrode and PVC matrix membrane NO_3^- ion electrode were made with the combination electrode shown in Fig. 2. The performance of the electrode was examined by measuring the e.m.f. of the following electrochemical cell:
Fig. 3. Calibration curves for Urushi matrix and PVC matrix nitrate ion electrodes.

(i) Cu|Urushi matrix membrane|sample|sat. KCl|Ag/AgCl

(ii) Ag|Urushi matrix membrane|sample||sat. KCl|Ag/AgCl

(iii) Ag/AgCl/Cu|Urushi matrix membrane|sample||sat. KCl|Ag/AgCl

(iv) Ag/AgCl|inner solution|PVC matrix membrane|sample||sat. KCl|Ag/AgCl

In a laboratory measurement, the e.m.f. data from four electrodes were simultaneously fed to a personal computer from the potentiometer (Model IOL-40) through an RS-232C interface.

2.6. Calibration

Each membrane with the combination electrode was immersed in 0.1–1000 mg l^{-1} NO_3-N standard solution (10^{-3} mol l^{-1} = 14 mg l^{-1} NO_3-N), and calibration curves for each membrane were measured. To each NO_3-N standard solution 5×10^{-2} mol l^{-1} K_2SO_4 solution was added to adjust the ionic strength. The electrode potentials were recorded after their values had stabilized to within ± 0.1 mV min^{-1}. Potential–concentration curves were plotted as shown in Fig. 3.

2.7. Stability of electrode potential

The stability of the electrode potential was measured as follows. Each electrode was left in 10 mg l^{-1} standard solution for 5 days and the calibration curves for each electrode were measured once a day. After the electrodes had dried in room air, the stability of the electrode potential was measured again using the same procedure. The electrode potentials in 10 mg l^{-1} standard solution were plotted as a function of elapsed time.
Fig. 4. Stability of Urushi matrix and PVC matrix nitrate ion electrode potentials.

2.8. Influence of pH

Each electrode was calibrated using standard solutions with pH varying from 1 to 12. The pH was adjusted by adding small volumes of H_2SO_4 or NaOH to the standard solution. The electrode potential were recorded after their values had stabilized, and were plotted as a function of pH and NO_3-N concentration.

2.9. Measurements of membrane impedance

The membrane impedance was measured with a Model PK-5 electrical conductivity meter (5 V a.c., 1 kHz) in 1 mol l⁻¹ KNO_3 solution using a platinum electrode at room temperature.

2.10. Influence of temperature

NO_3-N standard solutions from 1 to 1000 mg l⁻¹ were prepared in a water-bath at 5, 25, 45°C.

They were kept at a constant temperature to within ±0.1°C. The calibration curves for the electrode were measured in standard solution at 5°C and then at 25 and 45°C. The electrode potentials were recorded after their values had stabilized, and were plotted as a function of temperature and NO_3-N concentration.

2.11. Selectivity

Selectivity coefficients were determined by the mixed solution method, wherein the concentration of NO_3-N was fixed at 100 mg l⁻¹ and the concentration of an interfering ion was varied. The selectivity coefficients, $K_{A,B}^{pot}$, were calculated according to the equation $K_{A,B}^{pot} = C_A^{Z_B/Z_A}/C_B$, where C_A and C_B are the total concentration of NO_3-N and that of an interfering ion obtained graphically in the sample solution, respectively, and z_A and z_B are the charges of NO_3-N and the interfering ions, respectively.
Fig. 5. Effect of pH on Urushi matrix nitrate ion electrode.

2.12. Durability of membrane in long-term storage

The Urushi matrix membrane electrode and the PVC matrix membrane electrode were stored in air and water, respectively, and the calibration curves were measured once a month. The change in the slope between 10 and 100 mg l⁻¹ NO₃-N standard solution was investigated. The durability on long-term storage is obtained from the change in air and that on long-term use from the change in the water.

2.13. Analysis of soil

Andosol that mostly occurs in the Kanto area in Japan was used as a sample soil. The sample solution was prepared by the following two methods, and was analysed by the manual method with an ion-selective electrode.

The water extraction solution [2] was used to compare the present Urushi matrix membrane electrode with the conventional PVC matrix membrane electrode. The air-dried soil (10 g) was dissolved in 50 ml of 5×10^{-2} mol l⁻¹ K_2SO_4 solution and the solution was filtered through a filter-paper (Toyo No. 6). The NO_3-N concentration in the 1:5 water extraction solution was measured with the Urushi matrix combination electrode and the PVC matrix combination electrode. The values obtained with the Urushi matrix combination electrode were compared with those obtained with the PVC matrix combination electrode.

The direct analysis of soil with the Urushi matrix combination electrode was compared with a manual analytical measurement of the soil solution. The soil (about 300 g, contained about 80 wt.% of water) that was collected from farm land was mixed in an airtight plastic bag and was left to
Fig. 6. Effect of temperature on Urushi matrix nitrate ion electrode.

homogenize for 3 days in an oven at 30°C. The Urushi matrix membrane electrode was inserted into the soil from the plastic bag. The e.m.f. became stable after 1–3 min by slightly pressing the soil against the Urushi matrix membrane and the porous PTFE junction of the reference electrode. The soil solution was obtained from the soil (100 g) by centrifugation (8900 rev min^{-1}, 60 min). A manual analytical measurement of the soil solution was made by the following procedure (Bremner method). The NO_3^- was converted into NH_3 gas by steam distillation with a catalyst (Devarda's alloy), and was trapped as NH_4^+ ion in absorbent solution (2% boric acid). The NH_4^+ ion solution was titrated with 0.1 mol l^{-1} Na_2CO_3 with methyl red and bromocresol green indicators, and the NO_3-N concentration in the soil solution was calculated. The values obtained by means of the Urushi matrix combination electrode were plotted against those obtained by the manual analytical method.

3. Results and discussion

3.1. Membrane material and characteristics

We examined four ways of hardening the Urushi matrix membrane as shown in Table 1. Method I is Hiiro et al.'s method, in which the membrane was hardened at room temperature in their originally manufactured oven with a rotating electrode holder able to provide 80–90% relative humidity at 30°C for 1000 h. We tried their method, but could not obtain sufficiently hard membrane. Also, the hardening time of 1000 h was considered to be too long.

The hardening time was reduced when the temperature increased. Without affecting the characteristics of the slope and impedance, we lowered the hardening conditions in method II to 80°C and 50 h. As shown in Table 1, the slope and impedance characteristics of membranes I and II-2 were good, but we found that there was a
Fig. 7. Effect of temperature on PVC matrix nitrate ion electrode.

serious problem with the stability. As Fig. 4 shows, the e.m.f. of the electrode in a 100 mg l $^{-1}$ solution changed over several days. Although the e.m.f. change of the PVC matrix membrane electrode early in the measurement was within 1 mV h^{-1}, that of Urushi matrix membrane electrode was 3-8 mV h^{-1}.

We found that the surface of the copper disc had changed from metallic red to lusterless black when the Urushi matrix membrane of these electrodes was stripped off. We thought that the change in the e.m.f. occurred at the interface between the Urushi matrix membrane and the copper. Therefore, we tried to harden the Urushi matrix membrane on silver with plated Ag/AgCl (method III). As Hiiro et al. mentioned, we confirmed that the Urushi matrix membrane needed a copper catalyst for hardening. Although with conditions of 130°C and 8 h we were able to harden the Urushi matrix membrane on silver plated with Ag/AgCl, the membrane was too hard to respond

to the NO$_3$-N ion. After various examinations of the effect of lower temperatures on the response to the NO$_3$-N ion, we obtained good results at 100°C for 18 h.

The characteristics of the membrane III were good with regard to stability, but not impedance and slope. A hardening temperature of 100°C seemed to be too high.

We found that copper was indispensable for hardening as the Urushi matrix membrane silver plated with Ag/AgCl was superior in stability in the presence of copper. Furthermore, we tried to harden the Urushi matrix membrane on silver plated with Ag/AgCl and copper (method IV). The characteristics of membrane IV nearly equalled that of the PVC matrix membrane.

Table 1 shows the membrane composition, the contact metal, the hardening conditions and the characteristics of the Urushi matrix NO$_3^-$ ion electrode. For comparison, the membrane composition, the hardening conditions and the charac-

Table 2

Selectivity coefficients for the Urushi matrix NO_3 ion electrode and the PVC matrix NO_3^- ion electrode

Ion (j)	Selectivity coefficient ($K^{pot}_{NO_3,j}$)	
	Urushi matrix (IV-2) NO_3^- ion electrode	PVC matrix NO_3^- ion electrode
ClO_4	$> 10^3$	$> 10^3$
I^-	50	50
Br^-	1.5×10^{-1}	1.5×10^{-1}
HS	1×10^{-1}	1.5×10^{-1}
NO_2	5×10^{-2}	8×10^{-2}
CN	5×10^{-2}	7×10^{-2}
Cl^-	4×10^{-3}	8×10^{-3}
$RCOO$	1.5×10^{-3}	2.5×10^{-3}
HCO_3^-	1.5×10^{-3}	2×10^{-3}
SO_4^{2-}	$< 10^{-3}$	$< 10^{-3}$
$H_2PO_4^{2-}$	$< 10^{-3}$	$< 10^{-3}$
HPO_4^-	$< 10^{-3}$	$< 10^{-3}$
PO_4^{3-}	$< 10^{-3}$	$< 10^{-3}$

teristics of the PVC matrix NO_3 ion electrode are also shown in Table 1. In this case, PVC was used instead of Urushi and the contact metal was not used.

Fig. 3 shows the calibration curves for the Urushi matrix membrane electrode and the PVC matrix membrane electrode. The electrode potential of the PVC matrix membrane electrode is the e.m.f. when the inner solution is 1×10^{-2} mol l^{-1} KCl, 1×10^{-2} mol l^{-1} KNO_3, and can be changed by varying the composition of the inner solution. For the Urushi matrix membrane electrode, the electrode potential is changed with the

contact metal, which is copper or silver. The slope for 0.1–1 mg l^{-1} NO_3-N was -40 mV with the PVC matrix membrane electrode and was -35, -13, -38, -11, -15, -39 and -42 mV with the Urushi matrix membranes I-1, II-1, II-2, III-1, III-2, IV-1 and IV-2, respectively.

Fig. 4 shows the change in the electrode potential in 10 mg l^{-1} NO_3-N standard solution. Although the data for membranes I-1, II-2, III-2 and IV-1 are shown, the patterns of the changes between II-1 and II-2, between III-1 and III-2 and between IV-1 and IV-2 were almost the same. The pattern of the changes is obviously distinguished by the kind of contact metal (copper or silver). The change in electrode potential seems to be due to the potential change at the interface between the Urushi matrix membrane and the contact metal after the Urushi matrix membrane had gradually absorbed moisture. Therefore, after the 5-day measurement, and after the electrode had dried completely (for 1–2 weeks) in the room air, the same pattern of the potential change was repeated.

3.2. Effect of pH

The pH dependence of the Urushi matrix membrane electrode is shown in Fig. 5. It can be seen that the electrode is not influenced in the pH range 2–10. In the lower concentration range (1 mg l^{-1} NO_3-N), even between pH 2 and 10, a small increase in potential occurred. It would be preferable if the measurements were made at pH 7 with 0.05 mol l^{-1} phosphate buffer solution.

Table 3

Durability of the membrane on lont-term storage

Time (months)	Slope in 10–100 mg l^{-1} NO_3-N (mV)			
	Urushi matrix membrane		PVC matrix membrane	
	Storage in water	Storage in air	Storage in water	Storage in air

Fig. 8. Correlation between Urushi matrix electrode measurement and PVC matrix electrode measurement for the water extraction sample of soil.

3.3. Effect of temperature

The temperature dependences of the Urushi matrix membrane electrode and the PVC matrix membrane electrode are shown in Figs. 6 and 7, respectively. The isothermal point of the Urushi matrix membrane electrode is calculated as 10^7 mg l^{-1} NO_3-N; this is higher than the 5×10 mg l^{-1} NO_3-N for the PVC matrix membrane electrode. With increase from 10 to 100 and 1000 mg l^{-1} NO_3-N in the sample solution, the electrode potential of the Urushi matrix membrane electrode rises at 1.4, 1.2 and 1 mV °C^{-1} with increase in termperature, respectively (0.75, 0.6 and 0.4 mV °C^{-1} for the PVC matrix membrane electrode). For field measurements, the temperature compensation should be done electrically.

3.4. Effect of interfering compounds

The interference results are shown in Table 2. The selectivity coefficients followed those for most liquid ion-exchange membrane electrodes. There were no differences between the Urushi matrix membrane and PVC matrix membrane, essentially because the sensing membrane to NO_3^- ion was the same. Halide ions, especially Cl$^-$, mainly interfere with measurements with the NO_3^- ion electrode. In normal operation, interference from HCO_3^- and $RCOO^-$ should also be taken into account.

3.5. Durability of membrane
Table 3 shows the slope for 10–100 mg l^{-1}

Fig. 9. Correlation between direct measurement with Urushi matrix nitrate ion electrode and manual measurement by the Bremner method for the soil solution sample.

NO_3-N for the Urushi matrix membrane and PVC matrix membrane after long-term storage. The characteristics of the liquid membrane ion-selective electrode were gradually lost because a portion of the membrane components volatilized. The Urushi matrix membrane had kept its initial characteristics compared with those of the PVC membrane after 18 months in practical use.

3.6. Direct measurement of NO_3-N in upland soils

In the measurement of 1:5 water extraction solution, as Fig. 8 shows, the values with the Urushi matrix membrane electrode are good agreement with those with the PVC matrix membrane electrode ($r^2 = 0.996$, $y = 0.92x + 1.7$).

The correspondence between direct measurements on soils with the Urushi matrix combination electrode and the manual analytical measurement

of soil solution is shown in Fig. 9 ($r^2 = 0.994$, $y = 1.05x + 11$). Therefore, we conclude that the Urushi matrix NO_3^- ion electrode is able to measure NO_3^- ion in the soil solution when the electrode is directly inserted into the soils, without interference from small amounts of gravel.

The pH range of the upland soil used as vegetable crop soil was approximately 4–8. Although soils with pH 4 below exist (i.e. acid soils), these soils are not good for growing crops. For soils that need nutrition diagnosis, the Urushi matrix membrane electrode was able to measure NO_3^- ion directly without adding pH adjustment buffer solution. Concerning interferences, Milham et al. [3] suggested the use of a buffer solution to eliminate interfering ions such as Cl^-, HCO_3^- and $RCOO^-$ in soil analysis. Since buffer solution could not be used in the direct measurement of soils, the measured values for soils that included sea water were higher than the true values because of interference from Cl^-.

4. Conclusion

From studies of an Urushi matrix nitrate ion membrane and a contact metal, the Urushi matrix membrane electrode was shown to be equal to the PVC matrix membrane electrode with regard to detection range and selectivity. It was found that the Urushi matrix method is one of the most useful approaches for making a liquid membrane into the solid state. The Urushi matrix nitrate membrane had hardness and mechanical strength, and showed advantages of a short response time and a long lifetime. The combination of the Urushi matrix nitrate ion electrode with the porous PTFE junction reference electrode was able to measure NO_3-N directly in upland soils and was found to be very useful for the nutrition diagnosis of soils.

By making the liquid sensing membrane for an ion-selective electrode into the solid state, many practical applications can be expected in field measurements with ion-selective electrodes.

Abstract

A solvent extraction technique involving no critical clean-up steps was developed for the determination of methylmercury (MeHg) in environmental and biological samples by aqueous phase ethylation, room temperature precollection, gas chromatographic separation and cold vapor atomic fluorescence spectrometric detection. Samples were first digested with KOH–methanol. then acidified prior to extraction with methylene chloride. MeHg was back-extracted from the solvent phase into water prior to aqueous phase ethylation. Recoveries close to 100% were obtained with RSDs less than 5% for all samples analyzed, making direct standardization possible. The detection limits were about 0.08 ng g^{-1} when analyzing 0.1 g of dry sea plant homogenate and 0.02 ng g when analyzing 0.5 g of wet sediment samples. Various certified reference materials and intercomparison samples, including sediments, sea plants and tissues, were analyzed, and the results were in good agreement with the certified values. The technique was applied to the determination of MeHg in both sea plants from the Atlantic and the red blood protein of dolphins from the Mediteranean Sea. in sediments from the Mediterranean Sea and Minnesota rivers and in soils from different origins. Concentrations of MeHg in dolphin red blood protein samples were as high as 300 ng g^{-1}.

1. Introduction

Methods based on aqueous phase ethylation with sodium tetraethyl borate [1] for the determi-

nation of methylmercury (MeHg) by gas chromatography-cold vapor atomic fluorescence spectrometry (GC-CVAFS) have significant advantages over other methods, and are now in wide use [2,3]. The primary advantage of the methods lie in the easy isolation of MeHg from the sample matrix by a simple purging of the volatile ethylation product, methylethylmercury. Tedious and involved critical clean-up steps [4] are thus unnessary. However, owing to severe matrix interferences with the ethylation reaction [2,5], only very small sample sizes can be used, hence only samples with relatively higher MeHg concentration can be analyzed, limiting the method's applicability to samples with low MeHg concentrations. To eliminate these interferences, a distillation technique was developed [6,7] which allows the application of the ethylation procedure for low MeHg concentrations in complex matrices. This method is now widely used. A number of valuable results have been obtained using this technique [8,9], which greatly promoted research on the biogeochemical cycle of mercury. However, we found that when high Hg^{2+} containing samples were distilled, a large amount of Hg^{2+} was transfered to the distillates. It has been found that owing to the presence of a large amount of Hg^{2+}, MeHg artifact may be formed during ethylation reactions in some cases [6]. Since distillation cannot isolate MeHg from Hg^{2+}, this problem cannot be eliminated by the technique. In addition, when samples containing large amounts of volatile compounds are distilled, volatile components transferred to the distillate interfere with the ethylation reaction and/or deposit on the GC column, suppressing the GC signal and preventing accurate determinations. Moreover, the distillation technique requires unusual equipment which most general laboratories do not have. To overcome these problems, a simple solvent extraction technique involving no critical clean-up steps was developed.

Some solvent extraction procedures have been developed for determining MeHg by GC-electron capture detection. As this detection method is not specific for mercury, very critical and tedious clean-up steps had to be used [4,10] to avoid chromatographic interferences. In the present work, the mercury-specific atomic fluorescence de-

tector was used, eliminating chromatographic interferences.

The solvent extraction demonstrated here serves simply to isolate MeHg from the major matrix in order to eliminate interferences with the ethylation reaction, resulting in a simplified technique. Recently, another solvent extraction technique was developed for the determination of organic mercury compounds by HPLC-AFS [11]. In that procedure, the mercury was first chelated with dithizone reagent and extracted into chloroform in the presence of citrate buffer. The solvent phase was separated from the slurry by filtration. The derivative of inorganic mercury in the solvent phase, dithizone-mercury complex, was destroyed with HNO_3, and entered the aqueous phase, while MeHg remained in the solvent phase, thus separated from the inorganic mercury. The organic compounds were finally back-extracted into the aqueous phase with sodium thiosulfate solution buffered with ammonium acetate. A recovery of 80% was reported. Compared with that procedure, the technique presented here has the advantages that no buffers or chelators were used, and only HCl and CH_2Cl_2 were employed for the extraction. Recoveries close to 100% were obtained, making direct standardization possible for all kinds of samples, ensuring the reliability of the method.

2. Experimental

2.1. Instrumentation, materials and reagents

The instrumentation, materials and reagents used have been detailed elsewhere [2,3]. In the analytical procedure, a Model 2500 CVAFS mercury dector from Tekran (Canada) was also used, and only Tenax traps [3] were used for precollection of ethylation derivatives.

2.2. Solvent extraction procedure

Depending on the MeHg concentration, an appropriate aliquot of sample (typically 0.05-0.2 g of dry sample, or 0.1-0.5 g of wet sample) was weighted into a Teflon vial or bottle. In this work,

30 ml Teflon FEP bottles (H-06327, Cole Parmer, USA) were used. Two ml of 25% KOH–methanol were added and the bottle was then capped tightly and heated in an oven at 75°C for 3 h for digestion. The digestate was allowed to cool to room temperature. A 6 ml volume of CH_2Cl_2 (GC60616-4, GC^2, Baxter Scientific Products, USA) were added to the digestate, and 1.5 ml of concentrated HCl were then added slowly. The mixture was capped and shaken for 10 min with a shaker. The mixture was poured into a Teflon FEP separating funnel (50 ml, H-06125-10, Cole Parmer) and, after the phases had separated, the lower solvent phase CH_2Cl_2 was collected in a 125 ml Teflon bottle. Another 6 ml of CH_2Cl_2 were added to the separating funnel, the slurry was washed and then separated and CH_2Cl_2 was collected in the 125 ml Teflon bottle. For small sample sizes, the slurry was washed once only. For larger sample sizes, the slurry was washed twice. Then approximately 80 ml of deionized water were added to the solvent phase in the 125 ml Teflon bottle. This bottle was placed in a water-bath at 80°C for solvent evaporation, i.e. back-extraction. Residual solvent remaining after the back-extraction was purged with nitrogen or other gases for 2 min. Prior to the ethylation reaction, the final volume was brought to a known amount unless the whole extract was to be analyzed. Depending on the concentration of MeHg, an appropriate aliquot was placed in the bubbler for the ethylation reaction, following the procedure described elsewhere [3]. For non-homogeneous samples, large sizes are required, and the volume of KOH–methanol solution is proportionally increased. However, after alkaline digestion, only part of the digestates is quantitatively taken for solvent extraction.

3. Results and discussion

3.1. Alkaline digestion and sample size

Alkaline digestion has been widely used for the release of mercury compounds from tissues. Over the past decade, many certified reference materials and intercomparison samples have been analyzed

directly after alkaline digestion by aqueous phase ethylation and GC–CVAFS, with recoveries close to 100% [5], indicating that mercury compounds are released completely by alkaline digestion. This is the basis of the technique described here. It was found that 2 ml of 25% KOH–Methanol were sufficient for digesting dry samples up to 0.5 g. The use of a considerably larger sample size is not necessary since the CVAFS is an extremely sensitive detector. In this technique, the MeHg was finally extracted from an acidified slurry of KCl and sample substances. A larger sample size requires more alkali–methanol and HCl, yielding more slurry and making the following steps (separating and washing) difficult, ultimately reducing the recovery. Therefore, larger sample sizes are not recommended. However, for non-homogeneous samples, it may be necessary to use larger sample sizes to improve the analytical accuracy. In this case, a sample as large as several grams can be used and more KOH–methanol should be added. After the alkaline digestion, however, only an appropriate aliquot of digestate should be taken for solvent extraction. After separation of the solvent phase, the slurry needs to be washed again with CH_2Cl_2 to achieve maximum recovery. For smaller samples sizes, we washed the slurry once. For larger sample sizes, however, and depending on the amount of slurry, two or more washings were required.

3.2. Effect of acidification on extraction recovery

In principle, MeHg can be extracted quantitatively from an acidic solution into an organic solvent. In this work, HCl was used for neutralization and acidification of the strongly alkaline digestate slurry. To optimize the acidification conditions, a series of aliquots (0.135–0.150 g) of certified reference sediment, IAEA 356, were digested with 2 ml of 25% KOH–methanol. Following the addition of 6 ml of CH_2Cl_2 to each of the cooled digestates, various volumes of concentrated HCl were added, and the slurries were shaken for either 20 s or 10 min. The results are shown in Fig. 1. When 0.5 ml of HCl was added, the pH of the slurry was > 12 and the recoveries were very low. When 1 ml of HCl was added, the
Fig. 1. Effect of acidification on the extraction recovery as a function of shaking time: (■) 20 s; ( ) 10 min.

pH was < 2 and 100% recovery was reached by shaking the slurry for 10 min, indicating that the recovery increased with increasing acidification. In addition, it was found that the amount of inorganic mercury (Hg^{2+}) transferred to the organic solvent decreased with increasing HCl volume. Sediment samples generally contain higher concentrations of Hg^{2-}, and the transfer of Hg^{2+} to the extract can make chromatography difficult. This should be taken into account in optimizing the extraction conditions. The optimum conditions should be those at which the recovery of MeHg is maximized, while Hg^{2+} transfer to the solvent phase is minimized. Thus, using more HCl should be suggested. However, when HCl volumes were increased further, a decrease in MeHg recovery was found. This is because an increased HCl concentration may decompose some of MeHg. Using the amount of HCl chosen in this work, most of Hg^{2+} was isolated with the other matrix, and no problem caused by Hg^{2-} transferred to the extract was observed, and therefore it was not necessary to increase the HCl volume here. With respect to shaking time, the two curves in Fig. 1 show that, at the same acidification, shaking for 10 min generally yields higher recoveries. In addition, no plateau was found on the 20 s shaking curve, suggesting that a longer shaking time should be used.

3.3. Effect of shaking time on extraction recovery

To optimize the shaking time further, a series of IAEA 356 digestates acidified with 1 or 2 ml of HCl were shaken for different times. The results are illustrated in Fig. 2. Considering the results shown in Figs. 1 and 2 in detail, we decided to use 1.5 ml of HCl for acidification and to shake for 10 min.

3.4. Effect of the ratio of CH_2Cl_2 to KOH methanol solution on the extraction recovery

In principle, as the ratio of CH_2Cl_2 to KOH–methanol solution increases, the amount of MeHg in the CH_2Cl_2 phase should also increase. We found that recoveries close to 100% can be reached at a ratio of 3:1. Thus, when using 2 ml of KOH–methanol, 6 ml of CH_2Cl_2 should be used.

3.5. Analytical performance

The analytical performance of the technique was evaluated by analysis of various certified reference materials and intercomparison samples with different concentration levels. The results are listed in Table 1. It can be seen that, except for LUTS-1, excellent agreement was obtained
Fig. 2. Effect of shaking time on the extraction recovery as a function of acidification: (■) 1 ml of HCl; (□) 2 ml of HCl.

between the observed and certified values. For the material LUTS-1, the results are far from the certified value. We carefully analyzed it further by both direct ethylation of alkaline digestates and

NIES No. 9 (Sargasso)	5.4 ± 0.4	5.7 ± 0.1^a

^{a}Information only [10].

distillation. The results of these three techniques were in good agreement. This suggests that the concentration of MeHg in this sample is not as stable as that in dry biological materials, and that it has changed after several years of storage. It is worth noting that, for the analysis of the sea plant sample, we tried to use distillation, but severe interference with the ethylation reaction was observed. Apparently, the problem stems from volatile compounds transferred to the distillate, making the analysis impossible. However, no analytical problem was encountered with solvent extraction. In this case, the technique was the only choice. The results listed in Table 1 were obtained against pure aqueous standards without correction for spike recovery. This is a significant advantage compared with other techniques [2,6,7,11]. where the results need to be corrected for spike recoveries.

3.6. Application of the technique

As mentioned above, the technique developed here showed significant advantages for the analysis of samples containing high concentrations of Hg^{2+}, such as sediments. In addition, for samples containing large amounts of organic volatile compounds which may pass to the distillate during

distillation, thus causing an interference with the ethylation reaction, the solvent extraction should be preferred. The analysis of sea plants mentioned above is one of these cases. Eggs and milks are also rich in organic volatile compounds, while low in MeHg concentration, for which the technique would be the best choice.

In addition, the analysis of whole blood and red blood protein can show severe interferences with the ethylation reaction. We carefully analyzed red blood protein samples of 13 dolphins from the Mediterranean Sea by the direct ethylation of alkaline digestates. Poor spike recoveries were obtained, and the observed precision was poor. However, recoveries close to 100% were obtained with excellent precision using the solvent extraction technique. A mean concentration of 207.6 $\pm$ 72.5 ng g^{-1} was found by solvent extraction, compared with 78.8 $\pm$ 43.6 ng g^{-1} by direct ethylation of alkaline digestate. Unfortunately, there are no blood samples certified for MeHg. We also used the technique for the analysis of sediment and soil samples from the Mediterranean Sea and Minnesota rivers and also other origins with satisfactory results. Some of them are typical high Hg^{2+}-containing and organic-rich samples. We also used the technique for the determination of MeHg in sludge samples with good results. These sludge samples were dried by centrifugation prior to alkaline digestion and solvent extraction.

Abstract

A unique integrated separation-based fiber-optic sensor for remote analysis, that incorporates capillary electrophoresis (CE) directly at the fiber sensing terminus is described for the first time. Based on laser-induced fluorescence detection, the sensor offers the potential for high sensitivity. Although the broad-band nature of fluorescence spectra limits selectivity, the high separation power of CE provides a unique dimension of selectivity, while permitting a design of diminutive size. Previously reported fluorescence-based sensors that utilize a chemical reagent phase to impart selectivity tend to be inflexible (not readily adaptable to the detection of different species) and "one-measurement-only" sensors. Conversely, the CE-based fiber-optic sensor described here is both versatile and reusable. The analysis speed and the potential for remote control are further attributes which make the system amenable to remote sensing. A "single-fiber" optical detection arrangement and a "single-reservoir" CE system with the fiber-optic probing the outlet of the separation capillary are employed. A preliminary evaluation of the separation characteristics of this CE-based sensor is presented. Highlights include an observed separation efficiency of up to 3000 theoretical plates (8 cm separation capillary) and migration time reproducibility of less than 10% for frontal mode CE separations. The potential utility of the sensor for remote analysis is demonstrated with separations involving the CE analysis of charged fluorescent dyes, CE analysis of metal complexes based on in situ complexation and micellar electrokinetic capillary chromatographic analysis of neutral fluorescent compounds.

1. Introduction

A unique integrated separations-based fiber-optic sensor (SBFOS) for remote analysis, that incorporates capillary electrophoresis (CE) directly at the fiber terminus, is described for the first time. Fiber-optic-based sensors have been the focus of intensive research and development over the past two decades [1–6]. Since sensing applications involve in-situ measurements, the issue of selectivity is often critical. As a result, fiber-optic sensors have been demonstrated to yield selective detection in infrared [7], Raman [8,9] and surface-enhanced Raman spectroscopy [10–12] and various modes of spectroelectrochemistry [13]. Vibrational spectroscopic methods offer selectivity owing to the uniqueness of the spectra involved. Unfortunately, sensitivity is limited with those techniques. Although fluorescence-based detection is sensitive, spectral selectivity becomes more challenging owing to the broad-band nature of fluorescence spectra. However, fluorescence-based sensors that exhibit high selectivity have been developed by immobilizing at the fiber terminus substances such as permeability-selective polymer films [14–18] or chemically-selective affinity reagents (e.g. antibodies or enzymes) [19–24]. Such systems are generally inflexible and are not readily adaptable to the detection of different species. Furthermore, they tend to be "one-measurement-only" sensors. An extremely versatile element of selectivity that has not been adapted to fiber-optic sensing is that afforded by chemical separations. In particular, capillary electrokinetic separation techniques offer the attributes of high separation efficiency, speed, diminutive size, versatility and remote control, all of which are potentially important in the development of SBFOSs.

In the decade following the seminal paper describing modern CE [25], the prominence of the technique has grown dramatically. Most commonly, separations of ionic solutes are performed in modest length (25–75 cm), narrow bore (25–75 μm i.d.) capillaries filled with an aqueous running buffer solution. Electric fields of 100–500 V cm^{-1} transport solutes through the capillary based on electroosmotic flow (EOF) and electrophoretic migration [26,27]. Perhaps the most significant

advantage of the technique is the characteristic "plug-like" profile of EOF, which results in extraordinary efficiency (plate counts of 10^3–10^5 per cm of capillary are generally observed). Low-nl sample volume requirements and short analysis times are also relevant attractive features. As an electrokinetic phenomenon, CE has primarily been demonstrated to yield extremely efficient separations of charged solutes ranging from small inorganic ions to large proteins and oligonucleotides. However, neutral compounds have been separated via electrochromatographic modes of CE that involve adding micelles or cyclodextrins to the running buffer [28,29]. In fact, micellar electrokinetic capillary chromatography (MECC) has proven to be a valuable electrokinetic technique for separations of neutral compounds [28]. Another significant advantage of CE is the ease of such buffer modifications, thus affording tremendous flexibility for any single CE apparatus. In addition to the examples cited above, these buffer modifications include the use of zwitterionic substances, crown ethers, linear hydophilic polymers, organic modifiers, metal ions and complexing ligands [30]. In the light of the above factors, it is clear that CE has far-reaching applications and a wide range of selectivities. CE has been implemented in conjunction with electrochemical detection to probe the microenvironments of biological systems (e.g. single cells) using what have been termed "separations-based sensors" [31,32]. However, to our knowledge, separation technologies such as CE have not been incorporated as an element of selectivity in fiber-optic-based remote sensing.

The work reported here was undertaken to demonstrate the feasibility of integrating CE methodologies with fiber-optic sensing. Although capillary and fiber-optic dimensions are comparable, there are significant obstacles and complex considerations when integrating these technologies (see below). In this work, a "single-fiber" optical arrangement is employed [20–24]. The sensor is configured as a "single-reservoir" miniaturized CE system interfaced to a fiber-optic that monitors the outlet of the separation capillary. The relatively short separation capillary is simply filled with the buffer solution prior to measure-

ment. The sample acts as what is normally the injection-side reservoir and the performance of the sensor is evaluated in these studies using frontal electrokinetic modes of separation. The resulting linear sensor design should be well suited for many remote sensing applications.

We have demonstrated high sensitivity with fiber-optic sensors that employ laser-induced fluorescence (LIF) as the detection mode [20–24]. However, the work described in this paper was primarily focused on a preliminary evaluation of the separation (i.e. selectivity) characteristics of the SBFOS.

2. Experimental

2.1 Chemicals

The fluorescent dyes sodium fluorescein (E.M. Science, Cherry Hill, NJ, USA), Rhodamine 6G (Rhodamine 590) (Exiton, Dayton, OH, USA), and fluorescein isothiocyanate (FITC) (Sigma Chemical, St. Louis, MO, USA), were purchased at the highest commercially available purity and used as received. $MgSO_4$ and $CaSO_4$ (Baxter, Stone Mountain, GA, USA) were also used as received. The running buffer solution used was composed of 10 mM sodium phosphate, dibasic (J.T. Baker, Phillipsburg, NJ, USA) and 6 mM sodium tetraborate (Fisher Scientific, Fair Lawn, NJ, USA). Water used to prepare the buffer solution was purified with a Waters Milli-Q + filtration system. In general, the fluorescent dye solutions were approximately 0.1 mM in running buffer. A complexing agent, 8-hydroquinoline-5-sulfonic acid (HQS) (Sigma), was used for on-column (in situ) labeling of metal ions. For metal ion separations, the running buffer contained 2.5 mM HQS. Metal ion sample solutions were 0.5 mM $CaSO_4$ and 0.1 mM $MgSO_4$. A sample of Big Limestone Creek water was obtained from a site in Washington County, TN, and used in these studies without any modification. The methylamine and *n*-propylamine used for MECC work were obtained from Fisher and derivatized with 7-chloro-4-nitrobenzofurazan (NBD-C) from Aldrich Chemical (Milwaukee, WI, USA). If

derivatization was complete, sample solutions of the NBD-amines were 0.1–1 mM. The surfactant used for MECC separations, sodium dodecyl sulfate (SDS), was purchased at 99% purity from Sigma. Separation capillaries were obtained from Polymicro Technologies (Phoenix, AZ, USA) and rinsed with 0.1 M NaOH prior to use.

2.2. CE sensor

Fig. 1 depicts the general design of the sensor, which is composed of the following five essential components: (i) the separation capillary, (ii) the fiber-optic, (iii) a hydrostatic flow-restricting capillary, (iv) a low-volume, PEEK tee fitting and (v) the sample-side–detection-side electrode pair. Two such sensors were assembed for experiments performed at two separate sites, the University of Tennessee, Knoxville (UTK) and Oak Ridge National Laboratory (ORNL). The ORNL sensor was used for initial evaluations of the SBFOS involving CE separations of charged fluorescent dyes. The UTK sensor was used for all other SBFOS evaluations, involving CE separations of HQS–metal complexes and MECC separations of neutral fluorescently derivatized amines. Common to both sensors was the non-metallic PEEK tee (Upchurch, Model P712). The two opposing ports of the tee were used to position the fiber-optic on-axis efficiently with and very close to the end of the separation capillary. The third port (perpendicular to the separation/optical axis) allowed the flushing of the sensor. This side port also housed the restrictor capillary and detection-side electrode. Channels extending from each port to the central union of the tee were of diameter 0.020 in and length approximately 0.19 in. Other components of the sensor varied depending on the version involved (see below).

2.3 ORNL sensor

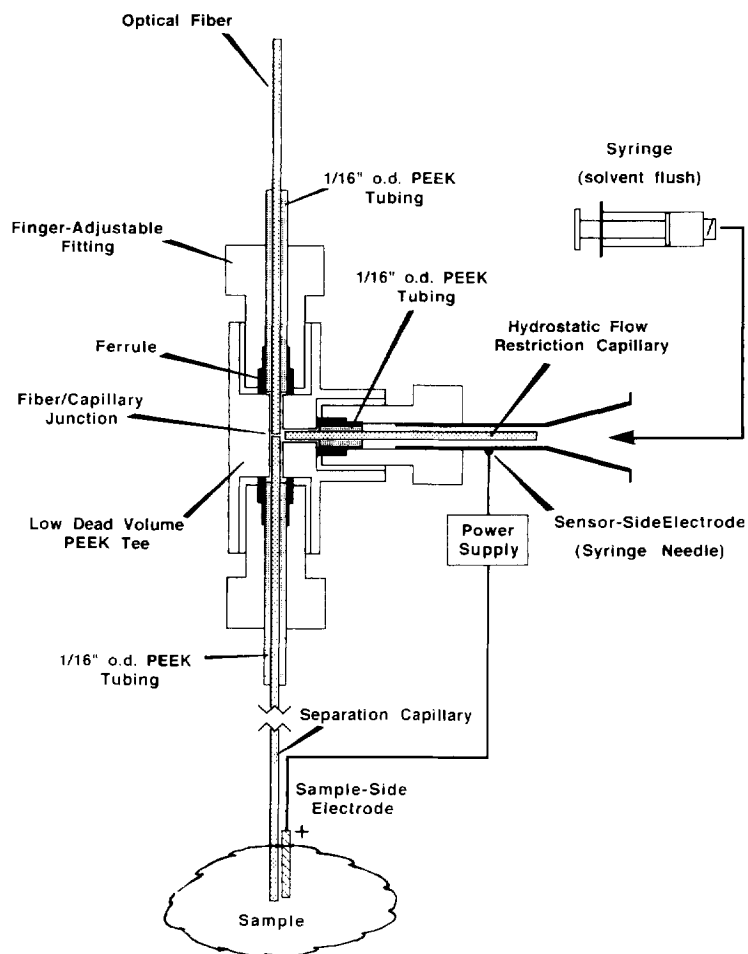
In addition to the tee and electrode pair, the SBFOS sensor assembled at ORNL was composed of the following: (i) separation capillary (8 cm × 50 μm i.d.), (ii) fiber-optic (General Fiber optics, Model 14-200, 1 m × 200 μm core diameter), and (iii) restrictor capillary (3 cm × 15 μm


Fig. 1. Depiction of the SBFOS

i.d.). The separation capillary was affixed (5 min epoxy, Devcon) within the 0.020 in bore of a 3 cm segment of PEEK tubing (1/16 in o.d.). The PEEK tubing provided an air-tight coupling to a flangeless ferrule and facilitated connection to the tee with a threaded, finger-adjustable fitting. The capillary itself extended from the fitting assembly into the narrow bore at the center of the tee. The ends of the 1 m fiber-optic were polished with alumina lapping paper down to 0.3 μm grain. The fiber was affixed within PEEK tubing and connected to the tee in a manner similar to that used for the separation capillary.

The side port, used for flushing or filling the sensor, was furnished with a syringe needle which had been modified to accommodate the restrictor

capillary during electrophoresis. The syringe needle was carefully secured within the bore of the finger-adjustable threaded fitting without displacing the ferrule. The restrictor capillary was affixed within a short (4–5 mm) section of 1/16 in o.d. PEEK tubing, allowing an air-tight seal with the ferrule. This capillary was also arranged to extend into the narrow bore of the tee as shown in Fig. 1. The metal shaft of the syringe served as the detection-side electrode, and was therefore a source of gas formation during electrophoresis. However, the side port capillary provided a physical barrier against the introduction of gas bubbles into the tee. Residual liquid in the syringe needle fitting cone which engulfed the outside end of the restriction capillary allowed completion of

the electrical circuit even though the side port was left open to the atmosphere during electrophoresis. The sample-side electrode, electrically isolated from the CE sensor assembly, was set at positive bias voltages during separations using a Hipotronics 20 kV high-voltage power supply (Brewster, NY, USA).

2.4. UTK sensor

The SBFOS sensor used for studies at UTK was assembled as described above except that the restrictor capillary was 5 cm × 25 μm i.d. and the fiber-optic was a Polymicro Technologies Model FVP 100 with a 100 μm core diameter. Because the fiber-optic was smaller in diameter than the ORNL version, the end to be inserted into the SBFOS was affixed within the bore of a 10 cm section of 180 μm i.d., 400 μm o.d. capillary. The fiber tip, cement and encasing capillary were then collectively polished to a flush surface with lapping paper. Otherwise, assembly and application to electrical fields for the two sensors were identical.

2.5 SBFOS optics and instrumentation

The optics and instrumentation varied slightly between the two sites. Fig. 2 illustrates the optical arrangement used for SBFOS detection of fluorescent dyes at the ORNL site. The 457.9 nm line (10 mW) of an argon ion laser (Coherent, Innova-70) was the excitation source. The laser beam was directed through the hole of a plane mirror into a 50× objective lens (Newport, Model L50X), which focused the laser beam on to the fiber-optic of the SBFOS. Optimum coupling of the laser beam to the fiber was facilitated with an x, y, z fiber positioner. The fiber transmitted both the laser excitation and sample fluorescence signal to and from the sensor, while the plane mirror (with the hole) served as a pseudo beam splitter, oriented at 45° with respect to the excitation beam axis. The fluorescence signal from the SBFOS exited the fiber and was collimated by the objective lens. A majority of this collimated signal beam was reflected 90° off-axis towards a relay fiber-optic (600 μm core, Fiberguide Industries).

A 480 nm "cut-on" filter was inserted into the signal beam to reject the unwanted Rayleigh scatter. The detector was an uncooled photomultiplier tube (PMT) (RCA, Model IP-28) operated at 1000 V. Photocurrents from the PMT were amplified by a picoammeter (Keithley, Model 485) and electropherograms were directly recorded with a strip-chart recorder (Kipp and Zonen, Model BD 40).

The UTK sensor optical system was very similar to the ORNL system, except for replacement of the Coherent argon ion laser with an He–Cd laser (Omnichrome, Series 74, 325 nm, 20 mW) for the detection of HQS–metal complexes and an air-cooled argon ion laser (Cyonics, Model 2201, 488 nm, 10 mW) for the detection of NBD-amines. In addition, the relay fiber-optic was omitted (i.e. the collimated signal beam was focused directly on to the PMT). All lenses were quartz and 400 nm "cut-on" and 500 nm "cut-on" filters were used to reject Rayleigh scatter when using the He–Cd and argon ion lasers,

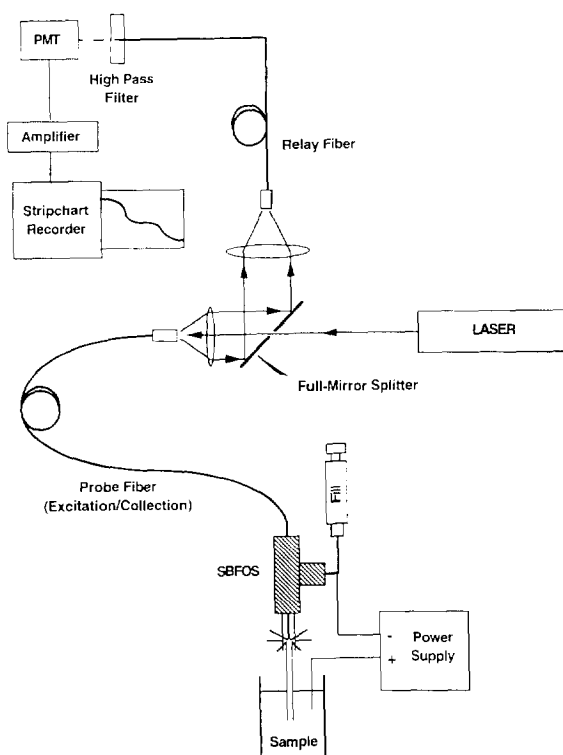

Fig. 2. Schematic diagram of the single fiber-based optical detection system.

respectively. Photocurrents from the PMT were amplified with a Pacific Precision Instruments (Concord, CA, USA), Model 126 photometer.

Conventional zonal and frontal CE separations were performed using a modular CE–LIF detection system that is described elsewhere [28]. The capillaries used for these conventional separations were typical in length (about 45 cm); however, the detection zone was positioned close to the inlet (about 8 cm) so as to mimic the sensor.

2.6 Sensor operation procedures

The first step in aligning the optics involved visually maximizing the coupling of the excitation beam on to the fiber (judged by monitoring the light intensity at the distal end of the fiber). Next, laser radiation was retro-passed into the system (i.e. made to impinge on the distal end of the fiber) and the lenses and mirror were adjusted to provide the proper alignment with the detector. Finally, the sensor was flushed with a fairly concentrated dye solution and signal levels were monitored as further positioning of the optical components was accomplished. Since this work focused on the separation characteristics of the SBFOS, little effort was made to fine tune the alignment or to use the best optical components.

Prior to each separation, the sensor was flushed with 0.1 M NaOH and then running buffer solution. Flushing steps were performed with an unmodified syringe needle (no restrictor capillary), taking care not to introduce gas bubbles into the system. In this case, the 16-gauge needle was inserted directly into the flangeless fitting ferrule, forming a snug fit. Subsequently, the flushing needle was replaced with the needle containing the restrictor capillary and the SBFOS was then submerged in the sample for initiation of the separation. Applied voltages with the SBFOS were relatively low (maximum of about 3 kV).

3. Results and discussion

Regardless of the selectivity and flexibility offered by CE, three major challenges must be addressed for its implementation in remote sens-

ing: (1) elimination (or acceptable reduction) of hydrostatic flow, (2) expulsion or elimination of electrolysis gases and (3) establishing suitable compromises between detectability and separation performance. In CE, elimination of gravity-driven hydrostatic flow is generally accomplished by the use of inlet and outlet buffer reservoirs at equal heights. As is demonstrated by the design depicted in Fig. 1, the SBFOS does not allow the luxury of level buffer reservoirs. If observed, a downward hydrostatic flow (away from the fiber-optic) in the separation capillary is expected to cause band dispersion [30]. Moreover, a relatively large applied field may be required to provide sufficient EOF to overcome the hydrostatic flow. Under these conditions, thermal dispersion of bands is also possible. The SBFOS described in this paper is designed to restrict gravity-driven hydrostatic flow by incorporating a narrow-bore capillary into the side port of the sensor (see Fig. 1), thereby relaxing inlet and outlet buffer reservoir position requirements. The relative positions of the ends of the separation capillary contribute less hydrostatic flow, making a vertical, linear capillary configuration feasible. It should be noted that incomplete dissipation of pressure applied during rinsing steps and/or pressure resulting from the build-up of electrolysis gases can also produce a detrimental hydrostatic flow with the SBFOS.

Owing to the small sample volumes associated with the use of CE, on-column detection is generally required to preserve the integrity of the separation. In this regard, the unique characteristics of lasers as excitation sources have rendered LIF detection extremely useful in CE [33–36]. Typical laboratory optical systems consist of extra-column lenses or fiber-optics for focusing and collecting excitation and signal radiation. It has recently been demonstrated by Taylor and Yeung [37,38] that the use of an excitation fiber-optic inserted into the end of a capillary for axial illumination yielded enhanced sensitivity. While such an arrangement demonstrates a potential for remote sensing, the apparent goal of that work was to utilize fiber-optic-based detection in CE, rather than incorporating CE as an element of selectivity in an optical configuration that is suitable for remote fiber-optic sensing.
Fig. 3. Plot of relative fluorescence signal intensity versus fiber-optic–capillary spacing. The signal was generated by drawing a solution of fluorescein into the SBFOS via a syringe.

In this work, we utilized an optical arrangement for sensing applications that employs a single fiber for both excitation and signal collection (see Fig. 2) [19]. The streamline linear geometry should be well suited for remote analysis. Although a narrow diameter or tapered fiber could be inserted into the separation capillary, we opted for placing a larger, and hence more stable, fiber directly adjacent to the exit of the capillary. This resembles the approach that Huang et al. [39] employed in the positioning of electrodes for electrochemical detection in CE. Since a fiber will collect light most efficiently only to distance of a couple of fiber diameters from its end [19], this configuration probes the extremely small space between the fiber and capillary and a sub-mm segment at the capillary outlet. This assumes that internal reflection in the capillary is not significant. Benoit and Yappert [40] described a fiber-optic sensor that employs a capillary, functioning as a partially reflecting waveguide, to enhance sensitivity. If this waveguide effect were operative in our work, it would be expected consistently to broaden bandfronts, which was not observed in these studies (see below).

Although the effective detector volume and signal are dramatically increased as the fiber is backed away from the separation capillary, an extra-column dead volume is created and this also can dramatically broaden bandfronts. These effects are demonstrated in Figs. 3 and 4. The SBFOS was filled with a fluorescein solution and used to generate the plot of signal versus fiber–capillary spacing shown in Fig. 3. While the signals increased with increased spacing, the sharpness of bandfronts degraded. This is demon-

Fig. 4. CE bandfronts for Rhodamine 6G obtained using the SBFOS with capillary fiber-optic spacings of (A) 0 mm and (B) approximately 1 mm.

strated in Fig. 4 using the SBFOS to obtain the
frontal CE bandfronts of an injected Rhodamine
6G solution. Under the SBFOS conditions em-
ployed, a relatively sharp bandfront at a migra-
tion time of 110 s is observed when the fiber is
directly touching the capillary (Fig. 4(A). With a
spacing estimated to be 1.0 mm, the bandfront is
substantially broadened (i.e. the efficiency is very
poor) and the migration time is greater than 1000
s (Fig. 4(B). Clearly, the fiber–capillary spacing
must be negligible in order to maximize bandfront
sharpness. Unfortunately, excessive rinsing and
manipulation of the SBFOS described here occa-
sionally produced broad bandfronts, indicating
that an appreciable fiber–capillary spacing had
been created.

To achieve a positive band velocity (V_b) (i.e.
toward the fiber-optic) electrophoretic flow (V_{elec}),
one must overcome the opposing hydrostatic flow
(V_{hy}) as described by the equation

$$V_b = V_{hy} + V_{elec} = V_{hy} + (\mu_{eo} + \mu_{elec})E \qquad (1)$$

where E is the applied field and μ_{eo} and μ_{elec} are
electroosmotic and electrophoretic mobilities, re-
spectively. Under the conditions employed in this
work, cathodic EOF is directed toward the fiber-
optic. As the voltage and (hence E) is increased,
the V_b values increase and the migration times
decrease. However, since it is necessary to over-
come V_{hy}, the linear relationship between E and
V_b that is characteristic of CE is not observed in
this work (see below). To illustrate the effect of
V_{hy}, conventional zonal CE separations of Rho-
damine 6G (cation), FITC (neutral) and fluores-
cein (anion) were performed using a very short
effective capillary length (8 cm) with equal inlet
and outlet reservoir heights (no V_{hy} case) and with
the capillary outlet raised approximately 8 cm
(opposing V_{hy} case). The results are shown in Fig.
5. Independent experiments produced a V_{hy} of
roughly 1.2 cm min^{-1} for the conditions used to
generate Fig. 5(B) and, indeed, the V_b of FITC
decreases from 4.6 to 3.3 cm min^{-1} when compar-
ing Fig. 5(A) and (B). The adverse effect of a
hydrostatic flow on efficiency is also obvious in
Fig. 5. Using migration times from Fig. 5(A), the
experimental values of μ_{eo} (marked by FITC),
μ_{elec} (Rhodamine 6G) and μ_{elec} (fluorescein) are

s^{-1}, respectively.

Despite the potential problems discussed above,
including band dispersion by Joule heating and
dead volume, some promising results were ob-
served in the CE separation of charged fluorescent
dyes. For example, an SBFOS separation of Rho-
damine 6G and fluorescein is shown in Fig. 6. The
peak-like shape of the fluorescein bandfront is
probably a result of photodegradation of that
solute. The efficiency of Rhodamine 6G is ap-

proximately 3000 plates. The equation $N = 16$ $(T_r/W)^2$ was used to determine the plate count (N), where the bandwidth (W) corresponds to the rise time of the bandfront between the baseline and the plateau. The retention time (T_r) corresponds to the elapsed time between the application of the voltage and the point of half-maximum intensity for the observed bandfront. The applied voltage is divided across the separation capillary, the restrictor capillary and the fiber–capillary junction. Since the last is not well defined, it is not possible to assign accurately a field to the separation or to calculate mobilities, as was possible with the separation shown in Fig. 5(A). The resolution (i.e. $\Delta T_r/W$) in this separation is approximately 7.

The effect of increasing the applied voltage on the performance of the SBFOS is demonstrated in Table 1, which also includes data on band velocity (and hence migration time) reproducibility (relative standard deviations for $n = 5$). When the voltage was increased to 3000 V, excessive currents were observed and the system eventually broke down (the current dropped to zero). Conversely, the system functioned at an applied voltage of 2500 V, yielding the data in the table. However, the current increase relative to the 1500 V case was considerably more than the expected 67%. This anomalous current effect, and the decrease in bandfront sharpness (the efficiency decreased about threefold), indicates excessive thermal load and a temperature increase in the system at the higher applied voltage. The lack of reproducibility in band velocity is probably due to a combination of heating effects and a lack of integrity in the conduction paths (i.e. the run-to-run currents exhibited a similar poor reproducibility).

The influence of V_{hy} on separations can also be seen in Table 1. As the applied voltage is increased from 1500 to 2500 V the resolution improves despite a decrease in efficiency. This unusual behavior is a result of the differences in $\mu_{eo} + \mu_{elec}$ for the two bands. The net mobility of the fluorescein anion is nearly four times smaller than that of the Rhodamine 6G cation. In the case of Rhodamine 6G, when the voltage is increased the band velocity nearly increases by the

expected 67%. Conversely, the impact of V_{hy} on V_b is much more signifcant for fluorescein and the increase in band velocity is much less than 67%. The net effect is a greater separation in the bandfronts of the two dyes at the higher applied voltage. Based on capillary diameter and length, the 3 cm × 15 μm i.d. restrictor capillary of the SBFOS used to generate the data in Table 1 should have reduced the hydrostatic flow fivefold in the 8 cm × 50 μm i.d. separation capillary. Future SBFOS designs will attempt to reduce V_{hy} further.

The frontal CE approach is instrumentally and operationally simple. Nevertheless, this mode of operation will influence both the detection and the separation characteristics of the SBFOS. With regard to the former, as each new front reaches the fiber-optic, the fluorescence background increases (i.e. the signal from the first component to elute contributes baseline noise that adversely affects the detectability and dynamic range for subsequent components). With regard to the separation characteristics, which are the focus of this paper, the running buffer in the capillary is displaced by sample solution as the separation proceeds. At some point, which is strongly influenced by the EOF, many CE systems will experience "reagent depletion" in the frontal mode of operation. For the simple case of natural fluorophores that can be separated based on differences in intrinsic mobility (e.g. see Fig. 6), there will not be a distinct point of reagent depletion. However, the EOF (and hence solute migration time) may be altered as the sample enters the sensor and this could complicate calibration. At times there may be advantages in reducing, eliminating or reversing the EOF via running buffer additives or capillary surface modification [28].

Most strategies for CE involve adding specific reagents to the running buffer to affect the separation or facilitate detection. In order for the SBFOS to be generally useful, it will be necessary to develop systems and protocols for which reliable analytical information is acquired before reagent depletion occurs. For example, a CE protocol we previously developed for the on-column labeling of metals with HQS was adapted in this work to the SBFOS [41]. HQS is a non-fluores-

Table 1
Effect of applied voltage on SBFOS separations of fluorescent dyes

Voltage (V)	Current (μA)	Rhodamine 6G bandfront		Fluorescein bandfront	
		V_b (cm min^{-1})	N	V_b (cm min^{-1})	R_s
1500	90	1.1 ($\pm$ 9%)	~3000	0.66 ($\pm$ 7%)	~7
2500	250	1.8 ($\pm$18%)	~1000	0.83 ($\pm$24%)	~9

cent, bidentated ligand that forms fluorescent complexes with a large number of metal ions. In addition to facilitating sensitive detection of the metals, the complexation conditions can be altered to adjust the effective mobility of a metal ion [41]. The SBFOS strategy involves first flushing the sensor with running buffer containing an appropriate concentration of HQS. When a field is applied, positively charged metals migrate quickly toward the fiber-optic (velocity greater than that of the sample solvent front which is driven largely by EOF) and negatively charged HQS will migrate slowly toward the fiber (velocity less than the solvent front). In essence, HQS rapidly meets the metals and, owing to the large formation constants involved, an equilibrium involving the various forms of complexed metal is established. This process reduces metal migration rates (due to the reduced charge of the complex relative to the free metal). The dynamics of these processes influence the sharpness and shape of the bandfronts, which migrate at rates characteristic of the metal.

Figs. 7–9 contain electropherograms illustrating separations of calcium and magnesium using in situ complexation with HQS and a frontal mode of operation. In Fig. 7(A), a conventional capillary frontal separation of the metals exhibits relative responses and mobilities similar to those observed in previous work involving zonal CE [41]. This separation was performed with HQS in both the running buffer and sample. Obviously, in remote analysis situations the sample will not contain running buffer reagents. When HQS is not present in the sample, the shapes of the bandfronts are altered (see Fig. 7(B)). The signal rises to a plateau, then drops back down to a lower plateau. This may be a result of a non-equi-

librium condition in the early stages of the separation (see above) or a manifestation of some stacking phenomena [42]. Nevertheless, the responses of the two metals are well separated and the overlay of the response of a sample with a twofold higher calcium concentration illustrates the potential of this approach for performing quantitative measurements. Signals fall to baseline values, indicating depletion of HQS in the system, at 350–400 s into the run. This is roughly the effective migration time of HQS.

Fig. 8 is an electropherogram of a calcium–magnesium sample (no HQS in the sample) obtained with the SBFOS that demonstrates its potential for remote sensing. The separation is considerably slower owing to a lower field and the presence of V_{hy}. This condition relaxes the non-equilibrium condition in the early stages of the

Fig. 6. Frontal capillary electropherogram of Rhodamine 6G and fluorescein (in order of elution) obtained using the SB-FOS. Conditions: 8.0 cm × 50 μm i.e. separation capillary and 3 cm × 15 μm i.d. restrictor capillary (ORNL sensor), applied voltage 1500 V, phosphate–borate (pH 9) running buffer, LIF detection using argon ion laser (see Experimental). The method for calculating efficiency as described in the text.
Fig. 7. Conventional frontal capillary electropherograms of calcium and magnesium (in order of elution) based on in situ HQS complexation with HQS in sample (A) and not in sample (B). Conditions: 40 cm (8 cm to detection zone) × 50 μm i.d. capillary, 190 V cm⁻¹ applied field. phosphate–borate (pH 8) running buffer with 2.5 mM HQS. LIF detection using He–Cd laser (see Experimental).

separation (see above) and may account for the absence of the dual plateau response seen in Fig. 7(B). The run was terminated before reagent depletion. Clearly, a shorter capillary could be used to reduce the analysis time. A duplicate run yielded similar results. Fig. 9 presents the results for the analysis of a ground water sample by using conventional frontal CE (Fig. 9(A) and the SBFOS (Fig. 9(B)), indicating the presence of calcium. Although calcium in this sample was not quantified and the sample was not analyzed by independent methods, the presence of a large concentration of calcium in a ground water source with the name Limestone Creek would not be surprising. The fact that the front in Fig. 9(B) occurs earlier than that for the SBFOS standard run shown in Fig. 8 may be due to changes in EOF due to differences in sample pH, or be simply a result of the poor migration time reproducibility of this design of SBFOS (see Table 1).

The MECC technique has greatly expanded the utility of CE and should be readily adaptable to the SBFOS. Neutral solutes are separated in MECC based on their distribution between the EOF-transported running buffer and an electrophoretically retarded micellar phase [28]. These solutes elute in a window that is created between the void time (t_0) and the effective retention time

of the micellar phase (t_m), which for the commonly employed SDS system occurs at about 3–4 times t_0. When the SBFOS is employed in this mode, reagent depletion should occur at about t_m (the negative micelles should migrate similarly to the HQS as described above). A MECC separation using the SBFOS is shown in Fig. 10. The baseline noise level is fairly high in these separations owing to an instability in the output of the laser employed. In Fig. 10(A) no SDS is present and the test solutes of NBD-methylamine and NBD-*n*-propylamine co-elute at t_0. When micelles are present (Fig. 10(B)), the solutes are easily separated before reagent depletion. Consistent with previous work [28], the signal is enhanced owing to the presence of the micelles. As was observed for SBFOS separations of the fluorescent dyes and HQS-metals, V_{hy} influences the separation of the NBD-amines. Normally, one would expect to observe less separation between these two NBD-amines [28], and experience reagent depletion at about 20–25 min (see above). However, the effect of V_{hy} is to decrease the observed migration rates, particularly for the more retained components (those with smaller V_{elec}), and delay reagent depletion. In a conventional (no V_{hy}) frontal MECC separation of

NBD-amines (not shown), reagent depletion was indeed observed at 3–4 times t_0.

Remote, in situ monitoring of chemicals offers many analytical advantages and challenges which are significant in the biomedical, environmental and industrial fields. Unfortunately, in situ measurements can be complicated and generally do not exhibit the analytical selectivity, sensitivity and reliability associated with conventional laboratory techniques. In this paper, we have described the design and fabrication and presented a preliminary evaluation of the performance of a fiber-optic sensor that utilizes CE techniques to impart a potentially versatile element of selectivity to the measurement process. In that regard, differ-

ent modes of operation are demonstrated under fairly realistic conditions. While improvements in the design, function and analytical reliability of the SBFOS are clearly needed, we feel that these preliminary results are sufficiently encouraging to warrant further research and development of the SBFOS.

Abstract

Disposable amperometric inhibition biosensors have been microfabricated by screen printing a tyrosinase-containing carbon ink. The decrease in the substrate (catechol) steady-state current, caused by the addition of various pesticides and herbicides. offers convenient quantitation of micromolar levels of these pollutants. Unlike esterase-based disposable strips, the tyrosinase thick-film devices can be fabricated by incorporating the enzyme within the carbon ink. and do not require a prolonged incubation step in the presence of the inhibitor. The effect of experimental variables, such as the enzyme loading or substrate concentration. is assessed. Applicability to an untreated river water sample is illustrated. Such use of single-use devices for monitoring toxins addresses the problem of irreversible enzyme inhibition. and holds great promise for on-site field analysis.

Keywords: Biosensing; Electrodes; Enzyme inhibitors; Screen printing; Tyrosinase

1. Introduction

Electrochemical biosensors hold great promise for the task of on-site environmental monitoring [1,2]. One promising strategy is to employ enzyme electrodes for measuring various toxins, via the perturbation/inhibition of the biocatalytic activity [3]. Useful devices have thus been designed for monitoring organophosphate or carbamate pesticides [3,4], cyanide [5,6] or toxic metals [7,8]. Single-use inhibitor biosensors, based on modern microfabrication technology, are particularly attractive for field deployment due to their extremely low cost, compatibility with hand-held analyzers, and the irreversible nature of many enzyme inhibition processes. Screen-printed disposable sensors, based on a cross-linked cholin-

esterase layer, have been developed in recent years for the detection of various pesticides [9,10].

In this paper we describe the characterization and attractive performance of single-use inhibitor bisensor strips based on screen printing of tyrosinase-containing carbon inks. Tyrosinase is prone to inhibition by a wide range of water pollutants [11]. Such inhibition is known to occur through interaction with the active copper site [12]. We reported recently on the one-step preparation of tyrosinase screen-printed electrodes [13]. The remarkable tolerance of tyrosinase to the high-temperature firing conditions resulted in a greatly simplified fabrication protocol and convenient quantitation of its phenolic substrates. Similarly, in the following sections we report on the suitability of these thick-film strips for amperometric monitoring of inhibitors of tyrosinase.

2. Experimental

2.1. Apparatus

All voltammetric experiments were carried out using an EG&G PAR Model 264A voltammetric analyzer, in connection with a Houston Omniscribe strip-chart Y–t recorder. The experiments were performed at room temperature in a 10 ml electrochemical cell (BAS, Model VC-2). The working electrode strip, reference electrode (Ag/AgCl, Model RE-1, BAS) and platinum wire electrode joined the cell through holes in the Teflon cover.

2.2. Screen-printing fabrication

A semiautomatic screen printer machine (Model TF-100, MPM Inc., Franklin, MA) was used for fabricating the working electrode strips. The modified inks were prepared by thoroughly mixing for 1 h the appropriate amount of a commerical carbon ink (Product No. C10903D14, Gwent Electronic Materials Ltd., UK) with the enzyme. Typical preparations were 0.6% enzyme ink (w/w). A group of 10 electrodes were printed each time onto an alumina ceramic plate (1.33 in. × 4.00 in.) through a patterned stencil. This

allowed batches of 30 electrodes to be printed by using 1 g of ink mixed with 6 mg of enzyme. Each electrode consisted of a 1.0×30 mm^2 area. The film was cured at a temperature of 110°C for 2 h. Then a layer of insulator was screen printed onto part of the ink, leaving a defined 1.0×5 mm^2 working-electrode area.

2.3. Reagents

Chemicals were analytical-reagent grade and used as received. All solutions were prepared with doubly-distilled water. The enzyme used, tyrosinase, 4400 units mg^{-1} solid, was obtained from Sigma (t-7755, EC 1.14.18.1). The supporting electrolyte was a 0.05 M phosphate buffer solution (PBS) pH 7.4. Catechol (Sigma), sodium diethyldithiocarbamate (Aldrich), thiourea (Fisher), benzoic acid (Baker), 2,4-dichlorophenoxyacetic acid (Sigma), 4,6-dinitro-o-cresol (Sigma), warfarin (Sigma), pentachlorophenol (Aldrich), atrazine (Chem Service), sodium nitrate (Aldrich), sodium nitrite (Fisher), sodium azide (Sigma), sodium fluoride (Baker), cadmium (Aldrich), and lead (Aldrich) were used.

2.4. Procedure

The screen-printed electrodes were used without any further pretreatment. The amperometric experiments were performed at a potential of -0.2 V, using a stirring rate of 400 rev min^{-1}. The substrate addition (5×10^{-5} M catechol) was follwed by additions of the target inhibitor, using microliter aliquots of the corresponding solutions. All measurements were performed at room temperature.

3. Results and discussion

Fig. 1 displays the amperometric response of strips containing different tyrosinase loadings to 5×10^{-5} M catechol (S), followed by successive additions of 1×10^{-5} M of diethyldithiocarbamate (I). The sensor responds very rapidly to these substrate and pesticide additions, indicating that its biocatalytic and inhibition activities are

maintained (despite the 2 h curing at 110°C); steady-state currents are obtained within ≈ 1 min. Such fast responses are attributed to the absence of supportive/external membranes, which is inherent in the screen-printing fabrication process. A preincubation period is not required, in contrast to strips based on immobilized acetylcholinesterase [10]. Both the substrate and inhibitor responses increase upon increasing the enzyme loading in the ink. The resulting calibration plots (also shown) indicate that the inhibitor response is nearly proportional to the enzymatic activity. Note that the ratio of inhibition signal/substrate signal increases initially (from 0.14 to 0.26), upon raising the enzyme loading from 0.3% to 0.6% w/w, and then decreases slightly to 0.24 for the 1% loading. Such trends reflect the fraction of the enzyme inhibited at a given inhibitor concentration.

Fig. 2 displays calibration plots obtained with the 0.6% w/w tyrosinase-containing strip for submillimolar concentrations of the pesticide diethyldithiocarbamate (A), thiourea (breakdown product of dithiocarbamate pesticides; B) the antifungal agent benzoic acid (C), and the herbicides 2,4-dichlorophenoxyacetic acid (D) or 4,6-dinitro-o-cresol (E). The new strips offer convenient quantitation of these toxins. However, as expected for inhibition processes, such plots are not linear.

Fig. 1. Enzyme loading studies at various tyrosinase screen-printed electrodes. Enzyme loading: (A) 0.3; (B) 0.6; (C) 1.0% w w. Also shown (inset) are the respective current–time recordings. Catechol, 5×10^{-5} M, was used as substrate (S); sodium diethyldithiocarbamate, 10^{-5} M per step, was used as inhibitor (I). Applied potential, -0.2 V; electrolyte, phosphate buffer (0.05 M, pH 7.4); stirring rate, 400 rev min^{-1}.

Fig. 2. Calibration plots obtained for inhibition at the 0.6% tyrosinase strip for: (A) sodium diethyldithiocarbamate; (B) thiourea; (C) benzoic acid; (D) 2,4-dichlorophenoxyacetic acid; (E) 4,6-dinitro-o-cresol. Other conditions are as given in Fig. 1.

A significant curvature is observed at high concentrations (reflecting saturation of the tyrosinase site). The quantitation of levels around the above such saturation is therefore limited. The trend in sensitivity: diethyldithiocarbamate > thiourea > benzoic acid > 2,4-dichlorophenoxyacetic acid > 4,6-dinitro-o-cresol, reflects the degree of inhibition. These profiles were used to estimate the apparent coefficients of inhibition, $I_{0.5}$, i.e. the concentrations corresponding to 50% of the inhibition signal, which were: 9.2×10^{-5} M (diethyldithiocarbamate), 1.0×10^{-4} M (benzoic acid) and 2.0×10^{-4} M (4,6-dinitro-o-cresol). The detection limits (S/N = 3) correspond to 2×10^{-6} M (diethyldithiocarbamate), 4×10^{-6} M (thiourea), 5×10^{-6} M (benzoic acid), 7×10^{-6} M (2,4-dichlorophenoxyacetic acid) and 9×10^{-6} M (2,4-dinitro-o-cresol). A lower sensitivity was observed for atrazine, pentachlorophenol or warfarin (not shown). No response was observed for similar additions of nitrate, nitrite or fluoride ions, sodium azide and lead or cadmium, over the concentration range 0.1–10 ppm, for each ion throughout that concentration range. The "tyrosinase-free" carbon strip, used as the control, was not responsive to any of the above 14 compounds.

Fig. 3 shows the influence of the substrate concentration upon the response of the screen-printed inhibitor biosensor. The diethyldithiocarbamate signal nearly doubles upon raising the catechol level from 2×10^{-5} to 5×10^{-5} M and
Fig. 3. Effect of substrate concentration on inhibition responses at 0.6% tyrosinase strip. Catechol concentration: (A) 2 × 10⁻⁵ M; (B) 5 × 10⁻⁵ M; (C) 1 × 10⁻⁴ M. Also shown (inset) are the corresponding current time recordings. Sodium diethyldithiocarbamate, 10⁻⁵ M per step, was used as inhibitor (I). Other conditions are as given in Fig. 2.

between 5×10^{-5} and 1×10^{-4} M. Note also the longer response times of the inhibitors signal at higher substrate concentrations. The shape of the resulting calibration plots is not greatly influenced by the catechol level. A potential of -0.2 V yielded the most favorable detection of the catechol substrate and the target inhibitors (not shown). As expected, such a low potential minimizes possible interference from coexisting constituents of relevant water samples. The data of Fig. 3 also indicate that the sensor is operating in the kinetic regime (with respect to the substrate reaction). It is thus essential to carefully control the substrate concentration.

Attempts to reuse the enzyme strips have been explored by repeating the calibration experiment (with intermittent water rinse). For thiourea the sensitivity decreased by 37% and by 54% for the second and third runs respectively (compared to the first run). Benzoic acid displayed 53% and 64% suppressions of the inhibitor response, while diethyldithiocarbamate yielded 67% and 79% losses of the initial signal (not shown). Such changes are expected for irreversible inhibition processes. (The catechol signal decreased in a similar fashion in the presence of the different inhibitors.) An irreversible inhibition was also reported for strips based on acetylcholinesterase [9]. The use of extremely

low cost single-use electrodes circumvents these inactivation effects. In contrast, conventional electrodes would require renewal of the enzyme layer.

The screen-printing process assures a good strip-to-strip reproducibility. For example, a relative standard deviation of 6.2% was calculated for the response for 1×10^{-5} M diethyldithiocarbamate at five different strips. Such reproducibility requires a uniform dispersion of the enzyme with the ink matrix. Manual mixing, for 60 min, was used to assure homogeneous dispersion of tyrosinase in the ink. It should be pointed out that in a few cases one or two strips from a 10-electrode lot would yield an unsatisfactory result. This can be readily detected prior to the inhibitor measurement from the magnitude of the substrate signal (this serves as a "built-in" quality test). The sensitivity of electrodes from different batches can differ by up to $\approx 30\%$ (requiring separate calibration for each batch). New strips displayed only 4% and 15% decreases in response after storage for 30 and 60 days respectively, in phosphate buffer at 5°C.

The environmental utility of the tyrosinase-based inhibitor biosensor is illustrated in Fig. 4. This shows the response for an untreated river water (Rio Grande) sample spiked with increasing

Fig. 4. Calibration plot obtained using a water sample from the Rio Grande river. No supporting electrolyte was used in this experiment. The inset shows the corresponding current–time recording. Catechol, 5×10^{-5} M, was used as substrate (S). Sodium diethyldithiocarbamate, 10^{-5} M per step, was used as inhibitor (I).

levels of diethyldithiocarbamate in 1×10^{-5} M steps. The strip responds rapidly to these micromolar concentration increments, despite the absence of deliberately added electrolyte. Similar to assays of "synthetic" samples, the response rises sharply with the inhibitor concentration at first (up to $\approx 4 \times 10^{-5}$ M), and then more slowly. However, caution is required when analyzing unknown samples due to the possible presence of mixtures of inhibitors.

In conclusion, the above experiments have demonstrated for the first time the utility of tyrosinase-based thick-film electrodes for monitoring enzyme inhibitors. The new strips offer convenient quantitation of micromolar concentrations of various water pollutants, and a nearly instantaneous response. A convenient one-step fabrication step is accomplished by incorporating the enzyme within the ink matrix. As is common for enzyme inhibition processes, such detection would not be specific in complex environmental samples. Such samples would thus benefit from designing arrays of several enzyme inhibition electrodes. Further improvements in the detectability are expected in connection with metallized carbon inks or bioamplification recycling reaction schemes. The coupling of the new disposable sensors with compact (hand-held) analyzers should facilitate the field testing of relevant enzyme inhibitors. Obviously, the same strips may also be useful for on-site environmental measurements of their phenolic substrates.

Ultraviolet spectrophotometric determination of copper in copper ores by flow-injection analysis

Amin T. Haj-Hussein*

Chemistry Department, Yarmouk University, Irbid, Jordan

Abstract

A flow-injection analysis (FIA) method for the ultraviolet spectrophotometric determination of copper in copper ores is described. The ore samples are dissolved in concentrated perchloric acid, the excess acid is neutralized with ammonia solution, and the resulting solution is used for the determination of copper. The UV-FIA system is based on the reaction of copper (II) ions with pyrophosphate and subsequent measurement of the absorbance of the dipyrophosphatocuprate (II) complex at 240 nm. The main factors which control the formation of this complex and the FIA variables influencing the system are discussed. The calibration graph is linear from 2 50 ppm copper. At a sampling rate of about 70 samples h $^{-1}$ with 50 μl sample injections, precision was about 1% relative standard deviation. Results obtained compare well with those obtained by atomic absorption spectrometry.

Keywords: Copper; Copper ores; Flow-injection analysis; Ultraviolet spectrophotometry

1. Introduction

The analysis of copper-containing materials has a vast literature. This is due to widespread interest in copper content in several branches of science (e.g. medicine, biology, industrial chemistry and geology). Copper is widely distributed in nature and is a major component of a wide range of minerals. It also occurs in smaller quantities in many metal ores. Geochemical prospecting and metallurgical analysis of copper made its determi-

nation in a great variety of samples necessary, and fast methods for continuous monitoring are still needed. Analyses for copper in copper ore samples can be performed by various methods including volumetry [1-5], gravimetry [6], electrogravimetry [6,7], potentiometry [7,8] spectrophotometry [9-11] and atomic absorption spectrometry (AAS) [11-14]. The analysis time for all these conventional methods is frequently significantly greater than that for automated methods. Moreover, reproducibility can seldom be matched by manual operations.

Because of the capabilities of flow-injection analysis (FIA), as developed by Ruzicka and

* Fax: (-962)-2-274-725.

Hansen [15], it is of interest to assess its value for copper ore analysis. The automatic nature of FIA ensures large throughputs and reduces the need for highly competent and well-organized analysts to perform the chemical analysis. Moreover, it offers great advantages such as flexibility, speed, high sampling rate and wide applicability in many fields.

In earlier work [16], it was found that Cu(II) ions react with pyrophosphate to form dipyrophosphatocuprate (II) complex, which exhibits a characteristic absorptivity in the ultraviolet region. The copper(II)-pyrophosphate system has been studied spectrophotometrically in the ultraviolet region for the determination of copper by Nebel and Boltz [17].

On the basis of these considerations, this work was undertaken to develop a method for the continuous ultraviolet spectrophotometric determination of copper in copper ores using FIA.

2. Experimental

2.1. Reagents

All chemicals used were of analytical reagent grade, unless otherwise specified; all solutions were prepared with deionized water.

2.1.1. Standard copper(II) solution

A stock solution of copper(II) (1000 ppm) was prepared by adding 1.5 ml of 60% perchloric acid to 0.1 g ($\pm$0.0001) of pure copper wire sample (99.9%; Merck). The mixture was heated gently under a fume hood until the sample was dissolved. After cooling, the solution was diluted to about 80 ml with water and ammonia solution (1 M) was added dropwise to neutralize the excess acid until the pH of the solution was about 5.0–5.5. The solution was made up to 100 ml with water. Working standards were prepared by diluting the stock solution with water.

2.1.2. Pyrophosphate reagent solution

These were 0.005–0.10 M sodium pyrophosphate (98% pure; Fluka) solutions at pH 5.0, 6.0. 8.0, 9.0, 10.0, 11.0 and 12.0. The pH of these

solutions were adjusted with perchloric acid or sodium hydroxide. All pH measurements were made using a Metrohm Herisau (Type E 520) pH meter.

2.1.3. Dissolution of copper ores

About 100 mg of sample (accurately weighed) was placed in a 25 ml volumetric flask and 1.5 ml of 60% perchloric acid and two small glass beads were added. A short-necked funnel was inserted into the neck of the flask. The mixture was heated gently under a fume hood until the sample was dissolved. After cooling for 3–4 min, about 50 ml of water was carefully added through the funnel. The contents were swirled and boiled for 5 min to expel hydrogen gas. On cooling, 1 M ammonia solution was added dropwise to neutralize the excess acid until the pH of the solution was about 5.0–5.5. The contents were digested for 5 min and the precipitate (mainly due to iron which is associated with copper ores) was allowed to settle. Finally the insoluble matter was filtered off and made up to 100 ml with water.

Sample solutions of five copper ores including native copper (Cu), bornite (Cu_5FeS_4), chalocite (Cu_2S), cuprite (Cu_2O) and malachite ($Cu_2CO_3(OH)_2$) were prepared. Working solutions were prepared by accurate dilution of each sample solution with water.

2.2. Apparatus

The flow diagram for the determination of copper is shown in Fig. 1. The FIA system was assembled from 0.51 mm Microline tubing. The manifold consists of two lines, the top one carrying the carrier into which the sample is injected and the lower carrying the reagent solution. Carrier and reagent solutions were delivered by an Ismatic peristaltic pump (Type MINI-S 860) operated with Tygon tubing. The sample is aspirated from the sample container into the injection valve using a Rheodyne four-way Teflon valve injector (Type 50). The injection sample is merged with the reagent stream in the reaction coil and then led to a flowthrough optical cell and finally to waste. A home-made confluence point with a mixing point was used to ensure rapid mixing of

the two streams in the 50 cm long coil. The absorbance was measured with a Varian DMS 100 UV–Visible spectrophotometer with a 10 mm micro flow-cell, 18 μl (Hellma type, Model QS178.12), and recorded with a Linear 1200 chart recorder.

2.3. FIA

The flow system illustrated in Fig. 1 is used. The sample solution (50 μl) injected into water (carrier stream flow rate, 0.6 ml min^{-1}) was merged into pyrophosphate (reagent stream flow rate, 0.6 ml min^{-1}) at point I in a confluence manner downstream. To ensure rapid mixing of the two streams, a "mixing point ii" is inserted immediately after the confluence point, forcing the combined stream through a 60° turn (during which the direction of flow is abruptly changed). After an injection, the valve was returned to the load position when the baseline was reached. The absorbance of the dipyrophosphatocuprate(II) complex is measured at 240 nm. The output of the ultraviolet spectrophotometer was registered on the chart recorder. When the baseline was reached, another slug of the sample could be injected. For calibration, a series of working standard solutions were injected. For calibration, a series of working standard solutions were injected before and after the sample runs. All solutions were analyzed in triplicate.

(C) carrier stream; (R) reagent stream; (Q) flow rate (ml min^{-1}); (S) sample injection; (I) confluence point (i) with mixing point (ii); (L) reaction coil; (F) flowthrough cell; (W) waste.
Fig. 2. Absorption spectrum for dipyrophosphatocuprate(II) ion at pH 9.0 with the manifold shown in Fig. 1. Carrier, water; concentration of pyrophosphate reagent; 0.05 M; concentration of Cu(II), 20 ppm; injection volume, 50 μl.

3. Results and discussion

Nitric acid in dilute and concentrated forms can be used for dissolution of copper ores. For sulfide ores, a strongly oxidizing solvent, aqua regia, or hot concentrated perchloric acid, which is a powerful oxidizing agent, can be used [11]. By using concentrated perchloric acid for dissolving sulfide copper ore samples, the process is simplified and accelerated. Moreover, liberation of sulfur and interferences of nitrite and nitrate ions, which absorb in the ultraviolet region, are avoided.

The FIA system used in this work allows rapid continuous analysis of copper by direct monitoring of the absorbance of the dipyrophosphato-cuprate(II) complex. Absorbance measurements were performed using the manifold shown in Fig. 1. The absorption spectrum for dipyrophos-phatocuprate(II) complex, obtained by injecting standard copper(II) solution (20 ppm) in the carrier stream and using 0.05 M pyrophosphate at pH 9.0 as reagent is shown in Fig. 2. The curve exhibits a band with maximum absorption at about 240 nm which was chosen as the optimum wavelength for studying the chemical variables and the FIA variables influencing the system.

3.1. Optimization of chemical variables

3.1.1. Pyrophosphate concentration

The effect of pyrophosphate concentration was determined using a concentration of 20 ppm of copper and a pH of 9.0. By injecting standard copper solution, the absorbance values at 240 nm were measured in the concentration range 0.005–0.100 M of pyrophosphate reagent solutions. Fig. 3 shows that the absorbance of the dipyrophosphatocuprate(II) complex formed is dependent on the pyrophosphate concentration. and a concentration of 0.025 M is necessary for the development of maximum absorbance. A large excess of pyrophosphate (0.05 M) is recommended to ensure sufficient reagent when larger amounts of copper are being measured.

3.1.2. pH

The effect of pH on the absorption spectra of solutions containing 10 ppm of copper and 0.05 M pyrophosphate was studied in the range 5.0–12.0. Fig. 4 shows that the maximum absorbance was obtained between pH 8.0 and 10.0. Therefore, a pH of 9.0 was recommended for attainment of maximum absorbance.

Fig. 4. Effect of pH on the determination of copper. Concentration of copper was 10 ppm; wavelength, 240 nm; other conditions as given in Fig. 2.

3.2. Optimization of FIA variables

3.2.1. Sample volume injection

As the sample volume increased from 25 to 100 μl, the signal increased by about 110% but tailing increased, thus lowering the sampling rate (90 to 30 samples h^{-1}). A 50 μl sample loop was selected for use.

3.2.2. Length of the reaction coil

Increasing the coil length lowered the peak height and increased the dispersion but improved the reproducibility, which was necessary to obtain a stable baseline. The coil lengths were optimized to give ample reaction time with minimum dispersion. A reactor length (L) of 50 cm and an i.d. of 0.51 mm were chosen for use.

3.2.3. Flow rate

The signal increased about 6% when the flow rate was changed from 0.74 to 1.6 ml min^{-1} but the residence time and dispersion were affected by the flow rate employed. Therefore, a flow rate of 1.2 ml min^{-1} (which is the sum of the flow rates of both lines of the two-line FIA system) was selected to achieve high sensitivity of the measure-

Fig. 3. Effect of pyrophosphate concentration on absorbance of dipyrophosphatocuprate(II) complex. Wavelength. 240 nm: other conditions as given in Fig. 2.
Fig. 5. Flow-injection signals for the ultraviolet determination of copper at a rate of approximately 70 samples h⁻¹ with the manifold shown in Fig. 1. Wavelength, 240 nm; other conditions as given in Fig. 2.

ments with a reasonable sampling rate. At this flow rate, the average sampling rate with 50 μl sample injections was around 70 samples h⁻¹.

3.3. Calibration

The flow system in Fig. 1 (reaction coil 50 cm long and 0.51 mm bore) was used for preparing the calibration graph. Standard copper solutions were injected from a sample loop of 25 cm of 0.51 mm bore Microline tubing (sample volume about 50 μl). Typical signals are shown in Fig. 5. The calibration graph is linear in the range 2–50 ppm copper. The limit of detection (3 SD) for copper was 0.3 ppm. For successive injections of a standard solution of copper (10 ppm), the precision of the method was found to be <1% RSD.

3.4. Interference study

In order to apply the automatic UV-FIA method for analysis of copper in copper ores, the interference effect of diverse ions which may be found in the common copper ores [18] were examined. The response produced by the standard solution containing 10 ppm of copper was compared with that produced by a similar copper

solution containing additions of various amounts of diverse ions. An error of less than 2.5% was considered to be tolerable. The following ions showed no interference at the concentrations (ppm) shown in parentheses: Ni^{2+} (100), Zn^{2+} (100), MoO_4^{2-} (100), Ca^{2+} (100), Mg^{2+} (100), Sn^{4+} (10) and AsO_4^{3-} (10). In contrast, Fe^{3+}, Pb^{2+} and Ag^- were found to cause serious interferences when their concentrations exceeded 1 ppm. In the determination of copper in copper ores, however, dissolving these ores in perchloric acid followed by addition of ammonia and filtration would remove Fe^{3+} as hydroxide. However, if Pb^{2+} and Ag^- are present in large amounts, they must be separated in some way. For trace amounts, the method of standard addition should ameliorate the problem somewhat.

3.5. Determination of copper in copper ores

The proposed method was applied to the determination of copper in native copper, sulfide copper ores (bornite and chalcocite), and oxidized copper ores (cuprite and malachite). The results (copper content, %) of the analyses are summarized in Table 1.

A measure of the reliability of the proposed method is given in Table 1 in which the results are

Table 1
Determination of copper in some copper ores by the proposed UV-FIA method and by AAS[a]

Sample[b]	Cu(II) content (%)	
	UV-FIA	AAS
Native copper	98.0	98.8
Bornite	30.8	29.8
Chalcocite	31.0	32.0
Cuprite	80.1	80.7
Malachite	55.8	54.2

[a] A Pye-Unicam SP9 atomic absorption spectrophotometer equipped with a copper hollow-cathode lamp was used. The wavelength was set at 324.8 nm and the operating conditions were adjusted following standard recommendations.
[b] Native copper (from new Tucson, AZ) was provided by the Geology Department, Yarmouk University. Bornite, chalcocite, cuprite and malachite were supplied by Dr. F. Krantz (Germany).

compared with those obtained using AAS by complete decomposition with nitric acid [11]. There is general agreement between the results of the two methods. It is also apparent that the results for copper were not affected by various elements in the ore samples.

Anodic stripping voltammetric determination of titanium(IV) using a carbon paste electrode modified with cetyltrimethylammonium bromide

Monika Stadlober, Kurt Kalcher*, Georg Raber, Christian Neuhold

Institut Für Analytische Chemie, Karl-Franzens Universität Graz, Universitätsplatz 1, A-8010 Graz, Austria

Abstract

A method is described for the voltammetric determination of titanium(IV) using a carbon paste electrode modified in situ with cetyltrimethylammonium bromide. The cationic micellar surfactant adsorbs onto the electrode particularly at negative potentials, simultaneously preconcentrating titanium(IV) as the oxalate complex with reduction to titanium(III). Anodic stripping voltammetry exploiting reoxidation can be used for the determination of trace levels of titanium(IV). Linearity between current and concentration exists between 5 and 160 $\mu g\ l^{-1}$ Ti(IV) (preconcentration time 2 min). The limit of detection (calculated as 3σ) is 0.1 $\mu g\ l^{-1}$, with a preconcentration time of 10 min.

Keywords: Anodic stripping voltammetry; Carbon paste electrodes; Cetyltrimethylammonium bromide; Titanium

1. Introduction

The determination of titanium(IV) by anodic stripping voltammetry is difficult, because at common potentials it cannot be reduced to the metallic state and deposited onto the electrode. Only the one-electron reduction of Ti(IV) to Ti(III), or the reverse oxidation, can be exploited by voltammetry [1]. Lingane and Kennedy [2] described the redox behaviour of titanium in strong mineral acids. At low hydrogen ion concentrations, the redox reaction is irreversible, because the Ti ions are solvated or even hydrolyzed. The reaction

becomes reversible on increasing the acidity of the supporting electrolyte, as higher acidity prevents formation of Ti(IV) hydroxo complexes, which are more difficult to reduce. By complexing titanium(IV) with organic acids such as oxalic acid, ethylenediaminetetraacetic acid (EDTA), citric acid, tartaric acid, salicylic acid, mandelic acid, and ascorbic acid, the electrode reaction becomes more reversible and can be better exploited for polarographic/voltammetric measurements [3–9].

Adsorptive stripping voltammetry with the use of complexing agents, which show excellent adsorption properties on the mercury electrode surface (Solochrome Violet RS, Cupferron, Pyrocatechol Violet, Beryllon III or 4-(2-pyridylazo)-resorcinol [10–15]), was often used to determine

* Corresponding author. Tel.: + 43 316 3805310; fax: − 43 316 384092.

trace levels of titanium. Another possibility is the exploitation of catalytic currents caused by chlorate or bromate during the reduction of titanium(IV) in the presence of oxalic acid, mandelic acid, or EDTA [16–20]. In this way differential pulse or square wave voltammetry or polarography combined with catalysis, which is mediation rather than catalysis, gives a further enhancement in sensitivity. The electrode process, however, is strongly irreversible; no reoxidation peak can be observed. Indirect polarographic methods are another approach for the determination of titanium [21].

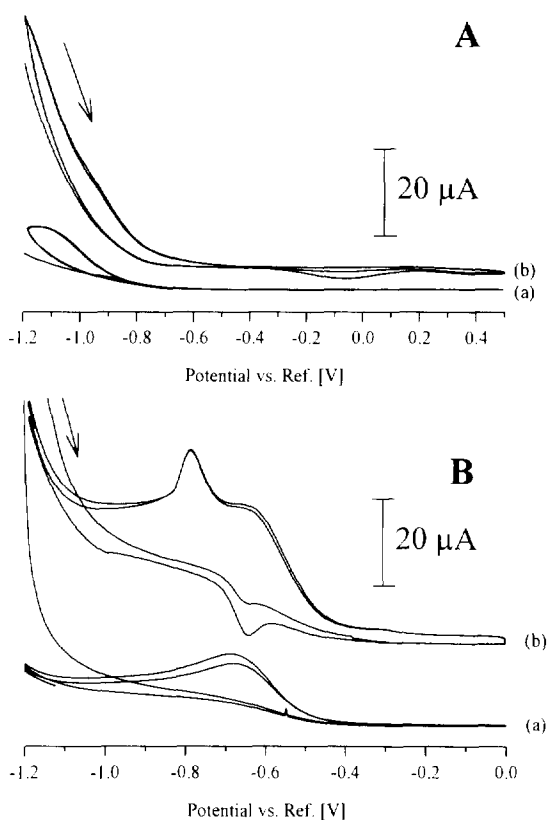

Fig. 1. Cyclic voltammograms of titanium(IV) at a plain (A) and a CTAB-modified (B) CPE. Equilibration time: 30 s; initial potential: − 1.2 V; final potential: (A) + 0.5 V, (B) 0 V; scan rate: 20 mV s⁻¹. (A) (a) 0, (b) 250 mg l⁻¹ titanium, supporting electrolyte 0.1 M KCl, 0.05 M acetate buffer, 0.01 M oxalic acid. (B) (a) 0, (b) 0.5 mg l⁻¹ titanium; supporting electrolyte 0.05 M acetate buffer, 0.01 M oxalic acid, 0.1 mM CTAB.

So far, no studies on the electrochemical determination of titanium with the use of carbon paste electrodes (CPEs) have been published. CPEs are very suitable for voltammetric and amperometric determinations because they are inexpensive, easy to handle and simple to modify [22,23]. With respect to the determination of titanium, in-situ modification with surfactants, in particular with cetyltrimethylammonium bromide (CTAB), is promising, since the anionic titanium species obtained by complexation can be preconcentrated on the electrode surface as lipophilic ion pairs.

CTAB is a cationic surfactant which belongs to the group of quaternary ammonium compounds. In suitable solvents it forms spherical micelles above the critical micellar concentration (CMC), which in water occurs at 0.9 mM (25°C). In the presence of electrolytes the CMC is lowered because of increased micellization from free ions. [24].

CTAB adsorbs onto the electrode surface by hydrophobic attraction and by electrostatic attraction at negative potentials. At concentrations lower than the CMC the surfactant acts as an ion-pairing agent, where monomers are adsorbed onto the electrode surface although only to a very small extent [25]. At concentrations higher than the CMC, strong adsorption of CTAB on the electrode surface is observed at negative potentials [25,26], which can lead to an extraordinary enhancement in the sensitivity of voltammetric measurements.

This paper describes a new and sensitive voltammetric method for the determination of titanium(IV) with CPEs by an adsorptive modification of the electrode with CTAB and accumulation of titanium (IV) as the oxalate complex.

2. Experimental

2.1. Apparatus

Voltammetric experiments were performed with a potentiostat Model 264A PAR (Princeton Applied Research) voltammetric analyzer in combination with an automatically controlled self-constructed cell compartment made of Plexiglass
Fig. 2. DP voltammograms of Ti(IV) with a CPE modified in situ with CTAB. Supporting electrolyte 0.05 M acetate buffer, 0.01 M oxalic acid, 0.1 mM CTAB; 2 min deposition at − 1.2 V; Ti(IV) concentration: (a) 0; (b) 30; (c) 60; (d) 90; (e) 120 μg l⁻¹.

[27]. The cell consisted of a glass thermostatable titration vessel (20–60 ml; Metrohm 6.1418.220) with a platinum wire as counter electrode and saturated calomel electrode (SCE; Ingold 303-NS) as reference. The latter was in contact with the solution via a salt bridge (1 M KCl) with a Vicor frit to avoid contamination of the reference electrode. The solution in the cell could be stirred (≈ 300 rev min⁻¹) with a Teflon-coated stirring bar when required. The measuring solution was deaerated with highly pure argon or nitrogen (99.999%) for at least 5 min before voltammetric measurements; during the measurements argon was passed over the solution. The temperature of the solution was kept constant at 20°C with a thermostat (Haake R20).

Voltammetric curves were registered either on X–Y recorder (Compensograph X-Y 1929, Siemens) with manual evaluation by the tangent fit method, or transferred to a personal computer after A D conversion by an appropriate interface [28].

2.2. Working electrode

The body of the carbon paste electrode con-

sisted of a Teflon rod (outer diameter 10 mm) with a 3 mm deep centric hole (diameter 7 mm) for the carbon paste filling and a platinum wire through the center of the rod for electrical contact.

The carbon paste was prepared by thoroughly mixing 5 g of spectral carbon powder (RWB, Ringsdorff-Werke, Germany) with 1.6 ml of liquid paraffin oil (Uvasol, Merck), until a homogeneous consistency was achieved. The paste was packed into the electrodes and smoothed off with a PTFE plate.

2.3. Reagents

Deionized water was distilled twice in a quartz still and then purified by a cartridge deionization system (Nanopure, Barnstead). Oxalic acid, acetic acid and sodium acetate were of suprapure grade (Merck). All other chemicals were of analytical grade (p.a., Merck). CTAB was recrystallized from a 4:1 (v/v) acetone–methanol mixture prior to use. Stock solutions of titanium (1000 mg l⁻¹ Ti) were prepared by dissolving 0.6642 g of potassium titanyl oxalate (Ventron, Karlsruhe, Germany) in 100 ml of 0.1 M aqueous oxalic acid. Stock solutions of lower concentrations were freshly prepared by dilution. Stock solutions of salts used for investigations of their interference effects has concentrations of 1 or 10 g l⁻¹ with respect to the ion.

2.4. Procedure

2.4.1. Voltammetry

The supporting electrolyte for the voltammetric measurements consisted of 0.05 M acetate buffer and 0.01 M oxalic acid (pH 4.3). CTAB was added at a concentration of 1 × 10⁻⁴ M. Cyclic voltammograms (CVs) were recorded from − 1.2 to 0 V with a scan rate of 20 mV s⁻¹ and an equilibration time of 30 s, beginning in the anodic direction.

All quantitative measurements were performed in differential pulse (DP) mode. The initial potential was − 1.2 V, the final potential 0

V, the pulse height 50 mV, and the scan rate 10 mV s^{-1}. Prior to the differential pulse voltammetry (DPV) measurements the electrode was conditioned by applying a potential of -1.2 V for 15 min in the supporting electrolyte containing CTAB. Subsequently, titanium was added to the solution and preconcentrated onto the electrode surface with the initial potential applied.

2.4.2. Regeneration

Complete removal of residual titanium on the electrode was achieved by exposing the electrode to a separate solution containing 0.1 M sodium salicylate and 0.05 M acetate buffer (pH 4.7), applying a potential of -1.2 V for 1 min and scanning to -0.2 V. After this, the cleaning was completed by a 1 min exposure of the electrode to a stirred solution of 1 M potassium bromide without the application of a potential.

2.4.3. Analysis of a mineral sample (stone wool)

About 200 mg of the sample (Heralan, Heraklith, Austria) was fused with a five fold excess of NaKCO$_3$ in a platinum crucible for 20 min.

Fig. 3. Dependence of the peak current on the concentration of CTAB in the measurement solution. Supporting electrolyte 0.05 M acetate buffer, 0.01 M oxalic acid; 50 μg l^{-1} Ti(IV), 2 min deposition at -1.2 V.

Afterwards the reaction product was dissolved in 50 ml of hydrochloric acid (5 M). The resulting solution containing solid silicate was heated on a sand bath until most of the hydrochloric acid had evaporated. Then HCl (15 ml, 10 M) was added again and evaporated almost to dryness. This procedure was repeated twice. The residue was dissolved in hydrochloric acid (3 M), and the silicic acid was filtered off. The filtrate was diluted to a volume of 100 ml. For the voltammetric determination a 10 μl aliquot was added to 20 ml of supporting electrolyte.

3. Results and discussion

3.1. Choice of modifier

In order to determine Ti(IV) by voltammetry using CPEs, it is necessary to transform it into a complex, because otherwise highly acidic solutions must be used, yielding voltamograms of poor quality [2]. With CPEs it is hardly possible to employ such media, as the background currents at negative potentials are considerably high due to enhanced hydrogen evolution. Nevertheless, acidic solutions are required for a successful reduction of Ti(IV).

The titanyl cation TiO^{2+} forms a stable anionic complex with oxalic acid with a formation constant of 5×10^{10} l^2 mol^{-2} according to [29].

$$\text{TiO}^{2+} + 2(\text{C}_2\text{O}_4)^{2-} \rightleftharpoons [\text{TiO}(\text{C}_2\text{O}_4)_2]^{2-} \tag{1}$$
At a mercury electrode reduction occurs at about -0.3 V vs. SCE at pH 1.2 [3]

$$[\text{TiO}(\text{C}_2\text{O}_4)_2]^{2-} + 2\text{H}^-$$

$$+ e^- \rightleftharpoons [\text{Ti}(\text{C}_2\text{O}_4)_2] + \text{H}_2\text{O} \tag{2}$$
When using a CPE reduction of [TiO(Ox)$_2$]$^{2-}$ occurs at about -0.9 V (pH 4.3) as a weak signal superimposed on the hydrogen evolution current. This can be clearly seen in the cyclic voltammogram recorded with an unmodified electrode (Fig. 1A). The electrode reaction is rather irreversible, since reoxidation is anodically shifted to about -0.05 V. On lowering the pH the shift
Fig. 4. Dependence of the DPV peak current on the titanium concentration. Supporting electrolyte 0.05 M acetate buffer, 0.01 M oxalic acid. 0.1 mM CTAB: deposition times: (a) 10; (b) 2; (c) 1 min.

becomes less, but the signal is still irreversible. Since the signals are always very small, the sensitivity is low and not suitable for trace analysis.

If CTAB is present in the solution at a concentration level higher than the CMC the titanium oxalate becomes preconcentrable at the electrode surface and yields a pronounced reduction and reoxidation signal of the redox couple $[TiO(Ox)_2]^{2-}$ $[Ti(Ox)_2]$ with a tremendous improvement in sensitivity (Fig. 1B).

The redox reaction without CTAB is strongly irreversible, whereas it becomes quasi-reversible in its presence. The reduction and reoxidation potentials occur at about -0.78 and -0.64 V vs. SCE respectively. The reduction signal shifts to more positive potentials compared to unmodified CPEs. This indicates that Ti(IV) is more easily reduced in the adsorbed form with cetyltrimethylammonium ions (CTA^-) than as a free complex in solution. However, the reoxidation potential shifts

to more negative values due to enhanced reversibility. Titanyl oxalate apparently shows a high affinity towards the postively charged CTA^+. Additionally it can be seen that the electrochemical response of titanium is overlapped by a broad wave caused by CTAB.

Other modifiers were investigated to determine their effect on the electrochemical behaviour of titanium. Anion exchangers, such as Amberlite LA2, Dowex 1 or Aliquat 336, yielded poor reproducibility and showed only low affinity towards titanyl oxalate.

Ion-pairing reagents other than CTAB, comprising lipophilic cations such as tetrabutylammonium bromide (TBAB), tetrabutylphosphonium bromide (TBPB), tetraphenylphosphonium chloride (TPPC), or tetraphenylammonium chloride (TPAC), were found to have an improving, albeit small, effect on the determination of titanium. This is due to the fact that the hydrophobic part of the counter ion is attracted by the lipophilic carbon paste, forming a monomolecular layer at the electrode surface, but interacts only slightly with titanyl oxalate. However, under open circuit conditions preconcentration of titanyl oxalate in the presence of the cationic surfactants is not effective.

The most sensitive and most reproducible results are obtained with an in-situ modification of the surface of the CPE with CTAB.

3.2. Preconcentration of titanium

Titanium as an oxalate complex can be preconcentrated onto the surface of CPEs in the presence of CTAB if a deposition potential more negative than -0.7 V is applied. If CTAB is used as a modifier in a separate solution under open circuit conditions titanium is also preconcentrable, but only to a much smaller extent requiring significantly higher Ti concentrations, probably due to washing out of accumulated species by medium exchange. Thus, application of a preconcentration potential for the determination of titanium at lower concentrations is essential.

The accumulation process can be explained analogously to reversed-phase ion-pair partitioning chromatography by two effects, i.e. in-situ

formation of an ion-exchanger at the electrode surface (A) and formation of ion pairs or micellar congregates in solution (B):

(A)

$$[CTA^-]_{x-mic,sol} \xrightarrow{-1.2\,V} [CTA^+]_{x-mic,surf} \qquad (3)$$

$$[CTA^-]_{x-mic,surf} + y[TiO(C_2O_4)_2]^{2-}{}_{sol}$$

$$\rightarrow \langle[CTA^-]_x\{[TiO(C_2O_4)_2]^{2-}\}_y\rangle_{surf} \qquad (4)$$

(B)

$$[CTA^+]_{x-mic,sol} + y[TiO(C_2O_4)_2]^{2-}{}_{sol}$$

$$\rightarrow \langle[CTA^+]_x\{[TiO(C_2O_4)_2]^{2-}\}_y\rangle_{sol} \qquad (5)$$

$$\langle[CTA^+]_x\{[TiO(C_2O_4)_2]^{2-}\}_y\rangle_{sol}$$

$$\xrightarrow{-1.2\,V} \langle[CTA^+]_x\{[TiO(C_2O_4)_2]^{2-}\}_y\rangle_{surf} \qquad (6)$$
The subscripts "sol" and "surf" designate the bulk solution and the electrode surface respectively; "mic" indicates micelle.

When the concentration of CTAB in solution is above the CMC, mass transport and adsorption are probable via micelles rather that via individual surfactant ions [26]. At CTA$^-$ concentrations below the CMC only monomers are adsorbed on the electrode surface; therefore, the background current is low but the transport of the titanyl oxalate anions towards the electrode surface can be performed only with monomers, which is obviously not so effective.

The titanyl oxalate anion will be reduced simultaneously during the adsorption:

$$\langle[CTA^-]_x\{[TiO(C_2O_4)_2]^{2-}\}_y\rangle_{surf} + 2yH^+ + ye$$

$$\xrightarrow{-1.2\,V} \langle[CTA^+]_x\{[Ti(C_2O_4)_2]^-\}_y\rangle_{surf} + yH_2O \qquad (7)$$

3.3. Determination of titanium with CTAB and oxalate

When preconcentrating Ti in the presence of CTAB there is an overlap of the peak in the blank curve with the titanium signal. In principle DP voltammograms could be recorded in both directions yielding a response for titanium, but scanning in the anodic direction is more favorable. The analyte [TiO(Ox)$_2$]$^{2-}$ can be preconcentrated only at potentials significantly higher than -0.6
V, because the negative potential has a favorable effect on the adsorption of CTA$^+$ micelles. Simultaneously, reduction of [TiO(Ox)$_2$]$^{2-}$ occurs yielding [Ti(Ox)$_2$]$^-$, which is then immobilized by ion pairing. Therefore, the reoxidation signal recorded in the anodic scan is much more pronounced than the corresponding reduction peak. Another reason for exploiting the reoxidation signal is that its height can be evaluated much better, because of lower background currents and only a very small overlapping signal of the blank curve. Anodic DP voltammograms are shown in Fig. 2. As expected the peak currents increase with increasing negative deposition potentials. The titanium reoxidation current increases linearly from -0.7 V to -1.3 V. The more negative the applied deposition potential, the more effective is adsorption of the positively charged CTA$^+$ micelles, and thus the better is the transport of titanyl oxalate to the electrode surface. For practical reasons a deposition potential of -1.2 V was found to be optimal, although the reoxidation currents obtained with -1.3 V are even higher. However, the background also increases strongly, deteriorating the determination.

Optimization of the CTAB concentration in solution shows that only concentrations above the CMC are effective for preconcentrating titanium at low concentrations (Fig. 3). A maximum is obtained with a concentration of about 0.15 mM CTAB. When the CTAB concentration is increased further, the peak current decreases slowly, whereas the background current increases. Although peak currents have a maximum value at a concentration of 0.15 mM, best results in terms of reproducibility were obtained with only 0.1 mM CTAB.

Other parameters which greatly influence the analytical performance of the determination of titanium are the composition and the pH of the measurement solution. Many different supporting electrolytes, such as potassium bromide (0.1 M), potassium chloride (0.1 M) and hydrochloric acid (0.001 M), sulphuric acid (0.01 M), sodium oxalate (0.05 M), sodium salicylate (0.01 M), and acetate buffer (0.05 M) and oxalic acid (0.01 M), were examined to obtain optimal titanium reoxidation signals. Best performance was achieved

Table 1

Change in the peak current of the titanium reoxidation signal caused by anionic components. with a solution containing acetate buffer (0.05 M) and oxalic acid (0.01 M) (pH 4.3).

When studying the influence of pH by addition of hydrochloric acid or sodium hydroxide to this solution the optimum was found at a value of 4.3. At pH 7 reoxidation could no longer be observed. This is also the case when decreasing the pH to 1.5. Also, the peak potential depends on the hydrogen ion concentration and decreases linearly with decreasing H$^+$ concentration with a slope of about 100 mV per pH unit. This suggests that two hydrogen ions are involved in the redox process according to Eq. (2).

The complete removal of accumulated titanium from the CTA$^+$-modified electrode surface requires further treatment of the electerode for repetitive use (regeneration). Various procedures including chemical and electrochemical treatment were investigated. The titanyl oxalate anions were not completely removed by exposing the electrode to a stirred aqueous solution of 1 M KBr; regeneration of the electrode surface via competitive ion exchange alone did not lead to complete regeneration of the surface. Therefore, it was nec-

essary to clean the electrode surface by electrochemical desorption of residual CTA$^+$-titanyl oxalate ion pairs. This was done in a stirred solution of 0.1 M sodium salicylate, as the latter is a very good counterion for CTAB [30]. The best method was found to be application of a potential of -1.2 V for 1 min and then scanning to -0.2 V. Ater this procedure the electrode was dipped into a stirred 1 M KBr solution for 1 min without the application of a potential.

The dependence of the reoxidation current on the deposition time gives a linear relation between current and time up to a period of 10 min. Longer times cause deviation from linearity due to the attainment of equilibrium conditions.

The dependence of the reoxidation current of titanium(IV) on the concentration, applying proper preconcentration times, is shown in Fig. 4. With a deposition time of 1 min a linear curve is obtained from 10–250 μg l^{-1} Ti(IV); with a 2 min deposition time linearity exists from 5–160 μg l^{-1}. When increasing the time of deposition up to 10 min, a linear range from 1–10 μg l^{-1} can be observed.

Table 2
Change in the peak current of the titanium reoxidation signal caused by cations; experimental parameters as in Table 1

The relative standard deviation is 4.0% for five repetitive measurements (50 μg l^{-1} Ti(IV), 2 min deposition time). The limit of detection (calculated as 3σ) of titanium is 0.46 μg l^{-1} with a deposition time of 2 min and 0.1 μg l^{-1} with 10 min.

3.4. Interferences

Interferences of many cations and anions with the reoxidation signal of titanium(III) were examined.

3.4.1. Anions

Common anions like nitrate, sulphate, phosphate, and chloride do not interfere even in a 500-fold mass excess with respect to titanium. The presence of a 500-fold excess of bromide results in slightly increasing background currents without changing the signal. The same excess of iodide leads to a diminution of the titanium signal by about 32%. This decrease is due to the fact that iodide is a very good counterion for CTAB micelles, because of its small hydrated ionic radius; competitive attraction between titanyl oxalate and iodide is the consequence. Fluoride already interferes at a five fold excess, owing to complexation of Ti(IV). Salicylate interferes by increasing the background current and decreasing the signal of titanium. This is obviously due to competitive concurrence for the ion exchanging groups. Vanadate and molybdate are complexed by oxalate forming ion pairs with CTAB; molybdate additionally yields an electrochemical response over-

lapping with the signal of titanium. Tungsten(VI) interferes severely, although no anionic complexes with oxalate are formed. Chromate and permanganate act as oxidizing agents for titanium(III), and therefore decrease its reoxidation currents.

3.4.2. Cations

Electroactive metal cations, which are reduced to the elemental state at a potential of -1.2 V, are accumulated onto the electrode surface. In the case where they do not form anionic oxalate complexes they interfere significantly at a 50-fold excess only, if the resulting electrochemical response overlaps with the reoxidation of Ti(III). At higher concentrations they show a decreasing effect on the titanium signal, if they are deposited on the electrode surface, because they reduce the available lipophilic surface area. Indium, thallium and copper form stable anionic oxalate complexes and give a reoxidation peak as well. Their preconcentration probably proceeds via direct electrolytic reduction as well as via the complex; they interfere at higher concentrations. Cobalt, nickel, zinc, aluminium, iron(III), uranium(VI), vanadium(IV), zirconium(IV), and gallium(III) are accumulated as anionic oxalate complexes, resulting in a decrease of the titanium reoxidation response. Chromium(III), manganese(II) and antimony(V) do not interfere severely up to a 50-fold excess because they do not form anionic oxalate complexes.

3.5. Sample

The proposed method was employed for the determination of titanium in a mineral sample (stone wool), where it is present as TiO_2. The sample, containing SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO, Na_2O and TiO_2 and small amounts of other oxides, was digested with an equimolar mixture of sodium and potassium carbonate as described above. Control analyses were performed with inductively-coupled plasma mass spectrometry (ICP-MS). Table 3 shows the results. Although the electrochemical method shows higher relative standard deviations, the agreement between the different methods is satisfactory.

Table 3
Results of the determination of titanium in a mineral sample (stone wool)

Sample	Concentration of TiO_2 obtained by voltammetry (% ± standard deviation)	Concentration of TiO_2 obtained by ICP-MS (% ± standard deviation)
1	3.6 ± 0.2 (3)[a]	3.62 ± 0.03
2	3.7 ± 0.2 (3)[a]	3.72 ± 0.04
Mean value	3.6 ± 0.2	3.67 ± 0.04

Supersonic Jet/Time-of-flight mass spectrometry of adenine using nanosecond and femtosecond lasers

Cheng-Huang Lin, Junichi Matsumoto, Satoshi Ohtake, Totaro Imasaka*

Department of Chemical Science and Technology, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812, Japan

Abstract

Mass spectra and ionization efficiencies of adenine were measured with nanosecond (15 ns) and femtosecond (500 fs) laser pulses at identical energy levels. A molecular ion is clearly observed in both spectra, but the efficiency is improved 10-fold when a femtosecond laser is used, indicating the distinct advantage of ultrashort laser pulses for multiphoton ionization of nucleobases in supersonic jet spectrometry.

Keywords: Adenine; Ionization efficiencies; Lasers; Mass spectra; Nucleobases

1. Introduction

A combination of laser-induced multiphoton ionization (MPI) and time-of-flight (TOF) mass spectrometry (MS) is an extremely useful technique in analytical spectroscopy [1,2]. The supersonic jet technique gives a narrow spectral feature in the ultraviolet and visible spectra and is, therefore, useful for the identification of molecules [3-5]. Such techniques have often been applied to polycyclic aromatic hydrocarbons (PAHs) [6,7] MPI/TOF-MS as well as fluorescence spectrome-

try have frequently been used for the detection of molecules. However, nucleobases have seldom been investigated with supersonic jet spectrometry. An examination of the literature reveals that only MPI/MS spectra of uracil, thymine [8], adenine, guanine [9], adenine–thymine and guanine–cytosine [10] have been reported. The reasons for this are obscure but are probably due to poor ionization efficiencies for nucleobases. Picosecond (and nanosecond) laser pulses have been used for efficient MPI in non-jet spectroscopy, e.g. for determination of PAHs with gas chromatographic detection [11]. Recently, femtosecond laser experiments have opened up a new field for examining rearrangements, fragmentations, and dissociations of small molecules when a su-

personic jet is used [12]. However, no quantitative evaluation of ultrashort laser pulses in analytical spectroscopy has been reported at the time of writing.

In this study, we report MPI/MS of the nucleobase adenine using an ultrashort pulse excimer laser. The mass spectra and ionization efficiencies obtained with nanosecond and femtosecond laser pulses are compared, in order to evaluate the advantages of femtosecond laser ionization in supersonic jet spectrometry.

2. Experimental

The experimental set-up comprises a nanosecond/femtosecond laser system and a supersonic jet/TOF mass spectrometer. The supersonic jet spectrometer used in this study has been reported in detail elsewhere [13,14]. The laser is commercially available from Lambda Physik and is only briefly described here. The laser system consists of a dye laser pumped by a XeCl excimer laser, and

a KrF excimer amplifier, as shown in Fig. 1. A quenched-cavity dye laser producing ≈ 200 ps pulses [15] is used as a pump source for a short-cavity dye laser to generate ≈ 9 ps pulses. After passing it through a gated-saturable absorber [16], the laser beam is then used to pump a distributed-feedback dye laser to generate ≈ 500 fs, 0.1 mJ pulses at 496 nm [17,18]. The laser beam is frequency-doubled to 248 nm by a β-BaB$_2$O$_4$ (BBO) crystal amplified to 20 mJ by a KrF amplifier. The peak laser power achieved is 40 GW. In contrast, the nanosecond laser pulse is generated by feedback of the amplified spontaneous emission (ASE) through the KrF discharge channel. It produces 15 ns, 10 mJ pulses at 248 nm. A mass spectrum was recorded using a digital oscilloscope (LeCroy 9360), and the signal was averaged 200 times. Adenine, which was used as a sample, was thermally vaporized by elevating the reservoir temperature to 300°C. The laser beam was focused into a supersonic jet using a quartz lens (1 m focal length) and the laser pulse energy was adjusted by passing it through a pinhole. Its value was monitored by a Joule Meter (Molectron, J3-05DW). Adenine was supplied by Kishida Chemicals (Osaka, Japan).

3. Results and discussion

The MPI/TOF mass spectrum was measured by changing the laser pulse energy from 0.02 to 1 mJ using the nanosecond/femtosecond laser. Fig. 2(A) shows the mass spectrum of adenine obtained using 15 ns (80 μJ) laser pulses. A signal peak at a flight time of 12.4 μs corresponds to a molecular ion of adenine (m/z 135), indicating a relatively soft ionization of the molecule. The mass spectrum for adenine has been reported by Li and Lubman [19], using a dye laser emitting at 222 nm, and showed a molecular ion and a fragment (m/z 108, M–HCN). The ionization potential of adenine is approximately 8.48 eV, and the laser wavelength used in this study (248 nm, 5.0 eV) is sufficiently short to allow two-photon ionization. When the laser pulse energy was increased to 1 mJ, the fragment signals (C1Hn, C2Hn. . . ; n = integer), which are negligibly small in Fig.

2(A), became stronger than the molecular ion signal. Fig. 2(B) shows the mass spectrum obtained using 500 fs (80 μJ) laser pulses. A strong mass peak corresponding to a molecular ion of adenine (flight time = 12.4 μs) is observed. The ionization efficiency is improved to 10-fold in comparison with the spectrum obtained using the nanosecond laser. This signal enhancement is slightly larger than the value obtained for thermally decomposed products of polystyrene (a six-fold increase), where softer ionization was also observed using femtosecond laser pulses [20]. The greater enhancement observed may be due to a faster relaxation rate, i.e. a shorter lifetime in the excited state for adenine in comparison with aromatic hydrocarbons, which result from the thermal decomposition products derived from polystyrene.

The ion signal in the mass spectrum increases with increase in the pulse energy in the experiments using both nanosecond and femtosecond lasers. However, the molecular ion is more efficiently dissociated to small fragments at higher pulse energies. Therefore, it is necessary to optimize the pulse energy to enhance ionization and to minimize photodissociation for sensitive detection of a molecular ion. The relationships between the ionization signals at m/z 135 and the laser

Fig. 2. Mass spectra for adenine, ionized at 248 nm and 80 μJ, using (A) 15 ns and (B) 500 fs laser pulses.
Fig. 3. Dependences of ion signal intensities at m/z 135 on laser pulse energy measured using (A) 15 ns and (B) 500 fs laser pulses. Many fragment peaks and signal peaks occurring from pump oil appear above 1.0 mJ, and so quantitative comparison is difficult above this pulse energy.

pulse energy are shown in Fig. 3. When a nanosecond laser is used, significant photodissociation occurs and the adenine signal decreases above 0.5 mJ. When a femtosecond laser is used, the ionization efficiency is always higher and increases to 1 mJ. This result implies that femtosecond MPI is desired for sensitive detection of a molecular ion.

In preliminary experiments, no signal could be observed for uracil. Two explanations are possible for low ionization efficiencies for nucleobases. First, the ionization potential of uracil might be sufficiently high that the molecule is not ionized using a conventional single-color UV laser. The order of ionization potentials for DNA and RNA bases is uracil (9.32–9.70 eV)>cytosine (8.87–9.43 eV)>thymine (8.68–8.94 eV)>adenine (8.26–8.91 eV)>guanine (7.77–8.30 eV) [21–24]. To overcome this problem, a far-UV laser and/or a two-color MPI scheme might be necessary [8]. The other possibility is that the fast relaxation of energy from the excited state, e.g. intramolecular radiationless transition or photodissociation, occurs before MPI. It is well known that the fluorescence quantum yields are much less for nucleobases, implying shorter lifetimes. Although the relaxation process is not fully understood for biological molecules such as nucleobases, the femtosecond laser may allow faster MPI than intramolecular energy relaxation because of the ultrashort pulse widths. The data presented herein

clearly show that the femtosecond laser is useful for inducing soft ionization of nucleobases and also for a significant improvement in ionization efficiency. The wavelength of the laser is, however, not adjusted to a specific transition, e.g. 0–0 transition. More efficient ionization could be accomplished using a tunable femtosecond laser.

Utility of quercetin for determination of some tertiary amine and quaternary ammonium salts

Fardous A. Mohamed, Abdel-Maaboud I. Mohamed, Horria A. Mohamed*, Samiha A. Hussein

Department of Pharmaceutical Analytical Chemistry, Faculty of Pharmacy, Assiut University, Assiut, Egypt

Abstract

A simple and sensitive spectrophotometric method for the assay of eight drugs containing quaternary ammonium or tertiary amine moieties is described. The method is based on the interaction of these drugs with quercetin after its oxidation with N-bromosuccinimide (as counter ion) to give highly colored ion-pairing complexes extractable with organic solvents. The absorbances of the colored complexes are measured in the range of 528–560 nm. Beer's law is obeyed for the studied drugs in the range 5–30 μg ml^{-1}. The method is successfully applied to the analysis of the studied drugs in commercial dosage forms.

Keywords: Ion pairing; Pharmaceuticals; Quercetin

1. Introduction

It is well known that a huge number of compounds belonging to different pharmaceutical classes contain either tertiary amine or quaternary ammonium moieties [1]. Accordingly, numerous spectrophotometric methods for their analysis have been reported [2–7]; few of them could be considered to be general for tertiary amines and many of these methods suffer from a lack of selectivity and simplicity.

Ion-pair formation methods provide a rapid and convenient technique for the measurement of tertiary amines and quaternary ammonium salts [8–11].

Quercetin is a naturally occurring flavonol which has been used before for the spectrophotometric and fluorimetric determination of metal ions [12].

In the present work, oxidized quercetin is used for extractive spectrophotometric determination of some tertiary amines and quaternary ammonium salts of different pharmacological classes, namely procaine · HCl and dibucaine · HCl (local anaesthetics), pheniramine maleate (antihistaminic), toclase citrate and oxeladine citrate (antitussives), butathamate citrate (sympathomimetic), oxyphenonium bromide (parasympatholytic) and cetylpyridinium chloride (antiseptic deter-

^{a} Correlation coefficient.

gent). The method is simple, sensitive and selective and can be applied to the analysis of pharmaceutical preparations. The proposed method has the additional advantage that primary and secondary amines do not interfere under the proposed reaction conditions.

2. Experimental

2.1. Instrument

A Uvidec-320 spectrophotometer (Jasco, Tokyo, Japan) was used.

2.2. Materials

The drugs listed in Table 1 are of pharmaceutical grade, obtained courtesy of the manufacturers, and were used as working standards without further treatment. The purities of the standards were checked according to some reported methods [1]. Pharmaceutical preparations were obtained locally. N-Bromosuccinimide (NBS) was obtained

from BDH (Poole, UK) and quercetin was from Merck (Darmstadt, Germany). All other chemicals and solvents used in this work were of analytical grade.

2.3. Reagents

2.3.1. NBS solution

NBS solution was 0.15% w/v in distilled water and was prepared fresh daily.

2.3.2. Quercetin solution

Quercetin solution was 0.2% w/v in ethanol.

2.3.3. Buffer solution

Teorell and Stenhagen buffer, pH 2.0–12.0, was used [13].

2.3.4. Standard drug solutions

Standard drug solutions were prepared by dissolving 50 mg of the studied drug (as a salt) in 100 ml of distilled water. Working standards covering the range 20–500 μg ml^{-1} were prepared by further dilution.

2.4. Preparation of samples

2.4.1. For tablets

Weigh and finely powder 20 tablets. Transfer an accurate weight of the powder equivalent to 50 mg of the drug into a 100 ml volumetric flask, shake thoroughly with about 75 ml of water for 10 min and then make up to volume with water. Filter and reject the first portion of filtrate. Dilute the prepared solution quantitatively with water to obtain the required concentration for analysis.

2.4.2. For injections

Mix well the contents of 10 ampoules. Dilute an accurately measured volume of the solution equivalent to 50 mg of drug quantitatively with water
Table 2

Effect of pH variation on the absorption intensity of the ion-pair complex of dibucaine · HCl (12 μg ml^{-1}) with oxidized quercetin

pH	Absorbance[a] (at 528 nm)
2.0	0.068
2.5	0.091
3.0	0.121
3.5	0.187
4.0	0.278
4.5	0.466

5.5	0.467
6.0	0.407
6.5	0.370
7.0	0.146
8.0	0.022

[a] Average of four determinations.

to 100 ml. Dilute the resulting solution quantitatively with water to obtain the required concentration for analysis.

2.4.3. Recovery study

Transfer an accurately weighed amount of declared drug (25 mg) for each preparation to a 100 ml volumetric flask containing an accurately weighed quantity of the powdered tablets or an accurately measured volume of injection solution (equivalent to 25 mg of drug). Either dissolve the contents of the flask in water and treat as described in Section 2.4.1, or dilute quantitatively with water to obtain the required concentration as described in Section 2.4.2.

2.5. Determination

To 1 ml of either standard or sample drug solution in a 10 ml volumetric flask, add 1 ml of buffer solution pH 5.0 followed by 0.5 ml of quercetin solution and 1.0 ml of NBS solution. Mix well and extract with two 10 ml portions of dichloroethane. Combine the organic solvent extracts, filter over about 2 g of anhydrous sodium sulphate and reject the first 5 ml of filtrate. Measure the absorbance of the solution at the specified maximum (Table 1) against a blank treated similarly.

3. Results and discussion

Preliminary investigations were carried out to test the reactivity of quercetin towards both tertiary amines and quaternary ammonium salts. Aqueous solutions of the tested compounds were

Table 3

ity of the method, preoxidation of quercetin with NBS was carried out. Highly colored reddish-violet ion-pairing complexes absorbing in the wavelength range 528–558 nm were produced. These complexes were also extractable with chloroform and dichloroethane.

Fig. 1 shows the absorption spectra of oxeladine citrate, pheniramine maleate and oxyphenonium bromide association complexes with quercetin–NBS reagents as representative examples. The complexes have absorption maxima in the range 528–535 nm for the tertiary amines and 550–560 nm for the quaternary ammonium compounds. Spectral characteristics of the studied compounds are summarized in Table 1.
Fig. 4. Absorption spectra of aqueous solution of (—) dibucaine · HCl (20 μg ml⁻¹), (. . .) reaction mixture containing dibucaine · HCl (20 μg ml⁻¹) and (   ) blank after extraction with a 10 ml portion of dichloroethane (all measured against distilled water as a blank solution).

mixed with ethanolic quercetin solution. Intense yellow products were produced which were extractable with organic solvents such as chloroform and dichlorethane.

In order to increase the sensitivity and selectiv-

The reaction conditions, including pH, quercetin and NBS concentrations, extraction solvents, reaction and stability times and interferences, were investigated and optimized for all studied drugs.

3.1. Effect of pH

The effect of pH was studied by extracting the colored complexes formed with buffer of different pH values. Table 2 shows that a pH range of 4.5–5.5 is recommended. A buffer solution of pH 5.0 was selected for all subsequent work.

3.2. Effect of quercetin concentration

Several solutions of quercetin in the concentration range 0.05–0.25% w/v were prepared and tested with the studied drugs (0.5 ml portions were used). The obtained absorbances were

Wavelength, nm.
— Dibucaine HCl .... blank
Fig. 5. Absorption spectra of (—) reaction mixture containing dibucaine · HCl (20 μg ml⁻¹) and (...) blank in dichloroethane after one extraction measured against pure dichloroethane.

plotted as a function of quercetin concentration. The highest color intensity was obtained using quercetin in concentrations ranging from 0.15 to 0.25% w/v (Fig. 2). Therefore 0.2% w/v quercetin solution was used for all subsequent work.

3.3. Effect of NBS concentration

In order to establish the optimal NBS concentration, aqueous solutions of NBS ranging from 0.025–0.2% w/v were added to quercetin solution and the reaction was carried out as usual. In each experiment 1 ml of NBS solution was used. Fig. 3 shows that 0.15% w/v NBS is the most suitable concentration for all the studied drugs. Concentrations greater than ≈ 0.175% w/v showed a marked decrease in absorption intensities, most probably due to the further oxidation of quercetin to other products [13].

3.4. Effect of solvents

Table 3 shows the effect of extraction with different organic solvents. The variations in the absorption intensity and wavelength of the ion-pairing complex from dibucaine · HCl were taken as being representative of the studied drugs. It is clear from the Table that the highest extraction efficiency is obtained using dichlorethane as extraction solvent. In addition, two extractions only (2 min shaking time) were found to be sufficient to achieve quantitative recovery of all the complexes in aqueous solution with good reproducibility and very small relative standard deviation (<2%). Figs. 4 and 5 show the absorption spectra of both experiment and blank (aqueous and organic phases) after one extraction for dibucaine · HCl, in addition to the spectrum of the pure drug.

Other solvents, such as methylene chloride and chloroform, can also be used. However, highly non-polar solvents such as carbon tetrachloride have very poor extractive efficiency for these dyes.

[b]Theoretical values of t and F at the 95% confidence limit are $t = 2.306$, $F = 6.39$.
[c]Ref. [15].
[d]Ref. [16].

3.5. Effect of time

The reaction between quercetin–NBS and tertiary amines or quaternary ammonium compounds is very rapid and the colored products can survive unchanged in aqueous solution before extraction for about 10 min without significant loss in intensity. However, at time > 10 min there may be a gradual decrease in the intensity of absorption in some cases.

Regarding the stability time of colored products after extraction with dichloroethane, it was noticed that absorbance was slightly increased in the first 5 min and then remained stable for at least 1 h.
Scheme 1. Suggested mechanism for the formation of an ion-pair complex.

3.6. Interferences

Primary and secondary amines do not interfere with the determinations (Table 4), but other tertiary amines and quaternary ammonium salts will interfere and thus require prior separation from each other if present in mixtures.

The presence of traces of water in the organic solvent extracts may cause discrepancy in absorbance measurements and subsequent variation in results and so they must be removed by filtration over about 2 g of anhydrous sodium sulphate.

Regression analysis indicated excellent conformity with Beer's law over the concentration ranges listed in Table 1 for each drug. Separate determinations at different concentration levels for each drug gave coefficients of variation not exceeding 2%.

Some commercial dosage forms were successfully analyzed by the proposed method and reported methods. Recovery experiments were performed for each drug in its dosage form. The results are listed in Table 5 which indicated that common additives and excipients, in addition to other UV-absorbing constituents present in some dosage forms such as antipyrine salicylate and caffeine in cosavil tablets, did not interfere with the determinations. The results were compared with those obtained from other reported methods and were found to be in good agreement.

3.7. Reaction mechanism

Depending on the nature of quercetin and previous reports concerning its oxidation products [14] a suggestion for the reaction mechanism can be outlined (Scheme 1). Quercetin, being a flavonol, undergoes oxidation of the pyrocatechol moiety in ring B in the presence of mild oxidants to produce the highly colored o-quinone derivative. Ionization of the hydroxyl group of ring C most probably becomes easier leading to anion formation. The anion then interacts with protonated tertiary amine or quaternary ammonium moieties to form the colored ion-pair complexes.

4. Conclusion

The proposed method is simple, rapid, free from interferences, and selective for tertiary amine and quaternary ammonium salts, especially those of very low absorptivity in the UV range. The use of oxidized quercetin as analytical reagent provides a fairly higher extraction efficiency and sensitivity compared to other similar ion-pairing reagents. The method can be successfully used for

the routine analysis of tertiary amine and quaternary ammonium salts in pure forms and in different formulations.

Abstract

A flowthrough spectrophotometric sensor for the determination of cobalt at the nanogram per millilitre level using pyridoxal 4-phenylthiosemicarbazone as reagent and integrated preconcentration and detection in the flow cell is proposed. The method is highly selective for cobalt(II); it features detection and determination limits of 0.02 and 0.06 μg ml^{-1} respectively, and a linear range of at least 0.04–18 μg ml^{-1}. The method is subject to very few interferences because the strongly acidic medium used prevents the formation of most complexes of the reagent with other metal ions. The method was applied to the determination of cobalt in pharmaceutical preparations.

Keywords: Cobalt; Flow injection; Flowthrough sensor; Pharmaceutical preparations; Spectrophotometry

1. Introduction

Several procedures for the flow-injection (FI) determination of cobalt, many of which use spectrophotometric or chemiluminescence detection, have been reported in the last few years. The spectrophotometric technique has been used in methods where cobalt acts as a catalyst for the oxidation of various coloured substances [1–5]. Differential kinetics have also been used for this purpose, particularly in the simultaneous determi-

nation of cobalt and nickel with salicylaldehyde thiosemicarbazone as reagent [6,7]. pH gradients have also been exploited for this purpose, in conjunction with 4-(2-pyridylazo) resorcinol [8]. However, the determination of cobalt usually involves gallic acid [9–11] or luminol [12,13], which are oxidized by hydrogen peroxide in the presence of the metal.

Both types of method are generally highly sensitive, with detection limits of a few nanograms or picograms per millilitre, which allows the determination of cobalt in biological samples and drinking waters. However, they are subject to a number of interferences which call for prior separations that normally make them time-consuming and unreliable.

Recently, a very selective method for the FI spectrophotometric determination of cobalt was developed. Based on the formation of a highly stable complex between cobalt and pyridoxal 4-phenyl-3-thiosemicarbazone (PPT) in a strongly acidic medium, the method is not very sensitive [14]. In this work, we improved its sensitivity and selectivity by using a flow manifold integrating preconcentration and detection in a sorbent material packed in a flow cell for the determination of

Table 1
Optimum values of FI variables

Sample flow rate (ml min⁻¹)	0.6
Reagent flow rate (ml min⁻¹)	0.4
3 M HClO₄ flow rate (ml min⁻¹)	0.6
Eluent flow rate (ml min⁻¹)	0.6
Length of reactor R_1 (cm)	116 (0.5 mm i.d.)
Length of reactor R_2 (cm)	150 (0.5 mm i.d.)
Length of reactor R_3 (cm)	35 (0.5 mm i.d.)
Injection loop volume (ml)	2.4 (in order to ensure approximately 30 s of constant absorbance before elution)

cobalt. This modified method provides better selectivity and sensitivity, with detection and determination limits of 0.02 and 0.06 μg ml⁻¹ respectively. The method relies on the recently developed flowthrough sensor technology [15,16] by which retention and detection are integrated in a FI system [17,18]. In this case, successive passage of the complex (previously formed in the flowing stream) and eluent through the flow cell and continuous photometric monitoring of the process provides the analytical information needed to determine the cobalt. The proposed method was used for the automatic on-line determination of this ion in vitamins contained in pharmaceutical preparations (it is present in the essential vitamin B_{12}) [19]. This vitamin takes part in a wide variety of metabolic processes involving factors that affect growth, homopoiesis and preservation of the intergrity of nerve cells.

2. Experimental

2.1. Reagents

All chemicals were of at least analytical-reagent grade, and bidistilled, deionized water was used throughout.

A stock solution of Co(II) was prepared from the nitrate (Merck P.A.) and standardized complexometrically. Standards of working strength were made by appropriate dilution as required.

A 0.05% solution of PPT was prepared by dissolving 0.05 g of the reagent in 30 ml of N,N-dimethylformamide (DMF) and diluting to 100 ml with water. The reagent was synthesized according to a procedure described elsewhere [20].

A 30% solution of perchloric acid in DMF–water (3/10, v/v) was used as eluent.

A 3 M perchloric acid solution was also used.

C_{18} in a Sep-Pak cartridge (Waters, Millipore Division), which demonstrated its resistance to the eluent, was used for retention–detection of cobalt in the flow cell.

2.2. Apparatus

A Hewlett-Packard 8452A diode-array detector interfaced to a Vectra ES/12 computer which delivered results through an HP Think-Jet printer was used. The flow manifold consisted of a Gilson Minipuls-3 peristaltic pump, a Rheodyne Type 50 six-port rotary valve and a Hellma OS 0.200 flow cell.

2.3. Manifold and procedure

Three different configurations were tested (Fig. 1). In the first configuration, the reagent was merged with 3 M HClO₄ to prevent the formation of complexes of other cations along reactor R_1; in this way, the reagent was retained first on the sorbent material (preconcentration step). When a preset volume of reagent had passed through the flow cell, V_{s1} was switched in order to introduce the sample. In this way, the reaction took place in the flow cell (reaction step) and the detector continuously monitored the absorbance increase (detection step). After the reaction was complete, V_{s2} was switched, thereby allowing the reaction product to be eluted from the sorbent material, which was thus made ready for a new sample.

In the second configuration, the sample was merged with the reagent along reactor R_1 and the

complex formed was merged with 3 M $HClO_4$ along reactor R_2, where a strongly acidic medium destroyed the complexes of other metal ions. The cobalt complex was retained on the sorbent material packed in the flow cell (preconcentration step) and the detector continuously monitored the signal increase up to a constant value. As the injection valve V_1 was switched to the "inject" position, the eluent passed through the flow cell to remove the retained complex and make the sorbent material ready for a new sample.

The third configuration was similar to the previous one but the sample was used to fill the injection loop instead of being continuously circulated as the carrier, thus reducing sample consumption.

3. Results and discussion

Cobalt forms a yellow 1:2 complex with PPT ($\lambda = 430$ nm, $\varepsilon = 1.35 \times 10^4$ 1 mol^{-1} cm^{-1}). The complex is stable in perchloric acid up to a concentration of 1.2 mol l$^-$ (12%) [14], conditions under which most of the complexes of PPT with other cations are not formed. This reaction can be carried out with the reagent or complex retained on a sorbent material. Thus in preliminary assays several sorbent materials were tested in order to find the most appropriate for this purpose. In an acid medium, the cobalt complex is in cationic form, so cationic exchange resins (Dowex, Amberlita, SP-Sephadex) were assayed; however, neither the reagent nor the complex was retained. Other sorbent materials, such as aluminium oxide, silicagel and C_{18}, were tested, but only the latter effectively retained both the reagent and the complex. The maximum absorption wavelength of the cobalt–PPT complex retained on C_{18} was 276 nm.

Of the buffered eluents tested, 30% perchloric acid in DMF–water proved to be the most efficient for removing the complex from the C_{18} without damaging it.

The next task was to select the most advantageous manifold among those shown in Fig. 1. The manifold depicted in Fig. 1a provided a poor response because the reagent was packed onto C_{18} phase before the passing of the sample, causing

the saturation of the C_{18} phase, so that subsequent passage of the sample through the sensor did not give a sensitive enough signal. The manifolds of Figs. 1b and 1c provided appropriate responses so that complex formed was passing directly through the sensor and the difference between blank and complex signals was better than the response provided by manifold 1a. Comparing manifolds 1b and 1c, the former was approximately 10 times more sensitive than the latter and so configuration 1b was finally selected.

3.1. Optimization of variables

The optimum reagent concentration was found to be 0.05% in DMF–water (3/10, v/v). The amount of DMF used was the minimum ensuring complete dissolution of the reagent, and DMF was also used in the eluent which also served as the carrier, in order to maximize peak height and ensure complete elution of the complex.

Based on the influence of the concentration of perchloric acid on the complex formation, 3 mol l^{-1} was found to be the optimum concentration as it produced the lowest standard deviation even though the peak height was somewhat greater with 1.5 mol l^{-1} perchloric acid. Obviously, once the different streams have merged, the acid concentration in the reaction plug will have been decreased by dilution.

The influence of the FI variables (stream flow rates, reactor lengths and injection volume) was studied and the optimum values found are summarized in Table 1.

Scans were performed in the kinetic mode at 276 nm for 150 s, in cycles of 2 s with an

5	2.0	2.2 $\pm$ 0.1
6	5.0	5.1 $\pm$ 0.5

integrating time of 1.5 s. The maximum signal measured corresponded to the time at which the analyte started to be eluted. Fig. 2 shows typical recordings obtained and the point for analytical measurements (marked with arrowheads). Under these final experimental conditions, a sampling rate of 15 samples h^{-1} was reached.

3.2. Calibration curve and precision

In order to establish the optimal range for the determination of cobalt by the proposed method, several standard solutions of cobalt(II) were ina-jected into the flow system under the optimum experimental conditions. From the data obtained, two linear calibration curves were obtained from 0.04–1 μg ml^{-1} and from 1–18 μg ml^{-1} cobalt (Table 2).

The detection and determination limits, defined as the concentrations of analyte giving signals equivalent to three and ten times respectively the standard deviation of the blank plus the net blank intensity, were calculated to be 0.02 and 0.06 μg ml^{-1} respectively.

Various synthetic samples were readily resolved using pertinent calibration graphs (Table 3).

3.3. Interferences

The effect of various ions on the determination of cobalt by the proposed method was examined under the optimum working conditions. For this purpose, variable amounts of the ionic species tested were added to a 0.2 μg ml^{-1} solution of Co(II) up to a maximum interferent:cobalt ratio of 225:1 M/M; if any compound was found to interfere, the ratio was gradually lowered until the interference disappeared. The tolerated limits, defined as the interferent concentration (μg ml^{-1}) resulting in a deviation of less than $\pm 5\%$ in the analytical response, are shown in Table 4.

3.4. Application of the proposed method: determination of cobalt in pharmaceutical preparations

In a reaction flask 0.5–2 ml of vitamin ampoules and 3–6 ml of concentrated nitric acid were placed, and the mixture was refluxed until a colorless or pale yellow solution was obtained. Then, 0.5–1 ml of hydrogen peroxide was added and the mixture evaporated to a small volume by heating on a hot-plate to remove nitric acid. Next, the mixture was adjusted to pH 2 with NaOH solution and diluted to an appropriate volume (100 ml). Aliquots (10–20 ml) of this solution were determined using the recommended procedure. The standard-addition method was used and the results were obtained by extrapolation. Such results are given in Table 5 as the averages of three separate determinations. As can be seen, the cobalt concentrations determined by the proposed method are quite consistent with the specified values.

Table 4

Influence of foreign species on the determination of cobalt(II) by the proposed method

[a–e] Composition of the pharmaceutical preparations:

[a] Nervobion "5000" (Merck). Vitamin B$_{12}$ (cyanocabalamin), equivalent to 0.2174 mg of cobalt, cocarboxylase (100 mg), pyridoxal-5-phosphate (100 mg), excipient (lidocaine) up to 2 ml.

[b] B$_{12}$ Latino depot (Syntex Latino, S.A.). Vitamin B$_{12}$ (cyanocobalamin), equivalent to 0.04348 mg of cobalt, excipient up to 1 ml.

[c] Neuromade fuerte (Knoll). Vitamin B$_{12}$ (cyanocobalamin), equivalent to 0.2174 mg of cobalt, pyridoxine CLH (100 mg), thiamine CLH (100 mg), lidocaine (6 mg), excipient up to 3 ml.

[d] Optovite B$_{12}$ (Normon, S.A.). Vitamin B$_{12}$ (cyanocobalamin), equivalent to 0.04348 mg of cobalt, excipient up to 2 ml.

[e] Neurodavur plus (Belmac, S.A.). Vitamin B$_{12}$ (hydroxycobalamin), equivalent to 0.2098 mg of cobalt, thiamine · HCl (50 mg), pyridoxine · HCl (50 mg), dexamethasone phosphate sodium (1.6 mg), lidocaine · HCl (12.5 mg), excipient up to 2.5 ml.

4. Conclusions

Automatic methods based on flowthrough sensors offer interesting assets such as simplicity, rapidity, low cost and flexibility. The proposed method exhibits selectivity (iron being the main interference, at a 25-fold level with respect to cobalt) and high sensitivity, with a detection limit of 0.02 μg ml^{-1}. It is more selective and simple than other continuous FI spectrophotometric

methods, because it requires neither separation nor masking of foreign species. The proposed method was successfully applied to the determination of cobalt in vitamins.

Novel rapid decomposition and dissolution method for silicates using a mixed potassium metaborate/potassium carbonate flux

Nobutaka Yoshikuni*

Laboratory of Materials Science, Faculty of Engineering, Chiba University, Yayoi-cho, Inage-ku, Chiba 263, Japan

Received 16 January 1996; revised 15 April 1996; accepted 29 April 1996

Abstract

A novel method for the rapid dissolution of fused silicates in mineral acid is described. Fusion with 2.5 g of a $KBO_2-K_2CO_3$ (3:2, w/w) mixture in a platinum crucible at 1000°C will decompose 0.1 g of silicate samples such as basalt rock, glass sand and powdered glass in 10 min, and the cooled fusion cakes can be completely dissolved by 20 ml of 3 N mineral acids such as hydrochloric, nitric and sulfuric acids in less than 1 min at about 50°C. Fusion with 5.0 g of a $KBO_2-K_2CO_3$ (3:2, w/w) mixture can completely decompose 0.1 g of chrome refractory in 20 min and the cooled melt can be dissolved by 80 ml of 3 N hydrochloric or sulfuric acids in less than 30 s.

Keywords: Decomposition; Dissolution; Potassium carbonate; Potassium metaborate; Silicates

1. Introduction

The rapid preparation of silicate samples is very important for automatic and routine analysis of a large number of samples. Therefore, the rapidity of wet analyses of silicate samples such as rocks, sediments, soils, glasses, minerals, ores, refractories and silicon semiconductor materials can be enhanced by the use of fast and efficient methods of decomposition and/or dissolution. Two approaches are taken to this problem [1-3]: (i) fusion with one of, or various combinations of, boric acid, alkali metal carbonate, alkali metal borate, sodium hydroxide, sodium peroxide and

potassium superoxide; or (ii) wet decomposition with mixtures of hydrofluoric acid and various mineral acids. Powerful techniques for fusion decomposition of silicate samples have been established using boric acid-lithium carbonate [4-6], alkali metal metaborate [7], alkali metal tetraborate [8], alkali metal tetraborate-alkali metal carbonate [9,10] or other borate binary mixed flux systems. However, the use of these borate fusion fluxes is restricted within narrow limits because the dissolution time of the cooled fusion cakes is most frequently long, i.e. a few minutes to a few tens of minutes, at room temperature. Long-term storage and treatment of sodium peroxide [26] or potassium superoxide [27] is not easy. Wet methods use many acid binary mixed systems such as

* Corresponding author. Fax: + 81 472 51 7337.

hydrofluoric–hydrochloric [11], nitric [12], perchloric [13,14], sulfuric acids [15] or hydrofluoric–aqua regia [16–19] and others [20–22], but the acid systems often require a long time for complete decomposition of silicate samples. The decomposition times of the acid systems varied from a few tens of minutes in some instances to as much as a few hours. Moreover, high presences are required for dissolving refractory minerals such as zircon. Yoshikuni [23] reported a fusion method for decomposition and faster dissolution of silicate samples such as bauxite, ilmenite, magnetite, quartz and zircon sand.

From a literature survey, it is clear that no attempts have been made to use the potassium metaborate–potassium carbonate binary mixed system in the decomposition of silicate samples. This paper presents the easy decomposition of silicate samples using a potassium metaborate–potassium carbonate (3:2, w/w) mixed flux and the rapid dissolution, in less than 1 min, of the cooled fusion cake with a mineral acid such as hydrochloric, nitric or sulfuric acid at about 50°C. 2.5 g of a mixed flux of potassium metaborate–potassium carbonate (3:2, w/w) can fuse 100 g of silicate samples such as basalt rock, glass sand or powdered glass in a platinum crucible at about 1000°C in only 10 min.

2. Experimental

2.1. Apparatus

A Hitachi U-3210 spectrophotometer was used.

2.2. Reagents and samples

All reagents used were of analytical grade and distilled deionized water was used throughout. Potassium carbonate anhydrous, iron(III) sulfate *n*-hydrate and hydrogen peroxide (30%) were from Wako Pure Chemical Co. (Tokyo, Japan). Lithium metaborate anhydrous and 1,5-diphenylcarbazide were from Merck. Potassium metaborate anhydrous and sodium metaborate tetrahydrate were of the highest purity available from Kanto Chemical Co. Inc. Sodium metabo-

rate anhydrous was prepared by heating the tetrahydrate for 1 h in a platinum dish on a hot-plate. EDTA-2Na and Arsenazo III were from Dojindo Laboratories (Kumamoto, Japan).

2.3. Solutions

Fe(III) solution was prepared by dissolving iron(III) sulfate *n*-hydrate in 1 N sulfuric acid to form a solution with a concentration of 10 mg ml^{-1} Fe with respect to EDTA.

Chromium (Cr = 1.007 mg ml^{-1}) and zirconium (Zr = 0.995 mg ml^{-1}) standard solutions for atomic absorption spectrometry were from Merck.

2.4. Decomposition and dissolution of silicate samples

An accurately weighed (100 mg) silicate sample such as basalt rock, glass sand or powdered glass is placed in a platinum crucible and mixed with a binary flux of KBO_2–K_2CO_3 (1.5 g/1.0 g). The mixture is fused by heating strongly for 10 min in a muffle furnace at about 1000°C with a Bunsen burner to yield a clear melt. After a few minutes, the melt is rapidly (about 1 min) dissolved in 20 ml of 3 M hydrochloric or 3 N sulfuric acid at about 50°C with magnetic stirring. The sample solution is diluted to 50 ml with 3 N sulfuric acid or 3 M hydrochloric acid in a standard flask and chromium and zirconium in the total volume of, or an aliquot of, the sample solution are determined by a spectrophotometric method using 1,5-diphenylcarbazide or Arsenazo III.

2.5. Decomposition and dissolution of chrome refractory

The sample (100 mg, accurately weighed) of chrome refractory is placed in a platinum crucible and mixed with a binary flux of KBO_2–K_2CO_3 (3 g/2 g). The mixture is fused by heating strongly for about 20 min in a muffle furnace with the burner to yield a clear melt. After cooling the melt, the platinum crucible is inserted into a 100 ml tall beaker and about 80 ml of 3 N sulfuric acid is added to the beaker. The cooled fusion

cake can be rapidly dissolved with magnetic stirring at about 50°C. The sample soution is diluted to 100 ml with 3 N sulfuric acid in a standard flask. After further dilution, chromium in the aliquot is determined by spectrophotometry.

2.6. Determination of chromium [24]

Add about 3 ml of iron solution (Fe = 10 mg ml^{-1}) and 1.0 ml of 30% hydrogen peroxide to a sample solution containing 3–10 μg of chromium in a 100 ml beaker. The pH of the solution is then adjusted from 13.0 to 13.5 with 8 M sodium hydroxide solution and the beaker, after covering with a watch glass, is heated to boiling for 10 min on a hot-plate. The solution is filtered with a No. 5A filter paper and the pH of the filtrate solution is adjusted to 1.0 with sulfuric acid (1:1). Add 2 ml of 1,5-diphenylcarbazide (1% in acetone–water, 1:1) to the solution and dilute to 50 ml with 0.05 N sulfuric acid in a standard flask. After 5 min, measure the absorbance at 540 nm versus a blank.

2.7. Determination of zirconium [25]

Transfer an aliquot (5.0 ml) of the sample solution to a 25 ml standard flask and add 1 ml of 1% Arsenazo III aqueous solution to the flask. Dilute to the mark and adjust to 9 M hydrochloric acid using concentrated hydrochloric acid and water. Measure the absorbance at 665 nm versus a blank.

3. Results and discussion

A binary flux (2.5 g) of potassium metaborate–potassium carbonate (3:2, w/w) mixture can fuse 0.1 g of basalt rock, glass sand or powdered glass samples by heating strongly for 10 min in a muffle furnace at about 1000°C in a platinum crucible. After cooling to room temperature, the melt is rapidly dissolved in 20 ml of 3 M hydrochloric acid as well as nitric and sulfuric acids within a few tens of seconds (Table 1) because the glassy fusion cakes are full of cracks after cooling the material to a solid state, in contrast to the fusion

flux of lithium metaborate–lithium carbonate mixture. In addition, this dissolution mechanism is an exothermic reaction. Silicate samples with a large Cr_2O_3 content such as chrome refractory (100 mg) cannot be completely decomposed with 2.5 g of KBO_2–K_2CO_3 (3:2, w/w) in binary mixed fusion for 30 min. 100 mg of the chrome refractory can be completely decomposed with 5.0 g of KBO_2–K_2CO_3 (3:2, w/w) in fusion for 20 min, and the cooled fusion cake can be dissolved in less than 60 s with 80 ml of 3 N sufluric or 3 M hydrochloric acid (Table 2). The decomposition of silicate samples with a fusion flux such as Li_2CO_3, Na_2CO_3, K_2CO_3, $CaCO_3$, $Li_2B_4O_7$, $Li_2B_4O_7$–$LiBO_2$, Li_2CO_3–$Li_2B_4O_7$, Na_2CO_3–$Na_2B_4O_7$ or K_2CO_3–$K_2B_4O_7$ systems is an excellent method but chrome refractory cannot be completely decomposed. Using a binary flux of KBO_2–K_2CO_3 mixture, the dissolution of the mixture at a 3:2 ratio is faster than at a 2:1 ratio with 3 M hydrochloric acid. Therefore, the composition of the KBO_2–K_2CO_3 fusion system is very important for rapid dissolution with mineral acid at room temperature. With a 3:2(w/w)MBO_2–M_2CO_3 mixture, the speed of dissolution of the cooled cakes with mineral acid increases as follows:

$$KBO_2 - K_2CO_3 > NaBO_2 - Na_2CO_3$$

$$\gg LiBO_2 - Li_2CO_3$$
$NaBO_2 \cdot H_2O$ cannot be used because the monohydrate flux bubbles on heating.

100 mg of glass sand can be easily decomposed with a fusion of KBO_2–K_2CO_3 3:2 w/w (2.5 g), and the cooled fusion cake can be rapidly dissolved with 3 M hydrochloric acid. Before the determination of zirconium, the sample solution was diluted several times and therefore the borate matrix did not interfere. The recovery of zirconium is quantitative (Table 2). After decomposition and dissolution of silicate samples such as basalt rock, chrome refractory, glass sand or powdered glass, 1 ml of 30% hydrogen peroxide is added to an aliquot of the sample solution which is adjusted to pH 13.0–13.5 with sodium hydroxide solution. At pH 13.0–13.5 in the sample solution, silica and borate are precipitated as a

[a] Decomposition time: 10 min for all samples. [b] Samples: Basalt rock SRM 688, chrome refractory SRM 103a and glass sand SRM 81a were from NIST (Gaithersburg, MD). Quartz and special glass were from Asahi Glass Co (Tokyo, Japan).

transparent gel containing adsorbed chromium ion, and hence chromium cannot be measured in the filtrate. With the addition of 30 mg of iron(III) ion to an aliquot of the sample solution, the adsorption sites of the transparent gel can be completely saturated and the chromium can be quantitatively recovered in the filtrate. Chromium in an aliquot of the sample solution can be easily oxidized in alkaline solution (pH 13), and excess hydrogen peroxide can be completely decomposed with a catalyst of iron(III) ion on a hot-plate. At such elevated flux/sample ratios, problems from blanks might arise, but the interference of borate matrix in the determination of chromium was not examined. Before the determination of chromium, a large portion of the borate matrix was removed with the previously mentioned method of precipitation–filtration and then the borate matrix did not interfere. The values for chromium in samples of basalt rock, chrome refractory and glass sand determined with this procedure were in good agreement with the certified values (Table 2).

Table 2

3.1. Application

Chromium in a powdered sample of a special glass plate from the Asahi Glass Company was spectrophotometrically determined with 1,5-diphenylcarbazide after decomposition and dissolution according to the above-mentioned procedures. The determined values of chromium in the glass plate samples were satisfactory with respect to the recommended values (Table 3).

4. Conclusions

The author has demonstrated a rapid dissolution method for the cooled cake of fused silicate samples such as basalt rock, glass sand, powdered glass and chrome refractory using potassium metaborate–potassium carbonate (KBO$_2$–K$_2$CO$_3$ = 3:2, w/w) binary mixed fusion flux and mineral acid dissolution systems at room temperature. The cooled cake can be instantaneously dis-

Received 5 September 1995; revised 22 April 1996; accepted 29 April 1996

Abstract

Some new chelating ion-exchange resins containing a hydroxamic acid moiety attached to a divinylbenzene styrene (DVBS) copolymer. i.e. glycine hydroximate in DVBS (GH-DVBS), anthranilic acid hydroximate in DVBS (AAH-DVBS), malonic acid dihydroximate in DVBS (MAH-DVBS) and iminodiacetic acid dihydroximate in DVBS (IDAAH-DVBS). have been synthesized and their various physicochemical characteristics studied. The degree of retention of metal ions by the resins at equilibrium has been determined in terms of the molar distribution coefficient (K_d). In general. the resins having a dihydroximate moiety are found to be more efficient compared to monohydroximate resins. However, it is of interest to note that the monohydroximate derivative of amino acid (GH-DVBS) showed better metal retention capability than the dihydroximate of carboxylic acid (MAH-DVBS). The selectivity of the resins for transition and highly charged metal ions is quite high compared to that for alkaline earth metals. All the synthesized resins can be utilized for the separation of a mixture of metal ions because the differences in the distribution coefficient values are large enough to permit good separations on columns. However, the GH-DVBS resin was tried for the separation of copper cobalt and copper nickel mixtures at pH 5.5 using the column mode of operation.

1. Introduction

Chelating ion-exchange resins having specific chelating groups attached to a polymer have found extensive use in the separation and concentration of metal ions [1–4], as floataids, depressants, flocculants and collectors, and in the extraction and concentration of metals from sea water [5,6]. An important feature of the chelating ion exchangers is the greater selectivity which they offer compared to conventional types of ion exchangers.

Chelex-100 is the most widely-used functionalized polymer for the preconcentration and separation of rare earth and heavy metals [7]. However, one of the disadvantages of this resin is that its affinity for alkaline earth metals is almost the same as that for zinc or other transition metal ions [8]. Therefore, there is a need to develop those functionalized polymers which show better affinity for transition metal ions as compared to alkali and alkaline earth metals.

---

* Corresponding author.

With the aim of synthesizing selective ion-exchange resins which require no preconcentration of the samples, do not form stable complexes with alkaline earth metals and are useful in mineral processing industries, we have synthesized chelating resins containing hydroximates of carboxylic and amino carboxylic acids.

The choice of hydroxamic acids is based on their extensive use as collectors for various minerals containing Sn, Fe, W, Cu, La, Ce, Nb, and Y metal ions [9]. Hydroxamic acids have found a variety of commercial applications in mineral processing in the former Soviet Union [10] under the trade name IM-50. Various studies have been made with hydroximate collectors in the floatation of haematite [11], pyrolusite [12], cassiterite [13], chrysocolla and rare earth bastnaesite ores [14]. However, little work is reported on chelating resins incorporating hydroxamic acid as a functional group. Cellulose hydroximate was prepared by Maekawa et al. [15] and was selective for copper, iron, cobalt and nickel. Malonic acid dihydroximate in divinylbenzene styrene (DVBS) was reported [16] for the recovery of U(VI) from sea water. However, no reports are available for the separation of other metal ions on this resin.

2. Experimental

Chelex-100 was procured from John Baker Inc. (Colorado, USA). Chloromethylated DVBS with 4% cross linking was procured from Thermax Pvt. Ltd. Other chemicals used were of analytical grade.

2.1. Synthesis of resins

2.1.1. Synthesis of glycine hydroximate in DVBS

Glycine hydroximate was synthesized in two steps as shown in Scheme 1.

#### 2.1.1.1. Incorporation of glycine ester in DVBS.
The chloromethylated DVB styrene beads (0.028 mol) were soaked in DMF overnight to allow swelling to occur. Glycine methyl ester (0.14 mol) was taken in DMF, heated for 10 min and then transferred to the flask containing swollen DVBS

beads. The reaction mixture was refluxed for 6 h. The product thus formed was filtered, washed with 80% aqueous methanol containing a few drops of nitric acid and dried in vacuum.

2.1.1.2. Preparation of glycine hydroximate in DVBS.
A methanolic solution of hydroxylamine hydrochloride (0.14 mol) was added to the previously filtered beads of glycine ester in DVBS. The reaction mixture was refluxed for 4 h. It was then cooled and freshly prepared sodium ethylate solution was added to it to adjust the pH to 9.2–9.3. The reaction mixture was refluxed again for 5 h. The product formed was filtered and treated successively with 0.1 N HCl, 0.1 N NaOH and 0.1 N HCl. Finally, it was washed with absolute alcohol and dried in vacuum.

2.1.2. Synthesis of anthranilic acid hydroximate and malonic acid dihydroximate in DVBS

Anthranilic acid hydroximate in DVBS was synthesised following a similar procedure to that employed for the synthesis of glycine hydroximate in DVBS by taking methyl anthranilate in place of glycine methylester (Scheme 2).
Scheme 1. Synthesis of glycine hydroximate in DVBS.
Scheme 2. Synthesis of anthranilic acid hydroximate in DVBS.

Malonic acid dihydroximate in DVBS was prepared by the reported method [17] as shown in Scheme 3.

2.1.3. Synthesis of iminodiacetic acid dihydroximate in DVBS

Iminodiacetic acid dihydroximate was prepared from Chelex-100, an iminodiacetic acid derivative of DVBS, as shown in Scheme 4.

2.1.3.1. Synthesis of the ester of Chelex-100. Chelex-100 (0.05 mol) was taken in methanol in a round-bottomed flask and dry HCl gas was passed through it until saturation was complete. The reaction mixture was refluxed for 3 h. The dimethylester of Chelex-100 was thus formed.

2.1.3.2. Synthesis of iminodiacetic acid dihydroximate in DVBS. A mixture of methyl ester of Chelex-100 (0.25 mol) and hydroxylamine hydrochloride (0.25 mol) in methanol was refluxed for 12 h. The pH of the reaction mixture was adjusted by sodium ethylate solution to 9.2. The product thus formed was filtered, washed with 80% ethanol and dried in vacuum.

2.2. Apparatus

Infrared spectra of the synthesized resins were recorded on a Shimadzu IR-400 spectrophotometer using KBr pellets. Nitrogen analysis was done using Kjeldahl's method. A Perkin-Elmer 2380 atomic absorption spectrophotometer was employed for the quantitative determination of metal ions.

2.3. Determination of distribution coefficients

A batch equilibration technique was employed for the investigation of metal uptake by the resins. The method involved equilibrating the H^+ form of resins with 1 ml of 1000 ppm metal ion solution and a known volume of sodium acetate–acetic acid buffer (pH range 4–7) for 1–10 h. Two phases were separated after equilibration and an aliquot of filtrate was analyzed for metal by atomic absorption spectrophotometery. The quantity of metal ion adsorbed by the resin was obtained by subtracting the concentration in the filtrate from the initial concentration.
Scheme 3. Synthesis of malonic acid dihydroximate in DVBS.
Scheme 4. Synthesis of iminodiacetic acid dihydroximate in DVBS.

The molar distribution coefficient (K_d) values were then calculated using the formula:

$$K_d =$$

$$\frac{\text{Amount of metal ion in resin per gram of resin}}{\text{Amount of metal ion in solution}}$$

$$\text{per milliliter of solution}$$

3. Results and discussion

The synthesized resins are highly stable in water and commonly used solvents in the pH range 4–7.

In the infrared spectra of hydroximate derivatives of DVBS, a band near 3450 cm^{-1} was assigned to ν(N–H) and another band near 1695–1650 cm^{-1} was assigned to C–O stretching vibrations of hydroxamic acid. The ν(C–O) band of carboxylic acids near 1580 cm^{-1} and the ν(C–O) band of esters near 1725 cm^{-1} disappeared in the spectra of hydroxamic acid derivatives.

The moisture content, bulk density, specific bulk volume, nitrogen content and degree of substitution of the resins are given in Table 1 and the pH titrations (determined by a batch method using 0.1 N NaOH) are represented in Fig. 1.

### 3.1. Uptake of metals by the resins

The molar distribution coefficient values of Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), U(VI) and W(VI) metal ions with GH-DVBS, AAH-DVBS, MAH-DVBS and IDAAH-DVBS are represented in Tables 2–5, respectively. The results indicate that the distribution coefficient values first increase, then attain a maximum and finally decrease with increasing pH.

Glycine hydroximate in DVBS shows maximum adsorption for Fe(II), Cu(II) and Zn(II) at pH 5.5, and for W(VI), U(VI), Co(II), and Ni(II) at pH 6.0. At pH 6.5, maximum adsorption of Cd(II) takes place whereas Ca(II) is adsorbed maximally at pH 4. At the pH of maximum adsorption, the selectivity order of various metal ions on this resin is as follows:

W(VI) > Fe(II) > U(VI) > Cu(II) > Zn(II)

> Cd(II) > Co(II) > Ni(II) > Ca(II)
The resin exhibits high selectivity for tungsten ($K_d = 10\,861$) and iron ($K_d = 5822$) which can be easily separated from all other metal ions at pH 6 and 5.5 respectively. This resin can be utilized for the separation of copper ($K_d = 1995$) from cobalt ($K_d = 412$) and nickel ($K_d = 478$) at pH 5.5. It also shows marked adsorption for uranium ($K_d = 2879$).

The sorption studies of various metal ions on AAH-DVBS resin reveal that Fe(II), Co(II), U(VI), and W(VI) are adsorbed maximally at pH 6, Zn(II) and Ni(II) at pH 5.5, Ca(II) at pH 4 and Cu(II) at pH 5. The metal ions show the following adsorption pattern at the pH of maximum adsorption:

W(VI) > Zn(II) > Fe(II) > Cu(II) > Cd(II)

> U(VI) > Co(II) > Ni(II) > Ca(II)
This resin is selective for tungsten, zinc, iron, and copper. The increased adsorption behaviour of anthranilic acid derivatives for zinc has already been discussed in our previous paper [18]. The separation of tungsten ($K_d = 4030$) from cobalt ($K_d = 572$), nickel ($K_d = 364$), copper ($K_d = 404$), cadmium ($K_d = 913$) and uranium ($K_d = 796$) can be achieved at pH 6.

Table 1
Resin characteristics

Resin	Moisture content (%)	Bulk density (g cm⁻³)	Specific bulk volume (cm³ g⁻¹)	Nitrogen content (%)	Degree of substitution (%)
GH-DVBS	11.80	0.60	1.66	1.86	20.66
AAH-DVBS	11.19	0.55	1.80	1.96	26.06
MAH-DVBS	10.11	0.89	1.12	2.73	34.51
IDAAH-DVBS	9.80	0.44	2.27	3.00	25.42

The distribution coefficient values of various metal ions, namely, Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), Ca(II), U(VI) and W(VI), with MAH-DVBS resin at the maximum adsorption pH are 1599, 546, 448, 904, 879, 843, 129, 1101 and 4030 respectively. The selectivity order is

$$W(VI) > Fe(II) > U(VI) > Cu(II) > Zn(II)$$

$$> Cd(II) > Co(II) > Ni(II) > Ca(II)$$
Sorption studies of various metal ions with IDAAH-DVBS resin suggest that it is the most
Fig. 1. pH titration curves for GH-DVBS, AAH-DVBS, MAH-DVBS and IDAAH-DVBS resins.

effective of the four synthesized resins for the selective adsorption of metal ions. At the pH of maximum adsorption, distribution coefficient values for Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), Ca(II), U(VI) and W(VI) are 36 489, 10 177, 7960, 32 483, 10 760, 8109, 395, 43 436 and 21 707 respectively and these values can be arranged in the following descending order of selectivity:

$$U(VI) > Fe(II) > Cu(II) > W(VI) > Zn(II)$$

$$> Co(II) > Cd(II) > Ni(II) > Ca(II)$$
Thus, the selectivity of this resin for uranium, iron, copper and tungsten is quite high. This order is consistent with the metal stability order given by Bogdanov [19] for hydroxamic acids:

Alkaline earth metals	Transition < metals	Rare < earths	Fe, Cu and < highly charged cations
Hydroxamic acids form chelates with high stability constants when complexed with ferrous, non-ferrous and rare earth metals whereas those with low stability order complex with alkali and alkaline earth metals [20]. Hydroxamic acid exists in two tautomeric forms:

Form 1.
Metal complexes are formed via the hydroxamide functional group (a) and not through the hydroxyoxime structure (b). Thus there is a con-

siderable covalency in the bonds formed (compared with the ionic characteristic of the bonds formed with the carboxylic group) and this contributes to the high selectivity of the hydroximate interaction with metals. Hydroxamic acids are weaker donors than the carboxylic acids but are more selective.

A perusal of the results shows that the four synthesized hydroximate resins are selective towards transition and highly charged metal ions [U(VI) and W(VI)] in comparison to alkaline earth metals, i.e. calcium. Therefore, the disadvantage of Chelex-100 can be overcome by utilizing these resins, especially IDAAH-DVBS where the order of K_d values is comparable with those of Chelex-100. This resin can be effectively used in the recovery of uranium from sea water of pH 6–8 [K_d of U(VI) at pH 6 = 43 436].

Among the four chelating resins reported, the dihydroximate of amino carboxylic acid (IDAAH-DVBS) is more effective than the monohydroximate of amino carboxylic acid (GH-DVBS) because of the extra coordinating sites in

the IDAAH-DVBS resin. However, even the dihydroximate of carboxylic acid (MAH-DVBS) is a weaker donor compared to the monohydroximate of amino carboxylic acid (GH-DVBS) although the former has a high degree of substitution. This is because of the presence of nitrogen, which increases the electron density on the coordinating oxygen of the amino acid hydroximate resin. GH-DVBS is also found to be a stronger donor compared to AAH-DVBS, which has a higher degree of substitution compared to GH-DVBS. Assuming that the phenyl group is electron-withdrawing [21], the electron density on the donor oxygen atom is decreased. Thus, AAH-DVBS is a strong acid, weak donor but more selective while GH-DVBS is a weak acid, strong donor and less selective.

3.2. Separation of metal ions by the resin

A study of the K_d values of various metal ions with GH-DVBS resin reveals that separation of a mixture of metal ions can be achieved using this resin. Copper ($K_d = 1995$) was separated from cobalt ($K_d = 412$) and nickel ($K_d = 478$) at pH 5.5 by GH-DVBS using column chromatography.

A 10 cm long glass column of uniform diameter (1 cm) was used for the separation of metal ions. The resin in the H$^+$ form was kept overnight in DMF to allow swelling to occur. The swollen resin was poured into the column to a height of 2–3 cm. The column was equilibrated with sodium acetate–acetic acid buffer of pH 5.5. 20 ml of a mixture containing 10 ml of each metal ion was loaded onto the column at a flow rate of 2 ml min^{-1} which is the normal flow rate of the medium height column under atmospheric pressure. The column was washed with the same buffer solution and the sorbed metal ions were eluted with 0.1 N HCl. 5 ml fractions were collected and were analyzed for metal ion concentration by atomic absorption spectrophotometry.

The quantitative separation of copper–cobalt and copper–nickel at pH 5.5 is shown in Figs. 2 and 3 respectively. Cobalt and nickel ions, being less strongly held by the resin, move down the column more rapidly and are collected before copper.

Fig. 2. Column separation of Co(II) and Cu(II) on GH-DVBS resin.

Fig. 3. Column separation of Ni(II) and Cu(II) on GH-DVBS resin.

Speciation of chromium (VI) and total chromium determination in welding dust samples by flow-injection analysis coupled to atomic absorption spectrometry

Louise Girard[1], Joseph Hubert*

Chemistry Department, University of Montreal, P.O. Box 6128, Station Centre-Ville, Montreal, Que., H3C 3J7, Canada

Abstract

We have studied the speciation of chromium (VI) in stainless-steel welding dusts. The approach used for the analysis of Cr(VI) and total Cr relies on a flow-injection analyzer (FIA) equipped with two different sequential detectors. The system measures Cr(VI), by colorimetry (with 1,5-diphenyl carbohydrazide) and total chromium content by flame atomic absorption spectroscopy (AAS). The extraction of the samples of welding-fume dusts is achieved in a buffer solution (acetic acid and sodium acetate at pH 4). This extraction procedure gives a 96% recovery of chromium (VI). The FIA–AAS system that has been described is also more sensitive, has a lower detection limit (0.005 μg ml^{-1}) and gives a better precision (< 1%) than other equivalent systems that have been previously described.

Keywords: Atomic absorption spectrometry; Chromium; Flow-injection analysis; Speciation; Welding dust

1. Introduction

Industrial development has brought many problems of environmental pollution and has also increased the exposure of workers to several toxic substances. Toxicological studies have shown that some essential and non-essential elements become toxic at a certain level of concentration. It has also been demonstrated that the degree of toxicity depends on the chemical form in which the toxic agent is present. In particular, it has been shown that the negative effect of an element on health could depend on its state of oxidation [1,2]. Chemical speciation has consequently become important. This type of analysis is difficult since, on the one hand, many precautions are necessary to avoid a modification of the analyte during the storage, processing and analysis of the sample and, on the other hand, it is obvious that the concentration of an element present in a particular oxidation state will be lower than, or at the very most equal to, the total concentration of the analyte.

[1] Present address: Chemistry and Biochemistry Department, University of Moncton, Moncton, N.B., E1A 3E9, Canada;

We have been particularly interested in the speciation of chromium. For this element, it is well known that the most toxic form is the hexavalent oxidation state. The high toxicity is related to its ability to cross the cell membrane and to its strong oxidation properties. Chromium (VI) compounds are widely used in industrial processes such as tanning, painting, plating, welding and metallurgy. Since welders are an important target group, we have chosen, as a typical sample, the welding dusts generated by the fumes of the stainless-steel welding process.

The chemical composition and physical form of this type of sample are extremely complex and variable. In addition, the solubility of the species found in welding-fume dusts is variable according to its chemical form and can change in a few hours or months following the time of sampling [3]. For chromium (VI) speciation several studies on extraction procedures have been reported. They rely on extractions under acidic [4–6], neutral [7] or basic conditions [8,9].

Several methods have been investigated for the speciation of Cr(VI): liquid chromatography, solvent extraction, flow-injection analysis, etc. [10,11]. The approach that we have used for the analysis relies on a flow-injection analyzer (FIA) equipped with two different sequential detectors. In this work, we will determine Cr(VI) and total chromium content in samples of welding fume dusts. The system will measure Cr(VI) by colorimetry and total chromium content by flame atomic absorption spectroscopy (AAS).

The reaction of Cr(VI) with 1,5-diphenyl carbohydrazide (DPC) is one of the best colorimetric methods for the determination of hexavalent chromium. The reaction is rapid and specific and, under proper acidic conditions, the ligand reacts little with the other transition metals. Furthermore, elements that are complexed by DPC have a different color to the Cr(VI) complex and this minimizes the risks of interference during the colorimetric determination. In acidic solution, DPC reacts with Cr(VI) to form an intense violet complex according to

$$2\,CrO_4^{2-} + 3\,H_4L + 8\,H^+ \rightleftharpoons$$

$$[Cr(III)(HL)_2]^+ + Cr^{3+} + H_2L + 8\,H_2O$$
where H_4L represents the DPC and H_2L the 1,5-diphenyl carbazone. The colored complex is believed to be a chelate of Cr(III) and 1,5-diphenyl carbazone [12]. The molar absorptivity of the chromium complex is of the order of 84 000 1 M $^{-1}$ cm $^{-1}$ at 540 nm. The direct reaction of the chromium (III) with H_2L is difficult in an aqueous medium and should not form another complex that could interfere in the analysis [12,13]. When the reaction is used for quantitation, it is necessary to study the possible interferences that can result from the reactions between the ligand and other elements or by a secondary reaction with the ligand under its oxidized form. The colorimetric reaction with DPC is the method used by Occupational Health Agencies in Canada and in the USA. The sequential determination of chromium (VI) and chromium (III) by FIA–AAS was described by Lynch et al. [14].

In this paper, we describe the FIA system that we have developed. The original system was based on the prototype developed by Lynch et al. [14]. This system has been modified and highly optimized to allow the speciation of chromium (VI) in stainless-steel welding-fume dust samples. The system has been fully automated, and its analytical performance and potential interferences were assessed. Finally, the method has been used for the analyses of welding-fume dusts.

2. Experimental

2.1. Instrumentation

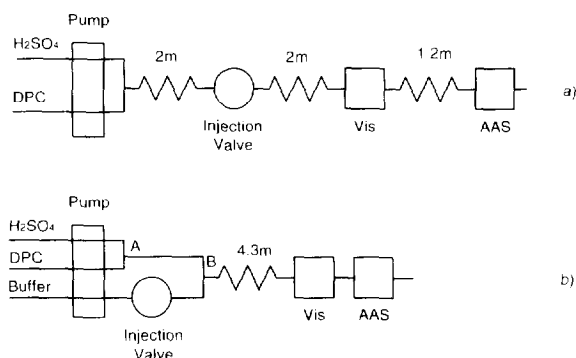
The FIA set-up used by Lynch et al. [14] and our system are shown in Fig. 1. The peristaltic pump is an eight-channel pump (Gilson, Villers-Bel, France) that has been modified to allow microcomputer control. The computer can also control the injection via a three-way pneumatic rotary valve (Rainin, Woburn, MA). The sampling loop can be filled either by a second peristaltic pump or with an automatic sampler. Two detectors are used: a UV–visible spectrophotometer (model 100-20, Hitachi, Tokyo, Japan) equipped with flowthrough micro-cell (Model 178.12 QS, Helma, Forest Hill, NY) and an


Fig. 1. Schematic representation of the FIA configurations: (a) used by Lynch et al. [14]. (b) used in this paper.

atomic absorption spectrometer (Model 2380, Perkin-Elmer, Norwalk, CT). An IBM-XT computer controls the pump and the injector and ensures instrument control and data acquisition. Control and data acquisition are done through a parallel digital interface (Model PI012, Metrabyte Corp., Taunton, MA). All the control and data acquisition hardware and software were developed in our laboratory. The optimized operating conditions are given in Table 1.

2.2. Reagents and solutions

All chemical products and solvents are of analytical grade. A 1000 μg ml⁻¹ standard solution

in Cr(VI) is freshly prepared from potassium dichromate, while the 1000 μg ml⁻¹ standard solution of Cr(III) comes from BDH (Montreal, Que., Canada). Diluted standard solutions are freshly prepared before each analysis. Solutions of potential interfering ions are prepared from 1000 μg ml⁻¹ standard solutions (BDH) or from the chloride or nitrate of the element of interest. The concentrated sulfuric acid ("Instra-analyzed"; Baker, Montreal, Que., Canada) is certified to contain < 0.0002 μg ml⁻¹ chromium. Solutions of DPC are obtained by dissolving the appropriate quantity of products in 100 ml of acetone. The volume is then completed to 1 l with the purified water (deionized, filtered on a carbon bed and with a Millipore filter 10 μm). The solutions are kept in the dark to avoid their decomposition. All containers are cleaned by soaking in a 50% nitric acid solution for at least 24 h and thoroughly washed with purified water before use.

2.3. Choice of the sampling membrane

Two membranes are usually used for sampling of the welding-fume dusts. The first is a filter made of mixed cellulose ester (FECM) and the other is a polyvinyl chloride membrane (PVC). Both membranes have a 8 μm porosity. The effect of membrane composition on the chromium speciation was evaluated using diluted standard solutions as samples. The solution containing the analyte is deposited on the different membranes and is dried overnight. The samples contain 2 and 20 μg of Cr(VI). Three successive extractions are performed with volumes of 5, 3 and 3 ml of an acetate buffer solution (pH 4). During the extractions the solution and membrane are first shaken manually and then placed in an ultrasonic bath for 5 min. The three extracts are then mixed, filtered and analyzed.

2.4. Generation of the welding-fume dust samples

The welding-fume dust samples are generated under rigorously controlled conditions to obtain deposits which are similar in terms of mass and composition. A special dust generation hood is used. The welding fumes are generated from a

Table 2
Typical composition of a stainless-steel welding rod[a]

Element	Fe	Cr	Ni	Mo	Mn	Si	C	P	S	Cu	V
Composition[b] ($\%$ w/w)	65.4	18.8	11.5	2.4	1.5	0.3	0.04	0.03	0.01	0.01	<0.01

[b] Values provided by the manufacturer.

welding rod and are aspirated through a membrane to collect the fine dust particles. The system is built to produce the same flow rate over the whole surface of the membrane to insure the uniformity of the deposit. A stainless-steel welding rod with a 2.4 mm diameter (Model E316-16, Arcweld) is used. The description and composition of the welding rod used are presented in Table 2. The diameter of the membrane is 293 mm and this allows collection of a sample with a large surface that can be subdivided into several smaller identical sub-samples. A system of rings is used to maintain the membrane and to mask its external part. This masked section is not in contact with generated fumes and serves as a blank for weightings and analyses. From the membrane several samples are punched in both the exposed and non-exposed zones. Approximately 20 blanks and 40 samples are thus obtained from one membrane. The position of each of these small membranes is noted to allow us to group the samples coming from different parts of the membrane in order to minimize the error that could be produced by heterogeneity of the deposit. The dust particle mass for each sample is obtained by subtracting the average mass of the blanks from the sum of the sample and filter masses.

2.5. Preparation of the welding dust samples

For the preparation of the standards, samples and blanks, all the glassware, polyethylene containers and pipette tips are cleaned by soaking in nitric acid (20% (v/v)) for at least 24 h and rinsed with purified water. Each membrane is inserted in a sample tube to which an 8 ml aliquot of an acetate buffer solution (pH 4) is added. The sample tube is hermetically closed, vigorously shaken by hand and, then left in an ultrasonic bath for an

hour. The solution is then filtered (0.45 μm filter, Millipore, Bedford, MA) to eliminate residual particles. Some of the samples are digested according to the standard analytical method 6-1 of the "Institut de Recherche en Santé et Sécurité" (IRSST) of Québec [15]. This method used a hot digestion with concentrated nitric acid followed by concentrated hydrochloric acid for complete dissolution of the sample.

2.6. Interference studies

To evaluate the level of interference, a series of solutions is prepared at three concentrations (10, 50 and 200 μg ml^{-1}) of the potential interfering ion and with a Cr(VI) concentration of 0.1 μg ml^{-1}. The potential interfering species examined are Co(II), Cr(II), Fe(II), Fe(III), Ni(II), Pb(II), V(V) and Mo(VI). The molar ratio of DPC to Cr is approximately 3200.

3. Results and discussion

3.1. FIA development and optimization

In the initial system proposed by Lynch et al. [14] (Fig. 1a) the injection valve is located directly in the reagent channel. Consequently, the reaction begins at both ends of the sample plug, then progresses towards the central part of the sample plug. In our system (Fig. 1b) we have modified the FIA configuration, firstly to allow for a more efficient (turbulent) mixing of the reagents and the sample, and secondly to prevent the problems related to the difference in refractive index between the carrier and the sample plug. A third tube is used to bring the sample or the blank to point B where the solutions are more efficiently

Table 3
Analytical performances of the FIA systems

Parameter	System[a]			
	A	B	C	D
Sensitivity (ml g⁻¹)	0.020	0.244	0.369	0.490
Dynamic range (g ml⁻¹)	0.1 20	0.01–2	0.01 2	0.01 1.5
Detection limit (g ml⁻¹)		0.005	0.005	0.002
Precision (%)[b]	1.6 (8)	0.8 (0.5)	0.6 (0.5)	1.3 (0.4)
Reproducibility	4 (8)	0.2 (0.5)	0.6 (0.5)	1.3 (0.4)
Number of measurements	16	10	3	5

[b] Values in parentheses are the chromium concentrations (g ml⁻¹).

mixed. This channel provides a more constant composition for the carrier flow and therefore avoids the problems related to the change in refraction index.

A standard optimization procedure of the FIA was performed. The reaction coil length (2.3–5.3 m), the reagent concentrations (H_2SO_4:0.036–0.2 M, DPC:0.016–0.057 M), the reagent flow rate ratio, the total flow rate, the coil temperature (20–60°C), the sample volume (30–400 μl) and the stopped flow time (0–60 s) were optimized. The range of the experimental parameters that has been investigated was limited by instrumental constraints (coil length), solubility problems (DPC concentration), Cr(VI) stability (H_2SO_4 concentration) and solvent boiling point (temperature). The optimized operating conditions of the FIA system are given in Table 1.

3.2. Analytical performances

The analytical performances were evaluated on synthetic samples to allow their comparison with previously reported data. The results obtained after optimization are reported in Table 3. The calibration curves were obtained from six standard solutions. For manual operation, the analytical sensitivity and reproducibility are higher than those reported by Lynch et al. [14]. The increase in sensitivity can be explained by a combination of several factors: a smaller dispersion obtained with a tube of smaller inside diameter, a different manifold and a careful optimization resulting in a

higher reagent concentration, the optimization of the ratio of the flow rates, reactor length and the increase in temperature. Since the sensitivity is increased by a factor of 10, the linear range is shifted toward lower concentrations from 0.01 to 2.00 μg ml⁻¹. The spectrophotometric detector is saturated if the concentration of Cr(VI) is raised to 3 μg ml⁻¹. The detection limit is 0.005 μg ml⁻¹ and the precision is excellent with a relative standard deviation of 0.8% at a concentration of 0.5 μg ml⁻¹. This represents a significant improvement compared to a value of 1.6% at 8 μg ml⁻¹ observed by Lynch et al. [14].

Microprocessor control of the pumping system allows a more precise and complex flow control and results in improved analytical performances (Table 3, columns C and D). The use of a stopped flow mode allows an increase of a factor of two in sensitivity. With a dynamic range up to 1.5 μg ml⁻¹, the sensitivity is 0.49 ml μg⁻¹. The precision is 0.5% at a concentration level of 0.4 μg ml⁻¹ and the limit of detection is 0.002 μg ml⁻¹ of chromium (VI). The sensitivity has increased by a factor of 25 compared to the results of Lynch et al. and the detection limit has decreased from 0.01 to 0.002 μg ml⁻¹. In addition, the sample-to-sample reproducibility is excellent.

3.3. Interference studies

Interferences can originate from two sources. The first type occurs when another element is complexed by DPC and the resulting complex has

an absorption band located at the same wavelength as the chromium complex. In this case, a positive interference occurs which will increase the absorption of the solution. This type of interference is a function of the concentration of the interfering elements and ther relative stability of their complexes with DPC. The second type of interfering species reacts with Cr(VI) and reduces it to Cr(III). Since chromium(III) has a small affinity for DPC the analytical signal will decrease. This interference is not only a function of the concentration levels, but also a function of pH and reaction time.

In our case, we wish to analyze stainless-steel welding-fume dusts and the elements that might be present in the sample are [4,6]: Fe, Ni, Mo, Mn, Si, Cu, Ca, Na, Ti, Co and V. According to the type of welding rod used, the concentrations and chemical forms of these elements can vary from sample to sample. The known interfering elements for the Cr–DPC system are Fe(III), Cu(II), Ni, V(VI), Pb, Cr(III), Sn(IV), Mo and Hg [16]. To assess the level of interference, a series of solutions of the interfering element are prepared at three concentrations (10, 50 and 200 μg ml^{-1}) with a constant Cr(VI) concentration of 0.1 μg ml^{-1}. The molar ratio of DPC to Cr is approximately 3200. The results obtained from the interference studies are given in Table 4.

For the trace elements (Co, Cu, Pb, V) present in stainless-steel welding rod the interferences are absent or negligible. Among the major elements (Cr, Fe and Mo), the effect of Mo(VI) can be neglected since this element will be present at low concentrations in the sample. In the case of Cr(III), a positive deviation of 20% is observed when its concentration is 500 times higher than that of Cr(VI). This ratio represents an extreme case which is not found in 'real' stainless-steel welding dusts. At lower levels (100 times or more) the interference is 2% or less. Iron(II) is a particular case since its shows a strong negative influence at molar ratios up to approximately 500 and a positive interference at higher molar ratios (1800). The effect of iron(II) can be explained in two ways: (i) Fe(II) can easily reduce Cr(VI) and induce a decrease in

absorbance; and (ii) Fe(III) obtained by oxidation, or the excess of Fe(II), can react with DPC and absorb moderately at the wavelength of analysis, producing a positive interference. Fortunately, high concentrations of iron(II) are not found in stainless-steel welding dusts [4]. Iron(III) also gives interferences and therefore the presence of iron could cause significant problems for the determination of Cr(VI) if present at high concentration. Fortunately iron is poorly extracted from the sample and the analysis is manageable (see Section 3.5.3).

Table 4
Interference studies for the chromium (VI) analysis

Species	Concentration (mg l^{-1})	Mass ratio	Molar ratio	Interference factor[a]
Co(II)	10	100	90	0.96

3.4. Sequential determination of chromium (VI) and total chromium by FIA–AAS

The coupling of the FIA system to AAS imposes a certain number of constraints. To avoid interferences of acids and other elements in the AAS determination of chromium a nitrous oxide–acetylene flame is used and the optimal conditions are reported in Table 1. From previous studies, it was shown that the signal intensity in AAS is different for chromium (VI) and chromium (III). To verify the importance of this effect, several solutions containing a total chromium concentration of 20 μg ml^{-1} made up of varying amounts of chromium (III) and chromium (VI) have been prepared. The maximum deviation is less than 2% under our optimal conditions, and consequently no effects of the oxidation state of chromium on the signal are observed. The coupling of the FIA to the AAS nebulizer sets the uptake rate of the nebulizer to 3.7 ml min^{-1}, without any loss in signal compared to a free uptake. The precision obtained for the peak height measurements is satisfactory: 0–1.8% for a concentration range of 0–32 μg ml^{-1}.

The calibration curves obtained for the sequential determination of chromium (VI) and total chromium are shown in Fig. 2.

3.5. Analysis of welding-fume dust samples

3.5.1. Comparison of the membranes used for the sampling

Two membranes are used to sample the welding-fume dusts: a filter of FECM and a PVC membrane. The first membrane is normally used with an acidic digestion for total dissolution of the whole sample and the membrane. In Table 5 the recoveries obtained with the two membranes are presented. The results obtained with the FECM membrane are very poor in terms of recovery. The loss of Cr(VI) can result from the filtration of the solution or loss by reduction of Cr(VI) [5]. The recoveries on the PVC membrane are excellent; they show that the membrane has no particular affinity for the analyte and the former can then be entirely recovered. This membrane is stable and chemically inert but is difficult

to wet. The extraction has therefore to be undertaken with care to ensure that the sample is in good contact with the extraction solution. The best extraction method consists of introducing the membrane in a sample tube that can be closed and to shake manually followed by shaking in an ultrasonic bath. The sample is then filtered.
Fig. 2. Calibration curves for (a) Cr (VI); (b) total Cr.

3.5.2. Extraction from the welding-fume dusts

A stainless-steel welding rod allows generation of a sample containing chromium and iron together; iron being the element that presents the greatest potential for interference. The composition of the welding rod is given in Table 2. To accomplish the speciation of Cr(VI) it is essential that this oxidation state be preserved during the entire analytical procedure. In addition, a complete extraction of chromium with minimal extraction of elements that could interfere with the analysis is also desirable.

The solubility of the different chemical forms of chromium depends on the pH. At very acidic pH (< 1), the majority of species are soluble, but Cr(VI) is reduced to Cr(III) at any pH lower than 4 [4,6]. Furthermore, the solubility of Cr(III) is at its maximum at a pH value less than 5. The optimum extraction pH range is therefore between 4 and 5. at this value, the major metals present in fume dusts, such as Fe, Mn and Ni, are slightly soluble [4] and will be extracted only slightly. Several solutions were evaluated for the extraction and the results obtained are shown in Table 6. A recovery of 100% is obtained with a total digestion in HNO_3–HCl. In this series of samples, the chromium is extracted with a recovery of ≥ 91% in all tested solutions and, as indicated by the standard deviation, no method of extraction is superior to the other methods in terms of the quantity of extracted analyte. However, extraction with an acetic acid and sodium

Table 5
Chromium (VI) recovery

[b] Total digestion.
[c] All the recoveries were measured on five samples with this exception where three samples were measured.

acetate buffer at pH 4 is far more advantageous in terms of extract stability. A study of the stability of Cr(VI) in this acetate buffer has shown that the concentration of the analyte is stable for more than 24 h. In addition, the same buffer is used as the matrix for the standard solutions and as the FIA carrier flow.

The detection limit for the determination of Cr(VI) by FIA is excellent (0.005 μg ml^{-1} or 1.5 μg); the dynamic range is from 0.005–1.5 μg ml^{-1}. The detection limit with AAS is poorer than normally observed (0.3 μg ml^{-1} or 85 μg), which can be explained by the sample dilution and the small sample volume (300 μl). The short-term precision is 0.5% and the reproducibility of a series of five measurements is 1.3% at a concentration level of 0.4 μg ml^{-1}. The precision for the total chromium determination by AAS does not exceed 2%.

To demonstrate that the method developed can be used in occupational health, Table 7 shows the concentrations of chromium in air equivalent to the lower limit of quantification and to the upper limit of the dynamic range for different sample volumes. Generally volumes of 180–600 l of air are sampled for the determination of total Cr and Cr(VI) respectively. Obviously an increase in the volume of air sampled will result in a lower quantification limit. The legal norms for total chromium and hexavalent chromium concentrations generally accepted by the Canadian and

Table 7
Equivalent chromium concentration in air

Air volume (L)	Lower limit of Quantification (mg m^{-3})	Legal norm (mg m^{-3})	Upper limit of linearity (mg m^{-3})
600	0.037	0.5 Cr	0.67
600	0.00067	0.05 Cr(VI)	0.020
180	0.12	0.5 Cr	2.2
180	0.0022	0.05 Cr(VI)	0.067

[a] The quantification limit is 10 × the detection limit.
[b] All the calculations were made assuming a final solution volume of 8.0 ml and sampling volumes of 180 and 600 l of air.

American Occupational Health Organizations are given and are well within the range of quantification of the FIA system.

3.5.3. Determination of Cr(VI), total Cr and Fe in samples of welding-fume dusts

The analyses of Cr(VI), total Cr and Fe have been performed by different techniques to obtain a good estimate of the potential of the FIA system for the determination of the total chromium, extractable chromium and hexavalent chromium contents of samples. The results obtained are shown in Table 8. Two processing procedures are used for the samples: (i) a complete digestion that allows the determination of the total chromium content; and (ii) an extraction with an acetate buffer (pH 4) which allows the determination of the extractable chromium.

First, the results obtained by FIA are compared with those obtained by well-known method for the speciation of chromium by complexation of

Table 8
Welding-fume dust analyses

Analyte	Concentration (mg g^{-1})	Measurement method
Total Cr after digestion	30 (6)[a]	AAS
Total Cr after extraction	25 (4)[b]	AAS
Extractable Cr(VI)	22.5 (0.6)[b]	DPC-FIA
Total Fe after digestion	34 (7)[a]	AAS
Extractable Fe	7.5 (3)[a]	AAS

[a] Mean and (standard deviation) for five samples.
[b] Mean and (standard deviation) for three samples.

Cr(VI) with ammonium pyrrolidine dithiocarbamate (APDC) followed by an extraction with 4-methylpentan-2-one (MIBK) and determination by AAS [16]. The concentration found by FIA in welding-fume dusts for Cr(VI) is 22.5 mg g^{-1} and is within the range of the value found by complexation with APDC (23 ± 3 mg g^{-1}). However, the precision obtained by the DPC-FIA method is better than that obtained by the other method.

The average quantity of total chromium is of the order of 30 mg g^{-1}. The greatest part of this chromium is in an extractable form (25 mg g^{-1}) and, as expected, the extractable chromium is mainly in its hexavalent form (22.5 mg g^{-1}).

From these measurements, it appears that only 83% of chromium is extracted from the sample. The proportion of extractable chromium varies with the fume samples and gives an indication of the variability of the composition of the welding-fume dusts. In our case, the two series of fume dust samples (Tables 7 and 8) have been generated at different times, and in different amounts, but from the same welding rod. Thus it is not suprising to find that the chemical composition varies not only with the composition of the welding rod but also as a function of the welding parameters used (voltage, current intensity, etc.) [17].

To be able to judge the quality of the extraction conditions used in terms of their potential to produce iron interferences, we have measured the portion of iron that is extracted. The quantity of iron contained in the sample is 34 mg g^{-1} and the amount of iron that is extracted in only 7.5 mg g^{-1}. This amount of iron would not cause any serious interference problem since, as indicated earlier, this interference is only important when the concentration of iron is about 100 times greater than that of Cr(VI) and when iron is in its divalent form (which is not the case here).

4. Conclusion

Elemental speciation requires a great specificity of the method of analysis and control of the chemical form of the analytes during the whole analytical procedure. The method and analyzer

that we have developed meet these demands. The extraction of the samples of welding-fume dusts in a buffer solution (acetic acid and acetate of sodium at pH 4) has proven comparable to that with other extraction solutions. The main advantage of this buffer is that it minimizes the extraction of iron and avoids the reduction of Cr(VI). The FIA–AAS system that has been described is also more sensitive, has a lower detection limit and gives a better precision than the system that developed by Lynch et al. [14].

Aqueous complexing of nickel and zinc with 3-(N-morpholino)propanesulfonic acid and the solubility products of nickel and zinc hydroxides

Simon R. Poulson*, James I. Drever

Department of Geology & Geophysics, University of Wyoming, Laramie, WY 82071-3006, USA

Abstract

Phosphate and carbonate buffers serve as excellent pH buffers at circumneutral values of pH, except for systems requiring significant concentrations of heavy metals, which are severely restricted by the low solubilities of heavy metal phosphates and carbonates. 3-(N-morpholino)propanesulfonic acid (MOPS; pK_a 7.2) is a suitable replacement buffer at circumneutral values of pH. However, only limited data are available concerning aqueous complexing involving MOPS. Aqueous complexing of nickel and zinc with MOPS has been investigated by the solubility method, using the sparingly soluble solids $Ni(OH)_2$ and $Zn(OH)_2$. Log K_{sp} values of -15.9 and -16.6 have been determined for $Ni(OH)_2$ and $Zn(OH)_2$ respectively. Experiments with MOPS indicate that there is negligible complexing between Zn and MOPS, but that significant Ni–MOPS complexing occurs, such that $Ni^{2+} + OH^- + MOPS^- \rightleftharpoons Ni(OH)MOPS^\circ$; log $K = +7.0$.

Keywords: Aqueous complexing; 3-(N-morpholino)propanesulfonic acid; Nickel; Solubility products; Zinc

1. Introduction

Carbonate and phosphate buffers have long been used as buffers for circumneutral values of pH. Correspondingly, a large database of aqueous complexation constants exists for carbonate and phosphate species, which has been incorporated into aqueous speciation programs such as MINTEQA2 [1] and WATEQ4F [2]. However, carbonate and phosphate buffers are not suitable for all experiments. In particular, the low solubilities of

heavy metal carbonates and phosphates (Table 1) severely limit the range of heavy metal concentrations that can be used in experiments buffered with either carbonate or phosphate buffers. This problem is particularly acute for researchers investigating the toxicity of heavy metals for various biological organisms, which frequently require circumneutral values of pH for growth. Alternative pH buffers with suitable values of pK_a have been made available by Good and co-workers [3–5]. However, only limited data are available concerning aqueous complexation between these buffers and metal cations.

* Corresponding author. Fax: + 1 307-766-6679.

The objective of this study is to evaluate aqueous complexation constants for nickel and zinc with the buffer 3-(N-morpholino)propanesulfonic acid (MOPS; $pK_a = 7.2$). The method employed to determine the aqueous complexation constants involved measurement of the solubilities of nickel and zinc hydroxides in the presence and absence of MOPS. Hence, the solubility products of nickel and zinc hydroxides were also determined during the course of the experiments.

2. Experimental

Values of aqueous complexation constants are commonly derived by potentiometric titration [3,6]. However, the low solubilities of heavy metal hydroxides (Table 1) at circumneutral pH demand low metal concentrations, which would lead to reduced sensitivity during titration. The approach used in this study was to compare the solubility of nickel and zinc hydroxides with and without the presence of MOPS. Increased solubility in the presence of MOPS is attributed to metal-MOPS complexing, while decreasing solubility in the presence of MOPS is attributed to precipitation of a metal-MOPS phase.

All experiments were designed to avoid the presence of carbonate in experimental solutions, in order to simplify the experimental system, to avoid possible metal-carbonate complexing, and to prevent the possible precipitation of metal carbonates. All solutions were prepared with water which had been purged of CO_2 by boiling and gassing with N_2 [7]. All experiments, pH measurements, and sampling of solutions were conducted

$Cu_3(PO_4)_2$	−36.9	$CuCO_3$	−9.9

in a glove bag purged with N_2. The solubilities of nickel hydroxide (Johnson Matthey Chemical Co.) and zinc hydroxide (Aldrich Chemical Co.) were determined at 22°C over a pH range of approximately 7–8.5, with $NaNO_3$ present in concentrations between 0.002 and 0.2 molal. pH was adjusted by the addition of HNO_3. Similar experiments were conducted with MOPS concentrations between 0.0008 and 0.2 molal. Experiments were conducted in 60 ml polyethylene bottles. pH was measured with an Orion Ross Sure-Flow combination electrode and a Beckman Φ21 pH meter, which was calibrated using pH 7 and 10 buffers. Samples were taken using a syringe, and filtered through a 0.45 μm syringe filter. Samples were acidified with HNO_3, and diluted where appropriate. Nickel concentrations were measured using a Thermo Jarrell Ash 3000 inductively-coupled plasma spectrophotometer, and zinc concentrations were measured using a Perkin-Elmer 2380 atomic absorption spectrophotometer. Samples were periodically sampled until repeated sampling indicated negligible changes in pH and metal concentration between sampling events. Equilibration time was approximately 70 days.

The activities of Ni^{2+}(aq) and Zn^{2+}(aq) were calculated using the program MINTEQA2 [1] for all experiments conducted in the absence of MOPS. A comparison of the MINTEQA2 and WATEQ4F [2] databases revealed that the relevant data used in these calculations are the same in each case. Combined with pH measurements, these data permit calculation of K_{sp} values for nickel and zinc hydroxides, which were added to the MINTEQA2 database, together with the K_a value for MOPS [4]. Measured metal concentrations in experiments conducted in the presence of MOPS were compared with calculated metal concentrations assuming no metal-MOPS interaction.

MINTEQA2 speciation calculations performed in this study require the activity of H^+ (provided by pH measurement), and do not require a conversion into H^+ concentration values. Equilibrium constants calculated in this study are thermodynamic constants. Aqueous activities have been calculated using the MINTEQA2 speciation program for a reference state of infinite dilution, accounting for speciation and correcting for ionic strength using the Davies equation.
Fig. 1. Calculated values of $\log a_{Ni^{2+}}$ vs. $\log a_{OH^-}$ for solutions saturated with $Ni(OH)_2$. Ionic strength $NaNO_3 = 0.002–0.2$ M.

3. Results

3.1. Solubility products

Values of $\log a_{Ni^{2+}}$ vs. $\log a_{OH^-}$ for Ni hydroxide solubility experiments conducted in the absence of MOPS are presented in Fig. 1. A linear least-squares fit for experiments with ionic strength between 0.002 and 0.02 molal yields:

$$\log a_{Ni^{2+}} = -15.42 - 1.92(\log a_{OH^-}) \tag{1}$$

with a correlation coefficient $R^2 = 0.999$. Using Eq. (1) for a value of $\log a_{OH^-} = -6.5$ gives $\log K_{sp}[Ni(OH)_2] = -15.9$. Data from experiments with an ionic strength of 0.2 molal yield systematically lower values of $a_{Ni^{2+}}$ for a given value of $\log a_{OH^-}$, although a linear least-squares fit yields an excellent correlation coefficient ($R^2 = 1.000$). The different values obtained from the high ionic strength experiments are attributed to incorrect modelling of activity coefficients using the Davies' equation in MINTEQA2 at these ionic strengths.

Values of $\log a_{Zn^{2+}}$ vs. $\log a_{OH^-}$ for Zn hydroxide solubility experiments conducted in the absence of MOPS are presented in Fig. 2. A linear least-squares fit for experiments with ionic strength between 0.002 and 0.02 molal yields:

$$\log a_{Zn^{2+}} = -16.70 - 2.01(\log a_{OH^-}) \tag{2}$$

with a correlation coefficient $R^2 = 0.999$. Using Eq. (2) for a value of $\log a_{OH^-} = -6.5$ gives $\log K_{sp}[Zn(OH)_2] = -16.6$. As in the case of the Ni hydroxide experiments, data from experiments with an ionic strength of 0.2 molal yield systematically lower values of $\log a_{Zn^{2+}}$ for a given value of $\log a_{OH^-}$, although a linear least-squares fit again yields an excellent correlation coefficient ($R^2 = 0.998$).

These values of K_{sp} compare favorably with previous measurements of K_{sp}. Compiled measurements [8,9] of $\log K_{sp}[Ni(OH)_2]$ have a range of values between -13.8 and -18.0, and an averaged $\log K$ value of -15.6, compared to a value of -15.9 measured in this study. Compiled measurements [8,9] of $\log K_{sp}[Zn(OH)_2]$ have a range of values between -13.2 and -18.0, and an averaged $\log K$ value of -16.3, compared to a value of -16.6 measured in this study.

3.2. Complexing with MOPS

Solution speciation calculations were performed for experiments conducted in the presence of MOPS and in equilibrium with Ni or Zn hydrox-
Fig. 2. Calculated values of $\log a_{Zn^{2+}}$ vs. $\log a_{OH}$ for solutions saturated with $Zn(OH)_2$. Ionic strength $NaNO_3 = 0.002$–0.2 M.

ide solid. Calculations at $I = 0.2$ molal were amended with an empirical correction factor to account for the inability of MINTEQA2 to accurately model activity coefficients at this ionic strength, although this correction factor was small. Using the values K_{sp} measured previously, calculated values of the saturation index with respect to $Zn(OH)_2$ are plotted vs. $a_{Zn^{2+}}$ in Fig. 3, and the calculated values of the saturation index with respect to $Ni(OH)_2$ are plotted vs. $\log a_{Ni^{2+}}$ in Fig. 4. The saturation index of $M(OH)_2$ is given by
Saturation index

$$= \log\{a_{M^{2+}} \cdot (a_{OH})^2 \, K_{sp}[M(OH)_2]\} \qquad (3)$$

Fig. 3 demonstrates that there is no systematic deviation of the value of the saturation index with respect to $Zn(OH)_2$ for experiments conducted in the presence of MOPS. The spread of saturation indices around zero (i.e. perfectly measured equilibrium) is similar for experiments conducted with or without MOPS. This indicates that the solubility of $Zn(OH)_2$ is not affected by the presence of MOPS, which implies that negligible Zn–MOPS complexing is taking place.

In contrast to Zn, Fig. 4 demonstrates that there is a deviation towards positive values of the saturation index with respect to $Ni(OH)_2$ for experiments conducted in the presence of MOPS, with the most positive values of the saturation index being associated with the highest concentration of MOPS. This indicates that the solubility of $Ni(OH)_2$ is increased by the presence of MOPS, and suggests that significant Ni–MOPS complexing is taking place. The measured Ni concentrations in the presence of MOPS are compared with the calculated Ni concentrations assuming no nickel–MOPS interaction, and the value of excess nickel is defined as

$$C_{Excess \, Ni} = C_{Measured \, Ni} - C_{Calculated \, Ni} \qquad (4)$$

Likely Ni–MOPS complexes include the simple 1:1 complex $NiMOPS^+$, and also the complex $Ni(OH)MOPS°$, as Ni forms a number of Ni–OH complexes. These complexes are formed accordingly:

$$Ni^{2+} + MOPS^- \rightleftharpoons NiMOPS^+ \qquad (5)$$

$$Ni^{2+} + OH^- + MOPS^- \rightleftharpoons Ni(OH)MOPS° \qquad (6)$$
If $NiMOPS^+$ is responsible for the increase in Ni concentration, then:

Fig. 3. Calculated values of log [saturation index $Zn(OH)_2$] for solutions with MOPS concentrations = 0–0.08 M.

$$a_{Excess\ Ni} = C_{Excess\ Ni} \cdot \gamma_{1\pm} \tag{7}$$

and a plot of $\log a_{Excess\ Ni}$ vs. $\log(a_{Ni^{2+}} \cdot a_{MOPS^-})$ should result in a straight line. If $Ni(OH)MOPS°$ is responsible for the increase in nickel concentration, then:

$$a_{Excess\ Ni} = C_{Excess\ Ni} \cdot \gamma_0 \tag{8}$$

and a plot of $\log a_{Excess\ Ni}$ vs. $\log(a_{Ni^{2+}} \cdot a_{OH^-} \cdot a_{MOPS^-})$ should result in a straight line. Values

of $a_{Ni^{2+}}$ and a_{MOPS^-} have been calculated using MINTEQA2, assuming that the fractions of Ni and MOPS present as the Ni–MOPS complex are small, i.e. values of $a_{Ni^{2+}}$ and a_{MOPS^-} are assumed to be unaffected by Ni–MOPS complexing. $\log(a_{Excess\ Ni})$ is plotted vs. $\log(a_{Ni^{2+}} \cdot a_{MOPS^-})$ and $\log(a_{Ni^{2+}} \cdot a_{OH^-} \cdot a_{MOPS^-})$ in Figs. 5 and 6. Linear least-squares fits give respectively:

Fig. 4. Calculated values of log [saturation index $Ni(OH)_2$] for solutions with MOPS concentrations = 0–0.2 M.
Fig. 5. Calculated values of $\log(a_{\text{Excess Ni}})$ vs. $\log(a_{\text{Ni}^2+} \cdot a_{\text{MOPS}^-})$.

$$\log(a_{\text{Excess Ni}}) = -0.20 + 0.81[\log(a_{\text{Ni}^2+} \cdot a_{\text{MOPS}^-})];$$

$$R^2 = 0.906 \qquad (9)$$

$$\log(a_{\text{Excess Ni}})$$

$$= 7.32 + 1.03[\log(a_{\text{Ni}^2+} \cdot a_{\text{OH}^-} \cdot a_{\text{MOPS}^-})];$$

$$R^2 = 0.969 \qquad (10)$$

The higher value of R^2, and the value of the slope

being very close to the expected value of one, both suggest that formation of the complex Ni(OH)MOPS° provides the best explanation of the experimental data, assuming that only one significant Ni–MOPS complex is formed. Hence:

$$K_{\text{Ni(OH)MOPS}°} = (a_{\text{Ni(OH)MOPS}°})/(a_{\text{Ni}^2+} \cdot a_{\text{OH}^-}$$
$$\cdot a_{\text{MOPS}^-}) \qquad (11)$$

Fig. 6. Calculated values of $\log(a_{\text{Excess Ni}})$ vs. $\log(a_{\text{Ni}^2+} \cdot a_{\text{OH}^-} \cdot a_{\text{MOPS}^-})$.

and substituting an intermediate value of $\log(a_{Ni^{2+}} \cdot a_{OH^-} \cdot a_{MOPS^-}) = -12$ into Eq. (10) yields a value of $\log K_{Ni(OH)MOPS^=} = +7.0$.

4. Discussion and conclusions

The extent of aqueous complexing between MOPS and Ni^{2+} and Zn^{2+} has been experimentally measured. Complexing between Zn and MOPS is negligible. Although complexing between Ni and MOPS is measurable, the extent of complexing is minor, especially for concentrations of MOPS used for the majority of biological experiments. An example calculation for a solution of 1 μM $Ni(NO_3)_2$ + 20 mM NaMOPS at pH 7 indicates that only 0.5% of the total Ni is present in solution as $Ni(OH)MOPS^\circ$.

The nature of the Ni–MOPS complex has not been determined, but is likely that complex formation is due to interaction of Ni^{2+} with the amine functional group present in MOPS. A systematic variation of metal–amine equilibrium constants across the transition metal series has long been known (the Irving–Williams order [10]). This results in the formation of stronger Ni–amine complexes than Zn–amine complexes, due to the crystal field/molecular orbital stabilization energy associated with the $3d^8$ electron configuration of Ni^{2+}, and the lack of any stabilization energy associated with the $3d^{10}$ electron configuration of Zn^{2+} [11]. This may explain why negligible Zn–MOPS complexing has been identified, while weak Ni–MOPS complexing has been measured.

Fluorimetric trace determination of cerium(III) with sodium triphosphate

Ayçiçek Akseli*, Yener Rakicioğlu

Department of Chemistry, Science and Letter Faculty, Istanbul Technical University, 80626 Maslak, Istanbul, Turkey

Abstract

Sodium triphosphate acts as a specific reagent for enhancing the fluorescence intensity of cerium(III). The purpose of this study was to investigate the spectrofluorimetric determination of trace amounts of Ce(III) in sodium triphosphate solution. The excitation and emission wavelengths are 303.5 nm and 353 nm respectively. Optimum sodium triphosphate concentration is found to be 0.074 g l^{-1} at room temperature. The fluorescence varies linearly with the concentration of cerium(III) in the range $0.001-45 \ \mu\text{g ml}^{-1}$. The detection limit is $9.4 \times 10^{-4} \ \mu\text{g ml}^{-1}$. The relative standard deviations for $30 \ \mu\text{g ml}^{-1}$ and $0.05 \ \mu\text{g ml}^{-1}$ Ce(III) in 0.074 g l^{-1} sodium triphosphate solution are 1.1% and 0.72% respectively. Quenching effects of other lanthanides and some inorganic anions are described. This method is a direct and rapid analytical method for the determination of Ce(III) in rare earth mixtures and cerium concentrates.

Keywords: Cerium determination; Fluorimetry; Molecular luminescence spectrometry; Sodium triphosphate

1. Introduction

The chemical properties of the rare earth elements are very similar. Consequently, it is difficult, and important, to find specific reactions for individual ions, especially in their mixtures.

The direct methods described in the literature for the fluorimetric determinations of cerium(III) are the fluorescence of Ce(III) in sulphate and chloride solutions at different pH [1–17], in perchloric acid and sulfuric acid medium [18], in perchloric acid [19] and phosphoric acid medium

[20], and the formation of Ce(III) complexes with hydroxyethylidenediphosphonic acid [21] and sulphonaphtholazo resorcinol [22], in hexametaphosphate solutions [23]. The indirect methods are the chemiluminescent reaction of lucigenin with hydrogen peroxide in the presence of cerium(III) [24], the decomposition of 2-[(8-hydroxy-5-sulpho-7-quinonyl)azo]-1,8-dihydroxy naphthalene-3,6-disulphonic acid with cerium(III) [25], and the oxidative reaction of cerium(IV) with an organic reagent [26–30]. In contrast, fluorimetric determinations of Ce(IV) with an organic reagent [31,32] and determinations of some inorganic and organic compounds with the cerium(IV)–cerium(III) system have been reported [33–35].

In this paper, the fluorescence properties of cerium(III) triphosphate are reported and a rapid and sensitive method for the determination of trace amounts of Ce(III) in solution is described.

2. Experimental

2.1. Apparatus

The fluorimetric measurements were carried out on a Perkin Elmer 204 fluorescence spectrophotometer with a 150 W xenon arc lamp. The fluorescence intensities of solutions were measured in 10 mm quartz cells. The excitation and emission slitwidths were 10 nm. The amplifier gain was adjusted according to the fluorescence intensity.

2.2. Reagents

Standard solutions of Ce(III) were prepared by dissolving $Ce(NO_3)_3 \cdot 6H_2O$ (Merck, "Extra Pure") and sodium triphosphate solution was prepared by dissolving $Na_5O_{10}P_3$ (Merck). Other reagents used were of analytical-reagent-grade and were at least 99.5% pure. All solutions were prepared by simply weighing and dissolving the undried chemicals. Ultrapure deionised water (Milli Q Millipore System) was employed for all dilutions.

2.3. Procedure

Apparent fluorescence excitation and emission spectra were measured at room temperature and optimum excitation and emission wavelengths were found from these spectra. A known amount of Ce(III) and 0.1 ml of 7.4 g l^{-1} sodium triphosphate were pipetted onto a 20 ml test tube. The mixture was diluted to 10 ml with deionized water. The fluorescence measurements were made at excitation and emission wavelengths of 303.5 and 353 nm respectively.

3. Results and discussion

3.1. Fluorescence spectra

Ce(III) fluoresces strongly in triphosphate solution when irradiated with ultraviolet light, and is the only lanthanide ion which is appreciably fluorescent under these conditions. Other lanthanide ions do not show any measurable fluorescence in this solution.

Fig. 1 shows the excitation and emission spectra of Ce(III) ion in 0.074 g l^{-1} sodium triphosphate solution. Maximum excitation and emission wavelengths are observed at 303.5 nm and 353 nm respectively.

Experimental results showed that Ce(III) in sodium triphosphate solution is more fluorescent than in solutions without sodium triphosphate, with sulfuric and hydrochloric acids. For sulfuric and hydrochloric acid solutions, we used optimum acid concentrations given in the literature [8,13]. These results are given in Table 1.

Fig. 1. Fluorescence spectra: (a) excitation; (b) emission. Curves (1): without sodium triphosphate; curves (2): with sodium triphosphate. Conditions: 30 μg ml^{-1} Ce(III) in 0.0074 g l^{-1} sodium triphosphate.

Table 1
Comparison of the fluorescence intensities of Ce(III) in different solutions. Excitation and emission wavelengths are 303.5 nm and 353 nm respectively

Concentration of Ce(III) (μg ml^{-1})	Fluorescence intensity			
	In pure aqueous solutions	In 39.2 g l^{-1} H$_2$SO$_4$ solution	In 255.5 g l^{-1} HCl solution	In 0.074 g l^{-1} sodium triphosphate solution
7.5	75	150	260	1800
15.0	150	300	520	3760
22.5	225	450	780	5760

3.2. Concentration of sodium triphosphate

The effect of sodium triphosphate concentration on the fluorescence intensity was studied for two different Ce(III) concentrations (30 μg ml^{-1} and 0.05 μg ml^{-1} Ce(III) respectively). Fig. 2 shows that maximum fluorescence intensity was obtained for 0.074 g l^{-1} sodium triphosphate.

3.3. Stability of fluorescence with time

The effect of time on the fluorescence intensity was investigated with 30 μg ml^{-1} and 0.05 μg
Fig. 2. Variation of fluorescence intensity with sodium triphosphate concentration. Conditions: (a) 30 μg ml^{-1} Ce(III); (b) 0.05 μg ml^{-1} Ce(III). Excitation wavelength: 303.5 nm; emission wavelength: 353 nm.

ml^{-1} Ce(III) in 0.074 g l^{-1} sodium triphosphate solutions. Fig. 3(a; curve 1) and Fig. 3(b; curve 1) show that the solutions were allowed to stand under normal laboratory conditions. Continuous irradiation (Fig. 3(a; curve 2) and Fig. 3(b; curve 2)) for 1 h causes reductions in the fluorescence intensity of 14.63% and 13.64% respectively.

3.4. Effect of pH

pH effect was studied in the range 1.35–10.80 by adjusting the pH with sulfuric acid or sodium hydroxide solution. The results shown in Fig. 4 indicate that the optimum pH range is 5.70–9.35. After studying a series of different buffer systems, it was found that only borax–hydrochloric acid buffer can be successfully used without causing any quenching. Nevertheless, in this study no
Fig. 3. Fluorescence intensity as a function of time. Conditions: 0.074 g l^{-1} sodium triphosphate solution. (a) 30 μg ml^{-1} Ce(III); (b) 0.05 μg ml^{-1} Ce(III). Curves (1): standing under normal laboratory conditions. Curves (2): continuous irradiation at 303.5 nm.
Fig. 4. Effect of pH on the fluorescence intensity. Conditions: 7.5 μg ml⁻¹ Ce(III) in 0.074 g l⁻¹ sodium triphosphate solution.

buffer was used because the pH of the solutions was always in the optimum range 5.70–9.35 during the entire procedure.
Fig. 5. Effect of temperature on the fluorescence intensity. Conditions: 15 μg ml⁻¹ Ce(III) in 0.074 g l⁻¹ sodium triphosphate solution.

3.5. Effect of temperature

As can be seen from Fig. 5, temperature effect is not pronounced between 10–50°C and room temperature is recommended.

3.6. Calibration graph

The calibration graph for the determination of Ce(III) was constructed under the optimum conditions. Excellent linearity was obtained over the range 0.001–45 μg ml⁻¹ Ce(III). The limit of detection is 9.4 × 10⁻⁴ μg ml⁻¹. It was calculated by multiplying the standard deviation of 16 blank measurements by three and dividing by the slope of the linear calibration curve. Table 2 lists the results of several methods used previously for the spectrofluorometric determination of cerium. It can be seen that the method proposed in this paper is the most sensitive.

3.7. Interferences

As can be seen from Table 3, when other lanthanides are present in relatively low concentrations in the sample no significant interference was observed.

The effects of La(III), Ho(III) and Lu(III) were also investigated. The amount of Ce(III) used is 15 μg ml⁻¹ in 0.074 g l⁻¹ sodium triphosphate solution. 20 μg ml⁻¹ La(III) did not show any interference, whereas 40.90% and 43.18% interferences were shown by 20 μg ml⁻¹ Ho(III) and 20 μg ml⁻¹ Lu(III) respectively.

The interference effects of diverse anions on the fluorescence intensity of 15 μg ml⁻¹ Ce(III) in 0.074 g l⁻¹ sodium triphosphate solution were also investigated. No interference was observed for 300 μg ml⁻¹ sulfate, nitrate, or chloride ions, whereas 30% interference was observed in the presence of 15 μg ml⁻¹ phosphate ions.

3.8. Application of the method

The procedure was applied to the determination of trace amounts of cerium in some synthetic mixtures. The results given in Table 3 indicate that the proposed method is suitable and can be successfully applied.

Table 2
Summary of several methods for the fluorimetric determination of cerium

Reagent	Limit of detection (μg ml^{-1})	Linear range (μg ml^{-1})	Ref.
H$_2$SO$_4$	–	$1.0 \times 10^{-3} - 1.0 \times 10^{-1}$	8
HCl	–	$1.4 \times 10^{-2} - 1.4 \times 10^{-1}$	13
Sulphonaphtholazoresorcinol	5.0×10^{-2}		22
Sodium hexametaphosphate	–	$1.0 \times 10^{-3} - 60$	23
Lucigenin (I)–H$_2$O$_2$ system		$8.0 \times 10^{-1} - 1.2$	24
Oxine-5-sulfonic acid		$1.0 \times 10^{-2} - 3.0$	26
Sodium-4.8-diamino-1,5-dihydroxyan-thraquinone-2,6-disulfonate		$2.0 \times 10^{-2} - 3.7 \times 10^{-1}$	27
1-amino-4-hydroxyanthraquinone		$1.0 \times 10^{-1} - 9.0 \times 10^{-1}$	28
Paracetamol	1.4×10^{-3}	$2.8 \times 10^{-2} - 1.12$	30
Sodium triphosphate	9.4×10^{-4}	$1.0 \times 10^{-3} - 45$	Present method

Table 3
Analysis of the synthetic mixtures in 0.074 g l^{-1} sodium triphosphate solutions

Mixture number	Mixture composition (μg ml^{-1})	Ce(III) found (μg ml^{-1})	Error (%)
1[a]	Ce(7.50), La(2.50), Pr(0.68), Nd(2.50), Sm(0.26), Eu(0.0075), Gd(0.30), Tb(0.10), Dy(0.12), Ho(0.03), Er(0.06), Yb(0.03), Lu(0.015), Tm(0.001)	7.43	0.93
2	Ce(10.00), Nd(5.00), Sm(2.00), Gd(2.00)	9.91	0.90
3	Ce(15.00), Sm(5.00), Tm(1.00), Yb(2.00)	14.85	1.00
4	Ce(22.50), Gd(5.00), Tm(2.00), Yb(2.00)	22.28	0.98
5	Ce(30.00), Dy(3.00), Sm(2.00), Nd(2.00)	29.73	0.90

[a]This mixture was prepared on the basis of relative concentrations of rare earths in Monazite mineral.

3.9. Precision

The precision was determined by measuring 16 solutions of the same sample 16 different times. The relative standard deviations of these measurements were 1.1% for 30 μg ml^{-1} and 0.72% for 0.05 μg ml^{-1} Ce(III) in 0.074 g l^{-1} sodium triphosphate solutions.

4. Conclusion

From the results presented it can be concluded that sodium triphosphate is a very suitable reagent and that the fluorimetric trace determination of Ce(III) with sodium triphosphate is a very easy, rapid, sensitive and inexpensive new method.

Calorimetry and potentiometry of chemical oscillations in Briggs–Rauscher reactions with simultaneous measurements of the produced oxygen volume[1]

Shuko Fujieda*, Hideko Ogata

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo 112, Japan

Abstract

The Briggs–Rauscher reaction is known as a nonlinear and non-equilibrium chemical oscillation reaction. The reaction solution is composed of malonic acid as organic substrate, hydrogen peroxide and iodate in sulphuric acid as oxidizing agent, and manganese (II) as metal catalyst. The calorimetric behaviour, in terms of the total heat Q and the heat evolving rate q for each chemical oscillation, was followed with the use of a heat exchange calorimeter of the batch type assembled by the authors. Simultaneously, the concentration of iodide ions produced as the intermediate species was measured as the potential difference E by the common potentiometric cell incorporated in the calorimeter and the released oxygen volume G was also observed by a simple flowmeter. The starting point of the peak on the curve of q against time t coincided with that in the curve of E against t. The switching concentration of iodide between radical and nonradical paths was calculated from literature values of rate constants. The heat evolving period of Q coincided with the period in the radical path. The curve of Q against t also coincided with that of G against t. The total volume of released oxygen was larger than that calculated from the stoichiometric reaction formula.

Keywords: Briggs–Rauscher reactions; Calorimetry; Chemical oscillations; Potentiometry; Produced oxygen volume

1. Introduction

The Belousov–Zhabotinskii (BZ) reaction is typical of nonlinear and non-equilibrium oscilla-

tion reactions and the reaction mechanism has been well studied [1]. In the best known BZ reaction, the oxidation of malonic acid by acidic bromate is catalyzed by the cerium (IV) salt or by ferroin (tris(1,10-phenanthroline) iron (II) complex).

The Briggs–Rauscher (BR) reaction was discovered in 1973 [2]. A mixture of hydrogen peroxide and iodate is used in sulphuric acid as the oxidizing agent, and manganese (II) ion is used as

the catalyst. Malonic acid (MA) is also used as the organic reaction substrate. The detailed reaction mechanism was studied in a series of reports [3–5]. The reaction process is more complex than that of the BZ reaction, as the BR reaction is composed of 30 elementary reactions which are divided into six steps. MA was expressed generally as RH [5].

In the stoichiometry, only reaction (1) may be relevant:

$$IO_3^- + 2H_2O_2 + RH + H^+ \rightarrow RI + 2O_2 + 3H_2O \tag{1}$$
However, reaction (1) is divided into reaction (2), reduction of iodate, and reaction (3), organic iodination:

$$IO_3^- + 2H_2O_2 + H^- \rightarrow HOI + 2O_2 + 2H_2O \tag{2}$$

$$HOI + RH \rightarrow RI + H_2O \tag{3}$$
Reaction (2) is derived from (I3) + (I2) + 2(D1) in Ref. [5] as a nonradical path, and also from 2(I5) + 4(M1) + 4(M2) + 2(O2) + (I4) as a radical path. The chemical oscillations may be caused by switching between these two paths. Reaction (3) is derived from (I1) + (C3) + (C4).

De Kepper and Epstein [6] demonstrated the phase diagrams of complicated intermediate compounds and distinguished the existence of oscillation and bistable steady states.

Nakanishi and Fujieda [7] developed heat exchange calorimetry [7]. Two vessels were fixed differentially in the water bath. Heat released in the reaction vessel was exchanged freely with the ambient water. The temperature change in each vessel was monitored via thermistors used as temperature sensors, and then converted to electric signals. The analogue computation was followed on line to obtain total heat effect Q and heat evolving rate q. As the bath water is controlled precisely within a narrow temperature range, chemical reactions can be conducted at almost constant temperature. Therefore, heat exchange calorimetry may be a very suitable method to follow the thermal behaviour in the BZ and BR reactions. Calorimetric studies using batch-type [8,9], flow-type [10] and continuous stirred tank reactors (CSTRs) have been reported for BZ reactions.

It appears that the reproducibility commonly used in analytical chemistry may be poor with respect to the period and amplitude of each chemical oscillation owing to delicate differences in experimental conditions, such as initial concentrations of each component, temperature and stirring rate. Therefore, simultaneous observations of chemical and physical quantities as far as possible are desired for an oscillation run.

In the present report, BR reactions of the batch type were studied to compare with the results of the BZ reactions. The heat exchange calorimeter was assembled, the fundamental concept and essential parts being almost the same as those reported previously [8]. The common potentiometric cell was incorporated. The Q and q values for every oscillation were observed. Simultaneously, the oscillation behaviour of the iodide ion produced as the intermediate species was monitored potentiometrically as E. The evolving rate of produced oxygen G and the total amount of released oxygen were measured with a simple apparatus.

2. Experimental

2.1. Reagents

All the reagents were of guaranteed grade and were used without further purification. The chemical oscillation systems were composed of potassium iodate, hydrogen peroxide, sulphuric acid, MA and manganese(II) sulphate, of which initial concentrations were in the ranges 0.040–0.080 M, 0.20–1.44 M, 0.018–0.071 M, 0.030–0.12 M and 0.0040–0.010 M respectively. As usual, deionized water was used after distillation. Solid MA was selected to start the oscillation reaction because of its rapid dissolution and ease of handling.

2.2. Apparatus

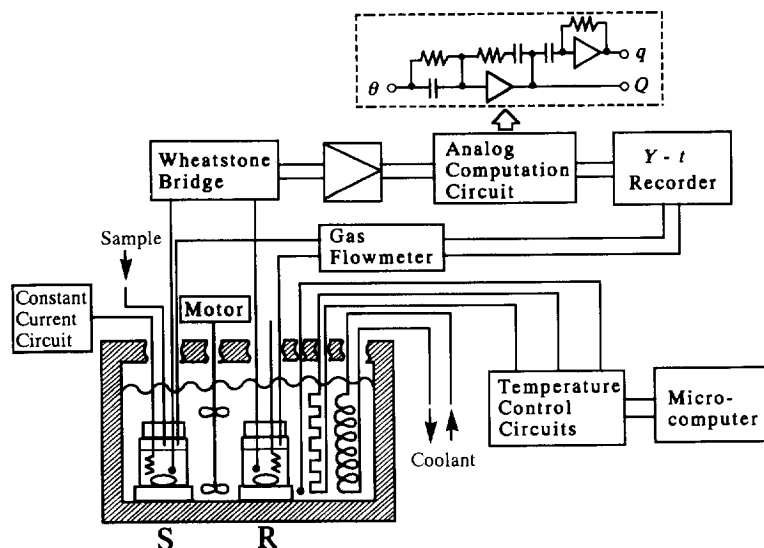
The block diagram of the assembled calorimeter system is shown in Fig. 1. An acryl box of 42 × 27 × 28 cm³ was used as the water bath and all surfaces were covered with thermal insulator boards 3 cm thick. About 28 dm³ of water was used in the bath, the temperature of the bath water being controlled by the previously reported


Fig. 1. Schematic diagram of the heat exchange calorimeter system for the batch run.

method [11] within ≤0.001°C at 25.0°C. Detailed illustrations of the sample and reference vessels denoted S and R respectively in Fig. 1 are shown in Fig. 2. The Ag–AgI indicating electrode (A) was made of a silver rod 2 mm in diameter. The salt bridge contained approximately 2% potassium nitrate in agar. The electric heater (H) was made from a metal-wound resistor (1/8 W, 49.98
Fig. 2. Details of the sample and reference vessels: S, sample; R, reference; E, potential difference; Q, total heat; q, heat evolving rate; G, oxygen evolving rate; A, Ag–AgI electrode; T, thermistor; H, electric heater element.

Ω) coated with epoxy resin. In the reference vessel, A, H, T and one end of the salt bridge were also installed to compensate for the effective heat capacity. The thermistors (MB, Technoseven Co., Yokohama, Japan) were installed in the S and R vessels as shown by T in Fig. 2. The B and R constants of the thermistor are defined by $R = A \exp(BT^{-1})$. The B constants were observed to be 3377.5 K and 3377.7 K and the resistances (R) to be 5.639 kΩ and 5.625 kΩ respectively, for S and R at 25.0°C. Magnetic stirrers of submarine type (M-3, Iuchi Seieido Co., Tokyo, Japan) were used for each vessel. The electric signals obtained as the unbalanced voltage of the Wheatstone bridge, which is proportional to the temperature observed as the difference between the two vessels, were converted to output voltages which are proportional to Q and q using the analogue operational amplifier (Op Amp) circuit. The output signals were recorded against time with two strip-chart recorders (R-02, Rika Denki Co., Tokyo, Japan).

The potentiometric cell was constructed in the usual manner. The potential difference E of iodide ions against the reference electrode, which was a commerically available saturated Ag–AgCl electrode, was monitored with a digital voltmeter and the strip-chart recorder.

The evolving rate of oxygen produced during the BR reaction was monitored by a simple flowmeter (Floweye 3850 MS, Kojima Seisakusho, Kyoto, Japan), and the output voltage G proportional to the released rate of oxygen was recorded against time. The total volume released by a run was measured primitively with glass burettes as usual in fundamental experiments.

2.3. Procedures

The temperature of the bath water was set to 25.0°C on the control panel. The required amount of water at a temperature near to 25°C was introduced into the water bath and the temperature control system controlled by an 8-bit small microcomputer (M5, SORD Co., Tokyo, Japan) was turned on. 50.0 g of water was used in the reference vessel. The required volumes of the stock solutions of hydrogen peroxide, potassium iodate in sulphuric acid and manganese sulphate were placed in the sample vessel which was fixed with the reference vessel in the water bath. After 40 or 50 min. temperature equilibrium in the water bath was attained and most of the electrical instruments, including the Wheatstone bridge and preamplifier (PM-16, Toa Dempa Co., Tokyo, Japan), were warmed up. Then, the offset voltage of the Op Amp in the analogue computation circuit was adjusted carefully to obtain an output voltage small enough to record horizontal baselines. Time constants in the analogue circuit were fitted to corresponding constants of the calorimeter by adjusting variable resistors on the circuit panel in the course of electrical heating. The Joule heat was accurately measured for the conversion from temperature to heat. To start the BR reaction, MA was added directly to the solution in the sample vessel, which was composed of iodate, sulphuric acid, hydrogen peroxide and Mn(II) salt, from the outside of the calorimeter and the outlet opened to the air was closed at the same time. The output voltages corresponding to Q, q, E and G were recorded on two two-pen recorders. After the chemical oscillation had finished, Joule heat was again observed.

3. Results and discussion

The BZ reactions comprise bromine chemistry and the BR reactions comprise iodine chemistry. Potentiometry of intermediate species, such as bromide and iodide, is commonly used to analyze the reaction mechanism of their chemical oscillations and to study the nature of their reactions. Both reactions are very sensitive to temperature in terms of their oscillation behaviour. Therefore, the execution of chemical oscillation reactions at a strictly constant temperature may be indispensable for precise estimations of chemical and physical properties. With heat exchange calorimetry, chemical reactions can be conducted within a very narrow range of temperatures.

In the calorimetry of chemical oscillation reactions, rapid thermal response may be indispensable. The calorimetric data of BZ reactions were presented by several researchers [12–14] but data for BR reactions are more scarce [15]. In heat exchange calorimetry, the response delay in the measuring system including a pair of thermistors can be expressed via a relation between the real temperature and the observed temperature in each vessel S and R using a constant β (see Ref. [7]). The delay constant can only be estimated experimentally, because it depends upon the assembled calorimeter and may be impossible to express mathematically. With this form of calorimetry, the response delay can be compensated for by on-line analogue computation. The speedy response to sudden thermal changes such as a step function was examined in a previous study [16]. Therefore, in the present work, the advantages of the calorimetric method were applied to study chemical oscillations of BR reactions at constant temperature and without a significant response delay.

The assembled calorimeter of the batch type shown in Fig. 1 was examined by electric heating prior to chemical reactions. The evolved heat was monitored from 1.023 J to 11.531 J by changing the electric current and the operating time. The heat range was selected in connection with each oscillation of the BR reactions. The standard deviation for 10 runs was 0.39% of the mean (mJ mm $^{-1}$ on the recorder used), which was precise
Fig. 3. Typical curves observed against time for the BR reaction in the solution composed of $[H_2O_2]_0 = 1.0$ M, $[KIO_3]_0 = 0.040$ M, $[MnSO_4]_0 = 0.010$ M, $[H_2SO_4]_0 = 0.020$ M and $[MA]_0 = 0.040$ M: E, potential difference; Q, total heat; q, heat evolving rate; G, oxygen evolving rate. At the position of the down arrow, an aliquot of solid MA was added to start the reaction.

enough to measure the heat evolution in every chemical oscillation.

Typical traces of simultaneous measurements for potential difference E, total heat Q, heat evolving rate q and oxygen evolving rate G are shown in Fig. 3 for a batch run. The pen differences on recorder charts were corrected. The initial concentrations of each species were $[H_2O_2]_0 = 1.0$ M, $[KIO_3]_0 = 0.040$ M, $[MA]_0 = 0.040$ M, $[MnSO_4]_0 = 0.010$ M and $[H_2SO_4]_0 = 0.020$ M. The start of the reaction by adding MA is indicated by a down arrow in curve E of Fig. 3. Endothermic curves in Q and q were observed as the heat of solution of MA to the acidic mixture of the other three components and some heat effect by iodination [17] as well, because it is possible that some iodine formation may take place. Detailed estimations of these heat effects

will be discussed separately in relation to minimal oscillation reactions. The induction period was then followed for ≈ 10 s. Heat and gas evolutions became more active after a time lapse of 1 min, and then gas evolution decreased to some extent. Heat evolution was 4.23 J in one cycle 1 min after the start, and corresponded to ≈ 105.8 J mol^{-1} KIO_3 in 0.020 M sulphuric acid. After the duration of the chemical oscillations, a fairly large heat evolution was maintained for about 20 min. At the end of heat evolution, the release of gas gradually finished. The ending patterns of E (obtained from the trace of the E versus time curve in the final stage of chemical oscillations and the final voltage of E at which the oscillation finished) in BR reactions may be more complex than those in BZ reactions and depend upon many factors including each initial concentration. A detailed discussion using a chemometrics approach may be presented separately.

The effect of stirring rate on the oscillation was examined. The influence on E was significant, maximum differences being about 55 mV 40 s after the start of the reaction with a change in the stirring rate from 200 to 700 rev min^{-1}. However, the effect on the oscillation period was small. In the present work, the rate was fixed at 400 rev min^{-1} due to calorimetric restrictions.

The oscillation behaviour was influenced largely by the initial concentration of MA. In the solution with $[MA]_0 = 0.060$ M, the oscillation period was almost constant at 8–11 s and Q was 5–10 J for six runs, for which reaction solutions were composed of $[H_2O_2]_0 = 0.72$ M, $[KIO_3]_0 = 0.080$ M, $[MnSO_4]_0 = 0.0040$ M and $[H_2SO_4]_0 = 0.018$ M. However, with the solution of $[MA]_0 = 0.030$ M, the period was gradually prolonged and Q was also enlarged slowly. For the BZ reaction, similar results were reported in the literature [1,8].

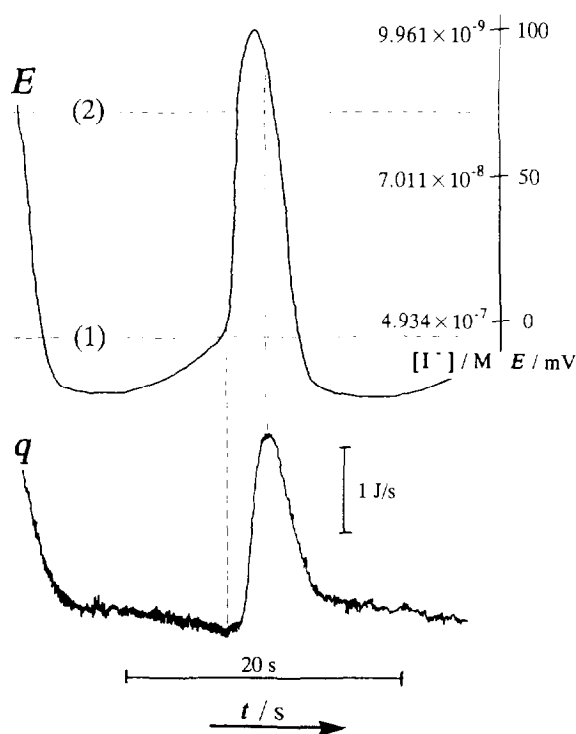
For discussing more explicit relations between potentiometric and calorimetric behaviour, q may be preferred to Q. One cycle of oscillation in E and q curves is shown in Fig. 4. The broken lines in the vertical direction correspond to the starting point and the maximum in the q curve. The maximum of q was not coincident with that of E. The switching concentration [5] was calculated using the literature values of rate constants [5,18].

The critical concentration of iodide, [I $^-$]$_{crit}$, can be obtained as $(k_{15}/k_{12})[KIO_3]_0$ from switching between (I2) and (I5) from Ref. [5]. The E_{crit} relation observed at [I $^-$]$_{crit}$ was obtained from fundamental knowledge of potentiometry to be $E_{crit} = E_s - E_r = (-0.15 - 0.059 \log[I^-]) - 0.2221$ at 25°C, where E_s and E_r are the potentials of the indicating and reference electrodes respectively. As a matter of course, nernstian response was examined with known potassium iodide solutions under experimental conditions as similar as possible. The response time was also rapid enough in comparison with the oscillation period. Increase in E corresponded to a decrease in the concentration of iodide ion. E_{crit} corresponding to [I $^-$]$_{crit}$ was calculated to be (1) -5.0 mV for $[KIO_3]_0 = 0.07919$ M using rate constants [18] of $k_{12} = 2.0 \times 10^9$ M^{-2} s^{-1} and $k_{15} = 1.516 \times 10^4$.

Fig. 4. One cycle of oscillation to compare E and q against time. The initial concentrations were as follows: [H$_2$O$_2$]$_0$. 0.7171 M; [KIO$_3$]$_0$, 0.07919 M; [MA]$_0$, 0.02998 M; [MnSO$_4$]$_0$. 0.009001 M; [H$_2$SO$_4$]$_0$, 0.07094 M. Switching concentrations calculated [18]: (1) from Noyes and Furrow; (2) from De Kepper and Epstein.

M $^{-2}$ s $^{-1}$ from Noyes and Furrow (1982), as shown in Fig. 4. However, for the same concentration of potassium iodate, E_{crit} was (2) 72.7 mV using rate constants [18] of $k_{12} = 2.0 \times 10^{10}$ M^{-2} s^{-1} and $k_{15} = 7.3 \times 10^3$ M^{-2} s^{-1} from De Kepper and Epstein (1982). In the case of $[KIO_3]_0 = 0.03959$ M, E_{crit} was obtained similarly as (1) 13.4 mV and (2) 91.3 mV. Since each initial concentration in this work was not adjusted to the literature values, agreement between experimental and calculation is not necessarily expected. Roughly speaking, when E is larger than the value (1), reactions in the radical path may be in the active state, and when E is smaller than (1), those in the nonradical path may be in the active state. The starting point of the peak on the E curve coincided with that of q. This means that heat evolution may begin instantaneously on switching to the radical path. In BZ reactions a fairly large heat evolution in each oscillation was observed in batch runs [8] and with a CSTR [10]. However, with minimal oscillations in solutions composed of Ce(III), bromate, bromide and sulphuric acid, heat evolution was not detected [17]. Of special interest here is the absence of MA. As for BR reactions, heat evolution may be involved in the process including the MA, even if an exothermic reaction is not included in the radical path.

The maximum q observed in Fig. 3 was 1.88 J s^{-1} (or 37.62 m W cm^{-3}) for a sample volume of 50.0 cm^3. Lamprecht [15] also measured the heat evolving rate and estimated it to be 2 m W cm^{-3} in the same volume of a mixture of [H$_2$O$_2$]$_0$ = 3.6 M, [KIO$_3$]$_0$ = 0.20 M, [MnSO$_4$]$_0$ = 0.020 M, [HClO$_4$]$_0$ = 0.15 M, [MA]$_0$ = 0.15 M and 0.01% of starch. In the present work, the corresponding value was much larger than that of Lamprecht. However, there were several differences between the methods such as experimental technique, initial concentrations of species, inclusion of starch, and the use of perchloric acid instead of sulphuric acid.

Roelofs [19] estimated the reaction enthalpy as $\Delta H = -565$ kJ mol^{-1} IO$_3^-$ for IO$_3^-$ + 6H$_2$O$_2$ + RH + H$^+$ → RI + 4O$_2$ + 7H$_2$O, instead of reaction (1). In the present study, the total Q from the beginning to the end of oscillations


amounted to 2.0 kJ or 1.0×10^3 kJ mol^{-1} IO$_3^-$, which was almost twice that found by Roelofs.

The maximum of E corresponded to the minimum of G. The most active period in the radical reaction may correspond to the period of lowered gas evolution.

Accurate estimation of the released oxygen volume was considered to be necessary for the correction of heat released by oxygen evolution. The total volume of oxygen released was measured for several combinations of three concentrations of hydrogen peroxide (0.36, 0.72 and 1.44 M) and MA (0.030, 0.060 and 0.120 M) with 0.079 M [IO$_3^-$]$_0$. All the observed volumes were larger than those calculated from reaction (1) at 25.0°C. However, some elementary reactions involving oxygen production exist which were not included in the fundamental equations [5]. Therefore, the observed volume may be larger than those calculated. Unfortunately, however, the correction for heat released was impossible due to the lack of the heat of gas evolution. Degn [20] also reported the released volume of carbon dioxide in the BZ reaction with simultaneous measurement of the potential differences of platinum and platinized platinum electrodes. The oscillations of oxygen release observed for the BR reaction in the present study were essentially similar to those for the BZ reaction given in the literature.

Near-infrared tetra-substituted aluminum 2, 3-naphthalocyanine dyes for optical fiber applications

Guillermo A. Casay, Narasimhachari Narayanan, Lawrence Evans III,
Tibor Czuppon, Gabor Patonay*

Department of Chemistry, Georgia State University, Atlanta, GA 30303, USA

Abstract

The synthesis and spectral characterization of several tetra-substituted aluminum 2, 3-naphthalocyanine dyes for the determination of metal ions is reported. The synthesis is done by means of a homogeneous phase reaction, replacing the previously used heterogeneous method. The new scheme allows for improved product yields, higher purity, better product reproducibility and can be monitored at different stages using UV–Vis–near-infrared spectroscopy. The incorporation of electron-donating or -withdrawing groups was found to influence the product yield and to cause a shift in the absorbance maximum. The typical shift in the excitation maximum (of up to 27 nm) enables the dye to match the output of semiconductor laser diodes. In addition the tetra-substituted groups were capable of undergoing an ion-exchange process with the metal ions which produced a change in the fluorescence signal of the dye. Similar results were achieved using an optical fiber metal probe. The detection of metal ions using the near-infrared dyes was accomplished via steady-state fluorescence using both a commerically available instrument and a fiber optic system and also via the fluorescence lifetime technique.

Keywords: Fluorescence; Fluorescence lifetime; Metal ions; NIR; Probes

1. Introduction

The development of a rapid method to determine metal ions in the environment has become the major priority of many health organizations [1,2]. Optical fiber chemical detectors (OFCDs)

have been shown to be a good method for the rapid determination of metal ions [3–8]. Compared to the conventionally used methods (atomic absorption, inductively-coupled plasma (ICP) emission and ICP–MS), OFCDs are smaller and more cost efficient [9,10]. The principle behind the OFCD is the ability to excite a molecular dye and then detect its emission signal via fiber optics. In the present study the authors have synthesized

* Corresponding author

several molecular dyes with the ability to bind metal ions through an ion-exchange process.

Most OFCDs reported in the literature was UV–Vis fluorophores such as rhodamine, fluorescein and their derivatives [4,11–14]. However, many of these probes suffer from spectral interferences either from other molecules with similar properties to the molecular probe or by direct interference [15–17]. For instance, many different polyaromatic hydrocarbons have emission spectra in the 200–600 nm region where many UV–Vis fluorophores also exhibit absorbance or fluorescence [18]. Also, assuming the fluorescence has been sufficiently quenched, the Raman shift (especially in water) may interfere with the fluorescent signal. The near-infrared (NIR) region (700–1000 nm) can be used as an alternative region of analysis for the application and developement of optical fiber metal probes. This particular region exhibts low background interference from many molecules and is ideal when laser diode excitation is coupled with silicon photodiode detectors to allow for a very sensitive detection system [10,19].

We are currently interested in the synthesis and development of new near-infrared dyes (NIRDs) that can be used in optical fiber applications, especially for the determination of metal ions [19–21]. The aluminum naphthalocyanine family of dyes characteristically exhibits a sharp Q-band at ≈ 780 nm which was found to be well suited for laser diode excitation. The Q-band is also well separated from a stronger band at ≈ 340 nm which minimizes band overlap [22,23]. The Stokes' shift exhibited by the dyes is very small, and can cause broadening of the emission band due to scattered light [24]. However, this can be resolved by exciting the NIRD at a wavelength blue-shifted with respect to the absorbance maximum or by using a bandpass filter. Exciting at a wavelength blue-shifted with respect to the absorbance maximum will cause the intensity of the emission band to be slightly lower but can be enhanced by increasing the output power of the light source.

We report in this paper the synthesis and spectroscopic characteristics of several new tetra-substituted aluminum 2,3-naphthalocyanine (AlNc) dyes synthesized in homogeneous phase which can

be followed by using UV–Vis–NIR spectroscopy. In earlier reports, the synthesis of AlNc dyes in a hetergeneous phase involved several disadvantages, such as low yields, complicated steps and random reproducibility [22,23]. The procedure reported here permits better control of the synthesis of the dye and significantly improves the final yield of the product. Also, the effect of the substituent moiety and the use of different solvents in the preparation of the NIR dyes will be examined to show their effect on the final product. The tetra-sulfonated AlNc derivative was used since its absorbance maximum (781 nm) was a good match for the wavelength output of the laser diode (780 nm). Results comparing the changes in the photochemical properties of the unbound and metal-bound tetra-sulfonated AlNc dye will be presented.

To determine the utility of the tetra-sulfonated dye in optical fiber probe applications, the dye was entrapped in a permeable polymer and the polymer attached to the probe support. As the metal ions move towards the dye, the metal ions exchange with the H^- on the HSO_3 inside the polymer matrix and, upon laser diode excitation, the fluorescence is acquired. Assuming a 1:1 ratio and that no other interfering ions take part in the equilibrium, the association of metal ions, M^+, with the NIRD can be represented as

$$[M^+] + [D^-] \rightleftharpoons [DM]$$

where the square brackets indicate molar concentrations of the metal ions, the NIR dye (D^-) and the dye–metal complex (DM) formed. At equilibrium, the binding of the metal ions to the dye (entrapped by the polymer at the end of the fibers), can be expressed as the optical fiber association constant K_{op}, where $K_{op} = [DM]/[M][D]$.

The optical fiber association constant of the dye can be determined by

$$\frac{1}{I_f} = \frac{1}{kD_T} + \left(\frac{1}{kD_T K_{op}}\right)\frac{1}{[M]} \qquad (1)$$

where I_f is the intensity of fluorescence measured, k is a constant dependent upon the quantum efficiency of the fluorescent process and D_T is the total concentration of the dye [25]. At low concentration, a plot of $1/I_f$ vs. $1/[M]$ produces a straight

2. Experimental

2.1. Synthesis of the unsubstituted AlNc

A solution of 5.0 g (28.0 mmol) of 2,3-dicyanonaphthalene and 100 ml of 1,2-dichlorobenzene was refluxed. Then 14 ml (14.0 mmol) of 1 M $AlCl_3$ in nitrobenzene (about twice the amount stoichiometrically required) was added. The reaction mixture was refluxed for 7 h and monitored every 30 min by a UV–Vis–NIR spectrometer for product formation and by TLC to check the starting material. The reaction mixture was cooled to room temperature and the solvents removed by steam distillation. The suspension obtained was filtered under pressure and washed thoroughly with acetone. The purity of the product was verified by ¹H NMR and C, H analysis (Table 1). The residue was extracted with acetic acid in a Soxhlet extractor and reprecipitated from concentrated sulfuric acid. The dark-green product was dried sat 125°C (yield 4.80 g, 88%).

2.2. Synthesis of the substituted AlNc

The initial step of the synthesis of the substituted AlNc dyes began with ortho-xylenes 1 (Aldrich). All other intermediates (2, 3, and 4)

and the final dyes 5 were purified by a column chromatography on silica gel. A scheme of the reaction steps used in this synthesis is shown in Fig. 1 and some of the substituted AlNc NIR dyes prepared using this scheme are shown in Table 2. The final products were characterized by traditional ¹H NMR, IR and C, H analysis (which had shown agreement in the ranges C ± 0.3 and H ± 0.1) and purified by reverse-phase HPLC, using RPC18 were aqueous solvents. Fig. 1 also shows a typical structure of the AlNc dyes with the tetrasubstituted groups located in the outer benzene ring.

2.3. Reagents and Methods

All starting materials were obtained from Sigma. All other organic and inorganic reagents: sodium hydroxide, sodium chloride, lithium hydroxide, lithium chloride, potassium hydroxide, potassium chloride, tetralin, anisole, quinoline, 1-chloronaphthalene, benzonitrile, 1,3,5-trichlorobenzenethanol, 1,2,4-trichlorobenzene, 1,2-dichlorobenzene, nitrobenzene, cadmium chloride, and ammonium hydroxide were obtained from Fisher Scientific. Spectragrade methanol was obtained from Aldrich.

For the metal ion investigations, stock solutions of 1000 ppm were prepared to provide suitable metal ion solutions. All successive dilutions were made from the stock solution in 5 ml vials using ultrapure water provided by a Nanopure water

purification system (Barnstead/Thermolyne Corp., Dubuque IA). Fresh dye samples were prepared as necessary using a 10^{-4} M stock solution of the NIR dye. Each sample of dye was dissolved in methanol unless otherwise specified. Some of the dyes required the addition of small amounts of DMSO (<2%) as a co-solvent to increase solubility in methanol. Solutions of 10^{-1} M metal ion with 10^{-4} M NIRD were prepared and stored in a freezer only for the duration of the experiments. All data reported were obtained at 20°C.

2.4. Apparatus

A Perkin-Elmer Lambda 2 UV–Vis–NIR spectrometer was used for the absorption measurements. The spectrometer was interfaced to a Zenith 286 computer equipped with a PECSS program to store data and control the spectrophotometer. Quartz cuvettes (Fisher) were used to house the samples for absorbance measurements.

Samples were prepared for relative comparison by diluting the dye stock solution to an absorbance intensity of 0.1. Under the conditions used in these experiments, reproducible absorbances of 0.25% ± 0.08% were obtained. Fluorescence measurements were conducted on a SLM8000 Aminco spectrofluorometer using an external laser diode excitation source. Laser diodes (Toshiba or Sharp) of 750–830 nm output wavelengths were used as the excitation source. The spectrofluorometer detector was operated in the photon counting mode at 1000 V. A PS/2 PC system controlled the data acquisition and stored the data automatically for later analysis. Slit widths of 4 mm were used during the experiments. A $12.5 \pm 10 \times 1$ mm³ Herasil (near-UV Silica) cell with all sides optically polished (3.5 ml) was purchased from Starna for fluorescence investigations.

The fluorescence lifetimes were measured on an ISS K2 multifrequency phase fluorometer (Champaign, IL). The light source was a 350 W Xenon

arc lamp and the signal was modulated by a Marconi model 2022D frequency synthesizer. The emitted light was modulated and detected via the combination of a second Marconi 2022D frequency synthesizer and a ENI 525LA amplifer coupled to a Hamamatsu R928 photomultiplier tube. Glycogen in water was used as the reference scattering solution for all observations. In cases where the emission band was close to the excitation band, excitation and emission polarizers were set at 0° and 55° respectively to maximize the signal.

2.5. Optical fiber apparatus

The optical fiber apparatus used for the detection of metal ions has been discussed previously and only major characteristics will be presented here [26]. Fig. 2. shows a cross-section diagram of the probe that has been used in these investigations. The unit was composed of two plastic fibers, one connected to the laser diode (Toshiba LTO23MFO) and the other to the detector (silicon photodiode). The ends of the fiber not attached to the detector or laser diode were fused together with poly (methyl methacrylate) (PMMA). The PMMA served as a support for the dye entrapped in the permeable polymer, poly (2-hydroxyl ethyl methacrylate) (PHEMA). A solution of dye with PHEMA polymer was coated onto the support and allowed to air dry. A 1.5:1 polymer:dye ratio was sufficient to collect the fluorescence signal. The optical probe was interfaced to the instrument using the fiber attachment of the instrument to the emission port. The optical fiber was positioned perpendicular to the

opening of the fiber bundle and a collecting lens (Melles Griot) was used to focus the signal from the excitation fiber.

Prefabricated probes were allowed to soak for 10 min in distilled water. Sampling was done of controlled concentrations from lowest to highest. The fluorescence signal was then recorded after immersion for 2 min to allow for ion equilibration. The probe was then removed, rinsed with distilled water and sampling of the next ion concentration was done.

3. Results and Discussion

The use of a homogenous reaction phase allowed for better product yields and a faster overall synthesis time (Table 2). The use of different solvents significantly minimized the reaction times. The results of these investigations are summarized in Table 3. The number and amount of isomers formed as final product were found to be solvent dependent. In some solvents, the formation of several isomers were unavoidable and could not be controlled, making the purification process and isolation of the desired dye more tedious. The purification of compound 5 was found to be dependent on the properties of R^2 which indicated what solvents were appropriate for the synthesis. Compound 5 (if $R^2 \neq H$) symbolized the structures of the four possible isomers that may have been introduced as by-products.

The nature of the R^2 moiety was found to significantly influence the physical and photochemical properties of the molecular dye. The data suggest that better product yields were ob-

tained when R_x^2 was an electron-withdrawing group and R_β^2 was a hydrogen substituent than when R_x^2 was a hydrogen substituent and R_β^2 was an electron-donating group. No final product was obtained when R_x^2 was an electron-donating group and R_β^2 was a hydrogen substitutent or when R_x^2 was a hydrogen substituent and R_β^2 was an electron-withdrawing group (Table 3). The introduction of electro-withdrawing and-donating moieties also caused shifts in the absorbance maxima.

During the synthesis of the naphthalocyanine compounds, we also observed that if 4 contains an oxygen link to a carbon, an extra equimolar amount of AlCl$_3$ per oxygen was needed to compensate for complexation losses (reaction time 4 h). Also, some polyaromatic by-products (λ_{max} = 400–600 nm) resulted from the interaction of AlCl$_3$ and 1,2-dichlorobenzene if excess AlCl$_3$ was used or the reaction time was too long (more than 10 h). This method was also successful with AlBr$_3$ and GaCl$_3$. The photochemical properties of the tetra-substituted dyes are found in Table 4.

Most of the spectral changes that we have observed using the sulfonated NIRD in the presence of metal ions were blue shifts of the Q-band at ≈783 nm. In the presence of Cd^{2+}, the absorbance maximum shifted to 755 nm. With Mg^{2+} present in solution, the fluoresence signal decreased without a blue shift in the wavelength of the emission band. Similar results were observed with Ba^{2+} and Cd^{2+}. Of the ions investigated, Pb^{2+} and Li$^+$ had the strongest effect on

the photophysical properties of the dyes. The effects of PbCl$_2$ and PbAc$_2$ were almost identical and the changes occurring in the dye resulted soley from the presence of Pb^{2+} and not the counter ion. Similar results were obtained with lithium.

Even though the presence of the counter ions using lead and lithium was not significant, other counter ions showed an effect in the absorbance maximum of the dye, namely OH$^-$. A greater blue shift is observed in very basic (OH$^-$) solutions than with Cl$^-$ ions, as shown in Fig. 3. The presence of OH$^-$ in the microenvironment of the dye increased the $\pi \to \pi^*$ transition gap of the molecule as measured by the larger blue shift of the Q-band. This may have been due to small pH

Fig. 1. General procedure used in the synthesis of tetra-substituted AlNc dyes where R represents different moieties.
Fig. 2. Cross-section diagram of an optical fiber probe used in this investigation. One fiber is used for excitation and the other is used to collect the fluorescence signal. The darker region represents the area where the optical fiber is collecting most of the fluorescence signal. In one set-up the detector was part of an in-house unit and in the other the probe was interfaced to an ISS K2 fluorometer.

changes in the microenvironment of the dye due to the strong stretching and bending modes of the OH^- groups in the NIR region. If the OH^- group was interacting only through ionic interactions at the peripheral rings, a red shift would have been produced; however, this was not observed since the OH^- groups were acting in a different dye location. Another strong possibility is the effect of the OH^- groups on the central atom, aluminum. The observed changes may be attributed to the effect of the extra orbital of the central atom, that disturbs the electron cloud of the inner nitrogens. The increased Van der Waals forces between the OH^- groups and the metal may have increased the $\pi \rightarrow \pi^*$ transitions gap, especially for the $a_{1u} \rightarrow e_g$ energy transition, thus producing the observed shift. The Van der Waals forces were the result of a strong hydrogen bond between the two center nitrogen atoms that are only partially bonded to the central atom. Steric hindrance by electrostatic repulsion between the extra molecules then changes the symmetry of the structure of D_{2h}. Further evidence of the effect of pH was observed at extreme levels (pH = 3 or pH = 9) where the absorbance maximum increased, therefore also affecting the molar absorption coefficient. Under neutral conditions, the molar absorption coefficients were 78 000 and 5000 for the $(HO_3S)_4$ $(5-O_2N)_4$ dyes respectively.

Under basic conditions (0.1 M NaOH) the absorption coefficient increased to 340 000 for the $(HO_3S)_4$ dye and 7000 for the $(5-O_2N)_4$ dye. A similar increase was observed under acidic conditions when using 0.05 M HCl where the molar absorption coefficient increased to 105 000 $(HO_3S)_4$ and 6600 $(5-O_2N)_4$ respectively.

Using laser diode excitation, the dye was detectable at the picomolar level. At low metal ion concentrations (1–5 ppm) a plot of the fluorescence signals versus the metal ion concentrations produced straight lines with correlation values of around $R = 0.9$. However, beyond 5 ppm the signal began decreasing as linearity diminished. This phenomenon was due to a blue shift of the absorbance band, which caused a mismatch with the wavelength output of the laser diode allowing for excitation on the right side of the absorbance band which gave a lower fluorescence signal.

The fluorescence stability of these NIR dyes was excellent when left at room temperature or stored at 4°C with no special treatment. The excitation source was applied to the NIR dye solution only when the fluorescence intensity was to be measured, to circumvent the possibility of photobleaching. A plot of the measured fluorescence signal for several of these dyes remained unchanged during these investigations. The average normalized intensity, after 28 measurements (30 min intervals), was 1.02 with a standard deviation of 0.01, which may have been due to solvent evaporation.

The fluorescence lifetime of the tetra-sulfonated dye with no metal ions present is 2.92 ns, as shown in Fig. 4. The fluorescence lifetime of the other naphthalocyanine derivatives varied from 1.75 ns to 4.00 ns, as shown in Table 4. In the presence of metal ions (Li^+, Na^+, K^+ and Rb^-), the fluorescence lifetime of the tetra-sulfonated dye decreased. The lifetimes were measured to be 1.56 ns, 1.53 ns, 1.50 ns and 1.43 ns respectively. This trend was found to be consistent with the ionic radii of the metal ions. As the ionic radii increased, the fluorescence lifetime of the dye decreased.

Typical response times of the probe (to 95% of the steady-state response) varied between 10 and 80 s. The longer times measured were at higher
Fig. 3. Blue shift of the absorbance maximum of a sulfonated dye. The nature of the counter ion produced different shifts. A larger shift was observed using OH⁻ rather than Cl⁻ counter ions.

metal ion concentrations. This difference may be attributed to a decrease in free volume in the polymer matrix or saturation of either of the binding sites of the dye. As the metal ions penetrated the matrix there was less free volume for the ions to move inside the matrix and therefore they became concentrated at the surface of the probe.

To determine the dynamic range of the optical probe, several controlled concentrations of metal ions were prepared. The tetra-sulfonated dye showed a good response to changes in metal ion

Fig. 4. Frequency-dependent demodulations and phase shifts for the tetrasulfonated AlNc dye taken in methanol using an excitation wavelength of 783 nm. The measured fluorescence lifetime of the dye is 2.92 ns.

concentration. Probes prepared with 1:1 and 3:2 polymer:dye ratios produced linear responses from 0 and 10 ppm and optical constants of 1.93×10^6 M^{-1} and 2.27×10^6 M^{-1}. The small difference between the two probes may have been the result of the difference in the amount of dye loaded.

4. Conclusion

The synthesis of tetra-substituted AlNc dyes in a homogenous phase was successfully accomplished and followed by UV–Vis–NIR spectroscopy. The photochemical properties of the dyes were determined and were applicable for the determination of metal ions. The data shown here demonstrate the use of a NIRD for the detection of metal ions comparable to the dyes used in the UV–Vis region. We have also demonstrated a very practical synthesis scheme with improved product yields. Additional work in this area will be directed towards the development of NIRDs that can be made more sensitive to specific metal ions by introducing crown moieties. There are many potential applications of NIR OFCDs for the determination of metal ions and their utility for the detection of metal ions may not be their only application. Investigations are also currently under way to evaluate their efficacy as pH probes.

Permselectivity of neurotransmitters at overoxidized polypyrrole-film-coated glassy carbon electrodes

Tian-Fang Kang*, Guo-Li Shen, Ru-Qin Yu

Department of Chemistry and Chemical Engineering, Hunan University, Changsha 410082, People's Republic of China

Abstract

The permselectivity of neurotransmitters such as dopamine, epinephrine, and norepinephrine at overoxidized polypyrrole (OPPY)-film-coated glassy carbon electrodes has been investigated. The chemically-modified electrodes exhibit attractive permselectivity and antifouling properties of rejecting anionic species, e.g. ascorbate, etc. Compared with the response of neurotransmitters at modified electrodes overoxidized in phosphate buffer solution (pH 7.4), higher sensitivity and reversibility response can be obtained at modified electrodes overoxidized in sodium hydroxide solution. The effect of film thickness on the permselective response was tested. Rotating disk electrode experiments were used to determine the apparent diffusion coefficients of several electroactive solutes in the OPPY films. The influence of the hydrophobicity of the organic ions on the permeability within the polymer films was discussed. Dopamine and epinephrine were determined at the 1×10^{-6}–1×10^{-4} M level by means of voltammetry after an exposure period of 2 min in 0.1 M phosphate buffer (pH 7.4) with detection limits of 8×10^{-7} M and 6×10^{-7} M respectively.

1. Introduction

In recent years there has been extensive interest in the field of polymer-modified electrodes [1,2]. Such sensors hold great promise for increasing the selectivity, sensitivity, and reproducibility of voltammetric measurements [3,4]. Chemically-modified electrodes have also been developed for the electrochemical determination of neurotrans-

mitters both in vivo and in vitro [5,6]. The voltammetric responses of the neurotransmitters, however, usually suffer from the interference of ascorbic acid which usually coexists in vivo as anions in high concentration.

Overoxidized polypyrrole OPPY-film-modified electrodes have been studied previously [7–9]. These electrodes are easily prepared by electropolymerization of pyrrole monomer with subsequent overoxidation treatment. It is known that the electrical conductivity is lost upon irreversible

* Corresponding author.

oxidation of polypyrrole at quite positive potentials [10,11], although the films still possess ionic conductivity. The OPPY films have been shown to possess excellent cation permselectivity. To our knowledge, although there have been several reports [12,13] of the electrochemical properties of dopamine (DA) at OPPY-film-coated electrodes prepared by different procedures, the permselectivity and voltammetric behaviour of other catecholamines, e.g. epinephrine (EP) and norepinephrine (NE), at the modified electrodes have not been reported. The biogenic amines co-exist with dopamine, ascorbic acid (AA) and uric acid (UA) in vivo. Clarifying their permselectivity and voltammetric properties at OPPY-film-coated electrodes is desirable for the development of the polymer-film-modified electrodes as neurotransmitter sensors. In this paper, the voltammetric responses of the OPPY-film-modified glassy carbon (GC) electrodes for DA, EP and NE as well as AA at physiological pH are evaluated. The apparent diffusion coefficients of DA, EP, etc. are determined by rotating disk electrode (RDE) experiments. The results of the study show that the OPPY-film-modified electrodes exhibit attractive permselective and antifouling properties.

2. Experimental

2.1. Apparatus and Reagents

All electrochemical experiments were performed with an EG&G PARC Model 273 potentiostat galvanostat and a Hewlett Packard X–Y recorder. An electrochemical cell with three electrodes was used for both the electropolymerization and electrochemical determinations. A bare or OPPY-film-coated GC disc electrode with an area of 0.20 cm^2 (Beijing Institute for Artificial Crystals) was used as working electrode, a platinum foil was used as auxiliary electrode and a saturated calomel electrode (SCE) as the reference electrode. All potentials were recorded relative to the SCE.

Pyrrole (Fluka) was purified by double distillation and was stored in a refrigerator. DA hydrochloride, NE hydrochloride, UA (Sigma), EP (Fluka), catechol and AA (Fisher) were used as received. All chemicals were of reagent grade. All solutions were prepared with doubly-distilled water and were degassed with high purity nitrogen for 10 min. Nitrogen was passed over the solution during the electrochemical measurements.

2.2. Preparation of OPPY-film-modified electrodes

The GC electrode was polished with 0.5 μm alumina paste for 5 min, and then ultrasonicated for 5 min in distilled water before use.

Polypyrrole films were electropolymerized on the GC electrode in a degassed solution of 0.1 M pyrrole and 0.1 M $NaClO_4$ with a constant current of 1 mA cm^{-2}. The thickness was controlled [14] by the amount of charge passed and was estimated to be ≈ 0.2 μm by passing 48 mC cm^{-2}. Polypyrrole films on the surface of GC electrodes were overoxidized at +1.0 V vs. SCE in 0.2 M NaOH solution, unless stated otherwise. The overoxidation process was monitored by following the current decay until the current levelled off. This took about 6 min for a 0.2 μm thick film.

2.3. RDE experiments

RDE experiments were carried out using a Model EG & G PARC 616 RDE system with a GC disk working electrode with an area of 0.13 cm^2, a platinum wire auxiliary electrode and a Ag/AgCl (KCl saturated) reference electrode.

2.4. Procedure for voltammetric assay

A 20 ml aliquot of 0.1 M phosphate buffer pH 7.4 was placed in a voltammetric cell, and the required volumes of standard solutions were added. The modified electrode was immersed in the solution with stirring to expose it to the analytes. After a given period of exposure, a potential scan was performed.

3. Results and Discussion

3.1. Voltammetric behaviour of neurotransmitters and other species at OPPY film electrodes

During overoxidation of polypyrrole in NaOH solution, nucleophilic attack of the radical cationic pyrrole units in the polymer by hydroxide ions takes place, resulting in loss of the conjugated structure and electrical conductivity. Meanwhile, the doping ions (ClO_4^-) are also expelled from the polymer film [11], forming a porous structure on the film. Electroactive species and electrolyte can still diffuse through the porous film to the underlying electrode surface. However, carbonyl groups and carboxylic groups are also produced in the polymer when the oxidation is taking place [15]. The diffusion of anions in the film is hindered by the carbonyl groups of high electron density and the ionized carboxylic groups.

It was reported that the optimum conditions for electrochemical activation of GC electrodes in the analysis of dopamine were a pH range of 13–14 and a potential of 1.2 V (vs. SCE) [16]. Similar conditions are used in this report for activation of a polypyrrole-film-coated GC electrode to be overoxidized. In order to estimate the activation of the underlying electrode surface arising from the treatment of a polypyrrole-film-coated GC electrode, a bare GC electrode was also treated under the same conditions as the polypyrrole-film-coated GC electrode. The treated bare GC electrode was also used as a working electrode to perform cyclic voltammetric experiments. Fig. 1 shows the cyclic voltammograms for a series of biologically important cationic, nonionic, and anionic species at OPPY-film-coated and bare GC electrodes.

Although both AA and UA were in the form of monovalent anions at pH 7.4, AA was more efficiently repelled from an OPPY-film-coated electrode surface than UA (Fig. 1). AA (1×10^{-3} M) was oxidized at the bare GC electrode, producing a large current peak, while its current response was almost completely suppressed at the OPPY-film-coated GC electrode. The response of UA (5×10^{-5} M) was also suppressed, although

not so completely, at the OPPY-film-coated electrode compared to the response at the bare GC electrode. UA is a more hydrophobic species than AA judging from the much lower solubility of UA in aqueous solution. The hydrophobicity difference between UA and AA is probably one of the reasons why there is an obvious difference in permeability between the two species within OPPY films. The voltammetric responses of UA and AA at OPPY-film-coated or bare GC electrodes were investigated in phosphate buffer solutions of different pH. It was found that the suppression of the OPPY films electrodes for the response of UA was obviously weaker than that for the response of AA over the pH range 7–9. A similar phenomenon, i.e. hydrophobic interaction between the monoanionic species, e.g. 3, 4-dihydroxyphenylacetic acid, and the OPPY film, which is favourable for permeation of these species into the OPPY film, was also observed by Palmisano et al. [15]. The large permeability of the cationic neurotransmitters DA, EP and NE, which are protonated at the physiological pH,
Fig. 1. Cyclic voltammograms for 1×10^{-4} M DA (A), catechol (B), EP (C), NE (D), 1×10^{-3} M AA (E), and 5×10^{-5} M UA (F) at OPPY-film-coated (solid lines) and bare GC electrodes (broken lines). Conditions: scan rate, 20 mV s^{-1}; electrolyte, 0.1 M phosphate buffer (pH 7.4); exposure time, 2 min.

results in faradaic responses significantly higher than that of the anionic species. The faradaic response obtained is close to that obtained with a bare GC electrode. The neutral catechol exhibits a similar behaviour. The voltammetric responses of the neurotransmitters usually suffer from the interference of AA which may coexist in vivo in the anionic form on high concentrations. For example, large overlapping oxidation peaks of neurotransmitters and other species tested were observed at the bare GC electrode. Therefore, the selective retardation of the electroactive anion ascorbate is of great significance for the development of neurochemical sensors. It has been shown [12] that if polypyrrole-film-coated GC electrodes are treated by overoxidation of polypyrrole in sodium hydroxide solution, rather than in other supporting electrolyte solutions, highly sensitive and reversible voltammetric responses for DA will be obtained. In the present investigation, it was also observed that the voltammetric responses of both EP and NE at the OPPY-film-modified electrodes overoxidized in strongly alkaline medium were of higher sensitivity and reversibility than those at the modified electrodes overoxidized in, say, a phosphate buffer solution (pH 7.4). In sodium hydroxide solution, the overoxidation of polypyrrole film proceeds faster than in median pH buffer solutions because hydroxide ions in sodium hydroxide solution act as nucleophilic reactants which are stronger than anionic species present in buffer solutions [11]. The highly sensitive and reversible voltammetric responses for catecholamines can be attributed to the activation of the matrix surface of the underlying GC electrodes. The electrochemical oxidation of the matrix surface will occur when the polypyrrole film coated at the surface of the GC electrode is overoxidized in sodium hydroxide solution at quite a positive potential, for example +1.0 V or +1.2 V vs. SCE [16].

Study of the effect of scan rate on the anodic peak height of DA and EP at the OPPY film electrode was performed by linear scan voltammetry. The peak height increased linearly with the square root of the scan rate. The results show that the electrochemical processes involving DA and EP at OPPY film electrodes are all diffusion-controlled [17].

Table 1
Effect of film thickness on permselective response at the 1×10^{-3} M level[a]

Thickness (μm)	$i_{p,DA}/i_{p,AA}$	$i_{p,EP}/i_{p,AA}$	$i_{p,NE}/i_{p,AA}$
0	2.43	2.26	2.12
0.2	52.8	51.5	50.2
0.4	87.6	82.4	79.8
0.6	284	273	265

[a] Other conditions as in Fig. 1.

3.2. Effect of OPPY film thickness

The permselective transport is strongly affected by the film thickness (Table 1). The sensitivity of a 0.2 μm OPPY-film-coated electrode for neurotransmitters was close to that of a bare electrode. However, the selectivity of the OPPY-film-coated electrode for neurotransmitters with respect to AA was much higher than that of the bare electrode. As film thickness increases, the sensitivity decreases but the neurotransmitter selectivity with respect to AA increases substantially.

A plot of linear scan voltammetric peak height as a function of the exposure time (Fig. 2) shows that the peak height of EP increased sharply with exposure time up to 3 min. With longer exposure times, up to 6 min, the slope decreased. Meanwhile, the slope for the 0.2 μm OPPY film de-

Fig. 2. Effect of exposure time on oxidation peak height of EP at OPPY film electrodes of (●) 0.2 and (○) 0.4 μm thickness. EP concentration: 1×10^{-4} M; phosphate buffer concentration: 0.1 M (pH 7.4); scan rate: 50 mV s^{-1}.

creased more quickly than that of a 0.4 μm OPPY film. This is not surprising, since prolonged exposure allows a larger quantity of analyte to diffuse into the film and saturation occurs more quickly for thinner films. When a polymer-film-coated electrode is exposed to an aqueous solution containing analyte, the response sensitivity depends on the film thickness [18]. Thicker film, for example 0.4 μm, results in a lower response sensitivity but, with an exposure time of, say, 3 min a wider linear response range. Because of the expected faster response time and higher sensitivity, it is more advantageous for the voltammetric determination of catecholamines to employ a thin, say 0.1 μm or 0.2 μm, OPPY film than a thicker one.

3.3. Determination of apparent diffusion coefficients

The apparent diffusion coefficients of DA, EP, UA and AA in OPPY film were determined by OPPY-film-coated RDE voltammetry in pH 7.4 phosphate buffer solution in order to evaluate the permeability of the solutes in the polymer film. In the permeability studies, the limiting current, i_l for the electrochemical reaction of a solute which partitions with partition coefficient α and diffuses into a RDE through a film barrier with diffusion constant D_m is described by the following equation [19,20]:

$$\frac{1}{i_l} = \frac{1}{nFA\alpha D_m C\delta_m^{-1}} + \frac{1}{0.62nFAD_s^{2/3}\nu^{-1/6}\omega^{1/2}C} \quad (1)$$

where A is the electrode area, δ_m is the film thickness, ω is the rotation speed of the electrode (rad s^{-1}) C and D_s are the bulk concentration and diffusion coefficient of the solute in solution respectively, and the other symbols have their usual meanings. The two terms on the right-hand side of Eq. (1) represent the reciprocal of the current that would be measured without the diffusion layer, and the reciprocal of the current without a film. The Koutecky–Levich plots are obtained by measuring the limiting current at different rotation speeds and plotting $1/i_l$ vs. $\omega^{-1/2}$. From the intercept the apparent diffusion coefficient αD_m can be obtained.

Table 2
Apparent diffusion coefficients measured with the RDE in 0.1 M phosphate buffer solution (pH 7.4) for some species[a]

Solute	pK_a[b]	Change	C (mM)	αD_m (10^{-9} cm^2 s^{-1})
DA	8.92	+1	0.10	21
EP	8.88	+1	0.10	16
UA	5.40	−1	0.10	2.8
AA	4.20	−1	4.0	0.42

[a] Polypyrrole film was overoxidized in 0.4 M phosphate buffer (pH 7.4). OPPY film thickness: 0.40 μm. Scan rate: 10 mVs^{-1}.
[b] References for pK_a values: DA and EP [21]; UA [22]; AA [23].

Table 2 lists the values of αD_m obtained for the solutes at different electrodes. The errors in the αD_m values are less than 20%. AA showed a small voltammetric response at a concentration of 4 mM but it is almost indistinguishable from the background signal at 0.5 mM levels. UA possesses a small solubility in neutral aqueous solutions. Therefore, concentrations of 4.0 mM AA and 0.10 mM UA were adopted in the RDE experiments. The results show that DA possesses a slightly higher permselectivity than EP at the OPPY-film-coated GC electrodes. However, the αD_m value of UA is higher by a factor of about seven than that of AA, which further confirms that UA possesses higher permeability than AA. The αD_m value of DA is about double that reported by Witkowski and Brajter-Toth [7]. This is probably due to the different preparation conditions of the OPPY film, i.e. different doping ions were applied during the electropolymerization of pyrrole monomer, etc.

3.4. Analytical applications

In order to evaluate the possibility of applying the OPPY film electrodes to the determination of neurotransmitters in practical samples, mixtures of DA or EP, AA and UA were prepared. The concentrations of AA and UA were 1×10^{-4} M and 1×10^{-5} M respectively. Linear scan voltammetry was adopted in the experiments. The results are shown in Table 3. The limit of detection was calculated as three times the noise of the determination of a low level of DA or EP. EP was

Table 3
Linear range and detection limit of DA and EP determinations[a]

Species	Linear range (M)	Correlation coefficient	Detection limit (M)
DA	1×10^{-6} 1×10^{-4}	0.999	8×10^{-7}
EP	1×10^{-6} 1×10^{-4}	0.998	6×10^{-7}

[a] Scan rate: 50 mV s^{-1}. Other conditions as in Fig. 1.

determined 12 times at the 5×10^{-5} M level with a 2 min exposure time. The relative standard deviation was 3.9%.

The stability of the OPPY film on GC was also tested. There were no obvious changes observed in the response of the OPPY film electrodes after the electrodes were stored in phosphate buffer for 8 days. This indicates that the OPPY film electrodes are stable in a quiescent solution. However, after repeated voltammetric determinations, for example over a period of 5 h, about 15% decrease in current sensitivity for 1×10^{-5} M EP was observed. This was obviously superior to the results obtained at an untreated bare GC electrode which was prone to contamination by EP oxidation products, resulting in reduction of response sensitivity.

4. Conclusions

OPPY films demonstrate large permeability for cationic and neutral catechols, for example DA. EP. NE or catechol, and very effective and selective retardation of electroactive anionic species such as ascorbate anions. The thinner the thickness of the OPPY film, the shorter the response time. Uniform thickness of OPPY films and stable adherence to the GC electrode surface are easily obtained by electropolymerization of pyrrole monomer. In contrast, neurotransmitters and catechols tested displayed excellent electrochemical reversibility at a polymer-film-coated GC electrode which had been treated in strong basic solution at +1.0 V vs. SCE. Therefore, high voltammetric response sensitivity for these species can be obtained. In particular, the enhanced selectivity obtained as a result of excluding anionic species could be very valuable in the development of neurochemical sensors.

Abstract

Batch-injection analysis exhibits the advantages of rapid and simple electroanalysis of microlitre samples. Nafion-coated mercury thin film electrodes have been evaluated for use in batch-injection analysis with anodic stripping voltammetry (BIA-ASV). The advantages of Nafion-coated electrodes in reducing electrode contamination by components of complex matrices are combined with the analysis of small microlitre sample volumes. The measurement of traces of lead and cadmium is used to illustrate the approach. An optimised procedure for formation of Nafion-coated mercury thin film electrodes is evolved. The relative sensitivity for BIA-ASV at electrodes with and without Nafion coatings is 0.9 and 0.8 for cadmium and lead respectively; detection limits are 2×10^{-9} M and 4×10^{-9} M. Studies were done concerning the influence of surfactants and their effect was found to be much less with the Nafion film coating. Applications to real environmental samples are demonstrated.

Keywords: Batch-injection analysis; Mercury film electrodes; Nafion-coated electrodes; Stripping voltammetry; Trace metals

1. Introduction

The batch-injection analysis (BIA) technique [1] was developed to enable the analysis of small ($\leqslant 100$ μl) volumes of liquid samples whilst retaining the advantage of convection in continuous flow systems. Recent work involving electrochemical detection has demonstrated the similarities between amperometric detection in BIA and the response obtained at wall-jet electrodes in continuous flow [2]. This similarity arises because in both techniques a fine jet of solution (in the BIA case from a micropipette tip) impinges on the centre of a disc electrode immersed in electrolyte solution; this configuration means that memory

* Corresponding author. Fax: (+351) 39-35295.

effects are almost zero. The advantages of the use of a programmable, motorised electronic micropipette have been shown [2,3]. BIA with voltammetric detection has also been demonstrated [4]: consecutive injections during a slow potential sweep lead to a point-by-point voltammetric curve, and cyclic voltammetry and square wave voltammetry can be done during the injection itself.

BIA with stripping voltammetry is also an exciting possibility. After initial studies showing its viability [5], BIA with anodic stripping voltammetry (BIA-ASV) has been explored in detail and nanomolar detection limits were reached with good sensitivity using square wave stripping [6]. The mercury thin film electrode (MTFE) was formed *in situ* and the influences of injected volume, preconcentration time, and micropipette dispension rate were investigated.

A particular benefit of the small sample volumes injected in BIA is that the contact time between sample and electrode is small. Problems of electrode fouling are thus reduced compared with continuous flow systems. Nevertheless, for complex matrices such as waste water with high surfactant levels and blood serum it is often necessary to reduce contamination even further, which can be done by suitable modification of the electrode surface.

Permselective electrode coatings have found use in reducing interference and contamination. Amongst those with applications in stripping voltammetry are Nafion (see e.g. Refs. [7-9]), cellulose acetate (see e.g. Ref. [10]) and dialysis membranes (see e.g. Ref. [11]). An additional benefit is the fact that any problems with adhesion of the mercury film to the glassy carbon substrate [12], which can occur under convective conditions, are removed.

Concerning Nafion films, the signal stability for differential pulse ASV was examined in detail for a number of Nafion-coated thin mercury film preparation methods [7], involving Nafion coating followed by mercury film deposition. Other work involved mixing a ligand specific for the metal ion to be determined, lead [8] and copper [9], with the solution of Nafion before coating.

The objective of this study was to reduce the interferences from complex matrices in the BIA-ASV technique through coating of the glassy carbon electrode with a thin Nafion film. Optimum experimental parameters are examined and comparison with results using a simple MTFE is presented. Application to trace metal determinations in environmental samples is described.

2. Experimental

A modified large open wall-jet cell constructed of perspex and filled with inert electrolyte was used as described previously [2]. The micropipette tip (internal tip diameter 0.47 mm) was fixed exactly over the centre of a glassy carbon (Tokai, GC-20) disc electrode, diameter 5 mm, at a distance of 2-3 mm. The cell also contained a platinum gauze counter electrode and a saturated calomel reference electrode.

A 5% solution of Nafion in low weight alcohols (Aldrich) was diluted with ethanol to prepare appropriate working solutions for forming the Nafion coatings. N,N-dimethylformamide (DMF) was of analytical grade (99.5%) and purchased from Fluka. The preparation of the Nafion-coated (NC) electrode is discussed below. Mercury films were made *in situ* by injection of 10 μl of a 10^{-1} M Hg(II) solution at -1.0 V applied potential. Unless stated otherwise the cell contained 0.1 M KNO_3/0.002 M HNO_3 supporting electrolyte. Injections were performed using a programmable motorised electronic micropipette (EDP Plus 100 EP-100, Rainin Instrument Co. Inc.). This micropipette, of maximum dispensing volume 100 μl, has three dispensing rates; the BIA-ASV measurements were conducted at the slowest dispensing rate, which was calibrated in this study as 22.7 μl s^{-1}.

A computer-controlled EG&G PAR273A potentiostat with M270 Research Electrochemistry Software was used for running the electrochemical experiments.

Solutions were prepared from analytical-grade chemical reagents and Millipore Milli-Q ultrapure water (resistivity $\geqslant 18$ MΩ cm). Stock solutions of 10^{-3} M Pb^{2+} and Cd^{2+} were prepared and di-

luted on the day as appropriate. The protein standard solution (Sigma) containing 0.5 g l^{-1} albumin and 0.3 g l^{-1} globulin; Triton X-100 (Sigma) and sodium dodecyl sulphate (SDS; Aldrich) were used as received in the corresponding studies after appropriate dilution. Experiments were conducted at room temperature (25 ± 1°C) and without deoxygenation.

2.1. Preparation of NCMTFE for BIA-ASV

Prior to polymer coating the glassy carbon electrode was polished using polishing foils with 0.3 μm alumina particles (Hirschmann, Germany), rinsed with Milli-Q water and allowed to dry.

The optimised procedure for forming the Nafion coating was as follows. First, 5 μl of 0.25% (w v) Nafion solution was applied, followed immediately by 3 μl of DMF, to the electrode surface with a micropipette. The solvents were evaporated in a warm air stream from an air gun while the electrode was rotated at 50 rev min^{-1}. The polymer film was then cured for 60 s in a hot air stream (about 70°C), holding the gun just a few millimetres above the electrode surface. The studies which led to this procedure are described in the next section.

The NC electrode was then placed in the BIA cell and mercury deposition was done in situ by injecting 10 μl of a solution of 0.1 M Hg^{2+} in 0.1 M KNO$_3$ 0.002 M HNO$_3$ and applying a deposition potential of -1.0 V during injection (≈ 0.4 s) and a further 60 s after the end of the injection period. As previously shown [6], continuing to apply a potential corresponding to the electrode deposition reaction after the end of the injection itself significantly increases the electrolysis efficiency. The NCMTFE was then ready for use in ASV experiments.

3. Results and discussion

3.1. Optimisation of preparation methods of NCMTFEs

The procedure of Nafion coating and mercury deposition onto a glassy carbon electrode for use in conjunction with BIA was studied with respect to practicality, the stability of the coating under the hydrodynamic conditions of BIA and the maximum attainable sensitivity for trace metal determinations.

There are two principal ways of preparing NCMTFEs. One possibility is to deposit mercury first followed by removal of the electrode from the plating solution and covering of the thin mercury film with a Nafion membrane under air [13]. Alternatively, the procedure can be reversed and the Nafion film prepared first followed by mercury deposition through the Nafion film [14]. The latter approach was found to be more convenient, particularly in a BIA arrangement; this is due to the fact that the mercury deposition can be performed in situ utilising the BIA approach [6]. In addition, covering a bare glassy carbon electrode with a Nafion film offers more freedom for varying the curing procedure parameters than in the presence of mercury, which may evaporate at higher temperatures.

Thus, the procedure of preparing the Nafion film first and then depositing mercury through the polymer film in the BIA cell was studied in detail with a view to optimisation of the relevant parameters. Initial studies used Nafion solutions alone for film formation, which led to films with a tendency to crack and have low adhesion. Previous studies suggested that the addition of a casting solvent can modify the properties of Nafion [15]. This was explored and it was found to be advantageous to employ DMF casting solvent and to heat during the formation of the Nafion film in order to improve its mechanical properties. In addition, preparing the Nafion film by spin-coating resulted in a more uniform polymer layer than under stationary conditions; a rotation speed of 50 rev min^{-1} was employed. For the size of the glassy carbon electrode used, 0.20 cm^2 area, 5 μl Nafion solution and 3 μl DMF were found to be appropriate.

The thickness of the Nafion film was varied using Nafion solutions of different concentration in the range 0.1–0.5% (w/v). The thinnest Nafion film made from 0.1% Nafion solution was found, after mercury deposition, to be insufficiently stable for BIA-ASV experiments. In contrast, using the

0.5% Nafion solution a stable Nafion film was obtained. but a substantial decrease in sensitivity for cadmium and lead determinations occurred in comparison with a MTFE without Nafion coating. As a compromise, employing a 0.25% Nafion solution yielded a film with sufficient stability under BIA conditions and acceptable relative sensitivities of 0.9 for cadmium and 0.8 for lead when compared with that for an uncovered MTFE (see below). Visually, the Nafion coating appeared transparent and uniform over the whole electrode surface, and resulted in homogeneous films without cracks, which was not possible without the addition of DMF casting solvent.

The above results led to the optimised procedure described in detail in Section 2.

3.2. Performance characteristics of BIA-ASV with NCTMFE

The determination of traces of cadmium and lead ions using square wave ASV was chosen in order to characterise the analytical features of the NCMTFE when incorporated in a BIA arrangement. Fig. 1 shows typical responses obtained for cadmium determinations in the concentration range $10^{-8}-10^{-7}$ M. For both cadmium and lead the calibration plots were highly linear as expressed by the linear regression data given in Table 1 for the the ions analysed separately and as a mixture. Fig. 2 illustrates the good reproducibility of repetitive trace metal determinations. No memory effects were observed providing that between successive measurements an injection of electrolyte was done at a conditioning potential of

Fig. 1. Concentration dependence of the BIA-ASV response obtained for cadmium determinations with a NCMTFE. Experimental conditions: injection volume. 50 μl; preconcentration, 30 s at -1.0 V vs. SCE; stripping mode, square wave voltammetry with amplitude 25 mV, scan increment 2 mV and frequency 100 Hz. Cadmium concentrations: (a) background; (b) 10^{-8}; (c) 2×10^{-8}; (d) 3×10^{-8}; (e) 5×10^{-8}; (f) 8×10^{-8}; (g) 10^{-7} M.

-0.2 V to ensure the removal of electroactive species from the vicinity of the electrode surface. This potential was applied constantly between determinations. Detection limits were determined on the basis of the 3σ criterion related to the baseline noise level and amounted to 5×10^{-9} M

Table 1
Results of linear regression of calibration data for cadmium and lead determinations by BIA-ASV using a NCMTFE (Pb^{2+}: $1 \times 10^{-8}-1 \times 10^{-7}$ M; Cd^{2+}: $5 \times 10^{-9}-1 \times 10^{-7}$ M)

Analyte	Slope (μA nM^{-1})	Intercept (μA)	Regression coefficient
Cd^{2+}	0.052	-0.07	0.9992 ($n = 7$)
Pb^{2+}	0.022	-0.01	0.9975 ($n = 6$)
Cd^{2+} (Pb^{2+})[a]	0.042	0.09	0.9976 ($n = 5$)
Pb^{2+} (Cd^{2+})[b]	0.023	0.05	0.9958 ($n = 5$)

[a] Cadmium determinations in the presence of equal amounts of lead.

Fig. 2. Reproducibility of BIA-ASV determinations at a NCMTFE for a cadmium concentration of 10⁻⁷ M. Other conditions as in Fig. 1.

and 1×10^{-8} M for cadmium and lead respectively.

The stripping peaks corresponding to cadmium and lead using a NCMTFE appear at potentials 12 mV more negative than in the case of measurements at a MTFE without Nafion coating. This probably reflects the cation exchanging behaviour of the Nafion coating which favours the oxidised state of the test species. However, there was only a slight effect on the shape of the signals, the peak width at half height increasing from 52 to 55 mV, suggesting that any kinetic limitations due to the Nafion film are not important.

The above results are based on injections of 50 μl of analyte solution and accumulation times of 30 s as suggested previously for BIA-ASV using an uncoated MTFE [6]. This was because, in the preconcentration step, the profile of signal height vs. injection volume reaches a maximum for this injection volume, due to the important contribution from diffusion to the electrode after the end of the injection itself of species remaining in the zone of the electrode. It was found during the course of this study that multiple injections of fractions of the total injection volume can lead to a further improvement in sensitivity using the multiple-dispense mode of the programmable micropipette without removing the pipette from the BIA cell. For example, four successive injections of 25 μl analyte with short periods in between yielded about 2.5 times higher signals in comparison to a single injection of 50 μl (note that an injection of 50 μl gives the same signal as injec-

tion of 100 μl, as explained above). The higher electrolysis efficiency obtainable via this multiple-injection approach is illustrated in Fig. 3 for BIA experiments using $K_4[Fe(CN)_6]$ oxidation as model reaction.

The multiple-injection technique was applied to trace metal determinations when the concentrations of the analyte species were close to the detection limit. In this way, the detection limit is reduced by a factor of 2.5 to 2×10^{-9} M and 4×10^{-9} M for cadmium and lead respectively. The analytical utility of this approach is demonstrated in Section 3.4.

3.3. Influence of matrix constituents on the BIA-ASV response

The effects of various organic surfactants on the response of the NCMTFE in BIA-ASV measurements were studied using cadmium as test analyte. Some common surface-active compounds, such as Triton X-100, and a protein

Fig. 3. BIA response for amperometric detection at +0.6 V vs. SCE for oxidation of 2 mM $K_4[Fe(CN)_6]$ in 0.4 M K_2SO_4 electrolyte using a bare glassy carbon electrode. The amperometric transient (a) corresponds to an injection of 50 μl of $K_4[Fe(CN)_6]$ solution while (b) represents the response for four consecutive injections of 25 μl analyte solution. The dispensing rate is 22.7 μl s⁻¹ in both cases.

Table 2
Effects of surface-active compounds on the BIA-ASV response for 50 μl injections of 10^{-7} M Cd^{2-} at a MTFE and a NCMTFE

Surface-Response active compound		c(mg l^{-1})				
		1	2	5	11	22
Triton X-100	ΔI_p (%) MTFE	-12	-21	-37	-81	-91
	ΔI_p (%) NCMTFE	-14	-17	-24	-37	-76
SDS [a]	ΔI_p (%) , MTFE	-14	-19	-24	-26	-27
	ΔI_p (%) NCMTFE	-3	-9		-20	-23
Protein standard	ΔI_p (%) MTFE		-8	-15	-20	-68
	ΔI_p (%) NCMTFE		-5	-6	-6	-6

[a] The measurements were performed in 0.1 M acetate buffer (pH 4.5).

standard, were chosen as representing different types of interference with faradaic electrode processes. The effects of the individual surfactants on the BIA-ASV response were examined with both the MTFE and the NCMTFE in order to obtain a direct comparison under identical conditions. The experimental approach used was to inject first a sample containing 10^{-7} M cadmium ions (without the surfactant) onto a newly prepared electrode. Next, samples containing the same concentration of metal ions but in the presence of increasing concentrations of surfactant were injected consecutively. Table 2 summarises the relevant results of these measurements. In all cases, the NCMTFE was clearly less susceptible to peak depression than the MTFE. As an example, Fig. 4 illustrates the different extent of signal depression due to the presence of Triton X-100 for (A) a MTFE and (B) a NCMTFE. In particular, the results obtained for samples with a matrix containing proteins indicate that the Nafion coating is an effective barrier to the transport of these potential interferents towards the mercury surface. which agrees with data found previously by other authors [14,16-18]. The slight decrease in the BIA-ASV signal of 5 or 6% obtained with the NCMTFE after additions of protein standard to the sample was even independent of the protein concentration in the range studied up to 22 mg l^{-1}. Thus, it can be speculated that the measured decrease in signal results from complexation of the analyte [19] rather than from electrode blocking effects.

3.4. Practical applications

The analytical utility of the NCMTFE in conjunction with BIA-ASV was investigated by applying it to the analysis of heavy metal traces, lead and cadmium, in environmental samples with complex matrices, using the standard addition method.

Fig. 5 illustrates the results obtained for an undiluted waste water sample using the technique of multiple standard additions and the evaluation of cadmium concentration—these samples were found not to contain lead at a detectable concentration. The rather low concentration of 5.0 ± 0.1

Fig. 4. BIA-ASV signals obtained with (A) MTFE and (B) NCMTFE for injections of samples containing 10^{-7} M Cd^{2+} in the absence (solid line) or in the presence (broken line) of 11 mg l^{-1} Triton X-100 surfactant. Other conditions as in Fig. 1.
Fig. 5. Evaluation of the cadmium determination in an undiluted waste water sample by BIA-ASV with a NCMTFE using the standard addition method. The signals for the original sample (S) and that obtained after standard addition correspond to a multiple-injection preconcentration of four consecutive injections of 25 μl within a total preconcentration period of 60 s.

nM (0.56 ± 0.1 ppb) cadmium showed the advantages of using the multiple-injection preconcentration procedure described above in order to increase electrolysis efficiency. Repetitive measurements showed almost no changes in the voltammetric response, which indicates effective protection of the NCMTFE against interfering matrix constituents.

In addition, a sample was taken from a car wash, which obviously contained a high amount of detergents. In this case, lead traces were quantified in this sample using multiple-injection preconcentration but no detectable traces of cadmium were encountered. The NCMTFE was not completely insensitive to the matrix constituents as indicated by a progressive signal decrease of the BIA-ASV response of a few percent for repetitive measurements. However, the technique of standard addition requires just a limited number of measurements and the contact time of the sample matrix with the electrode surface in the BIA mode is very short. Consequently, a lead concentration of 15.5 ± 0.9

nM (3.2 ± 0.2 ppb) was determined on the basis of measuring the signal from the sample solution and performing two standard additions for which the electrode characteristics can be assumed to remain constant.

Confirmation of the values was obtained by AAS with electrothermal atomization. The waste water sample led to 0.6 ppb and <0.05 ppb and the car wash sample to 0.15 ppb and 3.0 ppb for cadmium and lead respectively. The levels of lead in the first case and cadmium in the second are below BIA-ASV detection limits. Since electrochemical methods probe the amount of labile species in a given oxidation state rather than the total amount of the element as in AAS, the agreement between BIA-ASV with standard addition and AAS shows that in the samples tested all the metal ions are present in a labile form. In other cases, where a fraction of the metal ions is not labile, the electrochemical response will be lower, and standard addition will measure the concentration of these labile species.

For the environmental samples studied the performance characteristics of the NCMTFE were far superior to those of the MTFE with regards to fouling of the electrode surface by contaminants in complex matrices and the improved stabilisation of the mercury film. In fact, it was impossible to obtain meaningful results concerning the lead concentration in the car wash sample when using a bare MTFE.

4. Conclusions

It has been shown that NCMTFEs offer significant advantages compared to ordinary MTFEs for square wave ASV using the BIA technique, and these are particularly evident in the analysis of environmental sample containing high surfactant levels. The technique for the formation of the NCMTFE is simple. This, combined with the easy and rapid BIA-ASV procedure, demonstrates that it will be an important method for the determination of small (microlitre) volumes of traces of heavy metals in complex matrices.

Book reviews

Understanding Medications: What the Label Doesn't Tell You, by A. Burger, American Chemical Society, Washington, DC, 1995, xiv + 206 pp., ISBN 0-8412-3210-5.

The author of the book, Dr Alfred Burger, founded the Journal of Medicinal Chemistry in 1959 in collaboration with Arnold H Beckett. His inspiration for this book stems from the requirement to "satisfy and stimulate the curiosity of educated lay people who, on the whole, lack the biochemical and pharmacological background for the study of medicinal agents." The themes of the book are also described by the author as "the history, discovery, manufacture, action, acceptance and rejection of drugs".

Contained in the 21 small chapters is a wealth of information on drugs, albeit in a limited form, which indeed will satisfy most lay people. I found the text enjoyable and very easy to read–in a relaxed style somewhat similar to that found in Reader's Digest. Of course, whole books could have been written on each of the chapters so it will be very easy for a reviewer to criticise the oversimplicity of some of the contents. In the chapter on naming drugs it is interesting that not all trade names in the USA are the same as elsewhere, for example, the most common over-the-counter drug in the UK is paracetamol but the word paracetamol does not occur anywhere in the book. This is because the drug is known in the USA by the trade name Tylenol and the book correctly gives another corresponding nonproprietary name for the same drug as acetominophen.

The chapters devoted to drug categories are: neurohormones and drugs that affect the central nervous system, drugs for the relief of pain, local anesthetics, antispasmodics and antihistamines, drugs that act on the blood pressure and the heart, intestinal medications, hormones and vitamins, drugs for the treatment of cancer, drugs affecting the immune response, drugs for infectious diseases, antiparasitic drugs and antiviral drugs. There is also a chapter on research and a glossary of some chemical and medical terms. I found the explanation of X-ray diffraction in the glossary as "A method of determining the chemical structure of a compound by measuring the distances between it atoms" somewhat vague. I was also surprised to read under a heading on Diuretics that the concentration of salts (especially sodium chloride) for the mammalian body is one-fourth that of seawater, namely about 0.23%. It has been my understanding that the concentration of sodium chloride which is isotonic with blood is 0.9% w/v and this should be the value used in the book.

Overall, an interesting book which achieves its stated aims. A little more on the need for different dosage forms (i.e., tablets, capsules, injections, suppositories, etc.,) would be useful to satisfy the curiosity of the lay person.

Flow Injection Atomic Absorption Spectrometry, by Zhaolun Fang, Wiley, Chichester, 1995, xii + 306 pp., £60.00. ISBN 0-471-95331-8.

The combination of flow injection (FI) and atomic absorption spectrometry (AAS) has undergone a spectacular development within the past decade as reflected in the exponentionally increasing number of publications (more than 600 are included in the book). In fact, the effects are in the words of the author "so dramatic" that it has brought "new vitality to a technique [AAS] which otherwise seemed to be confronted by a period of stagnancy". Most of these novel developments have taken place since Burguera in 1989 edited the first monograph on FI-AAS, and for this reason it seems highly appropriate that Fang, who is one of the foremost authorities in the field, has undertaken to scrutinize, compile and communicate the current knowledge in this rapidly growing area.

His book is composed of twelve chapters. Chapter 1 gives a brief introduction to the basic principles of FI and some general aspects of FI-AAS, where it is noteworthy that Fang warns that "flow injection techniques are not as simple as they appear", implying that it is important to direct attention to technical and operational details to avoid detours and pitfalls. The core, mission and justification of his book is to assist the reader to design optimal systems for dedicated purposes. Chapter 2 deals with general instrumentation, where the author generously shares his wealth of practical experience, discusses advantages and disadvantages of the individual components (pumps, valves, tubings, etc.) and offers numerous useful operational hints. In fact, these aspects are characteristically manifested throughtout the text, where one is constantly reminded that this is a book written by a person who truly has hands-on experience with his subject. These introductory chapters (and sections of the following ones) inevitably imply recycling of material from his previous book on Flow Injection Separation and Preconcentration. This should not, however, be taken as a derogatory remark, because if one is not the fortunate owner of that book the material included here is essential prerequisites for sufficient appreciation of the ensuing chapters. The various modes of FI sample introduction used in AAS are treated in Chapter 3—detailed appropriately because it is well recog-

nised that this feature is indeed the 'Achilles heel' of atomic spectrometric techniques—followed by separate chapters on FI techniques for on-line dilution (Chapter 4) and sensitivity enhancement (Chapter 5), all used mainly in connection with flame spectrometry. For this reviewer, who has constantly advocated the exploitation of the potentials which are inherent in the concentration gradient created in FI, it is most satisfying to see that Fang stresses this point, which has been much overlooked in conjunction with FI-AAS. Chapter 6 is devoted to FI vapor generation methods, that is, hydride generation (HGAAS) and cold vapor (CVAAS), where advantage can not only be taken of separating the gaseous analyte species from possible interfering matrix constituents, but where one can also exploit kinetic discrimination to enhance the analytical signal in favour of the sample constituent. Chapter 7 treats the so-called indirect methods, that is, conversion techniques where a sample consitiuent via intelligent chemistry is converted into a species detectable by AAS. FI on-line preconcentration systems for flame and vapor generation AAS are discussed separately in Chapter 8, which relies heavily on the author's previous book, but also contains much new material in this rapidly expanding field and is a most illuminating section comprising much valuable information which will no doubt be of great value for the reader. In Chapter 9 FI techniques (including preconcentration techniques) used for electrothermal AAS are treated. Not surprisingly, this section draws heavily on the author's own results, where he, undisputably, has been one of the pioneers, and which area promises to be one of the most exciting ones in the future. Chapters 10 and 11 are devoted to FI calibration (by exploiting the concentration gradient of FI) and on-line digestion techniques. The last chapter (12) deals with the application of FI-AAS methods to the environmental, agricultural, clinical, pharmaceutical, geological and metallurgical fields, a compilation which should prove most useful for practising analytical chemists.

In the preface it is stated that the book may be used "both as a reference source and a laboratory manual, but some of the chapters may also be

used as textbook material". I am not sure that the author has managed to achieve all these goals satisfactorily (and it would, admittedly, also be virtually impossible to do so). While the book constitutes a homogenous entity when read as a whole, it is somewhat problematic to extract specific information on a certain subject (as guided from the otherwise detailed index) unless several sections are consulted simultaneously. Although Fang has tried to eliminate this shortcoming with a fine-masked net of cross references, it does in instances create more confusion than overview. On the other hand, it should be added that the book inevitably compels the reader to continue reading, which is a commendable asset. Some subjects, which to the AAS-practitioner might be termed to be rather exotic, are treated in unnecessary detail (e.g. thermospray and high pressure sample deposition), while others are mentioned merely superficially. This is especially true for the subject of speciation to which only half a page is devoted. To the excuse of the author it should be added that this area has received particular attentiion in the very recent past, and since the manuscript for Fang's book was concluded in late 1994, he really cannot be blamed. A neat detail which deserves to be mentioned is the way that Fang has compiled and combined the references and the FI-AAS bibliography at the end of his book. While the references are quoted in the "normal" fashion (i.e., without titles), the bibliographic ones include the full title of the individual papers which is most helpful.

Altogether Fang has written an authoritative book on a subject of vital interest, but also on a subject on which there is an expanding growth and practical interest. Therefore, I am sure that his book will stand out as a milestone, firstly because it is written by one of the foremost specialists in the field, and secondly because it contains a wealth of applicable information. Both for the beginner in the area of FI-AAS and for the experienced analyst the book should prove most useful and, what I find important, inspirational. The concluding chapter is virtually a gold mine as a reference source as well a practical guide for determining various elements in different matrices. Here the book not only proves its merits as

a handbook for the analytical chemist, but also as a viable practical tool. For all these reasons I am of the firm conviction that the book is a very good investment.

E.H. Hansen

Special Trends in Thermal Analysis, by F. Paulik, Wiley, Chichester, 1995, xvii + 459 pp., £90.00. ISBN 0-471-95769-0.

Can there be anyone who worked in the field of thermal analysis who has failed to notice one name recurring time and again with amazing frequency over the last thirty years— the name Paulik? Indeed, there were usually two Pauliks, the brothers Ferenc and Jenö, who make their name in the field of differential thermal analysis, designing and building their own apparatus in the 1950's, and applying it, and its later developments, to the investigation of countless materials of both synthetic and natural origin, so that this has come to be widely recoginsed as an essential tool in materials testing and chemical analysis.

This book— by Ferenc Paulik— is dedicated to the memory of his collaborator for over thirty years—his younger brother Jenö who died in 1988. It is a survey of the applications of these instruments, and in principle of any similar instruments operating in simultaneous measurement mode. This survey includes a comprehensive bibliography of over 2800 papers, spanning the years from the description of the original instrument in 1954 up to the present day (1995).

Part I of the book is concerned with experimental methodology, including dilatometry, thermogas titrimetry and evolved gas analysis. Part II reflects the Pauliks' view that recording thermal analysis data for a substance was just a beginning—they always pursued the interpretation of the curves in terms of chemical and physical changes, aided by evolved gas analysis or X-ray methods. So this part is concerned with the kinetics and mechanism of the processes occurring during heating of samples.

E.H. Hansen

Special Trends in Thermal Analysis, by F. Paulik, Wiley, Chichester, 1995, xvii + 459 pp., £90.00. ISBN 0-471-95769-0.

Can there be anyone who worked in the field of thermal analysis who has failed to notice one name recurring time and again with amazing frequency over the last thirty years— the name Paulik? Indeed, there were usually two Pauliks, the brothers Ferenc and Jenö, who make their name in the field of differential thermal analysis, designing and building their own apparatus in the 1950's, and applying it, and its later developments, to the investigation of countless materials of both synthetic and natural origin, so that this has come to be widely recoginsed as an essential tool in materials testing and chemical analysis.

This book—by Ferenc Paulik—is dedicated to the memory of his collaborator for over thirty years—his younger brother Jenö who died in 1988. It is a survey of the applications of these instruments, and in principle of any similar instruments operating in simultaneous measurement mode. This survey includes a comprehensive bibliography of over 2800 papers, spanning the years from the description of the original instrument in 1954 up to the present day (1995).

Part I of the book is concerned with experimental methodology, including dilatometry, thermo-gas titrimetry and evolved gas analysis. Part II reflects the Pauliks' view that recording thermal analysis data for a substance was just a beginning—they always pursued the interpretation of the curves in terms of chemical and physical changes, aided by evolved gas analysis or X-ray methods. So this part is concerned with the kinetics and mechanism of the processes occurring during heating of samples.

Part III of the book discusses the more recent topic of quasi-isothermal TG and DTA, which permits greatly improved resolution of decomposition steps by raising the temperature very slowly through the regions of change, maintaining a tiny but constant temperature difference between the sample and its environment, and thus overcoming the problem associated with earlier instruments that thermal analysis curves from different laboratories could vary significantly due to the use of different heating rates.

This unique, readable and well illustrated volume is authoritative. It is the voice of the master, or, rather, the voice of the master brothers, a fitting tribute, and an excellent handbook of the state of the art of thermal analysis.

I. Marr

Capillary Electrophoresis Guidebook: Principles, Operation and Applications, edited by K.D. Altria, Humana, Totawa, 1996, xi + 349 pp., US$74.50. ISBN 0-896-03315-5.

This book in two parts, is volume 52 in the series on Methods in Molecular Biology. Part 1 is ideal for those lacking in, or with limited knowledge of, the theory and the practice of capillary electrophoresis (CE). It is an excellent, easy-to-follow, instructive text, particularly on the practicalities of the methods and instrumentation involved in CE. By the frequent use of flow diagrams, clear figures and tables and the use of smaller print in the text to highlight important aspects of the instrumentation or essential steps in the methodology, the author guides the reader in a logical fashion from start up to the final step of running a successful, validated, separation. The text communicates to the reader the author's obvious enthusiasm and knowledge of CE.

The contents of Part 2 are more geared towards those with current or future research interests in CE. It reviews the methods and technologies which are commonly used at present, for example, chiral separations by CE, micellar electrokinetic chromatography, capillary gel electrophoresis, and capillary electrochromatography. The final chapter reviews the less common uses of CE and in so doing illustrates amply the potential of CE for the analysis of a very diverse range of subject matter. Though different authors contribute to Part 2, the high, uniform, standard of presentation of the text, as seen in Part 1, is maintained throughout Part 2. As per Part 1, up-to-date, appropriate references are included at the end of each of the chapters.

Though CE is a comparatively recent addition to available chromatographic separation techniques, its importance as a widely used separation method with a very diverse range of applications is encapsulated in this very worthwhile, well written, and referenced text.

R.R. Moody

Part III of the book discusses the more recent topic of quasi-isothermal TG and DTA, which permits greatly improved resolution of decomposition steps by raising the temperature very slowly through the regions of change, maintaining a tiny but constant temperature difference between the sample and its environment, and thus overcoming the problem associated with earlier instruments that thermal analysis curves from different laboratories could vary significantly due to the use of different heating rates.

This unique, readable and well illustrated volume is authoritative. It is the voice of the master, or, rather, the voice of the master brothers, a fitting tribute, and an excellent handbook of the state of the art of thermal analysis.

I. Marr

Capillary Electrophoresis Guidebook: Principles, Operation and Applications, edited by K.D. Altria, Humana, Totawa, 1996, xi + 349 pp., US$74.50. ISBN 0-896-03315-5.

This book in two parts, is volume 52 in the series on Methods in Molecular Biology. Part 1 is ideal for those lacking in, or with limited knowledge of, the theory and the practice of capillary electrophoresis (CE). It is an excellent, easy-to-follow, instructive text, particularly on the practicalities of the methods and instrumentation involved in CE. By the frequent use of flow diagrams, clear figures and tables and the use of smaller print in the text to highlight important aspects of the instrumentation or essential steps in the methodology, the author guides the reader in a logical fashion from start up to the final step of running a successful, validated, separation. The text communicates to the reader the author's obvious enthusiasm and knowledge of CE.

The contents of Part 2 are more geared towards those with current or future research interests in CE. It reviews the methods and technologies which are commonly used at present, for example, chiral separations by CE, micellar electrokinetic chromatography, capillary gel electrophoresis, and capillary electrochromatography. The final chapter reviews the less common uses of CE and in so doing illustrates amply the potential of CE for the analysis of a very diverse range of subject matter. Though different authors contribute to Part 2, the high, uniform, standard of presentation of the text, as seen in Part 1, is maintained throughout Part 2. As per Part 1, up-to-date, appropriate references are included at the end of each of the chapters.

Though CE is a comparatively recent addition to available chromatographic separation techniques, its importance as a widely used separation method with a very diverse range of applications is encapsulated in this very worthwhile, well written, and referenced text.

Polarographic determination of loratadine in pharmaceutical preparations

J.A. Squella*, J.C. Sturm, M.A. Diaz, H. Pessoa, L.J. Nuñez-Vergara

Bioelectrochemistry Laboratory, Chemical and Pharmaceutical Sciences Faculty, University of Chile, P.O. Box 233, Santiago 1, Chile

Abstract

Loratadine, a potent antihistamine drug, is not directly electroreducible at a dropping mercury electrode; however, by means of a nitration procedure it is possible to obtain a nitro-loratadine derivative which has been identified as 4-(8-chloro-7-nitro-5,6-dihydro-11H-benzo-[5,6]-cyclohepta-[1,2-b]-pyridin-11-ylidene)-1-piperidine carboxylic acid ethyl ester. The electrochemical reduction of this derivative at different pHs and concentrations using polarography and cyclic voltammetry was studied. The derivative exhibits a differential pulse polarographic peak due to the reduction of the nitro group. This peak was used in order to develop an analytical procedure for determining loratadine in pharmaceutical dosage forms.

The recovery study shows adequate accuracy and precision for the developed assay and the excipients do not interfere in the determination.

Keywords: Loratadine; Polarography; Drug analysis; Nitrated loratadine

1. Introduction

Loratadine (Fig. 1) is a potent, long-acting antihistamine which has a high selectivity for peripheral histamine H_1-receptors in the central nervous system (CNS) in vitro or in vivo. The drug displays little activity at acetylcholine or α_1-adrenergic receptors, and is inactive in animal models of assessing anticholinergic effects. Loratadine penetrates poorly into the CNS [1].

The therapeutic efficacy of loratadine has been investigated in allergic rhinitis, both seasonal and perennial, acute coryze (common cold) and chronic idiopathic urticaria. The recommended adult dosage of loratadine is 10 mg once daily while that of the combination tablet (5 mg loratadine plus 120 mg pseudoephedrine) is one tablet twice daily [2].

Radioimmunoassay and high performance liquid chromatography, with detection limits of 0.3 $\mu g\ l^{-1}$ and 0.6 $\mu g\ l^{-1}$ respectively, have been used to quantitate loratadine and its chief metabolite, descarboethoxy-loratadine, in plasma [3]. However, no analytical assays for pharmaceutical forms of loratadine have been reported to date.

Modern computer-based electrochemical instru-
mentation has increased the usefulness of electro-
chemical methods in pharmaceutical analysis and
there are several examples where electrochemical
determinations of drugs in pharmaceutical forms
have been developed [4–6]. A practical advantage
of polarography and voltammetric methods in the
determination of drugs in pharmaceutical forms is
that undissolved excipients or colored solutions
do not interfere to the extent that they do in other
methods. The prerequisite for direct determina-
tion without prior separation is that the drug is
more strongly adsorbed onto the electrode surface
than the excipients present in the formulation [7].

The purpose of this work is to investigate some
of the electrochemical properties of loratadine
and to work out a new method for loratadine
determination using principally differential pulse
polarography (DPP), for both the pure drug and
for commercial preparations.

2. Experimental

2.1. Apparatus

DPP, Tast polarography and cyclic voltammet-
ric experiments were carried out in an Inelecsa
assembly containing a PDC1212 potentiostat–
generator attached to an Acer 500 + PC computer
with suitable software for totally automated con-
trol of the experiments and data acquisition. A 50
ml thermostated cell equipped with a three-elec-
trode system was used. The working electrode was
a dropping mercury electrode (DME) and a hang-
ing mercury drop electrode (HMDE), Metrohm
model EA-290, for polarographic and cyclic
voltammetric experiments respectively. A satu-
rated calomel electrode (SCE) as a reference elec-
trode and a platinum wire as an auxiliary
electrode were also used.

Spectrophotometric measurements were carried
out with a Perkin-Elmer model 551 spectrophoto-
meter using 1 cm quartz cells. Spectra were
recorded between 200 and 400 nm, and quantita-
tive sample measurements were made at 270 nm.

A Varian XL-100 nuclear magnetic resonance
spectrometer, a Bruker AM-200 nuclear magnetic

resonance (NMR) spectrometer and a Perkin-
Elmer model 1310 IR spectrophotometer were
used. The IR spectra were obtained in 1% potas-
sium bromide pellets, and the NMR spectra were
carried out in deuterated chloroform with TMS as
internal standard.

2.2. Materials and reagents

Loratadine,   4-(8-chloro-5,6-dihydro-11H-
benzo-[5,6]-cyclohepta-[1,2-b]-pyridin-11-ylidene)
-1-piperidine carboxylic acid ethyl ester, was
obtained from Schering-Plough Laboratories
(Santiago, Chile; 99.7% chromatographically
pure). Clarityne® tablets containing 10 mg of
loratadine were commercially obtained. All
reagents and solvents were of analytical grade.

2.3. Procedures

2.3.1. Nitration mixture

A previously reported [8] modified mixture was
used. 500 mg of sodium nitrate was accurately
weighed and dissolved in 50 ml concentrated sul-
furic acid.

2.3.2. Nitration procedure

An accurately weighed amount of the drug (10
mg) was transferred to a 10 ml tube and treated
with 1 ml of nitration mixture. The drug was
solubilized in an ultrasonic bath for 1–5 min,
cooled over ice and diluted with 10 ml distilled
water. Then the solution was transferred to a 50
ml calibrated flask and diluted to volume with
distilled water in order to obtain a 5×10^{-4} M
standard solution of nitrated loratadine (NO_2-
loratadine).

Fig. 1. Chemical structures of (a) loratadine, (b) nitro-lo-
ratadine derivative.

2.3.3. Isolation of nitrated derivative

After the nitration procedure the solution was chromatographed on a silica column with chloroform:ethyl acetate (50:50) as eluant. The obtained solutions from the column were concentrated to give an oily yellow substance that was analyzed by IR and NMR.

2.3.4. Buffer solutions

To study the effect of pH on the electrochemical behavior of the nitrated loratadine, 0.1 M Britton–Robinson buffer with a pH range of 1.5–13.5 was used. 30% ethanol as a co-solvent was also used. For analytical studies a pH 12 buffer solution was prepared as follows: add 10 ml 5 M NaOH, 30 ml 0.4 M H_3BO_3 and 30 ml acetone and then make up to volume with distilled water.

2.3.5. Calibration curve

Solutions for the calibration curve were individually prepared by diluting the standard solution with pH 12 buffer to obtain solutions which varied from 1×10^{-5} M to 1×10^{-4} M.

2.3.6. Synthetic samples

Synthetic samples from recovery studies were prepared by weighing 10 mg plus suitable excipients according to the manufacturer's batch formulas for 10 mg loratadine tablets. The excipients tested were magnesium stearate, starch and lactose. The pure loratadine plus excipients mixture was homogenized and then the above nitration procedure was followed. Following the nitration procedure and suitable dilutions, the solutions were directly assayed by polarography and spectrophometry.

2.3.7. Tablet assay

Each loratadine tablet (Clarityne®, Lab. Schering, Santiago, Chile) was finely ground and then nitrated and diluted according to the above nitration procedure. After the nitration procedure and adequate dilutions the solutions were directly assayed by polarography and spectrophometry.

2.3.8. Polarography

Before the polarographic experiments all the solutions were purged with pure nitrogen for 5

min. All the potentials are referenced to the SCE. The operating conditions were (a) DPP mode: pulse amplitude, 50 mV; potential scan rate, 5 mV s^{-1}; drop time, 1 s; potential range, 0 to -1000 mV; current range, 1–10 μA full scale; (b) d.c. mode: potential scan rate, 5 mV s^{-1}; drop time, 1 s; potential range, 0 to -1000 mV; current range, 0.5–5 μA full scale.

2.3.9. Spectrophotometry

The same solutions as for the polarographic measurements were filtered and measured with the spectrophotometer at 269 nm. As a reference a buffer solution of pH 12 was used.

3. Results and discussion

Loratadine is not polarographically reducible as evidenced by the absence of waves in the available potential range. Consequently, in order to obtain a polarographic signal we tried a derivatization method in order to transform the drug into an electroactive moiety, in this case a nitration procedure. According to the described nitration procedure we have obtained a very well-defined polarographic peak, or wave (Fig. 2), with peak potential or half wave potential of -770 mV vs. SCE by differential pulse or d.c. polarography respectively. In addition, by following the limiting current of this peak, or wave, it is possible to control the nitration procedure. Specifically, this procedure is very sensitive to the following parameters: concentration of the nitration mixture, time of reaction and temperature. In Fig. 3 the dependence of the nitrate concentration of the nitration mixture on the peak current of the NO_2-loratadine derivative is shown. It can be concluded that above 7 mg sodium nitrate per ml H_2SO_4 the quantity of the NO_2-loratadine derivative remains constant. In order to obtain suitable nitration conditions we recommend a concentration of 10 mg sodium nitrate per ml H_2SO_4. The nitration procedure is only slightly dependent on reaction time. However, in order to secure both a complete dissolution of the drug and adequate reproducibility in terms of the extent of the reaction, a reaction time of 10 min is recommended.
Fig. 2. DP and d.c. polarograms of 5×10^{-5} M solution of treated loratadine in buffer, pH 12, aqueous buffer:acetone (70:30, v/v).

Furthermore, the nitration procedure is strongly dependent on temperature. In Fig. 4 the effect of increasing reaction temperature on the differential pulse polarogram of the reaction product is shown. From this behavior it can be concluded that at temperatures > 30°C a second peak appears, at approximately − 540 mV.

In order to confirm the nitration procedure and to identify the nitrated derivative we have used IR and NMR spectroscopy. Firstly, we have confirmed that nitration occurs by comparison of the IR spectrum of loratadine with the IR spectrum of the nitrate derivative. The latter spectrum shows two bands, at 1530 cm^{-1} and 1350 cm^{-1}, that do not appear in the loratadine IR spectrum. These bands are characteristic of nitro groups [9], thus confirming the nitration of loratadine. Secondly, considering the structural analysis of the

molecule, there are two main possibilities for nitration, namely the pyridine and chlorobenzene moieties (Fig. 1). However, the ^{1}H-NMR spectrum of the nitrated derivative shows the following signals: δ: 7.20 (d,d 1H, 3-H, $J = 8$ Hz); 7.50 (d,d, 1H, 4-H, $J = 8$, $J = 4.5$ Hz) and 8.47 (d,d, 1H, 2-H, $J = 8$, $J = 4.5$ Hz), indicating that there is not substitution in the pyridine moiety. Consequently, the nitro substitution occurs in position 7 of the chlorobenzene moiety, producing the nitro-loratadine derivative (Fig. 1). Furthermore, the second polarographic peak that appears at more anodic potential (Fig. 4) may be explained by considering a side product of the nitration reaction when the reaction temperature is > 30°C. This side product is a quinone derivative produced due to the further oxidation of the nitro derivative, according to Scheme 1. The quinone group was confirmed by the green color obtained in the presence of ammonia and the reduction peak at more anodic potentials can be ascribed to the reduction of the quinone moiety.

As a result of our selected temperature conditions (cooling over ice) only one peak due to the reduction of the NO_2-loratadine was observed. Specifically, the electroactivity is due to the four-electron reduction of the nitro-aromatic moiety

Fig. 3. Effect of the nitrate concentration in the nitration mixture on the nitro-loratadine derivative formation.

according to the well-known global mechanism [10]:

$$ArNO_2 + 4e^- + 4H^+ \rightarrow ArNHOH + H_2O \qquad (1)$$

To examine the effect of pH on the limiting current and peak potential, a series of d.c. and DP

polarograms were recorded for 5×10^{-5} M loratadine solutions in a 0.1 M Britton–Robinson buffer with 30% ethanol as a cosolvent. The behavior of the peak potential with pH is given in Fig. 5. As can be seen the peak potential was shifted to more negative values, showing a linear dependence between pH 1.5 and pH 10.5, with a break at approximately pH 5. Above pH 10.5 the potential peak is pH-independent, suggesting that no protons are involved previously or in the rate-determining step. This fact implies that in a strongly alkaline medium the rate-determining step is the transfer of the first electron, without previous protonation. This pH behavior is typical for nitroaromatic compounds [11]. Furthermore, linear sweep voltammetric experiments reveal the presence of a very sharp asymmetric peak indicating both the irreversible character of the reduction process and the weak adsorption of the electroactive species [12].

In contrast, the limiting current of the NO_2-loratadine derivative in DPP remains practically constant over all the pH range. However, in DPP the peak current shows a distinct change with pH (Fig. 6). This change is because in DPP mode the peak current is strongly dependent on the reversibility of the process, i.e. irreversible redox

systems result in lower and broader current peaks compared with those predicted for reversible systems [13]. In our case we have a distinct change in the reversibility of the electrode process with pH, with a greater degree of reversibility at basic pHs. To obtain better resolution and reproducibility we have selected pH 12 for further studies. In order to clarify the nature of the electrode process that controls the limiting current, we studied the limiting current behavior as a function of the height of the mercury column. From this study we obtained a linear relation between the limiting current and the square root of the height of the mercury column (corrected for back pressure), showing diffusion control of the electrode process. Consequently, we have also obtained a linear relation between the peak current and loratadine concentrations with a linear range between 1×10^{-7} M and 1×10^{-4} and a detection limit of 1×10^{-7} M by DPP at pH 12. The determination of the detection limit was effected by comparison with a blank signal, being positive when the signal surpassed the signal-to-noise ratio by a factor of three. In order to quantify the drug, we have used the calibration curve method with concentrations ranging between 1×10^{-5} M and 1×10^{-4} M. The calibration curve is described by the follow-
ing regression curve:

$$i_p(\mu A) = 80.02 \times 10^3 C(M) + 0.199 \qquad (2)$$

(correlation coefficient = 0.999, $n = 10$, pH = 12, $T = 25°C$), where i_p is the peak current and C is the loratadine concentration. The reproducibility of the method was calculated from ten independent runs of a 5×10^{-5} M loratadine solution, obtaining an RSD of 1.4%. In order to check the accuracy and precision of the developed method, we have also carried out a recovery study, obtaining a recovery of 98.97% with an RSD of 1.81%. From these results we can conclude that the method is sufficiently accurate and precise in order to be applied to pharmaceutical forms. The result for the individual tablet assay for commercial tablets containing 10 mg of loratadine shows a mean of 10.02 mg with an RSD of 1.67% for 10 individual tablets. Furthermore, to obtain comparative results a UV spectrophotometric method was also developed. Loratadine adsorption spectra exhibit two poorly-resolved absorption maxima at 240 and 280 nm; however, the NO_2-loratadine absorption spectrum exhibits a well-defined UV absorption maximum with a higher absorbance at 269 nm. The maximum exhibits a linear relation between absorbance and drug concentration. For analytical determination the calibration curve method, with concentrations ranging between 1×10^{-5} M and 1×10^{-4} M, was used. This curve is described by the following regression line:

$$A = 13.5 \times 10^3 C(M) - 3.8 \times 10^{-5} \qquad (3)$$

(correlation coefficient = 0.999, $n = 10$), where A is the absorbance of NO_2-loratadine solution at 269 nm. The results of the recovery study (99.9% recovery, 1.82% RSD) and individual tablet assay (10.08 mg, 1.83% RSD) are in accord with the polarographic results.

Although both the developed methods showed similar accuracy and precision, the principal advantage of the proposed polarographic method over the spectrophotometric method is that the excipients do not interfere and consequently the filtration procedure is not necessary.

The proposed polarographic method proved to have adequate precision and accuracy to enable

Fig. 6. Peak current dependence of the DPP peak in nitrated loratadine solutions.

reliable analysis of loratadine and is therefore recommended as a useful tool for the analysis of loratadine in pharmaceutical forms. Although it is an indirect method, it is not time consuming as the derivatization process is easy. Consequently, the present contribution is a good example of the fact that the availability of electrochemical techniques is not restricted to molecules with electroactive groups.

Spectrophotometric determination of periodate or iodate ions by liquid–liquid extraction as an ion-pair using tetramethylammonium iodide

M.S. El-Shahawi[*,1], F.A. Al-Hashemi

Chemistry Department, Faculty of Science, UAE University, Al-Ain, P.O. Box 17551, United Arab Emirates

Abstract

A simple and accurate extractive spectrophotometric procedure was developed for the microdetermination of periodate and iodate in aqueous media. The determination of periodate was based upon the extraction of the ion-pair formed between the periodate and tetramethylammonium iodide at pH 4 in chloroform followed by direct spectrophotometric measurements at 509, 358 and 288 nm. The optimum concentration range evaluated by Ringbom's plot, the molar absorptivity, the Sandell's sensitivity and the stoichiometry of the formed ion-pair were critically determined. Iodate could be determined quantitively by the proposed procedure after oxidation to periodate with potassium persulphate. The effect of the diverse ions on the determination of the periodate and/or iodate by the proposed procedures was also investigated. The application of the method for the analysis of iodate or periodate in the artificial fresh water was successfully carried out.

Keywords: Determination; Iodate; Ion-pair; Periodate

1. Introduction

Because iodate and periodate exclusively associate with oxidation of metal ions [1–6], polyhydroxylated compounds [6,7] and catalytic applications [8] at trace levels, sensitive methods are required for their reliable quantitification. Several spectrophotometric methods for the determination of both ions have been reported [9–13]. The existing methods for spectrophotometric determination of these ions were unsatisfactory for routine analysis as the procedures required direct maintenance of the experimental conditions (e.g. a strictly fixed pH, standing of the samples before the determination and low stability of the compound formed) and suffer from the lack of selectivity, sensitivity, the requirement of a laborious enrichment step and a low tolerance limit [12,13].

* Corresponding author.

[1]Permanent address: Chemistry Department, Faculty of Science at Damiatta, Mansoura University, Mansoura, Egypt.

The oxoanions are the least investigated species that form a liquid–liquid extractable ion-pair with onium cations [14–18]. The aim of the present study was to develop a simple and sensitive extraction spectrophotometric analytical procedure for the determination of periodate or iodate ions in aqueous matrices. The method we suggest is superior to some of the reported methods in sensitivity, and stability of the associate obtained [11–13].

2. Experimental

2.1. Reagents and materials

All the chemicals and solvents used were of analytical reagent grade. Britton–Robinson (B–R) buffer (pH 2.2–11.5) was prepared from boric, acetic and phosphoric acids and sodium hydroxide in double distilled water. Stock solutions of potassium periodate (BDH) and potassium iodate (1 mg ml^{-1}) were prepared separately by dissolving the extract weight of the corresponding salt in hot distilled water. The reagent tetramethylammonium iodide (Fluka, Purum > 98%) was used without further purification. Tetramethylammonium iodide (TMA$^+$I$^-$) (0.5% w/v) and potassium persulphate (2% w/v) were prepared in distilled water.

2.2. Apparatus

A Pye-Unicam Sp 8-400 double beam UV-visible spectrophotometer was used for recording the absorption spectra and the absorbance measurements with a quartz cell of 10 mm path length. A Phillips 9418 digital pH-meter was used for the pH measurements.

2.3. Recommended procedures

2.3.1. Determination of periodate ion

An aliquot (1–5 ml) of the aqueous solution of potassium periodate containing 1–50 μg of periodate ion was transferred to a 100 ml separating funnel. A volume of 10 ml of Britton–Robinson buffer (pH 4), 5 ml of water and 5 ml of te-

tramethylammonium iodide (0.5% w/v) were added and mixed. This was extracted twice with 5 ml of chloroform (2 × 2.5) and the extracts were collected in a 50 ml beaker containing anhydrous sodium sulphate (1 g). The beaker was swirled to mix the contents. The extract was transferred to a 10 ml volumetric flask, the residue was washed with 5 ml CHCl$_3$ and transfered to the volumetric flask. The solution was made up to the mark with the solvent. The absorbance of the organic phase was measured at 509, 358 and 288 nm against a reagent blank prepared under the same experimental condition.

2.3.2. Determination of iodate ion

A known volume (1–10 ml) of sodium iodate solution (containing 1–50 μg of iodate ions) was transferred to a 100 ml Erlenmeyer conical flask. A volume of 10 ml of potassium persulphate (2% w/v) and 10 ml of water were added to each flask, the solution was boiled for 10 min and the reaction mixture was allowed to cool. The pH of the solution was adjusted (pH 4) with 10 ml buffer followed by the addition of 5 ml of the reagent (TMA$^+$I$^-$). The reaction mixture and the washing solution of the flask were transferred to a 100 ml separating funnel. The formed ion-pair was extracted with 5 ml chloroform (2 × 2.5) and the recommended procedure for periodate determination was followed. A blank prepared under the same experimental conditions in the presence of potassium persulphate was run.

3. Results and discussion

The technique suggested for the determination of the periodate ions was based on its interaction in acidic medium with an excess of tetramethylammonium iodide. The solubility of the produced ion associate of the periodate with (TMA$^+$I$^-$) was investigated in the following solvents: dichloromethane, n-hexane, dichloroethane, isobutylether, benzene, nitrobenzene, tetrachloromethane, chloroform and toluene. The highest absorbance of the produced ion-associate was obtained in chloroform and toluene in a very short time. In chloroform the extraction was com-

plete and a better separation of phases was obtained. Therefore, chloroform was selected as a proper solvent for these reasons and because its greater density allows a better separation of the layers. The absorption spectrum of the formed yellow-violet ion-pair in chloroform extracted from the aqueous solution at pH 4 is given in Fig. 1(a). The coloured ion associate formed has three absorption maxima at 509, 358 and 288 nm in the UV-visible region whilst no peaks were found in this range in the spectra of $(TMA^+ I^-)$ and the periodate in chloroform. Therefore, the absorbance measurements for the ion-associate formed from the reaction of $(TMA^+ I^-)$ and IO_4^- were measured at 509, 358 and 288 nm. In Fig. 1(b) the absorption spectrum of iodine in chloroform is also given which differs from the spectrum of the postulated ion-pair.

The extraction of the formed ion-associate into chloroform was rapid and a shaking time of 2 min was selected in the subsequent work. The absorbance of the pink-coloured associate in chloro-

Fig. 2. Influence of pH of the aqueous phase on the absorbance of the extracted ion-pair in chloroform at 509 nm.

form was found to be constant up to 2 h for samples containing 0.05–10 μg ml^{-1} periodate in aqueous solution at pH 4 and $\lambda = 509$ and 358 nm. The addition of sodium chloride in the concentration range 0.01–0.5 mol l^{-1} did not improve the amount of the ion-associate extracted at 5 μg ml^{-1} periodate aqueous phase at pH 4 suggesting that the reaction is quantitative without salt effect.

To optimize the reaction conditions we studied the effect of the pH of the aqueous phase upon the interaction of the periodate with $(TMA^+ I^-)$ by measuring the absorbance of the produced ion-associate in chloroform. The final pH of each aqueous solution was measured before the extraction. The experimental data (Fig. 2)[1] showed that the maximum absorption of the produced ion-pair was obtained at pH 4. In strong (pH < 4) or weak acidic solution (4 < pH) the absorbance of the extracted species decreased owing to the incomplete dissociation of the periodate salt or the hydrolysis of the ion-associate formed. When HCl

Fig. 1. Absorption spectra of the extracted ion-pair formed between $(TMA^+ I^-)$ and periodate ions (a) at pH 4 or the aqueous phase and iodine (b) in chloroform.
[1] Each point in the figures represents an average of five measurements.

or $HClO_4$ was used instead of Britton–Robinson buffer (pH 3–4) no significant differences in the absorbance values were observed. Thus a B–R buffer solution of pH 4 was finally chosen and employed as described in the recommended procedures.

Tetramethylammonium hexafluorophosphate, tetraphenylphosphonium chloride, tetramethylammonium iodide, tetramethylammonium bromide, tetramethylammonium chloride and tetraphenylarsonium chloride were investigated at the optimum pH. Good results were obtained with tetramethylammonium iodide and the highest absorbance of the coloured associate was obtained in chloroform from an aqueous solution of pH 4. The effect of (TMA^+I^-) concentration upon the determination of periodate was studied. The absorbances of the extracted species in chloroform for a series of solutions containing 10–20 μg of periodate and various amounts of the reagent (TMA^+I^-) up to 1.2% (w/v) in water at pH 4 was examined. It was found that 5 ml of (TMA^+I^-) at a concentration of $\leqslant 0.5\%$ (w/v) was sufficient to form the ion-associate for 20 μg or less of periodate ion (Fig. 3).

Fig. 3. Dependence of the absorbance (at $\lambda = 509$ nm) of the formed ion-pair in chloroform with (TMA $^+$ I $^-$) concentration (% w/v) in aqueous solution.

The mechanism of the produced ion-associate was critically investigated. It appears from Fig. 1 that the extracted product is not iodine nor an ion-pair between periodate ion and TMA^+. Actually, the reaction of (TMA^+I^-) with periodate ions gave quasi-immediately a red-orange precipitate which was readily extracted in chloroform (in yellow-violet colour). This reaction appears to proceed in two successive steps: (1) a rapid one involving the liberation of some iodine and subsequently (2) formation of the precipitate. These results suggest the possible formation of the complex ion I_3^- which subsequently may interact with the tetramethylammonium cation. These results were also confirmed by reacting the triiodide ion I_3^- (prepared from $I_2 + KI$) with the tetramethylammonium cation followed by extracting the produced species in chloroform. The electronic spectrum of this species was exactly similar to the spectrum of the produced ion associate from the reaction of (TMA^+I^-) with periodate ions. Thus a possible mechanism of the produced ion-associate $(CH_3)_4N^+I_3^-$ is proposed as follows:

$$7(CH_3)_4N^+I^- + IO_4^- + 8H^+$$
$$\rightleftharpoons 4I_2 + 4H_2O + 7(CH_3)_4N^+ \qquad (1)$$

$$4(CH_3)_4N^+I^- + 4I_2 \rightleftharpoons 4(CH_3)_4N^+I_3^- \qquad (2)$$

and the overall reaction is

$$11(CH_3)_4N^+I^- + IO_4^- + 8H^+$$
$$\rightleftharpoons 4(CH_3)_4N^+I_3^- + 7(CH_3)_4N^+ + 4H_2O \qquad (3)$$
These results also explain why only $(CH_3)_4N^+I_3^-$ gives good results since there is a need to have an excess of iodide ion in solution to form the complex ion I_3^-, as indicated in Eqs. (1)–(3). For instance, with tetramethylammonium chloride periodate gives iodine at a slow rate but there is no iodide to form the complex ion I_3^-. However, on reacting periodate ions with tetramethylammonium bromide no colour is formed.

3.1. Photometric characteristics

The comoposition of the ion-pair $(CH_3)_4N^+I_3^-$ was established spectrophotometrically by the Job's method. Equimolar solutions of potassium

Fig. 4. Determination of the composition of the extracted ion-associate by the Job's method; $[IO_4] = 0.002$ (1 ml) and $[(TMA^+I^-)] = 0.001$ at 509 nm.

periodate and the (TMA^+I^-) reagent of a concentration of 0.001 M were mixed in complementary proportions to a fixed total volume and the pH of the solutions was adjusted to pH 4. The mixture was allowed to stand for 5 min for completion of the reaction. The ion-associate was then extracted with 5 ml chloroform and the absorbance was measured against a blank obtained by extraction of the reagent containing no periodate. A plot of absorbance of the extracted ion-associate in chloroform versus $[IO_4^-]/[IO_4^-] + [TMA^+I^-]$ produced a graph (Fig. 4) that indicated the formation of an associate having a periodate to a reagent ratio of 1:1.

Linear graphs at 509, 358 and 288 nm were obtained by recording the absorbance of the associate $(CH_3)_4N^+I_3^-$ in organic phase as a functionof periodate ion concentration. Beer's law was obeyed between 0.05–10 mg 1^{-1} periodate in aqueous solution of pH 4. The effective concentration of periodate as evaluated by Ringbom's plot [19] was found to be 0.2–7 mg 1^{-1}. The molar absorptivity calculated from Beer's law and

the Sandell [20] sensitivity index of the associate $(CH_3)_4N^+I_3^-$ at 509 and 358 nm was found to be 6.4×10^4 and 1.2×10^5 1 mol^{-1} cm^{-1} and 0.0003 and 0.0006 μg cm^{-2}, respectively. The selectivity and sensitivity of the spectrophotometric measurement is far better than the recent spectrophotometric procedure developed by Kamburova [13] and Fernandez-Gutierre et al. [21] since in the present work the measurements were carried out in the visible region while in the reported method [13] all the absorbance data were recorded in the UV region. The relative standard deviations of five measurements with 10 μg periodate, (at 95% confidence limit) of the method were 0.8% and 1.2% at 509 and 358 nm, respectively. Detection limits [22] of 0.016 and 0.03 μg ml^{-1} of periodate and regression coefficients of 0.996 and 0.942 were achieved by the proposed procedure at 358 and 509 nm, respectively. Regression analysis of the Beer–Lambert plot of the absorbance at 358 nm (A_{358}) and the concentration of periodate (C) in mg ml^{-1} in the range of 1–10 μg ml^{-1} gave the following linear regression equation:

$$A_{358} = 0.026 + 0.035C \qquad (n = 5) \qquad (4)$$

This equation has a slope of 0.035 with an intercept of 0.021.

3.2. Determination of iodate ions

Preliminary experiments showed interference of iodate with the proposed procedure of periodate determination. The reaction of the iodate ions with the reagent $(CH_3)_4N^+I_3^-$ is slow and possibly proceeds to produce the ion-associate $(CH_3)_4N^+I_3^-$ as follows:

$$5(CH_3)_4N^-I^- + IO_3^- + 6H^+$$

$$\rightleftharpoons 3I_2 + 5(CH_3)_4N^+ + 3H_2O \qquad (5)$$
The produced iodine may react with the iodide ion of the excess reagent $(CH_3)_4N^+I^-$ to form the complex ion I_3^- which subsequently reacts with the tetramethylammonium cation to form the ion-associate $(CH_3)_4N^+I_3^-$. Therefore different attempts involving oxidation of iodate to periodate were carried out. A series of oxidizing agents, e.g. $K_2S_2O_8$, H_2O_2 and $KMnO_4$ were used

for the possible oxidation of IO_3^- → IO_4^-. Boiling the iodate ions for 10 min with potassium persulphate (2% w/v) in water was found to be the most convenient procedure for the oxidation of the iodate to periodate without interference of the unreacted persulphate. The determination of various levels (1–50 μg ml^{-1}) of iodate in aqueous solution was carried out and satisfactory results with absolute standard deviations ($n = 5$) in the range 0.2–0.35 were achieved. A linear correlation ($r = 0.967$) was found between the absorbance at 509 nm (A_{509}) and concentration of iodate (C) in μg ml^{-1} in the range 1–20 μg ml^{-1}. Regression analysis of Beer's plot gave the following linear regressin equation:

$$A_{509} = 0.035 + 0.039C \qquad (n = 5) \qquad (6)$$

3.3. Effect of diverse ions

The selectivity of the proposed method in the presence of a relatively high excess (2 mg) of some ions, e.g. NO_3^-, Br^-, SO_4^{2-}, CO_3^{2-}, HCO_3^-, $S_2O_8^{2-}$, AsO_2^-, SbO_2^-, $EDTA^{2-}$, $C_2O_4^{2-}$, $S_2O_3^{2-}$, SCN^-, SeO_3^{2-}, TeO_4^{2-}, PO_4^{3-}, BiO_3^-, WO_4^{2-}, SeO_3^{2-}, BrO_3^- and MoO_4^{2-} upon the extraction equilibrium in the determination of 10 μg of periodate (or iodate) by the proposed procedure was studied. Good recoveries in the range 100 ± 2% were obtained with all the ions except $S_2O_3^{2-}$, and BiO_3^- ions interfered seriously. The tolerance limits of various cations (0.1 mg), e.g. NH_4^+, Al^{3+}, Cd^{2+}, Zn^{2+}, Pt^{2+}, Au^+, Pb^{2+}, Co^{2+}, Fe^{3+}, Bi^{3+}, Sn^{2+}, Ni^{2+}, Mg^{2+}, Ba^{2+} and Li^+, were also examined. All these ions did not interfere with the proposed method and a good recovery percentage (100 ± 1.5%) was achieved. The ions Mn^{2+}, Cr^{6+}, Cr^{3+}, Mn^{7+} and Ru^{3+} interfered seriously even at very low concentrations. The reason for these interferences is possibly attributed to the ability of periodate ions in the aqueous media to oxidize Mn^{2+}, Cr^{3+}, Ru^{3+} and $S_2O_3^{2-}$ producing MnO_4^-, $Cr_2O_7^{2-}$, RuO_4 and IO_3^- ions, respectively, at the developed experimental conditions as previously reported [4–6,23]. The produced species and the trioxobismuthate BiO_3^- are possibly able to oxidize the iodide ion in the reagent (TMA^+I^-)

producing iodine. A representative reaction possibly proceeds as follows:

$$Cr_2O_7^{2-} + 6(CH_3)_4N^-I^- + 14H^+$$

$$\rightleftharpoons 2Cr^{3+} + 6(CH_3)_4N^+ + 3I_2 + 7H_2O \qquad (7)$$
The produced iodine subsequently reacts with the iodide ion in the reagent (TMA^+I^-) forming the ion-associate ($(CH_3)_4N^+I_3^-$ as given in Eq. (2). On the other hand, the $S_2O_3^{2-}$ ions were found able to reduce the produced ion-associate $(CH_3)_4N^+$ I_3^- to the iodide ion.

The determination of 10 μg of periodate or iodate by the proposed procedure in artificial fresh water containing 10 mg l^{-1} of sodium, calcium, chloride, sulphate and bicarbonate together was carried out against a blank. The periodate or iodate concentrations were determined by the preconstructed standard curves. The precision was 0.7% and the percentage error was in the range −1.1%–1.3%.

4. Conclusion

The proposed procedure for periodate or iodate determination is superior as compared to most of the reported procedures. It offers many advantages, e.g. good precision, accuracy, the obtained associate is very stable and no standing time is needed before determining the ions. The clear advantages of the method are that it is applicable for IO_4^- (or IO_3^-) determination in artificial sea water. The determination of IO_4^- besides IO_3^- or iodate besides IO_4^- is not possible.

Cyanide thermodynamics
2. Stability constants of copper(I) cyanide complexes in aqueous acetonitrile mixtures[1]

K. Kurnia, D.E. Giles, P.M. May, P. Singh, G.T. Hefter*

Department of Chemistry, Murdoch University, Murdoch, WA 6150, Australia

Abstract

The stability (formation) constants of the binary $Cu(I)–CN^-$ complexes have been measured in five aqueous mixtures containing from 10% to 70% v/v acetonitrile (MeCN) by glass electrode potentiometry at 25°C and an ionic strength of 1 M ($NaClO_4$). The constants show monotonic increases with MeCN concentration, the changes being greatest for the higher order complexes, consistent with the unfavourable solvation of CN^- in these mixtures. The sparing solubility of CuCN(s) prevented determination of the stability constant for $CuCN^0$ (soln.) at low MeCN concentrations.

1. Introduction

In the absence of complexing agents Cu(I) is unstable in aqueous solution, disproportionating to metallic copper and the more common Cu(II) state [1]:

$$2Cu(I) \rightleftharpoons Cu(s) + Cu(II) \qquad K \approx 10^6$$
Accordingly, the complexation chemistry of Cu(I) in aqueous solutions is rather poorly understood compared with that of Cu(II). However, there is mounting evidence that Cu(I) may be the more important oxidation state in some biological systems [2,3] and in ore genesis and mineral transport processes [4]. In cyanide media Cu(I) is certainly predominant because, at least thermodynamically, Cu(II) is reduced by CN^-, forming cyanogen [5] in a reaction which may be notionally represented as

$$2Cu(II) + 2CN^- \rightleftharpoons 2Cu(I) + (CN)_2$$
This process is assisted by the very strong complexation [6,7] of Cu(I) by CN^-, presumably arising from the well-known $d_\pi–p_{\pi^*}$ 'back-bonding' of the d^{10} Cu(I) orbitals to the low-lying π^* orbitals of CN^-.

Despite their considerable importance in a variety of hydrometallurgical and environmental

situations [7] the stability constants of the $Cu(I)/CN^-$ complexes have not been well characterized in aqueous solution. There are seveal reasons for this, including the difficulty of detecting the $CuCN^0(aq)$ species on account of the instability of $Cu(I)$ at low CN^- concentrations, the sparing solubility of $CuCN(s)$, the very high stability of the $Cu(CN)_3^{2-}(aq)$ species and its similarity in strength to $Cu(CN)_4^{3-}(aq)$.

Copper(I) can also be stabilized in aqueous solution by the addition of certain miscible non-aqueous solvents, the best known of which are the nitriles [8–10]. Stabilization of $Cu(I)$ in aqueous acetonitrile has been exploited by Parker [11,12] to develop novel hydrometallurgical processes and by several workers [8,9] to study the complexation of $Cu(I)$ by acetonitrile (MeCN). Consequently, it seemed worthwhile to attempt a precise study of the $Cu(I)/CN^-$ system in aqueous MeCN solu-

2. Experimental

All reagents were analytical grade, used without further purification. All solutions were made with high purity water (Millipore Milli-Q system) boiled and purged with nitrogen gas to remove CO_2 and O_2. A stock solution of ≈ 0.2 M $Cu(I)$ was prepared by dissolving copper(I) cyanide (Fluka, 99%) in excess sodium cyanide (BDH, 97%) to give a final solution with $CN^-/Cu(I) \approx 4$. This solution was quite stable but was standardized from time to time against commercial 20.00 mM thiosulphate (BDH, concentrated volumetric standard) using the procedure described by Vogel [16]. Other reagents and methods of standardization were identical to those discussed in detail elsewhere [14,15].

Stability constants were obtained by glass electrode potentiometry at $25.0 \pm 0.005°C$ and with an ionic strength (I) of 1.00 M, maintained with $NaClO_4$. The cells used may be represented as

Reference half-cell	Salt bridge	Test solution	
$Ag|AgCl|0.95$ M $NaClO_4$	1 M $NaClO_4$	$(1-z)$ M $NaClO_4$	GE
0.05 M $NaCl$	$v\%$ MeCN/H_2O	x M $NaCN$, y M $NaOH$	
$v\%$ MeCN/H_2O		z M $CuClO_4$	
		$v\%$ MeCN/H_2O	
	E_{j1}	E_{j2}	

tions. Such data are also useful for optimizing a recently developed ion-exchange chromatographic procedure which employs MeCN/H_2O as the mobile phase to determine 'active' cyanide in complex metal/cyanide mixtures [13–15]. Such mixtures are typically encountered in the lixiviant solutions used for the recovery of gold from its ores and in effluents from electroplating and gold extraction plants [4].

The present paper therefore reports the stability constants of the cyanide complexes of $Cu(I)$ in aqueous acetonitrile mixtures containing up to 70% v/v MeCN, obtained by high precision glass electrode potentiometry. These data complement those previously reported for $Cd(II)$ and $Zn(II)$ cyanide complexes under the same conditions [14].

where v is the volume percentage of MeCN (in ml MeCN per 100 ml solution) in the aqueous solvent mixture, GE is a glass electrode and E_{j1} and E_{j2} are liquid junction potentials (LJPs). The glass electrodes (three separate GE/reference electrode combinations were used) were calibrated in terms of $[H^+]$. Since the cell is of the constant ionic strength type and $x, y, z \ll 1$ M the LJPs can be assumed to be constant [17].

The apparatus and general procedures for the titrations are given elsewhere [14,18]. Particular precautions were taken to minimize the volatilization of HCN and MeCN during the titrations. All titrations commenced at high pH (i.e. $-\log[H^+]$) ≈ 12.5, with varying total $Cu(I)$ concentrations (2.5–5.0 mM) and (total) $CN^-/Cu(I)$ ratios of four and five. The titrant was ≈ 50 mM $HClO_4$ in

$I = 1$ M $NaClO_4$ in the appropriate $MeCN/H_2O$ mixture.

During the course of the titrations a white precipitate was usually observed at pH ≈ 4.5 except at MeCN concentrations $\geqslant 50\%$ v/v. These precipitates were identified by X-ray diffraction to be CuCN ($K_{S0} = 3.2 \times 10^{-19}$ in water) [19]. Unlike the Cd(II) and, to a lesser extent, the Zn(II)/CN$^-$ systems [14,15,18], these precipitates did not in general re-dissolve at low pH. This made the determination of the lower order stability constants difficult in mixtures not rich in MeCN.

Complex formation in the Cu(I)/CN$^-$ system can be represented by the general equilibrium (omitting charges for simplicity):

$$pCu + qCN + rH_2O \rightleftharpoons Cu_p(CN)_q(OH)_r + rH$$
(1)
for which the corresponding overall stability (formation) constant of the complex $Cu_p(CN)_q(OH)_r$ is

$$\beta_{pqr} = \frac{[Cu_p(CN)_q(OH)_r]K_w^r}{[Cu]^p[CN]^q[OH]^r}$$
(2)

where

$$K_w = [H][OH] = \beta_{00-1}$$
(3)

is the ion product of water under the conditions of the experiment. Since HCN is a very weak acid [6,19] it is also necessary to know its association constant, K_{ass}:

Table 1
Formation constants of water and HCN in MeCN/H$_2$O mixtures at 25°C and $I = 1$ M (NaClO$_4$)[a]

%MeCN	pK$_w$	log K$_{ass}$ (HCN)
0.0	13.7518(8)	9.0330(10)
10.0	13.9162(10)	9.1209(15)
20.0	14.1920(10)	9.2844(11)
30.0	14.4184(7)	9.4260(20)
50.0	14.9705(9)	9.9338(24)
70.0	15.9189(17)	10.8531(26)

[a] Data from Ref. [15,20]. Values in parentheses are standard deviations in the last significant figure of the constant and refer to the internal precision of the computer calculations; the maximum uncertainties are generally an order of magnitude larger.

$$K_{ass} = \frac{[HCN]}{[H][CN]} = \beta_{011}$$
(4)

The determination of K_w and K_{ass} under conditions identical to the present study is described in detail elsewhere [20] but for convenience the values used in the determination of the Cu(I)/CN$^-$ complexes are listed in Table 1.

Stability constants for the Cu(I)/CN$^-$ system were obtained from the potentiometric data using the ESTA suite of programs [21–23]. Model selection was based on minimization of an objective function in total analytical hydrogen ion concentration with unit weights as defined in Ref. [21]. Species were generally considered acceptable only if the objective function was significantly reduced ($\geqslant 50\%$) by their inclusion, along with a consideration of the formation curves, and the standard deviations and chemical reasonableness of the complexes detected.

For a metal–cyanide system the metal–ion formation function, $\bar{Z}_M$, can be formulated (again omitting charges) as

$$\bar{Z}_M = [T_{CN} - A(1 - [H]\beta_{011})]/T_M$$
(5)

where T_i is the total (analytical) concentration of the species i (CN or M) and

$$A = [(T_H - [H] + K_w[H]^{-1})/\beta_{011}[H]]$$
(6)

When only mononuclear complexes (i.e. $p = 1$ in Eq. (1)) are formed, as in the present study, A is the free ligand concentration and $\bar{Z}_M$ can be considered as the average number of ligands bound per metal ion. When the most likely set of species was determined, the precision of the calculated formation constants was determined using a Monte-Carlo procedure as described previously [18,23].

3. Results and discussion

Typical titration data at low and high MeCN concentrations are shown in Figs. 1 and 2 respectively and require comment. Both curves exhibit the 'curl-backs' at high pH (low pA) characteristic of the presence of ternary complexes $Cu_p(CN)_q(OH)_r^{(p-q-r)+}$ and/or metal hydroxo complexes $Cu_p(OH)_r^{(p-r)+}$. However, as for the
Fig. 1. Observed formation function $\bar{Z}_M$ for the Cu(I)/CN$^-$ system in 30% v/v MeCN, typical of lower (⩽ 30% v/v) MeCN concentrations plotted against pA over the approximate pH range 5–12; the different symbols refer to differing values of T_{CN} and T_{Cu}. For discussion of the shapes of these curves see text.

Cd(II) and Zn(II) systems studied previously [14,18], these data had to be excluded from the analysis because of the unavailability of the formation constants for the Cu(I)/OH$^-$ complexes [19]. Attempts to measure the Cu(I)/OH$^-$ complexes by glass electrode potentiometry were unsuccessful due to precipitation of the sparingly soluble CuOH(s). Consequently, only the formation constants for the binary Cu(I)/CN$^-$ complexes could be determined.

The curves in Figs. 1 and 2 also share two other common features. First, they were independent of T_{Cu}, indicating that no 'polynuclear' ($p > 1$ in Eq.
Fig. 2. Observed formation function $\bar{Z}_M$ in 70% v/v MeCN, typical of higher (⩾ 50% v/v) MeCN concentrations, plotted against pA over the approximate pH range 2–12; the different symbols refer to differing values of T_{CN} and T_{Cu}. For discussion of the shapes of these curves see text.

(1)) species are formed over the concentration range studied. Secondly, $\bar{Z}_M$ barely rises above 3.0, which indicates that Cu(CN)$_3^{2-}$ is the predominant species and that, over the concentration ranges studied, Cu(CN)$_4^{3-}$ forms only to a very limited degree.

As noted above, precipitation of CuCN(s) at lower MeCN concentrations prevented the investigation of complexation at low free cyanide concentrations (high pA, low pH) so the formation function curves in Fig. 1 are limited to $\bar{Z}_M > 1.0$. Consequently it was not possible to evaluate β_{110}(CuCN^0) in these solutions. At higher MeCN concentrations no precipitation occurred and $\bar{Z}_M$ was determined down to zero (Fig. 2). As the measurements at high MeCN concentrations (⩾ 50% MeCN) were more straightforward they will be discussed first and in some detail.

3.1. 50–70% MeCN

At these relatively high MeCN concentrations no precipitation of CuCN(s) occurs and it was possible to obtain data over the pH range from 2 to 13. The plateaux at $\bar{Z}_M = 2.0$ and 3.0 (Fig. 2) indicate that the complexes Cu(CN)$_2^-$ and Cu(CN)$_3^{2-}$ were formed to a significant degree. Thus, model selection commenced with Cu(CN)$_2^-$ and Cu(CN)$_3^{2-}$. As it was possible to cover the low pH (high pA) region, the system could be studied where $\bar{Z}_M \rightarrow 1.0$ (Fig. 2). The lack of a plateau at $\bar{Z}_M = 1$ indicates that CuCN^0 never becomes predominant. Nevertheless, evidence for CuCN^0 was conclusive in both 50% and 70% MeCN/H$_2$O mixtures on the basis of our specified criteria: the objective function (OBJT) decreased by 94% and 99% in 50% and 70% MeCN respectively and the standard deviations for the other constants also improved. Consistent with the fact that $\bar{Z}_M > 3.0$ at high CN$^-$ concentration (low pH in Fig. 2), the addition of Cu(CN)$_4^{3-}$ had similar effects and was therefore accepted into the model. The 'best estimates' of the formation constants in these two media are summarized in Table 2. The low values of the objective function (especially in 70% MeCN) and the standard deviations on the β_{1q0} values are pleasing. It should be noted that the values listed

Table 2

[a] Species and stability constants as defined in Eqs. (1) and (2) respectively.
[b] Standard deviations refer to the internal precision of the computer calculations; maximum uncertainties are generally an order of magnitude larger.

in Table 2 represent the first time it has been possible to fix with any precision a value for β_{110} for the formation of the CuCN⁰ complex in any medium. This is undoubtedly a reflection of the stabilization of Cu(I) at low T_{CN} in the presence of high MeCN concentrations by complexation (i.e. solvation) of the CuCN⁰ complex by MeCN molecules in the solvent mixture. That is to say, the CuCN⁰ species detected here is better represented as $[Cu(NC)(NCCH_3)_n]^0$ (soln.) where n could be 1, 2, 3 or more (the CH₃CN molecules, being part of the solvent, are potentiometrically 'invisible'). This species is likely to have quite different characteristics to $[Cu(NC)(OH_2)_x]^0$ (aq), if such a species exists at all. Such considerations are probably best resolved by NMR spectroscopy but this is beyond the scope of the present study.

3.2. 10–30% MeCN

The 'best estimates' for the formation constants of the Cu(I)/CN⁻ complexes in 10–30% MeCN/H₂O mixtures are given in Table 3. As noted above, the accessible pH range in these solvent mixtures was limited by the precipitation of CuCN(s). Thus, as can be seen in Fig. 1, it was not possible to investigate below $\bar{Z}_M \approx 1.2$. Consequently, in 10% and 20% MeCN, β_{110}(CuCN⁰) was omitted and model selection was based on the two complexes for which the evidence (from the

inflection point at $\bar{Z}_M = 2.0$ and the plateau at $\bar{Z}_M = 3.0$) is clearcut: Cu(CN)₂⁻ and Cu(CN)₃²⁻. Inclusion of Cu(CN)₄³⁻ resulted in only small improvements in the unweighted objective function. However, as its incorporation lowered the standard deviations of β_{120} and β_{130} without significantly altering the optimized stability constants themselves, Cu(CN)₄³⁻ was retained in the final model. The difficulty of detecting Cu(CN)₄³⁻ is reflected in the $\bar{Z}_M$ values (Fig. 1), which barely rise above 3.0, and the large standard deviations for β_{140} (Table 3). Similar difficulties have been reported by previous workers [6].

In 30% MeCN (Fig. 1), where $\bar{Z}_M$ clearly falls below 2 at low pH values, indicating less than complete formation of Cu(CN)₂⁻, it was necessary to fix the value of β_{110} (CuCN⁰) to obtain a satisfactory fit. The value chosen, log $\beta_{110} = 8.76$, was that measured for 50% MeCN. Numerical attempts to simultaneously evaluate β_{110} with the other species in the model failed to converge.

3.3. The variation of $Cu(CN)_q^{(1-q)+}$ stabilities with solvent composition

The variation of the stability constants expressed as the change in log β_{1q0} between H₂O and MeCN/H₂O, of the three higher order cyanide complexes of Cu(I) is plotted in Fig. 3 as a function of MeCN concentration. The first complex is omitted because of the detection difficulties

at low MeCN concentrations. Given the instability of uncomplexed Cu(I) in aqueous solution and the fact that β_{1q0} values cannot be measured in NaClO₄ media in water [6], it is not possible at present to rationalise the results in terms of the solvation characteristics of each species. Nevertheless, some general observations can be made.
Fig. 3. Variation of the stability constants of $Cu(CN)_q^{(1-q)+}$ in MeCN H₂O mixtures:

$\Delta \log \beta_x = \{(\log \beta_{1q0})_{MeCN/H_2O} - (\log \beta_{1q0})_{H_2O}\}$ where $x = q$

Cu(I) is very strongly preferentially solvated by MeCN in MeCN/H₂O mixtures and its coordination sphere is likely to be fully occupied by MeCN molecules even in 10% MeCN/H₂O solutions [10-12]. Thus the increased stability of the $Cu(CN)_q^{(1-q)+}$ species is almost certainly due to the increasingly unfavourable solvation of CN⁻ as the MeCN concentration increases. This might at first seem surprising: the 'soft' MeCN might be expected to solvate the 'soft' CN⁻ quite well. Nevertheless, it is consistent with the data of Muir et al., [24] which show that $\Delta_t G(CN^-)$ is positive for transfer from H₂O to 70% MeCN. This interpretation is also consistent with the value of β_{140} showing the greatest increase (Fig. 3).

This can be seen more clearly by considering the (hypothetical) transfer of the reaction

$$Cu^+ (soln.) + xCN^- (soln.) \rightleftharpoons$$

$$Cu(CN)_x^{(1-x)+} (soln.) \qquad (7)$$
from H₂O to MeCN/H₂O mixtures. It is readily shown [25] that

$$\Delta_{r,t} G = -2.303 RT \Delta \log \beta_x$$

$$= \Delta_t G(Cu(CN)_x^{(1-x)+}) - \Delta_t G(Cu^+)$$

$$- x\Delta_t G(CN^-) \qquad (8)$$

where G is the Gibbs energy and the subscripts r and t refer to reaction (7) and the transfer process $(H_2O \rightarrow MeCN/H_2O)$ respectively. Strictly speaking, Eq. (8) should be expressed in terms of standard state (infinite dilution) values; however, activity effects should not be large in these significantly aqueous solutions. Assuming approximately equal changes in solvation for the transfer of the various $Cu(CN)_x^{(1-x)+}$ complexes, and given that $\Delta_t G(CN^-)$ is positive [24], Eq. (8) predicts that $\Delta \log \beta_x$ will become increasingly positive as x increases. The apparent flattening out of the curves at higher MeCN concentrations is probably related to the subtle interplay of the relative values of the solvation energies of each of the species involved in Eq. (7).

It is interesting that the variation of $\Delta \log \beta_x$ with solvent composition is rather similar to those observed for Zn(II) and Cd(II) [14,15]. On the basis of Eq. (8) and the expectation that Zn(II) and Cd(II) and (to a lesser extent) their cyanide complexes are significantly different from Cu(I), this is perhaps a little surprising. It is probably a reflection of the dominance of CN^- solvation in determining the strength of cyanide complexation in mixed solvents. A similar effect has been reported for the $ZnCl_n^{(2-n)+}$ complexes in MeCN/ H_2O mixtures [25].

Abstract

A low cost flow-injection analysis (FIA) with a dissolved oxygen (DO) detector and a xanthine oxidase immobilized column for the analysis of hypoxanthine as an index to determine degree of aging in meat was developed for quality control in the food industry. In this system, hypoxanthine is oxidized by an enzyme reaction with xanthine oxidase immobilized on the column to produce xanthine. Then the catalytic reaction between hypoxanthine and DO with xanthine oxidase proceeds with the DO concentration decreasing in the stream of the flow system. Decrease in the DO concentration was monitored by a DO detector located downstream of the flow system. This decrease in DO concentration was proportional to the hypoxanthine concentration. For detecting the decreased DO concentration efficiently a flow-through cell with a polarographic-type DO sensor was specially designed. As a result, a linear working curve was obtained from 3.68×10^{-5} to 1.84×10^{-3} M hypoxanthine concentrations with this FIA system. We applied the present system with a DO detector for the determination of hypoxanthine in meat samples and compared the results with those obtained by the conventional HPLC method. The data obtained with the present FIA method were in fairly good agreement with those obtained by the conventional HPLC method for the meat samples. Correlation factor and regression line between the two methods were 0.998 and $Y = 1.51X-32.64$ respectively. We concluded that the present FIA system with a DO detector was suitable as a simple, easy to handle and reliable instrument for quality control in the food industry.

Keywords: Aging of meat; DO detector; Enzyme reactor; Flow-injection; Hypoxathine

1. Introduction

Recently, quality control of meat has become increasingly important worldwide with the need to protect consumers from food poisoning using the directives ISO-9000 and HACCP [1]. When meat is not frozen during storage, bacterial distribution progresses and decays the meat, making it unsuitable for eating.

Therefore, there is a need to develop a simple meat aging sensing system based on the scientific background in knowing the period when the meat companies supply it to the customers.

[1] Presented at the Seventh International Conference on Flow Injection Analysis (ICFIA'95), held in Seattle, WA, USA, August 13-17, 1995.

Many indexes for aging in meat have been proposed, such as share force value [2], myofibrillar fragmentation index [3], disappearance of Troponin T, and 300 Da component [4] Mg–Ca-enhanced ATpase activity [5]. However, as these methods lack simplicity, rapidity and cost-effective performance, they were not suitable for routine use in quality control in meat-packing factories. Accordingly, quality control of aging in meat has been done by an organoleptics test by experts until now.

In previous papers, we found that hypoxanthine, which is a product of ATP as an energy source [6,7], is an aging-determining index for meat. There have been some reports on determination methods for hypoxanthine such as HPLC [8], amperometric detection [9,10], enzyme sensor [11], flow-injection analysis (FIA) systems with a biosensor [6,7] and optical detection [12]. Although there are advantages in constructing a measurement system using sensors and FIA, such as small amount of sample, simplicity, reduction of measurement time, selectivity, ease of handling and so on, there have been no practical studies on the application of a FIA system with a dissolved oxygen (DO) sensor for the determination of hypoxanthine as an index of aging in meat. Therefore, the development of a meat aging sensing system using a DO sensor as a detector in FIA which can measure hypoxanthine more simply and more rapidly is demanded because it is stable, selective, simple and easy to use over a long period.

Hypoxanthine is oxidized by the catalytic reaction of xanthine oxidase immobilized on the column, reducing the concentration of oxygen:

$$Hypoxanthine + O_2 \rightarrow Xanthine + H_2O$$

$$\uparrow$$

Xanthine oxidase
Accordingly, simple determination of hypoxanthine becomes possible by detecting the decrease in oxygen concentration electrochemically.

Based on this concept, we developed a simple FIA system for hypoxanthine using a DO detector and a enzyme reactor with immobilized xanthine oxidase to detect consumption of DO for fast quality control of meat aging. The DO sensor with an oxygen-selective permeable PTFE membrane was stable over a long period because it is durable to contamination from substances such as lipids and proteins in the meat samples. The sensor is also easy to handle and hypoxanthine oxidase is specific for hypoxanthine.

2. Experimental

2.1. Reagents

All chemicals used were of analytical-reagent grade. Xanthine oxidase from butter milk was obtained from Sigma. Pure water treated with a 0.45 μm membrane filter to give an electrical conductivity of less than 0.1 μS cm^{-2} was used throughout the work. A 0.1 M phosphate buffer (pH 7.0) was used as a carrier solution.

2.2. Preparation of xanthine oxidase immobilized column

A xanthine oxidase immobilized column was prepared by the following procedure.

(1) The porous silica beads, aminopropyl CPG (CPG Inc.), with a pore size of 500 Å and 200/400 mesh, were packed into a column (108 mm × 3 mm i.d.).

(2) A 0.1 M carbonate solution was circulated in the column for 30 min with a peristaltic pump.

(3) A 4% glutaraldehyde solution was circulated for 30 min in the same manner as above.

(4) After these procedures, the column was washed with pure water by the same procedure for 2 h.

(5) A solution of xanthine oxidase (5 units) was circulated for 2 h to immobilize the enzyme onto the porous silica beads.

(6) After circulating a 0.1 M glycine solution for 2 h, the column was filled with a 0.1 M phosphate buffer solution.

(7) The xanthine oxidase immobilized column solution thus prepared was stored in a refrigerator at 4°C.
Fig. 1. Outline of DO sensor for FIA system.

2.3. Fabrication of the DO detector

A DO sensor and a flow cell for FIA are shown in Figs. 1 and 2.

The detector was fabricated by assembling a small DO sensor (11 mm i.d. × 42 mm length) specially designed for a FIA system and a flow cell [26 mm × 40 mm × 30 mm (height × width ×
Fig. 2. DO detector for FIA system.
Fig. 3. FIA system with DO detector and xanthine oxidase immobilized column for hypoxanthine.

2.4. FIA system with DO detector

The one-channel FIA system consisted of a peristaltic pump (XV type; Alitea AB, Sweden), an injector (Rheodyne 7125; Rheodyne; Cotati, CA) a xanthine oxidase immobilized column, a DO detector, a current–voltage converter (ILO-50; DKK, Japan) and a recorder (250-F; Sekonic, Japan) as shown in Fig. 3. The flow rate of the pump was 1 ml min^{-1}. The 10 cm long PTFE tube (0.5 mm i.d.) from the mixing point and sample to the detector was determined experimentally. The phosphate buffer and sample were initially saturated with oxygen throughout this work.

By injecting a 20 μl sample into the buffer stream saturated with oxygen, the decreased oxygen content based on the enzyme reaction in the detector. Then, the decrease in the DO concentration in the stream was monitored by a detector located downstream of the flow system. This current intensity from the detector was amplified by the current–voltage converter and its signal was fed to the recorder. The concentration of hypoxanthine was determined by the change in the detector output which is observed as a peak-shaped signal (FIA signal) on the recorder. The height of the FIA signal is proportional to the hypoxanthine concentration.

3. Results and discussion

3.1. Optimum conditions for FIA system

Optimum conditions for this system were determined after varying the pH, flow rate of the pump, sample volume and column length.

Fig. 4 shows the effect of the pH of the samples on the FIA signal. The tests were carried out by changing the pH of the samples from 5 to 9 under the conditions of 1.47×10^{-4} M hypoxanthine and 108 mm $\times$ 3 mm i.d. column size. As a result, the maximum value was obtained at pH 7.0. This means that measurement at pH 7.0 was desirable to raise the activity of the immobilized hypoxanthine oxidase. Therefore, 0.1 M phosphate buffer (pH 7.0) was chosen as a carrier buffer for subsequent experiments.

Similarly, optimum values of flow rate, sample volume and column length were investigated. The results are shown in Table 1. It became apparent that determining the optimum values of pH, flow rate, sample volume and column length was very important for the determination of hypoxanthine with the present FIA system as decomposition and diffusion of hypoxanthine took place on the column as revealed by the stability and intensity of the FIA signal and the measurement range of the system.

3.2. Calibration curve for hypoxanthine

We prepared several standard solutions of hypoxanthine and investigated the relationship between the concentration and the peak height of the FIA signal with the analytical conditions

Table 1
Optimum conditions of FIA system with DO detector

Parameter	Optimum value	Range investigated
pH	7.0	5-9
Flow rate (ml min^{-1})	1	0.5-1.5
Sample volume (μl)	20	5-30
Column length (3 mm; mm i.d.)	108	63-126

shown in Table 1 which were determined experimentally. A linear calibration curve was obtained from 3.68×10^{-5} to 1.84×10^{-3} mol l^{-1} hypoxanthine as shown in Fig. 5. This shows that enzyme-catalytic conversion to xanthine by reaction of hypoxanthine and oxygen proceeds efficiently on the column. The lower detection limit was 1.84×10^{-3} mol l^{-1} for an S/N ratio of the FIA signal of three. The repeatability of the FIA signals was 1.6% in terms of the RSD for five injections of the same sample with a concentration of 1.10×10^{-3} M. The sampling rate was about 20 h^{-1}. This shows that the DO detector is suitable as a new simple FIA detector for hypoxanthine. The change in the baseline of the FIA system was about 1.8% of the peak height for the

Fig. 4. Effect of pH on FIA signal.
Fig. 5. Calibration curve for hypoxanthine.

measurement of 3.68×10^{-5} M hypoxanthine. The slope of the calibration curve in the range 3.68×10^{-5}–1.84×10^{-3} M hypoxanthine was 3.06×10^{-1} μA mmol l^{-1}.

3.3. Stability of xanthine oxidase immobilized column

The long term stability of the xanthine oxidase immobilized column was investigated. The column, stored at 4°C, was tested periodically for a 10^{-4} M hypoxanthine sample. After 1 month, the output signal from the detector had decreased by about 20% compared to the initial value. The column performance was checked at the same hypoxanthine concentration every 2 weeks. The signal from the detector was stable within $\pm$10% relative error for 5 months. The column performance after 1 year showed that the activity had decreased by 50% of the initial value. This means that the xanthine oxidase immobilized column was durable for 1 year. 150 measurements for meat samples were possible for one column.

3.4. Selectivity

The specificity of the present FIA system for hypoxanthine using the DO detector and the immobilized xanthine oxidase reactor was studied for several substances which often coexist in food samples. Peak height for a sample containing 10^{-4} M hypoxanthine was compared with those for 10^{-3} M concentrations of substances such as L-glutamic acid, L-lactate, glucose, pyruvic acid, inosine 5'-monophosphate, inosine, guanosine and guanine. No current from the detector was observed with any of these substances and they did not interfere with the determination of hypoxanthine because the enzyme reaction with xanthine oxidase was specific to hypoxanthine. However, the detector output with 10^{-4} M xanthine was 54% of that of hypoxanthine. This means that xanthine is also oxidized by xanthine oxidase. However, the hypoxanthine content was higher than that of xanthine in meat samples. Therefore, interference of xanthine in the FIA system can be ignored in this work.

Table 2
Analytical conditions of HPLC method for hypoxanthine

| Instrument:	Shimadzu LC-6A
Elution:	0.05 M phosphate buffer
Column:	Shim-pack CLC-ODS

Sample volume (μl):	20

3.5. Correlation between the present FIA method and the conventional HPLC method

We applied the present FIA system for the determination of hypoxanthine in six meat samples. The results were compared with data obtained by the conventional HPLC method with a UV detector. The 1 g meat samples for analysis were extracted into 20 ml of 10% perchloric acid and diluted with pure water to within the determination range of this system after neutralization of the meat extracts and elimination of perchlorate ion as potassium perchlorate. The analytical conditions for the HPLC method are shown in Table 2.

The correlation of the analytical results between the two methods is fairly good, as shown in Fig. 6. From these data, we obtained the regression line $Y = 1.02X$-4.54 and a correlation factor of 0.993. This seems to confirm that the present FIA system with a DO detector can be applied for the determination of hypoxanthine in meat samples.

3.6. Changes in amounts of hypoxanthine in meat samples

We applied the present FIA system to monitor the aging course of meat samples. Specimens of sirloin steak stored at 2°C were used for experiments conducted at regular time intervals. The result is shown in Fig. 7. We compared the
Fig. 6. Correlation between HPLC method and FIA method for determination of hypoxanthine.

change in the data obtained with the present method and the conventional method for the same storage period. The data from both methods showed the same tendency with the passing of time.

From these data it is clear that hypoxanthine is a good index for evaluating the aging time and the present FIA system is useful for the quality control of meat samples.
Fig. 7. Change in amount of hypoxanthine in meat stored at 10°C.

4. Conclusion

We have developed a FIA system with a DO detector for the determination of hypoxanthine in meat samples. The present FIA system has the specifications shown in Table 3. We conclude that the present FIA system has the advantages of simplicity, low cost, ease of maintenance, low consumption of reagents, ease of use and no need for a chemical analysis expert. The system is suitable as a quality control technique for the determination of hypoxanthine during the manufacturing process in the food industry. However, it is necessary to calibrate the system before every measurement because the activity of xanthine oxidase changes gradually over the course of a year. Therefore, it would be better to determine the more stable xanthine oxidase from the viewpoint of quality control online in the food industry.

The basic concept described in this paper would appear to be applicable to evaluate other taste-determining substances in food samples.

Studies of the chlorpheniramine solid-state ion-selective electrode

Chao-Lun Huang, Ju-Jie Ren, Da-Feng Xu*

Department of Pharmacy, Hebei Medical University, Shijiazhuang, People's Republic of China

Abstract

An Ag/AgCl solid-state electrode was prepared by using urea–formaldehyde resin as the frame material and KCl powder as the active material. Using the prepared Ag/AgCl solid-state electrode as substrate and chlorpheniramine tetraphenylborate ion-pair complex as the active component, a new type of solid-state chlorpheniramine ion-selective electrode was constructed. The properties of the electrode were studied in detail. The electrode shows a rather good stability and can be used in the potentiometric determination of chlorpheniramine.

1. Introduction

Many all-solid-state drug ion-selective electrodes have been reported [1–3]. Most of them were prepared by using graphite rod or inert metals as the substrate of the electrode. The shortcoming of this kind of electrode is that they usually show poor stability. The stability of a electrode is the key to obtaining precise results. Therefore, methods to raise the stability of a electrode are very important. Using urea–formaldehyde resin as the frame material and KCl powder as the active component, a Ag/AgCl solid-state electrode was prepared at first. By using the prepared Ag/AgCl solid-state electrode as the substrate, a new type of all-solid-state chlorpheniramine ion-selective electrode was constructed.

2. Experimental

2.1. Apparatus and reagents

The apparatus used for the measurement of the electrode potential was a PXJ-1B model digital pH/mV meter (Jiangsu Electroanalytical Instrument Factory). Chlorpheniramine ($C_{16}H_{19}ClN_2 \cdot C_4H_4O_4$) was supplied by the Pharmaceutical Factory of Hebei Medical University. Atropine sulfate (($C_{17}H_{23}NO_3)_2 \cdot H_2SO_4 \cdot H_2O$), sulfanilamide ($H_2NC_6H_4SO_2NH_2$), dicaine hydrochloride ($CH_3(CH_2)_3NHC_6H_4COOCH_2$-$CH_2N(CH_3)_2 \cdot HCl$), streptomycin sulfate (($C_{21}H_{39}N_7O_{12})_2 \cdot 3H_2SO_4$) and vitamin B_1 ($C_{12}H_{17}ClN_4OS \cdot HCl$) were kindly supplied by the manufacturers. Other reagents used were analytical grade.

2.2. Preparation of the active component

Chlorpheniramine tetraphenylborate was prepared by mixing 50 ml of 0.02 M chlorpheniramine and 50 ml of 0.02 M sodium tetraphenylborate solution. The resulting precipitate was filtered out on a porosity-4-sintered-glass crucible and washed several times with water, and then dried under vacuum at 313 K.

2.3. Preparation of the Ag/AgCl wire

A silver wire with a diameter of 0.5 mm was twisted into a spiral with a diameter of 3 mm and was then washed with acetone to remove the pollutants on its surface. Using the silver spiral as the cathode and a platinum wire as the anode, a thin sheet of pure silver was electroplated on the surface of the silver spiral with an electric current of 10 mA for 0.5 h in a electrolyte, which was prepared by mixing 3 g AgNO$_3$, 60 g KI and 7 ml 25% ammonia water and diluting to 100 ml with water. The electroplated silver spiral was washed with KI solution, ammonia water and water successively. Using the electroplated silver spiral as the anode and a platinum wire as the cathode, a thin sheet of AgCl was coated on the surface of the silver spiral by electrolyzing in 1 M HCl with a 3 mA electric current for 1 h. An Ag/AgCl wire was prepared after removing the silver spiral coated with a sheet of AgCl from the electrolysis bath and washing with water. The prepared Ag/AgCl wire was preserved in a KCl or HCl solution and kept away from light.

2.4. Preparation of the solid-state Ag/AgCl electrode

A mass of 60 g (1 mol) urea and 142 g (1.8 mol) formaldehyde were mixed in a 500 ml Wolff bottle, which was equipped with a stirrer and a reflux condenser. A 2 M KOH solution was added to the Wolff bottle until the pH of the mixture was 7–8. The mixture was reflux heated for 2 h. Then, between the Wolff bottle and the reflux condenser, an oil–water separator was fitted. Syrupy urea–formaldehyde resin polymer was obtained after about 40 ml water was separated by the separator.

A previously prepared Ag/AgCl wire was put in a polythylene molded pipe with a diameter of 1.4 cm.

A mass of 2 g KCl powder, which had been previously ground carefully, and 8 g syrupy urea–formaldehyde resin polymer was mixed thoroughly. Under the condition of stirring 1 M HCl solution was added until the pH of the mixture was 4–5, then, the mixture was transfered quickly to the polyethylene pipe. The Ag/AgCl solid-state electrode was obtained after keeping the mixture at room temperature for 24 h and removing from the pipe. Finally, the side wall of the prepared electrode was sealed with a thermoplastic pipe.

2.5. Preparation of chlorpheniramine solid-state electrode

The above prepared Ag/AgCl solid-state electrode was put in 10^{-3} M chlorpheniramine solution for 1 h. The water on the surface of the electrode was removed with filter paper.

Chlorpheniramine tetraphenylborate (5 mg) dissolved in 0.4 g dibutylphthalate was mixed with 4 g of 5% PVC solution in tetrahydrofuran. A solid-state chlorpheniramine ion-selective electrode was prepared by immersing one end of the prepared Ag/AgCl solid-state electrode in the above solution five or six times and drying at room temperature for 48 h. This electrode was called electrode A.

2.6. Preparation of electrode B

One end of a graphite rod of 99.99% purity, with a diameter of 1 cm was mechanically polished with emery paper to a mirror finish. Electrode B was prepared in a similar way to electrode A except the polished end of the graphite rod was used as the substrate of the chlorpheniramine solid-state electrode.

2.7. Preparation of the electrode C

Electrode C was prepared the same as electrode A except by using the prepared Ag/AgCl wire as the substrate of chlorpheniramine solid state electrode.

Table 1
Comparison of the stability of the three different chlorpheniramine electrodes

Electrode	Drifts in 8 h[a] (mV h^{-1})	Potentials[b] (mV)						
		1d	2d	3d	5d	10d	15d	20d
A	0.2	−27.0	−26.8	−26.8	−26.8	−26.5	−26.4	−26.1
B	12.0	70.8	67.4	63.5	60.8	59.2	54.3	53.6
C	10.0	−75.4	−63.4	−42.0	−7.4	3.9	9.9	16.4

[a] Potentials measured continuously in 10^{-3} M chlorpheniramine solutions for 8 h.
[b] Potentials measured in 10^{-3} M chlorpheniramine solution after preserving for different times and the electrode was kept dry after each measurement.

2.8. Preparation of the solutions

Total ionic strength adjustment buffer (TISAB): 0.05 mol $NaNO_3$ and 0.05 mol NaOAc (sodium acetate (CH_3COONa)) was dissolved in 0.05 mol AcOH (acetic acid (CH_3COOH)) and the mixture was diluted to 1000 ml with water. The ionic strength and pH of the buffer were 0.1 and 4.6 respectively.

Standard chlorpheniramine solution: chlorpheniramine (3.9080 g) was dissolved in 20 ml TISAB, and diluted to the mark in a 100 ml volumetric flask with TISAB, to give a 0.1 M standard solution. Series of standards were prepared by successive dilution to 10^{-2}–10^{-6} M with TISAB.

2.9. Measurements of electromotive force

The electromotive force (emf) measurements were made at a constant ionic strength, and the junction potential was kept constant. The cell can be expressed as Chlorpheniramine electrode |sample, $I = 0.1$|0.1 M $NaNO_3$|SCE.

3. Results and discussion

3.1. The stability of the electrode

The potential drift of the electrode was studied in 0.001 M chlorpheniramine solution when the emf of the cell had been measured for 8 h. The electrode potentials were measured after preserving the electrode for different times. The repro-

ducibility of the electrode stability was investigated by the reported method [4]. At first, the electrode potential was measured in a 0.001 M solution; when the electrode was transferred to a 0.01 M solution another potential was measured. The potential was measured again after transferring the electrode from the 0.01 M to 0.001 M solution. By repeating the transferring process five times, the greatest potential deviation obtained from the measurements was defined as the reproducibility of the electrode. The results (Tables 1 and 2) indicate that electrode B showed poor stability due to the irreversible state between the graphite rod and the PVC membrane [5]. Electrode C showed poor stability because the Ag/AgCl wire lacks chloride ions. Electrode A exhibits excellent stability and reproducibility due to the use of Ag/AgCl solid-state electrode as the substrate of the chlorpheniramine electrode. The substrate of electrode A was composed of urea–formaldehyde resin together with some water. Urea–formaldehyde resin has a three-dimensional

Table 2
Comparison of the reproducibility of the three different chlorpheniramine electrodes (five measuring times)

| Electrode	Chlorpheniramine concentration (M)	Mean value (mV)	RSD (%)	Reproducibility (mV)
A	0.01	31.3	0.18	0.2
	0.001	−27.1	0.33	
B	0.01	120.8	0.97	3.1
	0.001	63.6	2.02	
C	0.01	−24.0	2.72	1.5
	0.001	−82.3	0.78	

Fig. 1. Calibration curve of the all-solid-state chlorpheniramine electrode.

net structure. It can contain some water and provide ionic passage. The substrate was immersed in chlorpheniramine solution before being coated with PVC membrane; therefore, the pores of the urea–formaldehyde resin had some chlorpheniramine cations. Due to the existence of the exchangeable chlorpheniramine cation in the interface between the urea–formaldehyde resin and PVC membrane, the whole electrode was in a thermodynamic reversible state; as a result the stability of the electrode was greatly improved. Electrode A was used in subsequent studies.

3.2. Electrode calibration

The linear range of the electrode was measured. The results (Fig. 1) show that the linear range of the electrode is from 1.0×10^{-2} to 5.0×10^{-5} M with a slope of 58.2 mV per decade and a detection limit of 2.5×10^{-5} M.

3.3. Effect of pH

The influence of pH on the response of the chlorpheniramine electrode was studied by adjusting the pH of the chlorpheniramine solution with 0.1 M HCl or 0.1 M NaOH. The results (Fig. 2) show that the pH range, where the potential of the electrode remains constant, is 4–8.

3.4. Selectivity of the electrode

The selectivity coefficients for nine substances were determined by the mixed-solution method. The experimental data were treated by the reported method [6]. The method can be outlined as

follows: the response potential of a electrode measured in dilute solution with two kinds of coexisting ions can be expressed by Eq. (1)

$$E = E_o + S \ln(C_i + K_{ij}C_j^{Z_i/Z_j}) \tag{1}$$

where i is the measured ion, j is the interferential ion, Z_i is the electric charge number of i ions, Z_j is the electric charge number of j ion, S is the Nernst slope and K_{ij} is the selectivity coefficient. The appearance of Eq. (1) can be arranged to form Eq. (2)

$$e^{E/S} = e^{E_o/S}(C_i + K_{ij}C_j^{Z_i/Z_j}) \tag{2}$$

which is the equation of a straight line of slope $(e^{E_o/S})$ and intercept $e^{E_o/S} \cdot K_{ij}C_j^{Z_i/Z_j}$ when C_j was fixed. A series of solutions were prepared by fixing the concentration of j ions $(10^{-3}$ M) and changing the concentration of i ions from 10^{-2}–10^{-6} M. The electrode potentials of the series of solutions were measured and $e^{E/S}$ was plotted against C_i. From the slope and the intercept of the straight line K_{ij} can be obtained. All the calculations were completed by a computer. The results (Table 3) show that the electrode has a very good selectivity for chlorpheniramine except with dicaine hydrochloride.

3.5. Internal resistance, response time and life-span of the electrode

The internal resistance of the electrode was measured and the result was 2×10^5 Ω. The response time of the electrode in 10^{-1}–10^{-4} M concentration is less than 30 s and in 10^{-4}–10^{-6} M it is less than 2 min. The life-span of the electrode is 6 months.

Fig. 2. Effect of pH on the potential of the chlorpheniramine ion-selective electrode. Chlorpheniramine solution: curve 1, 10^{-2} M; 2, 10^{-3} M; curve 3, 10^{-4} M.

Table 3
Selectivity coefficients (mixed-solution procedure)

Interferent	K_{ij}
K^+	7.09×10^{-3}
Na^+	1.14×10^{-2}
Cu^{2+}	2.24×10^{-4}
Al^{3+}	9.50×10^{-5}
Vitamin B_1	1.02×10^{-2}
Sulfanilamide	2.01×10^{-3}

Dicaine hydrochloride	9.60×10^{-1}
Streptomycin sulfate	5.59×10^{-4}

Table 4
Recovery of chlorpheniramine (standard addition method)

Chlorpheniramine taken (mg)	Chlorpheniramine found (mg)	Recovery (%)
3.91	3.89	99.5
7.82	7.69	98.3
19.5	19.5	100.0
39.1	39.2	100.3
58.6	58.5	99.8
78.2	78.4	100.3
117	117	100.0

3.6. Advantages of the solid-state chlorpheniramine electrode

Ishibashi et al. [7] have reported a chlorpheniramine electrode based on a liquid or a PVC membrane containing the chlorpheniramine–tetraphenylborate ion pair. This needed the poisonous solvent nitrobenzene or an internal reference solution and an internal reference electrode. The internal reference solution must be changed periodically in order to ensure the precision of the measurement. The solid-state chlorpheniramine electrode in this paper can be prepared, used and preserved conveniently due to the fact that it does not need internal reference solution. The stability of the solid-state chlorpheniramine electrode is much better than the reported [7] liquid or PVC membrane chlorpheniramine electrode.

3.7. Applications to chlorpheniramine determination

The recovery test was carried out with the standard addition method. The results (Table 4) indicate that the average recovery is 99.7% and the coefficient of variation is 0.7%.

The electrode was applied to the actual determination of chlorpheniramine in chlorpheniramine tablets (labeled amount 4 mg per tablet) with the standard addition method. The results indicate that the average content of chlorpheniramine, when measured ten times, is 3.86 mg per tablet and the coefficient of variation is 1.2%. This agrees well with the Pharmacopoeia of the PR China. The electrode can, therefore, be applied to the rapid determination of chlorpheniramine.

Talanta

Stopped-flow kinetic determination of aluminum in Chinese tea leaves by fluoride ion-selective electrode potentiometry

Huaisheng Wang, Zihong Zhang, Ailing Sun, Daojie Liu, Renmin Liu*

Department of Chemistry, Liaocheng Teachers College, Liaocheng, Shandong, People's Republic of China

Abstract

A stopped-flow kinetic potentiometric method for the determination of aluminum is described, based on monitoring the reaction between aluminum and fluoride at pH 3.0 using fluoride ion-selective electrode. The initial rate of the reaction is proportional to the concentration of aluminum present in the solution. The method is simple and rapid and has been applied to the determination of aluminum in Chinese tea leaves after microwave digestion.

Keywords: Aluminum determination; Fluoride ion-selective electrode; Kinetic potentiometric method; Microwave digestion; Tea leaf analysis

1. Introduction

Aluminum is the third most abundant element in the Earth's crust. It is commonly found in living organisms consumed as food by human beings. Aluminum and the role it plays in the human body have been topics of interest over the past decade. Experimental evidence shows that aluminum is potentially toxic, expecially on accumulation in the human body, where it can damage various tissues and cells in the central nervous system [1,2]. Abnormal accumulation of aluminum in certain tissues of the human body was associated with abnormal skeletal metabolism [3] and various diseases, such as Alzheimer's disease [4], Osteomalacia[5] and Parkinsonism dementia [6].

There has been much interest in the possible biological function of aluminum in recent years. Hence, the development of a simple and reliable method for the determination of aluminum is urgently required for future surveys and for use in routine monitoring.

Many methods have been used for the determination of aluminum in food. The most widely used methods are electrothermal atomization atomic absorption spectrometry [7,8], inductively-coupled plasma optical emission spectrometry [9], and spectrophotometry [10,11].

The fluoride ion-selective electrode (ISE) can be used for the indirect determination of aluminum [12–15]. The method most commonly used is potentiometric titration of aluminum with

fluoride. Radic and Bralic [16] studied the kinetics of the $AlF_j^{(3-i)+}$ formation reaction in acidic solution using a fluoride ISE, and found that the initial formation, rate of the aluminum–fluoride complex was proportional to the amount of aluminum.

In the present work, a stopped-flow kinetic method for the determination of aluminum has been developed using a fluoride ISE. The proposed method is simple and useful. It has been applied to the determination of aluminum in Chinese tea leaves and of aluminum extracted from tea leaves by immersion in boiling water.

2. Experimental

2.1. Apparatus

Fig. 1 shows the flow system used in this experiment. Two two-channel peristaltic pumps (Jiangsu Electroanalytical Instrument Plant) controlled by a T1200XE computer (Toshiba) were used. The detector cell used is shown in Fig. 2. A 201 fluoride ISE (Jiangsu Electroanalytical Instrument Plant) was used as the sensor. The electrode potential was measured with an Orion SA720 pH/mV meter which is connected to the computer.

2.2. Reagents

All chemicals used were of analytical-reagent grade and the solutions were prepared with distilled–deionised water.

Fluoride solution. 0.1 M sodium fluoride solu-

Fig. 2. Schematic diagram of the detector cell: S and B, sample and buffer; W, waste; 1, 1.0 min i.d. conduit; 2, PTFE sleeve; 3, rubber O-ring.

tion was prepared with sodium fluoride (Beijing Chemical Plant). Solutions of other concentrations were prepared by diluting with deionised water.

Aluminum standard solution (0.0100 M). This was prepared by dissolving the appropriate amount of aluminum wire (99.99%); (Shanghai Chemical Reagent Plant) in 10 ml of 6 M hydrochloric acid. The solution was transferred to a 250 ml calibrated flask and diluted to the mark with deionised water. A series of aluminum working solutions were prepared by diluting the standard solution with buffer solution.

Buffer solution. A solution containing 0.1 M sodium dihydrogen orthophosphate (Shanghai Chemical Reagent Plant), 2.3 mM 1, 10-phenanthroline and 0.45 M hydroxylammonium was used as a buffer solution. The pH was adjusted with 5M sulfuric acid and 1 M sodium hydroxide. 1, 10-Phenanthroline and hydroxylammonium were used to overcome the interference of Fe^{3+}.

Nitric acid. Concentrated nitric acid (Jinan Chemical Reagent Plant), was used. Perchloric acid. 70% perchloric acid (Shanghai Taopu Chemical Plant) was used.

Fig. 1. Flow system for determination of aluminum: P, pump; mV, pH/mV meter detector; W, waste.
Fig. 3. Typical record curve: F . 50 μM; pH, 3.0; Al^{3+}: (1), 20 μM; (2), 50 μM; (3), 100 μM.

2.3. Measurement procedure

2.3.1. General Procedure

The flow system was connected with PTFE tubing (1.0 mm i.d.) according to Fig. 1. Pumps were started and the flow rate of every channel was adjusted to 2.0 ml min^{-1}. The electrode potential was recorded using the pH/mV meter. When the electrode potential reached equilibrium and a flat E–t line was observed, the pumps were stopped and the potential changes were recorded over a period of 1 min. The initial slope of the curve, $\Delta E/\Delta t$, is used as a measure of aluminum.

The standard solutions of aluminum were also analyzed by the same procedure. A calibration graph was constructed of logarithmic concentration of aluminum versus initial slope ($\Delta E/\Delta t$).

2.3.2. Digestion of tea sample

A Xianhua E-32 microwave oven (total microwave power 650 W) was used for the digestion of tea leaves. The digestion procedure was as follows. 0.2 g of tea leaves was heated (65 W, 10%) with 5 ml of nitric acid for 10 min. Then 2 ml of water was added. After 5 min of heating, 1 ml of 70% perchloric acid was added and the solution heated for another 5 min. Then 5 ml of water was added and heating was resumed for 15

min. The solution was diluted to 50 ml with water after cooling.

2.3.3. Determination conditions of the graphite-furnace atomic absorption spectometry (GFAAS)

A Hitachi 180-80 polarized Zeeman atomic absorption spectrophotometer (Hitachi Ltd., Tokyo, Japan) was used for GFAAS determination of aluminum. The instrumental conditions are as follows:

Light source:	Al hollow cathode lamp
Wavelength:	309.3 nm
Slit:	1.3 nm
Lamp current:	10 mA
Cuvette:	Tube type
Sample volume:	10 μl
Carrier gas flow:	200 ml min^{-1}

Graphite furnace program:

Step	Temperature (°C)	Time(s)
Drying	120	30
Ashing	1000	20
Atomization	2900	10
Cleaning	3000	5

3. Results and discussion

In aqueous solution aluminum ions are present as $Al[(Al(H_2O)_6]^{3+}$, which can be hydrolyzed to form $Al[(Al(H_2O)_5OH]^{2+}$, $Al[(Al(H_2O)_4(OH)_2]^+$ and $Al[(Al(H_2O)_3(OH)_3]$. Then reaction equations are as follows [17]:

$$[Al(H_2O)_6]^{3+} + H_2O$$
$$\rightleftharpoons [Al(H_2O)_5(OH)]^{2+} + H_3O^+$$

$$[Al(H_2O)_5(OH)]^{2+} + H_2O$$
$$\rightleftharpoons [Al(H_2O)_4(OH)_2]^+ + H_3O^+$$
Fig. 4. Influence of pH on determination of Al^{3+}: Al^{3+}, 50 μM; F^-, 50 μM.

$$[Al(H_2O)_4(OH)_2]^+ + H_2O$$
$$\rightleftharpoons [Al(H_2O)_3(OH)_3] + H_3O^+$$
Only in acidic medium can aluminum species be present mainly in the form of Al^{3+} (co-ordinated water has been omitted for simplicity). Al^{3+} can react with F^- to form the AlF^{2+} complex. This reaction can be monitored using a fluoride ISE.

Fig. 3 shows the typical potential–time curve of the fluoride ISE when fluoride was used for measuring (1) 20 μM, (2) 50 μM and (3) 100 μM Al^{3+}. The initial slope of the curve, $\Delta E/\Delta t$, is proportional to the concentration of aluminum present in the solution.

3.1. The influence of pH

The influence of pH on the determination of aluminum was investigated. Fig. 4 shows the change in the initial slope of the potential curve of the fluoride ISE with the pH of the solution in the range 1.0–5.0. The highest sensitivity is obtained at pH 3.0. An obvious decrease in the initial rate was found when the pH was altered from 3 to 5 and from 3 to 1. This may be due to the following reactions:

$$F^- + H^+ \rightleftharpoons HF$$

$$Al^{3+} + iOH^- \rightleftharpoons Al(OH)_i^{(3-i)+}$$
In highly acidic medium, F^- reacts with H^+ to form HF, leading to a decrease in the rate of complexation of Al^{3+} with F^-. In the solution of pH higher than 3.0, the hydrolysis reaction of Al^{3+} to $Al(OH)_i^{(3-i)+}$ reduces the free Al^{3+} concentration and the complexation rate is decreased.

Fig. 5. Influence of pH on determination of Fe^{3+}: Fe^{3+}, 100 μM; F^-, 100 μM.
Fig. 6. Calibration graph: (1), 15 μM F^-; (2), 50 μM F^-.

Table 1
Determination of aluminum in Chinese tea leaves

Sample	Proposed method (μg g^{-1})	GFAAS method (μg g^{-1})	Relative error (%)
1. Jasmine tea (Zhenghe, Fujian)[a]	526.4	544.2	−3.3
2. Xian Yin oolong tea (Fuzhou, Fujian)[a]	474.6	466.3	1.8
3. Ti Kun Yin (Anxi, Fujian)[a]	618.6	609.7	1.5
4. Early-spring band jasmine tea (You County, Hunan)[a]	708.2	717.8	−1.3

[a] The names in parentheses are the areas producing the tea leaves.

3.2. Interferences

Because the reaction of Fe^{3+} with F^- is similar to that of Al^{3+}, Fe^{3+} interferes with the determination of aluminum when using the fluoride electrode as the sensor. The initial slope, $\Delta E/\Delta t$, of the reaction of Fe^{3+} with fluoride in different pH buffer solutions is shown in Fig. 5. Although the highest value of $\Delta E/\Delta t$ is observed at pH 1.5, the value of the initial slope pH 3.0 is significant and has an intense effect on the determination of aluminum. Attempts to overcome the Fe^{3+} interference by a kinetic method (difference between the reactions of Fe^{3+} and Al^{3-} with F^-) are not feasible and an iron masking reagent must be used to remove the Fe^{3+} interference. A mixture of 1, 10-phenanthroline and hydroxlammonium was often used to mask Fe^{3+} in Al determination by spectrophotometry. We have found that this kind of solution is suitable for masking Fe^{3+} in the proposed method. In this study, the masking reagent used is a mixture of 2.5 mM 1, 10-phenanthroline and 0.45 M hydroxylammonium in the buffer solution. Using this masking reagent, no interference was found with 2.0 mM Fe^{3+} for the determination of 20 μM aluminum.

3.3. Effect of concentration of F^-

The effect of the concentration of F^- was also

investigated. The results indicate that only when the concentration of F^- is higher than 10 times the actual detection limit of the electrode can a linear calibration graph be obtained. The results also indicate that the concentration of F^- has a great effect on the linear range and the signal. The linear range of the calibration graph is about 0.3–4 times the concentration of F . When the concentration of F is low, a calibration graph with a gentle slope is obtained. When the concentration of F^- is high, a calibration graph with a steep slope is obtained.

3.4. Calibration graph

The standard aluminum solutions were analyzed by the proposed method. The calibration graphs were constructed by plotting the initial $\Delta E \Delta t$ versus $\log C_{Al}$. Fig. 6 shows the calibration graphs of Al^{3+} with fluoride concentrations of 15 μM and 50 μM. When the 15 μM fluoride solution was used, the linear range of the calibration graph for aluminum was 5–50 μM. The linear regression equation is

$$\Delta E/\Delta t = 0.816 \log C + 4.405 \quad (n = 6, r = 0.9991)$$
$$(C \text{ mol L}^{-1})$$

A linear calibration graph for 20–200 μM aluminum was obtained when 50 μM fluoride solution was . The linear regression equation is

Table 2
Percentage of aluminum extracted from tea leaves by immersion in boiling water

Sample[a]	Content after 1st extraction (μg g^{-1})	Content after 2nd extraction (μg g^{-1})	Degree of 1st extraction (%)	Degree of 2nd extraction (%)
1	332.7	261.5	36.8	24.4
2	383.0	349.3	19.6	8.8
3	486.2	424.9	21.4	12.6
4	478.7	258.3	32.4	21.4

[a] The samples are the same as those in Table 1.

$$\Delta E/\Delta t = 2.352 \log C + 11.908 \quad (n = 6, r = 0.9997)$$
$$(C \text{ mol L}^{-1})$$

The precision of the proposed method was investigated by using 15 μM fluoride solution. The 8 μM aluminum standard solution was determined seven times and relative standard deviation was 3.8%.

3.5. Applications

The proposed method has been applied to the determination of aluminum in Chinese tea leaves after microwave digestion. The samples were analyzed by the proposed method and by the GFAAS method. The results are shown in Table. 1

The percentage of aluminum extracted from tea leaves by boiling water was also investigated. Tea leaves were immersed in boiling water and the percentage of aluminum extracted was determined as follows 2.0 g of tea leaves was immersed in 100 ml of boiling water for 5 min, the solution was poured off and aluminum was determined in the residue by the proposed method. After a second immersion in boiling water the aluminum in the residue was determined again. The results are listed in Table 2. It can be seen that a certain amount of aluminum can be ingested by drinking tea made from Chinese tea leaves. According to the results given by Greger et al. [18], aluminum cannot be accumulated in the human body, if the total amount of aluminum absorbed is less than 125 mg/per day. Therefore, although the amount of aluminum in tea water exceeds the limit for the maximum allowable concentration of aluminum in drinking water, no accumulation of aluminum occurs for people drinking tea.

Solubility, dissociation and complexation with Nd(III) and Th(IV) of oxine, thenoyltrifluoroacetone and 1,10-phenanthroline in 5.0 m NaCl

Yuan-Xian Xia, Jian-Feng Chen, Gregory R. Choppin*

Department of Chemistry, The Florida State University, Talahassee, FL 32306-3006, USA

Abstract

Equilibria in the system of Nd(III) and Th(IV) with 8-hydroxyquinoline (oxine), thenoyltrifluoroacetone (HTTA) and 1,10-phenanthroline (phen) in 5.0 m NaCl solution have been investigated by spectroscopy and potentiometry. The solubility and deprotonation constants of the three organics were measured to be: $pK_s = 3.09 \pm 0.01$, $pK_{a1} = 5.82 \pm 0.02$, $pK_{a2} = 10.00 \pm 0.01$ for oxine; $pK_s = 2.49 \pm 0.01$, $pK_{a1} = 6.47 \pm 0.03$ for HTTA; $pK_s = 2.86 \pm 0.02$, $pK_{a2} = 5.82 \pm 0.05$ for phen. The stabilities of the corresponding metal complexes are in the order M(oxine) > M(TTA) > M(phen), where M = Nd(III), Th(IV). For all three organic ligands, the Th(IV) complexation is stronger than that of Nd(III).

Keywords: Complexation; Dissociation; HTTA; Neodymium(III); Oxine; 1,10-Phenanthroline; Solubility; Thorium(IV)

1. Introduction

Research into the methods of permanent disposal of the nuclear fission and activation products from nuclear reactor operation is being conducted in a number of countries. Underground salt beds are among the geological systems being investigated as sites for disposal of nuclear wastes. In order to be able to assess the effects of release of the long-lived actinide elements into the environment from such repositories, it is necessary to understand their chemistry under conditions encountered in brine solutions. In non-vitrified wastes the organic compounds present from the processing systems are not destroyed and may be a significant factor in increased solubilities and migration of the actinide cations. 8-Hydroxyquinoline (oxine or HOxn), thenoyltrifluoroacetone (HTTA) and 1,10-phenanthroline (phen) have been identified as three of the organics likely to be present in the nuclear wastes planned for disposal in the Waste Isolation Pilot Plant (WIPP) under study near Carlsbad, NM [1]. Although these organic compounds are sparingly soluble in aqueous systems, their complexation reactions with metal ions can compete with other chemical processes in the aqueous phase or at the aqueous–solid interface.

The published investigations of the heterogeneous equilibria of these organics in water or in aqueous electrolyte media have been limited to ionic strengths ≤ 2.0 m [2–4] and no data have been reported for more concentrated electrolyte solutions. The structures of these compounds are presented in Form 1.

The purpose of this study was to investigate the solubilities, proton dissociation and complexation interactions of Am(III) and Th(IV) with oxine, HTTA and phen in 5.0 m NaCl solution. Since the use of the solvent extraction technique for determining metal ion–ligand complexation is limited by the significant solubility of the three acids in organic solvents, a spectroscopic method, based on the spectral properties of the three ligands in the UV region, was used. As the spectroscopic technique required macro concentrations, Nd(III) was used as a chemical analog of Am(III) to avoid use of a macro amount of radioactive Am(III).

2. Experimental

2.1. Reagents

HTTA (Aldrich, A.C.S.) was purified by sublimation at 45°C. Oxine (Aldrich, A.C.S.) and phen (Aldrich, A.C.S.) were used without purification. All the other chemicals used were of A.C.S. grade unless specified. Stock solutions of the three compounds (1.0×10^{-4} M) were prepared by dissolving the required amount of solid in 5.0 m NaCl solution. The concentrations of the compounds were standardized by spectroscopy. A stock buffer solution consisting of 1.0 M acetate and 1.0 M hydroxylamine was prepared by dissolving the required amounts of soldium acetate and hydroxylamine with deionized water and adjusting to pH_m 4.1 (pH_m denotes pH meter reading).

A standard thorium stock solution of 0.10 M in 5.0 m NaCl at pH_m 1.0 was prepared by dissolving a weighed amount of anhydrous thorium chloride (99.9%, Stem Chemical) in 5.0 m NaCl, and adjusting to the desired pH_m with NaOH solution. A standard neodymium stock solution of 0.32 M in 5.0 m NaCl at pH_m 4.81 was
8 - hydroxyquinoline   **1,10 - phenanthroline**
thenoyltrifluoroacetone

Form 1

prepared by dissolution of the proper amount of Nd_2O_3 (99.9%, Aldrich) in 3–6 M HCl, followed by evaporation to dryness and dissolution of the solid in 5.0 m NaCl solution with adjustment to the desired pH_m. The concentrations of Nd and Th were standardized by titration with EDTA.

2.2. pcH measurement

A Corning Semimicro-Combination glass electrode/Accumet 950 pH/ion meter assembly was used in which the KCl solution of the electrode was replaced with a saturated NaCl solution. The electrode was calibrated using two standard pH buffer solutions: 0.05 M potassium biphthalate buffer pH 4.00 at 25°C (Fisher) and 0.05 M potassium phosphate monobasic–sodium hydroxide buffer pH 7.00 at 25°C (Fisher). The meter reading, pH_m, was converted to pcH ($= -\log$ [H^+]) using the following calibration equation [5,6]:

$$pcH = s\, pH_m + b \tag{1}$$

where $s = 1$ and b is the electrode parameter whose value for 5.0 m NaCl solution has been determined to be 1.06 ± 0.01 [6].

2.3. Spectrophotometric measurements

The absorption spectra were recorded on a Cary-14 UV–VIS spectrophotometer (upgraded by On-Line Instrument System) interfaced to a Zenith 248 computer in the wavelength range 200–400 nm. The spectra were measured against 5.0 m NaCl solution as the blank unless specified. The molar absorptivities calculated from calibrations with solutions of known concentration are 4.22×10^4 cm^2 mole^{-1} (253 nm) for oxine, 5.12×10^3 cm^2 mole^{-1} (263 nm) for HTTA and 2.76×10^4 cm^2 mole^{-1} (267 nm) for phen.

2.4. Solubility

For each organic compound, 12 portions (0.10 g each) of solid samples were placed in separate 25 ml glass vials and dissolved in 20.0 ml of 5.0 m NaCl stock solution. After shaking for 24 h, the solutions in the 36 vials were adjusted to the required pcH values by adding sodium hydroxide or hydrochloric acid. The vials were shaken vigorously for 7 days at $25.0 \pm 0.1°C$. The establishment of the dissolution equilibrium in each vial was confirmed when the same solubility was obtained for 7 days as after 1 month. The concentrations of the three organic compounds were measured by spectrophotometry.

2.5. Potentiometric titrations

The potentiometric titrations were conducted using a 50 ml water-jacketed vessel controlled to $25.0 \pm 0.1°C$ with an Isotemp constant temperature circulator. For each experiment, 10.0 ml of test solution was titrated with a standardized solution of 0.030 M NaOH in 5.0 m NaCl. The titrant was delivered to the cell via Teflon tubing by a Schott Gerate automatic buret. Nitrogen gas was bubbled through the solution to remove dissolved carbon dioxide. A differential graphical technique described elsewhere [6] was used to analyze the titration data. The method is based on the use of a differential quantity, Γ (equivalent to the buffer capacity), and a second quantity, Q, which are defined and related to each other as follows:

$$\Gamma = \frac{[(m - \tilde{n})C_{HmL} + C_H + C_{OH}]V_0}{2.303(V + V_0)^2} \cdot \frac{dV}{dpH_m} \qquad (2)$$

$$Q = \Gamma - [H^+] - [OH^-] = \sum_{i=1}^{m} \frac{K_{ai}[H^+]}{(K_{ai} + [H^+])^2} \cdot C_{HmL} \qquad (3)$$

where V_0 is the initial volume of test solution and V the volume of the titrant added, C_{HmL}, C_H and C_{OH} are respectively the initial concentrations of the ligand and the proton in the test solution and the concentration of the hydroxide ion in the titrant and $\tilde{n}$ is the protonation number defined as

$$\tilde{n} = \frac{\sum_{i=1}^{m} i[H_iL]}{C_{HmL}} \qquad (4)$$

Q is a quasi-parabolic function of pcH in which each peak in a Q vs. pcH plot corresponds to a dissociation sequence and the maximum value of the peak of Q_{max} ($= 0.25\ C_{HmL}$) occurs at pcH $=$ pK_{ai}.

2.6. Complexation

The complexation of each metal–ligand system was investigated by measuring the spectra of the ligand in the presence of varying amounts of the metal ion at constant pH$_m$. Six series of spectra were recorded for each combination of the two metal ions and three ligands. For Nd(III), pcH values for all three ligands were maintained at 5.87 by using a mixture of 0.010 M acetic and 0.010 M hydroxylamine as pcH buffer (the necessary corrections were made for the complexation competition by the two ligands). For Th(IV), a lower pcH range was chosen to avoid hydrolysis and difference spectra (against ligand solutions as blank) were recorded to detect the small amounts of the complexes formed.

Secondary stock solutions of the ligands of desired concentrations (depending on the molar absorptivities) were prepared by diluting the original ligand stock solutions with 5.0 m NaCl solution and adjusting to the required pcH. Ligand + metal stock solutions were prepared by mixing aliquots of the ligand stock solutions and the metal stock solutions,
Fig. 1. The stoichiometric solubilities of the three organic compounds as a function of pcH in 5.0 m NaCl solution: (■) oxine; (▲) phen; (●) HTTA.

diluting with 5.0 m NaCl solution and adjusting to the desired pcH. Final samples were prepared by mixing a variable volume of the secondary ligand stock solutions with a volume of the ligand–metal stock solution.

3. Results and discussion

3.1. Solubility

The stoichiometric solubilities of oxine, HTTA and phen in 5.0 m NaCl solution in the pcH range 5.0–11.0 are shown in Fig. 1. The solubility of oxine increases above $pcH \approx 8.5$ and below $pcH \approx 7$ with a minimum in the middle of the pcH region. This solubility pattern is consistent with that observed by Janjic et al. [2], who rationalized it quantitatively by a heterogeneous dissolution equilibrium with two stepwise proton dissociations. The stoichiometric solubility of phen decreases with pcH to ≈ 7.5, above this value it is constant. The opposite pattern was observed for HTTA, indicating that different protonation or deprotonation mechanisms may be involved for these two organics. The following equilibria were used to model quantitatively the solubility behavior:

$$H_nL(s) \xrightleftharpoons{K_s} H_nL(aq)$$

$(n = 1$ for oxine and HTTA, $n = 0$ for phen$)$ (5)

$$H_2Oxn^- \xrightleftharpoons{K_{a1}} HOxn + H^+ \xrightleftharpoons{K_{a2}} Oxn^- + 2H^-$$

(6)

$$Hphen^- \xrightleftharpoons{K_{a2}} phen + H^-$$

(7)

$$HTTA \xrightleftharpoons{K_{a1}} TTA^- + H^+$$

(8)
The stoichiometric solubilities, C_s, can be expressed as

(a) oxine:

$$C_s = \left(\frac{K_{a2}}{[H^+]} + 1 + \frac{[H^+]}{K_{a1}}\right) \cdot K_s$$

(9)

(b) HTTA:

$$C_s = \left(\frac{K_{a1}}{[H^+]} + 1\right) \cdot K_s$$

(10)

(c) phen:

$$C_s = \left(1 + \frac{[H^-]}{K_{a2}}\right) \cdot K_s$$

(11)

The corresponding equilibrium constants were calculated by least-squares analysis of the stoichiometric solubility data using Eqs. (9)–(11) with the results listed in Table 1. The solubility constants of oxine and phen are much lower than the reported values at low ionic strength, reflecting the 'salting out' effect of the ionic medium. Oxine has the lowest solubility among the three compounds, which may be due to the formation of an inner hydrogen bond $N \cdots H–O$ in the molecule.

3.2. Acid constants

The absorption spectra of oxine exhibit a shift of the peak at 253 nm to 236 nm as the pcH decreases from 12 to 8 (see Fig. 2a), while the shift is in the reverse direction from pcH 8 to 4. This is consistent with the dissociation mechanism deduced from the solubility study. The absorbances of oxine at 236 nm and 253 nm are plotted vs. pcH in Fig. 2b, indicating the existence of three species of the ligand. Accordingly, the expression to correlate the absorbance variation with the proton concentration can be written as [7]

$$\frac{1}{\varepsilon_i - \varepsilon_{i(L)}} = \frac{1}{\varepsilon_{i(HL)} - \varepsilon_{i(L)}} \cdot \left(1 + \frac{K_{a2}}{[H^+]}\right)$$

(12)

or

$$\frac{1}{\varepsilon_i - \varepsilon_{i(H_2L)}} = \frac{1}{\varepsilon_{i(HL)} - \varepsilon_{i(H_2L)}} \cdot \left(1 + \frac{[H^+]}{K_{a1}}\right) \qquad (13)$$

where ε_i is the observed absorptivity. $\varepsilon_{i(H_2L)}$, $\varepsilon_{i(HL)}$ and $\varepsilon_{i(L)}$ are the absorptivities of the species H_2Oxn^+, $HOxn$ and Oxn^- respectively. From the linear plots of $1/(\varepsilon_i - \varepsilon_{i(L)})$ vs. $1/[H^+]$ and $1/(\varepsilon_i - \varepsilon_{i(H_2L)})$ vs. $[H^+]$, the corresponding equilibrium constants were calculated to be $pK_{a1} = 5.78 \pm 0.03$ and $pK_{a2} = 10.11 \pm 0.03$ respectively from the absorbance data at pcH > 8 (using Eq. (12)) and at pcH < 8 (using Eq. (13)). Potentiometric titrations yielded values of $pK_{a1} = 5.82 \pm 0.02$ and $pK_{a2} = 10.00 \pm 0.01$, in good agreement with the result of the spectroscopic analysis.

The protonation of phen is evident from its absorption spectra at different pcH values. As shown in Fig. 3, five isobestic points were observed at 224, 239, 268, 284 and 292 nm. Schilt and Dunhar [8] assigned the first to the dissociation equilibrium of the biprotonated species, H_2phen^{2+}, the last three to the dissociation of the monoprotonated species, $Hphen^+$, and that at 239 nm to both reactions. The value of $pK_{a1} = -1.8-1.95$ given by some authors [8,9] for the first dissociation indicates the absence of

H_2phen^{2+} in the high pH_m region (pcH > 4.8), which agrees with the fact that the change of the spectra in Fig. 3 is a monotonic function of pH_m and with the solubility measurement described in the previous section. Following the procedure used for oxine, the deprotonation constant, pK_a, of $Hphen^+$ was calculated to be 5.81 ± 0.07, while potentiometric titration resulted in a value of 5.82 ± 0.05. This result, when compared with the reported value of 5.00(2) [10] at zero ionic strength, shows the 'salting out' effect of the ionic medium on acid dissociation. The existence of the species H_2phen^{2+} and $Hphen^+$ has been proposed [11] and their thermodynamic data were reported from calorimetric [12] and potentiometric titrations [13]. Although no evidence was found in the spectroscopic measurement, our potentiometric titration supported the existence of the species $Hphen^+$ since a significant improvement in the fit of the calculation resulted by inclusion of this species. In this study the single dissociation model as described in Eq. (7) was used in the modeling of the metal–ligand interactions.

The deprotonation of HTTA is reflected in an isobestic point at 310 nm as the pcH is varied. In the spectra, peaks at 269 and 292 nm and at low pcH can be assigned to the protonated keto form
Fig. 2(a)

of HTTA, and the peak at 350 nm can be assigned to the ionized enolate form, TTA⁻. The deprotonation constant, pK_{a1}, calculated from the absorbances using Eq. (12) has a value of 6.37 ± 0.04, which agrees with that from poten-

tiometric titration of $pK_{a1} = 6.47 \pm 0.03$.

Fig. 4 shows the speciation diagrams of oxine, phen and HTTA calculated using the pK_a values from the potentiometric titration experiment.
Fig. 3. The spectra of 2×10^{-5} M phen in 5.0 m NaCl. The corresponding pcH values are: (1) 4.85; (2) 5.51; (3) 5.74; (4) 5.83; (5) 6.26; (6) 6.67; (7) 7.36; (8) 7.98.

3.3. Complexation with Nd(III) and Th(IV)

Complexation of the three ligands with Nd(III) and Th(IV) cations was studied by spectrophotometry. Since low ligand concentrations were used to obtain a suitable absorbance in these experiments, a large excess of metal ion was added to give an observable amount of complex. Under such a condition, the following 1:1 metal–ligand complexation reactions may be dominant:

$$M^{n+} + L^{m-} \underset{}{\overset{\beta_1}{\rightleftharpoons}} ML^{(n-m)+}$$

($m = 0$ for phen, $m = 1$ for oxine and HTTA)

(14)
Fig. 4. The speciation diagram of oxine/HTTA/phen in 5.0 m NaCl solution: (——) oxine; (- - -) phen; (- • -) HTTA.

where M represents Nd(III) or Th(IV). The expression relating the change in absorbance and the metal concentration (C_M) can be simplified to [14]

$$\frac{1}{\varepsilon_i - \varepsilon_{i0}} = \frac{1}{\varepsilon_{i(ML)} - \varepsilon_{i0}} \cdot \left[1 + \frac{1 + \sum_{i=1}^{m} \frac{[H^+]^i}{K_{a1} \cdots K_{ai}}}{\beta_1 C_M} \right]$$

(15)

where ε_i and ε_{i0} are the observed absorbances of the ligand in the presence and the absence of the metal ion respectively, and $\varepsilon_{i(ML)}$ and β_1 are the absorbance and the stability constant of the complex formed respectively. The stability constant, β_1, can be calculated from a linear plot of $1/(\varepsilon_i - \varepsilon_{i0})$ vs. $1/C_M$ and from the dissociation constants, K_{ai}.

Plots of $1/(\varepsilon_i - \varepsilon_{i0})$ vs. $1/C_M$ were linear in all cases, confirming the formation of 1:1 complexes. Table 2 lists the stability constants calculated from the slopes and intercepts of the plots. Also included in the Table are values of log β_1 from the analysis of the data with the computer program SQUAD [15]. Corrections for the competition of the acetate buffer as a complexant of Nd were made using the values pK_a (acetic) = 5.130 [6] and log β_1(Nd–acetate) = 2.20. This value of β_1 is for AmAc$^-$ complexation [16] since data for NdAc$^-$ were unavailable. This correction increased the stability constants by 0.11. The complexation competition from hydroxylamine was neglected as no visible change in the hypersensitive spectrum of Nd(III) was observed upon addition of hydroxylamine up to a concentration of 0.01 M.

Complexation of actinide cations with these three ligands has not been investigated extensively. Skorik [17] reported the first stability constant data for the trivalent rare earth Sc(III) and Th(IV) complexes with oxine in 0.1 M NaClO$_4$ (measured by the potentiometric titration method). The values reported for Nd(III) and Th(IV) are: log β_1(Nd) = 6.66 ± 0.09 and log β_1(Th) = 11.70 ± 0.13. Considering that different ionic media and ionic strengths are involved, our values do not seem to disagree with those of Skorik. A value of log $K = 0.30$ was reported for the equilibrium constant of the Th(IV)–TTA complexation, [Th^{4+}][HTTA]/[ThTTA^{3+}][H$^+$], in

Table 2

[f] 8.0×10^{-5} M TTA at pcH 5.87 with Nd(III) from 0 to 0.0010 M.
[g] 8.0×10^{-5} M TTA at pcH 3.09 with Th(IV) from 0 to 0.014 M.

2.0 M (H, Na)ClO$_4$ from solvent extraction measurements [18]. Our value, calculated from pK_a data measured by potentiometric titration, is 0.67.

The complexation interactions of both metal ions follow the order: oxine > HTTA > phen, which is consistent with the basicities of the three ligands as reflected by their acid constant values. The strong interaction with oxine probably reflects formation of a chelate structure. The interactions of phen with Nd^{3+} and Th^{4+} are weaker than those with soft divalent cations, such as Ni^{2+} (log $\beta_1 = 8.60$), Cu^{2+} (log $\beta_1 = 9.08$ and Zn^{2+} (log $\beta_1 = 6.04$) [11], but stronger than those with the hard divalent cations Mg^{2+} (log $\beta_1 = 1.55$) and Ca^{2+} (log $\beta_1 = 1.09$) [19]. This suggests that phen behaves as a soft ligand.

4. Summary

The solubilities of the organic compounds studied in the neutral pcH range of natural waters are in the millimolar range. In the pcH 7-8 region, dissolved TTA is present as an anion, phen as a neutral species and oxine as a cation. Consequently only TTA and phen form complexes with actinide cations. The complexation of Nd(III) by

TTA at pcH 7 could compete with hydrolysis to increase the solubility of Nd(III) by 1-10%. However, the competition with hydrolysis of Th(IV) would provide an insignificant increase in Th(IV) solubility. The weaker complexation constants of phen indicate that this ligand would have even less effect on the solubilities of Nd(III) and Th(IV). Oxine would have no effect in the pcH 7-8 range.

Abstract

The use of four dithiocarbamates and three fluorinated β-diketones as potential chelating agents for three transition metal ions (Cd^{2+}, Pb^{2+}, and Hg^{2+}) extracted from spiked sand and filter paper samples by supercritical fluid extraction (SFE) was investigated. The extractions were performed at 45°C and 250 atm for spiked sand samples and at 60°C and 200 atm for filter paper samples using supercritical carbon dioxide modified with 5% methanol. At 250 atm and using carbon dioxide modified with 5% methanol, the recoveries of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions from spiked sand samples were $\geq 95\%$ with lithium bis(trifluoroethyl)dithiocarbamate (LiFDDC) as the chelating agent; they ranged from 83–97% with diethylammonium diethyldithiocarbamate and from 87–97% with sodium diethyldithiocarbamate as chelating agents, and from 68–96% with trifluoroacetylacetone, hexafluoroacetylacetone, and thenoylfluoroacetone as chelating agents. Ammonium pyrrolidinedithiocarbamate was not effective in the chelation SFE of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions from either spiked sand or spiked filter paper samples under the extraction conditions used. Supercritical carbon dioxide alone gave consistently lower analyte recoveries than supercritical carbon dioxide modified with 5% methanol. The results suggest that the solubility of the metal chelate in the supercritical fluid plays a more important role than the solubility of the chelating agent in the supercritical fluid, as long as sufficient chelating agent is present in the fluid phase. Fluorination of the chelating agent, as in the case of LiFDDC, increases the solubility of the metal chelate, and subsequently enhances the extraction efficiency for the metal ions.

1. Introduction

Supercritical fluid extraction (SFE) of organic compounds has gained acceptance as an alternative sample preparation technique in recent years [1–3]. Compared with conventional solvent extractions techniques, SFE offers several advantages including relatively high sample throughput and the reduction in both solvent usage and solvent waste generation, whilst still achieving analyte recoveries that are comparable to those achieved by Soxhlet and sonication techniques. Although most of the SFE studies published so far have focused on organic compounds, there is an increasing interest in extracting metal ions by SFE from solid samples [4–12]. Direct extraction of metal ions with supercritical CO_2 is not possible because of the charge neutralization requirement and the weak solvent–solute interactions. To extract metal ions with supercritical carbon dioxide it is necessary that metal ions be converted into neutral metal complexes that are soluble in supercritical carbon dioxide or supercritical carbon dioxide modified with small amounts of organic solvents.

The selection of suitable chelating agents is critical in the chelation–SFE of metal ions. Important requirements include high stability constants of the metal complexes, high solubilities of the chelating agents and their metal complexes in pure or modified supercritical carbon dioxide, fast chelation kinetics, and complexing specificity to allow selective extraction of a metal ion or a group of metal ions. We have recently demonstrated that lithium bis(trifluoroethyl)dithiocarbamate (LiFDDC) is an effective chelating agent for extracting several transition metal ions, including Cd^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+}, and Hg^{2+} ions, from solid and aqueous samples by SFE [6–8]. The successful use of LiFDDC as chelating agent is largely due to the fact that the solubilities of metal–FDDC complexes in supercritical carbon dioxide are generally 2–3 orders of

magnitude greater than those of the non-fluorinated analogues [4,5]. Wang and Marshall [9] reported recently that tetrabutylammonium dibutyldithiocarbamate (DBDTC) was effective in extracting Cd^{2+}, Pb^{2+}, and Zn^{2+} from aqueous matrices by SFE with carbon dioxide. Our other recent SFE studies indicated that several fluorinated β-diketones were effective chelating agents for thorium, uranium, lanthanide, and actinide metal ions [10–12]. Obviously, the successful use of chelation–SFE techniques for routine extraction metal ions also depends on the availablity of these chelating agents. LiFDDC and DBDTC are not available commercially; therefore, their routine use in SFE is currently limited because they are costly to synthesize in small quantities.

As part of a continuing development and evaluation program of new sample preparation techniques, conducted by the U.S. Environmental Protection Agency (EPA) through the Environmental Monitoring Systems Laboratory-Las Vegas (EMSL-LV), we investigated the use of several commercially available dithiocarbamates and fluorinated β-diketones as chelating agents for extracting metal ions by SFE. In this paper, we report the evaluation of four dithiocarbamates [LiFDDC, diethylammonium diethyldithiocarbamate (Et_2NH_2DDC), sodium diethyldithiocarbamate (NaDDC), ammonium pyrrolidinedithiocarbamate (APDC)] and three fluorinated β-diketones [trifluoroacetylacetone (TFA), hexafluoroacetylacetone (HFA), thenoyltrifluoroacetone (TTA)] as chelating agents for three transition metal ions (Cd^{2+}, Pb^{2+}, and Hg^{2+}) that were extracted from spiked sand and cellulose filter paper by SFE.

2. Experimental

2.1. Reagents and materials

The chelating agents Et_2NH_2DDC, NaDDC,

APDC, TFA, HFA, and TTA were purchased from Aldrich (Milwaukee, WI). LiFDDC was synthesized according to a procedure outlined in the literature [13]. The starting material, bis(trifluoroethyl)amine, was obtained from PCR Chemicals (Gainesville, FL) and other chemicals used in the synthesis, including n-butyllithium (2.5 M in hexane), carbon disulfide, and isopentane were obtained from Aldrich.

Stock solutions of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions at 1000 μg ml^{-1} were obtained from J.T. Baker Inc. (Phillipsburg, NJ). Spiked solutions were prepared from the stock solutions as needed. Deionized water from a Millipore Milli-Q system (Bedford, MA) was used for the preparation of all aqueous solutions.

Methylisobutylketone (MIBK) and nitric acid were Ultrex-grade ultrapure reagents from J.T. Baker Inc. All other reagents and solvents used in this study were of analytical grade and were obtained from Aldrich or Baxter Scientific (Mc-Gaw Park, IL). Purified sand was obtained from J.T. Baker Inc. Cellulose filter paper (Whatman 42) was obtained from Baxter Scientific. A local soil sample was obtained from a soil laboratory at the University of Idaho. SFC-grade carbon dioxide and carbon dioxide modified with 5% methanol (Scott Speciality Gases, Plumsteadville, PA) were used in all experiments reported here.

2.2. SFE apparatus

All experiments were performed with a laboratory-built SFE system. A 3.5 ml stainless-steel vessel obtained from Dionex (Sunnyvale, CA) was used as the extraction vessel. The extraction vessel was fitted with two two-way stainless-steel needle valves (Supelco, Inc., Bellefonte, PA) as the inlet and outlet valves, which were manually adjusted to perform the static and dynamic extractions. The extraction vessel was maintained at the desired temperature by placing it in a thermostated oven. The extraction fluid (SFC-grade carbon dioxide or carbon dioxide modified with 5% methanol) was delivered to the extraction vessel using a microprocessor-controlled high-pressure

pump (Haskel Inc., Burank, CA). The extraction pressure was controlled to ± 5 psi using a Setra Systems (Acton, MA) pressure transducer. Fused-silica tubing (50 μm i.d. $\times$ 20 cm length) was used as a restrictor. The flow rate of the extraction fluid was about 2.0 ml min^{-1} (as a liquid). The restrictor and the collection solvent were at room temperature before extraction. No attempt was made to control the temperature of the collection solvent during extraction.

2.3. SFE procedures

The spiked sand and filter paper samples were prepared as follows. A known amount (5 μg) of each element was spiked onto a pre-washed cellulose-based filter paper (Whatman 42) or onto sand (300 mg). The spiked samples were air-dried at room temperature overnight prior to extraction. To perform chelation–SFE, the spiked sample was placed in a sample holder made of a glass tube (0.9 cm o.d. $\times$ 0.7 cm i.d. $\times$ 3 cm length), which was plugged at one end with a piece of glass wool. After the sample was wetted with 10 μl of deionized water, the open end of the sample holder was plugged with a piece of glass wool. The sample holder was then placed into the extraction vessel. The chelating agent (50 mg) was placed into another glass tube (0.65 cm o.d. $\times$ 0.5 cm i.d. $\times$ 2 cm length), with the middle portion of the tube blown to a bulb-like shape to hold the chelating agent. The chelating agent holder was then partially inserted into the upstream end of the sample holder in the extraction vessel and the vessel was closed (Fig. 1). This arrangement is suitable for handling liquid ligands such as TFA and HFA. The chelation and extraction process
Fig. 1. Schematic diagram of the experimental system used for the SFE of metal ions: (1) CO_2 cylinder; (2) pump; (3) inlet valve; (4) oven; (5) pre-heat coil; (6) ligand holder; (7) sample holder; (8) extraction cell; (9) outlet valve; (10) collection vials.

was conducted in the static mode for 15 min, followed by dynamic extraction for an additional 15 min. The extracted metal chelates were collected in chloroform (4 ml each) and placed in two glass vials (1.2 cm i.d. × 10 cm length) connected in series.

2.4. Solubility measurement

The approximate solubilities of the three dithiocarbamates (NaDDC, Et_2NH_2DDC, and APDC) in supercritical carbon dioxide and carbon dioxide modified with 5% methanol were measured as follows. A known amount of the dithiocarbamate chelating agent was placed in the special holder described above. The holder was plugged with glass wool at both ends and inserted into an extraction vessel. The extraction vessel was heated to 60°C and pressurized to 200 atm using either supercritical carbon dioxide or carbon dioxide modified with 5% methanol. After a 30 min static step, the inlet valve of the extraction vessel was closed and its outlet valve was opened; the dissolved chelating agent was collected by immersing the restrictor outlet in a vial containing 4 ml of chloroform. After the extraction vessel was completely depressurized, the chelating agent holder was removed from the extraction vessel and the empty extraction vessel was re-installed in the oven. To recover any chelating agent that might have precipitated inside the extraction system during the depressurization step, the extraction vessel was extracted again with either supercritical carbon dioxide or carbon dioxide modified with 5% methanol at 60°C and 200 atm in the dynamic mode. The dynamic flushing step may contribute up to 10% of the total chelating agents collected in the collection vial. Precipitation of the chelating agent on the surface of the ligand holder may contribute to the uncertainties in solubility measurements. This source of error is probably small because the surface area of the ligand holder is small compared with the total surface of the SFE system. The concentration of the dithiocarbamate in the chloroform solution was measured with a spectrophotometer. The solubility was then calculated from the amount of dithiocarba-

mate recovered in the chloroform and the volume of the extraction vessel.

2.5. Analysis of extracted solid samples and SFE extracts

The concentrations of Cd^{2-} and Hg^{2+} in sand and cellulose-based filter paper samples and chloroform extracts were determined by neutron activation analysis (NAA). The details of the NAA system used have been reported previously [14]. The solid samples were placed in polyethylene vials; the vials were then sealed by heat and subjected to neutron irradiation. Standards were irradiated and counted under the same condition as samples. To determine the concentrations of mercury and cadmium complexes in the chloroform extracts, a known volume of the extract was transferred to polyethylene vials and evaporated to dryness in the vials prior to NAA. The samples and standards were irradiated for 1 h in a 1 MW TRIGA nuclear reactor at a steady flux of 6×10^{12} n cm^{-2} s^{-1} and counted on a large-volume ORTEC Ge(Li) detector with a resolution (FWHM) of about 2.3 keV at the 1332 keV ^{60}Co peak. The activities at the 336 and 279 keV gamma peaks from ^{115}Cd and ^{203}Hg respectively were used for the quantification of Cd^{2+} and Hg^{2+}. If sufficient ligand is present in the extraction system, quantitative recovery of extracted metal chelates can be achieved. Under our experimental conditions, the amount of metal collected generally agrees with that remaining in the sample to within a few percent.

The concentration of Pb^{2-} in chloroform extracts was determined by atomic absorption spectrophotometry (IL VIDEO 12 AAS) or inductively-coupled plasma mass spectrometry (ICP-MS) (Sciex Elan model 250). The metal chelate in the chloroform solutions was back-extracted with 5 ml of 50% (v/v) Ultrex HNO_3 for 1 h using a wrist-action mechanical shaker (Burrell model 75). After phase separation, the acid solutions were transferred to 10 ml volumetric flasks and diluted to volume for AAS or ICP-MS analysis.

[a] Extractions were performed in duplicate at 45°C and 100 atm or 250 atm, 15 min static followed by 15 min dynamic. The samples were 300 mg of sand spiked with 5 μg of each metal ion. The amount of chelating agent used was 50 mg per sample.

The paper samples were digested with concentrated nitric acid in beakers that were covered with glasses and heated on hot-plates to temperatures slightly below the boiling points of the sample solutions. The spiked metals in sand were extracted using 5% nitric acid. The acid solution from each sample was transferred to a 10 ml volumetric flask and diluted to volume for AAS or ICP-MS analysis.

3. Results and discussion

The recoveries of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions from spiked sand samples are summarized in Table 1. When extractions were performed with LiFDDC and supercritical CO_2 at 45°C and 100

atm, the recoveries from the spiked sand samples ranged from 90-93% for Cd^{2+} and Hg^{2+} ions and were 81% and 84% for Pb^{2+} ions. Et_2NH_2DDC and NaDDC were less effective than LiFDDC in extracting these metal ions; with Et_2NH_2DDC, recoveries from 70-78% for Pb^{2+} and Hg^{2+} ions and were 58 and 61% for Cd^{2+} ions; with NaDDC, recoveries of Pb^{2+}, Hg^{2+}, and Cd^{2+} were between 35 and 60%. APDC was the least effective chelating agent; none of the metal ions could be extracted with recoveries above 24%.

Higher recoveries were obtained with supercritical carbon dioxide modified with 5% methanol. When the extractions were performed with LiFDDC at 45°C and 100 atm, the recoveries of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions ranged from 89-94%;

[a] Extractions were performed in duplicate at 60°C and 200 atm, 15 min static followed by 15 min dynamic. The amount of chelating agent used was 50 mg per sample.

with Et_2NH_2DDC and NaDDC, recoveries ranged from 82–89% (except that the recovery of Cd^{2+} was only about 53% with NaDDC). Recoveries obtained with APDC as the complexing agent were also higher than those obtained with supercritical carbon dioxide alone.

When the pressure was increased from 100 atm to 250 atm (the temperature was maintained at 45°C), the recoveries increased noticeably. The increases were more pronounced with supercritical carbon dioxide modified with 5% methanol than with supercritical carbon dioxide along (Table 1). For example, the recoveries were 95% or greater for the three metal ions using LiFDDC, and they ranged from 83–97% with Et_2NH_2DDC or NaDDC. APDC was still not effective even with the increased extraction pressure.

The results for the spiked filter paper samples (Table 2) indicate that supercritical carbon dioxide modified with 5% methanol was also a more effective extraction fluid than supercritical carbon dioxide alone. When extraction was performed at 60°C and 200 atm with supercritical carbon dioxide modified with 5% methanol, the recoveries from spiked filter paper samples were ≥95% for the three metal ions when using LiFDDC, and ranged from 90–96% for Pb^{2+} and Hg^{2+} ions and from 70–75% for Cd^{2+} ions when using Et_2NH_2DDC and NaDDC. APDC was not effective in the chelation–SFE of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions from spiked filter paper samples under the extraction conditions used (recoveries ranged 16–51%).

The results in Tables 1 and 2 indicate that the fluorinated chelating agent LiFDDC is more ef-

[a] Duplicate determinations.

fective than its non-fluorinated analogues. This finding may be explained by the fact that the fluorinated metal–dithiocarbamate chelates have higher solubilities in supercritical carbon dioxide than their non-fluorinated analogues. It is known that fluorine substitution in metal chelates tends to enhance their solubilities in supercritical carbon dioxide significantly [6]. For example, the solubility of $Hg(FDDC)_2$ in supercritical carbon dioxide at 50°C and 150 atm has been determined to be $(5.0 \pm 0.4) \times 10^{-3}$ M, which is about 600 times greater than the non-fluorinated analogue $Hg(DDC)_2$ [5]. The solubility of $Hg(FDDC)_2$ in supercritical carbon dioxide modified with 5% methanol at the same temperature and pressure is about a factor of two higher than its solubility in supercritical carbon dioxide alone at 50°C and 150 atm [5]. The solubilities of $Pb(FDDC)_2$, $Pb(DDC)_2$, $Pb(PDC)_2$ in CO_2 at 50°C and 150 atm were determined by this study to be $(2.3 \pm 0.6) \times 10^{-4}$ M, $(1.2 \times 0.3) \times 10^{-6}$ M, and $(5.1 \times 0.2) \times 10^{-7}$ M respectively, i.e. the fluorinated complex is about 200 times more soluble than the non-fluorinated complex. APDC, which forms the $Pb(PDC)_2$ complex with a low solubility in supercritical CO_2, is also the least effective ligand for SFE of Pb. The solubility of $Cd(FDDC)_2$ has not

been measured because of the difficulties involved in preparation of the pure compound. However, based on the available solubility data of metal dithiocarbamates in supercritical CO_2, we expect the fluorinated $Cd(FDDC)_2$ to be more soluble than its non-fluorinated analogue.

We determined the approximate solubilities of three dithiocarbamates (Et_2NH_2DDC, NaDDC and APDC) in supercritical carbon dioxide and carbon dioxide modified with 5% methanol (Table 3). The results indicate that the solubilities of these dithiocarbamates in supercritical carbon dioxide modified with 5% methanol were approximately 2–5 times higher than those in supercritical carbon dioxide alone, and the solubilities of Et_2NH_2DDC in the supercritical fluids were approximately 25 times higher than that of NaDDC in supercritical carbon dioxide alone and approximately 60 times higher than that in supercritical carbon dioxide modified with 5% methanol. Although Et_2NH_2DDC was much more soluble than NaDDC, the recoveries of Cd^{2+}, Pb^{2+} and Hg^{2+} ions from the solid matrices were similar with either Et_2NH_2DDC or NaDDC because the chelates formed with Et_2NH_2DDC and NaDDC were identical. This suggests that the solubility of the metal chelate in the supercritical fluid plays a

Table 4

more important role than the solubility of the chelating agent, as long as sufficient chelating agent is present in the fluid phase.

The recoveries of Cd, Pb, and Hg from spiked sand samples by SFE using fluorinated β-diketones (TFA, HFA, and TTA) as chelating agents are summarized in Table 4. When the extractions were performed with carbon dioxide alone at 45°C and 100 atm or 250 atm, the recoveries of Cd^{2+}, Pb^{2+}, and Hg^{2+} ions ranged from 50–85% (21 and 24% for Cd^{2+} with TTA as chelating agent). When the extractions were performed with carbon dioxide modified with 5% methanol at 45°C and 100 atm or 250 atm, the recoveries ranged from 67–96% with TFA, HFA, and TTA as the chelating agents. The results indicate that the three fluorinated β-diketones are also effective chelating agents for Cd^{2+}, Pb^{2+}, and Hg^{2+} ions.

Table 5 shows the extraction of spiked Cd and Hg (5 μg each) from a real soil sample (300 mg) using LiFDDC, NaDDC, and HFA as chelating agents. This soil sample, obtained from Latah

County, ID, contains low levels of Cd and Hg (< 0.1 ppm) and hence is suitable for Cd and Hg spike experiments. According to Table 5, at 45°C and 250 atm LiFDDC can quantitatively extract all spiked Cd and Hg from the soil under the specified SFE conditions. NaDDC shows slightly lower extraction efficiencies for Cd and Hg in the real soil sample compared with the results observed from sand. HFA also shows lower extraction efficiencies for Cd and Hg in the real soil sample. The matrix appears to play a role in lowering metal extraction efficiencies from the real soil sample for some chelating agents.

4. Conclusions

The results of this study show that diethyldithiocarbamates (LiFDDC, Et_2NH_2DDC and NaDDC) and fluorinated β-diketones (TFA, HFA, and TTA) are effective chelating agents for extracting transition metal ions such as Cd^{2+}

Table 5
Extraction of spiked Cd^{2+} and Hg^{2+} from a soil sample using carbon dioxide with 5% methanol

Chelating agent	Cd (%)		Hg (%)	
	100 atm	250 atm	100 atm	250 atm
LiFDDC	85	97	86	103
	89	100	88	100
NaDDC	54	90	84	87
	50	84	82	90
HFA	40	53	68	81
	42	64	64	73

[a] SFE conditions: 300 mg of soil spiked with 5 μg of Cd^{2+} and Hg^{2+} each, 50 mg of LiFDDC or NaDDC or 50 μl of HFA, 200 μl of H_2O, 15 min static and 15 min dynamic extraction.

Pb^{2+}, and Hg^{2+} from solid matrices, including sand and filter paper, by SFE. The use of supercritical CO_2 modified with 5% methanol gave higher metal ion recoveries compared to those obtained with supercritical carbon dioxide alone. The results also suggest that the solubility of the metal chelate in the supercritical fluid plays a more important role than the solubility of the chelating agent for recovering metal ions, as long as sufficient chelating agent is present in the fluid phase. Fluorination of the chelating agent (as in the case of LiFDDC) increases the solubility of metal chelate and subsequently enhances the extraction recoveries of the metal ions. In real soil samples, LiFDDC is the most effective chelating agent for extracting spiked Cd and Hg ions. The native soil matrix appears to lower metal extraction efficiencies for the chelating agents. This study presents preliminary method development data concerning the effectiveness of some commercially available chelating agents for SFE of metals in simulated solid samples. Further studies of these and other chelating agents for SFE of metal ions in real soil samples are currently in progress.

Solid-phase extraction of metal ions and their estimation in vitamins, steel and milk using 3-hydroxy-2-methyl-1,4-naphthoquinone-immobilized silica gel

B.S. Garg*, J.S. Bist, R.K. Sharma*, N. Bhojak

Department of Chemistry, University of Delhi, Delhi 7, India

Abstract

3-Hydroxy-2-methyl-1,4-naphthoquinone-immobilized silica gel has been used for the adsorption and estimation of copper, cobalt, iron and zinc by both batch and column techniques. The distribution coefficient D determined for each metal ion was as follows (ml g^{-1}): Fe, 3.6×10^2; Cu, 3.9×10^2; Co, 3.8×10^2; Zn, 4.1×10^2. Methods have been developed to estimate zinc, copper and cobalt in milk, steel and vitamin samples respectively.

Keywords: 3-Hydroxy-2-methyl-1,4-naphthoquinone-immobilized silica gel; Metal ions; Milk; Solid-phase extraction; Steel; Vitamins

1. Introduction

Metal chelating resins (adsorbed or chemically-bonded chelates) have been found to be of great utility for the preconcentration and separation of trace metals from different matrices. Alkylamines [1], diamine [2], xanthate [3], dimethylglyoxime [4], n-butylamide [5], amidoxime [6], dithizone [7], 8-hydroxyquinoline [8], dithiocarbamates [9], propylenediamine tetraacetic acid [10], 3(1-imidazolyl)propyl [11], thiazolylazo anisole [12], salicyldehyde [13], 8-hydroxyquinone [14], 2,5-dimercapto [15], quinolylazo [16] and didecylamino tridecylammonium iodide [17] have been immobilized on various substrates. Chelex 100 [18,19],

Dionex [20], cyanex [21,22] and Amberlite [23,24] have also been used for the determination of various metal ions. The use of supports loaded with chelating reagents is particularly convenient because it is easy to prepare such resins, although their stabilities and collection abilities may be inferior to those of the chelating resins containing the various functionalized groups [25]. However, these modified sorbents have shown a lack of stability in high ionic strength media and low recovery if more than 300 ml of solution is used. Another disadvantage is the partial elution of the chelating reagent with perchloric or hydrochloric acid solutions of the concentration required for elution of metals forming very stable chelating complexes, which makes the use of the column impossible for several sorption–elution processes.

Chelex is also found to be ineffective for quantitative separation of many metal ions from water samples containing appreciable amounts of naturally occuring fulvic and humic acids [26,27]. This natural organic matter binds metals and competes with the Chelex, making it necessary to use an additional sample treatment such as irradiation with ultraviolet light [28]. Although many materials, such as silica, polystyrene and cellulose, have been used as solid supports for chelating groups, silica shows the fast metal ion-exchange kinetics and the good mechanical strength and swelling stability required for use in high-performance liquid chromatography [29]. Such columns are superior to conventional columns because of their high sorption efficiency even at very high flow rates. 3-Hydroxy-2-methyl-1,4-naphthoquinone and its derivatives are of considerable interest due to their widespread applications in the biological and analytical fields. Sharma and Sindhwani [30-32] have demonstrated the strong chelation behaviour of 3 - hydroxy - 2 - methyl - 1,4 - naphthoquinone (HMNQ) with transition and lanthanide metal ions. Higher sensitivity and selectivity of HMNQ derivatives towards the determination of metal ions have already been reported by Sharma and co-workers [33–37].

The present work describes the application of silica-based HMNQ complexing agent to the batch and column adsorption of various transition metals and its application in the estimation of metal ions in various samples.

2. Experimental

2.1. Apparatus

A digital (ECIL model) pH meter 5651A and a Schimadzu AA-640-13 atomic absorption spectrometer were used. A glass tube of 100 mm length and 7 mm i.d. was used as a chromatographic column.

2.2. Preparation

HMNQ was prepared from 2-methyl-1,4-naphthoquinone (Sigma) by the method of Fieser [38]. Its purity was checked by TLC and it was characterized by elemental analysis.

Preparation of immobilized silica gel was done as reported by Kubota and Moreira [13]. Immobilization of the organofunctional group on the silica gel was performed in two steps.

2.2.1. Step 1

Activated silica gel (silica was activated before modification in a high vacuum) was suspended in 10% v/v 3-amino propyl triethoxy silane in dry toluene. The mixture was refluxed for 12 h in a nitrogen atmosphere with constant stirring. The resulting product amino propyl silica gel (APSG) was filtered, washed consecutively with toluene, ethanol and acetone and then heated at 75°C for 10 h in a vacuum line.
R = Aminopropyl group

2.2.2. Step 2

The APSG was reacted with HMNQ in anhydrous diethyl ether with constant stirring. The mixture was filtered and washed and then solid, modified silica was heated at 55°C in a vacuum line.

$$Y - (CH_2)_3 - NH_2 + O = \overset{HO}{\underset{}{\bigcirc}}\overset{CH_3}{\underset{}{}} = O$$

$$Y - (CH_2)_3 - N = \overset{HO}{\underset{}{\bigcirc}}\overset{CH_3}{\underset{}{}} = O$$

Y = Solid support

The infrared spectrum confirmed the occurrence of the coupling reaction. The band at 1640 cm^{-1} is due to the C–N stretching frequency of the imino group.

2.3. Procedure

2.3.1. Batch experiment

The chelating silica gel was equilibrated with a suitable amount of metal ions for a certain period of time. The unextracted metal ions were determined by atomic absorption spectroscopy (AAS).

2.3.2. Column experiment

This study was carried out using a glass column packed with 1 g of immobilized silica gel through which 100 ml of solutions of individual metal ions were percolated at a flow rate of 3 ml min^{-1}. The metal ions were then eluted from the column using 1 N HCl/HNO$_3$ and determined by AAS. Each metal experiment was carried out in triplicate in order to determine the precision of the method.

2.3.3. Optimization of adsorption time

The time required for the solid liquid system to attain the equilibrium condition was determined by placing the solution of metal ions in a conical flask and shaking with modified silica gel. The supernatant from each flask was separated off at different time intervals and metal ions were determined. The amount of metal ions adsorbed by the solid phase was determined by the equation

$$N_f = (X - Y)/Z \tag{1}$$

where X is the initial amount of metal ion, Y is the amount of metal ions in the supernatant, N_f is the amount of metal ion adsorbed and Z is the mass of modified silica gel (g).

3. Results and discussion

3.1. Optimization of adsorption time

The time taken for the adsorption of the metal ion and the attainment of the equilibrium condition by the immobilized silica gel is of considerable importance. The time taken for the system to reach equilibrium is found to be about 10 min in the case of Zn, Fe and Cu, and 12 min in the case of Co (Fig. 1).
3.2. Effect of amount of modified silica gel

The percentage retention of metal ions on modified silica gel was determined by using different amounts of silica gel. The percentage retention of metal ion on modified silica gel was best when 0.1 g of modified silica gel was employed.

3.3. Effect of pH

Metal solutions were adjusted to the required pH and passed at a flow rate of 1 ml min^{-1}. Then the metal ions were eluted from the column. Subsequent atomic absorption analysis gave the percentage recoveries of the eluted metals at various pH. The pH range studied was between 2 and 9. This study of effect of pH on modified silica gel shows that maximum adsorption in the case of Fe occurs in the pH range 5–7. In the case of Co it occurs in the pH range 4.5–6.5. Cu shows maxi-
Fig. 1. Effect of time on adsorption.

mum adsorption in the pH range 3-7. In the case of Zn maximum adsorption occurs in the pH range 5-8 (Fig. 2).

3.4. Effect of flow rate

The dependence of the uptake of the transition metals on the flow rate was studied for Cu, Co, Fe and Zn at the pH of the aqueous metal ion solutions chosen for maximum complexation, the solution flow rate being varied from 0.5 to 5 ml min^{-1}. Adsorption was quantitative and reproducible in this range. The flow rate was maintained at 2 ml min^{-1} throughout the experiment.

3.5. Adsorption isotherms

The adsorption isotherms were determined using the batch techniques at 25°C. Solutions of metal ion in the concentration range 2×10^{-5}–2×10^{-3} mol l^{-1} were shaken for 45 min with modified silica gel. The supernatant from each flask was separated off, metal ions were determined using AAS and the amount of metal adsorbed was calculated using Eq. (1). The distribution coefficient, D is defined as $D = N_f/c$. Here N_f is expressed in mmol g^{-1} and c is in

mmol ml^{-1}. The average values of D calculated for each metal (ml g^{-1}) in the concentration range 2×10^{-5}–2×10^{-3} mol l^{-1} are found to be Fe, 3.6×10^2; Co, 3.8×10^2; Cu, 3.9×10^2; and Zn, 4.1×10^2 (Fig. 3).

3.6. Effect of temperature

Adsorption of metal ion is affected by the temperature, with the equilibrium constant decreasing as the temperature is lowered. Studies have shown that adsorption increases with temperature up to 40°C but remains constant after that.

3.7. Effect of electrolytes

Various electrolytes, such as sodium chloride, potassium nitrate and potassium chloride, caused no improvement in the adsorption.

3.8. Preconcentration and recovery of metal ions

The results of the preconcentration and recovery of the metal ions using the column method are shown in Table 1. It can be seen that in each instance the recovery is almost 96%. The volume of eluent was 10 ml in every case.
Fig. 2. Effect of pH on recovery of metal ion.

3.9. Determination of Cu in steel solution A and B

0.2 g of steel was added to a 250 ml calibrated flask. 10 ml of water and 4 ml of concentrated H_2SO_4 were then added. This solution was then boiled with 2.5 ml of nitric acid. Any solid that

Fig. 3. Adsorption isotherms of metal ion at 298 K.

appearing at this point redissolved in the next step. The flask was cooled and then 5 ml of concentrated H_2SO_4, 5 ml of 85% phosphoric acid, 2 ml of 0.1 m silver nitrate and 60 ml of H_2SO_4 were added in that order. Following this 5 g of potassium persulphate was then added. This solution was swirled until most of the salt had dissolved. The solution was boiled again for 5 min, cooled, and then 0.5 g of potassium periodate was added. This solution was boiled again, cooled to room temperature and diluted to 250 ml. Copper solution then passed through the column filled with silica gel. Copper ion was eluted from the column using 0.01 N HCl. The amount of copper ion was then determined by AAS. The results in Table 2 show that Cu in steel solution is completely recovered by immobilized silica gel. The recovery is almost 95%.

Table 1
Preconcentration and recovery of metal ions

Ion	Conc. of metal ions (mg l^{-1})	Vol. of eluent (ml)	Recovery (mg l^{-1})	Recovery (%)
Fe	5	10	4.85	97
Co	5	10	4.8	96
Cu	5	10	4.8	96
Zn	5	10	4.8	96

Table 2
Determination of Cu in steel solutions A and B

Sample	Certified composition	Cu taken	Cu found
A	Cu = 0.22, C = 0.24, Mn = 0.74, Si = 0.31, Cr = 1.17, Mo = 0.51	0.22	0.21
B	Si = 0.06, Zn = 0.045, Al = 7.50, Mn = 0.24, Cu = 0.04	0.04	0.031

3.10. Determination of Zn in milk sample

The required amount of the powdered sample (6.0 g) was mineralized in a kjeldahl flask with a sulphuric acid–nitric acid mixture. Most of the acid was neutralized with sodium hydroxide. The solution was then transferred to a 100 ml calibrated flask and diluted to volume with water. 10 ml aliquots of the sample solution were added to five conical flasks which contained 2 ml of stock solution, 5 ml of the buffer solution and 8 ml of distilled water. This solution was then passed through the column filled with modified silica gel. The metal ions were then eluted from the column using 0.01 N HCl/HNO_3 and determined using AAS. The results for determination of Zn in the milk sample are given in Table 3. The standard deviation was found to be 0.57.

3.11. Determination of cobalt in vitamins

The contents of 2 ml ampoules of Macraberin Forte injection were decomposed in a covered beaker by heating with concentrated nitric acid, first at low temperature to avoid violent reaction, then more strongly (with more acid) until the acid had evaporated. Finally, the residue was heated to

Table 3
Determination of zinc in milk samples (powdered milk)

Sample	Amount of Zn present $(\mu g\ g^{-1})$	Amount of Zn found $(\mu g\ g^{-1})$	Standard deviation
Sample 1	56	53	
Sample 2	56	54	0.57
Sample 3	56	54	

Table 4
Determination of cobalt in vitamin

Sample	Co present (mg l^{-1})	Co found (mg l^{-1})	Co found (%)	Standard deviation
1	22	21.0	95.5	
2	22	21.0	95.5	0.11
3	22	21.2	96.0	

about 400°C on a hot-plate, cooled to room temperature and dissolved in nitric acid(1 + 1) to give a solution which was slowly evaporated (1–2 h) on a steam bath. The residue was taken up in water (25 ml) to which concentrated nitric acid was added in 0.25 ml portions until a clear solution was obtained on gentle heating. This solution was then passed through the column containing modified silica gel. The metal ions were then eluted from the column using 0.01 N HCl/HNO_3. The cobalt content of this solution was determined using AAS. This method resulted in 95.5% recovery of cobalt in vitamins. The results are given in Table 4.

4. Conclusions

In conclusion, using a new type of HMNQ-immobilized silica gel iron, copper, cobalt and zinc can be readily determined. This solid-phase extraction method shows fast ion-exchange kinetics and high sorption efficiency. The proposed method is widely applicable for the measurement of trace copper, cobalt and zinc in a variety of samples such as steel, milk and vitamins.

Enhanced decompositions of some cyano complexes during diode array spectrophotometric measurements

Guillermo López-Cueto[a], José F. Rodríguez-Medina[b], Carlos Ubide[b],*

[a] *Departamento de Química Analítica, Facultad de Ciencias, Universidad de Alicante, Apdo. 99, 03080 Alicante, Spain*

Abstract

Acidic solutions of the Fe(III), Mo(V), W(V) and Mn(IV) cyano complexes are known to decompose photochemically. These reactions do not take place to an appreciable extent when the cyano complexes are subjected to spectrophotometric measurements by means of conventional spectrophotometers, but they do take place when diode array spectrophotometers are used. The reactions are autoaccelerated, at least in the cases of Mo(V), W(V) and Mn(IV), and consist of photoinduced reductions of the metal ion. This effect should be taken into account in all cases where the measured signal has to be used for quantitative purposes, but its significance must be emphasized mainly in the field of kinetic analysis, where it can lead to large errors. The extent of these reactions, and therefore the size of the errors, can be lowered by using UV cut-off filters and by taking discontinuous measurements with suitable integration times. All these possibilities, which are of general application, are discussed.

1. Introduction

Diode array spectrophotometers are able to acquire data at a rate of several spectra per second [1]. This makes them especially well suited to follow, in the UV–Visible region, systems moving to equilibrium (kinetic runs, chromatography, flow injection, etc.) [2], but they are also used instead of conventional spectrophotometers with systems at equilibrium. One of the key features of diode array spectrophotometers is that light of all energies in the UV–Visible region impinges simultaneously on the sample at any time, whilst in a conventional spectrophotometer only a narrow band of wavelengths does this. As a result, undesirable photochemical reactions happen much more easily in diode array spectrophotometers. The extent of these photochemical reactions, in each case, is usually related to the time the sample stays in the light beam. These reactions can be a significant source of errors, mainly in kinetic analysis, where reaction rates or any other kinetic variable are measured for quantitative analytical

* Corresponding author. Fax: (+34)43-21-22-36.

purposes. However, few specific cases of photochemical reactions have been reported to take place in diode array spectrophotometers [3].

A number of cyano complexes of the transition metals are known to undergo photolytic reactions [4,5]. The redox potentials for $Mn(CN)_6^{2-}$, $Mo(CN)_8^{3-}$, $W(CN)_8^{3-}$ and $Fe(CN)_6^{3-}$ are, (vs. NHE) 1.04 V [6], 0.725 V [7], 0.457 V [8] and 0.361 V [9] respectively. Accordingly, all these compounds have oxidizing properties, and some of them have been used as slow oxidizing reagents with inorganic as well as organic substrates in kinetic determinations [10–12]. Some of these cyano complexes can undergo thermal as well as photochemical decomposition, as has been reported for $Fe(CN)_6^{3-}$ [13] and $Mn(CN)_6^{2-}$ [14]. During study of the oxidation of aminophenols by octacyanomolybdate(V) (in order to propose a method for the simultaneous kinetic determination of aminophenol isomers) [12] we observed that the Mo(V) cyano complex underwent photolytic reduction if the reaction was monitored with a diode array spectrophotometer. In that particular case the photochemical reaction did not result in a problem; however, in general, if the reaction is going to be followed through the cyano complex concentration, high errors can be produced in the presence of photochemical reactions. The present paper shows that all the aforementioned complexes undergo photolytic decomposition to appreciable extents when exposed to the light beam of a diode array spectrophotometer; however, this problem can be reduced or even avoided by using suitable instrumental conditions, although a price may have to be paid for it.

2. Experimental

2.1. Apparatus

A Shimadzu UV-260 spectrophotometer with 1.0 cm pathlength fused-silica cells and constant temperature cell-holders was used as the conventional spectrophotometer. The temperature in the cell was continuously monitored by means of a small Pt 100 temperature probe installed just before the water entrance in the cell-holder, and

kept constant ($\pm 0.2^\circ C$) by circulating water from a Haake F3 K thermostat controlled by the probe. A microcomputer HP vectra ES/12, coupled to the spectrophotometer, controlled it, acquired the data and processed them via home-made programs. A diode array Hewlett Packard HP 8452A spectrophotometer with 1.0 cm pathlength fused-silica cell was also used. The cell temperature was controlled by the HP 89090A Peltier temperature control accessory ($\pm 0.2^\circ C$). To obtain reliable and reproducible measurements the solution in the cell was continuously stirred with a small magnetic stirrer incorporated into the Peltier system. A filters kit (HP part number 08451-60302) was sometimes used; because the kit is not compatible with the Peltier system, a water-circulating thermostatic bath was used in these cases. All the data were acquired with a Hewlett Packard HP vectra 386/25N coupled to the spectrophotometer.

Volumes <0.1 ml were added with Eppendorf micropipettes.

2.2. Reagents

Caesium octacyanomolybdate(V) dihydrate [15], caesium octacyanotungstate(V) dihydrate [15] and potassium hexacyanomanganate(III) [16] were prepared according to the procedures previously reported.

Hexacyanomanganate(IV) solution (2×10^{-4} M) was obtained by fast disproportionation of hexacyanomanganate(III) in 0.1 M H_2SO_4 according to the procedure previously reported [11]. Other cyano complex solutions (5×10^{-4} M unless otherwise stated) were prepared from the caesium or potassium salts in 0.1 M H_2SO_4.

Other chemicals as (potassium hexacyanoferrate(III) (Merck) and sulphuric acid (Riedel de Häen) were of analytical-reagent-grade and were used as received. Doubly-distilled water was used throughout.

2.3. Procedure

To a 1.0 cm cell 2.5 ml of 0.1 M H_2SO_4 was added and the cell was left to stand for 5 min in the controlled temperature cell-holder of the spec-

trophotometer (blank solution). A volume of 0.1 ml of the cyano complex solution was added (zero time) and the change of absorbance with time was followed either at a fixed wavelength (conventional) or along a part of the UV–Visible spectrum (diode array).

3. Results and discussion

Acidic solutions of $Mo(CN)_8^{3-}$ and $W(CN)_8^{3-}$ are stable in the dark, but $Fe(CN)_6^{3-}$ and $Mn(CN)_6^{2-}$ undergo thermal decomposition [13,14]; nevertheless, only $Mn(CN)_6^{2-}$ decomposes at an appreciable rate at room temperature (Fig. 1). These decompositions are apparently insensitive to the light levels present in a conventional spectrophotometer (corresponding to the wavelengths of their absorption maxima in the visible or near-UV regions) and therefore, the reactions proceed to the same extent both in the spectrophotometric cell and in the dark, indicating that only thermal reactions take place under these conditions. In contrast, when the cyano complexes are placed in the cell-holder of a diode array spectrophotometer significant differences in the reaction profiles are found (Fig. 2): $Mo(CN)_8^{3-}$ and $W(CN)_8^{3-}$ now decompose at a noticeable rate, the reaction being autoaccelerated
Fig. 1. Kinetic runs for the decomposition of cyano complexes in a conventional spectrophotometer: (1), Fe(III) (422 nm); (2) W(V) (388 nm); (3), Mo(V) (388 nm); (4), Mn(IV) (387 nm). H_2SO_4, 0.1 M. T, 40°C.
Fig. 2. Kinetic runs for the decomposition of cyano complexes in a diode array spectrophotometer: (1), Fe(III) (422 nm); (2), W(V) (388 nm); (3), Mo(V) (388 nm); (4), Mn(IV) (388 nm). H_2SO_4, 0.1 M. T, 25°C.

in both cases; the $Fe(CN)_6^{3-}$ decomposition is now perceptible and $Mn(CN)_6^{2-}$ decomposes at a much faster rate (the initial rate increases by a factor of about 3.5 in the latter case). This seems to indicate that, in additioin to the thermal decomposition, a parallel photodecomposition takes place in the cell of the diode array spectrophotometer. For instance, the reaction profile of the $Mn(CN)_6^{2-}$ decomposition shows an autoacceleration behaviour clearly different from the pseudo-first-order kinetics shown when a conventional spectrophotometer is used (Fig. 1). These differences can be attributed, therefore, to a photochemical effect caused by UV radiation of certain wavelengths present in the light beam of the diode array spectrophotometer. This is illustrated in Fig. 3, where the behaviour of a $Mo(CN)_8^{3-}$ solution subject to alternating periods of irradiation and darkness in a diode array spectrophotometer is shown.

As has been remarked on in the case of $Mn(CN)_6^{2-}$ solutions, the effect of irradiation is not only in terms of quantity but also in terms of quality. That is to say, the observed changes seem to affect both reaction rate and mechanism since the initial rate as well as the reaction propfiles change significantly. The autoaccelerated kinetic profile is a quite frequent feature of photoinitiated reactions, in which the absorption of a photon of

relatively high energy (UV region) leads to the formation of an electronically excited species which suffers subsequent reactions. These reactions can include dissociations accompanied by redox processes with participation of free radicals, which usually lead to chain mechanisms which are responsible for the autoacceleration kinetics. In these stepwise photoinduced reactions unusually high values of the quantum yield can be attained [17].

The reaction products under the conditions of Fig. 2 were not completely identified in the case of $Fe(CN)_6^{3-}$ and no attempt was made to elucidate the mechanism of its photodecomposition. It seems quite probable that free cyanogen radicals could be involved. In fact, it has been suggested that the photoinitiated aquation of hexacyanomanganate(III) is followed by the oxidation of released cyanide by unchanged $Fe(CN)_6^{3-}$ [18], and it has been proposed that this reaction proceeds via the formation of cyanogen radical as an intermediate species [19]. In the case of $Mo(CN)_8^{3-}$ and $W(CN)_8^{3-}$ the reaction products were identified as $Mo(CN)_8^{4-}$ and $W(CN)_8^{4-}$. This seems to support reaction mechanisms occurring via OH radicals [20] instead of via CN radicals [21]. In the case of $Mn(CN)_6^{2-}$ the reaction products were the same as those obtained in the thermal decomposition and so the stoichiometry of both the thermal and the photochemical reactions
Fig. 3. Decomposition of 10^{-3} M $Mo(CN)_8^{3-}$ in a diode array spectrophotometer and in the dark. H_2SO_4, 0.1 M. The sloping sections correspond to lighting times.
Fig. 4. Effect of filters and shutter on the photoinduced reduction of octacyanomolybdate (V). Curves (1)–(4) obtained in a diode array spectrophotometer. (1), No filter; (2), 265 nm cut-off filter (at 50% T); (3), 295 nm cut-off filter (at 50% T); (4), no filter but shutter active (measurements every 15 s; integration time, 2 s). Curve (5) obtained in a conventional spectrophotometer.

should be the same: the reduction of the metal ion by the coordinated cyanide [14].

Photochemical reactions produced in a diode array spectrophotometer can be an important source of errors, especially if the sample has to be in the light beam for a long time (kinetic runs). Therefore some tentative procedures were tested to prevent these disadvantages:

(1) The use of UV filters. Photochemical reactions are usually initiated by UV radiation which is more energetic than visible radiation, and so they can be prevented by the use of cut-off filters for the UV region. The effect of UV filters on the photoinduced reduction of $Mo(CN)_8^{3-}$ is shown in Fig. 4. The extent of the reaction is lower when a 265 nm cut-off filter is used (curve 2) than in the absence of a filter (curve 1); however, a 295 nm cut-off filter is more efficient (curve 3) because it cuts off a wider wavelength region. Even so, the prevention of the photochemical reaction is not complete (with curve 5, obtained by means of a conventional spectrophotometer).

(2) The use of the couple shutter–integration time. The reaction kinetics in a diode array spectrophotometer can be monitored discontinuously and the signal is integrated over short, fixed time intervals. When undesired photochemical reac-

tions can take place the shutter should be kept active (closed) whenever measurements are not being taken. The question is how long the shutter should be open for (integration time) in order to take reliable measurements. Obviously, very short integration times would not allow the photochemical reaction to go very far, but the value of the signal-to-noise ratio could become excessively low. Consequently the integration time should be optimized as the longest time that still makes the photochemical reaction negligible. In Fig. 4, it can be seen that a measurement every 15 s with an integration time of 2 s (curve 4) does not completely prevent the photochemical reduction of $Mo(CN)_8^{3-}$ but the result is better than the one obtained using the 295 nm cut-off filter (curve 3). Nonetheless, if the instrumental conditions used in curves (3) and (4) are combined (filter + shutter) no apparent photochemical reaction occurs and a profile similar to curve 5 is found.

4. Conclusion

From a general point of view it can be said that photochemical reactions are much more frequently originated by the light beam of a diode array spectrophotometer than by that of a conventional one. Kinetic analysis is especially subject to errors due to these effects. To avoid this drawback, some instrumental precautions can be taken, namely: UV cut-off filters, discontinuous measurements, use of the shutter, and short integration times. Though all these precautions can result in certain limitations (for instance the use of UV filters does not allow measurements to be taken in that region) and poorer precision will be obtained (fewer experimental points can be acquired, decreased signal/noise ratio, etc.), their use frequently allows one to take advantage of the instrumental possibilities of diode array spectrophotometers in unfavourable cases.

Simultaneous spectrophotometric determination of drugs in pharmaceutical preparations using multiple linear regression and partial least-squares regression, calibration and prediction methods

R.D. Bautista, F.J. Aberásturi, A.I. Jiménez, F. Jiménez*

Department of Analytical Chemistry, Nutrition and Food Science, Faculty of Chemistry, University of La Laguna, E-38071 La Laguna, Tenerife, Spain

Abstract

Two new methods for the simultaneous determination of acetylsalicylic acid, acetaminophen and caffeine based on total absorbance measurements and their processing by multiple linear regession and partial least-squares regression are proposed. The concentration ranges used to construct the calibration matrix were 4.0–12.0, 2.0–10.0 and 0.9–6.0 μg ml^{-1} for acetylsalicylic acid, acetaminophen and caffeine respectively. The proposed methods were validated by using a set of synthetic sample mixtures and subsequently applied to the determination of the three active principles in three different pharmaceutical preparations.

Keywords: Acetaminophen; Acetylsalicylic acid; Caffeine; Multiple linear regression; Partial least-squares; Simultaneous determination

1. Introduction

Multideterminations of analytes that exhibit absorbance signals in the UV–Vis region have become commonplace tasks in most analytical laboratories (clinical, food control, pharmaceutical, etc.), which address them in different—but not always effective—ways.

*Corresponding author.

The greatest difficulties with UV–Vis multidetermination methods arise when the analytes to be determined give partly or fully overlapped spectra, as is the case with the ingredients of most pharmaceutical preparations. As a result, the methods to be used in quality control analyses should be highly reliable as regards processing of calibration data and predicting the absorbance signals for the target analytes. The many choices available in this respect include univariate calibra-

tion [1,2] and multivariate calibration methods such as multiple linear regression (MLR) [3], partial least-squares regression (PLS) [4,5], iterative target transformation factor analysis (ITTFA) [6] and evolving factor analysis (EFA) [7].

This paper demonstrates the high potential of MLR and PLS-2 calibration–prediction methodologies for processing absorbance signals of drugs (specifically acetylsalicylic acid, acetaminophen and caffeine). Based on the results obtained, the multideterminations performed are not influenced by the prevailing strong spectral overlap throughout the absorption wavelength range.

Acetaminophen (AAP) and caffeine (CAF) have previously been determined in mixtures by use of derivative spectrophotometry [8] and PLS [9]. Also, these two drugs and acetylsalicylic acid (ASA) have been quantified jointly by HPLC [10–12] and spectrophotometry (using Kalman filtering) [13,14].

The proposed methods were validated by resolving synthetic mixtures of the three drugs, which were also subsequently determined in the three most widely used pharmaceutical preparations in Spain.

2. Theory

The theory and uses of multivariate calibration as applied to analytical chemistry are by now solidly established and have been the subject of several reviews and monographs [15,16], therefore only a brief outline of the methods used in this work is provided below.

2.1. Multiple linear regression method (MULTI3), using several standards of the analytes and their mixtures

If absorbance measurements for several solutions containing mixtures of the analytes are made in numbers exceeding the number of mixture components, then the system composed of the absorbance and concentration matrices will be overdimensioned and take the following matrix form:

$$A = KC$$

where A is the data absorbance calibration matrix, K is the matrix form which the proportionality constants are calculated from spectra for standard solutions of the pure analytes and/or their mixtures, and C is the concentration matrix. The C prediction concentration matrix can be calculated from the following equation:

$$C = (K'K)^{-1}K'A$$

where K' is the transpose of K and A is the absorbance matrix of unknown samples. Matrix K can be obtained in various ways. We calculated K values by MLR of data for mixtures of analytes of known composition. Mathematically, this entails solving an equation system of the following form at each wavelength:

$$a(\lambda, s) = e(\lambda) + \sum_{i=1}^{n} k(\lambda, i)c_{si}; \quad \forall s = 1 \ldots n_s$$

where a is the signal for mixture s at wavelength λ, $e(\lambda)$ is the independent fitting term at each λ value and c_{si} is the concentration of component i in mixture s. This equation can be solved by MLR when the number of mixtures exceeds the number of components. The deviation of the fit at each wavelength, $d(\lambda)$, can be calculated from:

$$d(\lambda) = \sqrt{\frac{\sum_{s=1}^{n_s} [a(s, \lambda) - \hat{a}(s, \lambda)]^2}{n_s - n}}$$

$d(\lambda)$ values are reused, after weighting (those wavelengths with the higher deviations are assigned smaller weights than the rest), in the initial fitting.

$$\frac{a(\lambda)}{d(\lambda)} = k'_0 + \sum_{i=1}^{n} \frac{k(i, \lambda)}{d(\lambda)} c_i; \quad \forall \lambda = 1 \ldots n_\lambda$$

2.2. PLS method

PLS analysis resolves matrices X and Y into the product of smaller matrices, namely P (the X loading matrix, which contains the directions of the principal components or axes) and T (the scores matrix, which includes the coordinates for the new axes) and Q (the Y loading matrix):

$$X = TP + E$$

$$Y = TQ + F$$

In our case, matrix X (the absorbance matrix) was composed of objects as rows $(1 \ldots N)$ and variables as columns $(1 \ldots K)$ (the calibration solutions and absorption wavelengths at which measurements were made respectively). Matrix Y (the concentration matrix) consisted of the calibration solutions as rows $(1 \ldots N)$ and the analyte concentrations as columns $(1 \ldots J)$. Finally, matrices E and F (the residual matrices) contained the model error and random noise respectively.

Scheme 1 shows the calibration and prediction processes, where W is the so-called "loadings weight matrix" or "PLS weights matrix".

3. Experimental

3.1. Apparatus

Spectra were recorded on a Hewlett-Packard HP 8452A diode array spectrophotometer furnished with quartz cuvettes of 1 cm pathlength that was interfaced to a Vectra ES computer and a Think Jet printer, also from Hewlett-Packard. The spectrophotometer measures each even wavelength.

A Radiometer PHM-84 digital pH-meter furnished with a combined glass–saturated calomel electrode was used for pH measurements. The meter was calibrated with at least two buffer solutions at pH 4.02 and 7.00.

An ultrasonic bath was also employed.

3.2. Computer hardware and software

Absorbance and derivative spectra were acquired and processed using the spectrophotometer's bundled software. Additional software used included a MLR programme (MULTI3) [17] and Unscrambler v. 5.0 [18] for calibration–prediction and experimental design. Exported data from the spectrophotometer were converted into MULTI3 and Unscrambler formats using the word processor WordPerfect 5.1 for filing in ASCII format. All software was run on a PC/AT 486 DX2 66 MHz computer.

3.3. Reagents

Standard solutions containing 100 μg ml^{-1} ASA, AAP and CAF were made by direct weighing of the required amount of commercially available reagent (Merck) and then dissolving in 0.1 M HCl.

An HAcO/NaAcO buffer (pH 5.5; 1.0 M) was also prepared.

All reagents and solvents used were of analytical grade and the water was doubly-distilled.

3.4. Analysis of synthetic mixtures

Ternary mixtures of ASA, AAP and CAF were prepared in triplicate as follows. A 25 ml flask was filled with 3 ml of HAcO/NaAcO buffer at pH 5.5, an appropriate volume of drug solution to obtain final concentrations of 4.0–12.0 μg ml^{-1} ASA, 2.0–10.0 μg ml^{-1} AAP and 0.9–6.0 μg ml^{-1} CAF, and bidistilled water to the mark.

Mixed spectra were recorded over the wavelength range 220–310 nm using a blank prepared in the same way as the mixtures but containing none of the analytes. An integration time of 1 s was employed in every experiment.

3.5. Simultaneous determination of ASA, AAP and CAF in pharmaceutical preparations

The contents of a pharmaceutical tablet or capsule, and/or 5 g of accurately weighed granules, were dissolved in doubly-distilled water with ultrasonication for 15 min. Then, the solutions were filtered through a Whatman No. 41 paper and the filtrates transferred to 1000 ml volumetric flasks and made up to volume with doubly-distilled water. Aliquots of these solutions were used in such a way that the concentration of each drug obtained upon dilution to 25 ml lay within the range of the calibration matrix. The dilute solutions were analysed in quintuplicate as described in the previous section.

4. Results and discussion

Fig. 1 shows the absorption spectra for aqueous solutions of ASA, AAP and CAF at pH 5.5. As

can be seen, ASA gave two absorption maxima (a stronger one at 224 nm and a weaker one at 288 nm), CAF also gave two (at 222 and 274 nm, the intensity of the latter band is higher) and AAP a single maximum (at 244 nm).

The simultaneous determination of these drugs in mixtures by conventional spectrophotometric methods is hindered by strong spectral overlap throughout the wavelength range. Such a determination could theoretically be facilitated by the use of a multivariate calibration method.

In order to establish the optimal measurement conditions for the joint determination, we used the univariate method to investigate the effect of experimental variables on the absorption spectra for the drugs studied.

We first checked the stability of the three analytes in aqueous solution. For this purpose, we recorded the UV absorbance spectra for solutions of the three drugs as a function of time and found that the spectra for AAP and CAF did not vary appreciably over a period of a few days provided that the solutions were

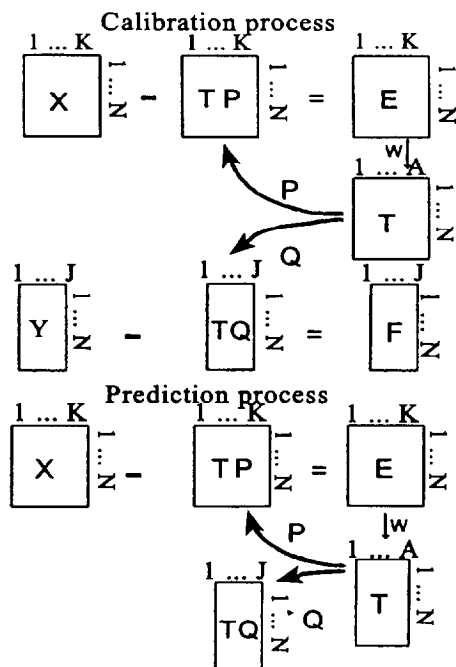
kept at room temperature in the dark. In contrast, the spectrum for ASA exhibited signs of instability 6 h after the solution was prepared, even under the same experimental conditions used for the other two drugs. The instability probably arose from hydrolysis in solution and compelled use to use freshly made solutions of ASA in subsequent experiments.

The influence of pH on the absorption spectrum for each drug was studied over the range 1.0–12.0; pH values were adjusted by addition of small volumes of dilute solutions of HCl and/or NaOH. The spectrum for ASA was found to be markedly affected by the pH of the medium: the absorbance signal increased with decreasing acidity as a new absorption maximum gradually appeared at 300 nm due to the hydrolysis product. In contrast, the signal for AAP was increased by highly acid or alkaline media and decreased over the pH range 4.0–8.0, coinciding with a hypsochromic shift in the absorption maximum. Finally, the spectrum for CAF exhibited no significant changes at any pH. In order to avoid the potential hydrolysis of the drugs by too acid or too alkaline a medium, pH 5.5 was adopted as optimal for subsequent experiments.

Of the different buffering solutions tested HAcO/NaAcO was found to result in signals coinciding with those obtained in its absence, and so was chosen for subsequent work. In order to determine the optimal buffer concentration, a series of experiments was conducted in the range 0.05–0.25 M. Such concentrations were found to have no effect on the spectra for the three drugs so an intermediate buffer concentration, 0.12 M, was adopted.

The temperature was found to have no appreciable effect on the spectra of the analytes, so 25°C was chosen for subsequent work.

4.1. Determination of ASA, AAP and CAF by MLR

The ASA–AAP–CAF mixture was resolved with the aid of the programme MULTI3. The calibration matrix was constructed according to a


Scheme 1.

$(2^n + 1)$ experimental design. The composition of the calibration solution used was as follows:

Analyte/solution	1	2	3	4	5	6	7	8	9
ASA	+	+	+	−	−	−	+	−	~
AAP	+	+	−	+	−	+	−	−	~
CAF	+	−	+	+	+	−	−	−	~

Level (+): ASA 12.0 μg ml^{-1}, AAP 10.0 μg ml^{-1}, CAF 6.0 μg ml^{-1}.
Level (−): ASA 4.0 μg ml^{-1}, AAP 2.0 μg ml^{-1}, CAF 0.9 μg ml^{-1}.
Level (~): ASA 8.0 μg ml^{-1}, AAP 6.0 μg ml^{-1}, CAF 3.5 μg ml^{-1}.

The method was validated using eight solutions encompassing the concentration range of the calibration matrix.
Fig. 1. Absorption spectra of ASA (8.0 μg ml^{-1}), AAP (3.0 μg ml^{-1}) and CAF (2.0 μg ml^{-1}) at pH 5.5, HAcO/NaAcO buffer.

-1

4.2. PLS

The same mixtures were employed as calibration matrix for applying PLS-2 using the software Unscrambler v.5.0.

Fig. 2 shows the variation of the residual variance with the number of factors used. As can be seen, the proposed model accounts for 100% of the data variance with only three factors. The first factor accounts for the variance of AAP, the second for that of CAF and the third for that of ASA.

Fig. 3 shows a plot of model scores against analyte concentrations in each calibration solution. As can be seen in Fig. 3a, a plot of score 2 vs. score 1, the solutions arranged themselves horizontally within each group according to the AAP concentration (i.e. an increase in the first and second scores led to an increase in the concentrations of AAP and CAF respectively). The third score (Fig. 3b) is related to the concentration of ASA: the solutions grouped vertically according to its concentration, an increase in which increased the third score.

The relationship between the scores and analyte concentrations confirms the hypothesis made in studying the variance of the residuals for the analyte solutions.

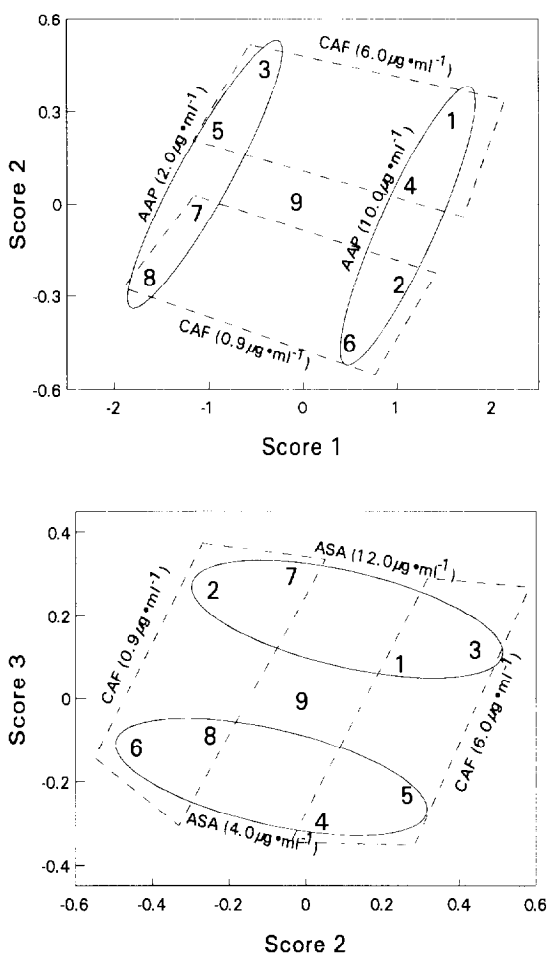
Fig. 4 shows the model loadings, each of which is related to one or more of the analytes in
Fig. 2. Explained variance in the calibration process as a function of the number of factors for (—) total variance of data, (- - -) variance of AAP data, (– – –) variance of CAF data and (—) variance of ASA data.


Fig. 3. Scores plot for the calibration set, showing the positions of the different solutions used (see text).

solution. The relationship is reflected in the spectral shape, which may coincide with that of one of the analytes or a combination of two or more. In our case, the first loading accounts for the variance of AAP, the second for that of CAF and the third for that of ASA. Finally, including a fourth loading lacks chemical significance.

4.3. Resolution of synthetic mixtures

In order to test the proposed methods, a set of synthetic mixtures containing the three analytes in variable proportions was prepared and analysed. Table 1 shows the results obtained using MLR. As can be seen, the errors made never exceeded 3.7%. The analyte resulting in the largest errors
Fig. 4. Loadings plot as a function of the wavelength (variables): (– – –) first loading (related to AAP); (———) second loading (related to CAF); (—) third loading (related to ASA); (—) fourth loading (lacks chemical significance).

was ASA, possibly because it was also that giving the lowest signals; the errors for the other two drugs were quite similar.

The results obtained by applying PLS-2 to the same sample set are listed in Table 2. As can be seen, the errors were also quite acceptable as they never exceeded 3.6%.

The predictive ability of a model can be defined in different ways. The most common is probably the standard error of prediction (SEP), which compares the concentration found by the model with the added concentration, and is given by

$$SEP = \sqrt{\frac{\sum_{i=1}^{N} (C_i^{Added} - C_i^{Found})^2}{N}}$$

where C_i^{Added} is the added concentration of the analyte, C_i^{Found} is the concentration found and N is the number of synthetic samples. Tables 1 and 2 show the errors made in the resolution of different synthetic mixtures.

4.4. Accuracy and precision

In order to check the goodness of the results, the amounts added and found in each synthetic solution were subjected to a statistical test aimed at discarding systematic errors. For this purpose, the mutual confidence region test, developed by Mandel and Linnig [19], was applied to slopes and

Table 1
Simultaneous determination of ASA, AAP and CAF in different synthetic mixtures using the MLR prediction method

Amount added (μg ml^{-1})			Amount found[a] (μg ml^{-1})			Error (%)		
ASA	AAP	CAF	ASA	AAP	CAF	ASA	AAP	CAF
10.00	7.00	5.40	9.68	7.01	5.31	−3.2	+0.1	−1.7
10.00	6.00	4.80	9.88	6.00	4.77	−1.2	0.0	−0.6
8.00	5.00	4.50	7.80	4.98	4.51	−2.5	−0.4	+0.2
6.00	4.00	4.20	5.78	4.01	4.18	−3.7	+0.3	−0.5

					SEP:	0.22	0.06	0.04

[a] Mean values of five determinations.

intercepts. The test revealed the absence of systematic errors in the determination of ASA by either method at a significance level of $p = 0.01$. Also, no systematic error was detected in the determination of AAP by MLR at $p = 0.1$ or by PLS-2 at $p = 0.01$. Finally, no systematic error was found for CAF as determined by MLR ($p = 0.05$) or PLS-2 ($p = 0.01$).

The precision of the proposed methods was determined by one-way ANOVA of six replicates processed on three consecutive days. Snedecor's F values were all below the tabulated value ($F = 3.68$, $n_1 = 2$, $n_2 = 15$), so there were

no significant differences between the results obtained in the determination of each pharmaceutical in the presence of the other two on different days.

4.5. Interferences

In order to apply these methods for the analysis of a pharmaceutical dosage form, the influences of commonly used excipients and tablet additives for these drugs were investigated. No interferences could be observed when up to a 100-fold excess of saccharose, glucose, cellulose,

lactose or starch was added to the synthetic mixtures to be analysed, for either of the methods.

Concerning the degradation products of the drugs, salicylic acid is the major degradation product interference, probably as a result of ASA hydrolysis into salicylic acid and acetic acid, but this effect is observed 10 h after the ASA solution was prepared. In order to avoid the hydrolysis of ASA, all experiments were made using fresh solutions.

4.6. Applications

The proposed methods were used to determine the three drugs in various pharmaceutical preparations: Fiorinal Sandoz Oral (capsules), Cerebrino Mandri (granules) and Neocibalena (tablets). These preparations are administered to patients with rheumatic or neuralgic pain (with or without concomitant fever).

The impurities and degradation products which may be encountered in pharmaceutical dosages, besides ASA, are: acetylsalicylic anhydride (0.0012–0.024%) and acetylsalicylsalicylic acid (0.03–0.1%); acetaminophen, p-aminophenol ($\not> 0.025\%$), p-chloroacetanilide (≤ 10 ppm), o-acetylacetaminophen (1.1–1.3%), inorganic chloride ($\not> 0.014\%$), inorganic sulfate (0.02%) and water ($\not> 0.5$). None of these impurities are in quantities to be of significant interference in the determination of the drugs. Moreover, the pharmacopeia limits for these drugs in the pharmaceutical preparations are between 90 and 110%.

Recovery studies of standard additions to commercial pharmaceuticals were also carried out to provide further support for the validity of the

Table 4
Simultaneous determination of ASA, AAP and CAF in pharmaceutical preparations using the MLR prediction method

[a] Mean values of five determinations.

proposed methods. The related data are given in Table 3; the mean percentage recoveries and their standard deviations. The results also confirm the precision and validity of the proposed methods.

Tables 4 and 5 show the results obtained in the simultaneous determination of the three drugs in the above-mentioned pharmaceutical preparations using MLR and PLS-2. As can be seen, all were consistent with the manufacturer's certified contents and the results are with the limits allowed by the Spanish Pharmacopeia.

5. Conclusions

Based on the results obtained in this work, application of multivariate calibration to the absorbance signals produced by drugs during their simultaneous determination in pharmaceutical preparations is an effective means for quality control of their manufacture. The ensuring methods are simple, precise and affordable; also, they require no complex pretreatment or chromatographic separation of the samples containing the active principles to the determined. Overall, they make a viable alternative to existing analytical methods for routine analyses.

Extraction and determination of crown ethers from water samples using a membrane disk and gas chromatography

Yadollah Yamini[a], Mojtaba Shamsipur[b,*]

[a]Department of Chemistry, Tarbiat Modarres University, Tehran, Iran
[b]Department of Chemistry, Razi University, Kermanshah, Iran

Abstract

A method for rapid extraction and determination of some crown ethers in aqueous matrices using octadecyl-bonded silica membrane disks and gas chromatography is presented. Extraction efficiency and the influence of vacuum pressure, pH, and type and least amount of eluting solvent used to extract the crown ethers from the membrane disks were evaluated. Extraction efficiencies > 95% were obtained for benzo-15-crown-5, benzo-18-crown-6 and dicyclohexyl-18-crown-6 using 5 ml of acetonitrile as eluting solvent. The limit of detection of the proposed method for the determination of the crown ethers is reported.

Keywords: Crown ethers; Gas chromatography; Membrane disk; Solid-phase extraction

1. Introduction

Macrocylic crown ethers, first synthesized by Pedersen [1], have been extensively used to selectively separate metal ions from their mixtures by solvent extraction [2–8] or by liquid membranes [9–15]. However, bleeding of crown ethers from the organic phase of the liquid membranes or solvent extraction systems, even at low levels, into the aqueous phases [14,16] causes complications in the separation process.

The problem of crown bleeding can be overcome by covalently attaching the macrocylces to

silica gel [17,18] or by using polycrown ethers [19,20]. Moreover, the precipitates of crown ethers with phosphomolybdic acid and phosphotungstic acid [21] and the coating of macrocyclic ligands on hydrophobic silica gel [7] have also been used to reduce the leaching of crown ethers during separation processes. However, even in these cases, crown ether bleeding can occur to some extent when aqueous samples containing metal ion or mineral acids as stripping agents are passed through the separation columns. Thus, to evaluate the efficient age of the columns, the development of methods for preconcentration and determination of low levels of crown ether bleeding into aqueous phases is of great importance.

* Corresponding author.

The use of classical methods of extraction for this purpose are usually time-consuming, labor-intensive and require large amounts of high purity solvents for extraction. Nevertheless, it is possible to extract the components of interest in the aqueous samples with minimal usage of organic solvents by means of solid-phase extraction (SPE) techniques [22]. In this method, the aqueous sample first passes through a cartridge or tube containing an adsorbent that retains the analytes. Then the analytes are eluted from the adsorbent using a minimal amount of a suitable organic solvent. The main limitation of the SPE cartridges and tubes is the tendency for fine particulates to plug the frits holding the adsorbent in place. However, this problem can be overcome by using flat disks with high cross-sectional area (SPE disks). The decreased back pressure encountered with the SPE disks makes much higher flow rates possible, and their wide bed decreases the chance of plugging. Recently, the SPE disks have been utilized for the extraction and determination of many different environmental matrices, such as pesticides, linear alkylbenzenesulfonates, polyaromatic hydrocarbons, etc. [23–30].

The aim of this work was the development of a rapid and efficient method for the extraction and determination of low levels of some crown ethers in aqueous media using a membrane disk and gas chromatography. Different experimental conditions, e.g. the type of eluting solvent, the effect of pH, the effect of vacuum pressure on extraction time and efficiency and the minimum amount of eluting solvent necessary to wash the disk, have been studied.

2. Experimental

2.1. Reagents

HPLC-grade methanol, acetonitrile, ethylacetate and dichloromethane (all from Aldrich) were used without any further purification. Reagent-grade 12-crown-4, 15-crown-5 (15C5), benzo-15-crown-5 (B15C5), 18-crown-6 (18C6), benzo-18-crown-6 (B18C6) and dicyclohexyl-18-crown-6 (DC18C6) were of the highest purity available

from Merck and were used as received. Standard solutions of crown ethers were prepared by dilution of different volumes of their 1000 ppm solutions to 500 ml with deionized water.

2.2. Sample extraction

Extractions were performed with 47 mm diameter × 0.5 thickness Empore membrane disks containing octadecyl-bonded silica (8 μm particles, 60 Å pore size) from J.T. Baker. The typical composition of the disks was 90% w/w octadecyl-bonded silica and 10% w/w PTFE fibers. The disks were used in conjunction with a standard Millipore 47 mm filtration apparatus.

Before extraction, each membrane was washed with 10 ml of eluting solvent to remove all contaminants arising from the manufacturing process and from the environment. After placing the membrane in the filtration apparatus and drawing air through the disk for several min, 10 ml of methanol was introduced into the reservoir of the apparatus and drawn slowly through the disk by applying a slight vacuum until a thin layer of methanol was left on the surface of the disk. Finally, a 10 ml portion of deionized water was used to rinse methanol. This step pre-wets the surface of the disk prior to extraction of crown ethers from water.

Immediately after completion of the washing process, 500 ml of water containing 2 mg of each crown ether was passed through the disk for about 10–22 min by applying a suitable vacuum. After drawing the aqueous sample through the disk, the vacuum was applied for an additional 5 min to remove the residual water from the disk. It is important to note that the surface of disk was not allowed to dry from the time the methanol was added until the extraction of crowns from water was completed.

After complete drying of the disk, the extraction funnel was transported to a second vacuum filtration flask containing a 25 mm × 200 mm test tube and the extracted crowns were eluted into the test tube by application of the eluting solvent. Then, the extract was completely transferred into a graduated cylinder and the solvent was evaporated to a final volume of 2 ml. 1 μl of this

solution was then injected onto the gas chromatograph. To demonstrate the efficiency of extraction of the membrane disk, the same concentration of crown ethers was prepared in 2 ml of the eluting solvent and a 1 μl portion of it was injected onto the gas chromatograph.

2.3. Apparatus

Gas chromatography was performed with a Philips Scientific model 4410 chromatograph equipped with a flame ionization detector and split/splitless injection, and fitted with a 25 m × 0.25 mm i.d. fused silica column coated with an immobilized film of BP-5. Nitrogen was used as the carrier gas at a flow rate of 1.5 ml min^{-1}. The injector and detector temperatures were 320°C and 300°C respectively. The oven temperature was 100°C for 0.5 min after injection and was then programmed at a rate of 20°C min^{-1} up to 300°C, where it was held for 5 min. The split ratio was 1:14. The pH measurements were carried out with a Metrohm pH-meter using a combined glass electrode.

3. Results and discussion

In this work octadecyl-bonded silica was evaluated for the extraction of crown ethers from their water samples. Deionized water spiked with low concentrations of crown ethers (4 mg l^{-1}) was extracted using membrane disks and the results obtained were compared with those from direct measurement of concentrated crown ethers using GC. Fig. 1 shows GC-flame ionization detection (FID) analysis of a crown ether mixture containing 12C4, 15C5, B15C5, 18C6, B18C6 and DC18C6, after membrane disk extraction and elution by acetonitrile. The elution order of the crowns used is the order of increasing molecular weight.

The membrane disk construction is similar to that of a reversed-phase column with a large diameter and short length. The use of smaller particles (8 μm, 60 Å pore diameter) and uniform packing in the disk results in a reasonable flow without excessive back pressure. The retention

mechanism of the SPE disk is based on the same sorption-desorption phenomena as in reversed-phase LC. In fact, the capacity factor determines whether a given compound can be quantitatively retained by the hydrophobic disk in an aqueous mobile phase, and whether it can be quantitatively eluted by an organic solvent. Also, as with LC columns, the efficiency of the extraction by membrane disks is a function of the particulate packing density and the linear velocity of the mobile phase through the stationary phase.

Table 1 illustrates the recovery data obtained for different crown ethers in water at a concentration of 4 mg l^{-1} using 10 ml of various eluting solvents. As can be seen, the capacity factor for 12C4 is almost zero and the amount of crown retained on the disk is negligible. 15C5 and 18C6 are retained on the disk very loosely and are easily washed off with water. However, for B15C5, B18C6 and DC18C6, due to their high lipophilic
Fig. 1. GC–FID chromatogram obtained for 4 mg l^{-1} aqueous solutions of the crown ethers used after following the proposed procedure: (1) solvent; (2) 15C5; (3) 18C6; (4) B15C5; (5) B18C6; (6) DC18C6. Conditions: initial volume of aqueous solution, 500 ml; volume of acetonitrile, 10 ml; final volume of the eluted solution, 1 ml; injection volume, 1 μl split; oven temperature, 100°C for 0.5 min after injection, then programmed at 20°C min^{-1} to 300°C which was held for 5 min.

Table 1
Percent recovery of crown ethers from membrane disk using 10 ml of different solvents at pH 6.8 and a vacuum pressure of 510 mmHg

Crown ether	Solvent			
	Methanol	Acetonitrile	Ethylacetate	Dichloromethane
12C4	0	0	0	0
15C5	4.2(1.1)[a]	4.4(5.7)	4.5(16.0)	5.2(6.5)
18C6	16.6(6.0)	19.5(5.8)	12.9(8.9)	15.9(5.0)
B15C5	72.4(12.4)	96.8(0.2)	84.0(7.4)	87.8(3.7)
B18C6	90.7(1.8)	98.6(4.8)	90.4(2.3)	91.8(4.5)
DC18C6	92.0(2.5)	101.3(5.7)	98.3(4.0)	99.0(2.8)

[a] %RSD based on three replicate analyses.

character, the k' values are high and they are retained by the membrane disk very tightly. The data given in Table 1 represent the influence of the properties of the eluting solvent on the recovery of crown ethers. It is seen that, among the four different organic solvents used, acetonitrile possesses the highest elution efficiency. It is noteworthy that, since the injector and detector temperatures were quite high and the initial column temperature (i.e. 100°C) was also much higher than the boiling point of acetonitrile, the use of acetonitrile as the eluting solvent resulted in no practical problem in GC measurements.

The influence of vacuum pressure (flow rate) on the percentage recoveries of the crown ethers used was studied in the range 560–710 mmHg. It was found that there is no recognizable correlation between flow rate and percentage recoveries of 2 mg of crown ether from 500 ml of deionized water. Similar results have been reported before [23,27,31].

It is well known that the packing density and linear velocity through membranes are two important factors in determining the effectiveness of reversed-phase interactions. An LC column of 4.6 mm i.d. at a flow rate of 1.5 ml min^{-1} possesses a linear velocity of 0.15 cm s^{-1} [23]. An SPE cartridge of 10.0 mm i.d. when used to process 1000 ml of water in 2 h, as recommended in the EPA Method 525 [32], has approximately the same linear velocity of 0.18 cm s^{-1}. The 47 mm i.d. EPA disk used in this study under a linear velocity of 0.18 cm s^{-1} has

a flow rate of 187.4 ml min^{-1}; thus, the optimum time for the extraction of crown ethers will be some 3 min. Obviously, for longer periods of time, the efficiency of extraction (and also the percentage recovery) is expected to be affected by the vacuum pressure only slightly.

In order to investigate the effect of pH on the SPE of crown ethers, the pH of aqueous samples was varied from 3 to 7, using perchloric acid, and the recommended procedure was followed at a vacuum pressure of 510 mmHg using 10 ml of acetonitrile as eluting solvent. It was found that, especially for more lipophilic crown ethers, the percentage recovery is nearly independent of pH. It is interesting to note that a similar pH effect has already been reported for the solvent extraction separation of different metal ions with crown ethers [4,33]. The results indicate that due to the negligible degree of protonation of crown ethers, their lipophilicity will remain unaffected by the existence of protons in solutions, even at an acid concentration of 10^{-3} M.

The least amount of acetonitrile necessary for the quantitative elution of crown ethers from the disk was studied and the results are given in Table 2. It is seen that 5.0 ml of acetonitrile seems to be adequate for the complete elution of crown ethers from the membrane disk. Under such conditions a pre-concentration factor of 100 will be obtained in transferring the crown ethers from the initial aqueous phase into the acetonitrile as eluting solvent.

Table 2
Percent recovery of crown ethers from membrane disk using different volumes of acetonitrile at pH 6.8 and 510 mmHg

Crown ether	Volume of acetonitrile (ml)			
	2.5	5.0	7.5	10.0
15C5	1.3(3.0)	1.4(0.5)	3.4(0.8)	4.4(5.7)
18C6	6.5(4.1)	9.7(6.0)	16.0(1.4)	19.5(5.8)
B15C5	71.4(1.6)	95.8(5.0)	95.3(2.1)	96.8(0.2)
B18C6	74.3(2.9)	104.7(4.1)	102.7(0.8)	98.6(4.8)
DC18C6	79.9(4.5)	103.4(4.1)	101.5(2.3)	101.3(5.7)

The limit of detection (LOD) of the proposed method for the determination of crown ethers with quantitative extraction efficiencies (i.e. B15C5, B18C6 and DC18C6) was studied under the optimal experimental conditions discussed. The LOD values obtained for B15C, B18C6 and DC18C6 are 0.07, 0.17 and 0.29 μg ml^{-1} respectively. It is interesting to note, however, that by using a 100 μl portion of the samples and a 4 min delay after injection (instead of 0.5 min) the LOD could be easily reduced to a part per billion level.

The results of this study demonstrate that the SPE using a membrane disk produces acceptable precision and accuracy data for the lipophilic crown compounds. This extraction–GC technique provided advantages in terms of analysis time, solvent use and solvent disposal. The basis of extraction is similar to reverse-phase LC. The capacity factor is very small for the more hydrophilic macrocycles 12C4, 15C5 and 18C6 so that these compounds could not be retained completely by the disk. In contrast, the more lipophilic crowns B15C5, B18C6 and DC18C6 with high capacity factors were retained completely by the disk. Finally, 5 ml of acetonitrile is enough for complete elution of the crown ethers B15C5, B18C6 and DC18C6 from the membrane disk. These crown ethers could be determined at sub microgram per milliliter levels.

Spectrophotometric and polarographic investigation of the ofloxacin–Cu(II) complexes

V. Kapetanović*, Lj. Milovanović, M. Erceg

Faculty of Pharmacy, University of Belgrade, Belgrade, Yugoslavia

Received 10 October 1995; revised 23 February 1996; accepted 15 May 1996

Abstract

By means of spectrophotometric methods it was found that ofloxacin reacts with copper(II) ions to form complexes with molar ratios of ofloxacin: Cu(II) of 1:1 at pH 4.00, 2:1 at pH 7.02 and 3:1 at pH 8.30. The stability constants of the complexes were determined. The formation of ofloxacin:Cu(II) 1:1 and 3:1 complexes was confirmed by a polarographic method and the corresponding overall stability constant was evaluated.

Keywords: Cu(II)–Ofloxacin complexes; Polarography; Spectrophotometry; Stability constants

1. Introduction

Ofloxacin, [9-fluoro-2,3-dihydro-3-methyl-10-(4-methyl-1-piperazinyl)-7-oxo-7H-pyrido-[1,2,3-de]-1,4-benzoxazine-6-carboxylic acid], is one of the 4-quinolone synthetic antibiotics (Fig. 1). As can be seen, ofloxacin possesses two relevant ionizable functional groups: a basic piperazinyl group in the 4'-position ($pK_{a,2} = 8.22$ [1] and 7.90 [2]) and a carboxylic acid group in the 6-position ($pK_{a,1} = 6.05$ [1] and 5.70 [2]). Ofloxacin belongs to the quinolone class of broad spectrum antibiotics developed during the last decade [3]. Quinolones are active against many gram-positive and gram-negative bacteria [4–6]. All quinolones possess a carboxylic acid moiety and the carbonyl group required for antimicrobial activity that is also thought to be a site of chelation interaction with various cations. A potential problem with the increasing use of quinolone-type antibiotics for treatment of systematic illness is the chelation and interaction of these compounds by several cations [7]. One outcome of these potential interactions could be a reduction in the bioavailability and effectiveness of quinolone compounds. This is especially emphasized when these drugs are co-administered with antacids or with vitamin preparations.

Quinolones also effect trace metal metabolism, being potent inhibitors of some copper- and zinc-dependent enzymes [8]. For this reason the complexing ability of these ligands with some essential bioelements in serum (Fe(III), Cu(II) etc.), as well as with Al(III) and Mg(II) ions in antacids is of special interest. The complexation of lomefloxacin with Al(III), Ca(II), Mg(II), Bi(III) and Fe(III) ions commonly found in antacid or vitamin

preparations was studied [9]. Two complexes, proposed to have stoichiometries of 2:1 and 3:1 (drug to metal), were observed. The metal complexes of cinoxacin with Ni(II) and Zn(II) ions were synthesized and isolated [10]. The crystal and molecular structures of the complexes were determined by X-ray structure analysis. It was shown that two cinoxinate ligands bind metal ions through one carboxylate oxygen atom and the exocyclic carbonyl oxygen atom. The complexation of two model compounds, lomefloxacin and norfloxacin, with Al(III) ions was studied using NMR [11].

Two complexes, proposed to have stoichiometries of 2:1 and 3:1 (drug:metal), were observed.

The reactions of ciprofloxacin and ofloxacin with Al(III), Mg(II), Ca(II) and Fe(II) ions in aqueous medium were studied using different spectroscopic techniques [12]. Formation constants of the 1:1 Fe(III) complexes of ciprofloxacin, enoxacin and ofloxacin [13] were determined by spectrophotometry. The optimum pH for complexation was found to be 3.8. The stability constant of the Oflx–Fe(III) complex was found to be $\log \beta_1 = 6.98$. The stability constants of lomefloxacin with Al(III), Ca(II), Mg(II), Mn(II), Fe(II), Co(II), Ni(II), Zn(II) and Cu(II) ions were determined by potentiometry [14]. Three complexes, with drug:metal molar ratios of 1:1, 2:1 and 3:1, were found in all cases except Ca(II) and Fe(II), where the formation of only 1:1 complexes was established. The stability constants for Cu(II)–lomefloxacin complexes were: $\log \beta_1 = 6.16$, $\log \beta_2 = 10.96$ and $\log \beta_3 = 13.41$. The same authors reported the stability constants for ofloxacin complexes of Ca(II), $\log \beta_1 = 2.12$; Mg(II), $\log \beta_1 = 2.82$, $\log \beta_2 = 5.48$; and Al(III), $\log \beta_1 = 7.13$, $\log \beta_2 = 12.53$ and $\log \beta_3 = 17.87$. No literature date were found for Cu(II)–ofloxacin complexes.

In this work the equilibria of ofloxacin–Cu(II) complexes were studied by applying spectrophotometric and polarographic methods.

2. Experimental

2.1. Apparatus

The following equipment was used: a PHM-62 Radiometer (Denmark) pH-meter with combined GK 2401B electrode, a UV–Vis Varian Super Scan 3 spectrophotometer with 1 cm quartz cells and a PAR-174A polarograph connected to a three-electrode cell (dropping mercury electrode, DME, saturated calomel electrode, SCE and Pt auxilary electrode). Differential-pulse polarography (DPP) was performed under the following conditions: forced drop time, 2 s; modulation amplitude, 25 mV; scan rate 2 mV s^{-1}; and mercury column height, 81 cm.

2.2. Reagents

All chemicals were of analytical-reagent grade and demineralized distilled water was used throughout. Ofloxacin working standard and Visiren tablets were from Jugoremedija (Zrenjanin, Yugoslavia). $Cu(NO_3)_2$, NaOH and $NaNO_3$ were p.a. grade (Merck).

2.3. Ofloxacin (oflx) stock aqueous solution

A 4×10^{-3} M solution was prepared by dissolving the appropriate amount of ofloxacin standard in demineralized water. 10^{-1} M $Cu(NO_3)_2$ stock solution was standardized by a complexometric method. Britton–Robinson buffer [15] (0.08 M) was used for investigations in the pH range 4.02–10.02. 2 M $NaNO_3$ solution was used to maintain constant ionic strength.

2.4. Procedure for calibration graph

Oflx solution, 2×10^{-3} M (0.25–2.5 ml), $Cu(NO_3)_2$ solution, 2×10^{-2} M (0.5 ml), and Britton–Robinson buffer pH 4.5 (5 ml) were pipetted into a 10 ml volumetric flask. After addition of 1 ml of 2 M sodium nitrate solution, the reaction mixture was diluted to 10 ml with water. The solution was mixed and the absorbance was measured at a wavelength of 360 nm against Oflx as the reagent blank. All measurements were performed at room temperature (25 ± 0.5°C).

2.5. Procedure for determination of oflx in pharmaceutical formulations

Sample amounts equivalent to the average weight of one 200 mg tablet of Oflx were weighted from a combined amount of 10 Visiren tablets. This procedure was used to compensate for any variation in the weights of individual tablets. Each sample was transferred with water to a 500 ml volumetric flask to make the final concentration of the solution approximately the same as that of the standard stock solution. An aliquot of the tablet sample was used in the same procedure as that described in Section 2.4.

3. Results and discussion

3.1. Absorption spectra

The reaction of Oflx with Cu(II) ion was investigated over the pH range 4.02–10.02 in Britton–Robinson buffer. The spectra were recorded at 350–450 nm. Since Cu(II) ion had no absorbance in this wavelength range and Oflx showed a high absorbance value with a λ_{max} value of 330 nm (Fig. 2, curve 14), the spectra denoted 1–13 are due to the formation of a complex between Oflx and the Cu(II) ion.

3.2. Effect of pH

The absorption spectra of a mixture of 6×10^{-4} M Oflx and 1×10^{-4} M Cu(II) solutions were recorded at constant ionic strength, $I = 0.2$ M, and are shown in Fig. 2 (curves 1–13). On increasing the pH of the solution from 4.00 to 8.50 the peak corresponding to the maximum of the complex

Fig. 3. Job's curves of equimolar solution at pH 7.02 (a), 8.30 (b) and 4.00 (c). $C_{Cu(II)} + C_{Oflx} = 4 \times 10^{-4}$ M (a,b); $C_{Cu(II)} + C_{Oflx} = 6 \times 10^{-4}$ M (c).

absorbance underwent a slight bathochromic shift ($360 \rightarrow 366$ nm). The complex was found to exhibit a maximum absorbance in the pH range 4.00–5.52 ($\lambda_{max} = 360$ nm), 6.01–7.53 ($\lambda_{max} = 363$ nm) and 8.00–9.00 ($\lambda_{max} = 365$ nm). Further increase in the pH to pH 9.00 resulted in a slight decrease in the absorbance of the complex. At pH > 9.00, a pronounced decrease in the absorbance of the complex can be observed due to the hydrolytic processes (curves 12 and 13). The spectra obtained in the investigated pH range show that more than one complex species is formed in the solution.

Further investigations were performed at the pHs where λ_{max} was constant, i.e. pH 4.00, 7.02 and 8.30.

3.3. Composition of the complexes

Job's method [16] of equimolar solution showed that 1:1, 2:1 and 3:1 Oflx:Cu(II) complexes were formed at pH 4.00, 7.02 and 8.30 respectively (Fig. 3a, 3b and 3c respectively). The Bent–French method [17] was used to find the number of Cu(II) ions in the complex. It was found that one Cu(II) ion participates in the formation of the complexes (the slope of $-\log A$ versus $-\log$ Cu(II) ion was 0.94).

Fig. 2. Absorption spectra of the system Oflx–Cu(II) at different pH values: (1) 4.02, (2) 4.50, (3) 5.00, (4) 5.52, (5) 6.01, (6) 6.50, (7) 7.02, (8) 7.53, (9) 8.00, (10) 8.50, (11) 9.00, (12) 9.52, (13) 10.02, (14) absorption spectrum of 6×10^{-4} M Oflx.

[b]Mean value of five determinations.

3.4. Stability constants of the complexes

The relative stability constants of the complexes were calculated according to the methods of Sommer and Tsin-Jao [18] and Asmus [19] and are presented in Table 1. Taking into account the following equilibria:

$$M + L \rightleftharpoons ML \tag{1}$$

$$\beta_1 = [ML]/[M][L] \tag{1'}$$

$$HL \rightleftharpoons H + L \tag{2}$$

$$K_{a,1} = [H][L]/[HL] \tag{2'}$$

where equilibrium (1) denotes the reaction of complex formation and (2) the reaction of ligand dissociation, the stability constant obtained under experimental conditions will be a conditional one and can be defined as

$$\beta'_1 = [ML]/[M][HL] \tag{3}$$

As Oflx is a weak acid, the concentration of L (according to equilibrium (2)) is strongly influenced by pH due to the protonation of the ligand. For this reason the real stability constant β_1 can be calculated using the following equation [20]:

$$\beta_1 = \beta'_1(1 + [H^+]/K_{a,1}) \tag{4}$$

where $[H^+]$ represents the hydrogen ion concentration (calculated from the activity at $I = 0.2$ M) and $K_{a,1} = 8.91 \times 10^{-7}$ is the first ionisation constant of Oflx [1]. As can be seen, the values of the stability constants obtained by different methods are in good agreement.

3.5. Polarographic investigations of the Oflx–Cu(II) complex

The peaks for Oflx ($E_p = -1.41$ V, curve 1), Cu(II) ion ($E_p = -0.06$ V, curve 2) and Oflx–Cu(II) mixture ($E_p = -0.29$ V, curve 3) obtained under the same experimental conditions of pH 7.50 (Britton–Robinson buffer, $I = 0.2$ M), are

Fig. 4. DP polarograms of (1) 1×10^{-4} M Oflx, (2) 5×10^{-5} M Cu(II) and (3) Oflx–Cu(II) mixture (5×10^{-5} M Cu(II) and 3×10^{-4} M Oflx); pH 7.50 (Britton–Robinson buffer); $I = 0.2$ M (NaNO₃).
Fig. 5. Dependence of the Oflx-Cu(II) complex diffusion current (curve 1) and $E_{1/2}$ (curve 2) on pH.

shown in Fig. 4. The appearance of a new peak at $E_p = -0.29$ V is due to the reduction of the polarographically active complex formed between Oflx and the Cu(II) ion.

3.6. pH dependence of the Oflx-Cu(ii) ion

The dependence of the diffusion current and $E_{1/2}$ value of the Oflx-Cu(II) complex on pH is shown in Fig. 5. The Cu(II) ion and Oflx concentrations were constant: 1×10^{-4} M and 6×10^{-4} M respectively. As can be seen, the diffusion current of the complex increases on going from pH 3.15 to 5.00, where its maximum is attained. It then slowly decreases until pH 7.65, where it becomes constant. From pH 9.10 the complex current decreases abruptly. A plot of $E_{1/2}$ vs. pH (from 3.15-8.60) was a straight line with a slope of 0.062 V, showing that two hydrogen ions were involved in the electrode process. The shape of the plot of the diffusion current vs. pH can be explained by the presence of different ionic species in the solution, i.e. different complex species (the first from pH 3.15-5.00; the second from 5.00-7.65 and the third from 7.65-9.10). This effect is a consequence of different diffusion coefficients of the ionic species present in the solution. By logarithmic analysis of d.c. polarograms of log $\bar{i}_d - i/\bar{i}$ vs. E throughout the pH range investigated, the slope of the straight line of 62 mV was obtained, indicating a two-electron reversible electrode process.

3.7. Composition and stability constants of the complex

The metal-to-ligand ratio in the complex was determined by amperometric titration of a 1×10^{-4} M Cu(II) solution with Oflx (at concentrations of 1×10^{-4}–8×10^{-4} M) in Britton–Robinson buffer at pH 8.30. The stoichiometric ratio of Oflx to Cu(II) in the complex and the stability constant were determined by Lingane's method [21]. By plotting the dependence of the peak potential difference between the complexed and free Cu(II) ions, ΔE_p, against the logarithm of the Oflx concentration, a coordination number of three ($p = 2.7$) and a conditional stability constant, log β'_3, were calculated from the slope and intercept of the straight line ($r = 0.9921$). The average value of the stability constant from five titrations is presented in Table 1. The results obtained by applying both spectrophotometric and polarographic methods show that Oflx forms very stable complexes with Cu(II) ions. By applying Lingane's polarographic method it was possible to calculate the overall stability constant of the complex with the maximum coordination number.

The stability constant of the Cu(II)–Oflx complex at pH 4.00 was determined by Leden's method [22]. Amperometric titrations of 1×10^{-4} M Cu(II) ion with Oflx, in the concentration range 4×10^{-5}–1×10^{-4} M, were done at pH 4.00, $I = 0.2$ M (NaNO$_3$). A lower pH was used to follow the free Cu(II) wave height, i.e. by calculating the free metal ion concentration. Equilibrium concentrations of the metal, M, and complex, ML, were determined from the wave height of the free copper(II) ion, [Cu^{2+}], while equilibrium concentrations of the free ligand, [Oflx], were calculated from its analytical concentration and the concentration of the complex. According to Leden's equation:

$$F_{[\text{oflx}]} = \beta_1 + \beta_2[\text{Oflx}] \tag{5}$$

where F is $C_{Cu}^{2+} - [Cu^{2+}]/[Oflx]$ and C_{Cu}^{2+} represents the total analytical concentration of Cu(II) ion. By applying the method of least-squares or by plotting the dependence of Leden's function, F vs. [Oflx], a straight line parallel with the x axis

was obtained with an intercept of $\beta'_1 = 1.71 \times 10^4$. This finding suggests the formation of a 1:1 Cu(II): Oflx complex at pH 4.00. By applying the method of continuous variations at pH 4.00, 7.02 and 8.30 it was clearly shown that the ratio of Oflx:Cu(II) was 1:1, 2:1 and 3:1 respectively.

Since no literature data were found on Oflx–Cu(II) complexes, comparison of the results can be made with the stability constants of the metal complexes of other quinolones, i.e. lomefloxacin [14]. According to these authors, the stability constants of the three complexes of lomefloxacin with Cu(II) ion were established as $\log \beta_1 = 6.16$, $\log \beta_2 = 10.96$ and $\log \beta_3 = 13.41$. The same authors give the stability constants for Oflx–Al(III) complexes as $\log \beta_1 = 7.13$, $\log \beta_2 = 12.53$ and $\log \beta_3 = 17.87$. Our experimental results show good agreement with literature data for ofloxacin–Al(III) complexes ($\log \beta_1$), while the stability constants of higher complexes differ, particularly the $\log \beta_3$ values. By comparing the stability constants obtained with Cu(II)–lomefloxacin complexes, a good agreement is obtained with β_1 and β_2, while the stability constant β_3 is higher.

From a critical review [23] relating to the dissociation and complexation of fluoroquinolones it is seen that stability constants studied to date differ by less than two orders of magnitude. The carbon NMR spectrum of lomefloxacin [11] and Al(III) ion revealed that the carboxylic acid carbon and keto carbon signals both showed upfield shifts in the presence of Al(III) ion due to the direct binding of the C3 and C4 oxygens of carboxylic and carbonyl groups to Al(III) ion. The structure of the 3:1 (drug:Al(III)) complex was proposed to consist of three drug molecules bound to the quinolone molecule with an octahedral geometry about the Al(III) ion.

Although there is no definite evidence in the literature concerning the possibility of metal ion coordination through the N'-piperazinyl group, NMR and spectral data given by Okabayashi et al. [14] showed little change of the piperazine group by addition of the Al(III) and Mg(II) ions to lomefloxacin. Since the piperazinyl group was protonated under the conditions of measurement the authors considered that the chelation of the ligand occurred between the carbonyl and car-

boxyl groups. Bearing in mind that our complexation studies were carried out over a wide pH range there is no doubt that the N'-piperazinyl group is available for complexation because at higher pH this atom is not protonated (at pH 8.30 about 60% of the anionic form of ofloxacin is present in the solution).

There is also clear evidence for the existence of three complexes formed between Oflx and Cu(II) ion and good reason to suppose that the site of binding of the Cu(II) ion is at the two carboxylic groups. This can be supported by the fact that two hydrogen ions were involved in the reduction process at the DME (results obtained by polarography). Taking into account the literature data, the experimental parameters obtained and the great affinity of copper(II) ion for nitrogen it can be supposed that the N'-piperazine atom is involved in the complexation. The polarographic method applied enabled us to prove that the polarographic activity of Oflx itself (the reduction of the double bond of the azinone ring [24]) is distorted by the presence of Cu(II) ion. The same height and position of the polarographic waves obtained by scanning the samples of Oflx in the absence and presence of Cu(II) ion showed that the double bond of the azinone ring was not involved in coordination. Similar results were reported by Mendozza-Diaz and Pannell [25] relating to the coordination of Cu(II) ion with nalidixic acid.

An attempt was made to use the Oflx–Cu(II) complex for the analytical determination of Oflx by applying a spectrophotometric method at pH 4.5, where the effects of hydrolytic processes of the Cu(II) ion were minimized.

3.8. Quantification of linearity of calibration graph

Beer's law was tested at pH 4.5 ($I = 0.2$ M). A linear dependence between the absorbance of the complex and the Oflx concentration is observed over the range of 18–180 mg ml^{-1} Oflx. The regression equation is $y = 2.2062 + 589.36x$ and the correlation coefficient, $r = 0.9998$ ($n = 5$), shows good linearity.

Table 2
Spectrophotometric and polarographic determination of Oflx in Visiren tablets (200 mg)

Method	Sample ($n = 6$)			
	Expected (mg)	Found ($\bar{x}$, mg)	Recovery (%)	RSD (%)
Spectrophotometric	200	197.18	98.59	0.072
Polarographic	200	197.40	98.70	0.043

3.9. Applications to tablets

The proposed method was successfully applied to the assay of Oflx in Visiren tablets. The results obtained by the spectrophotometric method were compared with the results obtained by the direct polarographic method for the determination of ofloxacin previously described [26] and presented in Table 2. The method is simple and gives accurate and reproducible results.

Determination of autoprotolysis constants of some non-aqueous solvents using coulometric titration

R. Mihajlović*, Z. Simić, Lj. Mihajlović, M. Vukićević

Department of Chemistry, Faculty of Sciences, University of Kragujevac, R. Domanovića 12, Kragujevac, Yugoslavia

Abstract

Autoprotolysis constants of acetonitrile, propionitrile, nitromethane, ethylene carbonate and dimethyl sulphoxide were determined using a coulometric–potentiometric method with a hydrogen/palladium electrode as generator. The method is based on the titration of a strong base, tetrabutylammonium hydroxide, with H^+ ions generated by anodic oxidation of hydrogen dissolved in palladium. The titration was carried out in a galvanic cell with glass and calomel electrodes at 25°C. The pK_s values for the investigated solvents are: acetonitrile, 28.8; propionitrile, 24.6; nitromethane, 23.7; ethylene carbonate, 21.5; and dimethyl sulphoxide 29.1. These data are in accordance with those reported in the literature.

1. Introduction

Dipolar aprotic solvents (DAS) are widely used in the analytical chemistry of non-aqueous solvents.

Dimethyl sulphoxide (DMSO) is one of the best solvents in the DAS group as it dissolves well numerous inorganic and organic substances (hydrocarbons, sugar, starch, cellulose, proteins, polyamides and various heterocyclic compounds). It has a high dielectric constant ($\varepsilon = 47$), in the range 18–189°C it is in the liquid state, and its autoprotolysis constant is 33.3 [1]. Since many inorganic salts dissolve well in DMSO, there are many electrolytes which can be used for electrolysis in this solvent, such as $NaClO_4$, $LiCl$, $NaNO_3$, NH_4PF_6, NH_4SCN, tetraalkyl ammonium salts, etc. The range of working potentials in the cathode compartments determines the potential of cation reduction (tetraalkyl ammonium ions are reduced at -2.8 V with respect to the saturated calomel electrode) [2] while the limit in the anodic compartments is the oxidation potential of DMSO. Calomel, modified calomel and some amalgam electrodes (Tl(Hg)/TlCl [3], Li(Hg)/LiCl [4]) are used as reference electrodes, DMSO shows the characteristics of a base ($pK = 0.91–1$) [5] because it reacts with strong acids to produce the corresponding salts

---

* Corresponding author

The autoprotolysis constant (pK_s) is an important physicochemical characteristic of a solvent because it indicates the conditions for acid–base titrations in the given solvent to a great extent. Therefore, interest in the determination of the above-mentioned characteristic of a solvent has been demonstrated in the literature.

The K_s value is a function of numerous parameters such as the acidity (K_a) and basicity (K_b) of the solvent, the dielectric permeability, the polarity of molecules, etc.

$$K_s = a_{H_{2S}} + a_S = F(K_a, K_b, \epsilon, E_s, \ldots)$$

If the solvent is more ionized, the autoprotolysis constant and the solvation ability of the substances dissolved by the solvent are increased, which causes stronger dissociation of the dissolved electrolyte. The solvents with higher K_s values have a weaker differentiating effect on the titration of multicomponent compounds.

K_s is one of the basic thermodynamic constants of solvents by which we can make a choice of the solvent for acid–base titrations. The relationship between the autoprotolysis constant (K_s) and the dissociation constant of the acid (or base) defined as the constant of titration is important when choosing the solvent for titration.

Different methods for the determination of the autoprotolysis constant of non-aqueous solvents are described in the literature and the obtained values for particular solvents differ to a great extent, indicating the difficulties encountered in the course of the determination.

Kreshkov et al. [6] determined potentiometrically the autoprotolysis constants of numerous non-aqueous solvents.

Bykova and Petrov [7] showed that the pK_s values of the solvents could be calculated on the basis of measuring the relative scale of acidity of the solvents (E_s). According to these authors the determination of the relative scale of acidity of non-aqueous solvents by the method of measuring the potentials of polyneutralization of $HClO_4$ and R_4NOH showed that the pH interval which could be used for acid–base titrations in many cases corresponded to a higher scale of acidity than could be calculated from K_s.

Coetze and Padmanabhan [8] determined the pK_s value of acetonitrile by determining the dissociation constants (K_b^d) of 1,3-diphenylguanidine conductrimetrically and potentiometrically ($K_{BH^+}^d$ and obtained the value of 28.5. Similarly, using the stronger base tetramethylguanidine (TMG), Kolthoff and Chantooni [9] obtained the value of 33.3 pK_s units.

The difference in pK_s values of different solvents obtained by various authors ranges from 3 pK_s units for ethanol [10,11] to 16 pK_s units for dimethyl sulphoxide [1,12]. One of the difficulties encountered in the determined of pK_s is the impossibility of producing an absolutely non-aqueous solvent. The presence of even the smallest amounts of water causes an increase an K_s; however, there are many factors that may also lead to an error such as an incomplete dissociation of the electrolytes used, the use of different methods for the determination of dissociation constants of the base and the corresponding conjugated acid, the impossibility of precise measurement of diffuse-phase potentials in the cell, etc.

The classical potentiometric method for the determination of the autoprotolysis constant is based on the addition of a titrant to the solution

Table 1

(strong acid or strong base), which causes difficulties since a certain amount of water is introduced into the investigated solution together with the titrant. To avoid the introduction of water with the titrant and to simplify the procedure for the determination of the pK_s of acetone and methylethyl ketone, in our previous work we determined the pK_s values of these solvents by titration with H^+ ions generated by hydrogen oxidation at a H_2/Pd anode [13]. In this paper we applied the same electrode for the determination of the pK_s values of acetonitrile, propionitrile, nitromethane, ethylene carbonate and dimethyl sulphoxide.

2. Experimental

2.1. Reagents

All chemicals used were of analytical-reagent grade and were obtained from Merck and Fluka. Before use, some solvents were purified as described elsewhere [14]. Dimethyl sulphoxide and ethylene carbonate were used without previous purification. Tetrabutylammonium hydroxide (0.1 M solution) was dissolved in an isopropanol–

methanol mixture. The standardization of this solution was carried out by coulometric titration with H^+ ions generated by anodic oxidation of hydrogen dissolved in palladium. A 0.025 M solution of tetraethylammonium perchlorate in the corresponding solvent was used as the supporting electrolyte.

2.2. Apparatus

The apparatus used for coulometric–potentiometric titration was described in the previous paper [13]. In the course of the titration the potential was measured by means of a Radiometer pHM-86 pH-meter with a Radiometer G202B glass electrode and a Radiometer K201 modified calomel electrode. The aqueous solution of KCl in the SCE is replaced by a methanolic solution of KCl. Before use of the glass electrode was kept in the corresponding solvent for 48 h. A constant temperature was maintained with a U 15C thermostat (NBE; Dresden, Germany).

2.3. Procedure

The procedure for the determination of the pK_s values of the investigated solvents was described in the previous paper.

	Average	830.4	−575.6

$$pK_s = \frac{830.4 - (-575.6)}{59.16} = 23.76$$

3. Results and discussion

Autoprotolysis constants of the investigated solvents were determined by E^o titration [15,16] in the following cell:

| Glass electrode | 0.025 M $(C_4H_9)_4NClO_4$, 0.002 M $(C_4H_9)_4NOH$.SH | Reference electrode |

In order to eliminate the introduction of a standard solution of mineral acid as the titrating agent, the base was titrated with protons generated by anodic oxidation of hydrogen dissolved in palladium in perchlorate medium. The titration was continued even after the equivalence point until twice the amount of protons required for the neutralization of the base was obtained. The e.m.f. of the cell at 25°C, at a constant ionic strength, is given by the following equations:

$$E = E_a^o + 0.05916 \log c_S -$$ (1)

$$E = E_b^o - 0.05916 \log c_{SH_2^+}$$ (2)

E_a^o and E_b^o are the specific cell constants for the basic and acidic regions respectively, and $c_S -$ and $c_{SH_2^+}$ denote molar concentrations of the lyate and lyonium ions respectively. The autoprotolysis constant of the solvent, $K_s = c_{SH} + c_S -$, is calcu-

lated from the expression:

$$pK_s = \frac{E_b^o - E_a^o}{59.16}$$ (3)

The value for the potential of the cell constant in the basic region E_b^o (mV) is calculated from the relation:

$$E_b^o = E - 59.16 \log \frac{Q_{EP} - Q}{FV}$$ (4)

where Q denotes the amount of charge used after the equivalence point, Q_{EP} is the amount of charge needed up to the equivalence point, V is the solution volume (ml) and F is Faraday's constant (96 500 C). In a similar manner, E_a^o in the acidic region was calculated from the equation:

$$E_a^o = E + 59.16 \log \frac{Q - Q_{EP}}{FV}$$ (5)

An example of the calculation of the pK_s value of acetonitrile on the basis of experimental data obtained in one titration is given in Table 1. As can be seen constant values of E_a^o and E_b^o are obtained at the titration points in the basic and acidic regions by Eqs. (3) and (4) respectively. The

Table 5

	Average	849.6	−421.9

$$pK_s = \frac{849.6 - (-421.9)}{59.16} = 21.49$$

Table 6
Autoprotolysis constants of solvents (pK_s) at 25°C, obtained by coulometry

Solvent	Present work	Literature			
		Found	Ref.	Calcd.	Ref.
Acetonitrile	28.8 ± 0.6	33.3	[9]	33.2	[7]
Propionitrile	24.6 ± 0.1				
Nitromethane	23.7 ± 0.1	24.0	[17]		
Ethylene carbonate	21.5 ± 0.4				
DMSO	29.0 ± 0.3	33.3	[1]	31.8	[7]

constant values (E_a° and E_b°) obtained in the intervals 20%–80% and 120%–180% respectively in the course of titration show that tetrabutylammonium hydroxide in this solvent is a strong base which dissociates into S^- and HS^+ ions. Constant values of E_a° and E_b° obtained in a wide titration range in the basic and acidic regions respectively, may serve as a criterion for the application of a strong base in the determination of pK_s using the E° titration method (Tables 2–5).

The pK_s values for the investigated non-aqueous solvents obtained coulometrically using a H_2/Pd generator electrode and a 0.025 M tetrabutylammonium perchlorate supporting electrolyte, as well as the data found in the literature obtained by other experimental techniques, are listed in Table 6. These data show that pK_s values obtained by the coulometric–potentiometric method (E° titration) differ from those reported in the literature. Even the pK_s values for certain solvents obtained by different authors differ widely. This can be explained by the fact that different authors used different experimental methods and therefore different conditions for the determination, or different calculation methods on the basis of the acidity scale for 'pure' solvents (the solvents without any additives).

The pK_s value is strongly influenced by the conditions of determination (the purity of the solvent, the strength of the base, the value of the diffuse potential, the type of electrolyte, etc.).

The pK_s values of the investigated solvents are somewhat lower than those reported in the literature (obtained either experimentally or by calcula-

tion), which can be explained by different conditions of investigation in the present work in comparison with those applied by other authors. The obtained pK_s values are concentration constants (at a concentration of 0.025 M tetrabutylammonium perchlorate) since in the medium of these solvents the ionic strength of the solution cannot be calculated accurately.

4. Conclusion

Using the coulometric–potentiometric method and a H_2/Pd electrode as a source of hydrogen ions for the titration of a strong base, the use of a standard acid solution as well as the water present in the acid solution are avoided. Thus the effect of water, one of the main causes of the lowering of pK_s values of non-aqueous solvents, is eliminated. In addition, the procedure for the determination of pK_s values is simplified by the application of coulometry since the change of the volume of the solution in the course of titration is eliminated as well.

Spectrophotometric estimation of rhenium with 5-chloro-2-hydroxythiobenzhydrazide after its extraction separation using n-octylaniline

S.S. Sawant, M.A. Anuse, M.B. Chavan*

Department of Chemistry, Shivaji University, Kolhapur 416004, India

Received 8 April 1993; revised 20 May 1996; accepted 23 May 1996

Abstract

A solution of n-octylaniline in chloroform extracts rhenium selectively from 0.12–0.16 M nitric acid medium. Rhenium from the organic phase is backstripped with 5% aqueous ammonia solution and estimated spectrophotometrically with 5-chloro-2-hydroxythiobenzhydrazide (5-Cl-2-OHTBH). 5-Cl-2-OHTBH forms a blue complex with rhenium on heating in the acidity range 0.40–3.5 M HCl. The complex is extracted into chloroform and its absorbance is measured at 580 nm. The complex is stable for more than 12 h with a molar extinction coefficient of $9.0 \times 10^3 \, 1 \, \text{mole}^{-1} \, \text{cm}^{-1}$ and a Sandell sensitivity of 0.019 μg cm^{-2}.

Keywords: 5-Chloro-2-hydroxythiobenzhydrazide; Extraction separation; n-Octylaniline; Rhenium

1. Introduction

n-Octylaniline has been employed as an extractant for noble metals [1–5]. It has also been applied successfully for the extraction separation and determination of indium(III), gallium(III) and thallium(III) [6]. Other high molecular weight amines such as TBA [7], Adogen 464 [8], Hostarex A 327 [9] and Aliquat 336 [10], and oxygenated solvents such as mesityl oxide [11], acetylacetone [12], diethyl ether [13], cyclohexanone [14] and ethylmethyl ketone [15] have been reported for the extraction separation of rhenium. However, some of these methods require preliminary separation of molybdenum.

The use of thiohydrazides in the spectrophoto-

metric determination of rhenium and platinum group metals has been described in a number of papers [16–24]. However, alcoholic solutions of some of these reagents need to be stored below 15°C. The complexes of rhenium with naphthalenethiocarboxhydrazide (NTH) [23] and 2-pyrrolethiocarboxhydrazide (PTH) [23] are not suitable for the colorimetric estimation of rhenium due to the lack of a suitable solvent while those with 2-furanthiocarboxhydrazide [23] and 2-thiophenethiocarboxhydrazide [23] are less sensitive and selective compared to 5-Cl-2-OHTBH.

Although the tin(II) chloride-thiocyanate [25] is a well-established spectrophotometric reagent for rhenium, the method suffers from: (i) limited acid range for complexation; (ii) dependence of colour intensity on the chloride concentration of the

* Corresponding author.

aqueous phase; (iii) occurrence of λ_{max} in the near-UV region; and (iv) difficulties in the colour development caused by the presence of multiple species in a given valence state.

Therefore, we recommend n-octylaniline as a selective extractant and 5-Cl-2-OHTBH as a colorimetric reagent for rhenium.

2. Experimental

2.1. Apparatus

A Carl Zeiss (Jena, Germany) spectrophotometer with 1 cm glass cells was used for absorbance measurements.

2.2. Reagents

Standard rhenium(VII) solution was obtained by dissolving potassium perrhenate (JM 99.9% pure) in doubly-distilled water and standardised by the nitron method [26].

Other standard solutions of different metals used to study the effect of diverse ions were prepared by dissolving weighed quantities of their salts in distilled water or dilute hydrochloric acid. Solutions of anions were prepared by dissolving the respective alkali metal salts in water. All the chemicals used were of A.R. grade.

2.3. Preparation of reagents

n-Octylaniline was synthesised from aniline and n-octanol by the method of Pohlandt [4].

5-Cl-2-OHTBH was synthesised according to the method of Jensen and Pedersen [27] and purified by recrystallisation from hot water by adding activated charcoal to obtain the colourless product.

2.4. Reagent solutions

10% n-octylaniline solution was prepared in doubly-distilled chloroform.

A 6.0×10^{-3} M solution of 5-Cl-2-OHTBH was prepared in doubly-distilled ethyl alcohol. The solution remains stable for 1 week.

2.5. Procedure

2.5.1. Extraction separation of rhenium using n-octylaniline

To an aliquot of solution containing 200 μg of rhenium(VII) in a 100 ml separatory funnel, sufficient nitric acid and water were added to give a final concentration of 0.12 M with respect to nitric acid in a total volume of 25 ml. The aqueous phase was equilibrated once with 10 ml of 10% n – octylaniline solution in chloroform for 45 s. The phases were allowed to separate, the metal from the organic phase was backstripped with two 10 ml portions of 5% aqueous ammonia solution and finally estimated spectrophotometrically with 5-Cl-2-OHTBH.

2.5.2. Spectrophotometric estimation of rhenium with 5-Cl-2-OHTBH

The aqueous ammonia solution containing rhenium was shaken with 5 ml of chloroform in order to remove traces of dissolved amine and then neutralised with HCl. Tin(II) chloride solution (1 ml, 10% in 2 M HCl) was added to reduce the metal, the solution was adjusted to 0.8 M HCl and then 5 ml of the reagent solution was added. It was then heated on a water bath for 30 min, cooled to room temperature, and the metal complex was extracted with two 10 ml portions of chloroform containing traces of pyridine. The chloroform extract was dried with anhydrous sodium sulphate, diluted to 25 ml with chloroform and the absorbance measured at 580 nm against the solvent blank.

3. Results and discussion

3.1. Extraction separation of rhenium with n-octylaniline

3.1.1. Effect of acidity

The extraction of rhenium with 10 ml of 10% n-octylaniline in chloroform was carried out from solutions in nitric, hydrobromic, hydrochloric and hydroidic acid media varying in the range 0.04–5.0 M.

Table 1
Effect of diverse ions on the determination of Re(VII) (0.200 mg)

Diverse ion added	Amount tolerated (mg)	Diverse ion added	Amount tolerated (mg)	Diverse ion added	Amount tolerated (mg)
Mn(II)	20	Cu(II)	1	Ca(II)	5
Hg(II)	5	Sn(II)	5	Ba(II)	5
V(V)	5	Th(IV)	5	Tartrate	25
U(V)	5	W(VI)	5	Citrate	100
Ni(II)	5	Se(IV)	1	Acetate	100
Pd(II)	1	Te(IV)	1	Thiocyanate	100
Os(VIII)	1	Rh(III)	1	Phosphate	25
Au(III)	1	Pt(IV)	1	Thiourea	25
Mo(VI)	2	Zn(II)	5	Oxalate	100
Bi(VIII)	5	Pb(II)	20	EDTA	100
Cd(II)	20	Ru(III)	1	Ascorbate	100
Tl(III)	5	Ti(IV)	1	Fluoride	100
Mg(II)	20	As(III)	5	Hydroxyamine hydrochloride	100
Fe(III)	20	Ag(II)	5		
Cr(VI)	1	Zr(IV)	1	H_2O_2 30% (100 v/v)	2 ml
Co(II)	5	Be(II)	5		
Ce(IV)	5				

The extraction was found to be quantitative from nitric acid (0.12–0.16 M) and hydrobromic acid (0.2 M), 50% from hydrochloric acid (2 M)

Fig. 1. Absorbance curves for Re-5-C-2-OHTBH complexes in chloroform. Re(VII): I, 4 ppm; II, 8 ppm; III, 12 ppm; IV, 16 ppm; V, 20 ppm.
-1

and 0% from hydroiodic acid. In the nitric acid system no emulsion is formed, and hence the use of the nitric acid system is recommended for further studies.
3.1.2. Distribution ratio as a function of n-octylaniline concentration

The concentration of n-octylaniline in chloroform was varied from 3–15% over the acidity range 0.04–0.5 M nitric acid. It was observed that extraction increases with the increase in acidity of the aqueous solution, becomes quantitative at 0.12–0.16 M and again decreases with a further increase in acidity. With 10% n-octylaniline in chloroform, the extraction was quantitative from 0.12–0.16 M nitric acid. There was no adverse effect with higher n-octylaniline concentrations.

3.1.3. Nature of the extracted species

The extraction mechanism may be formulated as shown below:

$$ReO_{4(aq)}^{-} + RNH_3^{+} NO_{3(org)}^{-}$$

$$\rightleftharpoons RNH_3^{+} ReO_{4(org)}^{-} + NO_{3(aq)}^{-}$$

Table 2
Determination of rhenium in synthetic mixtures: results of three determinations of each sample

Diverse elements taken (mg)	Re(VII) added (μg)	Re(VII) found (μg)
Mo(VI) 1, V(V) 5,	200	199.8
W(VI) 5, Fe(III) 5		200.0
		200.0
Co(II) 10, Cr(VI) 1,	200	200.2
Ni(II) 5, U(VI) 5,		200.0
Se(IV) 1, Te(IV) 1,		
Pt(IV) 1		
Mo(VI) 1, V(V) 4,	200	200.0
W(VI) 5, Os(VIII) 1,		199.5
Ru(III) 1, Rh(III) 1,		200.0

The equilibrium constant for the reaction is given by

$$K_c = \frac{[RNH_3^+ ReO_4^-]_{org}[NO_3^-]_{aq}}{[ReO_4^-]_{aq}[RNH_3^+ NO_3^-]_{org}}$$

The distribution ratio (K_D) for rhenium is given by the equation

$$K_D = \frac{[RNH_3^+ ReO_4^-]_{org}}{[ReO_4^-]_{aq}}$$

Therefore:

$$K_c = K_D \frac{[NO_3^-]_{aq}}{[RNH_3^+ NO_3^-]_{org}}$$

Taking logarithms of both sides and rearranging the terms, the equation at a constant concentration of nitrate ion in the aqueous solution becomes

$$\log K_D = x \, \log[RNH_3^+ NO_3^-]_{org}$$

$$+ (\log K_c - \log[NO_3^-]_{aq})$$

where x represents the number of amine molecules associated with each extracted metal atom.

The log–log plots of distribution ratio versus n-octylaniline concentration at 0.04 and 0.08 M nitric acid concentrations gave slopes of 1.0 and 1.1 respectively, indicating that the amine-to-metal ratio in the extracted species is 1:1 and that the probable extracted species is $RNH_3^+ ReO_4^-$.

Extraction was found to be more than 99.9% complete in 30 s; therefore a 45 s shaking period is recommended for quantitative extraction.

3.1.4. Effect of diverse ions

Several ions were examined for interference (Table 1). An error of $\pm 1.5\%$ in analyte recovery was considered tolerable. Only thiosulphate affected the extraction of rhenium.

3.2. Spectrophotometric estimation of rhenium with 5-Cl-2-OHTBH

3.2.1. Absorption spectrum

The absorption spectrum of the rhenium-5-Cl–2-OHTBH complex showed a maximum at 580 nm (Fig. 1). The reagent blank under similar conditions showed no absorption over the entire wavelength range.

3.2.2. Optimal conditions and spectral properties

The variation of the acidity of the aqueous phase revealed that the complex formation remained maximal and constant over the acidity range 0.40–3.5 M HCl. Different solvents were studied for extraction. Benzene, MIBK and chloroform were found to be good extractants; however, in benzene the complex is less stable and with MIBK it becomes turbid. Hence chloroform is recommended for extraction.

Under optimum conditions Beer's law is obeyed over the range 1–17 μg Re ml^{-1} and an apparent molar absorptivity of 9.0×10^3 l mole^{-1} cm^{-1} was obtained.

3.2.3. *Determination of rhenium in synthetic mixtures and alloy steels*

Tables 2 and 3 show the results for analysis of synthetic mixtures and alloy steel samples containing added rhenium.

Three samples of alloy steel (Nos. 33b, 33d and 320 from The Bureau of Analysed Samples Ltd., UK) were analysed separately.

A known weight (1 g) of alloy steel was dissolved in a mixture of 9 ml of concentrated sulphuric acid and 50 ml of water. After the initial reaction was over the solution was heated with 5 ml portions of nitric acid until white fumes were observed, boiled to dissolve soluble matter, filtered to remove silica and diluted to 100 ml with distilled water. An aliquot of this solution was analysed by the recommended procedure.

X-ray ionization and fragmentation for use with time-of-flight mass spectrometry

Robert T. Pogue[1], Vahid Majidi*

Department of Chemistry, University of Kentucky, Lexington, KY 40506, USA

Abstract

In this paper, we introduce laser desorption X-ray ionization for producing ions from the previously undetected neutral species present during laser desorption mass spectrometry. Studies involving the laser desorption of simple sugars were conducted to illustrate the differences between spectra with and without the X-ray source. Ionization was made possible by placing a 200 mCi Am X-ray source directly into the ionization chamber of a time-of-flight mass spectrometer.

Keywords: Fragmentation; Laser desorption mass spectrometry; Sugars; X-ray ionization

1. Introduction

Numerous methods are known for producing ions from neutral molecules in all states of matter. The ion production process can be accomplished through the use of electrons, ions, photons, fission fragments, and electric fields. Until now, ionizing radiation in the form of X-rays has been mostly overlooked as a possible method for producing ions within a mass spectrometer.

Laser desorption/ionization (LDI) [1] is commonly employed in the analysis of solid materials because it is a soft ionization technique, capable of producing molecular ions for most analytes.

Work by Karas et al. [2] has extended the usefulness of LDI by making it applicable to very high molecular weight compounds through the use of absorbing matrices. From its inception, however, it has been known that the laser desorption process produces gas-phase neutrals as well as ions. [1] Studies have shown not only that neutrals are produced during laser desorption, but that these neutrals may be produced in greater abundance, and for a longer period of time, than the ions. [3] Cotter [4] showed that neutrals may be emitted for as long as 10 ms after the cessation of the laser pulse.

Vertes et al. [5] have provided hydrodynamic models to explain the temperature, density and velocity distributions of laser plumes with time. Their models illustrate that the plume density is greatest directly above the target at the end of

laser irradiation. Later, after the cessation of the laser pulse, the desorbed packet begins to expand and drift away from the target surface.

Due to the large abundance of neutrals, and the extended time frame available, new methods have been introduced for post-desorption ionization of neutral species [3,4,6–8]. One of these methods, multi-photon ionization (MPI), involves the use of two distinct laser beams. These beams may be produced by separate lasers [8], or by splitting the output of a single laser [7]. MPI may be used either non-selectively, or as a selective tool for ionizing specific molecules [9]. The literature indicates that non-resonant (non-selective) ionization requires a high photon energy due to its inefficiency. One can then conclude that X-ray sources, due to their energetic nature, are ideally suited to fulfill this need. Several studies [10–12] have previously shown that soft X-rays produced by synchrotron sources can be used in combination with mass spectrometry. The use of natural sources, however, has largely been avoided due to safety, and other, concerns. With careful adherence to safety precautions, natural X-ray sources can be useful for mass spectrometric applications.

A typical radioactive X-ray source is capable of providing a high flux of X-rays at energies from approximately 3 to 30 keV. X-ray tubes have the added benefits of higher photon flux, user control of the wavelength at which the X-rays are emitted, and better shielding. The interaction of X-rays with gaseous materials has been previously exploited in the production of gas-filled detectors [13]. Veigele [14] and others have shown that the absorption cross-section for X-rays decreases as the photon energy increases. Evidence also indicates that the photoionization cross-section makes up a large percentage of the total cross-section at low photon energies.

Lasers have been used almost exclusively for producing the photons necessary for non-resonant MPI. In this paper, however, we introduce the use of X-rays for non-resonant ionization of neutral molecules produced in the laser desorption of sugar molecules. In addition, we have included evidence of ion production in a stream of aniline gas using only 241 Am X-rays as the ionization source. Although there are many possible expla-nations to describe the interactions between X-rays and gas-phase species, some of these explanations are more plausible than others. A few of these will be proposed, and their applicability and limitations discussed.

2. Experimental

2.1. Instrumental

The third harmonic frequency (355 nm) of a pulsed Nd:YAG laser (Spectra-Physics GCR-3, Mountain View, CA) was employed for desorption of sugar samples. Laser output was attenuated using neutral density filters in order to provide a suitable signal for analysis. The linear time-of-flight (TOF) mass analyzer was designed and built at the University of Kentucky; it consists of a 1.3 m flight tube typically held at 5×10^{-6} Torr. The repeller voltage was maintained at 2.5 kV and the microchannel plate detector (Chevron Assembly, Model 3025, Galileo Electro-Optics Corp., Sturbridge, MA) was biased at -2.0 kV. The signal was digitized using a Lecroy 8013A digitizer (Lecroy, Chesnut Ridge, NY) and transferred to an IBM-PC by software written with Asyst 3.0 (Asyst Software Technologies, Rochester, NY). Ten individual spectra were co-added in order to obtain the desired profiles. A 200 μCi ^{241}Am source was placed into a Delrin sheath which was attached directly to a blank vacuum flange. This X-ray source holder could then be easily inserted in, or removed from, the ionization chamber through an unused arm of a six-way cross. The orientation of the Am source with respect to the sample surface is illustrated in Fig. 1. For these experiments, the extraction plate and lens openings were 0.125 in. Care was taken to place the X-ray source as close as possible (approximately 0.40 in) to the sample surface to provide the maximum solid angle overlap of the X-rays with the dense laser plume that is present directly following the cessation of the laser pulse [5]. Data collection was initiated by the laser pulse to allow ions produced both from the laser pulse, and from the interaction of X-rays and neutrals, to be detected simultaneously.

Aniline profiles were collected using a magnetic mirror ion trap placed inside the ionization chamber of the TOF. Rare earth cobalt magnets (0.8 T, Edmund Scientific) replaced the extraction plate and electrostatic lenses shown in Fig. 1. The repeller was pulsed at 2.4 kV. Approximately 1×10^{-5} Torr of aniline was leaked directly into the trapping region. The X-ray source was placed perpendicular to the magnetic trap.

It is important to note that a radioactive source was used in these experiments, and that care must be taken when using an X-ray source of this type. The ^{241}Am source was placed in a lead-lined canister when not in use and covered with a lead foil. It is also suggested that the operator monitor his or her dosage regularly using radiation film badges. Additionally, proper authorization and certification must be obtained when using certain radioactive sources.

2.2. Samples

Saturated solutions of glucose and sucrose (unpurified) were prepared in deionized water. Aliquots of these solutions were placed on dry stainless-steel substrates (≈ 0.3 mm thick), and the solutions were allowed to dry. The substrates were then affixed to the center of the repeller plate. Aniline (Baker) was distilled prior to use.

Fig. 1. Three-dimensional view of the ionization chamber used in LD-XRI. Note that the desorption beam and ^{241}Am source are perpendicular to the direction of ion travel, and that the X-ray source is placed as close as possible to the sample surface.

Table 1
Photons emitted from ^{241}Am source

Energy(keV)	Intensity(%)	Assignment
59.5	36	γ
26.3	2.4	γ
20.8	4.9	L_γ
17.8	20	L_β
13.9[a]	13.3	L_α

[a] Not observed with our source.

3. Results and discussion

3.1. X-ray flux

The energies of the photons emitted from the source used for this set of experiments are given in Table 1. Not all of the photons emitted from the ^{241}Am source are within the useful region for ionization of carbon as described by Veigele [14]. It is important to note that the photons which have higher energies may also be absorbed by the laser generated plume; however, the probability of such interactions is less than for the lower energy X-ray photons. We determined, using experimental parameters, that approximately 1450 X-ray photons will be emitted from the 200 mCi source during the 195 ns residence time of ions in the ionization region (based on m/z 144). By approximating the interaction volume as that contained within the column defined by the repeller and the extraction orifice we calculated that approximately 25 photons can be expected to pass through the interaction region during the time that the laser plume is in residence. The number of photons which would react with the plume was determined using the equation $(N_a/N_0 = e^{-\mu x})$, where N_a/N_0 is the number of photons which will pass through the plume without interaction, and μ and x describe the interaction cross-section and the sample depth respectively.

From these calculations, it is apparent that an average of 4% of the X-ray photons will interact with the laser plume. By adding the resultant spectra from several events it is possible to obtain the profiles given in Figs. 2 and 3. Although several series of samples were analyzed and the results found to be reproducible, only representa-
Fig. 2. (A) Laser desorption TOF profile of glucose. (B) Laser desorption X-ray ionization profile of glucose: 355 nm desorption beam.

tive spectra are included. Additionally, as explained below, the primary interaction of a single photon results in a large number of secondary interactions and collisions which multiply the effect of the initial event.

3.2. Laser desorption mass spectrometry of sugars

Laser desorption profiles of glucose both with and without the presence of the X-ray source in the ionization chamber are displayed in Fig. 2. The base peak in Fig. 2A (m/z 145) is a dehydration product of the levoglucosan fragment. Noticeably absent are ions with $m/z > 145$. In the laser desorption X-ray ionization (LD-XRI) profile given in Fig. 2B, the molecular ion is present with a signal-to-noise ratio (S/N) of approximately 10. Peak broadening (30 ns at m/z 145), clearly visible when comparing Figs 2A and 2B, is most probably due to the lateral distribution of the X-ray-produced ions at the time of

ionization by the X-ray photons. As the lateral distribution of ions, with respect to the ion repeller, increases the kinetic energy, distribution of ions with the same mass-to-charge ratio will also increase. Although the intensity of the molecular ion is only a small fraction of that of the base peak, opportunities exist for improving the amount of interaction, and thus the intensities of desired ions, by using instrumental X-ray sources.

Similar spectra for the laser desorption of sucrose appear in Fig. 3. Note, again, the increase in peak width in the LD-XRI profiles, which indicates that neutral/photon interactions are occurring. Also important to note is the strong presence of ions at $m/z > 160$ in the LD-XRI profile. The molecular ion, in this profile, is of relatively high intensity compared with the corresponding glucose profile. The base peak in Fig. 3A (m/z 131) is most likely due to a simple cleavage reaction leaving the six-membered ring and its proton and hydroxyl substituents. Due to the structure of this compound and the repetitiveness of its sub-
Fig. 3. (A) Laser desorption TOF profile of sucrose. (B) Laser desorption X-ray ionization profile of sucrose: 355 nm desorption beam.

stituents, it is difficult to assign specific fragmentation pathways leading to the base peak. Because the same sample is used in Figs. 3A and 3B without removal from the ion source, it is surprising that the peak at this mass-to-charge ratio is weaker in Fig. 3B relative to the rest of the spectrum. This fact may point to selective ionization or fragmentation, during desorption or X-ray ionization, or to the presence of mechanisms which are not clearly evident from the information obtained in these experiments.

LDI experiments were conducted prior to the introduction of the [241]Am source, and after it had been removed from the ionization chamber, so that X-ray/solid interactions could be ruled out as a possible explanation for the observed effects.

3.3. Production of aniline ions in a magnetic ion trap

While conducting experiments using a mag-

netic mirror ion trap, we observed that the presence of the X-ray source in the ionization chamber of our mass spectrometer causes ion formation in gas-phase neutrals. It is important to note that ions were only visible, above the background, when the magnetic mirror was in place. This indicates that the high plume density present during laser desorption is a necessary condition for creating a useful ion signal. The ion storage property of the magnetic mirror allows the signal to be enhanced; however, the resolution is substantially degraded with respect to the LD-XRI profiles. These experiments also indicate that even at high pressure the background signal caused by the continuous X-ray source is not intense enough to cause significant changes in the background profile. For this reason, ionization events which occur after the passage of the laser plume will not cause spurious peaks in the mass profile or significantly affect peak shape.

3.4. Mechanisms of X-ray/neutral interaction

The major difficulty in determining the method of interaction between the X-rays and the gas-phase neutrals, in the TOF ionization chamber, is the high energy of the incident ionizing photons. Typical lasers used for ionization are the vacuum ultraviolet (VUV), ultraviolet (UV), or visible ranges, which encompass the region of the electromagnetic spectrum from 10–800 nm (130–2 eV). X-rays emitted from the 241 Am source have a minimum energy of 13.9 keV. Electrons at 70 eV are commonly used for electron impact ionization are considered a "hard" ionization source. LD XRI, as developed in this laboratory, exhibits soft ionization characteristics even though the ionizing radiation has several orders of magnitude more energy to transfer during a collision. It is our belief that this occurs via a multiple-step mechanism whereby the products of direct collision are involved in secondary collisions which produce the ions visible in the TOF profile. This mechanism is supported by ion counting calculations made by determining the current collected from the micro-channel plate detector. These calculations indicate that the highest number of primary collisions possible in the given time frame cannot account for the total number of ions which are being detected. In order to understand the processes which we believe are making up the total X-ray/neutral interaction mechanism, it is useful to treat direct and indirect processes separately.

3.4.1. Direct interaction

Models suggest that as the time following the cessation of the laser pulse and the distance above the target surface approach zero, the density of the laser-induced plume approaches that of the condensed phase [5]. Although it is not possible to claim that all of the collisions occur within these time and space boundaries, we can understand some of the collision processes better by using these constraints. A typical X-ray detector may be effective as a model for these interactions. As the X-ray passes through a gas-filled detector, interactions with the detector gas produce a large number of ion–electron pairs. Following the initial collision, a photoelectron is emitted with a kinetic energy equal to the energy of the photon minus the binding energy. If this primary collision is the only process which is occurring, the ions produced would then be repelled down the flight tube and detected by the microchannel plate. In a similar manner, ions may be produced which can be detected using TOF mass spectrometry. Spectra caused by direct interaction only would have low signal-to-noise ratios and would contain a large number of low molecular weight fragments of poor resolution. These fragments would result from vibrational dissociation of the primary ions, and could be produced throughout the ionization region and flight tube.

3.4.2. Indirect ionization by energetic fragments and secondary electrons

In the previous section, we considered only those interactions caused by direct collision with an X-ray photon. We may also assume that the products of primary collisions sufficient energy to ionize and/or fragment addition gaseous neutrals. As described in the previous section, a photoelectron may be emitted from the primary collision. This photon would have less energy the the primary photon, and therefore have a higher collision cross-section than its predecessor. Through additional collisions, the energy of the photon would decrease. The outcome would be similar to the Townsend Cascade which is the basis for gasfilled radiation detectors (see Ref. [13])

In addition to the photoelectrons which may be formed during X-ray neutral interaction, fragments formed due to vibrational excitation may be sufficiently energetic to cause secondary reactions. These fragments would have higher cross sections and lower kinetic energies than the photoelectrons and could be the source of the soft ionization processes which are observed.

Clearly, additional studies are necessary to determine what role each of the proposed mechanisms plays in the overall reaction mechanism. High sensitivity, and MS/MS, measurements may shed light on how each of the pathways contributes to cause the changes observed in the spectra. Additional work in this area is presently being conducted on these and other classes of compounds.

4. Conclusions

The use of X-rays as a supplemental ionization source for laser desorption mass spectrometry has been illustrated. For this study, a natural (radioactive) X-ray source was employed. The presence of molecular ion peaks in the LD-XRI spectra, which were not present in the LDI spectra, indicates that LD-XRI has the characteristics of a soft ionization source; however, the ionization mechanism is not clear.
